Abstract

Functional and long-term breeding programs with comprehensive recording of phenotypic information from smallholder dairy production systems in Africa are few, limiting herd productivity gains and profitability. To bridge the gap, a pilot information and communication technology-based platform for collation, evaluation and feedback on phenotypic and genomic data from smallholder farms in Tanzania and Ethiopia has been developed through the Africa Dairy Genetic Gains (ADGG) program initiated in 2016. In 2020, pedigree data from 65,624 and 110,959 animals in Tanzania and Ethiopia respectively was evaluated to develop restricted selection indexes and a genomic prediction pipeline for animals in the unique smallholder production environments. Integrated into ADGG, the iCow platform provides digital extension messages to farmers, sharing results from the genomic evaluation and breeding management support for improving productivity of their dairy animals. The genomic evaluation of crossbred dairy animals enables selective breeding for enhanced productivity in smallholder farming systems of Africa

Introduction

In rural areas of Africa, dairying is a mainstay for the majority of resource-poor households and a way out of poverty towards food security. It is estimated that 80% of the milk produced in the continent is from smallholder production systems (FAO, 2016), however comprehensive recording of animal performance is limited. Only two of the 44 countries in Sub-Saharan Africa are reported to have comprehensive national livestock identification, monitoring and recording systems in place in the State of the World Animal Genetic Resources reports (FAO, 2015; AU-IBAR, 2019). Limited information is available on animal productivity levels, costs of production and breeding technology adoption in smallholder farming systems (Rege *et al.*, 2011).

Data collation from dairy farming systems in Africa over time is implemented through small scale piloting of pre-designed tools and database management systems from countries with more advanced dairy sectors (Mrode *et al.*, 2020b). However, though successful with larger scale farming operations, infrastructure limitations and an inability to adequately identify, classify and evaluate the combinations of cross-bred animals reared in the smallholder farming systems restricts buy-in and use of data to inform decisions.

Most smallholder farmers in Africa own low milk-producing indigenous cows, and the few with genetically improved crossbred cows suffer heavy productivity losses due to the practice of continuous upgrading with exotic semen to levels that are beyond what the production systems can optimally support (Galukande *et al.*, 2013; Ojango *et al.*, 2017). The lack of functional local data collection and analytics systems that enable effective and sustained selection and use of uncertified crossbred bulls for breeding results in random backcrossing of crossbred cows to uncharacterized and less-productive bulls. The net result is continuous erosion of some of the gains from crossbreeding with long-term implications on the entire population.

Rapid expansion of information and communication technologies (ICT) alongside mobile based solutions for 'paperless' exchange of information has catalyzed a transformation for information sharing in the smallholder farming systems of Africa (World Bank, 2011; Mrode *et al.*, 2020b). Using ICT, from 2016 the African Dairy Genetic Gains (ADGG) project has sought to address limitations in data from smallholder dairy systems to identify and promote the use of more productive dairy genetics suited to the local production environments. This paper presents information on the multi-country dairy genetic data platform (ADGG-Platform) bridging the gap in information on the system characteristics, productive performance and genomic information on animals reared in African farming systems.

Methodology

The ADGG program initially chose Ethiopia and Tanzania as pilot countries to demonstrate how technological and institutional innovations can be integrated into interventions that enhance dairy productivity across diverse smallholder farming systems. In Sub-Saharan Africa, Ethiopia has the largest cattle population (65 million), while Tanzania has the third largest cattle population (30 Million) (FAOSTAT, 2022), reared by large numbers of smallholder farmers. The ADGG program supported through the Bill and Melinda Gates Foundation established centralized Dairy performance recording centre's (DPRC) in each country through which an initial 12,000 smallholder dairy herds were enrolled by trained national performance recording agents (PRA's). Desktop, Web, mobile tablet and sms based solutions were developed with dynamically defined user roles, using a RESTful Application Programming Interface (API) to safely authenticate and expose data from diverse sources through a single access point with individual country data mirrored at respective DPRC (https://portal.adgg.ilri.org/). The ADGG platform is designed to collate, process, interpret and generate feedback on both phenotypic (animal and environment descriptors, productive and reproductive performance measures, animal management practices and health interventions) and genomic (hair samples for genotyping animals) data from herds (Figure 1). Through partnership with Green Dreams Tech, the ADGG platform is integrated with iCOW (https://icow.co.ke/) to provide digital extension support and feedback from data analyses for farmers using text messages.

Results

Ethiopia and Tanzania have harmonized national cloud-based databases for registering and monitoring dairy cattle productivity that enable genetic evaluation of dairy animals across all farming systems in the countries. The number of farmers registered, and animals monitored over time through the ADGG platform are presented in Table 1. In 2021, up to 200 smallholder farmers enrolled in the program have begun to directly submit data on their animals onto the ADGG platform.

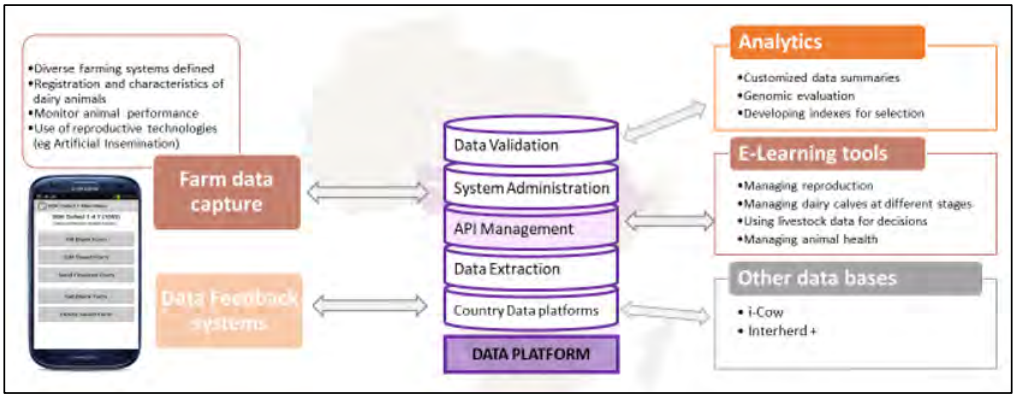

Figure 1. Overview of the ADGG data platform.

Table 1. Numbers of Farmers and animals registered, monitored and genotyped on the ADGG platform 2017-2021.

	Smallholder					Medium and large scale			
		Animals					Animals		
Country	Farms	Registered	With milk data	Test-day records	Animals sampled for genotyping	Farms	Registered	With milk data	Test-day records
Ethiopia	71,215	105,924	32,716	67,929	8,940	772	19,268	7,076	97,291
Tanzania	33,630	66,917	18,076	134,987	6,000	36	2,071	69	750
Total	104,845	172,849	50,792	202,916	14,940	808	21,339	7,145	98,041

Using genomic evaluation methodologies (Mrode *et al.*, 2019), phenotypic and genomic information on animals is evaluated annually on a country basis to determine best crossbred sires and cows for national use. In 2020, using pedigree files with 65,624 animals in Tanzania and 110,959 animals in Ethiopia, milk yield and body weight data for registered animals were evaluated and used to develop a restricted selection index to increase milk production with no change in body weight in order to improve efficiency such that animals produce more milk with less feed for maintenance (Mrode *et al.*, 2020a). Results of genomic prediction analyses for Ethiopia data were used to develop the first animal catalogue and certification system for Ethiopia (ILRI, 2021).

A genomic prediction pipeline developed for animals in the unique production environments (Mrode *et al.*, 2021) was used in preliminary principal component analyses of pooled genomic data for 2,363 Tanzania and 1,642 Ethiopian cows with milk records. Results indicate some degree of relatedness between animals in the two countries that will enable the implementation of regional joint evaluation of animals.

Medium and large-scale farmers who keep larger numbers of animals are known to provide breeding stock and replacement animals for smallholder farmers in Africa. Through combining data from animals reared in these systems with that from the smallholder farming systems more complex genomic prediction models can be explored in analyses to determine best animals for different management conditions.

Through policy dialogues with key stakeholders and government institutions at country level, frameworks and critical infrastructure, including partnerships with telecommunication companies have been developed at country level to support institutionalization of ICT systems for monitoring animal performance on smallholder farms (Gebreyohanes *et al.*, 2021).

Discussion

The ADGG data platform presents the first large scale source of genomic data and information on dairy cattle from smallholder farming systems in Africa, aligned to the Agenda 2063 of the African Union (AU) which seeks to harness Africa's animal genetic resources to address food and nutrition security in Africa. Through the ADGG training, information and feedback mechanisms, livestock keepers continue to adapt improved standards for producing clean milk, improve the quality of data on their animals, and adapt improved breeding and related management practices for their dairy animals. The growing data enables more accurate and reliable evaluation of crossbred dairy animals under smallholder dairy systems.

For the first time results from genomic evaluation of dairy animals reared under smallholder farming systems of Africa are available and being used to inform better use of crossbred dairy animals and provide top ranking locally adapted breeding bulls. Partnership arrangements with international genetic companies are underway to enable wider promotion and use of ADGG certified bulls.

460. Attitudes of Peruvian llama and alpaca farmers towards genetic improvement

M. Wurzinger* and G. Gutiérrez

Universidad Nacional Agraria La Molina, Avenida La Molina s/n, Lima, Peru; mwurzinger@lamolina.edu.pe

Abstract

This study aimed to assess llama and alpaca farmers' attitudes towards genetic improvement and compare them with currently implemented breeding practices. After data quality control, 76 interviews were considered for the llama survey and 82 for the alpaca survey. Breeders' attitudes were assessed through a series of attitudinal statements. In addition, information about farmers' profiles and their current breeding practices was collected in the online surveys. The majority of the participants use controlled mating and performance recording, whereas artificial insemination, parentage testing, embryo transfer can be neglected as the technology is not well developed for both species. Purchase of animals from other farmers is the most common sourcing of breeding stock. Overall, farmers had positive attitudes towards the use of breeding and reproduction technologies. They also agreed that comparing and exchanging breeding animals is useful and being a member of an association helps in genetic improvement.

Introduction

Llamas and alpacas play an essential role in the rural economy of the Peruvian High Andes. So far, there are some isolated initiatives to develop and implement breeding programs, but no national breeding programs are in place for both species (Gutiérrez *et al.*, 2018).

The successful implementation of breeding strategies depends on various factors. The readiness of farmers to actively participate in breeding programmes has been identified as an essential factor among others (Kosgey and Okeyo, 2007, Wurzinger *et al.*, 2011, Getachew *et al.*, 2018). However, farmers' willingness is influenced by various factors such as their knowledge, perception and attitude towards the proposed new technology. Farmers' attitudes are affected, in turn, by many personal factors (e.g. gender, age, marital status), socioeconomic factors (e.g. income, assets, education), and personality factors (e.g. self-confidence, readiness for innovation) as well as familiarity with the technology (Meijers *et al.*, 2015). In recent research, farmers' attitudes towards different breeding tools and how they can influence their interest in breeding programs have been investigated (Martin-Collado *et al.*, 2021, Zoma-Traoré *et al.*, 2021).

This study aimed to assess the attitudes of llama and alpaca farmers in the Peruvian Andes towards genetic improvement and contrast them with the current breeding practices.

Materials & methods

The survey for llama farmers was conducted between November and December 2020 and for alpaca farmers from April to May 2021. Both surveys were conducted online due to the COVID-19 pandemic. Invitations with a link to the survey were sent by email and to topic-specific WhatsApp groups. Contacted persons were also encouraged to forward the invitation to other interested farmers. Due to the online format, there is a limitation that farmers without internet access could not participate and therefore total inclusivity could not be ensured.

In total, 80 people answered the llama survey, and 85 people answered the alpaca survey. After data quality control, 76 interviews were considered for the llama survey and 82 for the alpaca survey. Breeders' attitudes were assessed through a series of attitudinal statements, towards which breeders stated their agreement,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_460, © M. Wurzinger and G. Gutiérrez 2022

using a five-level Likert scale: strongly disagree, disagree, somewhat disagree, somewhat agree, and agree. The option 'I do not know/have no opinion on this' was also included.

The list of attitudinal statements was defined from a study carried out by Martin-Collado *et al.*, 2021. The questions were adapted to local conditions taking into account local practices.

The final list consisted of 11 questions in which they should express their degree of agreement or disagreement. Additional information on the farmer' profile and currently used genetic improvement strategies and tools were also collected.

For data analysis, the questionnaires from departments Huánuco, Junín and Pasco were grouped into the 'Central region' and departments Arequipa, Ayacucho, Cusco, Huancavelica and Puno in the 'South region'. Descriptive statistics were performed using R software.

Results

Table 1 gives an overview of the age and education level of the interviewees from both surveys. The age range was between 21 and 70 years. The education level showed a high proportion (47-66%) of participants with a university education. Full-time but also part-time farmers took part in the survey.

The current use of breeding and reproduction technologies is summarized in Table 2. The results of the different study regions, but also both species, are very similar. The most common breeding practice is controlled mating, followed by keeping production records of individual animals. Farmers hardly use parentage testing, artificial insemination and embryo transfer.

63 and 26% of the llama farmers and 37 and 45% of the alpaca farmers from the Central and South region stated that they are currently a member of a farmer association.

Llama farmers specified that the most frequent source for a breeding male was the direct purchase from another farmer (37 and 39%), followed by selection within own herd (29% in both regions). 21% of the

Table 1. General information about llama and alpaca farmers.

	Llama farmers		Alpaca farmers	
	Central	South	Central	South
	n=38	n=38	n=19	n=63
Age of farmers, year				
mean	39	36	46	40
range (min-max)	21-64	20-65	32-61	20-70
Education (% of respondents):				
primary	5	3	0	2
secondary	15	14	47	15
technical training	21	35	6	17
university	59	48	47	66
Time for livestock keeping (% of respondents)				
≤50%	25	37	16	38
>50%	25	46	47	39
full time	50	17	37	23

Table 2. Current use of breeding and reproduction technologies (% of respondents).

	Llama farmers		Alpaca farmers

Pedigree recording	16	24	26	27
Performance recording	55	66	47	77
Controlled mating	82	76	79	86
Parentage testing	3	11	10	5
Artificial insemination	3	0	16	8
Embryo transfer	5	5	5	8

respondents stated that they use a mix of different sources. Purchase at an animal fair, exchange or rent of breeding males were less frequently mentioned.

Alpaca farmers indicated that the most common practice is the direct purchase from another farmer (68 and 41%), followed by selection within own herd (21 and 23%). In the southern region, a combination of different sources was mentioned by 18%, whereas 28% of farmers from the central region used different sources. Exchange or rent of breeding males plays only a minor role as three farmers only mentioned it.

Table 3 shows the attitudes of llama and alpaca farmers towards different breeding tools. Llama and alpaca farmers value performance more than the 'beauty' of their animals (statement 9). There is the K'ara type (meat type) and Chaku type (woolly type) in llamas. As these types are phenotypically very different and also have distinct production purposes, farmers would like to maintain these types and avoid crossbreeding. The same results can be observed in the alpaca survey, where farmers confirm their preference to maintain the Huancaya and the Suri type. These types show very distinct fibre characteristics. Farmers of both surveys stated that performance recording is needed (statement 2, 4) to improve their animals. Also, in both surveys, reproduction technologies were seen as useful and genomic information was rated as an important method in animal breeding (statement 3, 6). Statements 7, 10 and 11 are concerned with farmers' attitudes

Table 3. Attitudes of llama and alpaca farmers towards genetic improvement.[1]

Statements	Llama farmers		Alpaca farmers	
	Central	South	Central	South
	n=38	n=38	n=19	n=63
1. Important to maintain type	3.7±1.84	3.9±1.79	3.7±1.82	4.3±1.47
2. Phenotype sufficient to indicate performance	3.1±1.50	3.3±1.41	3.0±1.41	2.8±1.36
3. Genomic information is fastest tool	3.9±1.67	4.0±1.62	2.8±2.17	4.3±1.03
4. Performance records not needed	2.1±1.40	1.8±1.24	2.2±1.23	1.7±1.05
5. Phenotype of offspring good indicator	3.7±1.74	3.3±1.48	3.6±1.49	3.6±1.39
6. Reproduction technologies are not useful	1.7±1.60	2.8±1.70	3.1±1.49	2.6±1.52
7. Intra-herd comparison is important	4.1±1.44	4.3±1.27	3.7±1.45	4.2±1.30
8. Avoid crossbreeding of types	3.7±1.73	4.0±1.51	2.8±1.98	4.3±1.41
9. Phenotype more important than production	3.0±1.42	2.9±1.33	2.4±1.43	2.9±1.38
10. Exchange of animals is important	4.1±1.58	4.2±1.39	3.8±1.65	4.3±1.24
11. Membership in association is helpful	3.9±1.53	4.0±1.52	3.2±1.69	3.5±1.61

[1] 5=fully agree, 4=somehow agree, 3=somehow disagree, 2= disagree 1=completely disagree, 0=I don't know.

towards cooperation. In all three statements, farmers showed positive attitudes towards cooperation through animal comparison and exchange and joining an association.

Discussion

A very high number of farmers indicated that they have secondary or even university education, and these figures are far above those reported by Gutierrez *et al.* (2012). The sampling technique could explain this bias as farmers with an already greater interest in improving their herd management were willing to participate in the survey. Therefore, all results of this study should be interpreted with care. The current use of breeding and reproduction technologies did not differ between llama and alpaca farmers. In both species, artificial insemination and embryo transfer are not well developed as in other livestock and therefore not implemented routinely on farms. Natural mating is the method of choice, and therefore a high proportion of farmers use controlled mating.

Overall, farmers showed positive attitudes towards different breeding tools. Performance recording was seen as a helpful tool and is already implemented by more than 50% of the participants. The positive attitude towards the exchange of animals is also reflected in the current practice of purchasing breeding animals from other farmers. Being a member of an association was also perceived positively, although not all interviewees were already members of one. The study shows that farmers are open to new technologies and are interested in the genetic improvement of llamas and alpacas.

Acknowledgements

The author would like to thank all llama and alpaca farmers for taking their time to participate in the survey and to share their opinion with the research team.

Abstract

Genetic selection is important in choosing animals for the next generation. Animal breeders now choose selection candidates based on DNA markers, in addition to animal performance. There has been increased use of high-density SNP chips to enable selection of commercial broiler and layer chickens. However, genotyping a large number of selection candidates still carries a high cost. The aim of our study was to develop an economical 5K SNP panel for local Ghanian and Tanzanian chicken ecotypes using targeted genotyping by sequencing (GBS) for imputation to higher density. Low-density panel SNPs were selected from haplotype blocks and other important genomic regions across the chicken genome based on 600K SNP panel genotypes. A total of 188 birds were genotyped by GBS and an in-house shell script pipeline was utilized to obtain SNP calls. Our in-house pipeline was compared to a standard company pipeline and 600K SNP chip genotypes for validation. Selected SNPs were evenly distributed across the genome, with at least one SNP in each megabase region. Comparison of the two pipelines revealed a good genotype match for the 5K SNP panel. The 5K GBS panel and SNP calling pipeline are important tools to aid selective breeding in African chicken ecotypes.

Introduction

In the past decade, there has been an increase in the use of commercial high-density (HD) SNP chips for genotyping in chickens (Kranis *et al.*, 2013), which has accelerated genomic selection in broiler and layer breeding. The availability of genomic and phenotypic information enables genomic prediction of breeding values for selection candidates. Although HD SNP chips are commonly used, the costs to genotype a large number of selection candidates remains high. To reduce costs, the use of low-density (LD) panels followed by imputation to a high density could be a feasible approach (Habier *et al.*, 2009). Array-based genotyping platforms are commonly utilized in genotyping various livestock species. However, they include SNPs that may not be geographically representative and therefore, population diversity and estimates of recombination rates may be biased (Pérez-Enciso and Ferretti, 2010; Zhan *et al.*, 2011). In poultry, such studies have mostly been conducted in commercial layers and broilers, with limited focus on local African chicken ecotypes. New cost-effective next generation sequencing platforms such as genotyping by sequencing (GBS) have recently been developed. GBS was originally developed for plants (He *et al.*, 2014), and follows a simple protocol that provides high SNP coverage (Sonah *et al.*, 2013). The objective of this study was to develop a low-density SNP panel for Ghanaian and Tanzanian local chickens using targeted GBS.

Materials & methods

Experimental birds. Breeding flocks were established at the University of Ghana, Legon, Accra, Ghana, and Sokoine University of Agriculture, Morogoro, Tanzania. Breeder chickens from three Tanzanian (Kuchi, Morogoro Medium, and Ching'wekwe) ecotypes and three Ghanaian (Coastal Savannah, Forest and Interior Savannah) ecotypes were obtained.

SNP panel genotyping and quality control. Blood samples were collected from 1,440 Ghanaian and 1,399 Tanzanian chickens and stored onWhatman FTA cards (Sigma-Aldrich, St. Louis, MO, United States). All birds were genotyped using the Affymetrix Axiom® 600k Array (Thermo Fisher Scientific Inc., Calsbad, CA, USA) at GeneSeek (Lincoln, NE, USA) and Gallus gallus genome version 5 was used for annotation of the genotyping array. Quality control on the combined genotype data was performed using PLINK 1.9 (Chang et al., 2015) and SNPs were screened based on minor allele frequency (MAF)≥0.1 and call rate >95%. A total of 401,083 SNPs were utilized in the downstream analyses.

Selection of SNPs for the 5K GBS panel. SNPs for the 5K GBS panel were obtained across the chicken genome from various sources including haplotype block estimates based on the 2,839 birds, SNPs in the MHC regions provided by Hy-Line International., genome-wide association studies on the commercial Hy-Line Brown laying line (Rowland et al., 2018; Saelao et al., 2019) and in African local chicken ecotypes (Walugembe et al., 2019; Walugembe et al., 2020), and 379 SNPs selected across the genome to ensure that there was at least one SNP in each Mb region. Imputation for the combined genotype data was performed using Fimpute (Sargolzaei et al., 2014) to fill in missing genotypes. Haplotype blocks were estimated in PLINK 1.9 (Chang et al., 2015) using the following options; --blocks, --blocks-min-maf 0.1, and --blocks-strong-lowci 0.6. A total of 69,622 haplotype blocks were generated across the genome and 4,500 SNPs were selected based on these haplotype blocks. The number of SNPs selected for a chromosome was computed as x*4500/401803, where x is the number of 600K SNPs on the chromosome that passed quality control.

Sequencing and SNP calling. Blood samples were also collected from an additional 92 Tanzanian and 96 Ghanaian chickens, which were sequenced for the 5K low-density GBS panel with 100 bp paired-end on 4 lanes using Illumina Hiseq at GeneSeek. Of these, 25 birds were also genotyped on the Affymetrix Axiom® 600k Array. Sequence data were processed using an in-house pipeline by Interval Bio (Mountain View, CA, USA). With input from Interval Bio staff, we developed our own pipeline to process the raw sequence read data and target variant calling using shell scripts and various publicly available software tools (BWA, SAMtools, PICARDS, and BCFtools). The raw reads were aligned to the *Gallus gallus* 5 reference genome, and genotypes were obtained from the vcf file using in house python script. SNP genotype calls from our pipeline were compared to those of the Interval Bio pipeline for all 188 birds and to the 600K SNP genotypes for the 25 birds.

Results

Selection of SNPs for the 5K GBS panel. Initial selection of SNPs utilized LD based pruning methods, where SNPs in high LD were retained after pruning. Although this resulted in selection of SNPs that were distributed across the genome, most had MAF close to 0.5. This approach method was, therefore, replaced by the haplotype blocks method. The 4,500 SNPs selected based on haplotype blocks were evenly distributed across the genome, with MAF ranging from 0.1 to 0.5, as illustrated in Figure 1. Each Mb included at least one SNP and for regions where this was not achieved, a SNP was selected and added to the panel. Haplotype blocks were determined to contain SNPs that are in very strong LD with each other to minimize intra-block variance and maximize inter-block variance.

Comparison of SNP genotype calls. Figure 2 shows the comparison of genotype calls based on our and the Interval Bio pipeline. SNPs were ranked by the percentage of the 188 birds for which the genotype was called the same by both pipelines (Match%). For most of the 188 birds, the same genotype (Match%) was called by both pipelines, with a few cases where neither pipeline or only one of the pipelines made a genotype call. We removed about 80 SNPs where a different (Non-match%) genotype was called by the two pipelines for more than 20% of the birds.

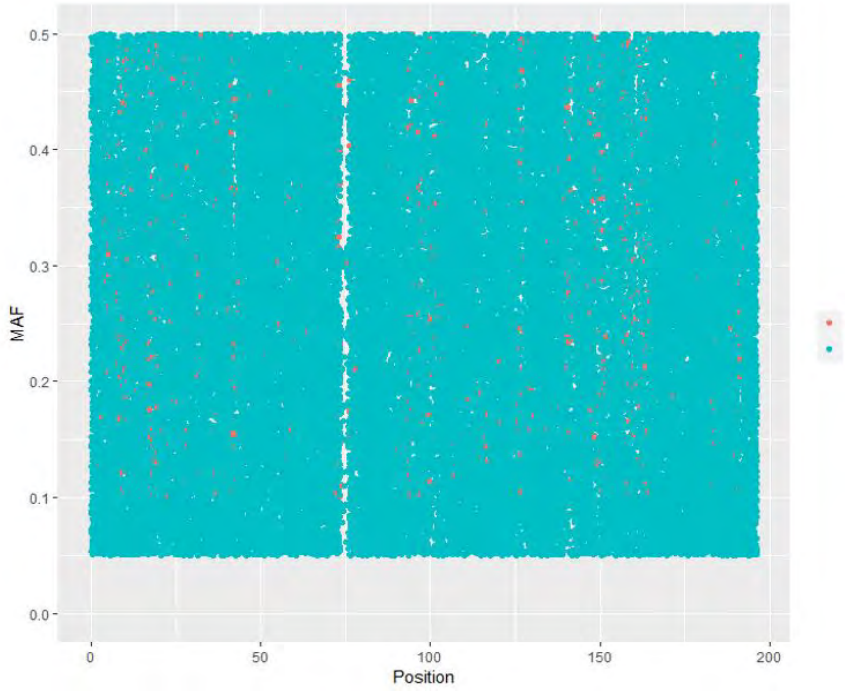

Figure 1. Distribution of the 805 selected SNPs (red) from the 71,725 SNPs that passed quality control on chromosome 1.

Figure 2. SNPs ranked by the % of birds for which the same genotype was called by both pipelines (light blue) along with the % for which different genotypes were called (red), the % for which only our pipeline did not (purple) or did (yellow) make a genotype call, and the % for which no call was made by both pipelines (dark blue).

Both pipelines had matching genotype calls with the 650K genotypes for the 25 birds that were genotyped on both the GBS and the 650K panel. These findings confirmed our low-density SNP panel list that would subsequently be used for genotyping on a GBS platform/protocol.

Discussion

To our knowledge, this is the first low-density SNP panel developed for African local chicken ecotypes, which can enable selective breeding of Africa local chickens using a cost-effective GBS. The panel has been used to genotype animals on a low density panel and imputation to a high density panel will be done using available imputation software programs.

The targeted GBS methodology employed here is one of the current methods of next generation sequencing for genotyping of SNPs and the availability of an excellent reference genome provides the basis for the selection of GBS restriction enzymes (de Donato *et al.*, 2013; Gurgul *et al.*, 2019).

Abstract

A study was carried out to assess how knowledge on genetic diversity and molecular analysis could be interpreted in the context of management system and production levels to develop genetic improvement strategies, considering the case of five indigenous chicken populations in Sri Lanka. Combination of molecular investigation with the production and environmental parameters was found to be important to assess the value of contribution of individuals to the diversity and adaptability. Our findings suggested that rearing system of indigenous chicken is the primary component that helps preserving genetic diversity, and the genetic makeup of the individuals play an important role in adaptability than in determining the productivity.

Introduction

Contribution of poultry meat and egg to global animal protein consumption is expected to increase to 38% by 2030 (Wahyono and Utami, 2018). Chicken meat and eggs are the best source of quality protein, particularly eggs carrying 87 NPU (Net Protein Utilization). Chicken products are the primary protein source for most of the rural communities in developing countries where poultry production is mainly based on indigenous ecotypes and scavenging backyard production system (Dematawewa, 2006). As a result of adaptation to varying environmental and management regimes, and due to low level of directional selection pressures, the indigenous poultry show high level of diversity. The pressures of production and economic standards prevailed in the industry have led to create a vacuum in continuous genetic progress of future poultry industry. While the commercial industry is currently shifting its attention more on health, product quality, and animal welfare, which now require access to diverse genotypes (Blackburn, 2006), the non-commercial or indigenous chicken populations are subjected to gradual genetic erosion due to lack of sustainable utilization programs. These two dichotomies would make the industry genetically stagnated in the future.

Despite the overall growth of commercial poultry industry, indigenous chickens remain as a predominant family industry in rural areas, owing to the balance between input and output levels under rural socio-economic conditions (DAPH, 2020). Scavenging or backyard system is the predominant practice found in indigenous chicken rearing in Sri Lanka (Gunaratne *et al.*, 1993; Silva, *et al.*, 2014 and 2016), where both nutritional and genetic improvements need to be addressed. In this context the wealth of molecular information generated so far to understand the extent and level of diversity needs to be interpreted in the context of the wide array of management systems and environmental regimes. This study attempted to relate the knowledge on genetic diversity and molecular analysis with the existing management and production standards to develop a strategy for improvement based on five indigenous chicken populations in Sri Lanka.

Materials & methods

A two-fold investigation of 132 sampling sites in five different regions in Sri Lanka; namely North Central province (NCP), North Western province (NWP), Western province (WP), Uva province (UP) and Southern province (SP) was carried out. One part of the study consists of molecular characterization of chicken by using Single Nucleotide Polymorphism (SNP) in mitochondrial D-loop of indigenous chicken from different geographical regions of Sri Lanka (results have been described elsewhere), and the other part of the study is to relate the molecular findings with the production and management aspects in development of sustainable utilization strategy.

The sampling locations or villages within the five regions were selected randomly. Sampling was carried out from households scattered within the village, and only one sample was taken from one household to avoid relatives been sampled for molecular analysis, incorporating diverse production and management information as far as possible.

The administration of questionnaire was carried out by a single visit to each household and multiple visits were made to regional veterinary office for data verification on farming conditions of the area.

Results

The molecular investigations related to the present study have been reported elsewhere (Silva *et al.*, 2008). The molecular findings based on the SNP analysis identified a comparatively high diversity with 42 haplotypes (31 unique haplotypes) belonging to six haplogroups, without a particular pattern of distribution with respect to geographical regions studied. Thus, the indigenous chickens in Sri Lanka are a mixture of diverse genotypes distributed all over the country.

The molecular diversity showed no association with the farming duration, purpose of farming, flock size, management practices (Table 1) and production standards (Table 2).

Table 1. Comparison of the management practices in different haplogroups identified among indigenous chicken in Sri Lanka.

Management criteria	Category	Haplogroup					
		A	B	C	D	E[1]	F[1]
Purpose (%)	Egg for hatching	79.5	90.9	81.8	80	100	100
	Egg for sale	18.2	6.8	13.6	20	0	0
	Egg and meat	2.3	2.3	4.6	0	0	0
Duration of farming (number)	≤1yr	6	6	3	1	1	0

Discussion

The management and production characteristics showed a random variation irrespective of the molecular categories (haplogroups), indicating no strong association of genetic categorization with performance of birds in village system. Given the fact that the within region variation of haplogroups is high and no regional specificity was observed in haplogroups (Silva *et al.*, 2008), this observation indicates that the level of performance of indigenous birds is mainly determined by the routine management criteria accepted by farmer communities. Thus, the genetic variation, as identified by the mitochondrial D-loop based haplotypes in this study, is not critical in determining the production in back-yard chicken rearing system. This could be a result of the system that allows no directional selection but stabilized natural selection. However, genotype is playing a key role in the process of adaptability (Barker, 2001), which is the major determinant in sustainability of the system. There was a high sustainability in the poultry production system, where most of the households continue to keep poultry for several decades. On the other hand, high adaptation to the environment by the population of birds reported here was confirmed by the less disease occurrence and absence of routine health care practices by the farming community. Thus, further molecular characterization needs to be done using the variability of the genes responsible for those characteristics.

The remarkably high adaptability of indigenous birds has been highlighted in many instances. This could be attributable to high genetic diversity existing among the indigenous chicken (Barker, 2001, Dessie *et al.*, 2011). O'Brien (1994) explained that genetic diversity can well be linked to the ability to respond to environmental changes. In a more specific study carried out to evaluate the level of diversity explained by the variation of mitochondrial DNA, Bazin *et al.* (2006) related the mitochondrial diversity with adaptive evolution of populations. Looking from a different dimension, Barker (2001) explained that responding to environmental factors or adaptation drives the process of maximizing the fitness, which consequently helps maintaining substantial genetic variance within population. The populations like Sri Lankan indigenous chicken, which evolve with varying environmental conditions, are easily adaptable and instrumental in conserving genetic variation through utilization.

Considering the high diversity in most livestock populations, Barker (2001) emphasized the value of multiple population breeding, where groups in each production system is considered as a separate breeding population. According to Namkoong (1998) the ensemble of breeding populations is a strategy for breeding to preserve production and adaptation in sustainable production system. This is basically because the populations in a system form factorial but not hierarchical breeding populations thus preserving the desired diversity (Namkoong, 1998). According to these observations the back-yard production system is the best arranged to preserve the genetic variation in the population. Therefore, the present study highlights

that the molecular investigations are to be interpreted in the context of the system with a proper evaluation on the trade-off of genes between adaptation and production.

Part 27

Breeding goals and selection strategies

463. Relative importance of selection objective traits in participatory breeding programs – MultiAtr software

R.N.B. Lobo

Embrapa Caprinos e Ovinos, Caixa postal 71, Sobral, CEP 62010-970, CE, Brazil; raimundo.lobo@embrapa.br

Abstract

The definition of selection objectives in animal breeding programs in developing countries is not a simple task, due to the lack of economic and productive data. Participatory rural appraisal tools contribute to this process. MultiAtr software was developed through linear programming with the simplex method, and an approximation to PAPRIKA method. Breeders (n=42) in Brazil and Colombia (n=77), participants of participatory breeding programs (PBP), were interviewed to define the traits priorities in their selection objectives for the production of meat from goats and sheep and dairy goats' system, respectively. The algorithm was used to estimate the relative importance of the traits of the selection aims. In Brazilian PBP, the most important traits were number of days for slaughter and animal adult weight. In Colombia, the most important traits were resistance to diseases and parasites, milk quality and milk production.

Introduction

In most developing countries, animal production, especially goats and sheep industries, tends to be disorganized and ultimately informal. Most business relationships are temporary and inconsistent and absent from legal contracts. Therefore, traditional breeding programs have not been effective. The attempts made were discontinued and did not reach the expected success. The reasons for this are due to the low level of production, the variety of local genetic resources (breeds, ecotypes, crossbreed, etc.) and the informality of the markets. A new approach to developing breeding programs in developing countries, especially in poor rural communities excluded from industrial programs, are participatory community-based breeding programs (CBBP), which take into account the needs, visions, decisions, and participation of the farmers, from inception to implementation (Sölkner *et al.* 1998; Wurzinger *et al.* 2011; Mueller *et al.*, 2015). Even in these programs, the decision-making process is complex and often demands time and difficulties for managers, project coordinators and, especially here, specialists in genetic improvement programs. Defining the weights of selection aim for a CBBP is among these challenges.

'Point', 'point-count', 'score' and 'linear' systems are known as additive multi-attribute value models with performance categories. They are solutions to generalized problems of how to combine alternative features on multiple criteria to rank the alternatives. Hansen and Ombler (2009) presented a method for 'scoring' such models to determine their values, based on decision makers' preferences. This method is called by the acronym PAPRIKA (Potentially All Pairwise RanKings of all possible Alternatives), and involves the decision maker's peer ranking. There are several applications of this type of model, to classify specific alternatives known by decision makers, such as prioritizing patients for access to health care, classifying students who apply to higher education schools, selecting immigrants by immigration services, etc. This method could be applicable to define the importance and weights of selection objectives in participatory breeding programs, based on the alternatives chosen and prioritized by the interviewed participants. The aim of this study was to identify the relative importance of economically important traits in two breeding programs (Brazil and Colombia), according to the vision and preference of the main decision makers, that is, the breeders, using a software that applies an approach to the PAPRIKA method.

Materials & methods

Information from two goats and sheep breeding programs was used, one in the semi-arid region of Brazil and the other in Colombia.

Brazil CBBP. The production system of this CBBP is for the production of meat from goats and sheep, with the animals managed in native pasture typical of the semiarid region of Brazil (Caatinga). Interviews were carried out throughout 2020, in seven districts of Tauá (four communities – Altamira, Lustal, Pitombeira and Veneza) and Parambu (three communities – Juazeiro, Novo Assis and Miranda), in the region of 'Sertões dos Inhamuns', in the state of Ceará, Brazil. All participants were adults and were between 18 and 89 years of age. A total of 42 breeders representing 122 families were interviewed in Tauá (nine in Altamira, five in Lustal, 12 in Pitombeiras and 16 in Veneza) and 40 breeders in Parambu (nine in Juazeiro, 18 in Miranda and 13 in Novo Assis). The traits of the selection objective, previously identified by the breeders were animal adult weight (WEI), average price of the animal at slaughter (AVP), fertility (FER), kids' survival (SUR), number of days for slaughter (DSL), number of deworming treatments (NDT), number of veterinary treatments (NVT), and animal weight loss in dry season (WTL). For each trait, three categories were defined to define the breeders' preferences (WEI = +5 kg on liveweight average, maintain average, -5 kg on liveweight average; AVP = +R$10.00 on the average price paid out by animal, +R$5.00 on the average price, maintain the current average price; FER = +10 kids/flock/year on the current average, +5 kids/flock/year on the current average, maintain the same average; SUR = +10 kids on the average of kids that survive until weaning/year, +5kids on this average, maintain the average; DSL = -2 weeks on average age at slaughter, -1 week on the average slaughter age, maintain the same average; NDT = -2 deworming/animal/year, -1deworming/animal/year, maintain the average; NVT = -2 treatment/animal/year, -1 treatment/animal/year, maintain the average; WTL = loss of until 5 kg on liveweight average, loss between 5 and 10 kg on liveweight average, maintain the current average).

Colombia participatory breeding program. In this country, the goat milk production system was considered. Interviews were carried out between August and November 2021, in three groups of interviewed, with the participation of 77 breeders, supported by Federación Nacional de Caprinocultores y Ovinocultores de Colombia (FEDEANCO), from different regions of the country (47 from Centro Andina Region, 11 from Caribe Region, six from Oriental Region, four from Coffee Axis Region, four from Pacific Region and five from other regions). The traits of the selection objective, previously identified by the breeders were adaptation (ADP), animal adult weight (WEI), fertility (FER), milk production (MLK), milk quality (MQU), mortality (MOR), persistence in lactation (PER), prolificacy (PRO), resistance to diseases and parasites (RES), and udder conformation (UDD). For each trait, three categories were defined to define the breeders' preferences (ADP = +20% on current average, +10% on the average, maintain average; WEI = +15 kg on liveweight average, +10 kg on average, maintain the average; FER = +20% on current average, +10% on the average, maintain average; MLK = +25% on current average, +15% on the average, maintain average; MQU = +25% on current average, +15% on the average, maintain average; MOR = -10% on current average, -5% on the average, maintain average; PER = +15% on current average, +10% on the average, maintain average; PRO = +15% on current average, +10% on the average, maintain average; RES = +30% on current average, +20% on the average, maintain average; UDD = +20% on current average, +10% on the average, maintain average).

MultiAtr software. The MultiAtr software was developed in FORTRAN language for use in command prompt (CMD). From the inequalities (strict preference) and equalities (indifference) corresponding to the explicitly classified pairs, the point values are obtained through linear programming with the simplex method according to an approximation of the PAPRIKA method. Although several solutions are possible for the linear program of inequalities and equalities, all the resulting point values reproduce the same

general classification of alternatives. For each respondent, the algorithm randomly presents the questions to be chosen with the combination between two objectives and two of their categories, in an inverse way in their levels. According to the example below:

****
WHAT IS YOUR PREFERENCE REGARDING THIS CHOICE? FERTILITY MORE 10% AND ADULT WEIGHT EQUAL IS ALREADY OR FERTILITY EQUAL IS ALREADY AND ADULT WEIGHT LESS 10KG TYPE 1 TO OPTION 1, 2 TO OPTION 2, 3 THEY ARE EQUAL, 4 TO SKIP AND 5 TO STOP
****

The maximum number of alternatives is defined by the number of categories to the power of the number of objectives. However, as the alternatives are arranged at different levels between the categories, according to the number of objectives and categories, the number of questions may not reach this maximum. Furthermore, according to the respondent's answers, some alternatives are eliminated as they are contradictory.

The algorithm was used to conduct interviews with participants in the aforementioned countries. Each participant was interviewed separately and their responses entered into the system. At the end of all interviews, the software estimated the priorities for selecting, according to the preference of their participants. Within each country, ANOVA of individual preferences, by region of that country, was performed to assess whether there were statistical differences between regional preferences.

Results

In Brazilian CBBP, the order of priority of the traits was DSL, WEI, FER, AVP, SUR, NVT, NDT and WTL (Table 1). Although there are some differences in this order between municipalities, and between districts, these differences are not statistically significant ($P>0.05$), and the general order should be considered.

In Colombian, for dairy goats' system, the order of preference of the traits, according to the perception of the breeders was RES, MQU, MLK, FER, PER, ADP, UDD, PRO, MOR and WEI (Table 2). Although there are some differences in this order between groups and between regions of the country (according to where the interviewees live), these differences are not statistically important ($P>0.05$), and the general order must be considered.

Discussion

The stated preference tools are widely used for valuation of non-marketed goods and services (Hoyos, 2010). In the livestock sector, a number of researchers applied them to identify trait preferences and estimate economic values for the traits in the breeding objective. This is quite useful and valid in CBBP, especially with regard to involvement and recognition of breeders' perceptions. A robust tool was developed to estimate these preferences, based on the PAPRIKA method, which has proved to be of great value in decision making (Hansen and Ombler, 2009). MultiAtr was able to quickly and consistently estimate the perception of breeders, in two participatory breeding programs, and reveal the importance of the traits of the selection objective of these programs.

The breeders in the Inhamuns region, in Brazil, are more concerned with increasing the animals' growth speed, the final weight of these animals and with the general fertility of the herd, in order to increase their income from the production of goats and sheep. On the other hand, in Colombia, the interviewees showed greater interest in increasing the resistance of their animals against diseases and parasites, not neglecting the aspects of milk production and quality, lactation persistence, adaptation and fertility.

Abstract

Angus HeiferSELECT is a genomic tool that provides genomic estimated breeding values (GEBV) for thirteen traits, to better inform the selection of replacement heifers. Using historical data, we validated predictions for birth weight (BW), weaning weight (WW), yearling weight (YW) and mature cow weight (MCW), based on the animal's self-performance and the average performance of their progeny. GEBV accuracies were higher for animals in the reference population and when self-performance data was considered. Accuracies were higher for MCW, followed by BW, YW and WW. After ranking animals based on GEBV, average progeny performance in the top versus bottom quartiles differed by 1.7, 5.9, 9.5 and 25.0 kg for BW, WW, YW and MCW, respectively. These numbers were about double when quartile differences were based on self-performance. We conclude that Angus HeiferSELECT GEBV can predict differences observed at the phenotypic level, which can add precision to the selection of superior replacement heifers.

Introduction

Targeted selection of replacement females is crucial to maintaining the best herd structure in commercial beef enterprises. The decision of which heifers to keep in the operation and which to sell potentially affects the profitability of the herd for years to come. One approach is to breed all available females and identify those that breed early. An alternative is to wait until after they wean their first calf and make a more informed decision based on progeny performance. However, for most producers, it is impractical to keep females which are not destined to remain in the breeding herd. Strategies to identify replacement heifers earlier include selection based on their date of birth, bodyweight, phenotypic evaluation including structural assessment, and pedigree information (Meat & Livestock Australia 2022). However, the additional use of genomic information can provide a more reliable method.

Angus HeiferSELECT (Angus Australia 2021) is an advanced genomic tool developed to inform the selection of replacement heifers in commercial beef breeding operations. It includes GEBV for thirteen maternal, growth, feed intake, carcase, and resilience traits. Thus, the tool provides information on traits that are otherwise difficult, time-consuming or expensive to measure using traditional methods, complementing other sources of information for the selection of replacement heifers. Similar tools with a genomic application at commercial level include Angus SteerSELECT (Hine *et al.* 2021), for the drafting of Angus steers, and Neogen's Igenity® Beef (Neogen 2022), which predicts the genetic potential of crossbred beef heifers, steers, and commercial bulls.

The accuracy of GEBV depends on several factors such as the heritability of the trait under evaluation, the size of the reference population, and the relatedness between animals being tested and animals in the reference population (Goddard and Hayes 2009). Hence, the objective of this study was to use historical data to validate accuracies of Angus HeiferSELECT GEBV and their association with performance for a range of growth traits, including birth weight (BW), weaning weight (WW), yearling weight (YW) and mature cow weight (MCW), based on the animal's self-performance as well as that of their progeny.

Materials & methods

Dataset. Data used in this study were accessed from the Angus Australia database. Data included: (1) HeiferSELECT GEBV for BW, WW, YW and MCW for all animals with genotype information in Angus Australia's Herd Book Register (HBR), Angus Performance Register (APR) or Angus Commercial Register (ACR) (n=153,978); (2) three generation pedigree information for all animals born from 2000 to 2021 (n=1,888,635); and (3) adjusted phenotypes for BW, WW, YW and MCW for all animals in the pedigree from a contemporary group of size ≥5 (Table 1). Phenotypes were adjusted for age at measurement, age of dam and contemporary group.

Accuracy analysis. For each trait, validation of GEBV (accuracy) was performed based on two Data Types: 1) Self-Performance: Pearson correlation between animals' GEBV and their own (adjusted) phenotype; and 2) Progeny Performance: Pearson correlation between parents' GEBV and the average (adjusted) phenotype of their progeny. In addition, different accuracy values were generated by grouping animals according to: (1) YOB: year of Birth was categorised into one of 5 categories: before 2000, 2001 to 2005, 2005 to 2010, 2011 to 2015, and 2016 or later; (2) Reference: whether or not the animals were included in the Angus HeiferSELECT reference population; (3) Trait: BW, WW, YW or MCW; and (4) Number of progeny: categorised from 1 to 24 and ≥25 for sires and 1 to 5 and ≥6 for dams.

ANOVA. An analysis of variance (ANOVA) was performed using PROC GLM (SAS Inst. Inc.) to identify significant effects influencing accuracy. Factors included in the ANOVA were Data Type, YOB, Reference, and Trait.

Q1Q4 quartile analyses. To evaluate the effect of genomic selection of parents on progeny performance, for each trait we ranked parents based on their GEBV. Then, we calculated the difference between the average progeny (adjusted) phenotype on the top and the bottom quartile, namely Q1Q4 measure, and compared it to the Q1Q4 measure based on self-performance.

Results

All factors considered (Data Type, YOB, Reference, and Trait), GEBV accuracy was estimated at an average of 0.40 (LSmeans). The ANOVA model explained 68.8% of the variation in the accuracy with the most

Table 1. Summary statistics for adjusted phenotypes, including Birth Weight (BW), Weaning Weight (WW), Yearling Weight (YW) and Mature Cow Weight (MCW), for data collected on the HeiferSELECT animals (self-performance) and the average of their progeny (progeny performance).

	N	Mean	SD	Min	Max
Self-performance					
BW	122,837	0.101	3.886	-23.0	23.4
WW	110,179	2.170	24.037	-182.1	173.9
YW	87,091	2.356	30.349	-201.1	195.0
MCW	7,993	2.662	50.104	-224.3	299.3
Progeny performance					
BW	32,499	0.035	3.084	-19.2	16.9
WW	26,283	0.642	19.567	-113.9	153.2
YW	21,458	0.723	23.867	-127.3	178.1
MCW	4,258	-0.070	41.390	-180.3	244.4

influential factors being Data Type ($P<0.0001$), followed by Trait ($P<0.0001$) and Reference ($P<0.001$). YOB was non-significant ($P>0.10$). Figure1 shows accuracies according to Data Type, Reference and Trait. There was a slight positive tendency for GEBV of sires and dams with a higher number of progeny to have higher accuracies, which was more apparent for BW (data not shown). The phenotypic differences between quartile one and quantile four (Q1Q4) for each trait, based on self and progeny performance, can be seen in Table 2.

Discussion

As expected, accuracies were higher for animals included in the reference populations and accuracies calculated based on self-performance were higher than those based on progeny performance. Accuracies were highest for MCW, followed by BW, YW and WW, which could have been influenced by differences in trait heritability, which follow the same trend (Torrez-Vázquez *et al.* 2018). When the parent was included in the reference population the accuracy was expected to be higher because its own (heritable) phenotype affects that of its progeny. However, no expectation existed about the impact of the number of progeny on the accuracy other than that the accuracy will be more accurately estimated when based on the results of more progeny. However, a slight increase in accuracies was observed for sires and dams with a higher number of progeny.

For the same trait, the Q1Q4 difference based on self-performance was about double that based on progeny performance, meeting inheritance expectations. For instance, animals ranked in Q1 for BW were, on average, 3.53 kg heavier than those ranked in Q4 when considering self-performance, while based on progeny performance the Q1Q4 diff was 1.71 kg. For MCW, Q1Q4 diff was 61 and 25 kg, respectively. Independent from the accuracy value for each trait, the difference between the top and bottom quartile could be translated into productivity differences, demonstrating the use of genomics to inform management decisions.

Figure 1. Accuracies based on self or progeny performance for animals, either in the Angus HeiferSELECT reference population (REF) or not (NOREF), for Birth Weight (BW), Weaning Weight (WW), Yearling Weight (YW) and Mature Cow Weight (MCW).

Table 2. Quartile analyses for Birth Weight (BW), Weaning Weight (WW), Yearling Weight (YW) and Mature Cow Weight (MCW) based on self-performance and average progeny performance when ranking parents by GEBV.

Angus HeiferSELECT predicts phenotypic differences in commercial Australian Angus cattle for BW, WW, YW or MCW, which was also reflected in the performance of their progeny. Therefore, this tool can add to the precision of selecting commercial replacement heifers that match the overall breeding objective when compared to the use of phenotypic measurements alone. The additional information provided by Angus HeiferSELECT can positively contribute to the productivity and profitability of commercial Australian Angus herds.

Abstract

A full-scale simulation that can cover all aspects of an ongoing breeding programme is a useful tool to test future breeding decisions. For example, dairy breeding is facing new challenges to include feed efficiency and methane emission traits in their breeding goals. To this end we have simulated a real size breeding programme of the Norwegian Red dairy cattle with detailed population structures and breeding decisions over the last 50 years. We simulated traditional progeny test and genomic selection scheme using AlphaSimR package. The simulation involved about 0.5 million animals per year spread across 7,000 herds with variable size, five groups of lactating cows, calves, heifers, and young, waiting, and proven bulls. This In-silico simulation tool will enable Geno SA – Norwegian Red breeding organisation to test future breeding directions, such as, including feed efficiency and methane emission traits into a selection index.

Introduction

Predicting future breeding outcomes is challenging due to the complexity of breeding programmes. Simulations have been widely used to predict the impact of various breeding decisions on future genetic trends. However, most simulation studies such as Wallen *et al.* (2017), often oversimplify breeding programmes by omitting breeding actions, downscaling the size of a breeding programme, and ignoring heterogeneity among different sub-populations. Therefore, results of such simulations must be interpreted with these limitations in mind. Accounting for such complexities in a simulation set-up can help to find better solutions for future challenges.

Dairy cattle breeding programmes are constantly improving. To maximize genetic gain these new findings, need to be optimally integrated in their breeding programs. One example is the integration of expensive and difficult to measure traits, such as feed efficiency and methane emissions. Deterministic prediction equations can be used to decide how many animals should be recorded (e.g. Daetwyler, *et al.* 2008) to maximize return on investment. However, such equations cannot take population and breeding programme structure into account.

Norwegian Red dairy cattle (NR) have a unique population structure and breeding history. NR is growing in popularity due to its high merit for production and functionally balanced cow, which is a product of selection towards such a breeding goal for at least 50 years. To improve this population even more, breeding organization of NR is evaluating data collection strategies to incorporate new traits, such as feed efficiency and methane emission. To support this aim we developed a simulation of a real size breeding programme of NR.

Materials & methods

We developed a simulation of a full population size of NR breeding programme including all live animals along with every single sub-population. We simulated the detailed population structure such as number of the herds, different lactating groups of the cows, the newborn calves, still-born calves, heifers, waiting bulls for progeny test, genotyped male and female calves, progeny and genomic tested bulls, proven bulls, and

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_465, © A. Ehsani *et al.* 2022

heifers for embryo transfer, according to the real population size of NR. Moreover, we accounted for the breeding history of the past 50 years and matched simulated trends in genomic and phenotypic parameters to real trends from the breeding data.

Data. First, we simulated a base population according to the cattle demographic history with effective population size of 250 to reflect the historical NR base population. Next, we simulated the 50 years of breeding under the breeding organization of NR, Geno SA (https://www.norwegianred.com, Table 1). The first 45 years of the simulation spanned years 1971 to 2015, where the NR breeding programme used the conventional progeny test scheme, and years 46-50 of the simulation spanned years 2016 to 2020, where NR breeding programme used the genomic selection scheme. We simulated milk yield trait with heritability of 0.19; additive genetic, permanent environment, herd-year, and residual variances of respectively 0.25, 0.35, 0.25, and 0.45 in an active population of 200,000 cows in five lactating groups producing the same number of calves with 1.5% stillborn, and 48,000 heifers. In the progeny testing scheme, there were five groups of selected young bulls and waiting bulls with 115 individuals each, and 16 proven bulls in service. In the genomic selection scheme 8,000 males were genotyped and 50 bulls with the highest estimated breeding value were selected for mating each year. Moreover, 22,000 female calves were selected for genotyping based on their parent average, and the top 90 heifers were selected for embryo transfer every year. The population consisted of 7,000 herds of variable size, matching the herd size distribution of NR in Norway with a Conway-Maxwell Poisson distribution with the mean of 29 and SD of 23.

Statistical models. We used repeatability animal model (Mrode 2014) for genetic evaluation. The statistical model used for progeny test scheme was:

$$y_{ijk} = \mu + a_i + pe_i + hy_j + e_{ijk} \quad (1)$$

where y_{ijk} is the phenotype of the individuals, μ is the general mean, a_i and pe_i are the random animal and permanent environmental effect for animal i, hy_j is the random herd-year effect for j^{th} herd-year and, e_{ijk} is random environmental effect respectively following $N\sim(0, A\sigma^2_a)$, $N\sim(0, I\sigma^2_{pe})$, $N\sim(0, I\sigma^2_{hy})$, *and* $N\sim(0, I\sigma^2_e)$. Variance components were based on estimated variance components in the NR population for milk yield with heritability of 0.192. Genomic evaluations were performed using the single-step method combining all the phenotypic, pedigree, and genomic information (Legarra *et al.* 2014).

The breeding programme was simulated using the AlphSimR package (Gaynor, *et al.* 2020) in R software (R Core Team, 2014) and genetic/genomic evaluations were performed using MiX99 (MiX99 Development Team, 2019). Ten replicates of the simulation were run to evaluate the genetic progress, as well as other genetic and non-genetic parameters.

Table 1. Simulation parameters.

Object	Value	Object	Value	Object	Value
Lactating cows[1]	200,000	chromosomes	29	herds	7,000
calves	200,000	QTLs	8,700	Mean herd size	29
Progeny test bulls	115	SNPs	58,000	SD herd size	23
Genomic test bulls	8,000	PT years	45	Bulls in service (PT)	16
Genomic test heifers	22,000	GT years	5	Bulls in service (GT)	50
Embryo transfer heifers	90	Ne	200	Lactating groups	5

[1] All the values are for one year simulation.

Results

To start with the simulation for the NR breeding program, we draw the overall picture of the two main breeding schemes, the conventional progeny testing scheme (Figure 1, left) for 45 years from 1971 to 2015 and the genomic selection scheme from 2016 to 2020 (Figure 1, right).

We have simulated every single sub-population stated in the Figure 1 as well as their distribution across the 7,000 herds. As stated earlier, the herd sizes and the spread of the herds over Norway is unique and needs a special care for a proper simulation.

AlphaSimR can incorporate any user defined effects such as herd, herd-year, permanent environmental effects, etc. to individuals or any groups of individuals like herds or sub-population groups such as cows in different lactations.

Figure 2 is a code snippet for assigning cows to herds and associating corresponding herd effects to a group of lactating cows. By grouping cows by lactation (five groups) and heifers inheriting the dams' herd we can simply simulate herd population structure with five AlphaSimR objects.

Evaluated genetic progress and other genetic and population parameters such as the level of inbreeding and heterozygosity, as well as genetic and phenotypic variances matched the observed trends in real breeding programme. Even though we needed to evaluate around 0.5 million individuals every year, the population size was not an issue in terms of computational limitations until the genomic selection scheme started. 30,000 new genotyped calves every year, increases the memory usage quadratically and will soon reach to the limit. We dealt with this issue using singular value decomposition procedure applied in the Mix99 software.

Discussion

We have generated *in silico* breeding program for NR using the AlphaSimR stochastic simulator. This is presenting the fundament for testing the potential changes in the future breeding programme of NR. This simulation will be used in the future to optimize phenotyping for traits that are expensive to record such as

