Analysis. We fitted five types of models to the aforementioned data: Pedigree BLUP (PBLUP), single-step Genomic BLUP (ssGBLUP), Bayesian Ridge Regression (BRR), and BayesC (a variable selection model with a point of mass at zero and a Gaussian slab). In all cases, the genotypes used to fit these models were those in the MD SNP panel. We fit ssGBLUP considering genotypes for either 50 or 100% of the animals (ssGBLUP_50 and ssGBLUP_100, respectively). The set of pigs with genotypes ignored in ssGBLUP_50 was randomly selected. The scenario ssGBLUP_50 provides a transition between PBLUP and ssGBLUP_100. The ssGBLUP (Legarra *et al.*, 2009) and PBLUP analyses were performed with the BLUPF90 software family (Misztal *et al.*, 2014). BRR and BayesC were fitted using the BGLR package in R (Habier *et al.*, 2011; Perez and de los Campos, 2014). Residuals were derived from the fitted models (i.e. phenotypes minus prediction). Subsequently we conducted marginal association tests between these residuals and genotypes of the MD and UHD panel, one SNP at a time. We determined significance using FDR<0.01. The association tests were conducted using the BGData package (Grueneberg and de los Campos, 2019).

Results

Results for all models under different panels are depicted in Figure 1. There is strong widespread leakage for PBLUP. Variants showing FDR<0.01 are spread across the genome, with very few regions devoid of them, especially in the UHD panel. These results reflect the amount of genetic signal missed by not including genomic information in the model.

The inclusion of genotype data under the ssGBLUP model strongly changes the leakage landscape, even though the pedigree still influences the model fit and predictors. Two major aspects of that change are the improved fitting of genome-wide (i.e. non-local) associations that were missed by PBLUP and the reduction of the strength of locally concentrated leakage peaks. That change is gradual with the inclusion of more genotypes in the data set. Some strong leakage regions in PBLUP (e.g. in chromosome 1) were solved by ssGBLUP under ssGBLUP_100, regardless of the panel used to evaluate it. This indicates that local modelling with differential prior weights might not be required to solve strong signals of local leakage. However, a couple of clear leakage peaks remain even when 100% of genotypes are included. One of them (in chromosome 2) is only detected using UHD. The strongest remaining leakage signal for ADG is in chromosome 17. Although its detected magnitude is stronger using UHD in the scan, it is still clear under MD, even if this same panel was used to fit the ssGBLUP. The association pattern resulting from the residuals of BRR is very similar to the ssGBLUP_100 scenario, with the latter showing the same peaks for both traits, albeit with slightly extra shrinkage.

The use of variable selection, as in BayesC, fully solves the strongest remaining leakage point in chromosome 17. This suggests that this region involves associations that are too strong to be allowed under Gaussian prior distributions but are efficiently accommodated by variable selection (and possibly other thick-tailed) priors. Under BayesC no leakage was detected with the MD panels used to build the predictors. However, scans

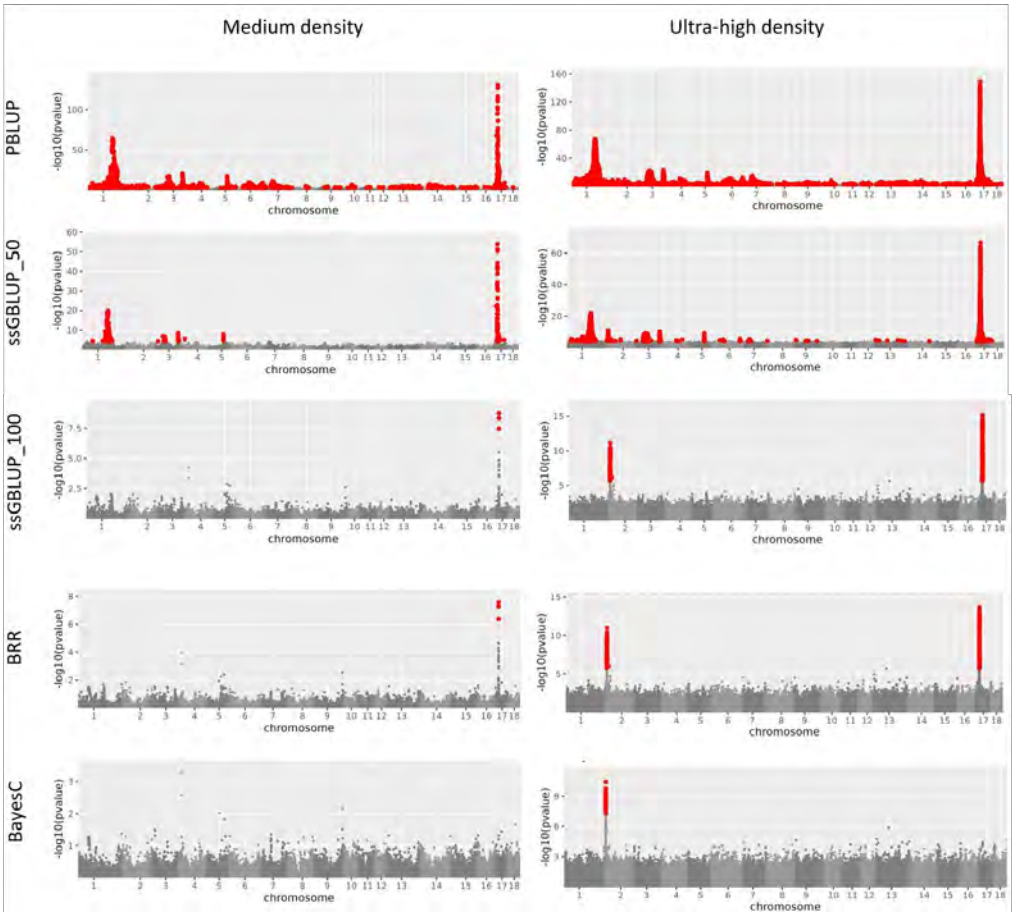

Figure 1. Manhattan plots depicting genomic signal leakage by model and SNP panel, with significant SNPs highlighted in red (FDR<0.01).

with the UHD panels indicated a leakage spot in chromosome 2 missed by the MD panel, suggesting that imperfect LD between the variants of the MD panel and causal variants may be generating signal leakage. Adding genomics and allowing thicker tails is not only insufficient to solve the leakage, but its magnitude is also hardly affected, indicating that this peak had a different nature from the one in chromosome 17.

Discussion and implications

Metrics typically used to compare genomic models are often based on an overall score, such as prediction correlation, AIC, BIC, etc. Such genome-wide summaries are affected by multiple competing factors and thus may not be enough to characterize how a model performs at capturing the genetic signals present in genomes for a trait. Here we present a complementary approach for evaluating and comparing models that allows characterizing genomic landscapes of signal leakage from a genetic predictor. Leakage can be widespread or concentrated in specific genomic regions. Peaks of leakage can result from different sources (e.g. over-shrinkage of marker effects, low LD between SNP panel used to build the predictor and a high association genomic region).

Relative to other methods to evaluate and compare models, the present approach potentially provides better insights about the existence or not of room for improvements, as well as directions on how problems detected using residual regressions can be addressed. For example, it is common to attempt to improve genomic predictors performance based on commercial SNP panels by adding sequence variants. Two common choices are either increasing the overall panel density or including SNPs from selected regions. The region selection involved in the latter is typically based on statistical information (e.g. GWAS), biological information (e.g. genes that are differentially expressed or assigned to relevant biological pathways), or a combination of both. However, these approaches are blind to the pattern of missed signals of the predictor that one wants to improve. For example, there is limited potential in adding variants pertaining to a few relevant regions if leakage is spread genome-wide with little regional concentration. Alternatively, even if leakage is more local, using GWAS or biological information may suggest the inclusion of variants from regions from which signals are already well captured by current predictors. The approach proposed here could describe the leakage pattern of a specific combination of panel and model and be used as a criterion to evaluate if/which genomic regions would present the best potential to harbour sequence variants that would improve this particular predictor.

Abstract

Prior biological information has the potential to guide and inform genomic prediction models, but the BayesRC approach is currently limited to the use of disjoint categorizations of genetic markers. We propose two novel Bayesian approaches to model cumulative (BayesRC+) or preferential (BayesRCπ) contributions of multiple biological categories for multi-annotated SNPs. We illustrate the performance of these approaches on data from a backcross population of growing pigs in conjunction with several different sets of annotations related to multiple production traits constructed using the PigQTLdb. On the two traits predicted, ADG and BFT, we observed improved prediction quality on ADG (up to 1.7-gain point) with both BayesRCpi and BayesRC+, and suitable annotation set.

Introduction

In plant and animal breeding, genomic prediction models have been widely developed and deployed in recent years to predict polygenic traits using genetic variants, typically single nucleotide polymorphisms (SNP). An interesting and potentially useful approach to improve upon existing genomic prediction models is to combine the use of genotype and phenotype data with prior biological information to better guide models. Most routinely used genomic prediction models are based on linear models, including notably genomic best linear unbiased prediction. Another family of models, known as the Bayesian alphabet (Habier *et al.*, 2011), uses a flexible set of assumptions about how individual SNPs contribute to the overall genomic variance. Among these, BayesR (Erbe *et al.*, 2012) assumes SNP effects arise from one of four groups (null, small, medium, or large variance) and has been shown to perform well for both prediction and quantitative trait loci (QTL) mapping (Moser *et al.*, 2015; Mollandin *et al.*, 2021). BayesRC extends BayesR to further incorporate prior biological information in the form of disjoint annotation categories (MacLeod *et al.*, 2016), but SNPs can only be assigned to a single annotation category. There thus remains a need for genomic prediction models able to capitalize on annotations of greater complexity, in particular those for which SNPs may potentially be assigned to multiple categories.

In this work, we present two novel extensions to BayesRC to deal with such complex, overlapping annotations, and we illustrate their utility on data from an experimental backcross population in growing pigs. This project is part of EuroFAANG (https://eurofaang.eu), a synergy of five Horizon 2020 projects that share the common goal to discover links between genotype to phenotype in farmed animals and meet global Functional Annotation of ANimal Genomes (FAANG) objectives.

Materials & methods

Bayesian genomic prediction with complex, overlapping annotations. The general statistical model for genomic prediction can be defined as:

$$\boldsymbol{y} = \boldsymbol{\mu} + \boldsymbol{X\beta} + \boldsymbol{e}, \quad e_i \sim N(0, \sigma_e^2) \tag{1}$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_303, © F. Mollandin *et al.* 2022

where $\boldsymbol{y}$ is a vector of phenotypes, μ an intercept, β the vector of SNP effects, X the centered and scaled marker matrix, and σ_e^2 the variance of the residuals e. We further assume that C = ($C_{i,j}$) denotes annotation categories, such that $C_{i,j}$ = 1 if SNP i is included in category j and 0 otherwise.