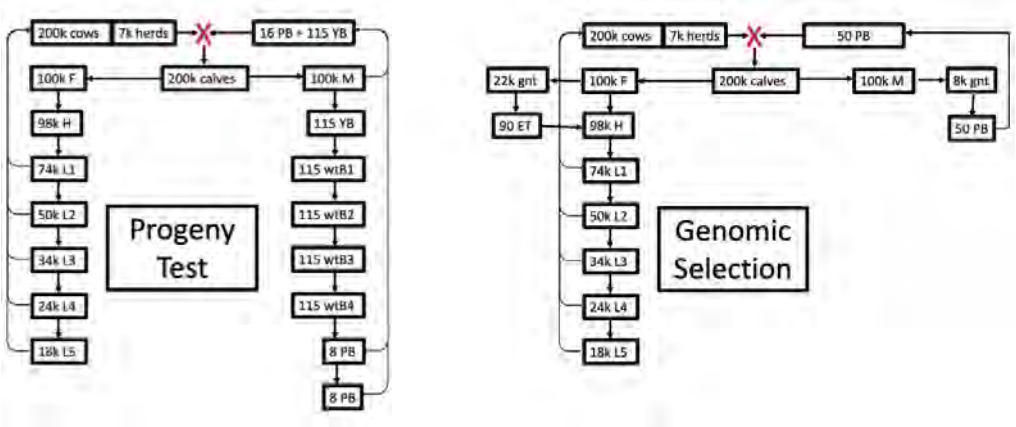

Figure 1. Population structure in the conventional progeny testing scheme (left) and the genomic selection scheme (right) for Norwegian Red dairy cattle breeding programme. PB = Proven Bulls, YB = Young Bulls, F = female calves, M = Male calves, H = Heifers, L1 to L5 refer to cows in lactations 1 to 5 respectively, wtB1 to wtB4 refer to waiting bulls in year 1 to 4 respectively, gnt = genotyped individuals, ET = Embryo transfer heifers.

```
Herd_Size = simcmp(n = (Number_Of_Herds),
                   v = c(Mean_Herd_Size, SD_Herd_Size))
Herd_Effects = rnorm(n = length(Herd_Size),
                     mean = 0,
                     sd = sqrt(Herd_Variance))
Herds_Data = data.frame(

feed efficiency and methane emission. The scenario with the maximum return on investment will be then suggested for the implementation in practice. We believe that having such a simulator is essential for every breeding programme, by which, every change in the future could be first tested *in silico* and then only the best solutions would be implemented in practice. After further testing and optimisation, we will share the AlphaSimR code with the research community.

466. Improving carcase value by incorporating primal weights into beef breeding objectives

N.R. Sarker*, B.J. Walmsley and S. Hermesch

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; nipa.bau02@gmail.com

Abstract

The impact selection for increased high-value primal cuts (HVC) has on improving beef profitability is important to explore. This study presented an approach that facilitates the extension of existing beef breeding objectives (BO) by including HVC. Economic values for HVC were derived for two different production systems: one pasture-based for the Australian domestic market (DPS) and the other grain-based for the Japanese market (JPS). The BO incorporated HVC on a percentage basis to maintain independence to carcase weight. The emphasis on HVC in the breeding objective was 8.78 and 10.77%, respectively, with annual predicted genetic gains from a mean of 0.10 and 0.18% in HVC for DPS and JPS, respectively. The addition of HVC increased the index response by 14.95 and 54.22% for DPS and JPS, respectively over the base scenario, which does not include primal cuts, indicating the potential of HVC to enhance selection for improved carcase value.

Introduction

In Australia, and most other countries, beef producers are currently paid on carcase weight, conformation and fat cover. These measurements provide the basis for payment to producers, with financial penalties for carcases that do not conform to desirable characteristics (Kenny *et al.*, 2020). The red meat yield, especially in primal cuts, dictates the economic and production efficiency at the processor level (Drennan *et al.*, 2009). Producing carcases with a higher proportion of red meat yield positively impacts beef processing profitability due to less fat and bone in the carcase. Overall, the proportion of primals, especially the high-value primals, is the main price determiner of a beef carcase for processors. The current beef breeding objectives do not include primal cuts. Therefore, the aim of this study was to derive economic values (EV) for high-value primal cuts (HVC) and predict responses to selection for HVC and other traits incorporated in current breeding objectives (BO) for Australian beef.

Materials & methods

Animal and primal cuts. Primal weights were recorded on 1,014 Angus cattle (876 steers and 138 heifers), from NSW Department of Primary Industries research herds. The animals were slaughtered between 2017 and 2020 at around 600 days of age and in lots of 23 to 54 animals per day. The primal cuts were classified into two groups based on their retail value; the HVC composed of the cube roll, striploin, tenderloin, rump, topside, intercostal and thick flank, and the low-value cuts (LVC) composed of the thin flank, hindquarter shank, forequarter shank, brisket, inside skirt, silverside, blade, rib set, chuck tender and chuck.

The breeding objective. In addition to the current BO traits, the BO included HVC to determine the value of increasing HVC at a fixed carcase weight. Breeding objectives were constructed for two terminal production systems relevant to Australian beef. One system was based on finishing steers off pasture for the Australian domestic market (DPS) with steers slaughtered at a target live weight of 620 kg. Marbling was assumed to have low value in this market. The other system was based on feedlot finishing steers for the high-quality Japanese market (JPS), where marbling was of high importance. JPS steers were slaughtered at a target live weight of 800 kg. Carcase prices at the farm-gate level were assumed to be $AUD5.40/kg and $AUD6.20/kg for the DPS and JPS markets, respectively.

Derivation of economic values for high-value cuts at farm-gate level. The BO defined HVC on a percentage basis rather than a weight basis to maintain independence from carcase weight. Firstly, the wholesale prices of different primal cuts were converted to farm-gate prices using the conversion factor k, so the derived EV of HVC was also at the farm-gate level. The factor k was calculated with Equation 1, Where P_p was the total farm-gate value of a carcase adjusted to a fixed weight of 305 kg or 350 kg for DPS and JPS, respectively.

$$k = P_p / \text{total weighted price of all primal cuts at the wholesale level} \quad (1)$$

Based on the weighted average of the difference between HVC and LVC, EVs were calculated by multiplying the price difference at farm-gate by 3.05 and 3.50 since a 1% increase in HVC represents 3.05 kg and 3.50 kg increases in HVC for DPS and JPS, respectively.

Beef index description. The BOs were developed with BreedObject (Barwick et al., 2005) and the selection criteria based around BREEDPLAN EBVs that align with terminal systems (Johnston et al., 1999). The EVs and parameters for BO (Table 1) and selection criteria (Table 2) traits used in this study were assembled from published (Archer et al., 2004; Wood *et al.*, 2004) and unpublished sources (pers. comm. Brad Walmsley, 2021). It was assumed that the live animal traits were recorded for the selection candidate, sire, dam and 25 half-sibs, while carcase traits except HVC were recorded for 25 half-sibs only. To investigate the effect of including HVC in beef breeding programmes, two different scenarios were modelled: one in which HVC was not included in the BOs, and another in which HVC was incorporated in the BOs without any relatives information for HVC. The annual response for each trait was predicted assuming an average generation interval of four years. Trait EVs were multiplied by their genetic standard deviation to show the relative importance of traits in BO.

Results

The HVC represented 8.78 and 10.77% of the BO emphasis for DPS and JPS, respectively (Table 3). This demonstrates that HVC could be important to include in future beef BOs. Inclusion of HVC in current

beef BO produced additional responses of 0.10 and 0.18% for DPS and JPS, respectively. Total responses improved when HVC was added to the current BO. The inclusion of HVC improved overall predicted index responses by $1.06 ($7.09 to $8.15) and $4.37 ($8.06 to $12.43) per year, respectively for DPS and JPS

and this equated to increases of 14.95 and 54.22%, respectively. Including HVC also changed the predicted responses of other BO traits favourably for both production systems. For instance, genetic gain for saleable meat percentage increased when HVC were included because of the positive genetic correlation between HVC and retail beef yield, which is one of the main profit drivers in beef terminal indexes. The response in marbling score was slightly decreased for the DPS. Another important trait in beef indexes was calving ease-direct, which also had a favourable response in the extended beef BOs. The inclusion of HVC in BOs trait could therefore be expected to be useful to improve overall selection response in both production systems in beef.

Discussion

Given current pricing systems, the findings of this study show that incorporating HVC into current breeding goals would benefit the beef industry. Selection for increased HVC resulted in increased responses for both production systems; however, in JPS, the relative importance of HVC was higher than DPS. If breeding values could be estimated by multi-trait animal models and made available, the EVs produced with the current model can be utilised to construct selection indices for beef in specific production systems. The model has a large number of traits, but it would be beneficial to include more carcase and meat quality traits. Broadening the breeding goal, particularly by including HVC, should result in more profitable animals; as a result, breeders' emphasis should include valuable primal cuts to increase the total market value of the carcase.

467. A method for partitioning trends in genetic mean and variance to understand breeding practices

T.P. Oliveira[1*], J. Obšteter[2], I. Pocrnic[1] and G. Gorjanc[1]

[1]The Roslin Institute and Royal (Dick) School of Veterinary Studies, The University of Edinburgh, Easter Bush, EH25 9RG, Edinburgh, Scotland, United Kingdom; [2]Agricultural Institute of Slovenia, Hacquetova ulica 17, 1000 Ljubljana, Slovenia; thiago.oliveira@ed.ac.uk

Abstract

Quantifying the sources of genetic change is essential for optimising breeding programmes. However, breeding programmes are often complex because many breeding groups are subject to different breeding actions. Understanding the contribution of these groups to changes in genetic mean and variance is essential to understanding genetic change in breeding programmes. Here we extend the previously developed method for analysing the contribution of groups to changes in genetic mean to analysing changes in genetic variance. We, expectedly, show that the contribution of females and males to change in genetic variance can differ and are not independent, indicating we should not look at the contributions in isolation.

Introduction

Quantifying sources of genetic change is essential for identifying key breeding actions and optimising breeding programmes. Due to the complexity of many breeding programmes, the observed genetic change is a sum of contributions from different groups of individuals (often referred to as selection pathways). These groups vary in their contribution due to different selection intensity, accuracy, genetic variation, generation interval, and dissemination. At the individual level, the breeding value of an individual can be partitioned as $a_i = \frac{1}{2}a_s + \frac{1}{2}a_m + w_i$, where a_i is the breeding values of the individual, a_s and a_m are breeding values of sire and dam, and w_i is the Mendelian sampling term. García-Cortés *et al.* (2008) provided a methodology to allocate these partitions of breeding values into group-specific contributions to the change in genetic mean. To gain insight into time-trends or other data partitions, they summarised group-specific contributions by a variable such as year, gender, population, etc. While García-Cortés *et al.* (2008) addressed the contribution of different groups to changes in genetic mean, breeding programmes should also consider the contribution of different groups to changes in genetic variance to fully understand drivers of genetic change in a population (Sorensen *et al.*, 2001; Lara *et al.*, 2021). Here we extend the method of García-Cortés *et al.* (2008) to analyse changes in genetic variance. We develop the method and demonstrate it with a simulation. We assume throughout we know the true breeding value. Future work will extend the method to estimated breeding values by applying the method on posterior samples of breeding values following the work of Sorensen *et al.* (1994; 2001) and Lara *et al.* (2021).

Materials & methods

Statistical framework. Let a be a vector of breeding values from a normal distribution with mean 0 and covariance $\mathbf{A}\sigma_a^2$. a can be written as a linear combination of breeding values from ancestors and individual's deviation from the ancestral expectation a = Tw, where T is a triangular matrix of expected gene flow between ancestors and individuals and $\mathbf{w} \sim \mathrm{N}(\mathbf{0}, \mathbf{W}\sigma_a^2)$ are Mendelian sampling terms representing deviations, with W being a diagonal matrix of variance coefficients and σ_a^2 the base population additive genetic variance (Henderson, 1976).

Assuming a factor with p groups and for any set $\sum_{j=1}^{p} \mathbf{P}_j = \mathbf{I}$, García-Cortés *et al.* (2008) partitioned the gene flow into contributions of each group by defining $\mathrm{T}_j = \mathrm{TP}_j$, and further partitioned the contribution of each group to breeding values *a priori* using the equality $\mathbf{a} = (\mathbf{T}_1 + \mathbf{T}_2 + \cdots + \mathbf{T}_p)\mathbf{w} = \mathbf{a}_1 + \mathbf{a}_2 + \cdots + \mathbf{a}_p$.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_467, © T.P. Oliveira *et al.* 2022

They further showed that these partitions can be estimated from data collected in breeding programmes (*posteriori*) by first estimating breeding values $\hat{\boldsymbol{a}} = E(\boldsymbol{a}|\boldsymbol{y})$ from phenotype data (y) and then partitioning $\hat{\mathbf{a}} = (\mathbf{T}_1 + \mathbf{T}_2 + \cdots + \mathbf{T}_p)\hat{\mathbf{w}} = \hat{\mathbf{a}}_1 + \hat{\mathbf{a}}_2 + \cdots + \hat{\mathbf{a}}_p$. By summarising these partitions, they quantified the contribution of each group (for example, males vs females) to the time-trend in genetic mean, where time-trend represents a change in genetic mean over time. This method has been implemented in the AlphaPart R package (Obšteter *et al.*, 2021), which efficiently calculates (via T^{-1}) and summarises such partitions by one or more variables, such as generation, selection status, etc. AlphaPart enables use of any function for the summarisation, that is, $f(a_j)$.

Here we extend the partitioning method to analyse the contribution of groups to genetic variance. Variance of breeding values is, *a priori*, $Var(\boldsymbol{a}) = Var(\boldsymbol{Tw}) = \boldsymbol{TWT}^T\sigma_a^2$. Using the equality $\mathbf{a} = (\mathbf{T}_1 + \mathbf{T}_2 + \cdots + \mathbf{T}_p)\mathbf{w} = \mathbf{a}_1 + \mathbf{a}_2 + \cdots + \mathbf{a}_p$, we can partition genetic variance as:

$$Var(\boldsymbol{a}) = Var\left((\mathbf{T}_1 + \mathbf{T}_2 + \cdots + \mathbf{T}_p)\boldsymbol{w}\right) = Var(\mathbf{T}_1\boldsymbol{w}) + Var(\mathbf{T}_2\boldsymbol{w}) + \cdots + Var(\mathbf{T}_p\boldsymbol{w}) +$$
$$2Cov(\mathbf{T}_1\boldsymbol{w}, \mathbf{T}_2\boldsymbol{w}) + \cdots + 2Cov(\mathbf{T}_p\boldsymbol{w}, \mathbf{T}_{p-1}\boldsymbol{w}) = \sum_{j=1}^{p}\mathbf{T}_j\boldsymbol{W}\mathbf{T}_j^T\sigma_a^2 +$$
$$2\sum_{j=1}^{p-1}\sum_{j'=j+1}^{p}\mathbf{T}_j\boldsymbol{W}\mathbf{T}_{j'}^T\sigma_a^2 = \sum_{j=1}^{p}\sigma_{a_j}^2 + 2\sum_{j=1}^{p-1}\sum_{j'=j+1}^{p}\sigma_{a_j,a_{j'}}.$$

While this 'theoretical' partitioning involves matrix products, we can also summarise partitions $a_1 + a_2 + \ldots + a_p$ (calculated via T^{-1}) by calculating variance of each partition $f(a_j) = Var(a_j)$ and covariance of each pair of partitions $f(a_j,a_{j'}) = \text{Cov}(a_j,a_{j'})$. The partitions can be summarised in many ways, for example, to quantify the contribution of males and females to change in genetic variance over time. We implemented this method in the AlphaPart R package (Obšteter *et al.*, 2021) with the summary method: summary(part, by = 'time', FUN = var), where part is an object with group-partitioned breeding values. This partitioning is for *a priori* or true breeding values. To estimate partitions of genetic variance from data collected in a breeding programme (*posteriori*) we would have to use methods from Sorensen *et al.* (2001) and Lara *et al.* (2021). While this is straightforward, we left this to future work.

Simulation. To illustrate the method, we have simulated one replication of a breeding programme with 1000 individuals over 40 generations. For the burn-in phase, generations -20 to 0, we selected the best 5 males (out of 500) as sires based on their phenotype and mated them with all 500 females from the previous generation and all 500 females from the current generation. These matings produced 1000 selection candidates for the next generation. After the burn-in phase, we tested two selection scenarios over additional 20 generations: we selected 5 best males from 500 male candidates based on their phenotypes (scenario 'phenotype') or true breeding values (scenario 'TBV'). The simulation was done with AlphaSimR version 1.0 (Gaynor *et al.*, 2020) using cattle genome, where we assumed 30,000 quantitative trait loci (QTL) with additive effects sampled from a normal distribution, and phenotype with heritability 0.3. With this simulation, we aimed to show how trends in genetic mean and variance come about due to the selection of males. We split T by using $\mathbf{P}_m + \mathbf{P}_f = \mathbf{I}$ and $\mathbf{P}_m^s + \mathbf{P}_m^n = \mathbf{P}_m$, where $\mathbf{P}_m$ is a diagonal matrix with ones in rows for males and zeros otherwise; $\mathbf{P}_f = \mathbf{I} - \mathbf{P}_m$; $\mathbf{P}_m^s$ is a diagonal matrix with ones in rows for selected males, and $\mathbf{P}_m^n = \mathbf{P}_m - \mathbf{P}_m^s$ is a diagonal matrix with ones in rows for non-selected males.

Results

Figure 1A shows time-trends in the genetic mean and variance and its partitioning by males and females, while Figure 1B represents trends partitions by selected males, non-selected males, and females. We scaled the genetic mean and variance of the base population respectively to zero and one to facilitate interpretation.

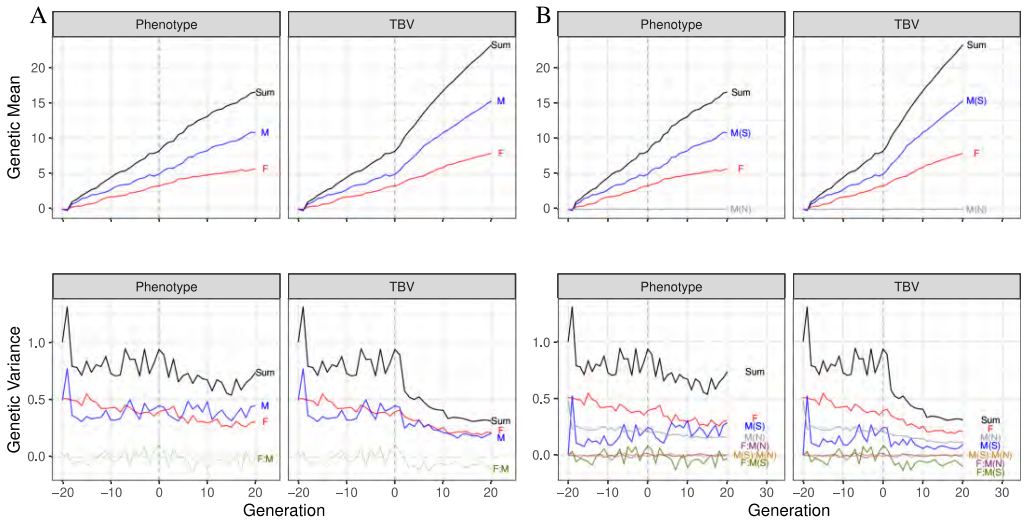

Figure 1. Partitioning of the total genetic mean and variance (Sum) over generation by (A) gender (male (M) and female (F)) and (B) gender and status (selected males (S) and non-selected males (N)). Each sub-figure shows the scenario with selection on phenotype (Phenotype, left) and selection on true breeding value (TBV, right). Covariance between two supposed levels A and B is represented using 'A:B'.

Figure 1A shows that selection of males contributed almost twice as much as females, which contributed only via dissemination of past male selection. However, if only sex is used to investigate the contribution of the males and females to the genetic variance, we can see that the contributions of males and females are very similar for both selection scenarios. In fact, males seem to be contributing a bit more to genetic variance than females in the phenotypic selection scenario. This observation raises a question, how can males contribute similar proportions to the genetic variance as females if we are selecting among males? The answer to this question is demonstrated in Figure 1B. Although non-selected sires do not contribute to the change in the genetic mean, they still contribute to the genetic variance. Selection on true breeding values clearly showed that the contribution of groups to genetic variance is a function of the intensity of selection. Selected males contributed least to genetic variance, followed by non-selected males and females. Partitioning in the scenarios with phenotype selection showed a similar result but selecting animals on their phenotype showed that the true partition for selected males may have a higher contribution to genetic variance than non-selected males.

Splitting the male contribution into selected and non-selected also shows that the negative covariance between male and female contributions in Figure 1A is driven by the covariance between female and selected male contributions (F:M(S)). The latter was consistently negative from generation 2 to 20 in the scenario with selection on true breeding values, resulting in a mean correlation of -0.52 (±0.12). This negative correlation means that the contribution of females and selected males to the genetic variance are not independent. That is, the total genetic variance is smaller than the sum of individual contributions.

Discussion

We presented a simple method for partitioning the trends in genetic mean and variance into contributions from different groups as an extension of the work of García-Cortés *et al.* (2008). We implement this method in the AlphaPart R package available from CRAN. This method can be a powerful and valuable

tool to understand how different breeding groups contribute to genetic mean and variance change. We demonstrated that the choice of groups is essential and that contributions are not independent. Hence, they should not be analysed in isolation from each other. Future work will apply the method to estimate trends in the genetic mean and variance following the work of Sorensen *et al.* (2001) and Lara *et al.* (2021).

468. A practical approach to predicting expected response to selection with a new index

X. Zhang*, P.R. Amer and C. Quinton

AbacusBio Ltd., 442 Moray Pl, Dunedin 9016, New Zealand; lzhang@abacusbio.co.nz

Abstract

Selection indexes need to be periodically evaluated and re-designed to adapt to new market trends and new included traits with economic weightings. Response to selection is one of the statistics used to predict the genetic trend, and to compare old and new indexes. The most popular method for response to selection requires knowledge of the selection intensity and generation intervals, which are hard to obtain. However, the ratio of these often unknow parameters can be assumed to remain constant and can be estimated by observation in an established breeding program. Therefore, we proposed a method to estimate the response to selection using a baseline selection index. The results show how new selection indexes can be characterised for estimated response to selection in trait units and economic units while avoiding making assumptions about breeding scheme design and structure. The new method is practical and easy to calculate, making index comparison straight-forward.

Introduction

Selection index redesign and updates occurs regularly across national breeding organisations as well as in commercial breeding companies. When changing the indexes, we generally evaluate a few statistical comparisons between old and new indexes with the help of a few graphics, such as: (1) degree of re-ranking among individuals displayed by scatterplots, index correlations, and percentage of re-ranking among the top-ranking individuals; (2) breeding objective trait percent emphasis pie charts or bar charts; (3) expected responses to selection in traits which are genetically correlated with the indexes, including non-index traits that have high correlations with the indexes. Among the three statistics, expected responses to selection are typically of most interested to animal geneticists. The objective of this study is to demonstrate a method to calculate the expected response to selection using known industry information without requiring detailed assumptions about the genetic improvement programs that drive genetic progress.

Materials & methods

Method. Response to selection (R) or change in true aggregated merit (ΔI) for an index is commonly calculated using a simple breeders' equation, such as that defined by Rendel and Robertson (1950) for example as:

$$R = \Delta I = \frac{i}{L_m + L_f} \cdot r_{TI} \cdot \sigma_T \quad (1)$$

where i is the average selection intensity of sire and dam, L_m and L_f are the generation intervals of males and females, r_{TI} is the correlation between g, the BV of a trait, and index I, and σ_T is the genetic SD of the trait.

For our example breeders' equation, we define $K = \frac{i}{L_m + L_f}$ as the effort of selection. A similar definition can typically be obtained for many other variations of the breeders' equation. Our method is underpinned by the assumption that selection effort K remains constant, even though the selection index is being changed. In the definition of selection index theory $r_{TI} = \frac{\sigma_I}{\sigma_T}$ (Gjedren, 1976). Combining this property of selection indexes with Equation 1 then $R = K \cdot \sigma_I$. In a situation where we have previously observed a change in a selection index in a particular period, we define this index as the baseline index and its change as R_{base}, i.e. $R_{base} = K_{base} \cdot \sigma_{Ibase}$, and

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_468, © X. Zhang *et al.* 2022

$$K_{base} = \frac{R_{base}}{\sigma_{I_{base}}} \quad (2)$$

We can use K_{base} as a baseline effort of selection to compare to a new index. With the same effort of selection over the same period of time, selection on a new index (I_{new}) will give response R_{new} in the new index as follows:

$$R_{new} = K_{base} \cdot \sigma_{I_{new}} = R_{base} \cdot \frac{\sigma_{I_{new}}}{\sigma_{I_{base}}} \quad (3)$$

And R_{new} is our interest. The response for any genetic trait of interest denoted g in its trait units when achieving R_{new} response in the new index is

$$R_{TU} = R_{new} \cdot b_{g,I_{new}}$$

where R_{TU} is the response in trait units, and $b_{g,I_{new}}$ is the regression coefficient of trait of interest g on the new selection index. Combining

$$b_{g,I_{new}} = \frac{\sigma_{g,I_{new}}}{\sigma^2_{I_{new}}} = \frac{r_{g,I_{new}} \cdot \sigma_g \cdot \sigma_{I_{new}}}{\sigma^2_{I_{new}}} = \frac{r_{g,I_{new}} \cdot \sigma_g}{\sigma_{I_{new}}} \quad (4)$$

where $r_{g,I_{new}}$ is the correlation between g and the new index. With Equation 3, the trait response in g when selecting on the new index is

$$R_{TU} = R_{new} \cdot \frac{r_{g,I_{new}} \cdot \sigma_g}{\sigma_{I_{new}}} = R_{base} \cdot \frac{\sigma_{I_{new}}}{\sigma_{I_{base}}} \cdot \frac{r_{g,I_{new}} \cdot \sigma_g}{\sigma_{I_{new}}} = R_{base} \cdot r_{g,I_{new}} \cdot \frac{\sigma_g}{\sigma_{I_{base}}} \quad (5)$$

The response in economic unit e.g. dollar will be

$$R_{EU} = R_{TU} \cdot a \quad (6)$$

where a is the economic weight of g. And the standardised response (i.e. expressed in SD of the trait of interest) will be

$$R_{STD} = \frac{R_{TU}}{\sigma_g} = r_{g,I_{new}} \cdot \frac{R_{base}}{\sigma_{I_{base}}} = r_{g,I_{new}} \cdot K_{base} \quad (7)$$

In the situation where $R_{base} = \sigma_{I_{base}}$ (i.e. we define the progress in the base index so as to quantify selection effort in index SD units) then K_{base} = 1 and the standardised response in g will be $R_{STD} = r_{g,I_{new}}$.

Materials. The economic weights of 13 traits in 2020 Australian dairy cow Balanced Performance Index (BPI) and health weighted index (HWI) were used here to demonstrate the response in trait unit (R_{TU}) and response in economic unit (R_{EU}) (Axford *et al.*, 2021; DataGene, 2020). The genomic Australian breeding value (ABV) predictions of 7,338 Holstein-Friesian bulls were used, excluding bulls with daughter fertility (FERT) accuracy less than 0.6, and bulls with missing ABV values. The R_{base} for the index was set to \$30 as observed annual response to selection (DataGene, 2021). An index testing app that has been developed by AbacusBio (Dunedin, New Zealand) to deploy the above methodology was used to calculate the two sets of response values and generate reports.

Results

Table 1 shows the R_{TU} and R_{EU} of 14 breeding objective traits and 3 monitor traits in BPI and HWI. Monitor traits had \$0 in economic weight therefore their R_{EU} were also 0. For example, the response to selection on

[2] Cheruiyot *et al.*, 2021.

BPI for the trait FERT in a year was estimated as an increase of 1.07% in 42-day calving rate, equivalent to $7.43 AUD increase in economic value.

Discussion

The most popular way of calculating response to selection requires the knowledge of selection intensity and generation interval of male and female selection candidates. The standardised response to selection is often used in selection index to predict the annual genetic progress. In this study, we demonstrated a method to calculate annual expected response without the knowledge of selection intensity and generation intervals, assuming their ratio remains constant in an established breeding programme. Then we used the observed baseline response to selection in the estimation of the new index. Our method is simpler and likely more accurate than the traditional method, because it can directly estimate the observed intensity to generation interval ratio based on the actual genetic trend under selection (Equation 2) and can avoid making assumptions about breeding scheme design. The forms of response to selection in trait units and in economic units rather than standardised response are more straight forward for practical use, easing the stakeholders' decision-making process.

When evaluating a national index where many different breeding programs operated by different companies have all contributed to genetic gains, our method eliminates the need for assumptions about each specific breeding structure and ultimate aggregation.

A limitation of our approach is that is we rely on the correlations among trait EBVs and indexes to estimate the response to selection, and this can change with different sets of candidates. These correlations are biased by prior selection of candidates, and this could be a problem when any new index being evaluated weights

traits radically different to the old reference index. However, in most instances, the impact of preselection of candidates based on the old index is consistent across the new and old indexes. This effect gets captured in K, and the regressions $b_{g,I_{new}}$ which are intrinsic to the method should be reasonably robust to prior selection affecting the variance of I_{new} which is the independent variable in the regression. In addition, using sets of estimated breeding values where there are mixtures of very old and much more recently born animals can introduce false correlation into the calculations due to genetic trends being greater in some traits than in others. Therefore, the choice of data input is important when evaluating indexes, although our experience across many different species and industries is that inferences about the future effects of new selection indexes are typically robust to whichever set of candidates estimated breeding values and indexes is chosen to deploy the method.

469. Theory and tools that are needed for the design and optimization of breeding programs

P.R. Amer

AbacusBio Limited P.O. Box 5585, Dunedin, New Zealand; pamer@abacusbio.co.nz

Abstract

Optimisation of genetic progress is of great interest and relevance to nearly all stakeholders in livestock genetic improvement and the wider supply chains that are impacted. However, many of the methods and tools developed and used by animal breeders assume that optimisation of genetic progress is the sole goal and focus of these stakeholders. In reality, the investor stakeholders in genetic progress are typically more strongly influenced by simple concepts and messages relating to things they can change, rather than complex black box representations of what a perfect breeding program would look like. Further, market share and price of germplasm sold relative to the costs of achieving genetic gains are important consideration. This paper first summarises the key issues facing many key investor stakeholders, and then describes at a high level the tools available to design and optimize breeding programs, and some potential gaps.

Introduction

The magnitude of investment in livestock genetic improvement globally must be at least hundreds of millions of dollars/euros, but the benefits in terms of increased farmer competitiveness, higher quality products, and lower costs of production which often lead also to lower consumer prices will be manyfold greater. Decision makers investing in livestock genetic improvement are predominantly interested in what they can do 'at the margin'. How much more benefit will they get relative to their change in total investment, or perhaps redirection of the investment they are making. Quite often the net benefits of marginal changes in investment in breeding program design are quite modest. From time to time as analysts, we might get the opportunity to design a new breeding program from scratch, but this is often a rarity. In this instance, the process can be more exciting, because of the broad nature of the decisions to be made, and quite a different approach is required. This paper presents the views of the author in terms of challenges and solutions associated with design and optimisation of breeding programs. This is then used as a baseline for commenting on the tools available, and what new tools might be most useful in the future.

Methods

Issues and challenges existing programs. The key decisions faced by investors in existing genetic improvement programs include:

- How much to invest in genetic improvement of new traits where there is currently direct financial incentive along the supply chain for their improvement?
- How much to invest in genetic improvement of new traits where there is currently no direct financial incentive along the supply chain for their improvement, but future incentives are anticipated?
- How much to invest in genomic reference population, how big they should be, and what phenotypes to collect, type of sample, and type of genotyping platform to use?
- How many and which selection candidates to genotype using what genotyping platform?
- What reproductive technologies are available and could be used to introduce new genetic variation, increase the pool of elite candidates and intensity of selection, multiply elite genetics, minimize risk of unfavourable mendelian sample in a single offspring from a mating pair?
- How to change the relative weighting placed on traits being selected now to maximise future industry benefits and/or future market share of gene-stock sales?

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_469, © P.R. Amer 2022

- How to select and mate individuals to optimise the trade-off between short term genetic gain, inbred offspring generation, and the long-term genetic diversity of the population?
- What opportunities are there to source elite genetics and/or introduce new genetic variation and genetic diversity from other countries, populations and breeds?

Issues and challenges new programs. The key issues faced by investors in a new genetic improvement program include;

- What foundation germplasm should I gather from which to build a new and genetically improved population?
- What traits are potentially easy to record and for which genetic gains will sufficiently catch the attention of the target market for improved germplasm to generate sales?
- What traits to record on what selection candidates and their relatives?
- Is a pure genomics approach likely to be superior than a more traditional design relying on information from individuals or their close relatives such as progeny testing?
- How long will it take before my investment starting today will yield a return that will convince key stakeholders that the investment is justified and worth continuing?

Existing tools and enhancement opportunities. A substantial proportion of animal breeding research addresses the need for fast, efficient and robust analysis of phenotypic, pedigree, and genomic data to help identify candidates who are superior for existing traits. In many instances, affordable canned software is available to complete basic analyses. More complex software systems can also be licensed at a much lower cost than individual redevelopment from scratch. Despite this, maintenance of entrenched legacy systems and a desire to completely control one's own destiny mean that custom systems are still common. Developers of these tools could focus more on issues influencing bias and inflation (over dispersed predictions) of estimated breeding values, as opposed to often focusing solely on prediction accuracy. In particular, when there are differences in the degree of over dispersion and/or biases for selection candidates arising from different breeding strategies (e.g. progeny test versus genomic selection), incorrect conclusions about the optimal breeding strategy can arise. These problems are exacerbated when industry loses confidence, for example when young bulls with high ranking from genomics typically drop once they have recorded daughters in the evaluation.

Beyond genomic prediction, design of breeding structures incorporating genomics often seems to be based on winning a large research budget and maximising animals genotyped. Sometimes an excessively high genotyping density is pursued to enable discovery of new variants that to date have made only a disappointing contribution to the rate of genetic gain. In some cases, commercial control of a large genotyping budget can be used as a barrier to market entry for potential new competitors but who cannot match the genotyping budget of the dominant market leaders. Equations which link accuracy of genomic prediction to training population size, prediction reliability of information contributing to training individual merit predictions, and effective population size, have proven a blunt, but useful tool when addressing genomic training population design issues. Unfortunately, the rather esoteric use of effective population size in the prediction formulae initially obscured the key issue of the importance of the degree of relatedness (number of meiosis) between selection candidates, and training population individuals. As more and more attempts are made to improve genomic prediction accuracy via causal variant discover, it may in the future be beneficial to account for the impact of genetic architecture of a trait on accuracy of genomic prediction from a specified training population.

A well-researched area relates to the trade-off between short-term genetic gain and long-term maintenance of genetic variation. Very powerful and useful tools have arisen from this research although their impact is

still limited in many cases. When a single decision-making entity is not responsible for all of the selections relevant for a single population, commercial interests are pushed by the market towards maximising their own short term competitive position. This can come at the expense of genetic diversity. In other situations, the unpredictable nature of the ability of selection candidates to contribute to the next generation becomes a problem. For example, if an optimal contributions selection algorithm identifies a single candidate for a relatively high contribution, but then that candidate fails on some physical or genetic criteria at the last minute prior to mating, the entire analysis may need to be reworked in a very short time frame. Systems that can identify interchangeable contributors to the next generation and/or optimise the contributions of families are important ways of overcoming these practical limitations. Provided all candidates have been genotyped, replacement of pedigree relationships with genomic relationships will be straight forward in these approaches. This will also open the way for sophisticated management of genetic disorders where frequency has increased sufficiently to be of concern to farmers.

In theory, accurate quantification of absolute economic values should be a key ingredient at the outset of designing a new breeding program and when considering reinvestment or redesign of an existing breeding program. In practice, this is seldom the case. Just as one does not usually learn to ride a bicycle by spending a large amount of time pointing the bicycle in some desired long-term direction of travel, the tendency is for breeding programs to initially follow a wobbly trajectory in terms of trait priorities. The direction of travel can be subsequently refined once the breeding program is up and running. Some basic knowledge of the value of genetic progress that is currently, and could potentially, be achieved is still critical to breeding program design. While in some cases, the value of genetic gain is considered from the perspective of the farmer end users of the genetic gain achieved, for competitive breeding companies, value of increased market share, and/or price received for germplasm units are also important. In many situations, the relationship between genetic merit and price received is exponential in nature, with elite offerings achieving very high premiums, while intermediate merit offerings realising much more modest prices. A market research philosophy is often helpful when considering breeding objectives to help drive adoption and market share gains. An accurate understanding of value is particularly important when considering the value from adding new traits into a new or existing breeding program.

Stochastic simulation tools have played a valuable role in uncovering key design nuances. However, they can be cumbersome to build and operate, and commonly fail to accommodate commercial and practical realities that constrain the design options in practice. Maximum benefits can be obtained from these approaches if great attention is paid to understanding the existing breeding program and industry structures, and the inherent constraints within them. Because decision makers are faced with simultaneously addressing many strategic and logistical decisions, results and interpretation of the simulations should be broken into simple step changes to current structures with a clear and compelling description of the benefits that should arise from each change. Because of this, the simulations should simplify as much as possible the aspects of industry structure and breeding scheme design that do not require a complex model representation. A fast turnaround on results, and ease of design modification are critical to facilitate an interactive process with key decision makers and industry representatives. In this way, the industry can build ownership in the results, and future changes in scheme design are more likely to be forthcoming.

Equations that express the annual rate of genetic progress in a trait or index as a function of selection accuracy, genetic standard deviation, and generation interval (sometimes referred to as the 'Breeders Equation'), is a classic and helpful tool for communicating the basic principles of breeding program design. However, there are many limitations to this approach. Firstly, the equations assume static rates of genetic gain, and fail to account for the transition from the status quo to the time any new breeding approach has an impact. This is particularly important when comparing a progeny testing strategy with a genomic

selection strategy. Genomic selection strategies potentially allow superior animals to be marketed within a much shorter time frame (basically at reproductive age), rather than waiting for performance records to be available on progeny, for example with a progeny testing strategy. The delays between selections in higher tiers of multi-tier pyramid breeding structures and commercial impacts can be very large, although the multiplication of benefits across a larger industry share mean that long term sustainability and competitiveness of the breeding program is improved.

Finally, selection index theory seems to be becoming something of a lost art in animal breeding. While the principles of selection index theory are fully embedded in mixed model equation methodology applied in animal breeding, genetic evaluation systems provide little insight into the design of breeding programs. The concepts of having contributing information sources from selection candidates along with their close relatives and recorded animals in genomic training populations to the accuracy of genetic evaluation are key to understanding and optimising breeding scheme design. Several existing tools are available, but there is an opportunity to generate shared libraries of source code that would allow a more flexible and modular approach to their application.

Discussion

Breeding schemes will deliver many billions of benefits to livestock industries around the world with the costs to run these schemes a small fraction of the benefits. Research into breeding scheme design has been instrumental in some step changes in breeding program approaches and has also generated a lot of useful tools to help with further refinements to breeding scheme designs. Stronger dialogue among industry, academia and government is required to make sure that future refinement of the tool set outlined in this paper is fit for purpose going forward. A better understanding of capital budgeting from an investment perspective, and cost benefit analysis, would be very valuable. Perhaps a new on-line forum that would allow new ideas, and past experiences to be shared in an open and constructive way. Internships that facilitate placement of young professionals in a range of different industry settings should continue to be encouraged to strengthen these important links.

470. General properties of the optimum selection index

R. Wellmann

University of Hohenheim, Department of Animal Genetics and Breeding, Garbenstraße 17, 70599 Stuttgart, Germany; r.wellmann@uni-hohenheim.de

Abstract

Selecting animals for breeding based on their selection index should maximize the genetic merit of a population in future generations. Selection index theory assumes traditionally that the vector with breeding values of an animal is a sufficient statistic from which the optimum selection index can be calculated. It is, however, intuitively obvious that selecting outcross animals for breeding can increase the genetic variance in future generations, and can thus accelerate future genetic progress. This calls the traditional assumption into question. It is shown that the optimum selection index for the additive model depends not only on the breeding values, but also on the allele contents of major QTLs, and on the kinship of the individual with the population.

Introduction

Selection index theory was founded by F.H. Smith, and L.N. Hazel in the 1940s. It is the standard tool used in livestock breeding to combine information on different traits into a single value. Selecting animals for breeding based on their index should maximize the genetic merit of the population in future generations. Traditional selection index theory is based on the assumption that genetic correlations and genetic variances do not change over time. Under this assumption, the optimum method for constructing selection indices generalizes the approach of Moav and Hill (1966). The authors assume that the total merit of an individual i is obtained by a non-linear function $\mathrm{TMI}(\mathrm{Ph}_i)$ from the K-vector Ph_i of phenotypes. The total merit function is integrated over the distribution of phenotypes, and is then considered a function $\overline{\mathrm{TMI}}(\mu)$ of the K-vector μ with trait means. For a planning horizon of n generations, the response area is defined as the set of all population means μ_n that could be achieved within n generations of selection. The response area is an ellipsoid with center equal to the current population mean μ_0. For a given breeding policy π, the population mean μ_n^π after n generations of selection belongs to the response area. The optimum breeding policy $\dot{\pi}$ is defined by the straight line from the current population mean μ_0 to the local maximum $\mu_n^{\dot{\pi}}$ of the total merit function. The method of Moav and Hill (1966) thus provides the solution to the problem of finding the optimum breeding policy π that maximizes the objective function $f(\pi) = \overline{\mathrm{TMI}}(\mu_n^\pi)$.

Dekkers *et al.* (1995) generalized the method to the more relevant case that future genetic gains are discounted. This leads to more emphasis being placed on the short-term than on the long-term response. In this case, the objective function has the general form $f(\pi) = \sum_n \zeta_n \overline{\mathrm{TMI}}(\mu_n^\pi)$, where μ_n^π is the expected population mean after n generations of selection under breeding policy π and ζ_n is the discount factor for generation n. The index weights for the optimum breeding policy depend on the population mean in the respective generation.

To our knowledge, all authors assume implicitly that the vectors with breeding values of the selection candidates are sufficient statistics from which the optimum selection index can be calculated. This paper summarizes recent work of the author that shows that this is not the case, and provides an overview on the general form of the optimum selection index for the additive genetic model.

Theory

The optimization problem. Let TMI(Phi) denote the total merit of an animal i with phenotype vector Ph_i. The objective of the breeding program is assumed to maximize the total merit of the breed in future generations. The expected total merit of the breed in n generations is:

$$\overline{\mathrm{TMI}}_n(\pi) = E_\pi\big(\mathrm{TMI}(\mathrm{Ph}_n)\big)$$

where Ph_n is the K-vector with phenotypic values of an individual that is randomly chosen from generation n, and π is the breeding policy followed for determining the matings in each generation based on the information that is available on the selection candidates. A general form of the objective function is:

$$f(\pi) = \sum_n \zeta_n \overline{\mathrm{TMI}}_n(\pi)$$

where ζ_n discounts future genetic gains. The optimum breeding policy $\dot{\pi}$ maximizes the objective function on a set Π of permissible breeding policies.

A decomposition of the objective function. Let the distribution of the phenotype vectors be indexed by a parameter $\xi \in \Xi$. That is, f_ξ is the density of the phenotype vector Ph_i for animals that are randomly chosen from the population. In the case of a multivariate normal distribution, we have $\xi = (\mu, \Sigma_P)$, where μ is the K-vector with trait means, and S_p is the $K \times K$ phenotypic covariance matrix.

The change of population parameters from one generation to the next is assumed to be deterministic. Let Θ be a set of population parameters such that first, $\xi = \xi(\theta)$ can be estimated from θ, and second, a mapping $\Gamma_\pi: \Theta \to \Theta$ exists that describes the change of the population from one generation to the next under a given breeding policy π. The breeding policy also determines the mating list $L \in \mathcal{L}$ of the selection candidates from the current generation based on the information that is available on the selection candidates. Let the population parameter $\theta_1(\mathrm{L})$ in Generation 1 be defined as a function of the mating list L. The expected population parameter in generation n≥1 equals

$$\theta_n^\pi(L) = \Gamma_\pi^{n-1}\big(\theta_1(L)\big)$$

and the expected total merit of the population in n generations is

$$\overline{\mathrm{TMI}}_n(\pi) = \overline{\mathrm{TMI}}(\xi_n^\pi) = \int \mathrm{TMI}(x) f_{\xi_n^\pi}(x)\, d\, x,$$

where $\xi_n^\pi = \xi\big(\theta_n^\pi(L)\big)$ extracts the parameter of the phenotypic distribution from $\theta_n^\pi(L)$.

An algorithm for finding the optimum breeding policy. The breeding policy affects the objective function in two ways. It determines the mating list of the selection candidates from the current generation, and it determines the change of population parameters from one generation to the next. Solving for the optimum breeding policy could be done with an iterative approach that assumes that the breeding policy used in later generations could be different from the breeding policy used in the current generation. This allows us to consider the mapping Γ_π to be known. The objective function then depends only on the mating list L_π of the selection candidates, so we can write $f(\pi) = f(L_\pi)$. The algorithm is initialized with some prior guess π_0 about the optimum breeding policy. In each iteration j, the breeding policy π_j for a certain generation could be determined that maximizes the objective function under the assumption that breeding policy π_{j-1} will be used thereafter.

The problem of finding the optimum breeding policy could be simplified by restricting the set Π of breeding policies to policies of a certain type. In the following, we assume that all permissible breeding policies implement truncation selection and random mating. The assumption of random mating allows us to compute the mating list from the vector c with genetic contributions of the selection candidates, so we can write $\theta_n^\pi(L) = \theta_n^\pi(c)$, and $f(L) = f(c)$. The index on which selection is based is given by the gradient of the objective function, so an animal is selected for breeding, if the selection index $I_i = \frac{\partial f}{\partial c_i}(\tilde{c})$ is larger than a certain threshold value, where vector $\tilde{c}$ contains some default contributions of the selection candidates.

Assumptions. We assume normally distributed phenotypes, an additive genetic model, and a parameter space Θ that contains all tuples $\theta_n^\pi = (\mu_n, p_n, \bar{f}_n)$, where μ_n is the vector with trait means, p_n is the Q-vector with the frequencies of known QTLs, and $\bar{f}_n$ is the average kinship of the population in generation n. Moreover, we assume a total merit function of the form:

$$\mathrm{TMI}(\mathrm{Ph}_i) = \tau_{\max} - \sum_{k=1}^{K} \omega_k |\mathrm{Ph}_{ik} - \mathrm{Opt}_k|$$

where Ph_i is the K-vector with phenotypes of animal i, τ_{max} is the maximum achievable total merit, Opt_k is the optimum for trait k, and ωk is the weight of trait k in the total merit index.

The selection index. The phenotypic variance of trait k in Generation n is:

$$\sigma_{Pnk}^2 = \mathrm{V}_{Ek} + (1 - \bar{f}_n)\mathrm{V}_{Ak} + \sum_{q=1}^{Q} 2p_{nq}(1 - p_{nq})a_{qk}^2$$

where V_{Ek} is the environmental variance, V_{Ak} is the polygenic additive variance of trait k in a non-inbred population, p_{nq} is the frequency of the alternative allele of QTL q in generation n, and a_{qk} is the additive effect of QTL q on trait k. We can write p_{nq}, μ_{nk} $\bar{f}_n$, and σ_{Pnk}^2 as functions of the vector c with genetic contributions of the selection candidates. It is shown in Wellmann (2022) that the optimum selection index I_i of an animal depends on the changes of these parameters in subsequent generations that would be induced by using that animal for breeding. That is, the selection index is a linear function of:

$$I_\mu^{nki} = \chi_\mu^{nk} \frac{\partial \mu_{nk}}{\partial c_i}(\tilde{c}), \quad I_q^{nki} = \chi_\sigma^{nk} \frac{\partial p_{nq}}{\partial c_i}(\tilde{c}), \quad \text{and} \quad I_f^{nki} = \chi_\sigma^{nk} \frac{\partial \bar{f}_n}{\partial c_i}(\tilde{c})$$

The weight χ_μ^{nk} placed on improving the mean of trait k in generation n is:

$$\chi_\mu^{nk} \propto 1 - 2\Phi(\Delta\sigma_{Pnk})$$

where Φ is the distribution function of the standard normal distribution, and $\Delta\sigma_{Pnk}$ is the number of phenotypic standard deviations, trait k is in generation n above the optimum. The weight χ_μ^{nk} approaches ±1 for large, and 0 for small values of $|\Delta\sigma_{Pnk}|$. That is, traits under directional selection are implicitly given large weights, while traits under stabilizing selection are given small weights.

The weight χ_σ^{nk} placed on adjusting the phenotypic variance of trait k in generation n is:

$$\chi_\sigma^{nk} \propto \sqrt{\frac{2}{\pi}} \exp\left(-\frac{(\Delta\sigma_{Pnk})^2}{2}\right)$$

The weight χ_σ^{nk} approaches 0 for large values, and ≈0.8 for small values of $|\Delta\sigma_{Pnk}|$. That is, for a trait under stabilizing selection, the selection index gives implicitly a high priority on reducing the phenotypic variance of that trait. This is because traits with a small phenotypic variance tend to deviate less from the optimum.

The envisaged reduction of the phenotypic variance could be achieved by driving QTL alleles to fixation or by inbreeding, whereby the latter would have unwanted side effects. We have:

$$\frac{\partial \mu_{1k}}{\partial c_i}(\tilde{c}) = \mathrm{EBV}_{ik},$$
$$\frac{\partial p_{1q}}{\partial c_i}(\tilde{c}) = \frac{X_{iq}}{2},$$
$$\frac{\partial \bar{f}_1}{\partial c_i}(\tilde{c}) = 2\bar{f}_i,$$

where EBV_{ik} is the breeding value of selection candidate i for trait k, X_{iq} is the allele content of the individual for QTL q, and $\bar{f}_i$ is the kinship of the individual with the population. The derivatives $\frac{\partial \mu_{nk}}{\partial c_i}(\tilde{c})$, $\frac{\partial p_{nq}}{\partial c_i}(\tilde{c})$ and $\frac{\partial \bar{f}_n}{\partial c_i}(\tilde{c})$ for $n>1$ are linear functions of these values. In particular, $\frac{\partial \mu_{nk}}{\partial c_i}(\tilde{c})$ depends on the kinship $\bar{f}_i$ of the selection candidate with the population. Hence, if selection candidate i has a small kinship with the population, then the use of that animal for breeding can have a delayed positive effect on the genetic gain in later generations. This delayed positive effect results from a better conservation of the genetic variance.

Discussion

The formulas presented in this paper are examined in greater detail in Wellmann (2022). They show that the optimum selection index for the additive model depends not only on the breeding values, but also on the allele contents of major QTLs, and on the kinship of the individual with the population. The index weights on the allele frequencies have the purpose to drive alleles to fixation when the trait mean approaches the optimum. This reduces the phenotypic variance, and thereby increases the total merit of the population. The index weight on the kinship has the purpose to balance the benefit that arises from using outcross individuals on increasing selection response in future generations, and the benefit that arises for traits under stabilizing selection from reducing the phenotypic variance. In a dominance model with inbreeding depression, the weight put on the kinship could also account for the negative effect of inbreeding depression. Selection in livestock breeding is currently not based on the optimum selection index, which might contribute to the low effective population sizes of various breeds.

Abstract

Bioeconomic models are commonly used in advanced breeding programs to calculate breeding objective economic values and index trait weightings. As industry genetic improvement programs expand to include more traits and diverse farming styles, models necessarily increase in complexity. Here we describe flexible modular approaches to bioeconomic models and breeding objective development that are readily adapted to new traits and farming systems. This approach allows substantial emphasis on user acceptability, transparency, and ultimately adoption of index-based selection.

Introduction

The goal of multi-trait breeding objective development is to derive the relative weightings for various goal traits to generate optimal overall genetic gain. Typically, in advanced animal breeding objective design this means calculating the economic value (EV) of each goal trait and generating selection index weightings. An EV can be defined as the change in profit per 1-unit change in the trait, independent of all other objective traits. While a technically efficient balance of traits is important, the balance of weightings can also have critical implications for index adoption, which can dramatically improve selection efficiency relative to reliance on ad-hoc threshold criteria.

The classic profit function and bioeconomic model approaches to EV calculation have been well described (e.g. Goddard, 1998). In a profit function approach, a simple linear profit equation is built that describes the influences all breeding objective traits have on profitability via revenues and costs. For each trait, the EV is calculated as the partial derivative of the profit function with respect to that trait keeping all other traits constant (at population mean). This process can work well in simple situations, with a small number of traits and straightforward associations with profit, and where genetic parameters among breeding objective traits that have direct economic value and available selection criteria (EBVs) are well established. However, modern large-scale breeding programs have many objective traits spanning production quantity and quality, fertility, survival, health and welfare. Environmental traits are a further new addition, and it is common for a number of these traits to have a complex or obscure relationships with system profitability. For example, in a dairy system, longevity will influence herd dynamics and age structure which in turn affect lactation patterns, fertility, and milk production; these all have revenue and cost, as well as environmental, implications. As stated by Nielsen *et al.* (2014), simple linear profit function approaches are usually inadequate to calculate EVs for advanced breeding programs.

Sophisticated bioeconomic models are a better approach to represent complex herd/flock structures and dynamics which are necessary to value functional traits such as longevity that are increasingly important to breeding programmes (Nielsen *et al.*, 2014). These models usually encompass many traits and accommodate sophisticated interactions among genetic traits and management variables. EVs are calculated from changes in revenues and costs that derive from trait changes. For breeding objective design, bioeconomic models are preferably designed specifically for calculating EVs; those built for other purposes (e.g. nutrition models) tend to contain over-complex interactions among traits, and/or between traits and management that are

irrelevant to EVs. Embedded genetic correlations/associations that violate the EV definition of change in profitability independent of other objective traits can be a particular concern. A challenge of bioeconomic models is the scale of knowledge needed. Analysts need a comprehensive understanding of the model contents and calculation processes to ensure EVs are correctly calculated and adapted for new knowledge, objectives and genetic evaluation development.

Modular bioeconomic model approach

Nielsen *et al.* (2014) proposed that a trait-by-trait or modular approach to bioeconomic modelling has advantages for calculating EVs in advanced breeding programmes. In this structure, the EV calculations for each trait are built as separate modules. For some traits the EV module can be based on simple profit functions. For traits with greater complexity, EV modules may contain detailed models of long-term growth or other biological change with calculated nutrient requirements, or herd structure models. Separate modules can be built for traits in alternate production systems within an industry and resultant EVs can be proportionately weighted to create an overall trait EV. Where a trait influences profitability at multiple points in time or in different generations, modules can be built for each trait and resultant EVs weighted by discounted genetic expressions (e.g. Amer, 1999; Quinton *et al.* 2021 mature cow body weight) to create an overall trait EV. It is crucial that economic, biological and environmental parameters are consistent, therefore all modules should draw from a common set of core input parameters. While care is required to avoid double-counting trait value across modules, in some instances, a small degree of double counting can great simplify the index calculation, without deviating from a highly efficient and industry accepted outcome. This modular bioeconomic model approach to breeding objective development has been successfully applied in a wide range of animal breeding objectives. Here we describe advantages of this approach with examples.

Transparency. Modularised bioeconomic modules are generally easier for all levels of breeding objective developers and users to understand and interpret. Transparency is key to uptake through stakeholders' understanding how their needs are included in the breeding objective design. In a large integrated model, many trait interactions can obscure the economic consequences of trait change; this can leave users disconnected and potentially sceptical of the methods. The modular approach allows each trait to be valued one at a time, which can be more intuitive for farmers and non-geneticists. The modular approach also allows application of subindexes that users can understand easily and apply for their specific selection targets. For instance in sheep, the New Zealand Maternal Worth (https://www.blnzgenetics.com/ram-selection-tools) standard index is built from a set of 5 subindex modules (lamb growth, adult size, reproduction, lamb survival, wool) that sum to the total index. Here, modularisation provides farmers with a middle ground that is more readily understood than 10 EBVs and a total index value. There is also a level of user customisation with optional add-on subindexes for meat yield, health, and other trait groups for farmers willing to record; EVs for each of these options are derived in specific trait modules.

Adaptable to new evaluations. With a modular structure, it is more straightforward to add or change individual trait EV calculations when genetic evaluations change, without having to re-calculate other goal trait EVs. This adaptability is increasingly important as genomics is rapidly adding new trait evaluations for both nucleus/breeder level and commercial animals. Axford (2018) described the challenge of adding Feed Saved to developed Australian dairy indexes (Byrne *et al.* 2016); here the modular approach allowed this trait to be incrementally added to the index without changing the EVs for other traits. It is also an advantage for genetic evaluation implementation code, minimizing the complexity of changes needed. Similarly, modularity allows exploration of traits where there is less confidence in genetic parameters or genetic relationships without influencing EV calculations of traits whose genetics are well understood.

Non-linear economic value flexibility. Non-linear EV functions are increasingly of interest in breeding objectives (Quinton et al. 2019;). In cases where a linear EV is too simple or does not reflect profitability in diverse populations, non-linear functions can provide more realistic valuation of traits within a breeding objective and are intuitive to users. However, in a fully integrated bioeconomic model where traits interact, non-linear functions can confuse the relationships between other traits and profitability and make it difficult to understand the exact drivers of correlated traits' EVs. Therefore, a modular approach that values each trait independently is critical to implement non-linear EV functions. We have had many favourable experiences with non-linear indexes in practice. For example, farmers generally wish to penalise very difficult calving bulls. However, they do not want a very easy calving bull to rank well if they do not deliver good growth and carcase composition; non-linear EV have therefore been implemented in beef and dairy beef objectives (Berry et al. 2019; Miller et al. 2021). Maternal milk production in extensively reared beef cattle is another trait where low milk is not desirable, but farmers also see little benefit from high milk production. In sheep where there is often a need to compare a large range of biological types using a single index, we have found the non-linear approach to work well for traits such as litter size and wool fibre diameter (Quinton et al. 2019).

Non-economic factor inclusion. Recent trait prioritisation surveys have revealed that functional health and welfare traits tend to be more important to farmers than economic calculations suggest, and intrinsic differences in farmers' trait priorities exist that are independent of economics (Martin-Collado et al., 2015, 2016; Santos et al. 2019, 2022). The modular approach allows pure economics EVs from a profit equation or bioeconomic model to be combined with preference-based weighting, which can increase farmers' acceptance of breeding objectives (Nielsen et al., 2014). This also applies to environmental impact traits such as methane production for which evaluations are now being implemented in several species. Methane production is generally closely associated with production traits and feed intake, but current carbon price-based economics tend not to incentivise emissions reduction. Therefore, some non-economic emphasis should be explored for methane while retaining the EVs for production traits that have clear economic drivers. Modularity allows flexibility in defining these non-economic traits' importance without influencing the balance among other traits that have more concrete economic value.

Transferable to new systems. As genetics providers expand markets, breeding programmes need to address the diversity of production systems and environments that can occur in an industry. A modular approach provides clear options for breeding objectives to address alternate production systems or environments within an industry. In these cases, trait EVs can be calculated separately for each system or environment, then these either proportionately weighted to create an overall trait EV (e.g. Quinton *et al.* 2021) or applied into separate indexes. Modules can be set up to deal with genotype by environment issues which might otherwise need more complex solutions, often involving multiple genetic evaluations.

Testing and implementation

As mentioned above, modularisation can risk double-counting the value of a trait if the modeller is not aware of the full bio-economic model contents. For example, feed intake traits are increasingly being added to breeding objectives, but EV calculations for these must consider the EBV definition (e.g. total intake vs residual intake) and if other traits such as growth have feed costs included in their EV calculation. Developers need a good understanding of all modules to ensure double-counting is avoided, and that correlations with important traits not in objective are included. To combine module EV results and evaluate how derived breeding objectives perform we test by applying EVs to real EBV data. In this way we can observe effects of trait correlations and differences in variance (see Zhang *et al.*, 2022).

Conclusions

Flexible approaches to breeding objective development facilitate the expansion of indexes to accommodate new traits in breeding programmes, allowing for a richer and more socially acceptable outcome from genetic selection. The modular approaches we have used for many different countries and species allow us to place substantial emphasis on user acceptability, transparency, and ultimately adoption of index-based selection and in this way have contributed substantially to the value of genetic progress being achieved.

472. Enhancement of the terminal carcass production index to incorporate birth weight and lambing ease in Australian sheep

E. Dehnavi* and A.A. Swan

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; edehnavi@une.edu.au

Abstract

Sires ranking highly on Australian terminal sheep indexes tend to have higher birth weight (BWT), which potentially translates to increased incidence of difficult births in commercial flocks. The Terminal Carcass Production industry index was therefore modified to include a penalty targeting a genetic change of -0.005 kg in BWT over 10 years. An alternative scenario was also considered, where an economic value for lambing ease (LE; %) was added to the index. The largest impact of the BWT penalty approach was a reduction in the response for growth traits with little improvement in LE but with minimal impact on carcass yield and eating quality. The economic value for LE was calculated as $1.15/1% improvement in lambing ease/ewe/year. Compared to the first approach, including LE in the index produced is preferred with similar outcomes for birth weight but with less impact on response for the growth traits and also resulted in a positive response in LE.

Introduction

Terminal sheep breeds in the LAMBPLAN genetic evaluation system in Australia have achieved high rates of genetic gain in growth and lean meat yield over an extended time period (Swan *et al.*, 2017). From 2017, new selection indexes were introduced to address declining eating quality, as described by Swan *et al.* (2015), including the Terminal Carcass Production (TCP) index which balances increasing growth and lean meat yield with modest improvements in eating quality.

Genetic trends over the past five years confirm that as selection emphasis has been directed to eating quality, with favourable changes in Australian Sheep Breeding Values (ASBVs) for intramuscular fat, shear force, and consumer eating quality, there have also been increases in birth weight. These increasing genetic trends in birth weight are higher than predicted and have potentially occurred due to breeders placing attention on the new eating quality ASBVs at the expense of birth weight.

Highly ranked sires that have high birth weight ASBVs may lead to a greater incidence of lambing difficulty. A genetic evaluation system for lambing difficulty from data recorded in terminal flocks is available for terminal sire breeds (Li *et al.* 2021), with ASBVs for the trait lambing ease. Therefore, to address this concern at selection, two modifications to TCP were considered: firstly; adding a desired gains penalty on increasing birth weight, and secondly; including an economic value for lambing ease directly in the breeding objective.

Materials & methods

Terminal carcass production breeding objective. The TCP breeding objective places emphasis on increasing post-weaning weight (PWT), carcass eye muscle depth (CEMD), lean meat yield (LMY), dressing percentage (DRESS) and consumer eating quality (MSA), while reducing carcass C-site subcutaneous fat (CCFAT; Swan et al. 2015). Balanced selection to overcome an antagonistic relationship between yield and eating quality attributes has been made possible through the availability of genomically enhanced ASBVs for these traits, along with two eating quality selection criteria traits, intramuscular fat (IMF) and shear force (SF5). Weightings for these traits are included in the TCP index.

Desired gains index for birth weight. Birth weight (BWT) was added to the TCP index (referred to as TCPB index) using a desired gains approach to hold BWT constant while maintaining gains in other traits. This was essentially done by calculating an index weight that targeted a genetic gain of -0.005 kg for BWT over 10 years. It was assumed that the traits measured to derive the desired gains index included BWT, weaning weight (WWT), PWT, post-weaning eye muscle depth (PEMD) and post-weaning fat depth (PFAT) from ultrasound scanning of live animals. In addition, genomic predictions for PWT, CEMD, CCFAT, LMY, DRESS, IMF, and SF5 were assumed to be available and used in the derivation of the index, following Dekkers (2007). Population structure parameters used to annualise predicted genetic gain were based on data extracted from the LAMPLAN terminal sire analysis (16 August 2021).

Relative economic value for lambing ease. The economic value for lambing ease was calculated assuming an underlying normally distributed liability, partitioned by thresholds (Meijering, 1980) into categories defined as 1 = no assistance (normal birth), 2 = moderate assistance (assisted, or evidence of difficult birth for an unassisted ewe), and 3 = hard assistance (Li *et al.* 2021). Thresholds between categories were derived from the LAMBPLAN terminal sire database, with probabilities for each category of 1=0.9006, 2=0.0775, and 3=0.0219. The lambing ease economic value was calculated by determining the change in profit from a 1% improvement in lambing ease, acting through reduced costs associated with lower incidence of difficult births in categories 2 and 3. Assumed costs associated with additional labour, lamb and ewe mortalities are shown in Table 1. Note that the inclusion of costs for dead lambs assumes that mortalities due to lambing difficulty are considered separately to other causes. Lamb mortality rates relative to unassisted live lambs (Table 1) were derived from observed lambing data in maternal breeds in the genetic evaluation system and represent ram breeder rather than commercial flocks. The 1% improvement in lambing ease was modelled by changing the probabilities for each category proportional to their distribution. The changes in proportions for each category were then multiplied by the associated cost relative to unassisted births and aggregated to calculate the overall economic value. This was expressed in terms of dollars per ewe joined per year through multiplication by 1.2 number of lambs born per ewe joined, representative of the Merino ewes most commonly mated to terminal sires. The TCP index augmented with lambing ease is referred to as the TCPL index.

Comparison of indexes. The TCP, TCPB, and TCPL indexes were calculated using ASBVs for 1,792 sires of Poll Dorset and White Suffolk progeny born in 2020 in the LAMPLAN terminal sire evaluation. An additional index, Lamb 2020 (LP2020) was also included for comparisons. The LP2020 is a legacy (pre-TCP) index which included emphasis on growth and yield, with a small penalty on increasing birth weight, but no emphasis on eating quality (Swan *et al*., 2017). The indexes were compared using 'selection advantage',

Table 1. Cost assumptions for moderate and hard lambing difficulty categories relative to live unassisted lambs used to calculate the economic value of lambing ease.

Item	Unit	Moderate	Hard
Stockman time	hours	0.2	0.85
Stockman cost per hour	$/hour	35	35
Relative percentage of lamb mortalities	%	30	45
Cost per dead lamb	$	250	250
Relative percentage of ewe mortalities	%	0	1
Cost per dead ewe	$	240	240
Total cost relative to no assistance	$	82	144.65

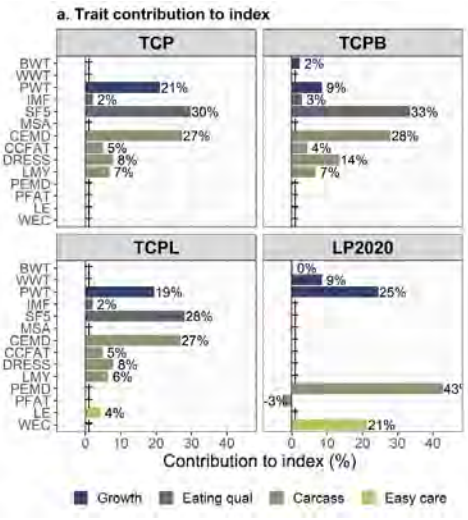
calculated as the trait superiority of the top 10% of sires selected on index, along with correlations between sire index values.

Results & discussion

The relative economic value for a 1% increase in lambing ease was calculated to be $1.15 per ewe per year. Byrne *et al.* (2010) calculated an economic value of -€0.247 for single-lambing difficulty per ewe. The relatively higher value calculated in this study was due to the inclusion of the costs of dead lambs along with higher lamb mortality rates in assisted categories. As noted above, these incidence and mortality rates have been derived from ram breeder flocks in the genetic evaluation system and may differ in commercial flocks. Survey data from commercial flocks would help to refine the calculations.

Comparing selection advantages for the top sires ranked on TCP, TCPB and TCPL indexes indicated that sires selected on TCPB index had lower average ASBVs for BWT by -0.09 kg, at the expense of 29% lower superiority for PWT (1.53 compared to 2.17 kg for TCP, Figure 1). The loss for WWT was relatively higher (0.60 compared to 1.06 kg for TCP). This was expected as birth weight had a 2% contribution to the TCPB index and there were high correlations between BWT and the other growth traits (Figure 1). The top sires remained negative for lambing ease (-0.46 and -0.16%) when ranked on the TCP and TCPB indexes, indicating that direct emphasis is required to achieve positive change in lambing ease.

Compared to TCPB, the TCPL index led to a lower reduction in superiority for weaning weight (0.94 kg for TCPL compared to 0.60 kg for TCPB) and post-weaning weight (2.02 compared to 1.53 kg). This shows that adding lambing ease directly to the TCPL index is beneficial in retaining response in growth traits compared to penalising birth weight through TCPB. While superiority for eating quality and carcass traits was marginally inferior for TCPL, differences with TCP and TCPB for these traits were not great. Importantly, TCPL was the only index to realise a favourable response in lambing ease, while at the same time giving the best outcome for birth weight (equal with TCPB).



b. Superiority of top 10% (n=1792)

trait	TCP	TCPB	TCPL	LP2020
BWT (kg)	-0.02†	-0.09	-0.07†	-0.05
WWT (kg)	1.06†	0.6†	0.94†	1.3

Traits that are not in objectives are specified by †.

Figure 1. Trait contribution to the current (TCP), modified (TCPB and TCPL) and previous (LP2020) indexes (a) and, trait selection advantages for the top 10% of current Poll Dorset and White Suffolk sires ranked on indexes (b). Abbreviations are described in the text.

The LP2020 index includes selection emphasis to limit birth weight, and the outcome was superior to TCP for this trait (-0.05 compared to -0.02 kg), while achieving the highest responses for growth traits of any index (1.3 kg for WWT and 2.5 kg for PWT). However, this comes at the cost of declining eating quality (IMF, SF5 and MSA), which is not included in the index. In addition, the response in lambing ease was unfavourable.

The correlation between TCP and TCPB indexes for these sires was 0.98, indicating that the modification has minimal impact on rankings overall, as expected from the small contribution of birth weight in the TCP index (2% of index gains in Figure 1). The correlation between TCP and TCPL was lower at 0.97 consistent with a slightly higher contribution from lambing ease to TCPL (4% in Figure 1). Correlations for LP2020 were lower at 0.86, 0.82 and 0.84 with the TCP, TCPB and TCPL indexes, respectively, due to the lack of any direct emphasis on carcass and eating quality traits.

Birth weight is not currently included in selection indexes for Australian sheep, but positive emphasis on birth weight may be useful where low birth weights are associated with poor lamb survival, whereas a negative penalty can be desirable when high birth weights lead to increased incidence of lambing difficulty. From a breeding objective perspective specifying economic values for survival and lambing ease directly will be preferable, as this study has shown for lambing ease. Accurate genetic evaluations are also required to support lambing ease ASBVs to be used in indexes, and while new genomically enhanced ASBVs will soon be available (Li *et al.* 2021), it is also important for breeders to improve the collection of data on lambing ease, survival, and birth weight to underpin the system.

Abstract

Economic selection indexes are the preferred method of practicing multiple trait selection. In the U.S., the majority of beef breed associations that have genetic evaluations provide generalized indexes. However, utilization of these tools has been less than is desired. IGENDEC, a web-based platform underpinned by a stochastic simulation, was written in the GO programming language, and was developed to enable the construction of user-specific economic selection indexes. The platform made use of user-specified breeding objectives, breeding systems, costs, returns, and phenotypic means. Interface level output included index weights and graphical representation of relative emphasis and Pearson correlations between the custom index and component trait expected progeny differences (EPD). The system has undergone beta testing and source code was placed in a publicly available repository. The USDA is an equal opportunity employer and provider.

Introduction

Germplasm selection at an enterprise level requires contemplating both genetic and economic progress. Selection index theory (Smith, 1936; Hazel and Lush, 1942) enables the construction of multi-trait selection tools towards improvement in a specified breeding goal. Common across animal industries and countries is the use of economic selection indexes which rank selection candidates on their genetic potential to improve net profit, where net profit should be defined at the commercial level. Critical to the formation of such selection tools are the underlying assumptions relative to expected costs and returns, breeding systems and objectives, and current levels of animal performance. Unique enterprise-level circumstances exist that can alter the economic weighting of traits in the decision-making process, and potentially lead to a re-ranking of selection candidates.

The objectives of the current work were to develop and deploy a web-based decision support platform (iGENDEC) that enables the comparison of selection candidates based on economically optimized indexes considering the unique circumstances of the user.

Materials & methods

Use cases. Three use cases were defined, including producers wishing to purchase germplasm; sell germplasm; or make mating decisions based on a custom index. The iGENDEC software can be used to create either generalized (i.e. breed association provided) or customized (i.e. unique to an enterprise) indexes. High-level breeding goals specified by the user included sale endpoints at weaning, after a backgrounding phase, and at slaughter (live- or carcass-basis). The goal considered can be terminal (no female replacements kept) or general purpose (female replacements retained).

Simulation model. The iGENDEC program was written in the GO programming language and has been tested on Linux systems. The stochastic simulation was modeled under the assumptions of a North

American beef industry setting. A cow herd was simulated and genetic values of bulls were perturbed by one unit, one trait at a time, to determine the Marginal Economic Value (MEV) of each trait in the breeding objective. The model accounted for discounted gene flow, discounted expression rates, and differences in planning horizons. Philosophically, planning horizon was thought of as the length of time (years) that the user wanted to consider in determining the economic impact of a genetic selection decision. Operationally, planning horizon represented the number of years simulated with the improved genetic merit of bulls.

Parameters. Hard-coded parameters included genetic and residual (co)variances, breed contrasts, and heterosis (direct and maternal) values. These parameters were obtained from the scientific literature (Koots et al., 1994a,b) and the U.S. Meat Animal Research Center (USMARC) Germplasm Evaluation (GPE) program (Schiermiester et al., 2015; Ahlberg et al., 2016; Kuehn and Thallman, 2017; Retallick et al., 2017; Freetly et al., 2020; Zimmermann et al., 2021). Breeds included as options were those with current genetic evaluations in the U.S. These parameters were contained in the program's master hjson file. User-defined parameters included value of cattle sold (US$/cwt) with differential values based on weight and sex classes and carcass quality, costs (variable cow costs, cost of feed for growing cattle), death loss rate due to dystocia, pregnancy rate, cow age distribution, breeds (bulls, cows, calves), and current phenotypic means. Default values for user-defined variables were also available. Economic index-specific parameters were specified in separate hjson files.

Web interface. The interface required user accounts that were password protected, allowing input through a series of drop-down menus (i.e. breeding objectives, breed selection) and either click and drag or tabular entry (i.e. cow age distribution, value of sale weight). Jobs saved under user-defined names and comments pertaining to a given job were allowed such that key components were easily remembered by the user for future reference. Previous jobs could be edited and re-run. The capability for user-specific branding existed such that an organization (i.e. breed association) could offer iGENDEC as a service to its membership and retain identity of the organization if iGENDEC were to be accessed through a common server external to the organization and available to numerous such organizations.

Industry engagement. An industry advisory board comprised of beef breed association technical staff, producers (seedstock and commercial), and extension personnel was established. The advisory board provided initial direction on the scope and structure of the project, then served as alpha-version testers. Additional beta-version testers were recruited from industry.

Results

User interface output. User-observed run time was ~2 minutes for most jobs. Run time increased roughly linearly with the length of the planning horizon. Resulting index weights were provided on screen and relative emphasis was depicted graphically using a pie chart. A bar chart depicted the Pearson correlations between the custom index and component EPD among the selection candidates. The user could download a csv file containing the custom index (default) and selected information from the group of individuals the user wished to apply the index to (i.e. animal identification, component EPD, etc.). The interpretation of differences between two animal's index values was the difference in enterprise-level net profit per exposure.

Software release. Source code and documentation were made available on github (https://github.com/blgolden/igendec). Although the current work has been supported by a competitive grant through the USDA-AFRI-CARE program (Award Number: 2018-68008-27888), sustainability of this system can only be achieved by availability to industry and corresponding use. To this end, the Beef Improvement Federation (BIF) is currently exploring a fee-based model for hosting iGENDEC.

Discussion

The development of decision support tools and systems (DSS) is not new (Newman *et al.*, 2000) and indeed current examples of such platforms exist outside of the U.S. (e.g. Barwick and Henzell, 2005; Dunne *et al.*, 2021). Historically such tools have not been maintained due to a lack of funding and less than ideal rates of adoption by end users. Lynch *et al.* (2000) detailed reasons why such decision support tools in agriculture suffer low adoptions rates, including: Lack of field testing; No end user input preceding and during development of the DSS; DSS complexity and possibly considerable data input; No reason seen for changing current management methods; Distrust for the output of a DSS because producers do not understand the underlying theories of the models; Mismatch of the DSS output with the decision-making style of the producer because the producer's conceptual models are excluded; and Unclear definition of the beneficiaries (e.g. scientists, primary producers, and technology transfer agents). To combat these known hurdles to software sustainability, the current project established an industry advisory board described above.

Model considerations such as discounted gene flow and discounted expression rates are not uncommon in the development of economic selection indexes. However, to our knowledge the notion of planning horizon has not been reported previously relative to the construction of economic indexes in beef cattle although this concept has been reported in dairy (McMahon *et al.*, 1985). Given that germplasm purchases (i.e. bull purchase) is an investment, the return on investment should have a specified time horizon. Shorter planning horizons favor traits that are expressed earlier in life (i.e. sale weight) while longer planning horizons tend to favor traits such as sustained fertility that are expressed much later. Pragmatically a user might specify a relatively short (e.g. five-year) planning horizon despite the desire to emphasize sustained fertility in a self-replacing herd simply due to the need for operating capital that can be generated by an increased emphasis on sale weight. Such trade-offs, and more formal comparisons of efficiency between short- and long-term horizons, is a needed area of future research.

The current framework of iGENDEC enables the addition of more breeds if and when additional organizations adopt genetic evaluations and the addition of new traits should genetic predictors become available. The vision for this system is that it has the capability of evolving as the needs of the U.S. beef industry evolves, but this requires that the current system be adopted and supported.

Abstract

Feed efficiency during lactation involves a set of phenotypic traits which form a complex system in which some traits exert causal effects on the others. We proposed a structural equation model to investigate the complex network involving the main components of lactation feed efficiency (i.e. daily lactation feed intake, dLFI; daily sow weight balance, dSWB; daily litter weight gain, dLWG; daily back fat thickness balance, dBFTB; sow metabolic body weight, SMBW), and to predict the effect of external interventions on the system using selection indices. Results indicate that dLFI and dLWG affect dSWB, and dSWB affect dBFTB and SMBW. Multiple indirect links contribute to these effects, especially on the latter two associations. Overall, selection strategies holding dLFI constant did not offer any advantage over the others.

Introduction

Improving feed efficiency during lactation (LFE) has many benefits in terms of economic costs and production-related drawbacks, as well as animal wellbeing. This is because milk yield is one of the most energy-demanding processes in the productive life of a sow (Thekkoot *et al.*, 2016). In order to define an optimal genetic selection strategy to improve LFE, knowledge regarding the variances and covariances among target traits is required at both the genetic and environmental levels. Estimates of such parameters are usually obtained by implementing a Multiple Trait Animal Model (MTAM). However, MTAM describes only association among traits, so no information is retrieved in terms of causal relationships. Associations can be due to common factors directly affecting two traits and/or a causal relationship between the two traits. In the latter case, factors affecting one trait have an indirect effect on the other trait through the causal link that exists from the first trait on the second. Structural equation models (SEM) (Gianola and Sorensen, 2004) allow the representation of causal mechanisms between variables, in which the magnitude of the causal relationships are described by model parameters called structural coefficients. Knowledge about such a causal structure allows the prediction of the effect of external interventions in a trait (e.g. management practices such as feed restriction or cross-fostering) on another trait. The objectives of this research were: (1) to investigate potential causal effects underlying the complex relationships among the main traits involved in LFE in sows; and (2) to propose a selection strategy, based on a selection index including or not FI records, for improving sow productivity with no impairment of its body condition, which is the main driver for future reproductive success.

Materials & methods

Animals and data. The data used for this analysis cover the first 10 generations of an experiment of divergent selection for residual feed intake (RFI) in pigs. The selection process is described in depth in Gilbert at al. (2007), and details about the recorded traits are in Gilbert *et al.* (2012). The main components of LFE considered in this study were daily lactation feed intake (dLFI), daily sow weight balance (dSWB), daily litter weight gain (dLWG), daily back fat thickness balance (dBFTB), and sow metabolic body weight (SMBW). The daily traits were computed as the difference between the corresponding trait at weaning (or at day 21 for dLWG) and at farrowing divided by the number of days in lactation, whereas SMBW was

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_474, © M. Mora *et al.* 2022

computed as the average between sow weight at weaning and sow weight at farrowing to the power of 0.75. After removing outliers, the dataset used for the analysis contained information regarding 1,342 farrowings from 576 sows.

Statistical analysis. To assess potential causal relationships between the main components of LFE the following two-steps procedure was implemented:

Step 1: Searching for recursive causal structure

The search of the casual structure was performed on the residual (co)variances obtained from a MTAM, as proposed by Valente *et al.* (2010). These (co)variances provide information from the joint distribution of phenotypic traits conditional to unobservable genetic and permanent environmental effects. The residual covariance matrix obtained from the MTAM was then used for the subsequent analysis of the inductive causation (IC) algorithm using a program written in R (Team, 2020) by Valente and Rosa (2013). This algorithm performs a series of statistical decisions based on partial correlations between pairs of traits based on their highest posterior density (HPD) intervals. This algorithm is well described in Valente *et al.* (2010). The output of the IC algorithm is typically a directed acyclic graph (DAG), which consists of a set of variables (symbolized by nodes) connected by directed edges (symbolized by arrows) representing direct causal relationships.

Step 2: Fitting a SEM

Once the recursive causal structure was established for the traits under study, a SEM with this specific structure was fitted:

$$y = \Lambda y + Xb + Z_1a + Z_2p + Z_3cg + e \quad (1)$$

where Λ is a ($t \times t$) matrix with zeros in the diagonal and with structural coefficients (λ) in the off diagonals (t is the number of traits), y is the vector of phenotypic records, b is the vector of systematic environmental effects including the effects of the farm (with 2 levels), parity order (with 5 levels: 1,2,3,4,>4) and the 2-degree polynomial of litter size at day 21 as a covariate; a, p, cg and e are the vectors of additive genetic effects, permanent effects, contemporary group effects and residual effects, and X, Z_1, Z_2 and Z_3 are incidence matrices relating systematic and random effects to y. Similarly to a MTAM, the SEM provides estimated (co)variance matrices, with the additional information of potential direct and indirect causal effects allowing the prediction of the consequences of external interventions on the system.

Both models were fitted using a Bayesian approach via Gibbs sampling algorithm with a chain of 2,000,000 iterations, a burn-in of 300,000 and an interval between saved samples of 100 using Gibbsf90 and Postgibbsf90 software (Misztal *et al.*, 2018).

Selection strategies. All genetic selection strategies proposed were based on selection indices in which the objectives were always increasing dLWG, reducing or keeping constant dLFI, and increasing or keeping constant dSWB through records on dLWG and dBFTB, and including or not records on dLFI. Since there is no published information regarding the economic weights of the analyzed traits, the selection index coefficients were computed for different combinations of three arbitrary values (0,1,2) with the appropriate sign according to the selection objective. An additional strategy was proposed which consisted in holding constant dLFI for all sows. The idea was to remove this source of variation so that variation in feed efficiency only depends on the variation in dBFTB and on the variation in dLWG, which are easy to measure.

Knowledge of the causal relationship among traits allows predicting the effect on selection response when the external intervention is applied, without the need of a new experiment and data analysis.

Results

Recursive causal structure. The IC algorithm using $HPD_{95\%}$ returned a DAG that indicated that dLFI and dLWG affected dSWB, with the posterior mean of the corresponding structural coefficients (PM) being 0.12 and -0.03 kg/d, respectively. In turn, dSWB influenced dBFTB and SMBW, with PM equal to 0.07 mm/d and -1.22 kg/d, respectively. These structural coefficients express the expected change in the affected trait by an increment of one unit in the causal trait.

Variance components and heritabilities. In SEM, variance components reflect direct effects of genetic and environmental factors on a trait whereas in MTAM they correspond to total effects, i.e. direct plus indirect effects mediated by other traits that have causal effects. Results from both models indicate that the analyzed traits show moderate to high heritabilities with posterior means (posterior SD) ranging from 0.16 (0.03) for dSWB to 0.41 (0.05) for SMBW in the MTAM (total heritability), and from 0.12 (0.03) for dBFTB to 0.36 (0.06) for SMBW in the SEM (direct heritability). For the traits which are phenotypically affected by one or two traits (i.e. dSWB, dBFTB and SMBW), residual and genetic variances were statistically lower in the SEM model compared to MTAM suggesting a relevant contribution of indirect effects to the variance of those traits.

Association between traits. Posterior means of correlations between traits for genetic, permanent, and contemporary group effects were marginally different between the two models (MTAM and SEM) for the traits that were not connected in the DAG, but differences were larger between the other traits. However, HPD95% intervals were relatively large in all cases precluding any claim of statistical difference. Multiple indirect effects contributed to associations between the analyzed traits. The most relevant were those involved in the association between dSWB and dBFTB, and between dSWB and SMBW.

Response to selection. For all selection strategies, responses followed a similar pattern and, for the same economic weights, responses to selection could not be considered statistically different between approaches. In general, it would be hard or not possible to decrease dLFI while increasing or keeping constant dSWB and increasing dLWG and a favorable response in all traits would be hardly achieved.

Discussion

We investigated the causal structure among traits involved in LFE, and estimated the magnitude of putative causal effects implicated in it using data from a population of pigs selected for RFI during growth.

Structural equation models describe the causal relationships that are present in biological systems, but with the specification of a potential causal structure underlying it. Implementing the IC algorithm is one of the many available strategies to search a network structure compatible with the joint probability distribution of the traits considered. However, in this approach, it is necessary to assume that there are no simultaneous relationships (i.e. feedbacks) between these traits. Moreover, in some situations, it may not be possible to find the links and the causal directions using only data information, so the incorporation of biological prior knowledge may be required to complete the causal structure specification. In our study, the data-driven IC algorithm yielded a full DAG indicating that an increase in dLFI would increase dSWB while an increase in dLWG would decrease dSWB and, in turn, an increase in dSWB would increase dBFTB while decreasing SMBW.

Estimated structural coefficients express the strength of each causal link among traits which is essential to quantify the component of every element of variance component matrices (variances and covariances) that comes from indirect sources of (co)variation. In our study, the most important causal effect was the one of dSWB on SMBW (-1.22 kg/d), indicating that dSWB has a negative effect on SMBW. Selection for increased dSWB would reduce requirements for maintenance given the low to moderate total genetic correlation between those traits (-0.28). The second most important causal effect was the one of dSWB on dBFTB (0.07 mm/d). Our results showed that both traits are highly correlated, with a total genetic correlation of 0.69 and direct genetic correlation of 0.31, indicating that indirect effects exerted by other traits are quite relevant in this relationship.

Knowing the proportion of the association between two traits that is due to either direct or indirect effects is important to design new selection strategies when an external intervention is performed. In our study, holding constant dLFI offered no clear advantage over other strategies.

Methods and tools: breeding goals

475. Manipulating response to selection on many traits

J.H.J. van der Werf* and S.A. Clark

School of Environmental and Rural Science, University. of New England, Armidale, NSW 2351, Australia; jvanderw@une.edu.au

Abstract

While selection index theory is a solid framework for a linear optimization of multiple trait selection, it does not always provide desirable selection responses. Responses can be manipulated by varying the economic weights used in a multiple trait index. However, trait responses depend not only on weights, but also on accuracies of the estimated breeding values (EBVs) as well correlations between these EBVs. Predicted selection responses for some traits can be in an undesirable direction if the traits have unfavourable correlations and if there is a large difference in the economic values of the standard deviation of the EBV, as in that case one trait dominates over the other. We extend insight in a two-trait example to a more general case with many traits in the breeding objective. We propose to investigate for each trait its correlation and its dominance relative to the other traits. These parameters can help determine a strategy to avoid undesirable trait responses, whether by changing economic weights or by aiming for more accurate EBVs, or by a combination of these.

Introduction

The balancing of selection and genetic gain among multiple traits is one of the main challenges of breeding programs. Selection index theory proposed by Hazel (1943) provides a simple and solid framework for providing index weights for the different sources of information available for the various traits. Currently, with most traits of relevance having estimated breeding values based on multivariate best linear unbiased prediction (BLUP), the optimal weights used for an index are simply the economic values derived from bioeconomic models of the relevant production system. These models do not require any information about genetic parameters and trait measurement. However, for predicting and understanding the response resulting from multiple trait selection, it is important to keep in mind that the selection response depends on the accuracy of the EBVs and the correlations among those EBVs. Both the accuracies and the correlations among EBVs are determined by the phenotypic information measured in breeding programs. Covariances among EBVs are easy to determine mathematically, and the response to index selection can be predicted as a result. However, when indexes contain many traits it is not always easy to fully comprehend the response and, more importantly, it is not always easy to see what levers can be used to achieve a more desirable response. Economic weights are frequently manipulated for that purpose, using trial and error, but this can be an inefficient approach if there is a lack of data for some traits.

The dynamics of multiple trait selection are easily illustrated by the simplest case of selection for two traits where graphical representation can be provided by the ellipse model (Moav and Hill, 1966). The ellipse is a graph showing all possible selection responses and the optimal response according to selection index theory is at the tangent of the ellipse and line of equal profit – LEP (Figure 1). The shape of the ellipse is determined by the correlation between EBVs, i.e. conditional on the information available in the breeding program, which is then assumed to be the same for all selection candidates. For a two-trait model, a challenge arises when traits have unfavourable correlations and when correlations between EBVs are high, in which the case the ellipse is relatively flat (Figure 1, left pane). A high correlation between EBVs can be due to having limited information available for one of the traits. In that case, the selection response can be very insensitive to economic if one trait is economically dominant, that is when the LEP is close to horizontal or close to vertical. For example, in dairy cattle EBVs for milk yield are often highly accurate, but

those for fertility are not if it is infrequently recorded. It can be difficult then to improve fertility without heavily compromising response for milk production. Sensitivity of trait response to economic weights is highest when the LEP is parallel to the main axis of the ellipse, which is when the economic weight per standard deviation of the EBV is equal for the two traits (Van der Werf *et al.*, 2018). The desired response in multiple trait selection can be achieved by changing the index weights or by increasing EBV accuracies, or both. Accuracies depend on the information collected in the breeding program, requiring investment, and this can refer to measurement of phenotypes on the selection candidates, on their relatives, or, increasingly, on measurement in reference populations for genomic selection. We will illustrate a method to predict the effect on response when changing economic weights and/or EBV accuracy, first in a two traits model and then suggest a generalization to the case with many traits.

Selection for two traits

We present first a two-trait example, similar to Van der Werf *et al.* (2018), representing the case with an unfavourable correlation (Figure 1). In the example, both traits are standardized to have a phenotypic variance of 1 and a heritability is equal to the genetic variance (σ_a^2) of 0.3 and economic weights (v_i, i = 1, 2) are 0.625 and 0.4. The genetic correlation is -0.5 and the phenotypic correlation is -0.1. Consider unequal information for traits 1 and 2, such that multivariate EBV accuracies (r_i, i = 1, 2) are 0.84 and 0.48. The shape of the ellipse is determined by the correlation between EBVs for the two traits (-0.91, Figure 1 left pane). Note that this correlation is much stronger than the genetic correlation as information from the correlated trait is used to estimate the EBV. The stronger the EBV correlation, the more difficult it is to improve both traits in the desired direction, i.e. into the top-right quadrant in Figure 1. Due to the limited information about trait 2, the selection index seeks an optimal solution by improving the trait with more information and with a higher economic weight. Changing the economic weight on trait 2 has limited impact on the optimal response and the weight for traits 2 would have to double at least to avoid a decline in trait 2. Improving the accuracy of the EBV of trait 2 results in a response such that trait 2 is not declining (Figure 1, right) and the EBV correlation is less strong (-0.61). Changing the economic weight will have a lot more effect in the desired direction of genetic change. It was shown that the point where $r_1.\sigma_{a1}.v_1 = r_2.\sigma_{a2}.v_2$ is where the index solution is most sensitive to economic weights, but it is also where both traits are improved in the desirable direction if EBV accuracies were close to 1 (Van der Werf *et al.*, 2018). The expression $r_i.\sigma_{ai}.v_i$ represents the dollar value of one standard deviation of the EBV of trait i ($v_{\sigma EBVi}$), and

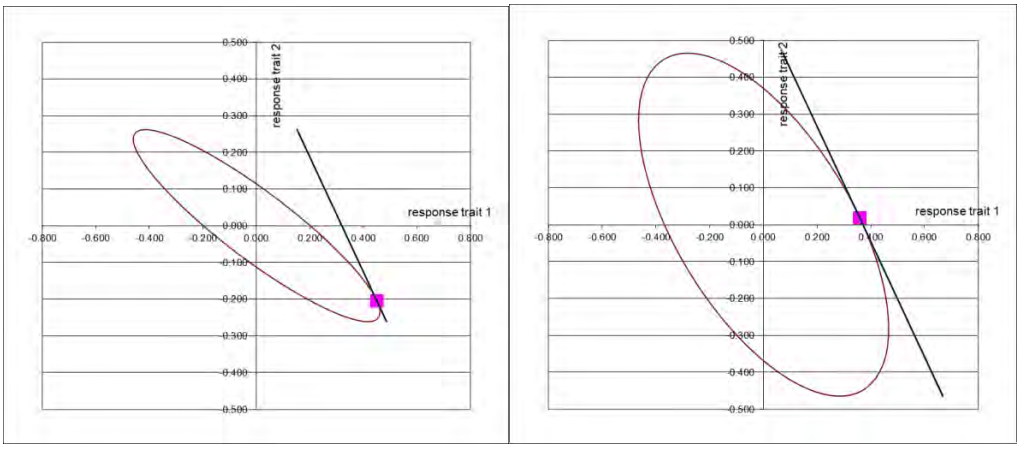

Figure 1. Index responses for two traits (square mark) when the economic values are 0.625 and 0.4 for traits 1 and 2, the accuracy of the EBV for trait 1 is 0.84 and for trait 2 it is 0.48 (left) or 0.84 (right).

these values are 0.23 and 0.10 for traits 1 and 2 in the left pane and 0.29 and 0.19 in the right pane. The expression $r_i.\sigma_{ai}.v_i$ can be used to predict the outcome of increasing the accuracy of the EBV of traits. The most sensitive point is when $r_2 = r_1.(v_{\sigma a1}/v_{\sigma a2})$. Hence, if the economic value per genetic standard deviation ($v_{\sigma ai}$) differs substantially between the traits, increasing the accuracy of traits has limited effect on trait responses to selection. However, if these values are similar, the optimal response more likely improves both traits if the accuracy of the EBVs are more similar. The same holds for working out index weights for selection: $v_1 = v_2\ (r_2\sigma_{a2} / r_1\sigma_{a2})$, i.e. when there is a large difference in EBV accuracy between the traits, trait responses will not be sensitive to changes in economic value, unless the least accurate trait has a much higher economic value per genetic standard deviation.

In conclusion, in the two-trait example, we can compare the economic value of one standard deviation of the EBVs for the traits, and if these differ a lot, we find that selection is dominated by the response for one trait. If the two traits have an unfavourably correlation, i.e. the correlation between EBVs has an opposite sign as the product of the economic values, it is likely that the response for the less dominant trait is not in the desired direction.

Extension to many traits

In a breeding objective with more than two traits it is not possible to rely on graphical representation to evaluate the sensitivity of the response to manipulating economic weights. Instead, we can look at one trait at a time, and look whether this is dominated by the other traits. These other traits can be summarised in a subindex $I_r = v_r'\hat{a}_r$, where v_r is the vector with economic values for the traits in the subindex, $\hat{a}_r$ is the vector of EBVs for these traits, and the genetic variance of this aggregate trait is equal to $\sigma^2_{Hr} = v_r'var(a_r)v_r$. The variance of the subindex is $\sigma^2_{Ir} = v_r'var(\hat{a}_r)v_r$ and the accuracy of the subindex is $r_1 = \sigma_{Ir} / \sigma_{Hr}$. Therefore, we can collapse the subindex into 'trait 1' with genetic standard deviation $\sigma_{a1} = \sigma^2_{Hr}$ and the economic value is $v_1 = 1$ as the index is in dollar values. The trait to be compared with the subindex, i.e. the breeding objective trait not included in the subindex, can be termed 'trait 2' with genetic standard deviation σ_{a2}, accuracy r_2 and economic values v_2. The correlation between the EBV for trait 2 and the subindex I_r ('trait 1') can be calculated using the covariance matrix between EBVs and v_r. If the sign of this correlation is not equal to the sign of v_2, then the trait under consideration is unfavourably correlated with the aggregate genotype of the other breeding objective traits. As in the two-trait example, we can now compare $r_1.\sigma_{a1}.v_1$ and $r_2.\sigma_{a2}.v_2$. If then also the economic value of the EBV standard deviation of the considered trait is much smaller than the standard deviation of the sub index, the considered trait is likely selected in the undesirable direction and either the accuracy or the index weight have to be increased to avoid that. In the case of many traits, the economic value of the subindex will be often much higher than that of an individual trait, so the correlation between the trait and the subindex will be critical in most cases.

Discussion

We have shown that the key parameters that drive response for each trait in multiple trait selection are its accuracy and the relative economic value of one genetic standard deviation of each trait. The product of these parameters, for each trait, determines the relative dominance of a trait in a multiple trait selection index. If a trait is not economically dominant, it is likely to see an unfavourable response when its correlation with the other traits is unfavourable. Whether this can be easily adjusted, either by increasing the accuracy of the trait EBV, or its weight, can be determined by these parameters.

Although selection index is a logical and straightforward framework to optimise selection on multiple traits, their proposed response is not always desirable. As a result, desired gains indexes are commonly used in practice where predicted index solutions based on derived economic weights are unsatisfactory. These can be simply derived mathematically, based on the theory presented. This is due to several factors. Individual

choices of breeders may differ from a formal economic model due to different market expectations, real or perceived competitive positions in the market. Moreover, the breeding objective may not be linear with more value given to a more balanced trait improvement. In fact, there is a well-known dispute between economists and experts in decision theory, the latter noting that negative outcomes are weighted about twice as much as positive outcomes (Kahneman, 2011). This principle could also be applied in index selection, by giving more negative weight to undesirable trait responses.

It is noted that in practice selection decisions are more dynamic, and made across candidates from different age classes. Therefore, selection accuracies differ among selection candidates. Moreover, genetic parameters will change after selection as a result of the Bulmer effect and selection decision are based not just on EBV but also co-ancestry and possibly other practal constraints. Tactical selection decisions can be optimised by decision tools such as MateSel (see Brian Kinghorn's paper at this conference). However, a fundamental understanding of the parameters driving multiple trait selection response is important and the theory discussed in this paper maybe useful to design strategies in breeding programs, in particular in relation to trait measurement.

Abstract

Several results of a divergent selection experiment for environmental variability of birth weight in mice are presented. Genetic control of environmental variability of birth weight is shown to be possible through selection. It is also shown that selection for homogeneity improved litter size, embryo and fetal survival, but also at birth, at weaning and at reproductive stage. It also improved fertility, reproductive longevity, and the response to feed restriction. Homogeneous animals were individually smaller, but females weaned 42% more total weight than heterogeneous ones. Signs of robustness and welfare were identified related to uniformity, suggesting this kind of selection would be very useful in livestock species.

Introduction

The main objective of animal breeding programs is to increase productivity. However, the focus is shifting to other types of traits. One of these types is trait homogeneity, where selection is for reduced trait variability. Homogeneity has been associated with a reduction in handling and production costs for the animal production industry, thus ensuring homogeneous batches of animals (Hennessy, 2005). It has also been associated with a decrease in mortality in prolific species and has also been related to robustness, improving functional traits. Finally, homogeneity has also been related to animals resistant to environmental challenges, also as a sign of robustness. Minimizing the residual variance is usually the selection criterion to increase homogeneity. In this work, results of a divergent selection experiment for environmental variability of birth weight in mice are presented. It was analysed if genetic control of environmental variability of birth weight was possible through selection and if it would affect other traits of interest.

Materials & methods

A divergent selection experiment was performed based on breeding values for environmental variability of birth weight in mice. Two divergent lines were created: High variability Line (H-line) and Low variability (L- line). These breeding values were predicted using a heteroscedastic model (SanCristobal *et al.*, 1998, Formoso-Rafferty *et al.*, 2016a). Birth weights were recorded for litters from 43 females per line. Each female produced one or two litters and each female was sired by a different male. Four males and four females from the best 11 females were selected as parents for the next generation, and selection was run for 29 generations. A total of 33,245 birth weight records of 3,687 litters after 29 generations and a pedigree of 32,885 animals were used. Genetic and phenotypic trends were analysed by drawing the average within-litter variance by line and generation. The heteroscedastic model included sex (male/female/unknown), parity number (2), litter size and generation as fixed effects and maternal genetic, litter and residual as random effects affecting the mean birth weight and also its environmental variability.

Genetic control of environmental variability of birth weight is possible through selection and also it produces changes in other traits. Then, in this work we include: (1) correlated trends in weights and

R.F. Veerkamp and Y. de Haas (eds)

litter size; (2) feed and reproductive efficiency; (3) reproductive longevity; (4) differences in heritabilities between lines; and (5) ovulation rate and embryo and fetal survival.

1. Phenotypic and/or genetic correlated trends were also analyzed for birth weight trait itself, weaning weight, total litter birth and weaning weights, litter size, survival at weaning and variability of both weaning weight and litter size (Formoso-Rafferty *et al.*, 2016b).
2. Animals from the H-line and L-line were used to study feed and reproductive efficiency. Records from a total of 271 females of five generations (10 to 14) were used. From 21 to 56 days, weekly body weight, weight gain, feed intake and cumulated transformation index were analyzed using a statistical model including line and generation as effects. Number of performed parturitions was also compared via a Chi-square test (Formoso-Rafferty *et al.*, 2018). For each line, 120 weaned females were used, that is, four complete sisters from each of 10 random litters from three consecutive generations of selection. Four groups were made within each generation according to combinations of restricted feeding or *ad libitum*, in two different periods, during growth and in reproductive stage. In each generation (12, 13 and 14), different levels of feed restriction were applied at 75, 90 and 85% (Formoso-Rafferty *et al.*, 2019).
3. To compare the reproductive longevity between selected lines, two generations of an initial number of 43 females and 43 males mated one to one per line, remained together to obtain consecutive parturitions. Females were discarded when the time elapsed since the last parturition was greater than 63 days. The time to the end of the reproductive period between both lines was compared by fitting a Cox proportional hazard regression model, and the farrowing rate in both lines was also compared using a Prentice-Willians-Peterson model (Formoso-Rafferty *et al.*, 2022).
4. As residual variance was not unique, estimations of heritabilities differed among levels of systematic effects, and among lines and generations. Data from the first eleven generations were used, totalling 15,431 birth weight records from 959 females and 1,641 litters in combination with 14,786 pedigree records. Estimates of the residual variance across levels of effects, keeping constant the additive genetic variance allowed to estimate different heritabilities (Formoso-Rafferty *et al.*, 2017).
5. Last studies in the mice divergent selection lines compared the fetal survival between 14 days of gestation and at birth, and the embryo survival from fecundation to 14 days assessing also the ovulation rate in both lines. A total of 138 H-line and 240 L-line ultrasound scans were performed at day 14 of the first gestation in order to address fetal mortality as the difference between number of fetuses in the scan and litter size at birth. Also, in order to determinate ovulation rate and embryo survival, a total of 48 H-line and 50 L-line females were sacrificed in their third gestation at day 14 and counted the corpora lutea presented in both ovaries (Formoso-Rafferty *et al.*, 2021).

Results

Average within-litter variance was diverging with variable success across generations and lines. In the last generation the variances were 0.0536 and 0.0096 g^2 for the H-line and L-line. This difference was also observed in the variance across litters being 0.0792 and 0.0149 g^2.

A genetic correlation between the birth weight and its environmental variability was consequently estimated to be 0.30 which led also to divergence in the within litter mean birth weight that reached averages of 1.87 g and 1.33 g for H-line and L-line. Divergence was also observed in the mean weaning weight that was 12.64 g and 8.53 g for H-line and L-line. Total litter weight was also higher in the H-line with an average of 83.25 g in contrast to 69.09 g in the L-line. However, accounting for differences between lines in litter size, survival at weaning and fertility, L-line weaned a total of 5,458 vs 3,829 g in the H-line. Litter size at birth also differed across generations between lines being in the last generation 7.54 and 9.02 pups, with a respective survival of 89 and 92% in the H-line and L-line. In this last generation, only 32 and 42 out of 43

females performed parturitions in H-line and L-line. Fourteen and 37 of the females reached two parities in H-line and L-line.

Regarding feed efficiency, results showed that accumulated transformation index was similar in both lines. However, concerning other traits, for the H-line and L-line, the number of parities was 1.464 vs 1.600, the litter size at the first parturition was 8.76 vs 9.98, the litter size at weaning was 7.61 vs 9.05, and the number of pups stillborn was 0.25 vs 0.11. Similar performance differences were observed at the second parturition, being all highly significant ($P<0.001$). When animals were fed under restriction, fertility was 33% in H-line and 72% in the L-line, survival at weaning was 65% in the H-line and 95% in the L-line, and survival at the reproductive stage was 60% in the H-line and 85% in the L-line, differing significantly between lines, but were not different in those animals fed *ad libitum*. Conversely, diet groups were found significantly different in the H-line but not different in the L-line. In the H-line, *ad libitum* animals survived 100% at weaning and 95% after reproductive stage and 100% performed parturition whilst restricted animals survived 65% at weaning and 60% after reproductive stage and only 33% performed parturition.

The reproductive longevity study revealed that the L-line was associated with almost three times higher delivery rate (2.93) with regard to the H-line. The Cox model showed that homogeneous females also presented 26% of the risk of stopping their reproductive life. The median reproductive days was 55.5 in the H-line, while the median was 252.5 days for the L-line females.

The birth weight heritability was different between lines and also across systematic effects levels. It was higher in L-line across generations (0.06 higher in eleventh generation). The heritability for birth weight ranged from 0.04 to 0.22 across different systematic effect levels. Using this findings, it could be possible to modulate the heritability of this trait by selecting to decrease residual variability.

Regarding reproductive analysis, there were no significant differences in the number of fetuses observed at 14 days between lines, but litter size at birth was significant higher in L-line (9.82 vs 8.36 pups). In the embryo survival analysis, there were no differences in the number of fetuses at 14 days. However, significant differences were found (H-line vs L-line) in: number of hydatidiform moles of the uterus (3.96 vs 1.27), corpora lutea (13.88 vs 11.53), embryo survival (0.53 vs 0.79) and ovules lost from corpora lutea to fetuses at 14 days (6.38 vs 2.59). Then, the higher litter size in L-line showed important advantages in terms of higher embryo and fetal survival.

Discussion

The genetic selection of environmental variability of birth weight was possible in mice. Clear divergent phenotypic trends were observed between lines for litter size, weaning weight and weaning weight standard deviation. This selection criterion directly affected other traits in such as litter size, total weaning weight, fertility and pup survival. The experiment led to two divergent lines with the L-line presenting benefits in production, animal welfare, heritability and traits usually considered indicators of robustness such as feed efficiency or reproductive longevity. This better performance of the L-line was achieved without extra energetic cost. Moreover, despite the selection process was designed and carried out identically, the selection response was asymmetric in favor the low variability line when compared with a control (Formoso-Rafferty *et al.*, 2020), therefore increasing BW homogeneity could be achieved in a few generations. Trends in predicted breeding values diverged according to the selection made, and were in the same direction for birth weight trait, increasing both in the H-line and decreasing in the L-line. In this sense and to study the genetic correlation between the trait and its variability, a simulation study showed that a scale effect (in the sense that the higher the mean of a variable, the higher its variability) would explain many genetic

correlations reported in the bibliography, and specifically that one found in the mice experiment (Tatliyer *et al.*, 2019). This fact should be take into account when applying this type of selection.

The animals of the L-line became homogeneous although smaller due to the genetic correlation between the trait and its variability. However, the selected homogeneity has also been accompanied by signs of greater robustness, with larger litter size, better survival and better reproductive performance without losses in total weaned weight. This contrasts with what has been observed in pigs, where there has been an increase in mortality as a consequence of the selection aimed at increasing litter size, which is linked to a greater heterogeneity of piglet weights at birth (Damgaard *et al.*, 2003). Therefore, it would be interesting to investigate whether selection to reduce birth weight variability would have the same effects in livestock species.

Abstract

Contribution of production, functional and feed efficiency traits to total economic response (Δ$) of a new economic index VEL+ for Holsteins in Chile were estimated using the selection index method with local and U.S. economic and genetic parameters. Contribution of the traits and trait groups on Δ$ was estimated as the difference for each evaluated index compared to the base index. We modelled a situation of genomic U.S. sire selection, adjusting the selection accuracy of each trait using estimates of genetic correlations between countries. Contribution of the production, functional, and feed efficiency traits group were 25.9, 38.5 and 4.6%, respectively. When reducing or increasing relative economic values of each trait by multiplying them by a range of values ranging from 0 to 1.5 in the index, protein yield (0.4 to 2.6%), fat yield (0.3 to 2.4%), and longevity (0.2 to 1.9%) were the traits with the greatest contributions to Δ$.

Introduction

Economic selection indices must be updated periodically to include new traits and reflect changing economic conditions and marketing systems, as well as changing genetic parameters among traits (Cole *et al.,* 2021). One approach to estimating these contributions is to assess the effect of modifying the relative economic values (REV) of each trait or group of traits on the total economic response of a selection index (Pryce *et al.,* 2009). This sensitivity analysis allows for an assessment of the robustness of indices against inaccurate REV. This is particularly important in situations where key information for some potentially important traits is not locally available.

This new index was based on a previous index for dairy production and functional traits in Chile. We evaluated the addition of two traits used in the United States to assess feed efficiency (VanRaden *et al.,* 2021) that are of interest to the Chilean dairy sector.

The objective of this work was to conduct a sensitivity analysis by determining the contribution of each trait and group of traits to total economic response (Δ$), changing the REV for each trait in a new economic index VEL+ (economic dairy value) developed in Chile for Holstein cattle.

Materials & methods

VEL+ economic index. An economic index (VEL) was developed based on data for a Holstein herd in southern Chile with a production system based on grazing with supplementation, with prices, milk payment systems, and productive parameters from 2019, which represent an average situation for this region (Cooperativa Agrícola y de Servicios, 2020). Traits considered in the VEL index were milk yield (MY), fat yield (FY), protein yield (PY), longevity (LONG), somatic cell score (SCS), calving interval (CI),

DOI: 10.3920/978-90-8686-940-4_477, © J.L. Chuma-Alvarez *et al.* 2022

and age at first calving (AFC). The economic values (Table 1) of the traits in the VEL index were estimated as the first partial derivatives of the economic benefit function with respect to each trait, as a way to calculate profit before and after the genetic change of one unit in a given trait (Weller, 1994).

To form the VEL+ index, body weight composite (BWC) and residual feed intake (RFI) from the U.S. CM$ (Cheese Merit) index were incorporated into the VEL index. The relative economic values (REV) of each trait in the VEL and the VEL+ indices were expressed by taking the economic value of one kg of protein yield as reference (Table 1).

Calculation of economic response. Economic response to selection (Δ$) of the traits included in the VEL+ index was calculated using selection index theory (Weller, 1994) with the Multiple Trait/desired gains spreadsheet developed by Van der Werf (2014) that calculate responses for multitrait selection in animal populations. The number of progeny equivalent to U.S. genomic evaluations were obtained by trait (Council on Dairy Cattle Breeding, 2021) and adjusted to Chile based on estimates of genetic correlations (less than 1) between the two countries obtained from genetic evaluations of bulls (Cooperativa Agrícola y de Servicios, 2020). Heritabilities and phenotypic variances of VEL index traits as well as genetic and phenotypic correlations were estimated using the COOPRINSEM historical archive for the population of Holstein cows from southern Chile that comprised the period 1998-2015. A range of 253,015 to 873,840 records were analysed. Genetic parameters and relative economic values for BWC and RFI for the U.S. population (Li et al., 2020; VanRaden, 2021) were adapted to the Chilean population.

Sensitivity analysis and experimental design. Δ$ was estimated as the sum of the products of trait selection response and corresponding economic values. Sensitivity analysis was made by multiplying the base REV of each trait or group of traits by a range of values from 0 to 1.5. Estimation of the contribution (%) of a given trait or group of traits with a specific modified REV was based on the difference between the Δ$ obtained with the modified REV and the Δ$ for the base index, and then expressed in percentage. This approach allows to estimate the robustness of the index against changes in the REV actually used when departing from the reference in the base index. Three groups of traits were formed, grouping MY, FY and PY as production traits, LONG, SCS, CI and AFC as functional traits, and BWC and RFI as feed efficiency traits.

Table 1. Economic values and economic response to selection (Δ$) by trait for base VEL+ index.

Trait		EV[1]	REV[2]	Δ$ (Chilean Pesos)	Contribution (%)
Milk yield (kg)	MY	-30	-0.01	-508	-0.66
Fat yield (kg)	FY	1,914	0.64	19,166	24.89
Protein yield (kg)	PY	2,981	1.00	8,645	11.23
Longevity (months)	LONG	15,818	5.31	29,194	37.92
SCS (log2)	SCS	-45,949	-15.41	4,952	6.43
Calving interval (days)	CI	-2,362	-0.79	4,536	5.89
Age at first calving (days)	AFC	-174	-0.06	1,053	1.37
Body weight composite (units)	BWC	-11,659	-3.91	8,468	11.00
Residual feed intake (kg)	RFI	-171	-0.06	1,482	1.93
Total				76,991	100.00

[1] Economic values in Chilean pesos.

[2] Relative economic values to 1 kg of protein yield.

Results

Table 1 lists the 9 traits that comprise the base VEL+ index, the units in which they are measured, the economic value of each unit, relative economic value, the economic response to selection (Δ$), and the contribution (%) of each trait.

The base VEL+ index (76,991 Chilean pesos) showed more Δ$ (10.8%) than base VEL (69,464 Chilean pesos), due to the inclusion of BWC and RFI. In the base VEL+ index the most important traits in terms of percent contribution were LONG, FY, PY and BWC; the lowest were AFC and RFI (Table 1).

When setting the REV of the given group of traits to zero in the index, the greatest contribution to Δ$ was for functional traits (38.5%), followed by production traits (25.9%), and feed efficiency traits (4.6%).

In the sensitivity analysis, the contributions of each trait to Δ$ with modified REV with a range of values (0.5-1.5) are shown in Figure 1. The traits that most contributed to Δ$ were PY (0.4 to 2.6%), FY (0.3 to 2.4%) and LONG (0.2 to 1.9%), and the trait with the lowest contributions was AFC (all <0.01%) across the range of levels. Other traits had intermediate contributions (Figure 1). Changing REV by 20% above (1.20) and below (0.80) the base REV caused very similar changes within each trait (Figure 1).

Discussion

In our analysis, exclusion of functional traits from the index would cause the greatest reduction in the index's Δ$ for genomic selection of Holstein bulls in Chile, followed by production and feed efficiency traits. With respect to individual trait sensitivity analysis, PY, FY and LONG represented the greatest contribution to Δ$, and their changes in REV had the greatest economic effects, unlike the three Australian indices evaluated by Pryce *et al.* (2009), where production traits contributed most to the total economic response, despite the fact that fertility and longevity had greater relative weights in these indices than in our indices. This may be because in our data fertility is more unfavourably genetically correlated with production.

In conclusion, the incorporation of BWC and RFI as feed efficiency traits in genomically evaluated bulls increase the expected economic response to selection, although the contribution of RFI is small due to the low accuracy of current genomic evaluations.

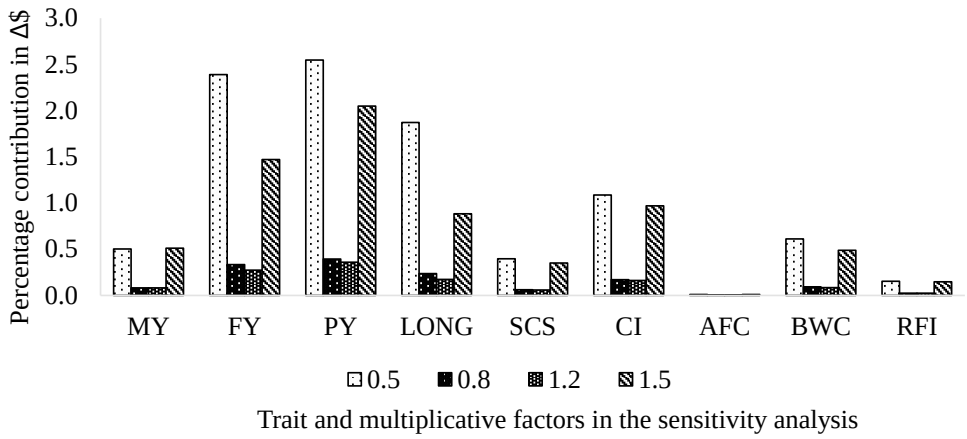

Figure 1. Percent contribution to total economic response (Δ$) for the VEL+ index, by changing the relative economic values of the trait by a multiplicative factor equal to 0.5, 0.8, 1.2, or 1.5.

Emphasis should be placed on obtaining precise REV for all traits, but the impact of inaccurate REV would be greater for PY, FY and LONG. The influence of uncertainty of REV values in BWC and RFI selection is likely to be small.

Maximum efficiency could be obtained by incorporating new traits and forming a new economic index that improves the feed efficiency of cows (VanRaden *et al.*, 2021), which would be advantageous to local dairy producers and those financing the breeding programs.

478. Opportunities for animal genetics to foster the ecological transition of livestock farming systems

D. Savietto*, F. Douhard, H. Gilbert, R. Rupp, L. Fortun-Lamothe and A. Ducos

GenPhySE, INRAE, Université de Toulouse, ENVT, 31326 Castanet Tolosan, France; davi.savietto@inrae.fr

Abstract

Industrial livestock systems faces a major crisis of legitimacy and animal breeding contributes to this situation. Worldwide, breeding goals focus on economic performance and rarely consider the environmental and social impacts. Agroecology offers a conceptual framework to think alternative solutions to face this crisis and to guide the transition of livestock farming towards nature-based systems. Animal genetics, as an essential component of animal husbandry, should contribute to this evolution. Based on the agroecological principles applied to animal farming and the efficiency-substitution-redesign (ESR) framework, we showed that animal breeding mainly focused on the E-S levels of the ESR framework and few on the redesign of animal farming. We then present some perspectives for the redesign of breeding goals, the use of the G×E interaction information in the evaluation of animals, and the benefits of managing the available genetic diversity of livestock species to fit to the needs of nature-inclusive systems.

Introduction

Over the brief period of the 20th century, agriculture in industrialised countries changed from small and diversified farms to big and specialized enterprises (Horrigan *et al.*, 2002). This change has been driven by the specialization of production (single animal species), the mechanization of the labour (e.g. milking machines) and the introduction of chemical (disinfectants) and pharmaceutical (antibiotics) inputs to assure production in a controlled environment. This industrialization process favoured the emergence of highly productive systems, designed to provide large amounts of low price food for consumers (Carolan, 2018).

Industrial farming, however, faces a major legitimacy crisis. The use of antibiotics in animal husbandry contributes to the emergence of antimicrobial resistant bacteria, the concentration of animals in a single place or region scales up environmental issues, while citizens (at least in Europe) increasingly reject intensive animal production and plead for the end of the cage age (https://www.endthecageage.eu/). In the face of this crisis, the livestock production must evolve towards systems that are more acceptable. In this context, nature-based systems, founded on the principles of agroecology (Altieri, 1989; Gliessman, 2015) need to be developed. Dumont *et al.* (2013) proposed five agroecological principles to initiate the transition of sustainable animal production systems by: (1) promoting integrated management of animal health; (2) reducing inputs needed for production; (3) decreasing pollution; (4) taking advantage of system diversity to strengthen their resilience; and (5) preserving biological diversity. So far, the contribution of animal breeding to those principles is not clear yet, whereas it might represent a key lever to foster the evolution in thinking livestock systems and their technics.

Ducos *et al.* (2021) reviewed the contribution of animal genetics to each agroecological principles. Through its contribution to increase the production performance in breeds reared in highly specialized systems, developments in animal breeding have also embraced the first three principles whereas the last two principles related to diversity to a large extent were neglected. In addition, most works to date have focused on a single principle and thus rarely addressed the necessary complementarity among principles.

This lack of complementarity lead us to classify most contributions of animal breeding to agroecology as 'shallow ecological contributions', as described in the efficiency-substitution-redesign (E-S-R) framework (Hill, 1985). For Hill (1985), the industrialization process tends to optimize every single element of the system in a search for more efficient (E) practices. Elements of the system may be substituted (S) by some alternative if their use is no longer efficient, controversial, (e.g. soybean linked to deforestation) or threatens human health (e.g. antibiotics). Hill (1985) argued that solutions based on the E-S approaches 'usually protect and perpetuate the causes of the problem', and pled for the deployment of preventive ecological-based solutions, which will require a deep redesign (R) of systems.

Here, based on the E-S-R framework (Hill, 1985) and on some existent alternative production models, we propose several perspectives for animal genetics to contribute to the ecological transition (the Redesign) of livestock production systems.

The efficiency-substitution-redesign (E-S-R) framework: a new paradigm for animal breeding

Animal genetics have mainly contributed to the E-S levels of the E-S-R framework/gradient (Table 1, adapted from Ducos *et al.*, 2021). For example, the selection for feed efficiency contributed to reduce the amount of cereal-based diets per unit of product (E). It also helped to improve the capacity of non-ruminant animals to grow using fibrous diets to reduce the high costs of cereal-based diets (S). On the other hand, selection of animals for integrated crop-livestock systems, or fed with food waste (from warehouses, restaurants, etc.), or capable of recycling food resources not edible (or not desirable) for human consumptions, are still scarce. Other domains of applied animal breeding, aiming at improving the health or adaptive capacity of animals, for instance, also focused on curative or shallow ecological solutions. Most advances in these domains concern the search for disease-resistant (or tolerant), long-living or robust individuals. Although desirable, the inclusion of these functional traits in the selection indexes still focus on the animal component of the system, leaving the capacity of animals to cope with their environment (i.e. the G×E interaction) unexplored. Indeed, selection populations are generally raised in controlled conditions set to avoid the G×E. Even when the G×E information is available the *E-S* dynamic prevails. As an example in dairy cattle, Interbull structures its evaluations to reduce the G×E across countries, creating a sort of standardization on the ranking of dairy bulls, in the search for the international – *universal* – animal (Chavinskaia *et al.*, 2017). This sort of normalization is not desirable for nature-based systems that usually face a broad range of constraints. Organic (a proxy of agroecology) dairy farmers seems to contribute to the development of agroecological systems through the adoption of 'home based' breeding practices such as the use local breeds, kin breeding, and crossbreeds to produce (Nauta *et al.*, 2005). Some organic farmers use high producing breeds, while the majority of them question the adequacy of specialized milk-type breeds to the organic system. For such farmers, the desired animal should 'take time to mature', 'yield less milk' (mentioned as less adapted to a low concentrate and high grass regime), 'live longer', and have a better 'integrity' and 'vitality' (Nauta *et al.*, 2005; Bieber *et al.*, 2019). This example of organic dairy cattle shed some light on which traits animal breeding may focus on to fit the needs of agroecological systems. This notably include functional traits (fertility, vitality, disease resistance-tolerance, functional longevity) and/or life history traits (age and size at maturity, growth pattern, number and frequency of reproductive events in the lifetime, etc.). The use of data from farms (companies, cooperatives and independent farms), the development of participatory selection programs and the redesign of the academic selection facilities and programs (at national and international level) may all contribute to breed animals capable of live and produce (animal products and ecological services) in a wide range of livestock production systems. This strategy may favour the development of tools and mathematical methods to quantify the potential interest of G×E interactions and promote their use. Other strategies may help to identify adapted genotypes for nature-based systems.

Table 1. Classification of present (and desirable) breeding goals in the efficiency, substitution, redesign framework of Hill (1985). Adapted from Ducos *et al.* (2021).

Domain	Transition gradient (E >> S >> R)		
	Efficiency (E)	**Substitution (S)**	**Redesign (R)**
Feed efficiency	Better efficiency in use of feed concentrates	Improved ability to valorize alternative feed resources	Search for individuals and populations adapted to systems using a wide range of feed resources (raw products, food waste, etc.)
Animal health	Sick and morbid individuals are less productive and not selected	Selection of diseases resistant/tolerant, robust individuals	Breeding within and between populations of animals living in the same ecological habitat. Favor traits related to the use of space and resources for health
Adaptability	Selection for milk persistence or longevity reduce the number of animals needed for production	Animals capable of using their body reserves to sustain (re)productive and immune functions when facing underfeeding or infection	Selection of multiple-traits at both individual and herd levels: able to digest a wide array of resources, docile towards humans, yet alert to predators, body reserves to fuel (re) production and as a safety deposit), immune function co-evolving with the pathogens present in the system, fur (plumage) adapted to the outdoor (color and density), etc.

Which genetics in a perspective of redesign animal breeding systems?

Agroecological (nature-based) systems combine crops and animals, facilitate nutrient cycling and the system's resilience as well as the preservation of biodiversity. A diversity of agroecological systems may emerge, each one combining different species and genotypes at a given place and time. In this aspect, one of the main challenges of animal breeding is to select farm animals economically valuable and helpful (interesting) for the system as a whole, providing ecological and social services to their abiotic and biotic environment. For this, we need to redesign breeding goals, and develop tools for the evaluation and use of the G×E information.

For animal genetics, the key issue relies in the optimization of the breeding goals. Worldwide, breeding goals mostly aim to increase profit by increasing production or reducing costs (feed, animal health) and rarely consider environmental and social impacts. New traits (in the *E-S* level), even those related to resilience, are usually evaluated under the industrialized systems or with limited reference to G×E and long-term climate change. In order to help farmers and breeders to transition towards resilient/agroecological breeding, the methods and models to optimize breeding goals need to evolve. Breeding goals should include multi-criteria assessments and combine targets not only related to economics, but also to labour, greenhouse gas emission, biodiversity, land use, and food competition. In this context, the notion of an 'eco-social' breeding objective that integrates all these aspects might be worth to explore. How to combine those targets with different metrics is an issue. In fact, calculations of greenhouse gas emissions based on unit of products tend to rate intensive livestock systems since they are more efficient at the animal scale, while metrics based on area or resources use tend to favour extensive ones (Garnett, 2011). Furthermore, breeding objectives will need to consider simultaneously the evolution of breeding systems and animals (within or across breeds) toward a balanced solution on the global scale (from the farm to the overall food system).

The agroecological framework also offers the opportunity to better value the genetic diversity of livestock species. First, there is a need to unravel and characterize the genetic basis for resilience and adaptation of commercial as well as hardy and underutilized breeds, with reference to environmental breeding conditions. Then, breeding programs will require to consider a variety of options including, crossbreeding, introgression, managing diversity within farms (within and across breeds and species).

[1]Nofima, P.O. Box 210, 1431 Ås, Norway; [2]The Fridtjof Nansen Institute (FNI), PB 326, 1326 Lysaker, Norway; [3]Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark; ingrid.olesen@nofima.no

Abstract

Rapid changes and innovations in food production are prompted by the increased demand of sustainably produced food, while addressing concerns of climate change and environmental impacts. To address complex societal issues, research and innovation policies, research bodies often request a framework for responsible research and innovation (RRI) to be applied for developments of new science and technologies. In addition to the individual researchers' and key actors' thinking and reflections in farm animal breeding, there is a need to look at mechanisms affecting ethical and social aspects of animal breeding at an institutional level. In this article we exemplify and discuss how breeders can define animal breeding objectives and develop technology strategies within the RRI framework to contribute more efficiently to sustainable animal production.

Introduction

Food production systems need rapid changes and adaptations to respond to the increased demand for sustainably produced food, while addressing the concerns of climate change and environmental and societal impacts. Commercial and idealistic interests push for various short and long-term objectives and strategies using new technologies in food production. We need to produce more food, more effectively, while respecting and responding to international agreements such as UN goals for sustainable development and the UNFCCC and its Paris agreement on climate change. Adopting new breeding technologies, such as gene editing, may contribute to food security. This has prompted a need for a more open dialogue between scientists, policy makers and the public. In response, EU research and innovation policies and research bodies have developed a framework for responsible research and innovation (RRI) to be applied when developing new science and technologies (EC, 2014). In Von Schomberg's (2012) definition, RRI is 'a transparent, interactive process by which societal actors and innovators become mutually responsive to each other with a view on the (ethical) acceptability, sustainability and societal desirability of the innovation process and its marketable products'.

Animal breeding programs can be viewed as continuous innovation processes as breeders are usually in a constant process of applying new (gene) technologies and methods. In addition to a focus on individual researchers' and key actors' thinking and reflections, there is a need to look at mechanisms affecting social and ethical consequences of animal breeding at an institutional level. In line with the framework of RRI, Olesen *et al.* (2000) concluded that 'important prerequisites for breeding programs for sustainable production are appropriate governmental policies, awareness of our way of thinking, and a more communal worldview informed by a subjective epistemology and a holistic ontology.' Hence, breeding objectives and strategies, informed by holistic assessments and more awareness among the actors, can facilitate socially accepted breeding programs contributing more efficiently to sustainable production meeting the current challenges of the environment, climate and the food system.

The objective of this article is to exemplify and discuss how animal breeding objectives and technology strategies can be defined and developed within the RRI framework.

The framework and requirements of RRI

RRI is a dynamic and iterative process inviting representatives of 'all' relevant stakeholders into a dialogue regarding the research/innovation process and its outcomes. RRI aims to align technological processes with societal values, expectations, and concerns. RRI can be seen as an additional layer through which societal views can be heard and taken into consideration, particularly in situations where the technological and societal developments move too fast for the electorate to affect legislation through voting and democratic means. The RRI process can be compared to traditional hearing processes related to legal acts and may supplement democratic processes. As such, RRI faces the same conflicts over values and distribution in society – how to deal with: (1) representation and asymmetrical power relations; (2) issues that do not involve win-win solutions; and (3) differences in interpretation of central concepts, as sustainability. In the Research Council of Norway (RCN), RRI includes four dimensions:

1. Anticipation: active engagement to describe, analyse and openly discuss foreseen impacts and uncertainties that might arise from processes or outcomes of the technology application.
2. Reflexivity: holistic reflections of (implicit) assumptions of research and innovation (regarding e.g. environmental and distributional effects), uncertainty and lacking knowledge.
3. Inclusion: invite all relevant stakeholders to contribute with views and opinions on the research trajectory, both on how the research is done and on the outcome.
4. Responsiveness: willingness to change the trajectory of research if results from above (e.g. stakeholders' feedback) reflect that the research is not likely to meet the desired impact.

RRI strategies for ensuring animal breeding within RRI

We discuss how breeders can comply with the four dimensions above expected by RCN to facilitate broader public acceptance of breeding schemes, and meet current complex challenges.

Anticipation. For analysing, and openly discussing the consequences of a breeding strategy or a breeding technology, an ethical matrix may be applied. Forsberg (2004) argued that public legitimacy is enhanced when the matrix method is applied in a participatory process to discuss various ethical concerns and how to ethically justify application of GMO rape seed. Furthermore, different consumer studies or surveys can be useful to anticipate impacts of different breeding objectives or strategies. For instance, Grimsrud *et al.* (2013) carried out an internet survey, which indicated a high willingness among Norwegian households to pay an extra tax to improve the welfare of farmed Atlantic salmon through increased resistance to diseases and salmon lice. The ethical matrix method is useful for broadening the range of concerns considered, but will not necessarily provide an agreed policy direction (e.g. on ethical or economic precedence).

Reflexivity. Breeders may commit to holistic reflections of the ethical, environmental, and political concerns relating to breeding choices to recognize and take social responsibility. Rosendal and Olesen (2022) discussed barriers to breed for increased lice resistance in Norwegian farmed Atlantic salmon, and factors that may explain the untapped potential of breeding for lice-resistance (market and regulation of breeding technologies). Based on interviews with breeders and farmers, it was concluded that market mechanisms were unsuitable, and policy instruments were not aimed at promoting lice resistance breeding. This gives rise to a paradoxical situation, which is allowing a greater number of stressful mechanical treatments of farmed salmon while the sea lice threat to wild salmon remains unchanged at an unacceptable high level in some regions. The study illustrated that there is little political willingness to interfere with the privately controlled breeding programmes, that are not transparent regarding some aspects. Social science findings might still have an impact in raising awareness among breeding actors.

Inclusion. Stakeholder participation is a central element in RRI, although challenging in terms of sufficient representation and asymmetrical power relations (Barnett and Finnemore, 2004). While traditional

stakeholder channels for policy involvement, such as lobbying, have been found to favour powerful actors, the same is largely true for other stakeholder processes (Orsini, 2016).

Effective involvement of some key stakeholders is currently facilitated automatically in cooperative breeding organisations and in integrated companies when key stakeholders (e.g. the farming members' representatives of the cooperative or farming managers of the integrated company) are consulted in decisions on breeding strategies. This illustrates how the organisation structure or business model allows for incorporating views and opinions of farmers and (or) other suppliers in decisions on developments within breeding and their outcome. In Norwegian dairy cattle breeding, the cooperative organisation Geno was particularly successful in implementing health and functional traits in the breeding objective in the early eighties as a response to the farmers' demand for healthy animals (FAO, 2007). Important factors for this success were a close cooperation with veterinarians on health recording and university geneticists as well as early responsiveness to farmers interests. The long-term strategy on sustainable production, rather than a short-term objective on yield only, still makes the Norwegian Red cattle breed competitive nationally as well as internationally.

Nielsen *et al.* (2006) presented a method to engage stakeholders when defining breeding goals for sustainable production. The method was based on how much, e.g. farmers or breeding organizations are willing to lose in gain in milk yield to improve traits related to sustainable production. Accepting a lower gain in milk yield, allows for increasing the value on e.g. mastitis resistance or reproduction.

These examples could speak in favour of RRI in relation to choices within traditional selective breeding where key stakeholders are relatively easy to identify. Similar representation may be challenging in processes linked to gene technology, with a broader range of issues to be raised.

Responsiveness. Responsiveness concerns whether the RRI process affects decision-making processes and technological choices. Stakeholder inclusion may enhance legitimacy but does not resolve which types of knowledge are more valid in the final decision, still to be made by the breeders. Social issues raised during the RRI may be further addressed by a relevant governmental body.

Both citizen panel and stakeholder involvement are examples of active engagement of stakeholders in a research project on gene editing in Cardiomyopathy syndrome in Atlantic salmon. A dynamic dialogue between lay people, industry representatives, NGO representatives, different scientists, and the project group include mutual learning activities with citizen panels and stakeholder workshops to build thrust and facilitate responsiveness.

Breeders can contribute to the public and regulatory discussions as well as to the education of stakeholders about breeding with research-based knowledge on e.g. animal welfare and consumer safety, environmental impacts and need for developing regulations and policies. The prospected opportunities of using gene editing have raised the discussion about softening the strict GMO regulations, encompassing gene edited products. Recent surveys have shown that most Norwegian consumers are positive towards using gene editing in plants and animals, if it is beneficial to society and contributes to sustainable development (Bioteknologirådet, 2020; Bugge, 2020). Therefore, the bulk of consumers tend to demand GMO labelling for gene edited organisms. By involving consumers in the gene technology innovation processes, the breeding organisations may comply to consumer preferences, and benefit from higher consumer acceptance. For example, breeders can respond by focusing on editing genes improving animal health and welfare or reducing unfavourable environmental impact with documented low risk.

Conclusions

Farm animal breeding programs, implementing new technologies and methods, can be viewed as continuous innovation processes calling for a framework of RRI to ensure consumers' and policy makers' acceptance and further licence to breed. Stakeholder engagement alone may not make innovations responsible or reduce the need for regulating technologies. Hence, the actions of anticipation, reflexivity (regarding assumptions, representation, power distribution, uncertainty and lacking knowledge), and finally responsiveness to all of these are also crucial for breeding programs' responsible outcome. By this, breeding programs can succeed in supporting a sustainable food system, that can meet the current and future complex challenges.

Abstract

Even when dairy cattle breeding organizations have no interest to implement environment-specific breeding programs, farmers may benefit from using herd-specific breeding goals instead of the main breeding goal of their breed. To assess this hypothesis, we constructed and compared four different breeding goals under conventional or organic farming system (two per system). The Total Merit Index derived from the simulated breeding goals were used to optimize the mating of 9,143 Montbéliarde females to 54 bulls. Despite strong correlations between the total merit indices (0.98), more than a quarter of the planned matings were different among the breeding goal considered. Results also showed that farmers would economically benefit from using herd-specific breeding goals instead of the main breeding goal of their breed without the need to create a specific breeding program.

Introduction

At breed's level, Mulder *et al.* (2006) showed that from dairy cattle breeding organizations' point of view (breeding elite sires), there is no need to implement environment-specific progeny testing breeding programs when the genetic correlation between two environments is higher than 0.61. More recently, Slagboom *et al.* (2019) reached similar conclusions under genomic selection. But at herd's level when optimizing the matings of their females, even if there is no need to create a specific breeding program, farmers may benefit from using herd-specific breeding goals instead of the main breeding goal of their breed. To test this hypothesis in the case of the Montbéliarde breed, we studied the situation under four distinct breeding goals (organic-based or conventional) for which different total merit indices were derived.

Materials & methods

Simulated mating plans. To assess the losses/gains related to the optimization of the matings based on a given expected economic score (EES) specific to a farming system (e.g. standard conventional farming system) while the females to be bred (and their future offspring) are raised under a different context (e.g. organic farming system), the average economic results of four mating plans (scenarios) were calculated using the EES values of each of the four farming systems (scales). Therefore, 9,143 genotyped Montbéliarde females from 160 French herds were virtually planned for mating with a set of 54 genotyped bulls, using a linear programming approach. It resulted in 4 mating plans, one per breeding goal tested. Mate allocation optimization was performed based on the EES of each potential mating. This EES accounts for the expected genetic merit of the progeny (expected Total Merit), mates' coancestry, type of semen (sexed or conventional) and risk to conceive an embryo affected by a genetic defect as in Bérodier *et al.* (2020).

Breeding goals definition. To assess the influence of a breeding goal on optimized mating plans, we constructed and compared four different breeding goals, similarly to the work of Slagboom *et al.* (2018): (1) the current breeding goal of the Montbéliarde breed which focuses on standard traits of economic interest but also includes type traits (STD_TYP); (2) an organic breeding goal based on economic optimization at farm level (ORG_ECO scenario); (3) a so-called 'ethic' organic breeding goal based on the four main international principles of organic agriculture set up by IFOAM (International Federation of

Organic Agriculture Movements), namely Health, Ecology, Fairness and Care (ORG_ETH scenario); (4) a conventional breeding goal based on economic optimization at herd level, consequently, not integrating type traits (STD_ECO scenario). The four main international principles of organic agriculture are not economically orientated. IFOAM asserts that organic farming should sustain and enhance the health of all beings, should be based on living ecological systems and cycles, should ensure fairness with regard to the common environment and life opportunities and should protect the health and well-being of current and future generations and the environment.

Genetic gain and inbreeding depression. The last update of the STD_TYP breeding goal was performed in 2012 based on economic optimization models and including the Montbéliarde breed specific expectations in terms of selection for type. The STD_ECO and ORG_ECO breeding goals were directly derived from economic models specific to the farming system considered (Pinard and Regaldo, 2013), respectively a conventional and an organic farming system. For ORG_ETH system, the challenge was to build a breeding goal that leads to genetic gain on the most important traits according to the four main principles of organic agriculture (and not a purely economic objective). Results from Slagboom *et al.* (2018) were adapted to the traits available for selection in the Montbéliarde breed in France. An in-house software developed by the Institut de l'Elevage was used. Briefly, this software simulates selection in a real population on the animals' estimated breeding values (EBV), provided as an input file with many different weight combinations until a response to selection maximizing economic gain is found. This software also accounts for specific constraints to prevent a negative selection response for a particular trait with no economic value associated (Fuerst-Waltl *et al.*, 2016), for instance traits related to the principles of organic agriculture. The use of data from a real population as an input enables the program to account for observed genetic correlations (positive or negative) between the different traits of the breeding goal. The inputs were: a dataset of 11,400 young Montbéliarde bulls born between 2013 and 2018 with their EBV; economic values of the genetic standard deviation of each trait; if necessary, constraints on responses to selection (e.g. no negative response to selection for dairy production traits). Correlations between the four Total Merit Index EBV (one per breeding goal) were calculated from the EBV of the 54 bulls and 9,143 females considered in this study (Table 1).

Table 2 provides the relative weights per genetic standard deviations unit for the traits included in our four simulated breeding goals. To calculate EES, the economic value associated to one genetic standard deviation of the simulated total merit indices (σ) and to the economic impact of 1% of inbreeding (λ) were calculated as in Bérodier *et al.* (2020) (Table 2).

Economic gain. The 16 economic results obtained from the simulated mating plan were expressed as a deviation from a random mating plan (i.e. where cows were mated at random to one of the 54 bulls available; Bérodier *et al.* (2020)). For instance, the expected average economic gain when optimizing the mate allocation based on STD_TYP information while the herd is under an ORG_ECO farming system, compared to a random mating situation, was calculated as:

$$\frac{\sum_{i=1}^{nb_couples} score_{i,ORG_{ECO}}(STD_TYP) - \sum_{j=1}^{nb_couples} score_{j,ORG_{ECO}}(RAND)}{nb_couples}$$

Table 1. Correlations between Total Merit Index EBV of the four breeding goals.

	STD_ECO	ORG_ECO	ORG_ETH
ORG_ECO	0.98		
ORG_ETH	0.81	0.76	
STD_TYP	0.85	0.88	0.62

Table 2. Traits' relative weights per genetic standard deviation and economic values associated to each breeding goal (= scenario).

	Trait[1] (%)														Value[2] (€)	
Scenario	FY	PY	FR	PR	CS	MS	CF	HF	CI	LO	CE	CM	MS	TT	σ	λ
STD_ECO	12	36			17	1	13	4		17					295	26.1
ORG_ECO	15	39			12	9	9	2		14					295	34.5
ORG_ETH	7	17			13	19	15	4		19	3	3			251	34.5
STD_TYP	1	9.8	4.8	29.4	8.7	5.8	9	4.5	4.5	5			5	12.5	246	26.1

[1] Traits included each breeding goal: Fat yield (FY), Protein yield (PY), Fat rate (FR), Protein rate (PR), Cells (CS), Mastitis (MS), Cow fertility (CF), Heifer fertility (HF), Calving to first insemination interval (CI), Longevity (LO), Calving Ease (CE), Calf Mortality (CM), Milking speed (MS), Type traits (TT).

[2] Economic values associated to one genetic standard deviation (σ) and to 1% of inbreeding (λ).ß

With $score_{i,ORG_ECO}$(STD_TYP) the ORG_ECO EES of couple i which was planned using linear programming mate allocation optimization base on STD_TYP information; $score_{j,ORG_ECO}$(RAND) the ORG_ECO EES of couple j which was planned using random mate allocation; nb_couples the number of couples to plan (9,143, the number of females to mate).

Results

Mate allocation value. Table 3 can be interpreted as follows: if breeders' breeding goal (scale) is ORG_ETH and their breeding plan are based on the STD_TYP information (scenario), they will earn on average 78€ more per mating over the productive life of an offspring by optimizing their matings using the STD_TYP total merit index whereas they could have earned on average 107,5€ more per offspring by optimizing their matings with the ORG_ETH total merit index.

As expected, for each economic score scale (i.e. for each farming system), the best average economic score is obtained with the scenario (i.e. with the mating plan) using the same information (Table 3). For instance, farmers in ORG_ETH farming systems can expect to increase on average its benefit from 29.5€ (=107.5-98) per per female offspring over its carrier when using ORG_ETH instead of STD_TYP breeding goal to optimize matings. In Table 4, the percentage of identical matings between two scenarios indicates that despite strong correlations between the total merit indices (e.g. 0.98 between the STD_ECO and ORG_ECO scenarios), more than a quarter of the planned matings are different. Similarly, the lower the correlations between the total merit indices of the different breeding goals, the lower the correlations between the bulls' contributions (i.e. their number of planned matings).

Table 3. Average economic score deviation (in euros) from random matings.

	Scale[1]			
Scenarios[2]	STD_ECO	ORG_ECO	ORG_ETH	STD_TYP

ORG_ECO	74%	-	70%	71%
ORG_ETH	58%	52%	-	55%
STD_TYP	53%	57%	45%	-

Discussion

These results confirm our hypothesis that farmers can benefit from using herd-specific breeding goals instead of the main breeding goal of their breed even when there is no need to create a specific breeding program adapted to their within-herd breeding goal. For the four breeding goals simulated, the correlations between the total merit indices are not low enough to justify the creation of new, separate selection schemes, according to Mulder *et al.* (2006) and Slagboom *et al.* (2018). Nevertheless, we have shown that the less farmers' breeding goal is correlated to the one of the breed (due to the specificities of their farming system and/or their own expectations), the more they could improve their within-herd breeding choices by using information specific to their farming system and their breeding goal. Indeed, access to EBV specific to their breeding goal and farming system would allow them to better select sires and make better matings plan choices in order to maximize the genetic and the economic gains for their own breeding goal. We recommend farmers to use the breeding goal that matches their production system.

481. A bio-economic model to estimate the economic value of sow feed intake during lactation

D.M. Thekkoot[1*], R.A Kemp[1] and J.C.M. Dekkers[2]

[1]Genesus Inc., 101 2nd Street, Oakville, R0H 0Y0, MB, Canada; [2]Iowa State University, Ames, IA 50011, USA; dinesh@genesus.com

Abstract

The objective of this paper was to develop a comprehensive bio-economic model to calculate the economic values of sow breeding goal traits. In addition to the regular production and management parameters, the model accounted for sow feed intake during lactation (SLFI) and its interactions with sow body resource mobilization during lactation and piglet weight gain during lactation, and how these traits could influence the successive gestation feed intake. Weighted by the genetic standard deviation of each trait, the number of piglets born had the highest contribution to the breeding goal (48%), followed by preweaning mortality (incl. stillborn) (45%), age of puberty and wean to service interval (both 3%), and SLFI (1%). The results show that incorporating this complex interaction resulted in a very small but negative economic value for SLFI.

Introduction

The goal of any pig breeding program is to increase producer profit without adversely affecting the overall health and welfare of the pigs. This is attained by using a total merit index, which is a linear function of estimated breeding values of economically important traits, weighted by their economic values. Economic values can be calculated from a system of equations known as a bio-economic model, which is a function of phenotypic traits and management factors that contribute to the profit of pork production (Tess *et al.*, 1983). Generally, traits considered for maternal lines include litter size, pre-weaning mortality, litter weight at weaning, sow longevity, etc. Typically, little emphasis is put on traits associated with lactation, such as sow feed intake during lactation (SLFI), likely because of the cost required for accurately measuring relevant phenotypes. Studies have shown that traits associated with lactation have a sizable genetic component and, hence, including them in the selection index should allow concurrent improvement of sow lactation performance, along with reproduction and grow-finish performance (Bergsma *et al.*, 2009, Thekkoot *et al.*, 2016). SLFI is a cost component and including it in the bio-economic model without accounting for other lactation factors such as sow body resource mobilization, piglet weight gain, and the impact of these on successive gestation feed intake, can lead to overestimation of the negative weight of SLFI (3.5% based on previous work (unpublished)), which can result in selection reducing sow feed intake during lactation. The objective of this paper was to accurately estimate the economic value of SLFI using a bio-economic model that takes the complex interactions of SLFI with body resource mobilization, piglet weight gain, and successive gestation feed intake into account.

Materials & methods

A deterministic bio-economic model was developed to describe the production of an F1 sow over 5 litters, covering the birth of the gilt (day 0) to the time of culling of the sow after the 5th parity. The model covers a basic farrow to wean operation and does not attempt to model all complexities of the production system. The time period was divided into 6 phases (the gilt phase, i.e. birth to first insemination, and parities 1, 2, 3, 4, and 5). Income and expenses for these periods were calculated separately and discounted to the time of birth of the sow (day 0). The net profit (NP) generated by the F1 sow was expressed as discounted Total Income (dTI) minus discounted Total Costs (dTC), i.e.

$$NP = dTI - dTC \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_481, © D.M. Thekkoot *et al.* 2022

Total income. Total income from the sow was derived from piglet sales at weaning (IWP) from all 5 parities and from the sale of the culled sow after the 5th parity (ICS). There was no income from the gilt phase. Income from parities 1 to 5 was calculated separately for each parity. In parities 1 to 4, income depended on the sale of piglets only, whereas income in parity 5 also included sale of the culled sow. Income from the sale of weaned piglets (IWP) depends on: (1) the total number of piglets weaned per parity (NW), which in turn depends on the total number of piglets born dead or alive (TNB) and total pre-weaning mortality (PWM). PWM depends on the number of stillborn piglets (SB), the number of piglets that died in the first 24 hours (PWMb24), and death after day 1 and before weaning (PWMa24); and (2) the price of a weaned piglet (PrWP). Income from the culled sow (ICW) depends on: (1) the proportion of sows that are culled after parity 5 (PCUS); (2) average weight of a culled sows (WCSS); and (3) price per kg of a culled sows (PrCUS). As a result, total income from all 5 parities before discounting can be written as:

$$\textit{Total income} = [5 \times (TNB - (SB + PWMb24 + PWMa24)) \times PrWP] + [PCUS \times WCSS \times PrCUS] \quad (2)$$

Total costs. Costs were calculated separately for each phase.

Cost of gilt phase. Costs incurred during this period depends on: (1) feed costs for the gilt (FCOG); (2) non-feed costs (NFCOG); and (3) the selection rate of gilts (gSelRate). The total cost in the gilt phase before discounting can then be written as:

$$\textit{Total cost in gilt phase} = (FCOG + NFCOG) / gSelRate \quad (3)$$

Cost in parity 1. This is the cost incurred from the day of the first insemination to the last day of the parity 1 wean to service interval and can be broadly divided into sow costs and piglet costs. Sow costs can then be divided into feed costs and non-feed costs. Each of these costs was further divided into three periods based on the physiological state of the sow (gestation, lactation, and wean to next service interval). Sow costs during gestation depended on: (1) gestation length (GL); (2) average feed intake during first gestation (GGADFI); (3) price per kg of gestation feed (pkgGFeed); and (4) non-feed cost in gestation (NFCG); costs during lactation depended on (5) lactation length (LL); (6) average feed intake during first parity lactation (GLADFI); (7) price per kg of lactation feed (pkgLFeed); and (8) non-feed cost in lactation (NFCL); costs from wean to next service depended on (9) wean to service interval (WSI); (10) average feed intake during wean to next service (WSIADFI); (11) price per kg of sow feed (pkgDFeed); and (12) non-feed cost from weaning to next service ((NFCWSI). Total sow costs in parity 1 before discounting can then be written as:

$$\textit{Total SOW cost parity 1} = [(GL \times GGADFI \times pkgGFeed) + (LL \times GLADFI \times pkgLFeed) + (WSI \times WSIADFI \times pkgDFeed)] + [(GL \times NFCG) + (LL \times NFCL) + (WSI \times NFCWSI)] \quad (4)$$

Piglet costs in parity 1 are divided into two components: (1) cost of raising piglets from birth to weaning; and (2) cost of disposing dead piglets. The cost of raising piglets depends on: (1) lactation length (LL); (2) cost (feed and non-feed) per piglet per day in the farrowing pen (CORPL); and (3) the total number of piglets weaned (TW). TW in turn depends on TNB, SB, PWMb24, and PWMa24. The total cost of disposing dead piglets depends on: (1) pre-weaning mortality (SB, PWMb24, PWMa24); and (2) the cost of disposing one dead piglet (CODPL). As most piglet deaths happen in the first 48 hours of birth, rearing costs of dead piglets can be ignored. Total piglet costs in parity 1 before discounting can then be written as:

$$\textit{Total piglet cost in parity 1} = [(LL \times (TNB - (SB + PWMb24 + PWMa24)) \times CORPL] + [(SB + PWMb24 + PWMa24) \times CODPL] \quad (5)$$

Costs in parities 2 to 5. During parity 2 to 5 gestation and lactation, all cost components are the same as in parity 1, except for feed intake. Sow feed intake during gestation for parities 2 to 5 depends on the energy balance from the previous lactation, which in turn depends on the number of piglets nursed, feed intake during lactation, and the change in body condition during lactation. During lactation, demand for energy is high, as the energy available to the sow has to be divided between its own growth, maintenance, and that required for milk production. Energy requirements during lactation (ERL) can be divided into three parts: (1) energy required for the maintenance of the sow during lactation (ERSM), which in turn depends on sow body weight at farrowing (SBWTF), bodyweight at weaning (SBWTW), and LL; (2) energy required for maintenance of the litter (ERLM), which depends on the average birth weight of the piglets (ABWT), average weaning weight of the piglets (AWWT), number of piglets weaned, and LL; and (3) energy required for growth of the litter (ERLG), which depends on ABWT, AWWT, NW, metabolizable energy content of 1 kg of body fat mass (MEFAT), metabolizable energy content of 1 kg of body protein mass (MEPROT), and average daily gain of piglets from birth to weaning (ADGBW). Each of these cost components can then be written as:

$$ERSM = 0.44 \times ((SBWTF + SBWTW) / 2)^{0.75} \times LL \quad (6)$$

$$ERLM = 0.44 \times ((ABWT + \mathrm{A}WWT) / 2)^{0.75} \times LL] \times \mathrm{NW} \quad (7)$$

$$ERLG = [\{((AWWT - ABWT) \times 0.135 + (0.00014 \times ADGBW))) \times MEFAT\} + \{((AWT - ABT) \times 0.16) \times MEPROT\}] \times NW \quad (8)$$

$$ERL = ERSM + ERLM + ERLG \quad (9)$$

Feed consumed and body resources mobilized are the two sources of energy for a sow during lactation. Energy available from feed intake during lactation (EFEED) depends on: (1) average daily feed intake during lactation (ADFIL); (2) LL; and (3) energy content in lactation feed (MELFEED), and can be written as:

$$EFEED = ADFIL \times LL \times MELFEED` \quad (10)$$

Total energy mobilized from body reserves during lactation (EMOBL) depends on: (1) body fat mobilized during lactation (BFMOBL); (2) body protein mobilized during lactation (PROMOBL); (3) metabolizable energy content in 1 kg of body fat mass (MEFAT); and (4) metabolizable energy content in 1 kg of body protein mass (MEPROT). The amount of fat and protein mobilized during lactation, in turn, depends on body weight loss (WTLOSS) and back fat loss (BFLOSS) during lactation. Total energy mobilized during lactation can then be written as:

$$EMOBL = [(0.1711 \times WTLOSS - 0.3113 \times BFLOSS) \times MEPROT] + (0.1027 \times WTLOSS + 1.904 \times BFLOSS) \times MEFAT]` \quad (11)$$

Eissen *et al.* (2000) stated that during lactation, when milk production is a high priority and nutrient intake is insufficient to meet demands, sows mobilize body reserves to maintain milk production. This will result in a negative energy balance or an energy deficit (ENERDEF) at the end of lactation, which is the difference between the available energy sources and energy demands during lactation. The sow recoups this energy deficit in the following gestation by increasing feed intake during gestation. The amount of additional feed intake depends on the energy deficit from the previous lactation (ENERDEF), the energy density of gestation feed (MEGFEED), the efficiency of converting feed to body reserve (EFFBDR), and the efficiency of converting body reserves to milk (EFBRML), and can be calculated as:

Additional gestational feed = ((*ENERDEF* / *MEGFEED*) / *EFFDBR*) / *EFBRML* (12)

Incorporating these equations into the bio-economic model allows feed intake during gestation in parities 2 to 5 to be calculated to estimate the economic value of SLFI.

Using this bio-economic model, we calculated the net profit for an F1 gilt utilizing trait means from Genesus herds and average North American prices and costs. The economic values were then calculated from the change in predicted profit based on a unit change in the population mean for the trait, keeping all other traits constant (Quinton *et al.*, 2006). The relative contribution of the traits to the breeding goal were calculated by multiplying the economic values for a unit change of the trait by its genetic standard deviation, as described by Amer *et al.* (2014).

Results

The economic values obtained from the bio-economic model resulted in the following relative contribution of traits to the breeding goal: total number of piglets born 48%, total preweaning mortality including stillborn 45%, age at puberty 3%, wean to service interval 3%, and sow lactation feed intake 1%. Litter size at birth was the highest contributor to the breeding objective, and agrees with the results of Quinton *et al.* (2006), Amer *et al.* (2014).

Discussion

The economic value of SLFI, was calculated as the change in profit by increasing the lactation feed intake by 1 kg per day, while keeping everything else constant in the bio-economic model. A bio-economic model that includes SLFI without considering factors such as sow body resource mobilization during lactation, and the impact of SLFI on successive gestation feed intake, resulted in negative relative weight of 3.5% for SLFI. An increase in feed intake during lactation will result in less body reserve mobilization during lactation, and the sow will compensate for this by reducing the feed intake in successive gestation. However, the economic value of SLFI also depends on the difference in energy density and in price between lactation and gestation feed, and on the efficiency with which these feeds are converted to metabolic needs. This complex interaction was incorporated into the bio-economic model that we developed. The results showed that by taking all these factors into consideration, the relative emphasis of SLFI was still negative (1%) but smaller than without accounting for these. Further investigation showed that the economic value of SLFI never became positive, as feed intake during first parity gestation was not affected by an increase in lactation feed intake, and the increase in revenue from a higher body weight of a culled sow was not sufficient to overcome the higher cost of lactation feed. These results show that the relative emphasis of SLFI was negative but very small.

482. Consequences of using different economic selection index methods on greenhouse gas emissions in beef cattle

B.J. Walmsley

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; brad.walmsley@dpi.nsw.gov.au

Abstract

The impacts of using partial (sub) indexes on expected greenhouse gas emissions (GHG) from a self-replacing cow herd producing 120-day grain-finished progeny is compared to selection with a full self-replacing BreedObject index. Sub-indexes only containing post-weaning traits of the slaughter progeny (terminal) and a maternal sub-index were developed using BreedObject. The terminal sub-index is expected to increase mature cow weight (MCW) and milk, resulting in increases in GHG emissions. In contrast, the full self-replacing index is expected to produce slight reductions in MCW and negligible change in milk, which results in decreases in GHG emissions of the cow herd and young animal at pasture. The maternal sub-index is expected to result in larger GHG emission reductions due to larger decreases in MCW as well as negligible change in milk. When constructing partial indexes, the implications on GHG emissions of the cow herd and progeny need to be carefully considered.

Introduction

Pressure is increasing to reduce greenhouse gas (GHG) emissions due to societal concerns about climate change. In livestock, attention is particularly focused on beef cattle because of the relatively large contribution made by enteric methane (Edenhofer *et al.* 2014). Blaxter and Clapperton (1965) showed the association between feed intake (FI) and GHG emissions, which Walmsley *et al.* (2019) used to show upward trends in GHG emissions due to increased FI from productivity gains in the absence of feed efficiency improvements (Walmsley *et al.* 2017). Barwick *et al.* (2019) demonstrated GHG emissions improvements could be made using full production system index selection when feed is appropriately costed, while still increasing net returns. Dividing the breeding objective into sub groupings (sub-indexes) has been proposed as a means of aiding adoption of genetic improvement (Dekkers and Gibson 1998; Wilmink 1996). However, using sub-indexes may not result in optimal selection (Dekkers and Gibson 1998; Barwick and Henzell 2005). The utility of any index is a function of its representation of the production system it is applied in. This has important implications for addressing GHG emissions given the cow herd accounts for the majority of feed-related costs (Walmsley *et al.* 2018). This study examines the impact the use of sub-indexes could have on GHG emissions compared to using a full production system (self-replacing) index.

Materials & methods

Breeding objectives. Breeding objectives for net return per cow mated were derived with BreedObject (Barwick and Henzell 2005) following the outline of Schneeberger *et al.* (1992), where EBVs are combined into one aggregate EBV for the breeding objective. The EBVs used were from the December 2021 BREEDPLAN analysis for 636 published Hereford sires. The BreedObject genetic parameters were derived from industry and literature estimates, and relevant for *Bos taurus* breeds in Australia. Parameter details can be requested from the author. Weightings (b) applied to the EBV selection criteria, û, are derived as:

$$b = G_{11}^{-1}G_{12}\nu \quad (1)$$

where G_{11} and G_{12} are the genetic variances and covariances among BREEDPLAN EBVs (G11) and between these and the objective traits (G12), respectively, and ν is a vector of trait economic values.

DOI: 10.3920/978-90-8686-940-4_482, © B.J. Walmsley 2022

The example production system included a pasture backgrounding period followed by a 120-day feedlot finishing period producing 620 kg *Bos taurus* steers at 21 months of age from a self-replacing cow herd at pasture. Traits in the breeding objective relating to the growing animal were sale liveweight (kg), dressing %, saleable meat %, rump fat depth (mm), marbling score (AUSMEAT scale, 1-12), feedlot entry liveweight (kg), weaning liveweight (direct; kg), residual feed intake-pasture (kg/day), and residual feed-intake feedlot (kg/day) plus cow herd traits; weaning liveweight (maternal; kg), calving ease (direct and maternal; %), mature cow weight (MCW, kg), cow weaning rate (%), and cow condition score at joining (1-15). The general form of the economic value for traits is change (Δ) in returns – Δ FI cost – Δ non-feed management cost. The FI associated with Δ in each objective trait was estimated using the equations described by Freer *et al.* (2007).

Constructing partial indexes. A full self-replacing index (Base), a terminal sub-index (TSub) focused on slaughter progeny and a maternal sub-index (MSub) were constructed using BreedObject. The TSub index only contained traits of the growing animal postweaning in the breeding objective but used the same cost structure as the base index. The MSub index was constructed to show what would be required to counter-balance outcomes from the TSub index. The MSub index used the same cost structure and contained all breeding objective traits but only took account of the maternal contribution to slaughter progeny post-weaning.

Production, feed intake and methane responses. Anticipated responses to selection using the Base and partial indexes were examined by comparing the selection differential in EBVs between the top 10% of sires and the whole published sire list when ranked on index. Estimates of genetic total FI (excluding any period of surplus feed) per sire were derived as presented by Walmsley *et al.* (2017). The breeding objective did not include GHG emissions and residual GHG emissions were not included as EBVs because they are not currently available and their associations with other traits are still under investigation. Methane production was derived using the phenotypic relationships between FI and methane production of Charmley *et al.* (2016) when animals were at pasture, Equation 7 of Johnson *et al.* (1993) when animals were in the feedlot, and the recommended global warming constant for methane (28; Edenhofer *et al.* 2014) for determining kg of CO_2-equivalent.

Results

Figure 1 shows calving ease, sale liveweight and cow weaning rate have the highest positive relative economic emphasis, while negative economic emphasis is placed on feed efficiency (reducing RFI is desired), MCW and milk, to reduce feed requirements. Selection differentials in Figure 2 show the Base index is expected to result in slight reductions in MCW and negligible change in milk while allowing improvements in the other production EBVs, such as calving ease, growth, carcass quality and fertility (negative desired). This index is also expected to result in reductions in both FI and GHG emissions of the cow herd (Figure 2b) and the young animal at pasture, but small increases for the young animal in the feedlot. In comparison, the TSub index is expected to increase growth capacity, which is associated with increases in MCW and milk EBVs. The TSub index is also expected to result in negligible change in calving ease, small improvements in fertility and carcass EBVs along with expected increases in both FI and GHG emissions across the production system.

The selection differentials in Figure 2 also show the MSub index is expected to reduce MCW which is expected to lead to reductions in FI and GHG emissions in the cow herd. The MSub index is also expected to improve fertility, calving ease and carcass traits, other than retail beef yield. However, growth potential is expected to decrease particularly for 600-day weight which also results in reductions in FI and GHG emissions for the young animal.

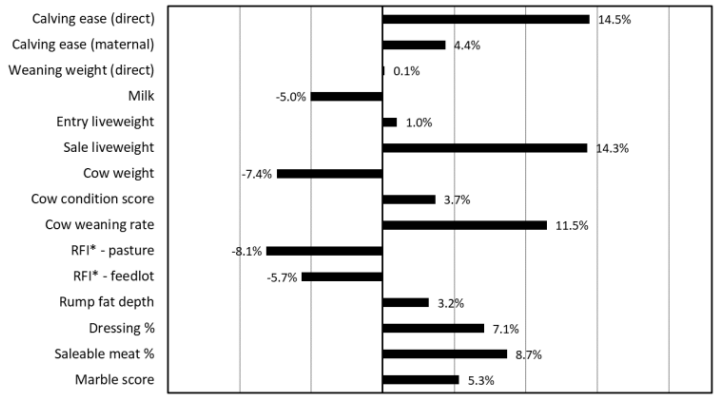

Figure 1. The relative economic emphasis on the breeding objective traits for a self-replacing production system producing 120-day grain-finished steers (Base index). RFI: residual feed intake.

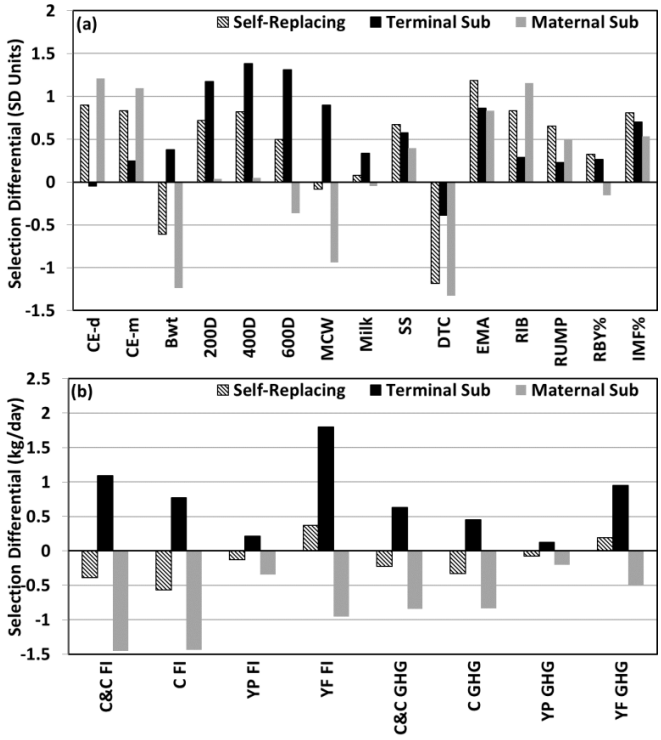

Figure 2. Selection differentials between top 10% and full published Hereford sire list ranked on the self-replacing index (base), the terminal sub-index (TSub) or the maternal sub-index (M-Sub) for (a) the BREEDPLAN EBVs and (b) estimated daily feed intake and greenhouse gas emissions. Traits: CE-d: calving ease-direct, CE-m: calving ease-maternal, Bwt: birth weight, 200D: 200-day weight, 400D: 400-day weight, 600D: 600-day weight, MCW: mature cow weight, Milk: 200-day maternal weight, SS: scrotal size, DTC: days-to-calving, EMA: eye muscle area, RIB: rib fat depth, RUMP: rump fat depth, RBY%: retail beef yield percentage, IMF%: intramuscular fat percentage, C&C: cow and calf at pasture, C: only cow at pasture, YP: young animal at pasture, YF: young animal in feedlot, FI: feed intake and GHG: GHG emissions.

Discussion

The results highlight if partial indexes intended for the post-weaning segment only were inappropriately applied then they should be expected to result in undesirable increases in FI and subsequently GHG emissions in the cow herd. The development of maternal indexes could be an avenue for partially countering such an outcome, but it comes with the added expense of maintaining two breeding nuclei and potentially compromising gains in production traits like retail beef yield or feedlot growth performance thus negatively impacting feedlot profitability. In contrast, a well-constructed self-replacing index is capable of restricting MCW while allowing other production traits to improve and result in a reduction in expected FI and GHG emissions. When constructing partial indexes, the potential implications on GHG emissions need to be carefully considered, particularly if there is scope for these indexes to be inappropriately used when breeding replacement females.

483. Impact of planning horizon length on the relative emphasis of traits in economic breeding goals

H.F. Valasek[1*], B.L. Golden[2] and M.L. Spangler[2]

[1]University of Nebraska-Lincoln, 1400 R St, Lincoln, NE 68583, USA; [2]Theta Solutions, LLC, 4745 Plover St NE, Olympia, WA 98516, USA; hvalasek2@huskers.unl.edu

Abstract

Unique situations exist in beef production herds that can affect the weighting of traits in an index (e.g. breeding system, economic costs/returns, current phenotypic performance). Given genetic purchasing decisions represent capital investments, the time horizon to determine economic impacts also represents a variable that differs between enterprises. The current study used an economic index construction platform (iGENDEC) to investigate the impact of planning horizon length (PH) on the relative emphasis of traits in the breeding goal for beef production systems. A general-purpose index was constructed for three breeding systems with six different PH (2-50 y). As PH increased, relative emphasis for sale weight (weaning or hot carcass) decreased and stayability increased. Rank correlations between indexes with 2 and 50 yr. PH were 0.72 and 0.64 for weaning and slaughter endpoints, respectively. Results illustrate that correctly determining PH can impact the rank of selection candidates and progress towards improved net profit.

Introduction

The concept of selection indexes as a means of multiple-trait selection towards an aggregate goal is not new (Hazel, 1943) and economic selection indexes have become common currency in making selection decisions across many species. The purpose of selection indexes is to select for maximize genetic improvement for the recognized economic selection criterion (Hazel *et al.*, 1994). Traditionally, the construction of selection indexes relied on several components including knowledge of economic, genetic, and phenotypic parameters that aligned with specified breeding goals. The design of a selection index requires the estimation of relative economic value as this derives the relative emphasis assigned to each trait (MacNeil *et al.*, 1997).

In general, selection indexes can be classified as either terminal or maternal depending on the breeding goal. In some species, such as beef cattle, general purpose indexes offer an opportunity for self-replacing commercial herds to place emphasis on both maternal and terminal traits. These general-purpose indexes could be targeted at different sale endpoints (i.e. weaning or slaughter). Regardless of index type, economically optimized indexes should provide an expectation of changes in net profit due to selection.

Enterprises experience unique situations that could change the relative emphasis of traits in enterprise-specific breeding goals. Differences in current levels of performance are known to impact the relative economic importance of traits (Enns *et al.*, 2006). The planning horizon (PH) assumed by an enterprise represents a complex decision that should be contemplated and requires consideration of breeding objectives and the need for revenue at alternative points in the future. Planning horizons are an instrumental aspect of creating a profitable sire selection program and allows a producer to capture monetary and genetic returns over the length of the PH considering the initial financial situation (McMahon *et al.*, 1985). Variation in PH account for the initial investment of a bull and how quickly a producer may need or want to generate revenue with that animal. The objectives of the current study were to investigate the impacts of different lengths of PH on the relative emphasis of traits in the breeding goal and the ranking of selection candidates.

Materials & methods

The selection indexes evaluated were produced by iGENDEC, a web-based platform for economic index construction in U.S. beef production systems (Spangler *et al.*, 2022). In brief, iGENDEC used a stochastic simulation to construct a cow herd and genetic values of bulls were modified by one unit, one trait at a time, to determine the Marginal Economic Value (MEV) of each trait in the breeding objective. The model accounted for discounted gene flow and discounted expression rates (McClintock and Cunningham, 1974). General-purpose selection indexes constructed assumed replacement females were retained and terminal animals were sold either at weaning or at slaughter. Traits included in the index for the weaning endpoint included weaning weight-direct (WW-D), weaning weight-maternal (WW-M), mature cow weight (MW), stayability (STAY), heifer pregnancy (HP), calving ease-direct (CE-D), and calving ease-maternal (CE-M). Traits included in the index when the endpoint was slaughter included the same traits as the weaning endpoint along with hot carcass weight (HCW), ribeye area (REA), fat depth (FAT), marbling score (MS), and feed intake (FI).

For each index described above, three breeding systems were assumed: Angus bulls bred to Angus cows, bulls and cows that were half Simmental and half Angus, and cows that were half Angus and half Hereford paired with Simmental bulls. These breeding systems were investigated to contrast the impact of different levels of direct (initial values of 0, 50, and 100%) and maternal heterosis (initial values of 0 and 100%). The initial phenotypic means were assumed to be the same in all breeding systems. Six PH lengths (2, 5, 10, 20, 30, and 50 yrs.) were evaluated to assess the implications of PH on the relative emphasis for each trait where relative emphasis was defined as the MEV multiplied by the genetic standard deviation of the trait and then divided by the sum of this product for all traits. Planning horizon represented the number of years simulated with the improved genetic merit of bulls. In total, 36 scenarios were investigated. The economic parameters were assumed the same in all scenarios.

In addition, an evaluation of HCW was conducted to determine the change in relative emphasis as hot carcass weight approached a pre-defined discount threshold of 477 kg as might exist in U.S. beef production systems. This evaluation was conducted using the purebred Angus production system at three different time horizons (2, 20, and 50 yrs.). Hot carcass weight started at 295 kg and increased by 45 kg to reach a final weight of 522 kg.

Using the 2 and 50 yr. PH for the purebred Angus system at both sale endpoints (weaning and slaughter), the indexes were applied to a group of selection candidates (n=27,123) to estimate rank correlations between indexes that differed in PH.

Results

For the indexes that assumed a weaning endpoint (Table 1), as the length of PH increased within, the relative emphasis shifted from WW-D to STAY and MW. Likewise, when the endpoint was slaughter (Table 2), a similar trend was observed as the relative emphasis of HCW decreased and the relative emphasis of STAY increased. The relative emphasis of STAY never exceed that of HCW, however, when weaning weight was the sale endpoint the relative emphasis of STAY was larger than the relative emphasis of WW-D at longer PH.

The Spearman's correlation coefficients between the rank of selection candidates based on a 2 and 50 yr. PH were 0.72 and 0.64 when the sale endpoint was weaning and slaughter, respectively.

Table 1. Comparison of relative emphasis for weaning weight and stayability for different Lengths of planning horizon for an index with a weaning sale endpoint.

	Purebred Angus		Angus-Simmental		Three breed cross	
Time horizon (years)	WW-D	STAY	WW-D	STAY	WW-D	STAY
2	0.873	0.000	0.794	0.000	0.911	0.000
5	0.702	0.016	0.501	0.271	0.555	0.262
10	0.440	0.249	0.402	0.264	0.459	0.179
20	0.337	0.329	0.322	0.310	0.313	0.323
30	0.295	0.353	0.284	0.347	0.268	0.385
50	0.276	0.354	0.263	0.359	0.239	0.411

Table 2. Comparison of relative emphasis for hot carcass weight and stayability for different lengths of planning horizon for an index with a slaughter endpoint.

	Purebred Angus		Angus-Simmental		Three breed cross	
Time horizon (years)	HCW	STAY	HCW	STAY	HCW	STAY
2	0.468	0.002	0.448	0.002	0.431	0.001
5	0.457	0.003	0.431	0.043	0.444	0.001
10	0.419	0.040	0.403	0.076	0.400	0.069
20	0.368	0.149	0.373	0.140	0.348	0.192
30	0.353	0.177	0.353	0.182	0.338	0.210
50	0.339	0.205	0.339	0.210	0.324	0.242

As the mean HCW increased towards the discount threshold the relative emphasis decreased (Table 3). Once HCW surpassed the pricing discount threshold, relative emphasis for HCW weight gradually increased.

Discussion

When the targeted sale endpoint was at weaning, the largest changes in the relative emphasis occurred between the 2 and 5 y PH (crossbred systems) or between the 5 and 10 y horizons (purebred system). Between these time points, the relative emphasis of WW-D decreased and the relative emphasis of STAY increased. When slaughter was considered the sale endpoint the changes in relative emphasis between HCW and STAY were more gradual and the largest differences occurred between the 10 and 20 y PH. Again, the trend was for the relative emphasis for HCW to decrease and the relative emphasis for STAY to increase.

Table 3. Relative emphasis of hot carcass weight for different hot carcass weight means and planning horizons when the discount threshold was 477 kg.

The shift in relative emphasis from the endpoint weight (weaning or hot carcass) to sustained reproductive traits (i.e. STAY) as PH increased was expected. As PH increased, the return on investment of a genetic purchasing decision shifted from traits expressed sooner. This represents an intuitive interaction between the discounted expression rate and the length of the PH. When the PH was short (e.g. 5 y or less), traits such as STAY may not have been fully expressed in all breeding females, whereas traits such as weight at sale had the opportunity to be expressed sooner. The relative emphasis for sale weight and STAY were not as large when the endpoint was slaughter as they were when the endpoint was weaning. This was an artifact of the slaughter index being comprised of more traits than the weaning index. As an example of the consequences of PH length on selection decisions, rank correlations in the purebred scenario were estimated for both sale endpoints between 2 and 50 y PH. The rank correlations were 0.72 and 0.64 for weaning and slaughter endpoints, respectively, suggesting considerable re-ranking among selection candidates.

The decrease in relative emphasis of HCW as the current mean of HCW increased was expected given a pricing discount threshold existed. Interestingly, once the mean HCW exceeded the discount threshold the relative emphasis began to increase suggesting that once the discount was already incurred there was economic incentive to increase sale weight. The relative emphasis of HCW at an assumed mean HCW decreased as length of PH increased. This illustrates a latent interaction between discounted gene flow and length of the PH.

Length of the planning horizon is an important consideration in constructing economic selection indexes. Further work is needed to formally compare the efficiency of indexes constructed under different planning horizon assumptions.

Abstract

The low pregnancy rate by artificial insemination in sheep represents a fundamental challenge for breeding programmes. In this species, estrous synchronization is done by manipulating hormonal regimens through the insertion of progestogens in intravaginal sponges, which may alter the vaginal microbiota and the success of artificial insemination. In this study, we analysed the microbiome of 94 vaginal swabs from 47 ewes with alternative treatments applied to the progesterone-releasing intravaginal devices, in two sample periods (before and after removing the devices) using nanopore-based metagenome sequencing. A lower abundance of the genera *Neisseria* (Proteobacteria) and *Oenococcus* (Firmicutes) was observed in pregnant compared to non-pregnant ewes. Although differences between treatments were not detected, the progestogen of the synchronization devices seemed to increase the alpha-diversity and decrease the abundance of harmful microorganisms belonging to Gammaproteobacteria and Fusobacteriia classes, suggesting that progestogens may have a beneficial effect on vaginal microbiota favouring the artificial insemination success.

Introduction

Ovine production has a great economic value in Spain, which is the second producer in Europe and the fifth worldwide. Artificial insemination (AI) is the key technology in dairy ruminants breeding programmes for progeny testing, connecting herds and disseminating genetic improvement. However, the efficiency of AI in sheep is low as fertility rates range from 30 to 60%. This low efficiency is due to the particular morphology of the reproductive tract of the ewe, the requirement of using fresh semen and the difficulty to determine the exact stage of the ovulatory cycle at the time of AI. A typical practice for oestrus synchronization is the use of progesterone-releasing intravaginal devices (PRID) consisting on a stainless spiral coil coated with an inert silicone rubber matrix impregnated in flugestone acetate (20 mg), allowing the alteration of ewes hormonal regime. However, our understanding of other factors that may affect the success of AI in sheep, such as the genital tract microbiota, is still low.

In recent years, the study of the composition and abundance of microbial communities (microbiota) has been facilitated by the advances of high-throughput sequencing technologies. In particular, metagenomics has emerged as the reference technique to directly analyse the genomes contained in an environmental sample (microbiome). While there is strong evidence of the role of the reproductive tract microbiota on fertility and sexual disease in humans (e.g. Kindinger *et al.* 2017), its study in livestock species is more limited (Quadros *et al.* 2020; Pascottini *et al.* 2021), and very few in sheep (Serrano *et al.* 2020; Koester *et al.* 2021).

The aim of this study was to elucidate the role of the vaginal microbiota in fertility of Assaf sheep by sequencing the microbial metagenome from pregnant and non-pregnant ewes. In addition, we evaluated the effect of PRIDs supplemented with different additives on the microbiota composition, and whether potential changes in that composition were related with the pregnancy rate. Additionally, the advantages of third-generation

nanopore sequencing technology (Oxford Nanopore Technologies, ONT) were exploited to study microbial genes and functional pathways (KEGGs, Kyoto Encyclopaedia of Genes and Genomes) involved in fertility.

Materials & methods

Experimental design, DNA extraction and sequencing. A total of 94 vaginal exudate (swabs) samples from 47 ewes from an Assaf flock were obtained in two sampling times. A first vaginal swab was collected from each female, immediately prior to insertion of PRIDs (S1 group). Intravaginal devices were removed 14 days later, and AI was conducted 55 hours after PRID removal. Just before insemination, a second sample of vaginal exudate was taken from each ewe (S2 group) in the same way as the first. At the time of PRID administration the ewes were divided in four batches, depending on alternative treatments added to the PRID (200 mg lyophilized): (1) *probiotic* (n=13), containing *Lactobacillus rhamnosus* and maltodextrine (excipient); (2) *maltodextrine*, the probiotic excipient (n=10); (3) *antibiotic*, containing Framitecin (n=13); and (4) *control*, no additive added in the PRID (n=11). Microbial DNA was extracted using the QIAamp ©DNA Microbiome extraction kit (Qiagen Inc., Valencia, CA, USA). Metagenome sequencing was performed in a MinION device (Oxford Nanopore, Oxford, UK) using the ligation sequencing kit (SQK-LSK109, Oxford Nanopore, Oxford, UK). Pregnancy status was assessed using ultrasonography pregnancy testing 42 days after AI. Notice that all samples (n=94) were used for comparison between sampling times, while only samples from the S2 group (n=47) were used for the analysis of pregnancy outcome.

Bioinformatics and statistical analyses. Base calling was performed with the Guppy 4.2.2 software (ONT). A first filtering of the host genome was performed by mapping the reads against *Ovis aries* reference genome (Oar_rambouillet_v1.0, GCA_002742125.1) using the BBMap software. The retained sequences were analysed using the *sqm*_longreads.pl SqueezeMeta 1.1.0 pipeline software (Tamames and Puente-Sánchez, 2019), which runs a Blastx search of the translated nucleotide reads against GenBank nr, and Kyoto Encyclopedia of Genes and Genomes (KEGG) databases obtaining taxa (phylum, class, and genus) and KEGG. Subsequently, quality filters were applied to remove unclassified taxa and those at a relative abundance threshold <0.1%. Imputation of zero values was performed using a Bayesian multiplicative replacement procedure. Normalization was implemented by applying the Centred Log-Ratio (CLR) transformation. Microbial abundance was evaluated using SQMtools and alpha-diversity by the Phyloseq software. The effect of microbiota on pregnancy rate, as well as the effect of PRID were assessed with PCA, PERMANOVA, and a differential abundance analysis, LIMMA R package. Quality filters and analyses were carried out using R-project (https://www.r-project.org).

Results

Of the 47 inseminated ewes, 26 were pregnant (four in the *probiotic*, seven in the *antibiotic*, six in the *maltodextrine*, and nine in the *control* groups) and 21 were not pregnant (nine in the *probiotic*, six in the *antibiotic*, four in the *maltodextrine* and two in the *control* groups).

No significant differences were observed in microbial alpha-diversity when comparing pregnant and non-pregnant groups, although it was higher in pregnant (56±11.6) than in non-pregnant (47.1±17.2) ewes. Differential abundance analysis revealed that *Oenococcus* (Bacilli) and *Neisseria* (Betaproteobacteria) genera were significantly more abundant in non-pregnant ewes. The comparison of microorganism abundance did not reveal significant differences between probiotic, maltodextrine, antibiotic and control groups, both in the analysis of pregnancy outcome and when comparing sampling times S1 and S2.

Regarding sampling times, alpha-diversity was significant higher in S2 (54.1±14) compared to S1 (39±13.2). Also, significant differences between both groups were found in terms of abundance as revealed by PCA, PERMANOVA and differential abundance analysis for genus, phylum and KEGGs (Figure 1).

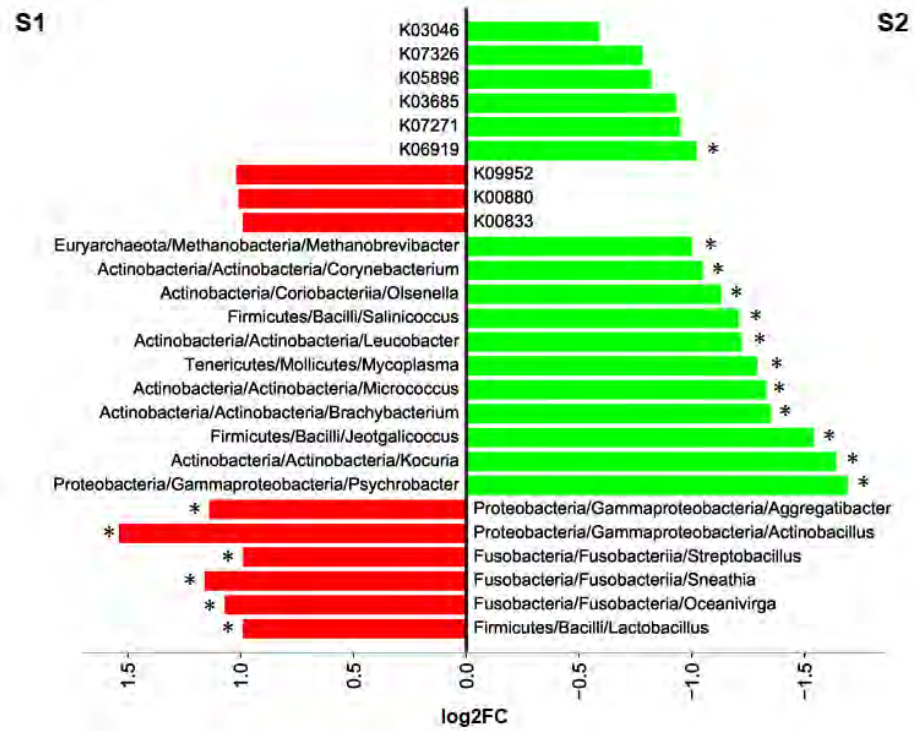

Figure 1. Differential abundance analysis for samples collected before PRIDs placement (S1) and after PRIDs removal (S2), corrected by PRID treatments, at phylum, class, genus and KEGG levels. Asterisks represent adjusted *P*-values at the 5% level. Bars without asterisk correspond to adjusted *P*-values at the 10% level. The x-axis represents the fold-change (FC).

So, Proteobacteria was the most abundant phylum in the S1 group, whereas Firmicutes was the most abundant phylum in S2. At the genus level, *Actinobacillus, Sneathia, Streptobacillus* and *Aggregatibacter* were significantly the most abundant in S1, whereas *Jeotgalicococcus, Kocuria* and *Psychrobacter* were significantly the most abundant in S2 (Figure 1). Concerning functional analysis (genes and genomes), K00800 (L-xylulokinase) and K09952 (CRISPR-associated endonuclease Csn1) KEGGs were significantly more abundant in the S1 group, while K06919 (DNA primase, phage- or plasmid-associated) was significantly more abundant in the S2 group.

Discussion

In this work we have investigated the role of vaginal microbiota in sheep AI pregnancy rate and the effect of different treatments added to PRIDs in its composition and abundance. Our results revealed a significantly higher abundance of the genus *Neisseria* in non-pregnant ewes, and this may be related with the AI failure. Species of this genus (*Neisseria gonorrhoeae*) have been found to trigger ectopic pregnancy and infertility in women (Smolarczyk *et al.* 2021).

In addition, we observed that the progestogen included in the synchronization sponges increased the alpha-diversity of the vaginal microbiota, suggesting a beneficial effect on pregnancy outcome. In line with this, a recent study by Koester *et al.* (2021) evaluating the microbial composition at a pre-breeding time point and after pregnancy testing found increased alpha-diversity associated with pregnancy rate.

Regarding the effect of the PRIDs (and irrespective of the treatment added) on the microbiota composition and abundance, our results showed that the genera *Actinobacillus* (Gammaproteobacteria) and *Sneathia* (Fusobacteriia) decreased in samples collected after the PRID removal (S2). Pathogenic species from these genera (e.g. *Actinobacillus seminis, Sneathia vaginalis* and *Streptobacillus notomytis*) have been associated to infertility in a recent studio by Serrano *et al.* (2020), which may suggest a beneficial effect of the synchronisation treatment for reproductive success. The authors also found that *Mageebacillus* and *Histophilus* were less abundant in the pregnant group, although this discrepancy with our results might be related with the different sequencing methods used (sequencing of the hypervariable regions V3-V4 of the 16S rRNA gene vs metagenome Nanopore sequencing).

From a functional perspective, we detected a higher abundance of sequences corresponding to L-xylulokinase (K00800) in the S2 sampling time. This KEGG is indirectly involved in the process of phage colonization of host bacteria, representing an essential enzyme for phage DNA replication (Wang *et al.* 2020). Its increase after the removal of the synchronization devices could be responsible for the decrease of harmful classes of bacteria such as Gammaproteobacteria and Fusobacteriia. Interestingly, these bacterial classes have more than 10 genes related to helicase and primase activities (K06919), involved in prokaryotic defence against foreign genetic elements, which were found in lower abundance in samples collected after the removal of the sponges (S2).

In conclusion, this study provides new insights about the effect of the progesterone-releasing intravaginal devices used to synchronize estrous on the vaginal microbial composition and abundance. Although preliminary, our results suggest a beneficial effect of the synchronization treatment, contributing to reduce the abundance of some genera associated with reproductive failure. This study also evidences the potential of nanopore sequencing not only to characterise the microbial populations present in a community but also to provide information about genes and pathways involved.

Abstract

Development of an effective direct transfer vitrification procedure for biopsied *in vitro* derived embryos is necessary for large scale use in the field and increased genetic gain in the cattle industry. One possible reason for insufficient results to date may be the swelling of embryos following warming/transfer. We used mathematical modelling of the volume changes of embryos during and following vitrification protocols, to study the effect of different temperatures and concentrations of cryoprotective agents (CPAs) and non-permeant solutes. The simulations showed no effect of temperature on the level of post-warming swelling at the assumed parameterizations. However, adapted vitrification media with lower concentrations of CPAs and higher non-permeant solutes led to clearly lower swelling after direct transfer, and could potentially be less toxic for the embryos, but also led to a stronger shrinking during vitrification. The alternative media and protocol seem promising, but empirical experiments are needed to validate this approach.

Introduction

Assisted reproductive techniques, such as *in vitro* fertilization and embryo transfer, are used in the cattle industry to decrease the generation interval and increase the genetic gain per generation (Crowe *et al.,* 2021*).* For instance, embryos may be biopsied to obtain a genomic estimated breeding value of each embryo. Embryos can then be frozen and stored in Liquid Nitrogen (LN_2). The use of frozen embryos increased over the past decade and in 2018, a total of 1.1 million of bovine embryos (*in vivo* derived or *in vitro*) were transferred of which 38.2% were frozen (Viana *et al.,* 2019). Direct transfer (DT) cryopreservation protocols allow a straw with an embryo to be thawed and used at the farm without laborious and complicated steps. This is very important for large scale use in the field as it does not require on-site equipment or expertise. Slow-freezing (SF) followed by direct transfer is currently possible and used for bovine embryos (Dochi *et al.,* 2019). Slow freezing at relatively low concentrations of cryoprotective agents (CPAs) allows formation of extracellular ice, which prevents intracellular ice formation. However, survival rates after SF of biopsied *in vitro* produced bovine embryos are lower than with vitrification (Najafzadeh *et al.,* 2021). In contrast, vitrification is fast and doesn't allow any ice formation, but requires high concentrations of cryoprotective agents and high cooling and warming rates. Current vitrification protocols result in good pregnancy rates, but do not allow direct transfer, hence they require one to three washing steps in the field (Ferré *et al.,* 2020). Therefore, DT vitrification methods (no washing steps) need to be developed. Addition of CPAs prior to vitrification, and removal of CPAs after vitrification can lead to stresses caused by massive volume changes, extremely high intracellular concentrations of CPAs and cytoplasmic salts, dehydration of the cellular cytoplasm, and excessive swelling of the cells upon removal of CPAs. We use mathematical modelling to describe transmembrane fluxes of water and CPAs following addition of CPAs prior to vitrification, and removal of CPAs after vitrification. Mathematical modelling allows us to 'look inside cells' as we can accurately calculate not only the volume changes of the cells but also the intra- and extracellular concentrations of water and all solutes at every point in time. The objectives of the present study were to use the mathematical modelling to explore possibilities to mitigate risks of swelling following direct transfer of vitrified bovine embryos. More precisely, we investigated the effect of different concentrations of permeant and non-permeant CPAs in the vitrification solution and of different temperatures after vitrification-warming on post-DT swelling.

Materials & methods

General mathematical model. The modeling of osmotic events was done using two parameter (2P) description of the transmembrane fluxes of water and CPA (Kleinhans, 1998). In this description, fluxes of water and CPA are proportional to the transmembrane difference of the chemical potential (ΔM) for water and for CPA, respectively. A full description will be detailed elsewhere (Woelders *et al.,* in preparation). It was assumed that the 'isotonic' (physiological) osmolality is 0.29 Osm/kg of water. Further, in the modelling, the embryo was considered as a single 'cell' that is confined by a single semipermeable outer cell membrane. This assumption is appropriate as the applied membrane permeability coefficients are 'empirical' phenomenological coefficients obtained by fitting actual empirical osmotic volume excursions of embryos. Assumed values for the permeability coefficients and other embryo characteristics were based on reported values for bovine blastocysts, morula's, and earlier embryo stages for various different CPAs (Woelders *et al.*, 2007; Jin *et al.*, 2011). Thus, it was assumed that embryos at isotonic conditions have volume and surface area of a sphere with a diameter (excluding the zona pellucida) of 120 µm, that the embryos surface area remains constant, and that the initial (isotonic) aqueous fraction is 0.8. Further it was assumed that the hydraulic conductivity, or L_p (at 25 °C, in the presence of EG and DMSO) is 1.0 µm/min/atm, that the membrane permeability for permeant CPAs (P_s) is equal for EG and DMSO, and has a value (at 25 °C) of 20 µm/min, and that the activation energy (E_a) of L_p is 6.5 kcal/mol and E_a of P_s is 7.3 kcal/mol. L_p and P_s at other temperatures were calculated as described in Woelders and Chaveiro, 2004.

Simulations. 'Standard' vitrification featured incubation in 'vitrification solution 1' (VS1; base medium with 7.5% ethylene glycol (EG) and 7.5% dimethyl sulfoxide (DMSO)) for 5 minutes, followed by incubation in 'vitrification solution 2' (VS2; base medium with 15% EG, 15% DMSO, 0.69M of sucrose, and 10 mg/ml Ficoll 400,000) for 1 minute, all at room temperature (RT; 22 °C). The osmolality of VS2 was 12 Osmol/kg of water. Direct transfer was then simulated as an immediate return to base medium (isotonic). Subsequently, similar simulations were run using different temperatures during 'direct transfer', as illustrated in Figure 1.

Then, we investigated the effect of the final amount of (permeant) CPAs taken up by the embryos on the level of embryo swelling after 'direct transfer'. This was done by using variations of VS1 and VS2, with reduced concentrations of the permeant CPAs, combined with elevated concentrations of the non-permeant solute sucrose in VS2, with in all cases a final osmolality of VS2 of 12 Osm./kg water, i.e. identical to that of the 'standard' vitrification protocol. In all VS1 and VS2 media the vol% of EG was equal to that of DMSO. Embryos were incubated in VS1 at RT for 10 min, allowing them to approach equilibrium. The molar concentrations of all base medium solutes was kept constant in all VS1 variants. For reasons explained in

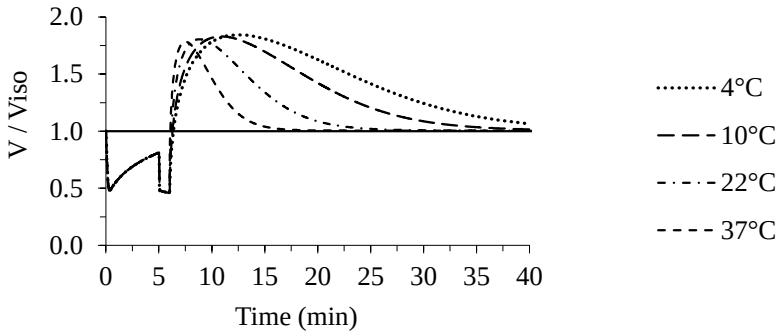

Figure 1. Predicted swelling of bovine embryos in a 'standard' vitrification protocol using different temperatures after warming/transfer. V/Viso is the embryo volume relative to the initial volume (Viso).

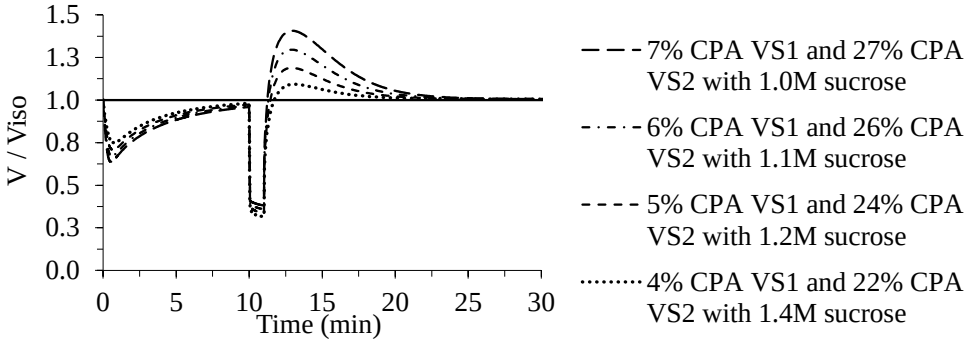

Figure 2. Predicted effect of VS1/VS2 with lower [CPA], with increased sucrose in VS2, all at room temperature. V/Viso is the embryo volume relative to the initial volume (Viso).

the discussion, in all VS1-VS2 combinations the ratio of permeant and non-permeant solutes in VS2 was made equal to that of VS1. VS1 and VS2 concentrations of CPA and sucrose are detailed in Figure 2.

Discussion

In this study, we used a mathematical model to predict volume changes of bovine embryos in different vitrification protocols, with a focus on swelling of the embryos following warming. As is well known, embryos first shrink rapidly after addition of CPA, due to osmotically driven rapid efflux of water, then reswell due to the continued entry of CPA. In two-step vitrification protocols, embryos in VS1 are usually allowed to reswell, i.e. to take up sufficient amounts of CPA approaching equilibrium. In a second (shorter) step in VS2, which has a much higher CPA concentration, the embryos merely shrink due to a rapid efflux of water, which concentrates all solutes inside the embryo. Transfer of embryos after vitrification/warming to a medium with less or with no CPAs is known to lead to strong swelling of embryos above their isotonic volume. Our simulations show that in the 'standard' protocol direct transfer to isotonic medium leads to swelling of the embryos to 1.8 times their initial volume (Figure 1). This represents the 'worst-case scenario', as we assumed immediate and complete mixing with isotonic medium. In reality, embryos placed together with a small volume of VS2 into the uterus will be progressively exposed to isotonic conditions, so swelling will be less. However, the level of swelling is considered to be potentially harmful. We have investigated whether the level of swelling depends on the temperature of the medium to which the embryos are exposed after warming. The rapidity of the swell and shrink cycle strongly depended on temperature, but temperature had only little effect on the peak level of swelling. The latter is due to the fact that at the assumed values of E_a of L_p and E_a of P_s, the rates of water flux and CPA flux had a similar dependence on temperature. If E_a of P_s were substantially higher, peak swelling could be much lower, but one would need to assume an unrealistically high value, four times higher than the value we used, to bring peak swelling down to 1.2 × Viso (data not shown).

Another approach we followed was to reduce the CPA intake of the embryos. In fact, this is what is achieved in protocols with shortened incubation in VS1, with the 'standard' (high) concentration of CPA (Ortiz-Escribano *et al.*, 2018). Here, we used a longer incubation (full equilibration) with a strongly reduced CPA concentration in VS1. The full equilibration allowed us to have control over the amount of CPA taken up by the embryos. The low concentrations of CPA in VS1 (4-7 vol.%, or 0.64-1.1 mol/l) were in the range of what is commonly used in slow freezing protocols, which is considered harmless for embryos during a 10 minute incubation. In VS2, we used elevated sucrose and lower CPA concentrations compared with the 'standard' VS2 such that the ratio of permeant and non-permeant solutes in VS2 was equal to that in VS1. This

ensures that there was no or little net influx or efflux of CPA during the short incubation in VS2. However, a rapid efflux of water was observed in VS2, which brought the intracellular osmolality to the level of the extracellular osmolality (of VS2) within a few seconds. This approach was shown to be highly effective in reducing the peak level of swelling of embryos following direct transfer (to 1.2-1.4× Viso). However, the lower concentration of CPA in VS1 led to stronger shrinking in VS2 (just prior to vitrification), with V/Viso of 0.32-0.38, compared with 0.46 in the standard protocol. The stronger shrinking may pose larger mechanical stress on the embryos, but at the same time, the lower concentrations of CPA used in VS1 and VS2 could be less toxic for the embryo. Empirical experiments are needed to show if these adapted media and protocols will result in adequate embryo survival and whether or not these sufficiently reduce post-warming swelling to allow direct transfer. This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project).

Abstract

Stallions are characterized by large variations in fertility among individuals. Those differences were previously linked, among other causes, to genetic factors. Hereby, we estimated breeding values for two fertility traits (fertility per season (Fert) and matings per foal produced (MpF)) analyzing a large dataset of ≈500,000 matings produced by 5,927 thoroughbred stallions during the last 35 years in Argentina. Pedigree data included 28,724 individuals showing an average Equivalent Complete Generation (ECG) of 6.47. Estimated Breeding Values (EBV) were estimated using a bivariate linear mixed model implemented in the BLUPF90 package. Heritabilities were 0.20±0.008 and 0.17±0.016 in Fert and MpF respectively. The genetic correlation between traits was -0.76. 5,927 individuals showed accuracy values higher than 50% in both traits. Interestingly only 43 individuals were included among the 100 less fertile in both traits, whereas 54 were included among the 100 most fertile. To our knowledge, this is one of the largest studies performed estimating fertility EBV's in stallions.

Introduction

Fertility is one of the key factors in any livestock production system. In horses, this is particularly important, since the species is well known for lower fertility rates in comparison with other livestock species. In addition, stallions are known for a large variability among individuals in terms of fertility, which was linked, among other factors, to genetic causes. However fertility-related traits are particularly difficult to model from a genetic point of view in the species since reliable phenotypic datasets are scarce (Laseca *et al.* 2021).

In stallions, fertility can be analyzed using different parameters. One of them is fertility per season, which is estimated as the number of foals produced by a stallion to the number of mares mated. However, this parameter does not take into account the number of matings necessary to produce a foal, and therefore, it can overestimate the real fertility of the individual. However, it can be solved by estimating the average number of matings necessary to produce each foal. This parameter allows discriminating stallions that need more mating to produce a foal from those that do not; allowing a more accurate value of individual fertility to be estimated. However, to our knowledge, large population studies analyzing stallion fertility are scarce.

The Thoroughbred (TB) is probably one of the oldest horse breeds, being characterized by an impressive racing ability, but also by a reduced genetic variation and increased inbreeding rates (Corbin *et al.* 2010). Furthermore, TBs are clustered from a genetic point of view in maternal families, in which the assignation of each individual to a certain genetic group is determined based on the direct relationship with one of the 43 founder mares of the breed (Hill *et al.* 2002). According to the International studbook, TBs can only be bred by natural mating, without the use of any assisted reproductive technique. But also, all the matings must be reported by the breeder to the breeders association, regardless of whether or not a pregnancy was produced. For that reason, large and reliable reproductive datasets in TBs could be gathered.

Therefore, we modeled and estimated the fertility of 6,713 TB horses using around 509,558 mating records collected during the last 35 years in Argentina.

DOI: 10.3920/978-90-8686-940-4_486, © A. Karlau *et al.* 2022

Materials & methods

The estimation of fertility phenotypes was made based on 509,558 mating records retrieved from the Studbook Argentino public database. The dataset included matings from 6,713 thoroughbred stallions and 86,106 breeding mares in Argentina, collected from 1986 to 2020. The fertility of the stallions was estimated using two different criteria. First, we determined the fertility per season (Fert) of each stallion as the relationship between the number of foals produced and the number of mares bred during each entire season. In addition, a second estimation of the stallion fertility was determined as the average number of matings per foal produced (MpF) during each season. On average, stallions were active during 5.35 seasons (ranging from 1 to 26).

EBV's for Fert and MpF were estimated using a restricted maximum likelihood (REML) animal bivariate model as follows:

$$y = \mu + age + F + Xb + Zu + e$$

where yi is the vector of each dependent variable, μ is the overall population mean, b is a vector of fixed effects, including *stud*, *size of the stud*, *season*, *number of matings per season* (in quartiles), *age of the stallion* (in yearly classes), and *maternal family* (43 classes); F is the inbreeding of the stallion included as a linear covariate, u is the vector of random effects due to the additive animal genetic effect, and e is the vector of the residual error; whereas X and Z are incidence matrices that relate the fixed and random effects with the dependent variable. Pedigree data of all known relatives (n=32,840) included in the additive genetic relationship matrix was also obtained from the Studbook Argentino. The genealogical information of the individuals averaged 6.47 ECG, with a maximum of 30. The average inbreeding of the individuals was 1.29%, but ranging between 0 and 26.06%. Genetic parameters were estimated in AIREMLF90 software from the BLUPF90 family (Misztal *et al.* 2002). Finally, data clustering and curation, pedigree handling and analysis, as well as the analysis of the results were performed in R, using *optisel*, *data table,* and *tydiverse* packages.

Results

The phenotypic dataset showed an average Fert of 53.15±23.16%. and 2.97±3.51 MpF. In both cases, the standard deviation was large, in comparison with average values. We also have not found any significant correlation (Spearman test, $P>0.05$) between the age of the stallion and Fert and MpF ($P>0.05$, Figure 1a).

However, the effect produced by the maternal family showed significant variations among groups in both traits (Figure 1b).

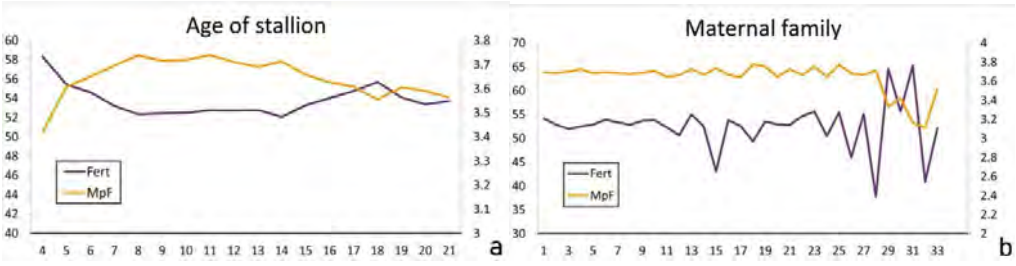

Figure 1. Phenotypic analysis of Fert (left axis in %) and MpF (right axis) clustered by stallion age(a) and family (b).

The genetic analysis showed moderate-to-high heritabilities (in comparison with previous estimations in horse fertility's traits). Fert h^2 was 0.20±0.008 and MpF h^2 was 0.17±0.016. In both cases, the standard deviations were 10 to 15 fold lower than the average values. Moreover, both traits were heavily negatively correlated (-0.76), which is expectable, since fertility is usually reduced when the number of matings per foal increases. It is noteworthy that 5,927 individuals (5,762 with phenotypic values and 165 estimated based on pedigree records), showed an accuracy of 62.87±8.04 for Fert and 61.23±7.53 for MpF.

The average Fert and MpF EVBs per season were estimated during the last 35 years (Figure 2a). the results demonstrated a general increase in the fertility of the breed. Finally, we determined the 1000 individuals showing the highest Fert and lowest MpF EBV's (top fertile individuals). Interestingly, only 660 of them were present in both groups (Figure 2b), showing a negative Spearman correlation of -0.399. However, the same analysis identifying the bottom 1000 less fertile individuals (low Fert and high Mpf) showed only 543 individuals in both groups but the correlation was close to -0.931.

Discussion

The principal challenge in assessing stallions' fertility is to obtain large and reliable phenotypic datasets. However, the precise recording and reproductive management employed in the TB breed make them almost the only exception. In this study, we were able to gather records of 500,000 matings by more than 6,000 individual stallions, occurring in Argentina during the past 35 years. The analysis, performed using a REML linear mixed model, has enabled >5,700 EBV's with an accuracy higher than 50%. To our knowledge, this is one of the biggest and most precise studies carried out to date, to estimate the genetic component of fertility in stallions using field data.

Declining fertility is commonly seen as stallions age (Turner 2019) and is usually due to diminishing testicular function, among other causes. However, we were not able to determine such a relationship in our data. Since TB horses are only bred by natural matings, it is a usual practice that mare and stallions are managed using fine-tuning strategies for improving reproductive outcomes. Among them, the management of aging stallions by reducing their activity and assigning them to mares with proven fertility is one of the most common strategies. Our results suggest the existence of such practices among Argentinean breeders, allowing them to obtain an increased number of foals from racing champions even at older ages.

We also detected differences in fertility of individuals belonging to certain maternal genetic lines. This characterization is considered an important indicator of genetic value in TBs, being commonly used to

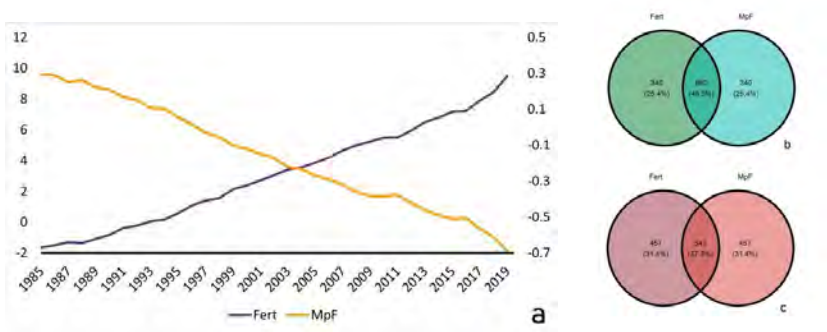

Figure 2. (a) Average EVB estimation per season. Fert (%) in left axis. MpF in number in right axis. On the right, comparison between the top 1000 most (b) and less (c) fertile individuals per trait.

select specific mating combinations. Since the existence of genetic differences among families was largely demonstrated using genomic data (Hill *et al.* 2002), our results suggest that those differences could affect the fertility of the individuals.

Both heritabilities (Fert=0.20 and MpF=0.17)) were high in comparison with previous reports on Spanish breeds (Gómez *et al.* 2020). Such differences could be explained by the differences in reproductive management (fine tunning in TB stallions and extensive breed in PRE), which allows maximizing the expression of genetic differences among individuals. This can also be observed in the genetic progress detected in the EBV's of Argentinean TBs during the last 35 years. Since maternal lineages are important in racing horses, it could be expected that stallions with less fertility and likely to fail to get a valuable mare pregnant are less and less employed, and consequently, the fertility of the breed is improved.

Finally, an interesting finding was the high negative correlation (-0.92) observed between traits in the 543 lowest fertile individuals, compared to a much lower negative correlation (-0.40), in the same analysis of the top 660 most fertile horses. Although further analysis is needed, these results suggest that less fertile stallions are heavily dependent on the number of matings per mare, whereas highly fertile stallions are not.

To our knowledge, this is one of the largest studies assessing stallion fertility from a genetic point of view. We demonstrated the existence of an interesting genetic variability among the Argentinean TB horses in terms of fertility, which showed moderate-to-high heritabilities in comparison to previous reports. Our study will also serve as a reliable comparison point to be employed by further studies estimating the fertility of stallions.

487. Bull effects on *in vitro* embryo production quality traits are repeatable and heritable

G. Gebreyesus[1*], J.B. Secher[2], M.S. Lund[1], K. Kupisiewicz[3], M. Ivask[4] and G. Su[1]

[1]Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark; [2]University of Copenhagen, Hoejbakkegaard Alle 5a, 2630 Taastrup, Denmark; [3]Viking Genetics, Ebeltoftvej 16, 8960 Randers, Denmark; [4]Estonian University of Life Sciences, Kreutzwaldi 62, 51014 Tartu, Estonia; grum.gebreyesus@qgg.au.dk

Abstract

In this study, *in vitro* production of embryos (IVP) was performed using oocytes aspirated from slaughterhouse ovaries and fertilized with ejaculates from 123 bulls aged between 10- and 92 months at semen collection. The restricted maximum likelihood approach was used to estimate genetic parameters for embryo production quality traits including blastocyst rate, hatch rate and an index trait combining Blastocyst rate, Kinetic Score, and Morphology score (BLxMxK). A total of 259 records were available for analysis. The results indicate that bulls at a younger age had better performances in all the studied IVP traits compared to bulls at later ages. The results also show low to high heritability and moderate to high repeatability for the IVP traits, suggesting the possibility of implementing selective breeding of bulls for better IVP performance.

Introduction

Genomic selection (GS) has revolutionized the cattle breeding industry through shortening generation interval, improving the accuracy of selection, reducing cost of breeding programs (Miglior *et al.*, 2017). In this context, combining GS with Assisted Reproductive technologies (ARTs) such as multiple ovulation, embryo transfer and *in vitro* fertilization (IVF), can allow not only improving selection accuracy but also maximizing the intensity of selection (Ponsart *et al.*, 2013; Kasinathan *et al.*, 2015). To the extent that the use of artificial insemination (AI) has allowed rapid and wide-spread use of bulls of superior genetic merit, ARTs can increase the reproduction of superior females (Tonhati *et al.*, 1999)

In vitro production of embryo (IVP) has become an alternative and highly competitive technique for multiple ovulation and embryo transfer (Boni, 2012), leading to increasing interest for harnessing the methodology, alongside GS, for rapid genetic gains in cattle and other livestock breeding. Several factors might affect the success of IVP in cattle including oocyte quality, sperm preparation methods, and media for *in vitro* maturation, fertilization and embryo culture (Akyol *et al.*, 2014). Studies have additionally shown inter-bull differences in IVP performances (Eyestone and First, 1989; Hillery *et al.*, 1990; Shi *et al.*, 1990). However, to our knowledge, no study investigated the extent of genetic control of these differences between bulls in IVP performances. Therefore, the objective of this study was to estimate genetic parameters for bulls' contributions to IVP quality traits.

Materials & methods

IVP experiments. IVP was performed in three different laboratories using the same chemically defined media from IVF Bioscience. All steps were performed according to manufacturer guidelines. In short: for each experiment, oocytes were aspirated from slaughterhouse ovaries, pooled and randomly divided into two or three groups containing at least 50 oocytes. One of the two groups served as control and the same bull was used as a control for all IVP experiments. The other groups were used as test groups, where ejaculates from one of 123 test bulls were used for fertilization. Ejaculates from 123 bulls aged between 10- and 92 months at semen collection were provided by Viking Genetics (Randers, Denmark). For the statistical analysis, age of bulls was categorized into 3 classes: (1) peripubertal (less than 12 mo, mean age =

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_487, © G. Gebreyesus *et al.* 2022

11 months), (2) pubertal (between 12 and 15 mo, mean age = 14 months), and (3) mature (more than 15 mo, mean age = 27 months) bulls. The following traits were assessed at day 7 and 8: (1) Blastocyst rate (Blast) calculated as number of blastocysts over the total number of inseminated oocytes; (2) Hatch rate (Hatch) was defined as the proportion of blastocysts that are hatched. Kinetic obtained by visual classification of each blastocyst as non-expanded, expanded or hatching/hatched, and scored as 1, 2 or 3, respectively; additionally, a Blastocyst rate × Kinetic Score × Morphology score (BL×M×K) (Avery and Greve, 2004) was calculated for each bull. For this calculation, morphology was first defined by scoring blastocysts as poor, good or excellent (scored as 1, 2 or 3). A total of 259 records where available for the analysis. All records for each trait and bull were subsequently normalized to the control bull as:

$$Normalized_{Trait_i} = \frac{Testbull_{trait_i}}{Controlbull_{trait_i}} \quad (1)$$

Where $Testbull_{trait_i}$ is the record for each test bull in trait i while $Controlbull_{trait_i}$ is the corresponding record measured for the control bull from the same experiment and in the same lab as for the test bull.

All bulls in the IVP experiments were genotyped using the Illumina Infinium BovineSNP50 BeadChip (50k). A total of 42,363 SNPs were available after quality control for the analyses.

Statistical analysis. The REML approach in DMU was used to estimate variance components and genetic parameters (Madsen and Jensen, 2013). The statistical model to describe observations of IVP traits is:

$$y = X\beta + Z_1 g + Z_2 c + e \quad (2)$$

Where y is the vector of phenotypes, β is the vector of fixed effects, i.e. bull age class (1-3), semen type (conventional and sexed), as well as month and year of oocyte collection, X is the incidence matrix relating observations with fixed effects, g is the vector of random additive genetic effects of bulls, Z_1 is the incidence matrix relating observations with random genetic effects, c is the vector of permanent environmental effects of bulls, Z_2 is the incidence matrix relating observations with permanent environmental effects, and e is the vector of residual effects. The random effects are assumed to be normally distributed. Thus $\mathbf{g} \sim N(\mathbf{0}, \mathbf{G}\sigma_g^2)$, where G is a genomic relationship matrix and σ_g^2 is the additive genetic variance; $\mathbf{c} \sim N(\mathbf{0}, \mathbf{I}\sigma_c^2)$, where I is an identity matrix and σ_c^2 is the permanent environmental variance; and $\mathbf{e} \sim N(\mathbf{0}, \mathbf{D}\sigma_e^2)$ where D is a diagonal matrix with elements $d_{ij} = \sqrt{(N_{oocyte_{test}} * N_{oocyte_{control}})}$, standardized to have a mean of one, to account for heterogeneous residual variances due to differences in the number of oocytes used in each record in the test and control. Heritability (h^2), was defined as:

$$h^2 = \frac{\sigma_g^2}{\sigma_g^2 + \sigma_c^2 + \sigma_e^2} \quad (3)$$

Repeatability (t) was defined as:

$$t = \frac{\sigma_g^2 + \sigma_c^2}{\sigma_g^2 + \sigma_c^2 + \sigma_e^2} \quad (4)$$

Results

IVP traits across bull age. Figure 1 presents box plots of phenotypic values for the studied IVP traits in the 3 age classes. Bulls at younger age had significantly higher performances in all the studied IVP traits, except hatch rate at day 7 (Hatch_D7), compared to bulls at later ages.

Heritability and repeatability estimates. Estimates of phenotypic variance, heritability, and repeatability in the IVP traits are presented in Table 1. Generally, low to high heritability and moderate

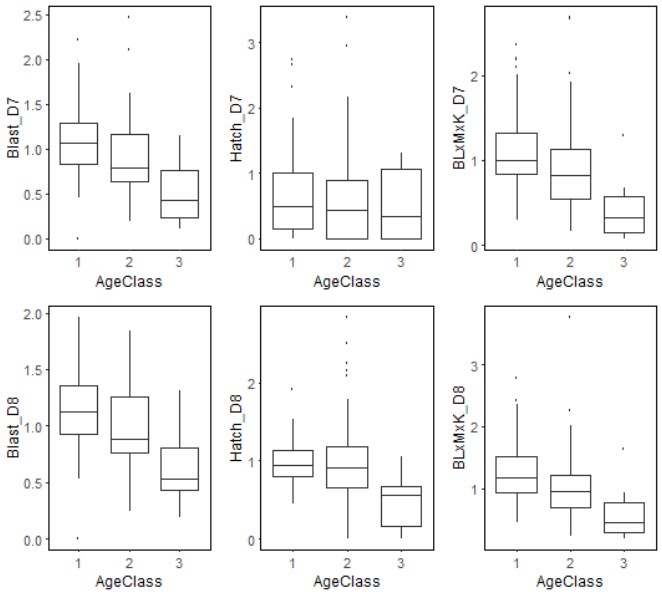

Figure 1. Plots of phenotypic measurements in IVP traits against age of bulls.

to high repeatability were estimated for the IVP traits. However, all estimates showed high standard errors. Compared to the IVP traits measured at day 7 after fertilization, relatively higher heritability and repeatability estimates were observed for the measurements on day 8.

Discussion

Blastocyst rates, morphology and kinetics have long been suggested as reliable indicators of the quality of an IVP system (Avery and Greve, 2004). Understanding the genetic underpinnings of these traits would allow implementation of selective breeding on bulls for enhanced performance in *in vitro* production of embryos. Despite high standard errors across estimates, our study suggests potentially substantial genetic control of the bull's contribution to the indicators of IVP success. Further studies with more sample size might be needed to validate the parameter estimates with probably lower standard errors. The study also reports significant effects of bull age on the IVP quality parameters. Effect of bull age have similarly been reported for male fertility related traits such as semen quality parameters (Olsen *et al.*, 2020; Gebreyesus *et al.*, 2021). Semen from younger bulls appear to result in higher blastocyst and hatch rates as well as

Table 1. Phenotypic variance (σ_p^2), heritability (h^2, with standard errors) and repeatability (t, with standard errors) for IVP traits.

Trait	σ_p^2	h^2 (SE)	t (SE)
Blast_D7	0.14	0.08 (0.25)	0.46 (0.26)
Blast_D8	0.12	0.19 (0.27)	0.54 (0.27)
Hatch_D7	0.44	0.10 (0.32)	0.79 (0.33)
Hatch_D8	0.14	0.19 (0.21)	0.28 (0.22)
BL×M×K_D7	0.20	0.18e-5 (0.26)	0.55 (0.27)
BL×M×K_D8	0.24	0.46 (0.29)	0.61 (0.30)

BL×M×K score at day 7 and 8 after fertilization. These results can provide useful inputs towards planning successful IVP systems.

488. Five years of optimizing the assisted reproduction protocol for European eel: what worked and what didn't?

A.P. Palstra[1*], P. Jéhannet[1], L.T.N. Heinsbroek[2] and W. Swinkels[3]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Wageningen Eel Reproduction Experts B.V., Mennonietenweg 13, 6702 AB Wageningen, the Netherlands; [3]Palingkwekerij Koolen B.V., Hongarijesedijk 12, 5571 XC Bergeijk, the Netherlands; arjan.palstra@wur.nl

Abstract

The production cycle of the European eel needs to be closed in order to supply aquaculture with juvenile glass eels and to alleviate fishery pressure on the natural population, thereby contributing to its recovery. Currently, we are able to produce larvae batches three times per week. Over the past five years we have executed experiments aiming to condition glass eels into high quality brood stock females and optimize the artificial reproduction protocol. Feminization of young juveniles contributes to shortening the generation time at least 5-fold. Simulated migration induces early sexual maturation. Steroid implants containing 17 methyltestosterone (17MT) and 17β estradiol (E2) induce the more advanced maturation stages and shorten the stressful period of weekly carp pituitary extract (CPE) injections to fully mature females. Instead of using CPE, stable eel-specific recombinant gonadotropins have been successfully applied to produce eel larvae.

Introduction

The life cycle of the European eel is fascinating. Eels can reside in the continental fresh waters for decades. Then, at a largely unspecified moment in autumn, they stop feeding, start swimming and only then does puberty commence. Still in pre-pubertal condition, the eel disappears into the ocean, and swims for up to 6,000 km. When arriving at the spawning grounds in the Sargasso Sea, each female eel consists of approximately 50% of ovarian tissue and is ready to spawn several million eggs. It is generally assumed that parents die shortly after spawning. However, most of the available knowledge comes from the laboratory (e.g. Palstra *et al.*, 2020), as there are no records of maturing or spawning European eels in the ocean, nor are there tracks of their carcasses. Since the eel cannot currently be propagated and raised to the juvenile glass eel stage, each large European eel, including those from the farm, once hatched in the Sargasso Sea.

In 2016, the Eel Reproduction Innovation Centre (EELRIC) was launched, as a collaborative initiative of Wageningen Livestock Research with the Dutch eel sector, united in the sustainable eel foundation DUPAN. The major aim of EELRIC is to close the production cycle of the European eel in order to supply eel aquaculture with juvenile glass eels and to alleviate fishery pressure on the natural population, thereby contributing to its recovery. Now, 5 years later, we are able to produce larvae batches from different females three times per week although larval quality is still often poor as evidenced by high mortalities during the first week and occurrence of deformities. Over the past five years we have executed many experiments aimed to condition glass eels into high quality brood stock females and optimize the artificial reproduction protocol. An overview is presented of the methods that worked and those that didn't.

Materials & methods

Feminization was applied as developed for Japanese eel by Chai *et al.* (2010) and involved feeding with E2 coated pellets for 5-7 months during the early elver stage. The simulated migration procedure was originally described by Mes *et al.* (2016; Figure 1). Eels were subjected to ~3,000 km simulated migration, and in combination with a single CPE injection (20 mg/kg), or a dopamine antagonist implant of eticlopride (Jolly *et al.*, 2016). In contrast to the routine protocol of weekly human chorionic gonadotropin (hCG) injections,

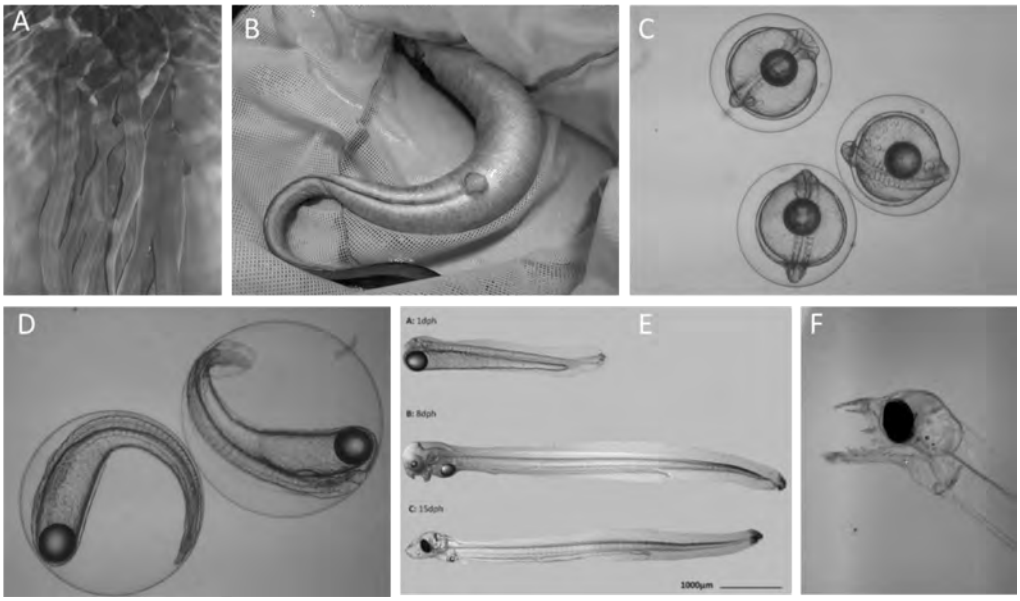

Figure 1. Photo panel showing (A) eels swimming during simulated migration; (B) mature eel with extruding egg bulb; (C) early eel embryos; (D) late eel embryos just before hatching; (E) eel larvae at 1-, 8- and 15-days post hatching (Jéhannet *et al.*, 2021); (F) eel larva at 15 days post hatching ready to initiate exogenous feeding.

males were matured by a single hCG injection (1000 IU; Kahn *et al.*, 1987) followed by a 2nd injection 24 h before stripping. Females were matured by weekly CPE injections (20 mg/kg) followed by a CPE booster at ~10% body weight increase and a single 17α,20β-dihydroxy-4-pregnen-3-one (DHP; 2 mg/kg) injection at ~20% body weight increase (Palstra *et al.*, 2005). The 17MT (5 mg), E2 (2 mg) and the combined 17MT+E2 implants were tested as pre-treatments for the weekly CPE injections (Thomson-Laing *et al.*, 2019). Three experiments have been executed testing weekly injections with recombinant FSH (recFSH: 6 or 12 µg) and LH (recLH: 10 or 20 µg) replacing CPE treatment.

Results

Feminization provides 99% females of which 90% reach 300 g in 12-30 months and can then be used as brood stock.

Simulated migration makes these feminized eels silver (larger eyes reflecting the oceanic phenotype) and induces early sexual maturation (increased Gonadosomatic Index – GSI). Simulated migration in combination with a single CPE injection increased the GSI further but not up to values indicating the onset of vitellogenesis (yolk deposition in the oocytes). Eticlopride was expected to lift the dopaminergic inhibition of gonadotropin production and release but did not show any additional effect on sexual maturation to simulated migration.

Both 17MT and E2 implants significantly increased GSI and oocyte diameter and decreased the number of weekly CPE injections required to mature the eels. The combined implants worked synergistically in advancing vitellogenesis (GSI of 6.6).

Eels that were treated with recFSH followed by recLH matured after 15-22 weeks, similar to eels that were treated with recFSH followed by CPE treatment, but different from eels treated with CPE of which most matured after 7-9 weeks. Larvae were produced from eels of all treatments (Figure 1).

Discussion

The feminization procedure also works for European eel and generation time is shortened by at least 5-fold. Simulated migration can be applied for the natural triggering of early sexual maturation but does not stimulate the more advanced maturation stages, even in combination with a single CPE injection or dopamine antagonist implant. 17MT+E2 implants do stimulate development to more advanced, vitellogenic stages of oocyte development. These implants can be considered as a pre-treatment to reduce the period of stressful weekly hormonal injections although 17MT implant treatment, followed in time by E2 treatment, may result in a more natural progression of steroid-mediated effects. For the first time, European eel larvae were produced with recombinant gonadotropins, but dose and durations still need optimization.

Acknowledgements

Abstract

Semen traits including ejaculate volume (EV, ml), sperm concentration (SC, 10^9/ml), initial sperm motility (ISM, %) and post-thaw motility (PTM, %) were analysed using random regression models. Data pertaining to 105,321 ejaculates from 297 Holstein-Friesian (HF) purebred and crossbred bulls collected from Bharatiya Agro Industries Foundation were utilized. 200,000 Gibbs samples were generated with a burn-in of 20,000 and thinning interval of 50 in a Bayesian framework. Legendre Polynomials with orders of fit up to five for additive and permanent environmental effects were used. Heritability estimates ranged from 0.2 to 0.5 for EV and 0.35 to 0.5 for SC in purebreds while it ranged from 0.05 to 0.45 for EV and 0.2 to 0.7 for SC in crossbreds. Estimates were very low for motility traits in both purebred and crossbred bulls. Random regression models in a Bayesian framework were useful for obtaining solutions for mixed models even with large number of parameters.

Introduction

The HF breed has been extensively used for crossbreeding to increase milk production. Since most of the selection is for milk yield, it is important to assess the semen parameters periodically to maintain optimum fertility. The Bayesian framework provides the advantage of robustness with less stringent assumptions about the distribution of parameters.

Random regression models have the ability to model the covariance of repeated data (longitudinal data) measured on the same animal through covariance structures. This ability to model a trait with age as a control variable helps in understanding the trajectory of various genetic parameters over the age of the bulls. Worldwide there are very few studies conducted using random regression models for semen traits in cattle (Al-Kanaan *et al.* 2015; Carabaño *et al.* 2007). The present study was carried out to understand the genetic variability of various semen traits over age the age of the bulls in HF purebred and crossbred cattle.

Materials & methods

Data pertaining to 105,321 ejaculates from 120 purebred and 177 crossbred HF bulls collected from Bharatiya Agro Industries Foundation (BAIF) were utilized for this study. The BAIF frozen semen stations are located at Uruli Kanchan (Maharashtra, India; 18.5°N and 73.8°E) and Dharouli (Haryana, Jind; 29.2°N and 76.2°E). Semen production data were available for 11 years (2010 to 2020) along with the pedigree information for 1,317 bulls. The founder population was imported between 1967-1974 from Canada, the USA, Denmark, and the Netherlands, where these bulls were proven through progeny testing.

Traits and factors included. Semen production traits included in the study were ejaculate volume (EV, ml), sperm concentration (SC, 10^9/ml), initial sperm motility (ISM, %) and post-thaw motility (PTM, %). The fixed effects included in the model were location (Pune or Jind), breed of bull (purebred or crossbred), order of ejaculate (first or second), the season (summer, monsoon, or winter), the year (2010 to 2020), age

of the bull (≤2 to >10 years), collection interval (≤2, 3, 4, ≥5 days) and collection time (5 AM to 12 PM), while semen collector and bull were included as random effects.

Statistical analysis. Gibbs sampling using Markov Chain Monte Carlo (MCMC) procedure was implemented to generate these samples which enabled the estimation of parameter estimates based on the given data set. 200,000 Gibbs samples were generated for each analysis with a burn-in of 20,000 and thinning interval of 50 Gibb samples. The stability of the model was ascertained using trace plots, which were obtained from post-Gibbs samples, of the parameters plotted along with the number of iterations.

The age of the bulls in days was taken as the control to obtain the trajectories of traits over the age of the bulls using random regression models. The various combinations of animal and permanent environment random effects were modelled using Legendre polynomials up to order of fit of five with error variances modelled as a homogenous class of random effect. Model selection was done based on Deviance Information Criterion (DIC).

$$Y_{ij} = Xb + \sum_{k=0}^{k_a-1} Z_a a_k + \sum_{k=0}^{k_p-1} Z_p p_k + C_m + e \quad (1)$$

Where Y_{ij}: semen trait of i^{th} animal at j^{th} age, b: vector of significant fixed effects or incidence matrix relating fixed effects with Y, a_k and p_k: set of n values (n = number of bulls) of k random regression coefficients corresponding to animal and permanent environment effects, with the order of fit k_a and k_p respectively, Z_a and Z_p are incidence matrices with dimensions $n \times k_a$ and $n \times k_p$ respectively, C_m: random effect of semen collector with mean zero and variance σ_m^2 and 'e' is the random residual heteroscedastic error variance. The model also included fixed regression for age with the order of that of the animal effect. The genetic (co) variance between ages was estimated from the matrix of random regression coefficients using the general expression

$$G_{xj} = \Phi_{xj} K_{xj} \Phi'_{xj} \quad (2)$$

Where G_x is the (co)variance matrix for x = animal or individual permanent environment and Φ_{xj} is the vector of Legendre polynomials for the random effect of x and j^{th} age group.

All analyses were done in a Bayesian framework using the BLUPF90 family of software (Misztal *et al.* 2018). THRGIBBS1F90 was used for generating Gibbs samples and Post-Gibbs analyses were done with POSTGIBBSF90.

Results

The trajectory of performance for semen production traits in HF purebred and crossbred bulls along with the mean and number of observations are represented in Figure 1 and Table 1. The variation in mean increased in all the traits after 90 months of age. The phenotypic characteristics for all traits in both breeds were comparable. Ejaculate volume showed an increasing trend with age up to 70 months, after which there was a slight decline, while sperm concentration showed a complementary trend in both breeds. Motility traits followed a consistent trajectory, but ISM was more variable than PTM.

Heritability and repeatability were unusually high for the initial and later periods which included ages beyond 36 to 120 months. As seen from Figure 1, the number of observations were lower and random regression models are also susceptible to the effect of extreme ages also known as 'end effect of the polynomials' (Meyer 2005). Hence, all the ages were presented for the period between 36 to 120 months after pruning off the extreme ages to obtain a relatively stable curve. In general, the genetic parameters had

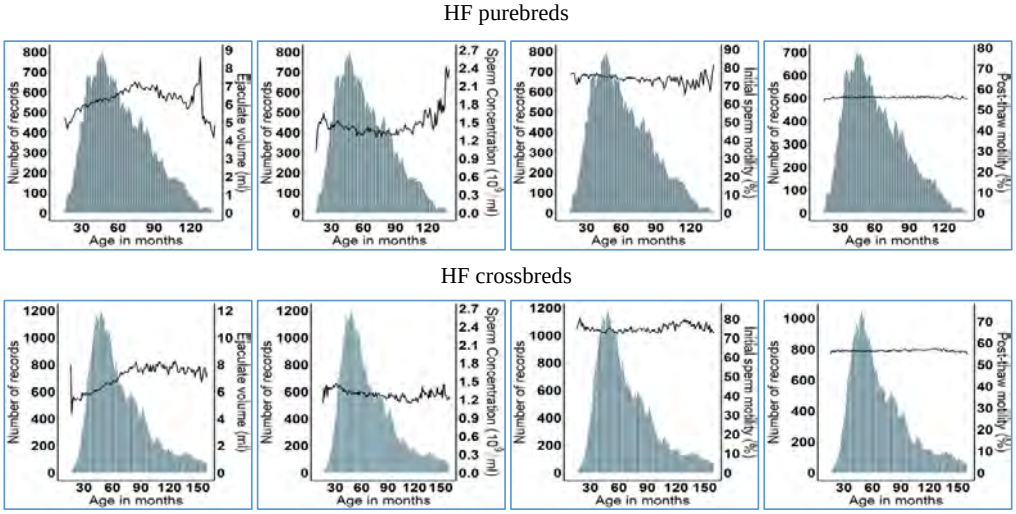

Figure 1. Semen production traits plotted with number of observations and mean across age in months.

Table 1. Range for the number of observations, mean, heritability and repeatability estimates in HF purebred and crossbred bulls.[1]

Trait	Range for n	Range for mean	Order of fit	Range for h^2	Range for r
HF purebreds					
EV	82-797	5.771-7.234	5×5	0.189-0.420	0.384-0.612
SC	82-797	1.261-1.713	5×5	0.344-0.498	0.614-0.827
ISM	81-794	65.423-77.000	5×5	0.035-0.188	0.073-0.339
PTM	66-699	55.160-56.770	5×5	0.000-0.001	0.001-0.002
HF crossbreds					
EV	153-1,192	5.750-8.227	5×5	0.036-0.460	0.113-0.901
SC	154-1,192	1.408-1.142	5×5	0.225-0.700	0.484-0.981
ISM	154-1,172	72.203-78.669	5×5	0.004-0.793	0.392-0.984
PTM	145-1,043	55.972-57.355	5×4	0.000-0.016	0.001-0.022

[1] n = number of records; EV = ejaculate volume (ml); SC = sperm concentration (10^9/ml); ISM = initial sperm motility (%); PTM = post-thaw motility (%); order of fit = legendre polynomial (additive × permanent environmental); h^2 = heritability; r = repeatability.

more uniformity in purebreds while those in crossbreds showed more waviness with a wider range, which could be attributed to less number of observations during nine to ten years of age in crossbreds compared to purebred bulls.

Legendre polynomials of order five for both additive and permanent environmental variance were suitable. Values of random regression models for heritability were more than those obtained through univariate analysis (Figure 2) carried out using a repeatability model with the bull effect included as the random effect. In purebreds, heritability for EV increased until the age of eight years and then decreased again, while in crossbreds, it increased until the end after a plateau in the middle. In purebreds, SC plateaued during the early ages, followed by a slight decline and a short crest, while in crossbreds, the dip and the ascent were more prominent. Motility traits, which are indicators of fertility, had low estimates of heritability. In

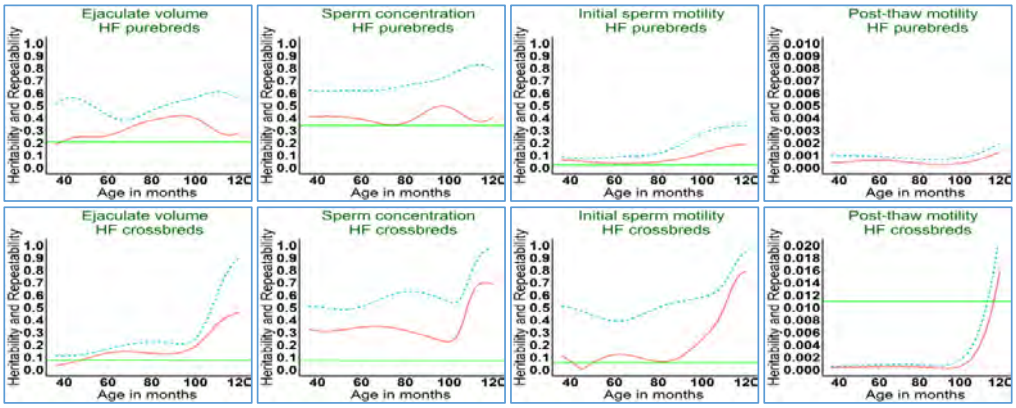

Figure 2. Heritability and repeatability estimates over the ages for semen production traits obtained through random regression models (Red line – Heritability; blue line – repeatability; green line- heritability obtained through univariate analysis).

purebreds, the trajectory was very uniform where repeatability closely resembled heritability. In crossbreds, ISM showed a wide variation in heritability and repeatability, whereas PTM was similar to that of purebreds.

Discussion

The semen production traits for HF purebreds and crossbreds observed in this study were better compared to estimates reported from other parts of the tropics (Gopinathan *et al.* 2018; Kawakami *et al.* 2016). This indicated optimum management practices followed at BAIF.

Precise estimates which were within the range of the estimates obtained in different studies from tropical countries (Atagi *et al.* 2017; Hagiya *et al.* 2017; Kawakami *et al.* 2016) were obtained for the genetic parameters using the Bayesian framework as seen from the low posterior standard deviations. The heritability of motility traits was low which warrants additional information from the relatives in selection programmes. In traits, like SC and ISM, the wide gap between heritability and repeatability could be due to the permanent effect of the environment on these traits. The order of fit used in the best model for the additive and permanent environmental effects were similar to the ones used by Carabano *et al.* (2007) in EV.

Higher estimates of heritability obtained through random regression models compared to univariate analyses could possibly indicate that the modelling of (co)variance functions in the form of random regression coefficients helped in accounting for a greater proportion of the additive genetic effect. As the semen traits are repeatable in nature, pedigree information accumulates over the lifetime of the bulls, which may explain the variation between the early and later stages of a bull's life.

To conclude, random regression models were successfully used to model semen traits over the age of the bull. Purebred HF had higher heritability estimates compared to the HF crossbred animals. The traits such as motility which are directly related to fertility were found to have very low heritability.

490. Removing the dopaminergic inhibition with CRISPR-Cas9 to study the progression of sexual maturation in zebrafish

P. Jéhannet[1*], A.A.C. De Wit[1], S. Brugman[1], Y. Zhang[2], J. Bogerd[2] and A.P. Palstra[1]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Utrecht University, Heidelberglaan 8, 3584 CS Utrecht, the Netherlands; pauline.jehannet@wur.nl

Abstract

In fish, dopaminergic neurones originating from the preoptic area innerve the region of the pituitary gland that harbors gonadotropin cells. The innervation inhibits the release of gonadotropins that are essential for sexual maturation. The dopaminergic inhibition, mediated by dopaminergic receptors, is a major bottleneck in the propagation of many fish species in aquaculture. In this study, we aimed to knock-out one of the three dopamine receptors paralogue (*drd2b*) that mediates the inhibitory control of gonadotropins in zebrafish *Danio rerio* to study the progression of sexual maturation and potential occurrence of side-effects. Here, *drd2b* heterozygote or mosaic mutants were produced with an efficiency up to 73%. Knocking-out *drd2b* could be lethal since *drd2b* is involved in crucial processes during early ontogeny. If future studies confirm that inactivating *drd2b* is lethal, it may be useful to produce inducible and/or spatially restricted mutants to study sexual maturation.

Introduction

In fish, oogenesis is controlled by two pituitary gonadotropins (Gths); the follicle stimulating hormone (Fsh) and the luteinizing hormone (Lh). Fsh and Lh regulate oogenesis consisting of the succeeding developmental stages of oogonia proliferation, oocyte growth, oocyte maturation and ovulation (reviewed by Lubzens *et al.*, 2010). In fish, Fsh activity is essential for oocyte growth and storage of lipids and yolk. When ending the growth period, Lh induces oocyte maturation and ovulation after which oocytes are released to the external environment and fertilized.

In fish, Gths production and release are under the dual control of gonadotropin releasing hormone (GnRH) and dopamine (DA) (reviewed by Dufour *et al.*, 2009). Dopaminergic neurons originating from the *nucleus anteroventralis* of the preoptic area (NPOav) directly innerve the region of the pituitary gland that harbors the gonadotropic cells, the *proximal pars distalis* (Jolly *et al.*, 2016). The dopaminergic innervation in the pituitary downregulates Gths release by counteracting the stimulatory effects of GnRH in many teleosts (reviewed by Dufour *et al.*, 2009). The effect of DA is mediated by D2 dopaminergic receptors (D2r) (reviewed by Dufour *et al.*, 2009) that are expressed in the pituitary (Jolly *et al.*, 2016). In zebrafish, one of the D2r paralogue, *drd2b*, is involved in mediating the inhibitory control of gonadotropins (Fontaine *et al.*, 2013).

Dopaminergic inhibition of the reproductive axis is present in many fishes belonging to the salmonids, cyprinids, silurids, percomorphs, elopomorphs but also in one chondrostean fish (reviewed by Dufour *et al.*, 2009). The inhibitory role of DA is one of the major bottlenecks in the propagation of many fish species in aquaculture. Treatment with pituitary extracts to circumvent the pituitary, but also with GnRH in combination with D2r antagonists to counteract dopaminergic inhibition, are used to induce sexual maturation and ovulation. Long term hormonal treatment can impact egg quality and thus it is essential to gain insights about the mechanisms of dopaminergic inhibition to gain control over it. Thus, we explored the feasibility of producing *drd2b* knock-out mutants with CRISPR-Cas9 in zebrafish as model species to study the progression of sexual maturation.

Materials & methods

An overview on how CRISPR-Cas9 induces targeted mutations is presented in Figure 1. In this study, two different protocols, applied by Utrecht University and Wageningen University & Research respectively, were used to explore the feasibility of producing *drd2b* mutants with CRISPR-Cas9. While Utrecht University follows the protocol of Essner *et al.* (2016), Wageningen University & Research used a combination of the Shawn Burgess lab protocol (Varshney *et al.*, 2015) and Hubrecht lab protocol. CRISPR-Cas9 activities were covered by GGO permits (Wageningen University & Research: IG 19-08; Utrecht University: IG 02-115).

sgRNA. At Utrecht University, the functional sgRNA was generated by mixing crRNA that was designed on the target sequence and the generic tracrRNA that anchors to the Cas9. Two crRNAs (AS and AX) were designed on the first exon of *drd2b* by using the IDT (Integrated DNA technologies, Coralville, United States) online tool after entering the *drd2b* sequence of *Danio rerio* (NM_197936.1). At Wageningen University & Research, the sgRNA was designed as follows (Figure 2): (1) the target sequence (20 nt) of the fourth exon of *drd2b* was designed by using the online tool of UCSC Genome Browser (Santa Cruz, United States); (2) the oligo A was ordered after adding the T7 promoter sequence (17 nt) and the first 20 nt of the gRNA to the respective 5' and 3' of the target sequence; (3) the generic oligo B (80 nt) that was complementary (20 nt) to the last part of oligo A was ordered; (4) both oligos were annealed and extended to produce a 117 nt double stranded DNA fragment that was *in vitro* transcribed to generate the sgRNA (Exon4).

Microinjections. At Utrecht University, the CRISPR-Cas9 solution was made by: (1) mixing and heating at 95 °C for 5 min 1 µl crRNA, 1 µl tracrRNA and 31.3 µl buffer to create the 3 µM sgRNA solution; (2) adding 0.5 µl Alt-R *S.p.* Hifi Cas9 Nuclease V3 (IDT, Coralville, USA) diluted in 9 µl Cas9 working buffer and 0.5 µl Phenol Red to a working concentration of 0.5 µg/µl; and (3) combining 3 µl of sgRNA with 3 µl diluted Cas9

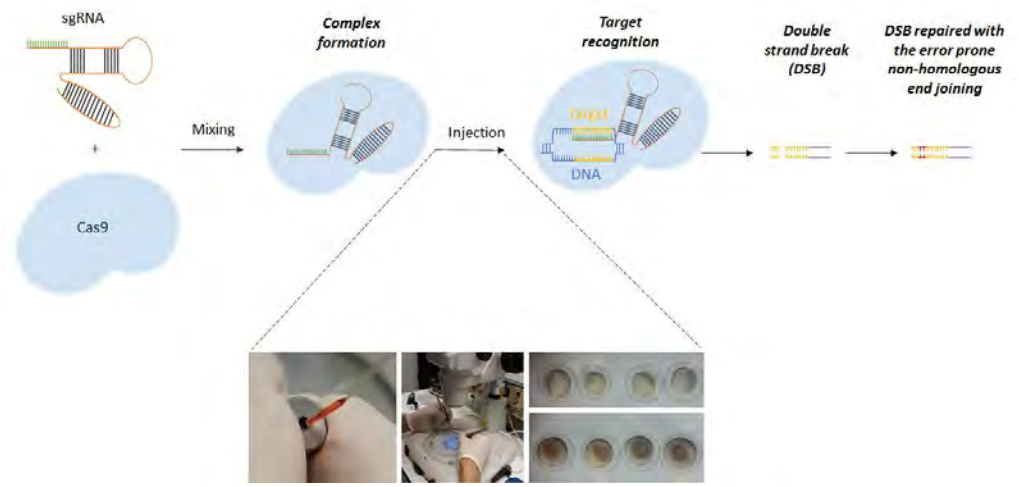

Figure 1. Overview of how the CRISPR-Cas9 system induces targeted mutations. CRISPR-Cas9 consists of two components: (1) a sgRNA that contains a guide sequence (designed by the user) which is complementary to the target sequence and (2) a scaffold sequence that is necessary for the Cas9 protein binding. Once mixed together, the sgRNA and Cas9 form a complex that binds to the target to induce a double strand break (DSB) within the DNA. The DSB will be repaired by the error prone non-homologous end joining (NHEJ) pathway that causes indels at the DSB site.

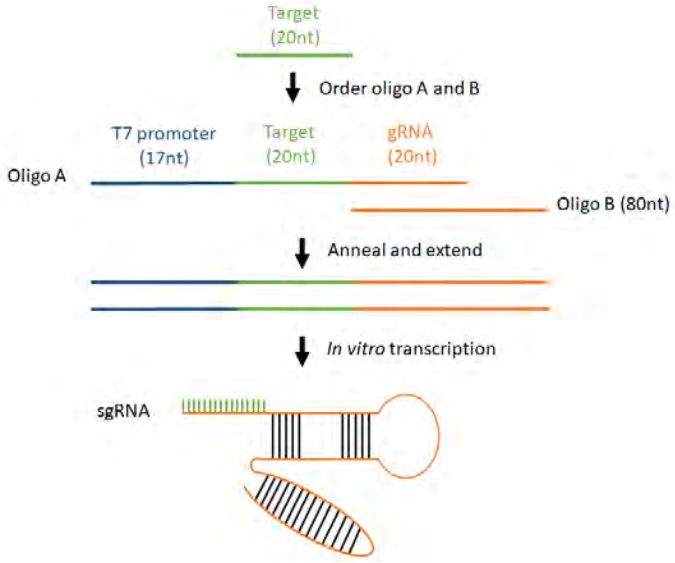

Figure 2. *In vitro* transcription of sgRNA (adapted from Varshney *et al.* 2015).

protein. At Wageningen University & Research, the CRISPR-Cas9 complex was made by mixing 600-900 ng sgRNA, 0.8 µl Alt-R *S.p.* Cas9 Nuclease V3 (IDT) at 5 ng/µl in 400 mM KCl, 0.3 µl Phenol Red and 400 mM KCl to a final volume of 6 µl. Injection mixes were loaded, calibrated under the binocular to inject 1 nl in at the 1-cell stage in zebrafish. Larvae were sampled at 2 days post hatching (dph) for DNA extraction to screen for mutation. Primers, that screened for the mutations were designed and PCR products sent for sequencing to check for mutation efficiency that was calculated as followed: (the number of zebrafish mutants confirmed by sequencing/ the total number of zebrafish sequenced) × 100%.

Results

An overview of the results is presented in Table 1. In zebrafish, ~300 eggs that were injected with CRISPR-Cas9 had a survival rate ranging from 6 to 40%. Screening showed that WT sequences had one clear peak for each nt in the *drd2b* sequence, while mutants had several peaks (two or more) for each nt around and after the protospacer adjacent motif (PAM) sequence (Figure 3); results suggesting that mutants were heterozygotes or mosaics. CRISPR-Cas9 induced mutations with an efficiency up to 73%.

Discussion

In zebrafish, *drd2b* mutants were produced but they were heterozygotes or mosaics. It is possible that homozygote mutants did not survive because knocking-out *drd2b* would be lethal. This hypothesis is

Table 1. Number of eggs injected with CRISPR-Cas9, survival rates and mutation efficiency for each target in zebrafish.

Target	Number of eggs injected	Survival rate (%)	Efficiency (%)
Exon 1, AS	300	6	33
Exon 1, AX	300	10	0
Exon 4	300	40	73

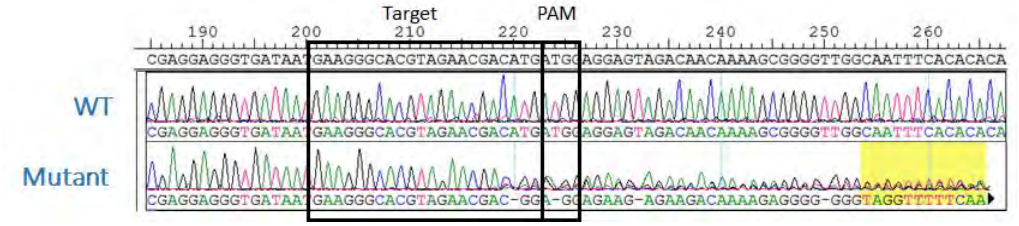

Figure 3. *Drd2b* sequences of the wild type (WT) and mutant in zebrafish *Danio rerio*.

supported by the study of Boehmler *et al.* (2004) who suggested that *drd2b* is involved in crucial processes (e.g. motor behaviour). Unfortunately, we could not confirm that knocking-out *drd2b* is lethal since the controls also died in this experiment. It is important to note that mutation in a seemingly crucial gene is not necessarily lethal (Ziv *et al.*, 2012). Future studies should investigate whether viable homozygous *drd2b* mutants can be produced. If knocking-out *drd2b* turns out to be lethal in zebrafish larvae, it might be useful to produce inducible and/or spatially restricted *drd2b* mutants to study the progression of sexual maturation. Gained knowledge could help to develop methodology to sexually mature fish with natural triggers rather than with artificial stimulators. The authors acknowledge Wageningen Livestock Research for funding this study as 'innovation challenge'.

491. Societal aspects of animal breeding: a bibliometric analysis

M. van der Sluis*, K.H. de Greef and G. Bonekamp

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands;
malou.vandersluis@wur.nl

Abstract

Societal and ethical issues addressed in animal breeding studies from 1990 onwards were examined by means of a bibliometric analysis. Using a specific set of search terms in Scopus, 673 publications of potential interest for societal aspects of animal breeding were found. Subsequent manual selection resulted in 270 relevant studies. Across the period from 1990 to the present, the number of publications addressing societal or ethical aspects of animal breeding, mainly focussing on animal welfare and behaviour or genetic modification, increased from the year 2000 and peaked around 2010. Of the 270 publications, 24% explicitly mentioned ethics, mainly in relation to genetic modification, biotechnology or animal welfare/behaviour. The minority of the publications (32%) were experimental studies. To conclude, only a minor part of publications on animal breeding explicitly address societal issues and, of these, the minority explicitly addresses ethics.

Introduction

Societal awareness of animal production has increased (Busch and Spiller, 2018), and animal breeding plays an important role in animal production. Animal breeding activities can be a cause for societal, and ethical, concern. Examples are concerns regarding genetic modification or gene editing, such as animal integrity or naturalness (e.g. Eriksson *et al.* (2018)), and regarding the impact of genetics, or the choices made by breeders, on animal welfare (e.g. Fernyhough *et al.* (2020)). To obtain a broader overview of the degree to which societal and ethical concerns in relation to animal breeding are addressed in the animal breeding literature, we here performed a bibliometric analysis in which we assessed general trends in publications on societal aspects of animal breeding, regarding the species and main societal or ethical issues under study. We specifically focussed on dairy cattle, pigs, and chickens, as these represent the major food producing sectors.

Materials & methods

Bibliometric approach. Scopus was used as the data source for this bibliometric analysis. The selection was performed in three steps (Table 1). The first step comprised the combination of a set of key words regarding: (1) animal; (2) breeding; (3) society; and (4) concerns. In the following two steps, false positive hits were excluded. To reduce subjectivity in the selection process, at least two people decided together which decision should be made in steps 2 and 3.

Data analysis. After selection of the final data set of publications, we assessed for each of the publications, based on the title and key words (and when not conclusive, based on the abstract), what topics were examined (Table 2). Moreover, each abstract was analysed for characterisation of the type of study as either 'experimental' (based on an experiment, a data set, simulation study or similar) or 'descriptive' (reviewing literature, reporting from expertise, et cetera), and to assess whether the term ethics was explicitly mentioned ('ethic', with potential prefixes or suffixes) or not.

Results

In total, 270 papers met all criteria (steps 1, 2 and 3). In total, 86 out of the 270 papers (32%) were experimental studies, with the remainder being mainly overviews, reviews, foresights and state of the

Table 1. Workflow and selection criteria used in the bibliometric analysis.

Steps in the workflow	
Step 1: Literature search (n=673)	Automated search in titles, abstracts and key words, in publications from 1990 onwards (search performed on the 3rd of December, 2021). Only publications with at least one of the required search terms for each of the categories below were included: - *Animal*: animal AND production; animal AND farm*; dairy AND cattle; poultry; pig* - *Breeding*: breeding AND selection; genetic AND selection; breeding AND genetic - *Society or ethics*: soci*; public; ethic*; moral* - *Concerns or discussion forms*: concern*; issue*; problem*; dilemma*; question*; demand*; worry; worries; debate; discourse; discussion
Step 2: Selection based on titles (n=400)	Manually excluding titles not meeting the criteria, mainly excluding publications on species outside the scope of this study (for example pigeons and guinea pigs, due to the term pig*)
Step 3: Selection based on animal breeding aspect (n=270)	Manually excluding publications that did not have animal breeding or genetic engineering in the species of interest as a topic of focus, based on the title, key words and abstract

Table 2. Structuring of topics examined in the publications.

Species under study	**What societal or ethical issue is explicitly mentioned?**	
	Animal (trait) related	**Methodology related**
Chickens	Animal health	Animal genetic resource management
Pigs	Animal welfare/behaviour	Biotechnology
Dairy cattle	Environment	Breeding goal definition
Across species	Food safety/security	Genetic modification
	Heat stress	General methods
	Meat quality	
	Multiple	
	Resilience/robustness	

art reports. The topics that were studied differed per species (Table 3). For chickens, the vast majority of publications focused on animal welfare and behaviour, while for pigs many studies focused on meat quality, besides animal welfare and behaviour. For cattle, aside from animal welfare and behaviour, many studies focussed on animal health. For the across-species papers, the majority focused on genetic modification. Out of the 270 publications, 65 (24%) mentioned ethics explicitly, resulting in 90 species-topic combinations that included ethics. Most ethics-mentioning papers were related to biotechnology, genetic modification or animal welfare and behaviour (Table 4).

The number of publications on societal or ethical aspects of animal breeding appears to start increasing around 2000, peaking in 2010 (Figure 1). Although this increase was visible for all three species, the topics that were discussed were different for the different species, with mostly trait-related publications for chickens and pigs, and more methodology-related papers for across species studies (Figure 1).

Discussion

In this study, we aimed to provide an overview of societal and ethical concerns that are raised in relation to animal breeding, using a bibliometric approach. Methodology-wise, it became clear that the specificity of the search string was low. After applying the manual exclusion steps in our initial search results, only 40% of the publications remained, highlighting the importance of manual selection steps in bibliometric analyses. The analysis revealed that a small number of topics received substantially more attention than others.

Table 3. Number of publications addressing specific topics by species. Publications addressing multiple topics or multiple of our key species (chickens, pigs and/or dairy cattle) are included multiple times, resulting in n=335. AGRM = animal genetic resource management.

Topic under study		Chickens	Pigs	Dairy cattle	Across species
Animal (trait) related	Animal health	3	5	12	9
	Animal welfare/behaviour	26	15	13	20
	Environment	0	1	4	5
	Food safety/security	2	1	6	3
	Heat stress	1	1	1	0
	Meat quality	1	11	0	1
	Multiple	4	2	2	4
	Resilience/robustness	2	1	1	2
Methodology related	AGRM	2	3	5	14
	Biotechnology	1	0	1	14
	Breeding goal definition	1	0	5	4
	Genetic modification	4	1	7	27
	General methods	1	1	5	7
Other	Other	6	16	26	25

Table 4. Publications explicitly mentioning ethics per species and topic, in percentages of the total number of publications mentioning ethics. Publications addressing multiple topics or multiple of our key species (chickens, pigs and/or dairy cattle) are included multiple times, resulting in n=90. AGRM = animal genetic resource management.

Topic under study		Chickens	Pigs	Dairy cattle	Across species
Animal (trait) related	Animal health	0%	1%	2%	2%
	Animal welfare/behaviour	7%	7%	6%	16%
	Environment	0%	1%	2%	2%
	Food safety/security	0%	0%	1%	0%
	Heat stress	0%	0%	0%	0%
	Meat quality	0%	3%	0%	0%
	Multiple	1%	0%	0%	0%
	Resilience/robustness	2%	0%	0%	1%
Methodology related	AGRM	0%	0%	0%	0%
	Biotechnology	1%	0%	1%	8%
	Breeding goal definition	0%	0%	0%	2%
	Genetic modification	2%	1%	3%	17%
	General methods	0%	0%	0%	1%
Other	Other	0%	3%	1%	4%

Unsurprisingly, animal welfare and behaviour, and genetic modification, were commonly addressed, also within the subset of studies that explicitly mentioned ethics. However, there were differences between species in what topics were mainly studied. This raises the question why, besides differences in the physiology or use of the animals, some topics are potentially considered of greater societal relevance in one species than in another. Future work examining the publications in detail, that is, (a selection of) the publications will

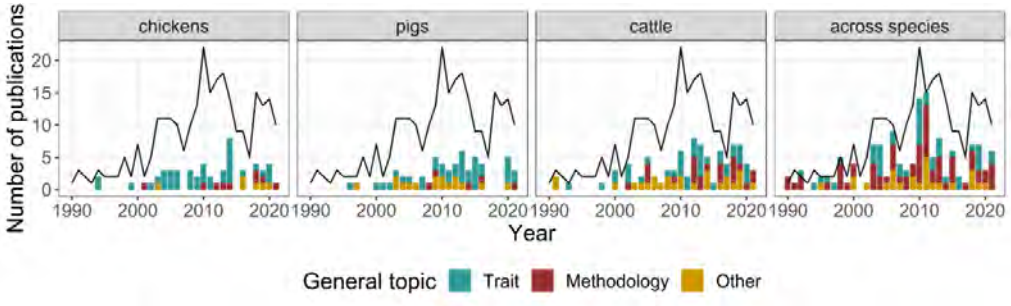

Figure 1. Number of publications on the different general topics and species. The black line represents the total number of publications by year (n=270), whereas the bars represent, per species, the number of studies focussing on certain general topics. Publications addressing multiple topics or multiple species categories are included multiple times, resulting in n=335 for the bar graphs.

be fully read, can possibly provide insight into the context in which the societal issues are raised and the reasoning behind the choice of topic. Even though the number of studies that address societal aspects of animal breeding increased after the year 2000, it appears that only a small proportion of the publications on animal breeding do so. A search for animal breeding studies on our species of interest from 1990 onwards, without the societal aspects constraint, resulted in approximately 24,500 publications (results not shown), of which the selection in this study forms only about 1%. Thus, only few publications on animal breeding address societal issues explicitly and, of these, the minority explicitly addresses ethics, mainly focussing on only a small subset of topics.

492. The need for harmonized, risk-based regulation of gene editing in livestock

A.L. Van Eenennaam* and M.L. Mueller

University of California, One Shields Avenue, Davis, CA 95616, USA; alvaneenennaam@ucdavis.edu

Abstract

One challenge for the incorporation of gene-editing into livestock breeding programs is the lack of international regulatory harmony. At the current time several jurisdictions are treating the risks associated with knockouts and intraspecies allele substitutions that could have been achieved using conventional breeding, in the same way as those associated with the random insertion of exogenous DNA achieved using traditional genetic engineering methods. Many of the potential hazards, such as novel allergens or toxins associated with a transgenic expression product, are not relevant to gene knockouts and cisgenic allele replacements. As a result, several countries are treating such products as analogous to those produced though conventional breeding. Subjecting gene-edited livestock to a unique regulatory burden, irrespective of the nature of the edit, is difficult to justify from a risk perspective. The lack of regulatory harmony with regard to gene-edited animals jeopardizes the global adoption of this technology in livestock breeding programs.

Introduction

In January 2017, the United States Food and Drug Administration (FDA) released a draft guidance signalling its intention to regulate intentional genomic alterations (IGA) in gene-edited animals as new animal drugs (FDA, 2017). The guidance reads, that 'a specific DNA alteration is an article that meets the definition of a new animal drug at each site in the genome where the alteration (insertion, substitution or deletion) occurs', and that 'in general, each specific genomic alteration is considered to be a separate new animal drug subject to new animal drug approval requirements.' By this definition, all gene-edited livestock are unapproved animal drugs and therefore are in general 'deemed unsafe'. As a result, edible products from gene-edited animals are not allowed enter the food or feed supply without prior FDA authorization. Rather, the FDA recommends that investigational animals and their biological products be disposed of by incineration, burial, or composting. To obtain approval for a new animal drug first means applying for an Investigational New Animal Drug (INAD). In this paper I will outline my experience as a university researcher working with gene-edited livestock, and the information that has been requested to comply with the regulatory requirements of the FDA, and contrast this to the regulatory approaches of various countries.

Materials & methods

In February 2021, an application for an INAD for gene-edited *NANOS3*-/- knock-out cattle was submitted to the FDA. These cattle were produced using Cas9 and CRISPR guide RNAs (gRNAs) targeting exon 1 of the bovine NANOS3 gene in bovine zygotes. The cattle were healthy and unremarkable other than the fact they lacked germ cells and were therefore infertile, as hypothesized. The gRNAs used for this experiment were designed and screened for potential off-target sites based on the bovine reference genome using bioinformatic tools, sgRNA Scorer 2.0 and Cas-OFFinder, respectively. Based on a systematic analysis of CRISPR-Cas9 mismatch tolerance only gRNAs that met specific mismatch parameters were selected. A mismatch is defined as a discrepancy between a base of the gRNA and the predicted off-target site. The gRNA selection criterion was: (1) at least 3 total mismatches; and (2) at least 1 of the mismatched bases was located in the seed region (8-10 bp proximal to the PAM site) of the gRNA. Our previous work in bovine zygotes using these design parameters for testing multiple gRNAs and targeting several different loci showed no off-target effects (Hennig *et al.* 2020).

CC BY

DOI: 10.3920/978-90-8686-940-4_492, © A.L. Van Eenennaam and M.L. Mueller 2022

The information required to support this INAD request was an overview of the project objectives, a description of the constructs or genomic alterations in the animal, a description of the method(s) or technologies used to produce and deliver/introduce the genomic alteration, and a description any completed studies including any relevant information from other animals in which the same genes have been knocked out (e.g. references to published articles characterising knockout mice). Additionally, a request for 'a categorical exclusion from the requirements to prepare an environmental assessment' was submitted to accompany the INAD file. When FDA reviews and approves new animal drugs, it has to comply with the requirements of the National Environmental Policy Act, which includes a review of environmental risks, if any, where required. Requesting this exclusion entailed certifying that no extraordinary circumstances existed whereby the gene-edited cattle could significantly affect the quality of the human environment. This required documenting the location of facilities where the animals were housed, containment measures, management practices and conditions for all facilities, animal waste and animal disposal, and a description of standard operating procedures, and submitting this information to allow for a determination to be made.

Results

Upon obtaining this INAD, an investigational food use authorization (FUA) was requested to introduce the knock-out cattle into the food supply at the completion of the experiment, rather than incinerating them. This required providing data outlined in Table 1. The off-target in silico analysis included 10 sequences with three mismatches to the guide sequence in the reference cattle genome. There were no sequences with less than three mismatches other than our target, as per our guide design criteria. Given the expense involved

Table 1. Information requested by the US FDA to consider authorizing food use of experimental gene-edited knockout cattle with Intentional Genomic Alterations (IGA).

A complete description of animals proposed to enter the human food supply:
Details regarding the species, class, and number of requested investigational animals, including the strategy used to produce the offspring.
Characterisation of the intentional genomic alteration (IGA) and any intended effects:
A description of the purpose of the IGA and the intended function (including location in the genome, impact on protein expression, if any, intended sequence, etc.) and details on how the alteration was achieved.
PCR genotyping data and/or sequencing data to demonstrate that the IGA is correctly targeted, as expected.
If available for comparison, you may also provide PCR genotyping data and/or sequencing data from non-edited comparators.
Justification that the IGA is expected to result only in the intended effect
i.e. knockout should not lead to any other changes in animals, which may impact the edible tissues. The justification may rely on available literature, phenotypic data on knockout animal models collected in lab (e.g. biomarker data), and other resources that report on germline abnormalities in knockout animals (e.g. cattle and mice).
Animal health data/information:
Any data/information collected on the health status of the animals that will enter the food supply. This includes visual observations, bloodwork including any hormone measurements, etc.
Compositional analysis:
Justification/explanation that no substantial differences in nutritional or composition content of edible tissues between edited and non-edited animals are expected as a result of the introduction of the IGA, including any unintended alterations. Data from other animals in the lineage or with a similar alteration that will aid in the evaluation can be submitted as justification.
Predicted off-targets:
Option 1: For each edited animal, PCR and/or sequence-verification of the absence of off-target effects in the 10 predicted regions identified via in silico analysis
Option 2: Justification for each of the 10 regions as to why there is no need to provide additional data that verifies the lack of an off-target. For example, justification could include information pertaining to the impact on protein expression (or lack thereof) or known impacts of the gene on human food/meat quality.

with performing this off-target sequence verification for 10 loci for each animal, and the fact that this analysis was unrelated to our scientific interest in these animals (meaning we would be doing this analysis solely for the FUA), the FUA was abandoned in favour of requesting a rendering use authorization. This meant that the animals would be allowed to enter the animal feed chain, rather than the human food chain at the completion of the experiment. To obtain rendering authorization required a separate application to the FDA Division of Animal Feeds. Similar information to that outlined for the FUA was requested but this request did not require off-target sequence verification. In December 2021 we obtained a feed use authorization for these animals to be rendered at the completion of the experiment.

Discussion

These regulatory exchanges involved a substantial investment of time, both for the regulators and investigators. Such regulatory interactions are not a routine part of basic academic research in animal breeding and genetics. Neither is disposing of all animals by incineration, burial, or composting at the completion of a research project. This is particularly expensive when working with large livestock species, and is a unique expense associated with the use of gene-editing in food animals not incurred when researching conventional breeding methods. Further, these regulatory data are typically being requested prior to the conclusion of the experimental work, rather than at the completion of the research when manuscripts describing and detailing the methods and results are typically being compiled and written. As such, preparing these documents required a dedicated time commitment solely for regulatory compliance, and pursuing a FUA would have required further additional experimental work.

Internationally harmonized guidelines for assessing the safety of foods derived from transgenic animals have been developed by Codex Alimentarius, but these do not consider aspects of animal welfare. Other

Prohibited	0

[1] Determined, [3] Proposed: No Unique Regulations: Gene-edited products that do not incorporate DNA from another species will be regulated as conventional products with no additional restrictions.

[2] Lightly Regulated: Some or all types of gene editing are regulated more strictly than conventional agriculture, but not as strictly as transgenic GMOs.

jurisdictions, notably in Europe, explicitly include aspects of animal health and welfare in the premarket assessment of genetically modified animals for food and feed purposes (van der Berg *et al.* 2020). In 2015, Argentina issued a regulation clarifying the regulatory status of gene-edited products (Lema 2019). It keeping with the definition in the Cartagena Protocol, it outlined that for a gene-edited organism to be a genetically modified organism (GMO), it had to 'possess a novel combination of genetic material'. The Argentine regulation calls for gene-edited plants and animals to be presented to the biosafety commission in order to establish, on a case by case basis, whether it is a GMO. An interesting aspect of this regulation is that there is an opportunity to present projects at the 'design stage', whereby a preliminary opinion based on the expected outcome will be issued by the commission.

Later, when the plants or animals have been obtained and fully characterised, applicants must present a follow up report that will be used to establish a final decision. That determination is mostly based on any changes present in the genome of the product intended to be sold commercially. Table 2 shows the evolving regulatory status of gene-edited crops and animals in different countries and regions throughout the world. It highlights the discrepancies between regulations for gene-edited food applications from the plant and animal kingdoms, and the current lack of global harmonization. Additionally, many regions are still developing their regulations. For example, no African nation has passed regulations for gene-edited animals. In practice, gene-edited animals will pose challenges in relation to aspects of traceability in the food chain. International harmonization of risk-based regulatory criteria will be essential to avoid trade obstacles, and in its absence gene-editing will likely play a limited role in livestock genetic improvement programs.

493. Broadening the ethical debate on breeding innovations, public engagement and the role of the Democs game

F.L.B. Meijboom[1*], D.M. Bruce[2], K. Kramer[1] and A. Bruce[3]

[1]Utrecht University, Faculty of Veterinary Medicine, Sustainable Animal Stewardship, Yalelaan 2, 3584 CM Utrecht, the Netherlands; [2]Edinethics Ltd, View Hill, 1 Peinsoraig, Uig, Isle of Skye IV51 9YD, United Kingdom; [3]University of Edinburgh, School of Social and Political Science, Old Surgeons' Hall, Edinburgh EH1 1LZ, United Kingdom; f.l.b.meijboom@uu.nl

Abstract

As genomic selection becomes increasingly important in livestock breeding, it also entails ethical and societal issues, and we are examining these as part of the BovReg project, funded by the Horizon 2020 programme of the European Union, on advanced cattle genomics. We argue that discussion of these issues must have broad scope, in at least three respects. Firstly, it should go beyond risk and animal welfare. Secondly, it should consider not only what is novel but assess also existing ethical issues in the light of genomic innovations. Lastly, because issues of animal production are of interest to European society, public engagement is an essential element for responsible innovation. To stimulate debate on genomic selection, we have created a Democs card game to engage with general publics and stakeholders. The game explains the context of current production and selection in cattle, examines ethical and social issues raised by breeding techniques, and invites players to form their own views.

The need for ethical reflection

Genomic selection has become an important tool in livestock breeding, with further potential to widen both the traits and the breeds to which it can be applied. It also entails ethical and societal choices, for example in balancing such factors as animal health and welfare, fertility and climate impact alongside improving yields. As part of the BovReg project (www.bovreg.eu) on advanced cattle genomics within the FAANG network, we are examining these ethical questions. In contrast to some other reproductive technologies in animal breeding, such as cloning or genome editing, genomic selection has not raised much ethical attention. This can be explained partly by the characteristics of the technology itself, which is about the use of genome-wide genetic markers to predict the breeding value of selection candidates. Genomic selection therefore does not cross species boundaries, or require applying new invasive techniques on animals. However, that genomic selection is in certain respects continuous with earlier breeding techniques does not imply that it raises no ethical issues. It is also the result of a rather limited view on what counts as relevant ethical considerations. However, genomic selection has not so far resulted in extensive public debate.

An analysis of the academic literature found only few papers pay attention to ethical aspects. One of them is by Mark and Sandøe (2010). They highlighted issues such as unexpected effects on animal welfare due to correlations with non-measured traits, a higher risk of spreading deleterious mutations, the centralisation of capabilities and increasing dominance of specific breeds. They also discuss concerns over increased monopoly within dairy cattle breeding. The paper stresses the importance that stakeholders monitor the effects of genomic selection and that breeding companies act responsibly. This is in line with the development and regular updates of Code-EFABAR which since 2006 has aimed to define and maintain good practices for farm animal breeding (Code-EFABAR 2020).

In this paper, we first argue that the discussion on genomic selection needs to reflect a wider range of ethical issues than is commonly the case. Secondly, we focus on extending discussion beyond the novel concerns, and lastly we argue that the current comparative lack of public debate provides an opportunity to work on

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_493, © F.L.B. Meijboom *et al.* 2022

public engagement. For this purpose, we have created a Democs card game to engage with general publics and stakeholders, on which we will elaborate in the second part of the paper.

Three factors to broaden the debate

A broader ethical scope: beyond risk and animal welfare. It is important to move away from confining ethical discussion to risk and safety. In response to legal frameworks and a no-harm principle, there is a tendency for ethical evaluation to focus primarily on the question to what extent a technology can harm others and what risks are involved (Fleming *et al.* 2018). Notwithstanding the importance of minimizing risks to food safety, genetic diversity and economic risks, an ethical evaluation of breeding innovations should encompass more than this dimension. In addition, given the duties we have towards animals and the environment, the ethical considerations should not be restricted to human-related issues.

There has been attention to the positive and negative impacts the technology can have for animals and their welfare (Mark and Sandøe, 2010, Windig 2012). This is a crucial dimension of the ethical assessment, as animal welfare is a core concept in animal ethics. Focussing ethical and public debates on animal welfare may overload the concept, however, because this invites people to 'translate' their wider concerns into issues of welfare. Therefore, we argue for a broader scope in the discussion on the ethics of genomic selection that includes risk and animal welfare related arguments, but also goes beyond them. Our mapping of the potential ethical issues showed views on genomic selection that cannot be reduced to animal welfare concerns. These included questions raised by more critical voices, of justice, autonomy (Coles *et al.*, 2015) and 'biopower' i.e. changing animal bodies and populations in a direction dictated by particular human interests (e.g. Twine, 2010). There needs to be room to discuss such ethical issues as the instrumentalization of animals, changing power relations among stakeholders in animal breeding, or human-oriented ideas about perfecting animals. Most of the latter concerns are not specific to genomic selection and are relevant in conventional breeding programs or even livestock farming in general. But we argue that this is a reason to take into account a second factor in broadening the ethical discussion.

Beyond what is novel. Especially when changes are mediated by technology the ethical analysis tend to focus what is, ethically speaking, novel about those technologies.' This starts from the assumption that the situation before the innovation was morally justified or acceptable. On that basis, genomic selection should be assessed only by considering whether it introduces novel ethical issues, compared with existing breeding practices. This view is problematic for two reasons, however.

Firstly, adding one element to an existing practice can have far-reaching consequences that expand dimensions that were already present in the existing situation. Not without reason, genomic selection is portrayed as a next step in the development of existing breeding programs and as a paradigm shift at the same time (Meuwissen *et al.* 2016). Secondly, it fails to reflect back on what may be ethically problematic in existing practices. The assumption that livestock breeding is an uncontroversial practice cannot be taken for granted, as the ethics of breeding animals has been widely discussed in various contexts (Olsson *et al.* 2006; Leenstra *et al.*, 2012; Farstad 2018). Therefore, ethical reflection on genomic selection should not only address novel issues of the technique on itself, but should consider it as part of the existing practices of breeding and livestock farming. This does not make the discussion easier, but can do justice to the complexity at stake. It is important that the discussion on the societal and ethical dimensions is not a task for only ethicists or social scientists. It needs the inclusion of stakeholders and the general public. This leads to our third factor.

Public engagement. Genomic livestock breeding is a complex technical field that requires multiple forms of expertise of highly skilled persons and specialised organisations, which tend also to be international.

The infrastructure needed to guarantee high quality in research, product development and implementation also leads to a gap between the experts in genomic selection, the users (farmers) and the general public. The economic relation between breeding companies and their clients, means that farmers may participate in discussions on breeding innovations, or have their views studied (e.g. Lund *et al.* 2021), but the general public is seldom consulted. This is problematic because public engagement is recognised as an essential element in responsible innovation (Owen *et al.* 2021). Only engaging with technical experts risks limiting the debate to dominant perspectives (Kayumova *et al.*, 2019). Two-way public engagement is crucial to invite lay persons to form their own views and enable them to participate in the debate, and to give the general public a voice in making breeding organizations, companies and governance institutions more responsive and accountable. In line with this step, it is important to engage with wider publics, who are showing an interest in animal production but are rarely consulted about the priorities and direction of livestock breeding. By the same token, general public comments need to be informed to have credibility, and communicating a complex subject such as genomic selection is challenging.

The Democs game

An integral part of the European BovReg project is to conduct public engagement as part of our aim for making responsible innovation. For this purpose, we have created a Democs card game, the purpose of which is to stimulate wider debate among stakeholders, and to give small groups of lay people in different European countries the opportunity to discuss and express their views about genomic selection in cattle, including ethical questions about breeding priorities and practices more generally. Democs has been a proven tool for 20 years to enable grassroots engagement on many technological issues in small groups, assuming no prior knowledge. The cards are the 'expert' and provide the basis for group learning and discussion. These cards have been written in a detailed iterative process drawing upon the technical, ethical and Democs game expertise and insights from BovReg partners.

Story cards introduce different aspects of cattle production, genomics and breeding through case studies of imaginary people involved the field or affected by it. These include a breeding company CEO, a genomics researcher, a veterinarian, an Alpine dairy farmer of specialty cheeses from local breeds, a government climate scientist, an environmentalist and an critical consumer. Each one explains their involvement and an ethical dilemma which it presents. Information Cards provide the context of different approaches of cattle production, with which publics may not be familiar. They explain genomic selection and its potential, and give information on animal health and welfare, land use, climate and environmental impacts. Issue Cards then open up relevant ethical and social issues arising from advanced breeding and production, expressing differing standpoints to reflect the range of opinions.

Players are invited to discuss and to form their own views built up from the suite of cards. There are two outputs. One is group opinion statements, written on Cluster Cards, based on the cards the group members have chosen to discuss. The second output is individual votes by each player on priorities and questions in cattle breeding, with their reasons in their own words. These outputs will be analysed, and are expected to provide valuable qualitative information on public views on genomic selection in cattle and related issues.

The game was first produced in a pilot version for beta testing for accuracy, balance and being understandable by lay people, and is now being finalised for distribution, with the expectation of being translated into various languages, so that people can take part in their 'mother tongue'. Covid restrictions on small face-to-face group meetings have delayed playing somewhat. We are investigating the feasibility to adapt the game to be played on-line, which is not a simple task for a tool that is designed to feature interactive discussion.

Conclusions

Breeding innovations raise ethical issues that are not limited to risk and animal welfare, and that go beyond what is novel about such innovations. Responsible innovation requires discussing such ethical issues with a wide range of stakeholders, and we invite engagement with those involved in livestock breeding and innovation. The Democs game that we have created facilitates the engagement of stakeholders, but especially of lay publics in ethical discussions on genomic selection and cattle breeding.

Abstract

The objective of this study was to better understand the positions of the stakeholders of the livestock sector with respect to the use of genome editing techniques. A qualitative survey by semi-directive interviews was conducted with different actors of the livestock sector. It allowed to establish a typology of stakeholders in five categories (opponent, skeptical, cautious, enthusiastic, convinced) and to characterize the main arguments associated with the position of the different stakeholders.

Introduction

Since the development of the Crispr-Cas9 system (Jinek *et al.*, 2012), genome editing (GnEd) staktools have gained a major place in biological research and the prospects for applications are numerous, in medicine for the treatment of many diseases, medical diagnosis or eradication of disease vectors (Ashmore-Harris and Fruhwirth, 2020), in bioindustry (biofuels; Lu *et al.*, 2022) or in agriculture. The application of GnEd in agriculture is nevertheless controversial. For some, its use is essential to be able to feed 9 billion people in 2050 and to succeed in the agroecological transition (Fan *et al.*, 2021). For others, there is a risk that genetic engineering is used to perpetuate unsustainable agricultural systems (Jacobsen *et al.*, 2013) and its use involves risks that are not yet fully controlled (Norris *et al.*, 2020). However, the controversy is currently limited to the scientific and professional communities directly concerned.

On the other hand, the status of genome-edited organisms varies around the world. In Europe, they fall within the scope of the regulation on Genetically Modified Organisms (Directive 2001/18/EC) since the July 25, 2018 ruling of the Court of Justice of the European Union. In the USA, the regulatory approach in animals is also very strict, based on the food, drug and cosmetic act. In other American countries (Argentina, Brazil, etc.), GnEd organisms produced by cisgenesis or intragenesis are not considered GMOs. In some European countries (United Kingdom, Norway), which have regulations similar to those of the EU, changes in regulations are being considered. In the EU, the question of regulatory changes is also being raised, at least for plants, following a recent report by the European Commission (Commission, 2021).

In this context (controversy, regulatory uncertainty), it seemed relevant to us to better identify the positions of the various actors in the field of livestock selection with regard to the potential use of genome editing techniques in livestock breeding. To this end, a qualitative survey was carried out by means of semi-directive interviews with people involved in the breeding sector. The objective of this article is to present the main results of this survey.

Materials & methods

The semi-structured interview is an approach widely used in sociology. It consists of a series of open-ended questions, prepared in advance by the interviewer, which allows the respondents to organize their answers as they wish. It aims to be representative of the diversity of opinions, without any quantitative objective (Delanoue *et al.*, 2018). In the present case, the question grid was completed by cards presenting typical

cases of genome editing use (hornless cattle, resistance to PRRS, hypoallergenic milk, myostatin) presented during the interview.

The interviews took place from October 2020 to February 2021. Most of the interviews were conducted by video conference, due to the Covid-19 pandemic. Respondents were mostly alone, but some interviews were conducted with 2 or even 3 respondents. They were recorded once the respondents had given their consent. The average duration of the interviews was 1 hour and 25 minutes. A total of 48 people were interviewed. Their distribution by activity sector is given in Table 1.

The respondents belonged to four sectors (ruminants, pigs, poultry and aquaculture) and, for some, to the plant sector. Two interviews were withdrawn from the survey because answers were vague an unclear. The final corpus studied was 46 respondents in 36 interviews. The interviews were analyzed by viewing the videos using a standardized analysis grid.

Results & discussion

The analysis of the surveys quickly revealed that knowledge of the subject was still limited to a very narrow sphere (mainly research and breeding sectors), who were familiar with the subject (specialists). The other respondents had varying degrees of knowledge of the subject and were grouped into 3 categories, layman (did not know), novice (superficial knowledge) and expert (followed the subject).

The controversy is built around uncertainties. We have grouped together in the diagram below (Figure 1) the main uncertainties expressed by the respondents. They were linked to the technology, its impact on the environment and/or biodiversity, on the animal and its socio-political impact. An uncertainty related to human health impact was also mentioned by a small number of respondents and was therefore classified as secondary. The uncertainties were linked to the major cross-cutting issues raised almost systematically by the respondents, namely: (1) the type of agricultural model in which GnEd tools is used; (2) the impacts of their use, particularly their irreversible nature; (3) ethical issues (link to living organisms, man's right to modify nature) and ownership of living organisms. The technological uncertainties concerned the mastery of the tool and the maturity of the related scientific knowledge, with references to older techniques and the 'Recombinetics' affair (Norris *et al.*, 2020), and fears about collateral effects on animal welfare or the environment.

Once the uncertainties had been identified, we looked to see if a typology of actors could be identified within our sample. As already indicated, one of the first differentiating factors was the level of knowledge of the subject. We also tried to get the respondents to express their position or that of their organization with regard to the use of GnEd (are you in favor or against the use of GnEd in livestock farming?). The individual

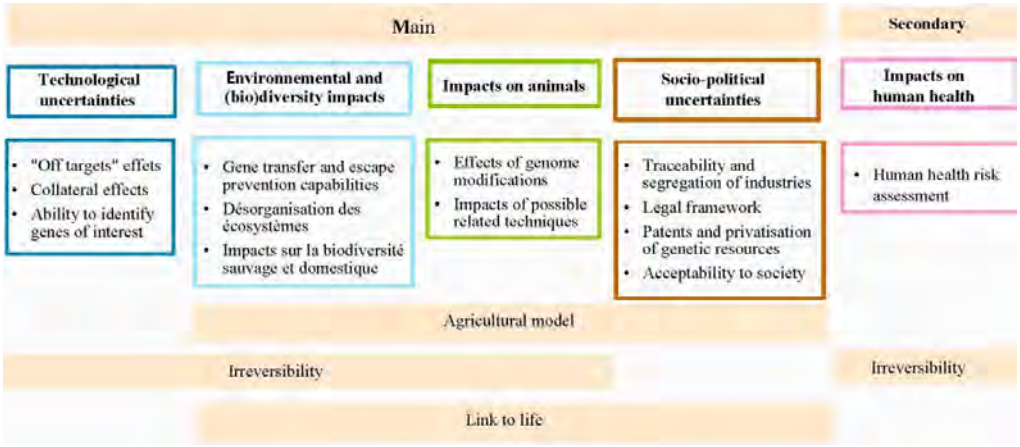

Figure 1. Uncertainties at the origin of the controversy on genome editing in livestock.

positions were analyzed, as the structures very rarely had any official or unofficial position on the subject. This analysis made it possible to construct a typology in five categories (Figure 2).

Two categories, located at the ends of the graph, represented the committed actors. They had a good or even very good knowledge of the subject and had a definite position on the use of GnEd. The convinced, who were closely linked to the R&D sector, were in favor of one or more types of use and considered that GnEd was compatible with all farming systems. Opponents often had a long-standing commitment against the use of genetic engineering in agriculture.

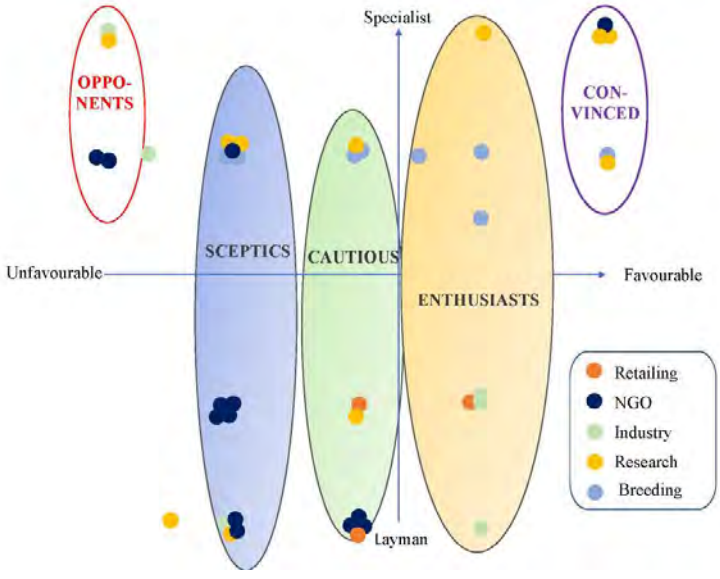

Figure 2. Typology of actors.

The other categories represented the bulk of the respondents (37/46). They expressed a less assertive position, but with differences in viewpoints that made it possible to group them into three categories: the sceptics, the cautious and the enthusiasts. Enthusiasts differed from the convinced in their lack of commitment and in their level of knowledge of the subject, from the specialist researcher who did not wish to get involved in the debate to the layman who saw many possibilities linked to the use of GnEd. Many in the agricultural sector hoped that GnEd will be an additional solution to the challenges facing their industry. The sceptics included respondents who were very skeptical about the use of GnEd, expressing doubts about the technological interest of GnEd and the possibility of using these tools in animal welfare friendly systems. This category included a larger number of NGOs and a researcher specializing in the subject. The cautious were a more difficult category to characterize. It included more actors with little knowledge of the subject and who had often not expressed a clear position on the use of GnEd.

Beyond the controversy over GnEd, the question of the farming system in which these techniques are used was a central issue for many stakeholders. This was often equated with highly intensive and unsustainable systems. The question of their use in more agro-ecological and sustainable systems remained highly debated.

Abstract

NANOS3 is known to be critical for germline development of both sexes in several organisms, but the role has not yet been characterized for male bovines. This study optimized a gene knockout (KO) approach using CRISPR/Cas9 in bovine zygotes to produce a live *NANOS3* KO bull. The co-injection of two selected guide RNA/Cas9 ribonucleoprotein complexes at 6 hours post fertilization achieved a high *NANOS3* KO rate in developing embryos. Subsequent embryo transfers resulted in a 25% pregnancy rate. A bull with no wildtype *NANOS3* alleles was produced and at sexual maturity he was found to have normal libido, an anatomically normal reproductive tract, and microscope evaluation of an ejaculate revealed seminal plasma only with no spermatozoa present, suggesting ablation of the germline. This study provides insights into bovine germline development and suggests the potential of *NANOS3* KO bulls to serve as hosts for germline complementation to enable donor-derived gamete production.

Introduction

NANOS3 is known to be critical for normal germline development in several organisms. Murine *Nanos3* is expressed by migrating primordial germ cells (PGCs) of both sexes, and the elimination of this gene results in the complete loss of male and female germ cells, but otherwise normal gonadal development (Tsuda *et al.* 2003). In humans, mutations in *NANOS3* are associated with germ cell loss and infertility (Julaton and Reijo Pera 2011). Also, a *NANOS3* knockout (KO) bovine female 200d-fetus was reported to phenocopy *Nanos3* KO mice (Ideta *et al.* 2016). However, the effect of knocking-out *NANOS3* on male bovine germline development has not yet been reported and no live *NANOS3* KO cattle have been produced to our knowledge. Characterization of the role of *NANOS3* in bulls and production of live *NANOS3* KO cattle will be important for further understanding bovine germline development. We hypothesized there would be a complete loss of germ cells in *NANOS3* KO bulls, making them ideal hosts for germline complementation to enable donor-derived gamete production. Germline complementation consists of using donor cells from one genetic background to complement or replace the germline of an otherwise sterile host of a different genetic background (Giassetti *et al.* 2019). Ultimately, germline complementation technology could enable more efficient and wide-spread dissemination of superior cattle genetics and/or traits improved via gene editing to enhance production efficiency. The objective of this study was to generate and characterize the germline development and reproductive capability of a CRISPR/Cas9 *NANOS3* KO bull.

Materials & methods

Guide RNA (gRNA) design and *in vitro* testing. Guide RNAs (gRNAs) targeting the bovine *NANOS3* exon one were designed and screened for potential off-target sites based on the bovine reference genome (ARS-UCD1.2) using sgRNA Scorer 2.0 (Chari *et al.* 2017) and Cas-OFFinder (Bae *et al.* 2014), respectively. Selected gRNAs had three or more total mismatches compared to the sequence for predicted off-target sites, and had at least one mismatch located in the seed region (8-10 bp proximal to the protospacer adjacent motif (PAM) site) of the gRNA (Hennig *et al.* 2020). Synthetic gRNA (Synthego, Menlo Park, CA, USA) cleavage efficiency was assessed by an *in vitro* cleavage assay, as previously described (Hennig *et al.* 2020).

Bovine embryo production. Bovine ovaries were obtained from a local processing plant. Cumulus-oocyte complexes (COCs) were aspirated from follicles and transferred to maturation media (IVF Bioscience, Falmouth, UK) for 21-24h. COC's were fertilized in SOF-IVF (Bakhtari and Ross 2014) with 2×10^6 sperm per ml for 6h. *In vitro* maturation and fertilization incubations were at 38.5 °C in a humidified 5% CO_2 incubator. Six hours post fertilization (hpf), presumptive zygotes were denuded by light vortex in SOF-HEPES (Bakhtari and Ross 2014) for 5 min. Zygotes were *in vitro* cultured (IVF Bioscience, Falmouth, UK) at 38.5 °C in a humidified atmosphere of 5% CO_2, 5% O_2, and 90% N_2 for 7-8 days.

gRNA *in vivo* testing. To determine the mutation rate for each individual gRNA and for dual guide RNA (dgRNA) combinations, 6-hpf zygotes were microinjected (i.e. laser-assisted cytoplasmic injection (Bogliotti *et al.* 2016)) with 6 pl of a solution containing 167 ng/µl of Cas9 protein (PNA Bio, Inc., Newbury Park, CA, USA) and 67 ng/µl of an individual gRNA or 67 ng/µl each of a combination of 2 gRNAs. The Cas9 protein and gRNA(s) were incubated together at room temperature for 30 minutes to form a ribonucleic protein (RNP) prior to microinjection. Microinjected embryos were incubated for 7-8 days and on day 7 embryos were scored for developmental stage reached. Blastocysts were individually collected in lysis buffer for DNA extraction. The *NANOS3* target region was amplified by two rounds of nested PCR using custom primers (Eurofins Genomics, Louisville, KY, USA). PCR products were visualized on a 1% agarose gel, purified using the QIAquick Gel Extraction Kit (Qiagen, Inc., Valencia, CA, USA) and Sanger sequenced (GeneWiz, South Plainfield, NJ, USA).

Embryo transfer (ET) & pregnancy monitoring. All animal procedures were approved by the Institutional Animal Care and Use Committee (IACUC) of the University of California (UC), Davis (#21513). Recipient females were synchronized in a standard fashion using a 7-day CoSynch + CIDR® protocol. Bovine embryos were *in vitro* produced and microinjected at 6-hpf with a dgRNA system, as described above. On day 7, microinjected blastocysts were selected and loaded individually into ET straws and transferred (one per recipient) into the recipients via a transcervical technique, placing the embryo in the uterine horn ipsilateral to the corpus luteum. Pregnancy was diagnosed initially via blood pregnancy-associated glycoproteins and followed by confirmatory transrectal ultrasound examinations. Pregnancies were routinely monitored with transrectal ultrasound.

Live animal evaluation. Blood samples were collected from new-born calves, DNA was extracted using a DNeasy® Blood & Tissue Kit (Qiagen, Inc., Valencia, CA, USA), and the *NANOS3* target region was amplified by PCR. PCR products were visualized on a 1% agarose gel, purified, and Sanger sequenced. Once the confirmed *NANOS3* edited males reached reproductive age (~12 months), a breeding soundness exam was conducted by UC Davis veterinarians. The breeding soundness exam followed the standards set forth by the Society for Theriogenology and included a general physical examination, inspection of reproductive organs, and semen collection via electroejaculation.

Results

Generation of CRISPR/Cas9 bovine NANOS3 KO embryos. Bovine *NANOS3* is a 2,633 bp gene with two exons (Figure 1A). Seven gRNAs were designed to target the larger exon 1 (451 bp), as it contains the coding region for the critical zinc finger binding domain. Four gRNAs (#1, #4, #5, #7) successfully cut the target region *in vitro*, so they were further tested *in vivo.* To determine blastocyst development rate and mutation efficiency, each gRNA was independently microinjected alongside Cas9 protein in groups of 30 zygotes, 6-hpf. Groups of 30 non-injected embryos were cultured as controls. All injected groups resulted in a blastocyst development rate of ≥20%, which was similar to other microinjected bovine embryo experiments (Hennig *et al.* 2020). Three individual gRNAs (#4, #5 and #7) resulted in >60% total mutation rate.

Figure 1. Bovine *CRISPR/Cas9 NANOS3* guide RNA design. (A) Diagram of bovine *NANOS3* gene and (B) guide RNA locations; checkmarks indicate successful *in vitro* cleavage assay and circles indicate guide RNAs selected for the dual guide RNA system.

Next, a dgRNA system, which is an efficient method for complete gene disruption in livestock species (Vilarino *et al.* 2017), was tested. gRNA #4 and #7 were selected based on their high individual mutation efficiencies (83 and 63%, respectively), and genomic locations, so that when co-injected they could introduce a deletion of 297 bp (Figure 1). The dgRNA_4+7 microinjections resulted in a similar blastocyst development rate to the individual gRNAs (19%) and >75% KO rate (i.e. 0 wild-type alleles) (n=28, 4 replicates).

Production of a CRISPR/Cas9 NANOS3 KO bull. For ET, *in vitro* produced bovine embryos were microinjected at 6-hpf with the dgRNA_4+7. On day 7 of *in vitro* culture, eight presumptive *NANOS3* KO blastocysts were selected and transferred into synchronized recipients. Twenty-one days after ET (28-day gestation), initial pregnancy rates were determined via a blood progesterone test (n=3/8, 38%). Ultrasound was used approximately one week later (35-day gestation) to confirm pregnancies (n=2/8, 25%), and around 60-days of gestation to determine foetal sex (one male and one female).

Two healthy calves one male (#838) and one female (#854) were born unassisted at the UC Davis Beef Barn in the fall of 2020; however, this paper will only focus on the resulting male (Figure 2). PCR and Sanger Sequence analysis of DNA extracted from blood indicated that #838 is a mosaic *NANOS3* KO, carrying at least four different KO alleles (Figure 2C). One allele has a large (298 bp) deletion and >3 alleles have small indels at one or both gRNA cut sites. All mutations present in #838 were predicted to disrupt *NANOS3* function.

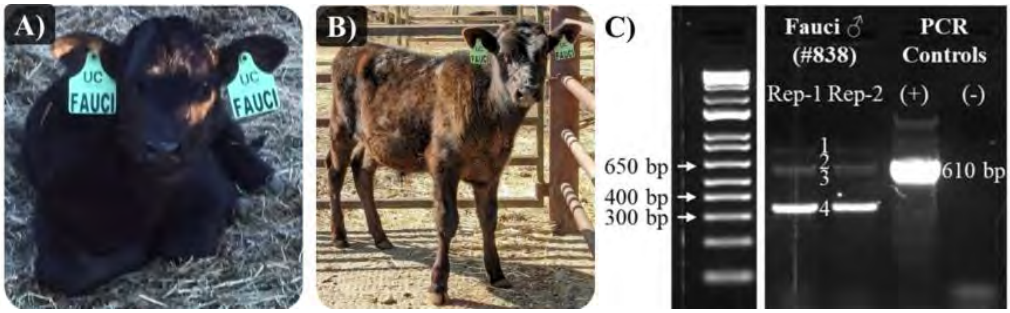

Figure 2. Production of a CRISPR/Cas9 *NANOS3* KO bull. Images of (A) 1-day-old #838 (named 'Fauci'), (B) 4-month-old #838, and (C) *NANOS3* PCR on DNA extracted from #838's blood. Numbers (1-4) represent different alleles visualized on a 1% agarose gel.

Phenotype of a CRISPR/Cas9 NANOS3 KO bull. To evaluate the potential for *NANOS3* KO cattle to serve as hosts for donor-derived gamete production, the reproductive development and capability of bull #838 was documented. The bull demonstrated normal libido and a 12-month breeding soundness exam found that #838 had an anatomically normal reproductive tract (i.e. accessory sex glands and penis) and normal testicular development, although the scrotal circumference (27 cm) was smaller than expected for age and breed matched controls. Microscope evaluation of an ejaculate obtained via electroejaculation revealed seminal plasma only with no spermatozoa present.

Discussion

We successfully produced a live bull calf with a targeted gene KO of *NANOS3* using a dgRNA gene editing approach in developing bovine zygotes. Although the bull was mosaic at the *NANOS3* target locus, no wildtype sequences remained, and all mutations resulted in *NANOS3* loss of function. The lack of spermatozoa in the ejaculate of this bull at sexual maturity supports the hypothesis that inactivation of *NANOS3* in male cattle will result in complete germline ablation. Importantly the bull had normal libido and an anatomically normal reproductive tract. This study demonstrates that *NANOS3* KO bulls have a phenotype that would be well suited to serve as hosts for germline complementation studies.

Challenges – use of multi-omics data

496. Using allele-specific expression to uncover *cis*-regulation in bovine muscle

Abstract

Allele-specific expression (ASE) analysis improves the understanding of transcription's *cis*-regulation. Herein, we used imputed SNPs along with RNA-Seq data from the *Longissiumus thoracis* muscle of 190 Nelore steers to identify functional *cis*-regulatory variants from ASE analysis. Using a Binomial Test, we identified 38,177 SNPs in ASE regions (ASE SNPs; FDR ≤0.05). We then searched for aseQTLs (SNPs potentially regulating the ASE) by comparing their heterozygosity to the measured allelic ratio under a Wilcoxon Rank Sum test. We identified 21,543 aseQTLs potentially regulating a total of 430 ASE SNPs (FDR ≤0.05). Based on a linear model, ASE SNPs and aseQTLs were associated with transcript abundance. We identified 3,333 SNPs acting as *cis*-eQTLs (FDR≤0.05). Results were integrated with previous ASE, functional regions, and meat quality-related differentially expressed genes data. This study described novel SNPs potentially regulating the transcription of genes that may affect beef traits.

Introduction

Genotypic and RNA sequencing (RNA-seq) data enable the identification of SNPs showing allele-specific expression (ASE SNPs), which consists in the imbalanced expression between alleles from each haplotype. Describing ASE regions improves the causal *cis*-regulatory variants screening (Guillocheau *et al.*, 2019). The ASE expression pattern responds to cumulative *cis*-regulatory mechanisms affecting the allele (Castel *et al.*, 2020), e.g. transcription factors (TFs) binding in accessible chromatin regions can be modulated by DNA methylation and histones modifications (Calo and Wysocka, 2013). These mechanisms can act on regulatory variants as aseQTLs, i.e. SNPs associated with the allelic imbalance (Battle *et al.*, 2014), and *cis*-eQTLs, i.e. SNPs regulating the expression of nearby transcripts (Gilad, Rifkin and Pritchard, 2008). In this study, we used a large dataset of imputed SNP genotypes to increase the power in detecting *cis*-regulatory variants in bovine muscle by using ASE approaches.

Materials & methods

Animal population, RNA, and DNA processing. The Nelore steers population was described elsewhere (Tizioto *et al.*, 2013). Here we used *Longissimus thoracis* muscle samples of a subset of this population (n=190) for which the RNA-Seq and high-density genotypic data were available. RNA was extracted from muscle tissue per sample, as previously reported (Cesar *et al.*, 2015). The RNA-Seq data were mapped to the bovine genome assembly ARS_UCD1.2 using the STAR software (Dobin *et al.*, 2013) with the default parameters. The WASP software (Van De Geijn *et al.*, 2015) was used to find and remove duplicated reads and those showing mapping bias. DNA extraction, quality control, and genotype calling were executed as described by Tizioto *et al.* (2013). BovineHD genotypes of the steers and a reference panel constructed from whole-genome sequence data of the 26 progenitors were used for imputation as previously described (Cardoso *et al.*, 2021). The imputed genotypes (4,812,912 SNPs) were phased using Beagle v.5.227 (Browning and Browning, 2008).

ASE-related SNPs identification. To identify ASE SNPs, we measured the allelic counts from heterozygous SNPs using ASE Read Counter from GATK v.4.2 (https://github.com/broadinstitute/gatk/). Ten reads mapping a SNP were required for ASE analysis. The allelic counts for each SNP were compared per animal using the Binomial Test against the expected value of 0.5. We used the Benjamini-Hochberg method to correct the False Discovery Rate (FDR) and significant SNPs were defined by FDR≤0.05. For the aseQTL analysis, we tested SNPs located up to 200 Kb upstream and downstream to each ASE SNPs position. Tests were performed as in a previous study (Bruscadin *et al.*, 2021), being significant those with FDR≤0.05. For the *cis*-eQTL screening, the RNA-Seq transcripts were quantified using Salmon (Patro *et al.*, 2017). The associations were conducted between transcripts abundance and either the respective ASE SNPs or the aseQTLs using a linear model implemented by MatrixEQTL (Xia *et al.*, 2017). The model included sequencing lane and the contemporary group as fixed effects, and age at slaughter as a covariate. Significant *cis*-eQTLs were the SNPs with associated FDR≤0.05.

Functional annotation and data integration. Annotation of ASE-related SNPs (ASE SNPs, aseQTLs, and *cis*-eQTLs) was conducted using the SNPEff software (Cingolani *et al.*, 2012). ASE genes were functionally annotated in the ClueGo plugin for Cytoscape (Bindea *et al.*, 2009). All ASE-related SNPs and ASE genes were compared with ASE data from *Limousin* cattle (Guillocheau *et al.*, 2019), Nelore cattle (de Souza *et al.*, 2020) and the GeneImprint database (https://www.geneimprint.com/). We also integrated with differentially expressed genes (DEGs) from the same population (Cesar *et al.*, 2016; Silva-Vignato *et al.*, 2017; Afonso *et al.*, 2019) and with Functional Annotation of Animal Genomes (FAANG) epigenetics data (Kern *et al.*, 2021).

Results

ASE SNPs in bovine muscle. Based on our criteria and quality control, 40,969 SNPs out of 4,812,912 SNPs were kept for further analyses. Significant ASE SNPs were frequent, being 60.9% of the tests significant (FDR≤0.05), comprising 38,177 ASE SNPs. Monoallelic expression was found for 37,227 SNPs in at least one sample. ASE SNPs were located in 7,448 genes (ASE genes), corresponding to 52.38% of all muscle-expressed genes of the bovine genome. Some of these ASE SNPs were predicted to have high impact effects as stop lost and gain, splice donor, and acceptor variations. The KEGG pathway enrichment retrieved 151 significant metabolic pathways (FDR≤0.05), including autophagy, endocytosis, focal adhesion, MAPK signaling pathway and proteasome.

aseQTLs were associated with the allelic imbalance of the identified ASE SNPs. We identified 21,543 aseQTLs associated with 430 ASE SNPs (FDR≤0.05). Forty aseQTLs located from 106,229,134 bp to 106,243,323 bp of BTA3 were associated with six ASE SNPs within the *NT5C1A* and *HEYL* genes. Most of the aseQTLs were located in intronic regions (50.4%), and some were located in high impact regions such as splice acceptor, start lost and stop gained regions. We found eight aseQTLs previously identified in the same population from HD Chip genotypes (Bruscadin *et al.*, 2021).

ASE SNPs and aseQTLs can affect transcripts' abundance. We identified 3,333 *cis*-eQTLs associated with the abundance of 758 transcripts. These *cis*-eQTLs included 2,098 ASE SNPs and 1,075 aseQTLs. Beta values (β, effects sizes) ranged from -823.08 to 862.80. The following *cis*-eQTLs presented the higher effects sizes: The A-allele of the BTA23:27522058 *cis*-eQTL was associated with the increased abundance of transcript *HSPA1A-201* (β=862.80, FDR=0.013; Figure 1A). *CKMT2-201* was positively regulated by the C-allele of the BTA7:81274253 *cis*-eQTL (β=98.88, FDR=0.008) (Figure 1B). Thirteen *cis*-eQTLs with identical genotypes located in the BTA29:49576764-49594787 window were associated with two different transcripts of the *TNNT3* gene, with its alternative allele upregulating the *TNNT3-205* (β=111.44, FDR=0.003; Figure 1C) and downregulating *TNNT3-206* (β=-823.08, FDR=0.010; Figure 1D)

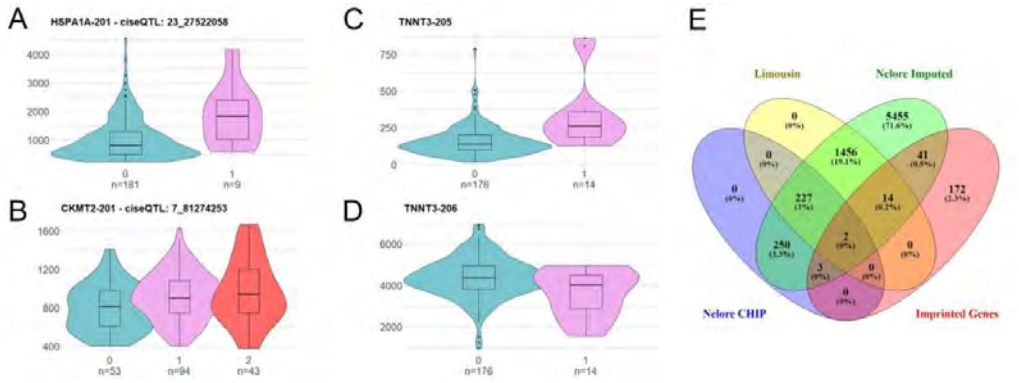

Figure 1. Violin plots showing the abundance of each transcript according to individual genotypes. The X-axis contains the genotypes, being '0' the reference homozygotes, '1' the heterozygotes and '2' the alternative homozygote. Y-axis contains the expression counts. (A) *HSPA1A-201*; (B) *CKMT2-201*; (C) *TNNT-205*, (D) *TNNT-206*. (E) Venn diagram of overlapping ASE genes.

Data integration showed functional evidence of ASE-related SNPs. A total of 482 ASE genes integrated with a previous study in Nelore (de Souza *et al.*, 2020), and 1,699 with *Limousin* cattle, corresponding to 90.94 and 80.17% of the ASE genes originally described, respectively (Figure 1E). We identified 5,495 novel ASE genes in bovine muscle. Furthermore, 51 ASE genes were previously reported as imprinted. Among them, seven in *Bos taurus,* of which five genes showed ASE SNPs with monoallelic expression in all samples of this study. We observed 1,450 ASE genes overlapping with DEGs previously identified in the muscle of the same Nelore population for fatty acid content (Cesar *et al.*, 2016), mineral content (Afonso *et al.*, 2019), and carcass quality traits (Silva-Vignato *et al.*, 2017). Additionally, we observed overlap with SNPs in accessible chromatin regions (ACR) or ChIP-Seq data from FAANG (Kern *et al.*, 2021), as for BTA23:27522058 *cis*-eQTL (Figure 1A) integrating with ACR, H3K27ac, H3K27me3, H3K4me1, and H3K4me3. BTA29:49580452 and BTA29:49580473 are *cis*-eQTLs for *TNNT3-205* (Figure 1C) and integrated with ACRs.

Discussion

Our results were consistent with known bovine ASE genes and indicated conservation of the ASE pattern in cattle muscle. The previous study in Nelore cattle identified 820 ASE SNPs (de Souza *et al.*, 2020), and 479 of them overlapped with our data (WASP filtered out the remaining). With the same population, but using imputation data, it was possible to identify 38,177 ASE SNPs. Additionally, we identified monoallelic expression in various ASE genes that overlapped with genes that are known to be imprinted in bovine. ASE genes are related to metabolic pathways underlying muscle homeostasis and were previously associated with meat-quality phenotypes. For example, *TNNT3* (Troponin 3) is related to muscle contraction (Wei and Jin, 2016) and *HSPA1A* (Heat Shock Protein Family A (Hsp70) Member 1A) was previously associated with ribeye area, water holding capacity, and cooking loss in the Nelore population used here (Tizioto *et al.*, 2013). The overlap of ASE-related SNPs and functional data from FAANG suggests potential mechanisms acting in transcript regulation, as the *cis*-regulation resulting from allele-specific permissive chromatin states. These epigenetic mechanisms need to be further explored in within-population experiments.

Abstract

To profile putative regulatory variants in the bovine and test their validity, we first characterized ~1 million putative regulatory elements by 'Assay for Transposase Accessible Chromatin using Sequencing (ATAC-Seq)' in 77 distinct types of tissues and cells. The elements collectively accounted for 10.3% of the genome, from which we identified 938,374 common DNA variants. We then analyzed bovine blood and liver RNA-Sequencing data and identified 5,336 and 3,613 *cis*-expression Quantitative Trait Loci (eQTL), respectively. Credible sets of DNA variants that drive these *cis*-eQTL were enriched in tissue-specific as well as tissue-shared putative regulatory elements identified by ATAC-Seq. These results pave the way to utilizing ATAC-Seq information to improve genomic selection.

Introduction

Genomic selection has had a tremendous impact on livestock selection in the last ten years (e.g. Georges *et al.*, 2019). The accuracy of selection nonetheless remains inferior to what may be expected given the heritability of the selected traits. This could be due to a number of factors including that all variants are generally given an equivalent weight in computing the additive relationship between animals for Restricted Maximum Likelihood analyses or equivalent prior probabilities of variant effects in Bayesian approaches. Only a minority of variants are indeed causative, with the remainder being (at best) passenger variants in linkage disequilibrium (LD) with one or more of the causative variants. It is generally believed that knowing the causative variants, or at least those that are more likely to be, may help further improve the accuracy of genomic selection.

Amongst causative variants, coding variants (including missense, nonsense, frameshift and splice site variants) are easily recognized. However, these account for only a limited part of the genetic variance for complex phenotypes. It is increasingly apparent that most of the genetic variation for complex traits is due to regulatory variants that act either by perturbing the expression profile of genes located in *cis*, or by perturbing the gene regulatory network and affecting the expression profile of a restricted number of core genes in *trans*. Active regulatory elements can be recognized by virtue of epigenetic features including chromatin accessibility, histone marks, transcriptional activity, their participation in loop structures, and transcription factor occupancy. However, regulatory variants remain difficult to identify, as the effect of polymorphisms on the functionality of proximal and distant *cis*-acting regulatory elements is difficult to predict.

In an effort to identify putative regulatory variants in the bovine, we herein report: (1) the generation of a comprehensive catalogue of bovine putative regulatory elements identified by Assay for Transposase Accessible Chromatin using Sequencing (ATAC-Seq); (2) the generation of a catalogue of common DNA

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_497, © C. Yuan *et al.* 2022

variants that map to identified proximal and distal putative regulatory elements; (3) the demonstration that variants that drive expression Quantitative Trait Loci (eQTL) in liver and blood are more likely to map to regulatory elements that are active in the relevant tissue, and hence that variants in these regulatory elements are more likely to be causative.

Materials & methods

ATAC-Seq. Libraries were constructed following Corces *et al.* (2017) using 78 tissues (65 tissue-types) collected from two juvenile males and 11 archived frozen samples (4 tissue types). Additionally, fifteen public ATAC-Seq data sets (eight tissue/cell-types) were included (Fang *et al.*, 2019, Foissac *et al.*, 2019, Halstead *et al.*, 2020, Johnston *et al.*, 2021). The ATAC-Seq reads were mapped to the bovine reference genome (ARS-UCD1.2) using Bowtie2 (Langmead and Salzberg, 2012) and peaks called with Macs2 (Zhang *et al.*, 2008). Peaks were merged across samples to build a reference chromatin accessibility map following Meuleman *et al.* (2020). The complexity of peak patterning was decomposed using non-negative matrix factorization (NMF) (Meuleman *et al.*, 2020). We used transcriptome data from Fang *et al.* (2020) for a correlation analysis.

eQTL analysis. 224 blood and 176 liver RNA-Seq samples collected from Holstein-Friesian cows were analyzed (Wathes *et al.*, 2021, Lee *et al.*, 2021). The reads were mapped to the reference genome using HISAT2 (Kim *et al.*, 2015). Transcript abundances were estimated using StringTie (Pertea *et al.*, 2015) based on a reference gene annotation (Bos_taurus.ARS-UCD1.2.105.gtf). The data were normalized within sample using DESeq2 (Anders and Huber, 2010) and across samples using inverse normal transformation. Genotypes obtained with 770 K single nucleotide polymorphism (SNP) arrays were further imputed to whole genome using Minimac4 (Das *et al.*, 2016) with the Damona population as a reference, yielding 8.4 million SNPs and 1.3 million insertion-deletions (INDELs) with minor allele frequency (MAF)>0.02. *Cis*-eQTL analyses were conducted using residuals corrected for country and hidden PEER factors (Stegle *et al.*, 2010) under an additive model using QTLtools (false discovery rate (FDR)<0.001) (Delaneau *et al.*, 2017). Enrichment analyses of eQTL variants in ATAC-Seq peaks were conducted following Trynka *et al.* (2017).

Results

Generating a catalogue of bovine cis-acting gene regulatory elements. 89 in-house and 15 publicly available ATAC-Seq data sets (including 77 tissue/cell types) were analyzed and identified on average 166,999 ATAC-Seq peaks per sample. To build a chromatin accessibility reference map, overlapping peaks were merged across the samples, yielding 977,261 chromatin accessible sites. 16 components (representing immune, liver, muscle, central nervous system, etc.) were identified from the 977,261 chromatin accessibility × 104 sample matrix by NMF (Figure 1). Public RNA-Seq data for 58 tissue types were used to search for correlations between chromatin accessibility and gene expression levels to connect regulatory elements with target genes. Highly significant enrichment of positive correlations for genes ≤250 Kb from ATAC-Seq peaks were observed, i.e. potential enhancer effects, without any enrichment for negative correlations, which would be expected for silencers.

Generating a catalogue of common variants mapping to cis-acting regulatory elements. A catalog of DNA variants called from 264 Holstein-Friesian animals containing ~7.6 million SNPs and ~1.2 million INDELs with MAF>0.05 were used. Of these 29,494 (0.34%) mapped to proximal and 909,074 (10.4%) to distal putative regulatory elements accounting respectively for 0.37 and 9.9% of sequence space, hence providing no strong evidence for detectable purifying selection.

Identifying bovine cis-eQTL in blood and liver. To identify putative causative variants affecting gene expression, eQTL analyses using 224 blood and 176 liver RNA-Seq data were performed. 5,336 (37% of

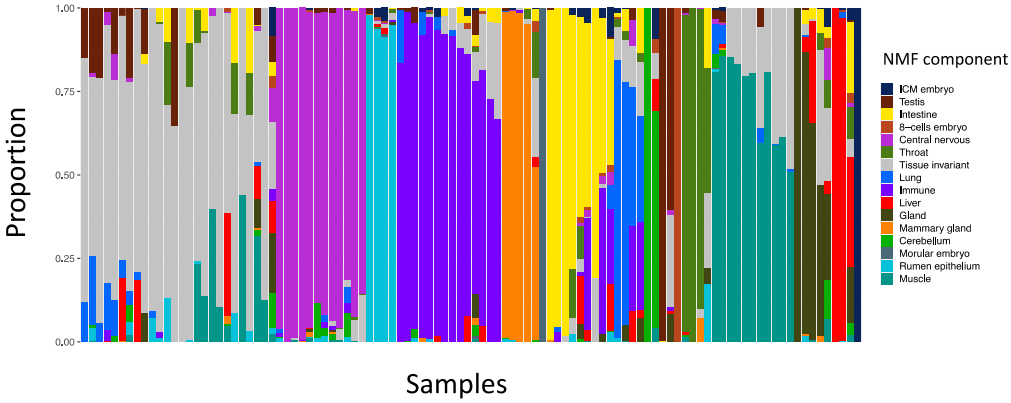

Figure 1. Identification of 16 components by NMF-decomposition of a 977,261 chromatin accessibility × 104 sample matrix and importance of the components in the bovine tissues.

genes) and 3,613 (23%) significant eQTL in the blood and liver, respectively, were obtained. The proportion of blood-eQTL that would also operate in liver (π_1) was estimated by following Storey and Tibshirani (2003) at 74%, while the proportion of liver-eQTL that would also operate in blood was estimated at 81%. These unexpectedly high values could in part be due to blood irrigating the liver.

eQTL-driving variants are enriched in variants mapping to ATAC-Seq peaks. It was assumed that, if variants mapping to ATAC-Seq peaks were indeed enriched in causative variants, they should be enriched in credible sets of variants driving *cis*-eQTL effects (i.e. the lead *cis*-eQTL SNPs and syntenic variants in LD with it). The significance of the overlap between *cis*-eQTL credible sets and ATAC-Seq peaks was evaluated by NMF components (by assigning each peak to its dominant NMF component). Credible variant sets ($r^2 \geq 0.8$) for 3,336 blood-specific *cis*-eQTL were significantly ($P<10^{-5}$) enriched in variants overlapping ATAC-Seq peaks that were assigned to the immune (1.21-fold enrichment), tissue-shared (1.17-fold) and pulmonary (1.15-fold) components. Credible sets for 1,613 liver-specific *cis*-eQTL were enriched in variants mapping to ATAC-Seq peaks assigned to the hepatic (1.42-fold), tissue-shared (1.21-fold) and pulmonary (1.15-fold) components. Permutation testing conditional on proximal vs distal status of the ATAC-Seq peaks indicated that the observed enrichment was not due to an enrichment of variants mapping to promotor regions irrespective of ATAC-Seq chromatin accessibility.

Discussion

These results indicate that genetic variants causing *cis*-eQTL are enriched in variants that map to ATAC-Seq peaks marking accessible chromatin regions, and hence likely to active regulatory elements, in the corresponding tissue. This suggests that sets of variants overlapping ATAC-Seq peaks are enriched for regulatory variants, and hence potentially driving organismal phenotypes. Assigning such variants with extra weight in genomic selection may therefore improve its accuracy. However, this putative improvement will dependent on: (1) the proportion of variants mapping to ATAC-Seq peaks that are indeed causative for a trait of interest; and (2) the proportion of causative regulatory variants that map to ATAC-Seq peaks. Further analyses are in progress to estimate these features, and to evaluate the impact of the identified variants sorted by the NMF component on genomic selection.

Abstract

Rumen microbiota plays an important role in ruminant metabolism as well as immunity development. As such, the microbiome serves as a link between diet and animal productivity. The aim of this study was to examine fecal samples of Afrikaner cattle at weaning age using 16S rRNA targeted metagenomics to determine if there are any association with above average performing animals and the rumen microbiome. Rumen microbiomes were similar with no statistically significant differences observed between above and below average performing animals. However, various individual microbial genera were found to be associated performance, such as the lactic acid bacteria (LAB) *Lactobacillus* and *Enterococcus.* This preliminary study highlights both the importance of the transmission of important maternal rumen microbiota to the offspring and the importance of host genetics for the colonization of these organisms.

Introduction

Feed costs can represent more than half of the total cost of production in the beef cattle industry (Mathews and McBride, 2011). This has led to various novel methods to improve feed efficiency and nutrient utilization. Rumen microbial communities are directly correlated to several host phenotypes, including feed efficiency (Myer *et al.*, 2017). These microorganisms produce glucogenic, lipogenic and aminogenic precursors that partake in energy metabolism (Hungate, 1975). This can represent up to 70% of the metabolic energy utilized by the animal (Bergman, 1990). As such, the microbiome may serve as a link between diet and animal productivity (Mullins *et al.*, 2013).

In general, it has been commonly accepted that diet is the main driving force shaping the gut microbial diversity (Spor *et al.*, 2011). However, more and more research are starting to indicate host genetics is also an important factor in determining the composition of gut microbiota. In mice, 18 quantitative trait loci (QTLs) were found to be associated with the relative abundance of microbial taxa in the gut (Benson *et al.*, 2010). More recently, 58 single nucleotide polymorphisms (SNPs) were also identified in reference to 33 fecal microbial taxa in humans (Turpin *et al.*, 2016). In ruminants it has been shown that rumen microbial diversities could be influenced by breed. For example, differences in the composition of rumen microbiota between Holstein and Jersey was detected while being fed on the same diet (Paz *et al.*, 2016). Of note are the recent reports of heritability estimates for rumen bacteria based on 750 lactating Holstein cows (Difford *et al.*, 2018). Based on all these finding, it is becoming more evident that host genetics are influencing the rumen microbiota, however, even though much research has been done on the influence of diet on the rumen microbiome, the connection between the microbiome, production traits and genetics in beef cattle remain unclear.

The aim of this preliminary study was to determine whether the rumen microbiome can serve as a predictor of performance in beef cattle.

Materials & methods

Sample and data collection. A total of 32 Afrikaner cattle were raised under the same feedlot conditions at the Paradys Experimental Farm facility of the University of the Free State, South Africa. When the animals were 257±27 days of age, approximately 10 g of fecal matter was collected from each animal. Fresh fecal matter was collected from the interior of the produced cowpat, in an effort to minimize environmental contamination, in a 50 ml Falcon tube. All samples were stored at -20 °C until further processing. Weaning weights of all animals were weighed at 223±16 days and all weights were adjusted to 205 days as well as for age of the dam.

DNA extraction and targeted 16S metagenomic sequencing. DNA was isolated from each fecal samples using ZymoBIOMICS DNA Miniprep Kit (Zymo Research). To assess the bacterial profiles, the V3-V4 region were amplified using the primers 341F (5'-CCTACGGGNGGCWGCAG-3') and 805R (5'-GACTACHVGGGTATCTAATCC-3'). Paired-end sequencing (2×300 bp) of amplicons was performed using the Illumina MiSeq at mrDNA (Shallowater, TX, USA).

Microbial composition analysis. Read data was analyzed using QIIME 2 (https://qiime2.org) (Caporaso *et al.*, 2010). Paired-end sequences imported into QIIME 2 were quality-controlled and combined using DADA2. The settings for quality control were based on the reads' quality distribution along the length of the sequence. This grouped sequences into amplicon sequence variants (ASVs) based on 99% sequence similarity. After building the ASV table and removing chimeras, taxonomy was assigned using the SILVA 132 database (SILVA).

Statistical analysis. The processed gene sequence data was further analyzed using RStudio, an integrated development environment (IDE) for the programming language R. The following R packages were used during the processing of the taxonomic data: Phyloseq (McMudie and Holmes 2013), Tidyverse (Wickham 2017), Vegan (Dixon, 2003).

To facilitate comparative analysis, animals were divided into three groups; one standard deviation above the mean weaning weight of all sampled animals (Above), one standard deviation below the mean weaning weight of all sampled animals (Below) and between one standard deviation above and below (Average). Permutational multivariate analysis of variance (PERMANOVA), using the adonis function in the R Vegan package, was used to determine significance in dissimilarity matrices across samples in these three categories. Differential abundance analysis between the three groups were performed using DeSeq2 (v 1.22.1) (Love *et al.*, 2014).

Results

Microbial diversities across all groups were similar (PERMANOVA, $P>0.05$). The microbial consortia were dominated by the phyla Actinobacteria, Bacteroidetes, Euryarchaeota and Firmicutes (Figure 1). DeSeq2 analysis identified various microbial genera associated with above and below average weaning weight performance. *Lactobacillus*, *Enterococcus* spp. and members of a Lachnospiracaea group were all associated with improved performance while *Bacillus* sp., *Psychrobacillus* and *Cellulosilyricum* sp. were associated with lower performance (Figure 2).

Discussion

In cattle, Firmicutes and Bacteroidetes are usually the most dominant phyla, however, there is no known 'normal' rumen microbiome (Henderson *et al.*, 2015). In this study, all animals were from the same breed and subjected to the same environmental conditions and diet. Although no statistically significant differences, for microbiome communities as a whole, were observed between above and below average performers

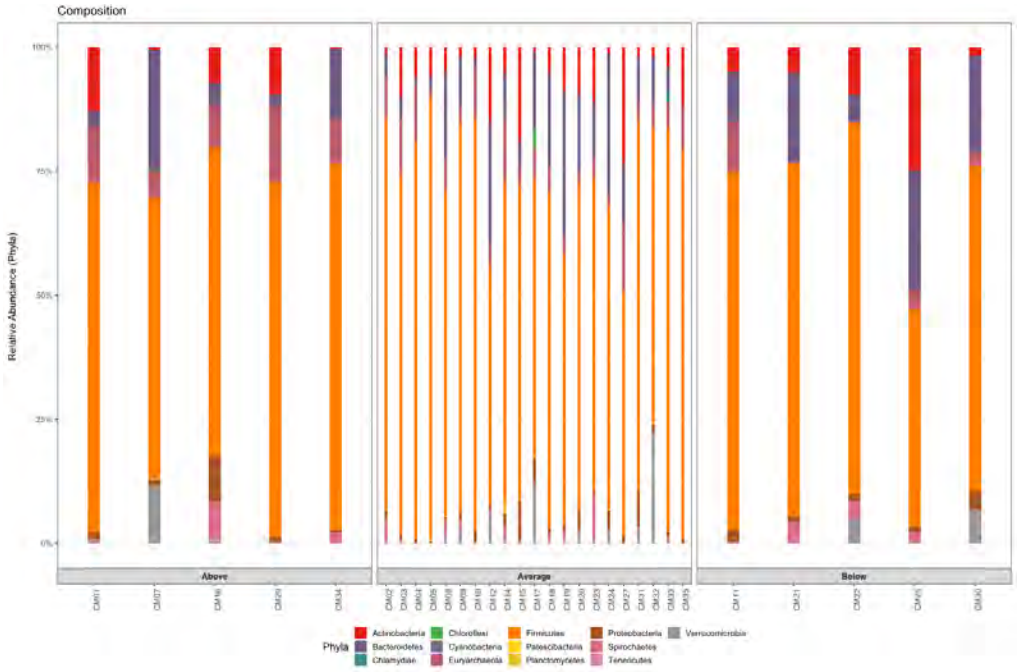

Figure 1. Phyla level bacterial diversity of fecal samples. Samples above and below one standard deviation from the mean were grouped together.

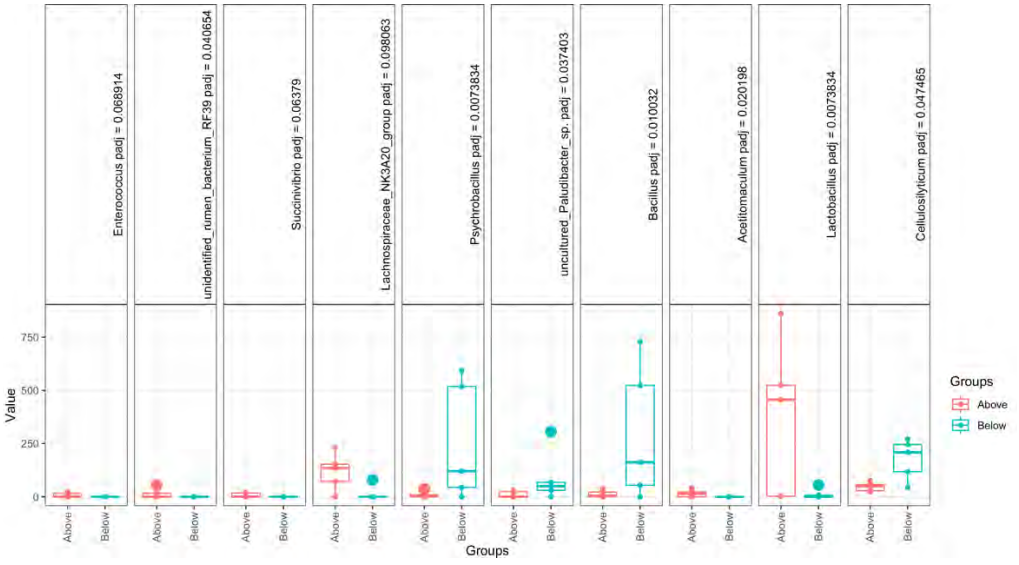

Figure 2. Differentially abundant genera between above and below average weaning weight performing samples.

for weaning weight (PERMANOVA, $P>0.05$), important differences were determined on a community member level. *Lactobacillus* and *Enterococcus* spp. were significantly (DeSeq2, $P<0.05$) more abundant in the samples from above average performing animals. A stable load of lactic acid bacteria (LAB), such as *Lactobacillus* and *Enterococcus,* has been shown to improve weight gain and immunocompetence in young calves as well as improve intestinal health and feed conversion efficiency (Al-Saiady, 2010). Also, early colonization by LAB in the intestine may decrease the adherence of pathogens to the intestinal mucosa.

Most studies on cattle production and LAB focus on feed additives. In this preliminary study the LAB was naturally occurring and appear to have contributed to the increased performance of the animals, however, a larger study with more animals would be required to validate these findings. The intestine of a newly born calf is sterile, thereafter a complex microbial ecosystem is established in the large intestine as the animal grows to maturity. The initial microbiota of the calf is thus influenced by the microbiota of the birth canal, the dam's fecal microbiota and the colostrum fed. As such, this preliminary study appears to hint that some part of the heritable maternal microbiome could result in improved production in the progeny and that host genetics might play an important role in improving colonization rates of LAB in the intestinal track.

499. Maternal effect on the metagenomic composition determining the intramuscular fat content in rabbits

A. Zubiri-Gaitán[1*], M. Mora[2], C. Casto-Rebollo[1], M.A. Santacreu[1], A. Blasco[1], P. Hernández[1] and N. Ibañez-Escriche[1]

Abstract

The intramuscular fat (IMF) content is one of the main parameters influencing meat quality and its deposition is influenced by the gut microbiome composition. This composition is determined by several effects including environmental, genomic, and maternal. A divergent selection experiment for IMF has been developed in rabbits. Embryos from the high-IMF (H) and low-IMF (L) lines were randomly transferred to dams of both lines. To evaluate the maternal effect, kits from the same genetic line but born from dams of the H and L lines were compared. The analysis performed confirmed the existence of an important maternal effect that affected the metagenome composition of the lines and, ultimately, their IMF content. The microbial genes discriminating between the groups were different when the genetic line of the kits varied. However, there were no important differences in their metabolomic pathways.

Introduction

The intramuscular fat (IMF) content is one of the main parameters influencing meat quality. The genetic and environmental factors influencing this trait have been extensively studied and, over the last few years, the gut metagenome has gained importance. Numerous studies suggest that the former plays an important role in the host metabolism affecting, among others, the energy harvest and fat deposition (Bäckhed *et al.* 2004; Khanal *et al.* 2020; Turnbaugh *et al.* 2006). The microbiome composition, and its metagenome, can be easily modified by environmental factors such as diet, and is also determined by the host's genome (Wen and Duffy 2017). The mother plays an important role in determining the microbiome composition as well. During labor, the microbiome composition of the kits is influenced due to the exposure to the vaginal microbiota of the mother and, after that, due to the microbiota of the milk ingested during breastfeeding (Wen and Duffy 2017). A better understanding of the maternal effects on the microbiome composition is key to optimize the phenotypic improvement of the populations.

A divergent selection experiment for IMF content in the *Longissimus thoracis et lumborum* muscle of rabbits has been developed at the Universitat Politècnica de València. The selection originated two lines, one with high-IMF (H) content and the other with low-IMF (L) content. These lines are exceptional to study the effects influencing the trait. The complete selection experiment is described in Martínez-Álvaro *et al.* (2016).

The objective of this study was to analyze the importance of the maternal effect in the metagenome composition of the divergent lines and, ultimately, on their intramuscular fat content.

Materials & methods

To evaluate the maternal effect, embryos from the H and L lines were randomly transferred to dams of both lines from the 10th generation of divergent selection. To do so, 14 dams from the H and 9 dams from the L line were used as embryo donors, and 8 dams from the H line and 6 from the L line were used as embryo recipients. The embryos were transferred to the recipients 72 h after the fertilization. Genotype information from a previous generation of selection was used to select fixed SNPs in each line, which would

allow identifying the genetic line of the kits. After the kits were born, DNA was extracted from an ear tissue sample, and the genotype of the selected SNPs was determined by HRM (high-resolution melting). Finally, 4 groups were obtained according to the genetic line of the recipient dam and of the kit. The groups were identified as HH, HL, LH, and LL. The first letter of each group indicates the genetic line of the dam and the second one is the genetic line of the kit. For this experiment, 73 rabbits from the 4 groups were used, distributed as follows: 20 HH, 19 HL, 19 LH, and 15 LL.

The kits were weaned at 28 days, housed collectively with their own litter, and fed *ad libitum* with a commercial diet until the slaughter at 9 weeks of age. Animals were deprived of food 4 h before the sampling. After slaughter, cecum content samples were collected, homogenized, and stored at -80 °C. The metagenome of the samples was sequenced at Sistemas Genómicos (Valencia, Spain). Sequencing was performed on NextSeq 550 sequencer (Illumina) with 150 bp paired-end chemistry. The data obtained were processed using the SqueezeMeta fully automatic metagenomics analysis pipeline (Tamames and Puente-Sánchez 2019), using the coassembly mode. The microbial genes and their metabolic routes were identified by homology to the Kyoto Encyclopaedia of Genes and Genomes (KEGG).

The dataset obtained had 7,195 microbial genes (MG). After exploratory analyses, all MGs that were undetected (i.e. 0 counts) in at least one sample were discarded. The final dataset had 4,572 MGs that accounted for more than 99.8% of the total counts of each sample. To deal with the compositional nature of the metagenomic data (Gloor *et al.* 2017), the counts was transformed using additive log-ratio (ALR) transformation. The reference gene for the ALR was selected according to the criteria established by Greenacre *et al.* (2021).

The maternal effect was evaluated by performing the following group comparisons: HH vs LH to evaluate the effect when the kits were from the H line, and HL vs LL to evaluate it when the kits were from the L line. The MGs discriminating between groups were identified by Projection to Latent Structures – Discriminant Analysis (PLS-DA), using the program SIMCA (Sartorius; Umea; Sweden). The model for each comparison was adjusted and the MGs responsible for the discrimination between maternal lines were identified using the variable importance in projection (VIP) value. A first variable selection step was performed to reduce the noise of the data, in which all the MGs with a VIP<1 were discarded. The models were then re-estimated and their adjustment was assessed with the coefficient of determination (R^2). The predictive capacity of the models was estimated with the Q^2, which is equivalent to a R^2 after cross-validation (CV). A misclassification table was elaborated for each model, based on the CV results. Finally, the MGs selected for both models were compared.

The same group comparisons were made to study the maternal effect on the IMF content. The differences were estimated as the phenotypic differences between groups. The model included the fixed effect of group and sex. Bayesian inference was applied using the program Rabbit (Institute for Animal Science and Technology, UPV, Valencia, Spain). The marginal posterior distributions of the phenotypic differences were obtained. The parameters of the posterior distributions taken into consideration account were the median of the phenotypic difference and the probability of the absolute value of the difference of being greater than zero.

Results

Figure 1 shows the projection of the samples into the space formed by the first two latent variables of the PLS-DA models (score plot). The number of MGs selected after the selection step were 1,763 for the model comparing HH vs LH, and 1,677 for the one comparing HL vs LL. Both models presented good adjustment (R^2>97%) and predictive capacity (Q^2>85%). Also, they were able to correctly classify all the samples after the cross-validation procedure, as evidenced by the percentage of classification (Table 1). The clear discrimination between the maternal lines in both models (i.e. independently of the genetic line of the kits) confirms the existence of a maternal effect that affected the metagenome composition of the lines.

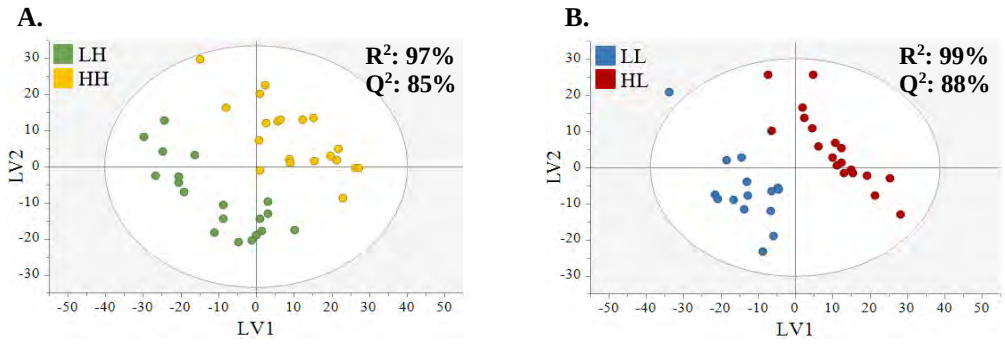

Figure 1. Projection of the samples in the space formed by the latent variables of each PLS-DA. HH, LH, HL, LL: the first letter indicates the genetic line of the dam and the second the genetic line of the kit. H: high-IMF; L: low-IMF. A. Model 1: maternal effect when the kits are from the H line. B. Model 2: maternal effect when the kits are from the L line.

Once the influence of the maternal effect was confirmed, the MGs responsible for the discrimination in both models were compared. Most of the MGs discriminating between the groups were different in both models (around 10% of overlap, Venn diagram not shown), meaning that the maternal effect on the metagenome composition is different according to the genetic line of the kit. However, when comparing the pathways in which those MGs were involved, common subgroups were found. The most affected pathways were carbohydrate transport and metabolism, amino acid transport and metabolism, energy production and conversion, cell envelope biogenesis, and signal transduction mechanisms, among others.

Differences were found in the IMF content of the kits, depending on the genetic line of their mother. The phenotypic difference between HH and LH was 0.03 g IMF/100 g of *LTL*, with a probability of 76% of being greater than 0. On the other hand, the difference between HL and LL was 0.04 g IMF/100 g of *LTL*, with an 82% probability of being greater than 0.

Discussion

The metagenome composition is influenced by several factors, including environmental, genetic, and maternal (Wen and Duffy 2017). The divergent lines used for this experiment were contemporarily reared, under the same environmental conditions, and were fed the same diet. Hence, no difference in their metagenome composition is expected due to environmental factors. Martínez-Álvaro *et al.* (2021) confirmed the influence of the metagenome composition on their IMF content, and the link between the host's genome and its metagenome, in a previous metagenomic analysis performed on these lines. However,

[1] Model 1: maternal effect when the kits are from the high-IMF line (H).

[2] Model 2: maternal effect when the kits are from the low-IMF line (L).

[3] HH, LH, HL, LL: the first letter indicates the genetic line of the dam, and the second one is the genetic line of the kit.

they could not differentiate between the genetic and the maternal effects. The experimental design of the present study and the comparisons made ensured the possibility of separating the maternal and the genetic effects, avoiding their confusion.

The mother alters the metagenome composition of the kit through several mechanisms, such as feeding. The microbiome composition of the milk, but also its nutrients, could influence the core metagenome of the kits. An analysis performed on the milk composition of these lines found important differences in their fat (higher in the H line) and lactose (higher in the L line) composition (results not shown). The former could explain the higher IMF content found on the kits born from a high-IMF line dam, and it provides evidence of a maternal environmental effect influencing the metagenome composition. Besides, the probabilities of difference in the IMF content, mentioned in the results section, give enough confidence to support the relevance of the maternal effect. Finally, El Nagar *et al.* (2021) also found a relevant maternal effect for IMF in a previous quantitative genetic study, reinforcing the results found in this experiment.

Several studies have suggested the importance of the maternal effect on the microbiome composition. However, this is the first study that allows to measure it directly because of the exceptional animal material used and the experimental design. Hence, the differences found between the groups can be directly attributed to the maternal effect on the gut metagenome composition. The results of this study proved that the mother plays an important role in determining the mentioned composition of the kits. Even though the results showed that the maternal effect was different according to the genetic line of the kit, a preliminary analysis suggested that the pathways affected were the same. A thorough biological analysis is still needed to elucidate the mechanisms by which the genetic and maternal factors influence on the gut metagenome composition and, ultimately, on the IMF deposition of these lines.

500. The gut microbiome profile varies among two maternal rabbit lines with different longevity

I. Biada*, N. Ibáñez-Escriche, A. Blasco and M.A. Santacreu

Institute for Animal Science and Technology, Universitat Politècnica de València, 46022 València, Spain; ibiada@posgrado.upv.es

Abstract

Analyses of the gut microbiome profile using bacterial 16S rRNA gene between two maternal rabbit lines (A and LP) and two groups of animals from line LP with different longevity (LLP and HLP, females up to four parities and with more than four parities, respectively) were carried out. For that, 298 soft faeces samples collected from 191 does were sequenced. After filtering and quality control, the sequences were analysed using QIIME2. Differences between lines A and LP (DLINES) and between groups LLP and HLP (DLP GROUPS) in both alpha and beta diversities indexes at first parity were observed. The PLS-DA analysis allowed us to identify 45 and 37 Amplicon Sequence Variants (ASVs) that were able to discriminate between lines A and LP, and between the two groups within line LP. *Eubacteriacea* and *Ruminococcus* were the main taxa presented in the final ASVs for both DLINES and DLP GROUPS comparison. Preliminary results support that gut microbiome profile is related to longevity and it could be used to improve resilience in rabbits commercial lines.

Introduction

Resilience and longevity are important traits on rabbits' production but are difficult as criteria of selection. Indirect selection for resilience has been proposed in rabbits by Argente *et al.* (2019) using a low heritability criterion (residual litter size variance), and line LP of this experiment was founded using longevity as a criterion for better resilience, but longevity shows also low heritability (Piles *et al.* 2006) and is recorded late in the animal's life when they die or are culled (Sánchez *et al.* 2008). An alternative criterion to increase longevity and resilience in rabbit production can be based on knowledge on the rabbit's gut microbiome. The gut microbiome is important in regulating traits related to health and welfare and it plays a key role in immune system development (Round and Mazmanian 2009). Therefore, the aim of this research was to compare the microbiota of two lines with different longevity to study the association between gut microbiota profile and longevity and resilience. Results from this study would allow stablishing a selection criteria based on the gut microbiome composition for improving the rabbit resilience.

Materials & methods

Animals. Two contemporaneous rabbit lines, line LP and A, with different criteria of foundation and currently selected for litter size at weaning were used in this experiment. Particularly, females of the 15th generation of line LP ('resilient' line) and of the 50th generation line A (standard line). Line LP was founded with females with a minimum of 25 parities and having an average prolificacy per parity close to the average of the Spanish commercial population in 2002 (Sánchez *et al.*, 2008). Line A has a New Zealand White origin. Females were housed at the farm of the Universitat Politècnica de València.

Sample collection and 16S rRNA gene sequencing. From both lines, soft faeces samples were taken from the anus after their first parities and the females were allowed to reach the maximum number of parities possible. The complete data set included 298 samples records, involving 191 does (117 of line LP, and 74 of line A), and the data set was recorded from 23/04/2019 to 20/07/2020. The 16S rRNA gene profile of the samples were analysed using amplicon sequencing protocol targeting the V3 and V4 hypervariable regions (459bp) of bacterial 16S rRNA gene with the primers designed surrounding conserved regions. The

DOI: 10.3920/978-90-8686-940-4_500, © I. Biada *et al.* 2022

microbial 16S rDNA profiles of the DNA extracts were analysed using MiSeq 16S rRNA gene-sequencing protocols (Illumina).

Bioinformatic analyses. The sequences of the amplicons were analysed using QIIME2 software version 2021.11 (Bolyen 2019) and sequences were clustered into ASVs using DADA2, the final table had 59072 ASVs. For Taxonomic annotation we used a Naive Bayes classified. This classifier was pre-trained on the SILVA database ('silva-138-99-nb-classifier').

Statistical analyses. Two comparisons were carried out: (1) the difference of the gut microbiota profile between lines A and LP at first parity (DLINES); (2) the difference of the gut microbiota profile at fist parity between animals of line LP reached five parities or more and the ones who died or were sacrificed before (DLP GROUPS).

Diversity measures. Alpha and beta diversity metrics were calculated after samples were subsampled without replacement (rarefied) to 24,000 sequences per sample. Four α-diversity metrics were computed: Shannon's diversity index (Shannon and Weaver 1949), Observed features (DeSantis *et al.* 2006), Evenness (Pielou 1966) and Faith's Phylogenetic Diversity (Faith 1992). A permutational multivariate analysis of variance (PERMANOVA) statistical test was applied on four dissimilarity matrixes (Bray-Curtis, Jaccard, Unweighted and Weighted Unifrac) to determine gut microbiome profile differences. To rule out differences due to a high degree of dispersion (within-group variance), we made a permutation test (PERMDISP).

PLS-DA (partial least squares discriminant analyses). The PLS-DA was performed at ASVs level after filtering samples <100 reads, ASVs<10 and not present in at least 20% of samples. Additive log ratio transformation was applied to the filtered abundance table (Greenacre 2018). The reference variable was those with the lowest coefficient of variation and a high mean of counts. Procrustes analysis was performed to verify the quality of the transformation (Greenacre *et al*., 2021). The Procrustes correlation was 0.98. PLS-DA was performed to address differences in the microbiota profiles with 'mixOmics' package of R (Lê Cao *et al.* 2011). Those ASVs with balance error rate (BER) of the classification between groups for each analysis (DLINES and DLP GROUPS) reaching the minimum value were identified. Finally, a permutation test and a confusion matrix were computed to check the robustness of PLS-DA for both analyses.

Results

Diversity measures. Table 1 showed differences on the Shannon and Observed Features α-diversities indexes in the two comparisons performed (DLINES and DLP GROUPS). The difference in Pielou's Evenness α-diversities index was found for the DLINES comparison, whereas for the DLP GROUPS comparison was in Faith paid index (Table 1). The Bray-Curtis, Jaccard Weighted and Unweighted Unifrac Matrixes β-diversities indexes showed differences between DLINES groups for the PERMANOVA test (P=0.013, P=0.001, P=0.005 and P=0.005). However, the weighted and unweighted Unifrac results could be due to high degree of dispersion according to the permutation test (P=0.004 and P=0.012). For the DLP GROUPS only the unweighted Unifrac showed clear differences between groups with a P-value of 0.013 for the PERMANOVA test and a P-value of 0.57 for the permutation test.

PLS-DA. PLS-DA models with the minimum BER identified 45 ASVs able to discriminate between groups for the DLINES comparison and 37 ASVs for the DLP GROUPS comparison (Figure 1).

The confusion matrix showed 80% true positives (sample correctly predicted to the line) and 86.5% true negatives (correctly predicted that the sample did not belong to the assigned line) for DLINES comparison. In the case of DLP GROUPS comparison these values were 79% true positives and 72.4% true negatives.

Table 1. Kruskal-Wallis test of Observed Features, Pielou Evenness, Shannon and Faiths pd α-diversity indexes for the line A and LP (DLINES) and line LP with less than 5 and more than 5 parities (DLP GROUPS).

Comparison	DLINES		DLP GROUPS	
	α-diversity	*P*-value	α-diversity	*P*-value
Pielou evenness	6.73	0.009	0.999	0.317
Faiths pd	1.91	0.166	6.19	0.013
Observed features	6.79	0.009	3.82	0.051
Shannon	4.25	0.039	3.09	0.079

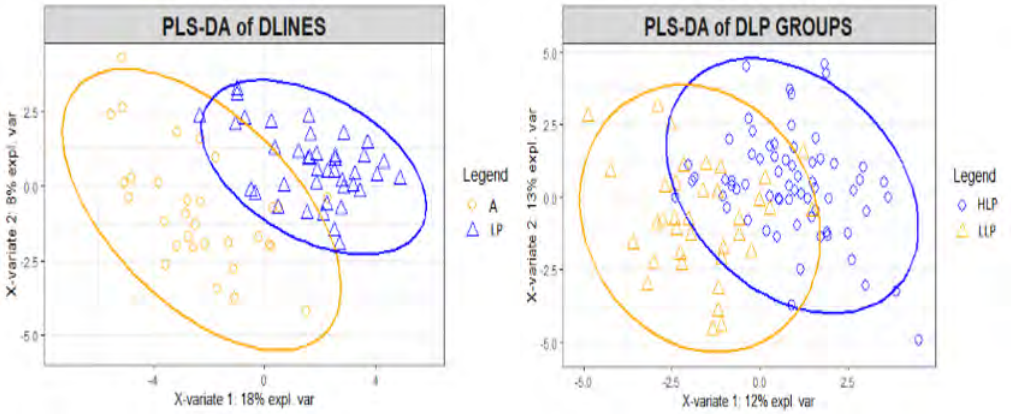

Figure 1. Representation of individual plots of first and second components of partial least squares discriminant analysis (PLS-DA) between line A and LP (DLINES, left plot) and between line LP with less than 5 (LLP) and more than 5 parities (HLP, right plot), each line is represented by a different colour, contoured by 95% confidence ellipses, n=71 for DLINES and n=103 for DLP GROUPS.

The permutation test showed ~50% of true positives and negatives for DLINES and DLP GROUPS. These results would indicate the ASVs identified in the PLS-DA not randomly discriminate between groups. After taxonomy annotation, *Eubacteriaceae* (35.5%), *Ruminococcus* (20%) *and Akkermansiaceae* (15.5%) were the main families of the 45 ASVs classifying between line A and LP (DLINES). For the DLP GROUPS comparison the main families identified were *Oscillospiraceae* (35.13%), *Eubacteriaceae* (16.2%), *Lachnospiraceae* (10.8%) and *Ruminococcus* (10.8%).

Discussion

The results of this study showed that the observed operational taxonomic units (OTUs) and Shannon α-diversities indexes representing community richness were greater in line A (less longevity) than in line LP. This will be in disagreement with the common assumption that animals with the greater diverse microbial community are potentially have better gut health (Fouhse *et al.*2016). However, in our study also the individuals of line LP with less longevity (<5 parties) showed a greater diversity than those with more longevity for the Faith pd index. Similar findings were presented in a recent study (Savietto *et al.* 2020). In addition, beta diversity metrics and PLS-DA analysis evidenced also differences between the gut microbiota profile of lines and individuals of different longevity. The ASVs identified in DLINES's PLS-DA belong mainly to Akkermansiaceae family. In rabbits Akkermansiaceae, especially Akkermansia muciniphila, plays a protective role in diet induced obesity and other diseases (Li *et al.* 2021, unpublished

data) and is also considered as beneficial microbe to immunity (Naito *et al.* 2018). The Eubacteriaceae and Ruminococcaceae families were present in DLINES and DLP GROUPS's PLS-DA. Eubacteriaceae and three groups from the family Ruminococcaceae belong to the bacterial taxa that are most common across the entire rabbit gastrointestinal tract (Cotozzolo *et al.* 2020) Ruminococcaceae are also a butyrate-producing bacteria which are associated with a healthy gut microbiome (Funosas *et al.* 2021).

501. Comparing methods to summarize gut microbiota composition in estimating microbiability of host phenotypes in swine

Y. He[1], C. Maltecca[1*], J. Howard[2], Y. Huang[2], K. Gray[2] and F. Tiezzi[1,3]

[1]Department of Animal Science, North Carolina State University, 120 W Broughton Dr, Raleigh, NC 27607, USA; [2]Smithfield Premium Genetics, Rose Hill, NC 28458, USA; [3]Department of Agriculture, Food, Environment and Forestry (DAGRI), University of Florence, Piazzale delle Cascine 18, 50144 Firenze, Italy; cmaltec@ncsu.edu

Abstract

This study aimed to investigate eight approaches (four kernel functions, two distance methods, and two ordination methods) for creating covariance matrices to summarize microbiome information among animals and assess their performance in estimating trait microbiability in three commercial swine breeds. We collected rectal swabs and measured several growth and carcass composition traits on 651 pigs (Duroc: n=205; Landrace: n=226; Large White: n=220) at market weight. Based on the matrix used, microbiability estimates ranged from 0.07 to 0.21 and 0.12 to 0.53 for Duroc, 0.03 to 0.21 and 0.05 to 0.44 for Landrace, and 0.02 to 0.24 and 0.05 to 0.52 for Large White pigs averaged over traits in the model with sire, pen, and microbiome, and model with only microbiome, respectively. We observed differences in the contribution to trait microbiability estimation across the eight matrices.

Introduction

Gut microbiota have recently received great attention in livestock research. In swine, the gut microbiome composition has been associated with variations in host phenotypes, such as meat quality and carcass traits (Khanal *et al.*, 2021), feed efficiency (Camarinha-Silva *et al.*, 2017), and feeding behaviour (He *et al.*, 2022). This proportion of phenotypic variance accounted by the microbiota composition was termed 'microbiability' by Difford *et al.* (Difford *et al.*, 2016). The microbial information of individuals in a group can be summarized in a square matrix M and inform a mixed linear model. Most studies used the method introduced by Ross *et al.* (2013) to construct the microbial relationship matrix for microbiability estimation and phenotype prediction (Camarinha-Silva *et al.*, 2017; Difford *et al.*, 2016; Khanal *et al.*, 2021). However, due to the complexity and special features of the microbiome data (Coenen *et al.*, 2020), other methods, such as distance matrix and ordination based on the sample covariance, could be considered as alternative approaches to summarize the microbial information. In recent studies, Saborío-Montero *et al.* (2021) evaluated different matrices based on ruminal microbiota in estimating microbiability for methane emission in cattle. Unfortunately, there is still a lack of relevant research in swine to the best of our knowledge. Thus, we applied eight approaches to build the microbial matrices and compare their contributions to estimating the trait microbiability in three pig breeds.

Materials & methods

Animal and data. This study included 651 boars from either three breeds: Duroc (DR; n=205), Landrace (LR; n=226), and Large White (LW; n=220). After weaning, pigs were kept by single-breed groups in 64 pens and fed the same pelleted feed throughout the fattening period. Growth and carcass composition traits, including body weight (BW), and ultrasound backfat thickness (BF), muscle depth (MD), and intramuscular fat (IMF) content, were measured on live animals when they reached the market weight at an average age of 156±3 days. Rectal swabs were taken from each pig at 158±4 days of age and subjected to 16S rRNA gene sequencing. The procedures for sequencing and processing the sequence data are described in our previous studies (He *et al.*, 2022; Lu *et al.*, 2018). The amplicon sequence variant (ASV) table was subjected to quality control. The ASVs were removed if the overall counts were less than 1000 across all

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_501, © Y. He *et al.* 2022

samples and with a prevalence rate less than 0.05. A total of 824 ASVs passed the quality control and was used in the analyses.

Microbial similarity matrices construction. We used eight methods from three types to create the M matrix, which captures the resemblance among individuals in a population based on the abundance of their gut microbiota. First, we used four general kernel functions described in (Montesinos-López *et al.*, 2021): Linear Kernel (LK), Polynomial Kernel (PK), Gaussian Kernel (GK), and Arc-cosine Kernel with one hidden layer (AK1) for creating the M matrix. The ASV counts were log-transformed, then centred and scaled before being used in the kernel functions provided in (Montesinos-López *et al.*, 2021). Then, we created two distance matrices: Bray-Curtis (BC) and Jaccard (JA), on the log-transformed ASV count data using the *vegdist* function of *vegan* package (Dixon, 2003) in R. The resulting distance matrices were square with zero on the diagonal and values ranging from zero to one on the off diagonal. The M matrix was then calculated by one minus each distance matrix. Lastly, two ordination methods: Metric Multidimensional Scaling (MDS; known as Principal Coordinates Analysis) and Detrended Correspondence Analysis (DCA) were used to construct the M matrices from the BC distance matrix. Ordinate vectors for MDS and projections for DCA were obtained using the *ordinate* function of the *phyloseq* package (McMurdie and Holmes, 2013). The procedures to build the M matrices from vectors and projections are described in (Saborío-Montero *et al.*, 2021).

Microbiability estimation. We fitted the following two models for each breed group to investigate the proportion of phenotypic variation explained by the gut microbiota composition, environment, and genetic background.

$$\text{Model_S_P_M: } y_{ijkl} = u + \text{sire}_i + \text{pen}_j + m_k + e_{ijkl} \quad (1)$$

$$\text{Model_M: } y_{kl} = u + m_k + e_{kl} \quad (2)$$

Where y is the trait measures, u was the overall intercept, sire_i was the random effects of i^{th} sire, pen_j is the random effect of j^{th} pen, m_k contains the random effects of gut microbiota for each individual with $m \sim N(0, M\sigma_m^2)$, where M is the microbial relationship matrix created by one of the eight methods described in the previous section and σ_m^2 is the microbial variance, e is the residual.

We fitted the Bayesian ridge regression models as implemented by *BGLR* package (Pérez and De Los Campos, 2014) in R. A Markov chain Monte Carlo algorithm was used to perform the analyses with 150,000 iterations, 50,000 iterations discarded as burn-in, and 10 iterations set as the thinning interval. The microbiability was calculated as the σ_m^2 over the total phenotypic variance.

Results

Pearson's correlation coefficients between the off-diagonal elements (beta-diversity) of the microbial similarity matrices are depicted in Figure 1. Overall, the patterns of correlations among matrices were similar across breeds. The highest correlations (r=0.99 to 1.00) were found between two distance-based matrices JA and BC in three breeds. Strong positive correlations (r=0.60 to 0.97) were found between LK and MDS, LK and AK1, BC and GK, JA and GK, and MDS and AK1 matrices. However, the beta-diversity among animals captured by JA and BC matrices was distinct from that captured by DCA, AK1, and PK, with negative to small correlations between the matrices.

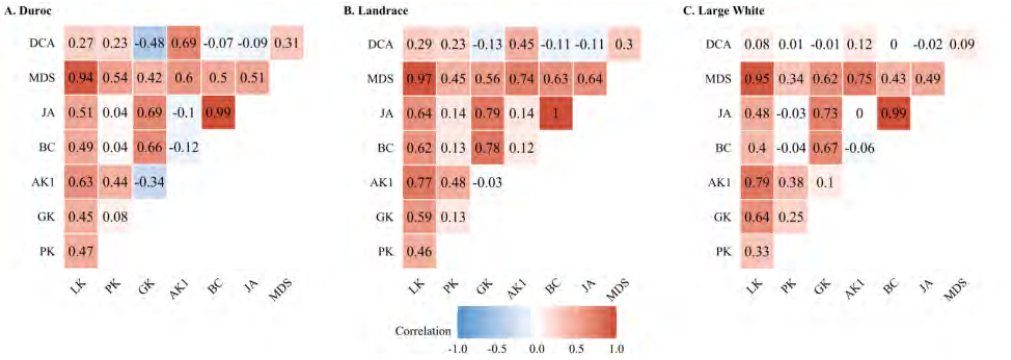

Figure 1. Pearson's correlation between off-diagonal elements of microbial similarity matrices in each breed. Correlations that are negative are shown in blue, while those that are positive are shown in red.

We estimated the variance components and calculated the proportion of host phenotypic variance due to pen, sire, or gut microbiota using the Model_S_P_M and Model_M (Figure 2). The pen and sire factors accounted for 6 to 46% and 6 to 20% of the phenotypic variance. The microbiability ranged from 0.03 to 0.32 and 0.02 to 0.52 for BW, from 0.02 to 0.29 and 0.02 to 0.64 for BF, from 0.02 to 0.18 and 0.08 to 0.69 for LD, and from 0.02 to 0.24 and 0.03 to 0.46 for IMF obtained by the Model_S_P_M and Model_M, respectively. In both models, the GK, JA, BR, and AK1 matrices had greater microbiability than the other matrices, while the DCA estimated the least microbiability. Moreover, the microbiability estimates were higher obtained by the Model_M than Model_S_P_M. There were also differences in the microbiability estimates among traits or breeds.

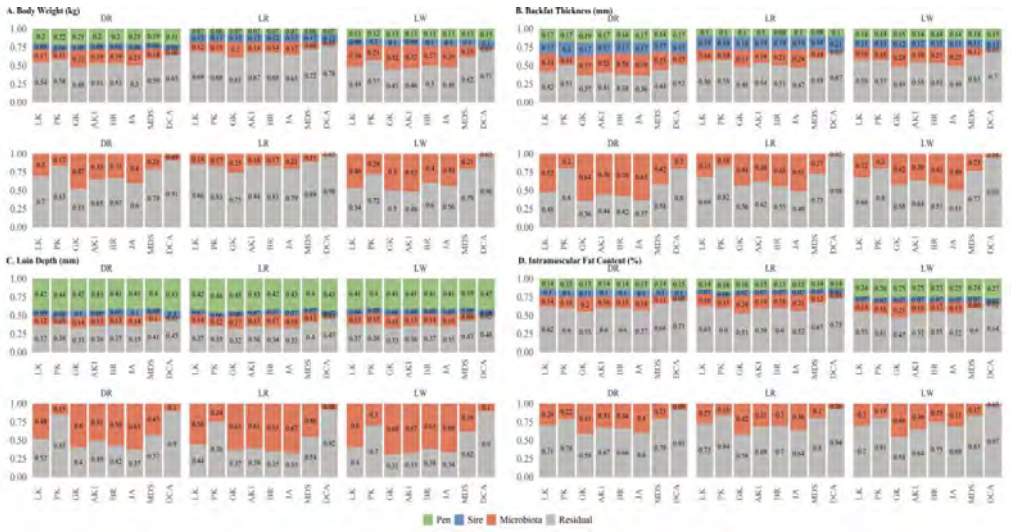

Figure 2. Proportions of variance component estimates for growth and carcass traits by breed. Plots for Model_S_P_M are in the odd row, while for Model_M are in the even row. The x axis represents eight matrices. The proportion value is indicated on the y axis.

Discussion

Our study used alternative approaches to measure resemblance in the gut microbiota composition among pigs and estimate microbiability in three western breeds. We observed differences in the beta-diversity estimated by the eight approaches by computing the correlation between the off-diagonal elements of paired matrices. The outcome was expected since different methods emphasize components of microbiome data in different ways when calculating the beta-diversity between pairs of samples (Tuomisto, 2010). Furthermore, we identified a close relationship between the JA and BC matrices in all three breeds, which agrees with the results reported by Saborío-Montero *et al.* (2021) based on the ruminal microbiota in dairy cattle.

We calculated the proportions of phenotypic variance explained by pen, sire, or gut microbiota in each breed population. The microbiability estimates varied depending on the matrix used, trait, and breed. Additionally, the total proportions of phenotypic variance due to the pen, sire, and microbiota in the Model_S_P_M and the microbiota in the Model_M were comparable in most cases. These findings suggest that the gut microbiota could be a valuable source of information for understanding performance traits in swine, especially in situations when systematic information is unavailable. However, more research is needed to validate our findings in larger populations.

Abstract

In vitro miniaturized and simplified three-dimensional versions of an organ, commonly known as organoids, are an important innovative key technology in human and, more recently, animal research. So far, the *in vitro* organoid system has been applied on a small number of animals in a research setting. However, to apply the *in vitro* organoid system on a larger scale for industrial purposes, a high throughput system needs to be developed. The major aim of this research is to pave the way for a high throughput *in vitro* organoid system of the pig intestinal tract to be used in animal breeding, nutrition, and health. We developed high throughput tools to generate organoids from pig intestines on a large scale. We also looked at different applications addressing intestinal functionality, which allow to accurately phenotype animals for complex traits. Organoid research enables animal breeding companies to switch more quickly towards less animal testing.

Introduction

Developments in cell biology show that it is possible to grow and maintain three-dimensional (3D) organ-like structures in culture for a virtually indefinite time. These structures, called organoids, contain multiple cell types, resemble the *in vivo* tissue, and recapitulate key function(s) of the organ. It has been demonstrated that organoids can be dissociated and seeded onto Matrigel- or collagen-coated Transwell membranes to form two-dimensional (2D) epithelial monolayers (Foulke-Abel *et al.*, 2014; Van der Hee *et al.*, 2020). These 2D cultures allow the study of interactions with apically applied exogenous stimuli, such as pathogens or compounds, i.e. feed ingredients (Kar *et al.*, 2020), nutrients, drugs, and chemicals. In previous studies, the transport and reaction on different agents has been investigated using 2D monolayers (Van der Hee *et al.*, 2020). Hence, the 2D organoid structure could potentially be used to test differences in responses to various exogenous stimuli between organoids derived from different animals. Organoids can then be used as a phenotyping tool in animal breeding. So far, porcine intestinal organoids have been used to study host-pathogen interaction in relation to feed efficiency on a small number of pigs (Ellen *et al.*, 2018). However, to apply the *in vitro* organoid system on a larger scale for industrial purposes, like phenotyping of animals, a high throughput system needs to be developed. The major aim of this research was to pave the way for high throughput *in vitro* organoid systems of the pig intestinal tract to use as a key technology in animal breeding, nutrition, and health. To develop an *in vitro* high throughput organoid system, several steps within the organoids system need to be optimized: (1) collection of tissue samples; (2) production of organoids; (3) storing of the tissue and organoids; and (4) testing. Furthermore, the resemblance between the *in vitro* system and the *in vivo* system needs to be validated.

Materials & methods

Collection of tissue samples. Tissue samples have been collected from the small intestine (jejunum and ileum) and large intestine (colon). These locations have been selected because the jejunum and ileum are important for nutritional research, whereas the colon could be beneficial in future research to collect tissue samples without sacrificing the animals. Tissue samples have been collected from the slaughterhouse. So far, tissue samples have been collected from 26 three-way crossbred (Synthetic boar × (Landrace × Large

White)) pigs raised at research farm 'Laverdonk' of Agrifirm Innovation Center (Heeswijk-Dinther, the Netherlands).

Establishing a cryo-stock for pig organoids. Adult stem cells (ASCs) from the collected tissue have been used to derive 3D organoids. In our study, intestinal crypts have been used. Under appropriate conditions using different growth factors and Matrigel, ASCs can grow, and their daughter cells can differentiate in multiple cell types, resulting in 3D structures (Kar *et al.*, 2021). We can produce large units of 'mother' organoids from a large number of animals to use as a phenotyping tool in animal breeding. We can also produce a large number of 'daughter' organoids to perform multiple tests on tissue from the same animal, for example for multiple phenotypes per pig or as a screening tool in animal nutrition. To validate the resemblance between the organoids and the respective tissue, gene expression measurements using RNA-Sequencing technology has been used as a read-out parameter. To trim low-quality data, we used Trim Galore version 0.6.6 (Krueger, 2018) and Cutadapt version 1.16 (Martin, 2016) with default settings except for length 35 (default 20) and stringency 6 (default 1). This resulted in paired-end reads if both reads were ≥35 bp. These trimmed reads were aligned against the pig reference genome (Ensembl *Sus scrofa* 11.1.103, (Howe *et al.*, 2021) using STAR version 2.7.3a with settings at default (Dobin *et al.*, 2013). Gene expression was quantified using RSEM version 1.3.0 (Li and Dewey, 2011) with default settings, except for the strand specific protocol, which was set to 0 to derive all upstream reads from the reverse strand. RSEM expected counts and Transcripts per Million (TPM) values were quantified. Principal component analyses have been performed to compare the tissue and organoids.

Optimization of the 2D monolayer Transwell system. Single cells, obtained after dissociation of 3D intestinal 'daughter' organoids, were seeded on Transwells to obtain 2D monolayers for further testing. We determined the optimal conditions to obtain stable and reproducible trans-epithelial electrical resistance (TER) values in 2D organoids, and to confirm the integrity and permeability of the monolayer. For this, the cellZscope (NanoAnalytics GmbH, Münster Germany) was used to measure the TER every half an hour to investigate the optimal Matrigel concentration, cell density, and timestamp.

Results

Gene expression from organoids act as a proxy for the respective tissue. We successfully produced organoids from different pigs and different locations. By measuring gene expression of both the tissue of interest and its derived organoids, we established if a relationship exists. Here, we targeted the colon as an example. When focusing on the moderate and highly expressed genes, i.e. transcripts per million above 100, we observed an overlap of 1,539 genes (75%) between tissue and organoids, 242 genes (12%) unique for tissue, and 276 genes (13%) unique for organoids. This shows that many genes are expressed in both the *in vivo* and *in vitro* situation. To assess the functionality of these genes we subsequently performed a Gene Ontology (GO) enrichment analysis for the genes in 'unique tissue', 'overlap', and 'unique organoids'. As we were interested in the biological processes that could be affected, we solely focused on the GO biological processes. Furthermore, we focused on the top 10 biological processes based on the false discovery rate (FDR<0.01, Table 1).

2D Transwell system. Figure 1 shows preliminary results of the TER measurements. So far, the optimal Matrigel concentration we observed is 1% with a cell density of 10^5 cells. This resulted in a window-of-opportunity to perform functional studies between approximately 80-90 hours after seeding, because the TER values were above 1000 Ωcm^2.

Table 1. Top 10 significantly enriched[1] Gene Ontology biological processes.

Ranking	'Unique tissue'	'Overlap'	'Unique organoid'
1	Immune response	Organonitrogen compound biosynthetic process	Small molecule metabolic process
2	Complement activation	Cellular amide metabolic process	Localization
3	Humoral immune response	Organonitrogen compound metabolic process	Macromolecule localization
4	RNA splicing	Peptide metabolic process	Organic substance transport
5	Iron ion transmembrane transport	Amide biosynthetic process	Actin filament organization
6	Immune system process	Translation	Cellular localization
7	RNA splicing, via transesterification reactions	Peptide biosynthetic process	Oxidation-reduction process
8	RNA splicing, via transesterification reactions with bulged adenosine as nucleophile	Generation of precursor metabolites and energy	Protein localization
9	MRNA splicing, via spliceosome	Oxidation-reduction process	Actin filament depolymerization
10	Tricarboxylic acid cycle	Protein metabolic process	Protein transport

[1] False discovery rate <0.01.

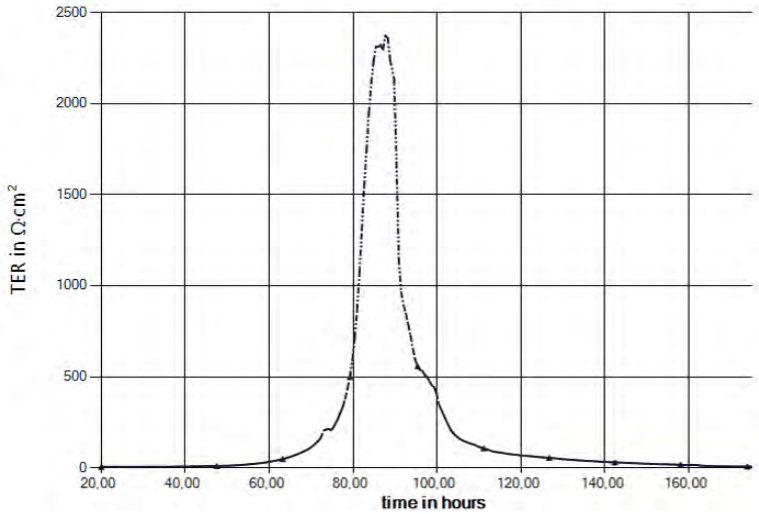

Figure 1. Trans-epithelial electrical resistance (TER) measurements with 1% Matrigel and 10^5 cells.

Discussion

Organoids have been identified as a key *in vitro* tool to reduce animal testing and to define new phenotypes for animal breeding. For pigs, especially for the intestinal tract, this *in vitro* system has been optimized. Results from the gene expression study of the colon indicate that organoids resemble the *in vivo* tissue to a large extend, which is in line with results for jejunum organoids (Van der Hee *et al.*, 2020). The main difference between tissue and organoids is the lack of immune cells in organoids, which our study showed by the genes from 'Unique tissue', indicating multiple processes involved in immunity. The GO terms of 'Unique organoid' genes showed more processes such as localization and actin organization, which was expected because the organoids grew in an artificial environment, i.e. Matrigel. The genes from 'Overlap' were by far the greatest number, i.e. 1,539 genes among the comparison. These 'Overlap' genes were more involved in generic biological processes, i.e. metabolic processes. As we aim to use the organoids as phenotyping and screening tool, similarity in metabolic processes between organoids and tissue is highly

important. Hence, the organoids are likely suitable for comparing responses of animals to exogenous stimuli on the organoids when this is related to metabolic processes, but not when the aim is to test the immune response.

Preliminary results of the 2D system show that a Matrigel concentration of 1% with 10^5 cells resulted in the most optimal TER values. For transport studies, TER values of >750 Ωcm^2 results in low variability between replicates (Van der Hee *et al.*, 2020). Future work will focus on extending the window-of-opportunity when the TER values are above a certain threshold, e.g. 1000 Ωcm^2. The latter will benefit the application for investigating differences between organoids derived from individual animals.

Currently, a high-throughput *in vitro* screening system is under development that will enable breeding and nutrition companies to test and phenotype pig intestinal organoids on a larger scale. Furthermore, simultaneously a biobank will be developed, including (intestinal) organoids and tissue from several pigs, for future new research questions.

503. Simulation of host-microbiome evolution throughout a divergent selection experiment

C. Casto-Rebollo[1*], I. Pocrnic[2], G. Gorjanc[2] and N. Ibáñez-Escriche[1]

[1]Institute for Animal Science and Technology, Universitat Politècnica de València, C/Camino de Vera s/n, 46022 València, Spain; [2]The Roslin Institute, The University of Edinburgh, Easter Bush Campus, Edinburgh, EH25 9RG, United Kingdom; cricasre@posgrado.upv.es

Abstract

The microbiome composition influences the host response to selection and shapes complex phenotypes. It is a multifactorial complex trait in which the microbial inheritance, the host-genome, and the own microbial interactions influence its variability. The expensive sequence-based techniques limit the availability of empirical data. Thus, other approaches are necessary to evaluate strategies for microbiome studies. This study aimed to develop a simulator following a long-term phenotype selection experiment in rabbits, considering both genome and microbiome inheritance. The result showed genetic, microbiome, and phenotypic trends across 13 generations. Differences in the microbiome contribution to the phenotype were shown only in the scenario with a high host genetic effect of the microbiome. This is a preliminary work and further improvements to the simulator will be shared with the research community.

Introduction

Each year, new research underpins the importance of the effect of microbiota on animals' phenotypes suggesting that this contribution is on par with the host genome (Camarinha-Silva *et al.*, 2017; Difford *et al.*, 2018). However, how the microbiome composition shapes complex phenotypes and mediates the host response to selection remains unclear (Henry *et al.*, 2021).

Animal's microbiome composition is established by both the transmission mode (microbial inheritance) and the host genome (microbial heritability). Microbial inheritance could be vertical or horizontal (Koskella *et al.*, 2017), depending on whether and in what quantity the microbiota in offspring came from their parents (Parental microbiota; PM) or their environment (Environmental microbiota; EM). Thus, the transmission mode plays a crucial role in the individual pool of available microbes (Dominguez-Bello *et al.*, 2010). On the other hand, microbial heritability could influence the dynamic nature of the microbiome in the host, so microbial composition can be considered as another quantitative trait of an animal (Pérez-Enciso *et al.*, 2021). Furthermore, other factors such as the microbial genome and the microbial interactions also shape the microbiome composition, which is clearly a multifactorial complex trait.

The expensive sequence-based techniques limit the availability of empirical data to study microbiome composition at scale. Moreover, the lack of consensus on theoretical models and analytic methodologies constrains comparisons between experiments and learning how various microbiome-related factors impact animal's phenotypes. Here we take a simulation approach to gain understanding of the key principles in studying the effect of the microbiome on phenotypes and selection response. To this end we have developed a simulator following a long-term phenotype selection experiment in rabbits (Blasco *et al.*, 2017), considering both genome and microbiome inheritance. The overall aim is to develop a tool for testing different data collection strategies and statistical models to further the study of microbiome in animal breeding.

Materials & methods

The developed simulator allows users to simulate a host genome, microbiome composition, and animal's phenotype as a function of genome, microbiome, and environment. In this study, we used this simulator to mimic a phenotypic divergent selection experiment modulated by the host-microbiome (Blasco *et al.*, 2017). Moreover, three scenarios were implemented to study microbial heritability and its effect on the phenotype. The simulation was repeated 10 times.

Genome simulation. The simulation of 1000 diploid genomes in the base population was performed with the AlphaSimR R package (Gaynor *et al.*, 2021), using the genome and demographic history of rabbits (*Oryctolagus cuniculus*). We simulated 21 chromosomes with a length of 1.28^{10} base pairs, 10,000 segregating sites, and 100 Quantitative Trait Loci (QTL) per chromosome. The allele substitution effects of loci QTLs (α) were sampled from gamma distribution, $\alpha \sim \Gamma(k=0.2, \theta=1)$. In the base population, the genetic values (gv) were distributed with mean 0 and genetic variance of 0.81 with a targeted heritability of 0.13 (for litter size from Blasco *et al.* (2017)).

Microbiome simulation. We simulated a parental (PM) and an environmental microbiome (EM) to model both aspects of microbiome inheritance. The species abundances (x_k) in PM and EM were sampled from a negative binomial distribution, $x_k \sim NB(r=2, q=0.0001)$. The total number of species was 1000 in EM and 600 in PM (with overlap between them). Both, PM, and EM, were simulated with a total species abundance of 10^8. The average of species abundance (μ_k) varied depending on the combination of the species in the individuals due to the microbiome inheritance. Hence, a simulation of 100,000 microbiome profiles was done to obtain μ_k in the founder population, considering that the microbiome inheritance was 100% of the microbial species from the PM (assuming a vertical transmission from the dam due to the delivery mode) and 15% from the EM. The stability of microbial species was computed as a coefficient of variation (CV), sampled from a uniform distribution U(0.01, 2). This CV allowed us to compute the species variance ($\sigma^2_{m_k}$) and simulate the microbiome for each animal in the base population (PM_i), sampling the abundance of each microbial species k from a normal distribution $N(\mu_k, \sigma^2_{m_k})$. A total of 35 microbial species were assigned an effect on the phenotype, following a gamma distribution, $\omega_k \sim \Gamma(k=0.2, \theta=5)$ (Pérez-Enciso *et al.*, 2021). The individual's microbiome value (mv) in the base population was distributed with mean 0 and microbiome variance (σ^2_m) of 0.81, to match the genetic variance (Pérez-Enciso *et al.*, 2021).

Phenotype simulation. The phenotype was simulated as:

$$y_i = \mu_P + \sum_{j=1}^{n} z_{ij}\alpha_j + \sum_{k=1}^{m} x_{ik}\omega_k + e_i \quad (1)$$

where y_i is the phenotype of individual i; μ_P is the phenotypic mean in the base population; $\sum_{j=1}^{n} z_{ij}\alpha_j$ is the gv_i of individual i, where z_{ij} is the genotype of individual I for SNP j and α_j is the allele substitution effect of the SNP j; $\sum_{k=1}^{m} x_{ik}\omega_k$ is the mv_i of individual i, where x_{ik} is the abundance of species k in individual i (Equation 2) and ω_k is the effect of species k on the host phenotype; and e_i is the residual of individual i distributed as $N(0, \sigma^2_e)$, were σ^2_e is the residual variance.

Inheritance. A divergent selection based on the female's phenotypes was simulated according to Blasco *et al.* (2017). In the base population, 125 individuals with the highest phenotype and 125 with the lowest phenotype were selected to initiate divergent populations. Breeding males were full-sibs of the best 25 breeding females from each divergent population. Each breeding male was mated with five breeding females, avoiding a close relationship among them. Thirteen discrete generations of selection were simulated simultaneously for the two divergent populations. In each generation, 125 breeding females and 25 breeding males were selected in each population. The breeding females were selected as in the

base population, and the breeding males were males from the offspring of the best female for each sire (best mating). Mating and genome inheritance were simulated using the AlphaSimR package (Gaynor *et al.*, 2021). Microbiome inheritance was 100% from the PM and 15% from the EM. The transmission EM was the same for all animals and the two divergent populations, but different between generations (EM_g). Hence, the microbiome composition in the offspring was computed using Equation 2.

Scenarios considered. Three scenarios were simulated to study how microbial heritability affected response to selection. The first scenario assumed the absence of microbial heritability (NMH), so there was no host genome effect on its microbiome. In the second and third scenarios, microbial heritability was included in the simulation. The second scenario assumed intermediate microbial heritability (IMH) from 0.25 to 0.50 and the third scenario assumed high microbial heritability (HMH) from 0.5 to 0.9. Consequently, the species abundance was considered as another quantitative trait simulated following Pérez-Enciso *et al.* (2021):

$$x_{ik} = \mu_k + \sum_{j=1}^{n} z_{ij}\beta_{jk} + e_{ik} \quad (2)$$

where x_{ik} is the abundance of the specie k in the individual i; μ_k is the average abundance of the specie k in the base population; $\sum_{j=1}^{n} z_{ij}\beta_{jk}$ is the genetic value (gv_{ik}) of individual I for the abundance of specie k, z_{ij} is the genotype of SNP j for individual i, β_{jk} being the substitution allele effect of SNP j for the species k; and e_{ik} is the residual of individual i for the species k distributed as $N(0, \sigma^2_{e_k})$, where $\sigma^2_{e_k}$ is residual variance for the species k. The gv_{ik} were distributed with mean 0 and microbial genetic variance ($\sigma^2_{m,g}$) according to each microbial heritability. We assumed that 10% of the total number of species (100) were under the genetic control of 10% of the QTLs (210). From these 100 species, 18 of them influence the phenotype (50% of total species influencing the phenotype).

Results & discussion

The simulation showed expected divergent trends throughout the 13 generations of selection (Figure 1). Although there were 35 microbial species with effect on host phenotype, and 18 of them under host genetic control, no differences were observed in phenotype trends between the scenarios NMH and IMH (Figure 1C). Differences in the phenotype trends were only shown with the scenario HMH (Figure 1C), that is when microbial heritability was high, from 0.5 to 0.9. In this scenario, microbiome value trend diverged more than with the NMH and IMH scenarios (Figure 1B). These preliminary results suggested that, under the assumed simulation, a high microbial heritability is necessary to observe a significant contribution of microbiome to response to selection. Likewise, the microbiome composition is multifactorial, and it has a huge variability within and between individuals. Another scenario considering only the effect of the host genome on the phenotype is necessary to fully assess the degree of microbiome contribution on the phenotype.

Conclusions

In this study, a simulator of the modulation of a host-microbiome evolution has been developed. The result showed genetic, microbiome, and phenotypic trends across 13 generations. Differences in the microbiome effect on the host phenotype were shown only in the scenario with high microbial heritability. This could be due to the reduction of the impact of the environmental microbiome. This is a preliminary work, and further improvements to the simulator will be shared with the research community.

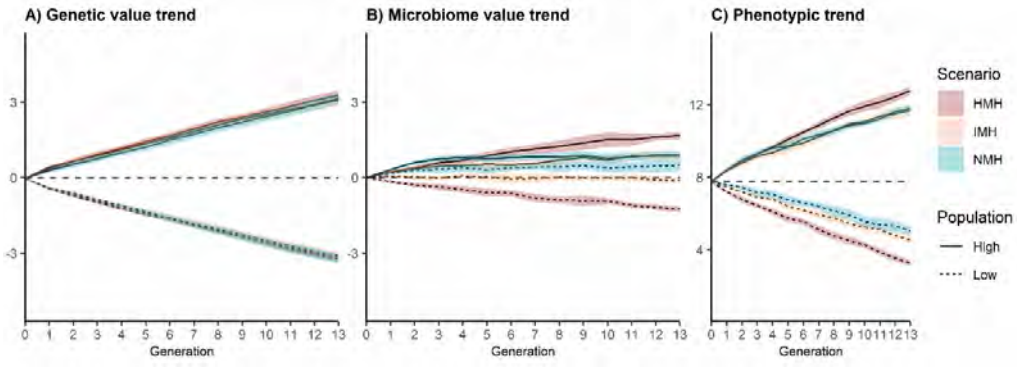

Figure 1. Genetic, microbiome, and phenotypic trends throughout a divergent selection experiment. Averages and 95% quantiles over replicates are shown for (A) genetic value, (B) microbiome value, and (C) phenotype value. HMH: High microbial heritability, IMH: Intermediate microbial heritability, NMH: No microbial heritability. High (dashed line) and Low are the two divergent populations.

Abstract

It is now widely accepted that animals' phenotypes are determined by the host genetic and the microbiome composition. For the genetic evaluation purpose, our objectives are to estimate the heritability and microbiability, and the additive metagenomic effect, assuming that these two components have additive effects. In this study were included, as dairy traits, milk production, fat and protein content; and 16S rRNA gene of rumen bacteria of 795 ewes. Two genomic models were used, a first model to predict individual microbiome contribution to phenotypes; and a second model to predict genetic effects on this predicted microbiome contribution. Results showed that the microbiabilities for milk traits were close to zero, and the residual heritabilities were not different from the trait heritabilities. By disentangling the milk traits' variance explained by the microbiome, we conclude that rumen bacteria abundances do not provide improved genetic evaluation of dairy traits in Lacaune sheep.

Introduction

The animal phenotypes are determined by the genetic component, the environmental conditions, and also by the digestive microbiome which is partially controlled by the host (Pérez-Enciso *et al.*, 2021). To disentangle the holobiont impact on phenotypes, Christensen *et al.* (2021) and Weishaar *et al.* (2020) proposed models to account for intermediate -OMICs data (i.e. metabolomics, transcriptomics, and metagenomics) in genetic evaluation. In polygastrics, the rumen microbiome is crucial, as it allows ruminants to digest plant fibre. Bacteria are able to degrade and ferment fibrous feedstuffs into nutrients, directly usable by the animal for maintenance, growth and lactation. Considering the relevance of rumen fermentation products in the mammary gland, and having demonstrated that rumen bacteria are controlled by host genome, we propose to apply the Christensen *et al.* (2021) methodology on a Lacaune dairy sheep dataset including metabarcoding (16S rRNA gene) as intermediate -OMIC trait, and dairy traits as phenotypes. The objectives are to estimate variance components, as heritability (h^2) and microbiability (m^2), and the additive part of the predicted metagenomic effect.

Materials & methods

Animals phenotyping. Data from 795 multiparous Lacaune dairy ewes were obtained from INRAE Experimental Unit of La Fage (UE 321 agreement A312031, Roquefort, France) between 2015 and 2019. All ewes (weighing 77 kg on average) raised indoors, and fed 93% meadow hay and silage plus 7% of concentrates diet (on dry matter basis). Daily milk production (MP), milk fat and protein contents (FC and PC, respectively) as weighted averages, were recorded as part of one official milk recording of the flock. In brief, two milk samples per animal for morning and afternoon milking were sent for analysis at the Interprofessional Milk Analysis Laboratory (Aurillac, France). Milk FC and PC were recorded for 777 ewes, and analysed with mid-infrared techniques with a Milko-Scan™ FT6000 instrument (Nanterre, France). Rumen sampling was performed within 3 days on morning or afternoon around the official milk recording of the flock. Ruminal content was sampled from each ewe using a vacuum pump and a medical gastric tube.

The protocol received approval from the French Ministry of Higher Education, Research and Innovation – Animal Ethics Committee (approval number: APAFIS#6292-2016080214271984 v8). After extraction, the DNA strands of the 795 samples were sequenced using v3-v4 region of 16S rRNA gene and processed with the FROGS 3.0 pipeline (Escudié *et al.*, 2018), removing operational taxonomic units (OTUs) with average abundances below 0.005%. As result, we obtained an abundance table with 2,059 OTUs.

Animals genotyping. DNA extraction from blood samples and genotyping were performed for 795 Lacaune ewes. From those ewes, 743 were genotyped using a medium-density SNP chip (Illumina Ovine SNP50 BeadChip, 54,241 SNPs), 314 at Laboratoire d'Analyses Génétiques pour les Espèces Animales (Jouy-en-Josas, France) and 429 at Aveyron-Labo (Rodez, France). The remaining 52 ewes were genotyped with a low-density SNP chip (Illumina Ovine SNP15, 16,681 SNPs) at Neogen (Lansing, USA) and imputed to a medium-density SNP chip genotypes in the framework of the Lacaune dairy sheep genomic selection program (Larroque *et al.*, 2017). SNPs were removed using a call rate <0.99 for SNPs, and <0.95 for individuals, and minor allele frequency <0.05. In total, 35,825 SNPs remained for the analyses.

Statistical analyses. The methodology used was that proposed by Christensen *et al.* (2021).

1. The first model for predicting individual contributions of metagenomics to phenotypes:

$$y = Wb + m + a_r + e \quad (1)$$

where; y is the vector of observations for the dairy traits; b is the vector of fixed effects; m is the vector of random rumen bacteria effect (metagenomic effect); a_r is the vector of random additive effects; and e is the vector of random residual effects. W is the incidence matrix for b.

2. Second model used estimates of m to predict the additive part of the predicted metagenomic effect:

$$\hat{m} = W\beta + g + e \quad (2)$$

where $\hat{m}$ is the predicted effects m in Equation 1; β is the vector of fixed effects; g is the vector of random additive effects; and ε is the vector of random residual effects. W is the incidence matrix for β. The same fixed effects (P<0.05) were included in both models: sampling year, days in milk (DIM), and litter size. The distributional assumptions are $m \sim N(0, M\sigma^2_m)$, $a_r \sim N(0, G\sigma^2_{a,r})$, $e \sim N(0, I\sigma^2_e)$, $g \sim N(0, G\sigma^2_g)$, $\varepsilon \sim N(0, I\sigma^2_\varepsilon)$, where M is the microbial similarity matrix, G is a genomic relationships matrix (VanRaden, 2008), I is an identity matrix; σ^2_m is the metagenomic effect variance, σ^2_a and σ^2_g are additive variances, and, σ^2_e and σ^2_ε are residual variances. The microbiability was estimated as $m^2 = \sigma^2_m/\sigma^2_y$, the residual heritability as $h^2_r = \sigma^2_{a,r}/\sigma^2_y$, and the heritability of metagenomic effect as $h^2_m = \sigma^2_g/(\sigma^2_g + \sigma^2_\varepsilon)$. These variance components were estimated using BLUPF90test (Misztal *et al.*, 2002) with OPTION method VCE. Thus, following the formula $h^2 = m^2h^2_m + h^2_r$ presented by Christensen *et al.* (2021), the heritability of the phenotype is decomposed into a metagenomic mediated heritability ($m^2h^2_m$), and residual heritability (h^2_r).

3. M matrix construction

The matrix was computed as a variance-covariance matrix from rumen bacteria abundances as follows:

$$M = XX'/n \quad (3)$$

where; X is the abundance matrix with n=2,059 OTUs with zeros corrected with the geometric Bayesian-multiplicative (GBM) method (Martín-Fernández *et al.*, 2015), and centred log-ratio (CLR) transformed, for the 795 ewes. OTU abundances were pre-corrected for the significant fixed effects (for more than 10% of OTUs), such as lactation number, sequencing run, and sampling time and order, all of them nested on sampling year, and total number of sequences per rumen sample. Then, the similarity among animals in rumen bacteria composition was estimated by constructing a microbial similarity matrix M as in Ross *et al.* (2013).

Results

The decomposition of the parameter estimation using the two proposed models is shown in Table 1, where we see that the microbiability is only different from zero for milk protein content. Although, the heritability of metagenomic effect is different from zero for MP and PC, but only the heritability of PC is slightly higher than the estimated residual heritability. For MP and FC, we obtained a null microbiability leading to heritability of phenotypes equal to residuals ones.

Table 1. Estimates of residual heritability (h^2_r), microbiability (m^2), heritability of metagenomic effect (h^2_m), and heritability of phenotype (h^2).[1]

Trait	h^2_r (SE)	m^2 (SE)	h^2_m (SE)	h^2
Milk production (ml)	0.250 (0.068)	0.00	0.083 (0.058)	0.250
Fat content (g/ml)	0.533 (0.066)	0.00	0.00	0.533
Protein content (g/ml)	0.515 (0.070)	0.040 (0.037)	0.046 (0.052)	0.517

[1] SE = standard error.

Discussion

The heritability estimates obtained were similar to Rupp *et al.* (2003) with 0.28 to 0.32 for annual MP, and 0.41 and 0.51 for annual FC and PC, using all Lacaune dairy ewes (up to 90,000 animals). This is the first estimate of the rumen microbiome contribution to the variability of milk traits, using the largest sample size from a single population of dairy ruminant. The variances explained by rumen bacteria (m^2) were close to zero for most dairy traits, and the genetic variances (h^2_m) were lower than 9%, which is consistent with the weak phenotypic correlations between milk traits and rumen bacteria demonstrated by Martinez Boggio *et al.* (2021). The higher m^2 of PC could be explained by the key role of rumen bacteria in the production of essential amino acids needed for milk proteins (Xue *et al.*, 2019). Our estimates were similar to those presented for dairy cows by Buitenhuis *et al.* (2019) for milk fat (0.08±0.07) and protein (0.08±0.09) contents, and Zhang *et al.* (2020) for methane emissions (0.07). Despite this, it is interesting that with the method proposed by Christensen *et al.* (2021) we can decompose the heritability, and identify which part of the genetic variance was explained by the rumen microbiome, and which was directly explained by the host genetic (residual heritability). In our study, as shown by the low microbiabilities obtained, most of the variance is not explained by the rumen microbiome, even if the M matrix is constructed by omitting OTUs with zero, or considering those present in at least 50% of the animals. But we could further study other traits such as milk fatty acids and proteins, for which preliminary results showed positive microbiabilities. So far, we can conclude that with our dataset, and the low genetic variance explained by metagenomic data, the rumen bacteria abundances do not provide improved genetic evaluation for dairy traits in sheep.

Abstract