Using the four-component mixture of BayesR as a base, we propose two alternative models to account for overlapping annotations (where $\Sigma_j\, C_{i,j} > 1$ for some i). The first, BayesRCπ, defines a mixture-of-mixtures prior for SNP effects to assign multi-annotated markers to the single annotation category that maximizes its conditional likelihood:

$$\beta_i \sim \sum_{j \in C_{i,j}=1} p_{i,j}\left(\pi_{1,j}\delta(0) + \pi_{2,j}N(0, 10^{-4}\sigma_g^2) + \pi_{3,j}N(0, 10^{-3}\sigma_g^2) + \pi_{4,j}N(0, 10^{-2}\sigma_g^2)\right) \quad (2)$$

such that $\delta(0)$ represents the dirac function at 0, $\Sigma_k\, \pi_{k,j}$ for all annotations j, σ_g^2 the total additive genetic variance, and $p_{i,j}$ the annotation mixing parameter with $\Sigma_j\, p_{i,j} = 1$ for all i. The second, BayesRC+, instead defines a cumulative mixture prior across categories for SNP effects:

$$\beta_i \sim \sum_{j \in C_{i,j}=1}\left(\pi_{1,j}\delta(0) + \pi_{2,j}N(0, 10^{-4}\sigma_g^2) + \pi_{3,j}N(0, 10^{-3}\sigma_g^2) + \pi_{4,j}N(0, 10^{-2}\sigma_g^2)\right) \quad (3)$$

In both models, all mixing proportions are assumed to follow flat Dirichlet priors and σ_g^2 an inverse X^2 prior. A Gibbs sampler is used for inference as posterior distributions are not tractable. Both BayesRCπ and BayesRC+ have been implemented in the BayesRCO software in Fortran; additional details can be found in the User's Guide (https://github.com/fmollandin/BayesRCO).

Genotype and phenotype data from a backcross pig population. A backcross (BC) population between Large White (LW; 3/4) and Creole (CR;1/4) pigs was established as previously described (Gourdine *et al.*, 2019). BC (n=1,297 from 130 LW sows) growing pigs raised in two environments (tropical and temperate) were related via genetically related sows sired with the same 10 F1 × CR LW boars. A common trait recording protocol was used in the two environments for phenotypic data. Phenotypes were pre-corrected for age, sex, and farm; we focus here on measures at 23 weeks for backfat thickness (BFT) and average daily weight gain (ADG). Animals were genotyped using the Illumina Porcine 60k BeadChip array; markers with minor allele frequencies greater than 0.01 were retained for the analysis (corresponding to 46,908 and 46,881 markers for ADG and BFT, respectively). To establish the potential impact of our models on prediction accuracy, we used a sibling-structured 10-fold cross validation procedure. For the descendants from each sire in turn, we calculated the correlation between their observed corrected phenotypes and those predicted from models constructed on the descendants of the remaining 9 sires; validation correlations were averaged across the ten folds.

PigQTLdb annotations. Animal QTLdb (https://www.animalgenome.org/QTLdb) groups together curated results from genotype-phenotype association studies in several livestock species (Hu *et al.*, 2021). Cross-experiment QTL data from PigQTLdb (Release 45; SS11.1) for traits relevant to pig production were downloaded for eleven trait sub-hierarchy categories (anatomy, behavioral, blood parameters, conformation, fatness, fatty acid content, feed conversion, fowth, immune capacity, litter traits, reproductive organs). An additional 'other' category was created for markers not included in PigQTLdb. Genotyped markers in our data were subsequently assigned to one or more annotation categories using three different strategies: (1) using the position of known PigQTLdb markers; (2) using the extended position of known PigQTLdb markers, including the nearest up- and downstream neighbors ('extended PigQTLdb'); and (3) using the extended position of known PigQTLdb markers as before, where neighboring markers were allowed ambiguous assignment to both trait-specific and 'other' categories ('fuzzy extended PigQTLdb').

In the three annotation construction strategies, 1.3, 4.9 and 17.7% of markers were respectively assigned to two or more categories.

Results

We compared the prediction accuracy of BayesRCπ and BayesRC+ to that of BayesR (ignoring annotation categories) and BayesRC (where a single category is allowed per marker). For the latter, multi-annotated SNPs were randomly assigned to a single category. We notably observed different trends for the two traits (Table 1). For ADG, we remark a loss in prediction accuracy compared to BayesR for all annotation-based models with straightforward pigQTLdb annotations; however, extending these annotations to include neighboring markers (extended and fuzzy extended pigQTLdb) led to improvements in prediction quality, with a 1.7-point gain in correlation for BayesRCπ with extended annotations. On the other hand, for BFT the use of annotations, regardless of how they are constructed, did not appear to lead to a marked improvement in prediction. This suggests that categorizations constructed from PigQTLdb contribute little pertinent information for the genomic prediction of BFT in our data, or that environment-dependent categories should be added to the model to account for the significant GxE affecting this trait (Gourdine *et al.*, 2019).

Discussion

In this work we have proposed two new approaches, BayesRCπ and BayesRC+, to fully capitalize on complex, overlapping annotations in genomic prediction. Both methods showed promise for incorporating partially overlapping categories from pigQTLdb in genomic prediction for a growing pig population, although a gain in predictive accuracy was observed for only one (ADG) of the two traits considered here. We also compared three strategies for constructing prior biological categories by extending pigQTLdb annotations in various ways to include neighboring markers, which has the potential to better exploit linkage disequilibrium around relevant markers. Taken together, these results suggest that the incorporation of complex annotations can lead to modest gains in prediction performance in some cases, even for moderate marker density SNP chips, but such gains depend strongly on the choice and construction of annotations and are unlikely to be universal across traits.

This work is part of the GENE-SWitCH project that has received funding from the European Union's Horizon 2020 Research and Innovation Programme under grant agreement no. 817998. The financial support of the French National Agency of Research (ANR PigHeaT, ANR-12-ADAP-0015) is also gratefully acknowledged.

Table 1. Validation correlation for two traits in pig data for BayesRCπ and BayesRC+ with different annotation strategies, as compared to BayesR and BayesRC.

Method	Annotations	ADG; mean (SD)	BFT; mean (SD)
BayesR	-	0.213 (±0.081)	0.265 (±0.161)
BayesRC	PigQTLdb (random)	0.200 (±0.105)	0.265 (±0.159)
	Extended pigQTLdb (random)	0.225 (±0.098)	0.258 (±0.157)
BayesRCπ	PigQTLdb	0.200 (±0.100)	0.266 (±0.157)
	Extended pigQTLdb	0.229 (±0.095)	0.254 (±0.162)
	Fuzzy extended pigQTLdb	0.226 (±0.096)	0.262 (±0.159)
BayesRC+	PigQTLdb	0.207 (±0.097)	0.273 (±0.163)
	Extended pigQTLdb	0.227 (±0.095)	0.271 (±0.158)

Abstract

Accuracy of genomic prediction is key for genetic progress in breeding programs and including genome functional annotation may help. Here we report on the added value of Combined Annotation Dependent Depletion (CADD) scores to weigh SNPs in GBLUP analyses. Multiple transformations of CADD scores were considered and empirically validated on a layer dataset including 5 traits and 18K animals with 27K SNP genotypes. This initial analysis revealed that the use of (squared) CADD scores yielded marginally higher accuracy for 3 traits. We anticipate that the added value of CADD scores will increase by using a higher number of SNPs and ultimately whole genome sequence SNPs.

Introduction

Since the introduction of genomic prediction (Meuwissen *et al.*, 2001), animal breeding has been transitioning towards approaches that increasingly exploit genomic information. An emerging strategy involves weighting of SNPs that have a higher probability of being causal or being tightly linked to causal variants (Xiang *et al.*, 2021).

The combined annotation dependent depletion (CADD) (Rentzsch *et al.*, 2019) model that was developed to investigate SNPs in human populations, can score variants at coding and non-coding locations in the genome. Similar models have been deployed for livestock species. For chicken and pig, so-called cCADD and pCADD scores were created, as a tool to prioritize variants and evaluate sequences to highlight new sites of interest to explain biological functions that are relevant to animal breeding (Groβ *et al.*, 2020).

The objective of this study is to validate the added value of CADD scores to weight SNPs in genomic prediction on five traits in commercial layers. We explore multiple weighting strategies, i.e. transformations of CADD scores, in GBLUP models. This project is part of EuroFAANG (https://eurofaang.eu), a synergy of five Horizon 2020 projects that share the common goal to discover links between genotype to phenotype in farmed animals and meet global Functional Annotation of ANimal Genomes (FAANG) objectives.

Materials & methods

Chicken CADD scores. The chicken CADD scores were retrieved from Groβ *et al.* (2020). CADD is a machine learning tool originally developed to identify deleterious variants in the human genome. CADD uses a wide range of annotations to predict impact from sequence variation. Important annotations include conservation scores, gene model annotations, epigenomic data, and functional predictions. CADD combines these annotations to provide an impact score for any possible SNP variant in the genome. The higher the CADD score, the more likely the variant has impact. The scores can be used to prioritize genetic variants in genetic evaluation.

Weighting SNPs in genomic prediction. A typical genomic relationship matrix G is computed as: $G=XX^T/c$, equivalently written as: $G=XIX^T/c$, where X contains centred (and possibly scaled) SNP genotypes, c is a constant, and I is an identity matrix (VanRaden, 2007). This implies that all SNPs have

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_304, © M.C.A.M. Bink *et al.* 2022

an equal weight of 1. The computation can be generalized as: $G_w=XDX^T/c$, where D is a diagonal matrix, with weights for each SNP on the diagonal that are proportional to the variance that this SNP explains. The calc_grm program (Vandenplas and Calus 2020) was used to compute G and G_w.

Scenarios of weights. In this approach, the weight represents the *a priori* variance associated with a particular SNP. So, if one SNP has a weight of 1, and another one has a weight of 2, this means that the second SNP explains twice as much variance as the first one. The CADD scores do not represent variances and therefore three options are considered to translate CADD scores into weights, i.e. original (CADD), squared (CADDsq), and square root (CADDrt) (Figure 1).

To develop a benchmark for these scenarios, two options were considered: [A] all SNPs having equal weights (Equal); [B] random values (Random). For option [B] 10 replicates were generated to provide standard error estimates. The random values were generated by squaring random draws from $N(0,1)$. Within each scenario, all weights are scaled by dividing by the average weight, such that after scaling the mean weight is equal to 1.

Layers dataset. The dataset was provided by the layer division (ISA BV) of Hendrix Genetics and pertains to the pure line WA of the commercial layer breeding program. A total of 18,419 animals was genotyped with a 60K SNP array. These genotypes were curated on minor allele frequency (>0.05) and missing values (<10%). SNPs with unknown position or located at sex chromosomes were also discarded. After quality control, 26,841 autosomal SNPs were available for further analyses. Including ancestors of the genotyped animals yielded a pedigree of 21,060 animals. The dataset included five traits, i.e. shell breaking strength (BS), egg number (EN), egg weight (EW), hatchability (HT), and survival (SV). The number of records varied between 2,361 and 5,802 (Table 1). The dataset has been pre-corrected for all non-genetic effects to ease analyses. The pre-correction was executed using the models as used in the routine genetic evaluations. That is, the feature 'yielddev' in the MiXBLUP software (www.mixblup.eu) was used to produce yield deviations, i.e. the sum of estimated animal & residual effects. Variance components were estimated using the average information restricted maximum likelihood algorithm implemented in the AIREMLF90 software (Misztal *et al.*, 2014), and yielded heritability estimates ranging from 0.06 to 0.75 (Table 1). When omitting SNP genotypes, the pedigree-based accuracy of EBV was between 0.06 and 0.37 for the validation animals.