Organoids ('mini-organs') derived from adult stem cells residing in tissues can provide near-physiological *in vitro* 'Reduction, Refinement, and Replacement (3Rs)' models for genotype-to-phenotype research in animal sciences. Our aim was to assess the effective ability and reliability of pig intestinal organoids to reflect the phenotypes of the specific gut portion they are derived from. To this issue we generated organoids from the small intestine (duodenum, jejunum, ileum) and colon from cryopreserved biopsies of four Large White pigs after adapting the protocol to commercial slaughter conditions and further standardization of lab culture and phenotyping procedures. Here we report the comparison of organoids cultured in three and two dimensions (3D and 2D) vs the original animal tissue in terms of morphology, number and growth rate, cell composition and barrier tissue integrity, and highlight the main organoid vs tissue specificities.

Introduction

Organoids ('mini-organs') can be obtained from embryonic cells, induced pluripotent stem cells and adult stem cells (from tissue biopsies of almost any organ and animal species). They are easily biobanked and amenable to many biochemical and genetic perturbations (Clevers, 2016). Gut organoids derived from intestinal crypts retain some of the key morphological and molecular features of the specific gut segment they derive from and are increasingly used in several farmed species, including pigs (Li *et al.*, 2019; Van der Hee *et al.*, 2020).

Organoids are regarded as promising, near-physiological *in vitro* '3Rs' models for genotype-to-phenotype research, e.g. to study in highly reproducible conditions how genetic variation may affect key cellular processes underlying complex traits relevant for sustainable productions (Clark *et al.*, 2020). However, little is known so far on the relative influence of experimental and biological factors on organoid phenotypes. Specific culture conditions, passaging and culturing time can change the cellular state within the organoids. Recent analyses of transcriptional variance in organoids derived from human biopsies pointed to the heterogeneity of cohorts, organoids production and growth (Criss *et al.*, 2021; Gehling *et al.*, 2021, Mohammadi *et al.*, 2021).

Our global aim is to assess to what extent porcine gut organoids derived from different segments of the small intestine (duodenum, jejunum, ileum) and colon recapitulate the phenotypic variability of the tissue they are derived from, with a focus on phenotypes involving gut innate immunity responses. We report here the morphology, number and growth rate, cell composition and barrier tissue integrity phenotypes of these multiple organoids in comparison to the original tissue as a result of their production and culture in our laboratory standardized conditions. These results paved the basis of a transcriptome study in progress.

Materials & methods

Generation and culture of pig 3D and 2D organoids from frozen tissues. Pig intestinal organoids were generated from cryopreserved intestinal biopsies of four 5-month-old biobanked Large White pigs as described (Beaumont *et al.*, 2021). Cell number was adjusted at each passage (10,000 cells seeded in 50 µl droplets with 6-8 mg/ml of Matrigel (Corning, ref 356231) in 24-well plates) with basal culture medium

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_505, © F. Blanc *et al.* 2022

(BCM) (Van der Hee *et al.*, 2018). Conditioned media were from the same batches and their optimal concentrations were experimentally tested. To obtain 2D layers, organoids were processed to obtain single cell suspensions, 30,000 cells were seeded on Transwells with 0.4 µm pore polycarbonate membrane inserts (Corning) or 96-well plates (Corning) pre-coated with 0.5% (v/v) Matrigel, and cultured in BCM supplemented with 10 µM Y27632 at first. BCM was then refreshed every 2 or 3 days until cells reached around 75% of confluence. Medium was then replaced by differentiation medium (BCM without Wnt3A conditioned medium) for 3 days. The Transepithelial electrical resistance (TEER) was assessed using the Epithelial Volt/Ohm Meter EVOM2 (WPI) on Transwells at confluence.

Evaluation of 3D & 2D organoid growth rate and count. Phase contrast microscopy images of developing 3D organoids at 5, 6 and 7 days of culture were obtained with a PlanApoN 2× objective. Organoids area and count were estimated by image analysis using Fiji (particles >2,000 µm^2 and circularity between 0.2 and 0.9 were kept for the analysis). Confluence of 2D layers was also estimated by image analysis with Fiji from daily-acquired phase contrast microscopy images.

Histology and immunohistochemical staining. Tissues and organoids in 3D and 2D-layers (insert membranes) were fixed in paraformaldehyde 4% for 1h and paraffin-embedded; 5 µm-sections were stained by hematoxylin-eosin-saffron (HES) or alcian blue/periodic acid Schiff, or with antibodies to detect chromogranin A (Novus biological, ref NBP2-34240), villin-1 (Novus biological, ref NBP1-85335), β-catenin (Novus biological, ref NBP2-34240), and occludin (ThermoFisher, ref 71-500). Detection was then performed with goat anti-rabbit IgG-AF647 (ThermoFisher, ref A-21245) and goat anti-mouse IgG-AF555 (ThermoFisher, ref A-21422) and DAPI as nuclear counterstaining. Images acquired with a digital slide scanner (Pannoramic SCAN, 3DHISTECH), objective 20× were analyzed using CaseViewer and QuantCenter softwares (3DHISTECH).

Statistical analyses. Data analyses were performed using R (v4.1.0). Principal Component Analyses (PCA) were performed using FactoMineR (v2.4) package using the imputePCA function of missMDA (v1.18) package to handle missing values, and visualized with the factoextra R package (v1.0.7).

Results & discussion

Optimized protocols for porcine tissue collection & 3D/2D gut organoid culture. We have optimized existing protocols to directly cryopreserve human intestinal tissues allowing to generate organoids after thawing (Tsai *et al.*, 2018) for the four gut regions (duodenum, jejunum, ileum and colon) from 4 Large White pigs at slaughter age. This method allows sampling and storing of a large number of animal samples at once, which would not be compatible with immediate labor-intensive organoid culture. In addition, this procedure has guaranteed organoid culture generation free from bacterial and fungal contaminations. We then progressed in the establishment of standardized protocols to grow organoids optimizing reproducibility. We found that mechanical and enzymatic digestions performed at each passage reduced the heterogeneity in organoid stages within the same culture. We also set up a fixed number of cells to seed at each passage and a weekly passaging frequency. For 2D gut organoid cultures, we have standardized the number of cells seeded in each well and evidenced a variability concerning the time needed to reach 75% of confluence (ranging from 5 to 9 days).

In those conditions, area of organoids doubled (mean × 2.1) from 5 to 7 days while their circularity decreased (means 0.679 after 5 days vs 0.618 after 7 days). Differences between the original gut segment organoids were derived from, could be revealed in terms of morphology (colon organoids were bigger and duodenum ones less circular) and density in cultures (higher for duodenum organoids and lower for ileum ones). We also observed a variability of organoid density within pigs. Morphology and structure of

organoids in both 3D and 2D resembled that of gut tissues. Labelling of goblet cells, mature enterocytes and neuroendocrine cells was in accordance with the original tissues (Figure 1).

Pig gut organoids retain original tissue characteristics. Gut tissues clearly clustered by the corresponding gut regions in a PCA analysis performed with the different histological and immunohistochemical phenotypes measured (Figure 2A). The four gut regions spread along the first dimension in the gut tract order, clearly opposing duodenum and colon. A thinner layer ($P<0.01$) was observed in duodenum and a higher cell density in jejunum ($P<0.05$). Villin-1 expression intensity was lower in colon ($P<0.05$) and neuroendocrine cell density was higher in duodenum ($P<0.001$). Goblet cell density increased along the digestive tract (lower for duodenum ($P<0.05$) and higher in colon ($P<0.01$)), while the proportion of acid vs neutral mucins decreased (higher in duodenum ($P<0.001$) and lower in colon ($P<0.05$)). These observations are in accordance with published data on these pig tissues (Święch *et al.*, 2019).

In our culture conditions, ileum organoids appeared different from all other gut-derived organoids (Figure 2B) in showing higher cell density ($P<0.01$) and higher goblet cell and neuroendocrine cell density ($P<0.001$ and $P<0.05$, respectively). Jejunum organoids showed also lower goblet cell density ($P<0.05$). Goblet cells were found at high levels in ileum organoids compared to jejunum and duodenum organoids. In colon organoids, goblet cells were also found at high levels although at a lower level than in ileum. Interestingly, in the latter, mucins were more acid than in colon organoids, as observed in the original tissues.

We are currently gaining insights into this comparison using transcriptomics to decipher to what extent pig organoids have retained transcript expression and functional pathways of the epithelia of the different gut segments.

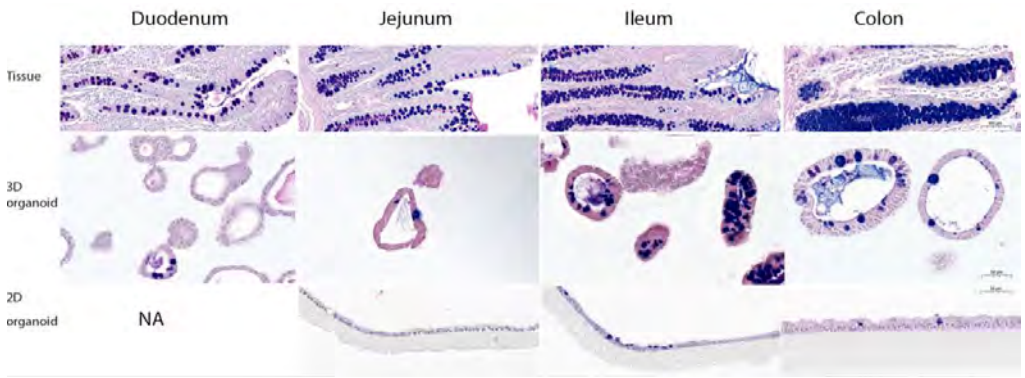

Figure 1. Representative alcian blue/periodic acid Schiff staining of gut tissues, 3D and 2D organoids for duodenum, jejunum, ileum and colon. NA: not yet available.

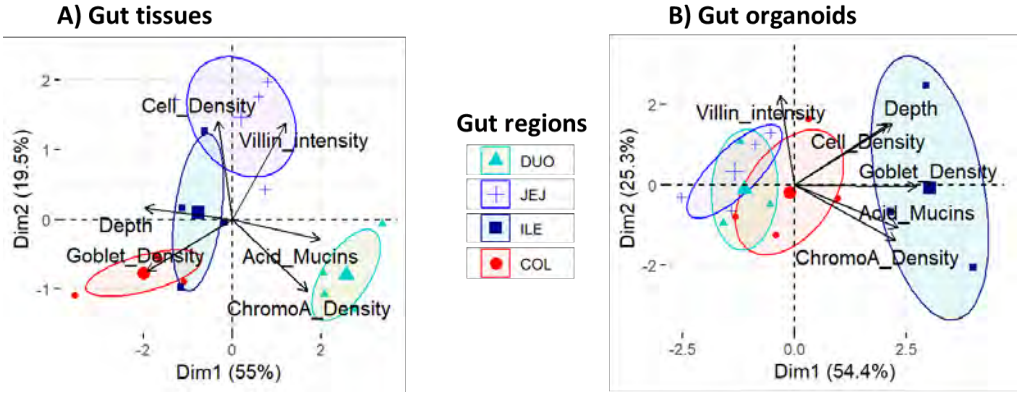

Figure 2. Principal component analyses of (A) gut tissues from different gut regions (duodenum, jejunum, ileum and colon), and (B) their derived organoids after 7 days of culture. Histological and immunohistochemical parameters included: depth of the layer (Depth), cell density (Cell_Density), goblet cell density (Goblet_Density), neuroendocrine cell density (ChromoA_Density), villin-1 expression intensity (Villin_Intensity) and percentage of acid mucins (Acid_Mucins).

Abstract

Recently, digestive efficiency (DE) was proposed as a trait of interest to improve feed efficiency (FE) in pigs, especially when they are fed with alternative feeding resources. Both are influenced by the host genetics, and also by the gut microbiota composition. The goal of this study was to quantify the impact of faecal microbial information on the prediction accuracies of genomic estimated breeding values (GEBVs) of FE and DE traits for pigs fed conventional or fiber diets. For DE traits, gains in prediction accuracy of GEBVs were increased by about 18% when microbial information was included in linear mixed models. In addition, these gains of prediction accuracy were very similar in both diets. For FE traits, no improvement was observed. Thus, the addition of microbial information in breeding programs is promising to better estimate GEBVs for DE traits.

Introduction

Feed costs in pig production currently represent between 60 to 70% of the total cost of pork production (Patience *et al.*, 2015). Feeding pigs with by-products from the agri-food and biofuel industry is an option to reduce feed costs and feed-food competition. In this context, feed efficiency (FE) remains the major objective of selection, but recent research suggested that digestive efficiency (DE) can contribute to FE (Harris *et al.*, 2012; Mauch *et al.*, 2018), and more especially with alternative feeding stuff (Déru *et al.*, 2021a). The DE is influenced by host genetics (Déru *et al.*, 2021a), and it has significant genetic correlations with some faecal microbiota traits (Déru *et al.*, 2021b). In addition, faecal microbiota can explain more than 44% of the phenotypic variation for DE traits (Verschuren *et al.*, 2020; Déru *et al.*, 2021c), and a moderate part, around 20%, for FE traits variance (Camarinha-Silva *et al.*, 2017, Aliakbari *et al.* 2021). The goal of the present study was to evaluate if adding microbial information in the prediction models of breeding values can improve their prediction accuracy for DE and FE traits.

Materials & methods

Animals and diets. Data comprised Large White male pigs reared at INRAE UE3P – France Génétique Porc phenotyping station. Couples of full-sibs were raised in post-weaning facilities until nine weeks of age. When moved to growing-finishing pens, one of the siblings was fed with a two-phase conventional (CO) European diet and the other one a two-phase high-fiber (HF) diet. Diets differed in net energy (NE) (9.6 MJ/kg of NE for the CO diet and 8.2 MJ/kg of NE for the HF diet), and neutral detergent fiber (from 13.90 to 15.12% for the CO diet; from 23.82 to 24.46% for the HF diet), as described in Déru *et al.* (2020).

Data. Individual average daily gain (ADG) and daily feed intake (DFI) were measured between 35 and 115 kg live weight, with GenStar single place electronic feeders (Genstar, Skiold Acemo, Pontivy, France). Feed conversion ratio (FCR) was calculated as DFI/ADG. Residual feed intake (RFI) was determined as a multiple linear regression of DFI on ADG, average metabolic body weight, lean meat percentage and carcass yield (Déru *et al.*, 2020). Microbiota composition and DE were obtained from a unique faecal spot

DOI: 10.3920/978-90-8686-940-4_506, © V. Déru *et al.* 2022

sampling at 16 weeks of age. The DE was predicted as digestibility coefficients (DC) of energy, nitrogen and organic matter using near infrared spectrometry (Déru *et al.*, 2021a). Microbiota composition was obtained from sequencing the V3-V4 regions of the 16S rRNA (Déru *et al.*, 2021b), and 14,366 operational taxonomic units (OTU) were identified. Sequence reads were rarefied at 10,000 sequences per sample.

Genotyping was carried out using 70K SNP GeneSeek GGP Porcine chip. Quality control (QC) was carried out: the call rate per individual, i.e. the percentage of genotype present per individual, with a threshold set at 95%, and the SNP call rate, i.e. the percentage of genotype by SNP with a threshold set at 95%. The SNPs with minor allele frequencies lower than 5%, with a significant deviation from Hardy-Weinberg equilibrium (P<0.000001) were also deleted. After QC, 48,919 markers were available for further analyses.

Genomic estimated breeding values (GEBVs) for FCR and RFI (FE traits), ADG, DFI, and DE traits were obtained for pigs that had all microbiota, genomic and digestive efficiency data, i.e. 1,082 pigs raised in 32 batches.

Statistical analyses. The microbial relationship matrix M was computed after filtering out the OTUs present in less than five samples and with an average abundance lower than 0.001% (2,399 OTUs kept), as $M = TT'/k$, where T is the $n \times k$ matrix containing the centred and standardized log abundancies of each OTU, n the number of pigs and k the number of OTUs (Ross *et al.*, 2013). The genomic relationship matrix G was constructed using the first VanRaden method (2008). Predictions were obtained with a Bayesian model fitted with the BGLR package in R (Pérez *et al.*, 2014). Two models were constructed, $y=X\beta +Zu+ Wm + e$ (model M+G) and $y=X\beta +Zu+ e$ (model G), with y the vector of phenotypes for a given trait, X the incidence matrix relating observations to fixed effects, β the vector of fixed effects, Z the incidence matrix for the genetic effects, $u \sim N(0, G\sigma^2_u)$ the vector of additive genetic effects, W the incidence matrix for the microbiota effects, $m \sim N(0, M\sigma^2_m)$ the vector of microbiota effects, and $e \sim N(0, I\sigma^2_e)$ the random residuals.

Gains of prediction accuracies. The advantage of including the microbial information to predict GEBVs was quantified via changes in prediction accuracies of GEBVs from model G to model M+G. A forward cross-validation approach was used, considering the first 25 batches of the population (876 pigs) as a reference population and the last seven batches (205 'candidate' pigs) as a validation population. The reference GEBV, $GEBV_{C,M+G,}$ were obtained with model M+G on the complete population (i.e. phenotypes available for the reference and validation sets). Then, to assess the gains in prediction accuracy with models M and M+G compared to this reference, the criteria ρ_M and ρ_{M+G} were computed as the Pearson correlation coefficients computed between $GEBV_{C,M+G}$ and GEBVs obtained with model G ($GEBV_{P,G}$) or M+G ($GEBV_{P,M+G}$) with a partial dataset, i.e. where phenotypes were available for the reference population and not available for the validation population (Legarra and Reverter, 2018). First, gains of prediction accuracies were obtained for the full validation set. Next, to test for differences in prediction accuracies between diets, ρ_M and ρ_{M+G} were computed separately for the CO (96 pigs) and the HF diet (109 pigs).

Results

The gains of prediction accuracy combining the microbiota and genomic effects were evaluated using the predictions of the M+G model for the complete dataset as reference GEBVs. Indeed, assuming that microbiota composition affects the trait variance components, it should be the model providing the most accurate GEBVs (David and Ricard, 2019). It should be noted that with the complete dataset, correlations between GEBVs obtained with model G and those with model M+G were high, ranging from 0.97 to 0.99 for ADG, DFI and FE traits, and from 0.80 to 0.85 for DC.

Table 1. Correlation coefficients ρ [95% confidence intervals] between estimated breeding values of the validation population obtained with the complete ($GEBV_{C,M+G}$), and with the partial datasets predicted without ($GEBV_{P,G}$) and with ($GEBV_{P,M+G}$) microbial information, considering both diets in the validation population, and separating the validation population according to the diet.[1]

DC of nitrogen	0.51 [0.40;0.61]	0.48 [0.31;0.62]	0.64 [0.39;0.66]	0.62 [0.53;0.70]	0.61 [0.47;0.72]	0.64 [0.51;0.74]

[1] FCR = feed conversion ratio; DFI = daily feed intake; ADG = average daily gain; RFI = residual feed intake; DC = digestibility coefficient; OM = organic matter; CO = conventional; HF = high fiber.

For FE traits, DFI and ADG, ρ were not improved with the model M+G in comparison to the model G (Table 1). In addition, no difference was observed between ρ computed separately for pigs fed the CO and the HF diets, except for DFI and RFI that had slightly higher gains of prediction accuracy in the CO than in the HF diet (for instance 0.72 vs 0.57 for DFI with CO and HF, respectively) with both models. For DE traits, ratios of prediction accuracies tended to be higher in model M+G (~0.65) than in model G (~0.53). There was no difference in prediction accuracy ratios based on the diet for DC, except for DC of nitrogen with model G that had lower ρ in CO than in HF diet. However, because 95% confidence intervals were large due to limited number of pigs in these sub-groups, these differences between diets were not significant.

Discussion

Based on these first results, the joint analysis of microbiota and genomic information does not appear to increase prediction accuracies of GEBVs for FE and growth traits. However, the addition of microbial information to genomic models seemed to improve prediction accuracies for DE traits. A previous study highlighted that a higher proportion of phenotypic variance was explained by gut microbiota for DE traits (≈ 50-60%) than for FE traits (≈ 20%) in this dataset (Déru *et al.*, 2021c). This could explain why adding microbial information in the linear mixed models has more impact for the former traits. However, we also previously found higher proportions of variance due to microbial information in the HF diet than in the CO diet for DE traits, which did not seem to affect the ratios of prediction accuracies obtained when microbial and genomic information were both included in the model. In addition, higher prediction accuracies were observed in the HF diet compared to the CO diet for DC of nitrogen. Previously, heterogeneity of residual variances was observed between diets for this trait (Déru *et al.*, 2021a), which could not be accounted for in the BGLR models, and could explain the higher prediction accuracies in the HF diet. Finally, the GEBV dispersions, appreciated via the regression of GEBVs with the complete dataset on GEBVs of the partial dataset with model G or model M+G (not presented), were also very similar in the two diets.

We can thus conclude that there is an advantage of adding microbial information in linear mixed models to improve the accuracy of breeding values only for DE traits. Furthermore, the accuracy of GEBV predictions was not impaired with the alternative high fiber diet.

507. Investigating new technologies for on-site real-time sequencing for any animal scientist

H. Ostrovski*, R.P. Savegnago, W. Huang and C. Gondro

Michigan State University, 474 S. Shaw Ln, East Lansing, MI 48824, USA; wackelha@msu.edu

Abstract

Genomic technologies have revolutionized animal breeding but their adoption in commercial animal production systems and throughout the supply chain has been limited due to the complexity of the technology that requires specialized laboratories and trained personnel. Now however, even untrained personnel can potentially easily and rapidly acquire genomic data directly at the sampling site by using small portable real-time sequencing devices. These new sequencing technologies can open a wealth of opportunities for livestock production systems including parentage testing, determination of breed composition, and product certification. This study aims to be the initial exploration into mobile sequencing devices to obtain whole genome information from an Akaushi bull with the Oxford Nanopore MinION. Results of this initial study are the first steps in providing a roadmap for practical adoption of on-site sequencing applications in agricultural production systems which should enable wider industry adoption of genomics to improve food security and livestock production efficiency.

Introduction

Whole genome sequencing has become a widespread practice in most biology disciplines. Both animal breeding and genetics research and the animal industry currently use this kind of data in genomic prediction, whole genome association to identify important QTL (Quantitative Trait Loci), to describe population structures and to understand how selection is being driven on different livestock species. The most recent generation of sequencers, i.e. the third generation, are defined by sequencing single molecules without PCR amplification (Dijk *et al*., 2018). These devices are the most user-friendly, with the products from Oxford Nanopore Technologies (ONT) boasting a small sequencer and straight-forward protocol for any person at various levels of experience. The MinION from ONT (Jain *et al*., 2016), is to be the focus of this study, as we explore the full range of sequencing abilities as a novice in this area by way of obtaining one whole genome sequence.

Understanding the full capabilities of the MinION is crucial in understanding breed composition, parentage or even tracing animal products through the system with an on-site, real-time protocol. Traceability of animal products via some type of genomic testing (DNA barcoding) has already been proposed (Galimberti *et al*., 2013) and studies have shown that even processed food (e.g. smoked fish and cooked meat) still has enough DNA present to be traceable (Aslan *et al*., 2009; Smith *et al*., 2008). The ability to ensure that the composition of a food product matches what is marketed on the label can increase transparency and trust in the system and help reduce the impact of fraudulent food (Spink and Moyer, 2011).

These new ONT technologies bypass sending samples to external labs and long wait times for final genomic information for obtaining real-time genomic sequencing. Establishing usable sequence protocols for all users of genomic information can rapidly increase the usage of this technology in the animal industry, which leads to an increase in the use of genomic data.

The goal of this study was to describe the best protocol to obtain whole genome sequencing of an Akaushi bull using the MinION from ONT. This study aims to be a helpful guide to current molecular geneticists as well as those who have no prior knowledge in the field of molecular genetics by outlining a better use of

this device to get whole genome sequence data without requiring any difficult lab skills. The methodologies of obtaining a DNA library and sequencing with the MinION will be the focus of this study.

Materials & methods

The subject of interest for obtaining whole genome sequence was a 6-month-old Akaushi bull. Whole blood was collected from this calf and DNA was extracted using the QIAamp blood kit. All experiments run on the MinION were done using the LSK-109 protocol, which is the ligation protocol provided by ONT. This protocol was laid out as an easy-to-use process, which included three steps: (1) DNA repair and end-prep; (2) adapter ligation and clean-up; and (3) priming and loading the flow cell. Seven runs of the same animal were done; each consisted of creating a library, loading it onto a flow cell and running the flow cell for approximately 72hrs.

Guppy basecaller was used to convert the raw signal into fastq files. Post-basecalling steps included removal of chemical adapters with porechop (Wick *et al*., 2017), reads alignment onto the reference genome from 1000 bull Genomes Project (Hayes and Daetwyler, 2019) using minimap2 (Li, 2018), sorting, indexing and merging of bam files with SAMtools (Li and Barrett, 2011; Li *et al.*, 2009), and variant calling with longshot (Edge and Bansal, 2019). BCFtools was used to access the statistics of the final vcf file.

Results

The sequencing protocol that was generated through all runs in this experiment differed from the original protocol taken from the Nanopore website. Many diagnosable issues may arise such as low-quality DNA, not enough or too much extracted DNA used in library prep or even low incubation temperatures with not enough time. Most of the diagnoses were taken from the Nanopore community page, which filled in the gaps of knowledge where the protocol was lacking. The protocol outlined here is aligned with many of the suggestions shared online, as well as trial and error from the runs done.

The final whole genome sequence obtained from this method had 5.2× coverage depth and 2,329,110 variants called. These variants called by longshot only include one sample, which may explain the low number of variants called. Of these variants called, there were 856,924 homozygous (1/1) calls and 926,780 heterozygous (1/0) calls. The output from each run on the MinION is in Table 1. The first runs had the worst outcome due to the learning curve of the protocol techniques that required some troubleshooting. By the final run, the protocol was working more efficiently, and the researcher had more practice with the laboratory techniques. This is still a low amount of coverage for producing a full genome sequence, with a more acceptable coverage hovering from 10-30x. Utilizing low-pass sequencing techniques may be able to bypass this issue and fill in the areas of lower coverage with reference genomes (Snelling *et al.*, 2020).

Table 1. Output of each MinION run at 72 hours.

Run number	Total Gb	Total reads	Mean length	Max length	Ultra-long reads
1	0.13	12,000	11,011	66,867	0
2	1.08	136,000	7,993	117,208	4
3	2.61	262,516	9,945	126,941	6
4	1.79	244,000	7,340	107,872	4
5	3.36	372,000	9,035	112,098	10
6	0.93	112,000	8,334	99,962	0
7	5.53	644,000	8,597	129,442	11

Discussion

The new frontier in animal sequencing is to get it out of the lab, speed up the results collected, and to make it available to all types of researchers and producers. The MinION has the possibility to do all these things, as the size and protocol are easily picked up and easy to adjust to any type of experiment with an experimenter of any skill level. The protocol provided by ONT for producing sequence could be more in-depth, as many steps were simply glazed over, and inexperienced lab users could easily be lead astray. Producing good results of each experiment run with the MinION depends on the user tweaking the amount of reagent used, the time spent incubating or even the time/speed of mixing. Understanding ONT protocols for a specific experiment for a beginner requires reliance on problem solving with the Nanopore community, which can make the sequencing process more labor intensive, with a constant 'debugging' of sorts of the MinION and library preparation. The bioinformatic pipeline produced for alignment of these reads consists of 3rd party software that is free to use except the base calling guppy software and the MinKNOW sequencing software. This could lead to issues for future users who may be using ONT products but do not have access to download this software.

The real-world utilization of this technology is immediately relevant for establishing a traceability system for premium and/or branded products subject to counterfeiting (e.g. wagyu beef or jamon Iberico) to build consumer trust and to detect mislabeled products that tarnish the product's reputation. Practical implementation of on-site, real-time sequencing is not a trivial task but there is a pressing need to improve data connections between farmers and customers, not only for the obvious reasons of improved food safety, but also to capture commercial opportunities through increased exports to other states and countries that already (or will soon) require traceability (Schroeder and Tonsor, 2012). This is a numbers game which, similarly to genomic selection, requires buy-in from the industry, but by implementing these technologies, databases of traceable products would make identification and certification as simple as a Google search.

The MinION has a long laundry list of pros and cons, but the novelty of this technology is important for use in the animal industry. This is because the idea of mobile sequencing, which can be used by any person of any skill level, is unheard of in the sequencing space. This is the only sequencer on the market that can be taken out of the laboratory, which opens the door to the opportunity of on-farm sequencing, at the right price. The practical application of this aspect allows for on-site diagnosis of disease, quick genomic sequencing of animals for quick parentage testing and even traceability of animal products that will become commonplace for the everyday scientist.

508. Impact of the bovine reference genome (ARS-UCD1.2) on functional annotation at genome, transcriptome and methylome level

A. Cánovas[1*], P.A.S. Fonseca[1], S. McKay[2] and J.F. Medrano[3]

[1]Department of Animal Biosciences, Centre for Genetic Improvement of Livestock, University of Guelph, N1G 2W1, Guelph, Ontario, Canada; [2]Department of Animal and Veterinary Sciences, University of Vermont, USA; [3]Department of Animal Science, University of California-Davis, Davis, CA 95616, USA; acanovas@uoguelph.ca

Abstract

The ARS-UCD 1.2 genome assembly was released with the expectation of improving continuity and accuracy of the assembly for the bovine reference genome compared with the previous assembly, UMD 3.1. Here, the impact of both reference genomes was compared at the genome, transcriptome and methylome level over the results obtained using different high-throughput OMICs technologies. In general, the ARS-UCD 1.2 outperformed the UMD 3.1 genome assembly. For genome wide association studies, a larger detection of positional and functional candidate genes was observed. In addition, a larger number of uniquely mapped reads, expressed genes, and transcripts was observed in transcriptome analyses using RNA-Sequencing. Interestingly, for the genome wide methylation analysis, the chance of annotating methylated sites in genic regions was ~40% higher than in intergenic regions. The results obtained allowed a proof-of-concept study to be performed regarding the advantages of the ARS-UCD 1.2 over the UMD 3.1 bovine genome assembly.

Introduction

The availability of a bovine reference genome substantially improved the elucidation of genetic mechanisms associated with complex traits. For more than a decade, the bovine reference genome UMD 3.1 was used as the main reference genome for genomic and transcriptomic analyses (Zimin *et al.*, 2009). However, mainly due to the limitations of the sequencing technologies, gaps in the annotation and poorly assembled regions are frequent in this version. Recently, the ARS-UCD 1.2, was released based on a *de Novo* assembly using single-molecule real-time sequencing (Rosen *et al.*, 2020). Theoretically, the use of longer reads in the process of genome assembly can result in improvements of continuity, accuracy, and completeness of assembly. Therefore, the objectives of this study were: (1) to evaluate the differences between the bovine reference assemblies UMD 3.1 and ARS-UCD 1.2 and to compare the results obtained at the genome, transcriptome, and methylome level using different high-throughput -OMICs technologies and approaches (genome wide association study (GWAS), RNA-Sequencing (RNA-Seq), and whole genome bisulfite sequencing (WGBS)); (2) to estimate the real impact of the new genome assembly for these technologies for functional annotation at the genome, transcriptome and methylome level.

Materials & methods

Phenotypes and genotypes used for genome-wide association studies. The phenotype evaluated was meat tenderness in beef cattle defined using Warner-Bratzler shear force to measure the *longissimus dorsi* muscle (LMD) that had been aged for 7-, 14- and 21-days post-mortem (LMD7, LMD14 and LMD21), respectively. A total of 1,740, 1,295, and 1,288 crossbred beef cattle were sampled for LMD7, LMD14 and LMD21, respectively. The mean (and standard deviation) breed composition of the six major breeds for these animals was: Angus (0.43±0.02), Simmental (0.33±0.17), Charolais (0.05±0.10), Piedmontese (0.05±0.15), Gelbvieh (0.02±0.07), and Limousin (0.01±0.05). The animals were genotyped using the Illumina BovineSNP 50K. A total of 37,564 autosomal markers were used after quality control. The weighted single-step method (Wang *et al.* 2012) was used to estimate the SNP effects, where a single-

trait model was considered with fixed effects including sex, herd, year, month of birth, expected breed composition, and slaughter age (Fonseca *et al.* 2022). The candidate windows associated were defined as those windows explaining more than 1% of the total genetic variance. The positional candidate genes within the candidate windows were annotated for both UMD 3.1 and ARS-UCD 1.2 assemblies using the GALLO package in R (Fonseca *et al.* 2020). The proportion of positional candidate genes (mapped within candidate windows) shared between each time-point and assemblies were compared. Additionally, the pairwise linkage disequilibrium (LD) pattern within the candidate windows was calculated using plink v1.9 (Purcell *et al.* 2007).

Comparison groups for transcriptomic analysis using RNA sequencing. A total of 12 milk somatic cell samples from six Holstein dairy cows diagnosed with mastitis according to the California Mastitis Test were collected and used in transcriptomic analyses. Immediately after diagnosis, two milk samples were taken from each cow, one sample from the mastitic udder quarter (n=6), and one from the udder quarter diagonal to the mastitic udder quarter and classified as healthy based on having a somatic cell count <100,000 cells/ml (Asselstine *et al.*, 2019; Guerrero *et al.*, 2015). Sequencing was completed with an Illumina HiSeq 2000 analyzer that yielded 100-bp single-read sequences. Sequence reads were assembled to the annotated UMD 3.1 and ARS-UCD 1.2 bovine reference genome using CLC genomics workbench software (CLC Bio, Aarhus, Denmark). Transcript levels were quantified in reads per kilobase per million mapped reads (RPKM). Analysis of differentially expressed (DE) genes and mRNA isoforms was performed between healthy and mastitic quarters by t-test. Genes and mRNA isoforms were considered significantly DE between healthy and mastitic udder quarters when they met the following significance thresholds: a false discovery rate (FDR) of $q<0.05$ and a fold-change (FC)$>|2|$. The percentage of uniquely mapped reads, total number of expressed genes (RPKM$\geq$0.2) and DE genes, total number of expressed mRNA isoforms, and number of DE mRNA isoforms between healthy and mastitic samples was compared between assemblies.

Whole genome bisulfite sequencing (WGBS) data processing, mapping and methylation calling. The samples used in this analysis were derived from biopsies of two brain areas, *amygdala* (*amy*) and cingulate gyrus (*gyrus*), from eight animals. The extracted DNA was used to prepare 150 bp paired end libraries and the WGBS was performed using the Illumina HiSeq X Ten platform (Illumina, San Diego, CA, USA). The methylation calling was performed using BSseeker2 software with default parameters. The percentage of methylated cytosine distribution was compared between assemblies for *amy* and *gyrus* in all methylation contexts (CG, CHG, and CHH). The bases with a frequency of methylated cytosine higher than zero were annotated based on their genomic function (i.e. intergenic, promoter, exon, and intron). An ordinal logistic regression was performed using the genomic function as the response variable, and the different assemblies were treated as fixed effects. The magnitude of the effect was estimated using the odds ratio between the reference genomic function (intergenic) and other genomic functions as the response variable. The significance of the odds ratio was assessed based on the 95% confidence interval (CI95%).

Results

A total of 119 and 103 genes were annotated within the candidate windows identified associated with beef meat quality from GWAS analysis using ARS-UCD1.2 and UMD3.1, respectively. For LMD7, the window explaining most of the total genetic variance was mapped on BTA29 for both assemblies, harbouring 52 (ARS-UCD1.2) and 40 (UMD 3.1) genes. In total, 29 genes were shared between these windows. The percentage of the genetic variance explained by the top window between assemblies for each meat quality trait varied only for LMD7 (4.63% in ARS-UCD1.2 and 4.58% in UMD3.1). The LD pattern across the markers mapped within these windows helped to explain this difference. The markers present uniquely in the UMD3.1 assembly within the candidate window have no significant LD with the markers present in both assemblies. On the other hand, the majority of the markers uniquely mapped in the candidate window

identified using the ARS-UCD 1.2 assembly show a moderate to strong LD with the makers mapped within the candidate window in both assemblies. These results suggest that the markers mapped uniquely within the candidate window identified using the UMD3.1 assembly mapped incorrectly due to possible assembly errors. At the transcriptome level, the RNA-Seq analysis revealed that 81.0 and 86.5% of the reads were uniquely mapped to the UMD3.1 (24,596 genes) and ARS-UCD1.2 (27,270 genes) reference genomes, respectively. The total number of genes expressed in healthy and mastitic groups was higher using the ARS-UCD1.2 (14,096 and 12,820, respectively) when compared to UMD 3.1 (13,356 and 12,145, respectively). In total, 449 genes were DE using the UMD 3.1, while 413 were identified as DE using the ARS-UCD 1.2. Of these, 353 genes were shared between both assemblies. The total number of transcripts expressed in the healthy and mastitic groups was 14,725 and 13,334 (UMD 3.1) and 21,808 and 19,173 (ARS-UCD1.2). In total, 516 DE transcripts were identified in both UMD 3.1 and ARS-UCD 1.2 assemblies, corresponding to 502 genes for UMD 3.1 and 469 genes for ARS-UCD 1.2. Of these 516 DE transcripts found using the UMD 3.1 and ARS-UCD 1.2 reference genomes, 322 DE transcripts were shared between the reference genomes, while 180 and 147 were unique to the UMD 3.1 and ARS-UCD 1.2 reference genomes, respectively. The comparison between assemblies at the methylome level suggested that there is not a different pattern of mean methylation percentage: UMD 3.1 (CHG: 0.67%±0.14, CHH: 0.76%±0.16, CG: 77.31%±1.99) and ARS-UCD 1.2 (CHG: 0.67%±0.14, CHH: 0.76%±0.16, CG: 76.88%±1.70). The methylated sites called tend to be mapped more frequently in intergenic and genic areas (exons, introns, and promoters) using the UMD 3.1 and ARS-UCD1.2, respectively. Significant odds ratio of 0.708 (CI95%= 0.707-0.708) and 0.716 (CI95%= 0.715-0.716) were obtained comparing the annotation records between assemblies. These results suggest that the use of the new bovine reference genome, ARS-UCD 1.2, results in 41.3 and 40% higher annotation of methylated sites in genic regions than intergenic regions, for *amy* and *gyrus* tissues, respectively.

Discussion

The functional analysis including the biological processes associated with the 23 genes annotated exclusively in the candidate window on BTA29 for the ARS-UCD1.2 assembly indicated that those genes are associated with cell-cell adhesion (*BAD*, *CCDC88B*, and *FERMT3*), response to lipids (*BAD*, and *ESSRA*), and regulation of proteolysis (*BAD*, and *PRDX5*), which are associated with meat quality characteristics, such as shear force, color, water retention, cocking loss, etc. (Zhang *et al.* 2013). At the transcriptome level using RNA-Seq technology, the better annotation of the new reference genome and the more complete coverage of ARS-UCD 1.2 can help to explain the smallest number of DE genes. The results obtained at the methylome level using WGBS reinforced better gene annotation available on ARS-UCD 1.2 reference genome due to the ~40% increase in probability of annotating methylated sites in genic regions. The number of methylation calls did not change between assemblies, suggesting that the differences in the percentage of methylation calls per genomic locations are explained by differences in gene annotation between the genomes. Novel genes were annotated by ARS-UCD 1.2 in regions that were previously being considered intergenic, which can be explained by the improvements of continuity, accuracy, and completeness of the ARS-UCD 1.2 assembly. These help to increase the functional interpretation of the results and to improve the detection of candidate genes associated with epigenetic markers. The results obtained here reinforce the advantages of the new bovine reference genome. The ARS-UCD 1.2 assembly is >100× more continuous than UMD3.1 and has complete coverage of the genome (Rosen *et al.*, 2020). Using a multi-OMICs approach, it was possible to perform a proof-of-concept study regarding the advantages of the ARS-UCD 1.2 over UMD 3.1 bovine genome assemblies.

Functional annotation of genomes: causal variants & gene discovery

509. Detection of genes influenced by environmentally responsive *cis*-regulatory variation in porcine immune cells

E. Murani*, F. Hadlich, S. Ponsuksili, and K. Wimmers

Research Institute for Farm Animal Biology (FBN Dummerstorf), Institute of Genome Biology, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany; murani@fbn-dummerstorf.de

Abstract

Genotype-by-environment interactions play an important role in adaptation. In spite of the growing relevance and interest in improving resilience of farm animals studies exploring functional genomic background of G×E interactions are scarce. Here we harnessed RNA-Seq data from an *in vitro* challenge experiment (using dexamethasone, lipopolysaccharide and their combination) in mononuclear leukocytes to detect genes influenced by environmentally responsive *cis*-regulatory variation in pigs using the GeneiASE method. We identified 82 genes showing condition-dependent allele specific expression in at least one of a total of four treatment comparisons. Several of the identified genes are involved in the regulation of response to stress, including *IDO1*, showing allele specific expression depending on LPS application. Our results demonstrate that the analysis of conditional ASE in cell culture models is a promising way to unravel the molecular background of G×E interactions as demonstrated previously in humans.

Introduction

Changes in gene expression facilitate rapid and quantitative responses and thus allow fine-tuned adaptation to environmental stimuli (López-Maury *et al.* 2008). Genetic variation in environmentally modulated transcriptional regulators and/or in their genomic response elements can lead to genotype-by-environment (G×E) interactions in the expression of the corresponding gene(s) and eventually to G×E variation in the phenotype. Gene expression can be considered as a quantitative trait and analysed using the same statistical genomics methods as quantitative phenotypic traits (eQTL analysis). However, this requires measurement of gene expression in large cohorts. The advent of next-generation sequencing for gene expression analysis (RNA-Seq) enables genome-wide analysis of expression imbalance of transcribed 'reporter' SNPs (allele-specific expression – ASE). ASE analysis is a sensitive approach to detect regulatory genetic variation acting in *cis*, i.e. directly on the linked gene(s), and performs with reasonable power also in relatively small cohorts. Comparison of ASE between different environments can be used to detect genes influenced by environmentally responsive *cis*-regulatory variation (Esgärd *et al.* 2016, Knowles *et al.* 2017). Impact of G×E interactions on ASE can be particularly well modelled and explored in cultured cells *in vitro* as demonstrated in humans (Moyerbrailean *et al.* 2016). Here we report analysis of ASE in RNA-Seq data from porcine peripheral blood mononuclear cells (PBMC) cultured in four different environments (Li *et al.* 2021). The four conditions included, besides control (C), stimulation with dexamethasone (DEX), lipopolysaccharide (LPS), and their combination (LPS+DEX). These conditions mimic the impact of neuroendocrine stress response (i.e. glucocorticoids), bacterial infection, and neuroimmunomodulation, on immune cells, respectively. The aim of this study is to identify genes whose expression is influenced by G×E interactions and thus to provide basis for genetic improvement of resilience in pigs.

Materials & methods

Cell Culture experiment and RNA-Seq. The cell culture experiment and data generation are described in detail in Li *et al.* (2021). Briefly, PBMC from 24 slaughter pigs (both sexes equally represented) were harvested for RNA extraction after stimulation for 2 h with either vehicle, DEX, LPS, or LPS+DEX. RNA-Seq was performed on an Illumina HiSeq 2500 sequencing platform with 2 × 101 bp paired-end reads. The resulting average sequencing depth was >20 M read pairs with an alignment rate of ~98%.

SNP Variant calling and counting. SNP calling and counting of reads per allele was based on pipeline described by Tomlinson *et al.* (2021). Parameter settings were taken from https://github.com/CRG-CNAG/CalliNGS-NF. The RNA-Seq reads were aligned to Sus.Scrofa 11.1 reference genome (annotation information from release 103) using STAR (v.2.7.8a) and filtered to remove duplicates and reads with ambiguous mapping. Variants were called using GATK (4.2.0.0) and used to make a masked genome sequence. Mapping and variant calling were then repeated using the masked genome to remove mapping bias.

ASE analysis using GeneiASE. Prior to ASE analysis, SNPs covered by less than 30 reads in total, less than 3 reads per either allele (in heterozygous samples), and with lower than 1% contribution to the total read count per allele, were discarded to increase reliability of the analysis. SNPs located on sex chromosomes, unmapped SNPs, as well as SNPs with ambiguous gene assignment were omitted. In addition, four samples (including data from all four treatments) were excluded based on principal-component analysis (Li *et al.* 2021), leaving 80 RNA-seq datasets for ASE analysis (20 samples × 4 conditions). ASE analysis was conducted using the GeneiASE method developed by Esgärd *et al.* (2016). GeneiASE performs gene-wise ASE analysis for genes with ≥2 SNPs within each informative sample. We implemented GeneiASE within each treatment (called static ASE), and between pairs of treatments in order to detect G×E interactions (called condition-dependent cd-ASE). The individual ASE results were combined across samples using Fisher's method and adjusted using Benjamini-Hochberg (BH) correction.

Functional annotation of ASE genes. Functional annotation of genes showing ASE was performed using the ToppGene online suite (https://toppgene.cchmc.org/enrichment.jsp). Overlapping QTLs were searched in the PigQTLdb (www.animalgenome.org).

Results

In total, we identified >4.4 M transcribed SNPs. After filtering, 75,620 informative SNPs remained for the ASE analysis. Out of 6,010 analysed genes we found significant static ASE (BH-FDR<0.05) in 1,184 genes in C, 1,198 genes in DEX, 1,068 genes in LPS, and 1,072 genes in LPS+DEX. Genes showing static ASE in each of the four treatments (n=509) were enriched for genes involved in the innate immune system (n=57). As previously reported (Li *et al.* 2021), DEX, LPS and their combination induced vast transcriptional changes compared to control, proving suitability of the treatments to study G×E interactions. Results of the cd-ASE analysis (genes with BH-FDR<0.05) are summarized in Table 1. The highest number of cd-ASE was detected in the comparison of the DEX with the LPS treatment, likely because these represent the most contrasting regulatory environments (anti-inflammatory vs inflammatory). In total, 82 different genes showed cd-ASE in at least one treatment. Functional annotation showed that these genes are mainly involved in the regulation of response to stress (GO:0080134, 17 genes). One of the most functionally relevant genes is *IDO1*, showing cd-ASE in all comparisons including LPS (i.e. excluding DEX vs C). Another gene with a similar pattern is ENSSSCG00000020967 (*CD300H* according to NCBI annotation). Interestingly, while *IDO1* is upregulated by LPS, ENSSSCG00000020967 shows the opposite response to LPS. No relevant overlapping QTLs were found in the PigQTLdb.

Table 1. Overview of the results of the cd-ASE analysis.

Comparison	# of analysed genes	# of genes showing cd-ASE
DEX vs C	3,649	13
LPS vs C	3,463	23
LPS+DEX vs C	3,478	26
DEX vs LPS	3,441	35

Discussion

In this study, we applied the GeneiASE method to detect genes influenced by environmentally responsive *cis*-regulatory variation. We identified 82 genes showing cd-ASE. *IDO1*, which showed ASE depending on LPS stimulation, is a rate-limiting enzyme of tryptophan catabolism along the kynurenine pathway. By controlling tryptophan availability and producing bioactive metabolites, IDO1 plays an important immunomodulatory role (Pallotta *et al.* 2021). Unfortunately, no relevant QTLs at the *IDO1* locus were found in PigQTLdb calling for further investigation of the causal regulatory variation and linking it with the immune response. The other promising candidate, ENSSSCG00000020967 (*CD300H*), is less well characterised, but is likely involved in innate immunity (Niizuma *et al.* 2015). The observation that genes showing conditional ASE are enriched for regulation of response to stress is in line with the view that stress-related genes are prone to environmentally responsive *cis*-regulatory variation which is beneficial for adaptation to changing environment. In addition to genes exhibiting conditional ASE, we identified several hundred genes showing static ASE. These represent additional potential candidates with impact on the immune and stress response. By performing gene-wise analysis we likely detected only a part of the present *cis*-regulatory variation. Our further investigation will therefore involve analysis of ASE for individual SNPs.

Abstract

While the quantitative trait locus (QTL) on BTA18 associated with paternal calving ease and still-birth in Holstein Friesian cattle and its cross is known for over 20 years now, to our knowledge, no study has yet identified the exact causal mutations. Here, we re-examined the region of this QTL on BTA18 and investigated possible reasons behind elusiveness of the exact causal mutations or genes. Using genotyping data of 2,697 German Holstein cattle, we identified the QTL in the region between 58 and 60 Mbp on BTA18. Subsequently, using WGS data, four SNPs in perfect LD with the QTL haplotype were also identified. Our analyses also revealed the abundance of segmental duplications (SDs) within and around the region of QTL. We hypothesize that the presence of complex SDs could have been the major factor contributing to the alignment-difficulty that we observed in our data and thus, concealing the underlying causal mutations.

Introduction

Holstein Friesian (HF) and its derived breeds are amongst the most economically important dairy cattle all over the world. However, certain pathological conditions in these animals, such as low fertility, dystocia or the production of weak calves, which die during the first 24 hours of birth, are some major issues which have significant economic impact on dairy industry. According to one estimate (Bellows *et al.*, 2002), these conditions could lead to a total loss of about 53.20 USD (~EUR 46.74-47.81) per dairy cow per year. It is noteworthy that a part of this financial losses can be attributed to genetic factors such as QTL affecting fertility in cattle. Indeed, for over 20 years now, QTL, having by far the most significant impact on fertility in HF and its derived breeds, is known. In fact, many studies (e.g. Cole *et al.*, 2009, Müller *et al.*, 2017) have mapped this QTL in the distal end (between 50 and 60 Mbp) of BTA18. Further, genes which are close to this region such as *SIGLEC5* and *ZNF613* are proposed as the candidate genes harboring the causal mutations (Cole *et al.*, 2009, Fang *et al.*, 2019). Despite the economic and ethical impact of this QTL none of the existing publications successfully pinpointed the causal genes or mutations. Therefore, the aim of the present study was to confirm the position of the significant QTL on BTA18 (ARS-UCD1.2) in an extended data set to Müller *et al.* (2017) and to investigate the region of interest in a subsequent mapping and WGS analyses.

Materials & methods

Animals, their phenotypes, and SNP array genotypes. The previous study by Müller *et al.* (2017) had a sample size of 2,572 daughter-proven Holstein sires. The data set was extended to 2,697 animals separated into 2,525 males and 172 females. Pedigree records and EBV for all animals were obtained from the official breeding value evaluation. The calving traits, paternal calving ease, and paternal stillbirth were the traits that we investigated here. Calving ease is segmented into the following four classes: Easy, normal, heavy and with veterinary assistance. Stillbirth is specified as an 'all-or-nothing' trait and defined as calving

where the calf was born dead or died within 48 hours. All 2,697 animals were genotyped as part of the projects mentioned above with the Illumina BovineSNP50 BeadChip version 1 or version 2. Additionally, 256 of the 2,697 animals were also genotyped with the BovineHD BeadChip. Subsequently, the physical positions of the SNPs from these SNP-chips were converted to the latest cattle assembly (ARS-UCD1.2). Next, genotypes were filtered using the standard criteria and phasing was carried out using *Beagle 5.0* (Browning and Browning, 2009, Browning *et al.*, 2018). To confirm the results by Müller *et al.* (2017) and to identify the position of the most significant QTL on the new assembly ARS-UCD1.2, Combined Linkage Disequilibrium and Linkage Analysis (cLDLA) analysis was performed. This approach was based on the well described method by (Meuwissen *et al.*, 2002) and is already elaborated in detail in our previous study (Gehrke *et al.*, 2020).

Whole genome sequencing (WGS) and targeted SNP genotyping. Four HF (2: heterozygous for the QTL, 1: homozygous for reference-QTL alleles, 1: homozygous for the QTL alleles), one Fleckvieh (FV) and one Kärntner Blondviehwere (KBV) animals were sequenced with long read Oxford Nanopore Technology (ONT). After standard filtering and correction procedure, these data were used to *de-novo* assemble BTA18 chromosome and for the calling of structural variations (SVs). We also downloaded publicly available whole-genome Illumina paired end sequences from additional 24 cattle samples (21 HF and 3 non-HF). After mapping these data against ARS-UCD1.2 cattle assembly, SNPs and indels were called using GATK haplotypecaller and SVs were called using *Lumpy* v0.3.1 (Layer *et al.*, 2014), *BREAKDANCER* v.1.4.5 (Chen *et al.*, 2009) and *MANTA* v1.6.0 (Chen *et al.*, 2016). Additionally, segmental duplications (SDs) were also identified from BTA18 using the approach as described in Dallery *et al.* (2017). Additionally, target SNP genotyping was performed by PCR-RFLP and PCR-based KASP technology for the SNPs that we identified as linked with the QTL. The genotyping was carried in 427 animals belonging to eight different breeds (Table 1).

Results

The *cLDLA* pipeline using 1,144 SNPs (from 50K SNP array) on BTA18 identified a region between 54,233,746 and 63,206,119 bp as having the genome-wide significant LRT values (Figure 1a). It indicates that this region harbored the QTL for the traits of paternal calving ease. After comparing the maternal and paternal haplotypes within the 40-SNP window harboring the LRT_{max} in the middle marker interval, we were able to identify a common putative harmful haplotype (Q) in 608 individuals that showed increased calving difficulties and stillbirth. Furthermore, using HD marker data of animals carrying Q/Q and q/Q genotypes, the putative harmful haplotype could be narrowed down to a region from 57,922,208-60,057,741 bp. Interestingly, in ONT and Illumina sequences of HF cattle, we observed a chromosomal segment of about 16,000 bp (58,846,130-58,861,709 bp), where no read could be mapped to the reference genome and therefore, it appeared as a widespread gap. However, this gap was also observed in zebu and non-HF taurine cattle. Because of this, we excluded this gap as a causal deletion inducing dystocia and stillbirth.

By analyzing publicly downloaded Illumina WGS data, we observed that 2 of the 21 HF samples were heterozygous (Q/q) for the QTL; therefore, we investigated whether we could find variants (SNPs, indels or SVs) from WGS data (Illumine and ONT) that are in perfect LD with the casual QTL. Our analysis revealed that of all the genomic variants that we detected (SNPs, indels or SVs), only four SNPs (Table 1) fulfilled this criterion. Further, except, rs381577268 (57,816,137 bp), which was located downstream of the zinc finger protein 613 (ZNF613) gene, all SNPs were intergenic. Additionally, target SNP genotyping in more than 400 animals of 8 taurine cattle breeds (Table 1) revealed that alternative alleles for these SNPs were only present in HF and HF-derived animals having the QTL.

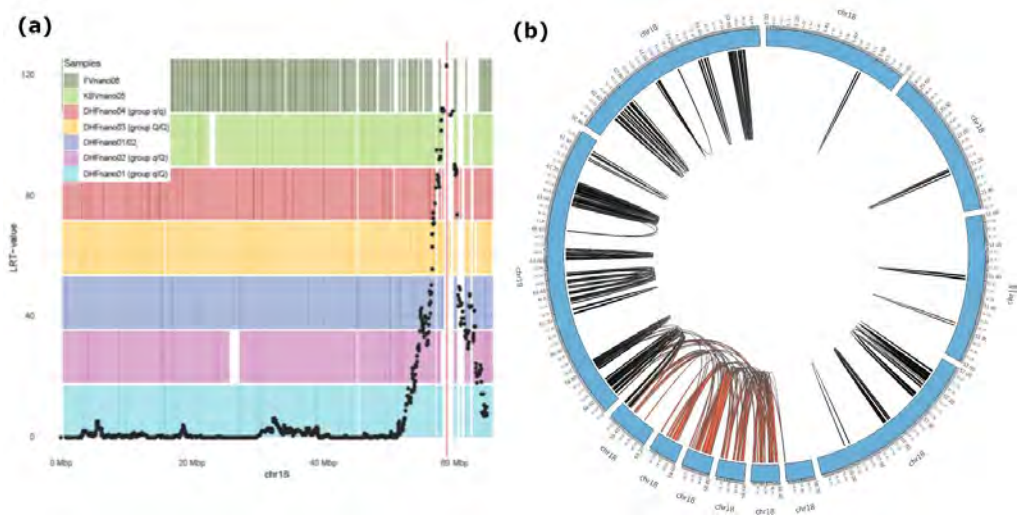

Figure 1. (a) distribution of the likelihood ratio test values (LRT) of paternal calving ease on BTA18 with the maximum peak (LRT_{max}=122.9) at 58,860,538 bp and coverage of BTA18 by contigs from *de novo* assemblies (from the top row: (1) FV; (2) KBV; (3) HF_qq; (4)HF_QQ; (5) HF_Qq: assembly of two heterozygous HF samples combined; (6) HF_Qq_1; (7) HF_Qq_2) (b) Distribution of the segmental duplications (SD) on BTA18 in the ARS-UCD1.2 assembly. Note, that chromosomal segments without any SD were not present in the circular figure. The links within the circle marks the detected SD. At the distal end of the chromosome and in the region between 58-60 Mbp we recognized an increased number ($P<1\times10^{-4}$) of SD compared to the residual chromosome. The red curves represent SD within the CI95% of the QTL (58,343,346-59,432,662 bp).

Table 1. Results of validation of candidate variants using PCR Genotyped breeds are Belgian Blue (BB), Braunvieh (BV), Charolais (CH), Fleckvieh (FV), Gelbvieh (GV), Jersey (JY), Limousin (LM) and Holstein Friesian (HF). Holstein Friesian samples are divided in four groups (Q/Q,Q/q,q/q,N/N); N/N group represented animals that are not used for mapping directly (no the official breeding values) but are ancestors or relatives usefully for derivation of haplotypes and imputation.

rs-ID / Position (bp) / Gene	Genotype*	BB	BV	CH	FV	GV	JY	LM	HF	HF q/q	HF q/Q	HF Q/Q	HF N/N
rs381577268	CC	24	23	9	22	22	17	13	166	141			25
57,816,137	CT				1**				98		86		12
ZNF613	TT								33			31	2
rs381878735	AA	23	23	9	21	22	16	13	141	131			10
59,574,329	AT				1**				86		83		3
ZNF665, ZNF677-like	TT								34			34	
rs464221818	CC	24	23	9	22	22	16	12	146	135			11
59,329,176	CT				1**				86		83		3
ZNF665-like	TT								34			34	
rs472502785	TT	24	23	9	20	22	16	13	142	131			11
59,345,689	TC				1**				86		83		3
ZNF665-like	CC								34			34	

** According to the pedigree records, this Fleckvieh bull contain 1.7% Holstein ancestry.

To avoid the reference bias, we also attempted to *de-novo* assemble the entire BTA18 using ONT sequences, however, the QTL region was marked by the lack of contiguity (Figure 1a) which was more pronounced in the region of QTL. Interestingly, investigation of the QTL region revealed that that this region (between 58 and 60 Mbp) present SV hotspot and contained higher number of SDs (Figure 1b) compared to the remaining chromosome ($P<1\times10^{-4}$).

Discussion

In agreement with the previous studies (Cole *et al.*, 2009: Müller *et al.*, 2017), we identified in HF a major QTL for calving traits at the interval from 58,343,346 to 59,432,662 bp with the peak value located at 58,860,538 bp. Further, the four SNPs that we identified in population wide LD with 'causal haplotype' could be used for monitoring of harmful QTL allele in HF as well as in HF upgraded breeds. Our results also suggested the presence of abundance of SDs in the critical region which could negatively affect the sequencing and *de novo* assembly in this region. Moreover, it is well known that SDs lead to more frequent non-allelic homologous recombination, and this is an essential mechanism for the formation of SV-hotspots leading to pathogenic structural changes (Lin and Gokcumen 2019). Consequently, the QTL allele itself could be an additional large pathogenic SV located in the major SV hotspots of the bovine genome.

511. Finding potentially causal genetic factors for meat tenderness using eQTL study in Hanwoo cattle

Y. Chung[1], K. Chung[2], P. Dinh[1], I. Choi[1] and S. Lee[1*]

[1]Chungnam National University, 99, Daehak-ro, Yuseong-gu, 34134, Daejeon, Republic of Korea; [2]Korea National College of Agriculture and Fisheries, 1515, Kongjwipatjwi-ro, Deokjin-gu, 54874, Jeollabuk-do, Republic of Korea; slee46@cnu.ac.kr

Abstract

Meat tenderness is a significant trait influencing eating quality of beef, which could affect consumer satisfaction and preference level. The discovery of causal genetic factors, including regulatory elements on tenderization is needed to improve beef tenderness efficiently. We found 166 putative core genes from an association study between Warner-Bratzler shear force (WBSF) and gene expression. Expression quantitative trait loci (eQTL) analysis with core genes was conducted, and 16 cis-eQTL SNPs for six core genes, *ASAP1*, *CAPN5*, *ELN*, *SUMF2*, *TTC8*, and *MGAT4A*, were identified. The major allele of cis-eQTLs for six core genes was correlated with gene expression, and increased expression level led to meat toughness. In particular, the major allele of rs133370240 in upstream region of *ELN* gene was overlapped with MZF1 binding sites involved with meat tenderization, suggesting that selection of the minor allele of SNPs will be effective in improving beef tenderness.

Introduction

Meat quality is determined by sensory traits including flavor, juiciness, and tenderness. Among them, meat tenderness has a significant influence on eating quality that is related to consumer's perception of beef quality (Koohmaraie *et al.* 2002). Therefore, the improvement of meat tenderness is prioritized on beef cattle. It is practical to utilize the causal factors to improve meat tenderness.

Many studies have been conducted to identify genetic factors such as protein biomarkers or differentially expressed genes (DEGs) (Diniz *et al.* 2019; Leal-Gutiérrez *et al.* 2020). Although functional studies have shown that genetic variants can significantly contribute to regulating gene expression (GE) as well as phenotype (Shi *et al.* 2021), there are limited studies on finding causal genetic variants using omics data.

The objective of this study is to explore causal genetic factors (genes and variants) that explain a path to phenotypic changes caused by regulatory elements.

Materials & methods

Animal data. We used the samples from *longissimus dorsi* muscle of 20 Hanwoo cattle (sire) with 30 months raised in beef feedlots of Hanwoo Experimental Station of National Institute of Animal Science (NIAS), Rural Development Administration (RDA), Republic of Korea (ethics committee approve number: 2015-150).

Association study for detecting core genes. mRNA samples were extracted from *longissimus dorsi* muscle of Hanwoo cattle. We mapped our data to the bovine reference genome (Bos taurus.UMD3.1), and obtained GE normalized using trimmed mean of M-value (TMM) method in edgeR package. An association study between phenotype (WBSF) and GE was conducted to identify core genes (P<0.01). The linear model to find core genes for WBSF is indicated as

$$y = u + e \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_511, © Y. Chung *et al.* 2022

where y is a vector of WBSF on 20 Hanwoo cattle, and u is a vector of the normalized GE for i^{th} gene (i = 1, …, n). e is a vector of residual effects. We detected the genes with significant regression coefficient (P<0.01), called as 'core genes'.

eQTL analysis. Single nucleotide polymorphism (SNP) chip data was available from the Illumina Bovine SNP777 BeadChip (777K) platform (UMD3.1), and we used 576,549 SNPs for 20 cattle. The cis-eQTLs were defined as SNPs located within 5 kb of transcription start site (TSS) or transcription termination sites (TTS) of the gene and detected with statistical significance (P<0.01). The linear model used is represented as:

$$y = m + e \quad (2)$$

Where y is a vector of GE of core genes, and m is a vector of the genotype of SNPs (0, 1, 2).

Transcription factor binding site (TFBS) enrichment analysis. To confirm if cis-eQTLs are on transcription factor binding sites (TFBS), we detected TFBSs using TFBSTools R package with JASPAR2020 database. The sequence information of mRNAs was obtained from ENSEMBL database, and one thousand base-pairs (1Kb) upstream from the transcription start site (TSS) were considered TF binding sites. The TFs with the accuracy score more than 0.9 and significantly P-value (Benjamini-Hochberg P<0.05) were selected.

Results

Putative core genes detection. An association study as preliminary analysis was conducted to find putative core genes with significant linear regression coefficient. 166 core genes were detected, and among them, 135 and 31 genes have positive and negative coefficients, respectively.

Cis-eQTLs detection. 16 significant cis-eQTL SNPs modulating GE of six core genes were detected from the association study between WBSF and GE of 166 core genes, *ASAP1* (ArfGAP With SH3 Domain, Ankyrin Repeat And PH Domain 1), *CAPN5* (Calpain 5), *ELN* (Elastin), *SUMF2* (Sulfatase Modifying Factor 2), *TTC8* (Tetratricopeptide Repeat Domain 8), and *MGAT4A* (Alpha-1,3-Mannosyl-Glycoprotein 4-Beta-N-Acetylglucosaminyltransferase A). 13 and 3 variants are in intron and upstream region, respectively (Table 1).

For five genes (*ASAP1*, *ELN*, *CAPN5*, *SUMF2*, and *TTC8*), expression levels tend to decrease in minor allele, leading to a reduction in WBSF, except for *TTC8* (Table 1, Figure 1A and 1B). On the other hand, the expression of *MGAT4A* tends to increase in animals with minor allele, and WBSF level tends to decrease.

TF binding site detection. A total of 26 TFs were significantly detected for six core genes, and among them, 13 TFs were common for all genes; Arnt, Ahr-Arnt, MZF1 (var.2), Pax2, SOX9, Sox17, SRY, Sox5, Hand1-Tcf3, HLTF, Nobox, ZNF354C, and Arid3a. We found that a cis-eQTL SNP, rs133370240 (25:33,825,442), in upstream region of *ELN* gene is located within a TF binding site, MZF1 (Figure 2).

Table 1. Significant cis-eQTLs for six putative core genes.

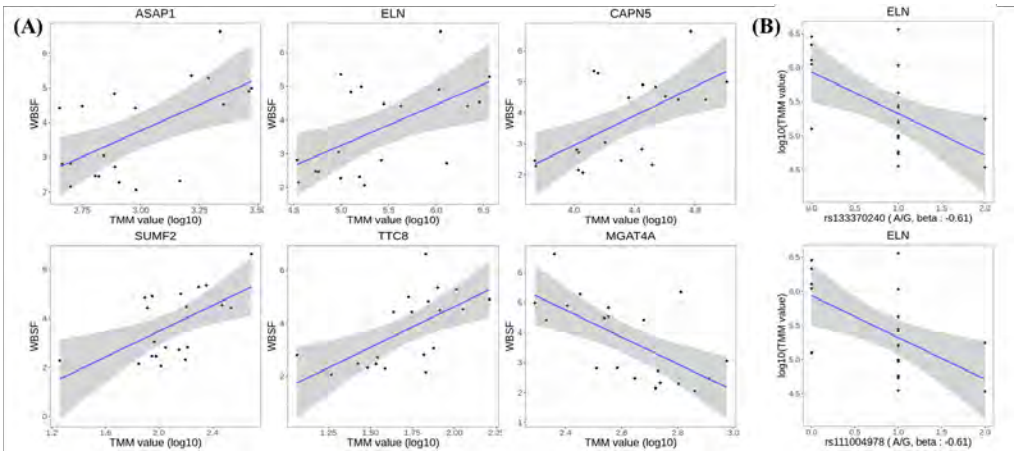

Figure 1. Gene expression and eQTL plot. Figure 1A indicates a change of WBSF depending on GE of six putative core genes, and Figure 1B shows a reduction of *ELN* expression in animals with minor allele of a variant.

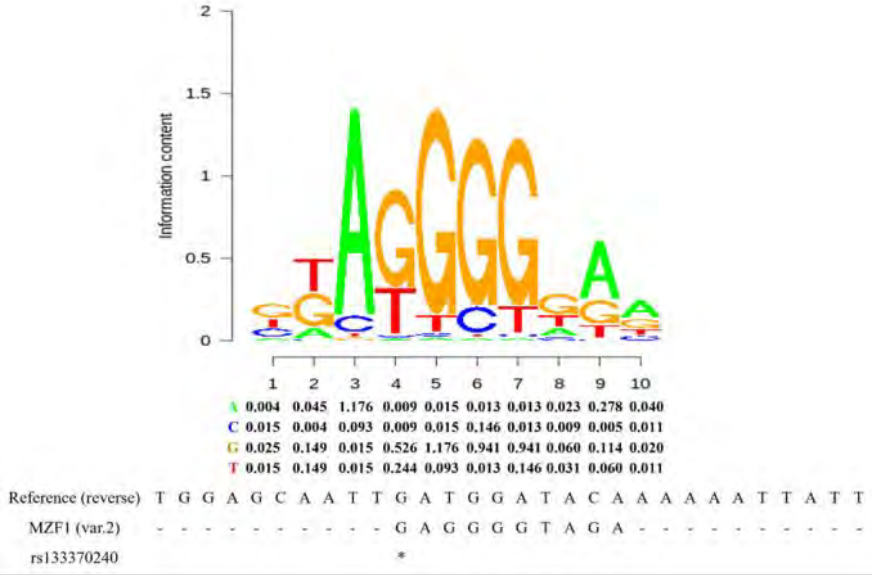

Figure 2. cis-eQTL SNP overlapping MZF1 binding site. Figure 2 indicates rs133370240 of *ELN* gene is in MZF1 binding site. The information content matrix (ICM) represents motif in the biological sequence and contains the weights associated with the occurrence of each nucleotide at the given position in a pattern.

Discussion

Our results showed 6 putative core genes and 16 cis-eQTL SNPs associated with meat tenderness. Major allele of cis-eQTL for *ASAP1*, *CAPN5*, *ELN*, and *SUMF2* was correlated with GE, and increasing GE led to meat toughness. The tendency shows that selection of the minor allele of the variants will be effective in improving beef tenderness.

Interestingly, the function of core genes is related to tenderness or intramuscular fat (IMF). For example, Tizioto *et al.* (2012) reported that a variant located in intron of *ASAP1* was associated with meat quality (tenderness). In terms of IMF, GE of *SUMF2* gene is associated with IMF deposition through glucose metabolism in pig (Ma *et al.* 2014). *ELN* expression is involved in extracellular component mass process for adipogenesis (Cesar *et al.* 2015). Finding genes related to IMF deposition could be due to high-concentration feeding system of Hanwoo cattle (Jo *et al.* 2012).

We identified that a cis-eQTL SNP (rs133370240) in upstream region of *ELN* was overlapped in MZF1 binding site. Compared to the minor allele of this variant, the major allele of this variant has MZF1 binding affinity, affecting GE and beef tenderization (Johnston *et al.* 2019). 13 common TFs including MZF1 for six core genes were found and the TFs have a role for muscle development (Patel *et al.* 2007; McKinnell *et al.* 2008).

In this study, although there are some limits such as a small sample sizes and validation using loss- and gain-of-function, our finding would serve as a basis for further studies to identify causal factors on meat tenderness.

512. The application of mixed linear models for the estimation of functional effects on bovine stature based on SNP summary

K. Kotlarz[1], B. Kosinska-Selbi[1], Z. Cai[2], G. Sahana[2] and J. Szyda[1,3*]

[1]Biostatistics Group, Department of Genetics, Wroclaw University of Environmental and Life Sciences, Kozuchowska 7, 51-631 Wroclaw, Poland; [2]Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark [3]National Research Institute of Animal Production, Krakowska 1, 32-083 Balice, Poland; joanna.szyda@upwr.edu.pl

Abstract

Genome-Wide Association Studies (GWAS) help identify polymorphic sites or genes linked to phenotypic variance, but a few genes / SNPs are unlikely to explain the phenotypic variability of complex traits. In the study, the focus was moved from single loci to functional units, expressed by the metabolic pathways (KEGG). Consequently, this study aimed to estimate KEGG effects on stature in three Nordic dairy cattle breeds using SNPs effects from GWAS as the dependent variable. The SNPs were annotated to genes, then the genes to KEGG pathways. The effects of KEGG were estimated separately for each breed using a mixed linear model incorporating the similarity between pathways expressed by common genes. The analysis yielded two conclusions: a single gene in a pathway's component may have a large impact on the pathway's overall effect or the high pathway effect may be due to the influence of many genes constituting the pathway.

Introduction

Genome-Wide Association Studies (GWAS) are very useful for the identification of polymorphic sites, typically Single Nucleotide Polymorphisms (SNPs), or sometimes genes associated with a phenotypic variation or with a disease. Nowadays, the common availability of SNPs obtained based on whole-genome sequencing allows for a very good resolution for the estimation of those associations. However, in the context of phenotypes undergoing a complex mode of inheritance, it is not expected that a few genes / SNPs suffice to explain the variability on a phenotypic level. As a consequence, we often manage to identify loci with a very high effect on the phenotypic variation, but still, a predominant proportion of this variation remains unexplained (Manolio *et al.* 2009), since it is often due to a combined effect of many loci, each with a moderate or small impact. Therefore, in our study, we moved the focus from individual loci to functional units, here expressed by the metabolic (KEGG) pathways, to better understand the physiological mechanisms underlying complex phenotypes. For this purpose, we use SNP summary statistics originating from the GWAS conducted for stature and based on whole-genome sequence data of three Nordic dairy cattle breeds.

Materials & methods

Material. The analysed data comprised SNP summary statistics from GWAS performed on 5,062 Danish Holstein bulls, 924 Danish Red Dairy Cattle bulls, and 2,122 Finnish Red Dairy Cattle bulls (Bouwman *et al.* 2018). The association was calculated for 25.4 million variants imputed with Minimac2 (Fuchsberger *et al.* 2015) from 630,000 SNPs using the 1000 Bull Genomes reference population from Run4, consisting of 1,147 individuals. SNP additive effects were estimated for deregressed EBVs serving as pseudophenotypes, separately for each breed with a single SNP, a mixed linear model including a polygenic effect described by a genomic relationship matrix implemented in the EMMAX software (Kang *et al.* 2010).

Statistical model. Based on their IDs, SNPs were annotated to genes corresponding to the ARS-UCD1.2 reference genome using BIOMART (Smedley *et al.* 2009), next KEGG manually drawn reference pathways (map) were annotated to genes using the David software (Huang *et al.* 2009). The effects of KEGG pathways

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_512, © K. Kotlarz *et al.* 2022

on stature were estimated separately for each breed using the following mixed linear model that accounted for the similarity between pathways:

$$\boldsymbol{y} = \boldsymbol{\mu} + \boldsymbol{Zt} + \boldsymbol{e} \tag{1}$$

where y is the vector of absolute values of SNP additive effects on stature from GWAS, μ represents the general mean, t is the random effect of KEGG pathways with a preimposed normal distribution defined by $N(0, \boldsymbol{V}\sigma_t^2)$, e is a vector of residuals distributed as $N(0, \boldsymbol{I}\sigma_e^2)$, Z is an incidence matrix for t. The similarity between KEGGs i and j, was introduced into the model by incorporating a nondiagonal KEGG covariance matrix V. This covariance was expressed by the Jaccard similarity coefficient:

$$J(i,j) = \frac{M}{N} \tag{2}$$

Where M represents the number of genes shared between KEGG i and j, while N represents the total number of genes involved in KEGG i and j. Variance components were assumed as known, amounting $\sigma_t^2 = 0.3\sigma_y^2$ and $\sigma_e^2 = 1 - \sigma_t^2$. To avoid effect confounding due to high linkage disequilibrium, only one SNP per gene (with the highest effect) was included in y.

Solutions. The mixed model equations (Henderson 1984) were used to obtain solutions for μ and t:

$$\begin{bmatrix} \hat{\boldsymbol{\mu}} \\ \hat{\boldsymbol{t}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{1}^T\boldsymbol{R}^{-1}\boldsymbol{1} & \boldsymbol{1}^T\boldsymbol{R}^{-1}\boldsymbol{Z} \\ \boldsymbol{Z}^T\boldsymbol{R}^{-1}\boldsymbol{1} & \boldsymbol{Z}^T\boldsymbol{R}^{-1}\boldsymbol{Z} + \boldsymbol{G}^{-1} \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{1}^T\boldsymbol{R}^{-1}\boldsymbol{y} \\ \boldsymbol{Z}^T\boldsymbol{R}^{-1}\boldsymbol{y} \end{bmatrix}, \text{ where } \boldsymbol{R} = \boldsymbol{I}\hat{\sigma}_e^2 \text{ and } \boldsymbol{G} = \boldsymbol{V}\hat{\sigma}_t^2 \tag{3}$$

To maximise the computational performance of the estimation/prediction process, a custom Python program implementing the NumPy library (Harris *et al.* 2020) was used. Since all calculations were carried out on a high-performance server, the NumPy library was also used to set the array indexing and order what further improved the computing time compared to a native Python application.

Results

Effects of 180 pathways were estimated. Table 1 summarises the top 10 pathways for each breed. Because NumPy and SciPy APIs are implemented with LAPACK and BLAS, which require Fortran memory layout, all input matrices were transformed to Fortran order to avoid costly transpose. In comparison to a fixed matrix input, this approach results in 10 times faster estimation process.

Discussion

While interpreting KEGG pathways effects two scenarios emerge. On the one hand, the overall high effect of a pathway may be driven by a high effect of a single gene that is this pathway's component – a situation that could have been detected in a conventional GWAS. On the other hand, the high pathway effect may be due to the influence of many genes constituting this pathway – a situation that may easily be missed in GWAS due to the small or moderate effects of particular genes. In our study, an emerging pattern is the high effect of pathways associated with the metabolism of xenobiotics (map00363, map00364, map00626, map00642, map00791). Already over 20 years ago Cheriathundam *et al.* (1998) indicated that the Growth hormone regulates the metabolism of enzymes from the cytochrome family which are responsible for the metabolism of a large number of xenobiotics. Furthermore, tetracycline (map00253) induces expression of the SHOX gene, which results in altered human growth (see e.g. Marchini *et al.* 2007). Bile acid synthesis (map00121) disorder in humans is known to influence weight and height (see e.g. Heubi and Setchell 2020).

513. Predicted isoforms of a Brahman cow revealed by full-length transcript sequencing

L.T. Nguyen[1*], Y. Cheng[2], R. Kuo[3], B.J. Hayes[1] and E.M. Ross[1]

[1]Centre for Animal Science, Queensland Alliance for Agriculture and Food Innovation, the University of Queensland, QLD 4072, Brisbane, Australia; [2]School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW, Australia; [3]The Roslin Institute and Royal School of Veterinary Studies, University of Edinburgh, EH25 9RG, United Kingdom; t.nguyen3@uq.edu.au

Abstract

Understanding transcriptome complexity is critical in connecting genomic sequence to gene function and phenotype. However, a complete catalogue of transcript isoforms in bovine species is still lacking. This study first processed PacBio isoform sequencing from eight tissues from a *Bos indicus* cow and two fetal tissues. The predicted transcript isoforms were compared to current bovine transcriptome annotation. In total, 149,793 isoforms were obtained from 31,363 genic loci, reporting an average of 4.7 transcripts per gene. Additionally, a large proportion (69%) of predicted transcripts were identified as novel isoforms, providing evidence and valuable datasets for improving the annotation of the bovine reference genome, which could be incorporated into genomic prediction models using appropriate methods to improve prediction accuracy.

Introduction

Precise gene annotations are essential to understanding the complexity of a species transcriptome and connecting genomic sequence to gene function and ultimately phenotype. To date, bovine transcriptome annotations are mostly based on short-read RNA sequencing platforms. However, short-read sequencing faces the challenge of lengthy transcripts, repetitive regions, and transposable elements. Long read sequencing technologies, represented by PacBio Sequencing (McCarthy, 2010; Rhoads and Au, 2015) and Oxford Nanopore Technologies (Loman and Watson, 2015; Bayega *et al.*, 2018), have overwhelmed this challenge by sequencing of full-length transcripts. In these recent years, PacBio single-molecule real-time (SMRT) isoform sequencing (ISO-seq) has been utilised to improve transcriptome annotations in humans (Tilgner *et al.* 2014), pig (Beiki *et al.* 2019), rabbit (Chen *et al.* 2017), chickens (Thomas *et al.* 2014) and Hereford cattle (Rosen *et al.* 2020; Halstead *et al.* 2021).

As a first step towards cataloguing *Bos indicus* transcript isoforms, this study analysed PacBio isoform sequence data from ten tissues from a *B. indicus* cow (Blood, Liver, Thyroid, Spleen, Kidney, Ovary, Uterus and Muscle) and two fetal tissues (Liver and Lung) using poly(A) selected PacBio Isoseq technology. The predicted transcript isoforms were then compared to current bovine transcriptome annotation.

Materials & methods

Animals and phenotypes. Animal use in this study was approved under animal ethics number QAAFI/270/17.

Sample collection and RNA extraction. The transcriptomes of eight tissues (whole blood, kidney, liver, muscle, spleen, ovary, uterus, and thyroid) from a Brahman cow and two tissues (liver and lung) from a fetus of the studied Brahman cow were sequenced by the Ramaciotti Centre for Genomics (UNSW Sydney, Australia) using PacBio Sequel system. Total RNA from each tissue was extracted using mirVAna miRNA isolation kit (Ambion) following the manufacturer's instruction. RNA purity was evaluated with a Nanodrop ND-1000 spectrophotometer (v.3.5.2, Thermo Fisher Scientific). QubitTM 4.0 Fluorometer with

Qubit RNA BR (Broad-range) assay kit (Thermo Fisher Scientific) was used to quantify RNA concentration. The assessment of RNA integrity was performed using Agilent 2100 Bioanalyser (Agilent Technologies). Only RNA with an integrity number greater than 8.0 was used for library preparation.

cDNA synthesis and sequencing. The RNA samples were converted to cDNA using the Lexogen TeloPrime kit (Lexogen) following the manufacture protocol. The cDNA libraries were sent to the Ramaciotti Centre for Genomics (UNSW Sydney, Australia) for sequencing on V3.0 sequencing chemistry using the PacBio Sequel system with 10-hour movies.

Sequencing data processing. The circular consensus sequences for each ZMW generated from each ISOseq library were only kept if they had at least two full-length reads longer than 100bp and predicted accuracy of 0.99. These ccs then went through the adapter removing, and poly(A) tails trimming steps to create full-length non-concatemer (FLNC) reads for further analysis.

Long read transcriptome annotation processing. Full length non-concatemer reads were mapped to the *Bos taurus* reference genome (ARS-UCD1.2) using Minimap2 (Li 2018) with parameters '*--secondary=no -ax splice -uf -C5*'. After mapping, resulting sam files from each tissue were then processed using TAMA collapse (Kuo *et al.* 2020) with parameters '*-x capped -a 100 -z 100 -sj sj_priority -lde 3 -sjt 10*'. The collapsed transcripts from different tissues were then merged using TAMA merge (Kuo *et al.* 2020) with parameters '*-a 300 -z 300 -m 30 -d merge_dup*' to create an Isoseq based transcriptome annotation.

Comparison of transcript structures across current NCBI RefSeq annotation (release 106). We used gffcompare v0.12.6 (Pertea *et al.* 2016) to compare NCBI RefSeq annotation gtf file to Isoseq transcriptome annotation file. Based on gffcompare class codes, predicted transcripts were classified as known isoforms (class code '='), novel isoforms (class codes 'c', 'k', 'j', 'm', 'n', or 'o'), novel loci (class code 'i', 'u', 'y' or 'x') or potential artifacts (class codes 'e', 's' or 'p').

Results

Across tissue, a total of approximately 5.0 M Iso-seq reads were observed, with an average of 502,712 Iso-seq reads (Table 1). The longest reads were observed from the Kidney library (length = 10.3 kb). Using the TAMA pipeline, this approach identified a total of 149,793 transcript isoforms at 31,363 genic loci, revealing an average of 4.7 transcripts per gene (tpg). The highest number of transcript isoforms was identified in the uterus tissue, followed by blood tissue, agreeing with the animal physiological stage (pregnant cow). Comparing predicted transcript isoforms with known transcripts in the current bovine genome annotation (NCBI RefSeq release 106) resulted in a total of 23,514 annotated transcripts exactly matching previously annotated transcripts (15.7% of all transcripts, Figure 1). The remaining predicted transcripts were classed into novel isoforms (69.6%), novel loci (12.7%) and potential artifacts (2%).

Discussion

This study revealed predicted transcript isoforms from a Brahman cow using long-read PacBio Isoseq technology. On average, 4.7 transcripts per gene (tpg) were identified closer to the ratio reported in human genome NCBI annotation (4.2tpg, NCBI release 109), one of the most complete transcriptome annotations. Compared to the bovine annotation, this number was higher than bovine NCBI annotation release 106 (1.59 tpg) and Oxford Nanopore Technologies bovine annotation (3.77 tpg). Out of 149,793 predicted transcript isoforms, over 69% were novel compared to current bovine NCBI annotation, revealing the complexity of the bovine transcriptome. A high percentage of novel isoforms has also been identified in other transcriptome annotation studies. For example, the percentage of novel transcript isoforms from improved pig and bovine transcriptome annotations were accounted for 80 and 60%, respectively (Beiki *et al.* 2019; Halstead *et al.* 2021).

Table 1. Summary of full length reads, genes and isoforms identified across tissues.

Sample	CCS[1] (%)	Full-length reads (%)	Mapped reads (%)	Mean / max. length (bp)	Genes / isoforms

Total					31,363/149,793

[1] CCS means circular consensus sequence.

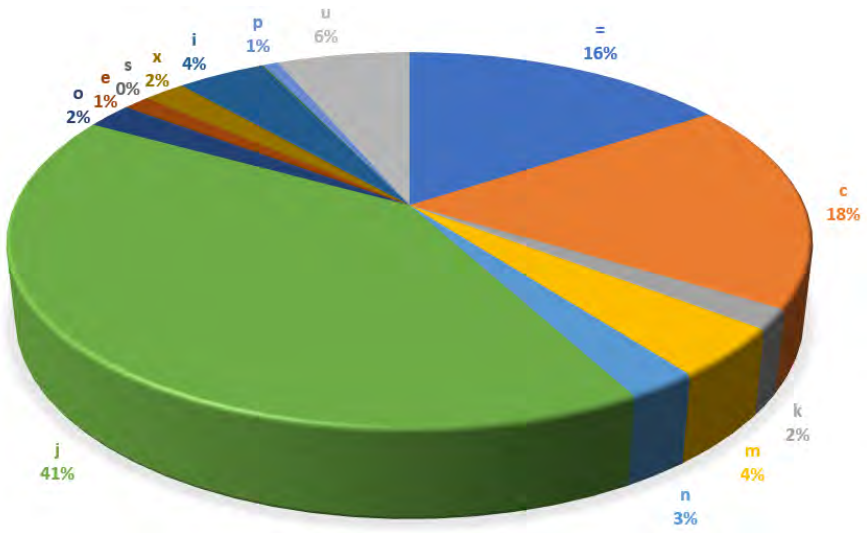

Figure 1. Comparison of predicted transcripts structure with known transcripts in NCBI genome annotation (release 106). Predicted transcripts were classified as known isoforms (class code '='), novel isoforms (class codes 'c', 'k', 'j', 'm', 'n', or 'o'), novel loci (class code 'i', 'u', 'y' or 'x') or potential artifacts (class codes 'e', 's' or 'p').

Compared to the current bovine transcriptome, this dataset has two significant differences. First, we sequenced each tissue in each SMRT cell, making our dataset valuable for tissue-specific transcripts. Second, this is the first Isoseq dataset generated for a *Bos indicus* breed (Brahman), whereas all current bovine transcriptome annotations were built from a *Bos taurus* breed (Hereford). This data will contribute to the improvement of the bovine transcriptome annotation and provides an opportunity for future comparative and evolutionary genomics studies. Also, an improved bovine transcriptome annotation for *Bos indicus* species could be useful for incorporating into genomic prediction models to improve prediction accuracy, as suggested by MacLeod *et al.* 2016 and Xu *et al.* 2020.

Abstract

The aim of this study was the meta-analysis (MA) of five GWAS for total number born (TNB) coming from five pig populations. MA was performed in METAL based on weighted Z-scores. As a result, two new SNPs were discovered that were not reported before as associated with TNB. First, on *Sus scrofa* chromosome (SSC) 14 located in intron of *FAM13C* gene. Second, on SSC9 located within intron of *AGMO gene*. pCADD analysis revealed a strong candidate causal gene underlying the QTL on SSC9. The third best hit and the most promising candidate gene for litter size was found within the *SOSTDC1* gene associated with lower male fertility in rats.

Introduction

Since the discovery of the first genomic association between litter size and estrogen receptor in 1996 (Rothschild *et al.*, 1996), there were high hopes in finding more genomic regions for reproduction traits. Currently, one of the most popular methods for uncovering the associations between traits and genes are genome-wide association studies (GWAS) using SNP BeadChip technology. In Pig QTL database already 1,625 QTLs are reported for different litter traits. Among them at least 356 are associated with total number born (TNB).

One of the main approaches to integrate and pool the results from GWAS is a meta-analysis (MA). MA could be used to increase the power of association studies combining datasets from different sources and to reduce false-positive associations (e.g. Sauvant *et al.*, 2020). Therefore, the aim of this study was to combine the full GWAS results for TNB from five studies and to perform MA in hopes of detecting new associations.

Materials & methods

The data for this study came from five full GWAS generated by: Uimari *et al.*, 2011, Sell-Kubiak *et al.*, 2015, Ma *et al.*, 2018, Balogh *et al.*, 2019, Zhang *et al.*, 2019. Detailed description of each study is presented in Table 1. The final dataset used for MA consisted of 63,531 SNPs.

Meta-analysis. METAL software (Willer *et al.*, 2010) was used to performed MA based on weighted Z-scores. This approach considers the *P*-value, direction of effect, and number of individuals present in each study. The method is most preferable when MA combines GWAS for differently defined phenotypes (Van den Berg *et al.* 2016) as in this study. The Bonferroni correction (less severe than using a threshold of $-\log_{10}(P\text{-value}) \geq 6$) was applied to established statistically significant associations. Post MA the search for candidate genes was done with Ensembl BioMart.

Candidate genes and causal variants. To assess possible candidate genes and variants underlying GWAS peaks from MA also the pCADD pipeline (Derks *et al.*, 2021) was used. The pipeline evaluates the presence of identified variants in a whole genome sequence (WGS) dataset in four elite breeds from Topigs Norsvin (WGS data description in Derks *et al.,* 2021). In short, we tested whether there are sequence variants in LD with the significant variant from the MA, and whether causal variants are likely to be identified. The

[1] deEBV i.e. deregressed breeding values of total number born; used to remove parents average.

[2] EBV i.e. direct breeding values of total number born.

[3] Bonferroni corrected *P*-value.

candidate variants in LD with the top SNP are ranked according to their pCADD score. The pCADD provides a per base impact score (Gross *et al.*, 2020) to distinguish between variants that likely have an impact (positive or negative) and variants that are benign. The pCADD pipeline additionally provides gene annotation and functional genomic information to further finemap the QTL region.

Results

Two SNPs were found to be significantly associated with TNB. First, *rs81300422* located on SSC9:84696142, which was, unfortunately, present only in one population of Finnish Landrace pigs (Uimari *et al.*, 2011). According to Ensembl Sscrofa11.1, it is located within an intron of a gene *AGMO*. Second, *rs80945731* located on *Sus scrofa* chromosome (SSC) 14:62633073, which was genotyped in four out of five populations (Uimari *et al.*, 2011; Ma *et al.*, 2018; Balogh *et al.*, 2019; Zhang *et al.*, 2019). Based on Ensembl Sscrofa11.1, this SNP is located in the intron region of the *FAM13C* gene.

Candidate genes and causal variants. To assess candidate causal genes at the two QTL loci we ran the pCADD-GWAS pipeline in four different breeds from Topigs Norsvin (Derks *et al.*, 2021). The *rs81300422* SNP on SSC9 was only present in a synthetic boar line (with 7% allele frequency). The third best hit with the pCADD pipeline (after two intergenic SNPs) is upstream of the *SOSTDC1* gene.

The *rs80945731* SNP on SSC14 was common in all four commercial breeding populations. The results yield SNPs within and close to the *PHYHIPL* and *FAM13C* genes. Thus, partially overlapping with the results of candidate gene search applying the classical approach.

Discussion

The meta-analysis of GWAS results coming from five different populations indicated two new SNPs associated with litter size. Even though our MA produced far less significant results than each of the GWAS separately this is the first time those SNPs are reported as associated with litter size.

Candidate genes on SSC9. The first of the SNPs *rs81300422* (genotyped only in one population used in MA) is located in the intron of not very well studied swine gene *AGMO* encoding enzyme Alkylglycerol monooxygenase. It is involved in the degradation of ether lipids (Watschinger and Werner, 2013) and is the only enzyme that can breakdown alkylglycerols and lysoalkylglycerophospholipids (Sailer *et al.*, 2021). *AGMO* was shown to be associated with many disorders in humans (Okur *et al.*, 2019), e.g. autism (Sebat *et al.*, 2007), type 2 diabetes (e.g. Fontaine-Bisson *et al.*, 2010) and immune defense (Sailer *et al.*, 2021). However, no link with fertility was reported.

Thus, far more interesting and promising as a candidate gene is *SOSTDC1*, indicated by pCADD analysis, which has been found to affect fertility in male rats (Pradhan *et al.*, 2019). *SOSTDC1* is a negative regulator of spermatogenesis, and downregulation of this gene during puberty is essential for quantitatively and qualitatively normal spermatogenesis governing male fertility. Further analysis comparing litter size between pigs with different genotype for *rs81300422* confirmed that the detected SNP is affecting TNB in pig population available for pCADD.

Candidate genes on SSC14. The second of the significant SNPs *rs80945731* (present in four populations used in MA) is located within a gene *FAM13C*, which was also confirmed by pCADD analysis. However, it does not have an immediate link with fertility in any specie. Nonetheless, it was expressed in swine adipose tissue and tissues of the nervous system (e.g. amygdala or medulla oblongata). In humans, *FAM13C* was shown to be associated with endometrial mixed adenocarcinoma (Stelzer *et al.*, 2016) as well as it has been used as a marker for prostate cancer (Burdelski *et al.*, 2017) or rectum adenocarcinoma survival predictor (Huang *et al.*, 2019). The second gene indicated by pCADD for *rs80945731* was *PHYHIPL* that is differentially expressed between early, full, and extended blastocysts in bovine IVP embryos (Georges *et al.*, 2019). Both *FAM13C* and *PHYHIPL* in humans were expressed (among others) in the tissue of the ovaries, uterus as well as prostate and testis (Stelzer *et al.*, 2016).

Conclusions

Presented results indicate that MA based on GWAS from five populations provided new insights into discovering genomic background of the litter size in pigs. Moreover, pCADD analysis brought us even closer to finding causal variants for TNB. Further studies should focus on *SOSTDC1* gene as its confirmed function has the strongest link with fertility.

Financial support

This project was financed by the National Science Centre, Poland (NCN SONATA grant no. 2016/23/D/NZ9/00029; ESK is the grant holder).

515. Selection signatures analyses revealed genes associated with adaptation in selected goat breeds in Kenya

R.W. Waineina[1,2*], T.O. Okeno[1], E.D. Ilatsia[2] and K. Ngeno[1]

[1]Department of Animal Sciences, Animal Breeding and Genomics Group, Egerton University, P.O. Box 536-20115, Egerton, Kenya; [2]Dairy Research Institute, Kenya Agricultural and Livestock Organization, P.O. Box 25-20117, Naivasha, Kenya; waineinaruth@gmail.com

Abstract

Artificial and natural selection in livestock is expected to leave unique footprints on their genomes. Goat breeds in Kenya have evolved for survival, breeding and production in various harsh ecological areas, and their genomes are likely to have acquired unique alleles for adaptation to such diverse production environments. To investigate signals of selection, we applied Integrated Haplotype Score (iHS) methods to 50K SNP genotype data from four selected goat breeds in Kenya. Following the analyses, a total of 171 candidate selection regions were detected in the studied breeds. Annotations of these regions yielded interesting genes potentially under strong positive selection including *SYT11, CCDC71, ALG14* and *UBQLN4* that are associated with multiple biological pathways underlying adaptation processes. Our results provide knowledge for the conservation and utilization of the goat genetic resources.

Introduction

Goats are spread all over the world, Africa included, following the pattern of human migrations with their livestock and trade routes (Luikart *et al.* 2001; Taberlet *et al.* 2008). In the process of migrations, they adapted to a wide range of various geographical conditions in the mountains to the desert and tropical regions of Africa. Goat populations were managed differently, with both natural and artificial selection playing a major role in their genetic variation due to the allowance of important gene flows among them, thus maintaining a wide range of genetic diversity (Taberlet *et al.* 2008). In the process of domestication, selection and breed formation, some regions within the goat genomes may have developed special patterns to mirror such development.

In Kenya, the indigenous goats (for example, Galla and small East Africa) and the crossbred of exotic and indigenous are known to be well adapted in various ecological areas (Ndeke *et al.* 2015; Kiura *et al.* 2020). It can therefore be assumed that these goats have evolved for survival, breeding and production in various ecological areas and their genome has footprints for adaptation to such environments and other traits of economic importance.

In goats, selection signature analyses using genome-wide SNPs have been done (Brito *et al.* 2017; Onzima *et al.* 2018). The approach has identified several putative genomic candidate regions and genes under selection that influenced some traits such as, thermo-tolerance, nervous and autoimmune response among others,

In this study, we used iHS method to identify footprints of selection. The objective of this study was to identify distinctive selection signatures in the genome of four breeds; Galla, Alpine, Saanen and Toggenburg goat breeds in Kenya.

Materials & methods

Animals and genotype control. Data used was obtained from 96 samples across four goat breeds; Galla (n=12), Alpine (n=29), Saanen (n=24) and Toggenburg (n=31). Animals were genotyped with the Illumina GoatSNP50 BeadChip (Tosser-Klopp *et al.* 2014) containing 53,347 single nucleotide polymorphisms

(SNPs). Quality control (QC) on genotype data were performed using PLINK v1.90 (Chang *et al.* 2015). The genotyping rate was 0.98. Out of the 96 samples, two samples failed due to missing genotype data (--mind 0.05); 1,079 variants were removed due to missing genotype data (--geno 0.1); 527 variants were removed due to Hardy-Weinberg exact test (--hwe 0.001), and 1,305 variants removed due to minor allele frequency lower than 0.05 threshold (--maf 0.05).

Identifying selection signatures. An iHS was estimated using *Fast*PHASE and performed using the *rehh* package (Gautier and Vitalis 2012) in R v. 3.4.4. Following analyses, the |iHS| scores were transformed into -log 10 [1 - 2| Φ iHS - 0.5|] in which Φ iHS is the cumulative Gaussian distribution function for better visualization and assessment of selection signals. According to Gautier and Naves (2011), and assuming a normal distribution, |iHS| scores can be interpreted as log10(1/P), where P is a one-sided *P*-value associated with the neutral hypothesis of no selection. In this study, all the SNPs ranking above 0.1 percentile of the |iHS| distribution were selected as candidates for selection.

Candidate genes associated with selection signature identification. Based on the above results, for all the SNPs passing the top 0.1% percentile threshold, we extracted goat genes mapping to 10 kb up-downstream of each SNP using BioMart tool based on the bovine reference genome assembly (ARS-UCD1.2).

Results

In Figure 1, the principal component 1, which accounts for 15.2% of the total variance separated Galla breed from the other three breeds. The principal component 2 accounts for 14.1% of the total variance, split the goat breeds into four clusters 1.

Figure 2 shows the genome-wide distribution of iHS values across the genome for each goat breed. A strong selective sweep was observed on chromosome 3 for both Galla and Saanen breeds.

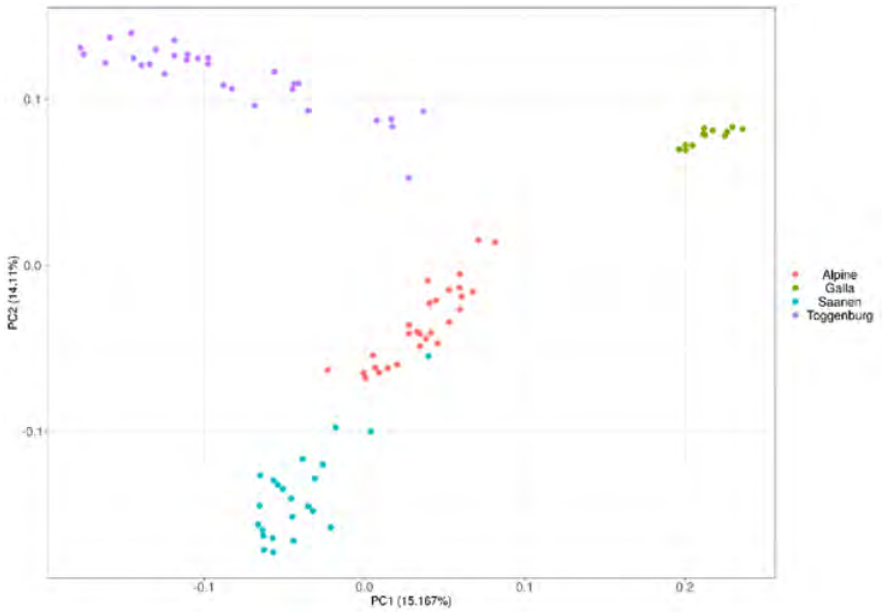

Figure 1. Principal components analysis plot based on SNP array data of goat breeds.

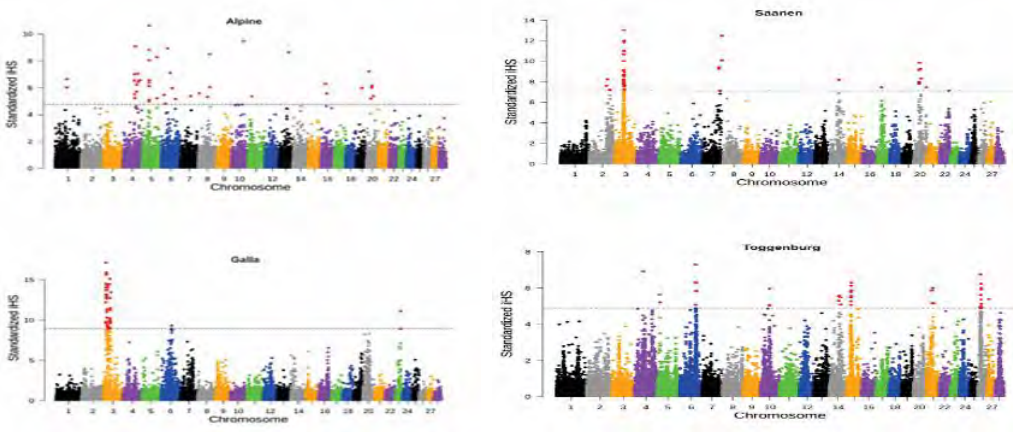

Figure 2. Genome-wide distribution of iHS values for Alpine, Galla, Saanen and Toggenburg goat breeds. The dashed line represents the top 0.01 percentile distribution of iHs values.

A total of 23, 28, 22 and 24 candidate genes overlapped with significant iHS genomic regions detected in Alpine, Galla, Saanen and Toggenburg goat, respectively. Some of the genes that overlapped with the topmost significant iHS genomic regions per breed include; *ALG14, ABCA4* in Saanen breed on Chr3(48504005 – 51372381), *SYT11,UBQLN4* on Chr3(14002666 – 46355720) in Galla breed.

Discussion

In this study, several top putative selective sweeps regions were detected by iHS analyses. A strong signal with the highest number of top candidates sweep regions was detected in Saanen and Galla breeds on chromosomes 3. The reasons why strong signals were detected in chromosomes 3 for the two breeds might be that their alleles have almost reached the point of fixation, this is in agreement with Waineina *et al.* (2021) findings that the two breeds were less admixed compared to the other breeds and are managed in seclusion from other breeds in this study.

Using the top SNPs identified, on chromosome 5 in Alpine breed, *CPNE8* was mapped, which is believed to cause Arthrogryposis multiplex congenita (*AMC*). Overexpression of *UBQLN4* gene, which has been detected in our study in Galla breed, has been associated with poor disease outcomes in various cancer diseases. Copine 8 *(CPNE8)* is a top candidate gene located on chromosome 5 in the Alpine breed which is a candidate quantitative trait gene for prion disease and incubation time in the mouse. The Synaptotagmin-11 *(SYT11)* gene is associated with pains in goats (Deng *et al.* 2018) which was detected on chromosome 1 in the Galla breed. *ABCA4* gene was detected in the Saanen breed, its mutations are responsible for Stargardt mascular degeneration, and related retinal degenerative diseases that cause significant loss in vision (Molday *et al.* 2009). The *CCDC71* is involved in innate and adaptive immunity in mammals (Gautier *et al.* 2009), while *ALG14* conditional mutants are sensitive to heat with reduced function mutants showing increased competitive fitness.

Conclusions

In this study, we investigated the signatures of selection of the four goat breeds in Kenya. The study identified several putative genomics regions. We found that *SYT11, CCDC71, ALG14, UBQLN4* genes may play an important role in underlying adaption to various environmental conditions. Our results provide knowledge for the conservation and utilization of the goat genetic resources in Kenya.

516. Investigation of host genetic role in PCV2 infections

H.R. Wijesena[1], K.M. Sutton[1], S.D. Kachman[2] and D.C. Ciobanu[1*]

[1]Animal Science Department, University of Nebraska-Lincoln, A218K Animal Science Complex, Lincoln, NE 68583-0908, USA; [2]Department of Statistics, University of Nebraska-Lincoln, 354B Hardin Hall, Lincoln, NE 68583-0963, USA; dciobanu@unl.edu

Abstract

A custom swine genotyping array (SowPro91, 111,141 SNPs) was designed to fine map two major QTL (SSC7 and SSC12) associated with PCV2b viral load. SowPro91 was enriched with SNPs in the SLA region of SSC7 QTL, and included the QTN for SSC12 QTL (*SYNGR2 p.Arg63Cys*). The tails of the distribution for PCV2b viral load (n=215) from the PCV2-dataset (n=974) were genotyped with SowPro91. SSC7 SNPs density varied substantially (1-463 SNPs/100 kb). As a result, BayesIM mapping precision was evaluated at multiple prior haplotype sizes (15-240 kb). *SYNGR2 p.Arg63Cys* effect was successfully mapped with shorter haplotypes (<120 kb). Multiple SSC7 QTLs mapped with short haplotypes harbored SNPs with large allelic frequency differences between pigs with extreme GPV for PCV2b viral load. Two closely located QTLs, mapped with short haplotypes, were simply a result of long-distance LD between regions. Further research is needed to genetically characterize this region for its role in immune response.

Introduction

Porcine Circovirus 2 (PCV2) is the etiological agent of a systemic disease that impacts growth and could lead to mortality. Our previous genome-wide association studies (GWAS) using Porcine SNP60 BeadArray (53,529 SNPs) identified two major genomic regions on *Sus scrofa* chromosome (SSC) 7 and 12 associated with viremia and PCV2-specific antibodies (Walker *et al.*, 2018). This study employed one of the largest PCV2 experimental infection data sets (n=974) in which host genetics represented by Porcine SNP60 BeadArray explained 64% of the phenotypic variation for PCV2b viral load. Gene annotation integrated with RNA/genome sequencing followed by *in vitro* gene editing models uncovered the *SYNGR2 p.Arg63Cys* as the source of the SSC12 QTL. The genetic basis of the QTL mapped on SSC7, next to Swine Leukocyte Antigen complex II locus (SLAII) is unknown. The SLA region is characterized by extended linkage disequilibrium (LD) and includes highly polymorphic genes involved in antigen recognition and immune response. Since commercial genotyping arrays are relatively limited in number of SNPs located in SLA region, a novel Affymetrix SNP array was designed (SowPro91) which saturated the SLA complex with SNPs discovered *via* genome and transcriptome sequencing. This array also included SNPs in genes with ontologies related to innate and adaptive immunity and causal variants known to affect viral disease susceptibility (e.g. *SYNGR2 p.Arg63Cys*). The objective of this study was to employ SowPro91 and fine map genomic regions and genetic variants located on SSC7 and associated with PCV2b viral load.

Materials & methods

Populations and phenotypes. Experimental design, procedures and animal use were approved by the IACUC of the University of Nebraska – Lincoln. Experimental PCV2b infection was carried out in 9 batches of maternal crossbred pigs (Large White × Landrace) generated by 14 genetic lines and 7 genetic programs (n=974). PCV2b viremia, specific antibodies and body weights were obtained at 0, 7, 14, 21 and 28 days post-infection (dpi). Experimental details were previously described (Walker *et al.*, 2018).

Sequencing and genotyping. SNPs discovered from RNA and genomic sequencing were used in the development of SowPro91 using Affymetrix Axiom myDesign technology. Transcribed SNPs were obtained from various RNAseq data sets and tissues, including peripheral blood from pigs that expressed extreme

DOI: 10.3920/978-90-8686-940-4_516, © H.R. Wijesena *et al.* 2022

levels of viremia (high and low) following an experimental infection with PCV2b (n=8, Walker *et al.*, 2018). Whole genome sequencing and SNP data was obtained from Landrace sires (n=20), a genetic line that contributed to 4 of the 9 batches of PCV2b experimental infections (Wijesena *et al.*, 2019). Genomic DNA was isolated from tail snips using DNeasy tissue kit (Qiagen). The DNA quantity was assessed by Qubit fluorometer (Thermo Fisher Scientific Inc.). A subset of animals representing the tails of the distribution for the residuals for PCV2b viral load (n=215) from the PCV2 dataset (n=974), was genotyped with SowPro91 (111,141 SNPs). The genotype data was filtered at ≥93% sample and ≥97% SNP call rates as described (Wijesena *et al.*, 2019; 2020).

DQB1 haplotyping. The densely polymorphic *DQB1* gene was genotyped by sequencing. Briefly, specific amplicons of the *DQB1* gene were sequenced and compared to full-length reference *DQB1* haplotypes (IPD, https://www.ebi.ac.uk/ipd/mhc). Reference SLAII haplotypes were assigned to pigs with extreme residuals for PCV2b viral load (n=136). Observed and imputed *DQB1* SNP genotypes were combined with SowPro91 in GWAS.

Statistical analyses. Bayes Interval Mapping (BayesIM) was implemented to estimate haplotype effects across the genome on PCV2b viral load. Based on SowPro91 and *DQB1* genotypes, a hidden Markov model was used to generate 8 haplotype states. QTLs were placed every 50 kb across the genome while prior average haplotype size was evaluated at 240, 120, 60, 30 and 15 kb. Model frequencies, genetic variances and haplotype effects were estimated at each locus across the genome. The statistical model included experimental infection batch, litter and pen as random effects, passive IgG and piglet age at infection as covariates.

Results

Recent studies on Porcine Reproductive and Respiratory Virus (PRRSV) and PCV2 showed that host genetics plays an important role in viral disease susceptibility in swine (e.g. Boddicker *et al.*, 2012; Walker *et al.*, 2018). Some of the QTLs detected were likely pathogen-specific such as the ones located on SSC5 (PRRSV) or SSC12 (PCV2). The broad location of the QTL mapped on SSC7 next to SLAII locus, appears to be common in both viruses. While the causal variant of the PCV2-specific SSC12 QTL was functionally demonstrated (Walker *et al.*, 2018) the genetic source of the SLA QTL is unknown.

Development of custom genotyping array. The SowPro91 custom array included 111,141 SNPs and it was designed to aid in fine mapping the QTL mapped near *SLA* locus (SSC7) for PCV2 related traits and other complex traits. Approximately 58% of the SowPro91 SNPs were identified using transcriptomic and genomic sequencing, while 39% of the array includes scaffold SNPs from Porcine SNP60 BeadArray. SowPro91 includes 4,579 SNPs in the broad *SLA* region (22.5-25.3 Mb). The vast majority of the SNPs were from our sequencing data (4,174 SNPs), supplemented by SNPs from Axiom Pig HD array (345 SNPs) and Porcine SNP60 BeadArray (41 SNPs). Across SSC7 (12,249 SNPs) there is an average of 10.9 SNPs/100 kb window. The density varies greatly across the chromosome since it is enriched in variants in the SLA region (Figure 1). While in the broad SLA region (22.5-25.3 Mb) there is an average of 163.5 SNPs/100 kb, outside this region there is an average of 7 SNPs/100 kb. The largest SNP density is located between 24.8-24.9 Mb with 463 SNPs. The average distance between the SNPs in the SLA region is 611.6 bp, while outside the region is 15,488.1 bp.

DQB1 haplotype diversity. Arrays are not effective in genotyping SNPs in dense polymorphic regions. As the result, the polymorphic *DQB1* gene, part of the SLAII, was genotyped by sequencing. The *DQB1* gene was characterized by substantial genetic diversity with 17 observed haplotypes in pigs with extreme residuals for PCV2 viral load. With the exception of a novel haplotype, all the other haplotypes were part

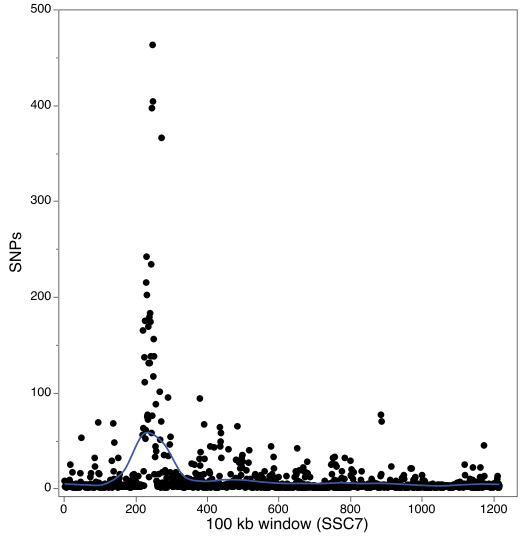

Figure 1. SNP density per 100 kb window on SSC7.

of the reference database. The observed and imputed genotypes of 119 SNPs in *DQB1* gene were combined with SowPro91 in GWAS.

Genome-wide association analyses. Since SNP density varied across SSC7, first we evaluated if prior haplotype size in BayesIM could impact QTL location and effect. While the SSC12 QTL chromosomal position is quite different from SSC7 QTL in terms of recombination rates and SNP density, we hypothesized that the location of the QTN on SSC12 (*SYNGR2 p.Arg63Cys*; 3,797,516 bp) could broadly inform some level of mapping precision for SSC7 QTL. QTL mapping was evaluated by BayesIM using prior average haplotype size of 15-240 kb. We expected that with longer prior haplotype size, the QTN effect will be distributed across different haplotypes sharing functional alleles. The QTL 'window' that included *SYNGR2 p.Arg63Cys* was detected in all models when haplotype size was ≤120 kb (Table 1); the actual distance of the mapped QTL from the QTN was -2,484 bp. At the longest prior haplotype size (240 kb) the QTL was placed farther apart from the QTN (-52, 484 bp). Also, the SSC12 QTL was associated with the largest model frequency at shorter prior haplotype sizes (15-60 kb). In contrast, the SSC7 QTL was the major haplotype at the longer haplotype sizes (120-240 kb). The difference in model frequency between top SSC7 QTL decreased with shorter haplotype size models. Consistent SSC7 QTLs were mapped at 22.1-22.2, 24.5 and 24.65 Mb (Figure 2).

Table 1. Model frequency of the major QTLs for PCV2b viral load using BayesIM.

Prior haplotype size (kb)	Major SSC7 QTL		Major SSC12 QTL	
	Location (Mb)	Model frequency	Location (Mb)	Model frequency
15	24.65	0.021	3.8	0.027
30	24.65	0.019	3.8	0.023
60	24.65	0.024	3.8	0.036
120	24.65	0.030	3.8	0.026
240	24.5	0.063	3.85	0.028

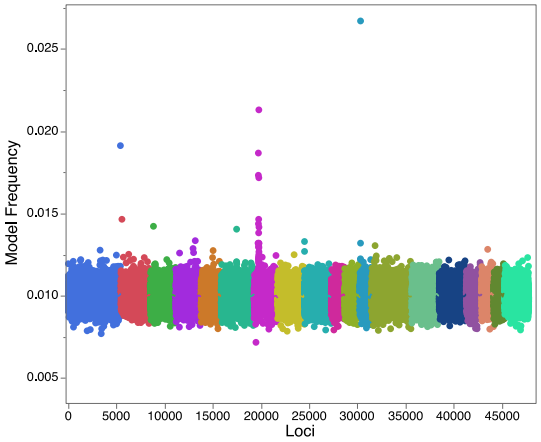

Figure 2. Genome-wide association between SowPro91/DQB1 genotypes and PCV2b viral load using BayesIM. Each dot represents the model frequency associated with 50 kb QTL.

To determine if SNPs located in two closely located major SSC7 QTLs (24.5 and 24.65 Mb) play a role in PCV2 susceptibility, allelic frequency differences were estimated between subsets of pigs representing the tails of the distribution for local genomic prediction values (GPV, 24-25 Mb) for PCV2b viral load. SNPs located in the QTL vicinity (24.5 and 24.65 Mb) displayed the largest differences in allelic frequency. Eleven SNPs had large differences in allelic frequency (>0.8; 24.47-24.65 Mb; Figure 3) with two SNPs having alternate alleles fixed in the subsets of pigs with extreme GPV. LD was estimated between these major candidate SNPs to assess if long LD was the source of these observed QTL. The QTLs mapped at 24.5 and 24.65 Mb are most likely a result of long-distance LD between major SNPs in these regions (r^2=0.61-1.0) (Figure 4). The proximal QTL (22.1/22.2 Mb) appeared to be independent due to low LD with major SNPs from 24.5 and 24.65 Mb QTL ($r^2 \leq 0.20$).

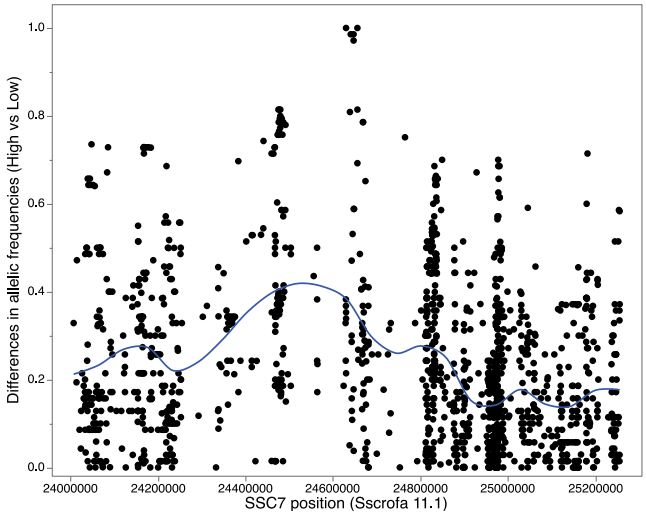

Figure 3. Allelic frequency differences between piglets with extreme local GPV across major SSC7 QTLs (24-25 Mb).

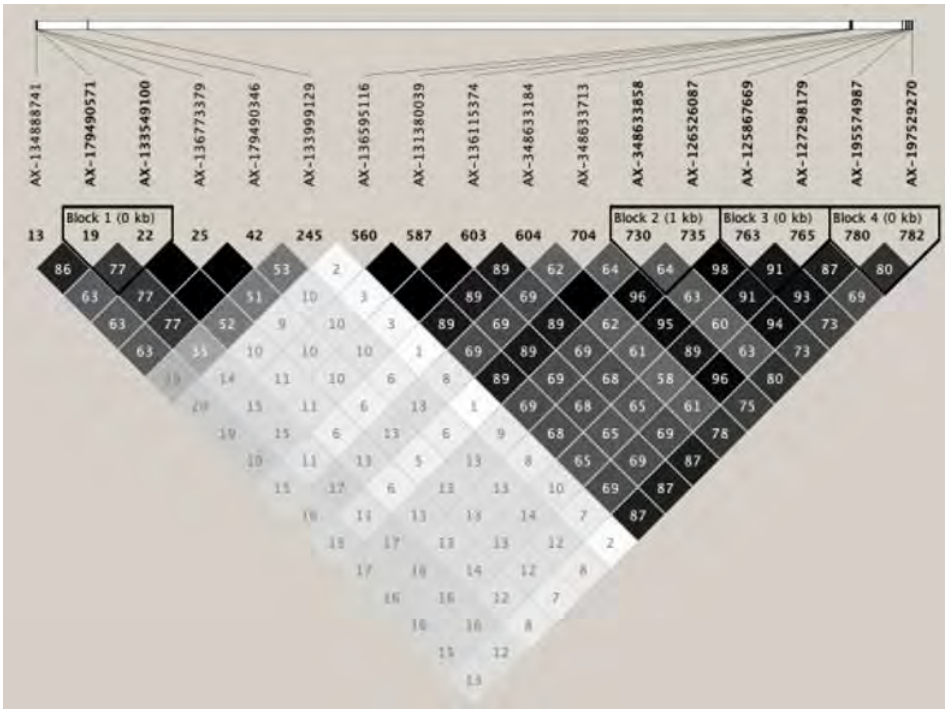

Figure 4. LD (r^2) between major candidate SNPs in the three SSC7 QTLs

Discussion

Detection of causal variants influencing viral disease could impact genetic improvement of modern genetic lines and animal welfare. Mapping precision is a key factor in QTL detection and discovery of functional variants. Previously, we showed that BayesIM was precise in fine mapping QTN, even at lower levels of local LD (Walker *et al.*, 2018). Using SowPro91 data, BayesIM and shorter prior haplotype models fine mapped a known SSC12 causal variant for PCV2b viral load. The short haplotype-based models appeared to detect multiple potentially distinct QTLs in the broad SLA region (SSC7). These regions harbor SNPs that displayed large differences in allelic frequencies between pigs with extreme PCV2b viral load. However, long-distance LD appeared to be the source of two closely located QTLs (24.5 and 24.65 Mb) that initially seemed distinct, especially when mapped with shorter haplotypes models. Further research is needed to characterize the genetic determinism in this highly complex SLA region, with potential broad implications in immune response and antigen recognition.

517. Olfaction: a critical force driving adaptive evolution in yaks

A. Kour[1*], S.K. Niranjan[2], S. Jayakumar[3], M. Pukhrambam[1] and M. Sarkar[1]

[1]ICAR-National Research Centre on Yak, Dirang, Arunachal Pradesh 790101, India, [2]ICAR-National Bureau of Animal Genetic Resources, Karnal, Haryana 132001, India, [3]ICAR-Directorate of Poultry Research, Hyderabad, Telangana 500030, India; aneet.kour@icar.gov.in

Abstract

Olfaction is genetically one of the highly evolved senses driving evolution for adaptation in mammals. The present study intended to highlight genomic regions under putative selective sweeps responsible for high-altitude adaptation in the genome of *Arunachali* yak, the only registered yak breed of India (till date). The data of *Arunachali* yak animals obtained through Double digest restriction-site associated DNA (ddRAD) sequencing was processed and 99,919 SNPs were filtered for further analysis. Genetic diversity elucidated based on nucleotide diversity (π=0.041 in 200 bp windows) and effective population size (Ne=83) was found to be optimum. Further, 207 regions across the genome were found to be putatively selected through De-correlated Composite of Multiple Signals (DCMS) statistic. Gene ontology analysis highlighted olfactory sensory perception as significantly overrepresented biological process. These findings reiterate evolutionary role of olfaction in environmental adaptation in one of the most unique germplasm.

Introduction

Sensory adaptations have long been postulated as an effective hypothesis underpinning divergent selection in heterogenous environments. Olfaction is phylogenetically one of the oldest senses helping organisms to interact fruitfully with their respective environments (Yohe and Brand, 2018). Besides imparting cognitive ability for food and life security, olfactory signals have also served as potential catalysts for social interaction and mating success. Thus on an evolutionary time scale, olfaction has immensely contributed to the overall fitness of an individual (Hoover, 2010).

Yak (*Bos grunniens*) is one of the evolutionarily unique species naturally selected to adapt in some of the harshest environmental conditions found on the planet (Qiu *et al.*, 2012). Geographical barriers along with cold and hypoxic conditions at high altitudes have posed a major challenge to the gene pool diversification in the species. It is also expected that certain regions in yak genome including olfactory perception must have been positively selected to ensure its viability and sustainability amidst environmental extremes (Wilkins *et al.*, 2014).

The present investigation was directed at peeking into the evolutionary history of *Arunachali* yak (the only registered yak breed of India till date) population in a holistic manner by estimating divergence in its gene pool and identifying signatures of selection in the breed. Since the breed is reared by tribal pastoralists for sustenance, artificial selection for performance traits has been negligible. Our findings would help us to outline new targets for selection and genetic improvement of the breed.

Methods

ddRAD sequencing was performed for 20 distantly related animals of *Arunachali* yak and the subsequent data generated (BioProject PRJNA577203) was analyzed for genomic diversity estimation and selection signatures identification.

Pre-processsing of the data. The paired-end FASTQ files were trimmed for the adapter sequences using PRINSEQ lite v0.20.4 (Schmieder and Edwards, 2011) and sequences with PHRED quality score less than 30 were discarded using Stacks (Catchen *et al*., 2011). The processed reads were aligned to *Bos taurus* reference genome assembly (ARS-UCD1.2) using Bowtie 2 (Langmead and Salzberg, 2012). Subsequently, VCFtools (Danecek *et al*., 2011) was used to generate SNPs at read depth 10 (RD 10) and finally, SNPs were filtered out based on quality control (QC) criteria like minor allele frequency (MAF) lesser than 0.05, Call rate (CR) lesser than 90% and *P*-value for Hardy-Weinberg Equilibrium (H-WE) lesser than 0.0001.

Genomic Diversity estimation. In order to assess genomic variability in the population, three indicators were used viz. nucleotide diversity (π), effective population size (N_e) and Runs of Homozygosity (ROH). π for the population was estimated in 200 bp windows of the genome using VCFtools (Danecek *et al*., 2011). N_e was determined using SNeP package in R (Barbato *et al*., 2015) whereas ROH patterns in 0-2 Mb, 2-4 Mb, 4-8 Mb and >8 Mb classes in the genome were assessed using detectRUNS package in R (Marras *et al*., 2015).

Selective sweep identification. Selection signatures in the population were identified by combining the allele-frequency spectrum based and haplotype based statistics like π, Tajima's D and Integrated Haplotype Score (iHS) using a composite measure of selection i.e. DCMS. Subsequently, the DCMS scores for 100 kb windows across the genome were calculated using MINOTAUR package (Lotterhos *et al*., 2017). SNP windows with significant *P*-values ($P \leq 0.01$) were examined for statistical overrepresentation of Gene Ontology (GO) terms in PANTHER (Mi *et al*., 2009) by providing the gene list from the putative regions under selective sweep. False Discovery Rate (FDR) value of ≤0.0001 was set as threshold for significance of GO terms.

Results

96.46 million paired-end raw reads were generated for the analysis. The average alignment rate was 97.71% and it was >85% for all the samples. After filtration, only 99,919 SNPs at RD10 passed the QC criteria and were comsidered for further analysis.

Genomic variability in the population. The average genomic divergence in the population measured using π across 200 bp windows in the genome was 0.041. N_e for the most recent generation (i.e. 13 generations ago) was estimated to be 83. ROH analysis revealed that a major proportion of ROHs (94.33%) were 0-2 Mb class followed by 4.66% in 2-4 Mb and 0.96% in 4-8 Mb category. In longer length category (>8 Mb), a negligible proportion of ROHs was observed (0.03%).

Regions under positive selection. DCMS scores were calculated in non-overlapping 100 kb SNP windows across each chromosome and subsequent *P*-values were calculated. 207 regions across the genome were found to be putatively under selection ($P<0.01$). These regions encompassed 611 protein-coding genes which were functionally annotated to identify the significant GO terms related to biological processes. Sensory perception of smell (GO:0007608) and its associated GO term (GO:0050911) were statistically overrepresented in the analysis (FDR<0.0001). Important genes identified in relation to these processes included: olfactory receptor (OR) genes like *OR5K3, OR5H6* and *OR1E1.*

Discussion

Arunachali yak population was found to be genetically diverse considering the narrow window size used for estimating π. Also, N_e estimates highlight that the number is still viable for long-term survival of the population (Meuwissen, 2009) although the small sample size considered may cloud the reliability of results. Higher prevalence of short and medium length ROHs was reflective of distant demographic and

selection events which resulted in repetitive shortening of chromosome segments due to recombination. Thus, DCMS was used to shed light on the putative regions under positive selection in *Arunachali* yak genome. Being a composite measure of selection, DCMS can perform with greater power and accuracy to detect selection signatures in sample sizes as low as 15 (Ma *et al.*, 2015).

GO terms related to sensory perception of smell were significantly overrepresented in the analysis highlighting the importance of olfaction in evolutionary history of yaks. Olfactory sensation is critical to population fitness as it regulates behaviours necessary for survival and reproduction of a species. It enables the organism to process and interact with various environmental cues and signals so as to facilitate activities like searching for food, attracting mates for procreation, maternal behaviour and resisting attack by predators (Meister 2015). It has also played an important role in speciation events occurring in response to changes in the environmental conditions through adaptation and natural selection of mates (Boughman 2002). As a result of this, each species has evolved its own olfactory strategies and is conditioned to recognize olfactory signals specific to its own evolutionary ecology (Hoover, 2010).

For ruminants residing at high altitude, sensation of olfaction is genetically one of the most evolved physiological adaptations (Friedrich and Weiner, 2020). Olfactory cognition is regulated by a major olfactory system involved in detecting different odorant molecules (or chemical compounds) and an accessory system sensing pheromones or chemical communication between organisms of same species, further eliciting a behavioural response (Hoover, 2010). In order to adapt to difficult environmental conditions of high altitudes and in response to the diversity in the distribution of vegetation at different altitudes, olfactory receptor (OR) genes in yaks have been highly selected and rapidly evolved during domestication (Zhang *et al.*, 2020). Also, pheromone communication may have played a major role in encouraging population fitness and gene pool diversity in the geographically isolated milieu of high altitudes. OR genes have also been reported to promote growth and development of hair follicles, further contributing to yak adaptation at high altitude (Busse *et al.*, 2014). Thus, development of olfactory sense in yaks may have been an important underlying factor ensuring natural selection for 'survival of the fittest'. Our findings shed light on the evolutionarily significant mechanism of olfaction underlying adaptation in yaks. Further, absence of artificial selection signatures for performance traits opens the prospects of genetic improvement in this unique germplasm.

Box 339, Bloemfontein, 9300, South Africa; zwanea@arc.agric.za

Abstract

Next generation sequencing have made it possible to study positive selection footprints and adaptation traits in livestock. South African (SA) Nguni cattle are well known for their adaption to harsh environments and can produce well. A total of 264 selective sweeps regions identified in Nguni were used to perform functional analysis of genes associated with phenotypic and adaptive characteristics. About 107 genes were identified across chromosomes with 58 genes associated with eight selected phenotypes queries. The $CRHR_2$ gene was associated with meat quality, *IRAK3* with decreased body size, feed intake and fatness, and *CARD15* gene was associated with disease resistance. Four genes (*SPI*, *YWHAZ*, *RGS4* and *RGS5*) were associated with myometrial relaxation in cattle. The *NOD2* and *IL21R* genes were associated with inflammatory bowel diseases whereas *CPLS* gene was associated with fat content in cattle. These genes were significant to the phenotypic and adaptive features present in SA Nguni cattle and will assist in breeding.

Introduction

Indigenous cattle breeds are important to human communities in Africa. South Africa (SA) is the home of five indigenous cattle breeds, Afrikaner, Bonsmara, Drakensberger, Nguni and Tuli. These breeds played a very important role in the history of the country, can survive in harsh local conditions, and are disease resistant. Nguni is a well-known cattle breed in SA due to its adaptive features, hardy and possess excellent resistant to parasites with natural immunity to tick-borne diseases (Mapholi *et al.*, 2015). It generally has a small body size, mostly horned with beautiful colors which makes the breed unique and easily distinguishable (Scholtz and Theunissen, 2010). Recent genomic technologies have made it possible to study the genomes of large animals to detect selection footprints to understand genetic architecture of local adaptation, phenotypic variation and gene function (Ramey *et al.*, 2013). Gene enrichment and pathway analyses can explore polygenic background of complex traits including leucosis, bull fertility, and meat quality on beef cattle. These analyses focus from a single gene to a group-based gene analysis and, findings of these analyses can help understand the genetic and biological architecture of complex traits (Visscher *et al.*, 2017). The aim of this study was to conduct functional enrichment analysis to identify genes pertaining phenotypic variation in SA Nguni cattle using selective sweeps. This information is important in breeding and improvement of these breeds.

Materials & methods

The Nguni selective sweeps data was obtained from the study of Zwane *et al.* (2019). Selective sweeps were identified using the Z-transformed pooled heterozygosity (ZHp) scores computed from a 50% overlapping sliding window approach, with SNP distribution of 150 kb windows. A total of 264 candidate selective sweep (ZHp Z-scores ≤-4) were used for gene enrichment analysis. The QTL information within the selective sweep regions was retrieved and visualized using Animal quantitative trait loci database (QTLdb). A database for annotation, visualization and integrated discovery (DAVID) v6.8 tool was used to convert the Gene ID list into gene names and symbols. In DAVID, the genes were examined to identify significant (P<0.05) gene ontology (GO) terms and for enrichment in molecular functional categories using Kyoto

Encyclopaedia of Genes and Genomes (KEGG) pathways, using selected phenotypes queries such as fat content, milk production, walking ability, heat tolerance, meat production, reproduction, bone and muscle development. The *P*-values were tested and adjusted by Benjamini correction, and the fold enrichment was used to select the top listed GO terms with statistical significance of $P<0.05$. The false discovery rate (FDR) was used to determine the significance of enrichment or overrepresentation of terms for each annotation (Lewin and Grieve, 2006).

Results

Figure 1 shows 264 candidate selective sweeps regions used for gene enrichment analysis while Table 1 indicate the top 10 genes identified in DAVID.

Discussion

From 264 candidate selective sweeps, the most significant selective sweep regions were identified in chromosome 8 and 19 (Figure 1). The sweeps identified 107 genes located in different chromosomes in

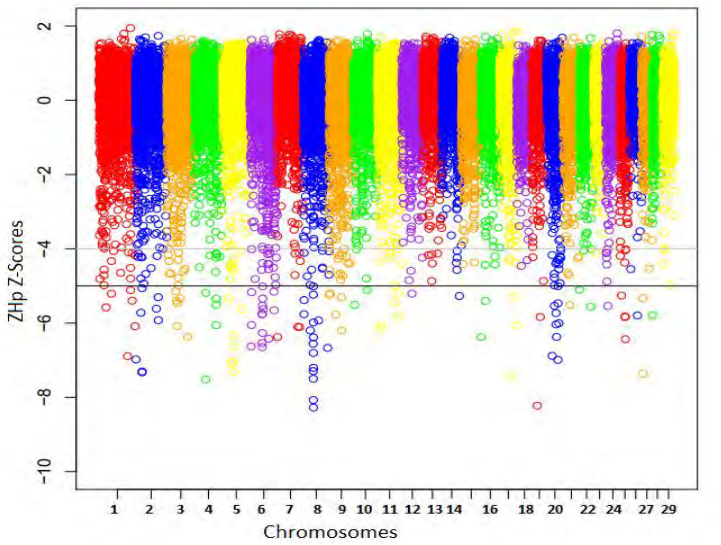

Figure 1. Candidate selective sweep regions (ZHp Z-Scores ≤-4) identified in South African Nguni cattle.

Table 1. List of top 10 genes identified within genomic location (strand) and their associated phenotypes/functions.

Gene symbol	Genomic location	Phenotype/function	Associated trait in cattle
CRHR2	4:66002072-66006203	Increased insulin sensitivity	reproduction, production
NOD2	18:19157447-19166134	Decreased tumour necrosis factor secretion	meat and carcass, health
YWHAZ	14:65584487-65617329	Abnormal skin morphology	exterior, milk
IRAK3	5:47796256-47839675	Decreased body size	meat and carcass, milk, exterior
IL21R	5:25233186-5:268874	Decreased T cell proliferation	milk, health
IMPDH1	4:66002072-66006203	Developmental growth, increased rate	reproduction, production
RGS4	3:6287012-6292402	Decreased systemic arterial diastolic blood pressure	milk, meat and carcass
PRKAA1	20:33688291-33716677	Slow postnatal weight gain	meat, milk, exterior
RGS5	3:6228349-6426528	Decreased total body fat amount	milk, meat and carcass
SP1	5:26753574-26759487	Decreased body size	milk, exterior

Nguni. These genes were previously associated with different functions in mice, human and cattle. Table 1 shows 10 significant genes identified on DAVID with $P<0.25$). Genes such as *CRHR2*, *NOD2*, *YWHAZ*, *IRAK3* and *IL21R* are among the top genes identified in Nguni. The *CRHR2* gene in chromosome 4 was associated with insulin sensitivity. This gene has been associate with juiciness and flavor in cattle (Jiang *et al.*, 2009). The NOD_2 gene, also known as *CARD15*, is a pattern recognition receptor for bacterial lipopolysaccharides which release inflammatory mediators that recognize the muramyl dipeptide and activate NF-kb that controls transcription of tumor necrosis factor-α, interferon-γ, interleukin-1β and interleukin-12 (Wang *et al.*, 2015). *CARD15* protein contributes to immune response of cells and plays an important role in antibodies production. The *CRHR2* gene has been associated with meat quality on Duroc × Pietrain populations (Casiro *et al.*, 2017) and the *CARD15* gene polymorphisms have been associated with tuberculosis susceptibility in Chinese Holstein cows (Wang *et al.*, 2015). Nguni cattle are known to be less susceptible to parasites disease affecting livestock in SA such as ticks and tick borne diseases. The presence of *IL21R* gene in Nguni could assist in the enhancement of their innate immunity.

The GO enrichment analysis have revealed the three molecular functions associated with kinase activity (GO:0004674~protein serine/threonine kinase activity; GO:0004672~protein kinase activity; GO:0016301~kinase activity). The protein kinase activity has been negatively associated with intramuscular fat content in longissimus dorsi muscle of beef cattle (Underwood *et al.*, 2008). This could justify the lean meat grades produced by Nguni cattle (Chulayo *et al.*, 2015). Enrichment analysis of genes was done using selected phenotype queries. Genes were mostly associated with walking ability, fat digestion, bone and muscle development, reproduction and heat tolerance. Genes identified in this study were highly significant to the molecular functions associated with phenotypic characteristics in Nguni cattle. This information is crucial and needed in changing environments.

Abstract

In the face of subsequently tightening animal welfare laws, genetic alternatives for docking tails of lambs in long-tailed sheep breeds are urgently needed. This study aimed to analyse the natural tail length variation in the Merinolandschaf breed and to identify possible causal genes for the short tail phenotype. Combined linkage disequilibrium and linkage mapping based on Illumina OvineSNP50 genotypes of 362 Merinolandschaf lambs resulted in two maximum likelihood ratio test statistic (LRT) peaks which were above the genome-wide significance threshold of LRT=16.63. *HOXB13* was identified as the most relevant candidate gene due to its proximity to the LRT maximum of 29.11 at position 37,311,843 bp on sheep chromosome 11 and its known function as an inhibitor of posterior axial growth. Further studies are needed for an Identification of the causal mutations, linked variants or more precise haplotypes to enable gene- or marker-assisted selection for breeding towards shorter tails

Introduction

Sedentary human communities began sheep management as early as 10,000-11,000 years BP in the Fertile Crescent (Zeder, 2008). It is thought that the Asiatic mouflon (*Ovis orientalis*) is the wild ancestor of domestic sheep. Like other wild sheep subspecies, it is a short-tailed hair sheep. The systematic production and processing of wool did occur several millennia later, leading to the '*Secondary Product Revolution*' (Sherratt, 1983) and the worldwide spread of wool sheep. Selection for fine wool fibers culminated in the economically most important sheep breed, the Merino. The common occurrence of fine wool and long tail in Merinos led to the frequent opinion that these phenotypes are genetically coupled or the result of the same artificial selector (Shelton, 1977). This assumption could not be proven directly. In today's sheep husbandry systems, the long woolly tail comes with several problems. Therefore, most lambs of long-tailed breeds are docked (Shelton, 1977). With the gradual introduction of restrictions on practices that cause suffering to animals, tail docking has come under scrutiny. This means that a long-term non-invasive alternative for the painful practice of tail docking is needed. Here, a genetic solution offers itself and medium to high heritability of tail length (TL) in different sheep breeds provides the genetic basis for breeding for shorter tails (see Greeff *et al.* (2015) and Branford Oltenacu and Boylan (1974)). Therefore, breeders in Australia, New Zealand and other countries attempted shortening of the tail by phenotypic selection within individual breeds. Unfortunately, several authors have observed severe dysfunction in animals homozygous for short-tailed alleles. This phenomenon has been observed in sheep (Carter (1976); James *et al.* (1991); Zhi *et al.* (2018)) as well as in dogs (e.g. Hytönen *et al.*, 2009), cats (e.g. Buckingham *et al.*, 2013) and mice (e.g. Beddington *et al.*, 1992). These undesirable negative side effects slowed down an active breeding programme against overlong tails in sheep breeds. Moreover, there have been no successful genetic mapping studies in Merino sheep breeds, and the possible relationship between this phenotype and dysfunctions has never been investigated on a genetic basis in Merinos. The aim of the present study was therefore to investigate the phenotypic and additive genetic variance in TL in *Merinolandschaf* and to map

the position of the mayor QTL(s) affecting TL. Together these objectives will enable more efficient breeding towards the short-tailed phenotype and thus improve animal welfare in sheep production without negative side effects.

Materials & methods

Animal samples, phenotypes and genotypes. Phenotyping of 362 lambs was conducted according to the method proposed by Eck *et al.* (2019). To correct the TL for body size and environmental factors, body weight (BW) and height at withers (WH) were measured and sex, age and litter size were recorded. To improve haplotype inference, we sampled and genotyped 22 fathers of above lambs. All sampled sheep were genotyped using Illumina's OvineSNP50 BeadChip, which contains 54,241 almost evenly distributed SNPs (Illumina, 2015). After quality filtering 45,114 markers remained. Haplotype phasing and imputation was conducted using a Hidden Markov Model implemented in Beagle version 5.0 (Browning *et al.*, 2018). To improve the accuracy of haplotyping and imputation, genotype and pedigree information from all available ovine data from the in-house database were added to the haplotyping design (Browning and Browning, 2011). Positions on the reference genome discussed below correspond to the Oar_4.0 reference genome

Estimation of heritability and Mixed linear model-based association analysis (MLMA). To estimate the proportion of variance in our phenotype explained by all SNPs we used the software GCTA v1.93.2, (Yang *et al.*, 2011). To map a putative TL locus, we performed a MLMA analyses with a leave-one-chromosome-out approach using the following model:

$$y = X\beta + Z_a a + Z_u u + e \quad (1)$$

Where y is the vector of TL (cm) and β a vector of fixed effects including the mean, sex, age, BW and WH at phenotyping. a is the vector of the additive effect (fixed) of the candidate marker to be tested for association, u is the vector of polygenic effect (random or accumulated) of all markers, excluding those on the chromosome which contains the candidate SNP. e is a vector of residuals. X, Z_a and Z_u are the incidence matrices for β, a and u, respectively. We considered 45,114 markers resulting in the suggestive *P*-value at 2.22×10^{-5} and genome-wide at 1.11×10^{-6} (Xiong *et al.* (2015)).

Combined linkage disequilibrium and linkage analysis (cLDLA). We also performed a haplotype-based cLDLA analyse. To account for linkage disequilibrium in the form of local haplotype relationships, the Locus IBD was estimated according to the method of Meuwissen and Goddard (2001) using sliding windows of 40 SNPs. Variance component analyses were carried out with the programme ASReml (Gilmour *et al.* (2009)) according to the method of Meuwissen *et al.* (2002). ASReml estimated the maximum likelihood, variance components, fixed and random effects simultaneously by considering the inverse of the genome-wide unified additive (see Powell *et al.* (2010)) and locus specific (see Lee and Van der Werf (2006) relationships matrices in the following mixed linear model:

$$y = X\beta + Z_1 u + Z_2 q + e \quad (2)$$

Where y is again the vector of TL and β is the vector of fixed effects (BW, WH, sex, age and the overall mean μ). u is the vector of random polygenic effects, q is the vector of random additive-genetic QTL effects and e is the vector of random residual. X, Z_1, Z_2 are incidence matrices linking the observed values with the fixed and random QTL effects. The logarithm of the likelihood estimated by ASReml for the model with ($log(L_1)$) and without QTL ($log(L_0)$) effects were then used for a likelihood ratio test statistic (LRT). The LRT values follow a χ^2 distribution with one degree of freedom (Heuven *et al.*, 2005) and were calculated as:

$$LRT_p = -2 \times (log(L_0) - log(L_{1p})) \quad (3)$$

where p refers to the position in the genome where the QTL effects are estimated (i.e. the centre of the sliding SNP window p). Bonferroni correction was carried out to account for multiple testing (Bland and Altman, 1995). This resulted in a corrected P-value of $<4.545\times10^{-5}$ and a corresponding LRT value with genome-wide significance is equal to 16.629. For all maxima of the LRT curve (*LRTmax*) that exceeded the genome-wide significance threshold, the 2-LOD (logarithm of the odds) criterion was used to determine the associated confidence intervals (van Ooijen, 1992).

Results

The GCTA-GREML resulted in SNP-based heritability of 0.992 with relatively low standard error of 0.12. Despite heritability close to 1 the association analysis revealed no genome-wide significant association between SNPs and TL. On the other side the haplotype based cLDLA mapping resulted in two genome wide significant QTLs associated with TL in Merinolandschaf (Figure 1). The most prominent and narrow peak is on the sheep chromosome 11 (OAR11) at position 37,111,462 bp with *LRTmax* = 29.46 corresponding to $P=5.71\times10^{-8}$. The second was mapped to the OAR2 at position 94,538,115 bp with *LRTmax* = 19.356 corresponding to $P=1.08\times10^{-5}$. The confidence interval for the *LRTmax* on OAR11 was set between positions 37,000,925 bp and 37,521,490 bp and for OAR2 between positions 93,441,900 bp and 96,402,884 bp. These intervals were then considered in the UCSC Genome Browser. *HOXB13* (37,290,203-37,292,513) as the most prominent candidate lies only 179-Kb proximal to the *LRTmax*.

Discussion

The results presented here suggest that TL inheritance is largely dependent on additive genetic variance (h^2 =0.992), but most likely due to the small sample size and the small number of markers, GWAS does not yield a significant relationship. The haplotype-based mapping resulted in one highly significant and fine mapped QTL on OAR11 and less sharp mapped but genome-wide significant QTL on OAR02. In our study, we could not detect any increase in the LRT curve in the candidate genes or regions detected in mapping studies of dogs, cats and mice. The confidence interval on OAR11 include complete ovine HOXB cluster and further seven genes. A corresponding literature search (see Diaz-Cuadros *et al.* (2021) for a review) clearly indicates *HOXB13* as the most likely gene causing the large effect in our design. The literature search for possible plausible candidates at OAR02 yielded hardly any useful results. We tried to improve our search with MGI Mammalian Phenotype level 4 (MMP4) ontology (66), but still we see no plausible link to our trait of interest. The haplotype analyses of the presented QTL regions will be used to select animals for capture sequencing of the confidence interval on OAR11 and OAR2. These analyses should yield promising causal candidate mutations, hopefully without the negative side effects mentioned above.

Abstract

A data mining method applied to large-scale genotyping data is proposed to detect recessive loci responsible for increased mortality in cattle and that have remained undetected by previous approaches. It is based on a screen for homozygous haplotype enrichment/depletion in groups of females with different life trajectories. After validation of the results in at risk and control mating, 34 deleterious haplotypes (13 in Holstein, 11 in Montbéliarde, and 10 in Normande) were identified, with frequencies ranging from 1.5 to 7.6%. Profiles of survival curves and causes of mortality differed greatly between loci, with early juvenile, late juvenile and evenly distributed death events. Candidate causal variants were found for fifteen haplotypes. A frameshift mutation of *NOA1* and a disruptive inframe deletion of *RFC5*, affecting two genes with no previous record of live homozygous mutants in mammals, were subject to phenotypical characterization.

Introduction

Due to their limited effective size and intense selection, cattle breeds experience a gradual increase in inbreeding, favouring the emergence of recessive defects. While a few of them are highly visible, many remain overlooked because they induce mortality during gestation or after birth but with non-specific symptoms. With the tremendous development of genomic selection and genotyping, new methods have been proposed to detect these defects such as the deficit in homozygotes (VanRaden *et al.*, 2011), reverse genetics (e.g. Michot *et al.*, 2016), or GWAS accounting for dominance (Reynolds *et al.*, 2021). In this paper, we propose another approach combining searches for enrichment/depletion in homozygotes and analyses of life trajectories. We demonstrate its detection power with the identification of several dozens of new defects responsible for increased mortality rate.

Materials & methods

Mapping of recessive loci and analysis of life trajectories. Information on pedigree and life trajectory (date of birth; lifespan; cause of death; and ages at first insemination, calving and lactation) was extracted from the French National database for 5.96 million Holstein, 1.63 million Montbéliarde, and 1.24 million Normande females with Illumina Bovine SNP50 array genotypes available for their sire and maternal grand sire (MGS). Among them, 8,203, 6,198 and 2,254 cases (heifers that died of natural cause before 3 years and were never inseminated) and 291,529, 141,343 and 56,095 controls (females that calved and started a first lactation) from the three breeds, respectively, were also genotyped with various Illumina arrays and their genotypes were imputed and phased to the Bovine SNP50 as described in Mesbah-Uddin *et al.* (2019). For sliding haplotypes of 20 markers we counted the number of homozygotes (hmz) observed (Nobs) within each group of genotyped individuals and in parallel we estimated the expected number of hmz (Nexp) using within-family transmission probability. We filtered haplotypes satisfying the following criteria: Nobs

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_520, © A. Guintard *et al.* 2022

≥10 in cases, increase in hmz (i.e. (Nobs-Nexp)/Nexp)) ≥25% in cases and ≤-25% in controls. Among stretches of consecutive haplotypes, we selected the one showing the highest increase in hmz in cases as the 'peak haplotype'. For validation we compared the proportions of animals belonging to three categories (case, control and others) using a *X* test with Benjamini-Hochberg correction; *P*-value≤5%) among the descendants of at-risk mating ('1'; carrier sire and carrier MGS) or control mating ('0'; noncarrier sire and MGS) born between 2000 and 2015 (and that were mostly not genotyped themselves). Then, for 34 validated haplotypes, we calculated the daily proportion of animals that died of a natural death (D), were slaughtered (S) or were still alive (A) over a period of 6 years for mating types 0 and 1. We also calculated the D0-D1, S0-S1 and A0-A1 differences in proportions on a daily basis and scored the days for which 25, 50, 75 and 100% of the maximum deviation between each difference in proportions was reached. Subsequently, we used these 12 parameters to perform a Principal Component Analysis (PCA) and a Hierarchical Clustering (HC) using RStudio package Factoshiny, v 1.2.5033.

Estimation of the effect of the haplotypes on various traits. For each of the 34 selected haplotypes we estimated the effects of the three genotypes on 11 traits (see results). We used yield deviation data corrected for environmental effects for each animal in a model including the haplotype as a fixed effect and a polygenic effect through a pedigree relationship matrix. Analyses were performed with BLUPF90 (Misztal *et al.*, 2014).The size of genotype groups ranged from 4 (minimum set value) to 346,210 animals.

Analysis of whole genome sequences. The genomes of 611 cattle from 22 breeds (including 190 Holstein, 72 Montbéliarde and 97 Normande individuals) were sequenced with Illumina technology and processed as described in Boussaha *et al.* (2016). Breed specific SNPs or short Indels carried by at least 50% of the haplotype carriers, predicted to be deleterious and located within ±10 Mb from the haplotype were considered as candidate causative mutations.

Clinical examination. Five *NOA1* and five *RFC5* homozygous mutants were subject to clinical examination ante and post mortem including blood dosage and histological analyses.

Results & discussion

Our screen for homozygous haplotype enrichment or depletion (HHED) in groups of females with different life trajectories identified numerous regions, which led us to consider the top 20 peak haplotypes per breed (Figure 1a). In total, 34 haplotypes (13 in Holstein, 11 in Montbéliarde, and 10 in Normande) with frequencies comprised between 1.5 and 7.6% were confirmed to increase juvenile mortality in validation populations. Among them only one haplotype colocalized with a deleterious locus previously reported, namely cholesterol deficiency in Holstein (CDH; e.g. Menzi *et al.*, 2016). The proportion of mating at risk between sire and MGS for one or more validated haplotypes reached 4.7, 7.1 and 8.4% for the three breeds, respectively. The subsequent analysis of the life trajectories of animals from at risk vs control mating using PCA and HC (Figure 1 b-f) distinguished three categories of haplotypes depending on the age and causes of death: early juvenile mortality (d), progressive mortality in juveniles and subadults (e) and increased mortality and premature culling throughout life (f).

For 11 traits routinely collected for evaluation purpose, high and negative effects were observed for the hmz carrier genotype while the heterozygous one showed low or no effect as compared with the noncarrier genotype (Figure 2a). This suggest that these deleterious haplotypes owe their presence in the populations mostly to genetic drift rather than hitchhiking or balancing selection.

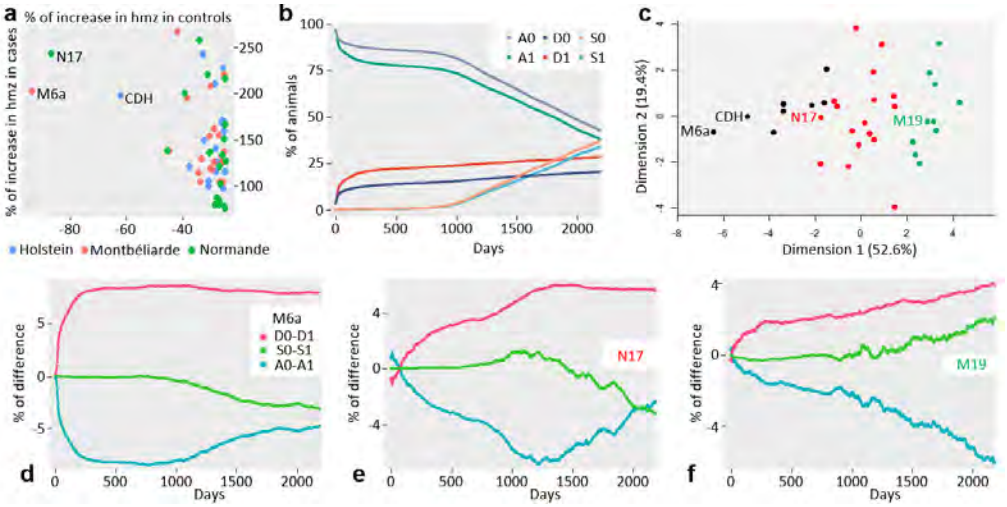

Figure 1. Mapping and characterization of life trajectories. a) increase in hmz in the case and control groups for the 60 selected haplotypes; c) daily proportion of animals from at risk (1) or control (0) mating for haplotype M6a that died (D), were slaughtered (S) or are alive (A); c) Results of PCA and HC for 34 haplotypes × 12 parameters. d-f) daily differences between D,S and E categories for mating types 0 and 1 for haplotypes M6a, N17 and M19, respectively.

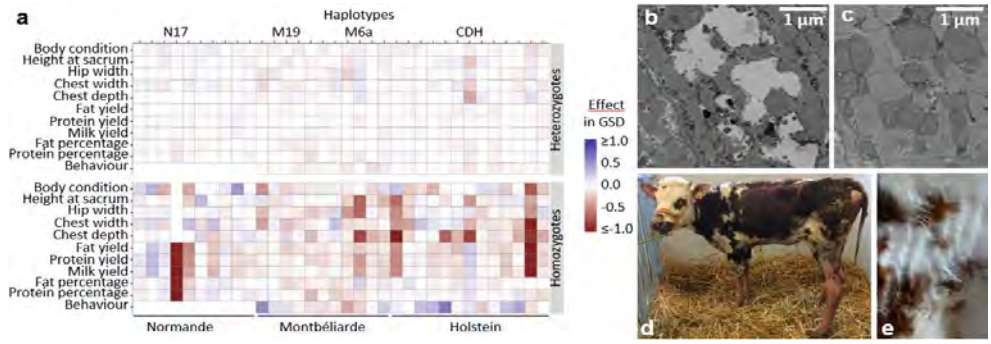

Figure 2. Effects of the 34 haplotypes on 11 traits (a) and results of clinical examinations (b-g). Electron microscopy of myocardium from NOA1-/- (b) and control (c) animals; General view (d) and detail of the fur of a RFC5-/- animal (e).

From whole genome sequences of 611 animals, we retained 22 promising candidates for 15 haplotypes, with predicted consequences including recessive metabolic, immune and neurological defects. Among them, candidate variants for haplotypes M6a in Montbéliarde and N17 in Normande affected genes with no previous record of live homozygous mutants in mammals, and were subject to phenotypical characterization. M6a candidate was a frameshift mutation of NOA1 (p.D400Rfs9) which is involved in the regulation of mitochondrial protein translation and respiration. Based on information of at risk mating data 50% of NOA1-/- individuals died before 41 days of life. The calves we examined were cachetic, had diarrhea and were unable to stand. Biochemical analyses (glycemia>1 g/l, creatine kinase>200 UI/l and K<2.5 mmol/l of serum) suggested that the organism responded to metabolic demand by lytic activity

of muscles, or even autophagy. After euthanasia, electron miscrocopy of myocardium revealed a nearly complete mitochondrial apoptosis and increased storage of glycogen (Figure 2b,c). Finally, N17 candidate was a disruptive inframe deletion of the RFC5 subunit (p.E369del) of a protein complex involved in DNA replication. RFC5-/- animals showed retarded growth, thin and curly hair, and alopecia of body extremities (Figure 2d,e). They died after recurrent episodes of diarrhea between six months and three years of age.

Conclusions

In conclusion, we propose an innovative strategy to detect deleterious recessive loci that remained overlooked by previous approaches. Taken as a whole, the dozen of loci validated within each breed is responsible for the death of 0.5 to 1% of the dairy females born each year in France. The management of all these new defects in selection will contribute to improve both animal welfare and the income of breeders.

Abstract

Seventeen male and female calves showing shortened gestation length and multiple fractures at birth were reported to the French National Observatory of Bovine Abnormalities (ONAB) among the descendants of a single Normande sire, suggesting autosomal inheritance with mosaicism. Clinical examination revealed clinical signs consistent with type II osteogenesis imperfecta (OI). Detailed analysis of gestation length and perinatal mortality supported a moderate proportion of affected calves (7.7%; 107 animals) and highlighted the underreporting of this congenital defect to the dedicated observatory. Genetic mapping, whole genome sequencing, and subsequent genotyping of cases and control animals identified a *de novo* missense substitution within the NC1 domain of *COL1A1* (Chr19 g.36473965G>A; p.D1412N). The same mutation has been reported several times to cause type II OI in human. In conclusion, we report the fourth mutation of *COL1A1* associated with type II OI in cattle and an interesting model for a syndrome also observed in human.

Introduction

In vertebrates, osteogenesis imperfecta (OI) constitutes a group of at least 15 genetic disorders characterized by bone deformity and fragility with various degrees of severity and possible addition of other symptoms (Sillence *et al.*, 1979; Besio *et al.*, 2019). Studies in humans have demonstrated that only two genes coding for the alpha 1 and alpha 2 chains of collagen type I account for 77% of cases, the rest being caused by mutations of at least 17 other genes (e.g. Marini *et al.*, 2007; Bardai *et al.* 2016). To date only three independent cases of OI have been characterized at the molecular level in cattle, all caused by *COL1A1* mutations (Bourneuf *et al.*, 2017; Jacinto *et al.*, 2021; Petersen *et al.*, 2019). From 2017 to 2019, 17 purebred Normande calves (9 males and 8 females) with symptoms consistent with OI were reported to the French National Observatory for Bovine Abnormalities (ONAB; doi.org/10.15454/BRKOV3). All cases were direct descendants from the same healthy Normande AI bull (called 'Ly.') suggesting an autosomal dominant inheritance with somatic or germline mosaicism. The purpose of this study was to characterize the clinical and genetic features of this new syndrome.

Materials & methods

Phenotypes. One affected calf and an unrelated control that died of natural death at one week of age were frozen at -20 °C and subjected to various analyses (CT scan, X-ray, necropsy, reassembly of limb bones and histology of bones and tendons). Gross clinical description and DNA samples were also available for 16 additional affected half-sibs. In addition, information on the date of birth, survival within 48h after delivery, and gestation length were recovered for 1,387 progeny of Ly. and 161,413 Normande calves from 63 control bulls born the same year as Ly. (mean=2,439±1,747 progeny per sire).

Genetic analyses. The 17 cases, 84 half-sib controls and Ly. were genotyped with various SNP arrays (Illumina, San Diego, USA) and then phased and imputed to the Bovine SNP50 in the framework of the French genomic evaluation as described in Mesbah-Uddin *et al.* (2019). Then, paternal phases were screened for

sliding haplotypes of 50 markers that were carried by all cases and by less than 50% of their half-sib controls. We subsequently sequenced the genome of one case using the Illumina NovaSeq platform (150 bp paired-end reads), processed the data in accordance with the guidelines of the 1000 Bull Genomes Project (Hayes and Daetwyler), and used 5,116 genomes from run 9 of the latter project as controls. A candidate mutation in the *COL1A1* gene was genotyped by PCR amplification with primers GCCTCCCAGAACATCACCTA and CTTTTCGGGGGTTTCAGTTT using Go Taq Flexi DNA polymerase (Promega), followed by Sanger sequencing (Eurofins MWG, Ebersberg, Germany).

Results

At necropsy, the frozen specimen presented light blue sclerae and dentinogenesis imperfecta with grey and friable teeth (not shown). CT scan and preparation of the skeleton revealed the existence of ancient fractures associated with bone loss or abnormal repair mainly located on the diaphysis of long bones, as well as recent limb and rib fractures probably due to the mechanical constraints of calving (Figure 1a-d).

This calf also suffered from arthrogryposis associated with a thickening of the joint capsules, and from a generalized osteopenia as revealed by a comparative x-ray analysis with a control calf (not shown). These symptoms fitted perfectly with the clinical features of the most severe form of OI, namely type II. The 17 cases all died at birth or soon after, and displayed twisted or broken limbs, as well as reduced gestation length (Figure 1e-g). Ly. was found to be the worst Normande bull for perinatal mortality with 15.9% of

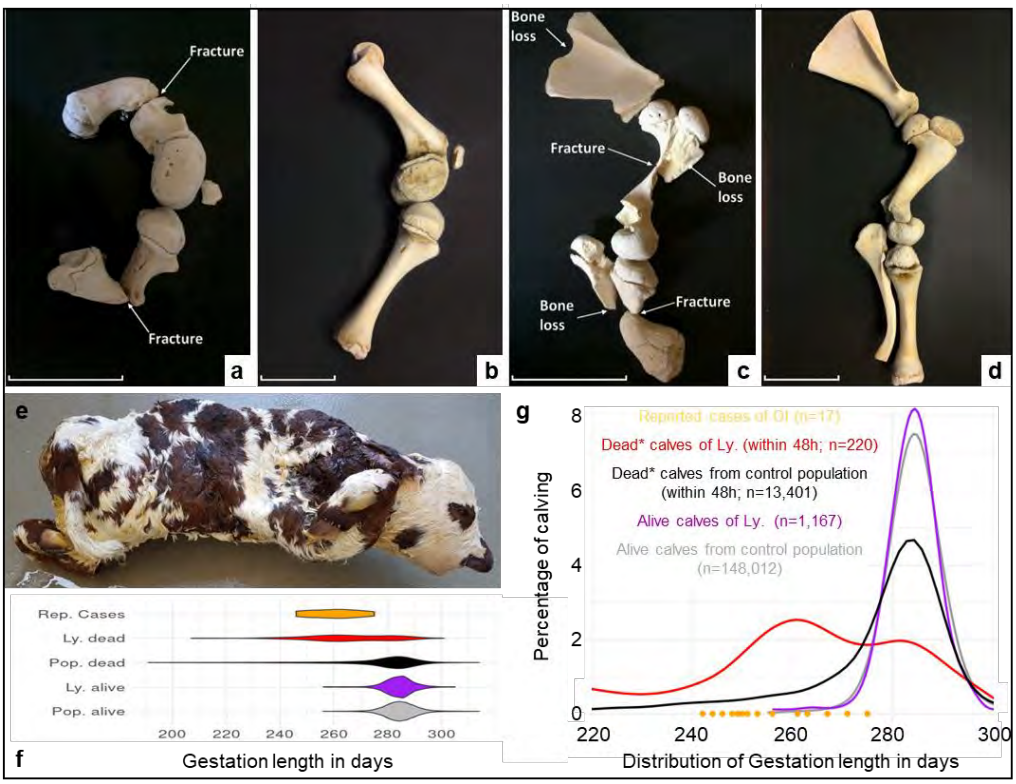

Figure 1. Clinical manifestation of OI. Details of bones from posterior (a,b) and anterior (c,d) limbs of case (a,c) and control (b,d) calves; general view of an OI calf (e); statistics on gestation length and perinatal mortality within the descendants of Ly. and control bulls (f) and related distributions (g).

calves declared as dead within 48h after birth versus 8.2±1.5% for 63 control sires. Assuming that this excess of perinatal mortality was due to OI, we estimated the proportion of affected calves to be 7.7% (i.e. 15.9-8.2%) among its progeny. This would represent 107 cases, which contrasts with the only 17 reported to us and highlights the underreporting of congenital defects to heredosurveillance platforms, even for textbook genetic syndromes. The gestation lengths of the perinatally dead calves of Ly. were significantly shorter than those of matched control calves ($P<2.2\times10^{-16}$; T test; Figure 1f) and showed a bimodal distribution with an additional subpopulation centered around 260 days that comprised the reported cases of OI (Figure 1g). This observation is in agreement with previous reports of premature rupture of membranes in sporadic cases of OI due to collagen defects, leading to preterm delivery (e.g. Cole *et al.*, 1992).

To gain insights into the genetic architecture of OI in this family, we analysed phased Bovine SNP50 genotypes from the 17 cases and 84 half-sib controls. Assuming autosomal dominant inheritance, we mapped the locus to chromosome 19 between positions 35,459,825 and 41,972,985 bp (ARS-UCD1 assembly). Then, by comparing whole-genome sequences of one case and 5,116 controls representing the worldwide cattle diversity, we identified a single heterozygous candidate variant in this interval: a missense variant affecting an aspartic acid residue within the NC1 domain of COL1A1 that is entirely conserved among vertebrates (Chr19 g.36473965G>A; p.D1412N; SIFT score = 0; Figure 2).

Interestingly, the same substitution has been reported three times (e.g. Bodian *et al.*, 2009) to be responsible for type II OI in human which supports its causality. As a further verification we genotyped the sire, 3 affected calves and 3 controls carrying the same paternal haplotype (but in the non mutated version) using PCR and Sanger sequencing and confirmed the *de novo* nature of this mutation. Finally, based on the small deviation of the 1:1 ratio for each paternal haplotype among the 84 control animals (i.e. 40 vs 44) we estimated a proportion of affected calf of 4.5% (4/88) which is consistent with our previous estimation of 7.7% based on the excess of perinatal mortality.

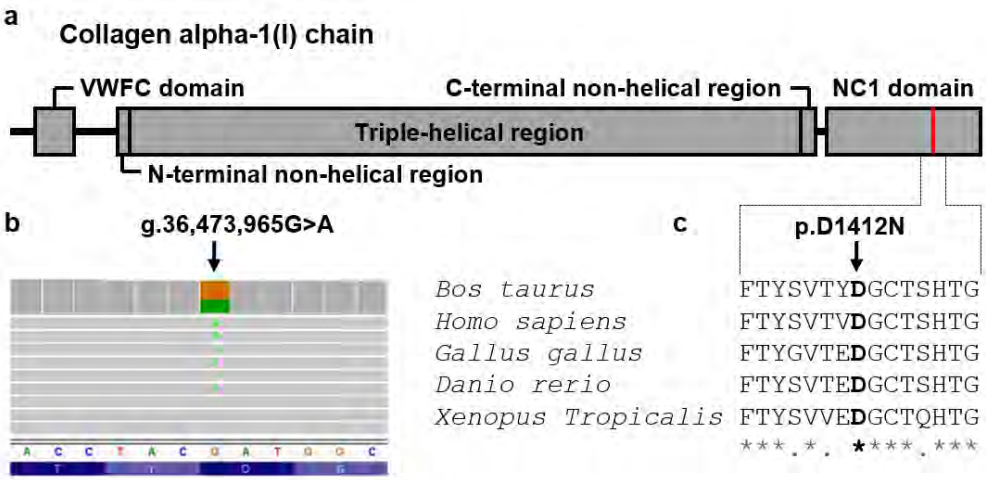

Figure 2. Details on the candidate variant. Functional domain of the bovine COL1A1 protein (a), Integrative genomic viewer screenshot showing the substitution at the DNA level (b), and multiple alignment of COL1A1 ortholog proteins from various vertebrate species (c).

Conclusions

In conclusion, we identified a *de novo* deleterious substitution of COL1A1 that: (1) is responsible for type II OI associated with preterm delivery in the progeny of a mosaic bull; and (2) corresponds to a mutation previously described in human patients suffering from the same syndrome. This study highlights the interest of large data sets available in livestock species to characterize genetic defects and in parallel raises the concern of underreporting of genetic defects to dedicated observatories.

522. CRISPR-Cas9 gene editing enables functional evaluation of a host *Synaptogyrin-2* missense variant in PCV2b infection

L.R. Walker*, H. Vu and D.C. Ciobanu

Animal Science Department, University of Nebraska-Lincoln, 3940 Fair St, Lincoln, NE 68583, USA; lianna.walker@huskers.unl.edu

Abstract

Porcine circovirus type 2 (PCV2) is a prevalent DNA virus affecting swine populations worldwide. Previously, we identified a missense variant within the host *Synaptogryin-2* gene (*SYNGR2 p.Arg63Cys*) significantly associated with PCV2b viral load. In this study, we successfully generated a porcine kidney 15 (PK15) clone homozygous for the 'favourable' *SYNGR2 p.63Cys* allele using *in vitro* CRISPR-Cas9 gene editing. Infection of this edited PK15 clone (*emSYNGR2*$^{+p.63Cys}$), demonstrated a significant reduction in total PCV2b replication starting at 48 hours post infection compared to wildtype PK15 cells (*wtSYNGR2*$^{+p.63Arg}$, $P<0.01$). Investigation into the fractional distribution (cell/supernatant) of total PCV2b copies revealed differences in infection dynamics between the variant cell lines across timepoints post infection. Based on these findings, we propose that the *SYNGR2 p.Arg63Cys* variant functions in the early stages of PCV2b infection, specifically in the endocytosis and/or translocation of virions to the nucleus for replication.

Introduction

Viral diseases continuously threaten the sustainability of livestock industries worldwide due to negative effects on growth and animal welfare. As our ability to investigate complex traits at the genomic level has improved, interest in identifying host variants involved in disease resistance across livestock species has also grown. Previously, we identified a missense variant within the host *Synaptogryin-2* gene (*SYNGR2 p.Arg63Cys*) significantly associated with susceptibility to Porcine Circovirus Type 2b (PCV2b), a prevalent DNA virus affecting swine populations across the globe (Walker *et al.* 2018). In this large-scale genome wide association analysis, the *SYNGR2 p.63Cys* allele was deemed 'favourable' and associated with lower PCV2b viral load following *in vivo* experimental challenge (Walker *et al.* 2018). Generation of a Porcine Kidney 15 (PK15) *SYNGR2* knock-out cell line using *in vitro* CRISPR-Cas9 gene editing validated the function of this gene in PCV2b infection (Walker *et al.* 2018). Specifically, *SYNGR2* knock-out resulted in a significant reduction in PCV2b replication by 24 hours post infection (hpi) compared to wildtype PK15 cells ($P<0.05$, Walker *et al.* 2018). However, this does not provide the necessary evidence to validate the function of the associated *SYNGR2 p.Arg63Cys* variant in PCV2b infection. In order to provide direct experimental evidence for the function of this missense variant, cells with alternate homozygous genotypes need to be simultaneously infected with PCV2b. The wildtype PK15 cell line is homozygous for the *SYNGR2 p.63Arg* allele. Therefore, the objective of this research was to generate PK15 clones homozygous for the alternate *SYNGR2 p.63Cys* allele via CRISPR-Cas9 gene editing. By infecting different *SYNGR2* genotypes within the same PK15 genetic background, we can not only validate the *in vivo* association, but better quantify the individual effect of the *SYNGR2 p.Arg63Cys* variant on PCV2b replication.

Materials & methods

PCV2b isolate and cell culture. The PCV2b strain (UNL2014001) utilized in this study was the same isolate used in the prior *in vivo* experimental infection (Walker *et al.* 2018). The PK15 cell line was grown in DMEM high glucose media supplemented with 10% FBS and 1% Penicillin-Streptomycin (5,000 U/ml) at 37 °C with 5% CO_2.

DOI: 10.3920/978-90-8686-940-4_522, © L.R. Walker *et al.* 2022

CRISPR-Cas9 gene editing. To generate *SYNGR2 p.Arg63Cys* variant PK15 clones, a single guide RNA was utilized targeting a PAM site overlapping the *SYNGR2 p.Arg63Cys* locus (IDT). The guide RNA was hybridized with fluorescently labelled Alt-R CRISPR-Cas9 tracrRNA ATTO 550 and Alt-R S.p. Hifi Cas9 Nuclease V3 following the manufacturer's protocol to form Ribonucleoprotein (RNP) complexes (IDT). A single stranded DNA (ssDNA) oligonucleotide (80bp) homologous to the non-targeting strand and encoding the alternate *SYNGR2 p.63Cys* allele was used as a template for homology directed repair (IDT). The ssDNA template (3nM) and RNP complexes (10nM guide RNA, 20nM cas9) were reverse transfected into PK15 cells using Lipofectamine RNAiMAX transfection reagent (Invitrogen). After 24 hours post transfection, the cells were collected and sorted using fluorescence-activated cell sorting into 96 well plates to generate single cell clones. Genomic DNA from each clone was extracted using QuickExtract DNA extraction solution (Lucigen) and genotyped for the *SYNGR2 p.Arg63Cys* variant by KASPar assay (LGC). RNA was isolated from selected clones using the RNeasy mini kit (Qiagen) and the full *SYNGR2* transcript was sequenced via Dideoxy sequencing to confirm genotypes.

PCV2b infection and quantification. Wildtype and edited PK15 clones were cultured in 12-well plates (4 cm^2) with 5.0×10^5 cells per well and infected with the PCV2b strain when 80-100% confluent at a multiplicity of infection (MOI)=0.00025. After one hour adsorption, cells were washed with PBS and fresh media was added (DMEM high glucose with 2% FBS). The cells were incubated at 37 °C with 5% CO_2 for up to three days. Control cells were maintained the same way and mock-inoculated with plain DMEM high glucose media. Supernatant and cell samples were collected at specific time points post infection and frozen at -80 °C. Viral DNA was extracted from samples using the QIAamp DNA mini kit (Qiagen). The amount of virus in each sample was determined via real-time quantitative-PCR (RT-qPCR) by plotting the cycle crossing thresholds obtained for technical triplicates on a standard curve generated by serial dilution of a PCV2b standard. The total number of viral copies per well for each time point post infection was calculated by summing the values obtained for the corresponding supernatant and cell fractions.

Results

Following CRISPR-Cas9 gene editing, more than 240 PK15 clones were genotyped for the *SYNGR2 p.Arg63Cys* variant. Of these, ~30 were identified as possible homozygotes for the *SYNGR2 p.63Cys* allele and four were confirmed to have clean sequences with precise edits at only the *SYNGR2 p.Arg63Cys* locus. One of these clones (*emSYNGR2*$^{+p.63Cys}$) was selected for initial comparison of PCV2b replication between *SYNGR2* genotypes. Specifically, wildtype PK15 (*wtSYNGR2*$^{+p.63Arg}$), the *SYNGR2* knock-out PK15 clone (*emSYNGR2*$^{-del}$) previously generated in our lab (Walker *et al.* 2018), and the newly generated *emSYNGR2*$^{+p.63Cys}$ PK15 clone were simultaneously infected with PCV2b in three independent replicates. As expected, the *emSYNGR2*$^{-del}$ cell line exhibited significantly less total viral copies per well than both the *wtSYNGR*$^{+p.63Arg}$ and *emSYNGR2*$^{+p.63Cys}$ cell lines starting at 24 hpi (P<0.01; Figure 1). A significant reduction in PCV2b replication was present in *emSYNGR2*$^{+p.63Cys}$ compared to *wtSYNGR2*$^{+p.63Arg}$ cells starting at 48 hpi (P<0.01; Figure 1). After 72 hpi, the amount of total virus was 140x the starting quantity (0 hpi) in *wtSYNGR2*$^{+p.63Arg}$ cells compared to only 32x in *emSYNGR2*$^{+p.63Cys}$ (P<0.05).

Analysis of the supernatant and cell fractions individually revealed interesting differences in infection profiles. Specifically, in the cell fraction a significant reduction in viral copies is observed at 24 hpi in *emSYNGR2*$^{+p.63Cys}$ compared to *wtSYNGR2*$^{+p.63Arg}$ (P<0.01; Figure 1), whereas, in supernatant the amount of virus is actually slightly higher at 24 hpi in *emSYNGR2*$^{+p.63Cys}$ than *wtSYNGR2*$^{+p.63Arg}$ (P=0.058; Figure 1). In order to further evaluate these differences, the proportion of total virus in each fraction was determined across time points. At 0 hpi, [3]80% of total viral copies are contained within the cell fraction for all three clones (Figure 2). While the proportion of total viral copies in the cell fraction remains fairly constant (>85%) for the *wtSYNGR2*$^{+p.63Arg}$ cells until 72 hpi, both the *emSYNGR2*$^{+p.63Cys}$ and *emSYNGR2*$^{-del}$ clones exhibit

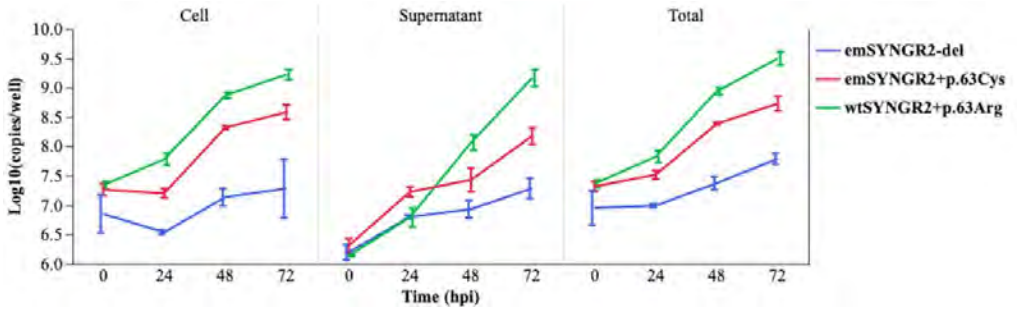

Figure 1. PCV2b copy number across timepoints post infection in PK15 cells with different *SYNGR2* genotypes. The collected cell and supernatant samples from each well were analysed individually (left and middle) and together to assess the total viral copy number per well (right).

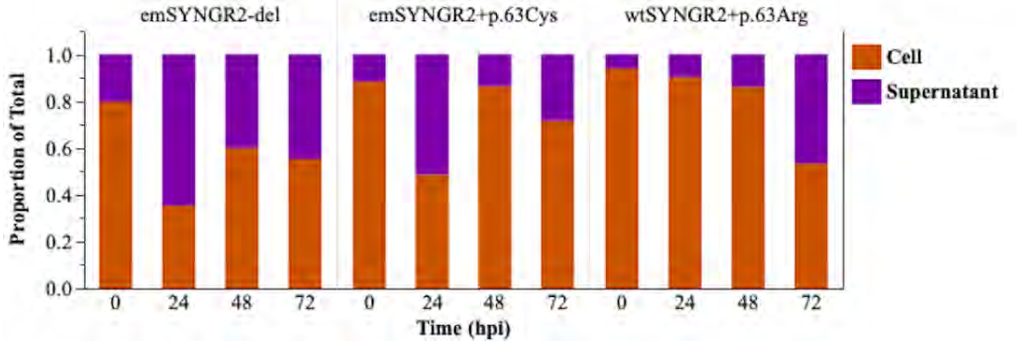

Figure 2. Proportion of total PCV2b copies in cell and supernatant fractions across timepoints post infection in PK15 cells with different *SYNGR2* genotypes.

dramatic changes in the fractional distribution of PCV2b copies (Figure 2). At 24 hpi, only 35 and 49% of total viral copies are present within the cell fraction for the *emSYNGR2*$^{-del}$ and *emSYNGR2*$^{+p.63Cys}$ clones, respectively (Figure 2). Interestingly, the proportion of total virus in each fraction for the *emSYNGR2*$^{+p.63Cys}$ clone 'recovers' back to that exhibited by the *wtSYNGR2*$^{+p.63Arg}$ clone by the 48 hpi (Figure 2), suggesting a potential lag in the early stages of PCV2b infection.

Discussion

In this study, we successfully implemented *in vitro* gene editing and obtained PK15 clones homozygous for the favourable *SYNGR2 p.63Cys* allele. Simultaneous infection of wildtype and edited cell lines provided direct experimental evidence for the role of the *SYNGR2 p.Arg63Cys* variant in PCV2b propagation and validation for the *in vivo* association with PCV2b viral load (Walker *et al.* 2018). Specifically, CRISPR-Cas9 mediated substitution of the *SYNGR2 p.63Arg* allele (*wtSYNGR2*$^{+p.63Arg}$) for the *SYNGR2 p.63Cys* allele (*emSYNGR2*$^{+p.63Cys}$) resulted in a significant reduction in PCV2b replication in PK15 cells. Further investigation into the fractional distribution of total PCV2b copies per well across time points post infection revealed differences in infection dynamics between the variant cell lines. PCV2b appears to still be able to attach and gain cellular entry into *SYNGR2* knock-out cells (*emSYNGR2*$^{-del}$), however, to a drastically lesser degree than in either of the *SYNGR2 p.Arg63Cys* variant cell lines with functional *SYNGR2* proteins. Interestingly, the prominent decrease in proportion of viral copies in the cellular fraction observed for the

emSYNGR2^{-del} clone at 24 hpi is mirrored by the *emSYNGR2*$^{+p.63Cys}$ clone, but not by the *wtSYNGR2*$^{+p.63Arg}$ cell line. Given that PCV2b replication is diminished in both the *emSYNGR2*$^{-del}$ and *emSYNGR2*$^{+p.63Cys}$ clones, the similar decrease in internalized virions observed at 24 hpi may reflect the underlying mechanism in which this gene and variant function in PCV2b infection.

Based on the current understanding and timeline of PCV2 morphogenesis in cell culture, the first 24 hours post infection predominantly corresponds to the first intracytoplasmic phase, in which PCV2 virions are internalized via endocytosis into early endosomes, followed by endosomal escape and translocation of cytoplasmic virions to the nucleus for replication (Rodriguez-Carino *et al.* 2011). *SYNGR2* has been identified as a component of cytoplasmic vesicles (ex. early endosomes) as well as involved in vesicle biogenesis to promote replication of a tick-borne human RNA virus, Severe Fever with Thrombocytopenia Syndrome virus (Sun *et al.* 2016). Additionally, *SYNGR2* has been further characterized as a necessary factor for internalization of a bacterial cytotoxin (Boesze-Battaglia *et al.* 2017, 2020). Therefore, a function of *SYNGR2* predominantly in the early stages of PCV2b infection is a logical conjecture. Specifically, we propose that the decrease in PCV2b replication as a result of *SYNGR2* knock-out or the *SYNGR2 p.63Cys* allele is due to impaired endocytosis and/or slower translocation of virions to the nucleus for replication. Further research will be required to identify the specific underlying mechanism in which the *SYNGR2 p.Arg63Cys* variant functions in PCV2b infection.

Abstract

Five partners of the H2020 BovReg project have performed sequence-based GWAS for 28 beef production traits (4 growth, 9 morphology, and/or 15 carcass traits) using 54,782 animals from 15 different purebred or crossbred cattle populations. These results were herein combined to conduct 16 different meta-analyses (MA) with both the z-score and the fixed effects MA methods. We identified QTL in 15 MA on BTA2, 5, 6, 7, 10, 11, 13, 14, 15, 17, and 20, most of them being common to several MA. Overall, the fixed effects method outperformed the z-score method in terms of significance level and number of QTL detected. Compared to within-population GWAS, MA found a higher number of QTL in which variants were more frequently located in genes (e.g. *MSTN*, *LCORL, ARRDC3, PLAG1, COL3A1*).

Introduction

When performed at the whole genome sequence (WGS) level, the meta-analysis (MA) of within-population GWAS results can be powerful and accurate to identify causal variants for complex traits (Bouwman *et al.*, 2018). One of the objectives of the H2020 BovReg project is to perform MA at the sequence level for various dairy and beef cattle traits. For beef production, five partners from France (INRAE/ULIM), Switzerland (ETH), Germany (FBN), and Canada (UAL) contributed with 54,782 animals from 15 purebred populations Charolais (CHA), Montbéliarde (MON), Normande (NOR), Limousine (LIM), Blonde d'Aquitaine (BLA), Brown Swiss (BSW), Original Braunvieh (OBR) or crossbred Charolais × Holstein (CH), and Angus, Charolais and beef composite (BP). Each partner conducted sequence-based within-population GWAS for 4 growth, 9 morphology, and/or 15 carcass traits. Here, we combine these GWAS results to conduct 16 MA with fixed effects and z-score methods.

Materials & methods

Within-population GWAS. Within-population GWAS were conducted on 54,782 steers, cows or bulls (19,656 females and 35,126 males) of 15 various populations. Depending on the population, 4 growth, 9 morphology, and/or 15 carcass traits were expressed as yield deviation (YD), daughter YD (DYD), deregressed proof (DRP) or adjusted performance (AP). All partners applied similar imputation and GWAS workflows. Genotypes, aligned on the ARS-UCD1.2 reference genome, were imputed using a stepwise approach: (1) 777K (HD) genotypes were imputed from 50k genotypes with Beagle (Browning and Browning, 2016) or FImpute (Sargolzaei *et al.*, 2014) using animals with HD genotypes as a reference; and (2) sequence variants were imputed using 372 to 3093 animals from the RUN7 or RUN8 reference panel of the 1000 Bull Genomes consortium (Bouwman *et al.*, 2018) with Minimac (Howie *et al.*, 2012) or Beagle. After filtering, allele dosages of between 12.9 and 20.6 million variants were tested for association with different traits in each population separately using GCTA software (Yang *et al.*, 2011) accounting for a polygenic effect estimated from 50k or HD SNPs. DRP and DYD were weighted to account for heterogeneous accuracy (Vandenplas, pers. comm.).

Meta-analyses. We then conducted 16 MA – 2, 5 and 9 for growth, morphology and carcass traits, respectively – combining GWAS results of 1 to 5 traits measured in 3 to 10 different populations from 2 to 5 partners (Table 1). We considered 29.6 million variants imputed by at least two different partners with concordant REF/ALT alleles. For each partner × trait × population combination, we retained variants with a MAF≥0.005 (0.02 for FBN which had a smaller sample size) and with an imputation R^2≥0.20, i.e. 17.9 to 24.9 million variants depending on the MA. Variant effects were standardized by the genetic standard deviation of the trait. The z-score (ZSc) and fixed effects (FE) MA methods implemented in the METAL software (Willer *et al.*, 2010) were applied. For each variant, the ZSc method converts the *P*-value in z-score $Z = S_i z_i w_i / (S_i w_i^2)$ where w_i is the square root of the sample size for study *i* and $z_i = F^{-1}(1 - p_i / 2)\times$(*effect direction for study i*), with p_i the *P*-value of the i^{th} study. The FE method assumes that the true effect of each allele is the same across the different studies and combines effects by weighting them by the inverse of their error variance. Therefore, both MA methods weight the different studies by their sample size. For all GWAS or MA results, we considered an uniform threshold ($-\log_{10}(P) = 8.7$) corresponding to the 5% genome-wide threshold of significance after Bonferroni correction for ~25 million variants.

Results

For 15 of the 16 MA conducted in this study, we found variants with significant effects with both ZSc and FE methods (Table 2). These variants defined QTL regions on BTA2, 5, 6, 7, 10, 11, 13, 14, 15, 17, and 20. The most significant QTL were located on BTA2 and 6 (Figure 1). In 12 of the 15 MA, the FE method identified a higher number of variants with significant effects than the ZSc method. In addition, QTL on BTA6 (C7), 13 (C5), 14 (M2), and 17 (C5) were detected only by the FE approach. In each of the 15 MA, variants with significant effects were also identified in 1 to 5 within-population GWAS. In 7 MA (G2, M1, M2, M5, C4, C5, and C8), the number of variants with significant effects was higher in at least

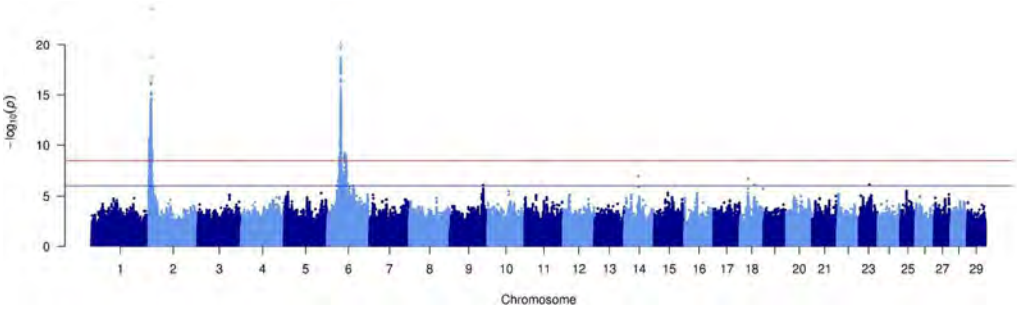

Figure 1. Manhattan plot obtained with M4 fixed effects MA results.

one elementary GWAS than in any of the MA methods used. However, compared to within-population GWAS, MA revealed: (a) more significant effects; (b) novel QTL on BTA2 (C1), 5 (G1), 6 (C7), 7 (M1 and M2), 10 (C1 and C4), 14 (M2), and 17 (C5); and (c) variants with the most significant effects in the QTL peaks (TOP1) more frequently located in genes (72% in fixed effects MA vs 62% in GWAS). For the most significant QTL identified on BTA2 in M1, M2, M4, and C4 MA, the TOP1 variant is a stop gained variant (rs110344317, Q204x) within the *MSTN* gene. In 10 MA (G1, G2, M3, M4, M5, C1, C4, C5, C6, and C9), we found a QTL on BTA6 with 7 unique TOP1 variants located within or near to the *LCORL* gene. For

other QTL, the variants with the most significant effects were located in *ANKAR*, *ASNSD1*, *SLC40A1*, and *COL3A1* (BTA2); *CCND2* (BTA5); *MLLT1*, *PIAS4*, and *ARRDC3* (BTA7); *GLDN* and *CYP19A1* (BTA10); *PLAG1* (BTA14); and *CHST1* and *SLC35C1* (BTA15).

Discussion

This study, conducted on imputed WGS of 54,782 animals from 15 populations of various breeds, is the first meta-analysis of this magnitude dedicated to cattle beef production. We show the value of MA, in complement to within-population GWAS, in identifying: (1) a larger number of QTL; (2) a lower number of variants in QTL; and (3) candidate variants located more frequently in genes. The use of more animals and the conservation of LD over shorter distances across breeds may explain the superiority of MA over GWAS in terms of power and mapping precision. By applying here the most commonly MA methods used for GWAS, i.e. ZSc and FE approaches, we confirm that the FE method appears more powerful in detecting QTL (Begum *et al.*, 2012), although MA combine substantially different traits in the present study. In several regions, MA directly pointed out variants in genes, including *MSTN*, *LCORL*, *ARRDC3*, and *PLAG1*, previously associated with morphology and carcass traits in various studies (e.g. Wang *et al.*, 2020). For example, the Q204X mutation, ranked 1st in the QTL peaks at the proximal end of BTA2 and causing a premature stop codon in the gene encoding myostatin (*MSTN*), was reported as one of the polymorphisms responsible for the double-muscled phenotype in several cattle breeds (Grobet *et al.*, 1998). We also identified dozens of other variants located in genes having a function that may be related to meat production traits (e.g. *COL3A1 collagen type III alpha 1 chain*). By better identifying genes and candidate causative variants associated with beef production traits in cattle, MA appears to be of great interest to decipher the biological mechanisms underlying these traits.

Abstract

With the aim of deciphering genetic variants affecting gene expression levels of duodenum, liver and muscle, the DNA and RNA of 300 pigs from three different breeds (Duroc, Landrace and Large White) was extracted and sequenced. After filtering and normalizing both the genomic and the transcriptomic datasets, expression genome-wide association studies (eGWAS) were conducted between 25,315,878 polymorphisms and the expression of 16,753 genes in duodenum, 15,710 genes in liver, and 13,887 genes in muscle. In total, more than 1.17×10^{12} combinations were performed, obtaining 19,926,590 significantly associated polymorphisms, which were grouped in 148,639 expression quantitative trait locus (eQTL) regions. Half of the polymorphisms were located in close proximity to their associated gene, but only 7,773 *cis*-eQTL regions were defined, the remaining being *trans*-eQTLs regions. Out of the cis-eQTL regions, 18 shared the same top polymorphism among the three tissues; thus, they were considered the strongest candidates for gene expression regulation.

Introduction

Rather than the usual measured phenotypes, gene expression acts as an 'intermediate phenotype', which is expected to be closer to the genomic information than a conventional end-trait phenotype (Stranger *et al.*, 2007). In this regard, genetic variants affecting gene-expression phenotypes are an important source of phenotypic variation. Over the last decade, expression genome-wide association studies (eGWAS) have become one of the most used methods to study the association of the polymorphisms distributed across the genome and the expression levels of a gene. At the time, this method used a limited dataset of genetic markers, but nowadays all the genetic variants found in the genomes of a population can be included, thanks in particular to the progress made to improve computing efficiency. In addition, RNA sequencing approaches have become cheaper and can be applied to larger datasets. This is crucial to understand the relationship between gene regulation mechanisms and the traits of interest, since more than 90% of the phenotype-associated polymorphisms are located within intergenic and intronic regions, rather than on the coding regions of a gene (Maurano *et al.*, 2012). When a location in the genome is found in association with the expression of a certain gene, an expression quantitative trait locus (eQTL) region is defined. Classically, *cis*-eQTL regions have been defined at 1 Mb of the gene analysed; otherwise, they are considered *trans*-eQTL regions. In this study we will aim to decipher potential genetic variants that could modify gene expression levels in duodenum, liver and muscle.

Materials & methods

Duodenum, liver and muscle samples were collected at slaughter from 300 pigs of three different breeds (n=100 Duroc, n=100 Landrace and n=100 Large White). Genomic DNA was extracted from blood (Duroc and Landrace) and liver (Large White) samples using NucleoSpin Blood kit (Macherey-Nagel, Düren, Germany). RNA from muscle samples was extracted using RiboPure™ RNA Purification Kit (Invitrogen, Carlsbad, CA, USA) and RNeasy Fibrous Tissue Mini Kit (Qiagen, Hilden, Germany), and RNA from

DOI: 10.3920/978-90-8686-940-4_524, © D. Crespo-Piazuelo *et al.* 2022

liver and duodenum samples was extracted using a chemagic™ 360 instrument with RNA Tissue10 Kit H96 (PerkinElmer, Baesweiler, Germany). The whole genome of the 300 pigs and the transcriptome from the three tissues (duodenum, liver and muscle; n=900) were paired-end (2×150bp) sequenced in an Illumina NovaSeq6000 platform (Illumina, San Diego, CA, USA). DNA sequences were mapped against the reference genome (Sscrofa11.1 assembly) with BWA-MEM/0.7.17 (H. Li, 2013) and the genetic variants were obtained with GATK/4.1.8.0 HaplotypeCaller (McKenna *et al.*, 2010). Then, the genetic variants were filtered (minor allele frequency below 5% and/or more than 10% missing genotype data) for downstream analyses.

RNA sequences were mapped against the reference genome (Sscrofa11.1 assembly) with STAR/v2.5.3a (Dobin *et al.*, 2013), counts were quantified by RSEM/1.3.0 (B. Li and Dewey, 2011) and normalized by TMM (trimmed mean of M-values). Genes with low expression (counts per million below 10/minimum library size in millions) and those that did not show expression in at least 5% of the animals were removed. Thereafter, eGWAS were conducted between the filtered polymorphisms and the normalized expression data using the fastGWA tool from GCTA/1.93.2 (Yang *et al.*, 2011) using the following model:

$$y_{hijk} = sex_{hj} + breed_{hk} + u_{hi} + s_{il} \cdot a_{hl} + e_{hijk}$$

where y_{hijk} corresponds to the expression of the hth gene in the ith individual of sex j and belonging to the kth breed; sex_{hj} corresponds to the jth sex effect (two levels); $breed_{hk}$ to the kth breed effect (three levels); u_{hi} is the infinitesimal genetic effect of the individual i, with u~MVN(0,G·σ^2_u), where G is the genomic relationship matrix calculated using the filtered autosomal polymorphisms and σ^2_u is the additive genetic variance to be estimated; s_{il} is the genotype (coded as 0, 1 or 2) for the lth polymorphism; and a_{hl} is the allele substitution effect of the lth polymorphism on the expression level of the hth gene; finally, e_{hijk} is the residual term. Bonferroni correction was applied to assess the statistical significance for the association studies at genome-wide level with the p.adjust function of R. Only those associations with an adjusted *P*-value<0.05 were considered significant.

Results

The whole genome sequence of the 300 pigs resulted in 44,127,400 genetic variants, which after the filtering step, got reduced to a total of 25,315,878 polymorphisms that were kept for the association analyses. Regarding the type of genetic variant, the polymorphisms were classified as SNPs (74.92%), insertions (13.88%) and deletions (11.20%). After normalizing and filtering the three transcriptomic datasets, 12,892 genes were expressed in all the three tissues, whereas 18,097 genes were expressed in total. For each tissue, eGWAS were conducted for 16,753 genes in duodenum, 15,710 genes in liver, and 13,887 genes in muscle. The eGWAS resulted in a total of 19,926,590 significant associations among the three tissues, which are detailed in Table 1. From all the significantly associated polymorphisms in the three tissues, 29.9-30.2% were novel variants and the remaining 69.8-70.1% were already described in the Ensembl database. In this regard, a polymorphism could be associated with the expression of more than one gene. Thus, in duodenum, 2,813,177 unique polymorphisms were associated with the expression of 6,551 genes; in liver, 4,187,249 unique polymorphisms were associated with the expression of 7,433 genes, and in muscle, 4,814,732 polymorphisms were associated with the expression of 7,496 genes. Out of these genes with any significant association 1,730 were expressed in the three tissues.

Table 1. Number of significantly associated variants and eQTL regions per tissue.

	Significantly associated variants		eQTL regions	
Tissue	**No.**	***cis*-regulatory elements[1]**	**No.**	***cis*-eQTL regions[2]**
Duodenum	4,802,045	2,260,300 (47.1%)	53,236	1,866 (3.5%)
Liver	7,024,941	3,756,049 (53.5%)	36,835	2,704 (7.3%)
Muscle	8,099,604	4,461,375 (55.1%)	58,568	3,203 (5.5%)
Total	19,926,590	10,477,724 (52.6%)	148,639	7,773 (5.2%)

[1] A *cis*-regulatory element was considered if the polymorphism was located at a maximum distance of 1 Mb from the associated gene.

[2] A *cis*-eQTL region was considered if the gene was located within it.

An eQTL region was defined ±1 Mb from a significantly associated polymorphism, which were merged into the same eQTL region if they intersected. Thus, 148,639 eQTL regions were defined (Table 1). However, this number of eQTL regions should be carefully considered as 43.52-59.82% were defined exclusively by a single polymorphism: 23,167 in duodenum, 21,828 in liver, and 35,033 in muscle. In proportion, the ratio of *cis*-eQTL regions defined by a single polymorphism was much lower (5.62-7.61%): 142 in duodenum, 152 in liver, and 191 muscle. For each eQTL region, most of the significant polymorphisms were located within 1 Mb of the top polymorphism of the region (Figure 1).

Regarding the location of the polymorphisms in respect to the expression of their associated gene, 47.1-55.3% of the polymorphisms were closer than 1 Mb to their gene. Despite so, only ~5% of the 148,639 eQTL regions defined were in *cis* (Table 1). When comparing the top polymorphisms of the eQTL regions found in all the three tissues, 332 genetic variants where shared between the three of them, being 18 of them cis-regulatory elements.

Discussion

In this study, more than 1.17×10^{12} combinations were performed through eGWAS in duodenum, liver, and muscle, obtaining 19,926,590 associated polymorphisms. These polymorphisms were grouped in 148,639 eQTL regions, but despite half of the polymorphisms being located in close proximity to their associated gene, only ~5% of the eQTLs regions were in *cis*. A possible explanation of this result is due to the fact that most of the *trans*-eQTL regions were defined by a single polymorphism. Hence, to avoid such artifacts, filters to define eQTL regions with 2 or more polymorphisms may be required.

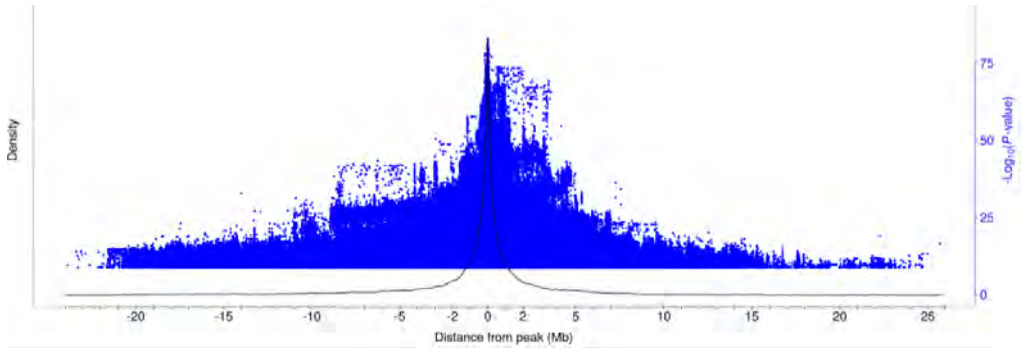

Figure 1. Density plot of the distance of the significant polymorphisms associated with liver gene expression to the peak of their eQTL region (sexual and mitochondrial chromosomes excluded). The significance of the polymorphisms is provided in blue dots.

Considering the distribution of the *P*-values due to linkage disequilibrium, the definition of *cis* elements if they were located at less than 1 Mb from their associated gene seemed appropriate, as they were rarely surpassing the 2 Mb. However, this definition may change depending on the structure of the population used.

One of the top 18 *cis*-regulatory elements of the eQTL regions found in common in the three tissues was a polymorphism located upstream the *SUPT3H* gene, a gene already identified by our group as a potential key regulator for health-related traits in pigs (Crespo-Piazuelo *et al.*, 2021). Five out of the 18 *cis*-regulatory elements were located in long non-coding RNAs (lncRNAs). Of interest was the polymorphism located upstream the *ENSSSCG00000041410* gene, which encodes for a lncRNA that was positively correlated in all the three tissues (r=0.590-0.732) with the expression of *TRIM39*, a nearby gene involved in the immune response and cell cycle progression (Suzuki *et al.*, 2016; Zhang *et al.*, 2012), and that has been already described as participating in the same processes regulated by lncRNAs (Zhou *et al.*, 2019). In conclusion, the identification of genetic variants associated with gene expression levels in the three tissues will contribute to shed light on the molecular mechanisms of regulatory variations to shape end-trait phenotypes.

Abstract

We analyzed juvenile mortality rates per sire family for four different periods in a population of Holstein heifers born between 2017 and 2020 in France and Wallony. The global mortality rate from birth to one year of life was 11.8% in the population of 1,001 sires, while it reached 30.6 and 19.9% in the progeny of two bulls, Mo and Pa, respectively. Various investigations were carried out on these two bulls and their progeny, including clinical examination, karyotyping, genetic mapping, and whole genome sequencing. Mo was found to carry a partial translocation from BTA29 to BTA26 while Pa was mosaic for a dominant nonsense mutation in the *GATA6* gene causing cardiac outflow tract defect in its progeny.

Introduction

Reducing juvenile mortality in cattle is important for both economic and animal welfare reasons. Previous studies have revealed a large variability between breeds and sire progeny groups (e.g. Leclerc *et al.* 2016), with some extreme cases due to dominant mutations causing various syndromes among the descendants of mosaic bulls (Bourneuf *et al.* 2017). The purpose of this study was twofold: to fine monitor calf mortality at the level of sire families within the French and Walloon Holstein populations, and to use this information to detect genetic defects that might have been overlooked by lack of specific symptoms.

Materials & methods

Analysis of mortality rates at different ages in the progeny of individual sires. Information on the pedigree, sex, date of birth, date of death, and cause of death (either natural or slaughter) of Holstein animals were recovered from the French and Walloon databases. To focus on the most reliable data, only female calves born between 2017 and 2020, which remained on their farm of birth during their first year of life, were selected. The final data set comprised 2.25 million daughters from 1,001 sires. The size of the half-sib families ranged from 100 to 37,839 individuals, with a mean of 2,246. Natural mortality rate was computed during the first year of life and for four sub-periods (perinatal, postnatal, pre-weaning and post-weaning) corresponding to distinct causes of death (Table 1; Santman-Berends *et al.*, 2019).

Clinical examination. Nine calves (both sexes) sired by two half-brother bulls (Mo: n=3 and Pa: n=6) that showed very high mortality rates were necropsied. Gross phenotypic description was also available for eight and seven additional presumably affected calves of each sire, respectively.

Molecular characterization of the genetic defects of sires Mo and Pa. Mo was karyotyped to screen for chromosomal abnormality while Pa was dead at time of the study and thus not available for blood sampling. Illumina Bovine SNP50 phased and imputed genotypes from Pa and 203 of its progeny were

extracted from the French genomic evaluation database. Assuming a dominant inheritance with somatic mosaicism in Pa, we performed transmission disequilibrium tests for 16,487 informative markers, 14 progeny that died before 50 days of age (incl. four necropsied), and 189 half-sib controls still alive at 2 years. We then sequenced the genome of one case with Illumina technology (150 bp paired-end reads), processed the data in accordance with the guidelines of the 1000 Bull Genomes Project (Hayes and Daetwyler 2019), and we used 5,116 genomes from run 9 of the latter project as controls.

Results & discussion

The natural mortality rate of heifers during their first year of life was of 11.8% on average, with 4.2% for perinatal, 2.9% for postnatal, 3.1% for pre-weaning and 3.2% for post-weaning mortalities (Table 1, Figure 1). These rates were lower than most of those reported in the literature (e.g. Leclerc *et al.* 2016), probably because we considered only females and sex is known to have a significant effect on juvenile mortality. Interestingly, natural mortality rates per period and per half-sib family showed approximately normal distribution suggesting quantitative inheritance. Yet we observed outlier families with possible mono or oligogenic inheritance of excess mortality and focused on the worst sire per category.

Among them, two bulls with high mortality rates (Mo and Pa), sired by the most popular bull sire of the cohort (Mogul) particularly retained our attention and were selected for further analysis. Karyotyping of Mo revealed a translocation of approximately the first half of bovine chromosome 29 (BTA29) onto

Table 1. Mortality rates in % for the worst bull per category (bolded) vs population means.

Bull	Bull sire	NB of calves	Perinatal	Postnatal	Pre-weaning	Post-weaning	Global mortality
			0-2 days	3-14 days	15-55 days	55-365 days	1-365 days
Mean of 1,001 bulls	2,250	4.2	2.9	3.1	3.2	11.8	
Mo	Mogul	108	**16.7**	**6.7**	2.4	**7.3**	**30.6**
Pa	Mogul	2,297	5.3	6.1	**6.3**	4.8	19.9

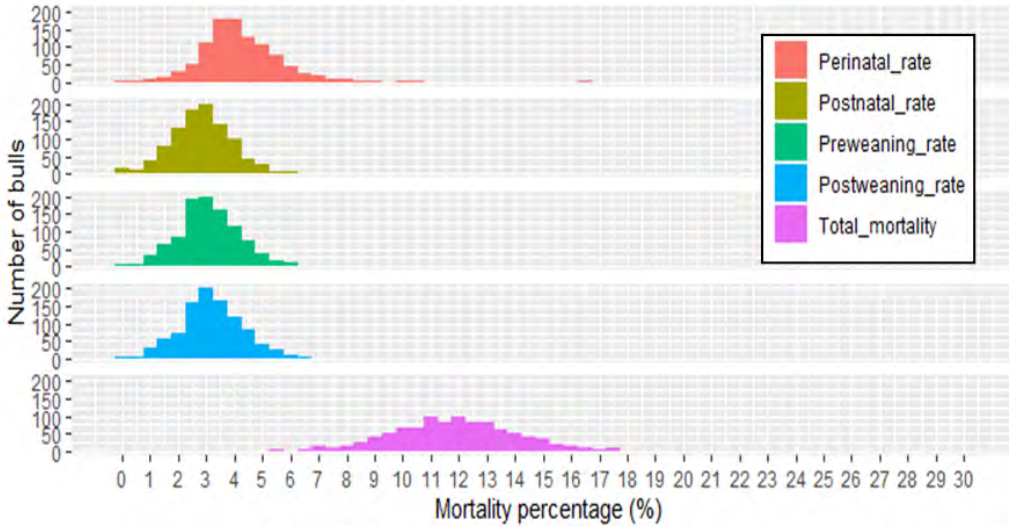

Figure 1. Histogram of distribution of mortality rates for each period of death.

BTA26 (Figure 2A). A survey by French and Belgian veterinarians enabled us to gather phenotypic information for six affected calves. The main clinical features included symptoms reminiscent of Jacobsen syndrome in human (i.e. cranial dimorphism, seizure and heart defects), a rare genetic defect caused by haploinsufficiency for more than 100 genes (Rodríguez-López *et al.* 2021) located in a region of HSA11q orthologous to the translocated segment of BTA29 (Figure 2B). In the near future, the genotyping of the affected calves with SNP arrays should allow us to confirm the diagnostic of partial monosomy of BTA29 and to precise the breakpoints of the translocation.

A different etiology was suspected for the excess of mortality observed among Pa's progeny, since the peak of mortality was later than for Mo's daughters and the symptoms were different. Indeed, necropsy of six affected calves revealed persistent *truncus arteriosus* (Figure 3A) and symptoms compatible with heart defects in seven additional cases. To gain insights into the molecular basis of this defect we analyzed Illumina Bovine SNP50 genotypes from 14 calves that died prematurely and 189 half-sib controls that had been genotyped for genomic evaluation. In doing so, we mapped the locus on BTA24 between positions 19,770,957 and 37,706,580 on ARS-UCD1 assembly. Subsequent sequencing of the genome of a necropsied calf and filtering for variants observed in 5,116 control genomes revealed a single heterozygous candidate variant within the interval: a thymine-to-adenine substitution in exon 2 of *GATA6* predicted to introduce a premature stop codon (chr24: g.34,187,181T>A; GATA6 p.417K>X). If translated the mutant protein would lack about 30% of amino acid sequence including important functional domains (ZF2, NLS and TAD3; Figure 3). Interestingly the loss of GATA6 heterozygosity has been associated with various defects of differentiation, development, and function of the heart in vertebrates, including abnormal septation of the aortopulmonary trunk (e.g. Kodo *et al.* 2009 and Figure 3B).

PCR and Sanger sequencing of the sire Pa, three affected calves and three control carrying the same paternal haplotype but in the non mutated version, confirmed the de novo nature of the nonsense variant. Finally, analyzing segregation distorsion of adjacent markers within the control calves (57:132 ratio) we estimated a proportion of 28.4% of mutants in the progeny of Pa.

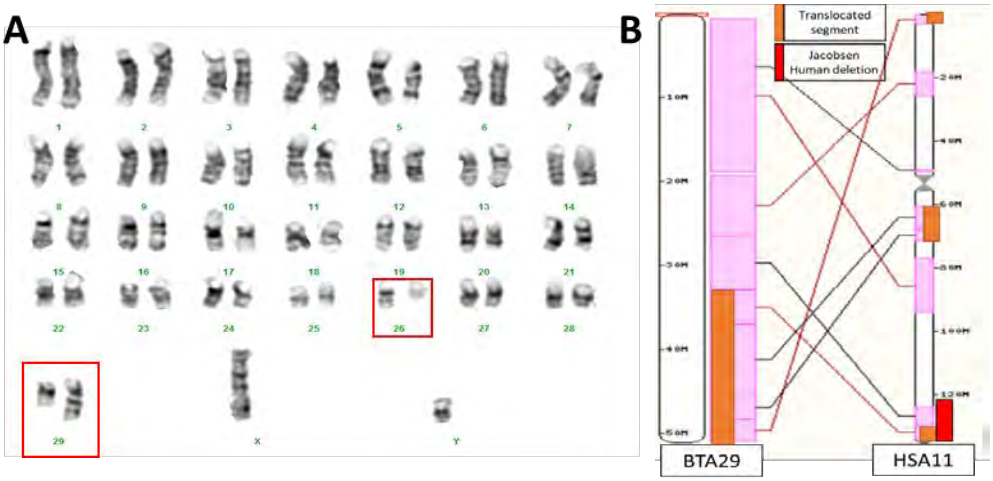

Figure 2. Karyotype of sire Mo (A) and synteny between BTA 29 and HSA11 (B).

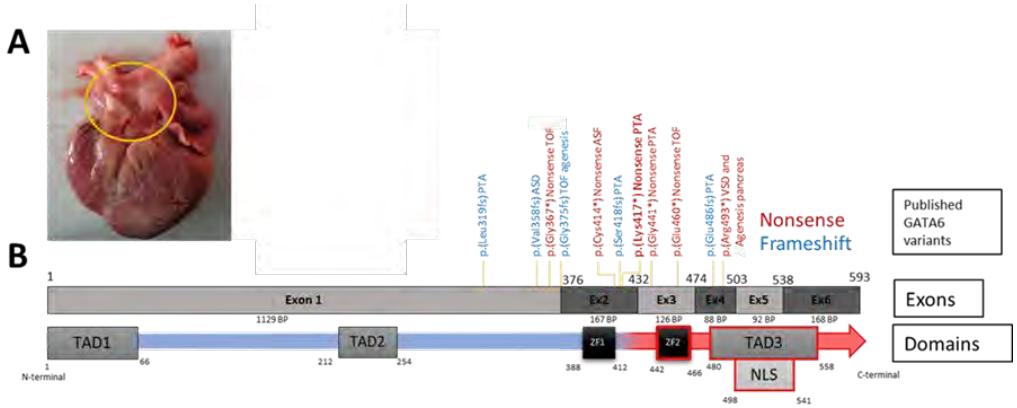

Figure 3. Bovine heart with persistent *truncus arteriosus* (A) and scheme of GATA6 with bovine mutation p.417K>X and deleterious variants reported in human (B).

Conclusions

By focusing on the progeny of extreme bulls for juvenile mortality, we have described bovine models for two syndromes also observed in humans. Our results demonstrate the suitability of our method to reveal genetic defects that are hardly detectable with traditional heredo-surveillance. Beyond this proof of concept, the calculation of mortality rates at different ages for the whole population of bulls pave the way for future detection of QTL associated with juvenile mortality.

526. Candidate genes for milk, growth and immune system traits in Brazilian Iberian-derived locally adapted cattle breeds

L.L. Verardo[1*], M.A. Machado[2], J.C.C. Panetto[2] and M.V.G.B. Silva[2]

[1]Universidade Federal dos Vales do Jequitinhonha e Mucuri, Campus JK, 39100-000 Diamantina, Brazil; [2]Brazilian Agricultural Research Corporation (EMBRAPA), Rua Eugênio do Nascimento, 610, 36038-330 Juiz de Fora, MG, Brazil; lucas.verardo@ufvjm.edu.br

Abstract

Along decades of breeding in a variable ecosystem throughout the country, the first taurine animals arrived in Brazil became adapted to a wide range of environments with different levels of improved fitness. We analyzed three cattle breeds representative of Brazilian Iberian-derived Locally Adapted cattle (Curraleiro Pé-Duro – CUR with 17 animals, and both Caracu lineages, Caracu Caldeano selected for milk – CCD with 55 animals, and Caracu selected for beef – CCB with 24) aimed to evaluate runs of homozygosity (ROH), identify ROH islands and functionally analyse the identified genes. We observed the occurrence of short ROH islands in all breeds, suggesting a successful matting scheme. Genes located in ROH islands were evaluated and explored throughout their biological processes (e.g. *PRLR* related with milk and growth traits in CCD and CCB; and *CAMKK2* related with immune system in CUR) providing information about the genetic architecture of the breeds.

Introduction

The first taurine animals were introduced in Brazil between sixteenth and seventeenth centuries. Along decades of breeding, these animals adapted to environments with different levels of improved fitness. They become recognized as Iberian-derived locally adapted breeds (Egito *et al.*, 2007; McManus *et al.*, 2009), such as the Caracu lineages (Caracu Caldeano, selected for dairy purpose, and Caracu, selected for beef) and Curraleiro Pé-Duro.

Runs of homozygosity (ROH) patterns may be helpful in understand the history of the population, breeding system, and pattern of geographic subdivision. ROH are continuous homozygous segments of DNA (Gibson *et al.*, 2006), and calculation of that is essential to identify islands and genes with a role in the population. The ROH islands shared among individuals, may be used to identify homozygous regions that result from selection events (Zhang *et al.*, 2015). Moreover, genes identified in those regions can be analysed through gene networks (Verardo *et al.*, 2021) aiming to a better understanding of their biological role in each population.

In this study, we assessed three cattle breeds representative of Brazilian Iberian-derived Locally Adapted cattle (Curraleiro Pé-Duro – CUR and both Caracu lineages, Caracu Caldeano selected for milk – CCD, and Caracu selected for beef – CCB) aimed to evaluate ROH across populations, identify ROH islands and functionally analyse the identified genes.

Materials & methods

Biological samples were obtained from Brazilian commercial herds, and DNA was extracted at the Embrapa Dairy Cattle Research Center. All animals were chosen according to their population representativeness in each breed, to avoid bias due to the use of a limited number of families in the population (lineages). Animals were genotyped using the Illumina Bovine HD Chip (777k SNPs). SNP genotypes from sexual chromosomes were excluded. Also, genotypes were excluded when the call rate <0.95 or minor allele frequency <0.01. In addition, samples showing overall call rates <0.90 were excluded from further analysis.

A total of 55, 24 and 17 animals genotyped with 624,609, 674,260 and 612,345 markers from CCD, CCB and CUR, respectively, were analysed after quality control.

The ROH were calculated using the software PLINK v1.07 (Purcell *et al.*, 2007) for each population with the following parameters: minimum window length of 120 SNPs, maximum gap size between two SNPs of 1000 kb, minimum ROH length of 1000 kb, minimum number of potential marked SNPs of 50, one heterozygote allowed per window, maximum of five missing calls per window, sliding window length of 50 SNPs and proportion of overlapping windows that must be a homozygous >0.05.

To identify ROH islands, the most observed homozygous segments shared by individuals in each breed were considered as an indication. The '--homozyg-group' function implemented in PLINK was used to assess ROH islands shared among individuals. Principal component analysis (PCA) was used to identify structure in the distribution of genetic variation across breeds. The GenBank annotation based on the ARS-UCD1.2 assembly of the bovine genome was used to identify genes. Gene networks highlighting biological processes among the gene sets of each breed were generated using the ClueGO plugin for Cytoscape (Bindea *et al.*, 2009). This procedure allowed the creation of gene networks highlighting biological roles, and the comparison of gene clusters by visualizing their functional differences or similarities.

Results

PCA analyses discriminated the three populations (Figure 1). The pattern of ROH differed across breeds (Figure 2A). CUR breed showed higher percentage of long-range ROH (>31 Mb; ~5%), while CCB showed the higher percentage of short range ROH (<5 Mb; ~90%). Based on ROH islands, regions were shared by more than 75% of the individuals in each breed (Table 1). Gene networks highlighting biological associations were generated based on genes found on ROH islands (Figure 2B). Several biological processes were highlighted.

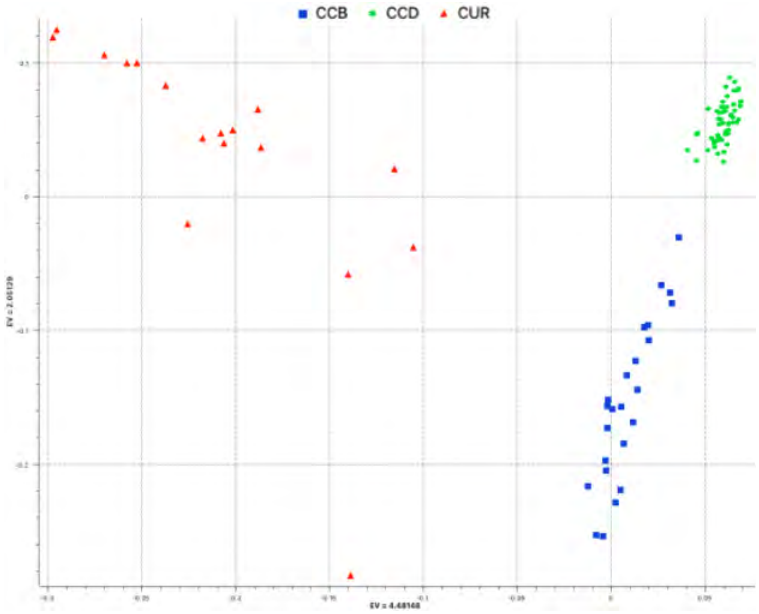

Figure 1. PCA analyses of three three Brazilian Iberian-derived naturalized cattle breeds. CCA: Caracu Caldeano (green); CCB: Caracu (blue); CUR: Curraleiro Pé-Duro (red).

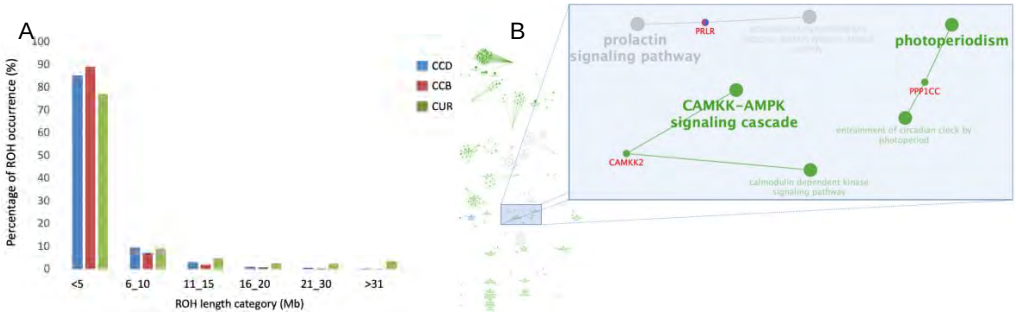

Figure 2. (A) Percentage of runs of homozygosity (ROH) per length categories in three Brazilian Iberian-derived naturalized cattle breeds. The sum of ROH was calculated per animal within each ROH length category. (B) Gene networks highlighting biological associations of genes found on ROH islands in three Brazilian Iberian-derived naturalized cattle breeds. Blue and red nodes are genes identified in CCA and CCB, respectively. Green nodes are biological processes related with genes identified in CUR breed. Grey nodes are biological processes shared between two breeds genes. Enriched terms are in bold.

[1] CUR: Curraleiro Pé-Duro; CCD: Caracu Caldeano; CCB: Caracu selected for beef.

Discussion

We evaluated the run of homozygosity in three Brazilian Iberian-derived Locally Adapted cattle. Since a run of homozygosity is the probability that all consecutive markers on a pair of homologous chromosome segments, in the same or different individual(s), display identical alleles (Hayes *et al.*, 2003), the extent and frequency of ROH may provide information about the ancestry of an individual and its population. Moreover, inbreeding may be inferred from the presence of long ROH, with longer segments indicating recent inbreeding within a population (Kirin *et al.*, 2010). We observed that the three breeds showed a similar occurrence of short ROH. This indicates a proper matting scheme to prevent higher inbreeding.

RHO islands were identified in the three breeds from which genes were retrieved and their biological processes analysed. In Caracu lineages (CCD and CCB), we identified islands in chromosome 20 with a gene associated, for example, with Prolactin signalling pathway (*PRLR*). *PRLR* encodes for prolactin receptor protein and was previously reported to be a useful genetic marker for milk production (Zhang *et al.*, 2008) and a promising candidate gene for growth traits in cattle (Lü *et al.*, 2011). This gene was also cited to present 'slick coat' mutations that confer thermotolerance to tropically adapted *Bos taurus* cattle (Littlejohn *et al.* 2014; Florez Murillo *et al.* 2021). Since CCD and CCB has been selected for dairy and beef, respectively, it makes sense to be fixing this gene, with a possible role in milking, growth and heat resilience. ROH island was observed on chromosome 17 of CUR breed. The biological process network hilighted a gene (*CAMKK2*) related with CAMKK-AMPK signalling pathway. This gene encodes for the calcium/calmodulin dependent protein kinase kinase 2 protein and have been cited to be involved in regulating important physiological and pathophysiological processes, including energy balance, adiposity, glucose homeostasis and inflammation (Raciopi and Means, 2012). Thus, it is possible that this gene may play a role in some of these processes in CUR breed.

We observed the occurrence of short ROH islands in all breeds, suggesting a successful matting scheme, also highlighted by a lower occurrence of long ROH. Genes located in ROH islands were explored via biological processes, providing genetic insights about the breeds.

527. Copy number variation analysis in Nguni and Bonsmara crossbred cattle

B. Bhika Kooverjee[1*], P. Soma[1], F.W.C Neser[2], M.A. van der Nest[3] and M.M Scholtz[1,2]

[1]Agricultural Research Council – Animal Production, Irene, South Africa; [2]Department of Animal, Wildlife and Grassland Sciences, University of the Free State, Bloemfontein, South Africa; [3]Agricultural Research Council – Biotechnology Platform, Onderstepoort, South Africa; kooverjeeb@arc.agric.za

Abstract

Crossbreeding is a useful tool in livestock systems in mitigating the effects of climate change. The aim of this study was to perform a copy number variation analysis in indigenous Nguni and Bonsmara crossbred cattle. Four crossbred individuals were sequenced at 10× coverage. Following quality control, sequence data were interrogated for CNVs using the panelcn.MOPS tool. CNVs detected harboured genes related to important biological processes. Genes relating to fertility (MTERF2), Heat tolerance (LOC109577026), Stress response (HTRA2) and carbohydrate metabolism (LOC109573033) was found in the Bonsmara-sired crossbreds. While genes relating to embryogenesis (*ARMCX1*) and lipid metabolism (*ENHO*) were found in the Nguni-sired crossbreds. Results of this study suggested these crossbred cattle display potential for inclusion in various crossbreeding programs as they harbour genetic resources that may enhance the presence of significant traits such as meat quality, heat tolerance and adaptation, while simultaneously limiting the adverse effect on the environment.

Introduction

Copy number variations (CNVs) is defined as the deletion or repetition of a genome copy number (Goshu *et al.*, 2018), and may have a functional and evolutionary impact (Keel *et al.*, 2016). Changes in gene copy number also influence gene dosage, unjustified gene fusion, gene interruption, and position effects (Liu *et al.*, 2010). Several studies attempted to increase the understanding why crossbred cattle differ in their response to environmental changes such as heat stress. Since CNVs are an important source of genetic variability associated with phenotypic variation, the aim of this study was to examine genome-wide copy number differences between F1 progeny sired from Nguni and Bonsmara dams and with F1 progeny sired from Bonsmara and Nguni dams, which are both indigenous breeds. For this purpose, the genomes of F1 progeny from Bonsmara × Nguni reciprocal crosses were sequenced and panelcn.MOPS, a read depth approach based on next-generation sequencing, was used to identify genes that differ in copy number variation between crossbred progeny from Bonsmara and Nguni sires.

Materials & methods

Ethical approval and animal selection. Ethical approval was obtained from the Agricultural Research Council, Animal Production Ethics Committee (APIEC21/06). Hair samples from two Nguni-sired (N×B) and two Bonsmara-sired (B×N) crossbred animals were collected from a crossbreeding project in the Northern Cape province.

DNA extraction and sequencing. DNA was extracted from hair samples using the Qiagen DNeasy Blood and tissue kit as per manufacturer's protocol. For whole genome sequencing of the four crossbreds, libraries were prepared according to the Illumina TruSeq Nano DNA Library Prep Kit sample preparation guide. Sequence reads were filtered for base quality and adapter trimming using Trimmomatic v0.36. After trimming, only pairs of DNA sequences with reads exceeding 36 bp were retained for analysis. BWA-MEM v0.7.17 software (Li and Durbin, 2009) was used to align sequences with the reference genome (*Bos_indicus*_1.0, Canavez *et al.*, 2012). The *Bos indicus* reference (GCF_000247795.1_*Bos_indicus*_1.0) was

chosen due to African Sanga cattle owning unique indicine ancestry that is highly distinguished from that found in modern cattle populations such as the Brahman and Nellore (van Marle-Koster *et al.,* 2021). The sequencing depth determined with Samtools depth command for the crossbred ranged from 14.7 to 19.8.

CNV analysis and gene annotation. The GUI version of PanelcnMOPS program, CNV Detective (https://www.bioinf.jku.at/software/panelcnmops/) was used to identify copy number variations in the crossbreds. The two Nguni-sired crossbreds were used as the control group while the two Bonsmara-sired crossbreds were used to represent the test group. Through the advanced option setting, the duplication threshold was set at 1.46, the deletion threshold was set at 0.57, along with minimum median RC/ROI ratio = 30 and the sex = male. Quality control (QC) involves the minimum median RC/ROI ratio, where, samples with a median RC across all ROIs that is lower than 0.55 times the median of all samples fail the first step of the sample QC. For each ROI, the ratio between the normalized RCs of each sample and the median across all remaining samples is calculated, when samples show a high variation in RC ratios it fails the second QC step. CNVs labelled with 'LowQual' were regarded as insignificant and removed. The gene content of significant CNV regions were assessed based on the gene annotation of the UMD3.1 genome assembly using Ensembl (Ensembl Genes104). The gene ontology terms (for biological processes, cellular component and molecular function) identified using PANTHER with Bonferoni correction with significance of $P<0.05$.

Results