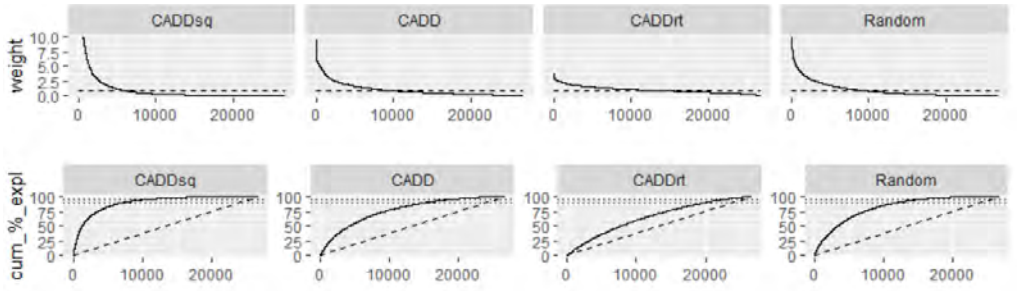

Figure 1. Distribution of weights (upper), and cumulative % of *a priori* explained genetic variances (lower) for CADD and random scores. Dashed lines pertain to scenario with equal weights, and dotted lines pertain to 90 and 95% explained variance.

Table 1. Numbers of records, heritability estimates, split dates for validation, and pedigree-based accuracy for validation animals, on five layers traits.

Trait	No. records	Heritability	CV hatch date	Accuracy$_{(ped)}$
Breaking strength (BS)	2,522	0.26	2014-11-04	0.25
Egg number (EN)	3,400	0.12	2014-11-04	0.11
Egg weight (EW)	5,802	0.75	2016-06-21	0.37
Hatchability (HT)	2,361	0.30	2016-06-21	0.20
Survival (SV)	3,536	0.06	2015-03-24	0.06

Validation set & accuracy. In animal breeding programs the main interest is in accurate breeding values on selection candidates. The forward validation scheme aligns best with this interest. Here, the dataset was split into a training set of 75% oldest animals and a validation set of 25% youngest animals. The patterns and numbers of records on the five traits differ substantially and therefore different dates were used to assign animals to subsets for each trait (Table 1). The validation set allowed a dissection in birthyears to assess impact of connectedness between training and validation animals with youngest animals least connected. Measure for accuracy was the correlation between estimated breeding values and pre-corrected phenotypes (on validation set). All data manipulation was done with dedicated R scripts (R Core Team, 2020).

Results

The weighting scenarios on CADD scores yielded accuracy estimates that were similar to those from Equal scenario (Figure 2) with slightly higher values for 3 traits (BS, HT, and SV). For these traits, the squared CADD scores yielded highest accuracies. Note that for the hatchability trait accuracies were not different from the Random scenario. For other traits the Random scenario always yielded the lowest accuracies. As expected, accuracies dropped for younger animals in the validation set (Figure 3) and these patterns were very similar for all scenarios (some not shown). The rate of drop in accuracy with age was trait dependent.

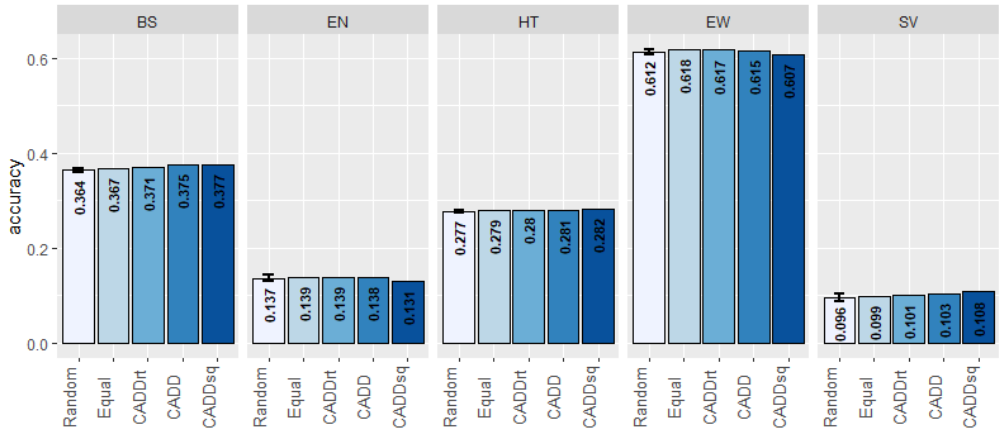

Figure 2. Accuracy of genomic prediction on validation animals for five traits and five weight scenarios (standard error bars are included for Random).

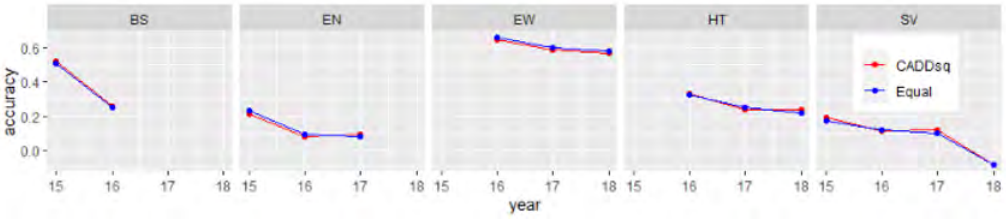

Figure 3. Accuracy estimates versus birthyear of validation animals.

Discussion

We reported on the use of CADD scores to weight SNPs in genomic prediction when using data from a 60K SNP array. These results did not show a consistent added value in predictive ability when using CADD scores to weight SNPs in GBLUP models for genomic prediction. Among the weighting scenarios some trends were observed. The square root CADD scores yielded accuracy closest to the Equal scenario while the squared CADD scores were always most different. This is consistent with the patterns of cumulative percentages explained genetic variance (Figure 1), where the square root CADD scores are most close to the Equal scenario. The trait-dependency of results points to potential differences in trait architecture with some traits highly polygenic and others pre-dominantly driven by fewer genes. This deserves further investigation. With whole genome sequence SNPs, it is known to be important to use a subset for genomic prediction. CADD enables selecting variants with impact, independent from the training data.

Abstract

Female fertility traits are often difficult and expensive to measure. Male fertility traits, however, are sometimes cheaper and easier to measure and are genetically correlated with female fertility. This study investigated the accuracy of genomic prediction using the SNP effects from male traits to estimate genomic breeding values for female traits. Three sets of genetically correlated male vs female traits in Brahman cattle were used, with varying trait correlation from low to high. A recently developed methodology termed correlation scan was used to interrogate the genome and identify SNPs that underpin the genomic correlations between male and female fertility. Some of the identified SNPs can be classified as 'correlation-drivers' for the genomic correlations. When these significant correlation-drivers were used in genomic predictions, we observed an increased accuracy, by as much as ~30%, compared to using the whole high-density SNP chip.

Introduction

Female fertility is a key driver of profitability of beef enterprise in tropical regions of the world (Taylor and Rudder 1986). However, most of the traits that define female fertility are often difficult and expensive to measure on commercial herds and are mostly available late in life (Hayes *et al.* 2018). These challenges make female fertility traits difficult to select for and make genetic progress (Hayes *et al.* 2018). Male fertility traits, for example, scrotal circumference, are relatively cheaper and easier to measure and are genetically correlated with expensive to measure female traits, such as age at puberty (Johnston *et al.* 2014; Olasege *et al.* 2021a). This implies that there are possibilities that some quantitative trait loci may affect both male and female traits in the same direction (Bolormaa *et al.* 2014).

Currently, there is a paucity of information on how accurately SNP effects from male fertility phenotypes can predict correlated female traits. Recently, Olasege *et al.* (2021b) developed a new methodology that can identify genomic regions driving and antagonizing correlated male and female fertility traits. This methodology uses best linear unbiased prediction (BLUP) solution of SNP effects to estimate the local correlations between studied traits using 500-SNPs in a 100-SNPs sliding window across each chromosome. The resulting estimates were used to infer drivers and antagonizers regions contributing to the overall genomic correlation between traits. However, the application of this methodology is yet to be tested on genomic predictions. Hence, the aim of this study was to examine the accuracy of across-sex genomic predictions using pre-selected SNPs with the new methodology compared to the whole high-density (HD) SNP chip.

Materials & methods

Traits, genotypes and estimated genomic correlations. The traits used in this study were a subset of male and female traits from our previous study (Olasege *et al.* 2021a). The traits were age at first corpus luteum (AGECL), scrotal circumference measured at 12-months (SC12) and serum levels of insulin growth hormone (IGF1 measured in bulls, IGF1b, or cows, IGF1c), all measured in Brahman (BB) population. Details about the pairwise genomic correlations for these traits are provided in Table 1. The selected

Table 1. Genomic correlation estimates for each pairwise trait used in this study.[1]

Pairwise traits	No of animals	Genomic correlation (S.E)	Degree of correlation
AGECL vs SC12	AGECL – 980 SC12 – 1,020	-0.32 (0.15)	Low
AGECL vs IGF1b	AGECL – 980 IGF1b – 964	-0.65 (0.13)	Moderate
IGF1c vs IGF1b	IGF1c – 995 IGF1b – 964	0.86 (0.11)	High

[1] AGECL, age at first *corpus luteum;* IGF1c, serum levels of insulin growth hormone (IGF1 measured in cows at 24-month, IGF1c, or in bulls at 6-month, IGF1b). SC12, scrotal circumference at 12-month. S.E; standard error.

pairwise traits represented three degrees of genomic correlation estimates i.e. low, moderate, and high. Briefly, across-sex genomic correlations were estimated through a bivariate analysis using linear mixed model fitted in GIBBS2F90 (Misztal *et al.* 2002). After quality control (i.e. excluding SNPs with minor allele frequency <5%), about 645K SNPs remained for BB datasets used for the analysis.

Identification and selection of correlation-driver set of SNPs. The correlation-driver set of SNPs were identified following the correlation scan methodology described by Olasege *et al.* (2021b). To avoid potential bias in downstream prediction analyses, we split the male and female data into training (80%) and validation set (20%) in a five-fold cross-validation. The male and female training sets were used to estimate genomic breeding values (GEBVs) for the respective male and female traits using GBLUP model:

$$y = Xb + Za + e \quad (1)$$

where *y* is the vector of phenotypic values, X is the incidence matrix of fixed effects, *b* is the vector of fixed effects, Z is the design matrix assigned to genomic breeding values, g is the vector of GEBVs for all animals and e is the vector of residuals. Vectors g and e are assumed to follow a normal distribution, thus $g \sim N(0, G\sigma^2 g)$ and $e \sim N(0, I\sigma^2 e)$. Matrix G is the genomic relationship matrix.