The results are indicated in Figure 1 and Table 1. Figure 1 displays the contribution of each copy number class to the total number of CNV calls per chromosome. In Table 1 the genes associated with different biological traits are listed.

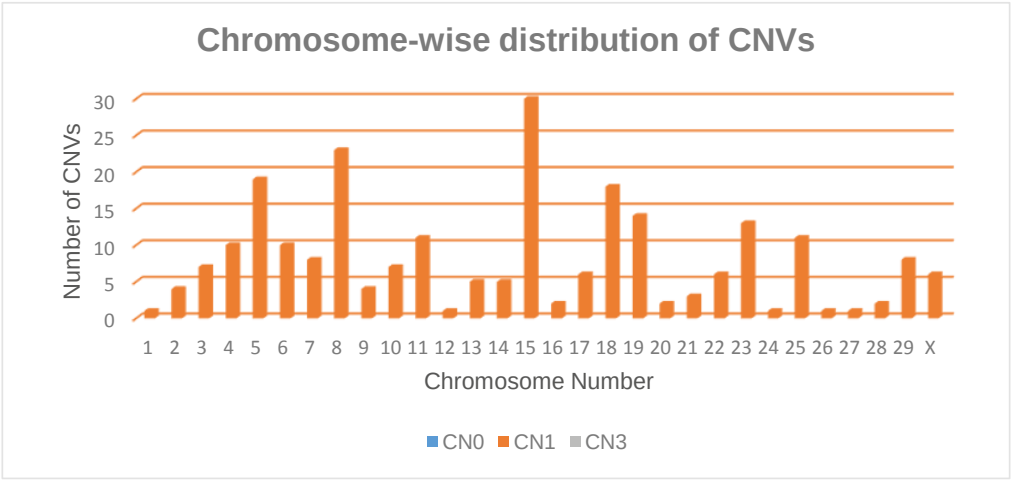

Figure 1. Bar plot displaying the contribution of each copy number class to the total number of CNV calls per chromosome. CN0 (blue) and CN1 (orange) represents the double and single copy number deletion events, respectively. CN3 (grey) represents the single duplication copy number events.

Table 1. CNV genes identified in the Nguni-sired (N×B) and Bonsmara-sired (B×N) crossbreds detected by panelcn.MOPS.

Discussion

In this study, two hundred and thirty-nine CNVs regions involving 2.29 Mbp (~0.092%) of the reference genome were identified in four animals from two crossbreds. CNVs ranged from 230 bp to 153,354 bp in size with an average length of 7,718 bp. Among these, 185 CNVs were deletions (losses) and 54 CNV duplications (gains). CNV analysis in numerous studies showed great variation in the number of CNV regions reported in cattle (Keel, *et al.,* 2016). A gene in B×N identified as LOC109577026 located on Chromosome 23 was shown to be involved with cellular response to heat stress (Sakatani *et al.*, 2012). Another gene identified that plays a role in adaptation, includes HtrA serine peptidase 2 (HTRA2) and also involved in cellular response to heat (Skorko-Glonek *et al.*, 1999) (Table 1). Reproduction is one of the key factors driving the economic efficacy through sustainable meat production in the beef industry. In this study, genes relating to animal development and fertility were detected. This include mitochondrial transcription termination factor 2 (MTERF2) located on Chromosome 5 in the B×N crossbreds and was previously identified as a candidate gene associated with reproductive traits in Nellore cattle (Oliveria Junior *et al.,* 2019). The armadillo repeat containing X-linked 1 gene located on the X Chromosome of the N×B crossbreds plays a role in embryogenesis during the development of embryos in humans (Kusuma *et al.,* 2010), while its function in cattle is still unclear. Additionally, genes relating to metabolism was detected in the both crossbreds. The carbohydrate sulfotransferase 6 (LOC109573033) located on Chromosome 18 in the B×N crosses is involved in carbohydrate metabolism and inflammatory response to pathogens (Tetas *et al.*, 2016)). While in the N×B crossbreds, the ENHO gene also known as adropin, located on Chromosome 8, plays a role in lipid metabolism and regulation of glucose homeostasis (Jasaszwili *et al.*, 2020). This is further supported by the GO terms cellular macromolecule biosynthetic process (GO: 0009059) and regulation of biological process (GO: 0050789). Overall, the functional genes identified were found to play a role in reproduction and metabolism in both crossbreds. It is therefore possible that these genes will play a role in adaptation to heat and other environmental stresses in both the Nguni-sired and Bonsmara-sired crossbreds.

Abstract

The ability of milk to coagulate is crucial for cheese production. Poorly or non-coagulating milk will affect industrial cheese production with lower cheese yield and longer processing time. We have previously shown that up to 19% of milk from Swedish Red Dairy Cattle is poorly coagulating and 18% is non-coagulating. We have also identified specific milk proteins and genetic variants as potential biomarkers for selective breeding. However, these variants are not fully characterized and show conflicting results between presumed genetic variants and actual protein masses. We re-sequenced the casein genes in 30 cows with varying milk coagulation properties and detailed analyses of their milk proteins. The analyses of three genes confirmed existing variation in the casein gene, and identified 77 single nucleotide polymorphisms in introns as well as at least ten insertions or deletions. No new coding variants were detected so far.

Introduction

Rennet induced milk coagulation is a crucial part of cheese production. Poorly and/or non-coagulating milk could lead to increased processing times as well as production losses. Earlier studies in Sweden showed that up to 37% of cows from the Swedish Red Dairy Cattle (RDC) produce poor or non-coagulating milk (Gustavsson *et al.*, 2014; Nilsson *et al.*, 2019). Heritability estimates for non-coagulating milk in RDC was estimated to be 0.45 in an earlier study of 395 cows (Gustavsson *et al.*, 2014). More recently, Duchemin *et al.* (2020) showed a heritability of 0.28 for non-coagulating milk with estimates of heritability for other coagulation measurements ranging between 0.32 and 0.56 in a larger study with 600 RDC cows. Duchemin *et al.* (2020) also showed moderate to strong phenotypic and genetic correlations between coagulation traits and the relative proportions of different casein proteins in the milk. The casein proteins in cows' milk are α_{S1}-, β-, α_{S2}- and κ-casein with corresponding genes CSN1S1, CSN2, CSN1S2, and CSN3. The casein genes are all clustered on bovine chromosome six. Using the same samples as Duchemin *et al.* (2020), Nilsson *et al.* (2020) studied different milk protein variants and their post-transcriptional modifications (PTM) in relation to coagulations properties. Nilsson *et al.* (2020) determined the different genetic variants and PTM of the casein proteins via LC-HRMS (liquid chromatography high resolution mass spectrometry). Nilsson *et al.* (2020) showed a significant effect of some casein variants on coagulation properties. These effects were mainly indirect and due to changes in the relative amounts of different caseins (Nilsson *et al.,* 2020). In order to better understand the functional role of caseins in coagulation properties a new project was initiated to follow a subset of samples from DNA sequence, to amino acid sequence and post-transcriptional changes of the resulting caseins. Here we present the initial phase of the project where we re-sequenced the casein genes in a subset of cows with different coagulation properties.

Materials & methods

From our earlier studies (Nilsson *et al.*, 2020; Duchemin *et al.,* 2020), 30 cows were selected based on their coagulation properties, protein genetic variants and PTM, availability of frozen milk samples for further analysis, limited relatedness between animals, and spread across the different farms. All cows had DNA available that was bio-banked at SLU.

Re-sequencing of casein genes. Primer sequences from the exons of all four casein genes were taken from Gallinat *et al.* (2013) resulting in 34 sequencing fragments. Sanger sequencing was done using the BigDye® Direct Cycle Sequencing kit (Applied Biosystems, Thermo Fisher). We followed the sequencing protocol exactly as described in the BigDye® manual (Thermo Fisher, online). Purification of the sequencing reactions was performed with BigDye® XTerminator kit (Applied Biosystems, Thermo Fisher). The sequencing reactions were then run in the Genetic Analyzer 3500xL (Applied Biosystems, Thermo Fisher). Sequence data was checked and edited manually using Chromas 2.5 (Chromas, Online) and BioEdit 7.2. (Hall, 1999).

Results

At the time of writing, the sequence analysis of CSN2, CSN3 and CSN1S1 was completed while the analysis of CSN1S2 was ongoing. In the sections below we will discuss our findings for each casein gene.

CSN2 (β-casein). The most notable result for CSN2 is that the cows were segregating for the proline to histidine amino acid substitution at exon 7 (His82Pro, Gallinat *et al.*, 2013) in the DNA sequence. This histidine substitution is present in several variants of β-casein (A1, B, and F/G). The A1 variant of β-casein has been associated to type I diabetes in humans (Elliott *et al.*, 1999), leading to a preference for milk with the A2 variant (Pro^{67}, in the mature protein, Caroli *et al.*, 2009) in several countries. Of the 30 cows, 6 were homozygous for the A1 variant, 11 were homozygous for the A2 variant, while the remaining 13 cows were heterozygous. There was no additional sequence variation in any of the exons in CSN2. This appears in disagreement with the protein mass data that showed additional variation related to exon 7 corresponding to β-casein variant B or F/E in one of the samples (Nilsson *et al.* 2020). Additional single nucleotide polymorphism (SNP) variation was detected in introns 2, 4, 5, and 6 as well as insertion/deletion (indel) variants in introns 2, 7, and 8. Exon 8, covering a single amino acid in mature protein (Val^{209}) appears to have a mutation in the primer site for 9 samples.

CSN3 (κ-casein). The analyses showed known amino acid changes in the DNA sequence (which includes the signal peptide) for exon 4 at amino acid positions 157 (Thr/Ile), 169 (Asp/Ala) and 176 (Ser/Gly) which, in combination, give rise to haplotypes A, B and E of κ-casein (Gallinat *et al.*, 2013). Fourteen cows had haplotypes AA, 7 had AB, 4 had AE, 2 had EE, 2 had BB and 1 cow had haplotype BE. For all cows the DNA derived haplotype agrees with the protein mass analysis. Two additional SNP were detected in exon 4: one synonymous mutation at amino acid position 189 just before a stop codon, and one non-synonymous mutation just after the stop codon. In addition, we found 3 SNP in intron 1, 11 SNP in intron 2, and 3 SNP plus 1 indel in intron 3.

CSN1S1 (α_{S1}-casein). In exon 17 we detected the Glu/Gly substitution at amino acid position 207 (Gallinat *et al.*, 2013) in the DNA sequence, corresponding to position 192 in the mature protein (Caroli *et al.*, 2009). This mutation gives rise to the C variant of αS1-casein. Two animals were heterozygous for the C variant and carried the common B variant as the other allele. The remaining animals were homozygous (BB) for the B variant and we did not observe the E variant in this sample. The sequencing analysis showed 47 SNP in introns and at least 6 indels. The detection of further indels was complicated due to extensive sequence slippage after a mononucleotide T repeat in the data for some primers.

Discussion

The coding variants detected in this study so far are in agreement with those previously described (e.g. Gallinat *et al.*, 2013), which means that we could not identify any new coding variants that could explain the differences in coagulation properties. For κ-casein, all the variants presented by Nilsson *et al.* (2020) were present in our subset of 30 samples. However, for β-casein, we only detected the A1 and A2 variants.

While the current study focused on the exons of the casein genes, many SNP and several indels were detected in the process. The potential role of these SNPs and indels in relation to both casein content and coagulation properties could be studied further by checking against a database of regulatory sequences and conservation across species. In the next phase of this project, milk samples will be subjected to protein sequencing, which will provide the amino acid sequences of the casein proteins, which can be compared to the amino acid sequences derived from the DNA data. By closing the gap between DNA sequence and functional protein properties we hope to understand more about the cheese coagulation properties of milk from RDC.

529. Major histocompatibility complex class II DRB gene Exon-2 of Indian camel breeds show limited genetic diversity

V. Prakash*, B. Jyotsana and S. Suthar

ICAR, National Research Centre on Camel, Bikaner, P.O. Box 07, 334001 Bikaner, India;
ved.prakash4@icar.gov.in

Abstract

Major histocompatibility complex (MHC) genes are the most polymorphic genes in vertebrates and play a crucial role in immunity and pathogen resistance. The blood samples were collected from six camel breeds namely Jaisalmeri, Jalori, Bikaneri, Kachchhi, Kharai and Malvi. The DNA was isolated from the blood, primers were synthesised and PCR amplification of MHC class II DRB gene fragment spanning exon-2 region was done. After sequencing of the PCR product, sequence variation, allele diversity and haplotype transmission pattern were analysed. The optimum annealing temperature was 57.5 °C. A 496 bp long MHC DRB gene region was amplified in six camel breeds. Camel MHC-DRB exon-2 region comprised of 270 bp and spanned from 116 to 385 bp of the amplified sequence. The variation at only four loci in exon-2 (NC_044530.1:g.[21049396A>G:21049451A>G:21049517A>G:21049598C>T]) contributed to allelic diversity. The sequence comparison revealed lower genetic variation in Indian camel compared to that observed in livestock species like cattle, buffalo, sheep and goat.

Introduction

In India, camel is an important animal specially in Rajasthan which have almost 60% of its area as desert land. According to 20th livestock census (2019) camel population of India is 0.25 million. India has 9 recognized camel breeds (NBAGR,2021). The camel has high heritage as well as cultural value. Today camel milk is in high demand because of its therapeutic properties (Singh *et al.,* 2017). Immune system of camel is very unique that impart strong resistance to many viral and microbial infections. It harbours unique antibodies that lacks light chain and have only heavy chain so their antibodies are several times smaller (nanobodies) compared to antibodies produced by other animals including humans. They can even interfere with enzyme binding sites, contributing to camels' remarkable disease resistance (Jassim *et al.,*2001). The mammalian Major Histocompatibility Complex (MHC) is a genetic region containing highly polymorphic genes with immunological functions. The antigen binding site is encoded by the second exon of genes encoding antigen presenting molecules. The exon 2 sequences of these MHC genes have evolved under the selective pressure of pathogens and the majority of the functionally important polymorphisms are concentrated in exon 2, which encodes the antigen-binding site of the molecule (Plasil *et al.*, 2016). Study on MHC class II genes in camel revealed low polymorphism in exon-2 region of DRB gene (Plasil *et al.,*2016). However, the study covered limited number of individual. The present study was planned to study genetic diversity in MHC-DRB class II exon-2 region of six Indian dromedary camel breeds.

Materials & methods

Animals DNA isolation and PCR amplification. About 10 ml of blood samples was collected aseptically through jugular vein puncture into vacutainer tube containing anticoagulant EDTA from 203 camels from six breed namely Jaisalmeri (35), Jalori(27), Bikaneri(45), Kachchhi(44), Kharai(30) and Malvi(22). Approval of Institutional Animal Ethics Committee (IAEC) was taken for the collection of blood from selected animals. Genomic DNA was isolated from the blood samples by 'Phenol: chloroform extraction' method as described by Sambrook *et al.* (2001) with slight modification. The integrity and the quality of extracted DNA was checked on 0.8% agarose. Only the DNA samples having concentration greater than 50 ng/µl with optical density of 1.6-1.8 was used for amplification of desired DNA fragment through PCR

R.F. Veerkamp and Y. de Haas (eds)

technique. Primers reported by Plasil *et al.* (2016) was utilised for amplification of targeted fragment. The PCR reactions were carried out in programmable thermocycler (Applied Biosystem gradient thermocycler) using PCR master mix (Promega). The quality and size of the PCR amplicons for studied MHC class II gene region were assessed on 1.5% agarose gel containing ethidium bromide (1% solution). PCR products were checked for amplification by electrophoresis on 2.0% agarose gel (Himedia), in parallel with 100 bp DNA marker (Thermo scientific).

Sequence based typing, deductional allele assignment and haplotype transmission. After purification of the amplified PCR products bidirectional sequencing using forward and reverse primers was done using Sanger Dideoxy Chain termination method (Eurofins Genomics). The forward and reverse sequences obtained for each fragment were edited using Codon Code Aligner software (USA) to arrive at resultant nucleotide sequences. Sequence based typing (SBT) of amplified product was done and homozygous and heterozygous genotype were identified. Cloning of heterozygous sample was done using pGEM®-T Easy Vector system II and sequencing of plasmid was done. Deduction allele assignment was done for allele identification. The sequence pattern of progeny and parents were analysed to understand haplotype transmission pattern.

Results

A 496 bp long MHC DRB gene spanning exon-2 region was amplified in six camel breeds (Figure 1). The amplified fragments were sequenced and analysed to identify the polymorphic locus. All six breed were found polymorphic in the amplified region. Exon-2 comprised of 270 bp and spanned from 116 to 385 bp of the amplified sequence. The sequence variation at positionNC_044530.1:g.[21049396A>G:21049451A>G:21049517A>G:21049598C>T were found in the exon-2 region (Figure 2, 3, 4 and 5). Frequency of the heterozygote and homozygotes genotype at different loci varied between breeds. Twelve different haplotype patterns were observed (Table 1). Kachchhi and Jalori breeds had the highest haplotype diversity. Transmission pattern analysis showed that alleles at different polymorphic loci of parents combined to generate different genotype in the progeny (Table 2).

Discussion

The first time Indian Dromedary MHC DRB gene exon-2 sequences were identified and polymorphism in it was detected. In the exon-2 region of DRB only limited variation was identified compared to that observed in livestock species like cattle, buffalo, sheep and goat. The findings are similar to reports of Plasil *et al.* (2016). The Kachchhi and Jalori breed had highest diversity. The exon-2 is transmitted as whole to progeny without any recombination.

Abstract

Nuclear factor-kappa light chain enhancer of activated B-cells (*NF-κB*) is a transcription factor (TF) considered to be a crucial element in several physiological processes, including fatty acid (FA) metabolism. This study aimed to identify differentially expressed genes (DEG) in liver of pigs fed with two different proportions of the soybean oil (SOY), which could be related to the *NF-κB* network. A total of 281 DEG between SOY (1.5%) and SOY (3.0%) diets (log2fold-change ≥1 or ≤-1; FDR-corrected *P*-value<0.1) were identified, in which 129 were down-regulated and 152 were up-regulated in SOY1.5 group. The gene-network enriched from DEG in response to an increase in the SOY in the liver transcriptomic profile provides us mechanisms to understand the regulatory effects of FAs, which may alter the behaviour of TFs and be modulated according to diet.

Introduction

Nuclear factor-kappa light chain enhancer of activated B-cells (*NF-κB*) is a protein complex of transcription factors, which plays critical roles in immunological processes, inflammation, proliferation, survival, and cell differentiation (Chen *et al.,* 1999). Moreover, *NF-κB* has been demonstrated to be involved in several physiological and pathological processes as well as in cell survival processes (Oeckinghaus and Ghosh, 2009).

The NF-κB protein complex are considered fundamental regulator of inflammation in liver cell populations and are critical for hepatocyte survival (Patterson and Georgel, 2014). Although not directly involved in fatty acid (FA) metabolism, *NF-κB* may act by activating the transcription of a series of enzymes that are related to inflammatory processes and signalling molecules synthesis (Patterson and Georgel, 2014). For instance, cyclooxygenases (COX) and lipoxygenase (LOX), which act in the conversion of members of omega-3 (n-3) and omega-6 (n-6) fatty acid families into signalling molecules that may activate or inhibit pathways related to inflammation processes (Schmitz and Ecker 2008). Then, the use of n-3 and n-6 fatty acids rich oils, such as soybean oil, in the diet reduce the levels of inflammatory mediators (Calder, 2010).

Therefore, maintaining an adequate regulation of this complex of transcription factors is considered by the literature as a critical factor for the maintenance of immune homeostasis of several tissues, besides regulating the expression of several genes related to immunological, inflammatory, as well as cell differentiation and survival processes. However, the transcription factors involved in key processes through the modification of gene expression in pigs are still poorly understood. This study aimed to identify differentially expressed genes (DEGs) in liver of immunocastrated male Large White pigs fed different levels of soybean oil, which could be related to the *NF-κB* network.

Materials & methods

All animal procedures were approved by the 'Luiz de Queiroz' College of Agriculture Animal Care and Use Committee (University of São Paulo, Piracicaba, Brazil, protocol number 2018.1787.11.6 and number CEUA 2018-28). In a 98-day study, 35 immunocastrated male pigs (halothane homozygous-negative (NN); average initial body weight of 28.44±2.95 kg) were assigned to one of two treatments in a randomized complete block design with six replicate pens per treatment. Dietary treatments consisted of corn-soybean meal diets supplemented with 1.5% SOY (SOY1.5) or 3% SOY (SOY3.0). There were 17 pigs in the SOY1.5 group and 18 in SOY3.0 group. Diets were formulated to meet or exceed Rostagno *et al.* (2011) recommendations for growing-finishing pigs, comprising 3.28 and 3.36 Mcal of metabolizable energy/kg of diet (as-fed basis) for the SOY1.5 and SOY3.0 groups, respectively. The details of animal housing and experimental diet compositions were mentioned by Almeida *et al.* (2021). All pigs were slaughtered with average final body weight of 133.9±9.4 kg and liver samples were collected, snap-frozen in liquid nitrogen, and then stored at -80 °C until analysis. Total RNA was extracted from liver tissue samples using commercial RNA extraction kits (RNeasy® Mini Kit, Qiagen), according to the manufacturer instructions. The mRNA library preparation and sequencing (RNA-Seq) were described in Fanalli *et al.* (2021). The RNA-Sequencing (RNA-Seq) data quality was checked using the FastQC, v. 0.11.8 software [http://www.bioinformatics.bbsrc.ac.uk/projects/fastqc/]. Adapters and bases with low PHRED score were removed using the Trim Galore v. 0.6.5. Reads with a minimum length of 70 bases were aligned and mapped to the reference pig genome (*Sus Scrofa*11.1) using the assembly available at Ensembl Release 102 [http://www.ensembl.org/Sus_scrofa/Info/Index]. Alignment and mapping were performed using the STAR v. 2.7.6a. The differential expressed genes (DEG) were identified using the DESeq2 package available at Bioconductor open-source software for bioinformatics (Love *et al.*, 2014), using multi-factor design. The functional enrichment analysis of DEG was performed to obtain (P<0.01) comparative networks by analyzing the single network (transcription factor) and process networks using the default parameters of MetaCore software (Clarivate Analytics) v. 21.3 build 70600, which were filtered for liver tissue and *Homo sapiens* species dataset to show activating and inhibiting effects. For the functional analysis to identify important transcription factor (TF) related to lipid homeostasis and immune response, the construction of the gene network by the TF mechanism was performed. For each TF of the master list, the algorithm generated a subnetwork with all the shortest paths to which the TF from the nearest recipient with direct ligands on the list.

Results

On average 78% of total paired reads aligned against the reference genome. After filtering, 19,250 genes were considered for differential gene expression analysis between the SOY1.5 and SOY3.0 group. A total of 281 DEG (log2fold-change ≥1 or ≤-1; FDR-corrected P-value<0.1) were identified, where 129 were down-regulated (log2FC ranging from -3.0 to -0.20) and 152 up-regulated (log2FC ranging from 4.8 to 0.24) in the SOY1.5 group by DESeq2 (Fanalli *et al.*,2022). We detected in the functional enrichment the networks related to inflammation such as Inflammation_IL-6 signaling with DEG *ORM1*, *CDKN1A* and Inflammation_Kallikrein-kinin system with DEG *KNG1* both networks involved with the *NF-κB* transcription factor (P<0.1). Among the total of DEG identified, we showed in the Figure 1 those 23 down-regulated (blue circles) and 21 up-regulated (red circles) in the SOY1.5 group, where the color shade represented the log2fold-change value. These DEG are target genes for the main TF network detected by MetaCore, which identified the *E2F1, SOX9, SMAD3, STAT3, ETS1, Tcf, PR (nuclear), Androgen receptor, TSHZ1, NF-κB and NF-κB1 (p150)* as TF (Figure 1).

Discussion

Previously, we demonstrated that feeding pig diets with SOY3.0 increased the proportion of oleic acid (OA, C18:1 n-9) and decreased the percentages of linoleic acid (LA, C18: 2 n-6) and alpha-linoleic acid (ALA, C18:3 n-3) in the loin intramuscular fat compared to those fed SOY1.5 (Almeida *et al.,* 2021). These

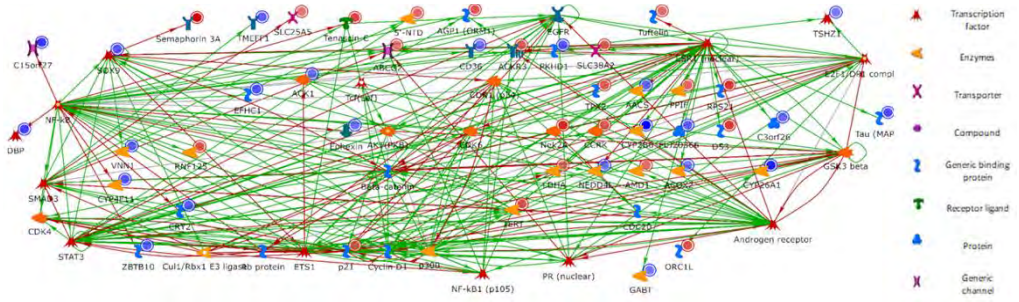

Figure 1. Network built based on the analysed networks (transcription factor) from the list of differentially expressed genes in the liver samples from pig fed with diets with 1.5 and 3.0% of soybean oil groups. Red circles represent up-regulated genes, whereas down-regulated genes are marked with blue circles. The color shade of the circles represents the log2fold-change value. Image created by MetaCore (Clarivate Analytics) [https://portal.genego.com/].

FA have been associated with the lower occurrence of some inflammatory diseases such as obesity, type 2 diabetes, and atherosclerosis (Jung *et al.*, 2008; Poudyal *et al.,* 2011). In the current study, we observed a significant (FDR 10%) number of DEGs in liver of pigs fed SOY1.5 vs SOY3.0, which were related to the network of important transcription factors linked to inflammatory response in liver tissue, being identified the *NF-κB*. *NF-κB* is related as a mediator in the process of vascular inflammation and one of the process networks enriched with DEGs is Inflammation_IL-6 signaling. Vascular inflammation is detected by the increase in circulating Interleukin-6 (IL-6), produced by inflammatory cells and secreted during inflammation by macrophages, endothelial cells, and fibroblasts, important in inducing B lymphocytes to differentiate into antibody-forming cells (plasma cells), in addition, IL6 signaling can lead to anti-apoptotic effects (Brasier, 2010). Another process network that *NF-κB* together DEG *KNG1* has been enriched with is the Inflammation_Kallikrein-kinin system related to inflammation, blood pressure control, coagulation (Peyrou, 2020).

A previous study carried out by Cai *et al.* (2005) reported that *NF-κB* is activated by genetic obesity and may be induced by diet (Chen *et al.,* 1999). The authors also observed that the lipid accumulation in the liver results in liver inflammation through *NF-κB* activation and cytokine production, causing insulin resistance both locally in the liver and systemically. The TF *NF-κB* has an important relationship to immunological and inflammation processes and can be activated by various stimuli, such as oxidizing free radicals and cytokines (Schmitz and Ecker 2008). As a key element of classical immunity, the proinflammatory *IKKβ / NF-κB* pathway modulates a wide range of cellular processes, including proliferation, immunity, inflammation, and apoptosis, from transcription of target genes. Furthermore, pro-inflammatory cytokine responses to dietary changes are induced via signalling pathways that mediate *NF-κB* activation (Bu *et al.*, 2021).

According to Rizzo and Laganà (2020), *NF-kB*, nuclear factor erythroid 2-related factor 2 (Nrf2), peroxisome proliferator-activated receptor gamma *(PPARγ)* and heat shock proteins (HSP), are affected by electrophilic long-chain FA n-3 derivatives and show effects in reducing inflammatory processes and oxidative stress. Using rat L6 myoblasts, Poletto *et al.* (2015) reported that FAs stimulated *NF-kB* expression. The authors demonstrated that gene expression may be regulated by OA and AL and 200 μM of either FA (OA or LA) is enough to increase *Rela* expression and protein binding to the *Slc2a4 – NF-kB* binding site in the skeletal muscle (Poletto *et al.,* 2015).

The network enriched from DEG in response to an increase in the soybean oil in the liver transcriptomic profile provides us with mechanisms to help understand the regulatory effects of fatty acids that can be altering the behaviour of transcription factors, which could be modulated according to diet. Further study to evaluate the effect of the two diets on the inflammatory response of the liver of the pigs used herein is necessary. Immunoassay tests from proteins extracted of the liver of the samples of this study are being performed by our group.

531. SPP1 gene polymorphisms within Intron-IV and Exon-IV region and their association with milk traits in Gaolao cattle

R.R. Kate, D.S. Kale*, J. Singh and D.V. Patil

Department of Animal Genetics and Breeding, Nagpur Veterinary College, Maharashtra Animal and Fishery Sciences University, Nagpur-06, Maharashtra, India; deepakkaleccmb@gmail.com

Abstract

Secreted phosphoprotein 1 (SPP1) is an acidic, phosphorylated glycoprotein exhibited impact on milk composition and yield. The aim was to detect SPP1 gene polymorphisms and reveal its association with milk traits in Gaolao Cattle. SPP1G1-*Bsr*I locus revealed frequency of TT genotype as 0.99 & CT as 0.01 respectively. The association of SPP1G1-*Bsr*I polymorphism with milk traits revealed significant difference in Milk yield and SNF % for CT genotype as compared to TT genotype. Milk yield (7.33±0.67) and SNF% (9.03±0.08) traits differed significantly for CT genotype as compared to TT genotype. Sequencing of SPP1G1-*Bsr*I locus-based TT and CT genotypes revealed G-A SNP at 32nd position. Significant differences were revealed for SNF% and Lactose% for SPP1G5-SSCP patterns A. SPP1G5-SSCP revealed SNPs A-G at 71st, A-C at 109th and A-C at 208th position. Identified significant association needs validation in large data sets with records for development of markers for bovine milk traits.

Introduction

Currently vast amount of animal genomic research work is being carried out to understand genetic mechanism behind milk production traits. Candidate gene analysis studies in dairy cattle will aid in development of gene level information database for its utilisation in further genetic improvement plans for the breed. Bovine SPP1 consists of six exons spanning about 7 kb of genomic DNA and encodes a 278 amino acid protein (Leonard *et al.* 2005). Due to significant impact of SPP1 gene on milk composition, it has become economically more relevant. Previous studies relating to the polymorphism of the Osteopontin gene analysed its effects on milk yield and milk composition. Genetic variants of SPP1 have been proposed to be associated with milk fat (Khatib *et al.* 2007), milk yield, and protein content in dairy cattle. In view of above, the present study was planned with the objectives to detect SPP1 gene polymorphisms and reveal association with milk traits in Gaolao Cattle using PCR-RFLP, PCR-SSCP and sequencing marker techniques.

Materials & methods

Experimental animals and DNA isolation. Blood was collected from 280 unrelated adult milking Gaolao cattle from the breeding tract & Farm. Test day milk was collected from the cows for estimation of Milk components like Fat %, Protein %, SNF% and recorded in the excel sheet.

PCR-RFLP & PCR-SSCP, DNA sequencing, bioinformatics and statistical analysis. Reported and designed primers amplifying variable regions of SPP1 gene were selected for their use in PCR-RFLP, PCR-SSCP, Sequencing and association analysis (Table 1).

Results

SPP1G1-BsrI PCR-RFLP Analysis. The 290 bp amplified products of Intron-IV region of SPP1 gene were digested using 5 Units of *BsrI* restriction enzyme. SPP1G1-*BsrI* locus was found polymorphic (Figure 1) with genotype frequency for TT genotype as 0.99, CT=0.01 & CC=0.00. The allele frequency for the Talleles was found 0.9946 and for allele C was 0.0054 at SPP1G1-*BsrI* locus. Hardy-Weinberg principle showed that the population of Gaolao cattle has reached a genetic equilibrium with respect to SPP1G1-*BsrI* locus.

SPP1G1-BsrI polymorphism and association Analysis. The association study of identified SPP1G1-*Bsr*I polymorphism with milk traits using SPSS revealed that there was significant difference in Milk yield and SNF % traits for CT genotype as compared to TT genotype at SPP1G1-*BsrI* locus (Table 2) in 208 experimental Gaolao animals. It was found that the milk yield (7.33±0.67) and SNF% (9.03±0.08) traits differed significantly at 5% level of significance for CT genotype as compared to TT genotype.

In SPP1G1-*Bsr* Locus, the PCR products of the Intron-IV region of SPP1gene representing TT and CT genotypes were sequenced which revealed G-A SNP at 32nd position in 236 bp SPP1 gene sequence (Figure 2).

[1] * indicates statistically significant at 0.05 (P<0.05) level.

The edited sequence of 322 bp was analysed using bioinformatics softwarewhich revealed SNPs A-G at 71st, A-C at 109th and A-C at 208th position in 322 bp (Figure 4). The alignment of 322 bp SPP1G5 amplified DNA sequence of SPP1 gene of Gaolao cattle with *Bos taurus* reference sequence (AY878328.1) revealed 02 computational SNPs viz; C-A at 109th position and C-A at 208th position.

Discussion

In present study the frequency of TT genotype at SPP1G1-*BsrI* locus was high as compared to CC genotype. The other researchers, Sharma *et al.* (2019) reported fixation of TT genotype in 147 animals of Sahiwal and Haryana cattle. The present study revealed significant difference in Milk yield and SNF % traits for CT genotype as compared to TT genotype (Table 3) in 208 Gaolao animals. It was found that the milk yield (7.33±0.67) and SNF% (9.03±0.08) traits differed significantly for CT genotype as compared to TT genotype. Leonard *et al.* (2005) screened 214 Holstein cows & reported association of C allele with increase in milk protein % & fat %. Khatib *et al.* (2007) reported association of C allele with increase in milk protein % & fat%. In conclusion, the findings of current study will fill the information gap about gene polymorphism at Intron-IV & Exon-IV region of SPP1 gene. The SPP1G1-*BsrI* locus was found significant for Milk yield and SNF % traits for CT genotype as compared to TT genotype. SPP1G5-SSCP polymorphism significant differences for SNF% and Lactose% traits with SSCP patterns A exhibited as compared to SSCP patterns B. The molecular genetic tools like PCR-RFLP, PCR-SSCP & SNP revealed genetic variation thus proving them as effective tools for marker trait association. The identified associations after validation in bigger database can be useful for selection and breeding decisions of indigenous dairy cattle.

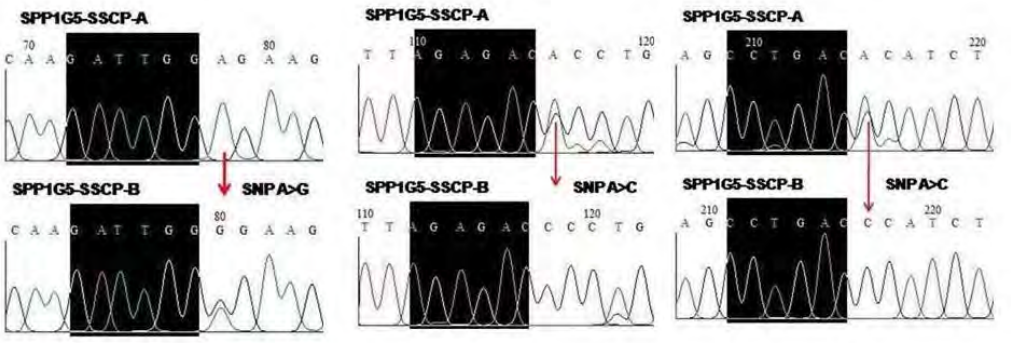

Figure 4. SNPs A-G at 71st, A-C at 109th and A-C at 208th position in 322 bp sequence of SPP1G5 amplicon in polymorphic SPP1G5-SSCP pattern-A & B in Gaolao Cattle Population.

532. Building *in vitro* tools for livestock genomics: chromosomal variation within the porcine PK15 cell line

M. Johnsson[1], J.M. Hickey[2] and M.K. Jungnickel[2*]

[1]Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; [2]The Roslin Institute and Royal (Dick) School of Veterinary Studies, The University of Edinburgh, Midlothian, EH25 9RG, Scotland, United Kingdom; melissa.jungnickel@roslin.ed.ac.uk

Abstract

In this work, we called variants and used read coverage in combination with within-sample allele frequency to detect potential aneuploidy in two samples of an immortalise Porcine Kidney Epithelial (PK15) cell line. Porcine cell culture and cell lines are powerful tools for functional genomics and *in vitro* phenotypic testing of candidate causal variants. However, to be utilised for any type of genomic or variant interrogation assay, the genome sequence and structure of cell lines must be realised. Read coverage and within-sample allele frequencies suggest that several chromosomes are fully or partially aneuploid in PK15, including potential triploidy of chromosome 4 and tetraploidy of chromosome 17. We compared two PK15 cultured cells samples: a new American Type Culture Collection (ATCC) sample and one that has been utilised within the laboratory for an extended period (>10 years). The older PK15 sample showed evidence of additional structural variation and potentially clonal variation. We discuss implications for livestock functional genomics.

Introduction

Cell lines are an essential tool for functional genomics and functional studies of potential causative genetic variants. Large-scale epigenomic projects like ENCODE rely heavily on cell lines as models of different cell types, and functional work on causative genes in livestock make use of the relatively few livestock cell lines that exist (e.g. Walker *et al.*, 2018).

Most CRISPR screens are conducted *in vitro*. This approach requires an exquisitely precise and detailed knowledge of the genome sequence of target cell lines. It is well established that such sequence details are essential prerequisites to design guide RNAs and direct Cas9/dCas9 function in CRISPR manipulation and perturbation assays. Less well known is the contribution of genome structure and cell line aneuploidy to CRISPR-genome interrogation. Aneuploidy, in which cells have an abnormal number of chromosomes, has been shown to have a devastating impact on cell phenotype and gene expression (Sheltzer *et al.*, 2012). To our knowledge, an impact of aneuploidy on CRISPR gene manipulation has not been previously considered.

For this project, we used short read sequencing to characterise the genome of PK15, a classic pig cell line established in 1955 or 1956 from the kidney of an adult pig (Harris, 1959; Ruddle, 1961). We called variants and used read coverage in combination with within-sample allele frequency to detect potential aneuploidy in two samples of the PK15 cell line.

Materials & methods

Samples and sequencing. We extracted DNA from two *in vitro* cultured PK15 cell lines. One PK15 cell line was ordered fresh from ATCC (product name: PK(15) CCL-33) and the other were PK15 cells that have been cultured at the Roslin Institute for >10 years. Whole-genome resequencing was performed on the Illumina platform by Genewiz (Essex) for the ATCC sample and Edinburgh Genomics (Edinburgh) for the Roslin sample.

Bioinformatics. We mapped reads to the Sscrofa11.1 reference genome (Warr *et al.,* 2020) with BWA MEM version 0.7.12 (Li, 2013) after trimming adapter and low-quality ends with Trimmomatic version 0.36. We removed duplicate alignments with Picard version 2.9.0 and called variants with GATK 3.5 (McKenna *et al.*, 2010) using the HaplotypeCaller and the GVCF workflow. We performed base quality score recalibration by first calling a preliminary set of variants, then using it as input to the GATK base quality score recalibration tool, and then calling a final set of variants using the recalibrated alignments. We filtered single nucleotide variants using the standard GATK hard filters. In order to estimate the allele frequencies within each sample, we extracted the allelic depth for each biallelic variant with bcftools version 1.10.2. In order to detect large-scale copy number variation and aneuploidy, we divided the pig genome chromosomes 1-18, X and Y into 10 kbp windows, and counted the number of reads mapping in each window with BEDTools version 2.26.0.

Results

The sequencing resulted in approximately 30X (ATCC sample) and 40X (Roslin sample) coverage of the pig genome. Variant calling detected 9,028,359 single nucleotide variants. Out of those, 3,565,539 were called as homozygous alternate in both samples, that is, they represent positions where the PK15 cell lines is likely to be fixed for a different allele than the Sscrofa11.1 reference genome.

Read coverage per chromosome suggest that several chromosomes are aneuploid in PK15. Figure 1 shows the average read coverage for a 10 kbp window on chromosomes 1-18, X and Y. In both samples, chromosomes 4, 9 and 17 have high read coverage. There are also differences between samples, such as high read coverage on chromosome 12 in the Roslin sample, not seen in the ATCC sample. When it comes to the sex chromosomes, the ATCC sample appears to be XX, consistent with the literature (Ruddle, 1961), while the Roslin sample appears to have lost one X chromosome and be X0.

Read coverage within chromosomes also suggest that there are large-scale structural variants within chromosomes. Figure 2 shows the read coverage in 10 kbp windows within four selected chromosomes. Chromosome 1, which shows little evidence of gross aneuploidy at the whole chromosome level (Figure 1), still potentially has a duplication within the Roslin sample, at around 200 Mbp. Chromosome 4 appears mostly triploid, but with several regions of higher and lower coverage especially in the Roslin sample. Chromosome 17 appears to be tetraploid in the ATCC sample and triploid in the Roslin sample.

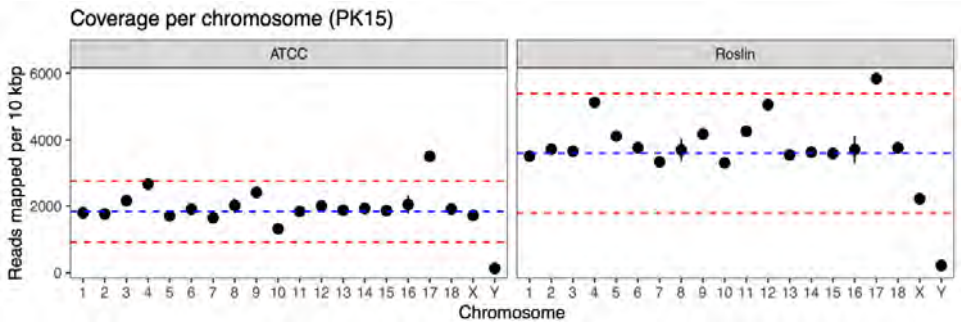

Figure 1. Average read coverage for 10 kbp windows on chromosomes 1-18, X and Y in the PK15 genome. Panels show the two samples of the cell line. Horizontal lines indicate the median coverage for a 10 kbp window (blue) as well as 0.5 × and 1.5 × the median (in red).

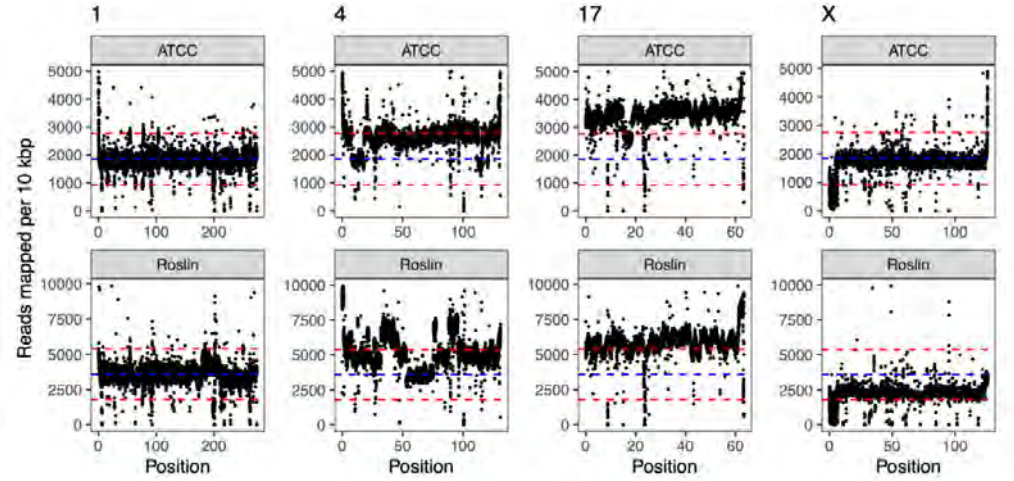

Figure 2. Read coverage in 10 kbp windows on chromosomes 1, 4, 17 and X in the PK15 genome. Panels show the two sample of the cell line. Horizontal lines indicate the median coverage for a 10 kbp window (blue) as well as 0.5 × and 1.5 × the median (in red).

Within-sample allele frequencies (Figure 3) for heterozygous sites also suggest aneuploidy. We find examples of chromosome that are likely diploid, triploid, tetraploid and haploid:

- For a diploid chromosome, one would expect a frequency of 1/2. Considering chromosome 1, the ATCC sample appears mostly diploid. In the Roslin sample, however, there are two distinct modes of allele frequency, suggesting that some part of the cell line has an aneuploid karyotype.
- For a triploid chromosome, allele frequencies should instead be 1/3 and 2/3. In both samples, chromosome 4 shows two allele frequency modes, suggesting triploidy.
- For a tetraploid chromosome resulting from a duplication of both homologous chromosomes, the expected allele frequency is 1/2. On chromosome 17, the ATCC has allele frequency centred on 0.5, while the Roslin sample shows two modes. As they both have high read coverage (Figure 2), we hypothesise that chromosome 17 is tetraploid in the ATCC sample and mostly triploid in the Roslin sample.
- For a haploid chromosome, only frequencies 0 and 1 are possible. In the Roslin sample, the X chromosome has very few heterozygous sites, suggesting that it is haploid.

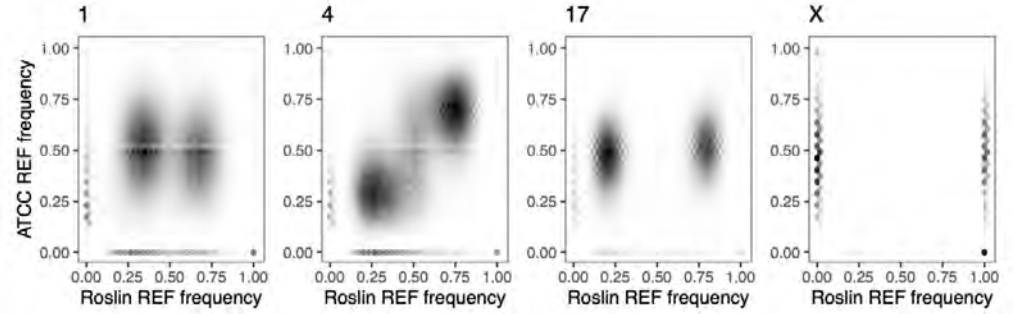

Figure 3. Within-sample allele frequency for the reference allele, calculated from allelic read counts, for single nucleotide variants that are heterozygous in at least one of the samples on chromosomes 1, 4, 17 and X.

Discussion

Our results suggest that the PK15 cell line has aneuploidies and complex structural variants in its genome. While such genome anomalies have not impacted over-expression studies that have been popular for the last 10-15 years (see review by (Prelich, 2012)), this cell line aneuploidy and clonal variation will directly impact CRISPR genome editing/genome manipulation studies; a genome editing assay with 20% homology-directed repair efficiency would generate repair rates of 4% in diploid and 0.8% in triploid genome sites respectively.

We are currently generating a more thorough bioinformatic to detect structural variants from short reads and segment the genome by ploidy. However, to fully describe the genome structure of a cell line, both long read sequencing and genome assembly is required. While currently too time consuming and expensive for routine cell line characterization, a method to examine cell line aneuploidy in more detail should be considered for key, routinely genome-manipulated and edited cell lines.

In summary, we suggest that genome aneuploidy should be considered when planning genome editing assays in *in vitro* cell lines.

533. Conserved non-coding elements of the bovine genome

N.K. Kadri* and H. Pausch

ETH Zürich, Universitätstrasse 2, 8092, Switzerland; naveen.kadri@usys.ethz.ch

Abstract

Conserved non-coding elements (CNEs) are common in the eukaryotic lineage. These sequences with unknown function are conserved over millions of years of evolutionary divergence. We compared bovine and human non-coding sequences and identified 23,401 unique CNEs with a median size of 226 bp (up to 1,884 bp) spanning 6.37 mb of the bovine genome. Most CNEs were found in the intergenic region and were spread non randomly in clusters across bovine autosomes. Most intergenic CNEs and their spatially associated genes were conserved in syntenic blocks across the two genomes. The associated genes were significantly enriched for 'developmental process' and 'anatomical structure development'. Further, these elements showed strong evolutionary constraint compared to their surrounding sequences and overall harboured 32% less variation than the protein coding sequences. These observations suggest that the CNEs detected are enriched for functional elements that may be essential for processes that are evolutionarily conserved across species.

Introduction

Non-coding genomic sequences that exhibit conservation across species are common in the eukaryotic lineage (Vavouri *et al.*, 2007). These sequences are commonly referred to as conserved non-coding elements (CNEs). Comparative genomics approaches have revealed CNEs even in distantly related species that may have diverged more than 400 million years ago (Polychronopoulos *et al.*, 2017). Although a regulatory role, particularly for genes involved in development processes is speculated and experimentally confirmed for some CNEs (Visel *et al.*, 2008), a definite functionality triggering the extreme conservation of non-coding sequence has not been fully elucidated (Harmston *et al.*, 2013; Polychronopoulos *et al.*, 2017). We herein survey the cattle genome for CNEs and examine their distribution, associated genes, and the functional constraint on them.

Materials & methods

Identification of CNEs. Conserved non-coding elements between cattle and human genomes were identified using CNEFinder (Ayad *et al.*, 2018). Soft masked reference sequences and annotation files of the human (GRCh38) and bovine (ARS-UCD1.2) genomes were retrieved from ensembl (v104). Following masking of the coding regions in the two genomes, non-coding sequences longer than 150 bp with at least 95% similarity between cattle and human were considered as CNE.

The evolutionary constraint on the identified CNEs and the surrounding sequence was quantified by counting the number of variants detected per 100 bp of the sequence. A variant catalogue containing 29.4 million variants previously established from whole genome sequencing data of 266 animals from 11 cattle breeds was used for this purpose (Kadri *et al.*, 2021).

Synteny and gene ontology enrichment analysis of CNE-associated genes. CNEs located outside annotated genes (n=14,025) were examined if their spatially associated genes are conserved in syntenic blocks across the two genomes. Specifically, we quantified the number of genes within 1 mb of the CNE on the bovine genome (CNE-associated genes) that had an orthologous gene (retrieved using Ensembl rest API; https://rest.ensembl.org/) within 1 mb of the corresponding conserved sequence on the human genome. CNE-associated genes conserved in synteny were then analysed for Gene Ontology (GO) enrichment. The

enrichment analysis was carried out on http://geneontology.org/. Statistical significance of enrichment was estimated using a binomial test, and Bonferroni correction was applied to account for multiple testing.

Simulation. A simulation study was carried out to investigate if the location of CNEs along the bovine genome matches with expectations assuming random placement. New locations were randomly assigned to CNEs on each chromosome restricting their placement to non-coding regions. This process was repeated 400,000 times and the mean distance between randomly placed CNEs was calculated for each replicate.

Results

CNEs appear in clusters and mostly reside in intergenic sequences. We searched for non-coding sequences longer than 150bp in the bovine genome that had more than 95% similarity with human non-coding sequences. This screen revealed a total of 23,401 unique bovine conserved non-coding elements (72 CNEs mapped to multiple regions of the human genome), with a median size of 226bp (up to 1,884 bp) covering 6.37 mb of the bovine genome. The density of CNEs varied considerably across chromosomes. While the mean density of CNEs was 2.5 kb/mb along the bovine genome, it ranged from 0.28 kb/mb on BTA3 to 6.9 kb/mb on BTA18 (Figure 1A). Most CNEs, as expectedwere in the intergenic part of the bovine genome (n=14,025, 59.93%). Of the remainder (n=9,376), 9,324 CNEs mapped to 2,156 unique genes, that included 1,967 protein coding, 151 lncRNA, 14 pseudogenes, 14 miRNA, 1 SnRNA and 7 miscRNA genes. CNEs were non-uniformly spread across the non-coding bovine genome. On average a CNE was identified within 100.7 kb of a neighbouring CNE. Such a clustering is highly unlikely assuming a random placement of CNEs along the genome (P<2.5e-06). In none of the simulated replicates the mean distance between consecutive CNEs was less than 100.7 kb.

CNEs are associated with genes coding for developmental process. Among the 9,376 CNEs in the non-coding part of the annotated genes, 8,851 mapped to 1,967 protein coding genes. The majority of these CNEs (n=8,150; 92.08%; affecting 1,735 genes) had similarity with sequences within their human orthologous genes. A GO enrichment analysis revealed that these 1,735 genes were significantly (>1.7-fold enrichment; P<2.49e-50) enriched for GO terms 'regulation of gene expression and 'regulation of macromolecule metabolic process'.

We examined if CNEs located outside annotated genes (n=14,025) and their spatially associated genes (within 1 mb) are conserved in syntenic blocks in the two genomes. Interestingly for >90% of CNEs (n=12,760) at least one human orthologue was found for CNE-associated genes and for more than half of the CNEs (n=7,496; 53.4%) human orthologues were found for more than 50% of CNE-associated genes. The resulting list of 9,612 CNE-associated genes conserved in syntenic blocks was also enriched for GO terms 'developmental process' and 'anatomical structure development' (>1.2-fold enrichment; P<8.74e-19).

When the enrichment analysis was repeated considering only the genes closest to CNEs, the resulting 712 CNE-associated genes were also enriched for GO terms 'developmental process' and 'anatomical structure development' (>2.3-fold enrichment; P<3.96e-45). In addition, GO terms 'nervous system development', 'multicellular organism development', 'system development', 'cell differentiation', 'cellular developmental process', and 'anatomical structure morphogenesis' were also significantly enriched (>2.3-fold enrichment; P<8.03e-42) among the genes closest to CNEs.

CNEs are depleted for variants. Next, we compared the evolutionary constraint on CNEs and their surrounding sequences by counting the number of overlapping variants. Variability was assessed separately for CNEs mapping inside and outside of the annotated genes. Nucleotides overlapping CNEs were less variable than their surrounding sequence (Figure 1B). Overall, CNEs were 32% less variable than the

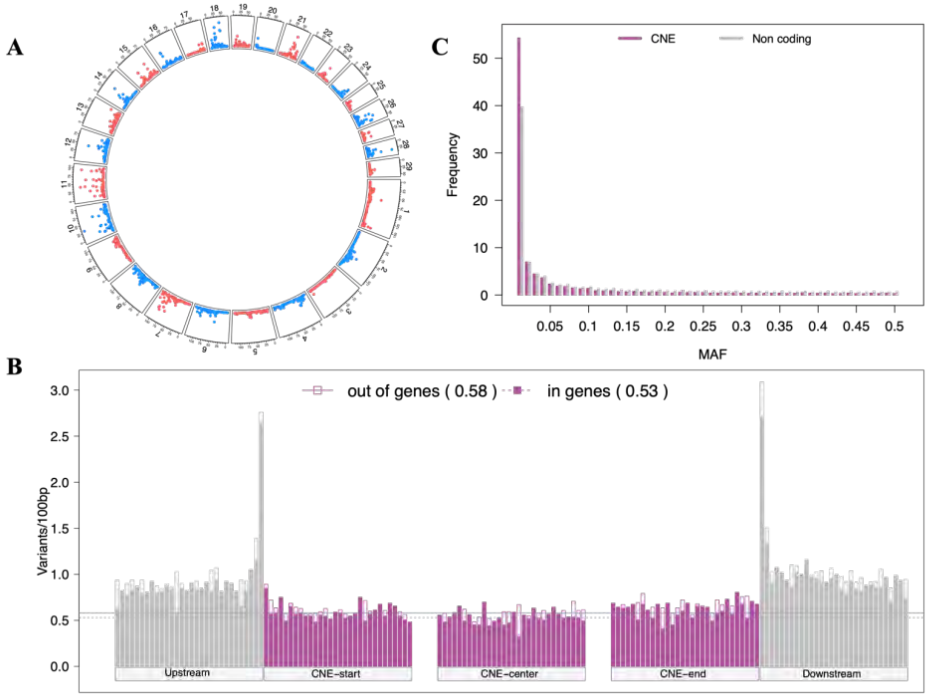

Figure 1. Distribution and functional constraint on the conserved non-coding elements (CNEs) in the bovine genome. The distribution (percentage of nucleotides overlapping CNEs in bins of 1 mb) along the bovine autosomes (A). The variability of nucleotides in and around the CNEs, quantified as number of variants per 100bp (B). CNEs mapping to inside and outside of the annotated genes are respectively represented with coloured and un-coloured bars. Minor allele frequency distribution of variants overlapping the CNEs (C).

coding sequence (0.56 per 100bp vs 0.81 per 100 bases; $P<2.2e-16$, Fisher's exact test). The constraint on CNEs mapping to annotated genes was significantly higher than for those in intergenic regions (0.53 vs 0.58 variants/100bp; $P=3.1e-17$, Fisher's exact test). Variants overlapping CNEs were enriched in lower Minor allele frequency (MAF) bins compared to variants overlapping non-conserved non-coding sequences in the bovine genome (Figure 1C).

Discussion

We identified CNEs spanning 6.3 mb of the bovine genome that have survived ~100 million years of evolution since the last cattle-human common ancestor (Liu *et al.*, 2006). Consistent with previous studies in other vertebrates, the identified CNEs appeared in clusters in the bovine genome (Woolfe *et al.*, 2005), mostly in so-called 'genomic regulatory blocks' with their associated genes (Polychronopoulos *et al.*, 2017). Genes in these syntenic blocks, as described previously (Harmston *et al.*, 2013), were enriched for those involved in developmental processes. Our study further revealed that nucleotides overlapping CNEs were less variable than the surrounding sequences and harboured variants enriched in low MAF bins suggesting purifying selection. Taken together, these observations suggest that the CNEs detected in this study are enriched for functional elements that may be essential for processes that are evolutionarily conserved across species.

We hypothesize that a larger fraction of the non-protein coding bovine genome is under purifying selection than detected in this study. The number of CNEs identified depends on the evolutionary divergence between the compared species and the thresholds used for similarity and sequence length (Harmston *et al.*, 2013). Comparison of the bovine genome with more closely related species, for example, other members of the Bovidae, is likely to yield a much larger set of lineage-specific CNEs (Chen *et al.*, 2019). An analysis of distantly related species, on the other hand, is expected to yield less CNEs but might increase the signal-to-noise ratio by filtering out slow-evolving neutral sequences (Woolfe *et al.*, 2005).

As more and more trait-associated variants are detected in non-coding regions of the genome (Georges *et al.*, 2018), systematic prediction of generally ignored non-coding functional features (e.g. Kadri *et al.*,2021) and detection of elements conserved without known functions using comparative genomics approaches seem necessary towards deciphering the molecular mechanism underlying statistical association.

Abstract

Differentiating causative variants from linked variants is a major challenge of modern genetics. Here, we describe development of a massively parallel reporter assay (MPRA), an *in vitro* method that enables simultaneous functional testing of thousands of candidate causative regulatory variants. Candidates for the MPRA were identified through analysis of two large molecular quantitative trait loci (QTL) datasets derived from sequencing of bovine mammary biopsies, comprising an expression QTL resource (n=371 cows), and a histone QTL dataset (n=99 cows). Candidates that overlapped with lactation QTL discovered from genome-wide association studies were further prioritised to yield a final library of 242,340 oligos representing 24,234 regulatory sequences for expression testing. This paper gives a brief description of the MPRA method, our candidate selection criteria, cloning approach, and the composition of the final oligo pool for expression analysis.

Introduction

Genome-wide association studies (GWAS) have identified thousands of highly associated variants for myriad traits. However for a given locus, identifying which variants are responsible for phenotypic variation is challenging, given that variants in strong linkage disequilibrium (LD) may appear equivalently associated. An emerging, lab-based method to differentiate between functional regulatory variants and those that are merely statistically correlated is the massively parallel reported assay (MPRA). While single gene reporter assays have been applied for decades, Tewhey *et al.* (2016) described a highly parallelised version of this approach that drastically changes the throughput potential of reporter-based tests. Here, pooled cloning approaches are used to quantify the expression of tens of thousands of alleles simultaneously. This method involves synthesis of oligonucleotide sequences (typically 100-200bp long; limited by microarray-based synthesis constraints) to test the ability of SNPs or short indels to drive expression of a reporter sequence. For a given biallelic variant, a typical design would therefore aim to compare short sequences that differ only by the two alleles of interest. These sequences are then cloned into an expression plasmid upstream of a reporter transcript, with constructs then transfected into the cell line of interest for expression testing. Unlike traditional reporter assays that use fluorescence or luminescence of the translated reporter to quantify expression, the MPRA uses RNA-sequencing of the expressed transcript, where barcodes engineered into the 3'UTR allow assignment of sequence reads to oligos (and by extension, alleles).

We have previously identified hundreds of QTL for bovine lactation traits (Lopdell *et al.* 2017; Tiplady *et al.* 2021). Using a large gene expression resource derived from sequencing of mammary biopsies from 371 lactating cows, we observe that expression QTL (eQTL) likely drive many of these effects, with regulatory mechanisms suggested for most loci. We have also generated chromatin immunoprecipitation-sequence data (ChIP-seq) for histone modifications using mammary biopsies from a subset of 99 animals from this eQTL dataset. These data have allowed identification of thousands of histone modification QTL (hQTL), suggesting further candidate causative variants that may underpin variation in lactation traits (Prowse-Wilkins *et al.*, *in preparation*). While these data highlight many candidate variants, individual loci are near-universally represented by multiple variants. To further fine map these signals, we herein report

development of a bovine MPRA, where we attempt to resolve hundreds of eQTL, hQTL, and lactation QTL to single causative nucleotides.

Methods

We targeted two major sources of QTL for variant selection and MPRA oligo design, described under the 'eQTL with lactation effects', and 'Mammary hQTL peak variants' subheadings below. A total of 3,144 haplotypes generated as part of a separate study were also included in the design, though this content was unrelated to the majority of the mammary/lactation focused content and thus is not described in detail in this paper.

eQTL with lactation effects. We intersected the list of lactation and milk FT-MIR QTL recently reported by Tiplady *et al.* (2021) with eQTL highlighted from the same study to target loci likely underpinned by regulatory mechanisms. Expression QTL were prioritised based on assessment of correlations with lactation/FT-MIR trait QTL, computed using $-\log_{10}$ *P*-values for the lists of variants between traits. Expression QTL selection differed from that described in Tiplady *et al.* (2021) in that the interval of variants used for correlation calculations was narrower (±10 kbp of the transcript in the current study), and the nominal correlation threshold applied was higher (minimum Pearson coefficient of 0.8 R^2). These criteria identified 139 lactation/ FT-MIR QTL:eQTL pairs, where we further categorised these signals based on three levels of priority. The categories included whether they presented hallmark genes that had been previously published in multiple lactation GWAS studies (first priority candidates), with second and third tier candidates showing more limited prior literature-based implication and less compelling correlations. The number of variants interrogated per locus was constrained on this basis, with a maximum attribution of 130, 80, and 30 variants for the first, second, and third tiers respectively. For selecting the subsets of variants from each locus, variants with an LD R^2>0.8 with the top-associated variant were targeted, with number constraints then applied to these lists. For oligos that contained multiple candidate variants, we also represented all haplotypic strings of these alleles, though additional constraints were applied to cap the total number of haplotypes for the most variable loci. We also included six negative control variants per gene, targeting sites from the 139 loci of interest that were unassociated with expression (*P*-value>0.75).

Mammary hQTL peak variants. We targeted candidate variants discovered through QTL-mapping of ChIP-seq data, based on quantitative histone modification assays for the H3K4Me1, H3K4Me3 and H3K27ac histone marks. These assays were applied to biopsies from 99 lactating cows that overlapped with the RNAseq population referenced in the preceding section. A manuscript describing this dataset is currently being drafted (Prowse-Wilkins *et al. in preparation*) and is further described in a separate WCGALP paper (Prowse-Wilkins *et al.* 2022). Candidates were selected if they overlapped a ChIP-seq peak, were significantly associated with histone modification for that peak, and were also associated with gene expression changes in *cis* (using the RNAseq dataset described above). However, unlike the '*eQTL with lactation effects*' candidates, we did not investigate haplotypes for the hQTL variant targets. We did, however, duplicate this content on the array for synthesis, a rule applied to all variants that weren't represented more than once via haplotypes (i.e. to provide additional redundancy in the oligo pool).

Cloning and barcoding strategy, oligo design and synthesis. We used the vectors and cloning strategy outlined by Tewhey *et al.* (2016). Exhaustive methods are reported in that paper, though we made modifications to their approach to enable greater flexibility regarding cloning of insert sequences, and the barcoding approach. For the former, we included additional restriction sites (SfiI, FseI, AsiSI, and NotI) to allow sticky end cloning options for integration of the oligo library and reporter transcript. Regarding barcoding, we adopted a hybrid approach that included 15bp barcodes generated as part of oligo synthesis (similar in approach to Choi *et al.* 2020) while maintaining capability to expand barcode diversity by PCR,

post-synthesis (as per Tewhey *et al.* 2016). For the 15bp 'hard-coded' barcodes, each oligo was represented by 10 sequences. For oligo design, custom scripts were implemented to extract 135bp strings from the ARS-UCD1.2 genome, centred on the variant of interest. Following *in silico* addition of barcodes, Gibson homology sequences, and restriction and primer binding sites, 208bp oligos were submitted to Agilent Technologies (Australia) for synthesis using the 244k format SurePrint oligo platform.

Results

Our selection criteria yielded 24,234 candidate regulatory oligos targeting 4,814 biallelic variants. Among the two major categories of targets, there were 15,600 haplotypes representing 2,787 variants for the 'eQTL with lactation effects' pool. Figure 1 shows the eQTL-implicated genes from this selection, highlighting 13, 18, and 55 genes for the first, second, and third priority tiers of candidates. For the 'mammary hQTL peak variant' selections, 3,976 regulatory oligos representing 994 variants were included. A total of 1,514 regulatory oligos were also included as negative controls in the design. When paired with ten 15bp barcodes per oligo, a final library 242,340 oligos was submitted for synthesis. At time of writing, the oligo library had been synthesised with characterisation, cloning, and expression testing pending.

Discussion

We herein report design and synthesis of a high density MPRA for the functional testing of bovine candidate regulatory variants. This experiment is motivated by our observation that many lactation QTL appear to be underpinned by regulatory mechanisms(Tiplady *et al.* 2021; Lopdell *et al.* 2017), a finding that is well-described for human complex traits and diseases(Maurano *et al.* 2012). Further, most loci present multiple non-coding candidates. While this is true in most species (including humans), GWAS in livestock species such as cattle present additional challenges, where selection has led to population structures that increase the range of LD and present a greater number of correlated variants as candidates(Goddard and Hayes 2009). An alternative approach to fine mapping is to test alleles for their functional consequences – using *in vitro* methods that remove variants from their native genomic and haplotypic contexts. In humans, a number of studies have demonstrated use of the MPRA to this end (e.g. investigation of melanoma (Choi *et al.* 2020) and hominid evolution variants (Jagoda *et al.* 2021)), though we are so far unaware of such methods being applied in domestic species.

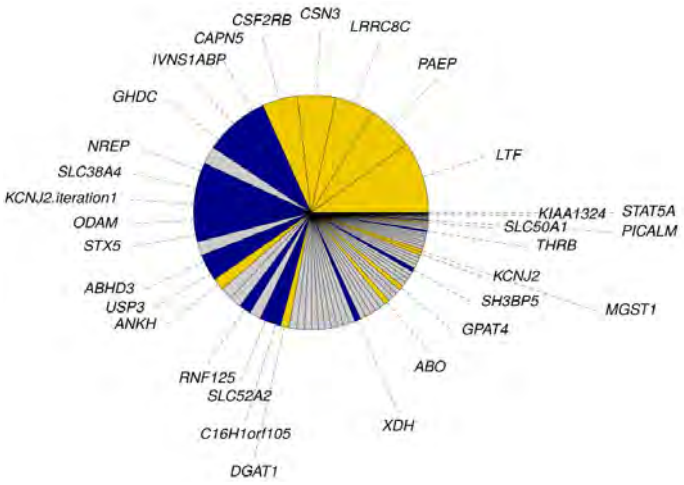

Figure 1. Genes with eQTL/lactation QTL targeted by the MPRA. Gene symbols shown for first (yellow) and second (blue) tiers only, slice area represents the number of haplotypes designed per gene.

We have taken a pragmatic design approach to the MPRA, representing hQTL and eQTL that overlap with loci associated with lactation and FT-MIR milk phenotypes. While cloning and transfection were pending at time of writing, our intention is to conduct expression testing in bovine mammary epithelial cells. Given the expression of major milk proteins in transformed mammary lines is limited at best (Huynh, Robitaille, and Turner 1991), we will target primary lactating mammary cells for transfection and have optimised methods to this end.

Summary

The objective of this study was to fine map the quantitative trait loci region of chromosome 27 which was previously reported as a major contributor of total genetic variation for resistance against cardiomyopathy syndrome in Atlantic salmon. The fine mapping using whole genome resequencing of individuals increased resolution of the targeted genomic region (Ssa27:10-12 Mbps), resulting in uncovering the two immune related genes (*HA1F* and *MR1*). Transcriptome analysis revealed only two differentially expressed genes, *MR1* and *HA1F* across resistant vs susceptible individuals. The gene *MR1* was highly expressed in the susceptible group with $\log_2$ fold change of 6.405 compared to resistant individuals. Contrary to *MR1* expression, *HA1F* gene was lowly expressed ($\log_2$ fold change of 2.099) in susceptible group. Moreover, the proteomics results partially validated the results of transcriptomics with the product of *MR1* being differentially produced across resistant vs susceptible individuals.

Introduction

Cardiomyopathy syndrome (CMS) is a severe cardiac disease of Atlantic salmon caused by piscine myocarditis virus (PMCV). The outbreak of CMS typically occurs several months after the sea transfer (during second year of production cycle) when the fish is a relatively large size (~3.6 kg). In most cases, no clinical signs are observed until the onset of mortality leading to compromised fish health/welfare and significant economic losses for salmon producers. The disease pathology develops slowly, and minor stressors such as treatment for sea lice infestation in the presence of CMS may trigger mass mortality (Garseth Å *et al.* 2018).

Cardiac histopathological examination of affected fish presents severe inflammation and necrosis mostly limited to the endocardium and spongy myocardium in the atrium and ventricle (Rodger *et al.* 2014), with a higher level of infiltration through mononuclear cells i.e. lymphocytes and macrophages (Ferguson *et al.* 1990; Timmerhaus *et al.* 2012). The heritability for resistance against CMS falls in the range of low to high depending on different factors e.g. type of data (survival, virus load or histology), challenge environment (field vs controlled) and/or population. Additionally, genomic regions on chromosomes 12 and 27 had previously been detected with effects on genetic variation for resistance against CMS (Boison *et al.* 2019; Hillestad *et al.* 2020). The genomic region of chromosome 27 had the largest effect, explaining ~30% of the genetic variance. In the current study, we aimed to fine map the genomic region(s) focusing mainly the quantitative trait loci (QTL) detected on chromosomes 27 to identify causative gene/mutation underlying the host resistance against CMS.

Materials & methods

The test population of this study originated from the breeding nucleus of MOWI ASA, with sampling performed from four year classes (YC2016, YC2017, YC2019 and YC2021). Individuals were selected from these four year classes were selected for two purposes: (1) whole genome resequencing to fine map the detected QTL region(s), where fin clips were sampled; and (2) functional level validation of causative genes through expression profiling (tissue from atrium and blood plasma for transcriptomics and proteomics,

respectively). Whole genome resequencing was performed on samples selected from YC2016, YC2017, and YC2019 while samples for transcriptomics and proteomics were obtained from YC2021.

All selected individuals had pedigree information available, were phenotyped for CMS either through company's routine challenge test or field outbreak and genotyped using NOFSAL03 Affymetrix axiom array (~55K SNPs). The selection of individuals was systematically performed limiting the number of sibs per family (offspring per sire ≤4 and dam ≤2), considering genomic breeding value and presence/state of the previously detected significantly associated haplotype. Individuals were categorized into three groups, resistant FUL (gEBVs>1.25 SD and 2 copies of the favorable haplotype), intermediate HET, (gEBVs>0.625 SD and one copy of the favorable haplotype), and susceptible DEL (gEBVs<1.25 SD and zero copy of the favorable haplotype). One hundred and fifty-seven samples were selected for whole genome resequencing from each of the three year classes distributed to all three groups (FUL, HET, and DEL). Additionally, 30 samples (10 from each FUL, HET, and DEL category) were selected from YC2021 for transcriptomics and mass spectrometry-based label-free proteomics, with each individual sampled for both atrium and blood plasma samples.

The whole genome resequencing was performed using the BGISEQ platform with 150 bp PE reads. The raw sequence reads were trimmed/filtered using Trimmomatic, and subsequently quality sequence data was aligned to the Atlantic salmon reference genome sequence (assembly ICSASG_v2) using BWA-MEM (version 0.7.13-r1126). The *mpileup* function of SAMtools (version 1.10) was then used to call variants and the call option of *bcftools* was used to call the genotype at each variant site for each individual. Informative SNP variants were annotated using the ensembl variant effect predictor to categorize variants based on their predicted effects (McLaren *et al.* 2016).

The transcriptome sequencing was performed using Illumina NovaSeq 6000 platform with 150bp paired end sequencing. After quality trimming/filtering of reads, higher quality reads were processed using STAR program (version 2.7.9a) to obtain count values of genes for each individual. The count values were then analyzed for differential expression of genes using edgeR (Robinson *et al.* 2009).

The plasma samples from each individual were digested by trypsin. The tryptic peptides were analyzed using a Q-Exactive hybrid quadrupole-orbitrap mass spectrometer, and the mass spectral data were analyzed by MaxQuant (version 2.0.3.0) for protein identification and quantification (Cox and Mann 2008). The statistical analyses were then carried out by Perseus, version 1.6.15.0 (Tyanova *et al.* 2016) and Unscrambler.

The selected individuals (n=157) used for fine mapping had phenotype information available, were genotyped using axiom array along with the new SNPs discovered through sequencing. A genome-wide association analysis was performed using the following linear mixed animal model implemented in GCTA program with '--mlma-loco' function (Yang *et al.* 2011).

$$y = \mu + Xb + Zu + e$$

where y is a vector of 'n' phenotypic records, μ is an overall mean, b is a vector of fixed effects of year class, u is a vector of additive genetic effects distributed as $u \sim N(0, G\sigma_u^2)$, where σ_u^2 is the additive genetic variance, G is a genomic relationship matrix; X and Z are the corresponding incidence matrices for fixed and additive effects, respectively, and e is the vector of random residual effects with $e \sim N(0, I\sigma_e^2)$.

Results & discussion

As the study was mainly focused on the major QTL of chromosome 27 specifically the region from 10 to 12 Mbp, hence 8,813 variants were discovered through sequencing within the region of interest. Out of these identified variants, 5 SNPs were annotated as high impact, broadly covering ~13 protein coding genes. Out of these ~13 genes, two genes (*MR1*, major histocompatibility complex class I-related gene protein-like and *HA1F*, class I histocompatibility antigen, F10 alpha chain-like) were directly related with immune function. Genome-wide association analysis including added SNPs discovered through resequencing produced a strong signal at the region of interest with increased resolution (Figure 1). However, the added SNPs did not show higher significance level than what was obtained from already available SNPs in the medium density array (Figure 1).

Pairwise comparison for differential expression of genes revealed only two differentially expressed genes, *MR1* and *HA1F* across FUL vs DEL individuals that crossed Benjamini and Hochberg adjusted *P*-values (Figure 2). The gene *MR1* was highly expressed in susceptible (DEL) group with $\log_2$ fold change 6.405 compared to resistant (FUL) individuals. Contrary to *MR1* expression, *HA1F* gene was lowly expressed in susceptible group with 2.099 $\log_2$ fold differences (Figure 2). The proteomics results validated the findings of transcriptomics showing that '*A0A1S3PYN4*' protein, which is a product of the *MR1* gene being significantly differentially produced across FUL vs DEL individuals. Both '*A0A1S3PYN4*' production and *MR1* gene expression was the highest in the susceptible group. The concordance of results at three levels across susceptible vs resistant groups, identified candidate genes through fine-mapping, transcriptomics, and proteomics certainly points to an underlying role of detected causative genes for resistance against CMS. The findings from the study indicates that the role of both genes is crucial for host to provide resistance against virus possibly through protein interactions at optimal level of expressions. As *HA1F* gene is expressed at a very low level (close to zero) in DEL and HET groups compared to FUL group which might be the causative factor for differential immune responses.

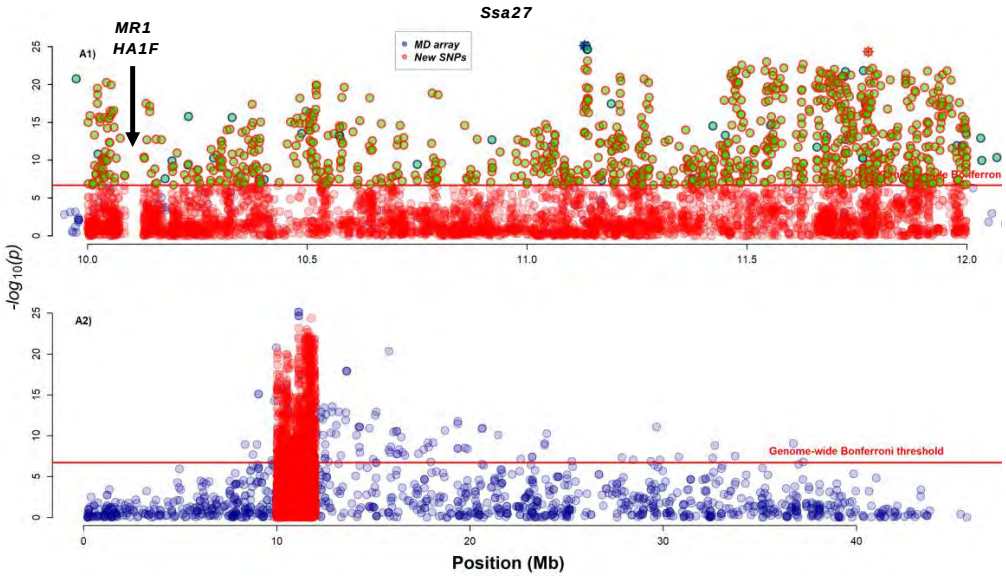

Figure 1. Genome-wide association of SNPs at chromosome 27 (Ssa27) depicting increased resolution using added SNPs from the sequence data. The solid red line is a genome-wide Bonferroni corrected threshold line. The asterisk blue and red SNPs are the highest significantly associated SNPs from the sequence and the array data, respectively. The black arow illustrates approximate position of candidate immune related genes.

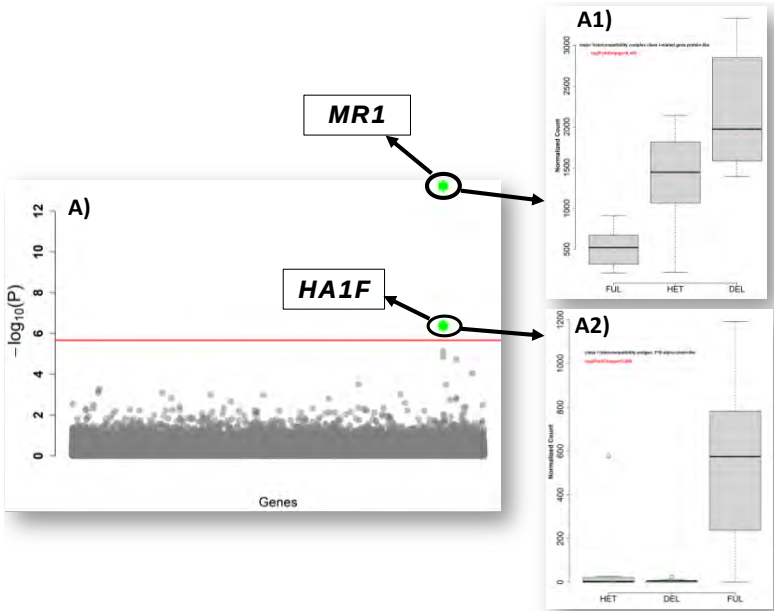

Figure 2. Significant differentially expressed genes across groups. Abstract

Natural variation in ear length is present in sheep (*Ovis aries*). *Anotia* describes the condition of the absence of the outer ear and *microtia* the condition of small ears. So far, the genetic basis of ear length regulation was studied in the Awassi, Duolang, Valle del Belice and Altay sheep breeds. The present study should add new insights to the genetics of ear length regulation in Slovenian and Greek sheep breeds. Here, a combined linkage disequilibrium and linkage analysis (cLDLA) approach for genetic mapping was applied. The conducted cLDLA on 166 individuals yielded two genome-wide and three suggestive significantly associated loci to the studied phenotype. In proximity to the strongest genetic signal the previously described *HMX1* locus is present. Our findings suggest that, while breed specific genetic regulation of ear length is possible, *HMX1* may be a main regulator of ear length in sheep breeds of a broad geographic region.

Introduction

In sheep (*Ovis aries*), natural variation in presence and length of head appendages could already be described more than 100 years ago in the case of horn (Arkell 1912) and the outer ear (Ritzman 1920; Lush 1930). If no outer ear structure is present, the condition is dubbed *anotia* and in the case of small ears *microtia*. Both are distinct to regular ear lengths of about 13 cm in our study cohort. As has already been shown in cattle (Allais-Bonnet *et al.* 2013), the genetic regulation of one head appendage (e.g. horn) can overlap with the gene regulatory network of another head appendage (e.g. eyelash). The same could apply to the presence and length of ears and horns in sheep, making *anotia* and *microtia* a very interesting breeding and developmental study target. To date, the genetics of the condition has been studied in the Awassi (Jawasreh *et al.* 2016; Jawasreh and Al-Omari 2020), Duolang (Gao *et al.* 2018), Valle del Belice (Mastrangelo *et al.* 2018) and Altay (He *et al.* 2020) sheep breeds. In any of those breeds, GWAS, local sequence alignment techniques or locus-specific SNP genotyping by PCR, yield different genes showing significant contributions to the described phenotype. The diversity of the results, pointing to the loci, *GATA6* (GATA binding protein 6), *DCC* (deleted in colorectal carcinoma), *CLRN1* (Clarin 1) and *HMX1* (H6 family homeobox 1), indicate a breed specificity in the genetic regulation of ear length. Here, we study the genetic basis of ear length variation in one Slovenian sheep breed, the Bovec sheep, and the seven Greek sheep breeds Argos, Chios Fat Tail, a local Peloponesus breed, Ikaria Fat Tail, Karpathos, Kasos and Lesbos Fat Tail and compare here investigated loci with previous described ones to examine commonalities and differences in the genetic regulation of ear length variation across sheep breeds.

Materials & methods

Animals, breeds, populations and phenotype recording. We measured the ear length (cm) of 166 (122 female and 44 male) sheep, aged two to 16 years. Twenty-two animals were from the Slovenian Bovec sheep breed and the remaining 144 from seven Greek breeds: Argos (20), Chios Fat Tail (33), a local Peloponesus breed (4), Ikaria Fat Tail (4), Karpathos (10), Kasos (6) and Lesbos Fat Tail (67). The ear lengths measured

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_536, © J. Klawatsch *et al.* 2022

ranged from about two to 15 cm and formed three categories: 1 'short-eared' with ear lengths of two to three cm, 2 'middle-eared' with six to nine cm and 3 'normal-eared' with ear lengths of ten to 15 cm. These three categories were used as phenotype for the genetic mapping study. According to our field observation, we consider category 1 as *anotia* and category 2 as *microtia*. The geographical origin and the distribution of ear length phenotypes of the studied individuals are shown in Figure 1.

Sampling, collection of biological material, DNA isolation and SNP genotyping. Blood samples were taken from studied animals in the course of routine examinations under good veterinary practice. Sampling took place in the period from 2018 to 2021 and samples were stored at -20 °C until lab analysis. DNA was isolated using the QIAmp DNA Blood Mini Kit (Qiagen, Valencia, USA) according to the manufacturer's instructions. SNP genotyping was conducted on the OvineSNP50 BeadChip (Illumina, San Diego, CA, United States) using standard procedures (http://www.illumina.com). The chip covers 54,241 SNPs.

SNP quality control, haplotyping, unified additive relationships (UAR) and genetic mapping. After genotyping and quality control, 166 animals with high genotype and phenotype quality remained in the data set. In order to impute missing genotypes and infer haplotype we used the Beagle software package (v 5.0) (Browning and Browning 2007; Browning *et al.* 2018) and included the genotype and pedigree information of all available ovine data from the in-house database, which also contained animals that are not phenotyped for ear length. To consider the genome-wide relationships between all animal pairs, a unified additive relationship (UAR) matrix was estimated according to Yang *et al.* (2010) by using the implementation in the R package snpReady (Granato *et al.* 2018). For performing the actual genetic mapping, a combined linkage disequilibrium and linkage analysis (cLDLA) approach was conducted as described in Meuwissen and Goddard (2001); and Gehrke *et al.* (2020). In addition to the genome-wide additive relationship matrix, we estimated a locus-specific IBD matrix and used ASReml (Gilmour AR 2009) to estimate the maximum likelihood, variance components, and fixed and random effects simultaneously. The following mixed linear model was applied:

$$y = X\beta + Z_1u + Z_2q + e \quad (1)$$

where y is the vector of the ear length phenotype; β is the vector of fixed effects including the overall mean (μ) and age at phenotyping; u is the vector of *n* random polygenic effects for each animal; q is the vector of

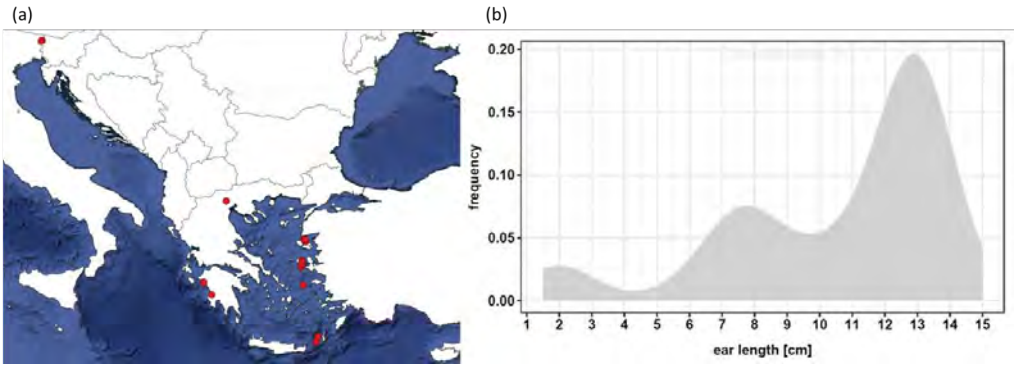

Figure 1. Map of the sampling locations of the studied breeds constructed with QGIS version 3.16.4 (QGIS.org 2021) (a) and distribution of the ear length phenotype in the study cohort (b).

random additive genetic effects of the putative QTL. Random residual effects were included in the vector e. The matrices X, Z_1 and Z_2 are the incidence matrices for the fixed and random effects. Finally, a likelihood ratio test (LRT) for the goodness-of-fit between the null hypothesis (H_0: model without a QTL effect) and the alternative hypothesis (H_1: model including a QTL effect) at each SNP interval midpoint was calculated.

Results

From the 166 studied individuals, 13 were short-eared, 50 medium-eared and 103 regular-eared. *LRT* values of cLDLA indicated two genome-wide and three chromosome-wide significant mapping results (Figure 2a). The strongest signal with an *LRT* value of 32.60 (P=1.13×10^{-8}) is on ovine chromosome 6 (OAR6) at position 6:114002547. In proximity to that position the *HMX1* locus can be found. Since a duplication of 76 bp in an evolutionarily conserved region near *HMX1* was previously described in Altay sheep (He *et al.* 2020) and later characterised in more detail in Awassi sheep (Jawasreh and Al-Omari 2020), we genotyped our mapping population for this candidate mutation. A second cLDLA which considered the *HMX1* genotype in our mapping population as a fixed effect was conducted and is shown in Figure 2b.

The cLDLA with *HMX1* as fixed effect clearly explains complete phenotypic variance on OAR6, reduces the LRT-peak on OAR4 and yield only some suggestive mapping signals. A mutation at *GATA6* exon 7 (OAR23) was discussed in Jawasreh and Al-Omari (2020) as a candidate in an epistatic interaction with *HMX1*. We also genotyped this candidate mutation in our mapping population and could not confirm any effects in our material. Also, we checked for further variations in the previously described target genes of *HMX1*, that are *SLC6A9*, *EPHA6*, *SGCG*, *TSHZ2*, *PTPRO* and *SEMA3F* (Boulling *et al.,* 2013). No noticeable difference in allelic frequencies of those genes per ear length group were found. Also, none of these loci is close to the suggestive significant threshold for association to ear length. In order to allow an insight for the size of the effect of *HMX1* and how it manifests across ear size categories, allele frequencies are presented in Table 1.

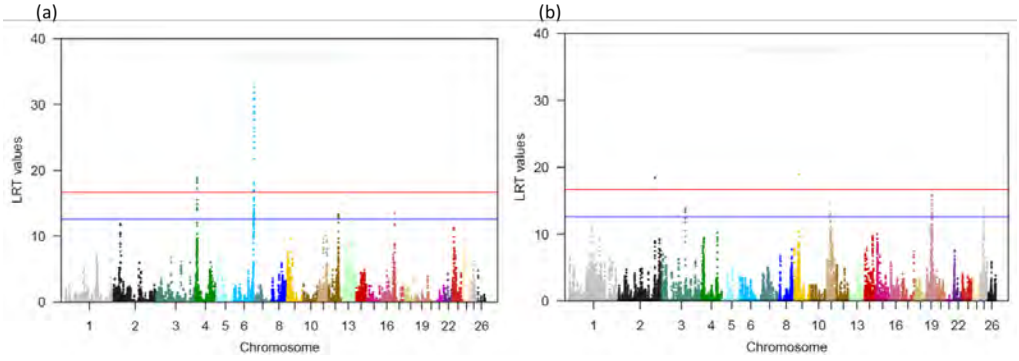

Figure 2. Likelihood ratio test (LRT) values for each genotyped position of a cLDLA for outer ear length without any genotype fixed effects (a) and with *HMX1* genotype data as a fixed effect (b). Genome-wide significance (red) and suggestive (chromosome-wide) significance (blue) thresholds are indicated as straight lines.

Table 1. Allele identities and frequencies of *HMX1* in the studied animals respective to the ear size categories. Frequencies for the allele of the reference sequence (d) and the allele with the 76 bp duplication (D) is shown.

	Anotia		Microtia		Regular ear length	
Allele identity	**d**	**D**	**d**	**D**	**d**	**D**
Allele frequency	0.038	0.96	0.53	0.47	0.97	0.034

Discussion

Anotia and *microtia* have been described in numerous Asian and European sheep breeds, and various previous mapping studies have yielded somewhat contradictory results. The study conducted here confirmed only *HMX1* as a plausible candidate cause and could not confirm any interaction with *GATA6*. We could also show that *anotia* and *microtia* in sheep from Central Asia to the Alps are caused by the same, presumably very old mutation and that both trait expressions only reflect different genotypes at the same locus. A large proportion of the sheep examined here were also phenotyped for horn status. This material will be supplemented by further phenotyped and genotyped sheep and used for further horn status mapping with focus on breeds with variable horn status and southern European origin which can complement the results discussed in Luhken *et al.* (2016).

Abstract

Variants that change the expression of genes, i.e. expression quantitative trait loci or eQTL, provide an alternative to identify causal mutations. However, previous studies found little overlap between eQTL and conventional QTL. Here, we mapped and compared eQTL from blood and milk cells in ~400 dairy cattle with complex trait genome-wide association studies (GWAS) and Bayesian mixture models (BayesR) in ~103k cows. Increasing the sample size of eQTL mapping significantly increases the overlap between eQTL and QTL. As an example, a cis eQTL at Chr13:36387662(rs20846618) or the gene mohawk homeobox (*MKX*, p_{eQTL}=4.7e-08) significantly affects rump angle ('pin set': p_{GWAS}=4.5e-10): a trait related to fertility and longevity. This eQTL is the top variant in BayesR mapping for rump angle. *MKX* is a transcription factor gene and is associated with tendon development and tail morphology in mice. Therefore, large-scale multi-omics fine-mapping can prioritise biologically sensible causal mutations for cattle complex traits.

Introduction

Most cattle traits of economic importance are complex where many DNA variants affect the trait, and each contributes a very small effect. This makes the identification of causal variants very difficult. Using sequence variants in genome-wide association studies (GWAS) increases the chance of identifying causal variants (Daetwyler *et al.* 2014). However, due to the very small effective population size (N_e) in livestock species, the linkage disequilibrium (LD) between variants is very high. This results in many significant variants being found in sequence GWAS yet little is known which ones are the causal variants. Therefore, strategies to refine GWAS results are needed. One strategy is for GWAS to have a very large sample size, potentially with a multi-breed population (Bouwman *et al.* 2018; van den Berg *et al.* 2020). However, QTL do not always overlap across breeds and it is not always easy to obtain large samples for small breeds, such as Jersey or Red cattle. An alternative approach is to use functional annotation (Clark *et al.* 2020), including how sequence variants change the expression of genes (Xiang *et al.* 2019; Liu *et al.* 2021; Xiang *et al.* 2021b). However, some primary efforts showed that there is very little overlap between eQTL and conventional QTL, such as QTL for protein% and fat% (Van Den Berg *et al.* 2019; van den Berg *et al.* 2020). However, these studies used a relatively small sample size for mapping of the eQTL (N~130).

In the current study, we significantly increased the sample size for the mapping of the eQTL (N~400). We show that with a large sample size in eQTL mapping, the current study detects many overlaps between eQTL and conventional QTL. We highlight examples and provide important updates on how eQTL contributes to QTL via biological mechanisms.

Materials & methods

RNA-seq data. The RNA-seq data was generated by Agriculture Victoria Research (AVR) in Victoria, Australia. Blood and milk samples were taken from 400 Holstein cows and 29 Jersey cows (milk sample only). The processing of milk samples followed what was described in (Chamberlain *et al.* 2018; Xiang *et al.* 2018). RNA sequence data of 356 Holstein and 26 Jersey with >50 million reads for milk cells or

DOI: 10.3920/978-90-8686-940-4_537, © R. Xiang *et al.* 2022

>25 million reads for white blood cells and had concordant alignment rate >80% were used. After quality control, raw reads of these data were aligned to the ARS-UCD1.2 reference bovine genome and gene counts were extracted.

Sequence genotypes. The sequence variants used were based on what was described in (Xiang *et al.* 2021a). Briefly, we used more than 16 million sequence variants imputed using Run7 of the 1000 Bull Genome with imputation accuracy R^2>0.4 and the minor allele frequency (MAF)>0.005 in both bulls and cows.

Conventional phenotypes. Data was collected by farmers and processed by DataGene Australia (http://www.datagene.com.au/) for the official May 2020 release of National breeding values. Phenotype data had a total of 103,350 cows, including Holstein (87,003), Jersey (13,353♀), cross-breed (5,037♀) and Australian Red dairy (3,379♀) breeds. We examined traits of protein%, fat% and pin set [detailed in (Xiang *et al.* 2021a)].

eQTL and QTL mapping. For expression of each gene after normalisation, a linear mixed model was fitted: $y = X\beta + Zg + Wv + e$ (1); Where y is an n × 1 vector gene expression or conventional phenotype (n is the number of individuals with RNA-seq data or conventional phenotype), β is a vector of fixed effects like breeds, different experiments; g is an n × 1 vector of the total genetic effects of the individuals with $g \sim N(0, G\sigma^2)$ where G is the genomic relationship matrix (GRM) built by all the variants; W is the design matrix of variant genotypes (0, 1, 2) and v is the variant additive effect; e is the error term. cis QTL is defined as variants within ±1 Mb of the gene. Significant eQTL or QTL were called if GWAS P-value <5e-8. In the milk cell eQTL mapping, the 1st 2 PCs were extracted from the expression count matrix and fitted as fixed effects along with other fixed effects. This aimed at adjusting for unrecorded fixed effects which may distort the eQTL mapping.

BayesR. We fitted the following model in BayesR (Erbe *et al.* 2012): $y = Wv + X\beta + e$ (2); where y was a vector of conventional phenotype, W was the design matrix of genotypes centred and standardised to have a unit variance; v was the vector of variant effects; X was the design matrix allocating phenotypes to fixed effects; β was the vector of fixed effects of breeds. As a result of the Monte Carlo Markov Chain (50,000 iterations with 25,000 burn-in), the effect v for each variant was jointly estimated with other variants. The prior of variant effects v followed a mixture distribution of four normal distributions including a null distribution, zero-effect $[N(0,0.0\sigma^2_g)]$, and three others: small-effect $[N(0,0.0001\sigma^2_g)]$, medium-effect $[N(0,0.001\sigma^2_g)]$ and large-effect $[N(0,0.01\sigma^2_g)]$, where σ^2_g was the additive genetic variance for the trait. to reduce the computational burden for bayesR, we used up to 2 million sequence variants which are from HD SNPs plus sequence variants under more than 1 ChIP-seq peaks (Kern *et al.* 2021; Prowse-Wilkins *et al.* 2021). The posterior inclusion probability (PIP, ranged from 0-1) of each variant in the model was obtained and was used to rank variants.

Results & discussion

We detected significant overlaps between eQTL (sample size ~400) and QTL (sample size ~104,000 of three breeds) for analysed traits (Table 1). For protein% and fat%, ~16.11% (1,828 variants) of QTL were eQTL from blood and ~8.05% of QTL were eQTL from milk cells. This represents a substantial increase in the concentration of eQTL in QTL, compared to the previous study by Van den Berg *et al.* (2020), where ~4.6% (1,496 variants) of milk percentage QTL were eQTL from blood and ~0.04% (13 variants) of QTL were eQTL from milk cells. In van den Berg *et al.*, the sample size of eQTL mapping was ~130 and GWAS used 94,321 cattle from 8 breeds. Thus, the sample size for the QTL mapping between the two studies is similar, but the sample size for eQTL mapping is about 2-3 times larger in the current study than in the previous

Table 1. Overlap between eQTL and conventional QTL. The total number (#) of variants, significant eQTL from blood and milk cells, and significant QTL for protein %, fat %, and pin set are given. The *P*-value ($p_{overlap}$) of the overlap was based on the hypergeometric test.

Tissue	# total variants	# sig eQTL	# sig QTL	# sig eQTL&QTL	% QTL as eQTL	$p_{overlap}$
Blood	11,669,532	486,311	16,855 (Prot%)	1,754	10.41%	1.2E-258
			11,345 (Fat%)	1,828	16.11%	0
			174 (Pin set)	34	19.54%	6.0E-14
Milk_cell	11,157,718	218,461	16,687 (Prot%)	825	4.94%	2.0E-121
			11,164 (Fat%)	899	8.05%	6.2E-269
			174 (Pin set)	25	14.37%	1.3E-14

study. Therefore, we demonstrate that increasing sample size is a key factor to map eQTL and to identify overlap with QTL.

There is a particular increase in the detection of eQTL in milk cells and its overlap with QTL in the current study compared to Van den Berg *et al.* (899 eQTL representing 8.05% of QTL VS 13 eQTL representing 0.04% of QTL). Along with a large sample size, adjusting PCs from the expression count matrix of milk cells in the linear model may also contribute to the increased power of the current eQTL mapping. When not correcting for PCs, there were a lot fewer significant eQTLs were called.

We also found ~20% of QTL for pin set being eQTL. Pin set is a type trait also known as rump angle. In Australian and US linear assessment systems, pin set is related to calving difficulty, fertility and longevity. To our knowledge, no QTL has been reported for this trait. We report a candidate causal mutation at Chr13:36387662 (rs208466183, ARS-UCD1.2) for pin set involving cis eQTL effects (Figure 1). This mutation has a p_{GWAS}=4.5e-10 and BayesR PIP=0.74 which is the highest PIP for BayesR mapping. Mutation at Chr13:36387662 affected the expression of mohawk homeobox (*MKX*) (p_{eQTL}=4.7e-08). In addition, after adjustment of fixed effects, the expression of *MKX* in milk cells is significantly associated with pin set (*P*=4.1e-11). *MKX* is a transcription factor and is associated with tendon development and tail morphology in mice (Ito *et al.* 2010). We, therefore, suggest the strong candidacy of Chr13:36387662 for pin set via cis-regulatory effects on *MKX*.

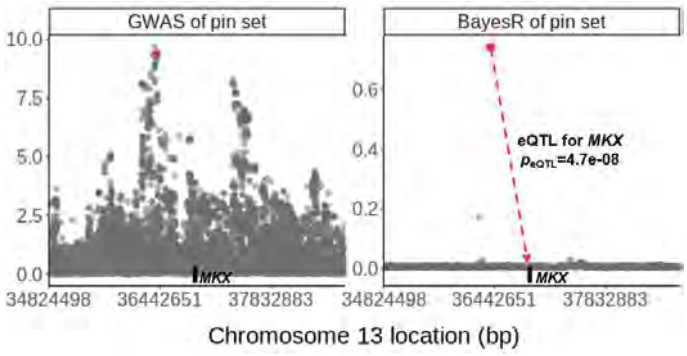

Figure 1. Candidate causal mutation Chr13:36387662 for pin set as a cis eQTL for mohawk homeobox (*MKX*). The y-axis for the left and right panel indicates -log10(p) of GWAS and posterior inclusion probability (PIP) of BayesR, respectively. Red dots indicate the mutation Chr13:36387662 and the dashed line indicates that Chr13:36387662 is a cis eQTL for *MKX*.

Conclusions

We found that increasing the sample size of this eQTL study significantly increased the identification of eQTL and its overlap with QTL. We promote the causal candidacy of Chr13:36387662 (rs208466183) for pin set via cis-regulatory effects on *MKX* expression, illuminating biological mechanisms with which cattle genes shape complex traits.

Abstract

There are remarkable phenotypic and physiological differences between taurine (*Bos taurus*) and indicine (*Bos indicus*) breeds such as their distinguishable meat quality and immune response. Here, we used muscle RNA-seq and genotyping data from 187 Nelore steers to explore the effect of copy number variations, which are located at taurus-indicus dissimilar genomic regions and ATAC-seq peaks, on the expression of local and distal genes. Therefore, we inferred the co-expression network for the target transcripts and performed a gene enrichment with the correlated transcripts. From seven polymorphic copy number variations identified at these regions, one gain at chromosome 15 was associated with a trans-upregulation of the transcription factor *PITX1* (Bonferroni adjusted *P*-value<0.05). This gain can be valuable for animal breeding as the *PITX1* network genes are enriched for meat quality related proteins such as actin and myosin as well as immune system proteins such as cytokine and toll-like receptors.

Introduction

The domestication of aurochs (*Bos primigenius*) gave rise to different taurine and indicine (*Bos indicus*) breeds. Beef production can be based on taurine, indicine or mixed breeds. However, the choice of the best breed for a specific production system depends on different factors such as climate and market positioning. Indicine are more resistant to tropical parasites whereas taurine breeds are adapted to temperate environments (Porto-Neto *et al.* 2014). On the other hand, taurine and indicine breeds have distinguishable meat quality properties such as fiber size and marbling (Rodrigues *et al.* 2017). Therefore, the differences between their genomes are expected to uncover candidate regions for the immune system and meat quality regulation. Genomic regions underlying taurine-indicine subspeciation can be uncovered by the sequence blocks that are dissimilar between their genomes, which can be detected by a synteny analysis. Although the term synteny classically refers to gene order, more recent definitions extended it to refer to any similar genome block between sequences, considering that important regulators may be located at intergenic intervals (i.e. microsynteny, Engström *et al.* 2007). Sequences showing synteny breaks among different species are usually enriched with copy number variations (CNVs), which are crucial for speciation events (Pös *et al.* 2021). Interestingly, frequent CNVs are common at regulatory regions with open chromatin and enriched for CpG islands. It has been shown that the effect of CNVs on the cattle muscle gene regulation is mostly distal and involves the interplay of different transcription factors (Geistlinger *et al.* 2018). Here, we evaluated the effect of CNVs on muscle gene expression (i.e. CNV-eQTLs) in our Nelore cattle population, focusing on regions potentially relevant to taurine-indicine subspeciation that are functional in muscle. Thus, we analysed exclusively those concomitantly located at open chromatin and microsynteny breaks (i.e. functional CNV-eQTLs located at subspeciation footprints). Lastly, we constructed a co-expression network for the target genes to account for the indirect effects of targeted transcription factors.

DOI: 10.3920/978-90-8686-940-4_538, © V.H. da Silva *et al.* 2022

Materials & methods

Detection of chromatin accessibility. We performed ATAC-seq in four meat samples to obtain the FASTA files (Morosini *et al.* unpublished data). Therefore, we produced the ATAC-seq pileup files from FASTA files using the nfcore/atacseq pipeline implemented in Nextflow (https://nf-co.re/atacseq). A consensus peak mapping was obtained from the four samples by considering only regions with counts higher than zero in all. In these regions, the average among samples was calculated and values higher than 0.5 were selected as genomic regions in an ATAC-seq peak.

Screening of synteny breaks between taurus-indicus genomes. The reference genomes ARS-UCD1.2 and UOA_Brahman were used to represent taurine and indicine sequences, respectively. We searched for sequences that chained into collinear blocks of synteny with the *FindSynteny* and mapped the results onto ARS-UCD1.2 genome with *AlignSynteny* function, both implemented in the R/Bioconductor package DECIPHER (Wright 2016).

Quantification of RNA abundances. The FASTQ files of 187 Nelore steers generated by the HiSeq 2500 sequencer were mapped and quantified by the Salmon software (Patro *et al*. 2017) with full decoy. Transcripts with abundance equal to zero in more than 5% of the animals were filtered out.

Genotyping and CNV detection. The *log2 R ratio* and *B allele frequency* values from SNP probes from 777 Nelore Steers genotyped with the Illumina 700k HD, mapped to ARS-UCD1.2 reference genome, were used to detect CNVs by a hidden Markov model based approach that is implemented in the PennCNV (Wang *et al.* 2007).

Identification of CNV effect on gene expression. The effect of CNVs on gene expression was analysed by an edgeR's ANOVA-like test implemented in the CNVRanger package (da Silva *et al.* 2020). The raw *P*-values were corrected for the number of transcripts to account for multiple tests using the Bonferroni correction. The effect on a target transcript (i.e. CNV-eQTLs) was classified as a cis-effect when the distance between CNV and gene was less than 1 Mb and trans-effect otherwise.

Construction of co-expression networks. We constructed co-expression networks of all filtered transcripts using the results from the PCIT algorithm (Reverter *et al.* 2008). The transcripts belonging to the co-expression network of the transcripts targeted by CNVs was subset and used for the target-specific gene enrichment.

Enrichment of genes within co-expression networks. All transcripts belonging to the network of affected transcripts were enriched for gene ontology terms and KEGG pathways with the *enrichKEGG* and *enrichGO* functions from the clusterProfiler package (Yu *et al*. 2012) using a q-value<0.05 as significant.

Results

We detected 7,756 consensus ATAC-seq peaks and 5,081 intervals with break of sequence microsynteny between indicus-taurus genomes with mean sizes of 2.3 kb and 3.2 kb, respectively. The microsynteny break regions encompassed 16.53 Mb of the autosomes (0.66%). We identified 5,956 CNVs with a mean size of 54.36 kb calls that are distributed among 187 Nelore steers with available RNA quantification. The RNA abundance of 14,471 transcripts remained after filtering.

A total of seven polymorphic CNV regions (>1% in frequency) overlapped with both ATAC-seq peaks and regions of microsynteny break. Only the CNV region at chr15-45962744:46353257 had at least ten samples with CNVs (i.e. gain samples) to attend to the minimum default for testing (Figure 1A). This region has two

possible loci, which are reflected by sample frequency (Figure 1A, 'gain samples' track). When this CNV region was refined to comprise only the downstream locus ATAC-seq (i.e. chr15-46210000-46360000, red rectangle), a copy gain was significantly associated with the abundance of the *PITX1-201* transcript (Bonferroni adjusted *P*-value<0.05, Figure 1B).

We found 96 transcripts in the *PITX1-201* co-expression network, which were enriched for four gene ontology terms and two KEGG pathways. The gene groups enriched were associated with muscular structure and protein binding related to myosin and actin as well as with immune system dynamics through cytokine interaction and toll-like signaling (Table 1).

Discussion

It is crucial to explore the functional effects of regions lacking synteny to understand how certain molecular mechanisms differ among species. We found evidence that a copy number gain, located at a taurus-indicus microsynteny break block with open chromatin in muscle, upregulates the expression of the transcription factor *PITX1*. The trans-effect of this gain at chromosome 15 on *PITX1* (chromosome 5) expression might be caused by an enhancer reflected by the ATAC-seq peak. This gene determines the morphology of muscle and tendons (DeLaurier *et al.* 2006) and is also associated with immunity-longevity tradeoff (Otarigho and Aballay 2021). Interestingly, taurine and indicine breeds have known differences regarding meat quality and immune response. Actin and myosin related pathways, which are known to affect meat quality (Asghar and Yeates 1978), were enriched in the *PITX1-201* co-expression network. Moreover, immune response pathways related to cytokine and toll-like receptors were also enriched. This copy gain at chromosome

15 may be relevant to animal breeding as it could contribute to the phenotypic differences among cattle subspecies. Future analysis may incorporate more animals and breeds to build a better understanding on the genomic variability within each subspecies and how it relates to this regulatory region. The distal effect of CNVs on the expression of transcription factors may help explain the regulatory landscape of genes affecting phenotypes of interest in cattle such as meat quality and immune response.

Abstract

Integrating data from high-throughput transcriptomic and genomic technologies offers a new opportunity to characterize the biological basis underlying complex traits, such as mastitis. Previous research using RNA-Sequencing technology from milk somatic cell samples from Holstein dairy cows identified 7 differentially expressed (DE; FDR<0.05, |FC|>2) functional candidate genes associated with mastitis resistance. Whole genome sequencing (WGS) was then used to deeply study the 7 DE functional candidate genes to identify single nucleotide polymorphisms (SNPs) and insertions / deletions (INDELs) that were fixed and uniquely present within an independent Holstein population. In total, WGS analysis identified 14 SNPs and 7 INDELs located within the 7 DE functional candidate genes associated with mastitis resistance. The identified functional variants could impact the host's response to the mastitis causing agent, aiding in breeding healthier dairy cows that are better able to cope with or resist mastitis.

Introduction

Mastitis is an inflammatory disease of the udder caused by different species of bacteria and it is extremely prevalent in the dairy industry. As mastitis is a very complex trait, it has yet to be effectively controlled at a low incidence rate. Whole genome sequencing (WGS) is a high-throughput technology to identify key differences in the genome, such as single nucleotide polymorphisms (SNP) and insertions / deletions (INDELs) that may impact the host's response to mastitis. Previous research using RNA- Sequencing technology (RNA-Seq) identified 7 functional candidate genes differentially expressed (DE) between healthy and mastitic samples (Asselstine *et al.*, 2019). Therefore, the objective of this study was to use WGS to identify potential SNPs and INDELs that were fixed and unique between a group of healthy and a group of mastitic Holstein dairy cows. Key variants which may create non-functional proteins could then be implemented into breeding strategies to select for and breed dairy cattle that are more resistant to mastitis disease, which would greatly benefit the dairy industry.

Materials & methods

Animal material and sample collection. Health records for a random subset of animals housed at the Ontario Dairy Research Center, Elora, ON were searched manually to identify healthy and mastitic animals. Animals were classified as 'mastitic' if they had at least 1 case of either clinical mastitis, diagnosed visually at the time of milking or subclinical mastitis, diagnosed via a high somatic cell count on a dairy herd improvement test, which was cultured to confirm the presence of an intramammary infection (n=7). In total, 7 animals had at least 1 case of mastitis in their lives. Alternatively, animals were classified as healthy if at the time of analysis, they had no reported cases of either clinical or subclinical mastitis (n=7). In total, 14 animals (7 healthy and 7 mastitic) were used to perform WGS analysis. Hair samples (approximately 80-100 follicles) from the tail end were individually collected from each of the 14 animals, sealed into a pre-labelled Zoetis hair sample collector (https://www.ordergeneticstestkits.com/storefrontB2CWEB/) and stored at room temperature in a sealed bag until WGS analysis could be completed.

Whole genome sequencing analysis. Whole genome sequencing analysis was completed at Neogen Canada (Edmonton, AB) using the Illumina HiSeq X (https://www.illumina.com/systems/sequencing-platforms/hiseq-x.html) with an average of 23.4±5.8 × coverage. All programs and parameters for SNP and INDEL detection were selected in accordance with the 1000 Bull Genome Project guidelines (http://www.1000bullgenomes.com). Briefly, single nucleotide polymorphisms (SNP), insertion / deletion (INDEL) detection was performed using the Read Mapping and Variant Calling workflow. The Raw fastq files were downloaded from the Nanuq interface on Génome Québec's website (https://cesgq.com/en-nanuq). Using FastQC, read quality control was performed on the high-throughput sequencing data. Trimmomatic, was then used to trim and crop the Illumina (FASTQ) data (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/; Bolger *et al.*, 2014). The trimmed reads were then mapped to the bovine reference genome ARS – UCD1.2 assembly using Burrow – Wheeler Aligner (BWA; https://github.com/lh3/bwa). Lastly, SNPs and INDELs were identified using the Genome Analysis Toolkit (GATK) Haplotype Caller (https://gatk.broadinstitute.org/hc/en-us). For each SNP and INDEL category, one VCF file was generated with the data for all animals included (7 mastitic and 7 healthy Holstein dairy cows).

Variant identification within DE candidate genes and variant effect predictor. After the VCF files for SNP and INDEL from the WGS analysis were obtained, CLC Genomics Workbench software (Aarhus, Denmark) was used to upload the VCF files for SNP and INDEL independently. Track tools was then used to inspect the 7 key functional candidate regions associated with mastitis resistance (Table 1) to identify SNPs and INDELs. Once these variants were identified, Variant Effect Prediction (VEP; McLaren *et al.*, 2016) from Ensembl was used to determine the potential causal effect of the variant within the functional candidate genes (Cánovas *et al.*, 2012; Cardoso *et al.*, 2018).

Results

SNPs and INDELs within functional candidate genes associated with mastitis resistance. The genomic coordinates and the related information of the 7 DE functional candidate genes used in this analysis can be found in Table 2. Looking deeply into the WGS results, in the healthy group, there are 6 unique and fixed variants (4 insertions, 2 deletions) within the functional candidate genes *FCER1G*, *GLYCAM1*, *CD74*, *NFKBIA*, and *BoLA – DRA*, which were previously identified using RNA-Seq (Asselstine *et al.*, 2019). Only two variants, one deletion in *FCER1G* and one deletion in *CD74* (both located in introns) had predicted effects of MODIFIER, meaning there is little to no evidence that these variants will have an impact on the functionality of the protein formed. However, as the remaining 4 variants (insertions) were also in intronic regions, although they did not have a predicted effect it is hypothesized they would also have a limited impact on the functionality of the protein formed. Within the 7 animals in the mastitic group,

[1] Unannotated: this refers to variants that are not yet annotated and thus the location in the gene is unknown.

there were 14 unique SNPs and 1 unique insertion fixed among all animals in the genes *GLYCAM1, CD74, B2M, SDS* and *BoLA – DRA*. Within the genes *GLYCAM1* and *B2M*, there were 2 unique variants (both located in introns) with predicted effects of MODIFIER and it is not expected that these specific variants would impact the protein functionality. There is also a SNP within *CD74,* but it is located in an intron. The gene with the most unique and fixed variants (7 SNPs) is *B2M*, however all of these variants are located in introns and aren't expected to impact the functionality of the protein. Alternatively, the genes *SDS* and *BoLA-DRA* have variants in the 5' UTR region (*SDS;* 2 SNPs) and 3' UTR region (*BoLA-DRA*; 2 SNPs) and variants located in these regions might modify regulatory elements, in turn affecting the interaction of UTRs and proteins and microRNAs.

Discussion

Although key variants were identified in the previous identified functional candidate genes using transcriptomics, future research should be focused on those located in exons, 3' UTR or 5' UTR regions, or those that are not yet annotated, as these could positively impact the functionality of these genes and could aid in the host responding to the mastitis causing agents. Similarly, emphasis should be placed on the candidate genes with the most functional and structural relevance, such as those which impact *B2M*. This gene is directly related with the major histocompatibility complex molecules and has multiple roles in immune regulatory mechanisms of defense toward internal or invasive threats (Liu *et al.*, 2018; Asselstine *et al.*, 2019). This gene also possesses antibacterial activity against *S. aureus*, which is a Gram-positive bacteria

and is considered one of the most contagious mastitis pathogens worldwide (Harmon, 1994; Botaro *et al.*, 2015).

In summary, our research used two different -OMICs technologies and approaches (RNA-Seq and WGS) to study the transcriptome and the genome across two independent populations of Holstein dairy cows. This allowed us to not only identify key DE functional candidate genes using RNA-Seq, but also identify potential SNPs and INDELs within these functional candidate regions that might impact mastitis resistance or the host's immune response using WGS. This research could benefit and positively impact the dairy industry by integrating functional SNPs and INDELs into genomic breeding programs, thus, helping producers decide the best animals to breed to decrease the prevalence of mastitis in their herds.

540. Allele specific expression as an indication of ploidy in pig IPECJ2 and chicken SL-29 cell lines

J. de Vos[1*], R.P.M.A. Crooijmans[1], M.F.L. Derks[1], S.L. Kloet[2], M.A.M. Groenen[1] and O. Madsen[1]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Leids Universitair Medisch Centrum, the Netherlands; jani.devos@wur.nl

Abstract

Cell lines are useful for investigating traits of interest e.g. intestinal absorption, feed efficiency and immunity in farm animals. We earlier investigated an intestinal cell line in pig and a fibroblast cell line in chicken and found chromosomal abnormalities by whole genome sequence (WGS) data analysis. Results from RNA-seq allele-specific expression analysis (ASE) in 4 cell lines showed aneuploidy in some chromosomes. In this paper we show that RNA-seq can be used to detect whole/partial chromosomal abnormalities based on ASE analysis.

Introduction

Pig and chicken are the primary sources for meat production worldwide and are also important for use as biomedical models and to study embryonic development. Cell lines are a valuable tool for gaining insight into genomic architecture and regulatory regions of genomes. Cell lines are derived from specific tissues of a species, and can either continue to divide endlessly or perish after a specific number of divisions (passages) (Verma *et al.*, 2020). Immortalized cell lines (i.e. that can be grown indefinitely) often show aneuploidy (presence of an abnormal number of chromosomes in a cell) or heteroploidy which is most pronounced in cancer cell lines (Verma *et al.*, 2020; Molina *et al.*, 2021). Animal cell lines from pig or chicken have proven useful to obtain insight in e.g. intestinal transport and immune function (Nossol *et al.*, 2015).

The phenotype of an individual is determined by gene expression which is a process where information from genes, encoded within DNA, is translated into proteins through RNA (Hartwell *et al.*, 2015). The phenomenon of unequal expression between alleles in diploid cells caused by either genetic variation or epigenetic regulation (cis-regulated gene expression) is known as ASE. Furthermore, non-haploid chromosomes show imbalances in gene transcriptional activity, implying that chromosomal abnormalities can influence gene expression of different alleles, resulting in ASE. Our aim was to investigate the usability of RNA-seq data to identify whole chromosomal abnormalities, with the pig IPEC-J2 and chicken SL-29 cell lines as model.

Materials & methods

Cell lines. The pig IPECJ67 cell line (IPECJ2 cells grown for 67 passages) and chicken SL-29 cell line (grown for 4 passages) used were obtained from the cell repositories at DSMZ (https://www.dsmz.de/collection/catalogue/details/culture/ACC-701) and ATCC (https://www.lgcstandards-atcc.org/products/all/CRL-1590.aspx?geo_country=nl#generalinformation) respectively. The pig cell line is derived from intestinal epithelial cells while the chicken cell line is derived from embryonic fibroblast cells.

Data analysis. Pig (Sus Scrofa 11.1) and chicken (Gallus gallus GRCg6a) reference genomes, together with ENSEMBL annotations (Sus Scrofa 11.1 release 103 & Gallus gallus GRCg6a release 94) were utilized for all data analyses of our study.

Whole genome sequencing. Whole genome sequences were trimmed using Sickle v1.33 (https://github.com/najoshi/sickle) in paired end mode, followed by alignment (bwa mem v0.7.15 (Li., 2013)) of the

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_540, © J. de Vos *et al.* 2022

trimmed reads, and removal of duplicates (Samblaster v0.1.26 (Faust and Hall, 2014)). Mate coordinates were added using samtools (v1.9, Li *et al.,* 2009). Single nucleotide variants (SNVs) were called using FreeBayes (v1.3.1), thereafter the read support ratio was assessed for heterozygous variants within the VCF file.

RNA sequencing. RNA-seq data (pig IPECJ67 and chicken SL-29) were trimmed for adapters, and minimum length using TrimGalore v0.6.4 (http://www.bioinformatics.babraham.ac.uk/projects/trim_galore/). FastQC v0.11.9 (Andrews *et al.*, 2010) was implemented to evaluate the quality of the data. RSEM (Li and Dewey, 2011) was used for alignment of the trimmed reads, as well as gene quantification (STAR v2.7.3a as aligner) (Dobin *et al.*, 2013). Average gene expression level per chromosome was calculated and plotted using a custom python script with the Seaborn package. Additional raw RNA-seq data from the PRJNA610529 project was downloaded from ENA. This data comprises a pig Jejunum organoid sample (12 weeks (SAMN14300021), a 5 week old pig Jejunum tissue sample (SAMN14300018), cell lines IPECJ87, an IPECJ2 cell line grown for 87 passages (SAMN14300016), and IPECJ91 an IPECJ2 cell line grown for 91 passages (SAMN14299997). We trimmed, aligned, and completed gene quantification of this data following the same procedure as the above for the IPECJ67 cell line. These samples were used to compare the average gene expression levels per chromosome in the tissue, organoid, and cell lines to the IPECJ67 cell line. Initial ASE analysis was completed with variant calls from WGS data (FreeBayes, Garrison and Marth, 2012) and aligned reads from RNA-seq using GATK ASEReader (McKenna *et al.,* 2010). Variant calling from RNA-seq alignments for SL-29, IPECJ67, IPECJ87, and IPECJ91 was completed using FreeBayes and thereafter allele specific expression analysis was completed using GATK ASEReader implementing the bam and VCF files. Results from the ASE analysis was plotted using Seaborn package in python.

Results

Chromosomal abnormalities within the cell-line genomes. In a previous study of the cell lines IPECJ67 and SL-29 we analysed the structure of the genome in multiple aspects using whole genome sequence data (de Vos *et al.* manuscript in preparation). In pig IPECJ67 we observed that chromosome 16 is diploid and chromosome 17 is triploid based on the frequency of the alleles (data not shown). Additionally, aneuploidy and structural variations were observed in many other chromosomes in the IPECJ67 cell line as well as chicken SL-29 (e.g. chromosome 20 is tetraploid).

Allele specific expression. RNA-seq data provides insight into gene expression levels at a chromosome-wide level. We investigated the expression of genes and transcripts in the pig IPECJ67, IPECJ87, IPECJ91 cell lines, jejunum intestinal tissue and jejunum derived organoid sample (data not shown). We found elevated gene expression on chromosome 17 in the cell lines compared to organoid and tissue whereas for the diploid chromosomes 15 and 16 similar gene expression levels across tissue, organoids and cell lines, with slightly higher expression levels in cell lines were observed. Investigating the allele specific expression of the IPECJ67 cell line (Figure 1) shows that the frequency of the allele expression displays a pattern that confirms chromosome 17 as triploid and chromosomes 15 and 16 as diploid.

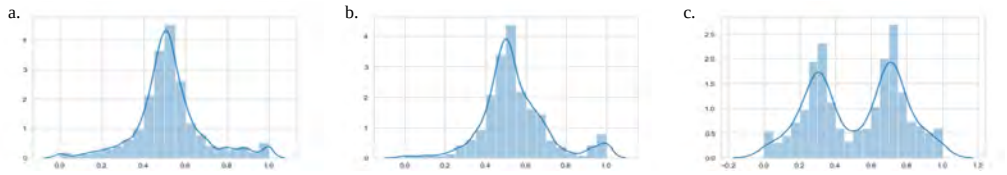

Figure 1. Allele specific expression of chromosomes 15(a), 16(b), 17(c) for the IPECJ67 cell line supports the ploidy level of the three chromosomes – allele expression of ~0.5 for diploids and allele expression of ~0.33 and ~0.7 for triploids, respectively.

Further investigation of the ASE and chromosomal abnormalities of the IPECJ2 derived cell lines cultured for a longer time also showed triploidy for chromosome 17 (Figure 2 c,f) in both cell cultures. Interestingly, chromosome 16 was observed as triploid (Figure 2 b,e) for these cell cultures, which is different from IPECJ67 which was diploid for chromosome 16 (Figure 1b).

Similar patterns of allele distribution for aneuploid chromosomes detected using ASE are observed on other chromosomes in pig IPECJ67 and in chicken SL-29 (data not shown). Lastly, we called the genome variation from the RNA-seq data and repeated the ASE analysis based on the RNA-seq called genome variation. This resulted in the same ASE results as using the variation called from the genome sequencing data (data not shown). Thus, genome sequencing is not required to detect genome aberrations based on ASE.

Discussion

Detecting chromosome abnormalities in e.g. cell lines is important as such abnormalities may influence the results obtained in cell line assays, especially if genes involved in the process studied show copy number variation as this will result in deviating expression (Figure 1c). Chromosome ploidy can be investigated by e.g. cytogenetic and whole genome sequencing methods, but these methods are generally not applied in standard cell-line research. As RNA-seq is (becoming) the general method used for gene expression detection, also in cell-lines, we investigated the potential of implementing RNA-seq as a tool for detecting chromosomal abnormalities through variant calling, ASE analysis and plotting the allele ratios. We observed similar patterns of allele support ratios from WGS variant calling and RNA-seq allelic expression variants. This suggests we do not need WGS data for detection of chromosomal abnormalities. We show that a larger number of passages of the IPECJ2 cell line results in an increased level of aneuploidy. Thus, our approach, using RNA-seq, is a sufficient and cost-effective tool to detect aneuploidy, which we suggest to be regularly applied in cell line experiments.

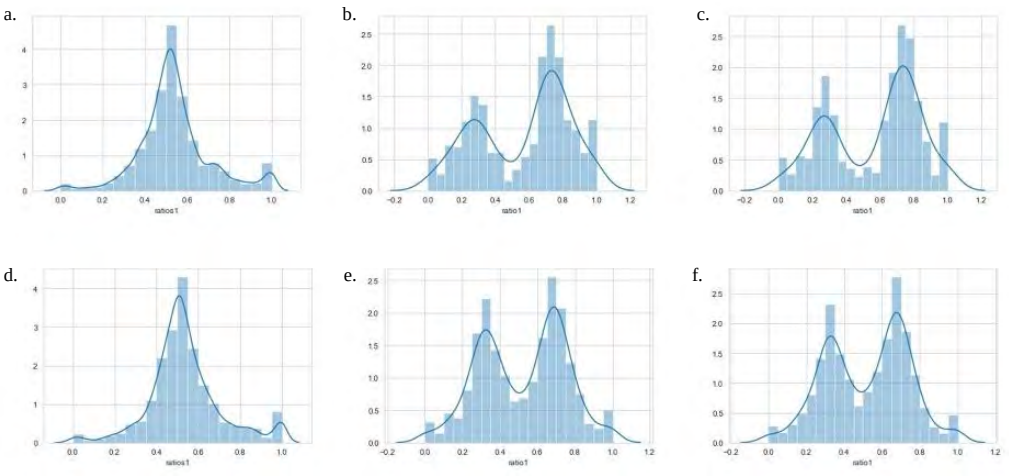

Figure 2. ASE for IPECJ2 derived cell lines cultured for a longer time (passages). IPECJ87 (a) chromosome 15, (b) chromosome 16, (c) chromosome 17. IPECJ91 (d) chromosome 15, (e) chromsome16, (f) chromosome17.

541. Segregation of the structural variant responds for mastitis resistance in re-sequencing Nordic Holstein animals

Z. Cai* and G. Sahana

Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark; zexi.cai@qgg.au.dk

Abstract

An important source of genome sequence variations, structural variants (SVs), are largely ignored due to the difficulty to precisely calling these variants. In this study, we used whole genome sequence (WGS) data to capture the SVs in various breeds. We have identified 84,561 SVs in 567 WGS animals. When compared the called SVs with the major quantitative trait locus for mastitis resistance on chromosome 6 near to *GC* gene, we found a duplication (DUP) is highly similar to previous reported copy number variant. Even though the linkage disequilibrium between the lead SNP for mastitis resistance and the called DUP is not complete, the SVs profile we obtained still showed the potential for identifying functional variants.

Introduction

Structural variants (SVs) are referred to the variants which are large in size (>50bp). The type of SVs include insertion (INS), deletion (DEL), duplication (DUP), copy number variants (CNV), inversion (INV), and translocations. Generally, such variants are difficult to capture using short-read sequencing due to the length of the sequence reads ranging 30-250bp. Therefore, SVs are not a typically included when using whole-genome sequence (WGS) data to obtain high density variants map. Recently, more and more reports have proven SVs are important variants that usually have high impact on the phenotypes (Mahmoud *et al.*, 2019) and have the potential to pinpoint the candidate genes in the GWAS hits. Therefore, calling for SVs for reference panel will be informative. Even though using short-read sequencing with moderate coverage to identify SVs is less powerful than long read sequencing and deep sequencing, the choice of the method could partially overcome the disadvantage of the short reads and achieve high accuracy of SVs calling.

In this study, we collected previously generated WGS dataset with moderate sequencing depth to obtain the SVs in various cattle breeds. Smoove (https://github.com/brentp/smoove) pipeline was used to call SVs, which perform the calling, filtering and annotation of SVs. The potential present of SVs around the known mastitis resistance quantitative trait locus (QTL) on chromosome 6 in Holstein cattle was investigated.

Materials & methods

Animals. In total, WGS from 567 animals were used in this study, which include 123 Holstein (HOL), 60 Jersey (JER), 175 Nordic Red Dairy cattle (RDC) and 209 from other breeds. DNA was extracted from semen samples using standard procedures at Aarhus University, Denmark. Sequencing was done using Illumina sequencing platform using shot-gun pair-end strategy with approximated 10 fold coverage.

Mapping and Structural variants calling. The raw reads were subjected to Trimmomatic 0.38 (Bolger *et al.*, 2014) to remove the adapter sequence and trim the low quality base. Then the clean reads were mapped to the cattle reference genome ARS-UCD1.2 (Rosen *et al.*, 2020) using *bwa mem* (Ma *et al.*, 2020) with parameter 'M' to mark shorter split hits as secondary. BaseRecalibrator was applied to the raw alignment bam files using GATK 3.8 (McKenna *et al.*, 2010). We applied the smoove (https://github.com/brentp/smoove) pipeline to call SVs using the base recalibrated bam files with default parameter. The statistics of the SVs in Holstein, Jersey and Nordic Red was calculated using PLINK v1.9 (Purcell *et al.*, 2007).

Locuszoom plot. We reused previous GWAS result (Cai *et al.*, 2018) of mastitis resistance in Danish Holstein as an example to show the potential function of structural variants. We applied the locuszoom (Pruim *et al.*, 2010) to visualize the surrounding region of the lead SNP. The regulatory elements were retrieved from previous study (Kern *et al.*, 2021) and severed as additional track.

Results & discussion

The statistics of the structural variants identified. We have identified 84,561 SVs, including 9,416 DUP, 59,709 DEL, 3,982 INV, 7,471 pairs of generic breakends (BND) across different chromosomes, and 3,983 BNDs within the same chromosome which could indicated large deletions. Furthermore, there are 66,031, 51,695 and 79,221 segregating SVs in HOL, JER and RDC respectively (Table 1). In addition, 45,894 SVs are shared by these three breeds, and RDC have largest number of breed-specific SVs (Figure 1). Besides, HOL and RDC also share a large number of SVs that are not presented in JER. The number of the SVs is affected by the number of samples and also the population, which is consistent with previous study (Kommadath *et al.*, 2019).

The QTL of mastitis resistance of chromosome 6. Previous studies have shown that there is a major QTL located on chromosome 6 near to *GC* gene for mastitis resistance. In our GWAS, we identified a SNP 6:86997761 with $-\log_{10}$ (*P*-value) equal to 10.51 as the lead SNP (Figure 2). In the SVs call, we identify 105 SVs located within the surrounding 1 Mb region (1 Mb up and 1 Mb down) of the lead SNP. We extracted

Table 1. The statistics of structural variants in Holstein, Jersey and Nordic Red cattle.

Breed	Number				Total
	DUP	DEL	INV	BND	
Holstein	6,449	39,619	3,192	16,771	66,031
Jersey	4,747	31,486	2,574	12,888	51,695
Nordic Red	7,412	49,238	3,595	18,976	79,221

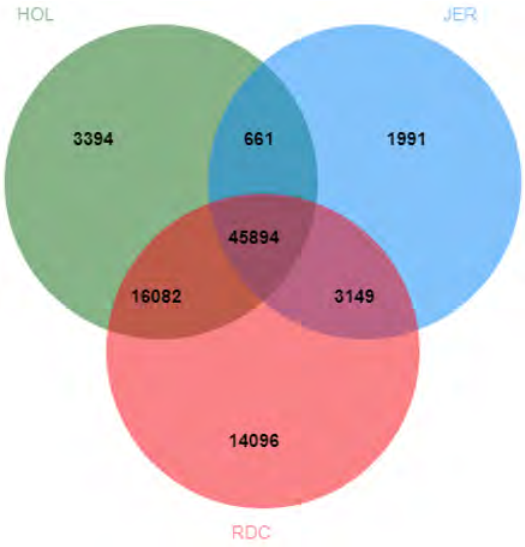

Figure 1. The venn plot shows the overlap of structural variants in Holstein (HOL), Jersey (JER) and Nordic Red Dairy cattle (RDC).

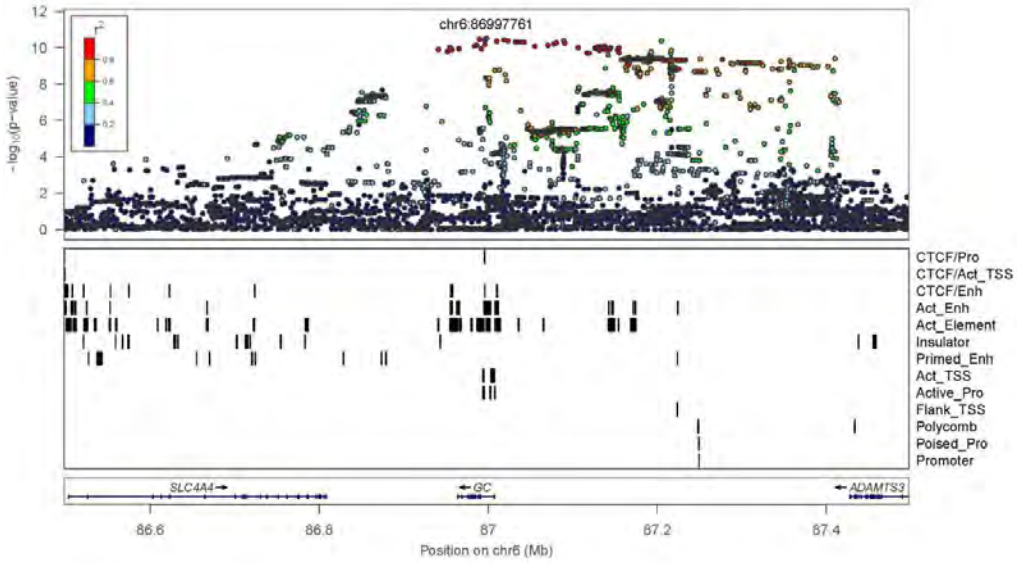

Figure 2. Locuszoom plot showed the lead SNP, LD pattern of the flanking SNPs, the flanking genes (with exon) and the predicted regulatory element from liver tissue.

the genotype of the lead SNP from the WGS animals and checking the LD pattern with the SVs. We only find 5 SVs are in LD with the lead SNP but none of them was in complete LD. These are a 863 bp DEL (r^2=0.22) start from 87,034,646, a 2,013 bp DEL (r^2=0.53) start from 87,065,781, a 272 bp DEL (r^2=0.54) start from 86,997,761, an 11,781 DUP (r^2=0.52) start from 86,949,652 and an 11,236 bp DUP (r^2=0.46) start from 86,950,196.

A previous study has identified a CNV ranging from 86,949,653 ~ 86,961,428 as a potential candidate mutation for the mastitis QTL (Lee *et al.*, 2021). In our case, we have a similar DUP ranging from 86,949,652 ~ 86,961,433. The annotation from smoove showed the start and end point could be imprecise, so it is highly possible these two mutations are the same or the region undergo similar evolutionary event. The flanking area of the lead SNPs and these five SVs are overlapped with active regulatory elements (Figure 2). Even though, the available evidence did not confirm the causality, the SVs profile show the potential for wider scanning for causal variants for QTL whole genome wide and their functional validation.

Abstract

Understanding how genomes, particularly genetic variants, instruct animals to develop and function is crucial for animal breeders. Copy number variants (CNVs), the gain or loss of DNA segments, can affect gene expression and alter phenotypes. However, most large-scale genetic analyses in animal breeding use single nucleotide polymorphism (SNP) genotypes from genotyping arrays, and efforts to incorporate CNVs are limited. In theory, variation from CNVs can be captured by SNPs, if they are in high linkage disequilibrium (LD). We evaluated the LD of CNV-SNP pairs in whole genome sequencing and genotyping array data. Our whole genome sequencing data showed that most CNVs have tagging SNPs. However, CNV-SNP pairs from genotyping array data were mostly in low LD, because most CNV-SNP pairs had unmatching allele frequencies. We conclude that most rare CNVs may not be fully captured by genotyping arrays.

Introduction

Bovine genomes harbour diverse types of genetic variants. Identifying and utilizing impactful genetic variants is of prime interest for animal breeders, given the economic importance of cattle populations. Copy numbre variants (CNVs) are a subset of structural variants, which include deletions (DELs) and duplications (DUPs) of DNA segments larger than 50 bp. Although CNVs are not as abundant as small genetic variants (e.g. SNPs), CNVs contribute disproportionally more to gene expression than SNPs (Chiang *et al.,* 2017; Scott *et al.,* 2021), hinting that they could be associated with phenotypes. Recent reports in farm animals, which unravelled high impact CNVs as causative variants underlying QTL of complex traits, also support the importance of CNVs (Lee *et al.* 2021; Derks *et al.* 2018; Kadri *et al.* 2014).

Despite the functional evidence of CNVs, their utilization in animal breeding is limited. To date, large-scale routine genetic analyses in breeding programmes, such as genomic prediction, have mostly focused on SNPs obtained from genotyping arrays. In theory, if those SNPs are in high LD with CNVs, the variation from CNVs can be captured by SNPs. To this end, we aimed at: (1) detecting CNVs in deeply sequenced genomes of Holstein Friesian (HF) cattle; (2) validating a subset of CNVs in an independent cohort using a direct genotyping approach; and (3) evaluating pairwise LD in CNV-SNP pairs in whole genome sequencing (WGS) and genotyping data.

Materials & methods

WGS data. A family cohort (DAMONA) consisting of 266 HF animals (including 127 trios) was sequenced using the Illumina HiSeq 2000 instrument. The data was aligned using BWA mem (version 0.7.9a-r786) (Li 2013) to the bovine reference genome ARS-UCD1.2 (Rosen *et al.* 2020). All samples had a minimum mean sequencing coverage of 15X, and the mean coverage was 26X.

SNP and CNV discovery in the WGS data. SNP variant calling was done using the GATK workflow (v4.1.7), and recalibrated using the following algorithms: BaseRecalibrator, HaplotypeCaller, GenomicsDBImport, GenotypeGVCF, GatherVcfs, Variant Recalibrator (DePristo *et al.* 2011; McKenna *et al.* 2010; Auwera *et al.* 2013). Variant Quality Score Recalibration (VQSR) at a truth sensitivity filter level of 97.5 was used to remove spurious variants. CNVs were detected using the Smoove pipeline, which utilized split and discordant reads evidence to discover CNVs in each sample, followed by population-wide genotyping (https://github.com/brentp/smoove). Subsequently, we used the fold-coverage change of read depth in CNVs to retain accurately genotyped biallelic CNVs, using Duphold (Pedersen and Quinlan 2019).

Genotyping data. To validate CNV discovery results, we genotyped a subset of CNVs by adding them in the custom part of the EuroGenomics SNP genotyping array, which harbours ~50K SNPs (Boichard *et al.* 2018). Probes targeting breakpoint sequences of 372 CNVs (342 deletions and 30 duplications) that appeared in non-repetitive regions, were added. Genotyping was done for 815 independent HF animals using their ear punch or blood samples.

LD analyses. Pairwise LD (r^2) for CNV-SNP pairs was calculated, to evaluate whether CNVs had tagging SNPs. This analysis was done separately for the WGS and EuroGenomics array data sets. SNPs located within 100-kb distance from CNV breakpoints (WGS) or CNV probes (array) were considered for LD calculation. Additionally, LD decay was compared between CNV-SNP and SNP-SNP pairs limited to the Eurogenomics array data. This analysis was done for common (allele frequency≥0.05) and rare (allele frequency<0.05) DELs separately. Due to a limited number, DUPs was not considered (n=19). The LD calculation was done using the PLINK software (Purcell *et al.* 2007).

Results

Overall variant discovery in the WGS data set. The SNP variant calling pipeline resulted in 11,030,905 SNPs from the 266 sequenced samples. Using the same WGS data set, we discovered 13,731 CNVs (12,200 deletions and 1,531 duplications). Genotyping accuracy of CNVs is lower than that of SNPs (Chiang *et al.* 2017). Hence, we applied read-depth based filters, resulting in 4,011 accurately genotyped biallelic CNVs (3,827 deletions and 184 duplications).

Validation of CNVs using genotyping arrays. We validated a subset of WGS CNVs, using a direct genotyping approach in 815 HF animals. All genotyped samples had a sample call rate >0.99). Of the 284 CNVs that passed the variant level filter, 229 were segregating (210 deletions and 19 duplications), showing a validation rate of 80% (229/284). The SNP genotyping results showed that 50,342 SNPs were segregating in the population. The minor frequency spectrum of CNVs was skewed towards rare variants, whereas that of SNPs were skewed towards common variants (Figure 1).

LD analyses in the WGS and the genotyping data. To evaluate whether WGS CNVs have tagging SNPs in WGS data, we calculated the LD of CNV-SNP pairs. A majority of biallelic WGS CNVs (97% of DELs and 93% of DUPs) had at least one WGS SNP in LD (r^2>0.8) within a 100-kb distance from the CNV. However, the same analyses based on the EuroGenomics array data revealed that only 15.4% of DELs and 4.5% of DUPs included on the array had a tagging array SNP (r^2>0.8) within a 100-kb distance. Lastly, the LD in the EuroGenomics array data confirmed that the CNV-SNP pairs have low LD than SNP-SNP pairs (Figure 2; analyses was done limited to DELs, due to low numbers of DUPs).

Discussion

A large percentage of the CNV in our WGS data set were well tagged by at least one WGS SNP. In a human study, only ~80% of CNVs had at least one tagging SNPs, based on low-pass WGS data (4-7X coverage;

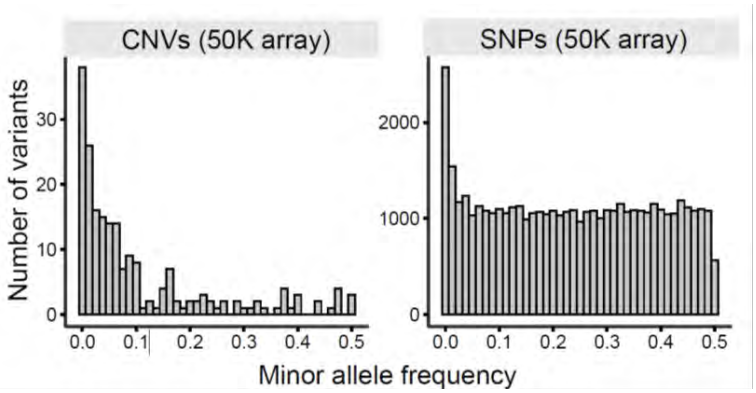

Figure 1. Minor allele frequency spectra of CNVs and SNPs obtained from the EuroGenomics array.

Sudmant *et al.* 2015). The higher LD in our data set is likely due to: (1) high relatedness among the animal samples, as opposed to the non-related human samples in Sudmant *et al.* (2015); and (2) deeper WGS data in our study. The deeper WGS contributed to more accurate genotyping of CNVs, which may have resulted in higher LD between CNV and SNP genotypes.

The LD between CNV and SNP in our array genotyped data set was low. The frequency spectra of CNVs and SNPs were discordant: CNVs were skewed towards rare variants, whereas SNPs were enriched for common variants. Thus, only a small fraction of CNVs, with high allele frequencies, was tagged by SNPs in the EuroGenomics array. Furthermore, the generally low LD in CNV-SNP pairs compared to SNP-SNP pairs confirmed previous findings based on the Illumina BovineHD Genotyping BeadChip data (Figure 2; Lee *et al.* 2020).

Taking these results together, we conclude that most CNVs have tagging SNPs, which can be identified in deep WGS data. However, such tagging SNPs may not be present in genotyping arrays, as arrays tend to harbour common SNPs. This, in turn, suggests that a small fraction of CNVs, segregating at high frequency, may be tagged well by SNPs in the genotyping arrays. However, most CNVs are rare, and hence not properly captured with the set of SNPs in genotyping arrays. To mitigate this gap, we propose to utilize the WGS CNV catalogue to prioritize likely functional CNVs, particularly rare ones, and directly genotype them.

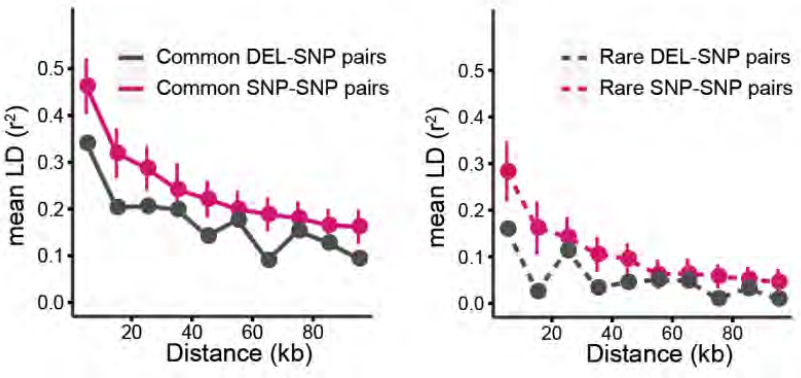

Figure 2. LD decay patterns in DEL-SNP and SNP-SNP pairs.

Funding

This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project 16022) and the Breed4Food partners Cobb Europe, CRV, Hendrix Genetics and Topigs Norsvin. The HF WGS data set was funded by the DAMONA ERC advanced grant to MG.

Abstract

To investigate the effect of DNA methylation on sex ratio variation in response to environmental temperature, in this study we used two sex-biased zebrafish families for genome-wide DNA methylation analysis using reduced representation bisulfite sequencing (RRBS). The results showed a higher number of differentially methylated CpG sites (DMCs) in the male-biased family (218,850) compared to the female-biased family (211,943). Likewise, a greater number of methylated positions was identified in the male gonads (4,151) than the female gonads (1,993). The effect of temperature showed more methylated positions in high incubation temperature than the control temperature. We also found differential methylation of many reproduction-related genes (e.g. *sox9a, gata4, lhx8a*) and genes involved in epigenetic mechanisms (e.g. *dnmt3bb.1, dimt1l, h1m*) in both families. We conclude that epigenetic modifications would be more critical in male-skewed sex ratio, which may have negative consequences for population fitness in thermosensitive species under rapid environmental changes.

Introduction

Phenotypic sexual plasticity in response to environmental conditions leads to sex-reversed individuals and variation in sex ratio, which consequently influence population dynamics and loss of biodiversity. This phenomenon is found in animal species with genotype-environment interaction (G×E) sex-determining system such as reptiles, amphibians, and fish (Piferrer *et al.*, 2019). The plasticity of sexual phenotype can be influenced by epigenetic mechanisms, which integrate genomic and environmental factors to generate a particular phenotype through changes in the transcriptional activity of genes in response to environmental stimuli (Piferrer *et al.*, 2019). Understanding the mechanisms underlying G×E sex-determining system is a fundamental research interest for conservation of natural populations and livestock species (Shao *et al.*, 2014) in order to develop counterstrategies for dealing with unforeseeable ecological consequences in light of global climate change. Zebrafish (*Danio rerio*), is an excellent research model to study the mechanism of sex determination and the effect of environmental changes on gonadal differentiation in vertebrates (Ribas and Piferrer, 2014). Hence, the main goal of this study was to investigate the epigenetic landscape of DNA methylation in the context of sexual plasticity in thermosensitive animal species using the zebrafish. Therefore, we performed genome-wide DNA methylation analysis in zebrafish gonad to address the effect of epigenetic modifications on sex ratio variation of sex-biased families in response to environmental temperature.

Materials & methods

In this trial, the fertilized eggs from 17 zebrafish families were divided in equal proportions and subjected to two different incubation temperatures: (1) control group was kept at a constant temperature of 28 °C throughout the experiment; (2) high incubation temperature group (treatment group) was exposed to high water temperature of 35 °C from 5 to 24 hours post fertilization. The phenotypic sex of all individuals was determined in the adult stage (90-120 days post fertilization). To select the male-biased (more than 60%

males in the control group) and the female-biased (less than 40% males in the control group) families (Liew *et al.*, 2012) for RRBS analysis, two decision criteria using a linear logistic model were applied: (1) a high difference in the proportion of males between the families under control condition; and (2) a high difference in the proportion of males between control and treatment groups within the families. After selecting the two sex-biased families with significant differences in sex ratio, a total number of 72 gonad tissue samples were collected from adult males and females of the control and treatment groups for laboratory analysis. The genomic DNA was isolated using the AllPrep DNA/RNA Mini Kit (Qiagen), which were then subjected to bisulfite conversion using the EZ DNA Methylation-Gold Kit (Zymo Research) according to the manufacturer's protocols. The RRBS libraries were sequenced for 121bp single reads on the HiSeq 2500 system according to the manufacturer's recommendations using the HiSeq SR Cluster and HiSeq SBS Kit v4 (Illumina). For bioinformatics analysis of raw data, the base call (BCL) files were converted into fastq files. The fastq files were further processed for quality control of sequencing reads. The cleaned reads were then mapped to the *Danio rerio* reference genome (GRCz11) and the methylation calls were performed using Bismark software. Differential methylation analysis was conducted using 'edgeR' package of R-program to identify the DMCs between (male-biased versus female-biased family in each gonad type) and within (male versus female gonads in each family type) families. The standard false discovery rate (FDR) approach was applied for methylation differences between the comparison groups (FDR<0.05). To assess the effect of DNA methylation on genes involved in sex determination of zebrafish, we generated a list of reproduction- and epigenetic-related genes (n=174 candidate genes) to align the results of DNA methylation with the candidate genes.

Results

Differentially methylated CpG sites between male-biased and female-biased families. To assess the differences in DNA methylation of sex-biased zebrafish families, we compared the methylation profiles of male-biased (MB) versus female-biased (FB) family within female and male gonads in control (FC, MC) and treatment (FT, MT) conditions in different experimental groups: FCMB vs FCFB, MCMB vs MCFB, FTMB vs FTFB, MTMB vs MTFB (Figure 1A and 1B). The gonadal tissue samples of 6 females and 12 males in each experimental group were analysed in this study. Analysis of the methylation profiles between the two sex-biased families in each gonad type revealed that a total of 805 CpGs in the control group and 1,188 CpGs in the treatment group were differentially methylated in the female gonads. The same comparison in the male gonads showed the differentially methylation of a total of 1,969 CpGs and 2,182 CpGs in the control and treatment groups, respectively. This observation indicates that the male gonads harbored more hypermethylated CpG sites than the female gonads and the treatment group more than the control group when comparing the two sex-biased families with different genetic background of sex determination. The analysis of the association between the DNA methylation changes of the nearest annotated DMCs genes (±10 kb distances away from transcription start site, TSS) comparing male-biased versus female-biased family (Figure 1A) and the candidate genes revealed the identification of 23 genes, in which two methyltransferase genes (*trmt10c* and *shmt2*) and one chromatin-related gene (*hmgn3*) and a subset of reproduction-related genes (e.g. *gdf9, star, nr5a2, piwil1, fmr1, sox3, lef1*) were detected in different experimental groups.

Differentially methylated CpG sites in male versus female gonads within sex-biased families. To understand the epigenetic mechanisms underlying plasticity of sexual development in zebrafish, we compared male versus female gonads within the two sex-biased families in different groups: MCMB vs FCMB, MCFB vs FCFB, MTMB vs FTMB, MTFB vs FTFB (Figure 2A and 2B). The DMCs within the male-biased family revealed a total of 201,139 hypermethylated sites in the male gonads, whereas only 17,711 hypermethylated sites were found in the female gonads. Similarly, in the female-biased family, a high number of hypermethylated CpGs were identified in the male gonads (193,121) compared to a

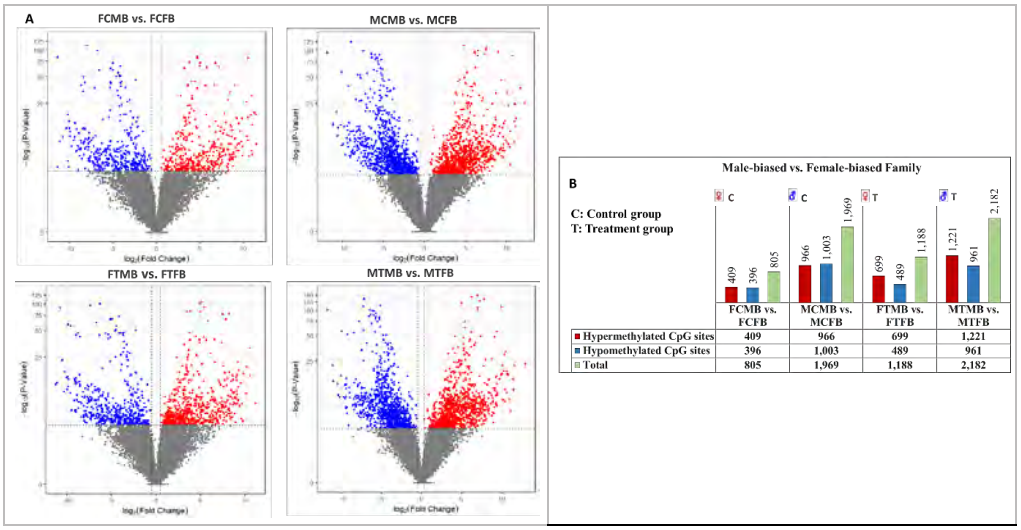

Figure 1. Differentially methylated CpG sites (DMCs) between sex-biased zebrafish families. (A) DMCs in male-biased versus female-biased family in each gonad type. (B) Overview of DMCs comparison between the two sex-biased families.

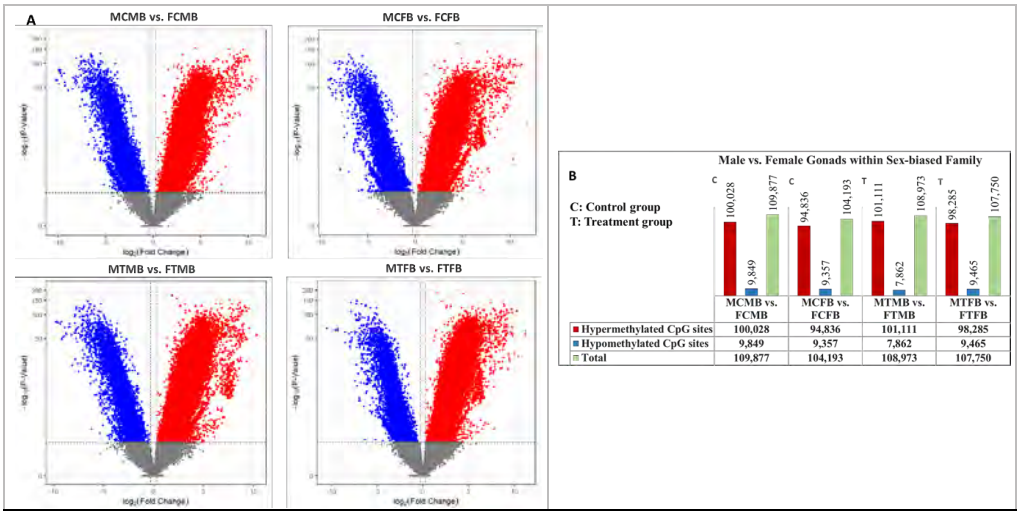

Figure 2. Differentially methylated CpG sites (DMCs) within each sex-biased zebrafish family. (A) DMCs in male versus female gonads within male-biased and female-biased families. (B) Overview of DMCs comparison within each sex-biased family.

lower number of hypermethylated CpGs in the female gonads (18,822). Our results demonstrate a higher number of hypermethylated sites in the male gonads versus a lower number of hypermethylated sites in the female gonads. Considering the effect of temperature on DMCs within both sex-biased families showed more hypermethylated CpGs in the treatment group than the control group. To find the effect of DNA methylation changes on genes within families (Figure 2A), we first annotated the DMCs with nearest genes (±10 kb distances away from TSS) comparing male versus female gonads, resulting in the detection of significant unique genes in each family (488 genes in MB and 389 genes in FB families in control group, 477 genes in MB and 426 genes in FB in treatment group) and significant common genes in overlap between the two sex-biased families (8,954 genes in control group and 8,988 genes in treatment group). These results were then used for the association between unique genes and candidate genes defined above, which revealed differential methylation of a few genes in all compared groups. However, in contrast to the unique genes, in the common genes of the two sex-biased families we identified a series of candidate reproduction-related (e.g. *sox9a, sox3, ctnnb1, lhx8a, gata4*) and epigenetic-related (e.g. *dnmt3bb.1, hdac4, hdac11, h1m*) genes in zebrafish gonad (100 candidate genes in control group and 104 candidate genes in treatment group).

Discussion

Epigenetically regulated sex determination in response to the environment plays a key role in phenotypic plasticity. Our study in sex-biased zebrafish families revealed pronounced differences in DMCs between male-biased and female-biased families, where the male gonads in the male-biased family showed more hypermethylated CpGs than the female gonads.

Identification of sex ratio variation in sex-biased zebrafish families with different genetic background of sex determination and different methylation in gonadal tissue in these families are evidence for epigenetic modifications underlying phenotypic sexual plasticity. The phenotypic divergence between the two sexes requires sex-specific gene regulation and differential sex-biased gene expression, which can be influenced by epigenetic regulatory mechanisms (Grath and Parsch, 2016). In this study, we identified the methylation of unique genes and a subset of the candidate genes studied here in each sex-biased family, especially in the group exposed to high temperature. These genes may directly or indirectly influence the gonadal development in downstream pathways, resulting in skewed sex ratios in a population. Among the differentially methylated candidate genes, the genes involved in testicular differentiation and spermatogenesis such as *sox9a*, *sox3*, and *gata4* were identified in our study. Likewise, the methylation of sex-biased genes involved in ovarian differentiation and folliculogenesis, such as *ctnnb1* and *lhx8a* was also observed in our analysis. We conclude that the effect of epigenetic modifications could be more critical in a population with male-skewed sex ratio with respect to rapid environmental changes under the predicted global warming scenario, which could not only lead to the extinction of natural populations but also have an impact on farm fish species.

Abstract

Genotyping strategies enable a large volume of information that can be used in livestock breeding programmes. Here, we analysed whether nanopore sequencing shows equivalent results to whole-genome bisulfite sequencing and whether the methylation patterns of a cow affect or modify its phenotype. A depth of 10× with Nanopore sequencing showed similar results to bisulfite sequencing (Pearson correlation=0.753). More efficient cows had lower methylated sites along their genomes. Animals on their first lactation showed a larger number of methylated sites than those in subsequent lactations. Understanding the mechanisms that control the imprinting of methylation marks and their effect on productive traits of the animals can lead to an improvement of breeding programmes.

Introduction

The study of the epigenome can improve our understanding of gene expression, regulation, and changes on the functional genome during the prenatal reprogramming or during long stress periods. The most common and well known epigenetics mark are cytosine methylations which consist in the addition of a methyl group to the fifth carbon of a cytosine. These changes usually occur in the context of cytosine-guanine dinucleotides (CpG).

Epigenetic studies are shedding light on different modifications and new approaches to improve animal adaptation to the environment and resistance to stress situations. The association between the methylome and productive traits can affect the health, welfare, and performance of animals. Studies in pigs have found that differentially methylated regions are partially responsible for meat quality (Li *et al.*, 2012). An actual association of heat stress and methylation pattern has yet to be found in dairy cattle but has already been suggested in some studies (Hao *et al.*, 2016). The genetic merit of an animal is estimated using its own information and that from its relatives. Genetic evaluation procedures include environmental effects to isolate genetic information from other effects that are not inherited. Epigenetic marks can interfere with this information because marks such as DNA methylations can modify the expression of certain genes and alter the expected phenotype. Methylation marks can be understood as the way the environment and the genome interact and add useful information to the actual genetic evaluations.

The challenge with epigenetic information lies in the difficulty of obtaining it from commercial populations and the costs associated to the process. Nanopore sequencing offers a different approach than whole-genome bisulfite sequencing (WGBS), e.g. the genome can be sequenced without PCR amplification or chemical labelling of the samples (Clarke *et al.*, 2009). Investigating how this technology can complement or substitute bisulfite sequencing would open new possibilities to the study of the epigenetic marks of livestock animals at farm scale, reducing costs, and accelerating the analyses.

The objective of this study was to evaluate the performance of Oxford Nanopore Technologies (ONT) sequencing platforms to evaluate methylation in livestock and perform a preliminary association analysis between methyl marks and feed efficiency and number of lactation.

Materials & methods

Animal sampling. Blood samples were extracted from 22 cows via venipuncture and stored in a Vacutainer™ with EDTA. Data from the official milk recording scheme were available, in addition to dry matter intake and feed efficiency (FE). Animals with a FE equal or greater than 1.5 were classified in the high efficiency group, where as those with a FE<1.5 were grouped as low efficiency.

DNA extraction. We used the Monarch® HMW DNA Extraction Kit (T3050L) for Cells & Blood (New England Biolabs®) to extract DNA for nanopore sequencing. The DNA for WGBS was extracted from a blood sample using the MasterPure™ DNA Purification Kit (Epicentre). The concentration samples were estimated using a NanoDrop UV/Vis spectrometer (NanoDrop Technologies Inc.) and a Qubit fluorometer (ThermoFisher Scientific, 150 Waltham, MA, USA).

DNA sequencing. DNA was sequenced using the MinION sequencer (Oxford Nanopore Technologies. ONT, Oxford, UK). Sample for the comparison with Illumina sequencer was run in a single flow cell to achieve a greater coverage meanwhile samples for methylation analyses were multiplexed and sequenced at low depth. The library was prepared using the Ligation Sequencing Kit (SQK-LSK109) and following the protocol provided by its manufacturer. The samples were multiplexed and the resulting library was sequenced using two R9.4 flow cell until exhaustion. Additionally, the sample from a cow, Montross Martha, was sequenced individually, after fragmenting DNA to an average length of 8 kb, at larger depth using a single R9.4 flow cell until exhaustion. This sample was also sequenced by WGBS by an external service (CNAG-CRG. Centro Nacional de Análisis Genómico), using the Kit Enzyme Methyl (NEB). Basecalling was performed using Guppy version 5.0.14 (nanoporetech.com/community). Quality control was performed using NanoPlot (v1.36.2) (de Coster *et al.* 2018), and a minimum threshold for Q-score was set to 9. The quality control of the WGBS was performed using FastQC (v0.11.7) (Andrews, 2010)

Methylation calling. The pipelines were implemented in the CESGA super-computing centre (Galicia, Spain). First, Nanopolish (v0.13.2) (Loman *et al.*, 2015) was used to extract the methylated sites from the samples. Sequences from WGBS were analysed using Bismark (v0.23.0) (Krueger and Andrews, 2011)

Comparison between ONT and WGBS. We compared the sites detected by each software and the correlation between their methylation likelihoods was estimated. Several coverage thresholds (1×, 5×, 10×, 15×, and 20×) were evaluated to determine the effect of sequencing depth and the potential implications in the reliability of the results.

Differential methylation. PycoMeth (Leger, 2020) was used to detect the methylation patterns based on likelihood ratios. A filter for sites with a sequencing depth larger than 10x was established. Sites with a *P*-value higher than 0.05 were discarded. We compared the methylation pattern of the high FE animals to the one of low FE animals and animals from first lactation with animals from second or further lactations. GCF_002263795.1_ARS-UCD1.2_genomic.gff was used to annotate the differentially methylated genes.

Results

Comparison of WGBS and nanopore sequencing. A total of 88.2 Gb was obtained by WGBS (coverage ~30×). The mean Q-score was of 38, which is equivalent to an error rate <0.01%. Sequences obtained using the MinION resulted in 28.4 Gb, which is equivalent to a coverage of ~7×. Their mean Q-score achieved

was 9.9, corresponding to an average error rate of 10%. We detected 21,694,649 possible methylated sites with the MinION and Nanopolish and 52,403,895 using bisulfite sequencing and Bismark.

Similarity between WGBS and ONT. After filtering on different coverages (Figure 1) we found that selecting sites with a coverage >10× resulted in a correlation of 0.75 and 4,652 sites detected using both sequencing platforms.

Differential methylation. Samples were sequenced with a mean coverage of 0.5×. After filtering for coverage>10× and *P*-value<0.05 we obtained 25 genome intervals showing differential methylated status between the FE groups and 29 of them for lactation groups. We observed more methylated sites in animals in their first lactation and more methylated sites in low FE animals. Genes like *gnas*, *nelfcd*, *insl3* and *b3gnt3* were the most differentially methylated between FE groups and *amot*, *ago2*, *chrac1*, *sept9* in the lactation groups.

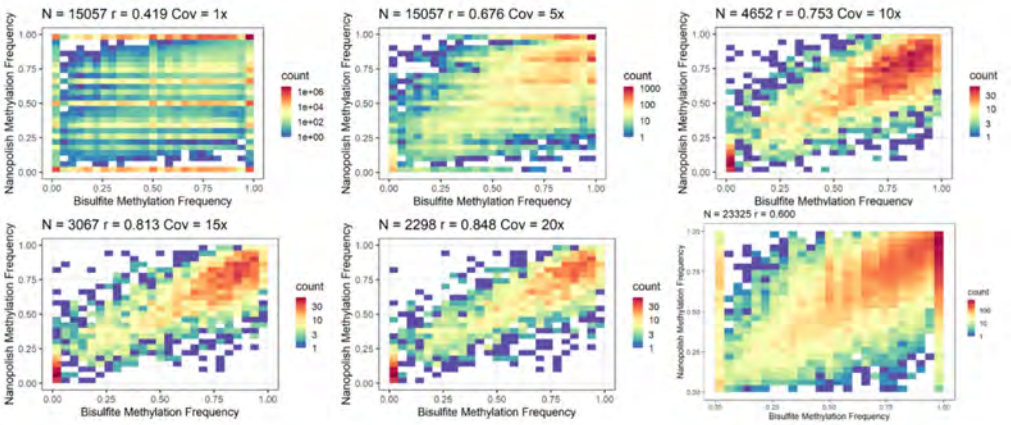

Figure 1. Different combinations of coverage and their respective correlations (r) and sites detected (N). Correlation filtered for 1×, 5×, 10×, 15×, 20× and last image illustrates filtering ONT sites by 15× and Illumina for 1×.

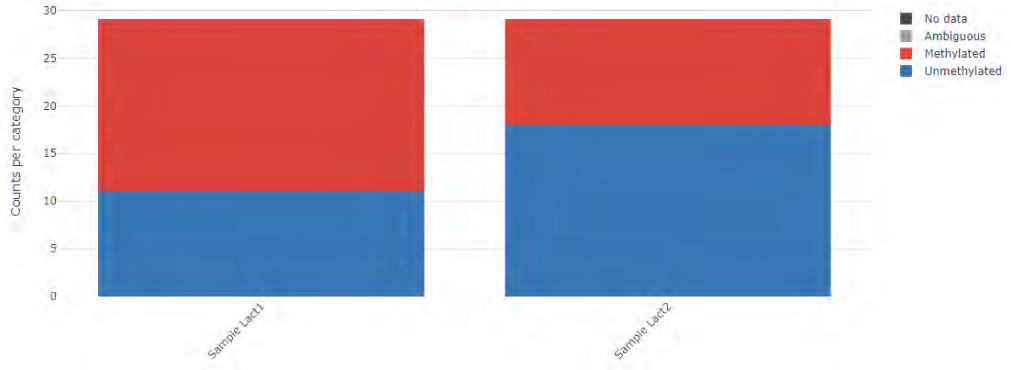

Figure 2. Comparison of methylation patterns alongside the genome of animals in their first lactation (LACT1) and animals in second or further lactations (LACT2). Red blocks represent methylated regions and blue ones represent unmethylated ones.

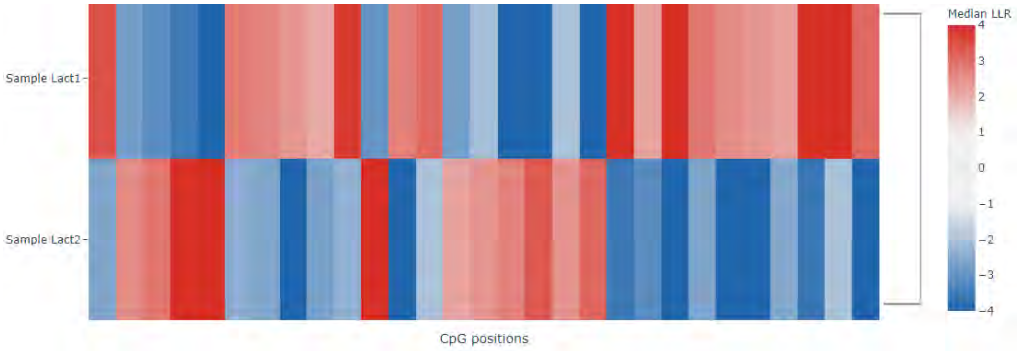

Figure 3. Comparison of methylation patterns alongside the genome of animals in their first lactation (LACT1) and animals in second or further lactations (LACT2). Red blocks represent methylated regions and blue ones represent unmethylated ones.

Discussion

Third-generation sequencing can help us to understand how the genome interacts with the environment and envision new opportunities to modify management practices and include epigenetic information in the breeding programmes. Nanopore sequencing enables new ways of studying epigenetics marks at farm level. Low cost and multiplexing capacity may allow implementing new technologies to improve animal wellbeing and adaptation to its environment. ONT offers the possibility to obtain genomic variants and genome methylation status simultaneously. We observed a good correlation between ONT and WGBS after filtering sites with a sequencing depth>10×. For future analysis, we suggest filtering the samples and keep sites with a coverage>10×.

Methylation patterns seem to clearly vary between different groups of animals. High feed efficient ones have less methylated sites than low FE animals. Preliminary selected genes like *gnas*, associated with performance traits (Sikora *et al.*, 2011), suggest that methylation marks could have an impact on the phenotype of the cow, by modulating gene expression and having and impact in the productive rates of the animal. Initially, we have observed that methylation levels are different between animals with different phenotypes (Lactation number and FE). It must be pointed out that our results were obtained from a reduced number of individuals and with a reduced genome coverage. Further studies may clarify how the methylation marks affect other traits of interest, and whether this information can increase the accuracy of genetic evaluations.

Abstract

A multi-dimensional transcriptome map was generated using a diverse catalogue of tissue samples collected from six individuals of both sexes, different ages, kept in different environments and from three divergent breeds/crosses. More than 15k genes exhibit at least one potentially novel transcript in comparison with existing annotations. Tissue-specific miRNAs were detected contributing to the understanding of vital body functions in bovine. PIWI-interacting RNAs (piRNAs) were detected in ovary and testis only and, the repertoire of piRNA clusters in the male germline was expanded. A regulatory landscape was also generated including open chromatin regions, putative active promoters and transcription start sites, active enhancers, repressive states and insulators. This constitutes a key repository dataset for biology-driven genomic prediction that will help the scientific community and industry stakeholders to apply genomics to address the challenges facing cattle production.

Introduction

In humans, a catalogue of functional elements in the genome was generated by the ENCODE consortium (ENCODE Project Consortium, 2012; Davis *et al.,* 2018) to link genotype to phenotype. In bovine, a comprehensive catalogue of functional elements still does not exist despite the huge contribution of bovids to global food production (Adesogan *et al.,* 2020). Recent efforts from the FAANG consortium have contributed to the functional annotation of the bovine genome but, with a limited number of tissues, individuals and populations analyzed (Foissac *et al.*, 2019; Kern *et al.,* 2021). Multi-dimensional functional annotation of the bovine genome built from a diverse catalogue of tissue samples collected from individuals of both sexes, different ages, kept in different environments and from divergent breeds/crosses is critical in linking genotype to phenotype in cattle, to further improve biology-driven genomic prediction models.

Materials & methods

Samples and tissues. A diverse catalogue of 129 tissue samples were collected from six individuals of both sexes, different ages, kept in different environments and from three divergent breeds/crosses: Belgian dairy (Holstein), Canadian beef composite (Kinsella) and German beef/dairy cross (Charolais × Holstein).

RNA isolation and library preparation. For transcriptome map generation, Total RNA was extracted using miRNeasy kit (QIAGEN) from the 129 snap-frozen tissues samples. After quality control (quantity, purity and integrity assessment), Total RNA libraries were generated using TruSeq Stranded Total RNA Library Prep Gold (Illumina); mRNA libraries using TruSeq Stranded mRNA Library Prep (Illumina); and small RNA libraries using QIAseq miRNA Library (QIAGEN).

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_545, © G.C.M. Moreira *et al.* 2022

For regulatory landscape generation, ATACseq libraries were generated using the ATACseq kit (Active Motif). The chromatin immunoprecipitations (ChIP) were performed for five antibodies (H3K4me3, H3K4me1, H3K27me3, H3K27ac and CTCF – all from Diagenode) using the iDeal ChIP-seq kit for TF (Diagenode); and ChIPseq libraries were prepared using the NEBNext Ultra DNA library prep kit for Illumina libraries (New England Biolabs).

Sequencing and analyses. Libraries were sequenced on the Illumina NovaSeq 6000 (150nt 25M paired-end – mRNA; 150nt 40M paired-end – Total RNA; 100nt/50nt 25M single-end – small-RNA; 150nt 50M paired-end – ATACseq; 100nt paired-end – ChIPseq 30M reads for narrow marks and CTCF; 35M reads for broad marks).

Data analyses for mRNA and Total RNA assays were performed using the BovReg pipeline (https://github.com/BovReg/rnaseq) and for small RNA, ATACseq and ChIPseq assays, using Nextflow/nf-core pipelines (smrnaseq-1.0.0, atacseq-1.2.1, chipseq-1.2.2). The ARS-UCD1.2_Btau5Y reference file from 1000bulls project was utilized. The GTF file from Ensembl v.102 with the coordinates lifted over to the 1000bulls reference genome was used.

For piRNA analyses, small-RNA were mapped to the genome and after the selection of reads ranging between 18-35nt, reads that mapped to rRNAs, miRNAs, snoRNAs, snRNAs, and tRNAs were removed. PiRNA clusters were detected using proTRAC software (Rosenkranz and Zischler, 2012) with default parameters.

Results

Transcriptome map. A *de novo* transcriptome assembly from mRNA and Total RNA assays was created. 43,117 genes were assembled and from those, more than 15K genes exhibit at least one potentially novel transcript in comparison with existing annotations (Table 1).

Based on mRNA assays, tissues originating from the central nervous system exhibit a greater number of genes with elevated expression compared to the other tissues (Figure 1A). Charolais × Holstein/adult testis exhibited four-fold more genes with elevated expression than Holstein/neonate testis and most of those are tissue enriched (elevated expression in testis compared to any other tissue), with GO terms enriched for spermatogenesis related processes known to occur in post-puberal testis (Figure 1A). When considering only tissues shared between the six animals, Holstein/neonate animals exhibited a greater number of genes expressed/assembled and also a greater number of genes with at least one potentially novel transcript compared to Kinsella crossbred/juvenile and Charolais × Holstein.

Table 1. Results from the comparison between BovReg transcriptome assembly and existing annotations.

BovReg annotation features	Compared with	
	Ensembl v.104[1]	NCBI v.106
Genes with at least one potentially novel transcript assembled	15,954	18,636
Complete transcripts with exact match of intron chain	37,257	34,430
Transcripts with partial match, encompassing or within reference transcripts	211,616	223,926
Novel transcripts – no match with reference (unknown, intergenic)	28,925	19,442

[1] To compare the *de novo* transcriptome assembly from BovReg with existing annotations, Ensembl v.104 annotation was utilized instead of v.102.

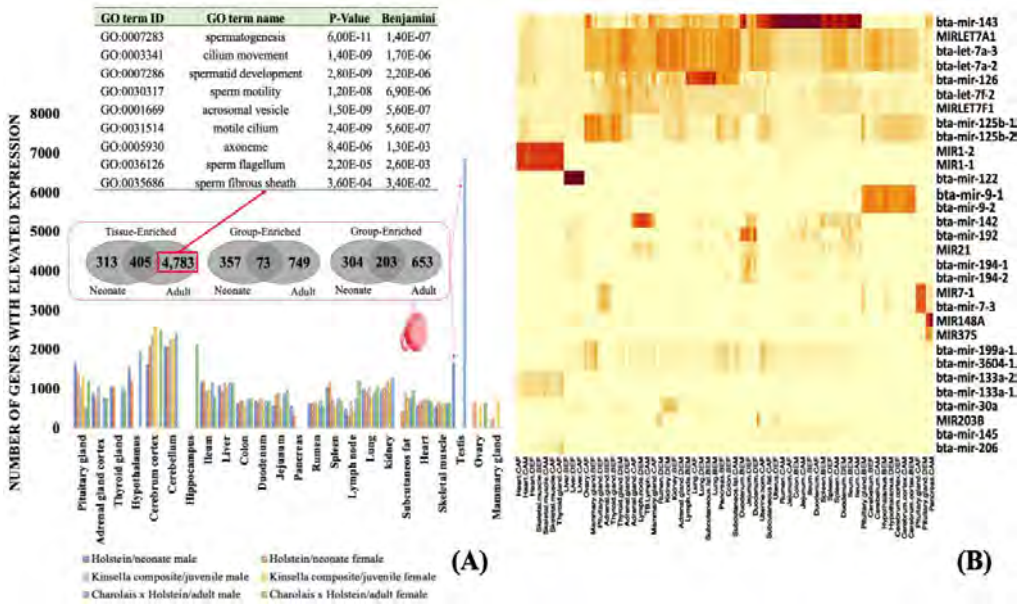

Figure 1. Overview of mRNA and miRNA specificity profiles in the bovine transcriptome (A) Genes with elevated expression (normalized by TPM) in each tissue; classification and GO enrichment of genes with elevated expression in testis. Elevated expression encompass three subcategory types (Jain and Tuteja, 2019): tissue enriched (at least 4× higher mRNA level compared to any other tissue); tissue enhanced (at least 4× higher average mRNA level in a group of 2-5 tissues compared to any other tissue) and; group enriched (at least 4x higher mRNA level compared to the average level in all other tissues). (B) Heatmap of the top 5 known miRNAs with the highest expression (normalized by CPM) in each tissue. MiRNAs in y-axis and tissues on x-axis; BEM: Belgian animal male; BEF: Belgian animal female; CAM: Canadian animal male; CAF: Canadian animal female; DEM: German animal male; DEF: German animal female.

In the small RNA dataset, miRNAs were the predominant class detected (with 81.1% of the reads corresponding to miRNAs, 0.4% to rRNA, 0.3% to tRNA, 3.02% to snoRNA, 0.93% to snRNA and 14.25% to either mitosRNA, unknown – including piRNAs – or artifacts). Taking the top five known miRNAs with the highest expression in each tissue, tissue-specific miRNAs were confirmed (Figure 1B) and most of these miRNAs are already known to play important roles in key biological processes. As an example, *Bta-mir-206* is highly expressed in skeletal muscle and is involved in muscular hypertrophy in Texel sheep (Clop *et al.*, 2006).

PIWI-interacting RNAs (piRNAs) were only detected in ovary and testis. PiRNAs are known to silence transposons and regulate gene expression (Czech and Hannon, 2016). In testis they represent up to 95% of small-RNAs in adult and around 30% in neonate. A huge proportion of piRNAs, especially those expressed in late spermatogenesis, are produced from large genomic regions known as piRNA clusters (Aravin *et al.*, 2007). A greater number of piRNA clusters were detected on neonate testis compared to adult testis and also, from what is known from the database (https://www.smallrnagroup.uni-mainz.de/piRNAclusterDB/), expanding the repertoire of piRNA clusters in bovine.

The data presented here will be combined with a new map of transcription start sites (TSS) (CAGE), lncRNA and circRNA, which will be generated in collaboration with other partners in the BovReg consortium, to create a multi-dimensional transcriptome map.

Regulatory regions. Preliminary ATACseq data revealed approximately 666K open chromatin regions in the bovine genome. From peak annotation relative to gene features, using the *de novo* transcriptome assembly ~4-fold more peaks were annotated in exons, ~3-fold more peaks annotated in promoter-TSS and in transcription termination sites (TTS) and ~2-fold less annotated in intergenic regions, compared with the annotation obtained using Ensembl v.102 assembly.

From preliminary ChIPseq data, 230,923 putative active promoters and transcription start sites (TSS) states (H3K4me3), 627,454 active enhancer states (H3K27ac and H3K4me1), 659,150 repressive states (H3K27me3) and 409,062 insulators bound by CTCF were detected.

Discussion

Despite a greater number of genes harboring potentially novel transcripts that are expressed in purebred/neonate compared to composite breeds/juvenile and adult animals, it is difficult to claim if the greater number is driven by age and/or breed. However, our findings demonstrate the importance of having different ages, breeds/crosses and environments to build a comprehensive functional annotation of bovine genome. Our investigation of gene expression regulation by miRNAs, especially the novel ones, provides important biological knowledge to better understand bovine physiology.

The repertoire of miRNAs, piRNAs and piRNA clusters in the bovine germline was expanded. There is a lack of information about piRNAs in the bovine germline and their potential impact on gene expression regulation, which emphasises the importance of the new annotation information provided by BovReg.

The data presented here already represents a substantial improvement on the functional annotation of the bovine genome. An integrative approach with the *de novo* transcriptome map, chromatin states as well as TSS catalogue will provide additional evidence to support the novel genes, miRNAs and piRNA clusters detected.

The BovReg project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 815668.

546. European project AQUA-FAANG: the epigenetic landscape of the Atlantic Salmon; focus on liver tissue

M.-O. Baudement*, G.B. Gillard, T. Podgorniak, L. Grønvold, S. Lien and M.P. Kent

Centre for Integrative Genetics (CIGENE), Faculty of Biosciences, Norwegian University of Life Sciences, 1430 Ås, Norway; marie-odile.baudement@nmbu.no

Abstract

As part of the European project AQUA-FAANG, we produced a body map of the epigenetic and regulatory landscape of Atlantic salmon, spanning different tissues in both sexes and at two stages of maturity. For this purpose, we developed and applied refined protocols for Chromatin ImmunoPrecipitation assays (ChIP-seq) and Transposase-Accessible Chromatin assays (ATAC-seq), complemented with RNA sequencing (RNA-seq). Our design of combining epigenetic and gene expression data sourced from the same individuals provides detailed insights into genome regulatory mechanisms. We showcase results here by comparing regulatory differences between liver of both mature and immature male and female salmon. We identify that differential expression of genes is associated with chromatin histone modifications and/or accessibility dichotomy between sex or maturity.

Introduction

The European project AQUA-FAANG aims to describe genome regulation of the most commercially important fish species in European aquaculture with refined protocols, which in turn will promote a better understanding of the biology of these organisms to improve fish production, welfare and commercial product quality (description of the project available at: https://www.aqua-faang.eu).

As part of this project, we will perform an epigenetic and regulatory analysis across different tissues, sexes and maturity states of the Atlantic salmon. We sampled five tissues (liver, brain, gonad, muscle, gill) from three mature and three immature male and female individuals (12 fish total, 60 samples) to analyse histone modifications by ChIP-seq (H3K4me1, H3K4me3, H3K27ac, and H3K27me3), chromatin accessibility by ATAC-seq and RNA-seq for gene expression. We describe here our results from liver tissue as a proof of concept. We find examples of highly expressed genes (*GYS2*), gender specific expression (*lipocalin*) as well as differentially expressed genes related to maturity (*EVLA*, *nAChRα4*). Together, these results corroborate the high quality of the genomic information obtained through our protocols and analysis, and future ability to describe the epigenetic landscape.

Materials & methods

Dissection of Atlantic salmon. Fish were euthanised by an overdose of tricaine methanesulfonate and sexed. Tissues were dissected, snap-frozen and conserved at -80 °C.

Chromatin ImmunoPrecipitation assays. Tissues were dissociated by dounce homogenization and crosslinked with 1% formaldehyde. Glycine was added and material was washed and recovered by centrifugation. The nuclei were resuspended with sonication buffer containing 1% Sodium Dodecyl Sulfate. Sonicated material was purified by proteinase K treatment and columns, quantified by Qubit and fragmentation was assessed using a Bioanalyzer. Tubes containing fragments with expected size (200-700 base pairs; 350 median) was diluted and used for immunoprecipitation. Detailed protocol available at: NMBU_SOP_ChIP_protocol

DOI: 10.3920/978-90-8686-940-4_546, © M.-O. Baudement *et al.* 2022

Transposase-accessible chromatin assays. Tissues were dissociated by dounce homogeneization. Nuclei were recovered, exempt from mitochondria contamination, after slow centrifugation in iodixanol gradient and washing step. 50,000 purified nuclei were resuspended with reaction mix containing transposase (100 nM final). Transposed DNA was then cleaned-up, PCR-amplified and assessed using a Bioanalyzer. Detailed protocol available at: NMBU_SOP_ATAC_protocol

Gene expression assays. PolyA RNA was isolated and purified with RNAeasy kit from pieces of tissues conserved in RNAlater buffer. RNA quality was assessed using a Bioanalyzer and Nanodrop. Detailed protocol available at: NMBU_SOP_RNAextraction_protocol

Library preparation and library sequencing. ChIP libraries were prepared with the Microplex v3 kit from Diagenode. ATAC libraries were prepared with NEBNext Ultra II Q5 Mater mix of Illumina. PolyA RNA libraries were prepared with NEBNext Ultra directional RNA Library Preparation kit for Illumina. All libraries were sequenced with an Illumina NovaSeq 6000 (150 base pair, paired end reads).

Library alignment, quality assessment, peak-calling, differential analysis, and repository. Sequencing data was processed through relevant nf-core pipelines (available at: https://nf-co.re); chipseq, atacseq or rnaseq, to produce results for data quality, read alignments, peak annotations, and gene expression analysis. Libraries of satisfactory quality were submitted to ENA (project PRJEB47410). The latest Ensembl rapid release genome of the Atlantic Salmon (v3) was used for alignment and gene annotations (available at: Salmo_salar_GCA_905237065.2)

Results

Assessment of epigenetic data generated. In this project we have generated and sequenced more than 300 libraries for Atlantic salmon (ChIP, ATAC and RNA). We showcase here a subset of results obtained for liver. To assess if our adaptation of ChIP and ATAC methods for this fish species was reliable (Table 1). We evaluated the similarity of the different ChIP libraries (H3K4me3 and H3K27ac peaks) generated by calculating the Jaccard index (Figure 1A). We saw as expected a progressive reduction of correlation from replicates with the highest correlation to histone modification showing independency of signals, with intermediate correlation by sex or maturity. We saw a large proportion of ChIP peaks overlapping with genomic features as expected (Figure 1B), with a concentration surrounding gene promoters and the transcription start sites (TSS). We saw relatively less concentration of ATAC peaks within promoters.

Table 1. Metrics about ChIP-seq data generated for liver tissue.

Type of library	Number of libraries[1]	Average number of read pairs (millions)		Number of peaks detected (thousand)[2]
		sequenced	aligned	
ChIP-H3K4me3	8	57 (8 SD)	31 (5 SD)	29 (3 SD)
ChIP-H3K27ac	8	56 (7 SD)	30 (5 SD)	27 (10 SD)
ATAC	12	49 (8 SD)	24 (4 SD)	146 (25 SD)
RNA	12	32 (2 SD)	30 (2 SD)	-

[1] Two sexes × two maturity stages × two replicates for ChIP, or three replicates for ATAC and RNA.

[2] MACS2 narrow peak detection for H3K4me3 and H3K27ac, broad peak for ATAC.

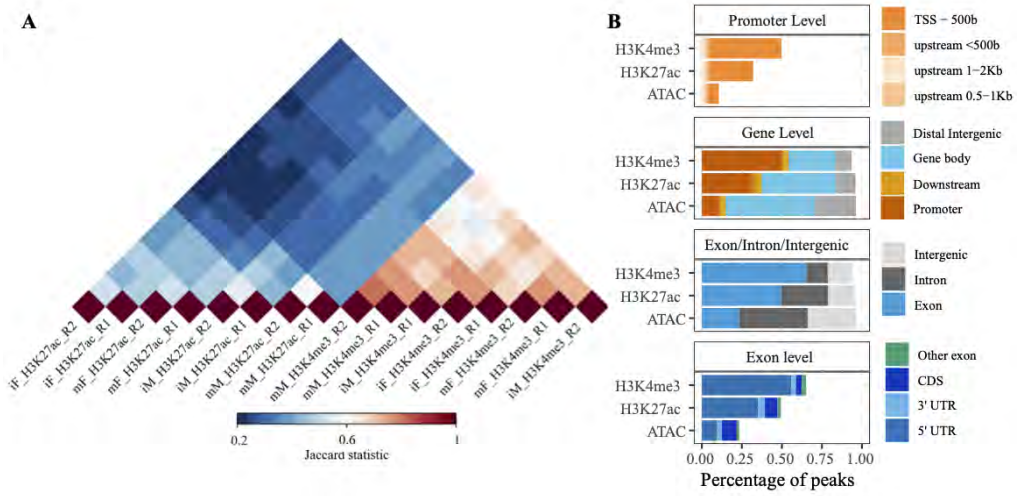

Figure 1. Assessment of peaks detected by ChIP and ATAC in liver. Similarity of peak datasets based on Jaccard statistics for two ChIP marks, H3K27ac and H3K4me3, across different liver libraries: immature female (iF), mature female (mF), immature male (iM), mature male (mM), and replicates (R1 and R2). B. Percentages of ChIP and ATAC peaks overlapping different genomic features.

Sex and maturity specific gene expression relate with chromatin environment. Differentially expressed genes (DEGs) between sex and/or maturity were identified (Figure 2). The chromatin state surrounding these DEGs was assessed by viewing H3K4me3, H3K27ac and ATAC peaks as tracks in a genome browser, alongside RNA expression levels. The gene *GYS2*, coding for a glycogen synthase, was found highly expressed in the liver of all individuals, in agreement with earlier studies in Masu salmon [Furukawa *et al.*, 2018] A gene coding for a lipocalin-like protein, suspected to be involved in sex(male) specificity in Tilapia [Shirak *et al.*, 2008] was found to be specifically expressed in males in our data. The gene *EVLA*, coding for Ena/Vasp protein is reported here has being expressed only in mature liver (independent of gender). EVLA has already been described to be involved in cytoskeleton remodelling (Ena) [Sechi and Wehland, 2004] and gluconeogenesis (vasodilator-stimulated phosphoprotein Vasp) (Tateya *et al.*, 2019), but a possible maturity-specific expression of this gene has not been reported previously. Lastly, a gene coding for a cholinergic receptor, nAChRα4, is presented here as being expressed specifically in immature individuals. Together, this first data exploration shows the high potential of better characterisation and new discoveries of genes potentially important for aquaculture.

Conclusions

We showcased here a first look at linking gene expression with the epigenetic landscape. Deeper exploration of this dataset will help to establish a better understanding of gene regulation of the salmonid genome as well as the discovery of new traits crucial for the sustainability of the fish industry for the coming years.

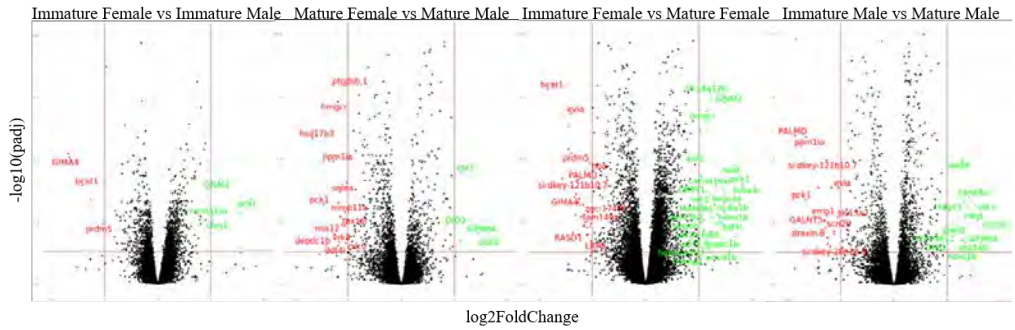

Figure 2. Differentially expressed genes in liver. Volcano plot highlighting genes highly differentially expressed between maturities or sexes in liver. Down-regulated (in red) and up-regulated genes (in green) between conditions are highlighted (FDR adjusted *P*-value<0.5 and absolute log2 fold change >5). For an overview, we display results within x and y limits up to an absolute value of 10.

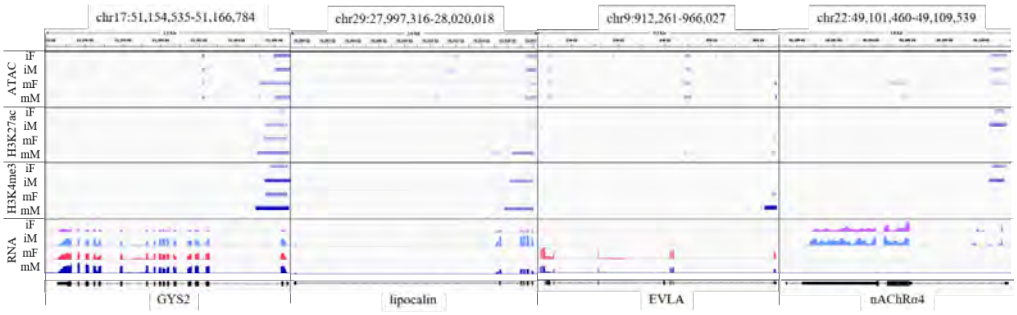

Figure 3. Epigenetic patterns of differentially expressed genes. Peaks from ChIP (H3K4me3, H3K27ac) and ATAC data are observed alongside RNA expression levels for select genes expression specificity: *GYS2* (no specificity), *lipocalin* (male-specific), *EVLA* (mature-specific) and *nAChRα4* (immature-specific).

Abstract

To investigate the roles of DNA methylation and gene expression during *Streptococcus uberis*-induced subclinical mastitis, the methylome and transcriptome profiles of milk somatic cells (MSC) from *S. uberis*-positive and control cows (n=3/group) were obtained by next-generation sequencing. Integration analysis between methylome and transcriptome profiles by MethGET revealed clear changes in the methylation levels of 585 promoters (pMeDEGs) and gene bodies of 424 genes (gbMeDEGs) in conjunction with gene expression changes (*P*-value<0.0005). The genes were significantly enriched in immune-related functions (antigen processing and cytokine activities). Applying the DIABLO method to pMeDEGs, the methylation status of 25 promoters and the expression of 10 genes were identified as candidate biomarkers as they were highly correlated and able to discriminate sick from healthy cows. Therefore, the integration analysis between the methylome and transcriptome profiles revealed important roles of pMeDEGs and gbMeDEGs in the host immune response to *S. uberis* infection, and the identified discriminant biomarkers could contribute to strategies for controlling *S. uberis-induced* mastitis.

Introduction

Subclinical mastitis is considered as one of the main challenges of the dairy industry. It is caused by different pathogens including *Streptococcus uberis*. Several investigations in the past decades have reported on the molecular mechanisms, and the genetic and epigenetic aspects of sub-clinical mastitis with aim to identify reliable biomarkers. DNA methylation, the most studied epigenetic mechanism, has been reported to play important regulatory roles in mammary gland health, including the development of mastitis due to *Staphyloccocus aureus* and *Escherichia coli* (Wang and Ibeagha-Awemu, 2020). However, the regulatory roles of DNA methylation during subclinical mastitis caused by *S. uberis* are not known. Therefore, this study profiled the global methylome and transcriptome of milk somatic cells from *S. uberis*-positive and control cows. Integration analysis of the methylome and transcriptome profiles was used to identify the methylome alterations that possibly caused changes in gene expression (transcriptome), their possible regulatory roles and candidate biomarkers that discriminate *S. uberis*-positive cows from healthy controls.

Materials & methods

Animals and samples. Two commercial farms (Quebec, Canada) were selected for the study. Cows with consistently very high (>350,000 cells/ml) or very low (<100,000 cell/ml) milk somatic cell counts (SCC) for three consecutive months were tested for the presence of mastitis pathogens. About 5 ml milk was collected per quarter of all selected cows and subjected to bacteriology (https://www.biovet-inc.com/). Cows positive for *S. uberis* only or negative for all mastitis pathogens were further selected. 200 ml milk was sampled from one quarter positive for *S. uberis* from each of three cows to constitute the test group. Similarly, 200 ml milk (composite of four quarters) was sampled from each of three cows to constitute the control group.

MSC were isolated immediately after milk collection by low speed centrifuge (1,500×*g* for 15 min at 4 °C), divided into two portions (TRIzol reagent added to the portion for RNA isolation) and stored at -80 °C.

DNA and RNA isolation, sequencing and bioinformatics analysis. Genomic DNA and total RNA were isolated from MSC by DNeasy Blood and Tissue Kit (Qiagen Inc., Toronto, ON, Canada) and RNeasy Mini Kit (Qiagen Inc., Toronto, ON, Canada), respectively. Purified DNA and RNA were subjected to whole-genome bisulfite sequencing (WGBS) and RNA-sequencing (RNA-Seq), respectively. Standard bioinformatics pipelines (methylseq and rnaseq) from nf-core (https://nf-co.re/methylseq/) were used to process the raw WGBS and RNA-Seq data. CpG sites or genes with at least 7 reads coverage were further analysed. MethGET software was used to correlate the methylome and transcriptome profiles (Teng *et al.*, 2020). Briefly, the DNA methylation status of the promoter (2 kb region upstream of the transcript start site) and gene body (exons and introns) of each gene were calculated per sample by averaging the methylation levels of all the CpG sites located in the corresponding regions. Then, the Gaussian Mixture Model (GMM) was incorporated to identify differential genes with DNA methylation alterations in their promoter regions (pMeDEG) or gene bodies (gbMeDEG) (P-value<0.0005 in GMM). Functional enrichment of methylated DEGs was done with ClusterProfiler (Wu *et al.*, 2021) and FDR<0.05 was considered as significant. Promoter methylation and gene expression values of pMeDEGs were then submitted to core DIABLO method from MixOmics R package to detect candidate biomarkers able to discriminate *S. uberis*-positive and control groups (Rohart *et al.*, 2017).

Results

Methylated differentially expressed genes and functional enrichment. A total of 585 pMeDEGs and 424 gbMeDEGs were identified (P<0.0005) by correlating gene expression and methylation status at the promoter (Figure 1A) or gene body, respectively. Merging pMeDEGs and gbMeDEGs revealed a total of 804 differentially expressed genes (MeDEGs), including 205 genes identified as both pMeDEGs and gbMeDEGs. Functional enrichment results were similar between pMeDEGs (2 GO and 14 KEGG pathways) and gbMeDEGs (1 GO and 20 KEGG pathways), with 11 commonly enriched KEGG pathways. However, functional annotations related to antigen processing (GO:0048002, GO:0019882 and bta04612) were only enriched by pMeDEGs. Meanwhile, more pathways with immune-related and disease functions were enriched by gbMeDEGs. Functional enrichment of MeDEGs indicated four biological processes GO terms (Figure 1B) and 28 KEGG pathways (Figure 1C), mostly having immune and disease related functions (Figure 2A,B).

Candidate biomarkers of S. uberis-induced mastitis. The application of DIABLO method to the promoter methylation and gene expression levels of pMeDEGs identified the methylation status of 25 promoters and the expression level of 10 genes as candidate biomarkers (Figure 2A). The *S. uberis*-positive and control groups were placed into two separate clusters, each with a corresponding set of candidate biomarkers (Figure 2B). Interestingly, both the promoter methylation and gene expression of *CCDC68* and *LOC112449619* were identified as candidate biomarkers. *CCDC68* was the second and third ranked promoter and gene biomarker, respectively. It should be noted that *FABP4* was enriched in inflammatory response (GO:0006954) GO term. Besides, *KLRC1,* a gene biomarker was enriched in three immune-related pathways, including antigen processing and presentation (bta04650), graft-versus-host disease(bta05332) and natural killer cell mediated cytotoxicity (bta04650).

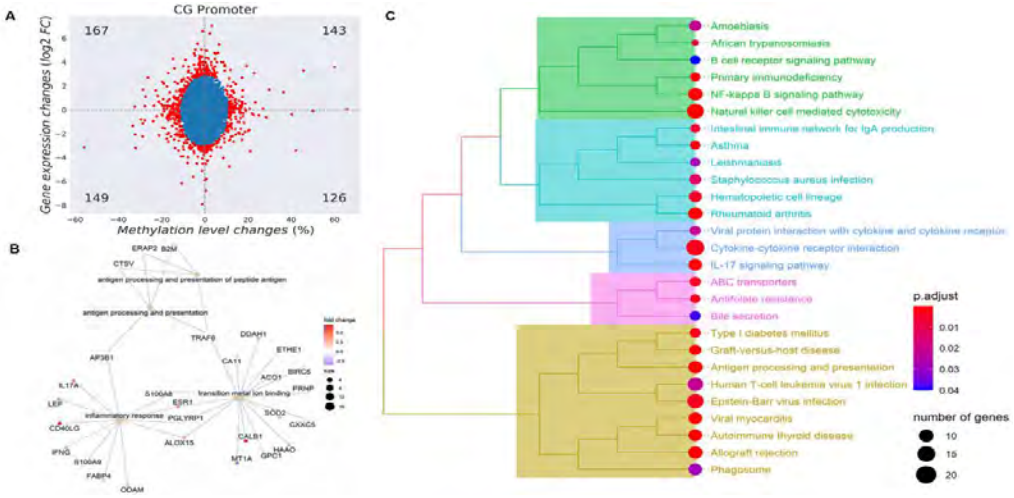

Figure 1. pMeDEGs and functional enrichment of MeDEGs. (A) Scatter plot showing changes in promoter DNA methylation and gene expression of pMeDEGs. (B) Enriched GO terms for MeDEGs showing interactions between genes. (C) Tree plot showing clusters of KEGG pathways enriched by MeDEGs.

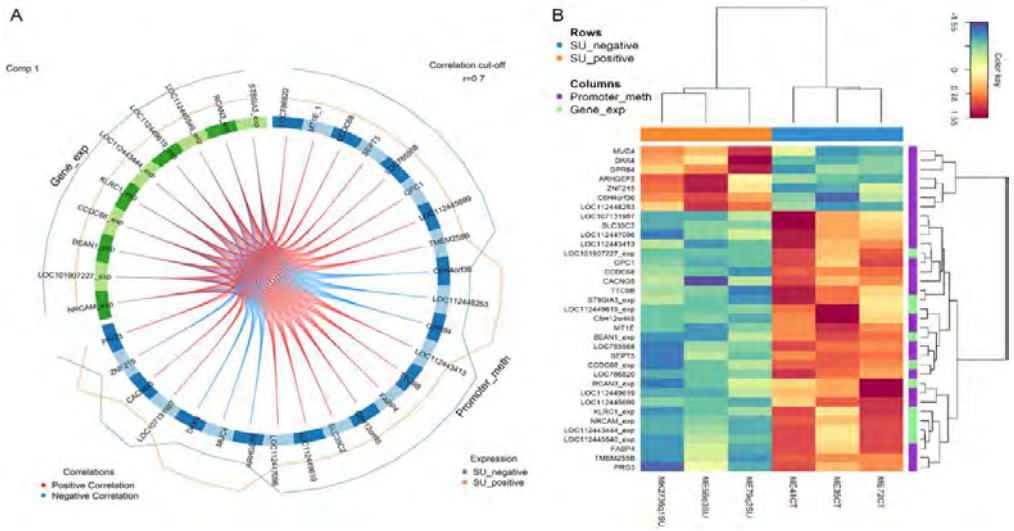

Figure 2. Candidate biomarkers distinguishing cows with *S. uberis*-induced subclinical mastitis from healthy controls. (A) The correlation between candidate biomarkers including the methylation status of 25 promoters (Blue) and the expression level of 10 genes (Green). (B) Plot showing two candidate biomarker clusters. Gene names with the extension '_exp' are gene biomarkers showing expression levels in corresponding rows, while others are promoter biomarkers showing promoter methylation status.

Discussion

Integration analysis between the global methylome and transcriptome profiles of milk somatic cells from *S. uberis*-positive and control cows revealed a total of 804 MeDEGs between the two groups. These MeDEGs with clear DNA methylation alterations in either promoters or gene bodies with associated gene expression changes gives clarity on the effects of DNA methylation changes on corresponding genes compared with consideration of DNA methylation alterations only. The functional enrichment of MeDEGs revealed their potential involvement in immune processes (Figure 1B,C), such as antigen processes, cytokine activities, and singling pathways of immune cells (B cell, T cell and natural killer cells), thereby highlighting the potential regulatory roles of DNA methylation alterations in the host immune response to *S. uberis*-induced mastitis. It also revealed the enrichment of key MeDEGs such as *IFNG*, *IL17A*, *CXCL2, etc.,* in multiple immune related pathways.

DNA methylation biomarkers intermediate environmental factors (exposome) and host genetics, and brings additional layer of information for exploring the unexplained portion of phenotypic variance in livestock traits (Ibeagha-Awemu and Yu, 2021). Compared to most studies which identify biomarkers independently from various types of data, this study incorporated the DIABLO discriminant analysis method to integrate the methylome and transcriptome datasets of the same samples and to identify highly correlated candidate biomarkers, including the methylation status of 25 promoters and the expression levels of 10 genes. The promoter methylation status and gene expression level of *CCDC68* and *LOC112449619* genes were both identified as candidate biomarkers. Furthermore, the promoter methylation status of CCDC68 was highly and significantly correlated with its gene expression level. *CCDC68* proteins are known to participate in a variety of regulatory functions associated with the development and evolution of various malignant tumors (Li *et al.*, 2021), suggesting potential roles in immune processes during *S. uberis* mastitis. To the best of our knowledge, this is the first association of methylated *CCDC68* gene with bovine mastitis, and deserves further investigation. Further candidate biomarkers (*FABP4*, *GPC1*, *KLRC1* and *NRCAM*) enriched in immune activities, emphasize their potential involvement in the host response to *S. uberis* infection. Therefore, the identified candidate discriminant biomarkers could support the development of management programs for mastitis control or breeding for mastitis resistance. However, confirmation of our results in a bigger population is necessary before application of the reported biomarkers for mastitis management due to the limited sample size of the current study and the possible effects of genetic variation on DNA methylation alterations not accounted for.

548. eQTL mapping in Brown Swiss bulls to identify variants associated with male fertility

X.M. Mapel*, M. Hiltpold, A. Lloret-Villas and H. Pausch

Animal Genomics, ETH Zürich, Universitätstrasse 2, 8092 Zürich, Switzerland; xenamarie.mapel@usys.ethz.ch

Abstract

Fertility is an essential component of the livestock industry. In cattle, numerous QTL for male reproductive success fall within regulatory regions. However, the effects of these loci have not been investigated in detail or on a large scale. Here, we assemble a sizeable cohort of mature bulls to detect expression quantitative trait loci (eQTL) and assess their effects on fertility-related genes. To do this, we sequenced genomes and total RNA from the testes of 72 bulls. We recovered 13,185,795 DNA sequence variants with minor allele frequency >5%, an average of 283,587,831 clean RNA reads per sample and 18,528 testis-expressed genes (TPM>0.2 in 75% of samples). In total, 2,178 genes had significant *cis*-eQTL at a false discovery rate of 5% (11.76% of expressed genes). Several genes associated with fertility, including *SPATA4* and *SPATA22* (which are responsible for reproductive processes), had significant *cis*-eQTL and variation in transcript abundance across genotypes.

Introduction

Efficient breeding operations require animals with consistent and reliable reproductive success. Artificial insemination centres often collect hundreds of ejaculates from a single bull which are then sold to a multitude of producers. Thus, bulls with impaired or complete loss of reproductive ability can be costly to both parties. The genetic basis of such subfertility is complex. Indeed, quantitative trait loci (QTL) associated with measures of male reproductive success have been identified in several breeds at varying frequencies (Hiltpold *et al.* 2020; Sweett *et al.* 2020). Further insight into these QTL and detection of additional expression QTL (eQTL) that impact the abundance of fertility-related genes can help producers select breeding bulls with high reproductive ability.

Complex traits – such as those associated with semen quality and male reproductive success – are influenced by a multitude of polymorphic sites, with many of those residing in regulatory regions (Xiang *et al.* 2019). For example, a QTL associated with sire non-return rate has been identified in a region that possibly regulates the expression of *SPATA16* (Hiltpold *et al.* 2021), a gene involved with spermatogenesis. Previously, testis eQTL were identified by the cGTEx consortium (https://cgtex.roslin.ed.ac.uk/). However, this dataset relied on samples that were collected at different points of time from various bovine sub-species and breeds and did not investigate the specific effects of testis eQTL. A uniform cohort with an abundance of sequence data would identify additional eQTL and enable the exploration of their effect on reproductive ability.

Here, we harness a cohort of Braunvieh (BV) bulls to identify *cis*-acting eQTL in male reproductive tissue and assess their effect on genes vital for reproduction. To do this, we relied on whole-genome sequence data and total RNA from the testis tissue of 72 bulls.

Materials & methods

Sampling, extraction, sequencing. We sampled testis tissue from 72 bulls (between 8 and 34 months of age) with various degrees of BV ancestry (i.e. Brown Swiss, Original BV, or a cross between one of these and a different breed). After regular slaughter, tissue was flash frozen with liquid nitrogen and kept at -80 °C until DNA and RNA extraction. Frozen testis tissue was homogenized with a Roche MagNA Lyser in 2M DTT

and RTL Buffer (QIAGEN). DNA and total RNA were extracted simultaneously with the Qiagen AllPrep Mini Kit (QIAGEN) following manufacture protocols. DNA concentration and quality was assessed with a Qubit 2.0 fluorometer (ThermoFisher) and RNA integrity was quantified with a RNA integrity number (RIN) inferred from a Bioanalyzer RNA 600 Nano assay (Agilent Tech.). Genomic libraries (paired-end, 150 bp) were sequenced on the Illumina NovaSeq6000. Total RNA libraries (paired-end, 150 bp) were prepared with the Illumina Stranded Total RNA kit and Illumina Ribo-Zero Plus, then sequenced with the Illumina NovaSeq6000. Library preparation and sequencing was conducted by the Function Genomic Centre Zurich.

DNA sequence data. We used fastp (v0.19.4; Chen *et al.* 2018) with default parameters to remove adapter sequences and low-quality bases, and trim poly-G tails from raw DNA sequence data. After quality control, between 70,493,763 and 307,416,205 reads per sample were aligned to the ARS-UCD1.2 reference genome (Rosen *et al.* 2020) with the mem-algorithm from BWA (v0.717; Li 2013) and the -M flag. We used Sambamba (v0.2.2; Tarasov *et al.* 2015) to sort the aligned reads by coordinates, then combined the read-group specific BAM files to create sample specific sorted BAM files. The MarkDuplicates module from Picard tools (https://broadinstitute.github.io/picard/) was used to mark duplicated reads in the merged and coordinate sorted BAM files. We used mosdepth (v0.2.2; Pedersen and Quinlan 2018) to infer the sequencing coverage at a given genomic position, which was then used to estimate the average coverage per sample and chromosome. Only high-quality reads (mapping quality >10 or without SAM flag 1796) were considered when calculating the average coverage. We called sequence variants for the 72 samples with 24 additional samples from multiple breeds (Brown Swiss=6, Fleckvieh=1, Holstein=7, Original BV=5 Simmental=5), totalling to 96 samples. SNPs and indels were genotyped with the multi-sample variant discovery approach from the Haplotype Caller, Genomics DBImport and GenotypeGVCFs modules in GATK (McKenna *et al.*, 2010). We filtered variants according to GATK's best-practice guidelines. PLINK (v1.9; Purcell 2007) was used to produce a genomic relationship matrix (GRM) for 72 bulls and was constructed with variant genotypes that had minor allele frequency (MAF) >0.5%.

RNA sequence data. We used fastp to remove and trim low-quality bases, adapter sequences, poly-A tails and poly-G tails from the raw RNA sequence data. Filtered reads were aligned to the Ensembl gene annotation (release 104) for cattle with STAR (v2.7.9a; Dobin *et al.* 2013) using the recommended default parameters. This resulted in between 191,160,837 and 386,773,085 clean reads per sample (mean: 283,587,831±43,284,185). Gene abundance, quantified as transcripts per million (TPM), was calculated with the QTLtools 'quan' function with the --filter-mapping-quality and --filter-failed-qc flags to ignore low-quality reads (v1.3.1; Delaneau *et al.* 2017). Reads were mapped to 27,270 coding and non-coding genes from the most-recent Ensembl gene annotation for cattle.

eQTL analysis. We used QTLtools to identify *cis*-acting eQTL for testis expressed genes. Considering our small sample size, we filtered genomic variants to only include genotypes with MAF >5% in the 72 samples. We filtered the TPM matrix to only contain genes that had expression >0.2 TPM in 75% of samples. Age of the bull, RIN value, mass of the sampled testis, season of sampling and the first ten PCs of the GRM (to account for relatedness) were included as covariates for eQTL mapping. We used the *cis* function to identify eQTL within 1 Mb of the transcription start site (TSS) and implemented the --normal flag to rank-normal transform the gene counts, then performed 1000 permutations to infer beta-approximated *P*-values. To identify independent-acting loci and account for multiple testing, we calculated 5% false discover rate (FDR) and used the conditional mode in QTLtools. Allelic fold change (aFC) was calculated for variants of interest with methods described in Mohammadi *et al.* (2017).

Results & discussion

The 72 genomes had moderate sequence depth, which ranged from 6.66 to 27.94 (mean=12.84±4.23). Variant calling identified 20,401,236 variants with MAF>0.5% and 13,185,795 variants with MAF>5.0%. We detected 18,528 genes expressed with >0.2 TPM in 75% of samples.

Of the 18,528 expressed genes considered, 2,178 had at least one significant eVariant (11.76% of testis expressed genes; Figure 1). Each gene's top eVariant was often within 100 kb of the TSS (1,438 variants; 66.0%) and the average distance from the most-significant variant to the TSS was 149,656±229,236 bp (median: 40,824 bp). The number of genes with significant eQTL varied chromosome-by-chromosome (Figure 1B), with BTA18 having the most (165 genes with at least one eQTL). We detected 466,573 significant variants total (using 5% FDR), which is similar to the number of splice-site associated variants in the same cohort of bulls (over 495,000 sQTL; Kadri *et al.* 2021). The conditional analysis revealed that 86 genes had two independently acting eQTL (4.0% of genes with eQTL, 0.5% of all testis expressed genes). We identified more genes with significant *cis*-eQTL than the cGTEx consortium (cGTEx: 809 expressed genes with *cis*-eQTL in bovine testis), which is likely due to our larger sample size, deeper RNA sequencing coverage and more-uniform dataset.

Several genes that are associated with crucial male reproductive processes had *cis*-eQTL. For example, we detected *cis*-eQTL for two genes from the *SPATA* gene family – a gene-set responsible for spermatogenesis and fertilization (Figure 1a; Table 1). Expression of *SPATA4* was associated with a QTL on BTA27 (lead variant: G>A; position 7,704,939; adjusted P=1.51×10^{-9}) while expression of *SPATA22* was associated with a QTL on BTA19 (lead variant: C>T position 24,111,667; adjusted P=7.61×10^{-7}). Lead variants for both eQTL demonstrated additive effects: the abundance of each gene decreased in animals that carried the alternate allele, with an aFC of -0.24 and -0.36 for *SPATA22* and *SPATA4*, respectively (Figure 2). Abnormalities in *SPATA22* and *SPATA4* have been linked to infertility in multiple species (Ishishita 2013; Sujit 2019). Both genes were present in cGTEx, however they did not identify proximal eQTL. Future analyses will further inform if, and how, these and similar eQTL impact male reproductive ability in cattle.

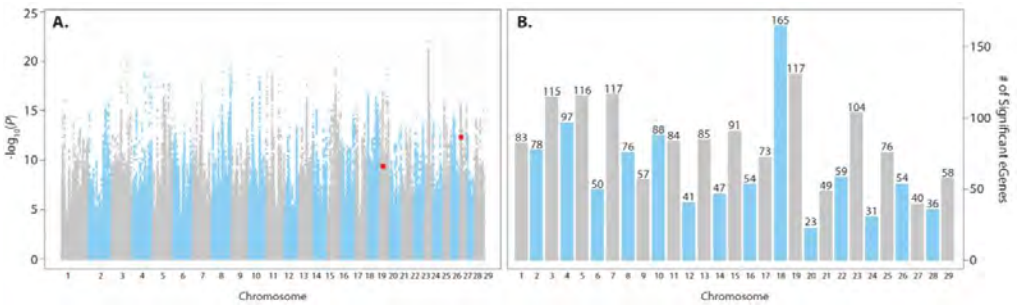

Figure 1. (A) Manhattan plot of genome-wide *cis*-eQTL with lead eVariants for *SPATA22* (chromosome 19) and *SPATA4* (chromosome 27) in red. (B) Number of testis-expressed genes with significant *cis*-eQTL per chromosome.

Table 1. Lead significant eVariants for *SPATA4* and *SPATA22*.

Gene	Position	# Variants in *Cis* window	aFC	Nominal *P*-value	Adjusted β *P*-value
SPATA4	27_7704939	16,450	-0.36	4.74×10^{-13}	1.51×10^{-9}
SPATA22	19_24111667	15,736	-0.24	3.99×10^{-10}	7.61×10^{-7}

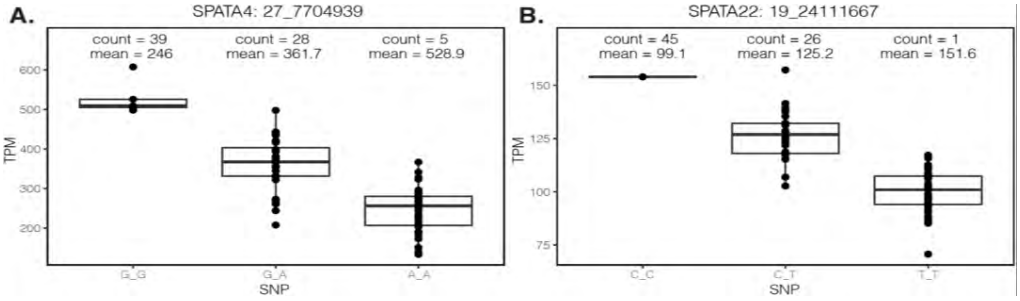

Figure 2. Abundance of *SPATA4* (A) and *SPATA22* (B) for different eVariant genotypes.

Conclusions

Here, we report the first analysis of a testis eQTL study in bulls and identify a large number of eQTL that warrant further investigation. Testing for *trans*-eQTL can uncover additional variants of interest. Furthermore, transcriptome-wide association analyses may help prioritize variants that are associated with variation in male reproduction.

Abstract

The *in silico* detection of expression quantitative trait loci (eQTL) demands high throughput processing from hundreds of samples, which is often a challenge to handle and run such large datasets. In order to focus on the core analysis, it is convenient to have simple coding and hassle-free installation of different software tools required for the bioinformatics workflow. In this context, the newly available technologies like workflow managers and software containers enabled to develop workflows with less complexity. In this study, we developed an eQTL bioinformatics pipeline with the workflow manager Nextflow and docker container software, for coding and installing the required software tools. This workflow can be portable to a different computer environment, and the results are reproducible. We tested the functionality of our workflow with a sample dataset and the runtime estimates from this demo run will provide important information in planning future analyses with much larger datasets.

Introduction

In recent years, large, cost-effectively sequenced transcriptome (RNA-Seq) and whole genome (WGS) data sets enabled association studies with gene expression as phenotype. These eQTL association studies identify the transcriptomic regulation at a genome wide scale by mapping the expression phenotype to a region on the genome (Gilad *et al.* 2008; Majewski and Pastinen 2011). The eQTL phenotype can be gene, transcript, exon expression or alternative splicing events. After high throughput sequencing, the main challenge in eQTL detection is to handle and process the large amount of generated data. When the data size is small (few gigabytes), it is convenient to implement the bioinformatics workflow with a simple computational script. However, things get complicated when dealing with large data especially in studies like eQTL, where generally thousands of RNA-Seq and WGS samples were analysed. In addition, it is not always possible to install multiple bioinformatics tools with different system requirements on a server maintained by an organization with centralized information technology support. Thus, to run such complex bioinformatics pipelines it is convenient to have a simple syntax declaration for calling the input data, executing the process and standard guidelines for installing all the required software tools. In this context, the concept of workflow managers and containers comes into play. Compared to traditional computational scripts used for bioinformatics workflows, the scripts developed using workflow managers are portable and reproducible on multiple server platforms. The most popular workflow managers for implementing bioinformatics pipelines are Snakemake (Molder *et al.* 2021) and Nextflow (Di Tommaso *et al.* 2017) among others. They use domain specific languages (DSLs), which have simple commands to run complex workflows, and the installation of all required software tools was standardised by using an open source package and environment systems like Conda (Anonymous 2020) or by container software with complete runtime environment like docker (Merkel 2014) or singularity (Kurtzer *et al.* 2017).

Materials & methods

In this current study, we used Nextflow_v21.04.1.5556 DSL2 for developing the workflow for eQTL detection in the bovine genome. Each step in the workflow was defined as an independent entity called 'Process' and they communicate with other process via input and output components called 'Channel'. In

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_549, © P.K. Chitneedi *et al.* 2022

the Nextflow DSL2, different processes can be written on separate files called 'Modules' independent of the main workflow script, which offers more flexibility to write complex workflows. All the required software to run the workflow were installed using the container software docker_v20.10.8, build 3967b7d. The docker environment was enabled for Nextflow by declaring in a configuration file 'nextflow.config'. In order to make the workflow easy to understand and troubleshoot potential errors, we divided the eQTL workflow into four NextFlow scripts as shown in Figure 1. Each script was further divided into individual modules, which perform a specific task within the workflow. In NextFlow DSL2, these modules were defined as individual entities, and they were invoked in the main script.

Script 0: Bovine genome STAR index. As a pre requisite to perform alignment using STAR (Dobin *et al.* 2013), it is required to perform the indexing of a reference genome, which was used repeatedly for aligning multiple samples. We built the STAR index for the latest bovine genome ARS-UCD1.2 and Ensembl annotation v102 using the STAR command '--runMode genomeGenerate'.

Script 1: RNA-Seq mapping and quantification of expression counts. Quality control and trimming of reads from samples with paired-end reads was carried out with FASTQC (http://www.bioinformaticsbabraham.ac.uk/projects/fastqc/) and trimmomatic v_0.36 (Bolger *et al.* 2014). The cleaned paired reads of each sample were forwarded to alignment using STAR_v2.7.0d. For the gene and transcript level counts, the reads were sorted by coordinates and for detecting splice junctions the reads were unsorted and we used '--outSAMstrandField intronMotif ' to determine the read origin either from intron or from splice junction. Using the StringTie_v1.3.3 (Pertea *et al.* 2015) assembler, we carried out the quantification and normalization at gene and transcript level, and where appropriate the strandedness of the RNA-Seq library was addressed with the StringTie options --rf for the first and --fr for the second stranded libraries. For detecting splice junctions the unsorted reads were indexed and sorted using Samtools_v1.9-4 and then exon-exon junctions were extracted from these bam files using regtools_v0.6.0 (Cotto *et al.* 2021) 'junctions extract', which was followed by clustering of introns found in the junction files to generate an across sample expression count matrix per each chromosome. Using leafcutter_v0.2.9 (Li *et al.* 2018) we estimated the top ten principal components (PCs). The count matrices and PCs were used in the model to detect splice eQTL in script 3.

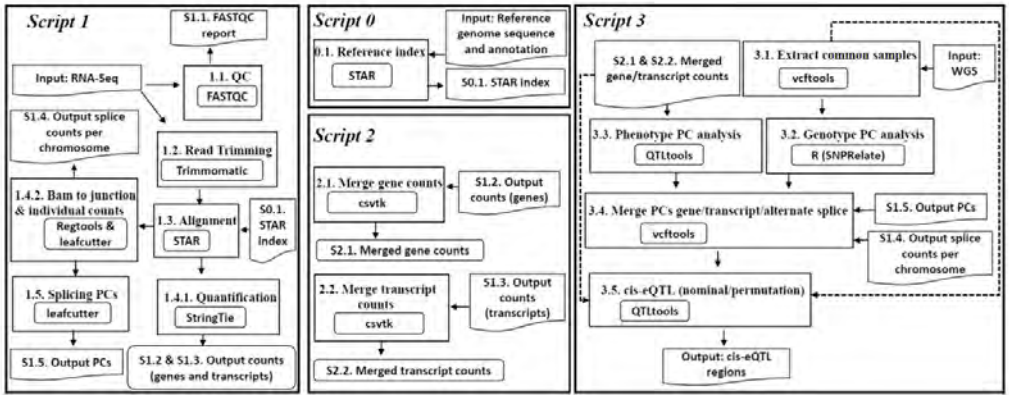

Figure 1. Diagrammatic representation of Bioinformatics workflow for eQTL detection designed using Nextflow DSL2. Each block represents individual scripts with different modules, input and output data flow.

Script 2: Merging count matrices at gene level and transcript level. After StringTie quantification, the output read count files are stored as .tsv (gene level) and .gtf (transcript level) output files. The TPM normalized expression counts of each sample at gene and transcript level were merged into matrix tables using csvtk --merge (https://bioinf.shenwei.me/csvtk/usage/). These tables were provided as input files to script 3 for the detection of eQTL.

Script 3: Estimating genotype and phenotype covariates and eQTL detection. The eQTL mapping was carried out with QTLtools_v1.3 (Delaneau *et al.* 2017). It expects three input files for mapping, genotype data in VCF format, phenotype data in .bed format and the principal components (PCs) as covariates. The input genotype data was filtered for the samples common to the phenotype input. Additionally, we filtered out the SNPs with minor allele frequency less 0.05. The population stratification present due to systematic ancestry differences in the data set was addressed by performing a PC analysis with genotype input using the R package SNPRelate (Zheng *et al.* 2012). Similarly, to address the outlier samples and batch effects in the RNA-Seq data at gene and transcript level, a phenotype PC analysis was performed with the QTLtools 'pca' command. For the eQTL mapping, the covariates include the top ten genotype PCs and top ten phenotype PCs. Finally, the nominal cis-eQTL mapping was carried out by QTLtools with the parameter --nominal 0.01, which provides as output only phenotype-variant pairs with a nominal *P*-value below 0.01, and the parameter --normal enforced the phenotypes to match a normal distribution N(0,1). In order to obtain the adjusted *P*-value for the cis associated phenotype and top variants, we performed permutation based QTL mapping also using QTLtools with the parameters --normal and --permute 1000.

Results & discussion

We developed this eQTL workflow with the primary goal of eQTL detection in the BovReg (https://www.bovreg.eu/) project with RNA-Seq phenotype and WGS data. To check the functionality of this eQTL workflow, we tested the workflow with 88 bovine liver RNA-Seq and the corresponding WGS data. The analysis was ran on Intel(R) Xeon(R) @ 2.10GHz server with 144 CPUs, 18 cores and 1TB RAM memory. Tests with a simple dataset will give an idea of how much runtime is required and potential pitfalls to consider, when running this workflow with much larger sample size. For the current test run, the WGS include 19,590,389 bi-allelic, polymorphic (MAF>0.005) variants across 29 autosomal chromosome, which were imputed using a stepwise strategy from 6k to 50k to HD to WGS (Pausch *et al.* 2016) with a mean imputation accuracy of 0.97 across different steps. The RNA-Seq samples consist of paired end libraries sequenced on the Illumina HiSeq 2500 system (Nolte *et al.* 2019; Heimes *et al.* 2020). The average number of input reads across 88 RNA samples were 56 million read pairs varying between 43 to 74 million read pairs. Although for this demo we used only paired-end reads, this pipeline will also work for single-read RNA-samples. The eQTL mapping will be carried out per chromosome by taking the WGS data for each chromosome for each iteration. By providing the configuration file and the scripts, this workflow can be portable, the analysis can reproducible on any Nextflow and docker installed computer. When executing the scripts the Nextflow installs all the required tools and users just have to take care of declaring the correct paths of input data. The Nextflow stores all log files and output data in a directory named as 'work'. This workflow was designed to copy all the important results from each step in a separate directory path. To run a workflow with large samples requires a rough estimation of runtime on a given computer infrastructure, as it takes few days to months to finish the analyses for large sample sizes. Thus, with the current demo of our eQTL workflow, we also checked the average runtime for 88 RNA-samples in the different processes on our local server. The alignment is the most time consuming process and took 108 hours for aligning all the 88 samples, while the runtime of the other processes in Script 1 varied from 1 to 10 hours. The runtime for Script 2 was just 2 minutes 41seconds, this was expected as this script only merges the available count information of different samples into a table. The final Script 3 with the PC analysis, QTL mapping and permutation across different levels (gene, transcript and splicing events) completed in 2 hours 28 min. This

runtime estimates provided us with valuable information to plan future analyses with higher sample size. Although this workflow was analysed using bovine datasets it can used for detecting eQTL in other species. In the future, the iteration of this workflow also includes allele specific expression and detection of trans-eQTL across different bovine tissues.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 815668.

Abstract

The global Functional Annotation of Farm Animal Genomes initiative (FAANG) aims to improve animal breeding by improved genomic prediction via integration of functional genomics information. The GENE-SWitCH project has produced extensive functional genomics information for a variety of important tissues at early embryonic timepoints for both chickens and pigs. These datasets will be integrated to produce both tissue and time-point specific transcript, gene, and regulatory annotation for both species. In this paper, we describe the aims of the project, and the initial release of both raw and processed data.

Introduction