After this, we then back-solved these GEBVs for each male and female traits (training sets) to obtain SNP effects using the method of Strandén and Garrick (2009):

$$\hat{\mathbf{u}} = \frac{1}{\sum_{j=1}^{m} 2p_j(1-p)} \mathbf{X}'\mathbf{G}^{-1}\hat{\mathbf{a}} \quad (2)$$

Where û is the vector of estimated SNP effects; *m* is the number of SNPs; p_j is the allele frequency of the second allele of the j^{th} marker; X is a matrix with gene contents for all markers; G is a genomic relationship matrix and â is a vector of GEBVs.

The SNP effects from the training sets for each pre-selected pair of male and female traits were used to perform a correlation scan using 500 SNPs in a 100 SNPs sliding window across each chromosome, as described by Olasege *et al.* (2021b). Consequently, the set of SNPs that drove the genomic correlation between pairs of male and female traits were identified and were termed as 'correlation-drivers'. Table 2 shows the average number of the correlation-driver SNPs across the five-folds, as compared to the HD SNPs set.

Genomic prediction analysis. The SNPs identified as correlation-drivers in pairwise correlation scan analysis were selected from training datasets of male traits and their effects were estimated using GBLUP model. These SNP effects were used to calculate GEBVs for the corresponding validation sets for the female traits using the equation: $GEBV_f=Z_f g_{m,}$ where Z_f is the incidence matrix of the additive allele score of each SNP for each female and g_m is corresponding SNP effect for each SNP in the males. The same procedure was followed for the estimation of GEBVs for validation sets of female traits using whole HD SNPs. The prediction accuracy was calculated as correlation between $GEBV_f$ and their phenotypes adjusted for fixed effects, averaged across the five validation groups, divided by the square root of heritability of the female traits.

Results

Accuracy of genomic prediction. Figure 1 shows the accuracy of genomic predictions (correlation-driver vs HD SNP set) using the SNP effects from male phenotypes to predict female traits, having varying degree of genomic correlations with male traits (low, ~-0.3; moderate, ~-0.6; and high, ~0.9). For the correlation-driver set of SNPs, accuracies were 0.15, 0.27, 0.38 for the low, moderate, and highly correlated traits, respectively. For HD SNP sets, prediction accuracies were 0.11, 0.20, and 0.29 for these pairs of correlated traits. Furthermore, the accuracy of genomic prediction increased as the genomic correlation between traits increased. In summary, the correlation-driver set of SNPs, on average, improved accuracy of genomic prediction across-sex by 30%, irrespective of the degree of genomic correlation between the male and female traits.

Table 2. The average number of correlation-driver and HD SNPs for the pairwise traits.[1]

Pairwise traits	No of correlation-driver SNPs, averaged across the five-folds	No of HD SNPs
AGECL vs SC12	216K	645K
AGECL vs IGF1b	284K	645K
IGF1c vs IGF1b	341K	645K

[1] AGECL, age at first *corpus luteum*; IGF1c, serum levels of insulin growth hormone (IGF1 measured in cows at 24-month, IGF1c, or in bulls at 6-month, IGF1b). SC12, scrotal circumference measured at 12-month.

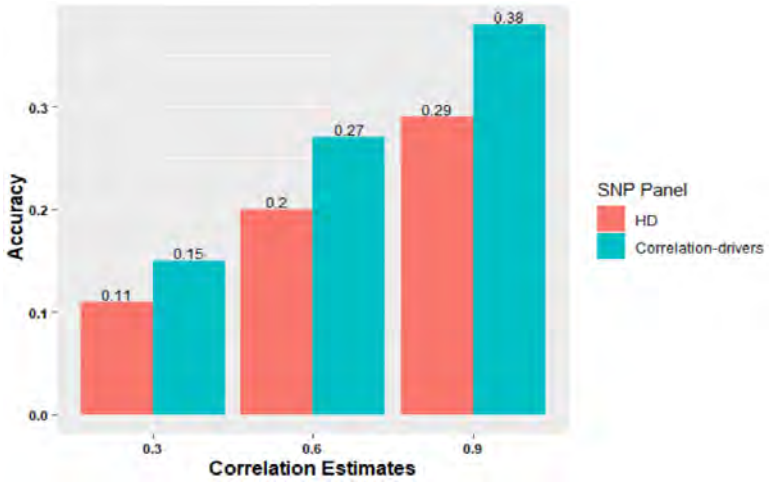

Figure 1. Comparison of the accuracy of genomic prediction (correlation-driver vs HD) using SNP effects from male traits to predict varying degrees of correlated female traits.

Discussion

The objective of this study was to investigate the possibilities of using cheap and easy-to-measure male fertility phenotypes to predict correlated female fertility traits that are difficult and expensive to measure. The results of our analyses using both the pre-selected correlation-driver and HD SNP sets show that female fertility traits can be predicted from correlated male fertility phenotypes. However, the pre-selected correlation-driver SNP sets demonstrated superiority in prediction accuracy (~30% increase) compared to the HD set of SNPs, irrespective of the degree of genomic correlation between the male and female traits. Although we used a relatively smaller sample size, these accuracies are likely to be further improved by using a larger sample size. Studies have shown that using pre-selected markers can improve genomic prediction accuracy (Raymond *et al.* 2018; Al Kalaldeh *et al.* 2019). The increase in accuracies for the correlation-driver SNPs set is expected since the direction of effects of these SNPs are the same for both male and female traits. It will be interesting to investigate the possibilities of using these set of SNPs in a different set of populations. This will be the next phase of research.

306. Genomic prediction with incomplete omics data

E. Karaman*, V. Milkeviych, Z. Cai, L. Janss, G. Sahana and M.S. Lund

Center for Quantitative Genetics and Genomics, Faculty of Technical Sciences, Aarhus University, 8830 Tjele, Denmark; emre@qgg.au.dk

Abstract

In animal breeding, there has been an increasing interest in investigating the added value of intermediate omics traits such as transcriptomes, metabolites and methylation patterns in genomic predictions. Such data are available only for small number of animals. The 'single-step genomic prediction' machinery, which was first proposed to combine pedigree information of a large number of individuals, and genomic information of a fraction of the population, can be useful to handle incomplete omics data. Such an approach, when applied to incomplete omics data scenarios, imply a simple linear relationship from genotypes to different omics traits, which in reality may be very complex. Little is known about the accuracy of genetic evaluations when the omics traits are generated for the whole population. Here, we present two different approaches to handle incomplete omics data, and investigate their impact on genomic predictions, using simulations.

Introduction

Genomic prediction relies on the estimation of the effects for tens of thousands of genetic variants (generally single nucleotide polymorphisms-SNPs) over the whole genome (Meuwissen *et al.*, 2001), and has received great attention in animal and plant breeding as well as in human genetics studies. Recently, research interests moved towards exploring the added value of intermediate omics traits, such as transcriptomes, metabolites, methylation patterns, etc. in genetic evaluations.

Christensen *et al.* (2021) provided formulas for breeding values required for genomic evaluation when intermediate traits are included, based on a set of two models: (1) a model relating intermediate omics traits to phenotypes; and (2) a model relating genotypes and intermediate omics traits. Such an approach has been used in transcriptome-wide association studies (TWAS) to discover gene-trait associations (Wainberg *et al.*, 2019). Analogous to conventional genomic predictions that estimates SNP effects in a reference population, TWAS first uses a reference population of individuals with SNP genotypes and gene expression data. This population is used to estimate the effect sizes of expression quantitative trait loci (eQTL). Second, expression levels are predicted for the individuals in an independent population, for which genotypes and phenotypes are available. Third, statistical associations are tested for their significance between predicted gene expression data and the trait (Wainberg *et al.*, 2019).

A limitation of incorporating intermediate omics traits in genomic predictions is that, they are available for only a fraction of the populations compared to the number of genotyped individuals. When omics data are available for only a subset of the population, a genomic relationship matrix between individuals with and without omics data can be used to predict (impute) the missing omics data (Christensen *et al.*, 2021). This, however, imply a simple linear relationship from genotypes to different omics traits, which in reality may be very complex. We hypothesize here that if the structure of the gene regulatory network (GRN) responsible for the complex trait can be inferred from the available omics data, the unobserved omics traits can be predicted more accurately, and in turn accuracy in genomic evaluations can be improved. In addition, assuming the consistency of underlying true GRN across breeds (Huang *et al.*, 2012), we further hypothesized that GRN estimated in one breed can be used to predict expression data in other breeds, and in turn for genomic predictions.

Materials & methods

Models. We used a two-level model as in Christensen *et al.* (2021) for genomic predictions.

$$\boldsymbol{y} = \mathbf{1}\mu + \mathbf{M}\boldsymbol{\alpha} + \boldsymbol{\epsilon} \tag{1}$$

$$\mathbf{m}_{\mathrm{i}} = \mathbf{1}\mu_{o,i} + \mathbf{g}_{\mathrm{i}} + \boldsymbol{e}_{\mathrm{i}},\ i = 1, \ldots, K \tag{2}$$

where $\mu_{o,i}$ is the mean of expression level i, m_{i} $(N \times 1)$ vector of expression levels, g_{i} is the vector of genetic effects with $\mathrm{g}_{\mathrm{i}} \sim N(0, \mathrm{G}\sigma_{\mathrm{g}}^{2})$ where G is a relationship matrix computed based on SNPs, and e_{i} is the vector of residuals with $e_{\mathrm{i}} \sim N(0, \mathrm{I}\sigma_{\mathrm{e}}^{2})$, for gene i. The μ is the phenotypic mean, M is an $(N \times K)$ matrix of expression levels, α is a $(K \times 1)$ vector of omics' effect sizes, and ε is environmental effect. Equation 2 is a linear mixed model (LMM) with an underlying assumption of a linear path between SNPs to expression levels through the G matrix, whereas from SNPs to expression levels there can be very complex relationships.

For GRN-based description of the relationship between omics expression levels and genetic effects, we replaced Equation 2 with a structural equation model (Equation 3) to describe the expression levels on K genes for individual j (Zhou and Cai, 2022):

$$\mathbf{m}_{\mathrm{j}} = \mathbf{b} + \boldsymbol{\Lambda}_1\mathbf{m}_{\mathrm{j}} + \boldsymbol{\Lambda}_2\mathbf{t}_{\mathrm{j}}^{*} + \boldsymbol{\varepsilon_j} \tag{3}$$

where b is a $(K \times 1)$ vector of general means, Λ_1 $(K \times K)$ and Λ_2 $\left(K \times (\sum_{k=1}^{K} n_k)\right)$ are matrices of the regulatory effects among genes behind expression levels, and among the candidate *cis*-eQTL, respectively,

$$\mathbf{t}_j^{*} = \begin{bmatrix} \mathbf{t}_{j1} \\ \vdots \\ \mathbf{t}_{jK} \end{bmatrix}$$

is a $\left((\sum_{k=1}^{K} n_k) \times 1\right)$ vector of genotypes of individual j where t_{jk} consists of centered genotype content at n_k candidate eQTL for gene k, b is a $(K \times 1)$ vector of means, and ε_j is a vector of residuals with $e_{\mathrm{i}} \sim N(0, \mathrm{I}\sigma_{\varepsilon}^{2})$. Rearranging Equation 3 we get:

$$\mathbf{m}_{\mathrm{j}} = \mathbf{b}^{*} + \boldsymbol{\Lambda}\mathbf{t}_{\mathrm{j}}^{*} + \boldsymbol{\varepsilon}_j^{*}$$

where $\mathbf{b}^{*} = (\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\mathbf{b}, \boldsymbol{\Lambda} = (\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\boldsymbol{\Lambda}_2$ is a $\left(K \times (\sum_{k=1}^{K} n_k)\right)$, and $\boldsymbol{\varepsilon}^{*} = (\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\boldsymbol{\varepsilon}$.