Genome annotation is often presented in a static, linear, fashion, as a set of genes, transcripts and regulatory regions which exist on the genome. However, we know that gene, transcript, and regulatory regions differ in both a time- and tissue- specific manner, hence current genome annotation data sets may miss important temporal and tissue-specific differences in the expression and use of functional genomic regions, and these regions may underlie key traits in livestock species. Addition of functional genomics information is therefore expected to improve animal breeding through improved genomic prediction (Andersson *et al.* 2015, Clark *et al.* 2020).

'The regulatory GENomE of SWine and CHicken: functional annotation during development (GENE-SWitCH)' project contributes to the global FAANG initiative and to EuroFAANG (https://eurofaang.eu), a synergy of five Horizon 2020 projects that share the common goal to discover links between genotype to phenotype in farmed animals and meet global FAANG objectives. A core activity of GENE-SWitCH is to generate extensive functional genomics information for key tissues during early development of both chickens and pigs, with the overall aim of improving genomic selection via more accurate genomic prediction using models that incorporate knowledge of functional regions of the genome.

Tissue- and time-point specific genome annotations are generated by standardized approaches (sampling, functional assays and analyses) to identify genes (coding and non-coding), transcripts, and regulatory sequences.

This paper constitutes a 'marker' paper of GENE-SWitCH in the context of the Toronto Statement on Pre-Publication Sharing (Toronto International Data Release Workshop Authors *et al.* 2009) in which we describe our plans for the first use of these data for genome-wide analyses and publication.

Materials & methods

Animals, tissues, time-points. Post-mortem samples were harvested from embryos (chicken: E8, E15; pig: 30, 70 days post-fertilisation) to capture early and late organogenesis; and from new born/hatched piglets and chicks. Large White pigs, that are one of the most widely used commercial pigs, were used. The chickens were from the Roslin broiler line.

Seven different tissues (liver, small intestine, kidney, lung, hindlimb muscle, brain, skin) were chosen to represent the three layers of embryonic and fetal development (endoderm, mesoderm, ectoderm) and the physiological functions of most relevance for the further integration in genomic prediction models.

Tissues and developmental stages were chosen to complement those being characterised in complementary USDA-funded chicken and pig projects, minimising duplication, whilst including some element of replication. Links to the data and metadata for all samples are available at https://data.faang.org/projects/GENE-SWitCH

Functional genomic assays. The samples have been processed to yield chromatin, DNA and RNA for the following assays: Promoter Capture Hi-C, ATAC-seq, methylation profiling by whole genome and reduced-representation bisulphite sequencing, long read RNA sequencing using Pacific BioSciences (PacBio) Iso-Seq, RNA-seq (poly-A+), small RNA-seq, and chromatin immunoprecipitation sequencing (ChIP-seq) for sequences bound by modified histones (H3K4me1, H3K4me3, H3K27Ac and H3K27me3) and CTCF. Analyses of the sequence data from these assays will allow us to identify open chromatin indicative of active elements of the genome and key regulatory elements including promoters and enhancers as well as a more comprehensive view of the chicken and porcine transcriptomes and their dynamics during development.

Pipelines of analysis. As a basis for bioinformatics analysis of the GENE-SWitCH data, the nf-core pipelines have been adopted (Ewels *et al.* 2020). In the case of RNA-Seq, a GENE-SWitCH specific pipeline has been developed, TAGADA, which has additional features, in particular annotation of long non-coding RNAs. For DNA methylation analysis an extension of the nf-core/methylseq pipeline (GSM), including downstream analysis, was developed. In the case of IsoSeq data, an nf-core pipeline did not exist, therefore an IsoSeq pipeline has been developed and will be submitted to nf-core. All GENE-SWitCH bioinformatics pipelines are available on the FAANG github page: https://github.com/orgs/FAANG/.

Results

The data production phase of the project is almost complete with the generation of ChIP-seq data due for completion in Spring 2022. The sequence data have been deposited in the public domain sequence databases in accordance with the FAANG Data Sharing guidelines (https://www.faang.org/data-share-principle). These data are indexed on the GENE-SWitCH project pages in the FAANG Data Portal (https://data.faang.org/projects/GENE-SWitCH). Only those assays which have been completed are listed below.

RNA-Seq data. RNA-Seq reads have been used to identify and quantify expression of both known and novel transcripts and genes. The vast majority of the known reference genes (73.1% for pig and 81.5% for chicken) and transcripts (72.0% for pig and 78.8% for chicken) are expressed (TPM≥0.1) in at least one sample. In terms of novel genes, we predict an additional 2,103 for pig and 1,642 for chicken. Meanwhile, there are two to three times as many nc transcripts in the novel gene annotation as in the reference gene annotation (+92% for pig and +192% for chicken). From the novel annotation spliced transcripts, 8.9 and 22.1% extend a reference transcript by adding at least one exon in 5' or 3' for pig and chicken respectively, and 34.2 and 41.8% represent completely novel spliced transcripts. Around 15,000 transcripts are predicted as lncRNAs in the two species, of which the majority (around 70%) are intergenic.

The hierarchical clustering based on reference gene expression for pig can be seen in Figure 1. Samples cluster first by tissue for cerebellum, kidney and liver while for lung, ileum, muscle and skin, this is the developmental stage which is the main criterion for clustering, especially for the earliest stage.

IsoSeq data. IsoSeq is a method which uses PacBio sequencing to produce high quality, full length transcript sequences. In the GENE-SWitCH project, samples were pooled across individuals to produce one IsoSeq dataset per tissue, time-point and species (42 datasets). At the point of submission, IsoSeq data is only available for chicken, and IsoSeq has previously been applied to chicken tissues by Kuo *et al.* (2017) providing a useful comparator. An initial annotation for chicken using the IsoSeq data has been produced using standard IsoSeq filtering and clustering techniques, chimera removal, and removal of low confidence annotations. The number of detected transcripts is four times higher than in the Ensembl v105 annotation, and 2.5 times higher than in Kuo *et al.* (2017). The number of detected genes is similar to Ensembl v105 (Ensembl 24,356, GENE-SWitCH 24,152), however, the GENE-SWitCH IsoSeq annotation predicts 6,865 potential new genes.

Small RNA-Seq data. Between 30 and 120 million reads were sequenced per sample. Out of those, a median of 57.6% for pig and 45.0% for chicken could be mapped to mirBase mature miRNAs. From the remaining reads, a median of 39.0% reads for pig and 53.5% reads for chicken could be mapped to mirBase hairpin miRNAs. Similar to RNA-Seq, hierarchical clustering based on miRBase mature miRNA normalized expression led to a clustering by tissue (results not shown). As for miRNA discovery, 6,012 and 9,905 miRNAs were detected for pig and chicken, of which 4,873 (81.1%) and 8,124 (82.0%) were predicted as novel.

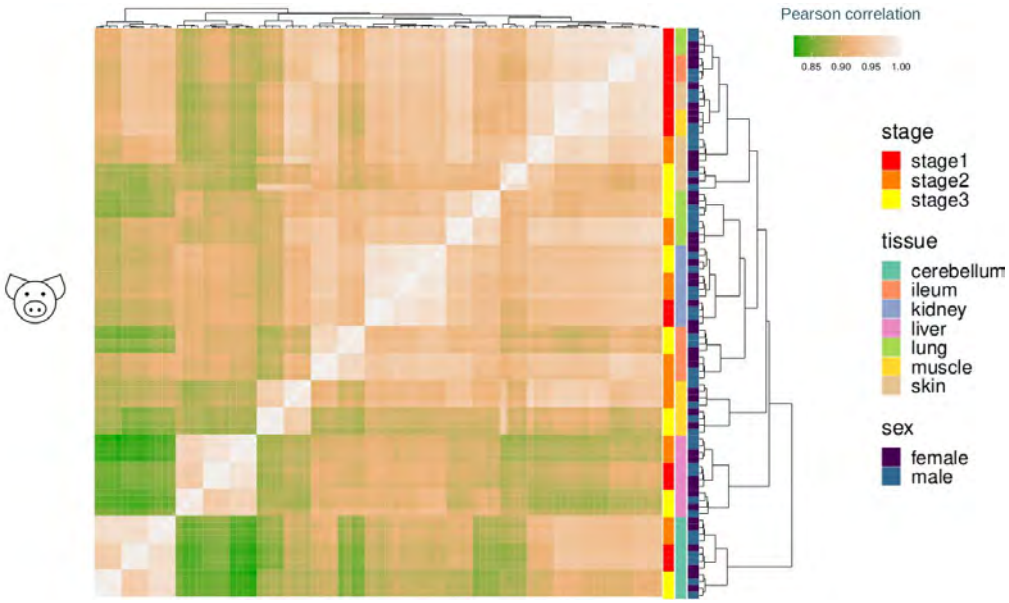

Figure 1. Hierarchical clustering of RNA-Seq data for pig. Hierarchical clustering of pig RNA-Seq data demonstrates that, as expected, samples largely cluster first by tissue, and then by developmental stage.

Bisulfite sequencing. Reduced-representation bisulfite sequencing was performed on 63 samples, and the remaining 21 samples were submitted for whole-genome bisulfite sequencing. Quality of all samples as well as mapping rates for both pig and chicken were very high. Clustering analysis of the samples provides insight into the development of the tissues, where we observe both tissue- and time-point- specific clustering in both species (results not shown).

Discussion

Functional genomics data is hypothesized to improve animal breeding by enabling more accurate genomic prediction, and a core aim of the GENE-SWitCH project is to produce extensive functional and regulatory genomics information for early developmental time-points in both pigs and chickens. Here, we have described an initial data release of both raw and processed data, as well as describing early results of how these data are likely to impact the genome annotation of these species. All data are available through the FAANG data portal.

We are using these multiple datasets: (1) to characterise the complexity of the coding and non-coding transcriptome and its dynamics during development in pigs and chickens; (2) to characterise the regulatory and epi- genomes of pigs and chickens; (3) to compare the regulatory landscape and its influence on gene expression and development in species separated by millions of years of evolutionary time (mammals, e.g. pigs and birds, e.g. chickens). In addition, to publishing the results of these analyses, enhanced annotation of the chicken and pig genomes will be released via the Ensembl Genome Browser (https://www.ensembl.org/index.html) initially as additional tracks in the Rapid Release site (https://rapid.ensembl.org/index.html). This enhanced annotation will facilitate the development of improved models for genomic prediction that incorporate knowledge of the likely functions of genome sequences as well as accounting for genetic variation.

Abstract

DNA methylation is an important epigenetic mark that is essential for genomic stability and maintenance throughout development. Advances in 'omics' technologies has fuelled investigation into the epigenome as a tool to enhance livestock selection and breeding practices; research into DNA methylation will deepen our understanding of gene-by-environment interactions and their influence on phenotypic outcomes in livestock. The recent release of a mammalian methylation array has enabled array-based 'epityping' of methylation across the Mammalia class. This array facilitates greater accessibility for investigation in the methylome within the livestock sector. Here we demonstrate the novel use of the mammalian methylation array in an epigenome-wide association study (EWAS) for age across four key ruminant species; deer, cattle, goat and sheep and identify many associated sites including two regions of note *TNRC6A and LHFPL4,* which have previously been correlated with the ageing process in independent studies.

Introduction

A wide range of techniques are available to explore DNA methylation from the single-gene level through to genome-wide profiling. Bisulphite treatment of DNA, the most widely adopted tool to profile methylation, converts unmethylated cytosines to uracil while leaving methylated cytosines unchanged. Bisulphite converted DNA can be analysed by sequenced based approaches, including whole genome bisulphite sequencing, the gold standard approach for comprehensive methylation profiling, and reduced representation bisulphite sequencing, a more cost-effective derivative. Alternatively, micro array-based analysis can provide single base resolution 'epi-typing' of targeted CpGs if a suitable BeadChip array is available for the species of interest. Until recently methylation arrays have only been available for three model species: human, rat and mouse. Recently, the mammalian methylation array was developed in an attempt to fill this gap (Arneson *et al.*, 2022). Built using probes conserved across the Mammalia class, it was designed to apply to all mammals, in order to drive down the cost of the chip through economies of scale. The BeadChip contains approximately 36,000 CpG sites built from sequence data from over 50 different mammalian species, facilitating the uptake of this technology in the animal genetics sector. Perhaps the greatest advantage of microarray technologies over sequence-based methods is the simple interpretation of the data without the requirement for computationally demanding bioinformatic analyses. Furthermore, no PCR amplification step is required, therefore, there is no bias towards shorter, less CpG rich fragments as is the case with bisulphite-sequencing. Here we demonstrate the application of the mammalian methylation array across four ruminant species and evaluate its potential as a tool to investigate the global methylation landscape and discover methylated sites associated with phenotypic outcomes in livestock, using age as an exemplar.

Materials & methods

Samples. The EWAS was performed on a previously described dataset (Caulton *et al.*, 2022). Briefly, this dataset consisted of 384 ear tissue samples from four different species: deer (Wapiti and Red pure and cross bred; ages ranged from 1 month to 13 years and 8 months old; n=96), sheep (composite breed; ages ranged

from 16 days to 7 years and 1 month old; n=90), cattle (Jersey/Friesian cross breed; ages ranged from 1 month to 11 years and 1 month old; n=96) and goat (Saanen breed; ages ranged from 2 weeks to 8 years and 7 months of age; n=96).

DNA preparation and Infinium microarray. DNA extraction, bisulphite conversion of DNA, typing of the samples on the custom Illumina methylation array 'HorvathMammalMethyl40' (Illumina, Inc., San Diego,CA, USA; Arneson *et al.*, 2021) was performed as described in Caulton *et al.*, 2022.

Characterising the global methylation landscape. The distribution of cytosines assayed via the mammalian methylation array was determined using the sheep dataset set as an example. Probe sequences were aligned to the Oar Rambouillet v1.0 genome, GenBank accession number: GCA_002742125.1. Global methylation levels were determined by averaging the methylation levels at shared cytosines (minimum of 5× coverage) between all sheep samples. A cytosine was defined as being highly methylated if on average the proportion of methylated reads to unmethylated reads was ≥0.5, moderately methylated if its methylation proportion was between 0.1 and 0.5 and lowly methylated if its proportion of methylated reads to unmethylated reads was ≤0.1. To determine how methylation was distributed within various features of the genome, the location of lowly, highly, and moderately methylated cytosines in relation to CDS, intronic regions, exonUTRs, 1 kb flanks, intergenic regions, transposable elements and lncRNAs was determined using intersectBed (Quinlan and Hall, 2010).

Age transformation. To test for associations with age across species with differing maximum lifespans, chronological age was transformed to relative age, in line with previous work for development of multispecies epigenetic clocks (Caulton *et al.*, 2022; Mammalian Methylation Consortium *et al.*, 2021).

$$RelativeAge = \frac{Age+2\times GT}{MaxAge+2\times GT} \quad (2)$$

$$LoglogAge = -log\big(-log(RelativeAge)\big) \quad (3)$$

Where *GT* is the species' gestational time and *MaxAge* its maximum lifespan. *RealtiveAge* is between 0 and 1 (for all species) and the double log transformation accounts for aging effects occurring more rapidly at younger (relative) ages.

Data quality control and epigenome-wide association study (EWAS). A Bartlett's test for homogeneity of variance of *LoglogAge* across species was non-significant and therefore a single association analysis was run including all species. Technical bias and batch effects were corrected for with the SeSAMe analysis suite (Zhou *et al.*, 2018) as described in Caulton *et al.,* 2022. Any residual effects were handled by including supplied (sex and species) and surrogate variables obtained by independent surrogate variable analysis (ISVA; Teschendorff *et al.*, 2011) in the EWAS models run in R (v4.1.0) using the Bioconductor package Meffil (Min *et al.*, 2018).

Results & discussion

The probes included on the mammalian methylation array were principally designed to target CpGs that are highly conserved across the Mammalia class. In addition, sites were specifically chosen for being distributed across a wide range of fractional methylation levels and preferentially selected for the array if they resided in gene or promoter regions (Arneson *et al.*, 2021). In human DNA, around 80% of the mammalian methylation array probe sequences are either in a gene body or promoter. In the sheep dataset (Figure 1), the proportion was much lower at 66.4%, likely a consequence of the sheep genome having poorer annotation compared to the human genome. The distribution of high, moderate, and lowly methylated sites within the sheep array dataset was 64.0, 20.7 and 15.3% respectively.

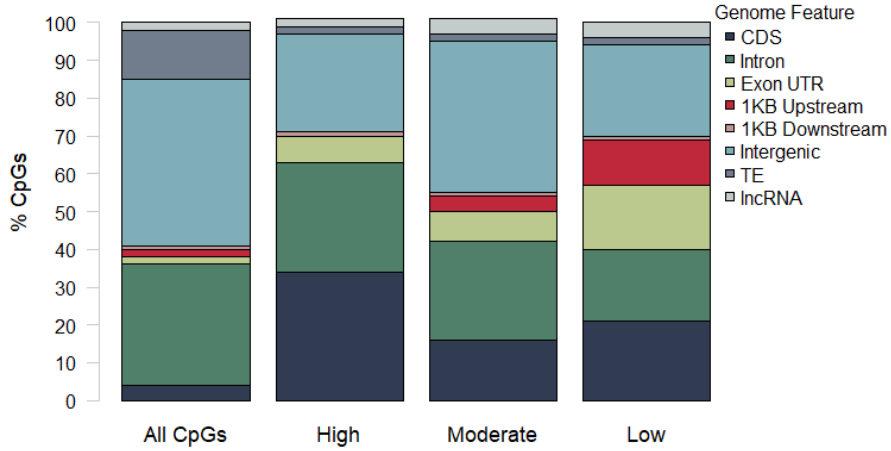

Figure 1: Distribution of CpG sites within different functional categories of the sheep genome (Oar Rambouillet v1.0). 'All CpGs' refers to the global distribution of CpGs in the complete genome. 'High', 'Moderate' and 'Low' refer to highly methylated, moderately methylated, and lowly methylated CpGs that were sampled via the array, respectively.

Genome wide profiling of DNA methylation using the Mammalian methylation array to determine methylation levels at ~36,000 CpG sites revealed a large number of positions that were strongly associated with age. The most highly associated cytosine cg09461098 (P=2.35e-50) resides on chromosome 16 in the gene *TNRC6A*. This cytosine was found to be highly predictive of chronological age in previous work to develop a biomarker for ageing in livestock (Caulton *et al.*, 2022) and has been linked to ageing in similar biomarker studies in prairie voles (Sailer *et al.*, 2020) and primates (Horvath *et al.*, 2020). In a recent study to develop a universal epigenetic biomarker of age, two cytosines cg12841266 and cg11084334 were highlighted as being the most predictive of age across all species (Mammalian Methylation Consortium *et al.*, 2021). In the EWAS performed here the same two positions on chromosome 3 ranked the 9th (P=4.54e-36) and the 25th (P=8.38e-24) most significant, respectively. Both sites are located in exon 2 of the *LHFPL4* gene. The association of this gene with ageing has been emphasised in multiple independent studies although its role is still unclear.

Here we describe the first use of the mammalian methylation array for EWAS studies in livestock species and demonstrate its potential as a tool to identify differentially methylated sites associated with phenotypic outcomes. The distribution of cytosines captured via the array are biased towards genic regions (gene body and promoter) which will aid in the discovery of genes under epigenetic regulation for traits of interest.

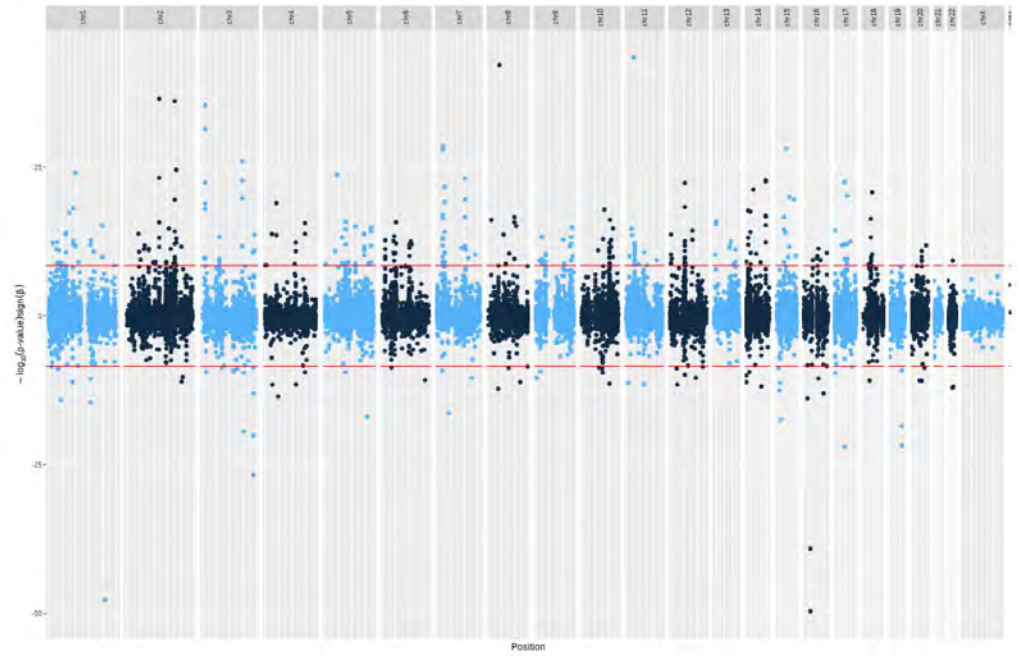

Figure 2. Manhattan plot of log(*P*-values) × effect sign from an epigenome-wide association analysis of relative age in New Zealand livestock (deer, cattle, sheep and goat), red lines indicate the Bonferroni significance threshold *P*=3.472e-9.

Abstract

Causal variants are enriched in functional non-coding regions of the genome, where it is hypothesised that they influence regulation of gene expression. Histone modifications are thought to mark many non-coding functional regions. Additionally, the height of some histone modification peaks has been found to be correlated with nearby gene expression, demonstrating a potential causal relationship between the two. Therefore, SNP which associate with differences in gene expression and with differences in peak height could be strong candidate causal variants. We found that QTL for peak height for three histone modifications (H3K4Me1, H3K4Me3 and H3K27ac) in ~100 mammary samples in dairy cows overlapped substantially with QTL for gene expression in ~400 mammary samples, thus identifying putative regulatory variants in the bovine genome.

Introduction

Gene expression QTL studies identify putative causal variants for differences in gene expression, which is thought to be a major contributor to phenotypic variation in other complex traits (Schadt *et al*., 2005). Most putative causal variants are found in non-coding regions of the genome (Cano-Gamez *et al*., 2020). It has been suggested that this is because they are in regulatory regions, which are controlling gene expression.

Regulatory regions can be identified by assaying for histone modifications using a technique called Chromatin Immunoprecipitation followed by sequencing (ChIP-seq) (Prowse-Wilkins *et al*., 2021). This method identifies the location of functional regions such as enhancers (marked by H3K4Me1), promoters (marked by H3K4Me3) and active regions of the genome (marked by H3K27ac). However, this assay also quantitively measures histone modification peak height. Peak height has been found to be correlated with gene expression (Cheng *et al*., 2012, Prowse-Wilkins *et al*., 2021), so it is thought that differences in peak heights may be altering gene expression. Therefore, a SNP which is altering peak height and gene expression may be altering gene expression by altering binding of histone modifications.

To identify SNP which are associating with differences in peak height and gene expression we undertook allele specific QTL analysis for these two molecular phenotypes. Allele specific QTL analysis measures the phenotype (in this case peak height or gene expression) on the maternal chromosome of an animal in comparison to the phenotype on the paternal chromosome (Chen *et al*., 2016). If a QTL is acting in cis and is heterozygous in the animal, the allele count at each homologous chromosome would be different. This analysis has the benefit of being measured within one homogeneous environment (one animal), which should limit background noise.

Allele specific QTL analysis was performed in ~400 RNA-seq samples and ~100 samples for 3 different histone modifications in the mammary gland of dairy cows. Our results revealed that, as expected, there was substantial overlap between SNP which were regulatory QTL (allele specific binding QTL or asbQTL) and SNP affecting gene expression (allele specific expression QTL or aseQTL).

Methods

ChIP-seq and RNA-seq data. RNA-seq and data analysis for 411 mammary biopsies was described in Littlejohn *et al.* (2016) and Lopdell *et al.* (2017). A subset of 101 mammary biopsies were assayed with ChIP-seq for H3K4Me3 and H3K4Me1 and a further subset of 37 of these were assayed for H3K27ac. The ChIP-seq assay and subsequent data analysis was as described in Prowse-Wilkins *et al.* (2021).

Allele counts. To prevent mapping bias to reference alleles, a masked genome was created from ARS-UCD1.2. with a neutral allele at variants which were heterozygous in the sequenced animals (MAF>1% n=14,536,882). Imputation to whole genome sequence and variant calling was described in Reynolds *et al.* (2021). Consensus peaks were produced by randomly sampling all bam files for each mark with SAMtools (Li *et al*., 2009) and calling peaks from combined reads. Exons were from the RefSeq protein-coding gene database (annotation release 106).

For each heterozygous SNP, alleles were defined as maternal or paternal based on the sire's genotype at that SNP. If the sire was homozygous, this allele was designated the paternal allele, if the sire was heterozygous, the maternal/paternal classification was based on the phasing of the previous SNP. Maternal and paternal read counts were calculated by counting alleles at heterozygous SNP under a consensus peak (peak SNP or pSNP) or within an exon (transcript SNP or tSNP) using GATK HaplotypeCaller and GenotypeGVCF using the option 'depth per allele by sample'. SNPs which were monoallelic were excluded from analysis as this was assumed to be an imputation error (the individual was not heterozygous at this SNP). If there were multiple heterozygous SNP in a peak/exon, the maternal counts for the SNP were summed and the paternal counts for the SNP were summed, to create one maternal count and one paternal count per feature.

QTL analysis. All SNPs within 1 mb of the midpoint of the peak/exon were tested for association with the phenotype (maternal and paternal allele counts at the exon or peak). We called these SNPs the driver SNPs (dSNPs). Two statistical tests were used to assess the significance of the relationship. The first test was used to filter for small sample sizes and/or where there were only a small number of animals heterozygous at the dSNP:

- For the first test, where: 0= reference allele and 1=alternate allele
- For each individual i that has dSNP genotype 1|0, let M_i = number of counts of the maternal allele at the phenotype
- For each individual i that has dSNP genotype 1|0, let P_i = number of counts of the paternal allele at the phenotype
- For each individual j that has dSNP genotype 0|1, let N_j = number of counts of the maternal allele at the phenotype
- For each individual j that has dSNP genotype 0|1, let Q_j = number of counts of the paternal allele at the phenotype

And $T = \sum M_i + \sum P_i + \sum N_j + \sum Q_j$ and $A = \sum M_i + \sum Q_j$

Then: $Z = \left(\frac{A}{T} - 0.5\right) \times \sqrt{4T}$ is approximately normally distributed.

P-values for the normal distribution were calculated in R. dSNPs which were significant at $P<0.0001$ were taken through to the second test.

For the second test: We calculated a linear model: $Y_i = a + bX_i$ where, for each individual i,

$$Y_i = \ln\left(\frac{maternal\ allele\ count + 10}{paternal\ allele\ count + 10}\right)$$

When individual i has dSNP genotype 0|0 or 1|1, *let* $X_i = 0$
When individual i has dSNP genotype 1|0, *let* $X_i = 1$
When individual i has dSNP genotype 0|1, *let* $X_i = -1$
P-values were calculated in R.

Results

ChIP-seq and RNA-seq data. After filtering for ChIP-seq quality (JSD>0.25) and for animals with a known sire, there were 337 RNA-seq samples and 99, 97 and 37 samples assayed for H3K4Me3, H3K4Me1 and H3K27ac respectively. Merging ChIP-seq bam files resulted in 97-199 million mapped reads for each mark and 400-700 thousand consensus peaks.

Allele Specific QTL analysis. There were more than 48,000 exons and more than 200,000 peaks tested for allele specific expression QTL and asbQTL (Table 1). Of these, 15,308 exons representing ~6,500 genes had significant aseQTL and between ~7,000 and 20,000 peaks had significant asbQTL.

Overlap between gene expression and histone modification QTL. There was more overlap between variants which were asbQTL and variants which were aseQTL than expected by chance (OR>3.1 Table 2). In total, 31% of aseQTL variants were also asbQTL variants for one of the three marks. SNPs which were both aseQTL and asbQTL variants had the same direction of effect on the peak height or gene expression more than 57% of the time (Table 2).

If the same dSNP was associated with differences in peak height and exon expression, we propose that it is possible to link a peak to the exon it is potentially regulating. We found between 5,350 and 24,423 peak-exon pairs which shared a significant dSNP in the same direction (Table 3), representing ~1,500-3,000 genes potentially regulated by ~2,000-6,000 functional regions.

Table 1. Summary of allele specific analysis results.

	Samples	Number of phenotypes tested	Number of phenotypes with at least one significant dSNP (*P*<0.0001)	Number of significant (*P*<0.0001) dSNPs
RNA	337	48,456	15,308	1,999,869
H3K4Me3	96	224,183	15,918	1,055,069
H3K4Me1	95	220,588	20,555	981,026
H3K27ac	36	283,235	7,963	154,739

Table 2. The number of SNPs identified as aseQTL or asbQTL variants, the overlap between them (odds ratio in brackets) and the total percentage where the direction of the SNP effect was the same.

	Total dSNPs tested	aseQTL	asbQTL	Overlap (odds ratio)	Same direction of SNP effect (%)
H3K4Me3			1,055,069	410,022 (4.3)	61.5
H3K4Me1	13,397,022	1,999,869	981,026	339,821 (3.4)	57.4
H3K27ac			154,739	53,829 (3.1)	66

Table 3. The number of peaks and exon with shared significant dSNP and the distance between the peak-exon pairs.

	Number of peak-exon pairs	Median distance (bp) between peak and exon	Peaks	Exons	Average exons per peak	Average peaks per exon
H3K27ac	5,350	344,811	2,017	2,949	3.1	2.2
H3K4Me3	24,423	340,445	6,052	7,466	4.8	4.1
H3K4Me1	19,541	375,841	6,145	6,603	3.7	3.7

Discussion

This study presents the largest survey of histone modifications in the bovine genome to date. Utilising the benefits of allele specific analysis to identify cis-QTL, we present millions of SNPs which were potentially influencing regulatory regions in the mammary gland of dairy cows. Further, we show that many of these SNPs were also affecting gene expression in the same tissue. By overlapping these two analyses we hypothesise that these SNPs are causal variants for differences in gene expression by affecting regulatory regions which are controlling gene expression. If that's the case, peaks which share a significant QTL variant with an exon are potentially regulating that exon. Therefore, we identified putative regulatory regions for between 1,500 and 3,000 genes in the bovine genome.

There are some major limitations to this study. While multiple studies have found correlations between peak height and gene expression (Cheng *et al*., 2012, Prowse-Wilkins *et al*., 2021), there are few that have proven this relationship is causal. Therefore, it may be a coincidence that QTL for both traits overlap, although there is 3-4 more times overlap than expected by chance. Secondly, allele specific QTL studies are subject to linkage disequilibrium (LD), meaning the significant SNP may be tagging the causal variant rather than be the causal variant themselves. Lastly, we provide no explanation for how the variants identified in this study are altering histone modification peak height. Future work will ascertain whether the variants fall within regulatory regions such as transcription factor binding sites and, ideally, would validate the potential causal variants identified.

Abstract

The histone modification H3K27me3 is linked to the regulation of different cell states. However, no study has focused on the influence of H3K27me3 over gene expression in Nelore cattle phenotypes. We used the TRIAGE model (a predictive method based on a score calculated using the inverse relationship of H3K27me3 and gene expression), modified here to analyze Nelore muscle samples contrasting for calcium (Ca) content. The aim was to identify putatively regulated genes, called Discordantly Ranked Genes (DRGs), related to this phenotype. We identified 209 DRGs, from which 10 (e.g. *COMP, MAFB* and *ITAG11*) were also previously reported as differentially expressed genes between animals contrasting for Ca content and 44 (e.g. *KCNJ5*, *IGF2* and *HOXA10*) underlie enriched pathways related to signaling, synaptic, neural, regulatory and addiction events, all pathways related to Ca content. Our approach can identify candidate genes to be regulated in bovine muscle according to Ca content.

Introduction

Despite the previous identification of genes and genomic regions involved with the calcium (Ca) concentration in Nelore cattle muscle (Tizioto *et al.*, 2014; Diniz *et al.*, 2019; Afonso *et al.*, 2019; Afonso *et al.*, 2020), the mechanisms regulating these genes are not yet fully understood. Amongst gene regulators are the histone modifications (HM), which can silence or activate gene expression, depending on the type of the modification (Kimura *et al.*, 2013). One of these HM is the histone-3-lysine-27-trimethylation (H3K27me3), which usually causes gene inactivation through heterochromatin formation (Cai *et al.*, 2021; Young *et al.*, 2011). To our knowledge, no study focused on the influence of H3K27me3 over gene expression in Nelore muscle tissue, the most common beef cattle in Brazil, or related it to phenotypes in bovine. One way of studying H3K27me3 is through a prediction methodology called TRIAGE (Shim *et al.*, 2020). TRIAGE is an *in silico* model to analyze the impact of this HM over gene expression of cell identity genes, based on the general repressive tendency mediated by H3K27me3 previously observed in human genes. As H3K27me3 still allows genes to be activated in different cell states (Cai *et al.*, 2021), e.g. differences in the mineral amount, we hypothesize that there is a relationship between H3K27me3 distribution in the genome and the variation in Ca concentration in muscle. Here we explore evidence of this possible relationship.

Materials & methods

Samples, phenotypes and expression data. From a subset of 113 *Longissimus thoracis* samples out of a Nelore steer population described in detail by Tizioto *et al.* (2013), we used the Genetic Estimated Breeding Value (GEBV) calculated using the spectrometry quantification of Ca raw values (Tizioto *et al.*, 2015) to select two contrasting sample groups of six samples each regarding Ca concentration. The RNA-seq data from the contrasting samples was previously obtained as described by Oliveira *et al.* (2018). The expression data were mapped to the bovine reference genome ARS-UCD 1.2 using the STAR software v.2.5.4 (Dobin *et al.*, 2013) as previously described (Diniz *et al.*, 2016). We normalized the expression data with the VST function from DESeq2 software (Love *et al.*, 2014) and adjusted for batch effects with the ARSyNseq function of the NOISeq software v.2.16.0 (Tarazona *et al.*, 2015).

TRIAGE methodology. Based on the TRIAGE methodology (Shim *et al.*, 2020), we calculated the discordant score (DS) for each gene in each sample extrapolating the repressive tendency score from human data (Shim *et al.*, 2020) to orthologous genes in *Bos taurus*. After that, the genes from each sample were ranked by the DS to identify genes putatively being regulated in Nelore muscle in regard to Ca content, called DRGs.

Discordantly ranked genes (DRGs). To identify the DRGs, we compared the ranks between the contrasting groups using the RankProd R package (pfp<0.01) (Hong *et al.*, 2006).

Functional enrichment analysis and integration data. A functional enrichment analysis with the DRGs was performed using the STRING app plugin (Doncheva *et al.*, 2016) to identify enriched metabolic pathways and biological functions. To incorporate a new layer of information in the gene regulation in muscle-related to Ca content, the DRGs were compared with previously published differentially expressed genes (DEGs) between the same contrasting sample groups for Ca (Afonso *et al.*, 2019).

Results

DRGs. We identified 209 DRGs for Ca content. Biologically, DRGs for Ca content are genes presenting their expression varying more between contrasting groups for this mineral in relation to the repressive tendency prediction made by the TRIAGE method. This means that these genes have a high tendency to be repressed by H3K27me3 in several tissues and present different transcription abundance between sample groups, suggesting that they are predicted to be regulated in Nelore muscle in relation to Ca mass fraction.

Functional enrichment analysis and integration. From the 209 DRGs for Ca content, 44 genes take part in enriched pathways (Figure 1). The enriched pathways are related to signaling, synaptic, neural, regulatory and addiction events. We identified known interactions among the coded proteins of most DRGs taking part in enriched pathways. Considering all DRGs, 10 genes were previously published DEGs for Ca content (i.e. *TMEM233, SCN3B, COMP, MAFB, C1QB, ITAG11, MKX, PDGFRA, KY* and *IGF2*) (Afonso *et al.*, 2019).

Discussion

The TRIAGE methodology can be applied to any cell type or species where H3K27me3 is a conserved epigenetic mechanism for the regulation of cell identity (Shim *et al.*, 2020). The results from our Nelore samples pointed to genes already related to muscle Ca mass fraction as presenting different rankings by the DS. These genes have predicted divergences in the regulation by this HM, having a high chance to be regulated by it in some tissues, such as muscle. Our results suggest that differences in DS between samples from the same tissues can be related to Ca quantification. There is a lack of studies relating H3K27me3 with phenotypes other than developmental stages or diseases, less so to mineral quantification. However, in

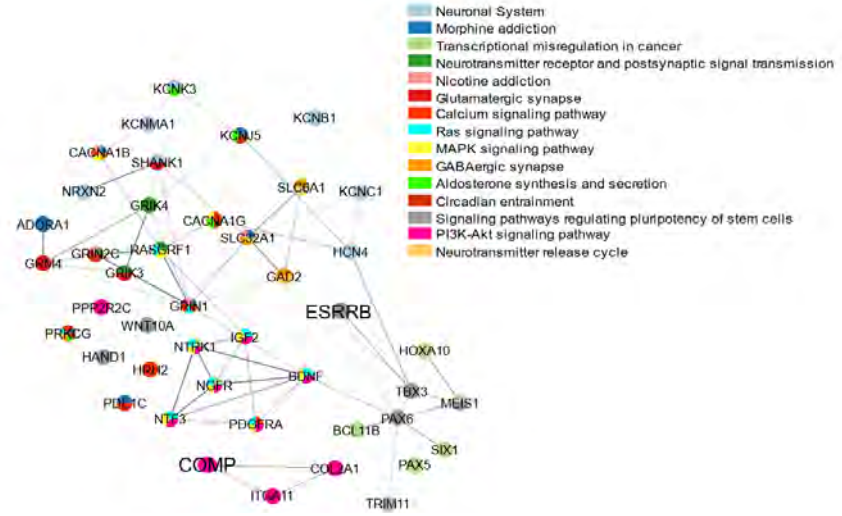

Figure 1. Protein-protein interaction network of the discordantly regulated genes (DRGs) taking part in enriched pathways.

Arabidopsis thaliana, it is known that this HM can contribute to the transcriptional regulation of TFs that are key regulators in iron uptake in a dependent Fe deficiency response. Hypothetically, H3K27me3 regulates the induction of these key regulator TFs target genes under Fe deficiency to facilitate iron acquisition while preventing iron overload (Park *et al.*, 2019), thus indicating that a relationship between Ca quantification and H3K27me3 could also be hypothesized.

Our results indicate genes putatively regulated in bovine muscle according to Ca concentration. Regarding the DRGs here identified that were described as DEGs (Afonso *et al.*, 2019), *MAFB* and *MKX* are also known bovine transcription factors (TFs) linked to Ca content. In humans, *MAFB* is an important TF for parathyroid embryogenesis and its expression correlates to extracellular Ca concentrations (Fabbri *et al.*, 2020). *MKX* is a TF linked to tendon repair in mice (Milet and Duprez, 2015), a tissue that increases its Ca content in response to mechanical deformation due to tensile strain, fluid flow, compression and vibration (Wall and Banes, 2005). Additionally, the enriched pathways mostly related to signaling, synaptic, neural, regulatory and addiction events, have known links to Ca content, showing the relationship among the DRGs and Ca content. Ca initiate synapses by acting in the release of neurotransmitters (Sudhof, 2012), thus linking it to addiction pathways also enriched here. More studies are needed to further understand the possible relationship between the H3K27me3 gene regulation and Ca content in Nelore muscle; however, this study proposes a new perspective to incorporate a layer of information regarding gene regulation.

Abstract

Recently, expressed genomic information e.g. expression quantitative loci (eQTL), have been utilised in both dairy and beef breeding to link genotype to phenotype. The fine mapping of promoters (transcription start sites; TSS) and enhancers (divergent amplifying segments local to TSS) in different populations of cattle across multiple tissues can help to unravel breed- and tissue-specific phenotypes. This study provides a high-resolution analysis of TSS complexity including drivers of transcription using Cap Analysis Gene Expression (CAGE) sequencing in 3 populations of cattle (Holstein, Charolais × Holstein and Kinsella beef composite; KC). We identified 55,139 TSS and 2,543 TSS-Enhancer regions shared by 3 populations along with population-specific sets. Comparative analysis revealed a cattle-specific set of TSS. Improving our understanding of the genomic architecture of gene expression and regulation in this way can help to inform the application of genomic technologies in breeding programmes for cattle.

Introduction

Mapping of the actively transcribed regions of the genome helps identify the drivers of gene expression, regulation and phenotypic plasticity. TSS within promoter regions provide information about how genes controlling traits of interest are expressed and regulated. These TSS can be specific to a tissue or pervasive across the breed/species. To improve TSS and enhancer annotation of the current cattle genome (ARS-UCD1.2), we used CAGE sequencing to create base-pair resolution expression profiles of TSS and their co-expressed short-range enhancers (<1 kb) in the ARS-UCD1.2_Btau5.0.1Y reference genome (1000bulls run7). We utilised publicly available CAGE datasets for human, chicken, mouse, rat, macaque monkey, dog and sheep for a cross-species comparative analysis of TSS and TSS-Enhancers and their co-expressive interaction. Using comparative analysis this study aims to provide a cattle-specific set of TSS and TSS-Enhancers in multiple tissues from dairy (Belgian Holstein), and cross-bred composite beef (KC) and beef/dairy cross (Charolais × Holstein) cattle.

Materials & methods

CAGE sequencing and analysis pipeline. A total of 105 samples from 24 different tissues were collected from 6 animals (3 populations, different ages and 2 sexes). Tissue representation for each breed was as follows: dairy (Holstein, n=43), composite beef (KC-composite, n=31) and beef/dairy cross (Charolais × Holstein, n=31). CAGE libraries were prepared as for (Salavati *et al.*2020) with some modifications of the barcodes to facilitate sequencing on an Illumina NextSeq 550 (50nt SE) and mapped against the ARS-UCD1.2_Btau5.0.1Y assembly using the nf-cage pipeline (BovReg 2021).

Transcription start site and enhancer prediction analysis. The base pair (bp) resolution output files were processed by CAGEfightR v.15.1 for cattle. For comparative analysis a CAGE dataset from sheep (Salavati *et al.* 2020) was mapped to ARS-UI_Rambv2.0 and also processed by CAGEfightR v.15.1. The uni- and bi-directional clustering algorithm of the CAGEfightR was used to predict putative TSS and TSS-Enhancers within each tissue individually (i.e. tissue-specific) and all tissues combined (species and population). Co-expression of predicted TSS and TSS-Enhancer regions was tested using a Kendall correlation test (P<0.05 sig.). Finally a hierarchical clustering of the super-enhancers was performed to identify longer (>1 kb) regulatory stretches of the genome.

Re-analysis of the Fantom5 CAGE datasets. Already mapped CAGE datasets from human (152), rat (13), mouse (17), chicken (32), dog (13) and Macaque monkey (15) were obtained from (Fantom5 2021). After conversion to bp resolution tracks similar analysis to the cattle and sheep was performed to identify putative TSS and TSS-Enhancer regions.

Results

An average (± SE) of 15.5±0.53 million reads per CAGE library were produced and a 94% mapping rate was achieved for the cattle dataset. Initially more than 4.5 million putative TSS and 57,412 TSS-Enhancer clusters were identified in total (min 10 read counts/cluster – Figure 1).

We considered a putative region, real/reproducible only when present across at least 2/3rd of the tissues. After such filtering 55,139 TSS and 2,543 TSS-Enhancers were detected for cattle (Table 1). Tissue-specific analysis captured, on average per tissue (± SE), 253,852±24,713 TSS clusters, 41.6% of which were novel. On average per tissue 12,138±889 TSS-Enhancer clusters were captured (27.6% novel). Population-specific analysis showed differences in TSS coordinates and expression levels between the populations. The highest number of population-specific TSS were in the KC-composite (3,102) followed by 1,152 in Holstein and

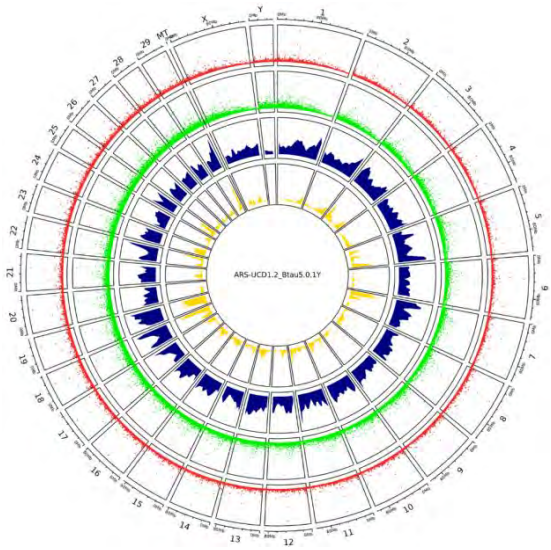

Figure 1. Distribution of uni-directional (TSS) and bi-directional (TSS-Enhancer) CAGE clusters within the cattle genome (ARS-UCD1.2_Btau5.0.1Y). The TSS clusters (red), TSS-Enhancer (green), significant positive (blue) and negative (yellow) correlation between co-expressed Enhancer and TSS(s) are shown in genomic tracks. The height of the tracks shows scaled expression or correlation coefficients (0-1).

1,092 in Charolais × Holstein. The same pattern was observed in the TSS-Enhancer clusters (419 in KC-composite, 286 in Charolais × Holstein and 202 in Holstein). A comparison of the sheep dataset and the cattle dataset is shown in Table 1. The higher number of identified regions in cattle is partly due to inclusion of multiple tissue samples from 3 populations (compared to a single animal for the sheep data).

The correlation (Kendall) analysis between a bi-directional cluster and multiple uni-directional clusters (significantly co-expressed TSS and TSS-Enhancers) showed on average 3.73±0.05 (median 3) and 22.8±0.02 (median 18) links in the sheep (3,694 regions) and cattle (641,028 regions) datasets respectively. The Kendall estimates of these significant co-expressed links were 0.547 and 0.363 for the sheep and cattle tissues respectively. The analysis of the super enhancers (stretches of bi-directional CAGE clusters) encompassing multiple enhancers within each stretch in the sheep dataset resulted in 2 super enhancer predictions. These stretches were formed of 6 TSS-Enhancer clusters (total 1,493) with the longest stretch of 5,172bp [cluster of 3 enhancers]. The similar analysis of the cattle CAGE dataset from 3 populations resulted in 20 super enhancer stretches from 65 TSS-Enhancer clusters (total 2,543). The longest stretch was 25,678bp which contained 6 TSS-Enhancers. The number of discovered super enhancer regions overall was higher in the cattle dataset (3 populations) compared to the sheep (single breed). A multi species metrics for available CAGE datasets is shown in Table 2.

Discussion

Recently there has been an influx of breed-specific reference assemblies in livestock species (Crysnanto *et al.*2021, Li *et al.*2019). To harness the full potential of these assemblies, identifying breed or population-specific promoter complexity is valuable within cattle genomic breeding programmes (Clark *et al.* 2020). To this aim, we used CAGE sequencing and publicly available datasets in a comparative analysis, to create further annotation underpinning the phenotypic diversity seen in 3 diverse cattle breeds. We identified more than 55k unique putative TSS coordinates (38% un-annotated regions of the cattle genome) compared to 27k TSS in sheep (7% unannotated regions). The promoter plasticity captured by the usage

of 3 divergent populations showed population-specific dominant TSS for the same genes across the breeds e.g. a *DGAT1* Holstein-specific TSS (overlapping milk yield QTLs) without expression in other breeds or *PLAG1* Charolais-specific TSS-Enhancer region (overlapping cow weight QTLs) that was not present in the other 2 populations. We will also compare the sheep and cattle datasets with other publicly available TSS and Enhancer genomic tracks to further identify regulatory regions specific to the cattle genome. Such information could be used to understand how the genome controls traits in different species, and to identify regions that are important to conserve in breeding programmes. The CAGE data produced for this study when combined with transcriptomic datasets (mRNA, miRNA and total RNA-Seq) produced by BovReg partners will provide a new comprehensive transcriptome annotation for the cattle genome. This high resolution annotation of the cattle genome will help to inform the application of genomic technologies in breeding programmes. The BovReg project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 815668.

Abstract

This study aimed to investigate the transcriptomic signature of claw horn disruption lesions (CHDL) in peripheral blood leucocytes (PBL) in dairy cattle. The PBL transcriptome of 24 cows, twelve cows susceptible (cases) and 12 resistant (controls) to CHDL were compared. Total RNA was extracted for RNA sequencing using Illumina technology. Raw reads were mapped to the cattle genome (ARS-UCD1.2) using the STAR aligner and differentially expressed gene (DEG) analysis was performed using DESeq2. Eighty-eight DEG genes were found between CHDL cases and controls; 82 were downregulated in CHDL cases. We found enrichment for Ca^{2+} transport and immune system related signalling among the DEG. In addition, the mineralisation associated genes *SPARC and CLEC3B* were downregulated and upregulated in CHDL cases, respectively. Moreover, three genes (*YAP1, DSP* and *PALLD*) associated with keratinocyte development were upregulated in the CHDL cases, which may suggest the presence of a reparative mechanism in the CHDL cases.

Introduction

Lameness is a debilitating and painful condition, which considerably compromises animal welfare and is associated with significant economic losses. Claw horn disruption lesions (CHDL), such as sole ulcers (SU), sole haemorrhage (SH), and white line disease (WLD), are responsible for most of the lameness cases in dairy cattle. CHDL have adverse impact on milk production (Amory *et al.*, 2008), reproductive performance (Charfeddine and Pérez-Cabal, 2017) and premature culling (Booth *et al.*, 2004). Considering its high prevalence within dairy herds (Murray *et al.*, 1996), CHDL is one of the dairy industry's most significant challenges. However, the aetiopathogenesis of CHDL is not entirely understood.

Systemic inflammation around calving could potentially compromise the suspensory apparatus via activating matrix metalloproteinases, which play a central role in the degradation of suspensory apparatus connective fibres. In addition, the activation of proinflammatory mediators associated with direct stimulation of lipolysis could also lead to fat mobilisation from the digital cushion and a reduction of the latter's protective properties (Kushibiki *et al.*, 2003). However, the complex role of inflammation in the development of CHDL has not yet been thoroughly addressed. Therefore, the objectives of this study were to: (1) shed new light on the role of systemic inflammation, and other potential underlying molecular mechanisms in CHDL pathogenesis; and (2) identify specific genes and pathways involved in CHDL susceptibility using RNA-Seq in peripheral blood leucocytes (PBL).

Materials & methods

Sample collection and RNA isolation. Blood samples were collected from 24 (12 cases (days in milk (DIM: 198±102)) and 12 controls (DIM: 195±100)) Holstein dairy cows (selected from more than 200 cows raised in two herds in northwest England, UK. The animals were selected based on the CHDL score, which was a combined SH, SU and WLD score. The SH, SU and WLD of individual cows were recorded for all

four feet as described before (Egger-Danner *et al.*, 2015) at four time-points: pre-calving stage (mean=55.3 days before calving), calving stage (mean=5.4 days in milk), early lactation stage (mean=83.9 days in milk), and late lactation stage (mean=199.6 days in milk). Each lesion severity was calculated as the average score across all assessed feet. The lesion was calculated for each time point, so each animal had four repeated records. Therefore, the final CHDL score was the sum of the mean score of SH, SU and WLD of four feet divided by number of measurements. Foot lesion identification and recording were performed by a qualified veterinarian. The selected animals were on the extreme of the CHDL phenotype distribution (CHDL average (SD)) scores for controls and cases were 0.16±0.05 and 0.67±0.17, respectively). Controls and cases were sampled in pairs within the same herd, ensuring they were of similar age, parity, and lactation stage to minimise any systematic noise affecting the subsequent RNA-Seq analysis. Peripheral blood leukocytes (PBL) were isolated by lysis of erythrocytes as described before (Werling *et al.* 1998). Total RNA from PBL was extracted using the RNeasy Mini kit (Qiagen, Hilden, Germany), according to the manufacturer's instructions.

RNA-seq and bioinformatic analysis. RNA-Seq library preparation was performed using Illumina TruSeq ribo-zero gold kit (Illumina, San Diego, USA) following the manufacturer's instruction. Paired-end, 2×150 bp, reads were obtained using the NovaSeq 6000 instrument with NovaSeq 6000 S4 reagent kit v1.5. The quality of sequence reads was assessed using FastQC (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/) before and after quality control included quality based read trimming and adapter removal using Trimmomatic v0.39. Reads that passed quality control were mapped to the ARS-UCD1.2 bovine genome assembly using STAR v2.7.0 with default parameters. Read counts per gene were obtained using the gene annotation file corresponding to the ARS-UCD1.2 bovine genome assembly (Ensemble release 104) and the featureCounts v2.0.2. Differentially expressed genes (DEG) between cases and controls were identified using DESeq2 v1.35.0. Genes with a very low expression (gene expression £2 crossing all the samples) were excluded from further analysis. The gene counts were normalised using the default parameters ('*sizeFactors*') in DESeq2. The model used for the DEG analysis included age, parity, and herd. We applied two thresholds for differential expression a) False Discovery Rate (FDR)£5% and Log Fold Change (LFC) ³2 and a milder threshold (b) absolute LFC³2, baseMean ³10 and unadjusted *P*-value£0.05. Gene Set Enrichment Analysis (GSEA) of the selected genes sets was performed using the clusterProfiler v3.14 and the genome-wide annotation for Bovine org.Bt.eg.db v3.14. Both Gene Ontology (GO) terms and the Kyoto Encyclopedia of Gene and Genomes (KEGG) pathway enrichment were applied to identify functional clusters of genes that differ in CHDL cases and controls.

Results & discussion

The sequencing generated, on average, 60,041,254 paired reads per sample. On average, 92.6% of the read pairs uniquely mapped to the bovine reference genome except for two CHDL cases, which were highly contaminated (with *Homo sapiens* reads) and removed from the downstream data analysis. After quantifying the expression of the 27,607 genes annotated from the *Bos taurus* reference genome, we excluded 2,714 genes due to low expression. We found 88 DEG between CHDL cases and controls, with 82 downregulated in CHDL cases. These downregulated genes were enriched for 12 molecular functions (MF) mainly associated with ion channel activity, and *CSN2* and *FUT9* were primarily involved in these GO pathways. *CSN2* encodes a member of the beta casein protein family, and associated diseases include milk allergy in humans and mastitis in dairy cow. GO annotations related to this gene include calcium ion binding, enzyme inhibitor activity and interleukin 2 (IL-2) pathway activity. The protein encoded by *FUT9* belongs to the glycosyltransferase family. It is localised to the golgi apparatus, and it is responsible for the expression of the glycan Lewis X factor (CD15). CD15 is a carbohydrate antigen associated with the cell surface of glycoproteins or glycolipids, including CD11b/CD18 (Mac-1) and CR3 β-chain. It is highly expressed by mature neutrophils, mediates neutrophil adhesion to dendritic cells, and has been shown to

affect a number of neutrophil functions, including adhesion to endothelium, phagocytosis, degranulation, and the respiratory burst. Downregulation of these two genes may suggest a reparative mechanism in the CHDL case.

Using the milder threshold, we found another 33 genes that could be potentially associated with CHDL (Table 1). Downstream analysis using this gene list identified enrichment for both Ca^{2+} binding and regulation of cytosolic Ca concentration and inflammatory signalling. These results may suggest a different Ca^{2+} transportation activity within the cytosol of the CHDL cow. Ca^{2+} binding proteins participate in numerous cellular functions by acting as Ca^{2+} transporters across the cell membrane or as Ca^{2+}-modulated sensors (Elíes *et al.*, 2019). Among these genes, *CLEC3B (*also called tetranectin, C-type lectin domain family 3 member B) binds plasminogen and is highly expressed in neutrophils. It shows high homology to cartilage proteoglycan core protein and has been shown to be involved with mineralisation (probably through the Ca^{2+} dependency), during osteogenesis. Downregulation of *CLEC3B* has been reported in various diseases, and *CLEC3B*-deficient mice impeded the mineralisation process in osteogenesis (Iba *et al.*, 2013). Moreover, it has been found that adipocytes are the primary source of circulating *SPARC (*secreted protein acidic and rich in cysteine, also known as Osteonectin (ON)) and that *SPARC* inhibits adipogenesis (Kos *et al.*, 2009). *SPARC* binds to a number of different extracellular matrix components, including thrombospondin 1, vitronectin, entactin/nidogen, fibrillar collagens (types I, II, III, and V), and collagen type IV, the prevalent collagen in basement membranes. Therefore, *SPARC* has the potential to contribute to the organisation of matrix in connective tissue as well as basement membranes. More importantly, similarly to *CLEC3B*, *SPARC* is a glycoprotein in the bone that binds calcium. It is secreted by osteoblasts during bone formation, initiating mineralisation and promoting mineral crystal formation. Osteonectin also shows affinity for collagen in addition to bone mineral calcium. Thus, the observed downregulated of *SPARC* and upregulated of *CLEC3B* in CHDL cases may suggests a substantial impairment of CHDL-affected cows to form new connective tissue/cartilages, and/or may be an underlying factor for the development of exostoses on the pedal bone that cause further damage to the digital cushion and the dermis seen in cows with chronic CHDL. Furthermore, three genes (*YAP1, DSP* and *PALLD*) associated with keratinocyte development were upregulated in CHDL cases, which might suggest a reparative mechanism in the CHDL case since keratinocytes may be forming the base of the claw horn in these cows.

Table 1. The higher abundant expressed protein-coding genes between CHDL cases and control cows[1].

[1] Gene were selected based on: LFC [3]2, unadjusted *P*-value £0.05 and baseMean[3]10.

[2] baseMean = average of normalized count values, divided by size factor calculated from DESeq2.

[3] LFC = log fold change.

Moreover, we found the gene that encodes *CCL20* was downregulated in CHDL cows. *CCL20* or macrophage inflammatory protein 3 Alpha acts as a ligand for C-C chemokine receptor *CCR6*. Signals through binding and activation of *CCR6* induces a strong chemotactic response and mobilisation of intracellular calcium ions. It is responsible for the chemotaxis of dendritic cells, effector/memory T-cells and B-cells and plays an important role at skin and mucosal surfaces under homeostatic and inflammatory conditions, as well as in pathology, including cancer and various autoimmune diseases. Moreover, three MHC 1 related protein-coding genes (*ENSBTAG00000038112*, *ENSBTAG00000036061*, *ENSBTAG00000046595*) were upregulated in CHDL cases. This suggests that a systematic inflammatory response may be present in CHDL cases. According to the current RNA-Seq analysis several DEG were uncharacterised protein-coding genes, or non-coding genes which encode structural or regulatory RNAs, especially miRNA (e.g. bta-mir-758 bta-mir-2284f, etc.). The next steps of this project would be to analyse small RNA and lncRNA data to identify other potential pathways and mechanisms underlying CHDL susceptibility. Moreover, we are currently generating RNA-Seq data from foot biopsy samples collected from the same CHDL cases and controls. The integration of the results of PBL and foot tissue RNA-Seq analysis will improve our understanding of the molecular architecture of a complex trait associated with bovine foot health. Identified and characterised variants can then be duly incorporated in the genomic evaluation process of individual animals and increase the accuracy of genomic prediction and, consequently, of genomic selection.

Abstract

Reproductive efficiency is one of the most important factors to achieve profitable ovine production systems. Reproduction during recognition of gestation might be compromised by external influences such like the thermal stress. The present study was aimed to assess the effect of this kind of stress on the gene expression of Interferon Tau (INFt) and Interferon Tau stimulated (ISG) genes. An experiment was designed considering a stress and a control group of Katahdin ewes under tropical conditions. RNA was obtained from leukocytes and a gene expression analysis performed using a Targeted RNAseq analysis. Non-clear evidence on differential gene expression between thermal stress animals and control group was found. A reclassification of groups by pregnancy revealed evidence of Interferon regulatory factor 1 (IRF-1) and INFt gene expression during the experiment independently of stress. Further validation of these outcomes will confirm expression of IRF-1 and INFt in peripherical blood nuclear cells during the maternal recognition stage.

Introduction

Reproductive efficiency is one of the most important factors to achieve profitable ovine production systems. However, acceptable reproductive levels in some regions depend on technification and environmental influences related to thermic stress. Some evidence indicate that the embryo maternal recognition viability might be compromised by unfavorable thermic conditions.

Embryo development during fertilization and implantation involves dynamic growth, cell proliferation, differentiation and many gene expression changes. Henceforth, if maternal body is exposed to thermal influences during this stage, the development of preimplantation is likely to be compromised directly by thermal stress and indirectly for influenced changes in reproductive tract (Takahashi, 2012).

The maternal recognition of the embryo in ruminants needs the embryo conceptus elongation and expression of Interferon tau (IFNt) gene (Hansen *et al.*, 2017). The INFt induces the increasing of several gene expression in endometrium following the successful implantation of the conceptus. The genes called Interferon tau stimulated genes (ISG) increase in specific stages during the first third of gestation and are considered as fundamental for uterine receptivity and implantation. ISG increasing and regulation has been identified not only in uterus, but also in corpus luteum, and circulating immune cells (Mauffré *et al.*, 2016). Other studies has demonstrated increasing of ISG also in liver, and ovine bone marrow. Furthermore, some evidence of ISG15, MX1 and MX2 ISG genes has been reported in cervix and vaginal mucosal in pregnant bovines (Kunii *et al.*, 2018). Studies suggest that some portion of uterine tissue secreted INFt goes

through the uterine vein and directly regulates ISG expression in peripheric blood cells and corpus luteum (Matsuyama *et al.*, 2012).

The objective of the present study was to study the ISG and INFt gene expression in blood nuclear cells of hair sheep ewes submitted to thermal stress in tropical conditions.

Materials & methods

An experiment was designed considering ten Katahdin ewes of same age and condition. One group (n=5) was submitted to thermal stress in a pen without shadow access during the day, and control group (n=5) with shadow access as main difference in management between groups. Feeding, water and space were the same. Experiment was carried on during late autumn season in 'El Salitre ranch' from the Centro Universitario Temascaltepec of Universidad del Estado de México, in Temascaltepec, Mexico. Both groups were managed with estrous synchronization protocols and natural mating. Assuming conception, different physiological and environmental indicators were recorded to assure standardized conditions as described by Gómez-Guzman *et al.* (2021). Peripherical blood samples were obtained at day 10, 13, 16, 18 and 23, considering the mating day as 0. Blood samples preserved in EDTA were maintained immediately in -70 °C liquid nitrogen freezing until their processing. Pregnancy test was performed at 52 days to corroborate ewe's condition. RNA extraction was performed using the RiboPure™ ThermoFisher commercial kit, following a verification and quantification using the Qubit 4.0 kit (Qubit™ dsDNA HS Assay Kit. Invitrogen, Carlsbad, CA, USA), and a final concentration by a GeneJET™ RNA Cleanup and Concentration Micro Kit (ThermoFisher, Waltham, Massachussets, EUA). Gene expression analysis was performed using the TruSeq Targeted RNA Expression in a Miniseq of Illumina following the degraded RNA protocol. All cDNA libraries were sequenced by single-end strategy (read longitude=150 bp). The expression panel included ISG15 (NM_001009735.1), MX1 (NM_001009753.1), MX2 (NM_001078652.1) and RTP4 (NM_001104930.1) genes (Mauffré *et al.*, 2016) and three new genes of importance for maternal recognition of gestation INFt (X56343.1), IRF-1 (NM_001009751.1) y IRF-2 (NM_001009740.1) (Choi *et al.,* 2001) and constitutive genes as controls.

Gene expression analysis consisted in a differential expression pipeline. From Illumina platform outcomes FASTQ files were generated for each sample, and a quality control analysis was performed by FastQC 0.11.2. Libraries adaptors were removed by trimmomatic. Alignments were performed by KALLISTO, HISAT, STAR using Ovis Aries reference genome (Nov. 2015, ISGC Oar_v4.0/oviAri4) from The UCSC Genome Browser. Quantification of reads from reference genes and expression normalization by transcripts per million (thousand) RSEM was used. Differential expression analysis was performed by Deseq2, as described by Gómez (2021).

Results

Non-clear evidence on differential gene expression was found between thermal stress and control group; however, all constitutive genes showed important amount of expression in both groups. Following this outcomes, a reclassification of groups was made independently of treatment group, considering the pregnancy test performed after the experiment as a sorting criterion. As shows in Figure 1, the transcripts abundance analysis (thousands of transcripts per million) indicated important differences in two assessed genes, IRF-1 and INFt. For IRF-1, during day 13 was significant expression differences ($P<0.0001$) between pregnant (n=4) and non-pregnant ewes (n=6). For INFt was found significant transcript abundance during days 10, 16, 18 and 23 ($P<0.0001$).

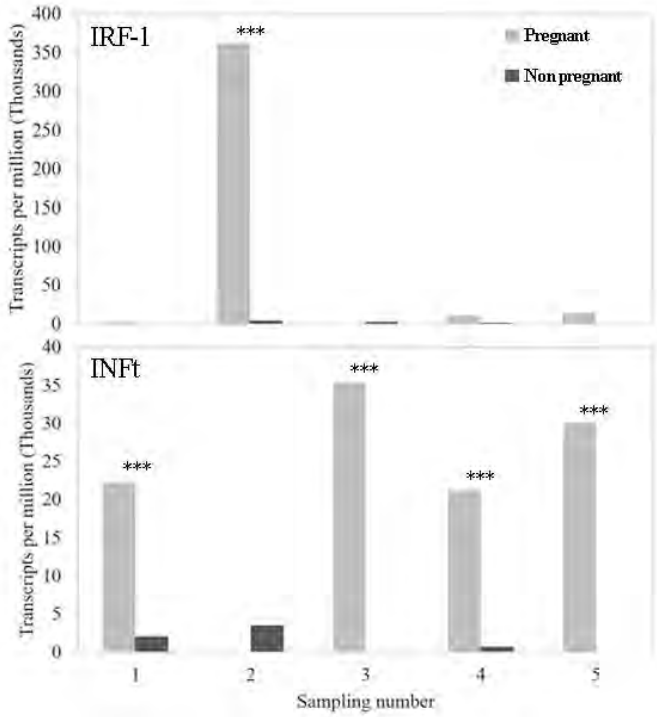

Figure 1. IRF-1 and INFt abundance of transcripts found in peripherical nuclear blood cells in pregnant and non-pregnant ewes.

Discussion

By targeted RNAseq was possible to find evidence of two maternal recognition genes expression in nuclear blood cells during the INFt expression window. Although not evidence on differential gene expression was possible to find under the original experiment arrangement (thermal stress vs control group), abundance analysis as a reliable biological transformation based on the transcript number, was able to show transcription evidences for IRF-1 and INFt genes. IRF-1 has been detected in stroma and glandular epithelia induced by INFt during early gestation (Choi *et al.*, 2001). INFt, has a key role in maternal recognition of gestation and is expected to express since day 8 to 10 in ewes, with secretion found in mononuclear trophectoderm cells from the concept (Hansen *et al.*, 2017). Transcripts from these two genes were found for the first time in leukocytes. Previously, ISG15, MX1, MX2 and RTP4 gene expression was found in these cells (Gifford *et al.*, 2008; Kose *et al.*, 2016). The potential use of these findings in gestation diagnostics has been proposed in ewes (Mauffré *et al.*, 2016) and heifers (Green *et al.,* 2010). Further validation of these outcomes will confirm the novelty of findings on INFt and IRF-1 gene expression in peripherical nuclear blood cells and their potential possible applications on pregnant ewes. Increasing of sample size and revision of technical limitations on RNA quality and availability from samples would improve future experiments for thermal stress differential expression assessments.

Abstract

Tick resistance is a desirable trait in beef cattle to minimise the incidence of cattle tick outbreaks and production loss in tropical and subtropical regions. Identification of genetic determinants of this trait will be beneficial for improved breeding programs. Using RNA-Sequencing, this study investigated gene expression data from skin of tick-infested Brangus cattle with high (n=5) and low (n=6) resistance. There were 229 significant differentially expressed genes (DEGs; FDR<0.05), of which 212 were target genes for 1,866 transcription factors expressed in skin. Regulatory impact factor analysis showed 158 significant TFs (P<0.05) of which *GRHL3*, and *DTX1* were also DEGs in the experiment. Biological pathway enrichment showed the significant TFs and DEGs feature in pathways such as response to infection, transcriptional regulation, and Notch signalling. These results highlight the application of bioinformatic approaches in the identification of key transcriptional factor that are potential drivers of differential expression of host resistance trait in cattle. Thus, these candidate genes could be further explored in gene selection programs to breed for tick resistance in crossbred cattle.

Introduction

Cattle tick infestations negatively affect animal health and cattle production in tropical and subtropical regions worldwide. Tick resistance in cattle is an attractive trait to include in breeding programs as a sustainable solution to control tick outbreaks. However, the selection of tick resistant cattle is still difficult in the field due to reliance on phenotypic assessment by tick scoring methods which are not widely standardised. The application of omics technologies, such as RNA-seq, offer an opportunity to investigate transcripts and regulatory elements associated to this trait. In this context, this paper presents data on skin gene expression from Brangus cattle of divergent host resistance phenotypes (high and low) following 12 weeks of artificial tick challenge with the cattle tick *Rhipicephalus australis*. We hypothesize it is possible to identify the key regulators among skin expressed transcription factors through bioinformatic analysis.

Materials & methods

Animals. 30 Brangus steers (~9 months old) without previous exposure to ticks were recruited for this study conducted under animal ethics approval (QAAFI/469/18). The animals were exposed to artificial infestation with approximately 10,000 tick larvae (*R. australis*) over 12 weeks, during which animals were ranked for their resistance to infestation and skin biopsies were collected on day 0 and week 12 of the trial. The number of developing adult ticks after an infestation cycle (21 days) was estimated with a tick scoring scale from 1 (<50 ticks = High resistance, HR) to 5 (>300 ticks = Low resistance, LR). Animals were ranked according to their mean tick score collected from week 8 to 15 of the trial and the top 6 and bottom 6 animals were selected for skin RNA-Sequencing experiments.

RNA isolation from skin biopsies and sequencing. RNA was extracted from frozen skin preserved in RNAlater reagent (Thermofisher, USA) using a protocol adapted from *Piper et al.* (2008) using the miRNeasy mini kit (QIAGEN, USA) as per manufacturer's instructions. RNA samples were treated with

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_557, © E. Mantilla Valdivieso *et al.* 2022

DNAse and RNA was quantified using the Nanodrop 2000 (Thermofisher, USA). The RNA RIN quality analysis was evaluated with the 2100 Bioanalyzer Instrument (Agilent Technologies, USA). The cDNA libraries were prepared with the TruSeq Stranded Total RNA kit with Ribo-depletion (Illumina, USA) and sequenced as 100 bp paired-end reads on one full S1 flowcell on the NovaSeq 6000 sequencer (Illumina, USA) through the Australian Genome Research Facility (Melbourne, AUS).

Bioinformatic pipeline. Quality control, mapping and quantification of RNA reads was performed with methods described previously (Mantilla Valdivieso *et al.* 2021) using the ARS_UCD1.2 genome and HISAT2 as the mapper tool. Gene expression was modelled with the edgeR package in RStudio (Robinson, McCarthy and Smyth 2009) using the trimmed mean of M-values (TMM) method. The linear model ~MTS+TPS+BIC+RIN was implemented to test for differentially expressed genes in the comparison of animals of low versus high mean tick score (MTS) accounting for the effects of timepoint tick score on week 12 (TPS), the proportion of individual *Bos indicus* content (BIC) (Hayes, Fordyce and Landmark 2019), and the RIN quality of the sample (RIN). Differentially expressed genes (DEGs) were considered significant based on a false discovery rate (FDR)<0.05. RIF analysis (Reverter *et al.* 2010) was implemented through the CeTF package in RStudio (Oliveira de Biagi *et al.* 2020) using filtered and normalised gene expression matrices (logCPMs) as input. The list of TFs and cofactors were obtained from the AnimalTFDBB bovine database (http://bioinfo.life.hust.edu.cn/AnimalTFDB/#!/download) to identify expressed TFs in our data. Functional enrichment of KEGG pathways was performed with the ClusterProfiler R package (Wu *et al.* 2021).

Results

A total of 17512 genes were expressed in cattle skin of low versus high host resistance Brangus cattle. EdgeR identified 229 significantly differentially expressed genes (DEGs; FDR<0.05) of which 128 were upregulated and 101 downregulated. Of these, 212 were target genes for 1866 transcription factors (TFs) expressed in skin (Figure 1A). Regulatory Impact Factor (RIF) analysis to predict key regulatory elements showed 158 significant TFs (*P*-value<0.05) based on metrics RIF1 and RIF2 metrics. Briefly, RIF1 captures TFs showing differential connectivity to DEGs found between high and low resistance phenotypes, whereas RIF2 focuses on TFs showing evidence as predictors of change in abundance of these DEGs. Furthermore, 2 transcription

Table 1. Transcription factors identified as significant by regulatory impact factor metrics (RIF1 and RIF2, $P<0.05$) and differential gene expression (FDR<0.05).

TF symbol	Name	RIF1[1]	RIF2[1]	logFC[2]	FDR[3]
GRHL3	grainyhead like transcription factor 3	0.50	-2.68	1.24	0.048
DTX1	deltex E3 ubiquitin ligase 1	-0.48	-1.96	-2.26	0.017

[1] RIF significance value based on z-scores above 1.96 standard deviation from the mean.
[2] FC = log2 fold change between low and high tick resistance animals.
[3] FDR = false discovery rate corrected (Benjamini-Hochberg) *P*-values.

factor genes *GRHL3*, and *DTX1* were found to be significant by both RIF metrics and differential genes expression in this experiment (Table 1). Functional biological enrichment of the significant TFs and DEGs (2077 genes) showed that the most represented pathways were related to immune response to infection and transcriptional misregulation in cancer (Figure 1B). Enriched pathways with fewer genes included basal transcription factors and the Notch signalling pathway.

Discussion

Artificial challenge with *R. australis* ticks promoted divergent phenotypes of host resistance as determined by their average tick burden during the infestation experiment. Skin transcriptomic data revealed 229 significant DEGs and 158 significant TFs in the comparison of low versus high host resistance Brangus steers. Of these, *GRHL3* (grainy head like transcription factor 3) and *DTX1* (deltex E3 ubiquitin ligase 1) were identified as key regulators by both differential expression and RIF analysis, with high RIF2 metric indicating these genes are potential useful predictors of change in abundance of the skin DEGs. *GRHL3* is an epidermal transcription factor which regulates the differentiation and migration transitions of the progenitor epidermal cell (Klein *et al.* 2017). The regulation of these steps in the epidermal differential process appears to be relevant during wound healing and tissue homeostasis. The upregulation of *GRHL3* in the skin of low host resistance cattle suggests participation in the modulation of gene expression in response to tick infestation. On the other hand, *DTX1* is a transcriptional factor target of the Notch signalling cascade with possible immune effects (Brandstadter and Maillard 2019). Likewise, functional enrichment analysis captured both immune and transcriptional regulation pathways overrepresented in the significant DEGs and TFs including the Notch signalling pathway, which plays multiple functions in the innate and adaptive immune cell development and is consequently relevant in host defence. Overall, these results contribute towards uncovering some of the biology behind this complex trait putting forward a list of candidate regulator genes that may be drivers of differential expression of tick resistance in cattle. Further cross-validation of the significant DEGs and TFs with other skin or blood gene expression studies will facilitate the identification of biomarkers of tick resistance. In this way, improved phenotyping approaches with predictive markers will provide an opportunity rapidly build reference populations for genetic evaluation in breeding programs for tick-endemic regions.

Abstract

The aim of this work was to identify functional variants potentially associated to complex phenotypes, to improve genomic selection. In this study, we combined genomics, transcriptomics and epigenomics data. First, we genotyped 100 pigs with the high-density genotyping array (with 660K markers). Then, we generated RNA-seq data on these animals in 4 biologically divergent tissues: liver, spleen, lung and muscle. We performed an expression GWAS (eGWAS) resulting in the identification of over 150,000 significant associations in each of the tissues. We were able to detect over 1,300 genes that showed a significant eGWAS associations. We also found an enrichment of eGWAS hits within regulatory elements such as enhancers and promoters, which indicates their pivotal role as drivers of phenotypic variation and thus are of highly relevance towards understanding the genetics of complex traits.

Introduction

Unravelling the genetic basis of economically important traits in livestock remains a challenge for the animal breeding sector, and this knowledge is essential to be able to meet the increased demands for higher sustainability.

Genome-wide association studies (GWAS) have been widely used in the sector to detect genetic variants involved in relevant traits. However, this approach alone is insufficient to pinpoint the causal variants for complex traits. A major proportion of phenotypic variation is expected to be due to variation in gene expression. Hence, additional novel approaches such as RNA-seq, that quantify gene expression levels from a given tissue type is inevitable to link genomic variation to changes in gene expression. The integration of GWAS and RNA-seq data, known as expression GWAS (eGWAS) can be used to identify genetic variants associated to gene expression levels.

The eGWAS studies provide novel regulatory variation affecting gene expression. Results can be further supported by annotated regulatory elements provided by the Functional Annotation of Animal Genomes (FAANG) consortium (FAANG data portal: https://data.faang.org/home) using different epigenetic assays. These annotated regulatory elements (RE), include among others, promoters, enhancers and TSS in a variety of mammalian tissues.

The aim of this study was to perform an eGWAS to identify regulatory variants affecting gene expression in a commercial pig breeding line in four different tissues: liver, spleen, lung and muscle. Moreover, we integrated epigenomic data recently generated by the FAANG consortium to assess the likelihood that the significant variants are found within RE such as promoters and enhancers.

Materials & methods

RNA extraction, sequencing and analysis. Four different tissues: liver, spleen, lung and muscle were extracted from 100 crossbred animals. The crossbred animals are resulting from a F1 sow (Landrace×LargeWhite) mated to a Synthetic boar line. RNA extractions were done with the Rneasy kit (Qiagen) following manufacturer's instructions. RNA samples were subjected to quality control parameters

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_558, © M. Gòdia *et al.* 2022

and subjected to library preparation with NEBNext® Ultra™ Directional RNA Library Prep Kit (New England Biolabs). Samples were sequenced at 150 bp paired-end on an Illumina 6000 sequencing platform.

The bioinformatic analysis was followed as in Kern *et al.* (2021). Briefly, RNA-seq reads were trimmed using TrimGalore! (https://www.bioinformatics.babraham.ac.uk/projects/trim_galore/). Filtered reads were aligned to the *Sus scrofa* genome (Sscrofa11.1) with Ensembl version 104, using STAR v.2.7.8 (Dobin *et al.* 2013). Gene counts were assessed with htseq-count v.0.11.1 (Anders *et al.* 2014) and TMM normalized with EdgeR (Robinson *et al.* 2009).

The gene regulatory elements enhancers and promoters, specific for each of the tissues, were extracted from the FAANG database.

DNA extraction and genotyping. DNA from the 100 animals was extracted from spleen using standard phenol-chloroform protocol. After passing the quality control filter parameters, DNA was genotyped using the high-density Axiom™ Porcine Genotyping Array (Thermo Fisher Scientific) that queries 660K variant markers.

eGWAS and enrichment for regulatory regions. eGWAS included 87 samples with RNA-seq and genotype data that passed quality control filters. The RNA expression levels of the detected genes (average >1 CPM) were taken as quantitative traits and tested for association with the genotypes that passed quality control using a linear model in each of the tissues using GCTA v1.25.3 software (Yang *et al.,* 2011) as:

$$Y_i = \mu + SNP_i + kinship + e_i$$

where (Y_i) is the CPM gene expression as a function of the population mean (μ), fixed effect of each SNP (SNP_i), *kinship* based on the genomic relationship matrix (GRM) (Yang *et al.,* 2011 and a random residual effect (e_i). Only associations of FDR≤0.05 were considered.

To identify enrichment of eGWAS hits within RE, genomic regions of the eGWAS hits were iteratively randomized 100 times using BEDtools shuffle (Quinlan *et al.,* 2010). Then, the enrichment of the real eGWAS hit coordinates at gene regulatory regions was assessed by comparison with the overlap of the randomized locations with the regulatory regions using a one-sample T-test (one-tailed).

Results

RNA sequencing. On average, we obtained 44 M reads per sample and tissue. Of these, a mean of 99.9% passed quality filters and on average, 95.1, 92.0, 93.8 and 94.7% of the reads were mapped to the porcine genome in liver, spleen, lung, and muscle, respectively. Considering an expression average abundance >1 CPM in the 100 samples, the number of genes detected in liver, spleen, lung, and muscle, was 12,556, 12,568, 13,211 and 12,516, respectively. Yet, the overall profile was very different between tissues.

eGWAS. The eGWAS analysis resulted in several significant associations, with spleen having the highest number of associations (262,545), and lung the highest number of different genes (2,692) (Table 1).

The numbers of significant associations annotated as *cis*-regulatory variants (≤1 Mbp distance from the associated gene) were 40,211, 67,166, 44,870 and 32,070 in liver, spleen, lung, and muscle, respectively. We also identified several hotspot variants, where the variant was associated with the expression of several genes (≥10). The tissue with the highest number of hotspot variants was lung (3,820 variants), and the tissue with the lowest number was muscle (1,118 variants).

Table 1. Expression GWAS analysis results from the association between genotypes and RNAseq data in the four tissues.

Tissue	Number of significant associations	Number of variants involved	Number of genes involved
Liver	191,622	95,030	1,655
Spleen	262,545	124,353	1,301
Lung	241,047	87,664	2,693
Muscle	149,425	76,300	1,490

Some eGWAS peaks of interest included genes such as *RDH16* (Retinol Dehydrogenase 16) in liver and *TF* (Transferrin) in lung (Figure 1). *RDH16* is involved in vitamin A metabolism, which plays an important role in the regulation of feed efficiency in pigs by affecting energy metabolism, that mediates fatty acid biosynthesis and steroid hormone metabolism (Zhao *et al.*, 2016). *TF* has been linked to play a role in acute respiratory distress syndrome (Upton *et al.,* 2003).

Enrichment at regulatory elements. The location of significant eGWAS hits identified were queried for their overlap within RE regions. We found that eGWAS hits were enriched in promoters and enhancers regions (*P*-value<2.2E-16) in all the four tissues studied. In contrast, the number of eGWAS hit variants found in other REs including insulators, polycomb repressed or low signal elements, was significantly lower than the random set, supporting the role of certain regulatory elements in gene expression levels.

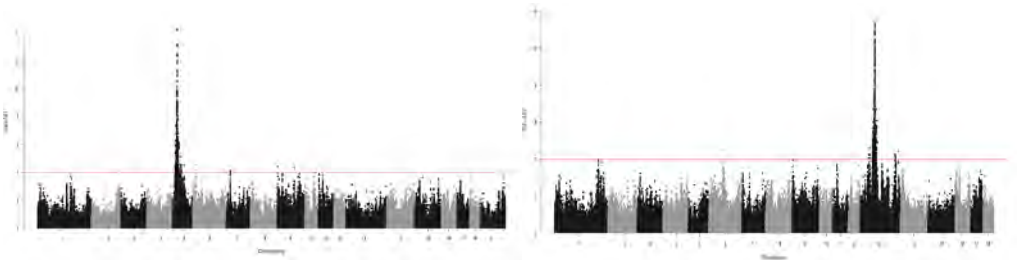

Figure 1. Manhattan plot of *RDH16* in liver (left) and *TF* in lung (right).

Discussion

In this study we report an analysis that compared the genome, transcriptome, and epigenome of biologically diverse tissues in pig. Results showed that the integrative approach of merging different techniques could help to identify variants or narrow down genomic regions involved in complex phenotypes of interest. The results can be integrated with existing QTL regions to identify potential causal variation underlying traits of interest and to understand and improve genomic selection in pig breeding programs.

559. Unravelling the transcriptomic control of growth traits in sheep during prenatal and postnatal development

S.A. Woolley*, M. Salavati and E.L. Clark

The Roslin Institute and Royal (Dick) School of Veterinary Studies, The University of Edinburgh, Easter Bush Campus, EH25 9RG, Midlothian, United Kingdom; shernae.woolley@roslin.ed.ac.uk

Abstract

Understanding gene expression in sheep can offer numerous opportunities to investigate the genomic control of health and productivity, and can help to inform future breeding programs. This study aims to identify transcriptionally active genes associated with growth through the analysis of RNA-sequencing (RNA-seq) data in Texel × Scottish Blackface sheep. Gene expression levels were estimated across tissues and developmental stages and allele-specific expression analysed. Tissue- and developmental stage-specific differences in gene expression were observed. Between day 100 of gestation and one week of age, differentially expressed genes related to muscle growth and development, were upregulated including *COL2A1* and *CDCA8* in liver and *MYH3*, *GDF5* and *COL9A2* in skeletal bicep muscle. Allele-specific expression analysis revealed genes exhibiting allelic imbalance in gene families related to growth. Integration of these results with GWAS data will assist the identification of expressed variants that are associated with growth traits in sheep.

Introduction

To meet future food production targets, and provide sufficient protein derived from red meat for a growing global population, improving the efficiency of sheep production is paramount. Growth traits in sheep are important for production and are often polygenic (Moghaddar *et al.* 2019), making the identification of trait-specific markers for genomic selection challenging. Genomic studies have accelerated the identification of key genes and variants of interest for growth traits, such as the mutation in the 3'UTR region of the myostatin gene associated with the double-muscling phenotype in Texel sheep (Clop *et al.* 2006). Investigation of the sheep transcriptome can offer insight into how gene expression influences growth traits, by measuring, for example, the up- or down- regulation of genes involved in muscle growth and differentiation through pre and postnatal development. This study aims to identify transcriptionally active genes associated with growth through the analysis of RNA-seq data across different developmental stages and tissue types in Texel × Scottish Blackface sheep.

Materials & methods

Animals. A dataset consisting of 48 samples from three prenatal and four postnatal developmental stages from Texel × Scottish Blackface sheep was generated for tissues associated with growth and development. The tissues used in this study were collected for the sheep gene expression atlas project (Clark *et al.* 2017). Prenatal time points: Day 23 whole embryo (n=3), day 23 maternal caruncle (n=2); Day 35 liver (n=3), placentome (n=2), maternal caruncle (n=2) and Day 100 liver, ovary, skeletal bicep muscle (n=4), placentome (n=2). Postnatal time points: Newborn liver (n=3), skeletal bicep muscle (n=3), ovary (n=2); One week of age liver (n=3), skeletal bicep muscle (n=3), ovary (n=2) and eight weeks of age liver (n=3), skeletal bicep muscle (n=3).

RNA extraction and sequencing. RNA was extracted from <100 mg of -80 °C frozen tissue samples using Trizol after homogenisation with ceramic beads. Samples with an RNA integrity number >6 were selected for RNA-seq and were sequenced by Novogene (Cambridge, United Kingdom) using the NEB Next® Ultra™ RNA Library Prep Kit. Libraries were sequenced on the NovaSeq 6000 platform (Illumina®, United States) at an expected depth of 60 million reads per sample with 150bp paired end reads.

Transcriptome analysis. After trimming and quality control, mapping of the RNA-seq data to the Oar_rambouillet_v1.0 (GCA_002742125.1; v103) assembly was performed by HISAT2 (v2.1.0) using standard parameters (Kim *et al.* 2019). To estimate RNA transcript abundance, transcript per million (TPM) counts were quantified with Kallisto (v0.44.0) (Bray *et al.* 2016). Based on the TPM estimates, gene-gene network analyses were performed in Graphia (v2.1) (Freeman *et al.* 2020). Functional gene enrichment using EnrichR (Chen *et al.* 2013) in RStudio (R v.3.6.1) was performed for the first 20 gene clusters generated from the gene-gene network analysis.

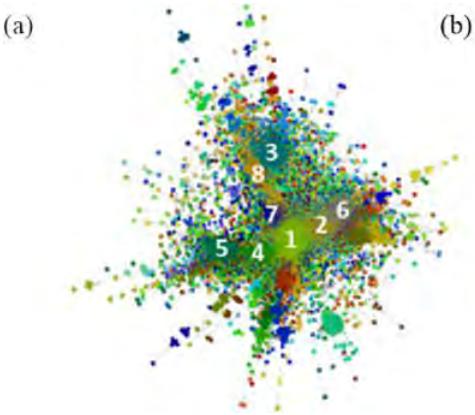
Differential gene expression. Differential gene expression between prenatal day 100 of gestation and postnatal one week of age was analysed using DESeq2 (Love *et al.* 2014), and the non-averaged transcript abundance counts per tissue type from Kallisto for liver and bicep muscle tissue. A likelihood ratio test (LRT) was used to compare a reduced model across each time point per tissue. The thresholds used for the reduced LRT model analysis included a p-adjusted value (p*adj*) <0.1 and a $\log_2$ change ($\log_2$FC) of 5. DESeq2 results were visualised in R studio using EnhancedVolcano (Blighe *et al.* 2021).

Allele-specific expression. In brief, allele-specific expression (ASE) analysis was conducted on all 48 RNA-seq samples. Reference mapping bias and ASE analysis was performed as previously described (Salavati *et al.* 2019). The Liptak score (transformed z score value) from the GeneiASE output (Edsgärd *et al.* 2016) was used as the proxy for the level of allelic imbalance.

Results

Transcriptome analysis. Gene-gene network analysis revealed large clusters of genes exhibiting tissue-specific expression in ovary, liver and skeletal bicep muscle tissues (Figure 1a and 1b). For skeletal bicep muscle tissue the genes within cluster four showed high expression levels at day 100 of gestation, and cluster five showed high expression levels in newborn to one-week-old lambs. Functional gene enrichment for cluster four showed associations of genes within this cluster with GO terms for muscle fibre organisation and development, and cluster five showed associations for muscle fibre organisation and contraction. The Myostatin (*GDF8*) gene, in cluster four, for example, which controls muscle development, showed increased expression at day 100 of gestation relative to the other developmental stages.

(a)



(b)

Cluster	Nodes	Tissue
1	6,288	All
2	1,154	Placentome and caruncle
3	767	Liver
4	591	Day 100 skeletal bicep
5	529	Skeletal bicep
6	523	Day 23 caruncle
7	426	Day 23 embryo
8	349	All

Figure 1. (a) Gene-gene network analysis showing large clusters of genes exhibiting tissue- and developmental stage-specific gene expression. Clusters are labelled according to the tissue type with the highest expression level for that cluster, with a Pearson correlation matrix (positive only) of 0.831 and a MCL granularity of 2.2, with the removal of components with a size ≤5. (b) The eight largest clusters with the number of nodes (genes) and the associated tissue type.

Differential gene expression. Rather than presenting all comparisons for differential gene expression analysis, here we focus on liver and skeletal bicep muscle tissue between one prenatal time point (day 100 of gestation) and one postnatal time point (one week of age). For liver tissue, comparing day 100 of gestation and one week of age showed 12% upregulated and 7.9% downregulated genes. In skeletal bicep muscle tissue, 23% of genes were upregulated and 23% were downregulated. Some differentially expressed genes associated with growth had a log2FC>5 (Figure 2). Genes in families associated with growth such as the myosin, TGF-beta and fibrillar collagen families were identified in skeletal bicep muscle tissue. This included the upregulation of the genes *MYH3*, *GDF5* and *COL9A2*. In liver tissue, genes in the fibrillar collagen family were also upregulated, such as the *COL2A1* gene.

Allele-specific expression. Within the top 20 highest liptak scores, for allelic imbalance, the genes *ACTB* and *ANXA2* showed a liptak score of ~946 for a day 100 of gestation sample and ~641 at a one week of age sample, respectively, in liver. For skeletal bicep muscle tissue, the genes *ACTB*, *IGF2* and *MYH2* had liptak scores of ~813 for a day 100 of gestation sample, ~408 for a day 100 of gestation sample and ~334 for a one week of age sample respectively. These genes were found to be members of gene families associated with growth, including either the actin, annexin, insulin family of polypeptide growth factors and myosin family of genes.

Discussion

Improved understanding of the sheep transcriptome provides opportunities to incorporate gene expression information in genomics enabled breeding programmes for sheep (Yuan *et al.* 2021). The initial results from this study identified large tissue-specific clusters of genes associated with growth and development. Differential gene expression analysis revealed upregulation of genes from both the collagen and myosin families, between pre and postnatal time points consistent with previous RNA-seq transcriptome studies (Clark *et al.* 2017). Differential gene expression and initial ASE analysis showed that genes within the myosin and TGF-beta families, including *MYH2*, *MYH3* and *GDF5*, exhibited significant allelic imbalance and/or upregulation in developing skeletal bicep muscle tissue, with *MYH3* associated with growth traits in cattle (Xu *et al.* 2014). Integration of our results with available eQTL datasets for tissues associated

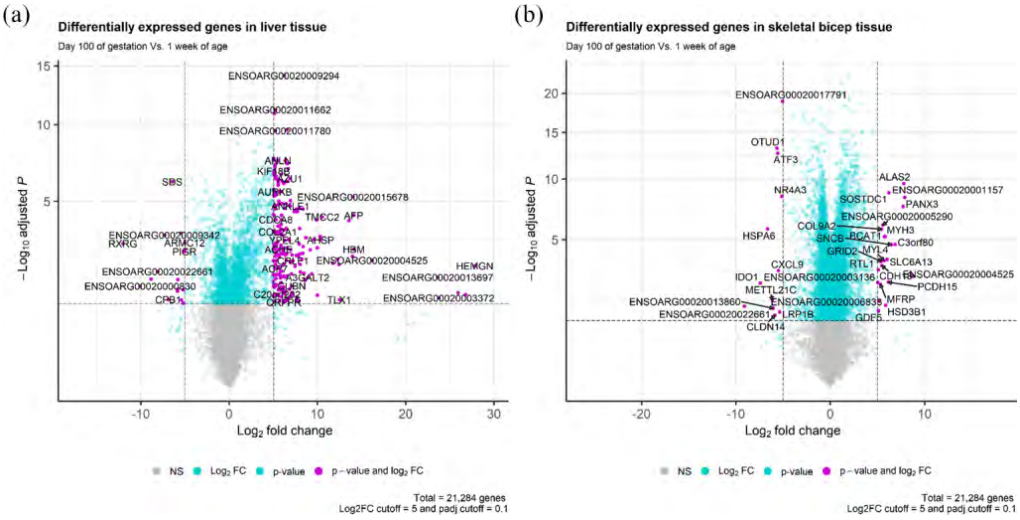


Figure 2. Volcano plots for prenatal time point day 100 of gestation and postnatal one week of age in (a) liver and (b) skeletal bicep muscle tissue, showing differential gene expression using DESeq2.

with growth (Yuan *et al.* 2021), and with information from GWAS, will identify expressed variants located in genomic regions associated with growth traits, which can be exploited in genomics-enabled breeding programmes for sheep. This work was funded by BBSRC award number BB/S01540X/1.

Abstract

RNA sequencing and high-density genotyping or whole genome sequencing can be used in tandem to identify genomic regions associated with the control of gene expression, also known as expression quantitative trait loci (eQTL) mapping. Whole blood is a convenient tissue for many purposes due to its ease of collection and relation to health. Whole blood RNA-seq data and high-density SNP array genotypes were generated on ~1,600 healthy nursery pigs as part of a study of resilience to a polymicrobial disease challenge. This data was used for genotype imputation to whole genome sequence with the reference panel and bioinformatics pipeline developed by the PigGTEx consortium to identify cis-eQTL. Cis-eQTL were typically associated with expression of one or two genes. Chromosome 12 was enriched for cis-eQTL. The results provide insights into the control of gene expression in whole blood, allowing further study of its relationship with disease resilience.

Introduction

Selection and breeding of livestock species thrives on understanding the genetic control of economically important phenotypes. Extensive research is ongoing to better understand the genetic links between phenotypes and genetic markers through intermediate phenotypes, such as gene expression. This research utilizes various tissues to identify these intermediate phenotypes, with one of the most common tissues being blood due to its ease of collection and its relevance to health. As a tissue, blood is interesting as it interacts with other tissues across the organism, which allows it to be used for the detection of abnormalities or changes within the body, such as the onset of disease, or a change in behavior or physiological status. Blood's interconnectedness to other tissues in an organism also provides difficulties, as gene expression levels in blood can be influenced by external factors such as stress, cell composition, and temporal transcriptional differences. This makes it of utmost importance to characterize these influential factors to enhance the informativeness of blood as a tissue and its use to address a multitude of other research questions. In addition to improving blood as a source of gene expression data, it is also important to link these data to economic traits in livestock such as disease resistance/resilience, response to environmental changes, or even just production traits. The use of gene expression data and dense marker genotypes throughout the entire genome allows for eQTL mapping to better understand regions of genomic regulatory control of transcriptomic variation and response to external stressors. Identification of eQTL may indicate hotspots that are indicative of specialized regions of overarching genetic control. The purpose of this study is to capitalize on a uniquely large dataset with both genome-wide SNP genotypes and RNA-seq data to identify cis-eQTL for gene expression in whole blood of young healthy pigs for their potential use to predict future trait phenotypes for the animal.

Materials & methods

Animals and samples. Blood samples were collected in Tempus tubes from ~1,600 healthy Landrace × Yorkshire nursery barrows during the quarantine phase of the natural disease challenge model described by Putz *et al.* (2018) and Cheng *et al.* (2020). Piglets were brought to the nursery in batches of 60 or 75 from one of seven different breeding companies. All pigs were genotyped for approximately 650k markers across the genome.

RNA-seq. RNA-seq data were obtained as per Lim *et al.* (2021). RNA-seq libraries were generated using QuantSeq 3' mRNA Library Prep Kit FWD for Illumina and the RNA Removal Solution Globin Block (Lexogen, Austria) (Lim *et al.* 2019). QuantSeq libraries from 96 samples were multiplexed and sequenced with single end 50bp using Illumina HiSeq 3000 Sequencing Systems (Illumina, USA) for the first 887 samples from Lim *et al.* (2021) and with single-end 100 bp using NovaSeq 6000 Sequencing Systems (Illumina, USA) for an additional 707 samples. QuantSeq reads were trimmed and filtered using BBDuk. Read quality control was performed using FASTQC and mapped using STAR 2.5.3a. Mapped reads were removed if they had a zero count for more than 80% of the samples or were mapped to globin genes, *HBA* and *HBB*. The remaining reads were normalized using EdgeR (Robinson *et al.* 2010).

PigGTEx. PigGTEx is a part of the FarmGTEx project, aiming to develop a comprehensive catalog of regulatory variants in the pig transcriptome. The eQTL mapping pipeline that was used was developed by PigGTEx as a derivative of the cattle GTEx (Liu *et al.* 2021), and was designed to impute genotypes up to a whole genome sequence reference and then perform eQTL mapping using the imputed genotypes and RNA-seq data, using the following softwares: Java, Plink (Chang *et al.* 2015; Purcell and Chang), Beagle (Browning *et al.* 2018), ConformGT, Bcftools (Li, 2011), and TensorQTL (Taylor-Weiner *et al.* 2019). Imputation to whole genome sequence was performed on a chromosome basis using ~1,600 external pigs with whole genome sequence data based on the reference genome Susscrofa11.1. eQTL mapping was performed using TensorQTL by utilizing gene expression data corrected for read counts following Lim *et al.* (2021) and the imputed genotypes. Additionally, PEER estimation (Stegle *et al.* 2012) was used to obtain ten factors from the expression data and PCA was used to obtain the first ten principle components from the imputed genotypes to utilize as covariates in eQTL mapping. Cis-eQTL were defined as eQTL that were within one megabase of the gene whose expression is being evaluated. Multiple testing correction of identified cis-eQTL was done using a q-value calculation based on the approach of Nettleton *et al.* (2006).

Results & discussion

A set of cis-eQTL was obtained for each chromosome for our pig population. From this, we were able to identify the total number of eQTL after q-value control for each chromosome (Table 1), as well as the distribution of the number of genes whose expression is associated with each cis-eQTL. Chromosome six had the largest number of unique cis-eQTL after filtering (268,389), while chromosome 16 had the smallest number of cis-eQTL (51,688). The number of detected cis-eQTL per chromosome generally decreased with chromosome size, except for chromosome 12, which had many unique cis-eQTL, despite its smaller physical size. The largest number of genes whose expression was significantly associated with a given cis-eQTL by chromosome ranged from 12 for chromosome 16 to 53 for chromosome 7. Most cis-eQTL, however, had less than 10 associated genes, with the median number of genes associated with an eQTL equal to five and most eQTL only being associated with one or two genes (Figure 1). The total number of unique genes with a significant cis-eQTL per chromosome ranged from 179 for chromosome 11 to 1,053 for chromosome 6. Again, chromosome 12 had many unique genes for its size, which suggests that chromosome 12 has an abundance of cis-eQTL associated with gene expression in whole blood.

Table 1. Total number of unique cis-eQTL and associated expressed genes (# genes) by chromosome and the maximum number (Max #) of genes whose expression is associated with a single eQTL.

Chromosome	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**
# cis-eQTL	247,046	229,560	194,465	150,175	118,033	268,389	154,336	119,889	140,710
# genes	864	952	763	568	569	1,053	661	342	493
Max # genes	34	50	51	44	35	48	53	20	25

# cis-eQTL	76,294	52,045	166,380	220,995	225,801	103,632	51,688	95,557	53,619
# genes	235	179	621	685	668	386	194	300	208
Max # genes	17	15	41	29	26	24	12	25	23

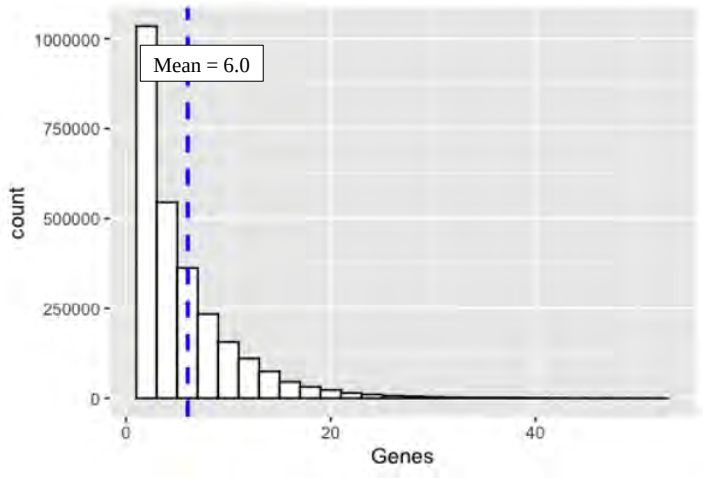

Figure 1. Frequency distribution of the number of genes whose expression is associated with each cis-eQTL.

Future analyses of eQTL for whole blood for this data set will involve an analysis of trans eQTL and of the associated genes and eQTL with disease resilience traits, following Lim *et al.* (2021). Cis- and trans-eQTL analyses after deconvolution of the gene expression data into various cell-type-specific proportions rather than gene expression of whole blood will also be conducted to identify putative regulatory regions associated with gene expression in these individual cell populations, in order to further develop and utilize blood as a tissue for understanding the biological processes behind economically important traits in swine. Through this approach it could become possible to use individual blood component gene expression profiles to identify individuals that are more or less resilient to disease.

Abstract

Structural variants (SV) have gained increasing interest within the last years. However, calling SVs from array genotypes or short-read data is known to suffer from high false-positive rates and low specificity at the same time. In contrast, long-read technologies promise to derive accurate and sensitive SV callsets. We hereby present the first study that uses PacBio and Nanopore long-reads to derive quantitative estimates of the amount of SVs in chicken, based on four trios. We estimated the mean size of the reference genome affected by at least heterozygous SV calls to range from 0.2% for insertions to 0.7% for deletions. We further compared the results to a short-read based calling approach. This revealed more than 2/3 of short-read based initial SV calls not being backed by long-read based calls, while more than 50% of the long-read based calls would have been missed by the short-read approach.

Introduction

During the last years, some prominent phenotypes were shown to be causally affected by structural variants (SV), e.g. different comb phenotypes in chickens (Imsland *et al.*, 2012). Effects of SV may, however, be missed by analyses based on single nucleotide polymorphism (SNP) markers, as linkage disequilibrium between SVs and neighbouring marker SNPs is not necessarily high (Geibel *et al.*, 2021). This has driven the interest in identifying SVs along the genome. SV calling so far was mostly based on SNP-array data or short-read sequence data, and heavily relied on auxiliary information like probe intensity, coverage, insert size distributions, split reads, or local assembly. This led to high false positive rates and low specificity at the same time, especially when calling insertions (INS; Delage *et al.*, 2020), or SVs in repetitive regions (Belyeu *et al.*, 2021). Previous estimates of the SV content of chicken genomes therefore varied massively and reached estimates up to 12.84% of the autosomal genome size (Fernandes *et al.*, 2021).

Many problems of calling SVs from short reads can be overcome by using long reads from Oxford Nanopore Technologies (ONT) or Pacific Biosciences (PacBio) sequencing, which are nowadays considered to strongly improve SV identification (Ho *et al.*, 2019; Sedlazeck *et al.*, 2018b). However, studies identifying SVs based on long read technologies in chickens have not been published to this date.

The goal of this study was to provide a reliable quantitative estimate of the affectedness of the chicken genome by SVs using long-read sequencing of four chicken trios. We further verified how many of these structural variants would have been discovered by short-read sequencing, providing an insight into the false-positive and false-negative rates of the latter approach.

Materials & methods

For the discovery of SVs, four chicken trios were sequenced. The trios were from a commercial White Leghorn line (WLA), a commercial Rhode Island Red line (BLA), a New Hampshire line (L68) and the intercross of an Araucana × WLA backcross experiment. Sequencing was done using Illumina short read sequencing (13 – 42X, 2×151 bp), ONT sequencing (6 – 22X; 3 – 22 kb mean read length) and PacBio HiFi sequencing (3 – 25X; 16 – 22 kb mean read length). Note that for the BLA trio, a fullsib of the offspring chicken, which was sequenced by Illumina and PacBio, was sequenced with ONT due to a shortage of available DNA.

SV calling was performed separately for the different sequencing techniques. The short reads were mapped against GRGC6a by bwa-mem (Li, 2013) and SVs were called by a consensus calling approach that involved parallel SV calling by delly (Rausch *et al.*, 2012), manta (Chen *et al.*, 2016) and lumpy (Layer *et al.*, 2014), followed by feeding the union of the SV calls into svtyper (Chiang *et al.*, 2015) for genotyping. As svtyper is not able to genotype INS, only the calls of manta were considered for INS. Non-default filters for the short read data were not applied at this stage, as the main intention was to see whether short-read data would have provided support for SVs found by long reads. Long reads (PacBio and ONT) were mapped by ngmlr (Sedlazeck *et al.*, 2018a), followed by SV calling and genotyping through sniffles (Sedlazeck *et al.*, 2018a), requiring a threshold of at least five supporting reads. Long-read-based SV detection was performed for the technologies separately as well as based on merged bam alignment files (LRcombined). Finally, a merged VCF was produced for further analysis, using survivor (Jeffares *et al.*, 2017) together with custom awk scripts to account for incompatibilities between the different tools. To account for bad breakpoint resolutions, SV of the same type with breakpoint differences of 1 kb or less were further merged into one SV. Analyses were thereby limited to autosomal deletions (DEL), duplications (DUP), insertions (INS), and inversions (INV) between 50 bp and one Mb. Note that these are early stage results, which will require further validation, e.g. by assessing Mendelian errors in the trios.

Results & discussion

The short-read based consensus calling approach (SRconsensus) identified a total of 32,111 SVs (15.6k DEL, 6.9k DUP, 6.6k INS, 2.9k INV), while 18,487 SVs were identified by the combined set of PacBio and ONT reads (LRcombined; 8k DEL, 1.2k DUP, 8.8k INS, 445 INV). Figure 1 shows the overlap between the different callsets. It is remarkable that more than 50% of the LRcombined SVs (10.5k) did not show even modest support in the SRconsensus set, while 2/3 of the SRconsensus SVs (21.6k) were not supported by long-read based calls. This indicates the known limitations of relatively non-sensitive and unreliable short-read calling algorithms requiring high manual curation effort (Belyeu *et al.*, 2021). However, against expectation (Delage *et al.*, 2020), more than 50% of the INS calls by manta were supported by long reads. Further, only very few DUP (1,244) were supported by the LRcombined set with close to no overlap to the SRconsensus set. This might partly be due to the fact that a high share of raw DUP calls in short-read data sets is expected to stem from mapping errors in badly assembled repetitive regions (Geibel *et al.*, 2021), which might be better resolved by long reads and called as INS rather than DUP then.

Generally, increasing the depth by combining the long-read sets improved the confidence in variant calls and 4k SVs were only discovered in the LRcombined set. Interestingly, slightly fewer SVs (3.3k) were called when only the PacBio set was used, but no longer when combining the sets. This might be a calling artefact, as sniffles has a special HiFi mode that trusts mappings with more confidence, but which could not be used for LRcombined, as LRcombined also included less accurate ONT data. Anyway, this needs further investigation.

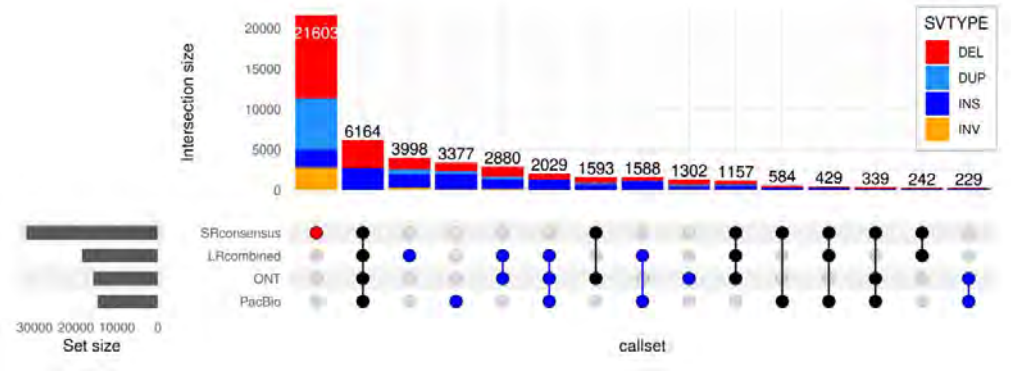

Figure 1. Upset plot showing the overlap between the callsets. Colours in the top plot indicate the proportion of SV types in the intersection. Colours in the intersection matrix instead indicate whether the SVs were found by long reads solely (blue), short reads solely (red) or by both techniques (black).

The length of the called SVs was only investigated for the most reliable set, LRcombined. Length distributions of the SVs (Figure 2A) spanned the complete investigated range between 50bp and one Mb, with lengths >100 kb (DUP and INV) respectively >10 kb (DEL and INS) being rare events. Median sizes of 913bp (DUP), 379bp (INV), 153bp (DEL), and 132bp (INS), however, showed that the vast majority of called SVs was even smaller than 1 kb.

We finally calculated the fraction of the autosomal reference genome that was affected by SV per individual (Figure 2B). This number varied on average between 0.2% for INS and 0.7% for DEL. This is more than what was discovered previously by highly curated short-read based callsets (e.g. Geibel *et al.*, 2021), but by far less than what array-based CNV studies regularly estimate (e.g. Fernandes *et al.*, 2021).

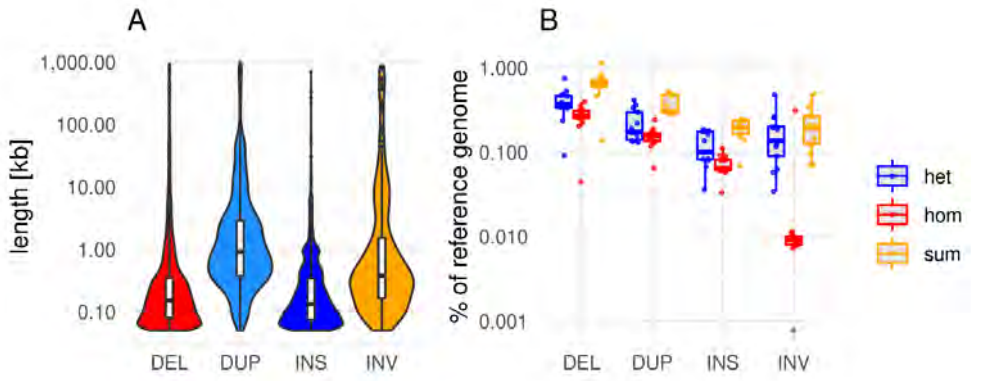

Figure 2. Distribution of SV lengths in the LRcombined callset (A). Percent of autosomal reference genome affected by heterozygous (het), homozygous (hom), or any (sum) SV genotypes by SV type in the LRcombined callset for the different chicken samples (B). Note the log-scaled y-axes.

Acknowledgements

The sequencing of the chicken was funded within the scope of the project IMAGE (www.imageh2020.eu; European Union's Horizon 2020 research and innovation programme under grant agreement No 677353). The Illumina sequencing was performed by the SNP&SEQ Technology Platform in Uppsala, Sweden. The facility is part of the National Genomics Infrastructure (NGI) Sweden and Science for Life Laboratory. The SNP&SEQ Platform is also supported by the Swedish Research Council and the Knut and Alice Wallenberg Foundation. Further, the PacBio sequencing was performed at NGI/ Uppsala Genome Center that has been funded by RFI/ VR and Science for Life Laboratory, Sweden. It was further supported by the National Genomics Infrastructure (NGI)/ Uppsala Genome Center and UPPMAX by providing assistance in massive parallel sequencing and computational infrastructure.

Abstract

De novo mutations arising in the germline add to genetic variation. The number of *de novo* mutations occurring every generation, especially structural variants, has not been well studied in most species, including livestock. We used whole-genome sequencing from 46 pig trios from two commercial lines to identify *de novo* structural variants (dnSVs) present in the offspring. We characterised these dnSV by identifying their parent-of-origin, predicting their causal mechanisms, and identifying their functional annotations. We identified four dnSVs, including two clusters of mutations. One of these clusters contained a deletion, and three duplications, one of which was inverted. This cluster was the only dnSV that could be phased and was located in the paternal haplotype of the proband. All four identified dnSVs were located within the introns of genes. Our study is the first of its kind to identify and characterise dnSVs using whole genome shotgun sequence data in pigs.

Introduction

Mutation is the fundamental source of genetic variation. There are two types of mutations that can be found in the germline, and therefore can be transmitted to the next generation: *de novo* mutations (DNM) which arise in the germline during gametogenesis (Bishop *et al.*, 2020) and mosaic mutations which have arisen early in the zygote cell during embryogenesis (Jin *et al.*, 2018; Sasani *et al.*, 2019). The genetic variation introduced by mutations, allows for continued selection and adaption in a population, with the tradeoff that DNMs can be deleterious and impact the fitness of an individual (Belyeu *et al.*, 2021).

Structural variants (SVs) are altered DNA segments larger than 50 base pairs, that are a change in copy number, chromosomal location or orientation (Escaramís *et al.*, 2015). The detection of *de novo* SVs (dnSVs) is important because they can change gene dosage and structure, and affect gene expression and function by gains or losses of DNA segments (Bhanuprakash *et al.*, 2018; Ran *et al.*, 2018). We aimed to detect dnSV in two commercial pig lines using whole genome sequencing of trios and characterise these dnSV, including predicting their causal mechanisms, functional annotations, and where possible, identifying the parent-of-origin.

Materials & methods

Samples. DNA from 117 individuals (46 trios from two commercial pig lines) was sequenced (Illumina paired-end sequencing, mean coverage = 30X) and aligned to the Sscrofa11.1 assembly (NCBI, 2017). Nine trios were excluded because of poor DNA sequence quality.

SV detection and de novo candidate filtering. We used a Smoove (v.0.2.8) pipeline (v.0.1.0) for calling SVs (Pita Barros, 2021). Three types of SVs were identified for our study: deletions, duplications, and inversions. We filtered SVs using Bcftools (v.1.9), VCFtools (v.4.0.0) and custom R (v.3.6.2) and Python

(v.2.7.15) scripts. SV were declared a dnSV when the proband was heterozygous for the SV and parents and unrelated trios did not have the SV. The sum of genotype quality (GQ) scores for a trio had to be greater than 120. We included additional filters based on SV type, checking depth fold-change, minimum and maximum allelic balance for probands and parents respectively, and a maximum of three reads supporting the dnSV were allowed in either parent. Finally, candidate sites were manually inspected using Integrative Genome Viewer (IGV) (Robinson *et al.*, 2011), to remove spurious dnSV cases.

Characterising dnSVs. To identify the parent-of-origin, we looked at informative SNPs located within the dnSVs. For deletions, the informative SNPs we used were homozygous for the alternative allele in the proband, and homozygous for the reference allele in one of the parents and for duplications, informative SNPs were heterozygous with a 2:1 ratio and one parent homozygous (for either allele) and the other heterozygous (Brandler *et al.*, 2016). Genes located within the dnSVs were retrieved from Ensembl (release 104, May 2021) and NCBI annotation (release 106, May 2017) using NCBI Genome Data Viewer (Rangwala *et al.*, 2021). We identified the most likely causal mechanisms for dnSV formation based on split reads spanning the breakpoints of the dnSVs. Based on the degree of sequence homology at junctions we classified them as either non-homology (Belyeu *et al.*, 2021) or microhomology (Hastings *et al.*, 2009; Quinlan *et al.*, 2010; Yan *et al.*, 2007).

Results

Identified dnSVs. A total of 90,031 structural variants (SVs), including 46,478 deletions, 6,541 duplications, 5,977 inversions, and 31,035 breakend class variants (not included in further analyses) were identified. After filtering for dnSVs, we retained 187 candidate dnSVs and after visual inspection, we identified four dnSVs (Table 1). We estimated a mutation rate of 0.108 per generation (1 dnSV per 9 offspring). We identified two DNM clusters. The first involved a 187-bp duplication, a *de novo* single nucleotide variant within the duplication and a small 11-bp deletion at the distal breakpoint of the duplication. The second was a complex dnSV cluster, which consisted of one deletion and three duplications, of which one duplication was inverted.

Characterising dnSVs. The complex dnSV cluster had informative SNPs in each of the four components identifying it as a paternal haplotype. The other dnSVs had no informative SNPs located within the breakpoints. All gene annotations and predicted mutational mechanisms are reported in Table 1.

Table 1. *De novo* structural variants detected in two pig lines using whole genome sequencing of trios.

Discussion

This is the first study to detect and characterise dnSV in pigs. The dnSV rate, 0.108, was similar to that found in humans Belyeu *et al.* (2021) (0.122). Some dnSVs could remain undetected because it is challenging to uniquely map short-reads to repetitive DNA (Weckselblatt and Rudd, 2015). The use of more costly long-read sequencing technologies would span these repetitive regions and aid in dnSV detection there. Regardless, the DNMs identified in this could contribute to the genetic improvement programs of the evaluated commercial lines in this study, if future studies show they affect production and functional traits.

Complex mutation clusters. Two of the four high evidence dnSVs co-occurred with other DNMs and were complex mutational clusters. The observation of mutational clusters is consistent with other studies (Brandler *et al.*, 2016; Hermetz *et al.*, 2014). A possible explanation are mutational hotspots, which means we would expect an increased number of standing variants near the breakpoints of dnSVs too (Brandler *et al.*, 2016). Understanding these complex mutation clusters is necessary to fully interpret the effects on phenotypic characteristics.

Mutational mechanisms. We found that three out of four high evidence dnSVs were mediated by mechanisms that do not require sequence homology at breakpoints. This agreed with the study by Belyeu *et al.* (2021), which showed that 75% of the detected dnSVs in humans lacked sequence homology. We found that the dnSV cluster arose through several mechanisms, including non-homology, micro-homology and an unidentified complex mechanism. In other SV studies classifications are more specific (Hastings, Lupski, *et al.*, 2009), however, identifying the exact causal mechanisms is complex, and mechanisms can act together (Hastings *et al.*, 2009).

Intronic dnSVs and gene expression. We found that the four dnSVs were overlapping within the first introns of protein-coding genes, where regulatory elements are known to be preferentially located (Rigau *et al.*, 2019). The three known genes, presented in Table 1, are: (*BICRAL)* associated with the Coffin-Siris Syndrome 3 in humans which causes congenital malformation including feeding difficulties and poor growth; (*NCKAP5*) associated with Attention Deficit-Hyperactivity Disorder and Drug-Induced Lupus Erythematosus in humans; and (*SLC14A*) involved in the urea transport family (GeneCards). However, the effects of the detected dnSVs on the pigs they were identified in, remains to be discovered.

Ethics statement

All biological material used in this study was collected as part of routine commercial operations.

Abstract

Chromosomal structural rearrangements are the cause of reproductive problems. They can be transmitted between generations by progeny carrying a balanced translocation. Detection and elimination of carrier bulls and their carrier progeny is desirable to increase on-farm conception rates. In this paper, we propose to detect these chromosomal abnormalities based on a significant association disequilibrium between markers of different chromosomes in the progeny of a bull. This approach applied to 2,445 Holstein artificial insemination (AI) sire families resulted in the detection of 10 candidate rearrangements (0.41% of bulls). Most of the suspected bulls had low conception rates (relative loss of 29-65% compared to breed average). While historically, translocation studies in cattle focused on targeted cases, our method can be used routinely to detect chromosomal rearrangements based on SNP genotypes available for genomic evaluation.

Introduction

Chromosomal abnormalities have been reported in many livestock species (e.g. Mallepaly *et al.*, 2017) with serious negative consequences for health and reproductive performances. In contrast to other species, in cattle, there are few systematic cytogenetic controls by banding, which probably leads to an underestimation of the phenomenon (De Lorenzi *et al.*, 2012). To date, only 20 reciprocal translocations and 42 Robertsonian fusions have been reported (Iannuzzi *et al.*, 2021). In this paper, a new routine method, using genomic information from halfsibs families, is proposed to detect structural rearrangements in AI sires.

Materials & methods

Genomic and cytogenetic analyses. Phased and imputed Illumina Bovine SNP50 genotypes were obtained from the French genomic evaluation database as described in Mesbah-Uddin *et al.*, 2019. We considered a total of 2,445 Holstein paternal families comprising from 30 to 12,600 halfsibs, all genotyped in France. The average number of informative SNPs on the 29 autosomes was 14,561±607 per bull. Genomic data were processed with R 3.6.2. Association correlations between SNPs were calculated using R package gaston 1.5.6. Significance thresholds under H0 were obtained empirically as follows: 100 bulls with more than 1,500 genotyped offspring and with good reproduction scores (i.e. assumed to have normal karyotype) were selected. For each bull, 10 samples of n progeny were randomly drawn for 12 given values of n between 25 and 1000. For each halfsib family of n individuals, a two-dimensional genome scan was used to detect the maximum correlation between markers of two distinct chromosomes (Rmax). This Rmax was scored if 19 informative adjacent markers on each chromosome had R levels values greater than 0.75 Rmax. If this condition was not met, we considered the next highest correlation between markers of distinct chromosomes and so on. For a given n, 1000 (=10×100) halfsib families were analysed. Thresholds corresponding to $P<0.001$ were obtained for any n between 25 and 1000 by fitting a regression curve to these data (n, Rmax). These thresholds, ranging from 1 to 0.24 for 30 to 1000 halfsibs, enabled us to detect bulls with putative chromosomal rearrangements. Correlation graphs displayed in the results were plotted with ggplot2 3.0.0. package of the R software. Finally, karyotypes of sire C and eight daughters of sire E were obtained from blood lymphocytes as described in Ducos *et al.*, 1998.

Reproduction data. Out of the 2,445 sires considered, the conception rate (CR, i.e. the number of calving occurring between 264 and 294 days after AI divided by the number of AIs) and non-return rates (NRRx; defined as proportion of cows not re-inseminated x days after AI) were calculated for 2,252 bulls that totalized at least 200 AIs with conventional semen between 2010-01-01 and 2020-12-31 (35 million AIs considered).

Results & discussion

In our dataset, ten bulls (0.41%) were suspected to carry a structural rearrangement with $P<0.001$ (Table 1). Surprisingly, none of them was Robertsonian, contrarily to what would be expected in a species with only acrocentric autosomes. The estimated size of the translocated segments ranged from 2 to 25 Mb (mean=10.3±8.2 Mb) and 15 out of the 29 autosomes were affected with two occurrences for BTA2 and three for BTA8 and BTA12.

We have begun collecting blood samples from these sires or their offspring for karyotyping. At time of writing, we had results for 2 bulls, confirming our findings. For bull C, we observed a reciprocal translocation between BTA 3 and 8 in both analyses (Figure 1a). For bull E, delineation of the rearrangement boundaries was made difficult by a run of homozygosity on BTA8 (b, up) and the small size of the segments involved. We observed additional material only on BTA8 (dark band) in the karyotype of some of the daughters. We hypothesize that this rearrangement is a simple insertion of chromosomal material from BTA4 into BTA8.

Table 1. Characteristics of the 10 putative rearrangements.

Bulls ID	A	B	C	D	E	F	G	H	I	J
Affected chromosomes	2,13	10,12	3,8	5,28	4,8	24,29	2,12	6,8	11,16	12,23
Genotyped progeny	36	35	512	68	519	59	49	100	43	41
CR (rank among 2,252 bulls in %)	21.8	24.1	21.2	14.3	28.7	21.5	15.7	43.8	26.1	21.6
	(99.7)	(99.6)	(99.8)	(100)	(99.2)	(99.8)	(99.9)	(29.0)	(99.6)	(99.7)

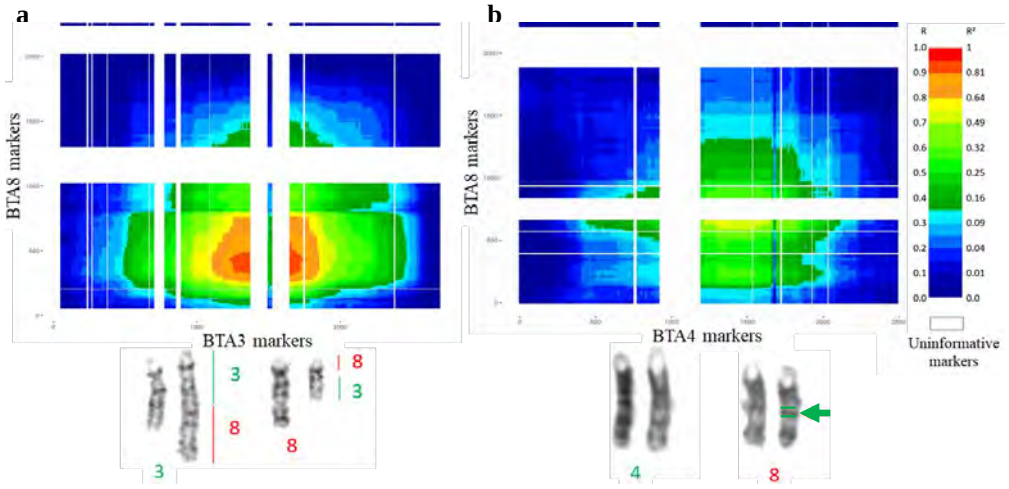

Figure 1. Linkage disequilibrium map of affected chromosomes (up) and details of karyotype (down) for bulls C (a) and E (b).

To precisely identify breakpoints and to search for motifs in their vicinity that could have favored chromosomal rearrangements, genomes of bulls A to J will be sequenced using PacBio CLR technology.

In a second step, we studied the reproductive performances of these ten bulls. Heterozygous carriers of structural chromosomal abnormalities, when they are fertile, can produce balanced (normal, rearranged) and unbalanced (with nullisomy and disomy) gametes. In most cases, unbalanced gametes cause early embryos or fetuses death (Raudsepp and Chowdhary, 2016). Nine bulls had a CR within the lowest percentile of their breed (Table 1) and represented 40% (9/2,252×100) of this worst percentile. Analyses of NRR over time supported early embryonic loss with distinct profiles (Figure 2).

For example, despite their low reproductive scores, bull E and D showed marked differences in the decrease of NNR as compared with the breed average, and thus of embryo and fetal losses (Figure 2a). Daily cumulative proportions of NRR loss also showed a diversity of patterns with bulls losing embryos rapidly (Bull C) versus bulls suspected of causing late fetal death (Bull J; Figure 2.b). This could be explained by the possible effects of rearrangements on semen production (Raudsepp and Chowdhary, 2016) and the diversity of consequences on early embryo or late fetal death (during organogenesis) depending on the genes carried and the size of the rearranged regions (Priya *et al.*, 2018). In our results, one bull (H) did not show evidence of reduced fertility. Further investigation should enable us to determine if this was a false positive or if this animal carries a rearrangement compatible with the survival of aneuploid conceptuses up to birth.

The high consequences on bull fertility of the rearrangements we have identified show that breeding companies should be immediately notified in case of high return rate (in worst 1% of the breed) and the suspect bulls should be at least karyotyped before continuing to sell their semen. Regardless of the genomic evaluation of sires, we advise companies to cull corresponding bulls to avoid a wide spread of abnormalities with long-term and costly consequences on the dairy sector. Non-carrier bulls can of course, be selected for the next generation.

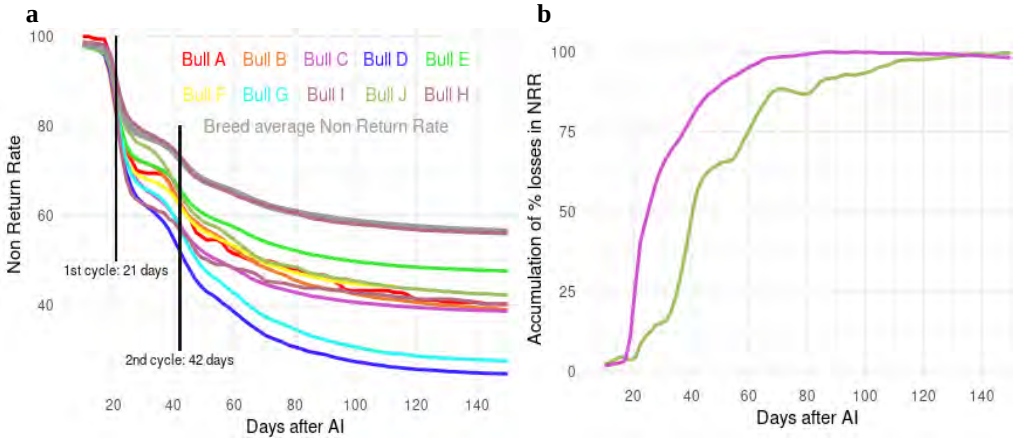

Figure 2. Non-Return Rate vs breed average (a) and daily accumulation of the proportion of losses in NRR for bulls C and J (b).

The method we propose in this communication may underestimate the occurrence of chromosomal abnormalities. Indeed, chromosomal abnormalities can cause sterility by azoospermia (Ghieh *et al.*, 2021). On the other hand, fertile bulls, because of their low fertility, might be prematurely culled because of their low NRR. They also have fewer calves and therefore fewer calves to be genomically tested by breeders, which decreases the accuracy and detection power of the method. We are working on complementary methods to detect suspect bulls based on genotypes of less than 30 daughters.

Despite this possible underestimation, our results are similar to studies in other species. Indeed, in human and swine populations, approximately 0.1 to 0.8% of individuals would carry a *de novo* chromosomal rearrangement (Barasc *et al.*, 2016; Tucker *et al.*, 1994). Furthermore, in humans, chromosomal abnormalities are estimated to cause half of embryo and fetus losses (Pylyp *et al.*, 2018).

Conclusions and perspectives

Chromosomal abnormalities have serious consequences for the dairy industry, especially with the high selection intensity of genomic breeding programs, narrowing down the number of bulls while allowing massive use of their semen before detecting problems with progeny tests. On the other hand, the large datasets generated in the framework of the genomic evaluation allow detection of rearrangements with high efficiency and higher resolution than the karyotyping banding method (5 to 10 Mb). The method proposed in this article can be used routinely to identify bulls with abnormal karyotypes and their balanced progeny to manage these defects in selection.

Abstract

Genomics related research in animal breeding is usually performed by comparing genomic information to an existing reference genome. However, even if the reference genome is of high quality, the use of a single reference genome has clear drawbacks. Therefore, the breeding community is shifting towards the construction of a pan-genome for important agricultural species. In this study we produced a pig pan-genome based on four different breeds (Landrace, Large White, Synthetic, Duroc) using the nanopore long read sequencing technology. We produced chromosome arm level assemblies comparable to the current *Sus scrofa* 11.1 reference genome. We identified between breed structural variation, which gives a unique insight in the genomic structural variation that define and differentiates breeds. The pig pan-genome will facilitate the discovery of novel variation providing a unique fundamental insight into breed genomic characteristics, which can subsequently be utilized for breeding.

Introduction

In recent decades, high quality reference genomes have become available for most important livestock species. The availability of the pig reference genome (of Duroc origin) together with gene annotation have revolutionized pig genomics and genetics research over the past decade (Groenen 2016). Despite the high quality of the reference genome, working with a single reference genome also has clear drawbacks (Ballouz *et al.* 2019), meaning that sequences deviating considerably from the reference will be interpreted as low-quality, so-called reference bias. One consequence of much (structural) variation is often missed. Structural variation includes various types of variation in which longer stretches of DNA are altered. Structural variants can have a large effect on phenotypes but they are often ignored or remain unidentified (Bickhart and Liu 2014). The developments in long-read sequencing technology, now enables these shortcomings to be addressed. Hence, current focus shifts towards the generation of a pangenome sequence (i.e. all genes and genetic variation within a species that is built from the alignment of different reference genomes) in many important agricultural species, including pigs (Tian *et al.* 2020). The pig pan-genome is particularly useful to identify presence/absence gene variations, structural variation, and other miscellaneous variations. In this study we aim to construct breed specific reference genomes of four commercial pig breeds and assess their structural variation.

Materials & methods

Samples. DNA from 30 individuals was sequenced using the nanopore technology to obtain long reads. Four individuals were sequenced on three flowcells to obtain high coverage sequence data to build breed specific reference genomes (Figure 1). The breeds comprise two dam lines (Large White and Landrace) and two sire lines (Duroc and Synthetic). Additionaly 26 animals were sequenced using one flowcell each. The Circulomics kit was used for DNA extraction. All flow cells were subject to three loadings to obtain optimum output. The average number of gigabases sequenced was 120 Gb, reflecting an average coverage of 48X per flowcell. The average read N50 was 42 kb.

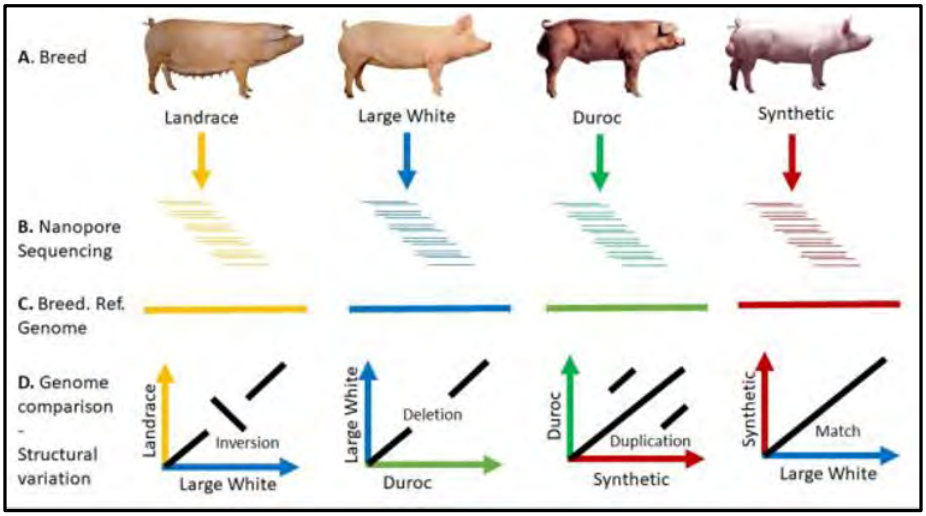

Figure 1. (A) Different pig breeds used in commercial pig breeding; (B) Long read sequencing; (C) Assembly of the long reads to produce breed specific reference genomes; (D) Genome comparison and types of structural variation between the breeds.

Genome Assembly and completeness. We used Flye 2.9 to produce a de novo assembly with the nanopore long reads to construct four breed-specific reference genomes (Kolmogorov *et al.* 2019). Further scaffolding was performed using ntLink (Coombe *et al.* 2021). Polishing was performed using Polca with Illumina short read data from the same individuals (Zimin and Salzberg 2020). The assemblies were anchored to the *Sus scrofa* 11.1 reference genome using RagTag (Alonge *et al.* 2019). The annotation from *Sus scrofa* 11.1 was lifted to the breed-specific reference genomes using Liftoff (Shumate and Salzberg 2020). We assessed the completeness using the BUSCO pipeline (Seppey *et al.* 2019) with the mammalian dataset.

Structural variation and functional prediction. We ran Syri to assess (structural) variation between the line specific genomes (including the *Sus scrofa* 11.1 reference genome) in a pairwise setting (Goel *et al.* 2019). Syri provides VCF files with all identified (structural) variation. We annotated the structural variation for their potential functional consequences using the Ensembl Variant Effect Predictor (VEP) build 104 (McLaren *et al.* 2016). For the one flowcell samples we mapped the samples to the breed reference genome using minimap2 (Li 2018). Subsequently we used Sniffles to assess structural variation between the sample and the breed specific reference genome.

Results

Breed-specific reference genomes. We constructed four breed specific reference genomes. We were able to generate chromosome arm level assemblies for each breed. The acrocentric chromosomes were covered in single scaffolds, whereas the other chromosomes were comprised of 2-4 scaffolds per chromosome. The N50 ranged from 66 to 84 Mb and the contig N50 ranged from 36 to 44 Mb, comparable to the contig N50 of the Sus scrofa 11.1 reference genome. The assembly statistics are given in Table 1.

The assembly completeness was 96.4% for all four breed specific reference genomes using the mammalian BUSCO dataset. The assembly completeness improved significantly after polishing with the Illumina short reads (from ~92 to ~96%).

Table 1. Assembly statistics.

	Sscrofa11.1	Duroc	Landrace	Large White	Synthetic
Assembly length	2,501,921,388	2,478,252,964	2,457,756,321	2,467,972,811	2,476,650,521

Structural variation compared to the Sus scrofa 11.1 reference genome. We used Syri to assess structural differences between the breed specific reference genomes and the 11.1 reference genome (Table 2). The Duroc genome has the least differences with the reference genome especially for the SNPs, inversions, and deletions category. Landrace has a higher number of deletions compared to the other breed-specific reference genomes. This is because we don't have short read data for Landrace (yet) and therefore this breed-specific reference genome remains unpolished, reflected in the number of indels (insertions, deletions).

Large structural variations. We identified various large structural differences between the breed specific reference genomes. First, we identified a 2.8 Mb inversion on chromosome 6 present in all four breed specific reference genomes, but not present in *Sus scrofa* 11.1. This is likely an assembly error in the reference genome. Next we identified a Large White specific 6.2 Mb inversion on chromosome 17. In addition, the start of chromosome 10 is incomplete in the 11.1 reference genome. This first 2 Mb of this chromosome is present in an unplaced scaffold in 11.1 but it's attached to chromosome 10 in our four breed specific reference genomes.

Table 2. Structural variation between the breed specific genomes and the Sus scrofa 11.1 reference genome.

Variation	Large White	Duroc	Synthetic	Landrace

Insertions	1.5 M	1.3 M	1.3 M	1.1 M
Deletions	785 K	667 K	812 K	4.2 M
Copygains	118	90	113	123
Copylosses	126	90	101	107

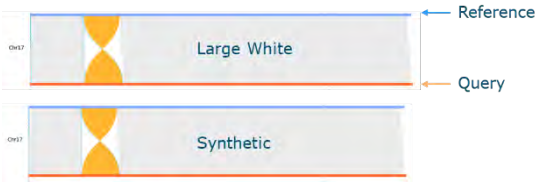

Figure 2. Large white specific (Synthetic is Large White based) inversion on chromosome 17.

Interestingly, we identified a translocation of the complete KIT locus (length 490 kb). The locus is translocated to position 55,035,942 on chromosome 8 (from 41,294,443). That translocation was not identified in the Duroc line specific genome.

Genes affected by structural variants. Table 3 shows the set of structural variants, the type of variants and the genes affected by the variants. Last four columns show the presence of the structural variants in breeds.

Discussion

The power of a commercial pig pangenome. This pig pangenome is a useful resource to identify structural variation between breeds as well as within breeds. Moreover, mapping of short read data will be improved once it is mapped to the pangenome graph instead of a single reference genome. Note that we cannot exclude that some of differences stem from assembly errors despite our high quality chromosome arm assemblies.

Genes affected by structural variation. We identified a set of genes affected by structural variation. Most of the variants disrupt part of the gene. It still remains to be investigated what the exact consequence of the variant is. It is possible that the variant only affects a single isoform of the affected gene. Nevertheless several shared variants are found between different breeds. These variants could have originated before the breed differentiation.

Within breed structural variation. Assessing within breed structural variation that segregates at moderate or low frequency will be highly valuable for breeding purposes. After identification, we plan to assess the phenotypic consequence of the structural variants and potentially add the variants to a SNPchip

Table 3. List of genes affected by structural variation (coding sequence). Notal means not aligned, and cpl means copy loss in query.

used for routine genotyping and enable selecting on identified variants. Moreover, we now map sequence reads to a reference genome constructed from an animal that belongs to the same population. This will greatly improve structural variation discovery because there are less structural differences between the sample and the reference genome.

Abstract

We present a comparative genetic analysis of the loci underlying genetic variation in mortality caused by warm water columnaris disease (CD) in farmed rainbow trout (*Oncorhynchus mykiss*) populations. We provide evidence for the conservation of major QTLs, and the putative role played by chromosomal rearrangements in determining resistance to CD. We genotyped 3,962 individuals from two populations experiencing a natural *Flavobacterium columnaris* outbreak. Association analyses identified a major QTL in both populations on chromosome Omy3 and a secondary on Omy5. The QTL on Omy5 was within a naturally occurring major inversion, for which we were able to determine that the ancestral haplotype was associated with lower mortality. Genetic correlation between mortality in the two populations was estimated at 0.64, implying that the populations share much of the same genetic architecture for mortality. Our QTL validation suggests that QTLs could be used in marker-assisted selection, or specifically modelled in genomic evaluation to improve resistance by selective breeding.

Introduction

Flavobacterium columnaris is the etiological cause of columnaris disease (CD), whose mortality is especially high in younger fish, killing fry between 12 to 48 hours after infection (Declercq *et al.* 2013). A vaccine is not available for salmonids, and disease management relies on antibiotics. There is therefore a strong interest in selecting for increased resistance in host species. Rainbow trout (*Oncorhynchus mykiss*) is a prominent aquaculture species worldwide and is one of the main species susceptible to CD. This species has been the subject of extensive genetic analysis, which has generated a reference genome, a commercial SNP chip (Palti *et al.* 2015), and detailed information about naturally occurring genomic rearrangements, such as inversions (Pearse *et al.* 2019), that are present in this species.

In aquaculture species, quantitative trait loci (QTL) are unusually prominent for disease resistance (Fraslin *et al.* 2020), perhaps because of the early phase of domestication. There are two approaches to use QTL information in selective breeding. In a genomic breeding value evaluation with tens of thousands of SNP markers, SNPs can be given a weighting relative to their allele substitution effect on a phenotype. In a simpler marker assisted selection (MAS), pedigree-based evaluation can be augmented by a few markers linked to major QTLs. Both approaches are possible in aquaculture (Houston *et al.* 2020).

We present the results of a genome-wide association study (GWAS) for mortality after a CD outbreak in rainbow trout from two Finnish broodstocks. We addressed the questions of: (1) whether the same chromosomal regions are associated with mortality in both populations; (2) what the heritability of mortality due to infection is; and (3) whether we observe a positive genetic correlation between the mortality trait in both populations. We discuss our results in the light of replicability of association analysis results, and of the conservation of effects of QTL, and other genomic structural variants.

Materials & methods

Populations and genotyping. The fish used in this study come from two broodstocks, one from Savon Taimen Oy (ST), and the second from the national breeding programme maintained by Natural Resources Institute Finland (Luke). 48 sires and 33 dams, and 25 sires and 100 dams were used to make offspring in the Luke and ST populations, respectively. In ST population, the offspring were all-female due to the use of neomale sires, while the Luke population was a mixed sex population. Offspring were raised in one farm in 6 tanks (3 for each population). A natural CD outbreak affected all tanks, and tissue samples were collected for dead and surviving fish (4,505 samples). DNA was extracted and genotyped using the commercially available 57K SNP Axiom™ Trout Genotyping Array. After quality control we had data for 25,853 SNPs and 1,284 ST samples, and 2,691 LUKE samples (1,341 females, 1,337 males). All markers were mapped against the Omyk_1.0 genome.

Statistical analysis. We used PLINK to calculate F_{ST}, and pairwise additive genetic relationship coefficients. We used Genome-wide Complex Trait Analysis (GCTA) to calculate the effective genomic relationship matrix (GRM), which was used in a subsequent GWAS. To study consistency of QTLs, GWAS was performed on each population and sex independently, later combining all samples together, and combining LUKE males and ST females. We used a mixed linear model with leave-one-chromosome-out approach (MLMA-LOCO) using Bonferroni corrected 5% significance thresholds at the genome-wide and chromosome-wide levels. We tested for the presence of a large inversion on chromosome Omy 5, using tagging SNPs (Liu *et al.* 2021). We were able to unequivocally identify the genotype of each fish for the presence of the Ancestral (A) or Rearranged (R) haplotypes. We used the threshold model using BLUPF90 software for the estimation the GRM and of heritability of mortality in each population independently, and to calculate the genetic correlation between the two populations.

Results

The average F_{ST} between ST and LUKE offspring was 0.03, indicating that the two populations were closely related. Pairwise additive genetic relationship between the two populations ranged between 0.00 and 0.34, with median of 0.00. Every single sample in both populations has at least one non-zero additive genetic relationship value with the other population.

GWAS identified a QTL on Omy3 above chromosome-wide significance in all cases (Figure 1A, B, D, E), and above genome-wide significance in all cases except ST fish (Figure 1C). The SNPs associated with this QTL explained between 4 and 12% of the genetic variance. We also observed an inversion on Omy5 (red dots), which is associated with a QTL of different effect in LUKE females and males (Figure 1A, B), reaching chromosome-wide significance in all samples together (Figure 1D). The same inversion reaches genome-wide significance in ST samples and in ST and LUKE male combined samples (Figure 1C, E). In LUKE males, ST, and both combined datasets the SNPs in the QTL on Omy5 explained between 3 and 15% of the genetic variance.

We observed that heritability is of the same magnitude in both populations. The posterior estimates of h^2 on the liability scale are for LUKE h^2=0.32, and for Savon Taimen h^2=0.36. The genetic correlation estimate is 0.64.

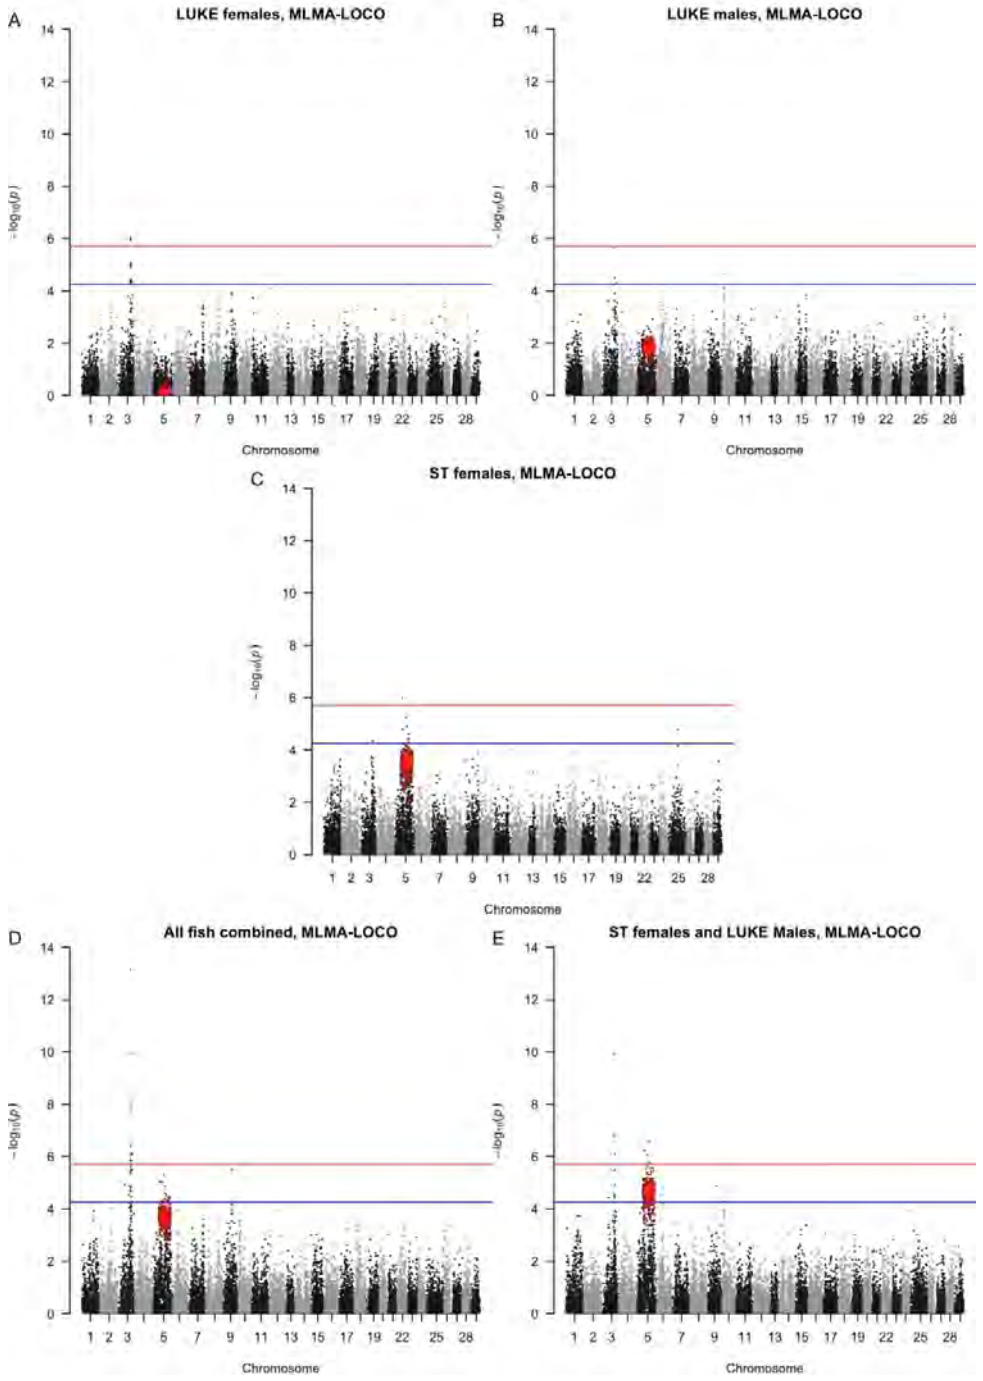

Figure 1. Manhattan plot of the genome wide association analysis in five subsets of the data. In red and in blue are the significance thresholds, respectively, genome-wide and chromosome-wide threshold. Red dots are SNPs tagging an inversion in Omy 05.

Discussion

Our results suggest that the two population we tested are closely related. Based on the F_{ST} comparisons reported by D'Ambrosio *et al.* (2017), the F_{ST} value we observe is consistent with populations separated by about five to ten generations. Our data provides an example of the conservation of QTL location and effect in closely related populations, and our approach to assess the genetic distance between two stocks used in a QTL mapping effort aids to understand the degree to which the stocks share common genetic determination.

The QTL on chromosomes Omy3 is found in both populations, the inversion on Omy 5 is also found in both populations, both with the same direction of allele substitution effect on mortality (in all cases, with the major allele associated with decreased mortality), even though the magnitude of allele substitution effects and the statistical significance shows variation across populations and sexes. The QTL on Omy 3 explains 4-12% of genetic variance, and was observed consistently in both populations. The most novel result we observed is the presence of a QTL associated with mortality on the large inversion present on chromosome Omy 5. In our data haplotype A is associated with a reduced mortality to CD especially in the ST population. In LUKE males, the same QTL effect on mortality is visible but it is weaker and non-significant. By combining LUKE males with ST data, the significance levels of this QTL were greatly elevated, implying the existence of a common QTL. In natural populations the A haplotype is strongly associated with the steelhead anadromous morph in females, and R haplotype is associated with a sedentary freshwater morph in males. The A haplotype is also associated with slightly slower growth, and exhibits a clinal distribution with the highest prevalence in southern rivers, and the frequency of individuals carrying the A haplotype, that also increases resistance against warm water CD, increases with warming water temperature (Pearse *et al.* 2019).

Heritability estimates indicate a moderate genetic effect on the phenotype, and genetic correlation was also moderate, indicating common shared genetic determinants across populations. The correlation between populations allowed to estimate heritability with higher precision than with one population alone. These results reflect both the consistency of QTL effects and of other minor genetic effects in determining the phenotype.

In our data we observe that the main QTLs explain 7 to 11% of the genetic variance, implying they would be a valid choice for MAS or weighted genomic evaluation for decreased mortality for CD. The inversion on Omy5 may be an effective target for MAS, because it can be extremely reliably tagged due to the inversion precluding recombination.

566. Multi-trait genome wide association study in correlated traits: fillet colour and body weight in Atlantic salmon

P. Sae-Lim*, S. Boison and M. Baranski

Mowi Genetics AS, Sandviksbodene 77A, 5035 Bergen, Norway; panya.sae-lim@mowi.com

Abstract

The 'redness' of the flesh ('fillet colour') is an economically important trait in Atlantic salmon. Pre-adjustment of fillet colour (measured as the concentration of the pigment astaxanthin) with body weight is usually performed in a genetic analysis to account for the correlation between these two traits, however multi-trait models are thought to offer superior power for genome-wide association studies (GWAS). In this study, allele substitution effects (*b*) and their significance levels from three different GWAS approaches were compared; single-trait (STGWAS), pre-adjusting fillet colour for body weight (STadjGWAS), and a multi-trait (MTGWAS). All GWAS analyses used 3,417 animals with 53,159 markers. All approaches consistently identified the most significant markers on chromosome 2 and 26, however MTGWAS increased *b* of fillet colour by 36.8 and 48.5% compared to STGWAS and STadjGWAS, and is therefore recommended as the optimal method to maximise the power of GWAS for correlated traits of this nature.

Introduction

The red colouration of Atlantic salmon flesh (hereafter referred to as 'fillet colour') is an economically important trait that is caused by the deposition of organic pigments, known as carotenoids. Specifically, it is the uptake of supplementary astaxanthin that is responsible and this process has been shown to be heritable with values ranging from 0.11 to 0.45 (Garber *et al.*, 2019; Kristjánsson *et al.*, 2020). Empirical data show that fast growing fish tend to deposit more supplementary astaxanthin. Hence, fillet colour usually correlates positively with body weight, therefore phenotypic variation in fillet colour may be partly explained by variation in body weight. However, pre-adjusting fillet colour by body weight may cause considerable changes in heritability and genetic correlation if fillet colour is not genetically independent from body weight. Kennedy *et al.* (1993) show that, when a derived trait is a linear function of two component traits, it can be optimally selected using an index of the two component traits. Nonetheless, GWAS tries to account for body weight by using it as a covariate when identifying QTL for several focal traits (fillet colour, fillet fat, lice count, etc.). We hypothesize that using body weight as a correlated trait in the MTGWAS will be a superior model that will also improve statistical power to detect candidate genes. The aim of this study was to compare allele substitution effects (*b*) of fillet colour and their significance level estimated with three different approaches in GWAS; single-trait (STGWAS), pre-adjusting fillet colour for body weight (STadjGWAS), and a multi-trait (MTGWAS) where fillet colour and body weight were simultaneously analysed.

Materials & methods

Phenotypes & genotypes. Fillet colour in this study is defined as the concentration of astaxanthin in the fillet estimated from near infrared spectrometry. The fillet colour and final body weight were obtained from 3,420 Atlantic salmon originating from 341 full-sib families of Mowi Genetics breeding population. The mean (standard deviation) of fillet colour and body weight was 5.09 (1.38) mg/kg fillet and 4.13 (1.13) kg, respectively. The regression coefficient of fillet colour on body weight indicated that fillet colour increased by 0.49 mg/kg per 1 kg body weight. Variance components of fillet colour and body weight were preliminary estimated with REML using bivariate animal mixed model in ASReml v4.1 prior to the GWAS analysis. The heritability (SE in parenthesis) for fillet colour and body weight was 0.44 (0.04) and 0.35 (0.04), respectively. The genetic correlation (SE in parenthesis) between fillet colour and body weight was 0.35 (0.07) but reduced to 0.08 (0.09) for fillet colour adjusted for body weight. Each individual was genotyped using a

ThermoFisher Axiom genotyping array containing 55,725 single nucleotide polymorphism (SNP) markers distributed over the salmon genome. Quality control of SNPs was performed in PLINK v1.9, based on the following criteria: SNPs were removed if (1) locus missing rate or individual missing rate was greater than 10%, (2) SNPs deviated from Hardy-Weinberg equilibrium with a *P*-value cut-off of 1×10^{-100}, and (3) minor allele frequency was lower than 0.01. After the quality control, 53,159 SNPs remained and the phenotypes reduced to 3,417 individuals.

Genome-wide association study (GWAS). We identified SNPs associated with fillet colour using three different approaches. For STGWAS and STadjGWAS, the analysis was performed using GCTA (Yang *et al.*, 2011), where the fixed covariates in the model were cages, sex, and principle components (PCA, number of PCA used until the inflation factor (λ) approached 1). For the MTGWAS, the analysis was performed using multivariate linear mixed model in GEMMA (Zhou and Stephens, 2014). The number of PCA dimensions in MTGWAS was set to be the same as STGWAS. A subset of top ranked markers associated with QTL for fillet colour from different approaches was taken from all the markers based on ten highest $-\log_{10}(0.05/\text{number of markers})$. The magnitude of marker effect estimates and their ranking due to *P*-value across different approaches were compared. The difference in marker estimates was quantified by calculating root mean square error (RMSE).

Results

The STGWAS identified the most significant SNPs associated with fillet colour on chromosome 2 and 26 (Figure 1). On chromosome 2, marker AX-88047706 was the most significant with an allele substitution effect estimate (*b*) of 0.26 mg/kg. However, a different marker (AX-96373699) in the same region was the most significant from the STadjGWAS and MTGWAS models. The *b* (0.35 mg/kg) of AX-96373699 from MTGWAS was greater than *b* (0.30 mg/kg) from STadjGWAS.

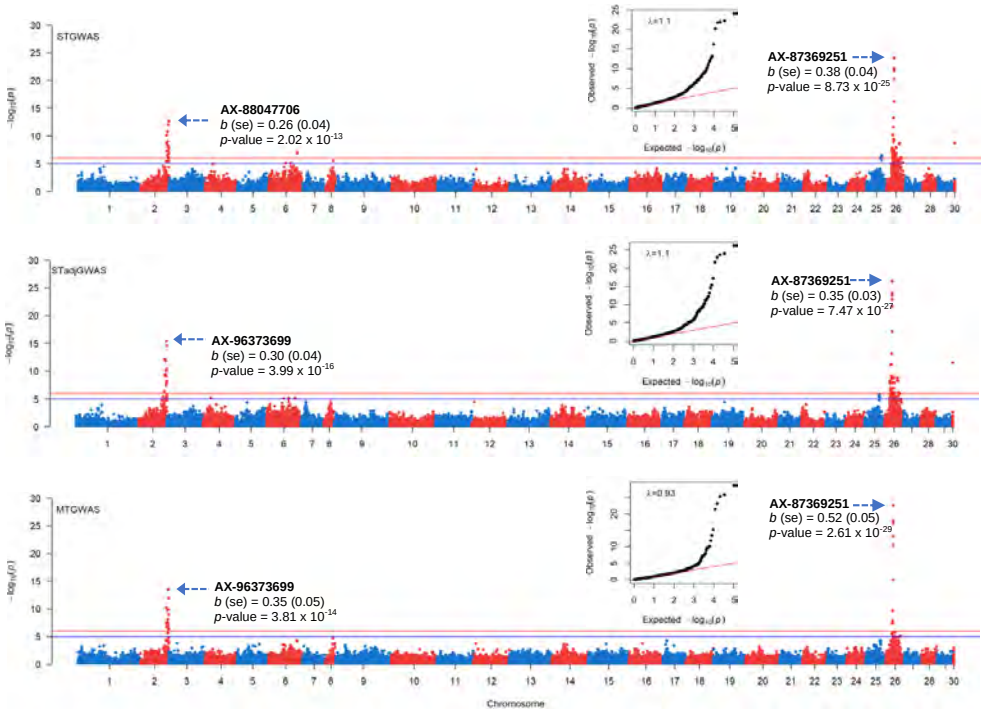

Figure 1. Single trait (STGWAS or STadjGWAS) and multi-trait genome-wide association (MTGWAS) on fillet colour and body weight in Norwegian Atlantic salmon.

On chromosome 26, marker AX-87369251 was the most significant from all the three models however, *b* from MTGWAS increased by 36.8% compared to STGWAS. Significant level based on *P*-value increased from 8.73×10^{-25} (STGWAS) to 2.61×10^{-29} (MTGWAS). The λ was equal to 1.1 in both STGWAS and STadjGWAS while λ reduced to 0.93 for MTGWAS.

The proportion of *b* to the mean of fillet colour of the top ten SNPs indicated the reduction in *b* for STadjGWAS compared to STGWAS. The MTGWAS revealed greater *b* in fillet colour for all top SNPs than STGWAS and STadjGWAS (Figure 2). The RMSE of *b* between STGWAS and MTGWAS of the ten most significant markers was 0.092 mg/kg and it slightly increased to 0.114 mg/kg for RMSE between STadjGWAS and MTGWAS.

Discussion

Two genomic regions on chromosome 2 and 26 were associated with fillet colour. The QTL peak on chromosome 26 has also been reported by Baranski *et al.* (2010) and Helgeland *et al.* (2019). Helgeland *et al.* (2019) reported *beta-carotene oxygenase 1 like* (*bco1l*) at chromosome 26 as the functional gene for fillet colour. In our study, because AX-87369251 is located not more than 500-100 bp from SNPs rs863442990 and rs863785818 reported by Helgeland *et al.* (2019), it is very likely that AX-87369251 is also associated with *bco1l*. The most significant marker on chromosome 2 was located at 70,851,651 bp and was close to the gene *ppa1b* (*Salmo salar* inorganic pyrophosphatase-like, LOC106608436). This enzyme hydrolyses inorganic pyrophosphate which could be a key process in the biosynthesis of astaxanthin (Muthuraman *et al.*, 2021).

Using a multi-trait GWAS to account for the relationship (genetic covariance) between body weight and fillet colour resulted in significant increase in allele substitution effect (*b*) and statistical significance (*P*-value). The increase in *b* could be explained by additional information from the genetically correlated trait (body weight). This phenomenon is similar to a change in breeding values when genetic evaluation is based on multiple correlated traits instead of a single trait. Furthermore, an increase in statistical power from MTGWAS models have been reported by Yoshida *et al.* (2021) for body traits in aquaculture; Broadaway *et al.* (2016) for morphological and physiological traits in cotton and Hackinger and Zeggini, (2017) in humans. Lastly, MTGWAS models may help uncover potential pleiotropic effects (Cai *et al.*, 2020; Chhetri *et al.*, 2019; Hackinger and Zeggini, 2017).

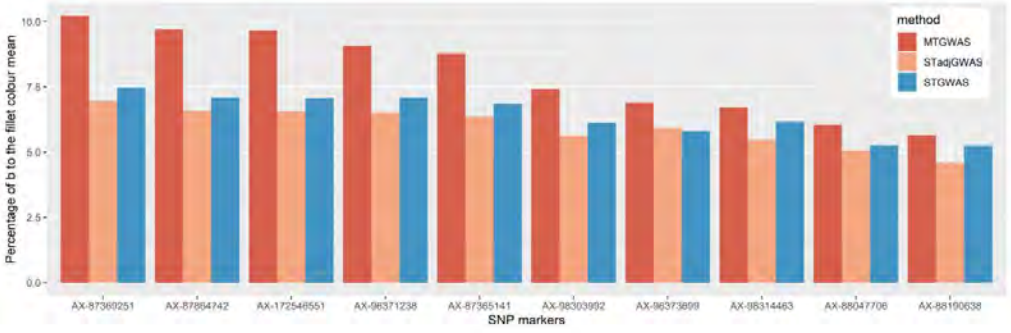

Figure 2. Percentage of allele substitution effect (*b*) to fillet colour mean of the top ten (ranked from highest to lowest) significant SNPs based on different methods of genome-wide association study.

In conclusion, two QTL regions on chromosome 2 and 26 were identified for fillet colour. The MTGWAS approach to account for relationship between fillet colour and body weight increased the magnitude of allele substitution effects of the most significant SNPs and also increased statistical power to detect the QTLs. Therefore, the MTGWAS model is recommended to identifying QTLs when a derived trait is a linear function of two component traits.

Abstract

The recent progress and cost reduction of genotyping technologies allows for the implementation of genomic selection (GS) on more and more cultivated species. In this study, we explore the genomic determinism of commercial traits and test the effectiveness and the possible cost reduction of GS in breeding programs of the cupped oyster *Crassostrea gigas*. Two populations of more than 1000 individuals have been phenotyped and genotyped for 40,000 SNP (Guitierez *et al.*, 2017). Heritability was estimated to be moderate for commercial traits of interest (between 0.19 and 0.34). The accuracy of the genomic prediction models outperformed the classical selection on pedigree by 22 to 55%. A limited linkage disequilibrium (LD) level (less than 0.1) was observed. These results suggest that the use of GS in oyster breeding can improve the selection of breeding candidates to enhance commercial traits but need a specific account and exploration of the very low LD.

Introduction

Growth, morphology, and color are essential characteristics for the oyster farming industry and have been the focus of breeding programs. As for other aquaculture species (salmon, sea bass, sea bream), the recent development of genomic tools in the cupped oyster (57K SNP genotyping chip) opens up the possibility of integrating genetic markers into breeding programs by through genomic selection (GS) (Hollenbeck and Johnston, 2018; Boudry *et al.*,2021). According to Lillehammer *et al.* (2013) and Guitierez *et al.* (2018), a few hundred to a few thousand markers could be enough to significantly increase the quality of predictions compared to the standard method of selection on relatives but this requires a sufficiently high LD. In this study we propose to estimate the genetic parameters and to test the efficiency of GS on two commercial breeding programs, on traits of interest, by comparing the accuracy of GS with a standard, pedigree-based approach and evaluating the usefulness of the available genotyping tool, by estimating SNP quality and LD between them.

Materials & methods

Biological material. The two populations in this study were derived from the breeding Company Vendée Naissain (Bouin, France) and SATMAR (Gattevile, France). They were reared on sea shore in Normandy. The first population consists of 1,261 offspring generated from 130 parents (64 males/69 females). The second population comprises 1,136 individuals including the 104 parents (59 males/45 females).

Phenotyping. All individuals were phenotyped for the same traits in both populations: total weight before opening, length, width and height of the shell, upper and the lower valve and wet meat weight. Meat yield was estimated using residue of linear regression between meat weight and total weight. A photo of all

DOI: 10.3920/978-90-8686-940-4_567, © A. Jourdan *et al.* 2022

the individuals was taken using a Canon EOS 2000D camera. Images were analysed with an automatic image analysis pipeline using the FIJI software to define surface measurements of the two valves and measurements of the mean external colour of the upper valve estimated in the CIE LAB space.

Genotyping. All individuals of the two populations, including parents and offspring, were genotyped on a bi-species Axiom Affimetrix 57K chip with 40,625 markers for the cupped oyster. A quality analysis carried out on the AxAS software made it possible to retain 14,469 quality markers.

Genetic parameter estimation. Genetic parameters and estimated breeding values (EBV) were estimated with BLUPF90 software suite under animal model. EBV were estimated using pedigree or genomic BLUP (Best Linear Unbiased Prediction). For each, the prediction accuracy was estimated in 40-replicated five-fold crossvalidations (training population 80%, validation population 20%). Prediction accuracy was calculated as the correlation between the predicted EBVs and the actual phenotypes of the validation population, divided by the square root of the heritability estimated. Prediction accuracy values were compared between the pedigree and genomic approaches.

Linkage disequilibrium (LD). The 14,469 good quality markers were blasted on the new reference genome (cgigas_uk_roslin_v1, GCA_902806645.1) in order to map the SNPs. Approximately 12,581 SNPs were well positioned on the 10 linkage groups. To estimate LD, we used the squared correlation based on genotypic allele counts (number of non-reference alleles at each locus) using the PLINK v1.9 software (Chang *et al.*, 2015). Pairwise LD between all SNPs in a 75-Mb long window were derived for each chromosome. The mean r^2 values was calculated for every 50 kb and covering up to 1000 kb.

Results

All of the traits measured have coefficient of variation between 13 and 53%. The two populations were phenotyped at three years post fertilization. The heritability estimated are limited to moderate ranging from 0.04 to 0.34 for color traits and between 0.19 and 0.27 for biometric traits. The gain in prediction accuracy of GBLUP compared to pedigree BLUP on classically measured and selected growth traits is presented in Figure 1. This figure shows GS is superior to selection on pedigree in most cases, with however median levels of gain in accuracy which vary according to the trait studied with values between 22.6 and 55%. The mapping of the 13,000 markers on the most recent assembly (cgigas_uk_roslin_v1, GCA_902806645.1) of the cupped oyster genome shows an important coverage heterogeneity. For example, only 159 markers belonging to chromosome 2 (73 Mb) were genotyped, while more than 2,000 were genotyped for chromosome 10 (58 Mb). The LD is represented by the r^2 as a function of the physical distance over the assembly of the oyster genome. We can observe in Figure 2 that we have a low level of DL with a slow decrease as a function of the distance. LD level is very low even over a short distance between markers (less than 0.1).

Discussion

In our study, we show moderate levels of heritability for production and quality traits. This level of heritability seems lower than when compared to other recent publications in Pacific or Portuguese oysters in Asia (Kong *et al.*, 2015). Difference in rearing methods (suspended *vs* bag) and practices (immersed vs on shore) may have a significant impact on expression of additive genetic components of oyster growth (Sheridan, 1997). Under this hypothesis, estimates of the heritability are moderate but adapted for setting up breeding programs in Europe as they are estimated in the environment of rearing. The medium density chip allows to investigate application of GS in Pacific oysters in other traits than OHsV1 genetic resistance (Guittierez *et al.,* 2017). The results obtained from cross-validation on genomic prediction are similar to

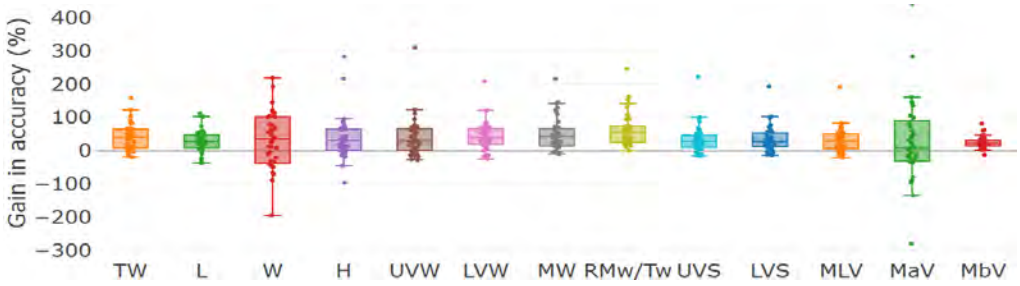

Figure 1. Boxplot of prediction accuracy gain (%) between GBLUP and BLUP for all the 40 simulations and all traits. TW = total weight; L = length; W = width; H = height; UVW = upper valve weight; LVW = lower valve weight; MW = wet meat weight; RMw/Tw = residual meat weight/total weight; UVS = upper valve surface; LVS = lower valve surface; MLV = mean upper valve L value; MaV = mean upper valve a value; MbV = mean upper valve b value.

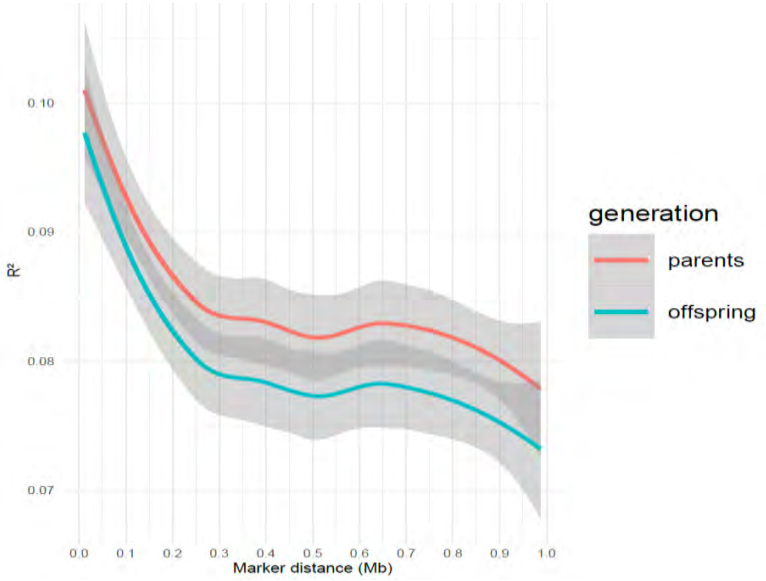

Figure 2. Decay of linkage disequilibrium (LD) with physical distance between markers for the first hatchery population.

those obtained on other aquaculture species with a clear improvement in the accuracy of the prediction. This therefore reinforces the interest of using genomic tools in the breeding programs of the cupped oyster.

One important result is very limited LD observed in two distinct populations. Indeed, to make GS more cost-effective, it is necessary to reduce the number of markers to be genotyped or to go through other methods of GS (such as GWAS) with fewer individuals to genotype. To achieve this, it is essential to have a sufficiently high level of LD in the population. Some parameters can influence the level of LD such as the number of generations for which they were raised in isolation or reduce the effective size (Ne) which would result into increase the levels of relatedness between individuals and therefore a greater extent of LD. Our LD levels are consistent with recent reports describing low levels of LD in wild populations of *C.gigas*

(Guittierez *et al.*, 2017). This result is questioning about the possibility to identify QTLs with repeated and conserved effects across generations with the actual genomic tools developed.

Abstract

Salmonid Rickettsial Syndrome (SRS) is one of the infectious disease causing significant mortality of Atlantic salmon in Chile. Survival to SRS is mainly recorded from two different challenge test models; intraperitoneal injection (IP) and cohabitation but their genetic correlation has not been estimated. The aim of this study was to estimate the genetic correlation between survival to SRS measured from IP and cohabitation experimental challenge test. Variance components were estimated from 3,488 animals using multi-trait animal mixed models. Heritability for survival day and survival binary was moderate and consistent across IP and cohabitation. Genetic correlation of survival day between IP and cohabitation was close to unity (0.933) but lower for genetic correlation of binary survival between IP and cohabitation (0.825). In conclusion, survival to SRS from different challenge test models are highly correlated. Therefore, IP model can be adopted as it results in lower cost of the experimental challenge test.

Introduction

Salmonid Rickettsial Syndrome (SRS) caused by a gram negative bacteria *Piscirickettsia salmonis* is one of the largest disease causing pathogen of Atlantic salmon in Chile (Departamento de Salud Animal, 2020). In 2020, SRS was estimated to cause ~67.3% of mortalities due to infectious diseases in the Chilean aquaculture industry (Departamento de Salud Animal, 2020). Genetic variation for resistance to SRS in Atlantic salmon has been reported in several populations and heritabilities range from 0.11 to 0.43 (Lhorente *et al.*, 2014; Moraleda *et al.*, 2021; Yáñez *et al.*, 2014). Data for estimating heritability and selection of candidates for genetic improvement in a breeding programme can be obtained from field outbreaks or laboratory challenge tests. Challenge trials have been commonly used because they can be routinely undertaken to provide reliable and repeatable phenotypic information for the breeding programme. Two main challenge test models: (1) intraperitoneal injection (IP) of the test fish; and (2) cohabitation of IP injected shedder fish with test fish; are commonly practiced in aquaculture. The IP model usually results in faster disease development and shorter challenge test duration. The cohabitation challenge model is developed to be reflective of the usual routes of infection which occurs during field outbreaks. Therefore, cohabitation challenge models results in slower disease development and longer challenge test duration than IP challenge models. In cases where both challenge models can be developed for the disease causing pathogen (e.g. SRS), IP models are usually adopted as it results in lower cost of the experimental challenge test. It can be argued that to adopt IP challenge test model for routine evaluation of resistance to disease pathogens (e.g. SRS) in breeding programme, the genetic correlation with cohabitation challenge test should be moderate to high. The aim of this study was to estimate the genetic correlation between resistance to SRS measured from IP and from cohabitation experimental challenge test.

Materials & methods

Animals. The fish used in this study originated from the 2017G yearclass of Mowi breeding nucleus in Chile. The population consisted of 109 fill-sib families from 74 sires and 109 dams with a mixture of 1:1 (66%), 1:2 (20%) and 1:3 (14%) mating ratios (sire:dam). Families were reared separately until tagging at an average body weight of 15 g.

CC BY

DOI: 10.3920/978-90-8686-940-4_568, © C. Manosalva *et al.* 2022

Experimental challenge test. Two batches of fish from the above population were generated for the experimental challenge test. The first population consisted of 1,090 fish (10 fish per family) and used for the IP challenge test, while 2,398 (22 fish per family) fish were used in the cohabitation challenge test. The average weight of the fish at start of the challenge test was 145 g. Both IP and Cohabitation challenge tests were undertaken in seawater at 15 °C and 32 ppt salinity. For the IP challenge test, the fish were equally split into three tanks and each fish was injected in the intraperitoneal region with 0.1 ml dose containing 3.5×10^3 colony forming units (cfu) of *P. salmonis* EM90 genogroup. Mortalities were recorded daily until the end of the challenge test (32 days post challenge). For the cohabitation challenge test, the fish were equally split into two tanks. A group of shedder fish (17% of the fish in the cohabitation challenge test) were injected in the intraperitoneal region with an 0.1 ml dose containing 1.1×10^5 cfu of *P. salmonis* EM90 genogroup. Dead fish were collected daily until 70 days post challenge when the experimental challenge test was terminated.

Phenotypes. We used survival days (number of days fish survived during the challenge test; all alive fish at the end of the experiment were assigned the maximum day post challenge) and binary survival phenotype (dead = 0, alive = 1 at the end of the challenge) for the analysis of resistance to SRS infection.

Statistical analysis. Genetic parameters were estimated using pedigree information for survival days (SurvDays) and for the binary survival (Surv) using a bivariate animal model within the challenge test model with the statistical model below:

$$Y = XB + ZU + WC + E,$$

where Y is the matrix of phenotypic records of two traits for all animals, X in the incidence matrix corresponding to fixed effect of tanks for the two traits, B is the matrix of fixed effect solution for tanks, Z is the incidence matrix corresponding to the random genetic effects of animals, U is the matrix of random additive genetic effects of animals with variance structure $G \otimes A$, where G is the genetic variance-covariance matrix among the two traits and A is the numerator relationship matrix constructed using pedigree information, W is the incidence matrix for the random common effects to full-sibs, C is the matrix of common effects to full-sibs, E is the matrix of random residual effects with a variance structure $R \otimes I$, where R is matrix of residual variances and covariance which was assumed to be non-zero. The same bivariate animal mixed model was applied to genetic correlations between the phenotypes from the IP and cohabitation challenge test models, except that residual covariance was assumed to be zero.

Results

The percentage mortality was 64 and 43% for IP and cohabitation challenge test model, respectively. As expected, the duration of the IP challenge test model was 45% lower than the cohabitation challenge test which ended after 70 days post challenge (Figure 1). Due to human error, we had to abruptly terminate one of the tanks for the cohabitation challenge test 48 days post challenge. The percentage mortality at the time of the termination was 32%. Initial results showed that the genetic correlation between tank 1 and tank 2 for the mortality and survival days of the cohabitation test was 0.917 (0.073), therefore the complete dataset was used for the final analysis.

Heritability estimate for survival days ranged from 0.207 to 0.241 and 0.175 to 0.253 for the binary survival phenotype (Table 1). The variance ratio of the effect common to full-sib ranged was about 14 and 2% in the IP and cohabitation challenge test model, respectively.

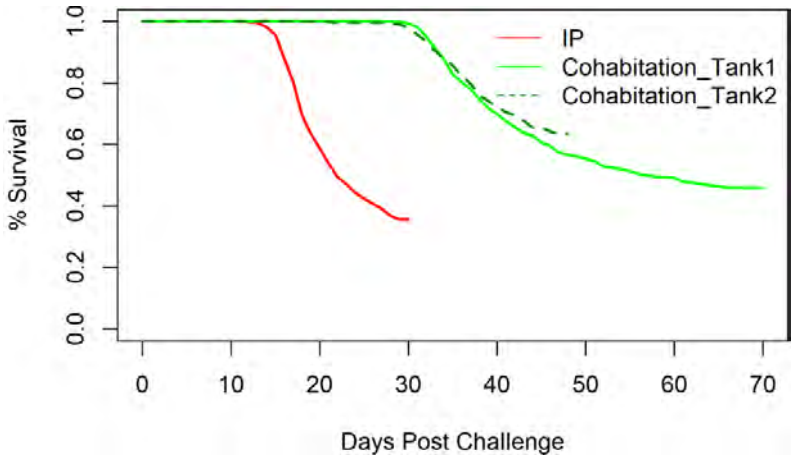

Figure 1. Survival curve for intraperitoneal (IP) and cohabitation challenge test model for SRS.

Table 1. Heritability on the diagonal and genetic correlation below the diagonal with standard errors in parentheses.

Challenge model	Trait	IP[1]		Cohabitation	
		SurvDays	Surv	SurvDays	Surv
IP	SurvDays[2]	0.241 (0.175)			
	Surv[3]	0.993 (0.043)	0.175 (0.148)		
Cohabitation	SurvDays	0.933 (0.291)	0.822 (0.353)	0.207 (0.081)	
	Surv	0.889 (0.315)	0.825 (0.350)	0.983 (0.019)	0.253 (0.085)

[1] IP = intraperitoneal challenge test model.

[2] SurvDays = survival days.

[3] Surv = binary survival.

The genetic correlation between survival days and binary survival was very high (>0.980) for both challenge test models. Finally, the genetic correlation between IP and cohabitation challenge test for survival days was 0.933 and 0.825 for binary survival.

Discussion

The aim of the study was to estimate heritability and the genetic correlation between IP and cohabitation challenge test models for resistance to SRS. As expected mortalities from the IP challenge model started 12 days post challenge, while the cohabitation test started 29 days post challenge. Similar trend in survival/mortality curve has been reported by Meza *et al.* (2019). The shorter challenge test duration from the IP model makes it a cheaper challenge test model to obtain phenotypes for selecting for resistance (arguably tolerance and/or recovery) to SRS infections.

The heritability estimate from both models were within the range of values reported (Lhorente *et al.*, 2014; Moraleda *et al.*, 2021; Yáñez *et al.*, 2014**).** Further analysis of the binary survival phenotype using a sire-dam threshold model resulted in heritability estimate on the liability scale of 0.246 (0.127) and 0.324 (0.096) for the IP and cohabitation challenge models, respectively.

Surprisingly, the estimate of the genetic correlation between IP and cohabitation challenge test models was high. The cohabitation challenge model mimics the natural route of infection, therefore multifaceted immune response (e.g. skin and gills) can be mounted by the fish against the infection, however the IP challenge test model bypasses the initial response barrier and therefore is expected trigger part of the resistance to SRS by the fish. Nonetheless, we still observe a high genetic correlation between the IP and the cohabitation challenge test. Joshi *et al.* (2020) recently reported a high (0.9) for survival of Nile tilapia to *Streptococcus agalactiae* between the IP and the cohabitation challenge test.

Conclusions

SRS is a heritable trait in breeding population of Mowi in Chile, with values ranging from 18 to 25%. Genetic correlation of IP vs cohabitation challenge test model was high, therefore we could select for SRS resistance using phenotypes generated from an IP challenge model.

Abstract

A genome-wide association study (GWAS) was used to search for QTL for resistance to Salmonid Rickettsial Salmonis (caused by *Septicaemia piscirickettsia*) in coho salmon. The coho population under study was admixed, consisting of animals from three pre-existing and distinct populations of domesticated coho. Although a major QTL was found, no single SNP was able to tag the QTL well in all three subpopulations. A system for tracking the good allele at the QTL (Q) as well as the sub-population Q was derived from was developed, facilitating more precise selection in the admixed population as well as in other populations. Later, new and better tag-SNPs were identified through fine-mapping, increasing the selection accuracy even further.

Introduction

Marker-assisted- as well as genomic selection is reliant upon DNA-markers which are sufficiently correlated to the DNA polymorphisms which affects the trait in question. This dependency is particularly pronounced when the training data, coming from relatives of the breeding candidates carrying both genotypes and phenotypes, cannot be refreshed frequently. In aquaculture, we often select for resistance to multiple pathogens, and it is not always cost-effective to measure the resistance to every pathogen in every new generation. In such cases, one may be tempted to rely on marker-trait associations identified in one or just a few underlying data sets, and even to apply marker-trait associations identified in one population on another population. This paper illustrates that this is not always a good idea and presents a generic QTL-tagging system applicable in admixed populations, based on the simultaneous detection of the beneficial allele and the population of origin of that allele. The method was applied to selection for increased resistance to the intracellular bacteria *Piscirickettia salmonis* in coho salmon (*Oncorhynchus kisutch).*

Materials & methods

Challenge tests. Challenge tests for resistance to *P. salmonis* were carried out using a cohabitant challenge model. The challenge was terminated 60 days post-infection.

Genotyping. Genotyping was carried out using Axiom Custom Arrays from ThermoFisher. Three arrays were used in the study: (1) Oki220k, the original array, containing 220k SNPs; (2) Oki72kv1, a lower-density array containing the 72k most informative SNPs from Oki220k; (3) Oki72kv2, similar to Oki72kv1 except that SNPs performing sub-optimally had been replaced by 8k SNPs located within the region of a QTL for SRS-resistance.

Genome-wide association study (GWAS). Standard GWASes were performed using the 'mixed linear model leaving-one-chromosome-out' (LOCO) option of GCTA.

Association analysis using combinations of SNPs. Within one particular chromosome, combinations of SNPs were tested for their association to the trait, as follows: (1) a data set (consisting of challenge-tested animals from a single population or a single sub-population) was phased using FImpute; (2) a region of interest was pinpointed, wherein a quantitative trait nucleotide (QTN) was thought to be located, and from

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_569, © T. Moen *et al.* 2022

this region, the genotypes of all polymorphic SNPs were extracted; (3) for each SNP-combination length L from 1 to 20, step 4 was carried out; (4) for each combination of L consecutive SNPs within the region, steps 5 to 7 were carried out; (5) the haplotypes carried by each animal were determined using the phased data set; (6) a mixed linear model was solved in DMU:

$y = 1\mu + Hh + g + e$

where y is a vector of binary phenotypes (survived = 1, dead = 0), μ is the overall mean, h is a vector of fixed haplotype effects, $g \sim N(0, A\sigma_g^2)$ is a vector of random additive genetic effects (derived from the pedigree), $e \sim N(0, I\sigma_e^2)$ is a vector of random residuals, H is a haplotype incidence matrix and A is the numerator relationship matrix; 7) a likelihood-ratio statistic for the effect of the haplotypes on the trait was calculated as $2\ln(L_{H1}) - 2\ln(L_{H0})$, where L_{H0} is the likelihood under the reduced model (no haplotype effects) and L_{H1} is the likelihood under the full model.

Identification of 'population-specific haplotypes'. A 'population-specific haplotype' was defined as a haplotype which was strongly associated to the good allele (Q) at the QTL in one of three subpopulations of an admixed population, while being absent (or having an allele frequency lower than 0.05) in the other two populations. To find such population-specific haplotypes, we first carried out association analysis using SNP-combinations, as described above. For every SNP-combination length from 1 to 20, we subsequently scanned all SNP-combinations for the presence of such population-specific haplotypes.

Genotyping of population-specific haplotypes. Once a population-specific haplotype had been found for each of the three subpopulations, the SNPs constituting all haplotypes could be genotyped in breeding candidates. The resulting genotypes were phased using the PHASE, whereupon each breeding candidate was checked for the presence of the population-specific haplotypes. If none of those were present, the animal as assigned genotype qq, if one was present it was assigned genotype Qq, and if two of three were present it was assigned genotype QQ.

Results

Initially, a challenge-test for SRS-resistance was performed on AquaGen's 2014 year-class of coho salmon. This year class was the founder population of AquaGen' 'even' year class population of coho (the species has a strict 2-year generation interval), and it was constituted by fish originating from three pre-existing and distinct populations of domesticated coho, purchased by AquaGen.

A GWAS was run on each of the three subpopulations constituting the C14 challenge test, named C14A, C14B, C14C hereafter. A large QTL for resistance to SRS was found on chromosome 21, explaining much of the genetic variation within individual subpopulations (Figure 1). However, no single SNP was able to tag the underlying QTN well in all three subpopulations. Similarly, an association analysis based on SNP-combinations was attempted, but no combination of SNPs was able to tag the QTN well.

Observing that the most significant SNPs from the GWAS performed on C14A, C14B, and C14C had: (1) a weak association to each other; and (2) low frequency of the beneficial allele (Q), we hypothesised that it might be possible to find haplotypes (multi-locus 'alleles' at SNP-combinations) which would be strongly associated to Q in one of the populations but absent in the other two. If one or more such 'population-specific' haplotypes could be found for each subpopulation, then these three or more haplotypes could jointly constitute a DNA-test for the QTN.

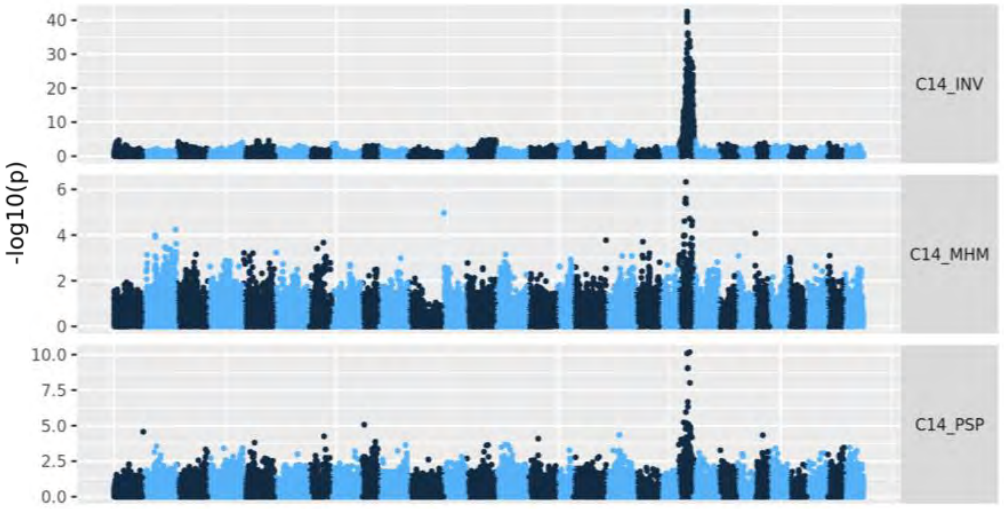

Figure 1. GWAS for resistance to *Piscirickettsia salmonis*.

The optimal combination of population-specific haplotypes was constituted by three haplotypes, each made from three distinct SNPs, i.e. nine SNPs were involved altogether. In terms of base pairs, the haplotypes covered 21 kb, 49 kb, and 56 kb, and the distance between them was 0.3 Mb and 4.6 Mb. Table 1 displays the allele substitution effect and the allele frequency of each haplotype within each of the three subpopulations.

The two-allele 'DNA-marker' derived from the three haplotypes (named 'HAP' from here on) was used for selection for a while, in situations where the breeding candidates did not have siblings with genotypes and phenotypes. In 2021, a new version of the 72k SNP-chip was made. This contained 8,342 more SNPs from within the QTL region, of which 10 were added due to their high LD to HAP (r^2>0.8). The new chip was used for genotyping a subset of the samples taken from C14A, C14B, C14C, as well C18 (grandchildren of C14), C17, and C19 (two consecutive generations of the 'odd' year class population).

Interestingly, when a GWAS was performed on the data from the new chip, two of the SNPs that had very high LD to HAP came out on top, being substantially more significant than the other SNPs.

Figure 2 shows how large a fraction of the genetic variance is explained by the original best tag-SNPs from the C14A, C14B, C14C, C17, C18, and C19 data sets, within those same data sets. HAP and the best single SNP from Oki72kv2 are also included. One can see that HAP is consistent across data sets, while none of the original tag-SNPs are. HAP explained 30% of the genetic variation across data sets. Within individual

Table 1. Properties of the best combination of population-specific haplotypes

Haplotype	Allele substitution effect[1] and frequency in:		
	C14A	C14B	C14C
C14A	0.21/0.27	NA/0.0	-0.001/0.003
C14B	0.01/0.001	0.26/0.08	0.32/0.02
C14C	0.02/0.002	NA/0.0	0.32/0.08

[1] The trait is survival (0 = affected, 1 = non-affected).

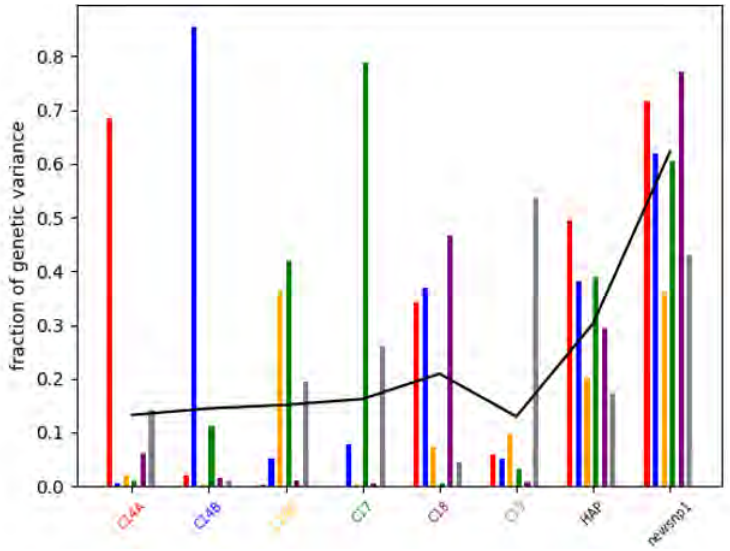

Figure 2. Fraction of genetic variance explained by various tag-SNPs.

data sets, the best tag-SNP from that population always outperforms HAP, as can be expected. The best SNPs from Oki72kv2 was both consistent across data sets, and outperformed the best original tag-SNPs in most of the data sets. Across data sets, the new best tag-SNP explained 60% of the genetic variation.

Discussion

The population-specific haplotype approach described here may be useful only under some particular circumstances. It is interesting to see that the approach was able to improve the overall accuracy of selection, thus solving the problem at hand. The case of SRS on coho salmon serves to illustrate that care should be taken before marker-trait associations identified in one population is applied on another, also when the effects of the markers is large. The results also highlight the importance of doing fine-mapping to optimise the tools of selection.

570. Potential of imputation for cost-efficient genomic selection for resistance to *Flavobacterium columnare* in Rainbow trout

Abstract

Columnaris disease (CD) is a major emerging disease affecting rainbow trout aquaculture. Selective breeding through genomic selection (GS) has potential to improve host resistance. However, GS is expensive partly due to the cost of genotyping high numbers of animals using high-density (HD) SNP arrays. The objective of this study was to assess the efficiency of GS for resistance to CD using ten *in silico* LD-panels combined with imputation. After a natural outbreak of CD, 2,874 challenged fish and 469 fish from the parental generation (n=81 parents) were genotyped with 27,907 SNPs. Using LD-panels (3,000 markers) alone or lower density panels (300 markers) along with imputation resulted in comparable accuracy to the 28K HD-panel, and 11% higher accuracy than pedigree-based predictions. Compared to using the commercial HD-panel, LD-panels with imputation may provide a more affordable route to genomic prediction of breeding values, supporting wider adoption of GS in aquaculture breeding programmes.

Introduction

Columnaris disease (CD) is an emerging problem for various aquaculture species worldwide. *Flavobacterium columnare*, the pathogen agent of CD, causes high levels of mortality in rainbow trout fry, causing significant annual economic losses to the industry. Improvement of disease resistance through selective breeding is a promising approach to reduce mortality, and could reduce disease incidence and reduce antibiotic use. Genomic selection (GS) uses genome-wide marker information gathered in a reference population to predict the breeding value for traits of economic interest in a target broodstock. GS is particularly applicable for traits difficult to measure in breeding candidates (such as disease resistance traits) and has been shown to be more accurate, and thus more efficient, than pedigree-based selection. However, the cost of genotyping large numbers of individuals required to perform GS is still prohibitive for many breeding programmes. Using low-density (LD) SNP panels could reduce the cost of genotyping (since LD panels are typically cheaper to genotype) while still achieving higher prediction accuracy than standard pedigree-based selection. Genotype imputation from low-density to high-density genotypes is therefore a promising approach to achieve a more affordable genomic selection. The aim of this study was to assess the efficiency of GS using low-density SNP panels along with imputation for this disease resistance trait.

Materials & methods

Fish rearing and disease outbreak management. In May 2019, 81 rainbow trout (33 females and 48 males) were selected among 567 fish from the Finnish national breeding programme maintained by Luke, based on their relationship and genetic contribution to maintain a predetermined inbreeding coefficient of less than 1% per generation. The 33 dams and 48 sires were mated to create 105 full-sib families. In June 2019, around 30,000 fry were separated into three fingerling tanks, about 100 fish per family per tank, at the farm of Hanka-Taimen Oy (Finland). From arrival at this new farm (considered as day 0 of the experiment), the fish mortality and any disease signs were monitored twice a day. On day 11 of the experiment, fish in all three tanks started to show signs of CD, some dead fish were sampled and sent to a veterinarian to confirm the CD diagnosis. From day 15 to 24, a piece of tail was taken, for later DNA extraction, from 510 fish per

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_570, © C. Fraslin *et al.* 2022

tanks, randomly chosen amongst the dead or dying fish with clear CD signs (considered as susceptible). At day 26, the three tanks were treated following the veterinarian guidelines against *F. columnare* with an approved treatment until day 32. On the last day of the experiment, day 99, a piece of tail was collected, for latter DNA extraction, on about 506 fish per tanks, randomly sampled among the fish still alive at that time (considered as resistant). In addition, the biggest fish among the sampled fish from each tank (n=164, 167, 168 for tanks 1, 2 and 3, respectively) were PIT-tagged and are considered as breeding candidates for the future broodstock

Genotyping, in silico low-density panels, and imputation. A total of 3,054 challenged fish (1,538 susceptible and 1,519 resistant) and 570 fish from the parental generation (including the 81 parents) were genotyped using the 57K SNP Axiom™ Trout Genotyping Array (Palti *et al.*, 2015). After quality controls, 2,874 challenged fish and 469 fish from the parental generation (n=78 parents of the challenged fish) genotyped with 27,907 informative SNPs were retained. Those 28K SNPs were considered as the high-density (HD) panel. The impact of reducing the SNP density on genomic prediction was tested with ten low-density (LD) SNP panels, created *in silico* (300; 500; 700; 1000; 3,000; 5,000; 7,000; 10,000; 15,000 and 20,000 SNPs). For each LD-panel, SNPs were sampled from the 28K HD-panel using the CVrepGPAcalc package (Tsairidou *et al.*, 2020). Two sampling approaches were used to create LD-panels: (1) SNPs were randomly sampled within each chromosome, with the number of SNP sampled from a given chromosome being proportional to the physical length of the chromosome in the *O. mykiss* reference genome (Omyk_0.1, Gao *et al.*, 2018); (2) SNPs were selected so that they would be equally spaced within each chromosome. Each LD-panel was replicated 10 times, with replicates allowed to overlap by chance and the final number of SNPs within each panel being allowed to slightly vary from the target density. FImpute3 (Sargolzaei *et al.*, 2014) was used to impute the *in silico* LD- genotyped offspring back to the full 28K SNPs using a combined population and pedigree based imputation method with the HD-genotyped parents (n=469) as the reference population.

Genetic parameter estimates and genomic selection. Disease resistance was analysed as a binary trait (0 = alive; 1 = dead) with the rearing tank as a fixed effect in the statistical model. Variance components and heritabilities were estimated using ASReml (v.4.1, Gilmour *et al.*, 2014) with two different approaches, a mixed linear BLUP animal model and a logistic regression model to assess the trait on the observed and underlying scale, respectively.

The (genomic) estimated breeding values {(G)EBV} of fish were computed using mixed linear BLUP animal model based on pedigree (PBLUP) or genomic (GBLUP) information using the BLUPF90 software (Misztal *et al.*, 2002). The efficiency of selection using pedigree-based or genomic information was estimated using Monte-Carlo 'leave-one-group-out' method by removing the known phenotype from 20% of the fish, and then using the phenotype and genotype data of the remaining 80% fish to predict the (G)EBVs of the 20% validation fish group. This procedure was repeated 20 times for the PBLUP, the HD-GBLUP, and for each of the 10 replicates of the LD-panels, pre and post-imputation. Accuracy of prediction was computed, for all SNP panels, as the mean over the 20 replicates of the correlation between the (G)EBV and the true phenotype of fish in the validation group, divided by the square root of the genomic-based heritability.

Results

Resistance to *F. columnare* was moderately heritable in this population with pedigree-based heritability estimated to be 0.18 (±0.038 se) and 0.35 (±0.046) on the observed and underlying logit scales, respectively. Genomic heritability was estimated to be 0.21 (±0.029 se) and 0.43 (±0.042 se) on the observed and underlying logit scales respectively. Pedigree-based prediction accuracy was estimated as 0.59 (±0.080 sd) and the use of genomic evaluation increased the prediction accuracy by 14% for the HD-GBLUP

(0.68±0.076 sd). Decreasing the number of SNPs tended to decrease the accuracy of genomic predictions (Figure 1), and no significant difference was observed between the two methods of sampling.

Prediction accuracies obtained with 300 to 500 SNPs were close to the accuracy obtained with the pedigree-based analysis (blue dotted line in Figure 1). Encouragingly, prediction accuracies obtained with LD-panels from 7,000 SNPs and above were close to the accuracy obtained with the HD-panel (-1% in accuracy compared with the HD-GBLUP). Accuracies obtained with 1000 SNPs were only 4% higher than those obtained with the pedigree, whereas the accuracy obtained with only 3,000 SNPs was 3% lower than the accuracies obtained with the HD-panel and thus 11% higher than the accuracy obtained with the pedigree only.

At the lowest densities (<3,000 SNPs, Figure 1) imputation (with FImpute3) had a positive impact on the accuracy of genomic prediction with the accuracy of genomic prediction obtained after imputation similar to the accuracy obtained with 3,000 SNPs.

Surprisingly, the accuracy of genomic prediction obtained with 3,000 SNPs was not significantly different before and after imputation and for 5,000 SNPs or higher, the accuracy of genomic prediction obtained after imputation was slightly lower than without imputation.

Discussion

The results presented here suggest that resistance to *F. columnare*, is moderately heritable in this population and could be improved through selective breeding. The results on genomic prediction are consistent with those from various aquaculture species that relatively LD SNP panels are, at least more efficient than pedigree-based selection and sometimes as efficient as full HD panels to accurately predict breeding values (see Houston *et al.*, 2020 for review). More specifically, using LD SNP panels (e.g. 3,000 to 7,000 markers) would results in comparable selection accuracy to the full 28K HD SNP panel. Imputation of very low density SNPs panels (e.g. 300-700 SNPs) resulted in an increase in genomic prediction accuracies compared to the low density panel alone, but this was not observed with imputation from higher densities (e.g. >5,000 SNPs).

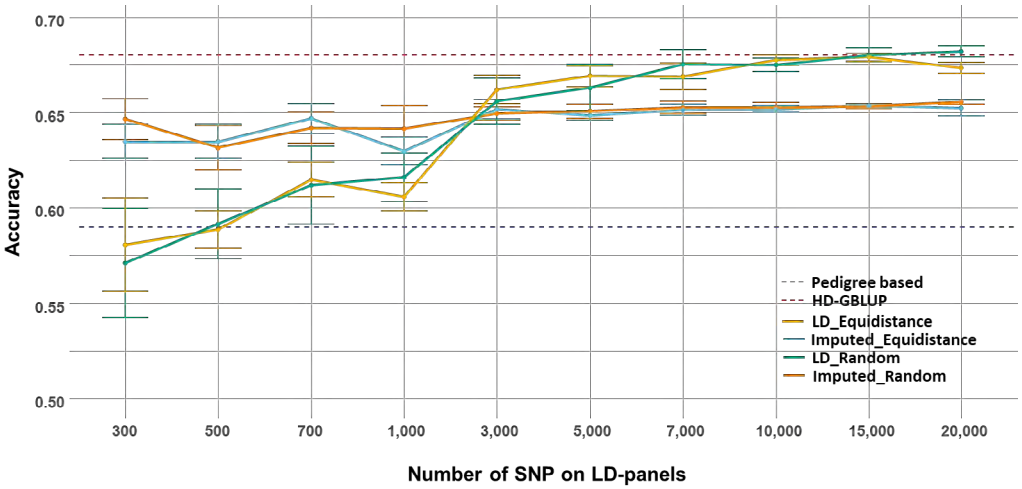

Figure 1. Accuracy of genomic prediction for resistance to *F. columnare* in rainbow trout, obtained with different SNP panels density, before and after imputation.

For rainbow trout, the high-density SNP array (57K SNPs) costs approximately 20€ per sample when genotyping a breeding population of 8,000 offspring and 200 parents. This is a total cost of about 164K €, which can be highly prohibitive for most breeding programmes. To implement genomic selection in their breeding programme, our results imply that the use of a cheaper low-density SNP array might be beneficial. For example, under the assumption a 3K SNP panel or array could be typed for all 8,200 fish at a cost of 15€ per sample, this would mean a 25% reduction in genotyping cost for a 3% decrease in accuracy compared to the full HD panel. Another possible scenario is that all offspring were typed for a very low density SNP panel (300 SNPs) at a cost of 7.5€ per sample, with parents typed for the existing 57K array at a higher per sample cost of 40€ per sample (the price is highly dependent of the number of samples genotyped), genotyping would cost 68K€. This reduces the genotyping cost by 59% compared to the price of the 57K SNP for only a 4% decrease in accuracy using the imputation approach. Moreover, *F. columnare* infects small fish, well before they can be individually tagged and identified. Therefore, even for an accurate pedigree-based evaluation, the offspring and parents needs to be genotyped in order to recover the pedigree, meaning that the 300 SNP panel could be combined purpose for both parentage assignment and imputation-based genomic selection.

In conclusion, genomic selection using low-density SNP panels may reduce costs of genomic selection in rainbow trout breeding without major reduction in breeding value prediction accuracy. Using low-density SNP panels (about 3,000 markers) or very low-density SNP panels (about 300 markers) combined with imputation may be a cost-effective genomic prediction of breeding values to improve resistance to *F. columnare*, in this rainbow trout population.

Abstract

For European sea bass (*Dicentrarchus labrax* L.) hatcheries, viral nervous necrosis mortality, post-stress cortisol concentration, antibody titer against nervous necrosis virus and body weight are interesting traits to be included in the breeding objectives. An experimental population (n=650) generated using a commercial broodstock was phenotyped for those traits and genotyped with a genome-wide SNP panel (16,075 markers). The accuracy of the genomic model in the prediction of estimated breeding values was assessed in a 5-fold random cross-validation and in a leave-one-family-out scenario, where the prediction equation was obtained by training the model on the estimated breeding values of all animals except the offspring of the parent used as test set. The accuracies (Pearson's r) were different across traits and equal to 0.90 (random cross-validation) and 0.59 (leave-one-family-out) for mortality, 0.86 and 0.60 for cortisol concentration, 0.79 and 0.01 for antibody titre, and 0.71 and 0.18 for body weight.

Introduction

In fish species, selective breeding to enhance disease resistance is considered a feasible and sustainable approach to prevent and control mortality from disease outbreaks (Ødegård *et al.* 2011). For the European sea bass (*Dicentrarchus labrax* L.) industry, viral nervous necrosis (VNN) is a major threat. Due to a moderate heritability and a significant negative genetic correlation with VNN mortality, antibody titre against nervous necrosis virus (NNV) antigens is a reasonable indicator trait to enhance VNN resistance. Conversely, serum post-stress cortisol concentration shows no genetic relationship with mortality (Faggion *et al.* 2021). However, this trait is important in a production context because stress tolerant fish have better efficiency, productivity and resilience (Castanheira *et al.* 2015). Traditional selective breeding approaches rely on estimated breeding values (EBV) predicted using individual phenotypes of the breeding candidates or their relatives through estimated additive genetic relationships based on their pedigrees. Routine individual phenotyping for complex traits such as VNN resistance, antibody titre or cortisol concentration is either difficult or unfeasible due high costs and time requirements, and the implementation of genomic selection procedures might be greatly beneficial. In this study, we assessed, the accuracy of a genomic prediction model using both random 5-fold cross-validation and, to mimic a real genomic selection scenario, leave-one-family-out validation.

Materials & methods

Production of experimental fish and phenotyping. The experimental population was produced by artificial fertilization using a commercial NNV-free breeding stock following a mating scheme based on an incomplete factorial design (sire-to-dam mating ratio: 8 to 5).

A 29 days-NNV challenge test was carried out using 650 randomly chosen fish (age: 548 d post-hatching, average body weight, BW: 146.4 g, CV% 29.18). Before being infected through intraperitoneal injection (0.1 ml, RGNNV 283.2009, batch 7/16; $10^{8.30}$ $TCID_{50}$ per ml), fish were subjected to an acute stress-test (confinement at high density), anesthetized (MS-222), individually PIT-tagged and blood sampled. Mortality (MORT) was recorded as 1 (dead) and 0 (survived). The survival rate at the end of the challenge

test was 52%. We used indirect ELISA assay to quantify antibodies against NNV (antibody titre, AT) in the blood serum of each fish following the protocol of Nuñez-Ortiz *et al.* (2016). Cortisol was extracted from blood serum following the protocol of Bertotto *et al.* (2010), and the concentration of cortisol (HC) of each sample was analysed using a solid-phase radioimmunoassay (Simontacchi *et al.* 1995).

Genotyping. Genotypes were obtained through the 2b-RAD method (Wang *et al.* 2012). After quality controls and imputation (FImpute, Sargolzaei *et al.* 2014), the number of available SNP genotypes per animal was 16,075. Parentage assignment and pedigree reconstruction were performed combining the software CERVUS 3.0 (Kalinowski *et al.* 2007) and the R package sequoia (Huisman 2017).

Pseudo-phenotypes. Breeding values (EBV) for the traits of interest were predicted using mixed animal models implementing a Bayesian approach using the TM software package (Legarra *et al.* 2008). For MORT, the variation in the phenotypic expression of the trait (y = 0 for survivors, y = 1 for the dead fish) was assumed to be dependent upon the value of an underlying continuous liability trait λ (Falconer and Mackay 1996) and analysed using a threshold model. The liability was modelled as:

$$\lambda = 1\mu + Xb + Wu + e \quad (1)$$

where λ is a vector of underlying liabilities, μ is the model intercept, 1 is an all-ones vector, b is a vector of unknown fixed parameters (fixed effects) due to the tank, X is an incidence matrix relating λ to b, u is a vector of unknown random animal additive genetic effects and e is a vector of random residuals.

For BW, HC and AT, the prediction of EBV was based on the following linear mixed model:

$$y = 1\mu + Wu + e \quad (2)$$

where y is a vector of observed phenotypes and 1, μ, W, u, e have the same meaning as above. Variance components for random effects, used to solve the model, were those reported in Faggion *et al.* (2021). The Gibbs sampler was run using 100,000 iterations with a burn-in of 5,000 iterations and a thinning interval of 10 samples.

Bayesian regression model and prediction performance. Genotypes at the 16,075 SNPs were used as predictors of the EBV by means of a Bayesian Ridge Regression (BRR) model fitted to the data using the package BGLR/R (Pérez and de Los Campos 2014) and having the following form:

$$y = 1\mu + \sum_{j=1}^{S} x_j b_j + e \quad (3)$$

where y is a vector of EBV, μ is the model intercept, 1 is an all-ones vector, x_j is a vector of genotypes at SNP j, coded as the number of copies of the minor allele (0, 1 or 2), b_j is the allele substitution effect for the minor allele at SNP j (to be estimated), S is the total number of SNP (S=16,075) and e is a vector of random residuals which was assumed to be $N(0, I\sigma_e^2)$ where N( ) indicates a normal probability density function, I is an identity matrix of appropriate order and σ_e^2 is the residual variance. A single Gibbs chain of 800,000 samples was generated, with a burn-in of 10,000 iterations and a thinning interval of 50 samples.

Predictive accuracy of the regression model was computed in a 5-fold cross-validation (CV). The data (n=650) was randomly split into five equally-sized subsets. Four were used as a training set to obtain solutions for allele substitution effects, while the fifth served as a test set. Predictions for each test set were saved and aggregated with those of the other test sets. A leave-one-family-out (LOFO) validation procedure focused on the parents of the challenge-tested fish was designed to mimic a real genomic selection scenario. The parents of the

experimental fish were used one-at-a-time as an independent test set. A genomic prediction equation was obtained for each investigated trait by training the BRR model on the EBV of all animals except the offspring of the sire (or dam) used as test set. The EBV of the parent in the test set was then predicted from the parent genotypes using the genomic prediction equation. Prediction for each parent was saved and, at the end of the LOFO, aggregated with those of the other parents. The Pearson product-moment correlation (r) between the observed and predicted values was computed as a measure of prediction accuracy in both validations.

Results

Scatterplots of the relationships between the EBV and its genomic prediction obtained in a random 5-fold cross-validation and in the LOFO validation procedure are presented in Figure 1 and Figure 2.

Discussion

In a random 5-fold cross-validation, the genomic prediction of the EBV as pseudo-phenotypes led to very high accuracies for MORT and HC and moderately high accuracies for BW and AT. However, those accuracies are unrealistic. To obtain a more realistic insight, we developed a LOFO validation. This was done to test the consistency of prediction equations in a long-term view: in commercial breeding, genomic models are trained firstly using a reference population consisting of full- and half-sibs, but the prediction equations should perform well even in future generations, when it is likely that the animals to be predicted are distant relatives of the animals included in the reference population. The LOFO accuracies were, in fact, lower than the random 5-fold cross-validation accuracies, but to a different extent across traits. For MORT and HC, omitting the progeny information in the training of the genomic models did not affect the accuracy of the genomic predicted breeding value of the parents, suggesting that in a scenario where the reference population consists of distant relatives of the animals to be predicted, the predictive performances of such models would be still acceptable. This is of great interest in an applied context, particularly when considering traits phenotyping difficulties and complexity. Conversely, the correlations between the observed and the predicted EBV dropped remarkably for BW and AT. The degree of genomic similarity between reference and testing populations, size and composition of the reference population, and the density of the marker array (Zhang *et al.* 2019) could affect genomic prediction accuracy dependent on trait-specific features. We observed weak genomic relationships between the parents of the challenged fish

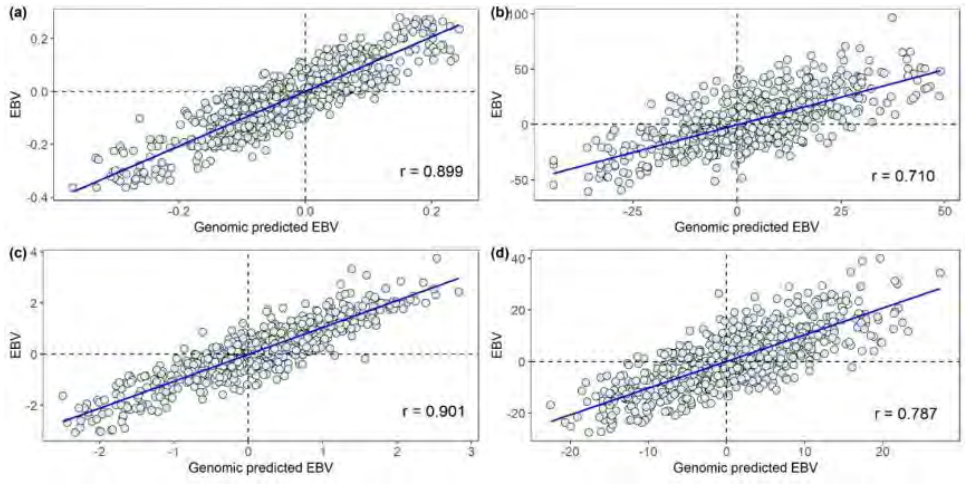

Figure 1. Relationships between EBV and their genomic predictions obtained in a random 5-fold cross-validation: (a) MORT; (b) BW; (c) HC; (d) AT. r: Pearson product-moment correlation.

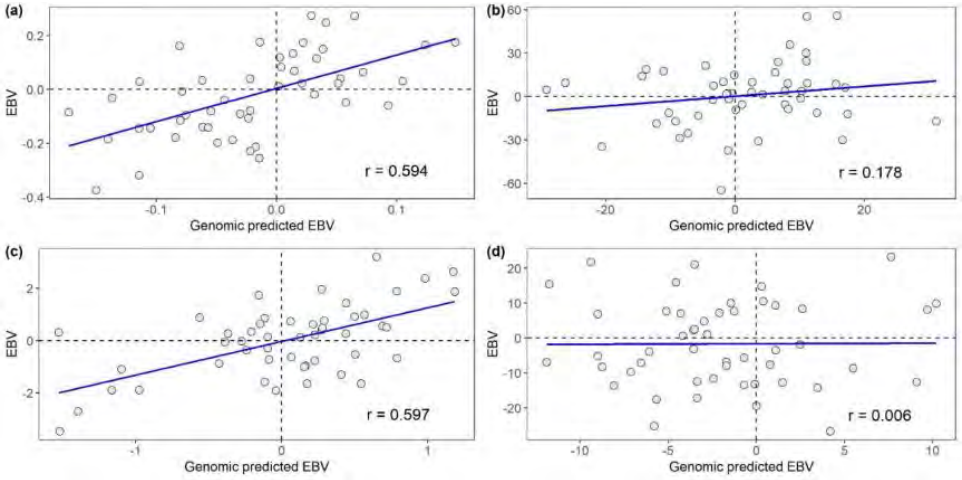

Figure 2. Relationships between EBV and their genomic predictions obtained for the parents of the challenged fish in a leave-one-family-out validation: (a) MORT; (b) BW; (c) HC; (d) AT. r: Pearson product-moment correlation.

(data not reported), implying that, in the LOFO procedure, the training of the genomic model was based on data of animals weakly related to the target individual. According to de los Campos *et al.* (2013), under perfect linkage disequilibrium between markers and causal loci, the prediction accuracy has an upper bound that depends on trait heritability and on realized genomic relationship between training and testing sets. Enlarging the size of the training population allows a high prediction accuracy (in terms of theoretical upper bound) even when genomic relationships are null or weak.

572. Genetics of parasite attraction in Atlantic salmon: potential for group-level protection against sea lice

J. Ødegård[1*], S. Kjøglum[1], M. Medina[1], J.S. Torgersen[1], S.A. Korsvoll[1], R. Deerenberg[2], J.M. Yáñez[3], D. Cichero[2], P. Lopez[2] and T. Moen[1]

Abstract

Sea lice are important copepod ectoparasites in salmonid aquaculture. Individual lice count has moderate heritability under challenge testing and has been suggested as a selection tool for parasite control. Recent studies indicate that parasite attraction is a major underlying cause of genetic variation in lice count, which is likely to cause within-group variation in parasite load, but its potential for group-level protection is unknown. Results from an ongoing divergent selection experiment are presented, with two salmon strains divergently selected for low/high pathogen burden. Under common-garden testing, the strains were extremely different. However, when tested separately using standard protocols, the difference was not significant. An alternative testing protocol with flow-through tanks was also applied, offering less 'favourable' conditions for the parasites, indicating some group-level protection (P=0.10). Further research is needed to assess the potential of lice attraction as a tool for parasite control under large-scale field conditions.

Introduction

Sea lice (*Lepeophtheirus salmonis* and *Caligus rogercresseyi*) are important copepod ectoparasites of farmed salmonids in the northern and southern hemispheres, respectively). Spread of sea lice from salmonid farming to wild salmonid populations is considered a major threat. Selection for reduced individual lice count has been suggested to control parasite burden in salmonid fish farming, and moderate heritabilities have been estimated for the trait (Gjerde *et al.* 2011; Tsai *et al.* 2016). Recent studies have shown very high genetic correlations between early (2 days post infestation) and late (15 days post infestation) lice counts, indicating that parasite load is primarily driven by differences in initial infestation and not by immune-mediated resistance (results not shown). Furthermore, Atlantic salmon selected for reduced lice count have been found to have lower levels of kairomones compounds, used by sea lice to find suitable hosts, in their mucus than salmon selected for increased lice count (Difford *et al.* 2021). Hence, lice attraction is likely a main contributor to within-test genetic variation in lice count. AquaGen also performed a common-garden lice (caligus) challenge experiment on Atlantic and coho salmon (results not shown), where initial lice counts were much higher in coho than Atlantic salmon. However, 12 days post infestation, lice count in cohos approached zero, but were unchanged in Atlantic salmon. This may be viewed as species-specific defence strategies against sea lice, with Atlantic salmon utilizing an avoidance strategy and cohos utilizing an immune-mediated resistance strategy. AquaGen conducted a selection experiment with two divergent selection lines (LPB = low parasite burden, HPB = high parasite burden) for salmon louse count (*L. salmonis*, attached stage). To date, four consecutive generations have been tested (year-classes 2011, 2014, 2017 and 2020). Genomic selection was performed using training data from common-garden sib-testing. The first aim of this study was to quantify the differentiation of the selection lines, both genetically and phenotypically. The second aim was to confirm whether selection for reduced sea louse attraction enhances group-level protection in salmon within a tank environment.

Materials & methods

Data. A total of 9,417 genotyped and phenotyped fish were included in the study. A genomic relationship matrix was computed using VanRaden method 1 (VanRaden 2008), utilizing data on 43,578 high-quality SNPs. Common-garden challenge tests were performed for all year-classes (Table 1). Some batches of fish were challenged twice (denoted A and B). For year class 2020, the common garden test (2020main) largely contained main nucleus families, while LPB and HPB selection strains were tested in a separate experiment (2020strain). Here, the two strains were tested in separate tanks (6 tanks per strain), and at high (25 lice/fish) and low (8 lice/fish) infestation pressure.