Data simulation. Genotypic data were simulated using XSim (Cheng *et al.* 2015), based on an imputed (50k->HD->WGS) whole genome sequenced SNPs (WGS) dataset for 5,783 Holstein (HOL), and 1,305 Jersey (JER) cows. We restricted ourselves to a randomly selected 0.25 Morgan (1 Mb = 1 Morgan) from chromosome 25, for the proof of concept. In total ten generations were simulated, and population sizes were the same as initial population sizes. The numbers of males were 500 (HOL) and 100 (JER), and sex was assigned at random.

In order to simulate eQTL and gene expression data, we randomly selected 10 of the genes within the selected chromosome region, using the information in the Ensembl database (Howe *et al.*, 2021). Then, for each of the 10 genes, we randomly selected 20 SNPs as a list of candidate eQTL, from 1 kb up- and downstream of the gene's TSS site. Two out of the 20 SNPs per gene were selected at random as the cis-eQTL of the gene. Expression data of individual j were simulated with $\mathbf{m}_{\mathrm{j}} = (\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\mathbf{b} + \boldsymbol{\Lambda}\mathbf{t}_{\mathrm{j}}^{*} + (\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\boldsymbol{\varepsilon}_j^{*}$ (Zhou and Cai, 2022), where $\mathbf{g}_{\mathrm{j}} = \boldsymbol{\Lambda}\mathbf{t}_{\mathrm{j}}^{*}$ includes the breeding values for omics traits, and each were assumed

to have the same heritability, $h_m^2 = 0.6$. The variances in $\boldsymbol{\varepsilon}_j^*$ of $(\mathbf{I} - \boldsymbol{\Lambda}_1)^{-1}\boldsymbol{\varepsilon}_j^*$, were set according to this heritability. The weight of each gene's expression data on the final trait phenotype, α_i, was simulated from the unit normal distribution. Genomic breeding value of each individual was obtained as $\mathbf{u}_j = \mathbf{g}_j' \boldsymbol{\alpha}$, and the trait heritability was set at 0.1 or 0.5. All these procedures described above were replicated 10 times. The simulated network structure (Figure 1) was the same for both breeds, as well as the heritabilities, across all the replicates. The complexity of the simulated network, the number of genes, heritabilities of the gene expressions and the traits were varied, but only the results from the parameters described above were presented here.

Analyses. We used generations 9 and 10 as reference and validation populations, respectively. All individuals had genotypes, whereas only 300 and 100 individuals from generation 9 had gene expression data (data were masked), for HOL and JER respectively. Individuals in generation 9 had also phenotypes, and phenotypes of individuals in generation 10 were masked. First, we generated (imputed) the omics data to the whole population by fitting a LMM or GRN model. This was done by using HOL (or JER) individuals' available gene expression and genotype data, together with the genotypes of HOL or JER, for which the omics data will be imputed. Second, breeding values were predicted using those imputed omics data by fitting the model in Equation 1. We used JWAS package in Julia language (Cheng *et al.*, 2018) for the analyses using Equations 1 and 2, and ssemQr package (Zhou and Cai, 2022) in R language for the analyses using Equation 3. It is worth to note that the analyses rely on 20 candidate eQTL SNPs of each gene, and two of those were used to generate the gene expression data, and thereby the phenotypes. Accuracy in genomic predictions were measured as the correlation between the true and predicted genomic breeding values, for individuals in generation 10.

Results

The accuracies from different scenarios are presented in Table 1. When the heritability of the trait was 0.5, accuracies from GRN and LMM were ranged between 0.89-0.99 and 0.82-0.95, respectively. In general, when the imputations were within-breed, genomic predictions were the highest. Using HOL as the reference to impute gene expressions of JER led to accuracies of 0.91 and 0.86, using GRN and LMM, respectively, for heritability of 0.1. Those were 0.97 and 0.93, when the heritability was 0.5.

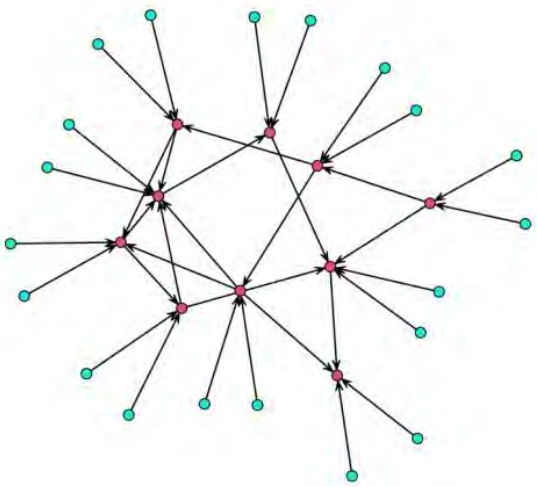

Figure 1. The structure of the simulated GRN. The red and blue circles stand for genes and eQTL.

Discussion

In this work, we have used a hierarchical modeling approach to describe the relationship between SNPs and phenotypes, which was earlier used for TWAS (Wainberg *et al.*, 2019) and recently for integrating intermediate omics traits in genomic prediction (Christensen *et al.*, 2021). So far, the approach has not been explored extensively for genomic prediction, and little is known about the accuracy of breeding value predictions when the omics traits are extended (imputed) to the whole population. We compared two approaches, LMM and GRN, to handle incomplete intermediate omics traits for genomic prediction, and showed that the LMM-based imputation approach was inferior to GRN-based approach, even when the simulated true GRN was not highly complex (Figure 1). Our results are only preliminary and shown here primarily for the purpose of illustrating the effectiveness of accounting for complex traits' genetic architecture, in genomic predictions integrating omics data. It is worth to note that the accuracies (Table 1) are generally much higher (above 0.8) than one might observe in real data. By design, all genes leading to ultimate trait phenotype was known, and the phenotypes were linearly related to steady-state expression levels of those genes. These conditions can hardly be met for real-life complex traits. Analogous to across breed genomic predictions, we used the estimated GRN for one breed to predict gene expression levels in another breed, though GRN is influenced by many factors. When gene expression and other relevant data for, for example genotypes of the two breeds, are available, it is more appropriate to use the estimated GRN in one breed to inform the estimation of GRN in the other, but not to replace it (Zhou and Cai., 2020).

Table 1. Prediction accuracies (standard errors).

Omics data	Prediction	Model for gene expression data			
		GRN		LMM	
		h^2=0.1	h^2=0.5	h^2=0.1	h^2=0.5
HOL	HOL	0.98(0.002)	0.99(0.000)	0.94(0.003)	0.95(0.003)
JER	JER	0.95(0.002)	0.98(0.002)	0.88(0.004)	0.94(0.001)
HOL	JER	0.91(0.007)	0.97(0.002)	0.86(0.008)	0.93(0.004)
JER	HOL	0.78(0.013)	0.89(0.009)	0.74(0.010)	0.82(0.011)

307. A Bayesian hierarchical model to integrate a mechanistic growth model in genomic prediction

H. Yu[1], J. van Milgen[2], E. Knol[3], R. Fernando[1] and J. Dekkers[1*]

[1]Iowa State University, Ames, IA 50011, USA; [2]PEGASE, INRAE, 35590 Saint-Gilles, France; [3]Topigs Norsvin, 6640 AA Beuningen, the Netherlands; jdekkers@iastate.edu

Abstract

Genomic prediction can improve the accuracy of estimated breeding values for traits driven by additive genetic effects within common settings but prediction of traits affected by non-additive genetic effects and G×E remains a challenge. Mechanistic growth models express growth performances in terms of nonlinear functional interactions between underlying latent traits and nutritional environmental effects. Assuming the latent traits are less affected by non-additive genetic effects and G×E, these models can capture certain non-additive genetic effects and G×E at the phenotype level and allow prediction at unobserved ages for longitudinal data, e.g. mature weight and mature feed intake. In this study, we developed a Bayesian hierarchical model to integrate a Gompertz model for body weight and feed intake into genomic prediction models for pigs. By predicting breeding values for biologically relevant underlying latent traits, these models have the potential to advance genetic improvement across populations and environments.

Introduction

Genomic prediction (GP) has facilitated genetic improvement by enabling more accurate estimated breeding values at an early age (Meuwissen *et al.*, 2001). While GP is effective in predicting traits dominated by additive genetic effects within common settings, challenges of predicting non-additive genetic effects and extrapolating to other conditions, such as to later ages or to other nutritional environments (G×E) remain. Previous attempts to address these challenges have mainly focused on statistical models, while augmentation of statistical models with biological information has received less attention. Developed from a nutrition perspective, mechanistic growth models (MGM) (e.g. Van Milgen *et al.*, 2008) describe growth performance as nonlinear functional interactions between underlying latent traits and nutritional environmental factors and can capture GxE and non-additive genetic effects that are created by the non-linear relationships embedded in the MGM. Following the pioneering ideas of Varona *et al.* (1997) and Bourdon (1998), several studies have sought to accommodate such MGM in genetic prediction (Doeschl-Wilson *et al.*, 2007; Cai *et al.*, 2012). Their successes were limited either by lack of appropriate statistical and computational methods or by the absence of genomic information. In plant breeding, crop growth models have recently been integrated into GP (Technow *et al.*, 2015; Messina *et al.*, 2018; Campbell *et al.*, 2020), leading to increases in prediction accuracies for performance in other environments compared to standard GP methods. Against this background, the objective of this study was to develop a Bayesian hierarchical model to integrate an MGM into GP for pigs.

Materials & methods

Bayesian hierarchical model for body weight and feed intake. The proposed model to integrate a MGM for body weight (BW) and daily feed intake (DFI) into GP is presented in Figure 1 and was implemented using the programming language Julia (Bezanson, Jeff, *et al.*, 2017). The MGM of the InraPorc model (van Milgen *et al.*, 2008), with a reparameterized Gompertz model for BW and a gamma function for DFI as a function of BW, was used to connect five latent traits to observed BW and DFI data. The five latent traits (i.e. DFI50, DFI100, Age115, Shape, and BW65, as defined in Figure 1, were chosen based on biological relevance, and they were modeled as a linear combination of an intercept (μ), contemporary group effects (CG), and additive SNP (α) and residual effects (e). Observed traits of BW and DFI were

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_307, © H. Yu *et al.* 2022

then modeled as a function of the latent variables through the MGM. While latent traits were modeled as additive effects without G×E, the MGM allows for certain non-additive genetic effects and G×E for BW and DFI by internally creating non-linearity and interactions among genetic and environmental effects. We implemented MCMC to sample the unknown parameters of the MGM using a multi-trait Bayesian regression model. Specifically, the μ, GC and α were sampled conditional on the latent traits using Gibbs sampling, while the five latent traits were jointly sampled using the Metropolis-Hastings algorithm, given the observed BW and DFI data. Variance components were obtained by Gibbs sampling.

Application. The model was applied to daily BW and DFI data from ~83 to ~186 days of age on 3,934 purebred boars in 97 contemporary groups, that were genotyped for 24K SNPs. Phenotypes of the 2,000 earlier born pigs were used as training and the remaining pigs as validation. Prediction bias and accuracy were estimated by forward cross-validation (CV) based on regression and correlation (divided by the square root of heritability) of observed BW and DFI adjusted for CG on predictions for the validation data. Because such CV does not allow evaluation of predictions for latent variables and for BW and DFI outside the observed age range, predictions were also evaluated using the linear regression (LR) method of Legarra and Reverter (2018), using predictions based on partial and whole data, which we applied to the non-linear models.

Results & discussion

Figure 2 shows GP for BW and DFI from 0 to 500 days for the validation data. Note that predictions extend outside the age range with phenotypes, which is facilitated by the MGM. The GP for BW and DFI plateaued at ~400 and ~300 days, respectively. Previous studies used a 2-step method to incorporate growth models into genetic evaluation (Kachman *et al.*, 1998; Vautier *et al.*, 2013), with latent variables estimated on an individual basis in a first step, using only that individual's data, followed by genetic analysis of the estimated latent variables as phenotypes. Our model integrates these two steps and leverages relationships among individuals to estimate the latent traits for all individuals, regardless of the amount of data available for each.

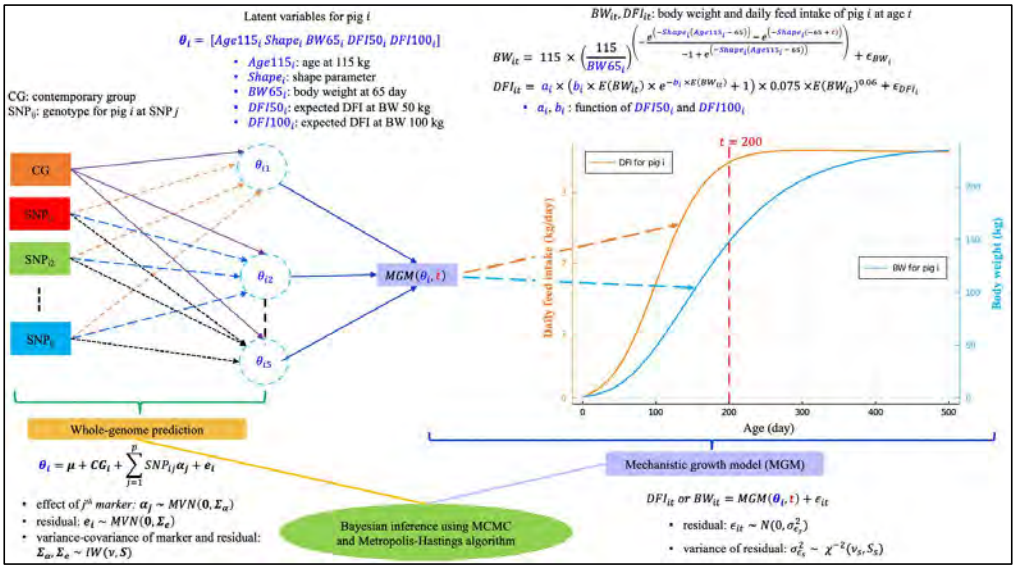

Figure 1. Structure of the Bayesian hierarchical model to integrate a mechanistic growth model (MGM) with five latent variables (blue font) for BW and DFI into genomic prediction.

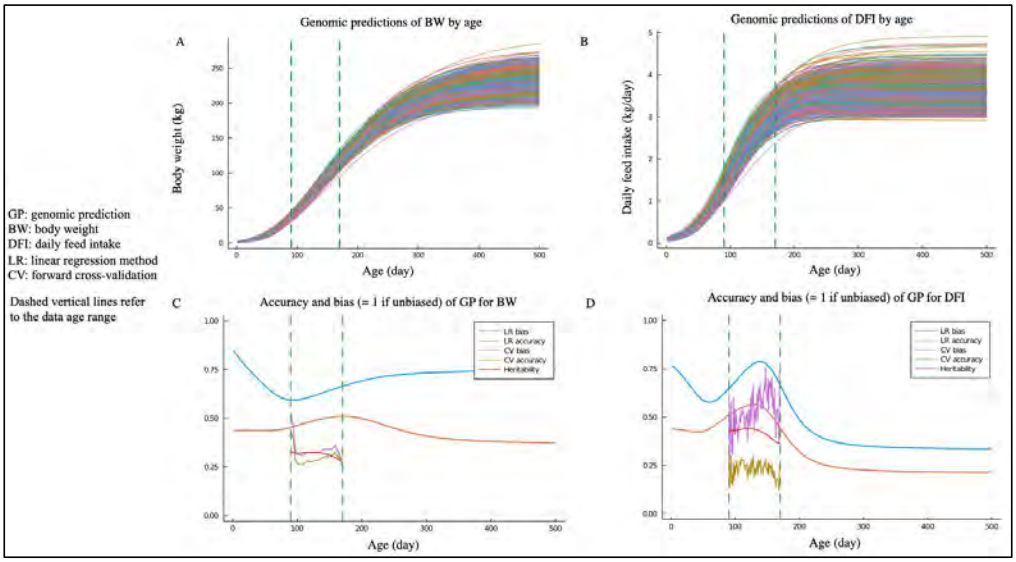

Figure 2. GP for BW (A) and DFI (B) for the validation data and estimates of bias and accuracy of GP of BW (C) and DFI (D) using the LR and CV methods.

Estimates of accuracy and bias for BW and DFI based on the LR and CV methods are also in Figure 2. Leveraging the LR method, we computed the accuracy and bias of GP of the latent traits (Table 1) and for BW and DFI outside the observed data (Figure 2). The LR method uses the relationship between predictions based on partial and whole data and can, therefore, estimate accuracy and bias of predictions of traits that do not have corresponding observed phenotypes (Legarra and Reverter, 2018). The latent traits have specific biological meaning related to growth processes based on the MGM of van Milgen *et al.* (2008). The GP for latent trait DFI100 had the highest accuracy (0.51), while the GP for Shape had the lowest accuracy (0.43). As Shape is related to the inflection point and mature weight, its low accuracy is likely because the BW and DFI data are from a very linear part of the growth curve. Prediction bias was found for all latent traits, ranging from 0.61 to 0.91, compared to the expectation of 1 for unbiased predictions.

Compared to the CV method, which only allows evaluation of predictions within the age range with phenotypes, the LR method resulted in much higher estimates of accuracy and lower estimates of bias (i.e. closer to 1) of predictions for BW and DFI for that age rage, although the trends with age were similar (Figure 2). Macedo *et al.* (2020) pointed out that the LR method can result in false estimates of bias when a seriously flawed model is fitted but that estimates of accuracy are robust. However, in a separate simulation study, we found that estimates of both bias and accuracy from the LR method can be biased when using a flawed model, in contrast to the CV method.

Table 1. Bias and accuracy of genomic predictions of latent traits based on the LR method.

	Age115	Shape	BW65	DFI50	DFI100
Bias (unbiased if = 1)	0.66	0.73	0.61	0.83	0.91
Accuracy	0.51	0.43	0.45	0.51	0.55

In conclusion, the proposed Bayesian hierarchical model allows GP for biologically relevant latent traits based on a MGM and can, thereby, accommodate certain non-additive genetic effects and G×E and allow prediction of traits outside the age range with data. Selection on GP for latent traits is expected to lead to greater rates of genetic improvement and the ability to better deal with G×E, if the latent traits are less affected by non-additive genetic effects and G×E. Whether they are, however, requires further investigation and potentially reparameterization of the latent variables. However, caution must be exercised when using the LR method to evaluate predictions as it may provide biased estimates of accuracy and bias when the model used is not valid for the data at hand.

308. Mega-scale mixed models for genome-wide prediction with thousands of high-throughput phenotyping traits

J. Qu[1], D.E. Runcie[2*] and H. Cheng[1*]

[1]*Department of Animal Science, University of California, Davis, One Shield Avenue, Davis, CA 95616, USA;* [2]*Department of Plant Sciences, University of California, Davis, One Shield Avenue, Davis, CA 95616, USA;* *deruncie@ucdavis.edu; qtlcheng@ucdavis.edu*

Abstract

Large-scale phenotypic data is widely available today due to advances in high-throughput phenotyping platforms. Genetic analyses of high-dimensional, highly correlated traits using conventional multivariate linear mixed models presents analytical and computational challenges. Here, we use a Bayesian sparse factor model to adapt multivariate linear mixed models to the application of genome-wide prediction with thousands of traits. We have implemented both kernel-based models (e.g. genomic best linear unbiased prediction (GBLUP)) and marker effects models (e.g. BayesC) in the Bayesian sparse factor model statistical framework. Our mega-scale mixed models show significant improvement for genetic value prediction in real data by leveraging information from thousands of traits jointly, particularly when using mixture priors on marker effects.

Introduction

With the recent advances in high-throughput phenotyping technologies, including multi-omics methodologies that are used for generating molecular phenotypes, statistical models that enable the joint analysis of large numbers of highly correlated traits are needed to enable efficient genomic selection. However, genomic analyses of high-dimensional, highly correlated trait data presents computational challenges. In the past several decades, multivariate linear mixed model (MvLMM) have been widely used for genetic analyses of two or more correlated traits (Henderson *et al.*, 1976). Since the number of covariance parameters in MvLMMs increases quadratically with the number of traits, and most algorithms used to fit MvLMMs require repeated inversions of the genetic and residual covariance matrices, MvLMMs can be susceptible to over-fitting and have a computational burden that grows cubically to quintically as the number of traits increases. To alleviate much of this computational burden, we re-parameterize MvLMMs as Bayesian sparse factor models to address these statistical and computational challenges.