Under a standard challenge protocol, water level is lowered, and water flow stopped before lice copepodites are added. This may give the parasites easy access to hosts, potentially masking strain differences. A second set of tank experiments (2020flow and 2020standard) was therefore initiated. Here, fish were recruited from the main AquaGen nucleus, where two genetically differentiated groups were selected based on their genomic breeding values for lice count. These two groups were compared under both standard challenge (2020standard: 3 mixed tanks + 3 tanks per group) and flow-through challenge models (2020flow: 2 mixed tanks + 3 tanks per group). For the latter challenge model, lice copepodites were added to the tank under constant waterflow, i.e. the lice had a limited time window to attach to a host before being flushed out.

Prediction of GEBVs. The data sets were phenotypically heterogeneous (Table 1). Therefore, we fit a heterogeneous variance model for the genetic and residual variances:

$$y = X\beta + Zg + e$$

where y is a vector of phenotypes (log of lice count), β is a vector of fixed effects (year-class/challenge model/challenge group combination and regression coefficients for body size). Variance components for each group were estimated separately for the different challenge-tests using genomic animal models with the GCTA (https://yanglab.westlake.edu.cn/software/gcta/) software and used as input parameters in the final joint model. The mixed model equation system was solved using custom-made Julia scripts (https://julialang.org/).

Table 1. Number of genotyped individuals and estimated variance components for different sea lice challenge tests.

Test	Type	N	Gen. var. (SE)	Res. var. (SE)	h^2 (SE)
2011A	Sea cage	1,431	0.074 (0.017)	0.355 (0.017)	0.172 (0.036)

2020flow	Sep. tanks	120	-	-	-
2020flow	Mixed tanks	24	-	-	-
2020standard	Sep. tanks	179	-	-	-
2020standard	Mixed tanks	76	-	-	-

Results

Number of genotyped individuals, estimated variance components and heritabilities for the different groups are presented in Table 1. The estimated within-test genomic heritabilities were 0.16-0.17 for sea cage testing and 0.20-0.28 for tank testing. Starting from the same original sub-population of the 2011 year-class, the estimated differentiation in GEBVs between the LPB and HPB strains increased from 0 (2011), 1.2 (2014), 2.5 (2017) and finally 3.2 (2020) genetic standard deviations (Figure 1).

Under common garden testing, the estimated genetic change was accompanied by a large phenotypic differentiation (Figure 2), with the LPB having an observed lice count of -19% (P=1.0e-12) and -55% (P<2.2e-16) relative to HPB, for the year classes 2014 and 2017, respectively. For year-class 2020 (2020strain), the LPB and HPB strains were tested in separate tanks, and the phenotypic differentiation dropped considerably for both high and low infestation levels, with LPB averaging -7% relative to HPB (P=0.18). This happened despite genetic differentiation being at its most extreme (3.2 genetic standard deviations). Hence, under a standard challenge model, selection for reduced attraction did not provide significant group-level protection in this challenge model. This applied to both infestation levels.

For the two differentiated groups from the main nucleus (tests 2020standard and 2020flow), the estimated genetic difference was 1.7 genetic standard deviations (i.e. half the difference between the LPB and HPB selection strains). Under common-garden testing, the new LPB group had lower lice counts than HPB in both ordinary and flow-through challenge models (-22%, P=0.005 and -29%, P=0.11, respectively). However, under separate tank testing, this effect was absent for the ordinary challenge model (+1%, P=0.86), but a moderately favourable effect was estimated for the flow-through model (-14%, P=0.10). Experimental tank did not have any significant effect within any of the treatments.

Discussion

The results indicate that divergent selection on lice count has a large (within-tank) effect under common-garden testing. However, when tested in separate tanks under standard conditions, the strain effect was in the right direction but no longer significant. The standard challenge protocol may give lice copepodites ample opportunity to attach to available hosts, potentially masking relevant tank-level genetic effects. For this purpose, a flow-through challenge model was developed, resulting in substantial group differences under common-garden testing, and likely some group-protection effect under separate tank testing. In

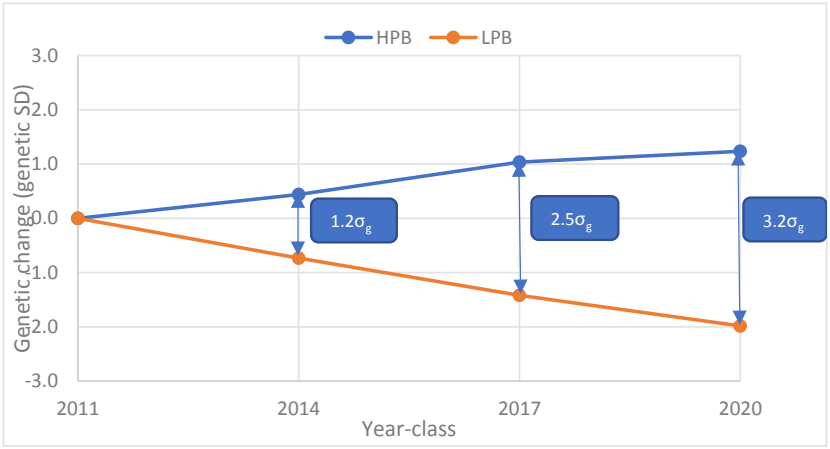

Figure 1. Estimated genetic trend for the LPB and HPB selection strains by generation (year-class).

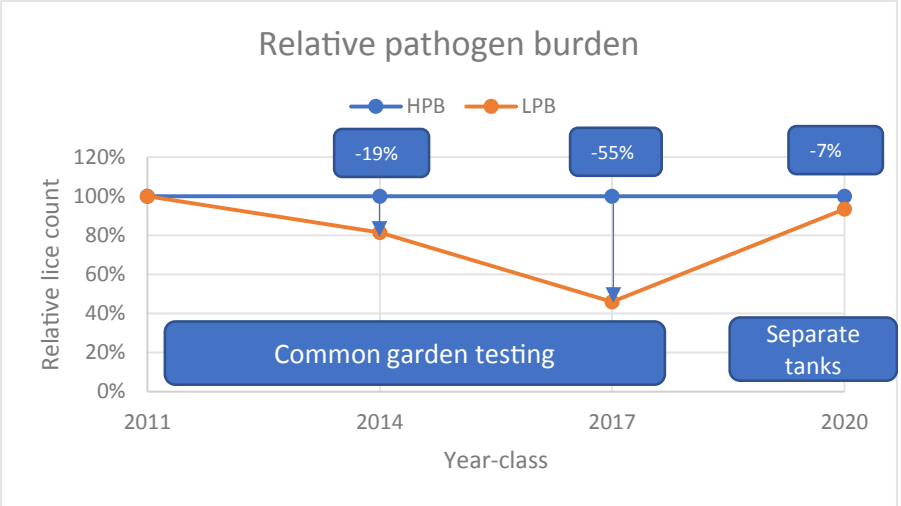

Figure 2. Relative observed phenotypic difference between the HPB and LPB selection strains by generation (year-class). Common garden testing was used for year-classes 2011-2017, while separate tanks were used for year-class 2020.

conclusion, genetic variation in salmon louse attraction had a large effect on within-tank distribution of lice, but, depending on conditions, smaller effects when strains are tested separately. Little is known about the group-level effects of parasite attraction under large-scale field conditions. More research is thus needed to what extent the effect is translated into commercial/field conditions.

Abstract

Viral nervous necrosis (VNN) presents a significant threat to the European seabass aquaculture industry, causing extensive losses due to mortality and impaired growth of infected fish. Selective breeding presents an opportunity to develop seabass strains with increased resistance, thus reducing the impact of the disease on the industry. Knowledge of the genetic architecture of the trait is important to inform selective breeding strategies, including use of genomic tools. In the current study the genetic basis of VNN resistance in European seabass was investigated through an extensive study based on nervous necrosis virus (NNV) challenge of juvenile seabass fish. The results highlighted moderate heritability (up to 0.39±0.05) of VNN resistance in farmed seabass. A major QTL was identified on LG12 or Chromosome 13 and impacted VNN resistance when defined as binary survival or as days to death. This QTL explains up to 37% of the genetic variation in VNN resistance, and therefore has a significant value for marker-assisted and genomic selection to improve resistance in sea bass breeding programmes. Together, our results provide insight into the genetic architecture of resistance to VNN that could further be utilized for enhancing genomic selection for more resistant fish.

Introduction

European sea bass (*D. labrax*) is a fish species with major economic and cultural importance to the European aquaculture industry (Vandeputte *et al.* 2019). Viral nervous necrosis (VNN) disease causes significant losses to farmed sea bass production through mortalities and impaired growth of the infected fish (Barsøe *et al.* 2021). Despite the significant economic impact of this disease to Mediterranean aquaculture, there are limited vaccination, therapeutic, and biosecurity control measures. Genetics studies have revealed significant, moderate heritability of host resistance to VNN in different seabass populations (Palaiokostas *et al.* 2018; Faggion *et al.* 2021; Griot *et al.* 2021). Additionally, genomic regions or markers have showed significant association with VNN resistance in different European sea bass populations (Palaiokostas *et al.* 2018; Griot *et al.* 2021). However, information remains sparse on the genetic architecture of host resistance to VNN in different farmed populations. Furthermore, identification of genetic markers or regions involved in regulating VNN resistance enable marker-assisted selection or enhance the genomic selection for more resistant fish which is a sustainable route to reduce the negative economic and animal welfare impact of VNN. Therefore, in the current study, the aim was to characterise the genetic resistance to VNN in sea bass, and to identify specific genomic regions and markers associated with the trait.

Materials & methods

Viral nervous necrosis challenge experiment and genotyping. Approximately 1,500 European seabass from a full factorial cross of 25 dams and 25 sires were challenged with nervous necrosis virus at a temperature of 25 °C. These fish were produced by Valle Ca' Zuliani Società Agricola in April 2020 and were challenged at a weight ranging from 6 to 20 grams at the Istituto Zooprofilattico Sperimentale delle Venezie facilities under the authorization of the Italian Ministry of Health (authorisation code 975/2016-PR). Mortality was recorded twice a day for a period of 29 days as the primary phenotype for the genetic analyses, with days to death (a.k.a survival time) also used as a phenotype. The days to death phenotype was considered both in mortalities only, and in all animals where survivors were assigned a high value equivalent to the termination of the trial. A total of 1,066 fish (including the 50 parents and 1,016 NNV challenged fish) were genotyped on the Thermo Fisher Scientific's Axiom 'MedFish' SNP array which contains circa 30K seabass SNPs (Penaloza *et al.* 2021).

Pedigree reconstruction and pedigree-based heritability estimation. Since the family structure was not known at the point of challenge, genotype data were used to reconstruct the pedigree. Circa 23,000 informative SNP marker genotypes were used to uniquely assign a dam and sire to each of the offspring using the APIS package (Griot *et al.* 2020) implemented in R, allowing for a Mendelian error rate of 5%. Subsequently, survival analyses were performed for the offspring for dam and sire families using the Survminer package (Kassambara *et al.* 2017) implemented in R. The reconstructed pedigree was used to fit a linear mixed animal model to estimate the heritability of VNN resistance in this population of farmed European sea bass using the ASReml software (Gilmour *et al.* 2015).

Genotype data processing, genomic heritability estimation, and genome-wide association study (GWAS) analyses. Genotype data were filtered using Plink (Purcell *et al.* 2007) to exclude SNPs with minor allele frequencies <5%, SNPs with missing genotype rate >5%, and SNPs that strongly (P<1E-4) deviated from Hardy Weinberg equilibrium. Additionally, individuals with high genotype missing rate (>10%) were also excluded from the analysis. All of the animals that passed the QC filters were retained, and the final dataset contained genotype data for 24,740 informative SNP markers. GWAS was performed on 990 fish which had high quality phenotype and genotype data. Phenotype records (i.e. binary survival and days to death) were firstly adjusted to account for population substructure using the first two principal components that explained 77.5% of the variation between the animals. The heritability of resistance to VNN was estimated using the genomic relationships, and an equivalent mixed linear model to that described above. GWA analyses were used to assess the association between SNP marker genotypes and the corrected VNN resistance phenotype data using the GCTA software (Yang *et al.* 2011). GWAS results were then visualized using Manhattan plots using the qqman package implemented in R (Turner 2014).

Results

Parentage assignment analysis revealed that every parent (sires and dams) in the study population contributed a significant number of progeny with moderate degree of variability. Survival analyses of the families revealed marked differences in mortality levels within and between families for both dam and sire parents over the challenge study time. In general, moderate and significant heritability was found for the three VNN resistance traits (Table 1).

A total of 528, 578 and 42 markers were identified as significantly (FDR<0.05) associated with binary survival, days to death (all animals), and days to death (mortalities only), respectively. Additionally, 92, 104 and 23 markers, respectively, showed suggestive (FDR<0.1) association with the same traits. For all the three traits, most (78 to 95%) of the significant SNP markers were located on LG12 (also denoted chromosome 13, Figure 1a, b and c), indicating presence of a major QTL on this chromosome. For all the three traits,

Table 1. Heritability estimates of VNN resistance in farmed seabass.

VNN resistance definition	Pedigree based $h^2 \pm SE$	Genomic $h^2 \pm SE$
Binary survival	0.38±0.10	0.37±0.05
Days to death (mortalities and survivors)	0.23±0.08	0.39±0.05
Days to death (mortalities only)	0.06±0.10	0.21±0.08

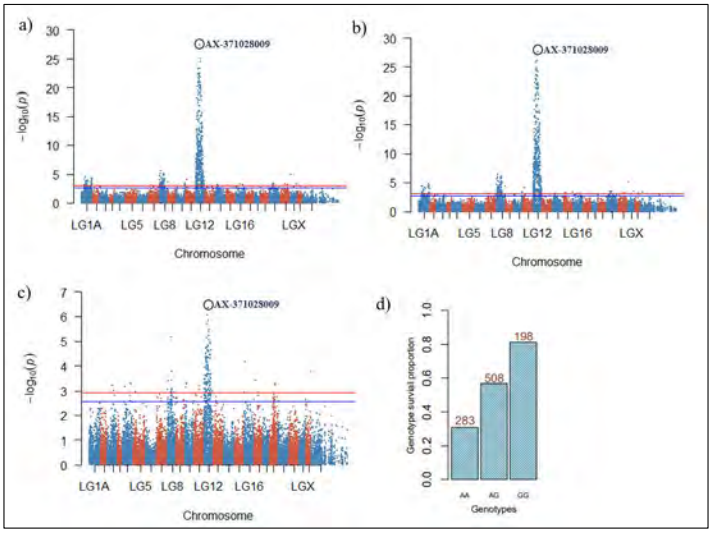

Figure 1. Manhattan plot summarizing genome-wide association study results for VNN resistance in European seabass defined as; (a) binary survival, (b) days to death for both mortalities and surviving fish, and (c) days to death with mortalities; and (d) bar plot showing survival proportion of individuals from the three genotype classes (AA, AG and GG) for the most significant SNP marker (AX-371028009), the numbers individuals with each of the three genotypes are provided above each bar in the plot.

AX-371028009 was the most significant SNP marker associated with each of the traits and explained 12.7, 14.0 and 6.3% of the phenotypic variation in VNN resistance when defined as binary survival, days to death (all animals), or days to death (mortalities only), respectively. This equates to 37.0, 36.0 and 29.8% of the additive genetic variance of the same traits, respectively. Indeed this SNP demonstrated additive genetic effect on VNN resistance in seabass with the homozygous genotype GG associated with the highest (81% survival rate) level of resistance, while the AA genotype associated with the lowest (30.7% survival rate) resistance (Figure 1d). This SNP is located within the 26th intron of the EML5 (EMAP Like 5) gene. EML5 encodes for the Echinoderm microtubule associated protein like 5, which is involved in regulating cytoskeleton rearrangement (O'Connor *et al.* 2004).

Discussion

The moderate heritability estimates of VNN resistance observed in the current study concur with the moderate to high heritability estimates of VNN resistance that have been reported in other farmed European seabass populations (Palaiokostas *et al.* 2018; Faggion *et al.* 2021; Griot *et al.* 2021). Together, these results highlight the potential for selective breeding as a viable as a sustainable approach to improve resistance and therefore reduce economic losses due to disease outbreaks on seabass farms. The GWAS

results presented herein are also in agreement with the recent discovery of a major QTL for VNN resistance on LG12 in different European seabass subpopulations (Griot *et al.* 2021) where the QTL explained up to 9.2% of the total genetic variability. Palaiokostas *et al.* (2018) did not identify such a major QTL on LG12, however they identified a SNP marker on LG12 that was significantly associated to VNN resistance and accounted for 4% of the total additive genetic variance (Palaiokostas *et al.* 2018). Therefore, the current study confirms the presence of a major VNN resistance locus on LG12 that can be utilized for breeding of more resistant seabass populations. Further analyses are underway using whole genome resequencing data for all animals, combined with gene expression comparison of resistant and susceptible animals, with a view to identifying the causative gene and variant for this major QTL.

Funding

The study was conducted as part of the AQUA-FAANG project, which has received funding from the European Union's Horizon 2020 research and innovation program under Grant Agreement No 817923.

Abstract

Resilience is the ability of an animal to adapt with environmental changes while maintaining consistent performance over time. A selective breeding program for growth in brackish water of Sukamandi strain tilapia is conducted in Indonesia. The resilience of fish is also important for producing tilapia in variable saline conditions. The objectives of this study were to estimate the genetic parameters of resilience for Sukamandi strain, expressed as consistency in growth. We used the log-transformed variance of deviations (LnVar) from weight, recorded five times during grow-out. We also estimate the correlation of LnVar with weight (W), daily growth coefficient (DGC), condition factor (K) and survival (S). The heritability of LnVar in time point 4 and 5 were 0.02 and 0.07, respectively. The genetic correlations were positive (0.35-0.76) for LnVar with W, DGC, S and negative (-0.31) with K. These estimates showed that selection for growth and survival will moderately increase LnVar and may lead to the decreasing resilience. However, selection for K could contribute to increased resiliency of tilapia.

Introduction

Resilience is the ability of the animal to cope with environmental changes, such as fluctuations in salinity (Berghof *et al.* 2019a, Mulder *et al.* 2017). Resilience in fish production refers to the consistency of production performance throughout time. A selective breeding program for growth rate of tilapia in brackish water is conducted in Indonesia. Selection is applied to the Sukamandi strain population, an inter-species hybrid created by mixing blue tilapia (*Oreochromis aureus*) and Nile tilapia (*Oreochromis niloticus*) (Yu *et al.* 2021). While focusing on growth, the resilience of fish is also considered important. To produce tilapia in conditions of varying salinity, a high resilience of tilapia is needed. In this paper, we estimate the genetic parameters for resilience of Sukamandi strain. The genetic parameter for resilience can be estimated based on longitudinal measurement by calculating deviations of observed from expected production (Friggens *et al.* 2017). Several potential resilience indicators have been investigated, including natural-log-transformed variance of deviations from mean (LnVar), skewness of deviations, and autocorrelation of deviations (Berghof *et al.* 2019a). LnVar was the most promising resilience trait based on its moderate heritability (Poppe *et al.* 2020; Berghof *et al.* 2019a). Furthermore, Berghof *et al.* (2019a) showed that including resilience trait in index selection would add economic benefit. Hence, correlated response of potential indicator for resilience with growth, factor condition and survival is important. In this study, we also estimate the correlation of LnVar with weight (W), daily growth coefficient (DGC), condition factor (K) and survival (S).

Materials & methods

Family production and testing environments. All families were produced using combination of one male mated to three females. After 7 days of mating, we collected the fertilized eggs or larva from a female mouth, and then incubated eggs in cone hatching jars until they became functional larva. In total 102 families were produced over a period of 28 days. We transferred 200 swim-up fry from each family for

R.F. Veerkamp and Y. de Haas (eds)

nursery period. After 3-4 weeks, we randomly tagged and weighed 40 individuals in each family using PIT (Passive Integrated Transponder) tags. From each family, 20 fingerlings were stocked for grow-out in monoculture and 20 in co-culture with shrimp. The test location for grow out of tilapia was at Technical Implementation Unit for Brackish water Culture Karawang, at salinity around 20 ppt. We stocked all families in the happa within two ponds with a stocking density of 5.1 fish per m^2. During stocking we reduced the salinity level from around 20 ppt to 10 ppt to reduce stress and mortality.

Trait measurements. We measured weight and length at 5 time points: stocking time (t_1), 3 time points after stocking time ($t_{2\text{-}4}$) and harvest time (t_5). We calculated the standardized deviations of body weight in each time point: (Wt_n - $\overline{W}t_n$) / SD_n. For each fish, we calculated the variance of these standardized deviations and log-transformed this variance using the natural logarithm to obtain LnVar. DGC, W, and S were evaluated at time point 4 and 5. DGC was calculated as:

$$DGC = \left(\frac{W_t^{\frac{1}{3}} - SW^{\frac{1}{3}}}{growing\ days}\right) x\ 100,$$

where SW is body weight at t_1, W_t is weight at t_n and growing days is the growing time between t_1 and t_n. We calculated K at t_4 with W in grams and L in mm:

$$K = \left(\frac{W_4}{{L_4}^3}\right) \times 10^5.$$

Data analysis – phenotypic and genetic parameters. Estimation of genetic parameters was carried out for W, LnVar, DGC and S at t_4 and t_5. Estimation of genetic parameters for K was conducted only at t_4 due to lacking L information at t_5. Fixed effects of happa and sex were fitted in the animal models for all traits. Genetic parameter were estimated by fitting a univariate animal model using ASReml version 4.1 (Gilmour *et al.* 2015):

$$y_{ijklm} = \mu + Happa_i + Sex_j + Init_k + Family_l + a_m + e_{ijklm}$$

where: y_{ijklm} is vector of trait; μ is overall mean; $Happa_i$ is fixed effect of happa; Sex_j is fixed effect of sex (l =m, f); $Init_k$ is initial weight for DGC and initial weight and length for K; $Family_l$ is full sib family as random common environmental effect; a_m is random additive genetic effect of the m-th individual; e_{ijklm} is random residual effect associated with an individual. The model was used to analyse the traits DGC and K. The same model was used for direct measurement trait of W, LnVar and S but excluded the initial value. We calculated the heritability as the ratio between additive genetic variance (σ_A^2) and phenotypic variance (σ_P^2), $\frac{\sigma_A^2}{\sigma_P^2}$.

Genetic and phenotypic correlations between different traits were obtained from bivariate analyses. The animal effects were distributed as N(0,A⊗G) with the additive genetic variance covariance matrix:

$$(G) = \begin{bmatrix} \sigma_{A,1}^2 & r_{A,12}\sigma_{A,1}\,\sigma_{A,2} \\ r_{A,12}\sigma_{A,1}\,\sigma_{A,2} & \sigma_{A,2}^2 \end{bmatrix},$$

where $\sigma_{A,1}^2$ ($\sigma_{A,2}^2$) is the additive genetic variance of trait 1 (trait 2), and $r_{A,12}\sigma_{A,1}\,\sigma_{A,2}$ is the additive genetic covariance between trait 1 and trait 2. The residuals were distributed as N(0, I⊗R) with residual variance-covariance matrix (R) is:

$$\begin{bmatrix} \sigma_{e,1}^2 & r_{e,12}\sigma_{e,1}\,\sigma_{e,2} \\ r_{A,12}\sigma_{A,1}\,\sigma_{A,2} & \sigma_{e,2}^2 \end{bmatrix},$$

where $\sigma^2_{e,1}$ ($\sigma^2_{e,2}$) is th e residual variance of trait 1 (trait 2), and $r_{e,12}\sigma_{e,1}\,\sigma_{e,2}$ is the residual covariance between trait 1 and trait 2. Genetic and phenotypic correlations among traits were calculated as the covariance divided by the product of the standard deviations of traits.

Results

The average stocking weight was similar between male (11.8±3.2 g) and female (10.1±2.8 g). Overall, the mean for all measured parameter were higher in male compared with the female. The survival rate at t_4 is 75.5% and 27.3% at t_5(Table 1).

Phenotypic and genetic parameters. We found low heritability for LnVar of 0.02±0.04 in t_4 and 0.07±0.07 in t_5. The heritability were low to moderate for W, DGC, K and S in t_4 (0.04-0.13) and t_5 (0.06-0.29) (Table 2). Common environmental effects due to family were decreasing and heritability were increasing for all estimated trait between t_4 and t_5.

The genetic correlations of LnVar with W, DGC and S were positive and moderate (0.35-0.76), while the correlations were negative between LnVar and K (-0.31±0.23). The genetic correlations between W, DGC and K were high (0.87-0.99). Furthermore, the genetic correlation of survival with W, DGC and K were negative and moderate between -0.26 and -0.76 (Table 3).

Table 1. Descriptive statistics of weight (W), variance of deviation (Var-dev), log transformed variance (LnVar), daily growth coefficient (DGC), condition factor (K) and survival (S) of Sukamandi strain tilapia for data point 4 (t_4) and 5 (t_5) in brackish water ponds.

S	0.01 (0.02)	-0.01 (0.02)	-0.03 (0.03)	-0.04 (0.03)	

Discussion

We reported low heritabilities for LnVar. This estimates was lower than previous estimates for heritability of LnVar such as LnVar heritability for chicken body weight of 0.10 (Berghof *et al.* 2019b). Common environmental effects decreased while heritability increased for all estimated trait between t_4 and t_5. We only estimated the genetic correlations in t_4 because the dataset became too small at t_5 due to mortality between t_4 and t_5 (Table 1). Genetic correlations between LnVar and W, DGC and S were positive and moderate (0.35-0.76). These positive correlation would mean that selection for growth and survival will moderately increase LnVar or decrease the resilience. In other words, a positive correlation is unfavorable for simultaneous improvement between resilience, growth and survival, whereas a negative correlation is beneficial. However, the negative and moderate genetic correlation estimated between LnVar and K (-0.31) showed that selection for K could contribute to greater resiliency to the salinity. Common environmental effects were strong up to t_4 and may have affected the estimates for heritability. Increased heritability of resilience was estimated at t_5, but based on a reduced dataset due to mortality.

Abstract

Knowledge of population structure and genetic variability within and between wild and farmed populations is important to achieve sustainable aquaculture production. In this study, these features were assessed for gilthead seabream and European seabass using a combined species SNP array newly developed. Population structure analyses revealed a clear differentiation between wild and farmed populations in both species, indicating that care must be taken to avoid escapes that could have undesirable genetic effects on native populations. Wild populations showed a low degree of differentiation, particularly in seabream. However, farmed populations were quite heterogeneous and showed a high degree of differentiation. In general, the effective population size was large ($>10^3$) for wild and small ($<10^2$) for farmed populations of both species. The low effective population size estimated for some farmed populations highlights the need of applying measures to control the rate at which genetic variability is lost.

Introduction

Knowledge of population structure and genetic diversity within and between wild and farmed fish populations is of paramount importance to develop optimal strategies for the conservation of native fish and to achieve sustainable aquaculture production. The success of any breeding programme is critically dependent on the way in which the base population of breeders is built. Given that base populations can be established from wild and farmed populations, it is necessary to determine the relatedness between them in order to optimise their creation (Fernández *et al.* 2014). Also, once genetic improvement programmes are operational, the control of inbreeding (or equivalently, the effective population size, N_e, a parameter inversely related to the loss of genetic variability) is needed to ensure their long-term sustainability.

Gilthead seabream (*Sparus aurata*) and European seabass (*Dicentrarchus labrax*) are two of the main cultured finfish species in Europe. Although still less developed than in salmonids, selective breeding is expected to play an increasingly important role in the commercial production of both species and different companies have initiated breeding programmes in recent years (Janssen *et al.* 2017).

Most studies investigating population structure in gilthead seabream and European seabass have been based on a limited number of genetic markers (mostly microsatellites). However, new genomic resources are now available, including a recently developed combined ~60K SNP array for both species (the MedFish array; Peñaloza *et al.* 2020).

The objective of this study was to make use of the MedFish SNP array to: (1) identify the extent of wild and farmed population stratification within species, considering the geographic origin of individuals; and (2) estimate N_e in populations of both species.

Materials & methods

Samples available came from 11 wild (W-) and 12 farmed (F-) seabream populations and from 9 wild and 15 farmed seabass populations, distributed from the Western to the Eastern Mediterranean Sea. Additionally, three wild seabream populations sampled in the Atlantic Ocean (W-SPA-1, W-SPA-2, W-FRA) were available for analyses. Populations were ordered according to their geographic location (Figure 1).

The total number of individuals genotyped with the SNP array was 462 and 516 for seabream and seabass, respectively. After quality control, the total number of SNPs available for analysis was 25,319 for seabream and 22,507 for seabass.

To assess population structure, a model-based clustering method was implemented using genotypic data and the software Admixture version 1.3.0 (Alexander *et al.* 2009). The analysis is based on maximum likelihood estimation of individual ancestries from SNP genotypes, providing the best proportions of admixing components (clusters) for any hypothetical number (K) of genetic groups (Liu *et al.* 2013). In order to identify the value of K for which the model has the best predictive accuracy, the Admixture software uses a cross-validation procedure, and the K value chosen is that with the lowest standard error for the cross-validation. Wild and farmed populations within each species were analysed jointly.

Estimates of current effective population size (N_e) were obtained for all populations from linkage disequilibrium (measured as r^2) between independent SNPs mapped in different chromosomes or linkage groups, following Waples (2006).

Results

The admixture model results revealed that the number of ancestral populations (K) with the lowest cross-validation error was 7 for seabream (Figures 1a, 1b) and 15 for seabass (Figures 1c, 1d). The results showed a clear differentiation between wild and farmed populations.

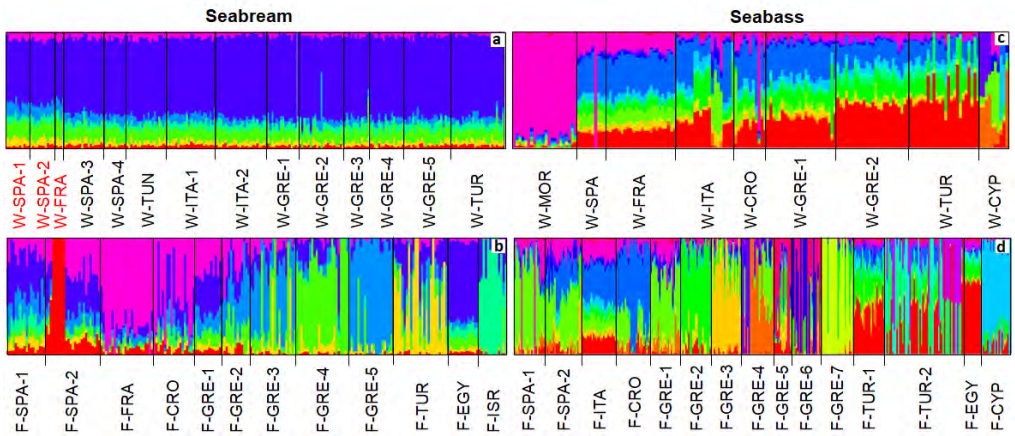

Figure 1. Admixture plots for wild (a, c) and farmed (b, d) seabream (a, b) and seabass (c, d) populations. Ancestry proportions are represented on the y-axis. Population codes (ordered according to their geographical location) are represented on the x-axis (MORocco, SPAin, FRAnce, TUNisia, ITAly, CROacia, GREece, TURkey, CYPrus, EGYpt, ISRael). Codes for populations sampled in the Atlantic Ocean are in red (a).

In general, there was very little differentiation among wild seabream populations although a slight differentiation was observed between Atlantic and Mediterranean populations (Figure 1a). Contrarily, farmed seabream populations were heterogeneous and showed different admixture proportions. It is worth to note that the F-EGY population showed admixture proportions similar to those found in wild populations (Figure 1b). It is also relevant the observation that some farmed populations (e.g. F-SPA-2) presented two clearly different groups, probably reflecting a very recent mixture of populations (Figure 1b).

Within wild seabass populations, the Moroccan population (W-MOR) was very different from the rest (Figure 1c). Also, the Cyprus population (W-CYP) had a different genetic makeup. For the rest of the wild seabass populations, a gradual change was observed in the proportions of different origins and this change was associated with the geographic locations as we move from West to East. It was also observed the presence of individuals within a particular population that clearly differed from others in the same population (e.g. in populations W-SPA and W-CRO, Figure 1c). As with seabream, farmed populations were very heterogeneous and there was no direct relationship between the genetic structure and the location of the populations. Also for seabass, some farmed populations (F-ITA, F-TUR-1 and F-EGY) showed admixture proportions similar to those found in wild populations (Figure 1d).

In general, estimates of N_e were very high for wild populations ($>10^3$) and relatively low ($<10^2$) for farmed populations of both species, but there were some exceptions (Table 1). Five farmed seabream populations and 12 farmed seabass populations had a N_e lower than 50 fish.

Discussion

This study provides new high-resolution population genetic data to inform future breeding and stock management of two key European aquaculture species. Given the clear differentiation between wild and farmed populations for both species, precautions must be taken to avoid escapes that could have undesirable genetic effects in native populations. In fact, the admixture results showed that, within a particular population, some wild individuals have a genetic composition very different from the rest of individuals in the population and they may represent escapees from local farms. These results were generally supported by Principal Component Analysis and hierarchical distance-based clustering methods (results not shown).

In general, the degree of differentiation among wild populations was low, particularly in seabream, indicating that considerable gene flow exists. Our results are in line with those obtained in previous studies that used a much more limited number of markers (e.g. Alarcón *et al.* 2004), although some studies have described differentiated clusters for Mediterranean wild seabass (e.g. Souche *et al.* 2015) rather than the gradual change in the genetic composition from West to East observed here.

Table 1. Estimates of N_e for wild (W) and farmed (F) populations of seabream and seabass.

N_e		Seabream		Seabass
$>10^3$	W:	SPA-1,3, FRA, ITA-1,2, GRE-1,3-5, TUR	W:	MOR, FRA, GRE-1,2
			F:	ITA, EGY
$<10^2$	W:	SPA-2, TUN*, GRE-2	W:	SPA, ITA*, CRO, TUR, CYP*
	F:	SPA-1,2*, GRE-1,2,3,(4-5)*, TUR*, ISR*	F:	SPA-1*,2*, CRO*, GRE-(1-7)*, TUR-1,2*, CYP*

*Populations with $N_e<50$.

On the contrary, farmed populations of both species were quite heterogeneous, which may indicate that they were generated from several origins. They also showed a high degree of differentiation, pointing to different fish sources for different companies. A few farmed populations showed genetic compositions similar to those found in wild populations, which may indicate that their selective breeding programmes are still in their beginnings or that broodstock has been recently renewed using wild fish as a means of mitigating inbreeding.

Given that there was no clear differentiation among wild populations, it is likely that the low N_e found for some wild populations can be due to escapees included in the samples or to a reduced number of families included in the samples. On the other hand, the unexpected high N_e estimated for some farmed populations agrees with the results of the Admixture analysis in which these populations showed admixture proportions very similar to those found in wild populations that may indicate that their selective breeding programmes are recent.

As in many other fish populations of different species (e.g. Saura *et al.* 2021), estimates of N_e below 50 fish were found in many farmed populations probably due to sampling a limited number of families when building them. These estimates are lower than the critical size of 50 needed to avoid inbreeding depression and retain fitness in the short-term (FAO, 2013) and highlights the need of applying selection and mating approaches designed to control inbreeding and loss of genetic variability.

Abstract

The aim of this study was to estimate between environment genetic correlations of thermal growth coefficient (TGC), condition factor (CF) and fillet fat (FF) of Chinook (king) salmon (*Oncorhynchus tshawytscha*) reared in tanks and commercial sea-pens (SP). 1,508 individuals from 44 pedigree families were tagged and reared for 12 months in seawater tanks up to ~1.50 kg. From the same families, 1,288 individuals were reared in SPs and measured at 2yrs old. All 2,796 individuals were genotyped using genotype-by-sequencing to generate a genomic relationship matrix. Estimates of heritabilities and genetic correlations were obtained using a bivariate animal model fitting contemporary group as fixed effect. Estimates of heritabilities were slightly lower in the SP traits indicating more environmental variation. The genetic correlations between tanks and SPs for TGC, CF and FF ranged from 0.46-0.78, suggesting that the Cawthron Finfish Research Centre tank evaluation can be used to predict family performance in this population.

Introduction

Chinook (king) salmon (*Oncorhynchus tshawytscha*) is an important aquaculture species in New Zealand (NZ) and selective breeding since the 1990s has resulted in significant gains in growth traits, flesh quality traits and fat content (Symonds *et al.*, 2019). With adequate genetic improvement in growth traits, breeders are considering incorporation of other economically important traits into the breeding programs such as environmental tolerance and feed conversion efficiency.

The Cawthron's Finfish Research Centre (FRC) facilities provide the opportunity for commercial salmon breeding programs to assess genotypes in trials that cannot be conducted in sea-pens. Phenotypes recorded in these facilities can be applied to pedigree-based or genomic evaluation of broodstock candidates. This provides the opportunity to evaluate traits that are extremely difficult to measure in the sea-pens such as feed efficiency and heat and hypoxia tolerance (Lulijwa *et al.*, 2021).

This study aimed to provide information about the genetic correlations among three commercially valuable traits, evaluated in related families reared in a commercial sea pen and a land-based tank system.

Materials & methods

Sanford family evaluation. Animals used in this study originated from the 2018-year class of the Sanford Chinook Salmon breeding program where selection is operated using non-overlapping generations of 3 years each. Assessment records of 1,288 animals from the 2018 cohort, were provided by Sanford. These animals were raised in SPs at Steward Island and sampled and measured during harvest on the 24 and 25th of June 2020. These animals originated from 126 crosses between 47 sires and 70 dams. Fillet fat (FF) data were measured using AgResearch's Hyperspectral method (Reis *et al.*, 2021).

Cawthron FRC evaluation and trial design. The 1,508 animals in the FRC tank evaluation were part of a larger trial evaluating family growth, feed efficiency and thermal tolerance (Lulijwa *et al.*, 2021). These salmon were sourced from the same 2018-year class families as the commercial breeding program families in the sea-pens. The 1,508 juveniles originated from 44 crosses between 33 sires and 36 dams. Fillet fat (FF) was measured using Fourier transform-near infrared reflectance (NIR) spectroscopy (Miller *et al.*, 2018).

Genotype data. All fish in this study were genotyped using Genotyping-by-Sequencing (GBS) following the methods described in Dodds *et al.* (2015), with the following modifications: Samples were digested with MspI as well as PstI and the fragments were size selected to the range 193-318bp (Pippin Prep) and sequenced with 384 samples (including controls) per lane of a HiSeq2500. Prior to this study, adapter-trimmed sequence reads from a set of 3,279 Chinook salmon from various captive stocks in NZ were used to detect 42,839 single nucleotide polymorphisms (SNPs) using UNEAK (Lu *et al.* 2013) and without using a reference genome. These SNPs were placed into a catalogue to allow counts of reference and alternate alleles for each variant using TagDigger (Clark and Sacks, 2016) on any subsequently sequenced sample.

Initially, 473 SNPs that were monomorphic in the study fish and 9 fish with mean read depth <0.3 were removed. The SNPs were further filtered to remove any with minor allele frequency <0.01, Hardy-Weinberg (HW) disequilibrium <-0.05 or with a depth-adjusted HW test (Dodds *et al.* 2018) *P*-value<10^{-100}. After filtering, 37,867 SNPs remained.

Statistical analysis. Thermal growth coefficient (TGC) was calculated using the modified formula of Cho (1992): TGC = $[(W_2^{0.333} - W_1^{0.333}) / (T \times t)] \times 1000$, where T is temperature (°C), W_1 and W_2 are the body weights (grams) at tagging and harvest, respectively and t is the number of days between those measurements. Condition factor (CF) was calculated as $(W/l^3) \times 100{,}000$, where l is length (mm). The length-weight relationship was evaluated using the log transformation formula of Le Cren (1951): $W = aL^b$ and the linear regression of the log-transformed equation: log(W) = log(a) +blog(L), where the parameters a and b were calculated with 'a' representing the intercept and 'b' the slope of the relationship.

Descriptive statistics for TGC, CF and FF were obtained using R. Genetic parameters were obtained using the Restricted Maximum Likelihood procedure in ASReml-R version 4 (Butler *et al.*, 2017) fitting a bivariate animal model represented as;

$$y_i = X_i b_i + Z_i u_i + e_i \quad (1)$$

where subscript *i* refers to trait environment, y_i is the vector of recorded phenotypes, X_i and Z_i are incidence matrices relating phenotypes with the fixed and random effects, b_i is the vector of the fixed effects of the contemporary group (defined as tank history for tank traits and harvest date for sea-pen traits), u_i is a vector of random additive genetic effects $\sim N(0, G_i\sigma^2_{gi})$ where G_i is the submatrix of G for animals in environment i and σ^2_{gi} is the additive genetic variance, e_i is a vector of random residual effects $\sim N(0, I_i\sigma^2_{ei})$ where I_i is an identity matrix and σ^2_{ei} is the residual variance. Additionally, $cov(u_1, u_2) = r_G \sigma_{g1} \sigma_{g2}$. The bivariate models were fitted for TGC, CF and FF for both environments.

Results

Descriptive statistics are summarised in Table 1.

The length-weight relationship of fish stocked in different tanks is presented in Table 2. For a 1% increase in length, we would expect a 3.39% increase in fish weight in the FRC tanks and a 2.62% increase in the sea-pens.

Table 1. Descriptive statistics of traits assessed in commercial sea-pens (average age 730 days) and the FRC tanks (average age 463 days) in New Zealand in 2021.

Location	Trait	n	Mean	SD[1]	Min	Max	CV[2] (%)
Tanks							
	Condition factor	1,397	2.33	0.21	1.25	2.97	9
	Fillet fat (g/100 g)	390	23.60	3.39	15.34	36.29	14
	TGC[3]	1,398	1.95	0.18	1.25	2.45	9
Sea-pens							
	Condition factor	1,288	1.95	0.18	1.32	3.34	9
	Fillet fat (g/100 g)	1,287	34.42	1.34	29.64	38.33	4
	TGC	1,288	2.69	0.17	2.08	3.21	6

[1] SD = Standard deviation across location.
[2] CV = coefficient of variation.
[3] TGC = thermal growth coefficient.

Table 2. The length weight relationship of Chinook Salmon reared in FRC tanks and commercial sea-pens.

Environment	Mean weight (g)	Correlation coefficient (r)	b[1]	SE[2]
Tanks	1,500	0.91	3.39	0.04
Sea-pens	6,390	0.83	2.62	0.05

[1] b = the slope of the relationship.
[2] SE = standard error of b.

Estimates of heritabilities and genetic correlations are presented in Table 3. All heritability estimates were greater in the FRC tanks compared to the commercial sea-pens. The genetic correlations between the traits were lowest for TGC and greatest for FF.

Discussion

Using a bivariate animal model, this study produced genetic correlations between TGC, CF and FF of Chinook salmon reared in two different environments. Growth performance was represented by the TGC and varied between the two environments (1.95 from tanks vs 2.69 from sea-pens). When length was regressed with weight, the slope value was significantly lower than critical isometric value (3) for the sea-pens indicating negative algometric growth; thus fish become more slender as they increase in length (Pauly 1984). In comparison the slope was greater than 3 for the animals in the tanks, indicating the fish becomes more round for its weight, as it grows longer (Thakur and Das 1974). The negative allometric growth in sea-pens could be due to different environment and/or feeding regimes in sea compared to in the tanks.

Table 3. Estimated heritabilities (±SE) and genetic correlations (rG) of weight, condition factor and fillet fat of Chinook Salmon reared in FRC tanks and commercial sea-pens.

Trait	Tank h^2	Sea-pen h^2	Genetic correlation
TGC[1]	0.52 (0.04)	0.39 (0.05)	0.46 (0.09)
Condition factor	0.42 (0.04)	0.37 (0.05)	0.60 (0.10)
Fillet fat	0.42 (0.10)	0.35 (0.04)	0.78 (0.13)

[1] TGC = thermal growth coefficient.

All heritability estimates were greater for traits observed in the tanks vs sea-pen. This could be attributed to the age differences and greater environmental variation in the sea-pen as the rearing conditions were tightly controlled throughout the FRC trial. Moderate to high heritabilities were observed for all traits. The heritabilities for TGC were similar to those obtained for body weight from Sanford of 0.30-0.48 (Symonds *et al.*, 2019) and within the range of heritabilities reported for TGC in Atlantic salmon (0.35-0.56; Thorland *et al.*, 2020).

This study provides the first heritability estimates of CF in NZ Chinook salmon. These estimates are greater than those reported in trout (0.19; Gjerde and Schaeffer 1989), similar to Atlantic Salmon (0.42; Garber *et al.*, 2019) and within the range of heritabilities (0-0.6) reported by Carlson and Seamons (2008). In the past, heritability estimates of flesh quality traits in this population ranged from 0.04-0.18 (Symonds *et al.*, 2019), which are similar estimates to those reported in Coho salmon (0.17; Neira *et al.*, 2004) and Atlantic salmon (0.28; Powell *et al.*, 2008) but are lower than the 0.35-0.42 obtained for FF in this study.

Results show substantial additive genetic variance for traits of interest that can be exploited through selective breeding. The genetic correlation for FF could be influenced by the difference in measuring FF. The low to moderate genetic correlations between the traits suggest the traits in the FRC tank evaluation are similar to those in the commercial sea-pen evaluation. These results support our hypothesis that tank evaluation can be used to predict commercial family performance, but the low correlations highlight the need to use information from sibs in both environments to optimise the response to selection. Future FRC studies will evaluate more difficult to measure traits that otherwise cannot be evaluated in the sea-pens, to enable selection for these desirable traits in broodstock.

Abstract

Phenotyping individual feed intake through direct measurements remains complex in fish, and one way to overcome this challenge is to find indirect criteria for estimating feed efficiency. This study investigated the correlations between fish residual feed intake (RFI) and fat content or the number of feed demands in ten isogenic lines of rainbow trout. We found positive correlations between RFI and fat content indicating that fatter fish tend to be less feed efficient. However, the association between RFI and fat content was not constant over time and was driven mostly by one replicate from one line. We also found positive correlations between RFI and the total number of feed demands. Our findings highlight the interest of using fat content in selective breeding programs to improve feed efficiency and highlighted the interest in exploring the relationship between feed efficiency and feeding behaviour in fish.

Introduction

Improving feed efficiency (FE) in fish can be achieved through various approaches, including husbandry, nutrition, and genetics. FE is one of the main traits of interest for fish breeding programs (Chavanne *et al.*, 2016). However, unless infrastructure is available for separately rear of families as previously done for Atlantic salmon in Norway, selection for FE remains challenging, as it requires precise recording of individual feed intake (FI). Several approaches can be used for phenotyping individual FI in fish, including video-recording during feeding, the use of radio-opaque feed, and the counting of uneaten pellets in individual rearing. Nevertheless, these methods have major drawbacks as reviewed by de Verdal *et al.* (2018).

On an experimental scale, one tool to overcome the drawbacks of typical FI assessment methods is using isogenic lines (Quillet *et al.*, 2007), within which all individuals are genetically identical. Because the genetic variability within an isogenic line is zero, fish belonging to the same line may be reared in the same tank allowing a precise assessment of FI of their shared genotype under conditions close to production systems (Knap and Kause, 2018). In addition, combining several isogenic lines gives access to the between-line genetic variability of FE (Grima *et al.*, 2008).

Many indirect criteria for estimating FE have been studied. Body weight loss and gain during feed deprivation (FD) and subsequent compensatory growth (CG) periods and fat content have been suggested as indirect estimators of FE (de Verdal *et al.*, 2018). Feed efficiency can also be linked to feeding behaviour. For example, Martins *et al.* (2006) have shown that African catfish with better FE spend less time eating. In Nile tilapia, Martins *et al.* (2011) found that FE was negatively correlated with feeding latency and positively correlated with feeding time and the number of feeding acts.

The objectives of the present study were to investigate the links between residual feed intake (RFI), fat content and feeding behaviour.

Materials & methods

Heterozygous isogenic lines. Parents were derived from the INRAE homozygous isogenic lines previously established after two generations of gynogenesis (Quillet *et al.*, 2007). Ten heterozygous isogenic lines were produced by mating females from a single maternal homozygous isogenic line (named B57) with sex-reversed XX males from ten other homozygous isogenic lines (A02, A03, A22, A36, AB1, AP2, B45, B61, N38, R25) to produce genetically identical heterozygous (h) individuals exhibiting performances across the range of the population from which the isogenic lines are derived. Only one maternal line was used to avoid maternal effects which could bias the results.

Successive experimental phases. The experiment reported here started at 137 days post fertilization (dpf). Feed intake was measured three times: from 265 dpf to 297 dpf (fi1) then from 439 to 469 dpf (fi2) and from 522 to 547 dpf (fi3). The first period (fi1) of FI assessment was performed under normal growth conditions, while the two others (fi2, fi3) followed FD periods. From 137 to 549 dpf, each line was reared separately into 1.8 m^3 outdoor tanks, with three triplicates per line, supplied with river water (11.3-16.0 °C). In order to keep a density below 50 kg m^{-3}, regular random eliminations were performed, and 100 fish per replicate remained at the end of the experiment. Commercial pellets were distributed by self-feeders (Imetronic®, France) throughout the experiment.

Weight and residual feed intake. Body weight (BW) was measured regularly throughout the experiment (n≈100 fish for each of three replicates). A way to measure FE is to estimate the residual feed intake (RFI) using linear regression analysis:

$$RFI = FI - (\beta_0 + \beta_1 xBW^{0.8} + \beta_2 xBWG) \quad (1)$$

With FI being the observed feed intake and $(\beta_0 + \beta_1 xBW^{0.8} + \beta_2 xBWG)$ being the predicted feed intake based on a linear regression of the observed FI on metabolic body weight ($BW^{0.8}$) and body weight gain (BWG).

Fat content. The total fat content in muscle was recorded three times during the experiment (at 471, 520, and 549 dpf, i.e. measurements made at the end of fi2, right before fi3 and at the end of fi3, respectively; n≈100 fish per replicate) using a Fish Torry Fat-meter® (Douirin *et al.*, 1998).

Feed demand. Self-feeders were used continuously throughout the experiment to characterize feeding behaviour for the ten isogenic lines by recording feed demands (i.e. rewarded, unrewarded, and both of them). This feeding technique is based on the learning ability of fish, and feed is delivered depending on their demand. In a self-feeding system, fish are assumed to precisely control their feeding by activating a 'trigger' sensor. All the self-feeders were connected to a computer system recording the feed demands.

Results

The correlations between RFI derived from the first measurement under normal feeding regime (fi1) and the two others measures following a FD period (fi2 and fi3) were low ($r \leq 0.25$, $P \geq 0.18$). However, the correlation between the last two RFI measured after FD, i.e. fi2 and fi3, was significant ($r=0.58$, $P<0.01$).

Muscle fat content was comparable across the lines at 471 dpf (5.9±0.8%), but a significant line effect was observed at 520 and 549 dpf. On average, fish lost between 20% (B61h) and 58% (N38h) of muscle fat during the FD period while they gained from 31% (AB1h) to 150% (N38h) of their muscle fat during the re-feeding period.

We found a positive correlation between RFI calculated from the two FI measurements following FD periods (fi2 and fi3) and the fat content measured at the end of the FI measurements (at 471 and 549 dpf). This correlation was only significant for the fi3 measurement period but mostly driven by one replicate belonging to AP2h (Figure 1). Overall, we found that RFI increased when fat content increased.

The daily profile of feeding behaviour differed significantly between lines only during the two last FI measurement periods (fi2 and fi3). Interestingly, we found significant correlations between RFI calculated from the first FI measurement period (fi1) and feeding behaviour, assessed as the total number of feed demands over the same period (r=0.42-0.49, $P \leq 0.02$; Figure 2). Such correlations were not found for the other FI measurement periods.

Discussion

Previous findings highlighted the relationship between fat content and feed efficiency in rainbow trout and other salmonid species. In rainbow trout, divergent selection for muscle fat content has been carried out (Quillet *et al.*, 2005). After four generations of selection, fish from the lean-muscle selected line had lower body and muscle lipid contents, and their feed conversion ratio (FCR) was improved by about 6-9% compared to the fat-muscle selected line (Kamalam *et al.*, 2012). Kause *et al.* (2016) have shown that rainbow trout with a low body fat content and low muscle fat content were more efficient in feed and protein utilization, highlighting that controlling fat deposition in fish breeding programs could improve FE and reduce nutrient waste. Our results, from isogenic lines, suggest that such conclusions need to be qualified.

In brown trout, Mambrini *et al.* (2004) found that selection for growth led to changes in feeding activity as assessed using self-feeders, but differences between control and selected lines were significant for only three out of the five periods investigated. We obtained similar results for rainbow trout isogenic lines. RFI was positively correlated with the number of feed demands at a routine feeding regime (i.e. without any FD),

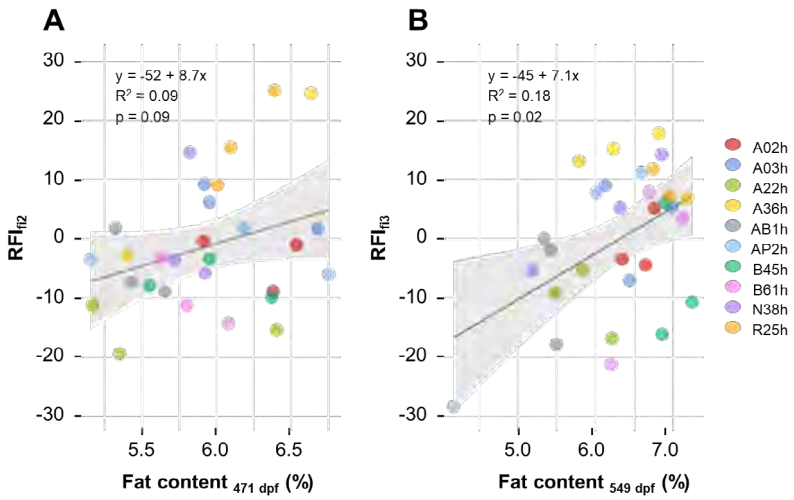

Figure 1. Relationship between fat content in muscle measured at 471 and 549 dpf, i.e. right after the two last feed intake periods: from 439 to 469 dpf (fi2) and from 522 to 547 dpf and the RFI calculated for the same periods: (A) fi2 and (B) fi3. Dots sharing the same colour are replicates of the same isogenic line. Grey shading areas indicate the 95% confidence intervals.

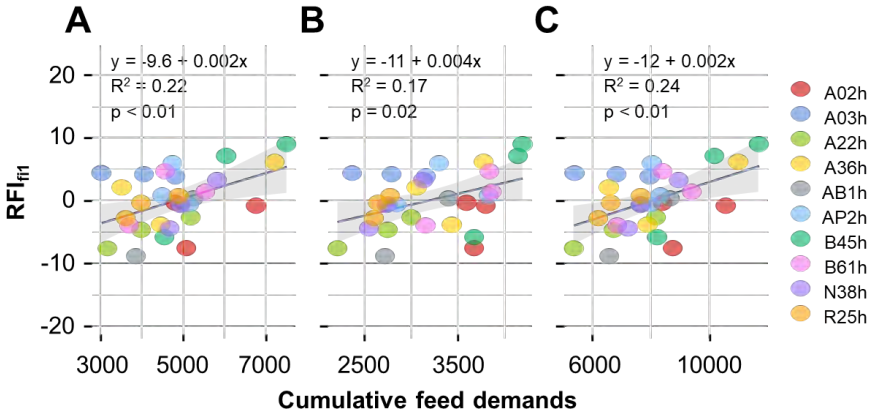

Figure 2. Relationship between the daily feed demands: (A) unrewarded, (B) rewarded and (C) total and the RFI calculated during the first feed intake period (from d 265 to 297 dpf; fi1). Dots sharing the same colour are replicates of a same isogenic line. Grey shading areas indicate the 95% confidence intervals.

but not after FD periods. In the regular feeding regime, the most feed-efficient isogenic lines (lower RFI) were the ones that requested less feed via the self-feeders. Such findings are in accordance with Martins *et al.* (2006, 2011), who found that, in African catfish or in Nile tilapia, the most feed efficient fish were the less active for eating.

To conclude, while we did not find clear evidence about the relevance of using fat content as an indirect selection criterion for FE in breeding programs, our results showed the interest in exploring other indirect selection criteria, particularly linked to feeding behaviour.

Abstract

The use of electronic sensors can greatly enhance our understanding of fish behaviour and physiology, and sensor data are emerging as key sources of information for improving aquaculture management practices. An integrated and interdisciplinary approach to monitor the activity pattern and physiological status of farmed fish, as well as environmental parameters, will enhance the sustainability and profitability of European aquaculture. For tailor made breeding programs, sensor technology offers the possibility to monitor traits in individual fish or families related to key factors that influence animal health and behaviour, such as hypoxia or sub-optimal water current. The better performing fish under these challenging environmental conditions can be selected for breeding.

Electronic sensors in aquaculture

Studying fish behaviour, physiology, health and welfare in aquaculture settings, as well as the farming environment, presents challenges because of the physical characteristics of water and the dimensions of the water bodies where the fish are cultured in. However, in recent years, the use of electronic sensors in aquaculture research is increasing, and is significantly improving our understanding of fish performance in aquaculture, as sensor data emerge as important sources of information for improving aquaculture management practices.

Collecting information of individual fish in aquaculture was difficult before sensor technology became available and often included catching, sedating and handling of the fish. Fish in aquaculture systems are grown in large water bodies in a high density, where the fish can't be distinguished individually for observation by the human eye or camera systems. Group observations during resting and feeding, monitoring fish growth and mortality, and monitoring the water quality, were, and often still are, management strategies to safeguard the fish in aquaculture systems.

Although sensors are widely used in terrestrial applications (Ellen *et al.,* 2019), their use in the marine environment and aquaculture was limited up to recent years because of the special attributes of water, the high cost of underwater sensors and malfunctions due to the harsh environment. Underwater sensors should be cost- and power-efficient, but also be robust and waterproof, non-metallic, and should have no effects on surrounding organisms (Parra *et al.,* 2018).

The various types of sensor technology that are nowadays available can be used to study the farming environment and to assess biomass and fish performance. Hence, depending on the purpose of the sensor and its physical appearance, sensors can be operated either inside the fish, attached to the fish, or placed in the water.

Biomass, environment, and fish tracking

Biomass estimators that can be installed on the feeding stations or on the cages or tanks, can provide information to monitor or expand the production. In addition, sensor- and camera systems may provide information for estimating the biomass in the cages and developing reliable fish feeding strategies.

Sensors that monitor the environment in aquaculture settings record parameters such as oxygen, temperature, salinity, sea current, pH, wind and CO_2. Whereas in open sea cages this information can be used for management practices, such as feeding strategy, in Recirculation Aquaculture Systems this information can give full adaptive control over water quality parameters.

When monitoring individual fish, electronic sensor tags can track and identify individual fish (Lembo *et al.,* 2002). This provides information on the swimming behaviour of the fish in the aquaculture setting. Depending on the type of sensor, these tags have to be recovered from the fish to obtain the data, or the sensor sends the data to an external receiver. Placed in or on fish, more advanced tags incorporate sensors that measure and record multiple environmental and/or biological parameters of the fish during production (Cooke *et al.,* 2016).

A combination of sensor technologies can form a wireless communication system to monitor large scale aquaculture activities, and increases the accuracy of data, processing and interpretation (Kessel *et al.,* 2014). These data provide the industry with information needed to facilitate performance, health and welfare and to optimise management practices.

Fish breeding

For breeding purposes, the availability of sensor technologies allows to track and monitor individual fish. A large amount of data can be obtained from individual fish for specific traits related to environmental factors that influence animal health and behaviour, such as hypoxia or water current, and this information can be linked to the genotype of the individual fish. Better performing fish on desired traits can then be selected for tailor made breeding programs.

Sensor types and possibilities

Accelerometer tags can transmit a 3D acceleration of the tagged fish when they are within the receiver array, or logged on the sensor. The fish acceleration is the result of measuring acceleration on three axes. Accelerometer tags can be used as measure of animal activity, such as swimming speed via tail beat acceleration, detecting mortality, feeding, spawning activity, nocturnal/diurnal activity, and activity responses to changing oxygen, salinity and temperature (https://www.vemco.com/products/v9ap-v13ap-accelerometer/; https://www.thelmabiotel.com/).

Other sensor types measure heart rate, activity and body temperature simultaneously. These are ideal for monitoring behaviour and stress response, animal welfare and fish physiology (https://www.cefastechnology.co.uk/products/data-storage-tags/g7/).

Sensors that can record physiological data from free-swimming fish can be placed either externally or internally on the fish. The sensors measure muscle activity using probes inserted into the musculature of the fish and can provide an estimate of the energetic costs associated with physical activity via electromyograms (EMGs). These are records of bioelectric potentials that are strongly correlated with the strength and duration of muscle contractions, and as indicators of the intensity of fish activity (http://www.lotek.com/cemg2-series-emg-transmitters.htm).

Limitations

Sensor technology that is used to obtain information on individual fish poses constraints in the form of time and money, and physical limitations. When the sensors are be placed on, and particularly in the fish, this requires surgery by qualified staff, and recovery time is needed. In addition, the sensors are expensive, with thousands or tens of thousands of euro's needed for the sensors alone. These two factors can form a

limitation to the number of fish equipped with a sensor. In addition, the environmental conditions for the sensors are challenging, especially in salt water. In addition, getting data from the sensors requires either retrieving the sensor physically from the fish, or having the fish swim in reach of receivers, which can also be challenging in (salt) water.

Case study

In a case study performed by researchers from Wageningen Livestock Research, electronic sensors were implanted in yellowtail kingfish (*Seriola lalandi*), a powerful and pelagic fish that lives in warmer waters worldwide. The STAR ODDI logger DST milli-HRT (Figure 1; https://www.star-oddi.com/products/data-loggers?sensors=heart-rate) monitors heart rate, body temperature and acceleration in the fish simultaneously and is ideal for monitoring behaviour and stress response of the fish. The logger takes a burst measurement of ECG at a programmed time interval and calculates the mean heart rate for each recording.

The fish were exposed to a series of increasing water flow speeds ranging from 0.2 to 1.0 m/s in a swim tunnel (van den Thillart *et al.,* 2004; Palstra *et al.,* 2015), forcing the fish to swim against the current. Preliminary results for heart rate and external acceleration at increasing swim speeds are shown in Figure 2. The heart rate remains at a (high) basal level at lower swim speeds, only to increase towards the highest speeds of 0.8 and 1.0 m/s. The external acceleration shows a similar pattern and appears, in this fish, to be correlated to the swim speed. However, preliminary data from other fish equipped with a sensor show that individual variation in heart rate and external acceleration at different swim speeds proves that electronic sensors indeed are a powerful tool to acquire in-dept physiological and performance information on individual fish that can be used for aquaculture management practices.

Concluding remarks

The use of electronic sensors offers great opportunities to study specific traits for breeding programs in individual fish in aquaculture settings. Enhanced environmental and biological sensor data collected by a network of electronic sensors can provide accurate measurements and predictive modelling of environmental conditions and desired traits on fish health, welfare and physiology, that can be linked to the genotype of the fish (Cooke *et al.,* 2016).

Abstract

Selective breeding is a promising solution to reduce fish farms vulnerability to heat peaks. Objectives of this study were to give a new insight on the genetic architecture of resistance to acute hyperthermia stress in rainbow trout. At 275 days post-fertilization, 1,384 fish were phenotyped for acute hyperthermia resistance and body weight. Challenged fish were genotyped for 57K SNP and their genotypes were imputed at high-density thanks to their parents being genotyped on a 665K SNP array. Heritability estimate of resistance to acute hyperthermia was 0.32±0.04. This trait was genetically negatively correlated with body weight (-0.58±0.17). The genome-wide association study revealed that resistance to acute hyperthermia is highly polygenic as altogether the 5 detected QTLs explained less than 5% of the genetic variance. The main QTL region explained 3% of the genetic variance and contained two candidate genes previously described to be associated with temperature resistance.

Introduction

Rainbow trout (*Oncorhynchus mykiss*), a cultured salmonid of major economic importance, thrives in a narrow cold thermal range (Bear *et al.*, 2007). Exposition to high temperatures leads to the impairing of production efficiency with growth reduction, increase of disease and mortality. Extreme temperature events such as heat waves are expected to increase in intensity and frequency with global warming. The reduction of their impact represents a major challenge for the aquaculture industry. Among existing solutions, genetic improvement by selective breeding is an interesting approach: progress is cumulative from a generation to another and genetically improved animals could be exported to any farm without any prior equipment required. In rainbow trout, genetic determinism of resistance to acute temperature stress has already been studied in a Canadian commercial population (Perry *et al.* 2005) and QTLs were detected (Jackson *et al.*, 1998; Perry *et al.*, 2001). However, these studies concern a single population, distant from our study population, and recent advances in genomics may provide more accurate results for QTL detection.

Objectives of the present study were to complement existing knowledge for introducing acute hyperthermia resistance trait in rainbow trout breeding programs by: (1) assessing genetic parameters for acute hyperthermia resistance in a new commercial population; (2) detecting with a powerful tool (new high-density SNP array) QTLs associated with acute hyperthermia resistance; and (3) identifying candidate genes.

Materials & methods

The experiment was carried out according to the European guidelines; the protocols were evaluated and approved by the ethic committee ANSES/ENVA/UPC No 16 and authorized by the French ministry of higher education and research (APAFIS#24441-2020022417122193).

CC BY

DOI: 10.3920/978-90-8686-940-4_579, © H. Lagarde *et al.* 2022

Study population. A total of 1,384 fish from 573 full-sib families was produced in a partial factorial mating design from 74 dams and 99 sires derived from the Viviers de Sarrance (Nouvelle-Aquitaine, France) breeding program. At 265-days post-fertilization (dpf), fish were tagged with ISO RFID tags and fin-clipped for later DNA extraction and genotyping. At 272 dpf, fish were transported to ANSES-SYSAAF Fortior Genetics platform (Brittany, France). The challenge to hyperthermia was spread over 7 days (between 275 dpf and 285 dpf) with 198±12 fish per group. Around 9 a.m., fish from one of the 7 batches were transferred to the challenge tank, supplied with identical river water. Once the transfer completed, temperature was gradually increased from initial river water temperature (17.3±0.7 °C) at a rate of 1.5±0.2 °C/hour. Above 27 °C, fish gradually began to lose equilibrium. Each fish losing equilibrium was removed from the tank and identified. The time was recorded and the fish was weighed and euthanized. The acute hyperthermia resistance phenotype was considered as time to loss of equilibrium (TLE). Body weight (BW) was measured to estimate phenotypic and genetic correlation between BW (mean BW 87±12 grams) and TLE. Fish were genotyped with the 57K Axiom™ Trout Genotyping array (Palti *et al.*, 2015) at the INRAE genotyping Platform Gentyane. Their parents were genotyped for 664,531 SNPs with a new high-density Axiom™ Trout Genotyping array. After quality control and parental assignation with APIS software (Griot *et al.*, 2020), the final dataset contained 1,332 offspring genotyped for 30,379 SNPs (LD genotypes). The parent's final dataset contained 172 individuals genotyped for 420,079 SNPs (HD genotypes). The mean number of progenies per sire, per dam and per full-sibs family were respectively 14.0±6.4, 18.7±7.5 and 2.4±2.5. Offspring's LD genotypes were imputed to HD thanks to the parental reference HD genotypes using FIMPUTE3 software (Sargolzaei *et al.*, 2014).

Statistical analysis. Genetic (co)variance components of acute hyperthermia resistance and body weight at 275 dpf were estimated with AIREML algorithm in BLUPF90 software (Misztal *et al.*, 2002) using the following animal model:

$$y_{ij} = \mu + day_i + a_j + \varepsilon_{ij} \quad (1)$$

where y_{ij} is the performance (TLE or BW at 275 days) of animal j, μ is the overall mean of the population, day_i is the fixed effect of day of challenge i, a_j is the additive effect of animal j and ε_{ij} is the random residual error. Both pedigree and genomic relationship matrices were built. The pedigree was constituted of 20,372 animals over ten generations. The genomic matrix was built with the HD genotypes.

GWAS was performed on temperature resistance trait using the Bayesian approach BayesCπ implemented in the BESSiE software with the following model:

$$TLE_{ij} = \mu + day_i + \sum_{k=1}^{n} \delta_{kl} z_{ijk} a_k + \varepsilon_{ijl} \quad (2)$$

With TLE_{ij}, the time before loss of equilibrium, the temperature resistance phenotype of animal j, μ the overall mean of the population, day_i the fixed effect of day of challenge i and n the total number of SNPs (420,079). δ_{kl} is an indicator variable: within a cycle l, δ_{kl}=1 if the effect of SNP k is estimated in this cycle or δ_{kl}=0 if not. In each cycle, δ_{kl} is sampled from a binomial distribution with a probability π that δ_{kl} was equal to 1. The proportion π was sampled from a beta distribution B(α,β) with α=400 and β=420,079; which represents approximatively 0.1% of SNPs selected at each cycle. z_{ijk} was the genotype on locus k for individual j of day i (coded as 0, 1, or 2), a_k the effect of the reference allele of SNP k, and ε_{ijl} the residual effect. The Markov chain Monte Carlo was run with 400,000 cycles and a burn-in period of 10,000 cycles. Results were saved every 40 cycles. The Bayes factor (BF) was calculated to quantify the degree of association between a SNP and the phenotype. Evidence for a QTL was provided by a value 2×ln(BF)≥6 at a peak SNP. A credibility interval for the QTL was computed around the peak SNP including all SNPs for

which 2×ln(BF)≥3 in a sliding window of 0.2 Mb. Genes in the QTL region were annotated with the NCBI *O. mykiss* genome assembly (GCA_013265735.3 USDA_OmykA_1.1) (Gao *et al.*, 2021).

Results & discussion

Genetic parameters of TLE and BW are presented in Table 1. Pedigree heritability and genomic heritability of acute hyperthermia resistance were estimated at similar values of 0.32±0.06 and 0.28±0.04. Those values are lower than the previous heritability estimate 0.41± 0.06 (Perry *et al.* 2005), but still suggest a good potential for genetic improvement. Heritability of BW was estimated to 0.14±0.04 with the pedigree relationship matrix and 0.20±0.04 with the genomic relationship one, which is consistent with previous estimates (e.g. Leeds *et al.*, 2016). Phenotypic correlation between acute hyperthermia resistance and BW was not statistically different from zero (-0.067±0.039), but the genetic correlation was estimated significantly negative (-0.58±0.17) while Perry *et al.* (2005) found it not significant (-0.032±0.18). If our result is confirmed, it will be necessary to consider the trade-off between temperature resistance and fish growth in selective breeding programs.

With an evidence threshold of 2×ln(BF) ≥6, five QTLs were found, located on three chromosomes (Figure 1). One QTL, located on chromosome 13, had a very high evidence (2×ln(BF) >10) and explained almost 3% of the genetic variance of acute hyperthermia resistance (Table 2). This result suggests that resistance to acute hyperthermia is a highly polygenic trait. In the credibility interval of this QTL, 81 genes were identified. In a window of 100Kb around the peak SNP of this QTL, we identified two genes, *HSP70* and *FKB10*, which are directly involved in proteins folding in generic response to stress exposure. Both genes have already been

Abstract

Critical swimming speed (U_{crit}) is an important measurement of swimming performance as well as a good indicator for cardio-respiratory health. It offers a new opportunity to select fish with better fitness. Here we present results from a GWAS study on critical swimming speed and growth in Nile tilapia under conditions of recurrent hypoxia. Heritability for U_{crit} was moderate (0.31±0.04). Large fish generally swim faster than smaller fish, whereas fish with better swimming performance tend to show slower growth later in life. Nine suggestive SNPs associated with swimming performance were identified under a hypoxic environment. A clear pleiotropic effect on growth traits was found for some of the SNPs associated with swimming performance, while other SNPs had only an effect on swimming performance, but not on growth. Our analyses sheds a first light on the genomic mechanisms of swimming performance and growth in Nile tilapia.

Introduction

Swimming performance is an important feature that correlates with fitness, survival, and metabolism in many aquacultural fish species (Palstra and Planas, 2012). Swimming performance in fish can be measured in a critical swimming challenge test, by which U_{crit} can be assessed. U_{crit} is the speed at which maximum oxygen uptake occurs. In tilapia, U_{crit} has been shown to be highly correlated with maximum metabolic rate (McKenzie *et al.*, 2003). However, it is unknown which QTLs are associated with U_{crit} in tilapia.

Nile tilapia (*Oreochromis niloticus*) is one of the most important farmed fish species in the world. Farming is mostly done in ponds and cages. However, for most smallholder farmers aeration of fishponds is not available or too expensive. In non-aerated ponds extreme hypoxia can occur, especially during the night when algae become net oxygen consumers (Mengistu *et al.*, 2020). Therefore, it is crucial to select tilapia that grow better under conditions where dissolved oxygen is limited.

The main objectives in this study were: (1) to estimate the genetic correlations between U_{crit} with body size traits at the swimming test, and with growth traits using a genomic relationship matrix, (2) to identify SNPs and genes associated with swimming performance and (3) to estimate the effect of candidate SNPs for U_{crit} on the growth traits.

Materials & methods

Experimental design and traits collection. The experimental design and data collection is described in full detail in Mengistu *et al.* (2021). Nile tilapia were collected as part of the GIFT selective breeding program. U_{crit} and body weight at test (BWtest) during the swimming test were recorded. After the swimming test, fish were stocked in non-aerated ponds for growing-out and harvested after 145 or 146 days. The stocking and harvest weight (Harw) were recorded, by and daily growth coefficient (DGC) was calculated.

SNP genotyping and quality control. The DNA was extracted and genotyped by Identigen (Dublin, Ireland) using an Axiom® SNP array, which contains 65K SNP markers dispersed over the Nile tilapia reference genome (Peñaloza *et al*., 2020). Data was filtered to meet a dish quality control >0.82 and call rate for samples >0.93, respectively. Next, a second quality control step was applied based on per SNP call rate and minor allele frequency statistics.

Genetic parameters estimation. Variance components and heritability for swimming performance traits including U_{crit}, BWtest, Harw and DGC were estimated using univariate models based on residual maximum likelihood method with the following model was applied:

$$y = Xb + Z_1a + Z_2c + e \quad (1)$$

Phenotypic and genetic correlations between U_{crit} and traits BWtest, Harw and DGC were estimated based on a bivariate linear model. The fixed effects were the same as in the univariate models for U_{crit}, BWtest, Harw and DGC traits.

Association analysis and candidate genes in QTLs. Animal phenotypes and genotypes were jointly analysed to identify genomic regions associated with U_{crit}. The following model was applied:

$$y = W\alpha + Z\mu + x\beta + \varepsilon \quad (2)$$

LD and haplotype blocks were analysed with LDBlockShow (Dong *et al*., 2020), while r^2>0.8 as cut-off for blocks. Putative candidate genes associated with swimming performances were characterized within a 200 kb window size (100 kb upstream and downstream) flanking the candidate SNPs.

The effect of candidate SNPs in swimming performance on growth. We estimated the genetic association between SNPs and DGC based on generalized linear model. The best fitting genetic model was evaluated based on Akaike Information Criterion score. The significant threshold was defined as adjusted *P*-value<0.05.

Results

Genetic parameters estimation with different traits at swimming test. The heritability for U_{crit} was 0.31 with standard error 0.043, while the heritability for body weight at swimming test was 0.27 (Table 1). The common environmental effects were not significant for both traits. The phenotypic and genetic correlations between U_{crit} and BWtest were 0.43 and 0.36 (Table 2), indicating that fish with better swimming capacity usually show big size. The estimated r_g between U_{crit} and harvest weight (-0.13±0.13) and U_{crit} and DGC (-0.26±0.13) were slightly negative but not different from zero, suggesting that U_{crit} might have a negative genetic correlation to body weight at harvest and growth until harvest.

Table 1. Variance components for U_{crit} and body weight traits.

Traits	σ^2_a	σ^2_e	σ^2_p	h^2
U_{crit}	5.15	11.72	16.88	0.31 (0.043)
BWtest	1.23	3.38	4.61	0.27 (0.043)

Table 2. Genetic and phenotypic correlations between U_{crit} and body weight traits.

Traits	r_g	r_p
BWtest	0.43±0.10	0.36±0.03
Harw	-0.13±0.13	0.06±0.04
DGC	-0.26±0.13	-0.01±0.04

Genome-wide association study for swimming performance. Nine SNPs located on LG12, LG13, LG14 and LG19 exceeded the genome-wide suggestive threshold for U_{crit} (Figure 1). All genes in the up- and down-stream 100 kb regions of the 9 suggestive SNPs in a high LD (r^2>0.8) were investigated, which were *limk1a*, *elna*, *lsamp, aipl1* and *dner* on LG14, *pprc1* and *rrp12* on LG13, *hectd1 and smyd1* on LG19 and LG12.

Pleiotropic SNPs with swimming performance and growth. In this study, we investigated the impact of candidate nine SNPs associated with U_{crit} on growth traits. Three of these nine SNPs were significantly associated with both harvest weight and DGC, and SNP genotypes that presented a low mean U_{crit} had a high mean harvest weight and DGC.

Discussion

The observed genetic correlation between U_{crit} and Harw, and U_{crit} and DGC, suggests an negative interaction between growth and critical swimming speed under hypoxic environment.

Our results show several QTLs involved in the swimming performance in Nile tilapia. Overall, 16 genes in high LD with the identified SNPs, could be interesting candidate genes in regulation of swimming performance. For instance, the *rrp12* gene has been associated with adaptation to low oxygen (Foll *et al.*, 2014) and *pprc1* is potentially involved in cardiac and exercise-related muscle activity (Uguccioni *et al.*, 2010).

Our results show only part of the SNPs to be significantly associated with harvest weight and DGC, which located on several genes (*hip1*, *hectd1*, *dner*). They potentially can be applied as biomarkers to select fish with good cardio-respiratory health and good growth.

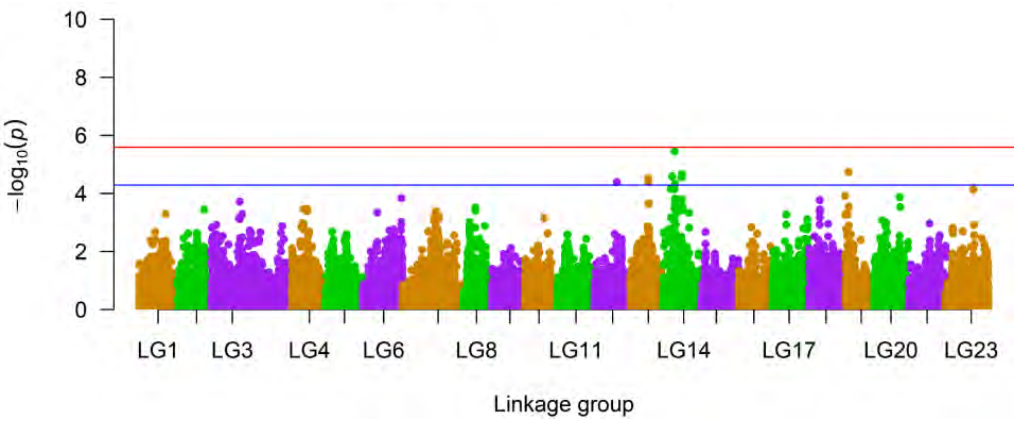

Figure 1. Manhattan plot for U_{crit}. The orange and blue horizontal line represent the genome-wide significance (2.57E-06) and suggestive significance threshold value (5.15E-05), respectively.

581. Optimizing genotyping effort in aquaculture breeding programs by pre-selection of candidates

Wageningen University & Research, P.O. Box 338, 6708 PB Wageningen, the Netherlands; chantal.roozeboom@wur.nl

Abstract

Highly fecund aquaculture species provide more opportunities to optimize genotyping effort in genomic selection programs through selective genotyping and pre-selection than other livestock species. The aim of this study is to optimize pre-selection in a simulated fish breeding program to achieve the highest genetic gain per genotyped fish under restricted inbreeding. We simulated breeding programs in R with pre-selection among all selection candidates, between full sib families and within full sib families and several pre-selection intensities within each of the strategies. Pre-selection always reduces genetic gain. However, when genotyping costs are taken into account, genetic gain per genotyped fish can be increased with pre-selection. Pre-selecting 40% of the candidates from all available selection candidates produced the highest additional genetic gain per genotyped fish.

Introduction

Aquaculture species are highly fecund and can produce large numbers of candidate offspring, and most fish breeding programs can produce sufficient numbers of sibs for sib testing if desired. Depending on the size of the candidate population, genotyping all available candidates can be prohibitively costly. However, genotyping costs can be reduced, for example by selectively genotyping the reference population (Gowane *et al.*, 2019), genotyping using cheaper, lower density SNP panels (Kriaridou *et al.*, 2020) or pre-selection of candidates. Pre-selection based on phenotypes measured at an early age can increase genetic gain (Martinez *et al.*, 2006), but Sae-Lim *et al.* (2013) showed that postponing pre-selection can be more effective because the genetic correlations between phenotypes measured closer to harvest and breeding goal traits are higher than for early phenotypes.

In this study, we focus on reducing genotyping costs by adding a pedigree-based pre-selection step immediately before genotyping and genomic selection. We aim to optimize this pre-selection to achieve the highest genetic gain per genotyped fish under restricted inbreeding, by simulating and comparing the predicted outcomes from a range of scenarios.

Materials & methods

To perform pedigree based preselection we simulated a family-based rainbow trout breeding program with controlled spawning, using stochastic simulations in R (Figure 1). We simulated the traits tagging weight, weight in nucleus measured on selection candidates, and weight at sea measured on sibs of the candidates in the production environment. Heritabilities and genetic correlations used (Table 1) are estimates from a real breeding program.

Table 1. Heritabilities (diagonal) and genetic correlations.

	Tagging weight	Weight nucleus	Weight sea
Tagging weight	0.26	0.38	0.29
Weight nucleus		0.33	0.64
Weight sea			0.32

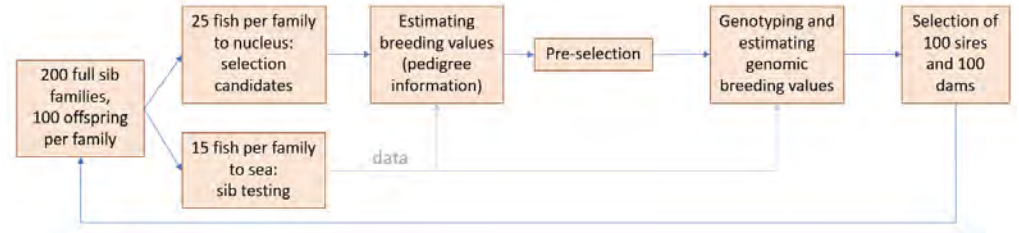

Figure 1. Design of the breeding program.

We simulated pre-selection based on a multi-trait selection index of traditional, pedigree-based estimated breeding values (EBVs) to identify fish for genotyping and final selection based on an index of genomically estimated EBVs (GEBVs) and optimal contribution selection to identify 100 replacement sires and 100 replacement dams each generation.

We simulated three pre-selection strategies: (1) the top 10, 20, 40, 60 or 80% of all selection candidates regardless of family membership (ALL); (2) the top 10, 20, 40, 60 or 80% selection candidates within each full sib family (WITHIN); or (3) the top 10, 20, 40, 60 or 80% of the full sib families (BETWEEN). The pre-selected and genotyped proportion varied between 400 and 3,200 selection candidates. The accuracy of the GEBV of weight at sea was simulated as a constant based on a reference population of 2,000 fish per generation. The accuracy of the GEBV for weight in the nucleus depended on the number of pre-selected and genotyped fish.

We simulated ten generations of selection for each scenario and calculated the average genetic gain and rate of inbreeding from 20 replicates. The additional genetic gain per genotyped fish was calculated as the difference in genetic gain with and without pre-selection divided by the number of genotyped fish.

Results

Without pre-selection, the genetic gain was 136.4 and 217.9 grams per generation for weight in the nucleus and weight at sea with genomic selection, and 106.7 and 147.2 grams per generation with pedigree selection. The rate of inbreeding was 0.73 and 0.44% without pre-selection with final selection based on EBV and GEBV, respectively.

Pre-selection always reduced genetic gain compared to genotyping all candidates (Figure 2). Genetic gain for both weight in the nucleus and weight at sea declines more rapidly with decreasing pre-selected proportion for the WITHIN strategy than for the ALL and BETWEEN strategies, except at the lowest pre-selected proportion. Regardless of the pre-selected proportion, the highest genetic gains were obtained for the ALL strategy. Pre-selected proportions smaller than 0.20 always resulted in genetic gains that were comparable or lower than gains from selection based on pedigree-based EBVs.

In the ALL and BETWEEN strategies, the rate of inbreeding increased when the pre-selected proportion decreased, but for the WITHIN strategy, the rate of inbreeding decreased. The rate of inbreeding increased most for the BETWEEN strategy to a value slightly exceeding the acceptable threshold of 1% with a 10% pre-selected proportion.

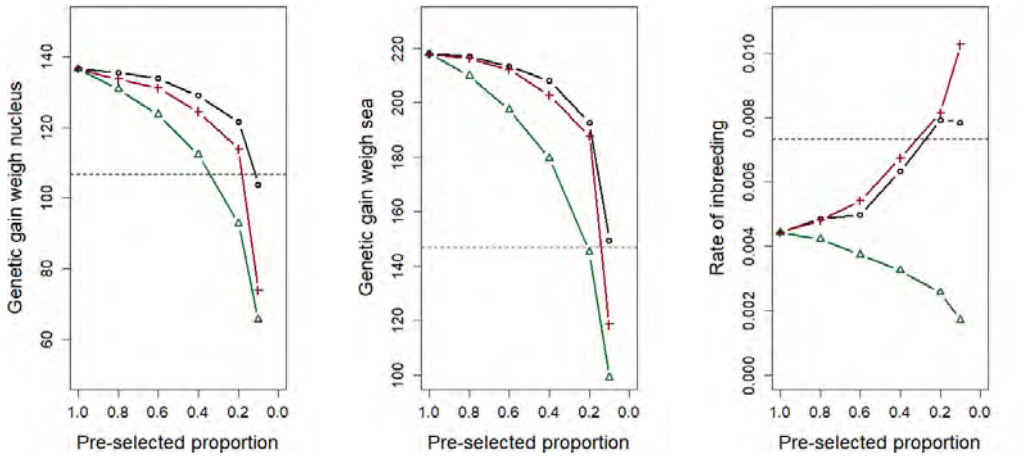

Figure 2. Genetic gain and rate of inbreeding. Genetic gain and rate of inbreeding by pre-selected proportion for the ALL (– O –), BETWEEN (– + –) and WITHIN (– Δ –) strategies. The --- reference line is the genetic gain and rate of inbreeding without genotyping.

The ALL and BETWEEN pre-selection strategies increased additional genetic gain per genotyped fish (Figure 3). For these two strategies, additional genetic gain per genotyped fish was highest at a pre-selected proportion of approximately 40%. Additional genetic gain per genotyped fish for the WITHIN strategy was maximized when nearly all candidates were genotyped (Figure 3). Additional genetic gain per genotyped fish for weight in nucleus followed a similar pattern to weight at sea (results not shown).

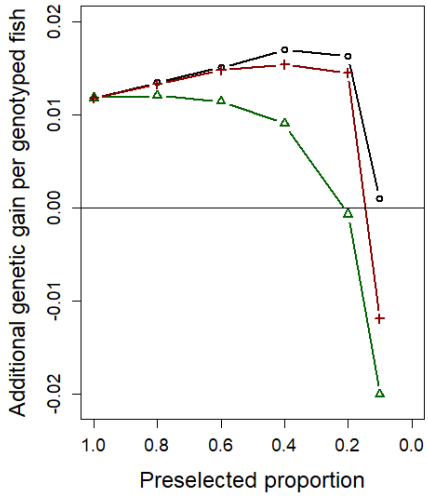

Figure 3 Additional genetic gain per genotyped fish for weight at sea. Lines are for the strategies ALL (– O –), BETWEEN (– + –) and WITHIN (– Δ –).

Discussion

Our simulations predict that pre-selection always reduces genetic gain compared to genotyping all candidates, but the relationship is highly non-linear. This non-linearity leads to an intermediate optimum in terms of genetic gain per genotyped fish. If a fixed budget is available for the breeding program, then pre-selection intensity can be adjusted to efficiently use the available budget. Applying the optimal pre-selection strategy and intensity can reduce genotyping cost while limiting the effects on genetic gain. Pre-selection at an earlier age can also limit cost for the breeding program (Sea-Lim *et al.*, 2013, Martinez *et al.*, 2006). However, this reduction is cost is due to lower rearing cost. The pre-selection in this study will not reduce rearing cost, only genotyping cost.

The choice of pre-selection strategy is important because it influences both the genetic gain and rate of inbreeding. To limit the effect of pre-selection on rate of inbreeding, optimal contributions in the pre-selection could be implemented in the ALL strategy. The rate of inbreeding was reduced when pre-selection took place within a full sib family. However, the WITHIN strategy is not recommended for pre-selection, given that the rate of genetic gain reduces more rapidly with this strategy. This rapid reduction may be because the number of families was much larger than the number of candidates per family.

Pre-selection among all selection candidates resulted in the highest genetic gain, because more fish from the best families could be selected compared to the scenarios in which pre-selection took place within a family. In the BETWEEN strategy, the number of selected families was lower than in the ALL strategy. Therefore, it prevents selecting good fish from families with lower average breeding values, especially at lower selected proportion.

Postponing pre-selection can result in higher genetic gains due to higher genetic correlations between the traits (Sae-Lim *et al.*, 2013). In this study, the pre-selection was immediately before genomic selection. However, pre-selection decreased the genetic gain, because the pre-selection was based on EBVs instead of GEBVs, which resulted in lower accuracies in the pre-selection step compared to genotyping all candidates and therefore lower genetic gains.

For a low genotyping budget, the BETWEEN strategy could be further optimized because the pre-selected proportion will be small, and final selection takes place mostly within the small number of pre-selected full sib families. This provides an opportunity to reduce the genotyping costs by using low density SNP panels and genotyping only the phenotypically most extreme fish from the training population, because within-family haplotype blocks can be accurately traced using low-density SNP panels and most of the within-family variance can be captured by genotyping only the phenotypically most extreme sibs for the training population (Ødegård and Meuwissen, 2014).

Conclusions

Our simulation results indicate that the reduction in genetic gain due to pre-selection is smallest when pre-selection takes place among all selection candidates. When genotyping cost are taken into account, higher genetic gains per genotyped fish are achieved with pre-selection. Pre-selecting approximately 40% from all selection candidates resulted in the highest additional genetic gain per genotyped fish.

Abstract

Gilthead seabream (*Sparus aurata*) is a key aquaculture species in the Mediterranean and surrounding regions. While many traits are of interest in seabream breeding programs, phenotypes of them cannot always be easily or accurately measured. Therefore, the objectives are to predict phenotypes of production traits by using automated measurements of body features from digital images and to obtain genetic correlations between measured and predicted phenotypes. The production traits analysed were harvest weight (HW), fillet weight (FW), and fillet percentage (F%). Each image feature was tested for prediction of phenotypes by using 10-fold cross-validation. The phenotypic and genetic correlations of measured and predicted phenotypes were 0.98 and 0.996 for HW, 0.93 and 0.99 for FW, 0.27 and 0.70 for F%, respectively. The relative efficiency of mass selection was higher for predicted phenotypes, except for HW.

Introduction

Gilthead seabream (*Sparus aurata*) is a key aquaculture species in the Mediterranean and surrounding regions. The aquacultural production of gilthead seabream increased by 90% between 2009 ande 2019 to 260,000 tons across 20 countries (FAO, 2021). However, only 60% of farmed seabream originated from commercial breeding programs in 2015 (Janssen *et al.*, 2015). In fish breeding programs, various traits are selected for to increase the production level, efficiency, and welfare of the fish. These traits are important for farmers as well as for other stakeholders. However, phenotypes of them cannot always be easily or accurately measured. Some traits, such as product quality traits, cannot be measured on live fish. Sib information can be used to select for such traits but using phenotypes of selection candidates is preferable and has three main advantages. First, both within family and between family variation can be utilized. Second, the accuracy of the estimated breeding values (EBV) will be higher. Third, using phenotypes of the selection candidates simplifies the breeding program and reduces the costs because fewer animals are needed to reach a certain accuracy of the EBVs.

Instead of actual phenotypes of difficult to measure traits, predictions of those phenotypes can be used for selection candidates. Predictions of the phenotypes from body measurements has been studied in various fish species. Manual measurements work well to predict the phenotypes of difficult to measure traits; however, manually measuring body features is labour intensive. Computer vision allows digital image acquisition and image processing for measurements of the fish by using dedicated software (Dowlati *et al.*, 2012). The measurements obtained from the images of fish can be used to establish predictions of the phenotypes. Furthermore, obtaining measurements from digital images can be automated (Navarro *et al.*, 2016).

Therefore, the objectives are to predict phenotypes of production traits by using automated measurements of body features from digital images and to obtain genetic correlations between measured and predicted phenotypes.

Materials & methods

Phenotypic data collection. For this experiment, a population of juveniles was produced by mass spawning of 33 males and 20 females on a single day. When fish reached an average weight of 3 grams, a batch of juveniles was stocked in a sea cage in southeast of Spain and grown under commercial conditions. Data on production traits were collected from the commercially produced fish that were harvested after a grow-out period of 500 days. After measuring harvest weight (HW), the fish were filleted, and fillet weight was recorded. Fillet percentage (F%) was calculated as (FW / HW) × 100.

Each fish was photographed after being taken out of the water. Measurements of body features from digital images were automated by using the Halcon 18.11 framework (MVTec Software GmbH, Munich, Germany). The body features measured from images included total area, fillet area, trunk area, head area, tail area, total length, standard length, height, head height, head length, total volume, and head excluded volume. Head proportion was calculated as head area divided by total area.

Prediction of traits. All variables measured on images were considered individually and combined as candidate predictors for each phenotype. Prediction accuracy was defined as the correlation between measured and predicted phenotypes and tested by using 10-fold cross-validation. Cross-validation was repeated 10 times to treat all the parts of the data as validation and test sets. Predictors were added to linear regression models with forward selection. For genetic analyses, each phenotype was predicted by using a linear model with all data and the combination of predictors that yielded the highest accuracy in cross-validation.

Estimation of heritabilities and correlations. Genetic correlations (r_g) between measured and predicted phenotypes were estimated by using a bivariate animal model in ASReml version 4.1 (Gilmour *et al.*, 2015). The bivariate animal model is:

$$y = X\beta + Zu + e \quad (1)$$

where y is a vector of measured and predicted phenotypes, β is the vector of fixed effect 'sampling day', u is the vector of random animal additive genetic effects:

$$\sim \left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, G \begin{bmatrix} \sigma^2_{a,T_M} & r_{a,T_{M,P}} \sigma_{a,T_M} \sigma_{a,T_P} \\ r_{a,T_{M,P}} \sigma_{a,T_M} \sigma_{a,T_P} & \sigma^2_{a,T_P} \end{bmatrix} \right),$$

where G is the genomic relationship matrix and σ^2_{a,T_M} is the additive genetic variance of measured trait, σ^2_{a,T_P} is the additive genetic variance of predicted trait, $r_{a,T_{M,P}}$ is the additive genetic correlation between the measured and predicted traits, and e is the vector of random residual effects

In case of mass selection, the relative efficiency (RE) was calculated as:

$$RE = \left(\sqrt{h^2_P / h^2_M} \right) \; x \; r_A \quad (2)$$

where h^2_P is the heritability of predicted phenotypes, h^2_M is the heritability of measured phenotypes, and r_A is the genetic correlation between measured and predicted phenotypes.

Results

Prediction of harvest weight. The accuracy of predicting phenotypes was 0.98 for HW, and the genetic correlation between measured and predicted phenotypes was 0.996±0.001. The model that yielded the highest accuracy of prediction contained head excluded volume and total area of the fish. The heritability

of the predicted HW (0.52±0.05) was slightly lower than measured HW (0.54±0.05). The RE of indirect selection for HW was 98%.

Prediction of fillet weight and fillet percentage. The accuracy of predicting phenotypes was 0.92 and 0.27 for FW and F%, and the genetic correlation between measured and predicted phenotypes was 0.99±0.005 and 0.74±0.13. The model that yielded the highest correlation for FW contained head excluded volume and total area of the fish. The heritability of the predicted FW (0.52±0.05) was slightly higher than measured FW (0.47±0.05). The relative efficiency of indirect selection for FW was 104%. The model that yielded the highest correlation for F% contained head proportion and head length of the fish. The heritability of the predicted F% (0.31±0.05) was higher than measured F% (0.12±0.04). The RE of indirect selection for F% was 119%.

Discussion

Our findings show that predicting phenotypes of gilthead seabream from digital images has strong potential to replace manual phenotyping in breeding programs. In case of mass selection, changing to predicted phenotypes would yield 4 and 19% more response for FW and F%, respectively. For HW, using predicted phenotypes would yield only 2% less response than using measured phenotypes.

Automation of phenotyping for fillet traits with digital images is advantageous due to two interrelated reasons. First reason is that the labour required for manual phenotyping increases if the breeding goal includes more than HW, especially when traits cannot be measured on live fish and siblings need to be phenotyped. In such cases, using image features to predict the phenotypes simplifies the breeding program because separate measurements for different traits will no longer be necessary and the fish does not have to be slaughtered. With a single image of the fish, it is possible to predict phenotypes for many traits. The second reason is that phenotypes can be obtained for selection candidates. Our findings imply that using digital images to phenotype for fillet traits is not only possible but also preferred in fish breeding programs. If predicted phenotypes are used, more response would be obtained in fillet traits and the response in HW would only slightly reduce in comparison to using measured phenotypes. Prediction of phenotypes provides benefits in genomic selection schemes as well. Predicted phenotypes become available on the selection candidates and the reference population contributes images and measured phenotypes to the training dataset for the genomic selection as well as the phenotype prediction models. Furthermore, prediction of phenotypes from images could enable application of genomic selection without genotyping the reference population. Genomic EBVs can be calculated for the selection candidates with the phenotypes predicted from image features. Not genotyping the reference population will affect the accuracy of genomic selection. This trade-off between the accuracy of genomic selection and accuracy of predicting phenotypes needs to be further investigated and optimized for each genomic selection scheme.

Certain strengths and limitations were recognized in this study. The main strengths of this study are that: (1) the measurements from digital images were automated, so the measurement error is minimal; (2) a genomic relationship matrix was used to estimate the genetic parameters. The advantage of using a genomic relationship matrix is that it improves the accuracy of the parameter estimates in comparison to using pedigree relationships (Veerkamp *et al.*, 2011). This study was performed with images from a single experimental seabream population that was produced as one batch with a full sib and half sib family structure. Accuracy of predicted phenotypes may reduce across different production batches or in unrelated populations of seabream. To avoid effects of overfitting, the predictions of phenotypes were evaluated with cross-validation, which is expected to result in a model with the strongest prediction ability to other populations. Before applying these models to predict the phenotypes of other seabream populations, it will be needed to test the model accuracies obtained in those populations. Extending the current dataset with

other unrelated seabream populations may change the accuracy of the predictions. Similar to reference datasets in genomic selection, the level of prediction accuracy will need to be assessed for situations where reference phenotype and image data are from more diverse background or when they are more distant from selection candidates.

Abstract

Barramundi is a popular fish for aquaculture due to strong consumer demand and ability to thrive in a range of salinities and culture systems. Genotype-by-environment interactions have been detected for growth rate among barramundi cultured in different production environments and genomic selection has been modelled to be efficient under such situations. The aim of this study was to explore the application of genomic selection for achieving genetic gain for growth rate in two diverse growing environments, recirculating brackish water tank and freshwater pond culture. Growth rate and 70K SNP genotype data was collected from a commercial scale cohort of families grown in the two environments. Estimated genomic breeding values, genetic parameters and economic data were used to compare predicted genetic gain and cost-benefit under three alternative breeding program designs. Results suggest that a single breeding program using genomic selection (general effects from an interaction model) would achieve high benefit-cost ratios.

Introduction

Barramundi is grown under a range of salinities (fresh water to fully marine) and culture systems (RAS to sea cages, Jerry, 2013). Significant genotype-by-environment interaction (G×E) has been detected for growth rate in these different environments (r_g from 0.59 to 0.94 for weight, depending on production environments compared (Domingos, *et al.*, 2013; Domingos, *et al.*, 2021; Khang, *et al.*, 2018). Genomic selection has been predicted to be effective in complex situations when strong G×E occurs (Mulder, 2016). Sukhavachana, *et al.* (2021) reported that harvest and fillet trait breeding value prediction accuracy was improved by 25% (10% for fillet yield) using genomic-informed (GBLUP), rather than traditional pedigree-based (PBLUP) prediction. The potential genetic gain from genomic selection, and the design of breeding programs servicing farms with diverse grow-out environments, needs further investigation.

The aim of this study was to compare genetic gain and benefit-cost ratios for alternative barramundi breeding program designs that service multiple environments with strong G×E.

Materials & methods

A cohort of barramundi was produced following commercial procedures at Mainstream Aquaculture Group Pty Ltd, Australia. Briefly, eight female and 16 male commercial broodstock were placed in a 30,000 l spawning tank (31 ppt salinity, 30.5 °C), cannulated to check for reproductive readiness and induced to mass-spawn using intramuscular injection of luteinizing hormone release hormone analogue (LHRHa) at a dosage of 50 µg/kg. Larviculture was conducted closely according to semi-automated commercial intensive protocols described by Schipp, *et al.* (2007). All broodstock were genotyped using a custom 70k Axiom™ myDesign™ SNP array (ThermoFisher Scientific™) (Jerry, *et al.*, 2022) and tagged with passive implant transponders (PIT). Larvae were reared to 30 days post hatch, split into groups and transferred

into nurseries at the grow-out sites; ponds located in Innisfail (QLD) and recirculating aquaculture tanks located in Werribee (VIC). Size grading was undertaken within both farm sites, but no culling of the smaller fish was conducted. Fish at both sites were fed a commercial pelleted diet under industry feed rates and practices until harvest (336 dph for VIC and 440 dph for QLD) at which time they were weighed.

A genomic relationship matrix (GRM), was compiled as described by VanRaden (2008), using the snpReady package in *R* (R Core Team, 2019). Estimated breeding values (EBVs) were calculated using restricted maximum likelihood (REML) in ASReml 4.0.1 (Gilmour, *et al.*, 2015) using the animal model: $y = \mu + Zu + e$, where y is the whole fish weight (WFW), μ is the overall mean for the trait, Z is the incidence matrix relating phenotypes to breeding values, u is the vector of breeding values, and e is the vector of random residual effects. The breeding values (u) were assumed to be normally distributed with variance equal to the genetic variance (V_A) and a covariance structure given by the pedigree (PBLUP) or the GRM (GBLUP). Three possible breeding program selection strategies were considered (as detailed in, Jerry, *et al.*, 2022);

1. two separate breeding programs for each farm site environment, each based on the performance of breeding candidates in that respective farm environment (*MULTIPLE*);
2. a single breeding program for both farm environments based on the general/main effect from the interaction model (*GENERAL*); and
3. a single breeding program based on the performance of breeding candidates in a single farm environment (*SINGLE*).

The expected rate of genetic gain was estimated as: $\Delta G = I * Ac * \sqrt{V_A}$, where I was the intensity of selection, Ac was the accuracy of GEBV prediction for each trait and V_A was the additive genetic variance estimated from the single trait GBLUP model for the trait within this environment, which gave the most conservative estimates of V_A.

The following parameters were assumed for the calculation of benefit-cost ratio: Phenotyping: 10,000 AU$ per cohort sampling. One cohort sampling per year for SINGLE, and two for GENERAL and MULTIPLE due to sampling in both environments. Genotyping: 40 AU$ per genotyped fish. All selection candidates were genotyped. Operational costs of 64 AU$ per fish for keeping the selection candidates and broodstock fish until phenotyping and 5,000 AU$ per broodstock fish from selection until mating. Generation interval of 3 years for males and 5 years for females. One additional kg of fish produced gives 3 AU$ extra income with 8 million fish produced per year, equally distributed between both environments. Each year 1000 selection candidates were produced and 300 broodstock selected. Profit was estimated as (income – cost), where income was calculated as the predicted additional kg fish produced and cost is the sum of phenotyping, genotyping and operational costs of each breeding program strategy.

Results

Genetic correlation of WFW between the two environments was found to be 0.54 (PBLUP) or 0.59 (GBLUP), which indicates strong G×E. Figure 1 shows the genetic gain per generation for VIC (blue bars) and QLD (orange bars). Genetic gain was higher in QLD than even in VIC, with GBLUP than with PBLUP and when the reference population was from the same environment as where gain was measured.

Figure 2 shows the accumulated profit if each of these breeding programs were run for 10 years (ignoring inflation). The most profitable strategy was GENERAL, closely followed by SINGLE QLD. The least profitable strategy was MULTIPLE. GBLUP was more profitable than PBLUP, reaching break half a year earlier, and after 10 years accumulated profit was 80% higher with GBLUP than with PBLUP.

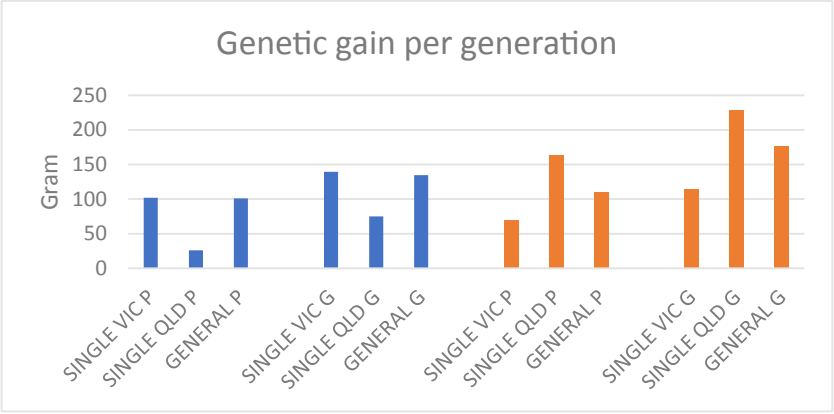

Figure 1. Genetic gain after one generation of selection in VIC (blue) and QLD (orange).

Figure 2. Accumulated profit (AU$) over 10 years for singleVIC (blue), single QLD (red), MULTIPLE (grey) and GENERAL (yellow).

Discussion

Despite the strong G×E documented in Jerry *et al*., (2022) we show that under the assumptions included here a single breeding program would be the most profitable option for barramundi,. The single breeding program could aim to improve general growth, taking phenotypes from both environments into account or to improve growth in the QLD environment, where genetic gain was highest. These two strategies would give similar profit over 10 years assuming that half the fish are produced in a VIC environment and half in a QLD environment. Although running two separate breeding programs was shown to be the least profitable strategy over 10 years, MULTIPLE would be the most profitable strategy after 14 years both for PBLUP and for GBLUP (results not shown).

This project was supported by CRC project funding from the Department of Industry, Innovation and Science, Commonwealth of Australia.

Abstract

The enteric microbiota has a vital role in animal health and performance. Gut microbial community structure varies widely between individuals, suggesting that in addition to environmental factors there is also a host genetic component. The aim of this study was to identify heritable host (chicken) genetic variation associated with the microbial community structure in two broiler (meat-type chicken) breeds, the indigenous Indian Kadaknath and the commercial Cobb400, raised in western parts of India under the local prevailing husbandry conditions. We collected blood and caecal lumen contents from 300 birds from each breed. All birds were genotyped with the 600K Affymetrix® Axiom® HD array and the caecal lumen microbiota was defined using DNA-metabarcoding. Variant component estimates and genome-wide association studies were conducted. Using these datasets, we identified significant heritability estimates and genomic associations at genome-wide level ($P<0.05$ Bonferroni corrected) between host genetic variation and gut microbiome composition in both chicken breeds under investigation.

Introduction

Enteric microbial communities are dynamic and complex, influencing host health and disease profoundly. It is common that microorganisms residing in the gut have established symbiotic relationships with their host (Krajmalnik-Brown *et al.*, 2012). Such microbial systems have coevolved with their host and contribute to fundamental functions such as regulation of host metabolic and immune pathways, and prevention of pathogen colonisation (Pickard *et al.*, 2017). Gut microbial composition is influenced by multiple extrinsic factors, including diet, environmental conditions (Rothschild *et al.*, 2018), and medication (Vangay *et al.*, 2015). These factors can modulate gut microbial communities leading to beneficial or detrimental changes in host physiological status. Variation within gut microbiota is also driven by intrinsic factors, such as host genetics (Zhao *et al.*, 2013). So far, there has been a limited number of studies looking at the contribution of host genetics to chicken microbiome, while the degree to which host genetics can modulate microbial composition remains largely unknown. According to our previous study chicken breed exert significant impact on caecal microbiome composition (Pandit *et al.*, 2018), suggesting that there is scope for host genetic studies to investigate the potential of selective breeding to promote protective gut microbiota. Selecting for genotypes that concourage protective enteric microbial populations can reduce dependence on antibiotic-mediated pathogen control. This study sought to investigate this possibility by studying the genomic architecture of gut microbiome composition in two chicken breeds, namely Kadaknath (an indigenous Indian breed) and Cobb400 (a commercial broiler line).

Materials & methods

Chicken populations, sample collection, and processing. Whole blood preserved on Flinders Technology Associates (FTA) cards and caecal lumen contents were collected from 600 chickens (300 Kadaknath and 300 Cobb400 of 36-40 days old) raised under the local prevailing husbandry conditions on 60 small to middle size farms located in Gujarat, India (as described by Hinsu *et al.*, 2018). Briefly, birds

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_584, © X. Dai *et al.* 2022

were reared together on 30 farms (n=5 per breed, for a total of 300 samples), or sampled directly from specialised in either Kadaknath or Cobb400 farms to increase the sample size (15 farms each breed, n=10 birds per farm, a total of 300 samples). Metadata related to bird and environmental variables were collected using a detailed questionnaire. Collection of caecal samples, total genomic bacterial DNA extraction, 16S rRNA gene amplification and 16S rDNA sequencing using the MiSeq platform were performed as described previously (Pandit *et al.*, 2018). Chicken genomic DNA was extracted from FTA cards using the Gensolve DNA recovery kit (GenTegra, Pleasnton, USA) and all chickens were genotyped using the 600K SNP Affymetrix high-density array (Kranis *et al.*, 2013).

Data and statistical analysis. 16S rDNA-sequencing data were analysed with QIIME 2. In particular, raw paired-end reads were denoised (i.e. amplification and sequencing noise removal), merged and chimera-checked by inferring the amplicon sequence variants (ASVs) with DADA2. The obtained ASVs table was normalised by rarefaction to an equal sequencing depth of 10,000 sequences per sample. All amplicon sequence variants (ASVs) were classified into the bacterial taxonomy using QIIME 2 and the SILVA database v.132. Low abundance bacterial genera (present in <5 samples and relative abundance <0.01%) were filtered out. Alpha (Inverse Simpson index) and beta diversity (weighted UniFrac and Bray-Curtis dissimilarity metrics) indices were calculated using the R *Phyloseq* package.

Alpha diversity, the first ten beta diversity Principal Coordinates Analysis (PCoA) axes and individual genera relative abundance were used as phenotypes for genome-wide association studies (GWAS). Data were analysed separately for each breed. Rare genera detected in <30% of samples were excluded from subsequent analyses. Individual genera present in <60%, but ³30% of samples were analysed as binary traits. Individual genera detected in ³60% of samples were analysed as continuous traits after normalisation using the rank-based inverse normal transformation of *GenABEL* package in R. The same normalisation function was used for alpha diversity. Multiple correspondence analyses (MCA) of bird and environmental farm variables were performed to identify key components explaining the phenotypic variance in recorded metadata using *FactoMineR* package in R.

Genotypic quality control was performed separately for each breed using PLINK v1.9 (Purcell *et al.*, 2007) with the parameters: sample call rate >90%, single nucleotide polymorphism (SNP) call rate >90%, minor allele frequency >5% and Hardy-Weinberg equilibrium P-value<10^{-6}. After these steps, 465,002 and 400,048 SNPs, 267 and 292 birds, respectively for Kadaknath and Cobb400 remained for subsequent analyses. Variance components to estimate the heritability for each trait of interest (alpha- and beta-diversity, individual genera abundance) per breed was estimated using GCTA v1.94 (Yang *et al.*, 2011). A univariate linear-mixed model was used which included the first four MCA components of farm practice categorical variables as fixed effects and the genomic relationship matrix among-individuals as a random effect. GWAS analyses was performed using the same model as the one used for the heritability estimation on GEMMA v0.98 (Zhou and Stephens, 2012). After Bonferroni correction, the P-value<0.05 genome-wide significance threshold was set at 1.1×10^{-6} and 1.2×10^{-6} for Kadaknath and Cobb400, respectively. Those SNPs that were significantly associated with microbial traits were remapped to the latest reference chicken genome assembly (GalGal6) using the NCBI remapping tool.

Results & discussion

This study was set out to evaluate the role of host genetics in shaping gut microbiota in two distinct chicken breeds. The alpha and beta diversity indices did not reveal any clear separation of the caecal microbiota between the two breeds (Figures 1A and 1B).These results could be partly attributed to the fact that the two breeds were raised in the same geographical region under similar management conditions and are consistent with previous reports showing that environmental factors have dominant roles in shaping gut

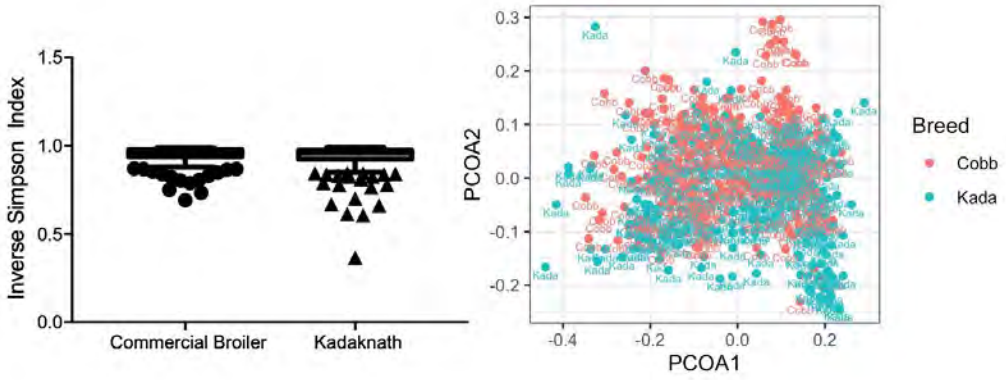

Figure 1. Characterisation of caecal microbiota sampled from Kadaknath and Cobb400 birds based upon 16S rDNA amplicon sequencing. A. Inverse Simpson index. B. Principal Coordinates Analysis (PCOA) plot based on Bray-Curtis distance.

microbiota (Rothschild *et al.*, 2018). The first four MCA components of the recorded metadata accounted for 71.2 and 75.3% of all the farm variability for Kadaknath and Cobb400, respectively, and therefore were included in the GWAS as fixed effects to reduce environmental noise.

We identified considerable heritable genetic variation for beta diversity as well as for individual microbial genera, some potentially pathogenic, in both breeds. Heritability estimates for beta diversity ranged from 0.01 to 0.76 in Kadaknath, and from 0 to 0.72 in Cobb400. In total, 47 and 25 SNPs were significantly associated at the genome wide level with gut microbiota structure in Kadaknath and Cobb400 birds, respectively. The relevant abundance of 39 and 35 individual microbial genera were analysed as binary and continuous traits, respectively. We identified several significant SNP at genome wide levels for the abundance of these genera in the caecal microbiota. Examples of genera of interest (i.e. those with pathogenic potential) included *Campylobacter, Ruminococcus, Alistipes, Helicobacter, Faecalibacterium*, and *Bacteroides* in Kadaknath (Figure 2A-F), and *Campylobacter, Enterococcus* and *Alistipes* in Cobb400 (Figure 2G-H). These potentially pathogenic bacteria could, directly and/or indirectly, influence the host and its enteric microbiota. Previous studies have shown that inflammatory immune responses induced by pathogens could influence the intestinal environment and its bacterial communities (Vangay *et al.*, 2015; Pickard *et al.*, 2017). Therefore, being able to influence their abundance through a selective breeding program would be of interest for productive performance as well as public health.

In conclusion, in this study we found that the microbial community structure and relative abundance of individual genera within chicken caecal microbiota are heritable polygenic traits. Our results corroborate the results of previous studies and support the possibility of breeding to establish enteric microbial populations in chickens that promote resistance against pathogen colonisation or improve performance. Further studies to unravel what constitutes a protective or productive microbiota are needed to facilitate future breeding programmes.

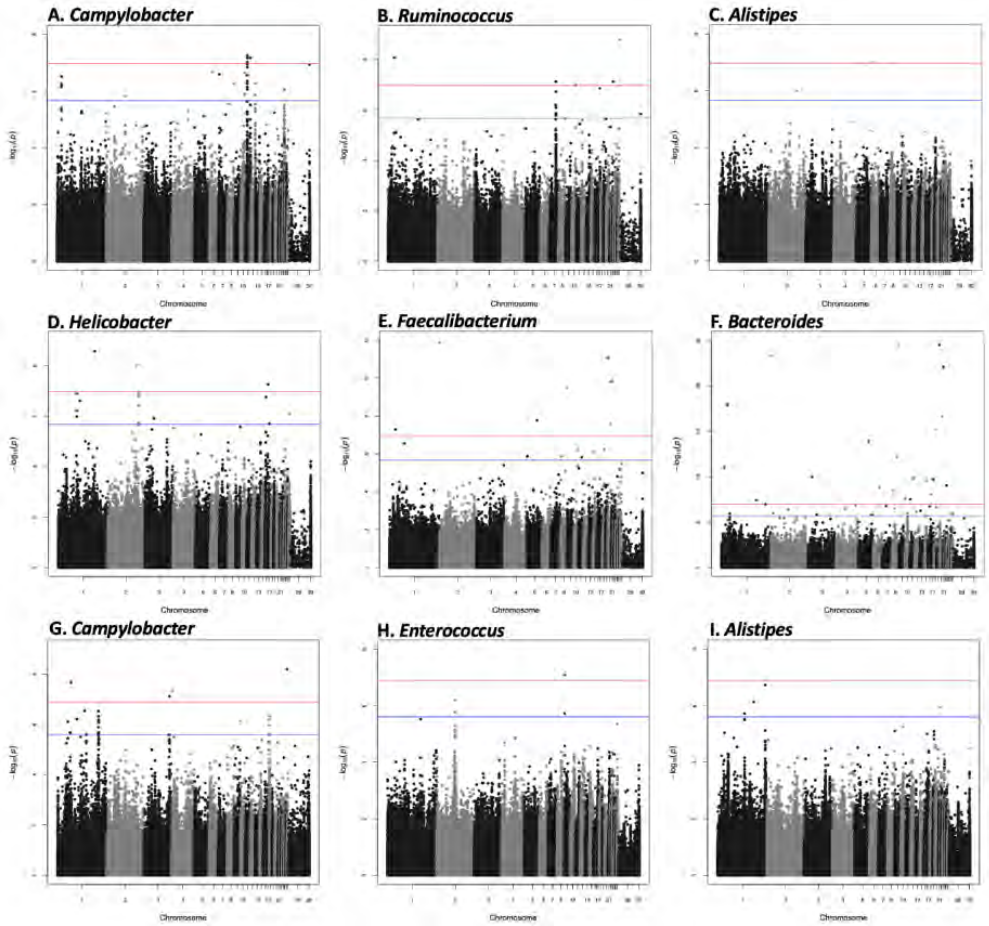

Figure 2. Manhattan plots of genome-wide association studies of relative abundance of potentially pathogenic genera in the caeca microbiota of Kadaknath (A-F) and Cobb400 (G-I) chicken breeds; in the x-axis is chromosome number; y-axis is -$\log_{10}$(*P*-value); red and blue horizontal lines show the genome-wide significant and suggestive significance (1 false discovery per genome scan) levels, respectively.

585. Breeding for an optimised gut microbiota composition for the improvement of phosphorus utilisation in Japanese quail

V. Haas*, S. Vollmar, A. Camarinha-Silva and J. Bennewitz

Institute of Animal Science, University of Hohenheim, Garbenstraße 17, 70599 Stuttgart, Germany;
valentin.haas@uni-hohenheim.de

Abstract

Phosphorus utilisation (PU) and correlated performance traits are typical quantitative traits with many genes with small effects. Through adaption of the microbes in the gastro intestinal tract (GIT) a better digestion of phytic acids bound P in the feed could be achieved. The classical breeding value g_i can be decomposed into a heritable contribution p_i that results from altered metabolic pathways and a heritable contribution m_i which results from altered digestion in the animal from the effect of the microbiota composition in the GIT, so $g_i = m_i + p_i$. Instead of selecting for the breeding value $\hat{g}_i$, it would be beneficial to split the breeding value for one trait into $\hat{m}_i$ and $\hat{p}_i$, by using an index. This enables a stronger selection pressure on the microbiota-mediated path, which is seen as beneficial from an animal welfare point of view. This study describes the index and its application to PU in Japanese quail.

Introduction

Efficiency traits are a major factor influencing the environmental balance in livestock production. They consist of two general components, the digestive efficiency and metabolic efficiency (Martin *et al.* 2021, Puillet *et al.* 2016). Digestive efficiency reflects the ability to absorb nutrients from the GIT into the bloodstream, whereas metabolic efficiency refers to the allocation and reallocation processes of the absorbed nutrients to the animal products. It was shown that efficiency traits are mainly conditioned by reallocation effects due to breeding. But, these reallocation effects can in turn negatively influence animal health (Huber 2018) and thus also animal welfare.

PU and its correlated traits are polygenetic traits that are influenced by many genes with small effects and have low to medium heritability (Beck *et al.* 2016; Vollmar *et al.* 2021). Increased native digestion of phytic acids P (primary form of storage in plant seeds) is targeted to reduce supplementation of mineral P in the feed and thereby reduce environmental impact. Native phytic acids degradation in the GIT can occur by phytases and phosphatases derived from the endogenous mucosa of the GIT, from some vegetable feed components, or from the gut microbiota (Rodehutscord, 2017).

The acquisition (i.e. digestion) pathway can be achieved through a proper community of the microbiota in the GIT. This can be confirmed by microbiabilites found for PU and other performance and efficiency traits (Vollmar *et al.* 2020). These microbiota influencing genes affect the phenotype not only directly by changing the metabolic pathways, but also indirectly by altering the microbiota composition of the animals GIT. The aim of this study was to review the hologenomic selection index proposed in an earlier study (Weishaar *et al.* 2019) and investigate the feasibility for the important trait PU in the model organism Japanese quail for commercial poultry.

Materials & methods

Experimental design and data collection. We used an F2 design of Japanese quail (Coturnix japonica) from two divergent lines from a previous study (Beck *et al.* 2016). The traits of this experiment were PU, body weight gain (BWG), feed intake (FI) and feed per gain (F:G), collected from the 10th to 15th day of life. The quail were slaughtered on day 15 to collect the ileum samples. All birds were incubated and slaughtered

on twelve different days treated as test days in the statistical analysis (Beck *et al.* 2016). The quail were 4k SNP genotyped and the ileum microbiota composition were performed by target amplicon sequencing (Borda-Molina *et al.* 2020; Vollmar *et al.* 2021). Microbiota sequences were clustered into operational taxonomic units (OTUs) at >97% similarity. The final data set contained 758 quail with SNP genotypes, microbiota composition of 1188 OTUs, and trait records (PU, BWG, FI, and F:G).

Statistical analyses. The genomic breeding values $\hat{g}_i$ for the trait were obtained with the genomic mixed model:

$$\mathbf{y} = \mu\,\mathbf{1} + \mathbf{Z_{td}td} + \mathbf{g} + \mathbf{e} \quad (1)$$

where y is the vector of observations (PU, FI, BWG or F:G) for *n* animals, μ the trait mean and 1 the vector of ones. The vector $\mathbf{td} \sim N(0, \mathbf{I}\sigma^2_{td})$ represents the random test day effects with variance σ^2_{td} and design matrix Z_{td}. Vector $\mathbf{g} \sim N(0, \mathbf{G}\sigma^2_a)$ contains the random animal effects with the genomic relationship matrix G, using SNP genotypes following Method 1 of VanRaden (2008), with additive genetic variance σ^2_a. The random residuals are stored in the vector $\mathbf{e} \sim N(0, \mathbf{I}\sigma^2_e)$.

The estimates $\hat{k}_i$ of the animal microbiota effects k_i on the phenotype were obtained using a microbial mixed model, which is similar to model (1), but with vector k instead of vector g:

$$\mathbf{y} = \mu\,\mathbf{1} + \mathbf{Z_{td}td} + \mathbf{Ik} + \mathbf{e} \quad (2)$$

vector k includes the random microbiota effect of all the animals with distribution $\mathbf{k} \sim N(0, \mathbf{M}\sigma^2_k)$, with microbial relationship matrix M (Camarinha-Silva *et al.* 2017) and microbial variance σ^2_k.

Subsequently, we used the estimated microbial animal effect $\hat{\mathbf{k}}$ for the traits from model (2) as observations in the following genomic model (3) to predict the genomic breeding value $\hat{m}_i$ for the microbiota-mediated effects m_i:

$$\hat{\mathbf{k}} = \mu\,\mathbf{1} + \mathbf{Im} + \mathbf{e} \quad (3)$$

with μ the overall mean, vector $\mathbf{m} \sim N(0, \mathbf{G}\sigma^2_m)$ the random animal effect with the genomic covariance matrix G, the SNP variance σ^2_m of the microbiota effect and e the residuals with variance σ^2_e. Models (1-3) were fitted using the package ASReml, which is available in R (Butler *et al.* 2009).

Since $\hat{m}_i$ estimates the microbiota effect m_i on the breeding value g_i, the estimates can be used to calculate the index:

$$I_i = \lambda_1 \hat{m}_i + \lambda_2 (\hat{g}_i - \hat{m}_i)$$

Microbial and genomic predictions were performed with repeated fivefold cross-validation, with a randomly selected reference population of 80% of the animals at each repetition (500 in total) for estimating OTU and/or SNP effects. The remaining 20% were used as the validation population from which the animal effects were predicted. The averaged Pearson correlations between the predicted animal effect and the observed animal phenotype were used as the accuracy of prediction. Based on these correlations, the confidence intervals were calculated.

We applied three kinds of predictions. In G-BLUP, we used model (1), in M-BLUP model (2), and for G-BLUP of the microbiota-mediated part of the trait, we used model (2) to obtain the random microbiota effect of the animals for the corresponding trait, which was subsequently used as an observation in the model (3).

Results

The results of the cross-validation of microbial and genomic predictions are presented in Table 1. The correlations $r_{\hat{g},y}$ between the genomic predictions $\hat{\mathbf{g}}$ and the observations of the traits y are at a similar level as the correlations $r_{\hat{m},y}$ between the genomic predictions of the microbiota-mediated part of the traits $\hat{\mathbf{m}}$ and the observations. The correlations $r_{\hat{k},y}$ between the microbial predictions $\hat{\mathbf{k}}$ and the trait observations y are slightly higher for PU and FI and markedly larger for BWG and F:G.

Discussion

The results from the microbial and genomic predictions (Table 1) confirmed the strong impact of the host genome and the microbiota composition on the traits. Furthermore, the two-step procedure proposed by Weishaar *et al.* (2020) to estimate a breeding value for the microbiota-mediated part of a trait was also successful in this study and it was most evident for PU and FI. The G-BLUP prediction accuracy for the microbiota-mediated part of the trait was only slightly lower than the prediction accuracy of the conventional G-BLUP. An explanation might be that the host genetic effect on the trait mediated by the microbiota is much stronger than the direct host path. The prediction methods have been further developed recently by Christensen *et al.* (2021).

The results of the two-step method proposed by Weishaar *et al.* (2020) clearly show the potential for predicting genomic breeding values for microbiota effects m_i on quantitative traits in Japanese quail. It is only possible to breed for the microbiota effect m_i of a trait, if the trait is heritable and influenced by the composition of the microbiota in the GIT. The selection response for the microbial effect m_i depends on the additive variance of the trait, the position in the GIT where the microbial samples were taken, the proportion of the additive variance that can be explained by the microbial effect m_i and the accuracy with which the OTU effects and the SNP effects were estimated (Weishaar *et al.* 2020).

PU is a typical trait for a potential breeding approach based on the GIT microbiota, i.e. for selecting the hologenome to achieve breeding success. It is known that poultry has a low endogenous phytase activity, but native phytic acid degradation in the GIT can occur by phytases and phosphatases from the gut microbiota. The proposed method enables to breed for an improved PU by optimising the GIT microbiota composition. Although it is well-known that the microbial colonisation of the GIT is influenced by the environment, there is a host genetic control that manifested in significant heritabilities of several microbial traits and this can be used for breeding, as proposed here.

Table 1. Results of the genomic and microbial trait predictions.[1]

Trait[2]	M-BLUP of y		G-BLUP of y		G-BLUP of microbiota-mediated y	
	$r_{\hat{k},y}$	95% CI	$r_{\hat{g},y}$	95% CI	$r_{\hat{m},y}$	95% CI
PU	0.221	0.091:0.351	0.181	0.048:0.320	0.162	0.006:0.313

BWG	0.338	0.201:0.464	0.131	-0.010:0.254	0.137	-0.030:0.294
F:G	0.307	0.100:0.470	0.097	-0.052:0.226	0.073	-0.069:0.225

[1] Estimated accuracy of the M-BLUPs ($r_{\hat{k},y}$) and G-BLUPs ($r_{\hat{g},y}$) of the trait observations and G-BLUPs of the microbiota-mediated part of the trait observations ($r_{\hat{m},y}$) with confidence intervals (CI).

[2] PU = P utilisation, FI = feed intake, BWG = body weight gain and F:G = feed per gain.

If the amount of excess P in livestock production and thus the use of mineral P is to be reduced, this can be done by looking at the microbiota composition in the GIT using the hologenomic approach.

586. High-resolution genotyping and analysis of *in silico* predicted proteins for classical MHC genes in Korean native chicken

T.K. Ediriweera[1], P. Manjula[2], E. Cho[1], M. Kim[1], S. Cho[1] and J.H. Lee[1*]

[1]Chungnam National University, 99 Daehak-ro, Yuseong-gu, 34134, Daejeon, Republic of Korea; [2]Uva Wellassa University, Passara Road, 90000, Badulla, Sri Lanka; junheon@cnu.ac.kr

Abstract

The major histocompatibility complex-*B* (MHC-*B*) region is of paramount importance in chicken immunogenesis. The Grey line, one of the five lines belong to the Korean native chicken (KNC) breed, was analysed for the MHC-*B* region by comparing with the *Gallus gallus* (Red junglefowl) reference with an especial focus on classical MHC class I and II genes (*BF-BL* genes) and their resultant proteins. This study concluded that the MHC-*B*, including classical class I and II genes and resultant proteins in the KNC Grey line, vary from the *G. gallus* (Red junglefowl) MHC-*B* remarkably by analysing the Next-Generation Sequencing (NGS) assembly along with *BF-BL* genes and their predicted proteins.

Introduction

The major histocompatibility complex-*B* (MHC-*B*) region possesses classical MHC class I and class II genes that are extremely important in recognizing foreign pathogenic peptides. They initiate the antigen presentation by producing class I and class II MHC molecules which are highly important for immune response and histocompatibility in chickens (Kaufman, 2018). The capability of identifying such foreign materials depends on the structures of peptide-binding grooves of MHC molecules (Koch *et al.*, 2007), and those structures are determined by the coding sequences (CDSs) of respective genes. Therefore, having a complete understanding of the resulting protein structures corresponding to their DNA sequence is immensely important. In consequence, obtaining the DNA sequences, identifying genes and CDSs, translating them into possible amino acid sequences, and predicting their features, need to be conducted to comprehend the importance and involvement of MHC molecules in the process of immunogenicity.

Therefore, this study focused on the MHC-*B* region of the KNC-Grey (KNC-G) line, an indigenous chicken line with superior meat quality in Korea (Nawarathne *et al.*, 2020) that currently demonstrates a trend towards commercial farming. The objectives of this study are to obtain the consensus DNA sequence from the *BG1-BF2* gene, including *BF1*, *BF2*, *BLB1*, *BLB2* genes of the KNC-G line, investigate the variants and features of *in silico* predicted class I & class II MHC proteins. Data from this study serve as base information for further studies, especially in the development of vaccines for key avian diseases (e.g. Avian influenza, Marek's disease, Newcastle disease, etc.). This will be useful in disease management, which is a critical aspect of concern in commercial farming.

Materials & methods

At the previous stage of this study, the MHC-*B* region of the KNC-G line was analysed using MHC-*B* linked microsatellite markers, and MHC-*B* based single nucleotide polymorphisms (SNP) panel having 90 SNPs. Thus, a homozygous individual for them was identified, followed by sampling for its blood and DNA extraction. Later, the extracted DNA was amplified for the MHC-*B* (from *BG1* to *BF2* gene) including *BF1*, *BF2* genes of MHC class I and *BLB1*, *BLB2* genes of MHC class II, using long-range polymerase chain reaction (PCR) techniques. After the PCR purification step, the sequencing was conducted using Illumina Next-Generation Sequencing (NGS).

The NGS reads were then processed and analysed using 'Geneious Prime molecular biology and Sequence analysis tools' [Geneious Prime 2020.0.1. (https://www.geneious.com), Biomatters, Ltd., Auckland, New Zealand]. Accordingly, the pre-processed NGS reads were assembled using the 'mapped to reference' technique, using '*Gallus gallus* genes, MHC region, partial and complete cds' sequence available in NCBI (Accession number: AB268588.1) as the reference. Then the consensus sequence was obtained, followed by variant analysis. Before mapping, the reference sequence was annotated directly with NCBI using Geneious Prime's GenBank accession tools. Accordingly, the genes and CDSs of the obtained consensus for the KNC-G line were recognized when it is accurately mapped to the reference.

The CDSs of MHC class I and II genes (*BF-BL* genes) of both reference and KNC-G line were then obtained and translated into amino acid sequences followed by prediction of antigenic regions, and transmembrane regions using EMBOSS protein analysis tools and transmembrane prediction plugins of Geneious Prime.

Results

The reference mapping-based assembly of the KNC-G line for its MHC-*B* (from *BG1* to *BF2* gene) region comprised 67,740 bp with 59,676 sequences in which the pairwise identity percentage was 80.9%. The GC content was 59.8% whereas the individual A, C, G, T contents were 20.2, 28.8, 31.0, and 20.0%, respectively. Further, there were 830 SNPs (576 transition SNPs and 254 transversion SNPs), of which 230 of them were in gene regions. In addition to SNPs, it contained 38 insertions, 40 deletions, and 65 substitutions.

However, addressing the prime focus, the DNA sequences for *BF-BL* genes were extracted from the main consensus and further analysed for their CDSs, amino acid sequences, properties, and features. Each time the considered genes of the KNC-G line have been compared with the reference. The results for predicted physical properties and features of obtained amino acid sequences based on their CDSs are presented in Table 1 and Figure 1.

Subfigures a, b, c, d of Figure 1 represent the predicted protein comparisons for *BF1*, *BF2*, *BLB1* and *BLB2* genes of the KNC-G line respectively. In each subfigure, the topmost 'identity' row indicates, the protein identity between predicted proteins of the particular KNC-G gene and its analogous reference gene. In here, the green colour means identical, and the white means non-identical. The blue lines and light-yellow lines demonstrate genes and CDSs, respectively. The antigenic regions, transmembrane regions, and potential extracellular regions for each protein have been predicted and marked with dark-red, dark-yellow, and light-pink colours, respectively. The composite colour bar remains beneath the illustrations of transmembrane and extracellular regions in reference ('Ref') side of each of the subfigures represent different amino acids of predicted protein with different colours. The bar with less dense colours immediately below this

Table 1. The properties of predicted proteins for major histocompatibility complex-*B* class I and II genes.

Gene that encodes the protein	Whether KNC/ Ref	Length (aa)	Molecular weight (kDa)	Isoelectric point	Charge at pH 7
BF1	KNC-G_BF1	355	39.201	5.27	-8.68
	Ref_BF1	360	39.713	6.77	-0.68
BF2	KNC-G_BF2	356	37.987	11.44	27.73
	Ref_BF2	356	37.851	11.53	30.56

	Ref_BLB1	264	26.946	11.72	20.19
BLB2	KNC-G_BLB2	263	29.294	6.12	-1.94
	Ref_BLB2	263	29.088	6.5	-0.94

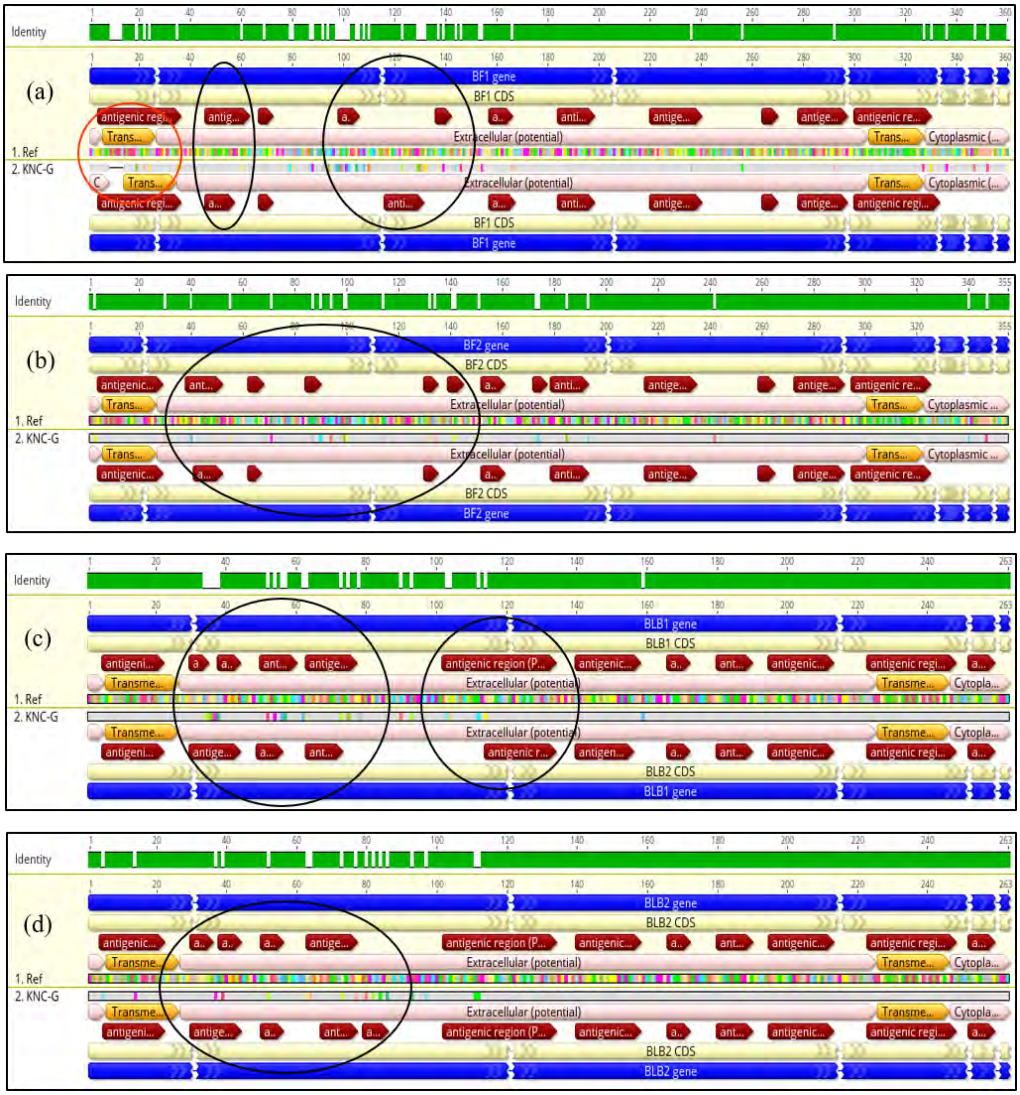

Figure 1. The features of predicted proteins for major histocompatibility complex-*B* class I and II genes.

composite colour bar indicates the amino acid disagreements of KNC-G based proteins compared to the reference. At last, the black and light-red circles highlight the prominent alterations in antigenic regions and transmembrane regions between the Reference and KNC-G based proteins respectively.

Discussion

The pairwise identity percentage of 80.9% between the KNC-G line and the reference gives a clear instinct that the MHC-*B* region has not completely conserved between the *Gallus gallus* (Red junglefowl) and the KNC-G line throughout their evolutionary process as they demonstrate a profound dissimilarity of about 19%. The high gene density in this MHC-*B* might be the reason to have a high GC content of 59.8% (Rao *et al.*, 2013).

Further, the high rate of polymorphisms suggests a high diversity within the MHC-*B* region. Especially the SNPs in gene regions reflect changes in resultant proteins. Hence, we were highly motivated to investigate the classical class I and II genes for their possible proteins.

Among all the four genes analysed for the changes in their properties and features, only *BF1* has demonstrated a deviation in amino acid length compared to the reference, and hence it can be considered a comparatively major effect. Accordingly, the other properties of *BF1*, including molecular weight, isoelectric point, and charge at pH 7, as well have noticeably diverged from the reference. In all the other three genes, despite the lengths being similar with the reference, the molecular weight, isoelectric point, and charge at pH 7 have been changed, due to amino acid variations. These changes resulting in an altered level of disease resistance/ susceptibility suggest a considerable difference in both MHC class I and II molecules.

Accordingly, they all were then analysed for antigenic regions and transmembrane regions. As demonstrated in Figure 1, black and light-red colour circles highlight the prominent alterations in antigenic regions and transmembrane regions respectively, that occurred due to the variations in their genes. These feature changes ultimately influence the competencies of both MHC class I and II molecules in pathogenic recognitions. Nevertheless, further studies need to be conducted to investigate their positive/ negative effect on infectious diseases.

Al-Shuhaib *et al.* (2019) also has employed a comparatively similar type of *in silico* approach to predict the effect of polymorphisms in resulting protein structures. Hence, this kind of *in silico* approach can be considered, fair and efficient to analyse the features of predicted proteins. However, the outcomes still need to be validated with *in vitro* experiments.

In conclusion, the MHC-*B* region of the KNC-G line considerably varies from the *Gallus gallus* (Red junglefowl) MHC-*B* region. As a result of the variations in the MHC class I and II genes, the MHC class I and II molecules are getting modified, thus possibly affecting their pathogenic identification abilities.

Abstract

Little information on the genetic architecture of production traits of indigenous African chicken exists. We estimated genetic parameters and performed a genome-wide association study using imputed 600K SNP genotypes on three Ghanaian chicken ecotypes (n=1,113). Variance components and heritabilities for body weight at 22 weeks (BW22), average daily gain (ADG), and carcass traits were estimated, as well as genetic and phenotypic correlations among them. Heritabilities for all traits were high (0.51-0.69), while those for carcass traits corrected for BW22 were moderate (0.21-0.38). Seven 1-Mb windows from six chromosomes each explained up to 25% of the genetic variance in these traits. These windows contained genes such as *FOXO1*, *NCARP*, *LCORL*, *LAP3*, *LDB2*, *TGFBR2*, and *TAPT1*, previously reported to have effects on growth and carcass traits. The moderate to high heritabilities and highly positive genetic correlations between them indicate that these traits can be improved through selective breeding.

Introduction

Indigenous African chickens have over the years adapted very well to harsh climatic and environmental conditions (Birteeb *et al.*, 2016). They have several desirable characteristics, including natural resistance against diseases like Newcastle disease (Mpenda *et al.*, 2018). They, however, tend to have lower growth rates and body sizes compared to exotic chicken breeds (Osei Amponsah et.al., 2011; Birteeb et.al., 2016). Therefore, in the quest to increase local chicken's body size and growth rate, many farmers introduce birds of unknown genetic composition into their flocks, potentially leading to the loss of important traits. Some studies on genetic production trait parameters of local chicken in Africa have been carried out (Osei-Amponsah *et al.*, 2013; Dekkers *et al.*, 2017), but very limited comprehensive genome-wide association studies (GWAS) to explore the genetic basis of these traits are available. Therefore, it is important to explore the genetic architecture of production traits in local chicken populations to identify their potential for genetic improvement, whilst preserving their genetic diversity and retaining their ability to withstand the harsh environmental conditions of their habitats. The objective of this study was, therefore, to estimate genetic parameters and explore the genetic architecture of body weight and carcass traits of three local chicken ecotypes in Ghana using a genome-wide association study.

Materials & methods

The chickens used in this study were offspring of those described in Walugembe *et al.* (2020). This study was conducted in four replicates, with a total of 1,113 chickens made up of the Forest, Interior Savanna and Coastal Savanna chicken ecotypes. Chickens were housed in deep litter pens and fed on a standard chick starter mash from day 1 to week 8 and on a standard chick grower mash from week 9 to week 22. Water was provided *ad libitum*. Vaccination, feeding, and general husbandry practices were the same for all the birds.

Body weights were taken bi-weekly from hatch until 22 weeks of age. Average daily gain (ADG) was calculated as the linear regression of body weight on age. At week 23, birds were humanely sacrificed, and

several carcass traits were measured, including weights of breast, drumstick, thigh, wings, overall dressed weight and dressed percentage.

Blood samples were collected from chicks at 5 weeks of age and DNA was isolated for genotyping by sequencing. The resulting genome sequences were run through a customised in-house SNP-pipeline which resulted in 5K SNP genotypes for each bird. These were then imputed to 382,240 SNPs using post-quality control high-density genotype data of relatives, as described by Walugembe *et al.* (2020). Imputation was performed using Fimpute (Sargolzaei *et al.,* 2014). The three local ecotypes studied here were derived from three ancestral populations (Walugembe *et al.*, 2020). Therefore, to infer the proportions of ancestral subpopulations for all chickens, we performed admixture analyses on the imputed genotypes using the Admixture software (Alexander *et al.,* 2009). The resulting ancestral subpopulation proportions were used as covariates in the downstream genetic analyses.

Variance components and heritabilities were estimated using a univariate model with the fixed effects of replicate, sex, and pen by replicate, ancestral subpopulation proportions as covariates, and random effects of animal genetics and a residual. The model (Model 1) is given by: $y = Xb + Z_a a + e$, where y is the vector of phenotypes; X is the incidence matrix relating fixed effects and covariates to vector y; b is the vector of fixed effects and covariates; Z_a is the incidence matrix relating the phenotypes to the vector of random bird genetic effects, *a*, with a genomic relationship matrix computed using method 1 of Van Raden (2008); and *e* is the vector of random residuals. Some carcass traits were also analyzed by including body weight at week 22 as a fixed covariate (referred to as Model 2). To estimate genetic and phenotypic correlations, we fit pairwise bivariate models with the same effects as in the univariate models. All models were implemented in ASReml 4 (Gilmour *et al.*, 2015).

We performed a GWAS using Bayes-B (Meuwissen *et al.*, 2001), as implemented in the JWAS package (Cheng *et al.*, 2018) to estimate the genetic variance explained by 1-Mb windows of SNPs across the genome. Both Models 1 and 2 were used. One-Mb windows that explained more than 1% of the genetic variance for a trait were considered significant. We used the Genome Data Viewer in NCBI with the *Gallus gallus* 6 genome build to identify candidate genes within the significant 1-Mb windows.

Results & discussion

Means and estimates of heritabilities, genetic and phenotypic correlations of the studied traits are in Table 1. The effects of ancestral subpopulation proportions were not significant for any of the traits. Replicate and sex were significant for all traits except for breast weight adjusted for BW22. When BW22 was included as a covariate (Model 2), it was significant for all traits.

Estimates of heritabilities based on Model 1 were high for all traits, ranging from 0.51 for thigh weight to 0.69 for ADG (Table 1), in line with the findings of Rance *et al.* (2002). Estimates of carcass trait heritabilities adjusted for BW22 were moderate and ranged from 0.21 for thigh weight to 0.38 for wing weight, and were similar to those reported by Gaya *et al.* (2012). All heritability estimates reduced when BW22 was included as a covariate, but the magnitude and direction of the phenotypic and genetic correlations did not change. Estimates of genetic and phenotypic correlations were all positive with moderate to high heritabilities. These findings agree with those previously reported by Zarehdaran *et al.* (2004) but not with the findings of Osei-Amponsah (2010), who reported weak to moderate negative correlations of live weight with most carcass traits at 24 weeks of age, except for carcass weight, for which the correlation was high and positive. The positive genetic correlations of body weight with carcass traits suggest that the carcass traits will improve with selection on body weight.

Table 1. Means and estimates of heritabilities (along diagonal) and of genetic (above diagonal) and phenotypic (below diagonal) correlations. In each cell, an estimate without BW22 covariate is on top and an estimate with covariate is beneath it.[1]

[1] wt: weight; all weights are given in grams.

After quality control, data on 1,113 birds and 382,240 SNPs were used for the GWAS analysis. When using Model 1, a 75 Mb region on chromosome 4 was significant for all traits except dressing %. This region explained 19.7, 11.6, 12.2, 20.6, 25.2, 19.6, and 14.0% of the genetic variance of BW22, ADG, breast weight, drumstick weight, wing weight, thigh weight and dressed weight, respectively. This region contains the *NCARP, LCORL, LAP 3, LDB2* and *TAPT1* candidate genes. The *NCAPG* gene has been reported to be associated with body size, ADG, carcass traits, and muscle development in beef cattle (Lindholm-Perry *et al.*, 2013). Polymorphisms in *LCORL* have been reported to be associated with growth traits in cattle (Lindholm-Perry *et al.*, 2013), while *LDB2* has been associated with body weight and ADG in chicken (Gu *et al.*, 2011). A 170-172 region on chromosome 1 explained 12.49, 10.6, 6.18, 3.11, 11.91, 11.12, and 14.04% of the genetic variance of BW22, ADG, dressed weight, breast weight, drumstick weight, thigh weight, and wing weight, respectively. This region includes the F*oxO1* gene, a transcription factor that plays a critical role in muscle growth, metabolism, and cell differentiation, and has been shown to be involved in regulating muscle fibre type specification (Yuan et.al., 2011). A 19 Mb window on chromosome 2 was found to explain 1.3% of the genetic variance of BW22. This region contains the *TGFBR2* gene, which, together with TGFB-2 proteins, seems to play a role in cell proliferation and differentiation, apoptosis, regulation of muscle tissues, body fat, and bone development. When BW22 was added to the model as a covariate (Model 2), there was a reduction in genetic variance for the carcass traits. Only 6.6% of the genetic variance of breast weight was now explained by three 1-Mb windows on three chromosomes. For drumstick weight, three 1-Mb windows on three chromosomes together explained only 4.4% of the genetic variance. One 1-Mb window explained 1% of the genetic variance of thigh weight, and four windows on four chromosomes together explained 10.2% of the genetic variance of wing weight.

Conclusions

The moderate to high heritabilities obtained for the studied traits and the positively high genetic correlations between them, coupled with the several 1-Mb windows that explained >1% of the genetic variance indicate that these traits can be improved in Ghanaian indigenous chicken populations through selective breeding.

588. Estimating environmental direct-maternal covariance in real data – illustration on broilers

H. Romé[1*], T.T. Chu[1,2], D. Marois[3], C.H. Huang[3], P. Madsen[1] and J. Jensen[1]

[1]Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark; [2]Faculty of Animal Science, Vietnam National University of Agriculture, Gia Lam, Hanoi, Vietnam; [3]Cobb-Vantress, P.O. Box 1030, 72761-1030 Siloam Springs, AR, USA; helene.rome@mbg.au.dk

Abstract

At early age performance of an individual might be influenced by maternal effects of both genetic and environmental origin. Because of this, a covariance structure arises between the direct and the maternal components. Estimating direct-maternal genetic covariance is easy. However, estimating direct-maternal environmental covariance is more complicated. This corresponds to estimating a covariance between residual environmental effect of the dam and her effect on her offspring. The aim of our paper was to illustrate a method to estimate easily direct-maternal environmental covariance using standard available breeding software. For this, we focused on body weight in two commercial lines of broilers, which is known to be influenced by maternal effects. Our model was implemented in DMU-software by augmenting the model with a dummy residual with a variance that was constrained to a fixed value. In both lines investigated, we found a negative direct-maternal genetic covariance and a positive direct-maternal environmental covariance.

Introduction

The phenotype of an individual (P_i) is determined by different factors such as the individual direct genetic effect (G_i) and individual environmental effect (E_i). This is represented in the famous equation $P = G + E$. At young age, the phenotype of an individual (P_i) could be also influenced by maternal effects such as maternal direct genetic effect (G_m) and maternal environmental effect (E_m). In such case, the phenotype of individual is then equivalent to the sum of individual effects and maternal effects. Thus, now we have $P_i = G_i + E_i + G_m + E_m$. This corresponds to the maternal animal model (MAM) developed by Willham (1963). In such situation, covariance structure arises between the individual and the maternal components. Therefore, one might assume that $cov(G_i,G_m)$ and $cov(E_i,E_m)$ are non-null.

Numerous studies have investigate the genetic direct-maternal covariance in different species (Cantet *et al.*, 1988; Koerhuis and Thompson, 1997; Meyer, 1992; Ogawa *et al.*, 2021; Robinson, 1996) ignoring the environmental covariance, e.g. assumed zero. Very few have focused on the environmental direct-maternal covariance (Bijma, 2006; Munilla and Cantet, 2015). This could be due to the ease of estimating genetic direct-maternal covariance using current breeding software, but also by the fact that it could be easier to understand and visualize the meaning of such covariance. Bijma (2006) explained nicely the environmental covariance structures that could arise depending on the number of batches of offspring and the number of offspring per batches per dam. He showed that when there are multiple offspring in multiple batches (and therefore raised in different environments), it is enough to estimate only two environment maternal effect; the maternal permanent environmental effect and the residual effect of the dam; and the correlation between them. Chicken is a good model for this, since it is possible to obtain multiple batches of progeny, each of them containing multiple progenies. Moreover, we know that traits as body weight are influenced by maternal effects (Chu *et al.*, 2020; Koerhuis and Thompson, 1997), especially at an early age. Munilla and Cantet (2015) proposed a method to estimate the environmental direct-maternal covariance, but because of heavy computation, its application to large dataset might be difficult. The aim of this paper is to propose a simple way to estimate the environmental direct-maternal covariance using REML and to estimate the

genetic direct-maternal covariance while considering the environmental direct maternal covariance at the same time.

Materials & methods

Populations. Our analysis focused on two commercial purebred broiler lines (A and B). For both lines, body weight (BW) at similar age were recorded (in grams) for all birds tested in 40 rounds of testing and selection. For Line A, BW was recorded on 179,897 females and 178,299 males. For Line B, BW was recorded on 366,680 females and 357,241 males. BW within sexes was considered as different traits because of known sexual dimorphism in broilers affecting body weight averages and variances Except for dams in the early selection rounds, all dams had their phenotypes (BW) included in the data. In the pedigree, there were 407,474 birds for Line A, and 828,299 birds for Line B.

Model. Body weight in males and in females were considered as different traits based on observation done on pre-analysis. Thus, we built a bivariate models, where subscript F and M stand for the sex, including the fixed effects (incidence matrix X, vector b), an additive genetic effect (incidence matrix Z, vector a), a maternal genetic effect (incidence matrix W vector m), a residual (incidence matrix B, vector e), a permanent maternal environmental effect (incidence matrix W vector pe) and an extra residual ε with constant variance set equal to c^2, where c^2 is a constant. The constant could be any value superior to 0 and lower than the residual variance, in our case, the constant was set to 1. Therefore, our model was as follow:

$$\begin{bmatrix} \boldsymbol{BW_F} \\ \boldsymbol{BW_M} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X_F} & 0 \\ 0 & \boldsymbol{X_M} \end{bmatrix} \begin{bmatrix} \boldsymbol{b_F} \\ \boldsymbol{b_M} \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z_F} & 0 & \boldsymbol{W_F} & 0 \\ 0 & \boldsymbol{Z_M} & 0 & \boldsymbol{W_M} \end{bmatrix} \begin{bmatrix} \boldsymbol{a_F} \\ \boldsymbol{a_M} \\ \boldsymbol{m_F} \\ \boldsymbol{m_M} \end{bmatrix} + \begin{bmatrix} \boldsymbol{B_F} & 0 & \boldsymbol{W_F} & 0 \\ \boldsymbol{0} & \boldsymbol{B_M} & 0 & \boldsymbol{W_M} \end{bmatrix} \begin{bmatrix} \boldsymbol{e_F} \\ \boldsymbol{e_M} \\ \boldsymbol{pe_F} \\ \boldsymbol{pe_M} \end{bmatrix} + \begin{bmatrix} \boldsymbol{\varepsilon_F} \\ \boldsymbol{\varepsilon_M} \end{bmatrix} \quad (1)$$

$$\begin{bmatrix} \boldsymbol{a_F} \\ \boldsymbol{a_M} \\ \boldsymbol{m_F} \\ \boldsymbol{m_M} \end{bmatrix} \sim MVN \left[0, \boldsymbol{A} \otimes \begin{pmatrix} \sigma^2_{a_F} & \sigma_{a_F a_M} & \sigma_{a_F m_F} & \sigma_{a_F m_M} \\ \sigma_{a_F a_F} & \sigma^2_{a_M} & \sigma_{a_M m_F} & \sigma_{a_M m_M} \\ \sigma_{a_F m_F} & \sigma_{a_M m_F} & \sigma^2_{m_F} & \sigma_{m_F m_M} \\ \sigma_{a_F m_M} & \sigma_{a_M m_M} & \sigma_{m_F m_M} & \sigma^2_{m_M} \end{pmatrix} \right]$$

$\begin{bmatrix} \boldsymbol{\varepsilon_F} \\ \boldsymbol{\varepsilon_M} \end{bmatrix} \sim N(0, \boldsymbol{I}c^2)$, where c^2 were constrained to 1.

Where A is the pedigree relationship matrix and I is an identity matrix.

Variance components were estimated using the DMU software package (Madsen and Jensen, 2013). Setting the covariance between the additive genetic effect and the maternal genetic effect is quite simple, as we can just assign these two components to the same covariance matrix. Same goes with the covariance between the permanent maternal environmental effect and the environmental effect. However, in most of the software to estimate variance components, the residual matrix is set automatically as the last matrix. Finally, the estimate of residual variance are $\sigma^2_{e_F} + c^2$ and $\sigma^2_{e_m} + c^2$.

Results

(Co)variance components estimated in both lines are presented in Table 1. We were able to estimate both genetic and environmental direct-maternal correlation. Phenotypic variances were higher in males than in females for both lines. Heritability estimates for body weight were slightly higher in Line A than in Line B. In both lines, we observed a negative genetic direct-maternal correlation and a positive environmental

Table 1. Variance components estimated for the 2 lines.

		σ^2_a	σ_{am}	σ^2_m	σ^2_e	σ^2_{epe}	σ^2_{pe}	r_{am}	r_{epe}	h^2
Line A	f	4,952 (340)	-795 (178)	1,016 (146)	14,772 (179)	1,048 (130)	727 (68)	-0.35 (0.06)	0.32 (0.04)	0.23 (0.01)
	m	8,170 (568)	-1,436 (292)	1,608 (237)	23,523 (297)	1,232 (164)	1,254 (107)	-0.40 (0.06)	0.29 (0.04)	0.24 (0.01)

direct-maternal correlation. Whereas environmental direct-maternal correlation were similar between the two lines (r_{epe}: 0.29~0.32), genetic direct-maternal correlation more extreme in line B (r_{am}: -0.46~-0.51) than in Line A (r_{am}: -0.35~-0.40).

Discussion

Negative direct-maternal covariance have been reported in many different cases but have often been received with scepticism (Cantet *et al.*, 1988; Koerhuis and Thompson, 1997; Meyer, 1997; Robinson, 1996). It was believed that this negative covariance was due to some negative environmental covariance that were ignored in the model (Falconer and Geerts, 1965; Robinson, 1996). Here, we were able to estimate both genetic and environmental direct-maternal covariance simultaneously. Whereas, the genetic correlation was strongly negative, the environmental one was positive. The negative genetic correlation could be easily explained by the resource allocation theory (Beilharz *et al.*, 1993). Indeed, one can imagine that a genotype selected on its ability to grow, will used most of its resources to this function and not to reproduction functions, especially if food input were limited. Therefore, egg contents maybe not optimal for embryonic development resulting in smaller chicks. The environmental direct-maternal correlation can be seen from different, partly overlapping, viewpoints. First, we can hypothesize that there is a correlation between the environment of the dam (considered as an individual) and the permanent effect on the group of offspring. In such case, a dam having a favourable environment for growth will influence positively the performances of its offspring by producing for example bigger eggs, resulting in bigger chicks at hatch (Abiola *et al.*, 2008; Pinchasov, 1991). As a second viewpoint, we can look at the environmental effect as the residual effect, which is really is, and so assume that this correlation is due to effects which are ignored in the model. We can also hypothesize that dam and offspring might share a common environment, which will be reflected in the covariance. For example, microbiome is heritable and is correlated to body weight (Meng *et al.*, 2014). As said before, the different point of view are not exclusives, and so the observed environmental direct-maternal covariance could be due to different factors. Adding extra layers of information (microbiome, non-additive genetic effects, etc.) into our model might help to better dissect the environmental direct-maternal covariance.

Munilla and Cantet (2015) proposed another approach that was described as computationally intense, and so that could be complicated to apply to large dataset. Here we presented a simple way to estimate the environmental direct-maternal covariance using REML. We applied our method to large datasets without increasing computation time or memory compared to models where the direct-maternal environmental covariance were ignored.

Furthermore, it would be interesting to investigate the effect of accounting for both genetic and environmental direct-maternal covariance on accuracy of prediction and on inflation of breeding values.

Conclusions

It is possible to estimate the environmental direct-maternal (i.e. dam-offspring) covariance using REML. In our case, the negative genetic direct-maternal covariance was associated with a positive environmental direct-maternal covariance.

Abstract

Molecular responses of broiler chickens to stressors would provide the essential architecture required to devise innovative strategies to mitigate them. Ileum tissues from chickens infected with *E. maxima* and reared under either thermoneutral (TN) or heat stress (HS) conditions were used to study the molecular mechanisms that underlie responses to these stressors. Chickens modulate the ileum transcriptome by catabolizing amino acids for energy when subjected to HS alone. Toll-like receptor and cytokine-cytokine receptor signaling were downregulated while PPAR and fatty acid degradation were upregulated. Fatty acid degradation, tryptophan and glutathione pathways were downregulated in the in chickens infected with *E. maxima* and reared under TN conditions. When chickens were infected with *E. maxima* and subjected to HS, they downregulated calcium signaling, tryptophan and fatty acid metabolism to reduce the nutrients available for scavenging by the parasite. The reduced nutrients available for the parasite to scavenge limit their reproductive ability.

Introduction

Eimeria spp. are apicomplexan parasites that cause coccidiosis in poultry. The economic impact of coccidiosis is estimated to be $3B globally. *Eimeria (E.) maxima* is one of the seven recognized species of coccidia that infect chickens. The disease is characterized by reduced growth and feed intake, apathy, diarrhea and in severe cases, mortality. *Eimeria maxima* specifically infects chicken at mid-gut regions proximal and distal to the Meckel's diverticulum. During infection, the parasite destroys the intestinal mucosa and impacts digestibility and nutrient absorption. The intestine undergoes enterocytic damage and epithelia sloughing predisposing the chicken to invasion of pathogens that causes other enteric diseases (Dubey and Jenkins, 2018).

Heat stress (HS) could be seasonal or an endemic stressor in the poultry industry that impacts health, feed intake, and growth of chickens leading to severe economic losses. Heat stress can lead to oxidative stress and that could have several negative physio-pathological effects on the birds. Impaired growth during HS can be attributed to reduced nutrient availability (Habashy *et al.*, 2017). Changes in nutrient metabolism and the heat load can significantly affect protein biosynthesis. Understanding the host molecular responses to *E. maxima* infection and temperature would allow for the development of novel mitigation strategies. We hypothesized that *E. maxima* infection and HS will elicit changes in the ileum transcriptome.

Materials & methods

Freshly sporulated *E. maxima* oocysts were counted suspended in PBS at a concentration of one 500 oocysts/ml Single oocysts were observed in 2µl droplets under light microscopy and collected. Twelve 14 days old-broilers kept in sterile isolators were infected with one oocyst suspended in 200µl of PBS via gavage. Fecal matter was collected from each isolator at 7 days post infection (dpi) and analyzed for the presence of oocysts by salt flotation. One volume of feces was solubilized in 9 volumes of saturated salt solution and the supernatant used to verify for the presence of oocysts in the presence of oocysts in a

McMaster chamber. The oocysts recovered from one of the chickens were sporulated in three consecutive passages. The purity of the *E. maxima* clone was verified by PCR (Jenkins *et al.*, 2006).

Six hundred 14-d old commercial broiler chickens were divided into 2 groups and reared at 20 °C (thermoneutral, TN) or 35 °C (HS). Each temperature group comprised of 30 groups of 10 chicks. Within each temperature group, half of the chicks were infected via gavage with 2×10^5 *E. maxima* sporulated oocysts suspended in water and the other half were mock infected with water. All chickens were raised in batteries with wired floor, with *ad libitum* access to feed and water. In all, there were 4 experimental groups: TN control [TNc], TN infected [TNi], HS control [HSc] and [HSi]. At 6 dpi, 5 chickens per group were randomly sampled, and ileum tissues were collected for RNA extraction and then sequenced using NGS Illumina sequencing platforms. Total RNA was extracted from the ileum tissue using Trizol reagents and purified with RNeasy mini kits. Concentration of the extracted RNA was assessed with UV absorbance and the $OD_{260/280}$ ratios for all samples were >1.9. All RNA samples displayed an RNA Integrity Number (RIN) of ≥9. cDNA libraries were prepared with 4 µg total DNA using TruSeq RNA sample Preparation Kit to obtain cDNA fragments of 229 bp average size, or 355 bp including adapter sequences. All 20 cDNA libraries were sequenced with 150 bp paired-end read using the Illumina HiSeq 2000 system.

Quality reads were aligned to *Gallus gallus* 5.0 using STAR aligner v.2.5.2b (Dobin *et al.*, 2013). Hit counts were counted using featureCounts v.1.5.2 (Liao *et al.*, 2014), using only unique reads. DESeq2 (Anders and Huber, 2010) was used for differential gene expression analysis. The Wald test was used to generate *P*-values and $\log_2$ fold changes (FC). Fold change were conducted for all orthogonal comparisons. Genes were considered as differentially expressed (DEGs) at FDR ≤0.05 and $\log_2$ FC>1. We performed gene ontology (GO) and KEGG pathway analyses for DEGs using ClueGo Plugin v1.x-v2.x.x within Cytoscape v3.7.2. (Shannon *et al.*, 2003). ClueGo integrated GO terms and KEGG pathways to create functionally organized pathways.

Results

Subjecting chickens to HS lead to gene expression changes in the ileum. The aldehyde dehydrogenase 7 family member A1(ALDH7A1), histidine ammonia lyase (HAL), glycine cleavage system protein H (GCSH) cholinergic receptor nicotinic Alpha 7 Subunit (CHRNA7), cholecystokinin A receptor (CCKAR), lipase G, endothelial type (LIPG) were upregulated in the HSc and the polymeric immunoglobulin receptor (PIGR), tumor necrosis factor receptor super family 13B (TNFRSF13B), relaxin 3, interleukin 8-like 1 (IL8L1) and DnaJ heat shock protein family (Hsp40) member A1 (DNAJA1) were downregulated in the HSc compared with the TNc group. The valine, leucine and isoleucine, tyrosine, lysine degradation and histidine metabolism pathways were upregulated while protein processing in endoplasmic reticulum, RNA degradation, cytokine-cytokine receptor interaction pathways were downregulated in the HSc group compared to the TNc group.

In the current study, the Aly/REF export factor (ALYREF), IL12β, hepatocyte growth factor (HGF), IL1β and integrin subunit alpha 2 (ITGA2) were upregulated while phosphoenolpyruvate carboxykinase 1 (PCK1), glucose 6 phosphatase catalytic subunit (G6PC), kynurenine-oxoglutarate transaminase 3 (KYAT3), propionyl-CoA carboxylase (PCCA) and the catalase (CAT) were downregulated in the TNi group compared with the TNc group. The RNA transport, spliceosome, toll-like receptor, cytokine-cytokine receptor signaling and proteasome pathways were upregulated while the peroxisome, PPAR, fatty acid degradation, tryptophan and glutathione pathways were downregulated in the TNi group compared with the TNc group.

When chickens under HS are infected with *E. maxima*, the genes that affect function in the ileum respond to the infection. The carnitine palmitoyltransferase 1A (CPT1A), crystallin alpha B (CPTT2) and acyl-CoA synthetase long chain family member 5 (ACSL5), relaxin 3 (RLN3) and IL8 were upregulated while acyl-CoA oxidase 3 (ACOX3), alcohol dehydrogenase 6 (ADH6) and acyl-CoA synthetase family member 1 (ACLS1) while dopa decarboxylase (DDC), indoleamine 2,3-dioxygenase (IDO), ryanodine receptor 2 (RYR2), calcium voltage-gated channel subunit alpha1 B (CACNA1B) and voltage dependent calcium channel protein (TPCN2) were downregulated in the HSi group compared to the HSc group. Among the upregulated pathways in the HSi group were proteasome, cell cycle, steroid biosynthesis and oxidative phosphorylation, however, calcium signaling, fatty acid degradation, tryptophan, neuroactive ligand receptor interaction and phosphatidylinositol pathways were downregulated in the HSi group compared to the HSc group.

Discussion

Several studies have shown that the chicken reorganizes its transcriptome to respond to stressors including heat. The current study shows significant upregulation of glycine, serine threonine, tyrosine and histidine metabolisms and lysine degradation. Several members of the aldehyde dehydrogenase (ALDH) are upregulated in the ileum. The ALDH7A1 gene encodes the enzyme antiquitin which is involved in the breakdown of amino acids, such as lysine. Lysine degradation is necessary for energy production (Brocker *et al.*, 2010). The hal gene encodes for the enzyme histidase that breaks down the histidine to form urocanic acid which is further catalyzed to form glutamic acid (Suchi *et al.*, 1995). The GCSH gene which was upregulated is part of the system that catalyzes the degradation of the amino acid glycine. The H protein (GCSH) shuttles the methylamine group of glycine from the P protein (GLDC) to the T protein (GCST) (Leung *et al.*, 2021). Most of the genes associated with amino acid networks encode for enzymes that degrade amino acids into other molecules for other functions or for the generation of energy. Heat stress causes significant reduction in feed intake leading to significant reductions in available nutrients and energy to the chicken. The data from the current study clearly indicate that, the energy need of chickens reared under HS may be partly met by degradation of amino acids such as lysine, glycine, histidine, valine, leucine and isoleucine. Downregulation of the cytokine-cytokine signaling and toll-like receptor pathways is an indication that immunity is suppressed during HS. The PIGR gene that binds to the polymeric IgA and IgM as well as the TNFRSF13B gene which is associated with immunodeficiency were downregulated in the HS uninfected group compared to the TN counterparts.

When chickens are infected with *E. maxima*, ALYREF, a nuclear protein and molecular chaperone which is involved in the spliceosome, RNA transport and mRNA surveillance is upregulated. It appears that there is a concerted effort to increase the maturation of the eukaryotic mRNA. There is a concomitant upregulation of the toll-like receptor pathway, cytokine-cytokine receptor interaction and other immune-related pathways. Several interleukins including IL10, IL22, IL10RA, IL17RA, IL12B, IL8L1, IL6R are all upregulated. Infection with *E. maxima* may increase oxidative stress and cause a reduction in the antioxidant capacity of the chicken. The peroxisome and glutathione metabolisms which play significant roles in ROS detoxification were downregulated. The PCCA gene involved in the catabolism of odd chain fatty acids, branched-chain amino acids isoleucine, threonine, methionine, and valine and other metabolites (Kalousek *et al.* 1980) was downregulated. The AU binding methylglutaconyl-coA hydratase, an enzyme critical in the leucine degradation pathway is downregulated. KYAT3 which encodes an enzyme involved in the catabolism of tryptophan is also downregulated. It appears that chickens infected with *E. maxima* modify their metabolism to reduce the catabolism of several amino acids to limit available amino acids available for scavenging by the parasite.

Chickens when infected with *E. maxima* and reared under HS tend to modify their physiology to limit the replication of the parasite (Schneiders *et al.*, 2020). Beta oxidation which is usually prominent under HS alone is reduced as evidenced by the downregulation of FA metabolism. The upregulation of CPT1A, CPTT2 and ACSL5 and downregulation of ACOX3, ADH6 and ACLS1 potentially limits the oxidation of long-chain FA. Tryptophan metabolism is also downregulated. Tryptophan (Tryp) is an essential amino acid which is catabolized to kynurenic acid. The IDO and DDC genes that are associated with the catabolism of tryptophan are all downregulated. Induction of IDO has been shown to deplete Tryp and subsequently limit the growth of *E. falciformis* in mouse (Schmid *et al.*, 2012). Tryptophan metabolism was downregulated regardless of the rearing temperature. The calcium signaling pathways was also downregulated. The RYR2 and RYR3 genes which form channels that transport Ca^{2+} are downregulated. These channels are embedded in the endoplasmic/sarcoplasm reticulum which acts as a storage center for Ca^{2+}. Calcium release might be triggered by increased cytoplasmic Ca^{2+} level due to the activation of the L-type calcium channel CACNA1B which was also downregulated in the HSi group compared with the HSc group. The ATP driven Ca^{2+} ion pump and TPCN were all downregulated. Long-chain FA, Tryp and Ca^{2+} may be among the nutrients and ions scavenged by *E. maxima* for replication, and downregulation of pathways may explain why replication of the parasite is limited under HS (Schneiders *et al.*, 2020).

Abstract

We investigated changes over time in heritability of a feed efficiency trait (FE), a carcass yield trait (CY), a growth trait (GT), and a leg disorder trait (DIS) in a broiler population. The data contained 200,093 (FE), 42,895 (CY), 203,060 (GT), and 63,349 (DIS), phenotypic records obtained over 55 mating groups then divided into 13 intervals. Pedigrees included 1,250,404 animals, of which 154,318 were genotyped. Genetic parameters were estimated with single-trait models for each interval with (GEN) and without genomic information (PED) using the BLUPF90 programs. Single-step was used in the former. Heritabilities changed from 0.38 to 0.23 (0.38 to 0.26) for GEN (PED) across performance traits and from 0.55 to 0.25 (0.55 to 0.28) for the disorder trait. Heritability estimates by PED were often higher than those from GEN, indicating bias. Genetic parameters should be updated regularly for unbiased estimation of breeding values and selection response.

Introduction

Accurate genetic parameters are crucial for unbiased estimation of breeding values and selection response in breeding programs. Genetic parameters are expected to change under selection, and the magnitude of the changes depends on the intensity of selection and the initial allele frequency (Walsh and Lynch, 2018). The additive genetic variance, and therefore, the heritability, can be reduced under selection due to the increased coancestry among animals (Walsh and Lynch, 2018). Another cause of reduction is the Bulmer effect, which creates negative linkage disequilibrium (i.e. negative covariance between pairs of loci) under directional or stabilizing selection (Bulmer, 1971). Due to strong selection, genetic parameters may change, leading to inaccurate predictions of genetic gain when using the old parameters. Thus, it is important to update the genetic parameters regularly.

Estimating genetic parameters over time is computationally costly with extensive data and under genomic selection because the genomic relationship matrix (G) is dense. According to Hidalgo *et al.* (2020), time intervals are useful to estimate genetic parameters over time so that only a fraction of the data is utilized in each analysis. Intervals need to be large enough and with sufficient data to avoid biases due to the averaged changes (Misztal *et al.*, 2021). The objective of this study was to estimate changes in heritability over time for growth, efficiency, and leg disorder traits in a broiler population under genomic selection using time intervals including or not genomic information.

Materials & methods

Data. The dataset used in this study was provided by Cobb-Vantress Inc. (Siloam Springs, AR). The whole dataset contained 200,093 phenotypes for FE, 42,895 for CY, 203,060 for GT, and 63,349 for DIS. The pedigree included 1,250,404 purebred broilers hatched over 7 years, resulting from 55 mating groups (MG). A total of 154,318 birds were genotyped with a 60K SNP panel. We defined 13 time intervals, the first interval comprised seven MG, and the remaining 12 of these intervals comprised eight MG. Each subsequent interval had four MG of overlapping data. For example, the first interval included data from MG one through seven, the second interval included data from MG four through eleven; therefore, the MG four to seven overlapped in intervals one and two. Only the most recent time intervals in the dataset

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_590, © J. Richter *et al.* 2022

contained genotypes (i.e. from MG 24 to 55). Intervals including genotypes had, on average, 38,000 genotyped animals except for the first interval only having ~16,000 genotyped animals.

Model and analysis. Single-trait linear models were used for the efficiency, yield, and growth traits (FE, CY, GT). These linear models included fixed effects of contemporary group (CG) and sex while having a random animal effect. Variance components for the linear models were estimated using the average information restricted maximum likelihood algorithm implemented in the AIREMLF90 software (Misztal *et al.*, 2014). A single trait threshold model was used for the leg disorder trait (DIS). This threshold model included a fixed effect of sex with a random effect of CG and a random animal effect. Variance components for the threshold model were estimated using a Bayesian approach via the Gibbs sampling algorithm as implemented in the THRGIBBS1F90 software (Misztal *et al.*, 2014). A single Gibbs chain of a total length of 100,000 rounds was initially generated. After discarding the initial 10,000 samples as burn-in, 1 in every 10 samples were stored to compute means and standard deviations of the posterior distributions. The means were used as estimates of the variance components, and their posterior standard deviations were considered a measurement of their estimation errors. The analyses to estimate variance components for all traits were performed, including (GEN) or not the genomic information (PED) for each interval.

The full form of the linear models was:

$$y = Xb+Za+e, \quad (1)$$

where y is a vector of phenotypes; b and a are vectors of fixed and random animal effects, respectively; X and Z are incidence matrices for b and a respectively; and e is a vector of random residuals.

For the categorical trait (DIS), the threshold model assumed an underlying distribution L. The model was:

$$L = X_l b_l + Z_l a_l + W_l c_l + e_l, \quad (2)$$

where L is a vector of underlying distribution of phenotype y; b_l is a vector of systematic effects; a_l is a vector of random animal effects; c_l is a vector of random CG effects; X_l, Z_l, and W_l are incidence matrices for b_l, a_l, and c_l, respectively; and e_l is a vector of random residuals for this threshold model. During the estimation process, the residual variance for DIS was fixed to 1 so that the model is identifiable.

Results

The posterior means and standard deviations for heritabilities estimated by GEN and PED are shown in Figure 1 for broiler performance and leg disorder traits; heritabilities for DIS are presented in the liability scale. Changes in heritability estimated by GEN (PED) from the first to the last interval, that is from 1-7 to 47-54 MG were from 0.31 to 0.19 (0.31 to 0.20) for FE, 0.60 to 0.38 (0.60 to 0.45) for CY, 0.25 to 0.11 (0.25 to 0.13) for GT, and 0.55 to 0.25 (0.55 to 0.28) for DIS.

Discussion

Although there was an overall decline, heritabilities seemed to stabilize during the last four intervals for FE, CY, and DIS. The stabilization of heritabilities happens because the recombination between unlinked loci removes linkage disequilibrium, regenerating genetic variance (Bulmer, 1971). Villanueva and Kennedy (1990) proved that a recombination-linkage disequilibrium is achieved after several generations of selection; therefore, the genetic variance and heritability will stabilize, provided that other components of the heritability remain unchanged.

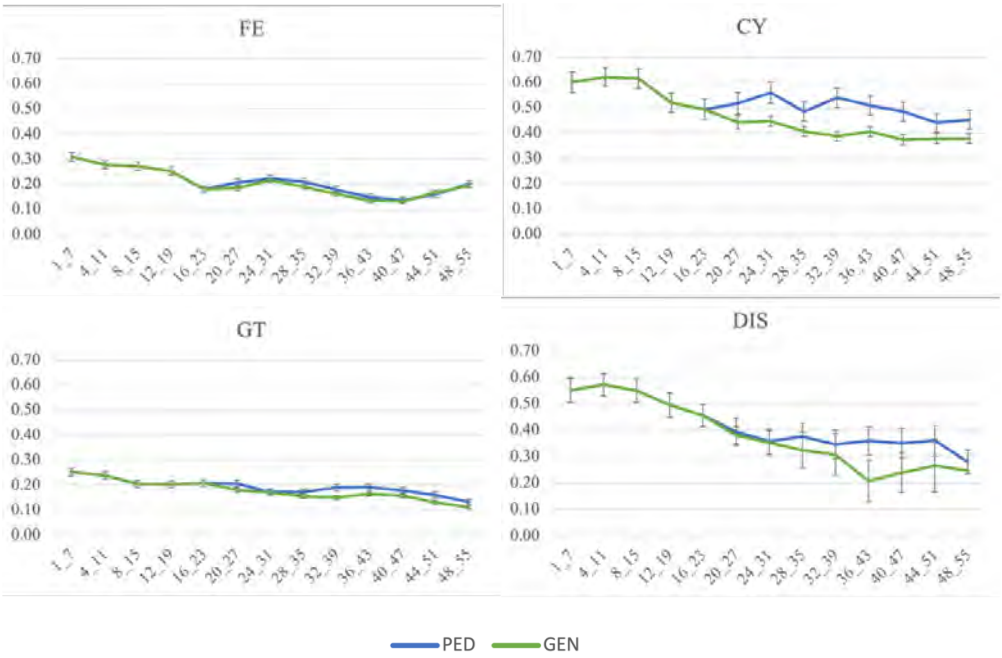

Figure 1. Posterior means and standard errors for estimated heritabilities for FE, CY, GT, and DIS estimated with (GEN) or without genotypes (PED). Heritabilities for all traits decreased over time.

Changes in heritabilities over time were similar with and without the inclusion of genomic information for FE; however, the heritability estimates by PED for CY, GT, and DIS were higher than those from GEN. Our results agreed with those found by Hidalgo *et al.* (2020). Those authors concluded that heritabilities estimated by GEN and PED were similar for traits under less intensive selection, in contrast, heritabilities differed for traits more intensively selected. Selection reduces heritabilities; therefore, it is important to update genetic parameters regularly to have unbiased estimation of breeding values and selection response. Heritability estimates may be biased if genomic information is ignored. This is a topic under further investigation.

Abstract

The White Striping (WS) is one of the most prevalent pectoral myopathies in chickens affecting meat quality. Its etiology, as well as the influence of diet, age and line, remains unclear. Therefore, effects of broiler line, nutrition and age were investigated to better understand and identify possible causative mechanisms triggering the onset and the progression of WS myopathy in the breast of broiler chickens. The most relevant macroscopic lesion observed was white striations on the surface of the breasts. For the lesion identified macroscopically, Ross had an odds ratio of 8.43 in relation to TT line, while for the microscopic lesion the odds ratio was 22.52. The high-performance diet had an odds ratio of 1.76 in relation to the regular diet for the macroscopic lesions only. Therefore, we have shown that the presence of WS increases with age even in broiler lines that have slower growth rate than commercial lines.

Introduction

In recent years, pectoral myopathies are among the main challenges of the poultry industry, since they negatively affect the sensorial and technological quality of meat (Kato *et al.*, 2019). Among the disorders that affect the breast muscles of fast-growing broilers, one of the most prevalent is the White Striping (WS), which consists macroscopically of the presence of superficial striated fat deposition that runs parallel to the muscle fibres. It affects meat quality, increasing the downgrading percentages and condemnation of breast fillets (Kuttappan *et al.*, 2013). The histological features mostly observed are myodegeneration, interstitial inflammation, infiltration of connective tissue and lipidosis (Vanhatalo *et al.*, 2021). The etiology of pectoral myopathies has been associated with several factors, from the rapid growth rate to the high-calorie diets and specific genotypes (Petracci, *et al.*, 2015). Moreover, heritability estimates for WS in different broiler lines suggest a relevant genetic component for the manifestation of WS (Lake *et al.*, 2021). Nowadays, whole transcriptome studies are making it possible to advance in the knowledge of the genetic mechanisms associated with WS (Marchesi *et al.*, 2018). However, a large amount of data from studies evaluating the physiological and histopathological changes in the *Pectoralis major* muscle across ages and lines are essential to achieve a comprehensive picture of the disorder. Hence, effects of broiler line, nutrition and age were investigated to identify possible causative mechanisms triggering the onset and the progression of WS myopathy in the breast of broiler chickens.

Materials & methods

This study was conducted with two lines of broiler chickens: a paternal broiler line developed by the Embrapa Swine and Poultry National Research Centre called TT and a commercial line of fast-growing broilers Ross AP 91. The TT pure line has been maintained under multi-trait selection, in open sided poultry houses, since 1992, in Concordia, Santa Catarina State, in the south of Brazil. The main traits under selection in TT pure line are body weight (BW), feed conversion, breast size (mass selection), carcass and cuts yield, abdominal fat (indirect selection based on non-selected sibs), fertility, hatchability of fertile eggs and chick viability (independent culling levels). For more information see Marchesi *et al.* (2018).

Experimental design. In this study, a 2×2 factorial design was used, with two broiler lines (Ross and TT) and two diets (normal and superior). About 2000 male broilers were raised in 60 boxes with 34 animals each. The diets were recommended for regular (2950-3050 kcal ME/kg; 24.4-21.2% CP) and high performance (3,250-3,200 kcal ME/kg; 22-24% CP) of broilers, according to the Brazilian Tables for Poultry and Swine (Rostagno, 2017).

Histopathological analysis. Approximately 30 chickens of each line and diet were weighed and slaughtered by cervical dislocation at 28, 35 and 42 days of age, following the procedures of the Ethics Committee for Animal Use (CEUA) from the Embrapa Swine and Poultry National Research Centre, under protocol # 08/2019. At necropsy, breast of all animals were visually evaluated for presence of superficial medium-to-thick white striations in the cranial part of the fillet or absence of WS (no white striations) (Kuttappan *et al.*, 2013). Subsequently, samples of 2 cm^2 from the centre-cranial part of *pectoralis major* were collected and fixed by immersion in 10% neutral buffered formalin. Fixed tissue sections were dehydrated and embedded in paraffin wax, and transverse and longitudinal fibre segment for each sample were sectioned at 4 mm and stained with hematoxylin and eosin (HE) for morphologic evaluation.

Statistical analyses. A logistic regression was applied to analyse WS as a categorical trait (0 = control and 1 = affected) with a model considering the fixed effects of age, line, diet and their interactions, which were performed using the Logistic procedure of the Statistical Analysis System© (SAS, 2012). This analysis was complemented with the evaluation of the association between the presence of the lesions with broilers body weight at slaughter. We also performed a c^2 test for the association between the micro and macroscopic evaluation of lesions.

Results

The observed means for body weight at 42 days of age (BW42) for Ross receiving the high performance diet was 3,349.93 (260.25) and for the regular diet was 3,237.97 (246.46). For the TT line, the observed BW42 was 2,809.23 (173.36) with the high performance diet and 2,806.90 (219.26) with the regular diet.

Pathology. The most relevant macroscopic lesion observed was white striations on the surface of the breasts. The main histological features of WS affected breast muscles from both broiler lines were mild to severe degeneration of muscle fibres, moderate to severe degeneration of muscle fibres associated with proliferation of connective tissue and deposition of adipocytes, and mild to severe degeneration of muscle fibres along with mild to severe increased of fat infiltrations (lipidosis).

Statistical analyses. The results from the logistic regression showed significant effects of line, diet and age for the presence of macroscopic lesions of WS in the broilers breasts. The microscopic lesions of WS were influenced only by line and age effects. There was an increase in the occurrence of lesions with age and the commercial line Ross showed more WS lesions than the TT line. Interestingly, at 28 days of age, the TT broilers showed no histological lesions (Figure 1A and 1B). For the lesions identified macroscopically, Ross had an odds ratio of 8.43 in relation to TT line, while for the microscopic lesions the odds ratio was 22.52. The high-performance diet had an odds ratio of 1.76 in relation to the regular diet for the macroscopic lesions only.

A negative association between body weight at slaughter and the presence of WS lesions was observed. However, this result was not consistent, since this association was significant for macroscopic lesions only at 42 days of age for both lines and for microscopic lesions only at 28 days for Ross and 42 days for TT (results not shown). There was a positive association ($P \leq 0.05$) between the macro and microscopic detection of WS lesions (Table 1), with an accuracy of 243/335.

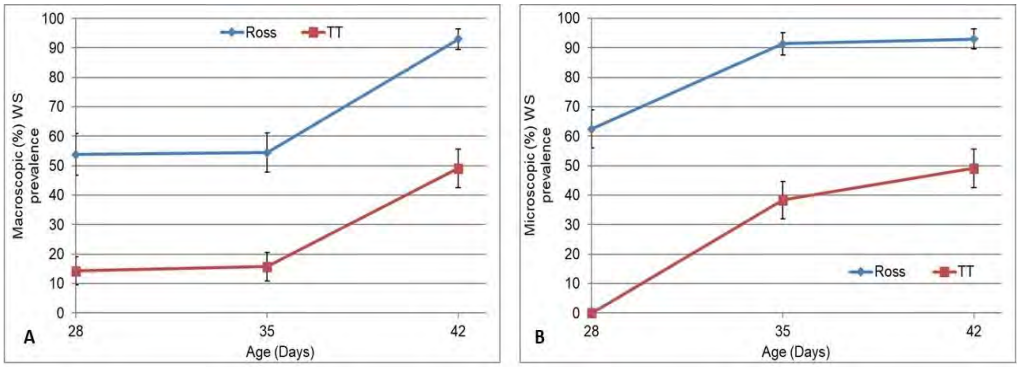

Figure 1. Prevalence and standard error of macroscopic (A) and histologic (B) presence of white striping in TT and Ross broilers breasts by age.

Table 1. Association between macroscopic and microscopic evaluation of lesions.

Macroscopic lesions	Microscopic lesions		Total
	Absent	Present	
Absent	118 (65.92%)	61 (34.08%)	179
Present	31 (19.87%)	125 (80.13%)	156
Total	149	186	335

Discussion

In the present study, histopathological changes occurring in WS indicate that the degenerative myopathy observed could be associated with increased growth rate in birds, since both gross and microscopic lesions were significantly influenced by genetic line. Swatland (1990) suggested that fast-growing broilers have muscles that outgrow their life support systems causing muscle damage. Moreover, it was observed an increase in the occurrence of lesions with age. The prevalence of WS lesions in the commercial line was much higher than in the TT in all evaluated ages, although the shape of the curves was similar. Interestingly, at 28 days of age, no microscopic lesion was detected in TT broilers. This result can be explained because the TT line was in its 27th generation of annual selection, while the commercial lines are originated from many more generations of continuous selection. The high performance diet was used especially to try to induce TT to develop white striping, as this line is a slower-growing line compared to Ross. The reason for the high-performance diet had an effect only in the macroscopic lesions of WS is still to be clarified. In our study, the association of WS lesions with body weight was significant only for specific ages, although we have not evaluated this association with breast weight and yield. We also observed a high concordance between the macro and microscopic detection of WS lesions, especially when WS was present.

Selection for breast yield traditionally focus on ages targeting hypertrophy, which occurs normally between 6 and 8 weeks of age, rather than hyperplastic growth. This results in increase in fibre size rather than fibre number, which could favour myopathies occurrence (Orlowski *et al.*, 2021). Therefore, we have shown that the presence of WS increases with age even in broiler lines that have slower growth rate than commercial lines. More physiological and histopathological data from chicken myopathies across different ages and genetic lines can provide essential information to help interpretate and better explore future integrated analyses from the omics methodologies such as RNA-seq, GWAS, exome and epigenome.

Abstract

Recombination, a feature of sexual reproduction, creates new combinations of genetic material during meiosis. Breeding strategies could benefit from an increased knowledge of recombination in avian livestock species, especially on recombination occurring in microchromosomes. We estimated recombination rates in male turkeys using medium density SNP genotype data from three commercial selection lines. Line 1 had a significantly higher genome-wide recombination rate than the other lines, however, the three lines shared the majority of the detected recombination hotspots. Recombination rate on microchromosomes was 2.3 to 2.7 times higher than on macrochromosomes. A genome-wide regression analysis was used to estimate SNP effects on crossover number. We identified several candidate genes and three functional enrichments. We have provided an updated estimate of the recombination rate in turkeys and found variation in recombination rate between lines and chromosomes.

Introduction

Recombination occurs when two homologous chromosomes break and exchange segments during meiosis. Higher recombination rates have been associated with regions that have higher GC content, the ends of chromosomes, and during meiosis in females. Recombination frequency and hotspot location have been associated with specific genes, for example, *PRDM9* and *RNF212* in mammals (Sandor, *et al.*, 2012). Simulations have shown that increasing the recombination rate in breeding program populations could improve long-term selection, by increasing response to selection and decreasing genetic variance loss (Battagin, *et al.*, 2016).

Birds and reptiles have microchromosomes, which are small, gene-rich chromosomes with a high GC content (Waters, *et al.*, 2021). Most birds species have about 31 microchromosomes that have higher recombination rates, mutation rates, number of interchromosomal interactions, and have more open chromatin than macrochromosomes (Aslam, *et al.*, 2010; Axelsson *et al.*, 2004; Perry *et al.*, 2020; Waters, *et al.*, 2021). Despite the dynamic nature of microchromosomes, proteins from their genes are highly conserved, which means that these proteins have esstential functions and microchromosomes are under greater selection pressure than macrochromosomes (Axelsson *et al.*, 2004).

Recombination within the genome of turkeys has not been well studied. Previous recombination estimates (Aslam *et al.* 2010) used 531 informative SNPs, consequently the resolution of detected crossover locations was poor. More recently, using higher density SNP genotyping, runs of homozygosity were detected in turkeys, which could give insight into recombination rate variation (Adams *et al.*, 2021). With the availability of this affordable, higher density SNP array, we have updated the estimate of turkey recombination, and characterised the variation seen across the genome, and within and between lines. This updated estimate of recombination could be used to develop and improve avian-specific breeding strategies.

Materials & methods

Samples. For this study we used 60K SNP genotype data from three turkey lines which included 1,889 individuals genotyped from line 1, 2,540 from line 2, and 2,410 individuals from line 3. We removed variants within each line that had a Mendelian error rate >0.05 or a minor allele frequency less than 0.01 using PLINK 1.9 (Purcell and Chang, 2021).

Recombination. We used LINKPHASE3 to detect crossover events in genotyped individuals with at least one parent genotyped using linkage information and a hidden Markov model to account for genotyping errors (Druet and Georges, 2015). We did not account for interference. Crossover positions were indicated by their two flanking, informative SNP markers and we averaged the two positions to simplify further calculations of the recombination rate. We calculated recombination rate as the number of crossovers divided by the physical distance. We identified recombination hotspots in sliding 1 Mb windows that had a recombination rate two and a half standard deviations greater than the genome-wide average recombination rate (calculated separately for each line).

Genome-wide association analysis. We used PLINK 1.9 to estimate SNP effects in a genome-wide association analysis of crossover number (Purcell and Chang, 2021). Phenotypes were the total number of crossovers detected in haplotypes inherited by an individual's offspring divided by their total number of offspring. We used line as a covariate in the genome-wide association analysis and the Benjamini and Yekutieli (2001) step-up false discovery method to correct the inflation of *P*-values. We used USCS Genome Browser (Navarro Gonzalez, *et al.*, 2021) to identify candidate genes based on the domestic chicken RefSeq Genes located 0.5 Mb upstream and downstream of SNPs of interest from the genome-wide analysis. Finally, we used String to identify functional enrichments in the candidate genes (Szklarczyk, *et al.*, 2019).

Results

Samples. After filtering SNPs for Mendelian errors and minor allele frequency in each line, 59,749 SNPs remained for line 1, 60,778 for line 2, and 61,704 variants for line 3.

Recombination. To accurately estimate recombination rates, only genotyped males (toms) with five or more offspring genotyped were included in our calculations. There were a total of 405 toms that fit this criterion: 84 from line 1, 159 from line 2, and 162 from line 3. There were only 12 females (hens) with genotypes that had at least five offspring (two from line 1, seven from line 2, and three from line 3) and these were removed from further analyses.

The first line had an average genome-wide recombination rate (3.9×10^{-8}) that was significantly higher than the other two lines (3.3×10^{-8} and 3.5×10^{-8}). Recombination rates for each chromosome, by line are shown in Figure 1. In general, as chromosome size decreased, recombination rate increased. Recombination rates were 2.3, 2.5, and 2.7 times higher in microchromosomes compared to macrochromosomes in the three lines respectively. A total of 28 recombination hotspots were identified, the majority of which were shared across the three lines. There were more than five times more hotspots identified on microchromosomes than on the macrochromosomes.

Genome-wide association analysis. Our genome-wide association analysis identified seven SNPs of interest. The candidate genes in the nearby regions are shown in Table 1. The String analyses identified three functional enrichments for all the candidate genes: 'biological pathways', 'molecular function', and 'cellular component'.

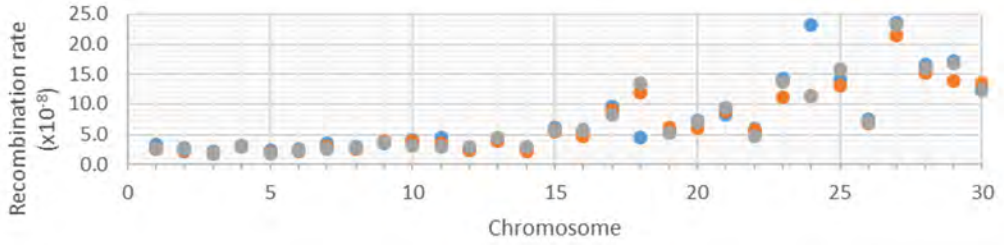

Figure 1. Male autosomal recombination rate in turkeys by chromosome and commercial selection line (line 1 (blue), line 2 (orange) and line 3 (grey)).

Discussion

Our results highlighted the variation in recombination rate across the turkey genome, within and between lines. This knowledge could contribute to future, avian-specific, breeding strategies that incorporate recombination. As with other species, recombination increased as chromosome size decreased. This was especially striking in our study because of the microchromosomes. Much of avian diversification has been attributed to the microchromosomes, which has likely been aided by this increased recombination rate (Singhal *et al.*, 2016; Axelsson *et al.*, 2004).

We didn't identify candidate genes that have been associated with recombination in other species. For example, *PRDM9*, which is associated with hotspot location and is highly conserved in mammals, is not present in most avian species including chicken (Singhal *et al.*, 2016). This has resulted in recombination hotspots in avian species that are concentrated at functional elements with greater access to recombination machinery, and highly conserved hotspots shared between species separated by millions of years (Singhal *et al.*, 2016). In agreement with this, we did not see variation in the location of recombination hotspots between turkey lines.

We identified several candidate genes including, *PSMA7*, which was a paralog of a gene, *PSMA8*, that has a role in meiotic exit and fertility in mice (Gómez *et al.*, 2019). Additionally, candidate genes had functional enrichments for: 'biological pathways', 'molecular function', and 'cellular component', with genes associated with DNA and chromatin binding, which might play a role in meiosis.

Abstract

Functional annotation of the chicken genome, especially the identification of regulatory elements, will play a significant role in identifying causative genetic variants associated with economically important traits. Using a bioinformatics pipeline that incorporates and analyzes (Chromatin Immunoprecipitation Sequencing (ChIP-seq), Assay for Transposase-Accessible Chromatin using sequencing (ATAC-seq), and RNA-seq datasets, we extend our annotation efforts to seven gut-associated tissues from two male chickens used in the FAANG pilot project. ChromHMM was used to predict a total of 15 chromatin states and 1,197,186 regulatory elements (excluding Quiescent) spanning 15 tissues (include 8 core tissues done previously) with 398,050 new regulatory elements were identified. These regulatory elements included 29,823 strong promoters, 104,560 active strong enhancers, and 73,582 repressors. This result provides a great resource for the farm animal genome community to further explore causative variants of complex traits.

Introduction

Chicken is one of most important farm animal species in the world. In addition, chicken is a model organism especially for developmental biology, immunology, and epigenetic regulation of gene expression (Beacon and Davie 2021). The Encyclopedia of DNA Elements (ENCODE) projects clearly demonstrated the important role of regulatory elements and their subsequent contribution to genetic variants associated with health and diseases (Kundaje *et al.* 2005; Gorkin *et al.* 2021). Similar to the ENCODE project, the Functional Annotation of Animal Genomes (FAANG) has made significant progress on the improvement of the annotation of farm animal genomes including chickens (Kern *et al.* 2021). Our group previously reported the annotations of functional elements of eight core tissues in chicken (Kern *et al.* 2021). However, as gene regulatory elements show distinct tissue-specific patterns that relate to biological relevant functions, more tissues in more developmental stages is needed.

In the current study, seven gut-associated tissues were further characterized. In total, 30 RNA-seq libraries, 30 ATAC-seq libraries and 150 ChIP-seq libraries are presented here. Here we present an updated annotation of regulatory elements in the chicken genome.

Materials & methods

Animals and tissues. The highly inbred Line 6 and Line 7 from the USDA, ARS, Avian Disease and Oncology Laboratory (ADOL) were intermated and two male F1 birds were grown then euthanized at 20 weeks of age. Tissue samples (15 for each bird) were flash frozen in liquid nitrogen then stored at -80 °C until further assay processing. The protocol no. 18464 for these animals was approved by Institutional Animal Care and Use Committee at the University of California, Davis.

Library preparation and sequencing. RNA-seq, ATAC-seq and ChIP-seq (H3K4me3, H3K4me1, H3K27ac and H3K27me3) experiments were performed on flash-frozen tissue samples. For RNA-seq experiments, total RNA was extracted using TRIzol (Thermo Fisher, #15596026) and treated with DNase I (Thermo Fisher, #EN0521). RNA integrity number was determined using an Agilent Bioanalyzer (Agilent Technologies, Santa Clara, CA, USA) and directional RNA-seq libraries were prepared using an NEBNext

Ultra RNA Library Prep Kit for Illumina (New England BioLabs, #E7530L) and sequenced on an Illumina Hiseq 4000 (Illumina, San Diego, CA, USA) with paired-end 150–base pair (bp) reads. For ATAC-seq experiments, libraries were generated from frozen tissue samples by a modified protocol (https://figshare.com/articles/dataset/Final_ATAC_protocol_docx/13891268) according to OmniATAC and cryopreserved nuclei protocols (Corces *et al.* 2017; Halstead *et al.* 2020). For ChIP-seq experiments, samples were processed as previous described (Kern *et al.* 2021). Libraries were sequenced on an Illumina HiSeq 4000 with read length of single-end 50 bp.

Data analysis. The UC Davis FAANG Functional Annotation Pipeline (https://github.com/kernco/functional-annotation) was applied to process the ChIP-seq, ATAC-seq, and RNA-seq data, as previously described (Kern *et al.* 2021). The galGal6 genome assembly and Ensembl genome annotation (v100) were used as reference for read alignments. ChromHMM (Ernst and Kellies 2012) (v.1.20) was used to train the chromatin state prediction model by integrating ChIP-seq (H3K4me3, H3K4me1, H3K27ac, H3K27me3, and input control) and ATAC-seq data from two biological replicates of 15 tissues.

Results & discussions

A total of 210 genome-wide sequencing datasets from 15 major tissues in chicken were used including four histone modifications (H3K4me3, H3K4me1, H3K27ac and H3K27me3), inputs control, ATAC-seq, and RNA-seq. There were 5,378,700,298 new raw reads with an average remaining retention rate of 74.94% generated in the gut-associated tissues (Table 1).

After peak calling, we obtained an average of 55,419, 68,898, 76,695, 23,655, 66,965 peaks for H3K27ac, H3K27me3, H3K4me1, H3K4me3, ATAC, with average covering 4.47%, 13.17%, 4.27%, 2.53%, and 4.58% of the entire genome, respectively (Figure 1a, b).

Table 1. Summary of sequence reads.

Assay	Raw reads	Trimmed	%	Unaligned	%	Filtered	%	Duplicates	%	Remaining	%
H3K27ac	46,196,825	52,027	0.12	1,183,361	2.57	2,393,492	5.33	8,658,969	19.91	33,908,976	73.83
H3K27me3	83,672,667	63,806	0.08	1,066,446	1.29	8,370,626	10.45	8,163,354	11.00	66,008,436	78.65
H3K4me1	47,330,470	50,216	0.13	1,031,343	2.08	3,410,564	7.52	4,776,934	11.26	38,061,413	80.32
H3K4me3	45,031,286	46,316	0.12	1,043,363	2.34	3,222,928	7.32	11,487,650	27.98	29,231,031	65.15
ATAC-seq	100,870,411	89,626	0.09	5,544,252	4.73	23,949,654	25.16	11,832,366	17.90	59,454,513	59.46
RNA-seq	61,091,219	269,064	0.46	2,992,939	4.87	1,549,822	2.61	0	0.00	56,279,394	92.22

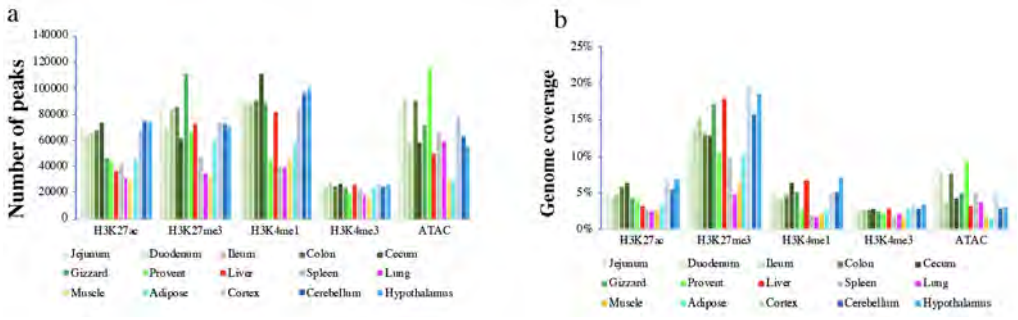

Figure 1. The summary of number of peaks and its genome coverage. a, Peak number, b peak genome coverage in each assay and each tissues.

Next, ChromHMM was used to predict 15 distinct chromatin states by combining all five epigenetic marks across 15 tissues. Each state was defined based on the combination of each marker in the previous studies (Pan *et al.* 2021) (Figure 2a). These states mainly represented promoters (TssA, TssAHet and TssBiv, covering 1.95% of the entire genome), TSS-proximal transcribed regions (TxFlnk, TxFlnkWk and TxFlnkHet, covering 1.55% of the genome), enhancers (EnhA, EnhAMe, EnhAWk, EnhAHet and EnhPois, covering 9.42% of the genome), repressed regions (Repr and ReprWk, covering 21.94% of the genome) and quiescent regions (Qui, 61.44%) (Figure 2d). In total, we identified 1,197,186 regulatory elements (excluding Qui) spanning 15 tissues, including 29,823 strong promoters (TssA), 104,560 active strong enhancers (EnhA), and 73,582 repressors (Repr). We also explored the regulator enrichment in gene element, and found that promoters had higher enrichment in TSS, 5'UTR, CpG islands than enhancers. As expected, both active promoters and enhancers were significantly enriched in the expressed gene' TSS and gene body than in the repressed genes (Figure 2e). Compared with our previous study with eight core tissues (Kern *et al.* 2021), we found 398,050 new regulatory elements (excluding Qui) in these gut-associated tissues. For the 41,802 strong enhancers (EnhA), the Gene Ontology (GO) biological process related to striated muscle cell differentiation and intestinal epithelial cell differentiation were significantly enriched, which suggest important roles of these enhancers on the regulation of genes associated with gut function.

In summary, a more comprehensive functional annotation of regulatory elements across 15 tissues in the chicken genome was generated. This resource should enhance the ability of the animal genome community to identify causative variants associated with economically important traits and further understand the function of these variants in farm animals.

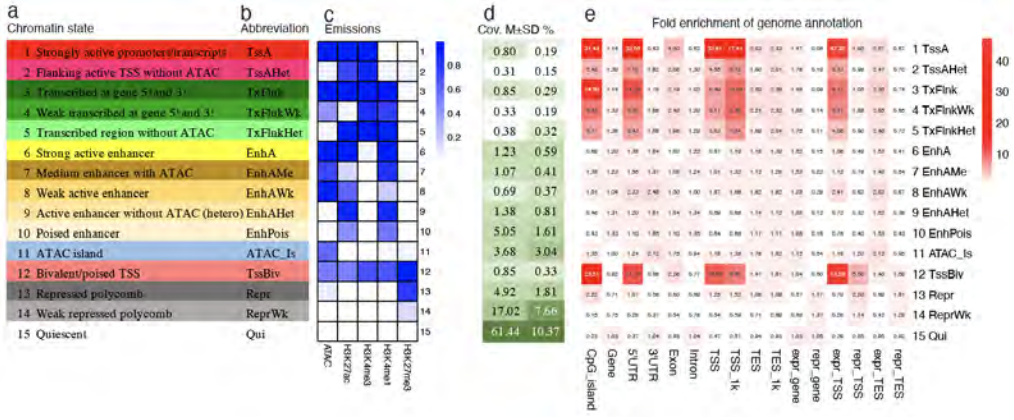

Figure 2. Prediction and characterization of chromatin states across 15 tissues. a, b, Definitions and abbreviations of 15 chromatin states. c, Emission probabilities of individual epigenetic marks for each chromatin state. The color from white to deep blue indicates emission probability (0-1). d, Genomic coverage of each chromatin state. M±SD, mean ± standard deviation. e, Average enrichment of chromatin states for genomic annotations, including CpG islands, genes, TSS/TES_1K (±1 kb around TSS and TES), expressed genes (TPM≥0.1), and repressed genes (TPM<0.1) in each tissue.

Abstract

Coccidiosis is a catastrophic disease in the chicken industry, and *Eimeria tenella* is the most critical species. To observe the response under *E. tenella* infection, RNA sequencing was used for comparison between infected and control groups. Samples were collected at 4, 7, and 21 days post-infection (dpi) from both groups. In total, 999 significant differentially expressed genes (DEGs) were detected and grouped into three clusters based on gene expression pattern and clustered to the different three groups using co-expression value. GO and KEGG analyses were conducted for each clustered group, and GSEA was performed on 4 and 7 dpi. As a result, lists of pathways and genes involved in the host response were revealed. And we observed that the innate immune system was activated initially for defence and downregulated for anti-inflammation. The significant DEGs identified in this study will be utilized for further knowledge of coccidiosis resistance in chickens.

Introduction

Coccidiosis is a parasitic disease that causes the most remarkable economic loss in the poultry industry (Blake *et al.*, 2014). Among the causative species, *Eimeria tenella* is the most pathogenic protozoan strain, mainly parasitic on the cecum and increases severe inflammations (Georgieva *et al.*, 2006). To cope with the loss by the disease, genomic selection based on immune-associated genes can be employed to develop disease-resistant animals and reduce recurring prevention costs. In this study, genes and pathways associated with the host response of broiler chickens after *E. tenella* infection were investigated based on gene expression patterns and relationships.

Materials & methods

Animals and sample preparation. A total of 39 male broilers were used and separated into two treatments; 21 birds of positive control (PC) and 18 birds of negative control (NC). The 14 days old chickens in the PC group were orally challenged with 10 times overdosed coccidiosis vaccine (Livacox® T™; Biopharm Co., Prague, Czech Republic). At the 4, 7, and 21 days post-infection (dpi), 7 birds from PC and 6 birds from NC were humanly slaughtered respectively; also the cecum tissues of them were collected. Further, the samples were stored at -80 °C with RNA-later solution.

RNA isolation, complementary DNA (cDNA) library construction, and RNA-Seq. RNA was isolated from the tissue samples using TRIzol reagent (Invitrogen, Carlsbad, CA, USA). The cDNA library was constructed using TruSeq Stranded mRNA sample preparation kit (Illumina, San Diego, CA, USA) with RNA samples. After library construction, samples were sequenced using Illumina's NovaSeq 6000 platform.