We have implemented both kernel-based models (e.g. GBLUP) and marker effects models (e.g. BayesC) in Bayesian sparse factor models to accommodate genome-enabled analysis with thousands of traits. Based on the assumption that the covariances among large sets of traits can be explained by a small set of latent factors (e.g. through gene regulatory networks), MegaLMM (Runcie *et al.*, 2013, Runcie *et al.*, 2021) was developed to incorporate genomic data through one (or more) genomic relationship matrices (e.g. MegaGBLUP). These kernel-based models impose specific assumptions about the distribution and effect sizes of the underlying causal genetic variants, and does not allow direct inference on the effects of the causal loci. On the other hand, marker effects models such as the Bayesian Alphabet methods (Cheng *et al.*, 2015; Habier *et al.*, 2011; Meuwissen *et al.*, 2001) encode a wide range of different and more flexible prior distributions on the effect sizes of causal genomic variants and allow for inference of the causal variants themselves. In this paper, marker effects models are incorporated into the Bayesian sparse factor model framework (hereinafter referred to as MegaBayesianAlphabet) to analyze thousands of traits for genome-wide prediction and genome-wide association. We focus on the mixture prior in BayesC due to its incorporation of biologically meaningful assumptions. Extensions of MegaBayesianAlphabet using other mixture priors on marker effects should be straightforward. The objectives of this paper are to show the

significant improvement in genomic prediction by leveraging information from thousands of traits and mixture priors on marker effects in MegaBayesianAlphabet.

Materials & methods

MvLMMs are extended as Bayesian sparse factor models by introducing K independent (unobserved) latent factors to account for the covariances among t observed traits ($t >> K$).

Model description and prior specification in MegaBayesianAlphabet. Variation among t observed traits is decomposed into two parts: the variation caused by dependencies on K independent latent factors, which induces correlations among the t observed traits, and the variation that is idiosyncratic to each trait. In MegaBayesianAlphabet, genetic values of latent factors are defined as a linear combination of all marker effects, and priors from the Bayesian Alphabet methods are assigned to the marker effects. The model specification of MegaBayesianAlphabet is described below.

$$Y = F\Lambda + X_1B_1 + X_{2R}B_{2R} + E_R \quad (1)$$

With

$$F = X_{2F}B_{2F} + E_F \quad (2)$$

where Y is a matrix of observations for n individuals on t traits, F is a matrix of latent factors for the n individuals across K latent factors, and Λ is a factor loading matrix whose elements describe the corresponding factor-trait relationships. The K latent factors in F are further decomposed into genetic effects and residual effects as shown in Equation 2. X_1 is an incidence matrix allocating the observations to fixed effects in B_1. Residuals conditional on latent factors are similarly decomposed into trait-specific genetic effects (i.e. $X_{2R}B_{2R}$) and trait-specific residual effects (i.e. E_R). The model structure of MegaLMM (e.g. MegaGBLUP) is similar to MegaBayesianAlphabet, except that the genetic effects in MegaGBLUP are expressed as a single random effect based on a genomic relationship matrix. If all sources of correlation among observed traits are explained by the latent factors, residuals conditional on these factors become uncorrelated. With the independence between latent factors, samples at each iteration of MCMC chains can be obtained simultaneously in parallel, which leads to significant decline in the computational cost of model fitting.

In this paper, the BayesC prior is used for the marker effects and we term this specific version of MegaBayesAlphabet: MegaBayesC. In MegaBayesC, the prior distribution of the marker effect at locus i for the k^{th} latent factor is shown as follows.

$$\mathbf{b}_{2F_{k(i)}} = \begin{cases} N\left(0, \sigma^2_{B2F_k}\right) & \text{probability}(1 - \pi_{F_k}) \\ 0 & \text{probability } (\pi_{F_k}) \end{cases} \quad (3)$$

where $0, \sigma^2_{B2F_k}$ is the variance of marker effects corresponding to factor k. Note that if marker inclusion probabilities for all factors were set to 1.0, the model is equivalent to RR-BLUP, and we term this specific version of MegaBayesianAlphabet: MegaRRBLUP. A BayesC mixture prior is also used for the elements of the factor loading matrix (Λ). To improve the identifiability of the model, we introduce an additional parameter (τ_k) to the included-variable variance that is stochastically increasing across factors. For the factor loading that describes the relationship between factor k and trait j, its prior distribution is shown as follows.

$$\mathbf{\Lambda}_{k,j} = \begin{cases} N\left(0, \tau_k^{-1}\sigma^2_{R_j}\right) & \text{probability}(1 - \pi_{\Lambda_k}) \\ 0 & \text{probability } (\pi_{\Lambda_k}) \end{cases} \quad (4)$$

Through this prior specification, an appropriate level of truncation on the rows of Λ is able to ensure that the contribution from additional factors beyond the truncation point is negligible (Bhattacharya *et al.*, 2011).

Data and analysis. Best linear unbiased estimators (BLUEs) of grain yield and reflectances from 62 wavelength bands collected with an aerial hyperspectral camera at each of 10 time-points during the growing season for 1,033 bread wheat lines were downloaded from CIMMYT Research Data (Krause *et al.*, 2019). In our analysis, the 620 hyperspectral BLUEs measured at 10 time points were used as secondary traits to improve the prediction of the genetic value of grain yield, which is served as a focal trait in our prediction scenario. Four different models were used to predict the grain yield: traditional single-trait GBLUP, MegaGBLUP, MegaRRBLUP, and MegaBayesC. In MegaRRBLUP and MegaBayesC, the probability of an element from Λ being zero was considered as known and set to be 0.9 to introduce sparsity and to shorten the time required for its convergence, while the probability of a marker having a null effect on a latent factor was considered as unknown and was estimated. Trait-specific genetic effects are not considered in these analyses. Cross-validation was used to evaluate the predictive performance of different models by masking the grain yield of half of the population during model fitting and comparing the masked values to model predictions. 20 replicates were done with different masked lines.

Results & discussion

Here, we tested if MegaBayesianAlphabet models could match or exceed the performance of MegaLMM in trait-assisted genomic prediction using data from a breeding trial of bread wheat. As a baseline, we performed conventional univariate GBLUP-based genomic value prediction as well. As shown in Figure 1, univariate GBLUP achieved a prediction accuracy of 0.43 in this dataset. MegaGBLUP was fitted in MegaLMM (Runcie *et al.*, 2021) using a single random effect to account for the genetic values among observed traits based on a genomic relationship matrix. The achieved prediction accuracy of MegaGBLUP was 0.69. MegaRRBLUP was fitted in MegaBayesianAlphabet and achieved a prediction accuracy of 0.68. No significant difference was observed between MegaGBLUP and MegaRRBLUP, which is expected due

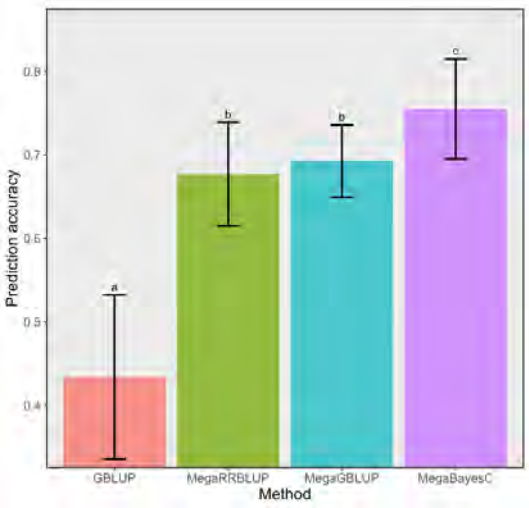

Figure 1. Genomic value prediction performance of four models for wheat yield. Bars show the mean prediction accuracy (± standard error) for each model, and letters show the statistical significance of mean difference between methods based on a paired t-test.

to the equivalence between RR-BLUP and GBLUP in terms of prediction of genetic values as reported in single-trait analysis (Meuwissen *et al.*, 2001; Habier *et al.*, 2007). MegaBayesC, instead of fitting all markers in the model as in MegaRRBLUP, used a mixture prior for the marker effects and achieved a significantly higher prediction accuracy than the other three methods, with an average accuracy of 0.75. These results show that the use of biologically meaningful prior on marker effects can further improve the genomic selection in breeding programs when large amounts of traits were used to assist the prediction of focal trait.

In MegaBayesianAlphabet, due to the independence among latent factors, and the independence among traits conditional on factors, marker effects can be efficiently sampled from a set of univariate BayesC models in parallel across traits and factors at each iteration of MCMC. The Gibbs sampling method used for estimating marker effects, however, can still be time-consuming for large amounts of SNP. To overcome the intractability problem faced by genome-enabled analysis incorporating both large-scale phenotypic data and genomic data, further investigation such as a pre-selection process to narrow down the number of SNPs is needed.

309. Nordic Holstein single-step test day model using metafounders and blending of foreign information

M. Koivula[1*], I. Strandén[1], G.P. Aamand[2] and E.A. Mäntysaari[1]

[1]Natural Resources Institute Finland (Luke), 31600 Jokioinen, Finland; [2]NAV Nordic Cattle Genetic Evaluation, 8200 Aarhus N, Denmark; minna.koivula@luke.fi

Abstract

The aim of the study was to compare the metafounders approach (MF) to conventional genetic unknown parent groups (UPG) and to estimate the effect of blending the external information. All results were compared also to results from the official EBV model (AM). The results showed that both the traditional UPG and the MF approach can be implemented in ssGTBLUP together with the blending of foreign information. However, the MF approach was slightly more effective in reducing bias in young bulls.

Introduction

The use of sires from international populations is common in dairy cattle breeding. The exchange of sire genotypes allows national breeding programs to properly integrate multi-trait cross-country assessments (MACE; Schaeffer, 1994) by Interbull (Uppsala, Sweden) into domestic evaluations. The integration of bull information by blending MACE yield indices into the Nordic test-day (TD) model was introduced by Pitkänen *et al.* (2020).

In single-step models, an unsolved model problem is how to build genomic (G) and pedigree (A_{22}) relationship matrices which meet the theoretical assumptions of the same scale and equal base populations. For example, base population allele frequencies (AF) can be used (VanRaden, 2008), and elements of G can be scaled and centered to have on average the same diagonal and off-diagonal elements as in A_{22} (Christensen, 2012). The metafounder (MF) approach proposed by Legarra *et al.* (2015) attempts to make the A and A_{22} matrices compatible with the G matrix. In the MF approach, allele frequencies (AF) equal to 0.5 for all markers are assumed in the G matrix (Garcia-Baccino *et al.* 2017) and the A matrix has MF or pseudo-individuals with self-relationships. The MF are like unknown parent groups (UPG) but allow a related base population with nonzero inbreeding coefficients (e.g. Legarra *et al.* 2015; Garcia-Baccino *et al.* 2017). The relationships within and between the MF are modelled by a Γ matrix, which thereafter is used in forming the pedigree-based relationship matrix (A_Γ).

The objectives of this study were to compare the performance of the MF approach to the corresponding model with UPG and to address the effect of integration of external information into Nordic Holstein test day (TD) model evaluations. The MF was applied, and MACE information was included in the single-step (model called GT_B_MF), and in the animal model (AM_B_MF). To compare method differences, we run separately also ssGTBLUP with MACE information and the QP transformation where UPGs were included with the QP transformation (GT_B), and ssGTBLUP without MACE information using either the QP transformation (GT) or the metafounders (GT_MF). All the results were compared also to results from the official EBV model (AM).