Data processing to quantify DEGs. Generated reads from sequencing were aligned to the chicken reference genome (*GRCg6a)*, and gene annotation step was conducted using *Gallus gallus* GTF v102 (Ensembl, https://www.ensembl.org). Gene expressions were calculated by the trimmed mean of M-value (TMM) algorithm. The PC and NC groups were compared at each time point to find differentially expressed genes (DEGs). DEGs were calculated based on the significance thresholds: false discovery rate (FDR)<0.05 and absolute fold change >2.

Grouping genes using expression patterns and co-expression. After defining DEGs, genes were grouped using two different ways. The first clustering method was based on the reads counts using a *k*-means clustering algorithm to categorize genes with expression patterns. For the second clustering method, the gene co-expression networks (GCNs) were constructed using correlation among gene expressions.

Functional analysis. Functional studies including gene ontology (GO) enrichment analysis and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis were conducted with each group of genes. Biological process and molecular function databases were used for GO analysis. A *P*-value less than 0.05 was set on the criteria for both analyses. Gene set enrichment analysis (GSEA) was performed using normalized reads counts of all genes at 4 and 7 dpi, and the significance was assessed with FDR less than 0.05.

Results

A total of 999 unique DEGs, containing 511, 615, and 2 DEGs at 4, 7, and 21 dpi respectively, were observed. The three *k*-means clustering groups (Type 1, 2, and 3), which comprise 436, 414, and 149 DEGs respectively, are presented in Figure 1. Three of the constructed GCNs were named GCN278, GCN53, and GCN40: 278, 53, and 40 being the number of DEGs in the respective network.

Table 1 and 2 summarise the results of GO and KEGG analysis of the entire 6 groups of DEGs, respectively. The result of GO for the Type 2 group was excluded from Table 2, as there were no significant terms.

GSEA was conducted on the GO and KEGG databases and proceeded except for 21 dpi which had a small number of DEGs observed. In the results of 4 dpi, the highest score of GO and KEGG terms for upregulation was related to the steroid biosynthesis. Additionally, the keratinization-related term was also highly significant at 4 dpi. In the case of the downregulation, only the ribosome term was identified at 4 dpi. The results of the 7 dpi KEGG database presented the functions related to the nutritional metabolism and intracellular ribosome for upregulation.

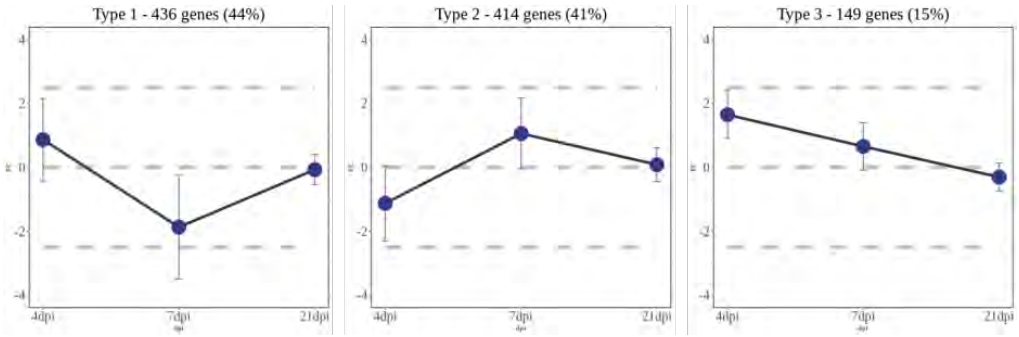

Figure 1. Three types of differentially expressed gene clusters separated based on gene expression patterns.

Table 1. GO analysis results of gene groups clustered with two different methods: expression pattern and gene co-expression. GO terms of the Type 2 were omitted.

	GO term	Count		GO term	Count
Type 1 cluster	Lipid metabolic process	12	GCN278 cluster	Signaling receptor activator activity	9
	Oxidation-reduction process	8		Hormone activity	5
	Homeostatic process	10		Cellular homeostasis	9
	Regulation of biological quality	16		Antibiotic metabolic process	4
	Regulation of hormone levels	5		Epithelium development	8
Type 3 cluster	Regulation of response to external stimulus	6	GCN53 cluster	Guanyl nucleotide binding	3
	Cytokine secretion	3		Nucleotide binding	4
	Response to organic substance	8		Defense response to virus	4
	Inflammatory response	4		Immune system process	6
	Innate immune response	3		Positive regulation of cytokine production	2
			GCN40 cluster	Protein tyrosine kinase activity	2
				Positive regulation of immune system process	3
				Antigen receptor-mediated signaling pathway	2
				Leukocyte migration	2
				Cell-cell adhesion	2

Table 2. KEGG analysis results of gene groups clustered with two different methods: expression pattern and gene co-expression.

	KEGG term	Count		KEGG term	Count
Type 1 cluster	Steroid biosynthesis	5	GCN278 cluster	Galactose metabolism	6
	Steroid hormone biosynthesis	4		Oxidative phosphorylation	8
	Cytokine-cytokine receptor interaction	10		Phagosome	8
	Linoleic acid metabolism	3		Steroid hormone biosynthesis	4
	Glycolysis / Gluconeogenesis	4		PPAR signaling pathway	4
Type 2 cluster	Drug metabolism - cytochrome P450	5	GCN53 cluster	Influenza A	7
	Metabolism of xenobiotics by cytochrome P450	5		Herpes simplex virus 1 infection	6
	ABC transporters	5		RIG-I-like receptor signaling pathway	4
	PPAR signaling pathway	6		NOD-like receptor signaling pathway	5
	Intestinal immune network for IgA production	4		Toll-like receptor signaling pathway	3
Type 3 cluster	Pentose and glucuronate interconversions	4	GCN40 cluster	Cytokine-cytokine receptor interaction	5
	Glycerolipid metabolism	3		Ether lipid metabolism	3
	Folate biosynthesis	2		alpha-Linolenic acid metabolism	2
	Phagosome	4		Glycerophospholipid metabolism	3
	ECM-receptor interaction	3		Intestinal immune network for IgA production	2

Discussion

Functional analysis results of Type 1 suggested that lipid synthesis and metabolism were activated at 4 dpi. According to Galluzzi *et al.* (2017) and Liu *et al.* (2021), endoplasmic reticulum (ER) stress is caused by *E. tenella* infection and induces the unfolded protein response (UPR) within cells. ER stress and excessive UPR disrupt cell homeostasis; therefore, lipid regulation fails. Furthermore, under the influence of ER stress, the cells tend to reduce the number of the ribosome for lessening protein synthesis and transport

(Han *et al.*, 2016, Hotamisligil, 2010). The downregulation of the ribosome term at 4 dpi in GSEA was verified for this reason. In 7 dpi, however, the ribosome term was again upregulated, possibly due to the relative relief of ER homeostasis at the particular time.

The genes belonging to the Type 3 group and GCN53 were characterized with innate immune response-based functions. It suggested that the natural immune system was initially activated following the timely expression pattern of the Type 3 group genes. According to the GCN53 KEGG result, the recognition receptor signalling pathways, as a considerable role for defence in *E. tenella* infection, were associated with the regulation of inflammation (Franchi *et al.*, 2009, Haunshi *et al.*, 2017).

Cytokine-cytokine receptor interaction term had the most significant number of genes in KEGG results of the Type 1 gene group. Further, the genes belonging to the term (*IL13RA2*, *CXCL13*, *CXCR5*, *GDF15*, *IL7R*, *IL12RB2*, *BMP7*, *TNFRSF11B*, *IL22*, and *IFNGR1*) were reported to be related with not only the inflammatory pathway but also activation of immune response (Wischhusen *et al.*, 2020, Yun *et al.*, 2000, Zou *et al.*, 1997). According to the expression patterns of the Type 1 genes, the initial innate immune responses were to defend chicken itself following downregulation of those genes was one of the mechanisms for regulating inflammation.

Abstract

Recombinant vaccine which contains immunoprotective antigens such as apical membrane antigen 1 (AMA1) has shown promising prospect in curtailing chicken coccidiosis- a global burden in poultry industry. However, understanding the naturally occurring diversity among these antigens is crucial for vaccine effectiveness. The present study aimed to determine diversity of AMA1 of *Eimeria tenella* isolates from broiler and free-range chickens in KwaZulu-Natal province of South Africa. Polymerase chain reaction (PCR) amplification of *E. tenella* AMA1 (EtAMA1) was carried out from both broilers and free-range chicken fecal samples respectively. Sequence analysis revealed low levels of diversity in broiler chickens compared to AMA1 sequences in the free-range chickens. Similarly, haplotype network analysis identified 5 haplotypes to be unique from the existing ones. This study provides baseline information on the diversity of EtAMA1 isolates from chicken farms in KwaZulu-Natal province of South Africa and is crucial to designing effective vaccines.

Introduction

The annual global productivity loss due to chicken coccidiosis has been a major concern in the poultry industry and has triggered the continuous design of effective control measures (Blake *et al.*, 2020). Control of coccidiosis through live vaccines which entails the use of live *Eimeria* parasite either in attenuated or non-attenuated form has been effective in the control of this disease. However, the cost of production of live vaccines has shifted attention to other alternatives such as recombinant vaccines. Recombinant vaccines have become popular especially with the discovery of different partially immunoprotective antigens and increase in the number of vaccine delivery systems that can be used in chickens (Clark *et al.*, 2017). The effectiveness of recombinant vaccines relies on low genetic variability among these antigens (Clark *et al.*, 2017) and as such, exploring the genetic diversity among these antigens becomes imperative. Notably among these vaccine antigens used in the design of recombinant vaccines are apical membrane antigen 1 (AMA1) and immune and mapped protein (IMP-1) (Tang *et al.*, 2019).

Apical membrane antigen 1 (AMA1) is a highly conserved microneme protein among apicomplexans. However, in *Eimeria* parasites, there is dearth of information on the diversity of AMA1 in South Africa. This study therefore aimed to determine antigenic diversity among AMA1 of *E. tenella* isolates from broiler and free-range chickens in KwaZulu-Natal province of South Africa.

Materials & methods

Sample collection and processing. Three hundred chicken fecal samples were randomly collected from January to October 2018 from 12 broiler farms together with 42 samples from indigenous chickens from different localities. Samples were collected following the procedure described by Kumar *et al.* (2014) after

DOI: 10.3920/978-90-8686-940-4_595, © A.J. Fatoba *et al.* 2022

which they were stored at 4 °C until further use. The fecal samples were screened for *Eimeria* oocyst using fecal floatation method. In both broiler and free-range chickens, one hundred and two (102) and twenty-five (25) samples respectively had *Eimeria* oocyst. From the positive samples, oocysts per gram (OPG) of feces were determined using a McMaster counting chamber following a standard protocol. Samples with OPG greater or equal to 250 OPG in broiler (n=90) and free-range (n=19) were selected for DNA extraction.

DNA extraction and PCR amplification of Eimeria tenella. QiaAmp DNA stool Mini Kit (Germany) was used for the extraction of genomic DNA based on the manufacturer's protocol with minor modifications. Agarose gel (1.5%) and Nanodrop™ 1000 spectrophotometer (Thermo Scientific, USA) at 260 nm absorbance were used to check the quality and concentration of the extracted DNA. PCR protocol targeting internal transcribed spacer 1 region of the genome was carried out. After the detection of *E. tenella*, primers were designed with primer3 software to amplify EtAMA1 and the amplicons were sent for sequencing at Inqaba Biotech (South Africa).

Sequence analysis, polymorphism and statistical analyses. Sequences were edited, trimmed and consensus sequences were generated using BioEdit version 7.0. Sequences were further compared with published EtAMA1 sequences in the GenBank using BLAST tool and multiple sequence alignment was done using ClustalW programme in MEGA version 6.0. Nucleotide diversity was calculated using both the number of mutation and the sliding window method (100bp length and step size of 25bp). The number of haplotypes (*H*), haplotype diversity (*Hd*), average number of nucleotide difference (k), and polymorphic sites were also calculated with DnaSP 5.10.01 software. Haplotype median-joining network of the AMA1 sequences in this study and other sequences in the GenBank were constructed with Network software version 5.0 (http://www.fluxus-engineering.com). The ratio of non-synonymous to synonymous substitution (*dN/dS*) was calculated using Nei-Gojobori method (Jukes-Cantor correction) and significance was tested with Z-test using MEGA version 6.0. Departure from neutrality was evaluated using Tajima's D, Fu and Li's D* and Fu and Li's F* based on the following: (1) the number of mutations at ($P<0.05$); (2) sliding window of 100bp with a step size of 25bp.

Results

Comparison of genetic diversity between EtAMA1 sequences of broiler chicken in this study and Genbank sequences. As shown in Table 1, comparing the EtAMA1 sequences of broiler in this study with the retrieved EtAMA1 sequences from the Genbank generated 135 polymorphic sites. Nucleotide and haplotype diversities of 0.458 and 0.795 were obtained respectively from this comparison. Also, Tajima's D (1.869; $P>0.10$) showed non-significant balancing selection while Fu and Li's D** (1.561; $P<0.02$) and Fu and Li's F** (1.749; $P<0.02$) all had significant positive values which are indication of balancing selection. On the contrary, a synonymous to non-synonymous mutation (*dN/dS*) of 0.889 was obtained, indicative of a negative or purifying selection on the EtAMA1 sequences. Further analysis using sliding window technique of 100bp and 25bp step size showed all the three (3) parameters of selection with significant positive values at some nucleotide positions.

Comparison of genetic diversity between EtAMA1 sequences of free-range chicken in this study and Genbank sequences. Nucleotide and haplotype diversities of 0.367 and 0.727 respectively were obtained when the sequences of EtAMA1 from free-range chickens were compared with sequences from the Genbank. The three selection parameters: Tajima's D (-0.376; $P>0.10$); Fu and Li's D (0.754; $P>0.01$) and Fu and Li's F (0.488; $P>0.01$) all had negative and positive values but were non-significant (Table 1). Similarly, a contrasting positive or balancing selection was indicated by the synonymous to non-synonymous mutation value of 1.282. Sliding window techniques of 100bp and 25bp step size also showed the gross insignificance of values of these three parameters.

Table 1. Comparison of genetic diversity between EtAMA1 sequences from broiler and free-range chicken in this study and Genbank sequences.[1]

Chicken type	Antigen	N	S	$\pi \pm$ S.D	*dN/dS*	k	*H*	*Hd* $\pm$ S.D	Tajima's D	Fu and Li's D*	Fu and Li's F*
Broiler	EtAMA1	13	134	0.458±0.050	0.889	62.6	7	0.795±0.109	1.869	1.561**	1.749**
Free-range	EtAMA1	11	140	0.367±0.076	1.282	50.3	6	0.727±0.144	-0.376	0.754	0.488

[1] N: number of sequences tested; S: segregating or variable sites; π: nucleotide diversity based on jukes cantor; k: average number of nucleotide difference; H: number of haplotypes; Hd: haplotype diversity.

Discussion

In this study, higher diversity parameters were observed in EtAMA1 sequences from indigenous chickens compared to broilers chickens when the sequences were analyzed with GenBank sequences. This is in contrast to the report of Blake *et al.* (2015) who reported low levels of diversity of EtAMA1 sequences from different geographical regions. The scavenging life-style of indigenous chickens exposes them to myriad of diseases (Bettridge *et al.* 2014). This could contribute to the high level of diversity of EtAMA1 sequences among indigenous chickens in this study compared to broiler chicken production with intensive management system. In addition, analysis of selection signatures for EtAMA1 sequences in this study and those retrieved from Genbank were also performed and non-synonymous to synonymous substitution parameter (*dN/dS*) values of 0.889 and 1.282 were obtained for both broiler and indigenous chickens respectively which indicate both purifying/negative and positive selections. Due to this contrasting result of diversity parameters, *dN/dS* has been criticized as poor evaluator of selection signatures among *Eimeria* vaccine candidates. Similarly, considering the insignificant values of neutrality parameter (Tajima's D) for EtAMA1 in this study, EtAMA1 is under neutral selection. Although few significant values were obtained for Fu and Li's F* and Fu and Li's D* neutrality parameters in this study, we are of the opinion that this contrasting result could be due to the partial length of EtAMA1 sequenced in this study compared to the full-length of EtAMA1 reported by Blake *et al.* (2015). In conclusion, this study confirmed low diversity among EtAMA1 sequences in the study area which potentially indicated the reliability of this as a vaccine candidate. However, further studies on AMA1 in this region are still necessary possibly with larger sample size and full-length sequences of EtAMA1 from different provinces of South Africa.

596. Chicken quantitative traits follow the omnigenic model

P. Davoodi, A. Ehsani*, R. Vaez Torshizi and A.A Masoudi

Tarbiat Modares University, 14445-336, Tehran, Iran; alireza.ehsani@modares.ac.ir

Abstract

To comprehend the association structure between genome and complex traits, we investigated the different aspects of the novel omnigenic model for 23 traits in six trait categories in F2 cross-bred chickens from the perspectives of association signals, genomic heritability, overlapped genes, and predicted gene networks. In the current study, the high SNP-based heritability was obtained when the genetic architecture of traits was predominantly additive and non-significant markers contributed greater to explaining heritability. Moreover, we distinguished overlapping genes among apparently distinct traits indicating that traits are not inherited independently. The findings showed that the GWAS signals (core genes) were few and on average with greater beta effect sizes. Conversely, peripheral genes with non-significant effects appeared highly with co-expression connectivity in predicted gene networks. All results together allowed us to experimentally infer the highlighted role for peripheral genes in chicken's complex traits which supports the establishment of the 'omnigenic' model.

Introduction

For a long time now, the main goal of animal genetics has always been genetic progress in economic phenotypes alongside discover the relationship between genotype and phenotype. The power of genome-wide association studies (GWAS) to detect an association between genomic markers and a trait is strongly limited by the experimental sample size, trait's genetic architecture, and stringent significance threshold. Therefore, the genetic association with quantitative traits seems to be undetectable by GWAS (Visscher *et al.* 2017). There is still a complex maze from sequence to biological consequence besides the environment, which can cause phenotypic variation and make this involute route even more complicated. Because the two main models of infinitesimal and finite loci, despite their advantages in genetic studies, have some inconsistencies and shortcomings (Visscher *et al.* 2012, Nelson *et al.* 2013, Turelli 2017, Visscher *et al.* 2017), the researchers attempt to answer the demand for a new model, namely the omnigenic model, for comprehensive genetic interpretation (Boyle *et al.* 2017). According to this model, there is a small number of 'core genes' having a direct biological effect on a particular trait, and also there is a large number of regulatory genes that contribute to the expression of quantitative traits. Because the 'peripheral genes' are much greater than the number of core genes affecting a trait they explain more fractions of heritability (Boyle *et al.* 2017, Liu *et al.* 2019, Mathieson 2021). In recent years, the omnigenic model has been studied in human disease (Peedicayil and Grayson 2018, Rammos *et al.* 2019) and on the behavioural traits of Drosophila Melanogaster (Zhang *et al.* 2019). However, no results of the omnigenic model have been so far reported for farm animals. Therefore, the present study aimed to investigate whether the distinct groups of quantitative traits in broiler chickens follow the omnigenic model.

Materials & methods

Up to 312 chickens for different traits in the F2 population descended from reciprocal crosses between the Arian line and Iranian native Urmia chickens were used as the experimental population. All congruent approaches of GWAS, SNP-based heritability, heritability partitioning, finding overlapped genes, and gene network prediction were performed to establish if there was an omnigenic model present across the different groups of quantitative traits including growth-related traits, feed efficiency-related traits, immune-related traits, blood parameters, carcass-related traits, and plumage colour. GWASs were performed using the mixed linear model with the leave one chromosome out (LOCO) approach. The model includes the

overall mean, covariate variables of sex and first principal component and SNP effects (fixed effects), polygenic effects (random effects), and residual effects (random effects). For estimating the phenotypic variance proportion explained by all SNPs, the Genome-based restricted maximum likelihood (GREML) method was applied. GWASs and estimation of SNP-based heritability and heritability partitioning were performed on GCTA (Yang *et al.* 2011, Stanton-Geddes *et al.* 2013). SNP-based heritability was partitioned into four groups of significant, suggestive, non-significant, and all SNPs to determine the contribution of each group to explain phenotypic variation. Overlapped genes were discovered by the GALLO R package by using suggestive genes for each trait and accounting for pleiotropic genes (Fonseca *et al.* 2020). Integrative network prediction was performed on Cytoscape through GeneMANIA to discover different sources of gene-gene connections among significant genes in six groups of traits (Montojo *et al.* 2014).

Results

GWASs performed on 23 chicken traits, and the 44 annotated genes related to the significant markers were used for further studies. The SNP-based heritability for 23 traits and the heritability contribution explained by significant, suggestive, non-significant, and all SNPs are shown in Figure 1. The results indicated that non-significant SNPs can explain the majority of genomic heritability in each trait (orange line in Figure 1). In contrast, significant SNPs resulting from GWASs in all traits explained tiny parts of heritabilities (red line in Figure 1). Furthermore, integrated network analysis of 44 coding genes related to six groups of chicken traits (Figure 2, Left) has consisted of 51.61% of co-expression, 16.62% of genetic interactions, 16.17% of physical interactions, 7.17% of co-localization, and 6.72% of pathways. Co-expression was the dominant type of connection in this network. In the predicted gene network only black circles with the first letter of the trait categories are defined as core genes for the certain trait and other circles act as peripheral genes. Also, the overlapped genes insignificant level depicted in this network (Figure 2, Left) by including the first letter of traits on black circles (gene) so the black circles that possess more than one letter indicate, that gene affects more than one trait. Moreover, we distinguished overlapping or pleiotropic genes among apparently distinct traits with a heat map matrix of shared genes using suggestive genes (Figure 2, Right), which indicates that traits are not inherited independently and common genes or variants can affect them simultaneously.

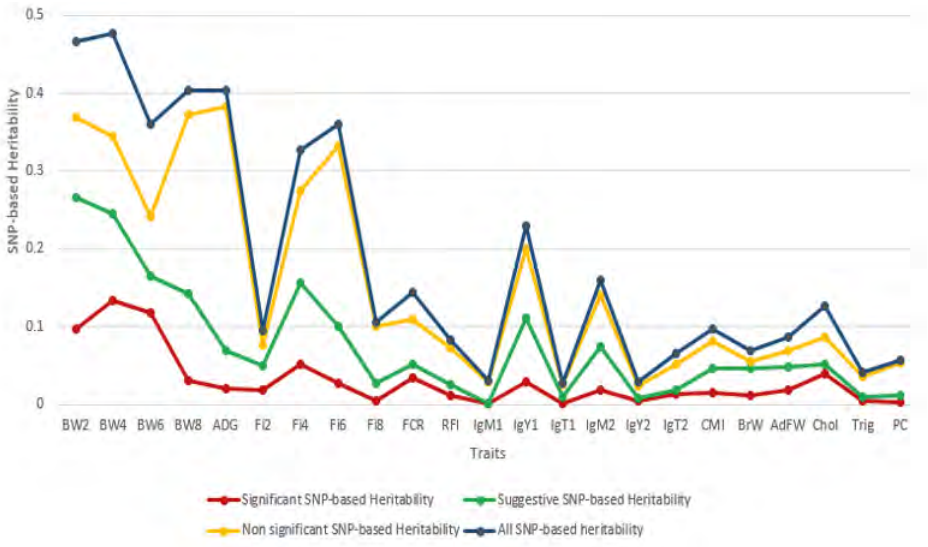

Figure 1. Heritability is explained by significant, suggestive, non-significant, and all SNPs.

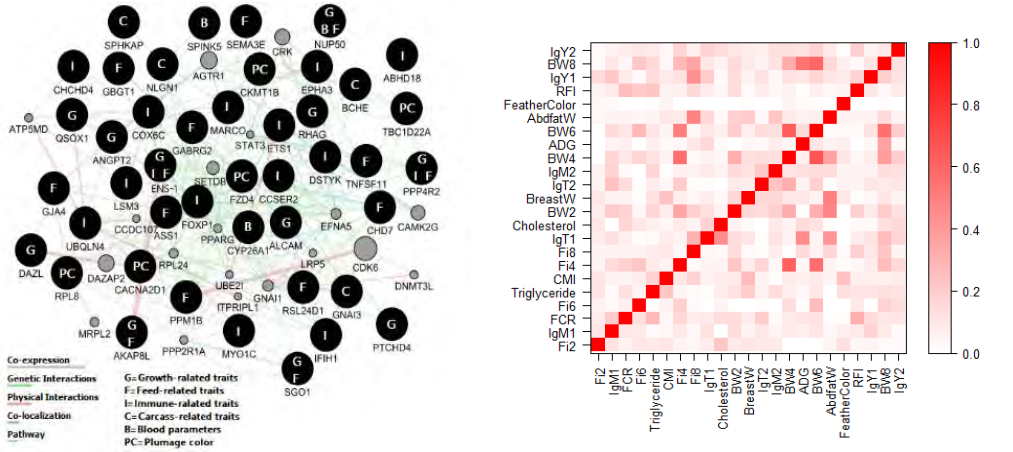

Figure 2. Left; An integrated network of 44 genes related to six groups of chicken traits. Right; the heat map matrix of overlapped genes among 23 traits in suggestive gene level (2,000 genes).

Discussion

From the results of the heritabilities partitioned into significant, suggestive, non-significant, and all SNPs, non-significant SNPs explained the highest phenotypic variation, which is in agreement with previous results (Yang *et al.* 2010, Wood *et al.* 2014). The overlapped genes in different trait groups support the evidence of pleiotropy among traits, implying that traits are not inherited independently. According to GWAS results, the core genes (related to the significant SNPs) were few with additive and traceable effects through GWASs, but they explained only a small part of the trait' heritability because they were small in number. On the other hand, peripheral genes (genes annotated for non-significant variants) were not strictly detectable individually due to their small effect sizes in genomic scans, but they were very large in number (perhaps all non-significant variants in GWAS). Therefore, their cumulative effects were much greater than the effect of significant variants (Figure 1). Furthermore, the gene network with a dominant level of co-expression in the current study and SNP-based heritability estimation revealed that the omnigenic model has better conformity to the genetic architecture in chicken traits than the polygenic model. Surprisingly by adding any gene set, even randomly selected genes, we achieved a connected gene network (not shown). It has been interesting to obtain a set of agreements with other researchers (Boyle *et al.* 2017, Shen and Shi 2017) in the light of the omnigenic theory in chickens' quantitative traits, which offers the bipartite genetic involvement in the development of complex traits, including the direct effects of core genes and the indirect effects of peripheral or helping genes. Overall, low and high contribution of significant and non-significant SNPs respectively on heritability, the high level of co-expression in a gene network, and the presence of overlapped genes experimentally support the establishment of the omnigenic model which highlights the role of peripheral genes in chicken's complex traits.

Abstract

Prior studies on the transcriptomes of the hypothalamus and ovary revealed that *MAP3K8* is one of the candidate genes that might affect egg production in White Muscovy ducks. However, the functional role of this gene in the egg production traits of Muscovy ducks remains unknown. We first examined the relative expression profile and then identified variants within *MAP3K8* that may affect egg production traits (age at first egg (AFE), number of eggs at 300 days (N300D), and number of eggs at 59 weeks (N59W)) in 507 ducks. A total of seven mutations were identified and association analysis of the single nucleotide polymorphism (SNPs) with egg production traits showed variations at g.148303340 G>A, g.148303208 T>C, g.148290065 A>G, and g. 148290061 A>T of *MAP3K8* with number of eggs at 59weeks. This study sheds new knowledge on the molecular mechanism that might be regulating egg production traits in Muscovy ducks.

Introduction

Muscovy duck (*Cairina moschata*) was first domesticated in South America (Stahl 2005; Stahl 2008) and later introduced to Asia, Africa, and Europe (Rojas and Arias-Sosa 2021). In China, black and white Muscovy ducks are commonly raised. Previous studies on the transcriptomes of the hypothalamus and ovarian revealed several pathways related to egg production, including MAPK signaling, ECM-receptor interaction, and Apelin signaling pathway. These pathways were identified using the highest and lowest egg-producing White Muscovy ducks (Bello *et al.* 2021). However, the functional roles of *MAP3K8* on the tissues and egg production traits of Muscovy ducks remain unknown. *MAP3K8* gene has been assumed to be involved in the MAPK signaling pathway which in turn participates in LH and FSH-induced steroidogenesis in granulosa cells (Seger *et al.* 2017). *MAP3K8* was predicted as a target gene of miRNA-509-3p that promotes the secretion of oestradiol (Huang *et al.*, 2016), which is an important hormone in egg ovulation. Interestingly, MAP3K8 was found to be associated with the MAPK pathway which was one of the enriched pathways that affect egg production in our previous study (Bello *et al.* 2021). Although, the functional roles of *MAP3K8* in the tissues and egg production traits of white muscovy ducks remain unknown. Thus, we first examined the mRNA expression of *MAP3K8* in eight tissues and also evaluated the polymorphism of *MAP3K8* gene and its association with egg production traits to identify genetic markers for the improvement of egg production of White Muscovy ducks.

Materials & methods

Experimental animals. Same experimental birds used in our previous study (Bello *et al.* 2021).

DOI: 10.3920/978-90-8686-940-4_597, © S.F. Bello *et al.* 2022

Blood sampling and DNA extraction. 2 ml of blood was collected from individual Muscovy ducks through their wing-web into EDTA tubes at 56 weeks of age. Genomic DNA was extracted from the 10µl whole blood of the individual Muscovy ducks using E.Z.N.A.™ NRBC Blood DNA kit (OMEGA, Bio-tek, USA). All DNA samples were diluted to a working concentration of 50 ng/µl and stored at -20 °C for further use.

Collection of tissue samples. Based on the number of the egg at 59weeks, the four lowest (LP) and four highest producing (HP) Muscovy ducks within the same egg number from each group were selected for tissues collection. The eight selected ducks were slaughtered, and eight different tissues, including the cerebrum, cerebellum, etc. were collected.

Primer design, PCR amplification, SNP detection, PCR amplification of SNP sites and genotyping by DNA sequencing. *MAP3K8* has 10 exons and is located on chromosome 2 (148288602-148307555bp) with the accession number 101791769 of the *Anas platyrhynchos* (mallard) genome. Seven pairs of primers were designed to amplify different regions of this gene. DNA mixed pool was constructed with 10µl DNA sample each of 20 randomly selected individuals with equal concentration. The PCR products were sequenced directly using the ABI-3730XL DNA analyzer (USA) by Sangon Biotech Company (Guangzhou, China). Trimming and alignment of sequences, and SNP discovery were conducted using SnapGene® 4.3.6 software.

RNA extraction and synthesis of cDNA. Total RNA was extracted from the eight different tissue selected using MagZol Reagent (Magen, Guangzhou, China). Then, total RNA samples were reversely transcribed to cDNA using HiScript® II RT SuperMix for qPCR (+gDNA wiper) (Vazyme Biotech Co, Ltd. Cat# R223-01).

Primers and quantitative real time-PCR (qRT-PCR). Primers were designed according to the NCBI database sequences of the *MAP3K8* with Accession number XM_027450562.2 using Primer premier version 5.0 software (Applied Biosystems). The MonAmp™ ChemoHS qPCR kit (Monad, Suzhou, China, Cat# MQ00401) was used to perform qRT-PCR. The qRT-PCR reaction was performed in CFX96 (Bio-Rad, United States).

Statistical analysis. Association analyses of single nucleotide polymorphisms with egg production traits of 507 Muscovy laying ducks were analyzed using the GLM procedure in SPSS 21.0. The significant differences between the average expression of the LP and HP tissues were examined with a t-test. Differences between the genotypes were analyzed using SPSS 21.0 (IBM, Chicago, IL, United States). The difference with P-value≤0.05 was considered significant in analyses. The model below was adopted: $Y_{ijkl} = \mu + K_i + L_j + M_k + e_{ijkl}$, where: Y_{ijkl} = phenotype of the egg production traits, such as age at first egg (days), number of eggs at 300 days, and number of eggs at 59 weeks; μ = population mean; K_i= fixed effect of the SNP genotypes; L_j = fixed effect of the Sire; M_k = fixed effect of the Dam; e_{ijkl}= random error.

Results

Sequences and variation at AKT3 gene. Amplification of *MAP3K8* gene was done using seven pairs of primers to determine the specific locus carrying the mutation. Further, only two of the designed primers showed seven significant SNP sites when aligned with the reference genome of *Anas platyrhynchos* (mallard). Three variation sites were identified at the exon 3 (g.148303340 G>A, g.148303241 G>C and g.148303208 T>C) while four variations were detected at the intron 9 (g.148290274 T>C, g.148290240 G>A, g.148290065 A>G and g.148290061 A>T). In addition, we did not observe any synonymous amino acid substitution at these SNPs sites. These variations were further used to test their association with egg production traits in 507 Muscovy ducks.

Association analyses of AKT3 with egg production traits

The association between the seven *MAP3K8* polymorphic sites and egg production traits (age at first egg laid, the number of eggs at 300 days of age, and the number of eggs at 59 weeks of age) were analyzed using 507 ducks samples. The least-square mean and standard error of mean (SEM) values of genotypes of each significant SNPs for egg production traits are shown in Table 1. There is a significant difference (P>0.05) in the genotypes of g.148303340 G>A, g.148303208 T>C, g.148290065 A>G, and g.148290061 A>T with the number of eggs at 59 weeks (Table 1).

Relative expression level of MAP3K8 gene in the tissues of White Muscovy ducks. The pattern of the mRNA level of *MAP3K8* across the ovary, oviduct, and hypothalamus. In the three tissues, the mRNA expression of the *MAP3K8* gene in HP ducks is significantly (P<0.01 or P<0.5) higher than in the LP with the *MAP3K8* expression highest in the oviduct among the three (Figure 1a). Cerebrum, cerebellum, and pituitary tissues had similar expression trends of the *MAP3K8* gene in the HP ducks, while the pituitary of the HP ducks showed the highest expression levels of the *MAP3K8* gene (Figure 1b). We found significantly higher expression of *MAP3K8* in HP's subcutaneous and abdominal fats compared to the LP counterpart (P<0.001). Although, the abdominal fat of the LP had a lower expression of *MAP3K8* when compared to its subcutaneous fat (Figure 1c). Together, this result suggests that there is variation in the expression of *MAP3K8* in the eight selected tissues of HP and LP.

Discussion

The study of genes that are linked to economic traits is one of the important aspects of animal breeding to aid improvement. Egg production is a major economic trait of poultry species (Bao *et al.* 2021) which declines with ovarian aging (Hao *et al.* 2021). In this study, pituitary has the highest mRNA level. It has been reported that MAP3K8 is highly expressed in the brain (Banerjee *et al.* 2006). g.148303340 G>A, g. 148303208 T>C, g. 148290065 A>G, and g. 148290061 A>T were significantly (P<0.05) associated with number of eggs at 59 weeks.

Abstract

Bone weakness is a key challenge in laying hens. Detailed measurements on layers' bone combined with genotypes via GWAS analysis would identify QTLs affecting bone health. Infrared spectroscopy and thermogravimetry measurements on tibia and humerus medullary and cortical bones of 924 Rhode Island Red laying hens, were performed and combined with genotypes (57k SNP markers) for GWAS analysis. The results showed 13 SNP markers significantly ($P<10^{-5}$ to $<10^{-7}$) associated with tibia cortical lipid (chromosomes 2 and 3), humerus medullary score (chromosome 9), and tibia cortical mineral content (chromosome Z). Further analysis is needed to determine the potential correlations (LD) between these significant markers and other QTL throughout the Rhode Island Red genome.

Introduction

Most laying hens display a high tendency to suffer from bone damage (deviations or fractures), which is a major welfare challenge in the egg industry. Gregory and Wilkins (1989) reported ~30% of commercial layers with at least one bone fracture. Another recent study reported ~70% of keel bone fractures in Danish laying farms (Thøfner *et al.*, 2021), this may be due to an increase of alternative housing systems. Housing, nutrition and genetics all contribute to bone health; the genetic component is particularly relevant in White Leghorn and Rhode Island Red breeds as they both represent the main grandparents of commercial layers.

To better understand bone health in these breeds, a detailed bone phenotyping (~55 traits) study was performed, including measurements for medullary and cortical bone separately in addition to whole bone strengths, egg production, and body weights (Dunn *et al.*, 2021). The medullary measurements showed 0.18-0.41 heritability and 0.6-0.9 genetic correlations with tibia strengths traits in the Rhode Island Red breed. These moderate to strong heritabilities and strong genetic correlations suggest that genome-wide association (GWAS) could reveal genomic regions, which contribute to multiple aspects of bone health in laying hens. In this paper, we present preliminary results from a GWAS to find genetic marker associations with 47 bone measurements in a cohort of 924 Rhode Island Red laying hens.

Materials & methods

Animals and phenotyping. A group of 924 RIR hens were investigated, which are bred for Lohmann Brown commercial layers (Lohmann Breeders GmbH, Germany). Hens from four hatches were assigned into two houses equipped with cages. Each cage had a perch and was occupied by two birds: one RIR bird and a companion from another breed. Hens were euthanized at 68 weeks of age, weighed, and bone samples were collected including humerus, tibia, and keel bone for further measurements as described previously (Dunn *et al.*, 2021).

DOI: 10.3920/978-90-8686-940-4_598, © M. Sallam *et al.* 2022

The measurements included: a bone index, (0·27×KeelDensity + 0·37×HumerusStrength + 0·61×TibiaStrength – 0·25×BodyWeight) following (Bishop *et al.*, 2000) to jointly map correlated effects on all three bone sites, the mineral content in tibia cortical bone (determined by thermogravimetric analysis, represents carbonate apatite; calcium phosphate with some CO_3 substitution of the PO_4), lipid content in tibia cortical bone (determined by infrared spectroscopy at main peak 1,710 cm^{-1}) and humerus medullary bone score (on a scale of 0-3 where 0 represents no medullary bone and 3 a diaphyseal medullary cavity filled with bone).

Genotyping. For genome-wide association studies, the hens were genotyped on 57,636 single nucleotide polymorphisms using the Illumina Infinium assay. The genotyping was performed by the SNP&SEQ Technology Platform, Uppsala University, Sweden. We aligned the sequences flanking the markers against the GRCg6a chicken reference genome to find physical marker positions. 188 SNPs were removed because of high missingness and 21,230 were monomorphic in the sample, leaving 36,218 markers for GWAS.

GWAS. For testing each SNP marker association with the trait of interest, we used the following linear mixed model implemented in GEMMA (Zhou and Stephens, 2012):

$$y = X\,b + g\,snp + Z\,hen + e \quad (1)$$

where y is the standardized trait measurement, X and Z are design matrices that relate the measurement y to the corresponding fixed and random effect, *g* is the marker effect, and hen the genomic breeding value for each hen based on genomic relationship matrix. We included hatch and house as fixed effects, and body weight as a covariate.

Results

Three traits showed associations with *P*-value<10^{-5}: tibia cortical lipid (on chromosomes 2 and 3), humerus medullary score (on chromosome 9), and tibia cortical mineral content (on chromosome Z). Figure 1 shows Manhattan plots of these three traits. Table 1 shows position, estimated marker effect and *P*-value for the most significant associations. In addition, we report the result of bone index (Figure 1) as a joint measure of bone quality, previously used in selection and genetic mapping studies.

Table 1. The most significant SNP markers with their positions, estimated marker effect and *P*-value.

	SNP position			
Trait	**Chr.**	**Base pair**	**Effect size[1]**	***P*-value[2]**
Tibia cortical lipid	2	2585350	-0.27	8.64E-06

[1] All traits were standardized (with zero mean and one standard deviation) to facilitate effect size interpretation.

[2] Wald test *P*-value.

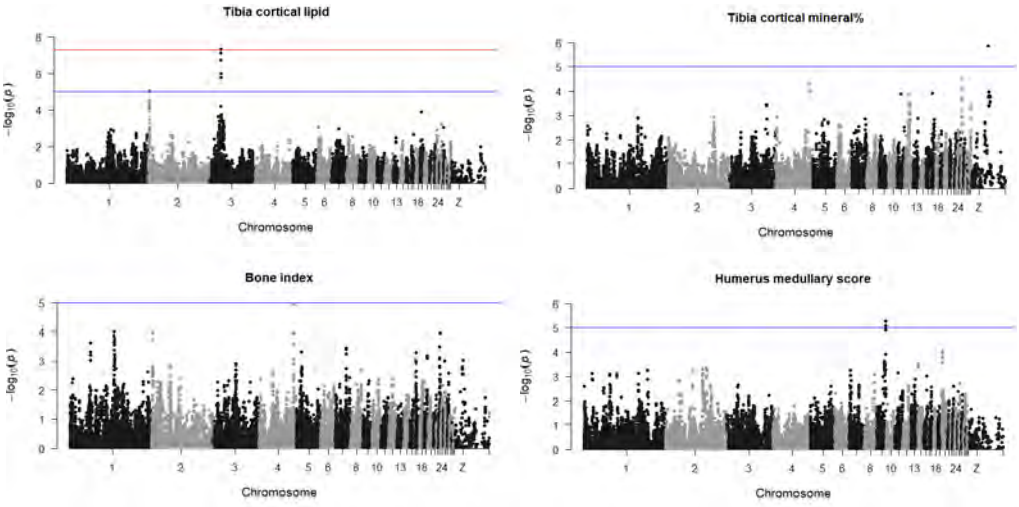

Figure 1. Manhattan plots showing $-\log_{10}$(Wald *P*-value) for each SNP marker in Tibia cortical lipid/mineral%, humerus medullary score, and bone index. The red line is to the conventional significance threshold of 5×10^{-8} and the blue a suggestive threshold of 10^{-5}.

Discussion

In this study, we detected seven loci associated with bone traits in a Rhode Island Red population. Tibia cortical lipid showed the most significant associations. Tibia cortical lipid is phenotypically correlated with the degree of mineralization (mineral% and phosphate/organic ratio) of both medulla and cortex, tibia breaking strength and density. Varying levels of lipids may be caused by variation in the cell population of the cortex. It remains to be investigated whether lipid content may be used as an intermediary physiological phenotype for bone quality.

The regions represent novel associations for bone traits. None overlap the tibial breaking strength QTL detected by Raymond *et al.* (2018) in White Leghorn layers of the Lohmann breeding program. When comparing to QTL in Chicken QTLdb, overlaps included QTL for feed intake (Mignon-Grasteau *et al.*, 2015) and comb, feather and wattle traits in a Chinese chicken breed (Sun *et al.*, 2015). The lipid association on chromosome 2 overlaps a suggestive locus for cortical carbonate content from Johnsson *et al.* (2021).

In contrast, there were no strong associations for bone breaking strength and the bone index. Tibia and humerus breaking strength show high heritabilities (~0.5) in this population (Dunn *et al.*, 2021). The genomic heritabilities estimated in the current GWAS were comparable: 0.47 for tibia breaking strength, 0.35 for humerus breaking strength and 0.48 for bone index. This suggests that the SNP chip tags most of the additive genetic variance in the trait, without detecting major QTL. Previously, a major QTL for tibial breaking strength has been detected and fine-mapped to the *cystathionine beta synthase* (*CBS*) gene in White Leghorn line (De Koning *et al.*, 2020). This locus was not detected in the current Rhode Island Red line. This finding suggests a polygenic architecture for bone-breaking strength in Rhode Island Red.

This study demonstrates the importance of developing bone measurements that enable large-scale genetic mapping studies and genomic selection of bone traits. Ideally, recording should be possible on live birds and for the keel bone, which appears the most important for layer health yet hardest to accurately phenotype (Thøfner *et al.*, 2021).

599. Determining the heritability of premaxillary bone shape and size within two populations of pure line laying hens

S. Struthers[1,2*], B. Andersson[3], M. Schmutz[3], H.A. McCormack[1], P.W. Wilson[1], I.C. Dunn[1], V. Sandilands[2] and J.J. Schoenebeck[1]

Abstract

Severe feather pecking (SFP) is a serious animal welfare and economic concern in commercial poultry species, particularly laying hens. The increasing demand for a ban on beak treatment presents a challenge to reducing the incidence of SFP. Considerable variation in beak shape exists within and between laying hen lines and there is the potential to genetically select hens whose beak shapes cause less damage when engaging in SFP behaviour. First, the range of phenotypes for both the external beak shapes and the underlying bones needs to be identified. The aim of this study was to estimate the heritability of the shape and size of the premaxillary bone within the top beak of two pure laying hen lines. It was found that both shape and size were heritable within the two lines, suggesting that bone shape could be incorporated into selection indices to help reduce the incidence of SFP.

Introduction

Chickens use their beaks for many important functions including feeding, drinking, maintaining plumage, and establishing social order; however, beyond these functions, birds can develop abnormal beak-related behaviours such as severe feather pecking (SFP). SFP involves the pecking at, pulling, and removal of feathers which results in large denuded areas on the body and make birds susceptible to cannibalism (Savory, 1995). Beak treatment is the shortening and blunting of beak length via hot-blade or infrared methods. Beak treatment is used to pre-emptively limit SFP damage but does not address the cause of the behaviour itself. There is increasing demand to ban beak treatment and rely on environmental enrichment and genetic selection. Selective breeding against SFP has been successful in laying hens (Rodenburg *et al.*, 2003; Grams *et al.*, 2015); however, incorporating behavioural data into a breeding programme can be challenging. A solution may be to select for traits such as plumage cover, liveability, and beak shape that are related to SFP behaviour but are easier to measure (Ellen *et al.*, 2019).

The extent to which beak shape can help reduce the incidence of SFP is not fully understood. Icken *et al.* (2017) found that beak shape was heritable and that hens with naturally shorter (blunter) top beaks had improved plumage cover and liveability. This suggests that selection for beak shape can reduce the damage that birds can inflict when engaging in SFP behaviour. Struthers *et al.* (2021) analysed the morphological variation of the premaxillary bone (within the top beak) in two pure White Leghorn laying hen lines, since the shape of the bone may influence external beak shape. The authors found that the shape and size of the premaxillary bones differed significantly between the two lines. Using the bone phenotypes from Struthers *et al.* (2021), the objective of this study was to determine the heritability of the shape and size of the premaxillary bone (within the top beak) within two pure lines of White Leghorn laying hens.

Materials & methods

This study was reviewed and approved by the Animal Welfare and Ethical Review Body at the Roslin Institute (University of Edinburgh).

DOI: 10.3920/978-90-8686-940-4_599, © S. Struthers *et al.* 2022

Animals. Hens used for this study were from two pure line populations (Line A and B) of White Leghorn laying hens and were approximately 40 weeks of age. Both Line A (n=387) and Line B (n=432) hens contribute to the four-line breeding scheme of Lohmann Selected Leghorn (LSL) hybrid layers. Hens from both lines were housed in conventional cages (n=200) in family groups (full and/or half-siblings) with a maximum of five birds per cage.

Radiographic examination and analysis. Lateral head radiographs were collected from the birds and analysed using the methods described by Struthers *et al.* (2021). To summarise, the premaxillary bone in each radiograph was landmarked in ImageJ (v.1.53g; National Institutes of Health, Bethesda, MD) using 13 landmarks. The landmark coordinates were imported into R (v.3.6.1; R Core Team (2019)) for geometric morphometric analyses using the package Geomorph (v.4.0.0; Adams *et al.* (2021)). Within Geomorph, Procrustes superimposition was used to standardise all the landmarks in each radiograph by superimposing, re-scaling, and rotating them to a common orientation. The covariation of the transformed landmarks was analysed using principal components analysis and multivariate regression. The Procrustes superimposition also created an average bone shape by identifying the centre point (centroid) of all the landmarks in each radiograph. The centroid size was used as a proxy for relative bone size.

Statistical analysis. To estimate heritabilities and genetic and environmental correlations between principal component (PC) scores and centroid size, the following bivariate model was fitted for each line in ASReml (v4.1.1068; VSN International):

$$y = X\beta + Zu + e \quad (1)$$

where y is a vector containing the phenotypic values for each trait for all birds, β is a vector of fixed effects, and u is a vector of random genetic effects. X and Z are the known design matrices for β and u, respectively, and e is a vector of residual errors. Narrow-sense heritability was calculated as $h^2a = \sigma^2a/\sigma^2p$, with σ^2a being the additive genetic variance and σ^2p the phenotypic variance.

Results

From the geometric morphometric analyses conducted by Struthers *et al.* (2021), three PCs were found to explain 85% of the total variation in premaxillary bone shape within the two hen populations; therefore, heritability estimates were determined for the three PCs and the centroid size (Table 1 and 2).

Table 1. Estimates of heritabilities (diagonal), genetic correlations (below the diagonal) and environmental correlations (above the diagonal), with standard errors, between premaxillary bone principal component (PC) scores and centroid size for Line A hens[1].

	PC1 score	PC2 score	PC3 score	Centroid size
PC1 score	**0.41±0.14**	-0.33±0.17	0.23±0.13	**0.86±0.06**
PC2 score	-0.18±0.23	**0.54±0.15**	**0.33±0.15**	**-0.48±0.19**
PC3 score	0.01±0.42	-0.46±0.42	0.13±0.12	0.12±0.13
Centroid size	**0.62±0.15**	0.05±0.24	0.04±0.42	**0.44±0.15**

[1] Values in bold are considered significant.

Table 2. Estimates of heritabilities (diagonal), genetic correlations (below the diagonal) and environmental correlations (above the diagonal), with standard errors, between premaxillary bone principal component (PC) scores and centroid size for Line B hens[1].

	PC1 score	PC2 score	PC3 score	Centroid size
PC1 score	0.14±0.11	**-0.25±0.10**	0.07±0.16	**0.88±0.03**
PC2 score	-0.17±0.47	0.22±0.12	0.02±0.16	**-0.35±0.10**
PC3 score	-0.12±0.35	-0.14±0.30	**0.59±0.15**	0.00±0.17
Centroid size	**0.63±0.24**	-0.30±0.36	-0.01±0.27	**0.24±0.12**

[1] Values in bold are considered significant.

PC1 described the curvature of the bone tip and the width of the caudal end (towards the head) of the bone. Heritability estimates for PC1 scores were 0.41±0.14 for Line A hens and 0.14±0.11 for Line B. PC2 described bone length. Heritability estimates were 0.54±0.15 for Line A hens and 0.22±0.12 for Line B. Heritability estimates of PC scores and centroid size were higher for Line A hens than Line B apart from PC3 scores. PC3 described a slight narrowing vs widening of the caudal-most (towards the head) ventral margin (bottom edge) of the premaxillary bone. Heritability estimates were 0.13±0.12 for Line A hens and 0.59±0.15 for Line B. For centroid size, heritability estimates were 0.44±0.15 for Line A hens and 0.24±0.12 for Line B.

For both lines, there was a significant positive genetic correlation between PC1 score and centroid size (Tables 1 and 2). Although mostly non-significant, genetic correlation estimates were primarily positive for Line A hens and primarily negative for Line B. For environmental correlations, there was a significant positive correlation between PC1 score and centroid size for both lines. There was also a significant negative correlation between PC2 score and centroid size for both lines. Line A hens showed a positive correlation between PC2 and PC3 scores (Table 1). For Line B, there was also a significant negative correlation between PC1 and PC2 scores (Table 2).

Discussion

Reducing SFP within commercial laying hen flocks remains a challenge to the poultry industry and research into why hens feather peck and how to mitigate the behaviour has been ongoing since the late 1930's (Kennard, 1937). Researchers and primary breeding companies have investigated using group selection for traits such as plumage cover and liveability to reduce the incidence of SFP (Icken *et al.*, 2017; Ellen and Bijma, 2019). These traits were found to have moderate heritabilities and selection for them reduced the incidence of SFP and SFP-related injuries; however, only victims of SFP can be identified rather than the instigator (for plumage cover selection) and selection candidates are often housed individually, making group selection for liveability difficult (Brinker *et al.*, 2014; Ellen and Bijma, 2019).

Beak shape has the potential to be incorporated into selection indices to help reduce the incidence of SFP (Icken *et al.*, 2017) but in order for multivariate beak shape data to be useful, the phenotypes need to be collected in live animals. Struthers *et al.* (2021) developed the novel capability of using radiography for the application of geometric morphometrics (analysis of shape) in live, non-sedated laying hens. Radiography offers the advantage of being able to analyse both the external beak shape and the underlying bones. To our knowledge, this is the first study to estimate the heritability of the premaxillary bone within the top beak of laying hens. This experiment is part of a larger study aimed at understanding the morphology and genetics of beak shape and the underlying bones that provide its structure.

The heritability values found in the present study suggest that it would be possible to incorporate multivariate shape data into selection indices to guide the selection of hens whose beak shapes cause the least damage to other birds when engaging in SFP behaviour. The heritability estimates for bone PC scores (i.e. bone shape) are similar to beak length heritabilities reported by Icken *et al.* (2017). The authors used a device that measured the length of the top beak that overhangs the bottom. However, although assumed, it is not yet verified that external beak shape reflects the underlying shape of the bones. Thus, some caution should be used when comparing the heritability estimates of the present study to those who analyses were done using external beak shape measurements. The strong, positive correlations between PC1 scores and centroid size for each line were not surprising as Struthers *et al.* (2021) found that premaxillary bone shape was significantly associated with bone size and accounted for nearly half of the total shape variation.

The results of this study demonstrate that the heritability of premaxillary bone shape varies between the two pure line populations studied. However, there were similarities between the two lines for the strong positive genetic and environmental correlations between PC1 score and centroid size and moderate negative environmental correlations between PC2 score and centroid size. Overall, the results of the present study agree with previous studies in that the shape of the beak and its underlying bones may be advantageous to include within breeding programme selection indices.

Abstract

The main objective of this study was to quantify genotype-by-environment interactions for egg quality traits and body weight in laying hens between cage and cage-free systems. Records of 18,524 eggs for quality traits and 10,266 hens for body weight from a pedigreed Rhode Island Red line were used. Hens were hatched across 5 batches from 2018 to 2020, siblings are housed in two systems: a cage and a floor system. Random regressions were modelled to estimate variance components. Heritability estimates were moderate to high in both systems (0.29-0.77). Genetic correlations between the cage and the floor system were high (≥0.79), and genetic correlations between the intercept and the slope of the reaction norm ranged from -0.69 to 0.27. The results indicate that there is no need to maintain a dedicated breeding programme per system, if the breeding goals are identical, which is unlikely.

Introduction

A few breeding companies are supplying farmers with laying hens all over the world. Purebred birds of the *nuclei* of these breeding companies are housed in cages to ensure pedigree and performance monitoring. Although most of the egg production is produced in cage systems, there is a large diversity in farming systems. Some alternative systems to cage are expanding, for instance in 2020, 52% of laying hens are raised in cage-free systems in E.U. (barn, free-range, and organic; European Commission, 2021). In all these systems, breeding goals include the number of eggs produced, egg qualities (regarding the albumen, yolk, and shell), feed efficiency, behaviour, fertility and disease resistance. In the current situation, birds are selected in the *nuclei* based on performance in cage system. Some studies indicate that some major traits such as egg production traits may be under the influence of genotype-by-environment interactions (G×E), which can affect the ranking of selection candidates (Icken *et al.*, 2008; Mulder, 2017). However, it is still unclear whether there is a need to develop a breeding programme dedicated to cage-free systems because the selection candidate would be different from those in the cage system. Our objective is to quantify G×E for egg quality traits and body weight in laying hens between cage and cage-free systems.

Materials & methods

Birds and farming system. Records from the *nucleus* of a Rhode Island Red line of the breeding company Novogen were used in this study. Hens were hatched across 5 batches from 2018 to 2020. They were raised on a floor in a barn until 17 weeks of age. Then, they were either bred in collective cages or a floor system until 64 weeks of age. On average, data from 1,633 cages for the cage system and 365 hens for the floor system was retrieved per batch. The cages included a living area (with free access to food and water). The floor system included individual nests overlaid on two rows (about 1 nest for 5 hens), and a living area on floor pens (with free access to food and water). Hens were housed in cages of 5 full sisters in the cage system and raised with the entire cohort in the floor system, including the cocks (about 1 cock for 10 hens).

The pedigree for each recorded individual was traced back over at least 5 generations.

Traits. At 50 weeks of age, egg quality was recorded twice for each cage in the cage system or each hen in the floor system, and body weight once. A total of 18,524 eggs were collected: 16,331 from the cage system

and 2,193 from the floor system. A total of 10,266 hens were weighed: 9,025 from the cage system and 1,412 from the floor system. All traits were named according to the Animal Trait Ontology for Livestock (ATOL). Five egg quality traits were studied: eggshell colour (ESC), eggshell strength (ESS), eggshell shape index (ESshape), Haugh value (HV), and egg weight (EW). The body weight was recorded at 50 weeks of age (BW). ESC was determined by a chromameter, ESS was determined by a compression instrument, EW was determined by a weighing scale, ESshape is calculated from egg diameter and EW, HV was determined by a tripod methodology, and BW was determined by a weighing scale. Further details on the measurements are available on the ontology website (Picard Druet *et al.*, 2020).

Models. Because the hens in a cage are full sibs, the sire and dam of the cage were known: animal models were used for both cage and floor environments, considering each egg as an individual. Body weight was recorded at the individual level in both systems. Variance components were estimated using an average information restricted maximum likelihood method applied to univariate reaction norm models:

$$y_{ij} = \mu + CG_{ij} + \beta_1 age_{ij} + \beta_2 x_{ij} + a_{int_i} + a_{slp_i} x_{ij} + e_{ij}$$

Where y_{ij} was the observed phenotype on the j[th] egg of the i[th] 'animal' (either egg or hen, depending on the system), μ the overall mean, CG_{ij} was the fixed effect for the contemporary group (hatching date, location of the cage in the barn), β_1 was the regression coefficient on the age in weeks, β_1 was the regression coefficient on the environmental gradient x (x=0 for the cage system and x=1 for the floor system), a_{int_i} was the random additive genetic effect for the intercept of the reaction norm of the i[th] 'animal', a_{slp_i} was the random additive genetic effect for the slope of the reaction norm of the i[th] 'animal', and e was the random residual effect. For BW, the same model was used except that there is a single record per animal. The additive genetic effects were assumed to be normally distributed. Heterogeneity in residual variance was modelled with a residual variance for the cage system and a residual variance for the floor system. The residual effects were assumed to be normally distributed.

Genetic parameters were calculated from the estimated variance components (additive genetic variance for the intercept, additive genetic variance for the slope, additive genetic covariance of the intercept and the slope, and the residual variance) according to the theory (Falconer and Mackay, 1996; de Jong and Bijma, 2002).

Log-likelihood ratio test (LRT) with a reduced model without the random regression term were performed to test the significant level of the random additive genetic effect for the slope of the reaction norm.

Software. Data handling was performed with base-R (R Core Team, 2020). The variance components estimation and the calculations of genetic parameters were performed with the statistical software ASReml 4.2 (Gilmour *et al.*, 2021).

Results & discussion

We found that egg quality traits and BW were moderately to highly heritable in both environments (with heritability estimates ranging from 0.29 to 0.77; Table 1). This is consistent with other studies where heritability for these traits ranged from 0.24 to 0.60 (Beaumont *et al.*, 2010; Mulder *et al.*, 2016; Picard Druet *et al.*, 2020). Our results indicated that heritability estimates in the floor system were often higher than in the cage system. Both the additive genetic variance tended to be higher and the residual variance tended to be lower in the floor system compared to the cage system (data not shown). It is possible that the additive genetic variance was underestimated because of the loss of information about the individual that laid the egg and that estimation of a permanent environment variance was needed (repeated measures

Table 1. Genetic parameters[1] for egg production traits and mature body weight.

Traits	h^2_{cage}	h^2_{floor}	$r_{(cage,floor)}$	$r_{(int,slp)}$
ESC	0.55 (0.03)	0.74 (0.02)	0.79 (0.05)	-0.03 (0.09)[2]
ESS	0.33 (0.02)	0.31 (0.04)	0.93 (0.05)	0.15 (0.23)[2]
ESshape	0.47 (0.03)	0.58 (0.03)	0.92 (0.04)	0.19 (0.18)[2]
HV	0.29 (0.02)	0.45 (0.03)	0.96 (0.04)	0.04 (0.26)[2]
EW	0.62 (0.03)	0.77 (0.01)	0.93 (0.03)	0.27 (0.13)
BW	0.61 (0.02)	0.50 (0.01)	0.87 (0.04)	-0.69 (0.08)

[1] Estimates, with standard errors in brackets, of heritability of the traits in cage (h^2_{cage}) or floor system (h^2_{floor}), and genetic correlation between the two systems ($r_{(cage,floor)}$) and between the intercept and the slope of the reaction norm ($r_{(int,slp)}$).
[2] Not significantly different from zero (LRT).

with 2 eggs per hen), or that the unbalanced design biased the estimation of variance components (88% of the observation came from the cage system and 12% from the floor system). We tried to fit a permanent environment random effect of the cage in the cage system and of the hen in the floor system but the model did not converge.

We found that the genetic correlations between the cage and the floor system were very high ($r_{(cage,floor)} \geq 0.79$). To our knowledge, this is the first study about the same traits with the same purebred population in two environments. It is often admitted that when a genetic correlation between two traits is higher than 0.80, then these two traits are genetically similar enough to consider only one of them in the breeding programme. This genetic correlation is also used as an indicator of the importance of G×E when using a character-state model (same trait in different environments like in our study; Falconer and Mackay, 1996). Although a genetic correlation of 0.80 is high, it is not one (unity). Therefore, re-ranking of selection candidates may occur due to G×E. We used univariate random regression models to assess the stability of the genotype thanks to another genetic parameter: the genetic correlation between the intercept and the slope of the reaction norm models (de Jong and Bijma, 2002). We assumed the systems to be on a continuous scale from the reference environment (cage system) to another graduation of the environment (floor system). We found that the genetic correlations between the intercept and the slope of the reaction norms varied from -0.69 to 0.27 and that most of them were not significantly different from zero. The estimated $r_{(int,slp)}$ for EW was 0.27, meaning that the higher the breeding value for EW in the cage system (reference environment), the higher the genetic sensitivity to changing to floor system. However, this trait is particular because the breeding goal is not to increase EW but to keep it within a defined range. Giving the high $r_{(cage,floor)}$, it is possible that re-ranking only occur for extreme breeding values, which would not be a problem. The estimated $r_{(int,slp)}$ for BW is -0.69, meaning that the higher the breeding value for BW in the cage system (reference environment), the lower the genetic sensitivity to changing to floor system. The estimated $r_{(int,slp)}$ for the other traits were not significantly different from zero, indicating that selecting on the level would not change the sensitivity to environmental change.

Conclusions

In the present study, all egg quality traits and adult body weight displayed high heritability estimates, high genetic correlations between the cage and the floor systems, yet different genetic correlations between the intercept and the slope of the reaction norm models. Considering the breeding goals for all these traits, our results indicate that there is no need to maintain a breeding programme per system. However, other major traits need to be studied (egg number or disease resistance). These conclusions hold only if the breeding goals are the same between the two systems, which is unlikely (see Phocas *et al.*, 2016).

Abstract

Poultry production systems are currently dealing with some important issues like animal welfare, environmental impacts of soy imports from overseas, and the decline of genetic diversity. Therefore, an alternative approach to poultry production was tested in this study using six different chicken genotypes in terms of fattening performance of males and laying performance of females. Two traditional chicken breeds, Vorwerkhuhn (VH) and Bresse Gauloise (BG), and a commercial layer genotype, White Rock (WR) as well as crossbreds thereof were fed diets containing either 20% vicin-rich or vicin-poor faba beans. The genotype BG and the crossing genotypes with BG exhibited the best growth performance. WR and BG × WR cross showed the best performance regarding the egg production and egg quality. Taken together, the dietary effect revealed only small negative impacts of vicin. In terms of dual-purpose usage, crossing BG with WR seems to be the most promising variant studied here.

Introduction

In recent decades, poultry production has developed into a highly diversified sector with chicken lines genetically specialized either for egg production or for meat production (Krautwald-Junghanns *et al.*, 2018). In poultry production, both sexes of meat type chickens are used for meat production, whereas the male chicks of layer lines are not used and are culled on their first day of life due to their low growth potential and the associated economic disadvantages. This is problematic in respect to animal welfare and ethical aspects and is therefore no longer permitted in Germany. In this context, the fattening of the cocks of heavy layer hybrids or the use of dual-purpose-breeds have been examined (Damme *et al.*, 2003), showing that the layer cockerels are clearly inferior to commercial broilers. The use of local breeds might be an alternative solution to serve niche markets in a regional context. These breeds historically have been used for both egg and meat production and are nowadays mostly kept by hobby breeders. To supply the poultry industry with high-quality protein feed, the EU imports large quantities of soybeans from overseas. The use of genetically modified seeds is common in the main producing countries and is viewed critically by European consumers. In addition, the negative environmental impact of the soybean production, especially in South America (Barona, *et al.*, 2010), suggest a reduction in soy imports in favour of regional protein crops in Germany. A suitable regional protein crop is the faba bean (*Vicia faba*). However, antinutritional substances such as the glycosides vicin and convicin (VC) have so far restricted the use of field beans in animal feed. The main objective of this study is therefore to evaluate the fattening and laying performance of animals of two local pure breeds compared to a commercial line and their crosses, and to quantify the effect of feeding faba bean with different VC content on performance parameters.

Materials & methods

This study included three purebred and three crossbred genotypes of domestic chicken. The purebred genotypes were Vorwerkhuhn (VH), Bresse Gauloise (BG), and White Rock (WR). VH is a local chicken

breed from Germany, which was originally bred for dual-purpose usage. The BG hens originated from the Bresse region in the south of the french Burgundy County. The WR is a commercial layer parent stocks from Lohmann breeders company (Cuxhaven, Germany). In order to quantify the effect of genotypes and feeding on fattening performance, in a first experiment (A) male chicks of the purebred lines (120 chicks of BG and WR each and 94 chicks VH) at 4 weeks of age were subjected to three different feeding treatments. Two diets contained faba beans as an alternative source of protein, while the third diet was a soybean-based standard feed as control (soy). The feeding treatment with faba beans comprised a diet containing 20% of a VC-rich faba bean variety Fuego (VC+) and the other 20% of a VC-poor variety Tiffany (VC-). In experiment B, 120 birds from three crosses (VH males × BG females: VBG, VH males × WR males: VWR, and BG male × WR female: BWR) were subjected to the same feeding regime from 4 weeks of age as described for the purebreds. The animals of both experiments were slaughtered at a target weight of ca. 2,100 g to assess fattening performance. Therefore, the slaughter age of the breeds varied between 10 to 17 weeks of life. Due to the difference in slaughter age and for comparability of genotypes, in this paper fattening performance was analysed for a time window of 4 to 10 weeks, considering the effects of genotypes, feeding treatment, regression effect of pre-treatment weight, regression effect of age in the linear and quadratic terms, and random effect of pen. In order to quantify the influence of the different genotypes and feeding treatments on laying performance and egg quality, two consecutive trials were conducted. As described above, trial A tested purebred hens of the VH, BG, and WR breeds. Trial B dealt with their crosses (VBG, VWR, VWR). In both experiments, the testing period lasted from the18th until the 52nd week of age. Egg weight and eggshell quality was analysed at four different time points (week 26, 34, 42 and 50). At each time point, 96 randomly selected eggs from four consecutive days were analyzed per genotype × diet combination. The statistical analysis of the laying performance was carried out using a polynomial growth function as described above for weight development. The egg quality parameters were analysed by considering the effect of genotype, diet, age, and their interactions.

Results

Weight gain and feed efficiency. The comparison of the genotypes from week five to ten showed differences between the respective genotypes, which became clearer with increasing age (Figure 1). Statistical analysis of weight at 10 weeks of age showed that the animals of BG breed had the highest weight of 1,823 g, followed by the two BG crosses VBG (1,580 g) and BWR (1,536 g), which were both significantly different from the purebred BG genotypes at this age. The VH animals weighed 1,342 g, which was significantly less than the BG roosters and its crosses, but heavier than the WR animals (1,286 g). The weight of the VWR birds (1,312 g) was in between the VH and WR roosters. There was a significant effect of feeding treatment on the weight of animals with a difference of 19 g between VC- and soy, and 21 g between VC+ and soy. Within the respective genotypes, no significant differences in the growth performance of animals were observed between the feeding treatments. In terms of feed efficiency BG (2.56 kg/kg) outperformed the other genotypes. VBG showed an FCR of 2.76, which was significantly better than VWR (2.91). BWR, VH, and WR ranked between these two genotypes with FCRs of 2.74, 2.82, and 2.84, respectively. There were no statistically significant differences in FCR between the feeding groups in general and within the respective genotypes as well as in the separate analysis of the genotypes over the entire experimental period.

Egg performance and egg quality. The egg production curves of the different genotypes are shown in Figure 2. The purebreds differed significantly from each other at all experimental times. As expected, WR achieved the highest performance in the purebred lines (peak performance 100%), followed by BG and VH. The VH hens showed the lowest laying performance, which resulted from a delayed laying maturity and a peak performance of only about 56%. The crossbreds were significantly different from each other from weeks 18 to 48, but in weeks 49 to 51, the difference between VWR and VBG became smaller and was no longer statistically significant due to the low persistency of VWR. VWR hens had similar performance

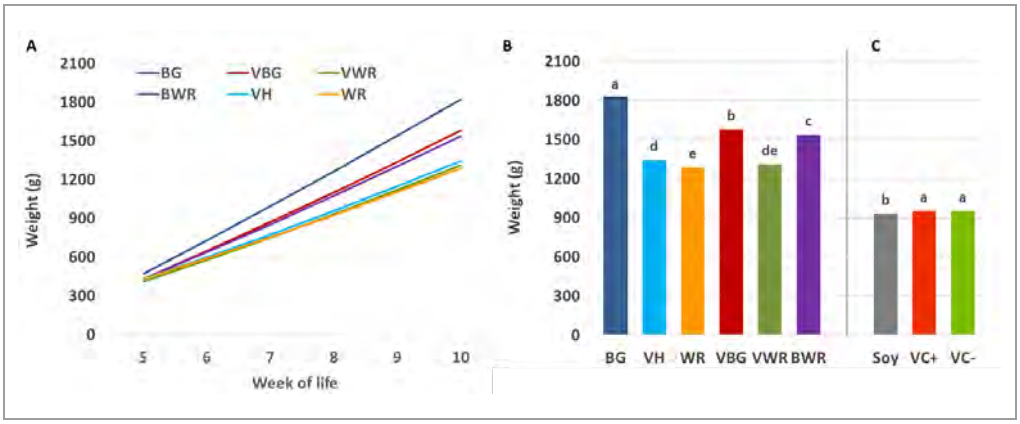

Figure 1. Weight gain of different genotypes and diets. (A) Effect of genotype on weight development from five to ten week of life. (B) LS-means for bodyweight of the respective genotypes at week ten of age. (C) LS-means for bodyweight of the different feeding groups adjusted by the mean of age.

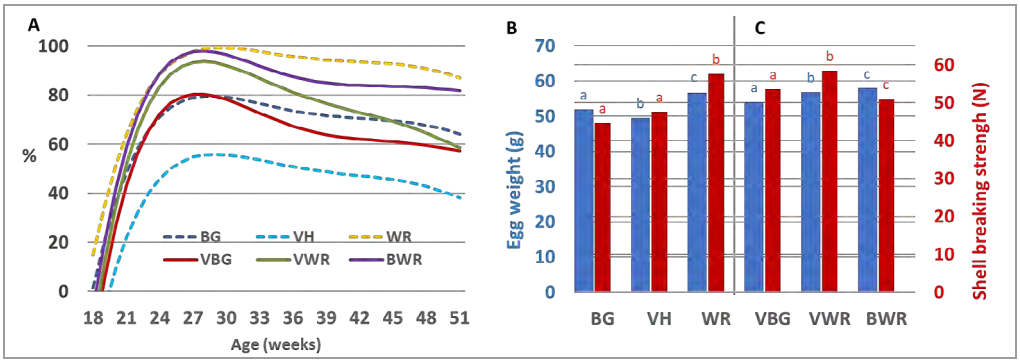

Figure 2. The effect of different genotypes on egg performance and egg quality Comparison of laying performance (A), egg weight (B) and eggshell breaking strength (C) of purebreds and crossbred genotypes.

compared to BWR hens, but were worse regarding laying persistency. The laying performance of VBG was lower compared to BWR and VWR.

There was a significant difference in egg weight between all genotypes. Among the purebred genotypes, WR hens produced the significantly highest egg weights (56.6 g), followed by BG (51.9 g) and VW hens (49.4 g). In the crossbreeds, the highest egg weights were found for the BWR genotype (58.0 g), while VBG laid the lightest eggs (54.0 g).

No significant interaction between genotypes and feeding was detected for egg weight. However, for both purebred and crossbred genotypes, the VC+ group laid significantly smaller eggs than the soybean and VC- groups, but these differences were not pronounced and amounted to 1.1 g or even less. Shell strength was significantly highest for WR (57.68 N) and for the crossbred genotype VWR (58.41 N). The purebred BG and VH hens exhibited values below 50 N. The differences between the dietary groups were only found in the crossbreds, where the VC+ group showed a significantly reduced eggshell breaking strength.

Discussion

The observed performance difference between the purebreds is caused by their genetic background, indicating the BG is a meat-type dual purpose breed, whereas the VH is a layer-type dual purpose breed and the WR is a parental layer genotype. The meat-type BG is the most suitable for fattening among the tested genotype due to its high growth rate and good feed efficiency. These findings are in line with those reported by Lambertz *et al.* (2018) for BG and their crosses with New Hampshire hens. As a cross-breeding partner, BG shortens the fattening period and improves the feed efficiency of layer genotypes VH and WR. The laying performance and egg weight of the local breeds and especially of VH breed has been considerably lower than WR breed. With regard to the shell breaking strength, there was also a clear difference between the commercial WR line and the local breeds BG and VH in the present study, which demonstrates a long-term genetic selection effect. The laying performance of the crossing genotypes in the first half of the laying period was more similar to the performance level of the maternal genotype than to the paternal. However, in the second half of the laying period, there was a decrease in direction of the paternal performance, although BWR showed a much better persistency than VWR in the laying performance. The mean egg weights of the crossing genotypes were higher than the mean of the parental pure lines for all genotypes. However, this difference cannot be construed directly as a heterosis effect, since it could be confounded with the effect of different experimental series. Concerning eggshell parameters, the values of the cross genotypes were between the parental lines. Overall, no adverse effect of VC containing feeds on laying and fattening parameters was detected, with the exception of a marginal negative effect on egg weight. Since our study deals with dual-purpose genotypes, both the fattening performance of the males and the laying performance of the females should be considered for a final conclusion. The performance test of the males showed that the BG breed improved the fattening performance of the layer-type VH and WR chickens. Therefore, considering both sexes, the BWR hybrids seem to be the most promising cross.

Abstract

Heterosis is the phenomenon that hybrids display better performance than the parental average. In this study, we aimed to quantify egg-laying performance, and heterosis for a complete diallel cross of Beijing-You and White leghorn chickens. Egg weight, egg production and egg quality traits were measured, and heterosis was estimated. We found significant heterosis for egg weight, egg number and age at first egg in the cross lines. Favourable heterosis was also observed for egg quality traits except albumen height and Haugh unit. Moreover, for egg weight, heterosis tended to be higher if Beijing-You was the sire line and White Leghorn was the dam line which was in contrast to egg production traits.

Introduction

Heterosis is the phenomenon that performance in hybrids is superior to the average performance of their parents. At present, most eggs, chicken meat, and pork are produced from hybrid animals. Utilization of heterosis in commercial breeding schemes relies on investigating the best crossbreeding combinations performance from extensive cross-examination Therefore, in this study, a complete diallel cross of Beijing-You (Y) and White Leghorn (W) was constructed to evaluate heterosis of egg-laying performance in chickens.

Materials & methods

Population. Two breeds (Y, Beijing-You, a Chinese local breed; W, White Leghorn, a high productive breed) with a large difference in egg-laying performance were chosen. The two breeds were mated to generate four genetic groups: (1) 30 Y roosters were mated with 150 Y hens to generate YY offspring; (2) the same roosters were mated with 150 W hens to generate YW offspring; (3) 30 W roosters were mated with 150 W hens to generate WW offspring; and (4) the same roosters were mated with 150 Y hens to generate WY offspring.

Egg-laying performance. Egg laying characteristics measured were age at first egg (AFE), egg number until 43 weeks of age (EN43), average clutch length (ACL), and oviposition period (OP), weight of first egg (FEW), egg weight every 4 week from 28 weeks of age till 68 weeks of age, and egg quality traits at 32 weeks of age: shell colour (SC), shell strength (SI), shell thickness (ST), albumen height (Alh), Haugh unit (HU), egg shape index (ESI), yolk ratio (YR), and shell ratio (SR).

Statistics analysis. Heterosis and genetic parameters were estimated using the following model:

$$y_{ijk} = \mu + b_i + a_j + e_{ijk}$$

Where y_{ijk} is the phenotypic value, μ is the population average, b_i is the fixed effect of genetic group (YY, YW, WW and WY), a_j is the random animal effect with 2,485 animals included in the pedigree, e_{ijk} is the random error.

Estimated differences between YW and mid-parent value (MPV), between WY and MPV, and between YW and WY and their Wald F statistics were obtained by ASReml.

Results

Descriptive statistics. The mean egg weight increased with aging (Table 1). The standard deviation for egg number at 43 weeks of age and age at first egg were higher than oviposition period and average clutch length (Table 1). Descriptive statistics for egg quality traits is provided in Table 2.

Genetic parameter analysis. Estimated heritability for egg weight at 28 to 64 weeks of age was high (0.56-0.77), with the highest value at 52 and 64 weeks of age (Table 3). Genetic correlations between egg weight at different ages were high (0.86-0.98), especially for consecutive time points. Age at first egg was negatively correlated with egg number until 43 weeks of age (r_g=-0.47, Table 3). The heritability for all egg quality traits at 32 weeks of age was moderate (0.31-0.50, Table 4). Shell thickness had a strong genetic correlation with both shell ratio (r_g=0.85), and shell strength (r_g=0.69, Table 4).

Predicted values. Both YW and WY showed significant heterosis (1.07%-6.65%) for egg weight throughout the laying period. The heterosis for egg weight increased with advancing age, and was higher for YW than for WY (Figure 1). Age at first egg and egg number until 43 weeks of age showed favourable heterosis, and the heterosis for egg number was higher for WY than for YW. While oviposition period differed between WY and MPV, and between YW and WY. Except for albumen height and Haugh unit, all egg quality traits presented favourable heterosis. For shell colour, yolk weight, shell strength, and shell thickness, hybrid performance was higher than MPV, while the reverse was observed for Haugh unit. Heterosis for yolk weight, yolk ratio, and egg shape index in YW was higher than in WY (Table 5).

Discussion

Egg-laying performance is an important economic trait. The pedigree-based heritability estimates for egg weight and egg quality traits were slightly higher than those in a Rhode Island Red (RIR) population (Liu *et al.*, 2018a, 2018b). The estimate of egg number and age at first egg were similar to RIR population (Liu *et al.*, 2019). The genetic and phenotypic correlation among all egg-laying traits were similar to previously reported estimates (Liu *et al.*, 2018a, 2018b, 2019).With the extension of the laying period egg weight increases which confirms results of other studies (Ledur *et al.*, 2002).

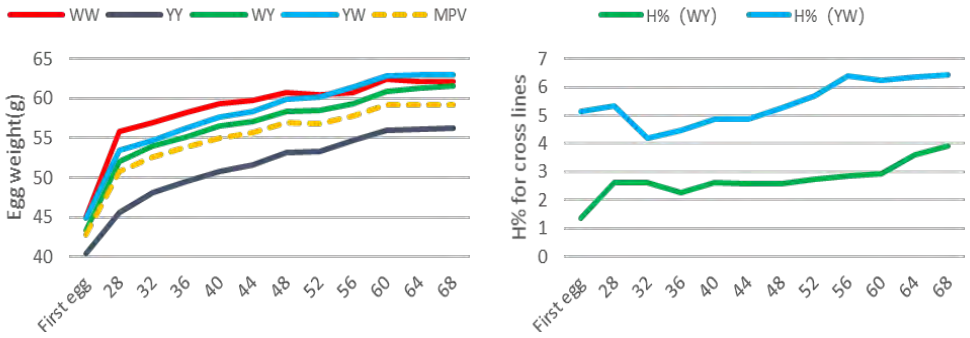

Figure 1. Predicted egg weight for the four genetic groups and heterosis for the two reciprocal crosses.

Table 5. Predicted values for egg production and egg quality traits.

Trait		MPV	H%(WY)	H%(YW)	*P*-value		
					WY vs MPV	YW vs MPV	WY vs YW
Egg production	EN43	109.97	3.01	1.87	<0.01	<0.01	<0.01

	YR	28.58	1.91	2.08	<0.01	0.05	<0.01
	SR	9.86	1.32	3.00	<0.01	<0.01	0.21

In this experiment, significant heterosis was observed for egg weight, egg number, average clutch length and Haugh unit, which was consistent with other studies (Abplanalp *et al.* 1984; Ledur *et al.* 2000; Emmerson *et al.* 2002; Ledur *et al.* 2002). But heterosis for egg number and age at first egg was smaller than Williams *et al.* results in fowl (2002) and Emmerson *et al.* in turkey (2002). Our results showed that the level of heterosis is both dependent on the trait and the reciprocal cross.

Throughout the experimental period, we found higher heterosis for egg number in WY than YW, and higher for egg weight in YW than WY. There was a strong divergence in heterosis for these traits, illustrating the complexity of non-additive genetic variation and the difficulty in predicting heterosis. Sutherland *et al.* (2018) also found differences between reciprocal crosses for growth traits in chickens, and suggested that one or more Z-linked genes may underlie this difference.

In conclusion, favourable heterosis was observed for most egg-laying performance traits in a cross between Beijing-You and White Leghorn chickens. Moreover, a considerable difference in heterosis between the two reciprocal crosses was observed. The molecular mechanisms underlying heterosis will be further explored in a subsequent genome-wide association study.

Abstract

Probiotic *Bacillus amyloliquefaciens* CECT 5940 *(B. amyloliquefaciens)* and *Bacillus subtilis DSM 32315 (B. subtilis)* have positive effects as feed additives on chicken health and performance. However, the underlying modes of action are still elusive, they may have a direct effect on the immune system. Here, we investigated direct effects of *B. amyloliquefaciens* and *B. subtilis* on peripheral blood mononuclear cells (PBMCs) *in vitro*. Flow cytometric analysis revealed a higher Δ relative cell count of CD4+ T-helper cells ($P<0.1$; $P<0.05$) and CD4+CD25+ activated T-helper cells ($P<0.05$; $P<0.01$) in the cultured chicken PBMCs after treatment with both *Bacillus* strains. Furthermore, we found a higher Δ relative cell count of CD8+ cytotoxic T-cells ($P<0.05$) and CD8+CD25+ activated cytotoxic T-cells ($P<0.05$) after treatment with *B. subtilis.* Hence, we suggest a direct immunomodulatory effect of *B. subtilis* and *B. amyloliquefaciens* on chicken PBMCs.

Introduction

Poultry is the cheapest source of animal protein worldwide and the second largest source of meat after pork (Wahyono and Utami, 2018). However, there is growing concern about the resistance of pathogenic bacteria against antibiotics, residual antibiotics in meat products for human nutrition (Sato *et al.*, 2019), and public health risk from zoonotic pathogens like *Salmonella* and *Campylobacter*. Since the subtherapeutic usage of antibiotics was forbidden in farming in the EU in 2006 (Council Regulation EC 70/524/ EEC), alternatives such as prebiotics, probiotics, synbiotics, and trace elements have ascended to improve the health of the animal and to reduce the usage of antibiotics. Among most widely and commonly used probiotics are *Bacillus* spp., spore forming bacteria with resistance to high temperatures and harsh storage conditions. They are generally considered as safe strains for use in poultry production (Penaloza-Vazquez *et al.*, 2019). *Bacillus amyloliquefaciens* CECT 5940 (*B. amyloliquefaciens*) and *Bacillus subtilis DSM 32315* (*B. subtilis*) were shown to have positive effects on pathogenic bacteria such as *Clostridium perfringens* (Gharib-Naseri *et al.*, 2021, Lei *et al.*, 2015) and *to* improve growth performance, increase feed efficiency, manipulate the intestinal structure and microbial composition of the gut (Ma *et al.*, 2018). However, the underlying mechanisms of action of these probiotics are still unknown. They could have a direct effect on the immune system or e.g. interact with the microbiome. This study aims to enlighten the mechanisms of probiotics. We examined the direct effects of *B. amyloliquefaciens* CECT 5940 and *B. subtilis DSM 32315 on T-helper cells and cytotoxic T-cells as two major components of the adaptive immune response. The results could* help to improve health in chicken farming and to prevent infectious diseases and the use of antibiotics.

Materials & methods

We conducted cell culture experiments using a previously described cell culture model with chicken PBMCs (Larsberg *et al.* 2021) in co-culture with *B. amyloliquefaciens* CECT 5940 and *B. subtilis DSM 32315*. The blood of Cobb500 broiler chicken was collected in polystyrene tubes pre-filled with sodium citrate (VACUETTE®, Greiner Bio-One, Kremsmünster, Austria). For lymphocyte isolation, blood was

diluted with PBS (Gibco™, ThermoFisher Scientific, Waltham, MA, USA) containing 2 mM EDTA (Carl Roth, Karlsruhe, Germany) in the ratio 1:2 and mixed with 3% dextran (Carl Roth, Karlsruhe, Germany) in a ratio of 1:0.4. The suspension was centrifuged at 50×*g* for 20 min. The upper phase was carefully layered on an equal volume of a solution of polysucrose and sodium diatrizoate (Histopaque-1077, Sigma-Aldrich, St. Louis, MO, USA) and centrifuged at 900×*g* for 30 min without break to separate PBMCs from the residual blood. PBMCs from the interphase were transferred to a PBS-coated 50 ml tube and washed twice with PBS by centrifugation at 400×*g* for 10 min. Thereafter, PBMCs were resuspended in Roswell Park Memorial Institute (RPMI) 1640 medium (Gibco™, ThermoFisher Scientific, Waltham, MA, USA) containing glucose, 10% chicken serum, and 1% Pen/Strep before culture at 41 °C with 5% CO_2. For co-culture experiments, 1×10^6 cells (Tali® Image-Based Cytometer, Invitrogen™, ThermoFisher Scientific, Waltham, MA, USA) were treated with vital bacteria from the probiotic strains *B. amyloliquefaciens* CECT 5940 and *B. subtilis DSM 32315* in a ratio of 1:3 (PBMCs:*Bacillus*) for 24 h in RPMI 1640 supplemented with 10% chicken serum in a 24-well plate. 10 µg/ml concanavalin A (conA) was used as a positive control for proliferation. Untreated cells cultured in RPMI 1640 medium served as a negative control. Thereafter, cells were harvested, centrifuged at 400×*g* for 10 min before staining with different antibodies. Immune cells were stained with antibodies labelling T-helper cells (CD4-SPRD, CT-4, SouthernBiotech, Birmingham, AL, USA) and cytotoxic T-cells (CD8-APC, CT-8, ThermoFisher Scientific, Waltham, MA, USA). Furthermore, the T-cell activation was investigated (CD25-FITC, AbD13504, Bio-Rad Laboratories, Hercules, CA, USA). DAPI was used as a viability marker. 20,000 vital cells were acquired on a BD FACSCanto™ II (Becton Dickinson, Franklin Lakes, NJ, USA). The cell count was calculated relative to the vital PBMCs measured. Due to high variation in the immune response capacity, the results are displayed as the Δ relative cell count, representing the difference of the relative cell count between the treatment and the respective untreated negative control for every biological replicate. Statistical analysis was performed by a one sample *t*-test against a hypothetical value 0. All tests were executed using GraphPad Prism 8.0.2 (GraphPad Software, San Diego, CA, USA). Differences between groups were considered statistically significant at $P<0.05$.

Results

To investigate direct effects of *B. amyloliquefaciens* (Figure 1) and *B. subtilis* (Figure 2) on the adaptive immune cells, we assessed the Δ relative cell count of CD4+ T-helper cells (Figure 1a, Figure 2a), CD4+CD25+ activated T-helper cells (Figure 1b, Figure 2b), CD8+ cytotoxic T-cells (Figure 2c) and CD8CD25+ activated cytotoxic T-cells (Figure 2d).

As expected, conA as a positive control increased the Δ relative cell count of CD4+ T-helper cells (Figure 1a, $P<0.01$) and CD4+CD25+ activated T-helper cells (Figure 1b, $P<0.0001$). After treatment with *B. amyloliquefaciens*, we detected a higher Δ relative cell count of CD4+CD25+ activated T-helper cells (Figure 1b, $P<0.05$) and of CD4+ T-helper cells (Figure 1a, $P<0.1$). There was no difference for cytotoxic T-cells (data not shown).

As expected, conA increased the Δ relative cell count of T-helper cells (Figure 2a, $P<0.0001$; Figure 2b, $P<0.0001$) and cytotoxic T-cells (Figure 2c; Figure 2d, $P<0.0001$) also in the experiments with *B. subtilis* treatment. Furthermore, we found a higher Δ relative cell count of CD4+ T-helper cells (Figure 2a, $P<0.05$) and CD4+CD25+ activated T-helper cells (Figure 2b, $P<0.01$) after treatment with *B. subtilis*. Moreover, the Δ relative cell count of CD8+ cytotoxic T-cells (Figure 2c, $P<0.05$) and CD8+CD25+ activated cytotoxic T-cells (Figure 2d, $P<0.05$) increased in the presence of *B. subtilis*.

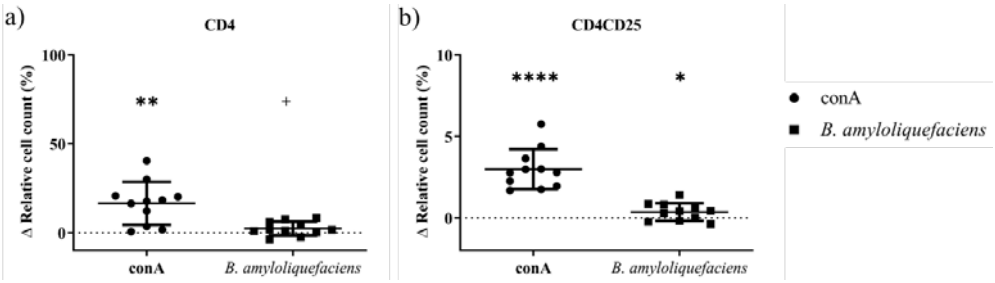

Figure 1. *In vitro* effects of *B. amyloliquefaciens* CECT 5940 on T-helper cells. CD4+ T-helper cells (a) and CD4+CD25+ activated T-helper cells (b). The Δ relative cell count was calculated as the difference of the relative cell count between the treatment and the respective untreated negative control measured on a BD FACSCanto™ II. Cells were treated with *B. amyloliquefaciens* in a ratio of 1:3 (PBMCs:*Bacillus*), with 10 µg/ml conA (positive control) or left untreated (negative control). Error bars show SD. Significance is shown as +, *P*<0.1; *, *P*<0.05; **, *P*<0.01; ****, *P*<0.0001.

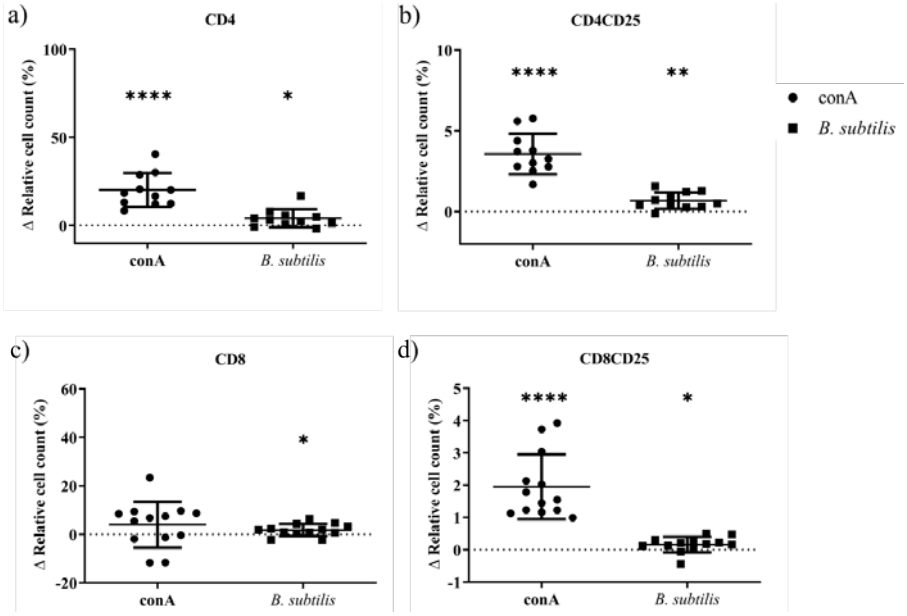

Figure 2. *In vitro* effects of *B. subtilis DSM 32315* on T-helper cells and cytotoxic T-cells. CD4+ T-helper cells (a), CD4+CD25+ activated T-helper cells (b), CD8+ cytotoxic T-cells (c), and CD8+CD25+ activated cytotoxic T-cells (d). The Δ relative cell count was calculated as the difference of the relative cell count between the treatment and the respective untreated negative control measured on a BD FACSCanto™ II. Cells were treated with *B. subtilis* in a ratio of 1:3 (PBMCs:*Bacillus*), with 10 µg/ml conA (positive control) or left untreated (negative control). Error bars show SD. Significance is shown as *, *P*<0.05; **, *P*<0.01; ****, *P*<0.0001.

Discussion

We investigated the effects of two *Bacillus* strains, *B. amyloliquefaciens* and *B. subtilis* in a cell culture system with chicken adaptive immune cells (Larsberg *et al.*, 2021). We detected stimulating effects of both strains on the activation (percentage of CD4+CD25+ activated T-helper cells), as well as on the proliferation (percentage of CD4+ T-helper cells) of T-helper cells. In the treatment with *B. amyloliquefaciens,* we found no effect on cytotoxic T-cells. That hints towards an *in vitro* stimulation of T-helper cells through *B. amyloliquefaciens* bacteria which was already observed *in vivo* (Dorigam *et al.*, 2019).

In the experiments with *Bacillus subtilis*, we found stimulating effects on T-helper cells as well as on cytotoxic T-cells. This finding is in line with observations in a previous *in vivo* study in chicken with probiotic *Lactobacillus acidophilus* LA5 (Asgari *et al.*, 2016). Moreover, *Bacillus subtilis* spores, as adjuvants, were shown to enhance CD4+ and CD8+ T-cell responses *in vivo* against avian influenza H9N2 (Lee *et al.*, 2020). In a necrotic enteritis challenge, *Bacillus subtilis* DSM 32315 was shown to reduce pathology and improve performance of broilers. Thus, *Bacillus subtilis* DSM32315 may improve the performance through modulation of T-cell responses in chicken. This ongoing study provides evidence of a direct immunomodulatory effect of *B. amyloliquefaciens* CECT 5940 and *Bacillus subtilis* DSM 32315 on chicken immune cells. Therefore, it can be suggested that the administration of these probiotics can improve the adaptive immune defence in chicken and thereby the usage of antibiotics could be reduced in chicken farming.

604. Strain and age effects, as well as genetic parameters for adult traits in ostriches

S.W.P. Cloete[1,2*], A. Engelbrecht[3] and Z. Brand[3]

[1]Stellenbosch University, Private Bag X1, 7602 Matieland, South Africa; [2]Western Cape Department of Agriculture, 7607 Elsenburg, South Africa; [3]Western Cape Department of Agriculture, 6620 Oudtshoorn, South Africa; schalkc2@sun.ac.za

Abstract

This study investigated the effects of strain (South African Black – SAB; Zimbabwean Blue – ZB; Kenyan Red – KR) on adult traits in ostriches. SAB females outperformed ZB and KR birds for reproduction traits, but had a lower adult weight than the other strains. KR birds were heavier than SAB birds, but lighter than ZB birds. Feather weight and hair scores were poorer in KR birds than in the other strains. All traits were heritable, estimates ranging from 0.10 for chick production to 0.42 for adult weight. Corresponding values for animal permanent environment ranged from 0.17 for egg production to 0.37 for feather weight and hair score. No conclusive unfavourable genetic correlations were found among traits, thereby simplifying selection decisions for the economically important traits included in the study.

Introduction

Income from an ostrich farming enterprise is derived from skins, meat and feathers (Cloete *et al.*, 2008b). As most skins and meat are produced by surplus birds not retained for breeding in their flock of origin, the importance of reproduction is evident in commercial enterprises. Apart from reproduction, adult weight is a key input trait, which is indicative of lifetime maintenance requirements, while feather weight and hair follicle prevalence has also been identified as key traits in ostriches (Engelbrecht *et al.*, 2019). Hair follicle prevalence can only be scored on the leather obtained from slaughter birds, but the prevalence of bristle hairs on live adult birds may be used as a proxy (Engelbrecht and Cloete, 2021). Furthermore, commercial ostrich production may also benefit from genetics from other ostrich strains (Cloete *et al.*, 2008a; Davids, 2011).

Against this background, we studied strain effects of South African Black (SAB), Zimbabwean Blue (ZB) and Kenyan Red (KR) birds. We also derived genetic parameters for traits that were identified as economically important in adult ostriches.

Materials & methods

The study was undertaken on the multi-breed ostrich resource flock on the Oudtshoorn Research farm of the Western Cape Department of Agriculture (Cloete *et al.*, 2008a; Davids 2011; Brand and Cloete, 2015). Data of pure SAB, ZB and KR breeding pairs were used. Details of data recording for annual egg production (EP) and chick production (CP) of females as well as adult weight (AW) of males and females at the commencement of breeding can be obtained from Cloete *et al.* (2006). These data were recorded over a 31-year period from 1990 to 2020. Total feather weight (TFW) was defined as the total weight of six feather classes, as defined by Brand and Cloete (2009; 2015) and recorded from 2001 to 2020. The presence of bristle hairs was scored (HS) on a 5-point linear scale (negligible – excessive) at the commencement of breeding from 2016 to 2020. The number of records available for analysis amounted to 1,328 for HS, 2,818 for TFW, 3,868 for EP and CP and 8,125 for AW.

All data were analysed with ASReml (Gilmour *et al.*, 2015), fitting the fixed effects of strain (SAB, ZB or KR), sex (male or female, only for AW, TFW and HS), animal age (2- to 10+ years of age) and production year

R.F. Veerkamp and Y. de Haas (eds)

(as defined previously). Two-factor interactions of strain with age and sex with year were also considered. Once an operational model for a specific trait were identified, the random effects of additive animal, animal permanent environment (PE) and service sire PE (only for EP and CP) were added and evaluated with the log likelihood ratio test. Three-trait analyses were then conducted to draw up a complete set of genetic, animal PE, environmental and phenotypic correlations among traits.

Results

Expressed relative to SAB performance, female EP amounted to 65% in ZB and 72% in KR females ($P<0.05$; Table 1). Corresponding figures for CP were respectively 69 and 79%. ZB and KR birds were respectively 13.3 and 5.5% heavier than SAB birds, the difference between the former strains also reaching significance ($P<0.05$), SAB and ZB birds did not differ for TFW and HS ($P>0.05$). TFW was lower in KR birds than in the other strains, while HS was higher for KR birds (both $P<0.05$).

Strain interacted with animal age for all traits ($P<0.05$). The CP of the SAB strain increased from 2- to 3-year-old females with little subsequent change (Figure 1a). In ZB females, CP increased to around 6 years of age before starting to decline. In KR females, in contrast, the initial increase in CP was followed by a further increase from 8 to 10 years. AW generally increased to maxima at 4-5 years in the SAB and ZB strains and 3-7 years in the KR strain (Figure 1b). AW tended to decline at ages subsequent to the peak weights.

Table 1. Predicted means (±SE) for the effect of strain on egg production (EP), chick production (CP), adult weight (AW), total feather weight (TFW) and hair score (HS) in adult ostriches.[1]

Strain	Trait				
	EP	CP	AW (kg)	TFW (g)	HS (n)
SA Black	46.1±0.5^{b}	21.7±0.3^{b}	120±1^{a}	748±4^{b}	2.35±0.05^{a}
Zimbabwean Blue	30.0±1.1^{a}	15.0±0.8^{a}	136±1^{b}	761±5^{b}	2.32±0.06^{a}
Kenyan Red	33.4±1.8^{a}	17.1±1.3^{a}	126±1^{b}	658±5^{a}	2.91±0.06^{b}

[1] Means with different superscripts differ in collumns ($P<0.05$).

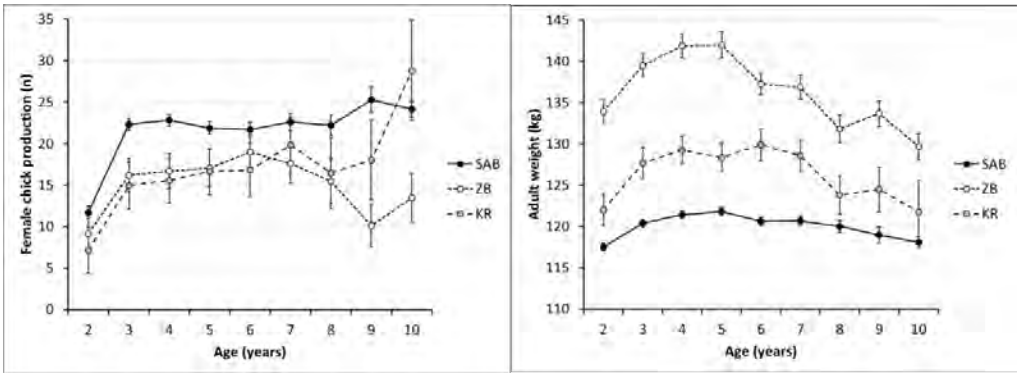

Figure 1. Predicted means (±SE) depicting the interaction of strain with animal age for chick production as a reproductive trait (a) and adult weight (b).

All traits were heritable, with estimates ranging from 0.10 for CP to 0.42 for AW (Table 2). The corresponding range for animal PE values was from 0.17 for EP to 0.37 for TFW and HS. The service sire PE effect was significant for EP at 0.03±0.01 and CP at 0.05±0.01 (not tabulated). The genetic correlation approaching unity between EP and CP was the only significant genetic correlation. The absolute direction of the negative genetic correlations of reproduction with HS was favourable, but countered by positive correlations at the animal PE level (Table 2). Other significant favourable animal PE correlations were between EP and CP, AW and TFW and TFW and HS.

Discussion

This study confirms superior reproduction but a lower mature body weight in SAB birds compared to the other strains (Table 1), which are consistent with previous studies comparing SAB and ZB birds (Cloete *et al.*, 2008a). Davids (2011) also compared all three strains and similarly reported that ZB and KR birds were heavier, but with an inferior performance for CP compared to SABs. The KR birds were intermediate for EP, not differing from either of the other strain in the latter study. The lower feather weight of KR birds compared to the SAB strain was consistent with previous results (Brand and Cloete, 2015). However, these authors, as well as Brand and Cloete (2009) also reported a lower feather weight for ZB birds, which was not found in this study. No previous results for strain effects on HS are available to support the poorer performance of the KR strain in this respect.

The age trend for SAB females for CP in Figure 1a was consistent with the trend reported by Cloete *et al.* (2006). Earlier studies by Cloete *et al.* (1998) and Bunter (2002) reported age trends more similar to those of the ZB in the present study. To our knowledge, it is the first report of the influence of age on CP in KR birds. It is possible that the increase in CP from 8 to 10 years was caused by the retention of reproductive females to later ages, as the KR was by far the smallest group and therefore difficult to maintain. The general trend in AW as animal age changed was consistent with previous reports (Bunter, 2002; Cloete *et al.*, 2006), but the trends for ZB and KR birds seem to be accentuated relative to the SAB birds. No previous studies were done on age effects in the former strains, making it impossible to relate the results obtained to the literature.

Table 2. (Co)variance ratios (±SE) for and among egg production (EP), chick production (CP), adult weight (AW), total feather weight (TFW) and hair score (HS) in adult ostriches.

Parameters and traits	Trait				
	EP	CP	AW (kg)	TFW (g)	HS (n)
Heritability in bold on the diagonal, genetic correlations below and phenotypic correlations above the diagonal					
EP	**0.15±0.04**	0.77±0.01	0.03±0.03	-0.21±0.03	0.08±0.05
CP	0.98±0.03	**0.10±0.03**	0.01±0.03	-0.22±0.03	0.07±0.05
AW	-0.07±0.14	0.02±0.15	**0.42±0.04**	0.17±0.03	-0.02±0.04
TFW	0.03±0.20	-0.20±0.21	0.06±0.15	**0.21±0.05**	-0.14±0.05
HS	-0.27±0.26	-0.34±0.29	0.20±0.19	0.28±0.32	**0.23±0.08**
Animal PE effects in bold on the diagonal, Animal PE correlations below and environmental correlations above the diagonal					
EP	**0.17±0.04**	0.76±0.01	0.16±0.02	-0.22±0.04	0.06±0.05
CP	0.76±0.05	**0.20±0.03**	0.10±0.02	-0.17±0.04	0.06±0.05
AW	-0.07±0.12	-0.13±0.10	**0.30±0.03**	0.02±0.02	-0.01±0.04
TFW	-0.44±0.14	-0.36±0.11	0.43±0.07	**0.37±0.05**	-0.01±0.08
HS	0.40±0.22	0.36±0.19	-0.23±0.13	-0.46±0.14	**0.37±0.08**

Estimates of h^2 for EP and CP were consistent, but at the lower end of the range of previous values reviewed by Cloete *et al.* (2008b). This result could be due to the inclusion of the other strains in the present analysis, as previous results were obtained on SABs only. It did correspond closely with the more recent paper by Cloete *et al.* (2019) on the SAB, though. It is thus plausible that the recent introduction of new birds from commercial strains affected the partitioning of variances between h^2 and animal PE. Service sire PE effects were also similar to the review by Cloete *et al.* (2008b) and results of Cloete *et al.* (2019). The h^2 of AW was consistent with values reviewed by Cloete *et al.* (2008b), but the h^2 of TFW was slightly lower than the previous estimate of 0.30 reported by Brand and Cloete (2009) on SAB and ZB birds only. Brand and Cloete (2015), reported a lower h^2 of 0.12, but it should be remembered that they analysed weights of six different feather classes individually instead of total feather weight. The only previous h^2 for HS in adult birds amounted to 0.23 in the same flock (Engelbrecht and Cloete, 2021). The near-to-unity genetic correlation between EP and CP accorded with previous results (Cloete *et al.*, 2008b).

To conclude, it is evident that ostrich strain affected all traits, the SAB performing better for reproduction and poorer for AW. Moreover, all traits were variable and heritable and should respond to directed selection. No conclusive unfavourable genetic correlations were found, simplifying selection decisions for adult traits in ostriches.

605. Economic value and production characteristics of table honey

E.A. Frost[1,2*], N.C. Chapman[3], R.G. Banks[1], S.F. Walkom[1] and S. Hermesch[1]

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]New South Wales Department of Primary Industries, Paterson, NSW, 2421, Australia; [3]University of Sydney, Macleay Building A12, Science Rd, Camperdown 2006, Australia; elizabeth.frost@dpi.nsw.gov.au

Abstract

Most honey produced globally is classed as table honey, for direct consumption, as distinct from higher value medicinal grade honeys. Economic value of honey was based on domestic table honey price in AU$ derived from Australia (AU) and United States (US), from 2010-2021 and sourced from AU honey processors and the US Department of Agriculture. For 2021, average AU and US domestic honey values were AU$5.70 and AU$6.53 per kg respectively. Domestic price slopes for 2010-2021 were similar for AU and US at an increase of AU$0.28 per year. Characteristics for honey production (HP) per hive per year were collated from four manuscripts and three AU datasets, presenting a substantial range of means (8.5 to 123.3 kg), and standard deviations (2.6 to 42.8 kg). Variability in HP between studies is attributed to differences in phenotyping, genotype, environment and production scale.

Introduction

Honey accounts for 85% of Australian (AU) beekeeper income (ABARES, 2016). Surveyed AU beekeepers nominated honey production (HP) as the top trait for selection (Chapman and Frost, 2020). Due to lack of selection for the trait, a need to improve overall beekeeper management, and variable access to nectar-yielding plant species, HP is not fully realised. In regard to genetic improvement, Petersen's (2020) review of honey bee breeding program design notes selective breeding in honey bees is primarily undertaken by researchers for a single trait or in small-scale production systems, with little uptake from or benefit to beekeepers operating large-scale production systems. Such large-scale systems are common in AU. The National Honey Bee Genetic Improvement Program (Plan Bee) will develop a breeding program to improve productivity of the large-scale AU beekeeping industry. As a first step towards this aim, deriving the economic value of table honey and evaluating HP phenotype data on individual hives with fixed queens over twelve months is necessary because the beekeeping industry lacks formalised breeding objectives for large-scale production systems. Literature was reviewed for the economic value of table honey. A lack of economic value, besides subjective weighting of traits by percentage value out of 100, (Van Engelsdorp and Otis, 2000, Zakour and Bienefeld, 2014) necessitated the present study to derive it. This study derives the economic value of honey in two beekeeping industries with comparable production systems (AU and United States (US)) and summarises HP characteristics.

Materials & methods

The economic value for honey was derived and prices over time for two comparable markets (AU and US domestic and AU export) were documented. Cost of production was examined in the AU context. Published and unpublished AU data for HP per hive in large-scale systems across one full and two partial twelve month seasons were compared with other studies including HP characteristics.

Results

Production characteristics varied considerably between studies (Table 1). Variability reflects differences in phenotyping, genotype, environment and production system. Phenotyping methods included estimation of HP by number of honey combs times a factor of 2.5 (Zakour *et al.,* 2012), measuring weight difference of

Table 1. Overview of honey production characteristics for hives with a fixed queen over single or multiple honey harvesting events in one or more twelve month periods.[1]

Study	Mean	*S*	Min/Max	PS
Banks et al. (2020) AU Pop 1 2018-19	41.5	18.2	0.0/136.0	Large
Banks et al. (2020) AU Pop 2 2019-20	123.3	42.8	25.6/195.9	Large
Bienefeld and Pirchner (1990) Germany	24.1	13.9	0.0/99.8	Mixed
Brascamp et al. (2018) Austria	30.0	15.8	0.1/202.0	Mixed
Zakour et al. (2012) Syria Pop 1	8.5	3.3	0.5/23.8	Mixed
Zakour et al. (2012) Syria Pop 2	10.2	2.6	1.0/20.0	Mixed
Plan Bee AU 2021	44.2	14.8	0.0/96.6	Large

[1] *S* = standard deviation; *Min* = minimum; *Max* = maximum; *PS* = production system; *Pop* = population.

combs before and after extraction of honey plus an estimate of honey remaining in the broodnest (Bienefeld and Pirchner, 1990), and weight difference of combs before and after honey extraction by itself (Banks *et al.*, 2020, *Brascamp et al.,* 2018, Plan Bee, 2021). Subspecies of honey bees analysed included *Apis mellifera syriaca* (Zakour *et al.,* 2012), *Apis mellifera carnica* (Bienefeld and Pirchner, 1990, Brascamp *et al.,* 2018) and *Apis mellifera* hybrids (Banks *et al.*, 2020, Plan Bee, 2021). Production systems can reflect hives fixed in one location or migrated between locations, small (<200 hives) or large scale (>200 hives), and mixed (both small and large scale included). A mean of 30 kg for HP across 18 Austrian production years (Brascamp, 2016) compared to means of 41.5 and 44.19 for partial and 123.27 for full AU production years (*Banks et al., 2020* and Plan Bee, 2021 datasets) illustrates the difference between European and AU production systems and environments. Datasets from AU (Banks *et al.*, 2020, Plan Bee, 2021) were generated from large scale, migratory production systems. Other datasets (Bienefeld and Pirchner, 1990, Brascamp *et al.,* 2018, Zakour *et al.,* 2012) included both stationary and migratory small (< 200 hives per beekeeper) and large-scale production systems (>200 hives per beekeeper).

Economic value. The economic value of honey was derived from the price in AU$ of one kilogram of honey. Average honey prices from AU and US domestic markets and AU export markets from 2010 to 2021 were sourced from the AU beekeeping industry and US Department of Agriculture. Average annual exchange rates from 2010 to 2020 (www.exchangerates.org.uk) were used to convert US$/lb to AU$/kg for US domestic and US$/kg to AU$/kg for AU export prices. Linear regression was used to quantify the change in honey price for different markets over time. The export market price for table honey was higher than domestic market prices in recent years. The high export price in 2020 is a result of depressed domestic supply and increased demand from overseas markets. The economic value of honey was AU$5.70/kg for the 2021 AU domestic market, with 2022 economic value of AU$6.42/kg expected. Linear regression of table honey price for AU and US domestic shows a steady increase in domestic price (Figure 1). Honey price (AU and US domestic) over time generated a positive, parallel slope of 0.28. Export price (AU) yielded a slope of 1.32. Price for table honey increased consistently over time with minimal variation from the overall slope which explained 81 to 85% (coefficients of determination) of the variation in price of honey over time.

Expected costs to large scale AU producers for each added kg honey per hive are hardware, labour and freight. Large variability in HP across AU hives (Table 1), indicates that an increase of 1 kg per hive can be captured within existing hardware (i.e. honey boxes, cooperative-owned bulk containers) and available labour, negating any increase in equipment or labour at this stage (Banks *et al.*, 2020, N.G. Bingley, C.C. Cooper, C.F. Horner, personal communications). Given our mean, freight is the only added cost to produce additional honey (AU$0.04/kg) at the current time so the economic value of HP is given as price per kilogram AU$5.70 on the domestic market.

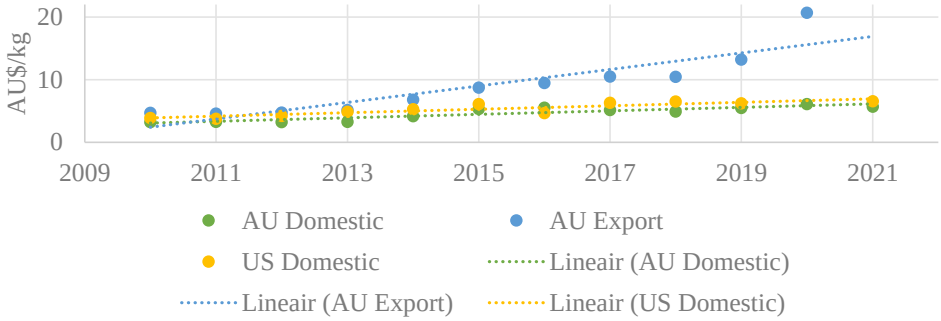

Figure 1. Honey (AU$/kg) price over time in different markets.

Discussion

Price differences illustrate variation in economic value for table honey over time and between markets which need to be considered in bee breeding programs. Although economic value was not found in the literature, the price weighting of honey as a subjective percentage (34.4±2.40% and 55.3% respectively), in addition to other traits totalling 100%, shows a range of trait emphasis in breeding objectives specific to production system, genotype and environment between Canada and Syria (Van Engelsdorp and Otis, 2000, Zakour and Bienefeld, 2014). This highlights the need for AU economic models to derive relative economic values for top AU traits. Secure growth in the AU domestic market supports increased selection for HP. Where export market targeting is possible at the producer level, an extra value upward of AU$15/kg, excluding marketing costs, is expected. Datasets from AU are testament to environmental conditions for HP which surpass those in other study environments. Additionally, the AU datasets result from large-scale production systems which migrate hives to multiple honey making events in a twelve-month period. Comparatively, other datasets include a mix of small and large-scale production systems and both migratory and stationary honey producers. The substantial range in HP characteristics between the literature and AU datasets highlights the need to establish the differences between datasets in other countries and AU genotypes, environment and production systems to ensure accurate analysis. AU datasets presented are indicative of large-scale production systems where colonies are transported to subsequent honey production environments unique in aspects of climate, plant species, nectar production and duration to those northern hemisphere environments within the literature. Phenotyping is currently underway in AU through Plan Bee. Phenotypic data for AU-preferred traits and pedigree information will enable selection tailored to the AU environment, thereby improving the viability of the AU beekeeping industry and contributing to a global model applicable to large-scale production systems.

Abstract

The study was conducted to explore alternatives for mating control as a part of honey bee breeding programs for genetic improvement & conservation of local honey bee (*Apis mellifera*) populations in Croatia (HR), Macedonia (MK) and Slovenia (SI). We observed nuptial flights of 87 virgin queens (30 in HR, 35 in MK and 22 in SI) on potential sites. Mating success was related to the presence of drone producing colonies, but even at locations chosen for their isolation from known apiaries, mating success of 70% was achieved. On average, queens performed nuptial flights on 1.8 days in HR, 1.6 to 4.3 days in MK and 1.6 to 2.4 days in SI. Unsuccessful nuptial flights were two/threefold shorter than successful flights.

Introduction

Breeding programs for genetic improvement and conservation of local honey bee (*Apis mellifera*) populations have been in place for at least a decade in Croatia (HR), Macedonia (MK) and Slovenia (SI). However, the selection progress has been slower than expected due to the lack of efficient mating control as one of the crucial elements of the breeding programs (Uzunov *et al.*, 2017, Plate *et al.*, 2019). The mating behaviour of honey bees is complex: the queen performs nuptial flights and mates with 7-17 drones that can originate from many different colonies within a 10 km radius (Koeniger *et al.*, 2014). High colony density and lack of geographically isolated areas are recognised as the main factors for the unsatisfactory employment of mating control. However, by scouting possible isolated places or utilizing other means of mating control, such unfavourable situations may be counteracted. Such studies include identifying isolated locations by employing on-field observations and complementary laboratory investigations, investment in technical and human capacities in case of instrumental insemination, or intensive cooperation with surrounding beekeepers if an overflow with selected drones is the strategy. The project BeeConSel, funded by EEA & Norway Grants Fund for Regional Cooperation (2020-2023) provides an opportunity for investigation of alternatives for overcoming the deficiency of existing mating control. The preliminary results from the field investigations by observations on the queens' nuptial flights in the project's initial year are presented and discussed in detail in the next paragraphs.

Materials & methods

In June and July of 2021, the field investigations and data collection were conducted by direct observations. Virgin queens were placed into drone-free mini mating boxes (nucs) with around 700 worker bees and solid food, and kept 72 h in a dark and cool room. Forty-eight hours before the observations began, they were placed in the observation sites with an installed queen excluder on the entrance (Büchler *et al.*, 2013; Scheiner *et al.*, 2013). Nuptial flights were observed on 87 queens: 30 in Croatia (*A. m. carnica*), 35 in Macedonia (*A. m. macedonica*) and 22 in Slovenia (*A. m. carnica)*. The candidate locations were

selected in each country based on the following main criteria: expected low density or absence of managed and/or feral colonies, geographical isolation, good logistical accessibility, and suitable weather/climate. In Croatia, observations were done on a flatland mating station (Batina, 240 m a.s.l.) flooded with drones originating from 96 drone producing colonies (DPC), headed by sister queens. No other managed colonies were expected to be present withing a diameter of 6 km. In Macedonia, the observations were done on three micro-locations in the frame of the mountainous region of Mavrovo plateau (>1,680 m a.s.l.). At the location MK-Belicki, 17 managed colonies were identified 2.5 km away at the end of observations. The locations MK-Crkva and MK-Cavkarnik were at 3 km air-distance from the next same apiary, that was lower in altitude by 400 m. Following the observations, the queens in the last two locations were allowed to freely fly for two additional days. Three locations were investigated in Slovenia in deep Alpine valleys: Vrata (1,020 m a.s.l.) with direct observation and no known managed/feral colonies present, Krma 0 (960 m a.s.l) with five DPC at the location and Krma 1 which was 1 km further in the valley at 1,015 m a.s.l. Three queens in Krma 0 were observed by video surveillance. The field study was done following a tailored protocol for direct observation (Uzunov *et al.*, *in preparation*). For at least 5 days from 11:00 to 17:00 queens' nuptial flight parameters were monitored and recorded: flight frequency, flight duration, observed mating sign and weather conditions. The direct observations were done by installing an extension on the mating box entrance with a transparent cover and queen excluder allowing observation and control of any queen flight attempt (Koeniger, 1981). At the time of the field studies, the weather conditions were suitable in all sites, although with noticeable variations (particularly wind) between the micro-locations in Macedonia.

Results

The number of observed, active and mated queens, the average number of flying days and flight frequency, as well as the queen's average flight duration with or without the mating sign per country and location are presented in the Table 1.

A mating success of over 76% was achieved in HR-Batina where 96 DPCs were placed and over 91% in MK-Cavkarnik where an apiary was at a distance of 3 km. In contrast, the mating success in SI-Krma 1, where 5 DPCs were present 1 km away from the locations with mating boxes, was only 56%. In SI-Vrata,

Table 1. Descriptive statistics of the main parameters from the observations. The minimum and maximum values are given in round brackets.

	Number of queens		Aver. per queen		Aver. flight dur./queen**

where no managed or feral colonies were known to exist 70% of the virgin queens succeeded in mating. In the remaining two Macedonian locations MK-Belicki and MK-Crkva, the mating success was below 55%.

The average number of flying days per queen and the average flight frequencies were in the expected biological range except the high values in MK-Belicki (average of 4.3 flying days and 8.8 flights per queen). The lowest values for average number of flying days were recorded in HR-Batina (1.8) and SI-Krma 0 (1.6). Almost on all locations, the average flights' duration per queen returning to the mating box without a mating sign were two to threefold shorter than the flights with a mating sign. The highest average differences of 3.7 times, between flights with and without observed mating sign, was recorded in MK-Belicki.

Discussion

In HR-Batina, where the location was saturated with a sufficient number of drones, the results of high mating success (76.7%) show the importance of the availability of a high number of mature airborne drones. Under such conditions, the queens flew on a low number of days (1.8) and had a regular flight frequency (3.8) per queen, reducing the risk of additional flights and engendering possible losses, clearly listing the location as a good candidate for setting up a mating station, and making the approach of 'drone flooding' appear promising. With a queens' flight speed of around 20 km/h (Koeniger *et al.*, 2014) and an average flight duration of 14 minutes for those returning with a mating sign, we estimated an average distance of 1.5 km to the potential mating site(s), taking into account the time of around 5 min for the mating *rendezvous* with the drones (Koeniger *et al.*, 2014). Still, a successful flight as short as 4 minutes indicate that the queen was mated close by.

With five DPCs employed at the locations SI-Krma 1, partial mating success was obtained with 56%. According to Tiesler *et al.* (2016), the required number of DPCs ranges from 8 for 50 virgin queens to a minimum of 20 DPCs for 500 virgin queens. Nevertheless, due to the small sample size, the results from SI-Krma 0 needs to be interpreted with caution even though the flight activities indicate that the queens' mating was efficient. On the other hand, the unsatisfactory results from SI-Krma 1 might be a consequence of the ambiental conditions with brief sunny periods due to high mountain walls or rough transportation to the location. Finally, the results from the supposedly drone-free location SI-Vrata, show that there seems to be a significant drone 'noise' from the surrounding area; however, the average duration of mating flights – both with or without a mating sign, was the longest of all studied locations. This may indicate that distance alone is not always sufficient to predict the suitability of a candidate location.

In Macedonia, we recognised the possibility of using MK-Belicki as the most prosperous location for establishing a reliable mating station. All queens were flying but only 42% of queens (n=5) were producing worker brood. The above-average number of flying days and high average frequency of 8.8 flights per queen indicate a queen's excessive efforts for finding partners (Uzunov *et al.*, 2014) even under the fact that 17 managed (but not DPC) colonies were later discovered 2.5 km away. At MK-Crkva, almost 82% of the queens flew but 55% of the queens (n=6) successfully produced worker brood even with the existence of an apiary in the vicinity of 3 km. However, the queens' flight activities were lower and similar to the locations saturated with drones. The persistent wind occurrence recorded during the observations might affect queens flight performance at this location (Koeniger *et al.*, 2014). MK-Cavkarnik, with the highest mating success (91.7%) among the Macedonian locations, even it is on the same distance from the next apiary as MK-Crkva is (but in different direction), seems an unsuitable choice for setting up a mating station. Such prediction is also based on the queens' flight activities and in particular, the short duration of 3 minutes for the performed successful flight in MK-Cavkarnik. Koeniger and Koeniger (2007) and Heidinger *et al.* (2014) found shorter mating flight duration in an area saturated with drones, while in the area with a low number of colonies, mating flights were longer (Koeniger *et al.*, 1989). The obvious relationship between

the duration of mating flights and the number/vicinity of potential mating partners, also observed in the present experiment, suggest that this parameter can be used as an additional indicator for judging of the suitability of a location for isolated mating.

In order to answer the question of the achievable mating purity with greater certainty, an analysis of the drone's origin and semen composition are indispensable. This information will be available before the beginning of the next beekeeping season. Therefore, in the following two seasons, the activities will be focused on verifying the current locations using sufficient DPCs or exploring new sites by observations on the queens and drones' nuptial flights.

607. A model for, and early implementation of, genomic selection in the Australian honey bee population

N.C. Chapman[1], E.A. Frost[2,3] and R.G. Banks[3*]

[1]University of Sydney, Macleay Building A12, Science Rd, Camperdown 2006, Australia; [2]New South Wales Department of Primary Industries, Paterson, NSW, 2421, Australia; [3]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, Armidale, NSW, 2350, Australia; rbanks@une.edu.au

Abstract

Genetic improvement has been limited in the Australian honey bee population, despite the direct and indirect economic significance of the industry. Recently, significant industry and community investment has established the foundation for a national R&D and improvement program centred on objective evaluation and genomic selection, underpinning strong industry and community engagement. This paper outlines the key elements of that program, its goals, and early steps in implementation, and highlights the transformative potential of the program.

Introduction

The Western honey bee (*Apis mellifera*) was introduced to Australia within the wider process of colonisation and development of British/European agricultural practices, and now contributes to the Australian economy in two ways:

- directly, through honey production, which is worth an estimated $AUD150m per year; and
- indirectly, through pollination 'services' provided to a range of introduced crops. In the absence of alternative means of pollination, the value of these services has been estimated at upwards of $AUD5-6bn per year.

In recent years the critical importance of the honey bee has been brought into sharper focus by awareness of threats affecting honey bee populations globally, and in particular by the risk posed by the Varroa mite (*Varroa destructor*), which is currently not present in Australia. Australia maintains strict border quarantine protocols against Varroa (and other threats to honey bees), but it is generally accepted that the mite will enter and establish in the country at some point. Further, importation of genetic material from overseas populations is very limited, again reflecting the quarantine protocols.

A further challenge is the highly variable nature of the Australian climate, with frequent droughts impacting production, and making performance recording across time challenging.

Despite these contributions and recognition of threats, there have been limited systematic wide-scale attempts at genetic improvement of the population. There have been studies outlining scope for improvement via selection and estimating potential value of such improvement (Oldroyd, 1984, Banks *et al.*, 2020). It has become apparent that this situation likely reflects, firstly, very limited performance recording, meaning that queens are marketed primarily on the reputation of the breeder, and secondly (and essentially the flipside of the same issue) no real incentive for queen breeders to invest time and effort in such recording.

Together, these facts mean that the industry has little or no awareness of objectively described differences in genetic merit and what they mean for honey production and/or pollination economics, and extremely limited datasets. While genetic improvement focussed on honey production and health traits would deliver private benefits, there is clear evidence of a market failure in their delivery, and a strong case for government and industry intervention.

DOI: 10.3920/978-90-8686-940-4_607, © N.C. Chapman *et al.* 2022

A recent response to this risky situation has developed through two investment steps:

- establishment of a research honey bee population at Tocal College, a research and outreach centre of the NSW Department of Primary Industries, with capacity to manage upwards of 250 hives/colonies for phenotyping at any one time;
- support for a collaborative R&D program known as Plan Bee, which aims to build on the infrastructure establishment of the facility at Tocal.

This paper outlines how these responses establish a platform for industry-wide implementation of genomic selection, and the opportunities that would present.

Key elements of Plan Bee

As noted above, systematic performance recording in honey bees is very limited in Australia, with essentially three sustained programs of any scale. These three programs have provided queens to the research facility at Tocal College, augmented by sampling from a range of smaller queen breeding operations across Australia, to establish initial samples of c. 250 queens. These queens have been introduced to hives, and detailed recording of performance, including weight of honey produced, temperament, and health traits, has commenced, along with sampling for genotyping.

Alongside, and complementing this core activity, are:

- widespread industry consultation to establish a Data Definition Manual (Chapman and Frost, 2021)– describing and defining traits which could be recorded;
- development of an industry database and procedures for analysis of data collected to produce estimates of genetic merit;
- a strong engagement effort to encourage performance recording and submission of data to the industry database; and
- careful data collection focussed on pollination activities in conjunction with key providers and users of pollination services.

The target outcomes of the first, current phase of Plan Bee activity include:

- the trait definition manual (Chapman and Frost, 2021);
- extension materials for performance recording;
- extension materials on genetic information and principles of genetic improvement;
- objectively evaluated queens, as potential sources of genetic material for industry;
- the initial core of a genomic reference population, incorporating queens sampled at tocal along with queens managed by industry queen breeders;
- initial models for wider industry participation in recording and utilisation of evaluated genetic material, including industry consultation around feasibility, practicality, etc.

While there is much to be done in development of these models, the combination of a sound reference population with large-scale multiplication of elite material provides scope for relatively rapid industry change and return on industry and government co-investment. In this sense the timing of this initiative in terms of availability of genomic technologies, coupled with the inherent reproductive capacity of honey bees and use of techniques such as AI, is extremely serendipitous (and change may be less limited by the need to achieve very widespread performance recording).

Current funding has a limited term, but it is anticipated that momentum from early progress will underpin continued co-investment by industry and government to maintain a program.

Potential impacts of a successful Plan Bee

Plan Bee has the potential to transform the Australian honey bee industry and community, through a range of important outcomes.

The scope for direct utilisation of elite genetic material is essentially unlimited, and is already being taken up. Backed by strong communication around the expected differences in hive performance, and the value of performance data, it is expected that this access could rapidly lift the performance of hives on a wide scale, which in turn should strengthen already widespread community interest in bees and beekeeping, and stimulate increased data collection. The awareness of how widely people can contribute to 'helping our bees' should develop a sense of community responsibility and opportunity.

At the professional level, the scope for accessing elite material can establish the basis of a more certain business model for queen breeders, multipliers and providers of pollination services. In this context, strong extension of the concept of genetic merit and how to use objective estimates of it, will be fundamental.

Together, these point to a much more engaged and integrated industry and beekeeping community, which is in itself valuable.

Earlier studies have suggested ample scope for genetic improvement in honey bees in Australia, and there is no reason why this cannot be realised given a sufficiently large recorded population and use of sound genetic analysis. The most challenging aspect of this outcome will be to develop methods to mitigate risks around Varroa. Plan Bee data recording will include hygienic tests, but the opportunity will also exist to collaborate with research and industry in other countries to screen genomic variation in the Australian population against reference datasets that include survival and performance in the presence of Varroa. Should Varroa enter Australia, the infrastructure of a well-recorded and genomically characterised population should enable a more rapid response. In this context, it is valuable that a small importation of Varroa-resistant genetic material has been sampled for inclusion in the first-year intake for Plan Bee.

The wide sampling of the Australian honey bee population already underway, coupled with genotyping of all sampled material, will provide a basis for immediate implementation of selection using genomic information to maintain diversity. Previous work suggests the existence of diversity at specific loci and between small samples of the population, but establishing as wide a sample base of the population as possible will maximise capacity to maintain genetic progress in the absence of importation from overseas.

While the model for an ongoing program is to be developed, initial modelling suggests (Banks *et al*., 2021) that a program centred on recording and genotyping of c. 2,000 queens per year, can generate valuable progress and be attractive economically, simply based on increased honey production. The modelling assumed ongoing national costs (database and analysis, extension and communication), but there is scope to develop approaches that combine collective (government and/or industry) and private contributions. Such models will need to incorporate suitable forms of participation or membership, with a wide range of options potentially available.

Collaboration with overseas programs has been flagged earlier in the context of Varroa, but more generally, having a sound and broadly based recording and evaluation program in place in Australia will greatly enhance scope for international collaboration, both in breeding and more broadly in R&D. In particular, understanding of genomic relatedness between countries' populations may enable a more nuanced approach to import and export of genetic material, which could benefit both Australia and international partners.

Conclusions

Plan Bee offers, and is already starting to deliver, a unique opportunity for transformation in the Australian honey bee industry. This transformation can include wide involvement and participation, very valuable genetic progress, and massive reduction of production and disease risk.

While this is obviously exciting for Australia and its own honey bee industry, there may be valuable outcomes for other countries, and at the same time, a model of industry transformation focussed on genomic selection underpinned by mixed (i.e. public and private) investment and strong industry and community engagement. This may provide learnings useful to other industries in both the 'developed' and 'developing' countries (Marshall *et al*., 2019).

Abstract

A growing interest across Europe is emerging to maintain the genetic integrity of honey bee populations and subspecies. In this study we combined different approaches to obtain an over-time distribution map of the main *Apis mellifera* mitochondrial DNA (mtDNA) lineages in the North of Italy. mtDNA was analysed from individual honey bees and from honey. Honey is a source of environmental DNA (eDNA), which also contains traces of the DNA of the honey bees that have produced it. A total of about 1,600 honey samples produced in the North of Italy over four years (2018-2021) where analysed to detect the A, C1, C2 and M mtDNA lineages. The obtained results will be useful to design conservation strategies of *A. mellifera* genetic resources in Italy. We demonstrated that eDNA from honey can be exploited to design a cost-effective population genetic study in *A. mellifera*.

Introduction

Because of the role that *Apis mellifera* plays in the agroecological systems, a growing interest across Europe is emerging to maintain the genetic integrity of honey bee populations and subspecies, which might be well adapted to local environments (De la Rúa *et al.* 2009). A combination of different factors threats the genetic integrity of *A. mellifera* populations. For example, beekeeping activities, including the transhumance of colonies and extensive trading of queen bees increase admixture between populations. The effect of harmful pesticides for the honey bees, the action of extreme climatic waves and their consequence on honey bee health can cause the loss of many colonies which could contribute to the reduction of the effective population size and incentive the use of non-autochthonous queens to replace dead families.

More than 30 *A. mellifera* subspecies and ecotypes have been described using morphometrical descriptors (Ruttner, 1988) which have been integrated with information on mitochondrial DNA (mtDNA) lineages and sub-lineages and nuclear genome polymorphisms (Cournet and Garnery,1991; Wallberg *et al.*, 2014). Due to its geographical position, Italy is a unique case in Europe as it hosts natural populations of four *A. mellifera* subspecies (Fontana *et al.*, 2018; Franck *et al.*, 2000; Ruttner, 1988; Vecchi, 1927): *A. m. ligustica* (which mainly carries the C1 mitotype but also the M7 mitotype) whose origin is from the Italian peninsula; *A. m. siciliana* (which has mitotypes of the African originated A lineage), native of the Sicily island; *A. m. mellifera* (which carries M mitotypes), originally distributed in small areas of the Western Alpine arch; and *A. m. carnica* (which mainly carries the C2 mitotype), with natural populations in the North-East part of Italy, close to the border with Austria and Slovenia (Sinacori *et al.*, 1998; Muñoz *et al.*, 2009; Franck *et al.*, 2000).

Several national and regional legislative acts have been introduced in order to protect Italian native honey bee subspecies. Starting from 2017 current legislation takes initiatives to safeguard the subspecies of *A. m. ligustica* by limiting or banning other subspecies used in beekeeping practice, including the use of hybrid (if not natural) in some Italian regions (Fontana *et al.* 2018).

We recently developed two assays to discriminate the main three mtDNA lineages (A, C and M) of *A. mellifera* and the two main mitotypes (C1 and C2) of the C lineage using honey as a source of environmental DNA (eDNA), which also contains traces of the DNA of the honey bees that have produced it (Utzeri *et*

al. 2018, 2022). We already applied the method that discriminates the A, C and M lineages to obtain an updated distribution map of the A. mellifera mitotypes over all Italy by analysing more than 600 honey samples produced in the year 2018 (Utzeri *et al.* 2021).

In this study, using honey bees and honey samples collected from the same colonies and region, we first compared the morphometric results and the mtDNA lineage frequency obtained by analysing DNA extracted from honey bees and honey. Then using many other honey samples produced in four years in all regions of the North of Italy, we obtained a distribution map of the A, C1, C2 and M mitotypes based on eDNA recovered from this food matrix.

Materials & methods

Honey bees and honey samples. Eighty samples of honey bees (~60 workers), each from a single colony from which honey (extracted from a single honey comb) was collected, were obtained from 45 beekeepers of the Emilia-Romagna region in the year 2020. These honey bees were morphometrically characterized for the identification of the *A. mellifera* subspecies of the family. For these colonies, 3-10 workers for each colony and the corresponding honey samples were used for DNA analysis. In addition, a total of 1588 commercial honey samples, produced over four years from apiaries located in all regions of the North of Italy (from west to east and north to south: Liguria, Piedmont, Valle d'Aosta, Lombardy, Trentino-Alto Adige, Friuli-Venezia Giulia, Veneto and Emilia-Romagna) were provided directly by many beekeepers. Table 1 reports the number of honey samples per region and year of production. All these samples were used for DNA analysis.

DNA analyses. DNA extraction from honey samples was performed following the protocol previously described by Utzeri *et al.* (2018). DNA extraction from individual workers was carried out using the Wizard® Genomic DNA Purification Kit (Promega, Promega Corporation, Madison, WI, USA) following the manufacturer's instructions. DNA extracted from honey was analysed with the PCR primers and method described by Utzeri *et al.* (2018) that can distinguish the three main mtDNA lineages (A, C and M) and with the Sanger sequencing assay reported by Utzeri *et al.* (2022) that discriminate the C1 and C2 mitotypes. As honey samples, if not directly sampled from a single honey comb, can be derived from more than one colony, more mtDNA lineages can be identified with the methods described by Utzeri *et al.* (2018, 2022). DNA extracted from individual worker and larvae samples was amplified with the primer pair E2–H2 (Garnery *et al.* (1992) that target the intergenic COI-COII mtDNA region. Sanger sequencing was then used to identify the amplified mitotypes after sequence data analyses carried out with MEGA X (Kumar *et al.* 2018) and BLASTN.

Table 1. Number of commercial honey samples analysed and produced by beekeepers in different regions and over the four years (2018-2021).

Region	2018	2019	2020	2021	Total per region
Liguria	6	7	9	10	32
Piedmont	56	84	136	91	367
Valle d'Aosta	11	22	26	11	70
Lombardy	74	98	126	128	426
Trentino Alto Adige	20	21	18	14	73
Friuli-Venezia Giulia	22	13	17	26	78
Veneto	41	24	69	51	185
Emilia Romagna	100	42	153	62	357
Total per year	330	311	554	393	1588

Results

Morphometric analysis of the honey bees indicated that about 60% of colonies sampled in Emilia-Romagna could be considered of *A. m. ligustica*. All honey samples obtained from these families had only the C mitotype using the method of Utzeri *et al.* (2018). These results were confirmed by mtDNA analysis of the single honey bees belonging to the same colonies. Among the remaining 40% of these colonies, five of them had honey that had the A+C+M mitotype, confirmed by individual honey bee analyses. This could be probably due to substitutions of the queens or drift of honey bees from close colonies in the apiary.

Considering all honey samples produced in Emilia-Romagna over all four years (n. 367; the region that accounted the largest number of analysed samples), about 77-82% of them had only the C mitotype. The proportion of honey samples with only the C mitotype tended to increase in the latest years. An overview of the distribution of the honey samples with different mitotypes in the four years and divided by administrative provinces of this region is shown in Figure 1. Honey samples that had only the C mitotype were also analysed to distinguish between the C1 and C2 sub-mitotypes. About 10% of these honey samples had both C1+C2 or only C2 mitotypes.

A similar distribution of honey with different mitotypes was also obtained in all other regions of the North of Italy. Honey samples with the C2 mitotype were more frequent in the North-East regions (i.e. Trentino-Alto Adige, Friuli-Venezia Giulia and Veneto), which are close to the border with Austria and Slovenia where *A. m. carnica* can be considered the autochthonous honey bee subspecies.

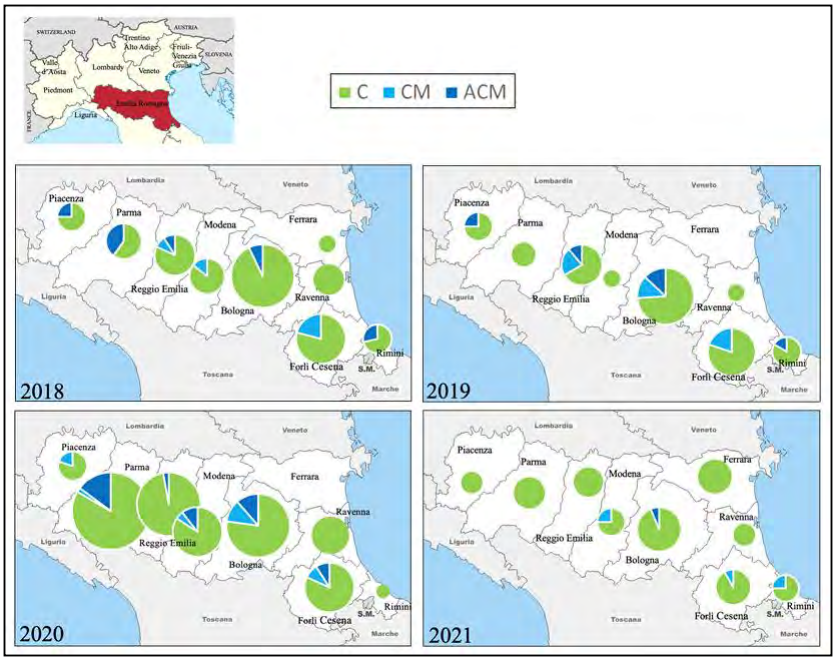

Figure 1. Distribution of honey samples produced in the Emilia-Romagna region (in red in the top set) in the years 2018-2021 that had different mitotypes, as obtained using the method of Utzeri *et al.* (2018). Information is also divided by the administrative provinces of this region. The size of the charts is proportional to the number of honey samples analysed. The different colours in the charts indicates the honey samples that had different mitotypes or their combinations.

Discussion

The combination and comparison of the different approaches and methods that we used gave a general overview of the *A. mellifera* populations in the North of Italy. As honey DNA is highly degraded (Utzeri *et al.* 2018), only short fragments can be amplified which are not fully informative. Therefore, only the main mtDNA lineages or target informative mtDNA sites can be analysed. Despite that, eDNA from this matrix could provide an interesting overview of the A. mellifera mitotypes present in the North of Italy. The current picture might be derived by the admixture of different sub-species as already reported (Utzeri *et al.* 2021). Mitochondrial DNA analysis can integrate morphometric evaluations. As similar results were obtained considering individual bee mitotype analyses and mtDNA lineage detection in honey samples, the use of eDNA from honey can be considered very useful to design a cost-effective population genetic study in *A. mellifera*, even over time. We are working to implement the analysis of nuclear genome polymorphisms using honey DNA to further strengthen the usefulness of eDNA in honey bee population genomic studies.

609. Using genomics to predict drone quality: why are there so many 'dud' male honey bees?

G.P. Slater* and B.A. Harpur

Department of Entomology, Purdue University, 901 W. State St. Lafayette, IN 47905, USA; garett.p.slater@gmail.com

Abstract

Beekeepers are faced with severe challenges that affect their colonies' health. Among the most highly-reported of those challenges is queen failure. Queens can fail because they have mated with low-quality drones. In this study, we aim to develop a rapid, high-throughput method for beekeepers and queen producers to identify high-quality line using genomics. We use a multi-omics, field-based approach to quantify the genetic features associated with poor sperm production in drones. To do this, we compare the reproductive quality of drones sourced from lines available to beekeepers in the US and raised in a common apiary. We then created crosses of these lines and will use these crosses to identify regions of the genome associated with reproductive traits. We found variation in sperm traits, which is likely inherited. Once identified, these makers will allow beekeepers to identify reproductively-viable lines and reduce the chance of queen failure in their yards.

Introduction

One of the most pressing issues facing commercial beekeepers in the United States is the poor quality of queens they are provided from out-of-state suppliers. For example, over 220 beekeepers in North Dakota (one of the most active beekeeping states of the United States) manage approximately 667,000 colonies. Many of these colonies are re-queened during the spring, a relatively new practice that has become common commercial beekeepers because of the high rates of queen failure. Queen failure is among the top three reported causes of colony death (Steinhauer *et al.*, 2014). A shocking 30% of commercially-purchased queens used for replacement fail within six months of establishment in a colony (Pettis *et al.*, 2016). The cause of queen losses is multifarious, but poor-quality sperm is a primary culprit (Pettis *et al.*, 2016).

In the United States, where beekeepers lost an average of ~30% of their colonies over the 2016-2017 year (Steinhauer *et al.*, 2014), queen failure needs to be addressed to create a sustainable industry. Male honey bees – drones – play a critical role in determining a queen's likelihood of surviving (Slater *et al.*, 2021). Queens can fail because they have mated with males who produced low-quality sperm. If drones are not producing healthy sperm (Fisher *et al.*, 2018), their mates will not produce healthy colonies (Slater *et al.*, 2021). Beekeepers can see these effects: a symptom of poor drone sperm quality includes spotty brood pattern, slow colony build-up and high supersedure rates.

We know comparatively little about the role genetics plays in shaping drone reproductive traits (Rangel and Fisher, 2019). Genetic variation across United States populations likely contributes to low quality male bees and queen failures. Honey bees are non-native to North America and originate from centuries of importation from genetically- and geographically-distinct lineages. F_{st} ranges from 0.3 to 0.6 on average among native sub-species populations across Eurasia (Harpur *et al.*, 2014). Further, among the fastest-evolving genes in the honey bee genome are those associated with spermatogenesis (Harpur *et al.*, 2014). This rapid evolution is likely due to variation in mating behavior across the honey bee's range (Wallberg *et al.*, 2014) and may have led to variation in male reproductive senescence, strategy, and morphology (Slater *et al.*, 2021). This standing genetic variation can contribute to phenotypic differences observed among honey bee line in North America (Slater *et al.*, 2021) and contribute to the success (or failure) of

colonies. Initial work in our lab demonstrates that there is variation in the reproductive quality of drones originating from four independent sources around the United States (unpublished). One major question for beekeepers, bee breeders, and researchers is how much do drone reproductive characters differ among stocks of honey bees? If reproductive variation among stocks does have a genetic component, we could be able to predict the quality of drones through sequencing.

Methods reproductive phenotyping. Our first goal is to establish when and how reproductive traits (flight behavior and sperm quality) vary among the honey bee lines. To accomplish this, we paired passive data collection (Figure 1) with high throughput sperm phenotyping. Purdue research apiary maintains four lines commonly used by beekeepers. These lines are often used by beekeepers and purchased at a premium because they are an 'identified' line or because they express valuable traits. For ten colonies within each line, we caged queens on drone comb for 24 hours and reared the resulting eggs until drones emerged as adults. We then marked 20 adult drones from each colony (n=1000) with RFID tags (Microsensys, Atlanta, GA; Figure 1B) and randomly placed drones into one of two colonies kept separately at two independent yards (to prevent drift). Each colony is fitted with an RF detector that will log when drones leave and return to their colonies. Drones leave colonies regularly to mate with queens and they do so at specific times of the day (Slater *et al.*, 2021). By tracking this behavior, we can uncover how much variation exists among lines for when drones leave to mate with queens and how frequently they leave.

Drones begin to sexually mature at 10-21 days old (Metz and Tarpy 2019). Beginning on day ten, we began sampling ten drones from each line from within our two host colonies. Each drone was first identified by its RFID tag and then semen was collected. Sperm was immediately stored in sperm diluent (Slater *et al.*, 2021) and then tested for viability and concentration using a standard fluorescent-based assay (Metz and Tarpy 2019). We used an Opera Phenix HCS system, a confocal robotic- and software-assisted system that can visualize 96 fluorescently-labelled samples in three dimensions and count labelled sperm cells (live, dead and total). This protocol resulted in an un-parallel look at the sperm quality, sperm morphology, and reproductive behavior (when drones leave to mate) for the four honey bee lines available to beekeepers in the United States.

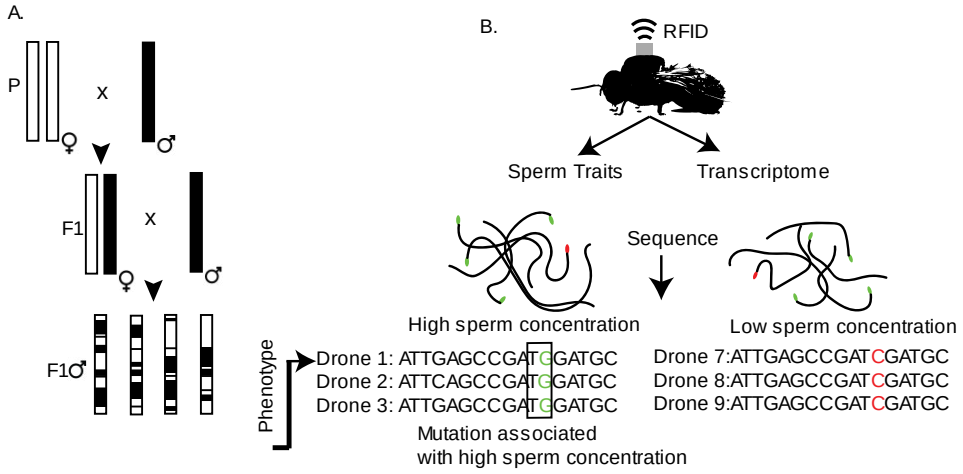

Figure 1. Experimental design. (A) Using RFID tags, we tracked male fight behavior. Beginning on day 10 (peak male reproductive age), we assessed male sperm viability and concentration. (B) We created F2 crosses from the two lines with largest differences in reproductive traits. These F2 cross were then phenotyped for reproductive traits along with the parentals.

Crossing parental stocks. In order to identify the variants associated with drone reproductive traits, we produced genetic crosses between the two most divergence lines (Figure 1A). Drones from these two lines (labeled Line 1 and Line 2) differed significantly in both flight and sperm traits. We found Line 1 drones produce more sperm and flew for longer durations at age 14 than Line 2. These significant line differences allow us to quantify how genetics contributes to reproductive variation and pinpoint the regions of the genome that contribute to this variation. Crosses were performed at Purdue university's research apiary. To produce genetic crosses, queens from each line began as mated queens from their original beekeeper source or location to ensure the queens mated with local drones. Line 1 (shown in Figure 1A as diploid chromosomes in white) queens were crossed to line 2 drones (haploid and in black) to create ten F1 queens. We then produced F2 open-mated queens from the F1 crosses. As a result of recombination, each queen produced drones that are mosaic in ancestry across the genome. These F2 drones expressed the phenotype of whichever parental allele (black or white) they inherited (Figure 1A, example highlighted in green). We then repeated our phenotyping (Figure 1B, above) with 1000 F2 drones each tagged with RFID tags.

Results

We used a Generalized Linear Mixed Model (GLMM) to test whether line had a strong effect on drone reproductive traits. Additional fixed effects include age, body weight, and age of first flight. We found breeding line and age had the most significant impact on sperm concentration (Line: $P<0.0001$, Age: $P<0.0001$) and mean flight duration at age 14 (Line: $P<0.0001$, Age: $P<0.0001$). We then isolated the most divergent lines and found that Line 1 produced drones with significantly more sperm that flew longer durations than Line 2 (Figure 2A; ANOVA; Sperm Concentration: $F_{1,161}=12.345$, $P<0.001$; Mean Flight Duration: $F_{1,167}=4.870$, $P=0.00884$). In addition, Line 1 and 2 drones differed in body weight (ANOVA $F_{1,167}=3.9554$, $P=0.04673$), sperm viability (ANOVA $F_{2,170}=7.286$, $P=0.00092$), proportion Day 14 maturity ($X^2=12.404$, $P=0.00042$), flights per day (ANOVA $F_{1,161}=10.395$, $P<0.0001$), first flight age (ANOVA $F_{1,161}=7.372$, $P=0.00086$), head length (ANOVA $F_{1,161}=10.452$, $P<0.0001$), and front wing length (ANOVA $F_{1,161}=13.564$, $P<0.0001$). Because of these results, we produced genetic crosses between only Lines 1 and 2.

F2 crosses were produced from Lines 1 and 2 (Figure 3) and phenotyped for reproductive traits. The F2 drones produced significantly more sperm than Line 2 (ANOVA $F_{2,473}=10.452$ $P<0.0001$), but less than Line 1 (ANOVA $F_{1,473}=2.462$, $P=0.117$). Thus, inherited markers are associated with sperm production.

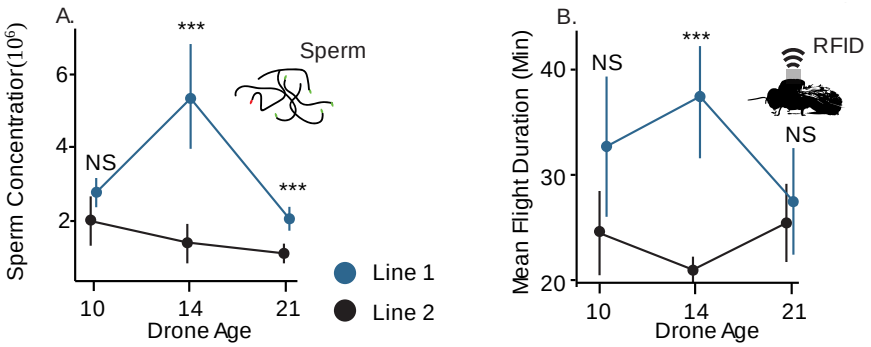

Figure 2. Line comparisons for flight and sperm traits. Line 1 and 2 displayed the most divergence in reproductive traits. (A) Drone sperm concentration from Line 1 was significantly higher than Line 2 at ages 14 and 21 ($P<0.0001$; ANOVA). (B) Line 1 drone flight duration was also higher than Line 2 at age 14 ($P<0.05$ ANOVA), but not 10 and 21.

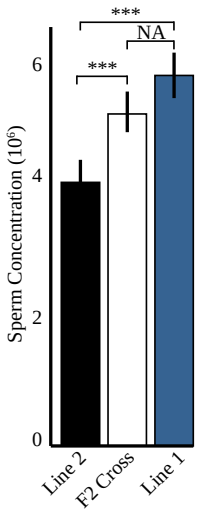

Figure 3. Parental and F2 phenotyping. Drones from Line 1 produced significantly more sperm than Line 2 ($P<0.05$; ANOVA). and the F2 cross ($P=0.117$; ANOVA). The F2 produced more sperm than Line 2.

Discussion

We found significant variation among honey bee breeding lines in both flight and sperm reproductive traits (flight duration and sperm concentration), especially between Line 1 and Line 2. We then produced genetic crosses between Line 1 and 2, and phenotyped these alongside the original parental colonies. We found the F2 colonies produced drones with sperm concentration higher than Line 2, but lower than Line 1. This signifies drones express the phenotype of the inherited parental allele (Figure 1). Thus, there is an important genetic component to this drone reproductive trait.

Next, we will identify genetic markers associated with flight behavior and sperm quality of drones (Figure 1). By integrating phenotypic and genotypic data for both parental and F2 drones, we can associate the effects of segregating genetic variation (genetic markers) on phenotypic variation. These markers will allow beekeepers to identify reproductively viable breeding lines and reduce the chance of queen failure in their yards. Furthermore, it empowers beekeepers to incorporate genetic information into breeding programs.

Abstract

Single nucleotide polymorphism (SNP) arrays are a powerful genotyping tool used in genetic research and selective breeding. The black soldier fly (BSF) *Hermetia illucens* L. is becoming an economically-important entomoculture species. However, the lack of genotyping tools can imped investment in more efficient selection programs based on genomic selection. The purpose of this study was to call SNPs from DNA pool sequencing that will be used later to design high, medium and low-density SNPs chips. Pooled DNA library preparation was performed using several BSF populations from the breeding companies Innovafeed and Agronutris. Generated library pools were sequenced on Illumina platform in 2×150bp and the sequences were assigned to the samples based on their index sequence. Over 300 million of Paired-End reads and 43X of sequencing depth was obtained on average per pool. The last BSF genome with chromosome assembly level (≈1 Gb) was used as reference to call 52 million SNPs. Filters based on Quality, Minor Allele Frequency (MAF), genome coverage (depth) and non-informative sites were used to yield a final set of 9.7 million high quality SNPs that can be later used to develop the first genotyping chip for BSF.

Introduction

Use of genomic tools is now widespread in livestock and other animal species to support genetic improvement e.g. for pedigree tracing and genomic or markers assisted selection. Black Soldier Fly (BSF) is a promising candidate for the development of the insect farming industry. In this species, pioneering works led to the contig-assembly of two reference mitochondrial genomes (Qi *et al.*, 2017; Zhan *et al.*, 2020) as well as a high quality chromosomal-scale nuclear genome (Generalovic *et al.*, 2021). According to our knowledge, genomic resources as SNP markers are still limited and/or publicly available for this species, which can limit the development of selective breeding programs.

With the development of next-generation sequencing (NGS), the cost of sequencing has declined significantly, making the identification of genomic resources feasible in non-model species. Among the panoply of sequencing strategies available, whole-genome sequencing of pools of individuals (Pool-seq) is an effective strategy because it's used for the identification of high-quality SNPs (Bansal, 2010), and provides a cost-effective alternative to sequencing individuals separately (Schlotterer *et al.*, 2014).

In this work, sequencing of DNA pools was used to detect high-quality SNPs in BSF. We expect that the development of these genomic resources will provide a basis for the development of genomic tools to support selective BSF breeding in the future.

Materials & methods

The methodological approach used in this study consists of the following steps: (1) preparation of several BSF pool samples from the French breeding companies Agronutris and Innovafeed; (2) Total DNA was extracted at IRBI (CNRS, France) using the Modified NucleoMag Tissue method (Macherey-Nagel) with automation on epMotion 5075; (3) Preparation of genomic libraries using the Illumina DNA Prep kit; (4)

Sequencing of the libraries on the Illumina platform in 2×150 bp in order to obtain a sequencing depth of 30X per pool samples, i.e. a global output of 100 Gb of data; (5) Sorting of the sequences per pool samples. Steps 3, 4 and 5 were performed at GenoScreen.

Sequence quality was evaluated with FastQC version 0.11.15 (http://bioinformatics.babraham.ac.uk/projects/fastqc). Low quality bases and adapter contamination were removed with Trimmomatic version 0.33 (Bolger *et al.*, 2014) with the following options: ILLUMINACLIP 2:30:10, LEADING 3, TRAILING 3, SLIDINGWINDOW 4:15, MINLEN 36. Reads were mapped [BWA 0.7.5a-r405 (Li and Durbin, 2009)] to the last high-quality *H. illucens* reference genome (Generalovic *et al.*, 2021) using default parameters. The resulting alignments were converted to BAM format and PCR duplicates were removed using PicardTools (v1.12). The resulting files were realigned around indels using SAMtools 0.1.17 (Li *et al.*, 2009). Base quality score recalibration and novel SNP discovery were carried out using HaplotypeCaller algorithm of Genome Analysis Toolkit (GATK) v4.0 with standard parameters (DePristo *et al.*, 2011). VCFtools (http://vcftools.sourceforge.net/) was used to remove INDELs variation and retain only biallelic variants (SNPs).

The initial SNP set was filtered with multiple steps and parameters. First, we calculated the minor allele frequencies (MAFs) and missing rates using VCFtools, and the SNPs with MAF≤0.05 and missing rate ≥0.1 were excluded. We also filtered the SNPs using several quality criteria: Qual By Depth (QD), Fisher Strand (FS), Strand Odds Ratio (SOR), RMS Mapping Quality (MQ), depth (MIN_DEPTH=30; MAX_DEPTH=150).

Results

The sequencing run results allow us to obtain an average sequencing coverage of 43X per pool (Table 1).

These pool-seq sequencing data were aligned to the BSF reference genome, and more than 63 million variants (SNPs, INDELs, etc.) were detected. After the filtering to retain only biallellic SNPs, we obtained a preliminary VCF file with 52 million SNPs (Figure 1).

From this data, filters based on quality, missing rate, Minor Allele Frequency (MAF), genome coverage (depth), and non-informative sites were used to obtain a final set of 9.7 million high-quality SNPs (Figure 2) that can be used later to develop the first genotyping chip for BSF.

Table 1. Number of paired-end reads and sequencing depth obtained per sample pool.

Pool samples	Number of paired-end reads	Output (in Gb)	% ≥ Q30[1]	Sequencing coverage
Pool 1	306,393,544	46.27	92.46	46X
Pool 2	282,164,146	42.61	92.86	43X
Pool 3	259,851,540	39.24	92.42	39X

[1] Quality score is usually annotated QXX, where 'XX' represents the score. This is interpreted as follows: for one base, there is a probability of error (Pε), with $P\varepsilon = 10^{(-XX/10)}$ and therefore, $QXX = -10 \times \log_{10} P\varepsilon$. A Q30 score is associated with an error rate of 1/1000 (0.1%). For a 2×150 bp Illumina run, the specifications are to obtain more than 80% of reads with a score >Q30.

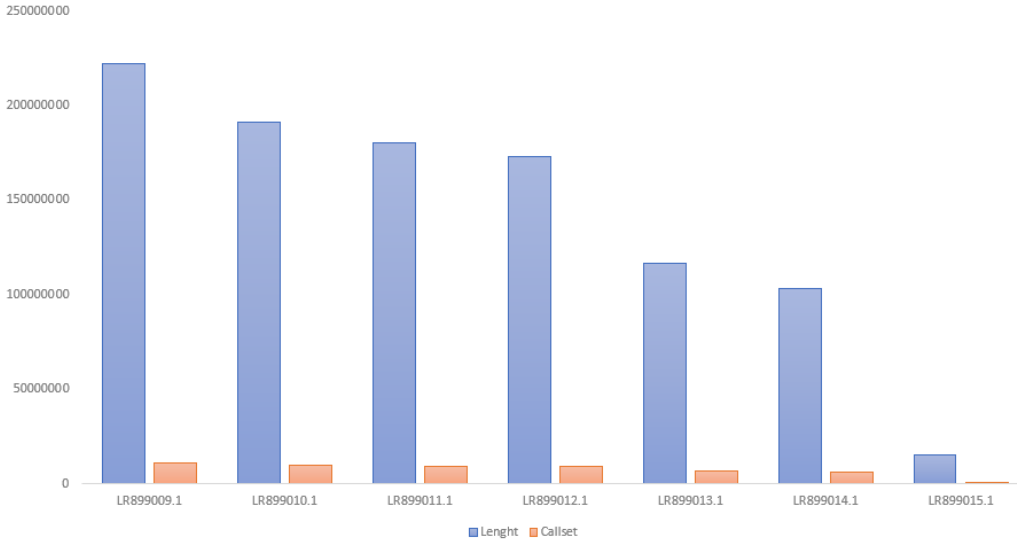

Figure 1. Distribution of (the 52 million) identified SNPs compared to seven chromosome size in BSF genome. For chromosome LR899009.1, 10,826,924 SNPs were called out of 222,122,703; For LR899010.1, 9,784,094 SNPs out of 191,142,057; For LR899011.1, 9,430,128 SNPs out of 180,357,958; For LR899012.1, 8,868,232 SNPs out of 173,077,783; For LR899013.1, 6,481,853 SNPs out of 116,824,456; For LR899014.1, 5,996,179 SNPs out of 103,444,952; For LR899015.1, 598,190 SNPs out of 15,435,017.

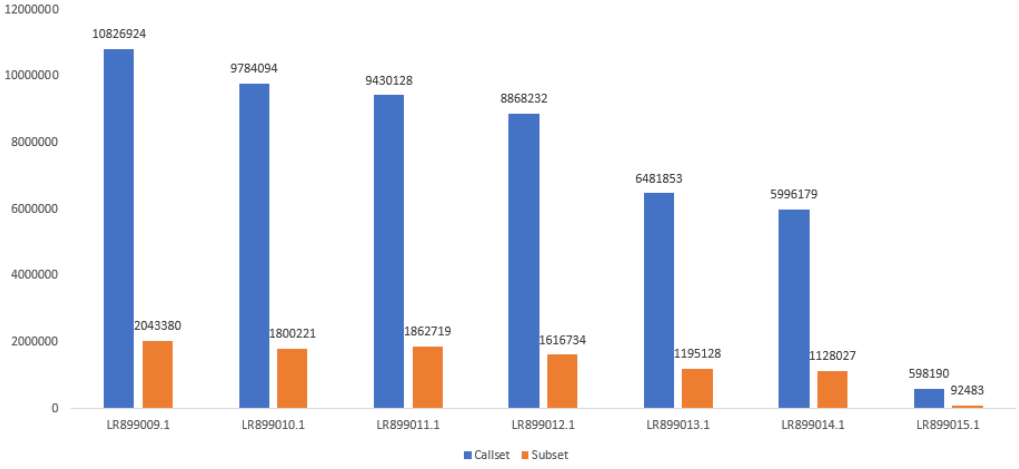

Figure 2. Distribution on the seven BSF chromosomes of the 9.7 million selected SNPs in comparison to 52 million identified in Figure 1.

Conclusions

Large-scale genome sequencing of different BSF origins by pool sequencing allowed us to identify a high-quality and diverse candidate SNP set for BSF's nascent breeding industry. Beyond their use in genomic selection, these genomic resources will be useful to improve breeding practices in BSF e.g. to manage inbreeding with adapted panels for DNA parentage assignment or pedigree tracing, to design more efficient breeding programs, to identify chromosome regions associated with performances (QTL) by association genetic studies (GWAS) and/or also speed up diffusion of broodstock with higher breeding values.

Abstract

The black soldier fly (BSF) *Hermetia illucens* is a cosmopolitan fly heavily used by industrial companies to reduce biowaste and produce protein and fat for poultry and aquaculture feed. However, the natural history and the genetic diversity of the BSF are poorly known. In this study, we analysed 677 cytochrome c oxidase 1(CO1) sequences derived from samples found all over the five continents, leading us to discover 52 haplotypes, including ten major haplotypes. We refined the definition of these haplotypes by sequencing 59 mitochondrial genomes. We could derive an estimate of the separation events of the different haplotypes at more than two million years for the oldest branches. This worldwide cryptic genetic and genomic diversity is mirrored at a local scale in France, in which we found five major haplotypes sometimes in sympatry.

Introduction

The black soldier fly (BSF) *Hermetia illucens* (Linnaeus, 1758) is a Diptera of the Stratiomyidae family. The BSF is a cosmopolitan fly found in tropical, subtropical, and tempered regions, from the 40th parallel North and the 45th South (Mason, Rozkošný, and Hauser 2009; Rozkosný 1983). Studies based on naturalistic observations were first discovered in Malta in 1926 (Lindner 1936). Currently, the BSF can be found on the whole European territory, with few exceptions. It is reasonable to assume that the rise of international traffic and the industrial use of the BSF may have led to a steady flow of introductions in France and worldwide (Craig Sheppard *et al.* 1994; Leclercq 1969). Industrial companies heavily use the BSF to reduce biowastes (Gold *et al.* 2018; Hoc *et al.* 2020), to produce protein (Ewald *et al.* 2020; Giannetto *et al.* 2019; Hoc *et al.* 2020), and fat (Ewald *et al.* 2020; Hoc *et al.* 2020; Spranghers *et al.* 2017). These products are used to make animal food (Huis 2013) or biodiesel (Leong *et al.* 2016; Surendra *et al.* 2020). BSF industries face similar issues as other farms: knowing how to master their model's biological and genetic aspects to get the best out of it. To this end, it is crucial to know the genetic diversity of BSF existing internationally, nationally, and locally. Within the framework of the BSF industry, phylogeography can allow on the one side to account for genetic diversity at different scales (global, national, and local) and, on the other side, to have keys on the geographical origin of the species present in a territory or used by companies. In this study, we quantified this diversity at different scales: worldwide by studying the variation within the CO1 gene, and more locally at the level of France. We also analysed the role of livestock BSF farming in the diversity present on the French territory.

Materials & methods

We carried out a sampling of BSF worldwide with a focus on France. We also gathered all the CO1 sequences available in the databases (NCBI and BOLD [ncbi.nlm.nih.gov/ & boldsystems.org/]). All samples were stored in absolute ethanol at -20 °C before DNA extraction. All samples were extracted under the same conditions using a Macherey-Nagel AXG100 kit. Using specific primers, we amplified and sequenced the CO1 sequences. In addition, a total of 56 BSF were used for whole-genome sequencing using the Illumina method. Mitochondrial DNA sequences were reconstructed using Unicycler software and annotated with MITOS. All bioinformatics analyses were conducted using the tools available in Geneious software (R19 geneious.com/). For phylogenies, we used MEGAX (Kumar *et al.* 2018) and BEAST (Suchard *et al.* 2018).

The visuals were made using PopArt (Leigh and Bryant 2015) for the haplotype network and Itol (itol.embl.de/) for the phylogeny representation.

Results

We reconstructed a haplotype network from the analysis of 677 sequences spanning 658 nucleotides of the CO1 mitochondrial gene. A total of 52 distinct haplotypes were delineated from the analysis of this CO1 fragment of one to 230 fly samples (Figure 1). We visualized the actual distribution of the different haplotypes found previously on a distribution map (Figure 2).

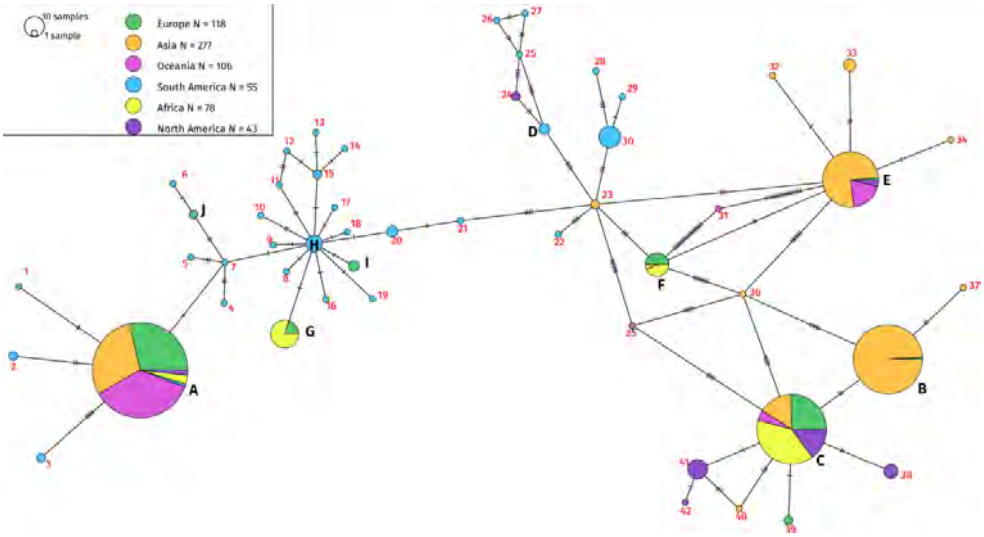

Figure 1. CO1 haplotype network of *Hermetia illucens*. Method use: minimum spanning network.

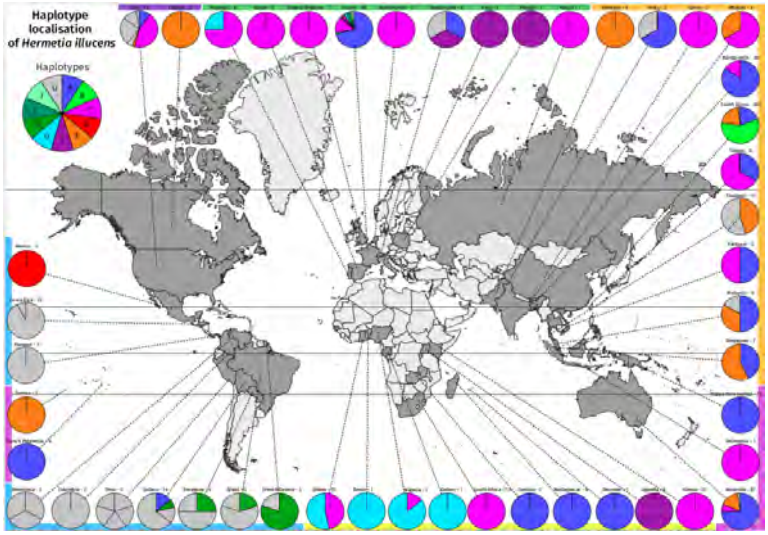

Figure 2. World CO1 haplotype distribution. Haplotype was define using the Figure 1 results.

The complete mitochondrial genome phylogeny demonstrates the very high genetic divergence among BSF populations found with the CO1 gene analysis. Two major divisions emerge within the tree: group C and others. Two subgroups emerge within the C group. The other large group contains the sequences of the A D I G and H haplotypes. The time tree (Figure 3) gives us information about the divergence time of the different mitochondrial genomes. We obtained identical Bayesian and ML trees. We noted a relatively long divergence between haplotype C and the others (2.2 million years). The others have diverged more recently (about 1.2 million years). Within the C haplotype, a divergence has been about 300,000 years, while in the other groups, the divergence times are much lower, about 20,000 years for the A haplotype.

Discussion

H. illucens is now considered a species of major interest for the food industry (Tomberlin and van Huis 2020). Thus, it became urgent to study the genetic diversity within the different populations at different scales. Analysing the different haplotypes in the same geographical area is a powerful tool to study the recent history of BSF. This study uncovered a high genetic variability of mitogenomes within the species *H. illucens*. We found that haplotype C is the most divergent. The dating of the separation events with the other haplotypes goes back more than 2 million years. We found a well-resolved separation within haplotype C (>95%); the other haplotypes are also well resolved (>95%). The analysis of complete mitogenomes supports the hypothesis of several distinct introductions in Europe and other continents. Even at a national

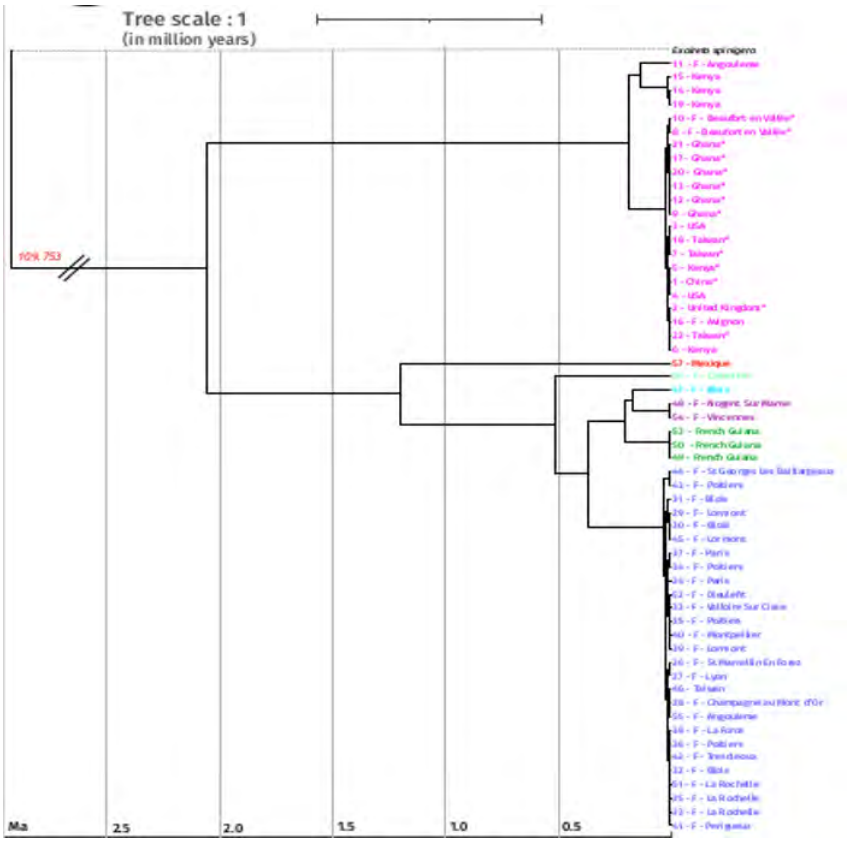

Figure 3 Phylogenetic time tree of *Hermetia illucens* based on the mitochondrial DNA. Rooted with *Exaireta spinigera*.

scale, the BSF genetic diversity is vast. By taking the example of France, we were able to show that the diversity observed at the global scale is also found at the national scale (five of the ten major haplotypes found worldwide). Moreover, we have haplotype mixtures at the local level, confirming the observations on microsatellite data (Kaya *et al.* 2021). For example, in the region of Paris, we have a mix of three haplotypes (A, F, and I). In the region of Montpellier, a mix of four haplotypes (A, B, C, and E). We also evidence that the mitochondrial genome is ideally suited to differentiate the genetic diversity and resolve phylogenetic relationships. It allows us to date the natural history of the BSF, bringing a sum of details that were impossible to distinguish based only on the CO1. Complete mitochondrial genome data allows us to make a robust and well-resolved time tree of the species. The divergence times between the different haplotypes are surprisingly long (more than two million years for the most divergent lineages), and the differences observed between the sequences prove that there is still unsuspected and hidden genomic diversity for the species. Comparing it to Drosophila, two million years correspond to many speciation events leading to different reproductively isolated species (Russo *et al.* 2013).

612. Impact of genetic selection in insect populations using different selection designs – a simulation study

R.S.C. Rikkers*, J.W.M. Bastiaansen, A.C. Bouwman and E.D. Ellen

Animal Breeding and Genomics, Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; roxann1.rikkers@wur.nl

Abstract

Insects are highly nutritious and rich in proteins and could help fulfil the worldwide increasing demand for proteins. Selection can provide lasting genetic improvements. Therefore, the aim of this study was to investigate the effect of genetic parameters in four different selection designs using a simulation study. Simulated were a mixed, half sib and full sib selection design and a combination of phenotypic selection and/or breeding values as selection method. The results show that in ten generations an improvement in body mass and development time is possible in all four selection designs and only minor differences between these designs were observed. Using estimated genetic parameters from literature, an improvement of 146-150% in biomass yield per year was observed. Thus, selection can provide lasting genetic improvements in insect populations, however inbreeding should be monitored and estimation of genetic parameters is necessary to prevent unfavourable correlated responses.

Introduction

Insects are considered to be highly nutritious and rich in proteins (Rumpold and Schlüter, 2013a) and improving the production of insects could help fulfil the worldwide increasing demand for food and proteins in 2050 (FAO, 2012). Rumpold and Schlüter (2013b) concluded that in order to maximize protein production the appropriate species should be selected. These species must be suitable for mass production and should have characteristics like good health, efficient and high quality proteins. Genetic selection could improve these important characteristics within a species, however setting up an insect breeding program has some challenges. Insect populations are often kept in large groups and individual identification is not possible. Furthermore, insects often have multiple mates and the number of mates has an effect on the fecundity of females (Pai and Yan, 2005). Considering these factors the application of genetic selection in insect populations is challenging. To show the potential and impact of genetic selection in insect populations we have conducted a simulation study that mimic flour beetle (*Tribolium castaneum*) populations. Simulated traits were pupal body mass (BM), development time (DT) till first day of pupation and biomass per year (BY). The effect of genetic parameters (heritability and genetic correlation) was investigated using single trait selection on BM in four different selection designs. To show the impact of genetic parameters on response to selection.

Materials & methods

To simulate BM and DT in flour beetle populations we used estimated genetic parameters from Ellen *et al.* (2016; Table 1). A simulation program (RStudio; R Core Team, 2019) was used to simulate four selection designs: a mixed parents design (MixedSel), a Half Sib (HS) family design (HSfam) and two versions of a Full Sib (FS) family design (FSfam and FSfamBV). Of the four selection designs, MixedSel would be the least expensive and FSfamBV would be the most expensive and labour intensive design for insect producers, since animals have to be kept individually to be able to identify them.

Basic simulation program. Phenotypes for BM and DT of the founder population were simulated as $P = \mu + A + E$, where A and E were randomly drawn from a multivariate normal distribution, where the covariance matrices of A and E were based on estimates by Ellen *et al.* (2016). Phenotypes for each

DOI: 10.3920/978-90-8686-940-4_612, © R.S.C. Rikkers *et al.* 2022

Table 1. Parameters for body mass (BM) in mg and development time (DT) in days.

Trait	Mean	h^2	σ_a^2	σ_p^2
BM	2.33	0.38	0.027	0.071
DT	27.05	0.41	2.526	6.114

consecutive generation were simulated similarly, however $A = 0.5\ A_{sire} + 0.5\ A_{dam} + MS$ and MS (mendelian sampling) is drawn from a covariance matrix adjusted for inbreeding. The simulation program was applied for a given number of batches, generations and replicates. To reduce the amount of inbreeding a batch rotation scheme was simulated where males rotate over batches.

In the MixedSel design males and females where kept together and mated at random. Per batch, selection candidates to produce the next generation were phenotypically selected on highest BM. In the HSfam design, individual males were kept with multiple females, creating HS families where sire-pedigree information was available. For each sire the BM estimated breeding values (EBV) were calculated using a univariate model in ASReml (Gilmour, *et al.*, 2015) and HS families were ranked on sire EBV. Offspring from 50% of the best performing sires were ranked on BM phenotype and selection candidates were phenotypically selected from this ranking. In the FSfam design individual males were kept with one female, creating FS families. The selection families were ranked on the average BM EBV of the sire and dam. Offspring from 50% of the best performing families were ranked on BM phenotype and selection candidates were phenotypically selected from this ranking. The FSfamBV design was identical to the FSfam design, however before hatching the eggs where kept individually making it possible to identify each insect individually and know their associated pedigree. BM EBVs for each individual were estimated using a univariate animal model in ASReml. Individuals with the highest BM EBV were selected to produce the next generation. An overview and detailed information of the four selection designs is given in Table 2.

Scenarios. We have tested the effect of: (1) genetic correlation; and (2) heritability (h^2) on response to selection in the four selection designs. In scenario 1 three genetic correlations between BM and DT were simulated, 0.15 as estimated by Ellen *et al.* (2016; Scenario 1A), a strongly positive (0.70; Scenario 1B) and a strongly negative (-0.70; Scenario 1C) genetic correlation. A high positive or high negative genetic correlation is unlikely in real life, however to study the effect of genetic parameters on the four selection designs a correlation estimated in literature and two extreme scenarios were chosen. In scenario 2 we replaced the estimated heritability for BM ($h^2 = 0.38$) with a h^2 of 0.10 to investigate the impact of a lower h^2 when performing genetic selection. Results were presented as the biomass yield per year (BY) which was calculated as BY = (BM / DT) × 365. The baseline BY based on Ellen *et al.* (2016; Table 1) is 31.44 mg BY ((2.33 / 27.05) × 365).

Table 2. Detailed information per generation on batch level.

	MixedSel	HSfam	FSfam	FSfamBV
Mating	Random	1:2	1:1	1:1
# males	20	10	20	20
# females	20	20	20	20
Selected prop.	0.100	0.075	0.100	0.100
Selection	↑ BM	↑ BM within best families	↑ BM within best families	↑ EBV BM
Pedigree	-	6 generations	6 generations	6 generations

Results

The highest BM improvement after ten generations was found in the FSfamBV design 3.72±0.04 mg, although FSfam and HSfam showed similar results, respectively 3.67±0.05 and 3.70±0.04 (Table 3). MixedSel (phenotypic selection) resulted in a total of 45.29 mg BY, while adding more pedigree information (HSfam, FSfam and FSfamBV) resulted in ~46.5 mg BY. Inbreeding was lowest in the MixedBase design and highest in the FSfamBV design. Using more pedigree information in the breeding program increased inbreeding (Table 3), even though a rotational scheme was used to reduce inbreeding.

Scenario 1A (genetic parameters estimated by Ellen *et al.* (2016)) yielded a biomass between 45.29 (MixedSel) and 46.72 (FSfam) mg per year (Table 4). Scenario 1B (high positive genetic correlation) showed a lower BY after ten generations, whereas scenario 1C (high negative genetic correlation) showed a higher BY after ten generations in the four selection designs compared to scenario 1A and 1B. Furthermore, reducing the BM h^2 (scenario 2) resulted in lower improvement of BY in all selection designs compared to scenario 1A.

Discussion

We compared four different selection designs in simulated insect populations and the effect of genetic parameters on these four methods. As expected, the genetic parameters have an impact on the selection response (how fast you can improve your population). The favourable direction of breeders would likely be a higher BM and a shorter DT, as this gives the fastest increase in BY. A strong positive genetic correlation (scenario 1B) resulted in a lower BY, because DT becomes longer reducing the number of pupa grown per year. Furthermore a lower heritability (scenario 2) resulted in less improvement of BY after ten generations, compared to a higher heritability (scenario 1A). Ellen *et al.* (2016) estimated a genetic correlation between BM and DT of 0.15±0.10 and Mwenya *et al.* (1986) estimated genetic correlations of 0.15±0.14

and 0.45±0.10 depending on the mating design. Our results show that selection on more than one trait (multi trait) and knowing the correct genetic parameters is important to prevent unfavourable correlated responses. In our simulation study inbreeding was relatively low. However, including pedigree information increased the inbreeding rate. So far, inbreeding has not been considered in insect production. However, Rhode *et al.* (2020) showed a black soldier fly population collapsing after five generations due to a lack of genetic diversity. Comparable to conventional livestock breeding programs, monitoring of inbreeding in insect populations is important.

Insect breeders face many challenges, conventional livestock breeders do not face, such as the difficulty to identify an individual insect. Remating, where females lay eggs from multiple males, affects identification and the number of mates has an effect on the fecundity of a female (Pai and Yan, 2003). In all scenarios the differences between the four selection designs were relatively small. Considering the costs and labour intensiveness of breeding programs where insects are kept individually (FSfamBV) and the responses observed in phenotypic selection (MixedSel) being similar, using pedigree information and/or breeding value estimation is not beneficial in the case of single trait selection.

To conclude, genetic selection could improve important characteristics in insect populations. Using single trait selection, a MixedSel or HS design, without individual identification, is favourable. However, breeding programs contain more than one trait and therefore, future research should focus on multi-trait selection. For insect populations, inbreeding should be monitored and estimation of genetic parameters is necessary to prevent unfavourable correlated responses.

Abstract

The aim of this study was to design a scheme for black soldier flies (BSF, *Hermetia illuscens*) to collect data and estimate genetic parameters for the recorded traits. A full sib family design was implemented in a practically feasible way to record multiple traits on the same individuals across a number of families. Genetic parameters were estimated using a linear mixed model. Heritability estimates for body weight at prepupa, body weight at pupa, development time to prepupa was 0.25, 0.45 and 0.38, respectively. The common environmental effect was large at the larval stage and reduced after housing the BSF individually. In general, body weight showed a positive phenotypic correlation between the S2, prepupa and pupa stages, and development time was positively correlated with body weight at (pre)pupa stage. In conclusion, a full sib family design is a practically feasible way to collect data for estimation of genetic parameters in the BSF.

Introduction

Insects are an alternative protein source that can add to the challenge in the food transition we are facing today. Insects can be used as feed for pigs, chickens and fish, or directly for human consumption. In both cases, large quantities of the tiny bugs are needed to obtain sufficient product. Phenotypic selection of larger individuals is effective in insect systems to increase mass (Morales-Ramos *et al.*, 2018). Phenotypic selection for morphological traits is in general very effective, as body mass has a moderate to high heritability in most species (e.g. Visscher *et al.*, 2008). However, for most insect populations produced for edible proteins the genetic parameters are unknown, and neither are their unfavourable genetic correlations with other important traits. Insect species have the major limitation that they are difficult to track individually over time, which makes it difficult to collect suitable datasets similar to what is common in larger livestock species. Black Soldier Flies (BSF, *Hermetia illuscens*) can upcycle low-quality organic waste-streams into high-quality proteins and are currently the most used species for livestock feed. Therefore, the aim of this study was to design a scheme for BSF to collect data and estimate genetic parameters for the recorded traits.

Materials & methods

Data collection design. A full sib (FS) family design was implemented in a practically feasible way to record multiple traits on the same individuals across a number of FS families (Figure 1). Data was collected in 5 batches at a commercial BSF facility. At random, 5 to 10 fresh egg clutches were collected in each batch from the general population, assuming each clutch is one FS family. Each clutch was split in half and each half was placed in a container with standard feed. Hence each FS family was housed in two groups (i.e. two common environments) under similar conditions. Please note that the common environment is nested within family, as mixing of families was impossible due to lack of identification. After 10 days, 30 larvae were individually weighted from each family-environment combination (Body Weight Stage 1, BW_S1), and housed individually in tubes with standard feed. They were individually weighted again after 7 days (Body Weight Stage 2, BW_S2). At that moment, half of the 30 individuals per family-environment combination were freeze dried, and weighted afterwards (Dry Weight Stage 2, DW_S2), they were stored for

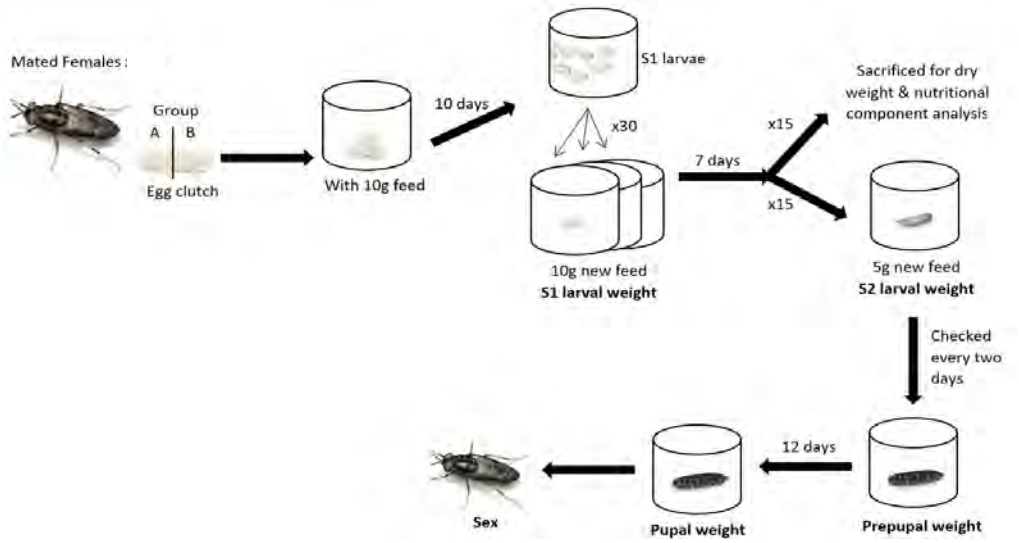

Figure 1. Schematic overview of the data collection.

other purposes. The remaining 15 individuals per family-environment combination were kept individually for further measurements. Every two days they were checked to see if they had reached the prepupa stage (black but still mobile), and if so they were weighted (Body Weight prepupa, BW_prepupa), and the day was recorded. The number of days from start of the batch till weight measurement of prepupa was included as a trait to represent development time to prepupa (Development Time, DevTime). The final pupal weight (black and immobile) was measured 12 days after reaching prepupa stage (Body Weight pupa, BW_pupa). Furthermore, it was recorded if they emerged to adults, and what their sex was based on adult morphology.

Estimation of genetic parameters. Genetic parameters were estimated using the following linear mixed model in ASReml (Gilmour *et al.*, 2015):

$$y = Xb + Zfam + Wc + e \quad (1)$$

Where *y* is the vector of observations, *b* vector of fixed effects, including the mean, sex as a fixed regression, with males being 0, females being 1, and individuals with unknow sex (the ones freeze dried and non-emerging) were included as 0.5 assuming a 50/50 sex ratio. Batch was included as a random effect. BW_S1 was not measured in batch 1. For BW_prepupa a fixed regression was included on number of days till prepupa weight measurement (i.e. DevTime). *fam* is the vector of random family effects, *c* is the vector of common environment nested within family, and *e* is the vector of random residual effects. The *X*, *Z* and *W* are the design matrices relating observations to the respective levels of fixed and random effects. Random effects were assumed to be normally distributed: $fam \sim N(0, I\sigma^2_{fam})$; $c \sim N(0, I\sigma^2_c)$; $e \sim N(0, I\sigma^2_e)$ with I as identity matrix.

The additive genetic variance (σ^2_a) is estimated as two times the family variance σ^2_{fam}. The heritability was estimated as:

$$h^2 = (2 * \sigma^2_{fam})/(\sigma^2_{fam} + \sigma^2_c + \sigma^2_e) \quad (2)$$

The contribution of the common environment to the phenotypic variation was estimated by:

$$c^2 = (\sigma_c^2)/(\sigma_{fam}^2 + \sigma_c^2 + \sigma_e^2) \quad (3)$$

Phenotypic correlations were estimated in a bivariate fashion with model 1 excluding the family and common environmental components. The dataset was too small to estimate genetic correlations.

Results

In total 2,731 larvae were recorded, of which 1,285 were followed until emergence to adulthood. A total of 6 traits were measured, their mean is given in Table 1.

Heritability estimates are given in Table 2, the three weight traits at larval stage had large standard errors, hence we were not able to declare them significantly different from zero. From Table 2 it can be seen that the common environmental effect was largest on the first body weight measure (BW_S1) and reduced substantially when individuals were housed individually and as time between group housing and trait measure increased.

The strongest phenotypic correlation (0.81) was found between prepupa and pupa body weight (Table 3), which were both unfavourably correlated with DevTime.

Table 1. Descriptive statistics of measured traits in commercial BSF.

Trait	N	Fam[1]	Mean (sd)	Min	Max
BW_S1 (mg)	2,318	39	6.62 (4.32)	0.25	39.01
BW_S2 (g)	2,731	44	0.23 (0.05)	0.01	0.35

BW_prepupa			0.81 (0.01)	0.62 (0.02)
BW_pupa				0.41 (0.02)

Discussion

Insects are very small and hard to identify individually over time, which is the main limitation for the estimation of genetic parameters, and even more so for genetic selection programs. The FS family design presented here is practically feasible, as it allows to collect data on individuals from different families not knowing the parents. Ideally multiple families were housed in the same group to disentangle the common environmental effect further. A maternal effect may be present in insects as the conditions under which the mother developed and laid her eggs potentially play a role (Mousseau and Dingle 1991), but the applied design did not allow to estimate maternal effects.

For a general full sib design we estimated that with 15 individuals from 45 families we would be able to estimate heritabilities of 0.3 with a standard error around 0.08 (following Falconer and Mackay, 1996). The obtained standard errors of our experiment were higher, as there are always factors that cannot be controlled in real life. However, reaching standard errors of 0.11-0.16 for the traits measured later in the lifecycle was satisfying. Collecting data on more families will improve the heritability estimates further.

The standard errors of the heritability were higher for the traits at larval stage. At the larval stages the common environment played an important role in the phenotypic variation observed. The common environmental factor is only a short common environment from egg clutch collection till 10 days thereafter, closest to the larval stage, which explains the large common environmental effect at the larval stage. The common environmental impact reduced as the individuals were housed individually for longer time. However, at the later life stages the differences in individual environment may be confounded with individual genetic potential, even though it was averaged within family. Taken this together with the fact that the family variance also includes a potential maternal effect, the heritability estimates are likely somewhat overestimated.

The positive phenotypic correlation between body weight at S2, prepupa and pupa stages can be exploited to select for body weight at an earlier developmental stage. The positive correlation between body weight at (pre)pupa and development time is unfavourable, as this would increase the generation interval. Considering profitable protein production, body weight and development time should be weighted in a selection index to obtain an optimum in the total mass produced per year for instance.

In conclusion, a FS family design is a practically feasible way to collect data for estimation of genetic parameters. The number of families measured is an important factor in decreasing the standard error of the estimates, in practise more families are needed than estimated theoretically, due to uncontrollable factors that play a role in practical situations.

Abstract

The rapid life cycle of most insects allows for the direct comparison of simulated and realised genetic gain from insect breeding schemes, enabling real-time optimisation of the breeding scheme design. However, rearing and maintenance of insects gives rise to major challenges due to specific dietary and environmental requirements, complex life cycles and reproductive patterns and this adds complexity to all aspects of the breeding plan implementation. We have developed an experimental design for large-scale individual phenotyping and tracing pedigree records and applied this to estimate genetic parameters for larval size and egg-to-adult development time using the housefly (*Musca domestica*) as a model species. These parameters contribute valuable information on the potentials for genetic improvement in this species and the methods and results presented can be used more generally in the process of insect breeding scheme implementation and optimisation.

Introduction

Using insects as food and feed has received renewed attention in the last decade, partly due to the ability of many insect species to utilise low-value waste products and convert this input into high-value protein for a more sustainable food and feed production (Van Huis and Oonincx, 2017, for a review). This has initiated an interest in the optimisation of insect farming through the manipulation of environmental factors (Tomberlin and Cammack, 2017). Selective breeding has historically been an important tool in the improvement of crop and livestock production but has so far received little attention within insect production (Eriksson and Picard, 2021). Many insect species are short-lived and highly fecund, theoretically enabling rapid and transgenerational optimisation of production efficiency through selective breeding. Variance components and heritabilities of economically important traits are key indicators of the potential for successful genetic improvement (Hill, 2010). Insects pose a challenge when attempting to estimate such parameters partly due to their rearing requirements, fragility, mode of reproduction and, occasionally, metamorphic life cycle. These fundamental challenges call for novel methods and protocols which can be applied in insect breeding schemes. In this study, we construct a two-generation pedigree by implementing a full-sib/half-sib mating design using the housefly (*Musca domestica* L.) as a model organism for holometabolous dipterans, an insect order highly suitable for converting organic waste into valuable protein products (Pastor *et al.*, 2015). We then estimate genetic parameters for two production-relevant traits, larval size (LS) and egg-to-adult development time (DT), using a large-scale laboratory experimental setup, designed to fit the unique biology and life cycle of holometabolous insects.

Materials & methods

Population. The housefly population used in the experiment was an outbred population established in June 2021 with flies collected from six cattle farms distributed across Denmark. The population was since maintained in the lab at a census size of ~15,000 individuals divided into three replicate populations of ~5,000 individuals, maintained in fly cages (30×30×30 cm) with ~1000 flies in each cage. In every generation, offspring from the five cages of a replicate population were intermixed at the pupal stage and

DOI: 10.3920/978-90-8686-940-4_614, © L.S. Hansen *et al.* 2022

randomly distributed into new cages. Flies were reared under standard laboratory conditions at 23 °C, 40-60% relative humidity with a photoperiod of 12:12 h (light:dark) throughout their lifecycle. Larvae were reared on a standard laboratory larval medium composed of wheat bran, alfalfa meal, dry yeast, malt and tap water and adults had access to water and a petri dish filled with equal parts of granulated sugar, icing sugar and powdered milk.

Family generation. A nested paternal half-sib/full-sib design was used when generating the families in this experiment (Figure 1). The parent-generation was established by anesthetising and sorting newly emerged flies every 24 hours into sex-, age- and replicate-specific virgin cages. Virgin flies had access to granulated sugar, icing sugar, powdered milk and water.

At the age of 10 d ± 12 h, one male and five female flies were sorted into glass jars (H: 11.5 cm, Ø: 6 cm) for mating. Each jar was sealed with a foam stopper fitted with a micro centrifuge tube with 10% sugar solution. From the three replicate populations, 30, 30 and 19 mating jars were established over several days depending on when the flies reached the age of 10 days. A large number of virgin flies from replicate 3 were lost due to a technical error. Therefore, a second round of matings from replicates 1 and 2 were established with 14-day old virgin females to compensate for the reduction in family number from replicate 3. A total of 94 mating jars were established when combining all replicate populations. Flies were allowed to mate for 30 hours, where after all flies in each jar were anesthetised and females were sorted into oviposition vials (H: 9 cm, Ø: 2.5 cm) with 3 g fresh medium and kept in climate chambers at 23 °C, 60-70% relative humidity under a 12:12 h (light:dark) photoperiod. Oviposition vials were subsequently checked for eggs every 12 hours until the female had either oviposited >20 eggs in one oviposition event or died. If <20 eggs were found, females were transferred to a new oviposition vial with fresh medium. If >20 eggs were found, these were distributed into new vials with 10 g of fresh medium. The first 20 eggs were designated for the measurement of LS, and the next 20 eggs were designated for the measurement of DT, ensuring that the two traits were recorded on full siblings. Eggs for the two traits were always collected from the same oviposition event and if a female only oviposited enough eggs for one group, then no eggs were collected to measure DT. The offspring were subsequently reared under the same conditions as the females. A total of 256 families were established to measure LS (94, 107 and 55 for replicate 1, 2 and 3, respectively), and 244 families were established to measure DT (87, 103 and 54 for replicate 1, 2 and 3, respectively).

Phenotyping. LS was measured at day seven of the offspring life cycle using an automated size estimation procedure as described in Laursen *et al.* (2021). Full siblings from a vial were distributed individually into a numbered well-plate and mean larval surface area for all larvae in each family was acquired using a 60 s acquisition time. The numbering of the plate allowed individual ID-assignment. DT was estimated

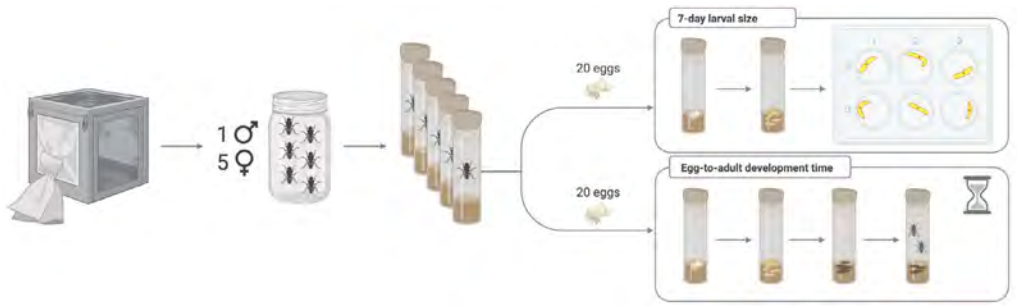

Figure 1. Schematic illustration of the experimental setup (created with BioRender.com).

every 12 hours by checking vials for newly emerged adults, which were removed from the vials and sexed. Individual IDs were assigned, and development time calculated for each emerged adult (±12 h). All vials were continuously checked until four days had passed where no flies emerged.

Statistical analysis. Variance components for LS was estimated with a univariate linear Gaussian sire-model using the full-sib family mean:

$$y = X\beta + Zs + e \quad (1)$$

and DT was analysed using a univariate linear Gaussian animal-model:

$$y = X\beta + Z_1 a + Z_2 vial + e \quad (2)$$

where y was the vector of observations of either mean LS or DT; β was a vector of fixed effects including replicate, ID of the person sorting the eggs (four groups), sex (only for DT) and dam age (2 groups, only for LS); s was the vector of random sire genetic effects, $N(0, \boldsymbol{I}\sigma_s^2)$; a was the vector of random animal additive genetic effects, $N(0, \boldsymbol{A}\sigma_a^2)$; vial was a vector of random rearing vial effects, $N(0, \boldsymbol{I}\sigma_{vial}^2)$; e was the vector of random residuals, $N(0, \boldsymbol{I}\sigma_e^2)$; I was the identity matrix, A was the additive genetic relationship matrix, and X, Z, Z_1 and Z_2 were the corresponding incidence matrices. Narrow-sense heritabilities were estimated as $h^2 = \frac{4\sigma_s^2}{\sigma_s^2+\sigma_e^2}$ when using the sire model, and as $h^2 = \frac{\sigma_a^2}{\sigma_a^2+\sigma_{vial}^2+\sigma_e^2}$ when using the animal model. Variance components were estimated using REML with the average information algorithm (AI-REML) implemented in the DMU software package (Madsen *et al.*, 2006; Madsen and Jensen, 2013).

Results

LS was measured on 1,725 larvae from 184 dams representing 73 sires, and DT was estimated for 630 flies from 97 dams representing 21 sires. The number of larvae measured in each full-sib family ranged from 1-20 larvae, and the number of adult offspring emerging ranged from 1-17 flies. Descriptive statistics for both traits are presented in Table 1.

The estimated heritabilities (Table 2) were moderate for both LS and DT. The random effect of rearing vial contributes with a large portion of the total variance for DT.

Table 1. Descriptive statistics for the traits mean 7-day larval size (based on full-sib family means) and egg-to-adult development time in houseflies (*Musca domestica*).

Trait	Unit	No. records	Mean	SD	Median	Min	Max
Mean 7-day larval size	mm^2	184	15.99	8.19	16.24	2.63	30.81
Egg-to-adult development time	Hours	630	500.29	45.17	494.0	422.0	686.0

Table 2. Estimated genetic (σ_a^2), rearing vial (σ_{vial}^2) and error (σ_e^2) variances and heritabilities (h^2) for mean 7-day larval size and egg-to-adult development time with the corresponding standard error SE(h^2) from univariate trait analysis.

Trait	σ_a^2	σ_{vial}^2	σ_e^2	$h^2 \pm SE(h^2)$
Mean 7-day larval size	6.05	-	46.70	0.13±0.33
Egg-to-adult development time	480.42	1,019.92	453.00	0.25±0.44

Discussion

This study aimed at estimating variance components and heritabilities for two production relevant traits in housefly larvae and adults, using a complex mating design frequently applied in aquacultural species (Gjerde *et al.*, 1996). Few studies have presented genetic parameters for traits relevant for protein production in holometabolous species such as the housefly (e.g. Bryant and Meffert, 1998). Estimating genetic parameters for holometabolous species is challenging, partly because physical tagging for individual identification is impossible due to metamorphosis, optimal rearing conditions and environmental susceptibility are life-stage specific and isolated rearing introduces undesired variation, all of which are required to obtain accurate phenotypes from individuals with known genetic relationships. We present moderate heritability estimates for the two investigated traits, but the challenges are reflected by the large variation around the estimates. Additional challenges will arise in coupling phenotypes from different life-stages to estimate genetic correlations. We have approached this issue by designing the experiment so that the two traits were obtained from full-sibs from the same oviposition event. The methods and results presented here constitute the first steps towards the practical implementation of insect breeding plans. Next steps include estimation of the genetic correlations between DT and LS and other traits relevant for insect production (work in progress). Subsequently we will evaluate the potential of genetic gain of selective breeding through simulation studies and compare this with the realised gain obtained from laboratory selective breeding.

Abstract

Black soldier fly farming has increased in recent years. The black soldier fly larvae convert low-grade organic materials into high-value food, feed and technical products. To meet the rising demands for proteins in the feed and food industries, there is a need to improve the efficiency of production. Selective breeding can play an important role in such a scenario. Here we present the outcomes of a breeding program for increased larval weight, that started in 2019. The performance of the selected line over the base population line was evaluated in six rounds, under different environmental conditions. Under industrial conditions, an average improvement of +39% in larval weight, +34% in wet crate yield, +26% in dry matter crate yield, +32% in crude protein crate yield and +21% crude fat crate yield was achieved. This research clearly demonstrates the potential of selective breeding for improved efficiency when farming black soldier fly.

Introduction

The black soldier fly (BSF), *Hermetia illucens* L., is globally utilized for organic waste remediation to produce various products of interest. The industrial production cycle for BSF typically lasts 40-45 days and consists of four stages: the breed (where flies mate to produce eggs), the nursery (eggs hatch into young larvae), the rearing (young larvae grow to harvestable larvae) and the pupation (only for the breeding animals; incubation of prepupae to pupae that will eclose to adult flies). The key stage of production is the rearing stage, where young larvae convert low-grade organic waste into derivable products such as protein meal, fat and frass (fertilizer).

In addition to its use in aquaculture and pet food diets, the European Commission has recently authorized the use of insects derived processed animal proteins in monogastric livestock diets (Commission Regulation (EU) 2021/1372 amending Annex IV to Regulation (EC) No 999/2001). At present, the demand for insect protein is higher than the supply, and the demand is expected to grow 50 times more by 2030 globally (Ploegmakers, 2021). One means of increasing supply is selective breeding, which has been widely applied in plants and other animal species, but not yet reported in BSF.

In mealworms, pupal body mass of *Tenebrio molitor* increased 66% after eight years of selection (Morales-Ramos *et al.*, 2019). In addition, studies reported body mass to be medium to high heritable trait in different insects' orders, with heritability estimates ranging from 0.2 to 0.6 (Dingle *et al.*, 1980; Iyengar and Eisener, 1999; Saastamoinen, 2008; Jumbo-Lucioni *et al.*, 2010; Ellen *et al.*, 2015; Facchini *et al.*, 2021). These heritability estimates show that the population mean for body mass can be improved through selective breeding.

In 2019, we started a selective breeding program for increased larval body weight in BSF. In this paper, we present how the outcomes of this three-year program translated under industrial production conditions. Our research findings are relevant as they provide an indication of the role that selective breeding may play in improving the performance of BSF.

Materials & methods

Black soldier fly lines. The aim of the study was to assess the differences in the rearing larval performance of the Body Weight line (BW) compared to the Base Population line (BP) over multiple consecutive rounds. The improved BW line was derived from the BP line in March 2019 and was selected each generation for increased larval body weight following a genetic improvement program.

Experimental setup. To compare the two lines, six sequential rounds were carried out between May 2020 and June 2021. Three different generations of the BW line were used in this study. For the first, second and third rounds, BW animals were sampled from the Genetics lab in May 2020, September 2020, and January 2021 respectively. Each round was characterized by a different production setting. Table 1 summarizes the settings which differed in feed type, rearing environment, larval density and feed ration.

For the first three rounds, a control BP group was set up next to the BW line. Six crates per line were set up in parallel. Operators were blinded to avoid bias from treating the animals differently based on the line. In round one and three, operators could feed different amounts on a crate level, according to their discretion. In round two, operators were instructed to deliberately feed the same amount on crate level, even if the animals indicated different needs.

For the last three rounds, no control BP group was setup next to the 6-10 BW line crates for logistic reasons. Therefore, from fourth round onwards, the comparisons were made with BP data derived from randomly selected production batches harvested during the 15 flanking days before and after the BW experimental batch (a minimum of 35 crates). The feeding amounts for BW line henceforth were determined based on experience from previous three rounds and with the aim of maximizing crate output per unit within the existing production system.

Rearing and data collection. On the 7th day of the experiments (harvest day at the farm), larvae were separated from leftover substrate by sieving. For all rounds and both lines, average larval weight (mg) was measured at harvest day. Larvae were randomly picked from each crate from different locations within the crate. Larvae were cleaned and 100 larvae were randomly sampled and weighed. Average larval weight was determined by dividing the sample weight (mg) by the number of larvae in the sample Wet crate yield (kg),

Table 1. Summary of the experimental setup. Density and feed ration (grams of feed per larva) are represented as deviations (Δ) in percentage from a common benchmark set at BP industrial production conditions.

Round	Feed type	Environment	Line	Δ density	Δ feed ration
1 May-20	A	1	BW	-15%	21%
			BP	-15%	4%
2 Sep-20	A	2	BW	-55%	135%
			BP	-55%	135%
3 Jan-21	B	2	BW	-27%	58%
			BP	-27%	12%
4 Mar-21	B	2	BW	0%	30%
		3	BP	0%	-2%
5 May-21	B	3	BW	0%	30%
			BP	0%	0%
6 Jun-21	B	3	BW	0%	22%
			BP	0%	0%

which reflects the total larval yield of the crate, was obtained after sieving. For nutritional composition analysis, an equivalent volume of larvae from all crates per line per round was mixed and analysed for dry matter (DM), crude protein and crude fat. The feed conversion ratio and protein conversion ratio were also determined, yet not presented as they were not significantly different between the BP and BW line.

Statistical analysis. For all traits, a paired samples t-test was used to test the difference between the two population means. All analyses were carried out in R statistical computing environment version 4.0.0 (R Development Core Team, 2020).

For average larval weight, the following linear regression was fitted to test the relationship between average larval weight and the explanatory variables through ANOVA (Equation 1):

$$y_{ijk} = \mu + L_i + F_k + R_j + \varepsilon_{ijk} \quad (1)$$

where μ represents the overall mean, L is the fixed effect of the line (i = BW, BP), F is a covariate for the adjusted feed ration (feed amount/estimated larvae density), R is the fixed effect of the round (j =1, 6) and ε represents the random error term.

Results & discussion

T-test results showed a significant difference between BW and BP average performances for larval weight (t (5) =10.988 P<0.001), wet crate yield (t (5) =6.0535, P<0.001), DM crate yield (t (5) =7.4597, P<0.001), crude protein per crate (t (5) =5.2401, P<0.01), and crude fat per crate (t (5) =5.7807, P<0.01) (Figure 1).

Table 2 reports the results from the linear regression model. All variables showed a significant effect on average larval weight. Interest is on the variance explained by genetics represented by the variable Line. The variable Line explained the largest part (47%) of the variance in the model. This reveals the inherent genetic difference in average larval weight of the BW line compared to the BP line.

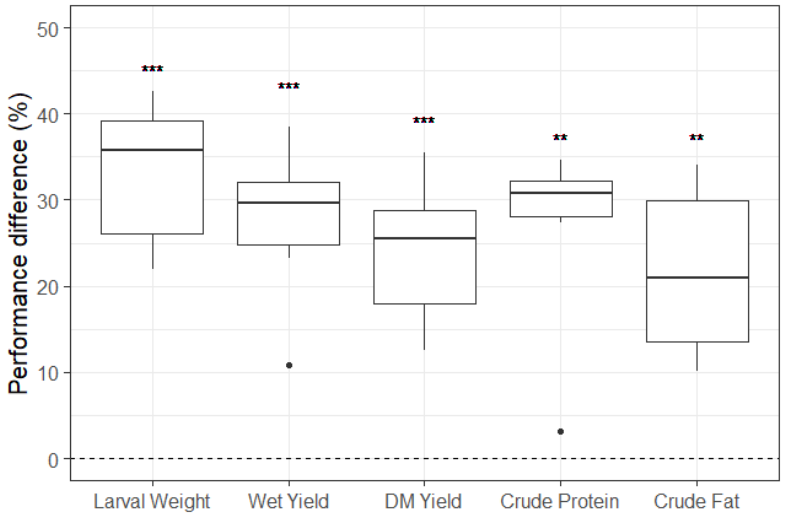

Figure 1. Performance differences in average crate outputs between BW and BP line. Boxplots represent the distribution of the results from all the six rounds for larval weight, wet yield, dry matter (DM) yield, crude protein, crude fat; ***: P< 0.001, **: P<0.01.

Table 2. Analysis of variance for average larval weight.[1]

Variable	Df	Sum sq	Mean sq	F value	Pr(>F)
Line	1	112,118	112,118	1,228.06	$P<0.001$
Adj. Feed ration	1	82,464	82,464	903.24	$P<0.001$
Round	5	15,860	3,172	34.74	$P<0.001$
Residual	302	27,572	91		

[1] Df = degrees of freedom; Sum sq = sum of squares; Mean sq = mean sum of squares.

In rounds five and six, under fully automated production settings, we found an average improvement of BW over BP of +39% in average larval weight +34% in wet crate yield, +26% in DM crate yield, +32% in crude protein per crate and +21% crude fat per crate.

Conclusions

Overall, results show that substantial genetic improvement can be realized in larvae weight in BSF which translates into improvement in crate yield. In other words, the selection under the genetic improvement program conditions translated into improvements in the industrial setting.