Materials & methods

The official Nordic HOL milk production evaluation data obtained from the Nordic Cattle Genetic Evaluation (NAV) were used in all analyses of this study. The official evaluation includes TD records from milk, fat and protein production from the first three lactations as multiple traits. The TD data included 8.5 million cows with a total of 173.7 million records and 10.9 million animals in the pedigree. There were

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_309, © M. Koivula *et al.* 2022

274,145 genotyped animals. After the same edits used in current NAV HOL genomic evaluations, 46,342 SNP markers on the 29 bovine autosomes were available for further analysis.

Models. The Nordic multiple traits reduced rank random regression TD model with heterogeneous variance (HV) correction (Lidauer *et al.*, 2015) was used. The model specifies 27 traits: 3 countries (DFS: Denmark, Finland and Sweden), 3 yield traits, 3 lactations. Each animal receives 15 solutions for the random regression effects. With the data used, the mixed model equations (MME) had 155.8 million animal equations and a total of 444.2 million equations. For the validation of bull (G)EBVs, the last four years of observations were removed from the full data.

All models were solved with MiX99 software (Strandén and Lidauer, 1999). The single-step model used ssGTBLUP with efficient computations (Mäntysaari *et al.*, 2017). In all single-step models, the genomic relationship matrix was based on VanRaden method 1 with a 30% residual polygenic proportion, AF of 0.5 for all the markers, and in UPG models diagonals in G were scaled by trace(A_{22})/trace(G).

Four single-step models were tested: GT, GT_B, GT_MF and GT_B_MF. In the GT and GT_B models, 176 genetic groups were included using QP transformation (detailed description in Koivula *et al.*, 2021). The GT_MF and GT_B_MF models used the MF approach. The MF approach needs a covariance matrix, denoted Γ, for the metafounders. The 176 UPGs were used as metafounders. The UPGs were based on 4 breed groups (HOL, RDC, JER, other) and 5 country of origin groups within Holstein (HOLdnk, HOLswe, HOLfin, HOLother, HOLred). Within each of these 9 sources, UPG were further grouped by birth year decade and by selection path when appropriate. For the Γ matrix of the 9 base metafounders, we defined a covariance function (CF) model (Kirkpatrick *et al.*, 1994) described in Kudinov *et al.* (2021). After solving the Γ matrix for the 176 MF, we computed the Γ matrix compliant inbreeding coefficients needed for the inverses A_Γ and A_{22}^Γ in the MME.

Foreign information was included in the GT_B and GT_B_MF models. The external information from MACE was included as described by Pitkänen *et al.* (2020). A bull was considered to have additional information in MACE when its reliability for milk, protein and fat indices in MACE were at least 0.01 units higher compared to the Nordic evaluation reliability. The integration process had three steps: (1) effective record contributions (ERC) in MACE and in the national evaluations were calculated for the selected bulls; (2) yield indices and ERC were used to calculate multi-trait deregressed proofs (DRPs) separately using the Nordic and the MACE data. Finally, (3) based on the two DRPs and the two ERCs, pseudo-observations were calculated for the selected 31,779 bulls and were included in the TD data. In addition, the official animal model (AM) and animal model AM_B_MF using blending with MF were performed.

Results & discussion

Table 1 illustrates the linear regression validation results (LR, Legarra and Reverter, 2018) from the different models for 524 DFS Holstein validation bulls. The level differences in the (G)EBV predictions were corrected by standardizing the mean of cows born 2007 to be the same in all models. The b_0 column has the mean difference (kg) between the full and reduced run (G)EBVs. This illustrates the realized bias between the full and reduced evaluation. The results indicate that the use of the MF approach led to a somewhat lower bias and higher coefficient of correlation (R^2) in the single-step evaluations. The regression coefficient (b_1) was on average 2% units higher for the MF models than for the QP models suggesting somewhat less overdispersion of GEBVs. These results support the earlier findings that the MF approach may improve the single-step evaluations. The inclusion of external information also improved the evaluations and together with the MF approach gave the best validation results. The blending of foreign information had, in general, a positive effect on the R^2 values but, on the other hand, does not improve the bias problem.

Table 1. Bull LR validation (Bulls=524) results. Regression coefficients (b_1) and coefficient of correlation (R^2) from different models. The b_0= mean(Full_(G)EBV − reduced_(G)EBV). The single-step models: unknown parent groups (UPG) using the QP transformation (GT) or the metafounder (MF) approach (GT_MF), UPG using the QP transformation and the blending of foreign information (GT_B), and the MF approach with the blending of foreign information (GT_B_MF). The animal models: the official model (AM), and the MF approach with the blending of foreign information (AM_B_MF).

	Model	b_0	b_1	R^2
Milk	AM	-101.7	0.84	0.32
	AM_B_MF	-109.86	0.89	0.35
	GT	-319.84	0.87	0.67
	GT_MF	-272.31	0.89	0.68
	GT_B	-306.32	0.86	0.69
	GT_B_MF	-267.07	0.88	0.71
Protein	AM	0.80	0.74	0.24
	AM_B_MF	-0.31	0.83	0.28
	GT	-11.10	0.81	0.63
	GT_MF	-9.71	0.83	0.64
	GT_B	-11.04	0.79	0.64
	GT_B_MF	-9.73	0.82	0.67
Fat	AM	-2.18	0.73	0.23
	AM_B_MF	-2.55	0.80	0.26
	GT	-16.16	0.82	0.64
	GT_MF	-14.67	0.85	0.65
	GT_B	-14.76	0.81	0.66
	GT_B_MF	-13.38	0.84	0.68

The genetic trend of protein for the genotyped Nordic Holstein bulls is presented in Figure 1. The figure shows that with the full data the genetic trends were similar with different single-step models, and the correlations between GEBVs varied from 0.985 to 1.00. The differences between the models can be observed in the reduced data runs. The most obvious difference is seen between the models using the QP transformation and the MF approach. The MF approach model does not increase the genetic trend of young bulls as much as the QP model. Also, the blending of foreign information increases the genetic trend of young bulls, but the increase is not as high when the MF approach is used. The animal model EBVs showed a much lower genetic trend compared to the single-step models, but with the MF approach and the inclusion of MACE information, the b_1 and R^2 also improved in the animal model.

Conclusions

It seems that both the traditional genetic groups and the MF approach can be implemented in ssGTBLUP together with the blending of foreign information. However, it seems that the MF approach can be slightly more efficient in reducing bias in young bulls.

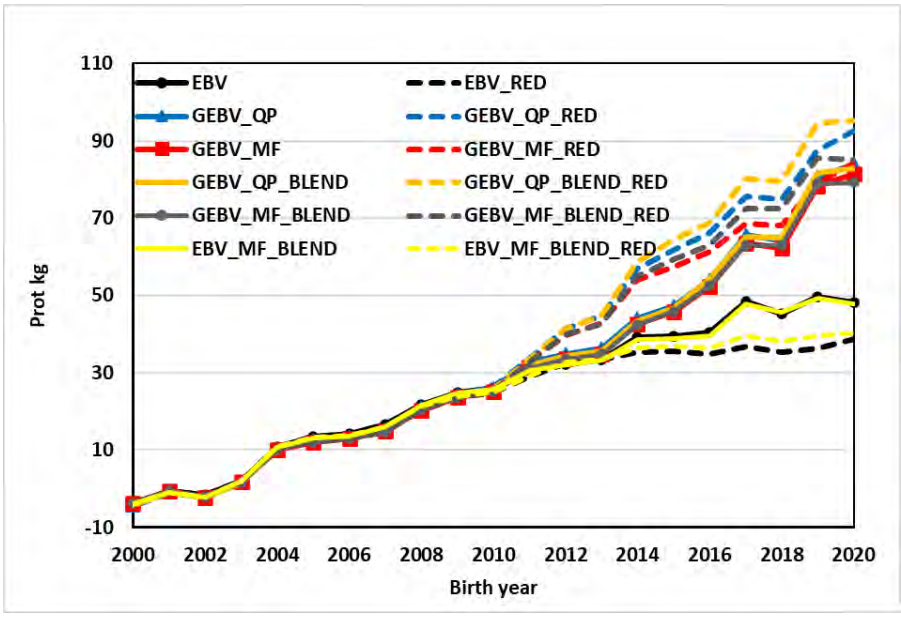

Figure 1. Genetic trends by birth year for protein from different models. The single-step models: unknown parent groups (UPG) using the QP transformation (GT) or the metafounder (MF) approach (GT_MF), UPG using the QP transformation and the blending of foreign information (GT_B) and the MF approach with the blending of foreign information (GT_B_MF). The animal models: the official model (AM), and the MF approach with the blending of foreign information (AM_B_MF). The *RED indicates the reduced data run.

310. Effects of missing or wrong pedigree records on Single-Step predictions

E.C.G. Pimentel*, C. Edel, R. Emmerling and K.-U. Götz

Abstract

The Single-Step model combines information from pedigree, genotypes and phenotypes at the same time. Inconsistencies between genotypes and pedigree records lead to bias in predictions. This problem has been addressed so far at the level of overall statistics, such as reliabilities, regression coefficients and genetic trends. The purpose of this study was to investigate the effects of pedigree errors at the level of individual predictions. We used a small example pedigree to show how predictions become biased when a pedigree record is wrong or missing. We further used real data to illustrate the common case of wrong or missing maternal grandsire when the dam is not genotyped. When the pedigree record was wrong, estimated breeding values were not much affected but estimated mendelian sampling terms were biased upwards. When it was missing, both estimates were notably biased upwards. Further studies are needed to investigate the cumulative effects of this bias.

Introduction

Genetic evaluations with the Single-Step model combine simultaneously all information from pedigree, genotypes and phenotypes (Legarra *et al.*, 2009; Christensen and Lund, 2010). One issue of major importance in a Single-Step model is the compatibility between the pedigree and the genotypic information, which makes pedigree correctness as crucial as ever before.

Wrong pedigree records are a common problem in livestock populations. Visscher *et al.* (2002) reported pedigree error rates in dairy herds ranging from 5 to 15%. The availability of large-scale genotypic information created the opportunity to correct or fill in wrong or missing pedigree records. Therefore, problems at the level of parent-offspring relationships can be often avoided through checks for genotype conflicts and parent search. So the rate of missing or wrong sires of genotyped individuals should be very low when most or even all potential sires are genotyped, which is often a realistic scenario. In such situations, problems will most commonly occur in the case of missing maternal grandsires (MGS) if the dam is not genotyped, where attempts to discover the MGS often end up with multiple putative MGS.

Misztal *et al.* (2017) suggested the use of scaling factors to set different weights on the genomic and the numerator relationship matrix. According to Tsuruta *et al.* (2019) this could account indirectly for missing pedigree information. However, such scaling parameters operate in a very unspecific way. Tsuruta *et al.* (2019) investigated the effects of missing pedigrees on predictions from the Single-Step model in terms of overall bias and genetic trends. The objective of this study is to investigate and illustrate the effects of missing or wrong pedigree information on Single-Step predictions at the individual animal level.

Materials & methods

Example pedigree. The pedigree depicted in Table 1 was used to construct the covariance matrix H assumed in a Single-Step model:

$$\mathbf{H} = \begin{matrix} \mathbf{A_{11} - A_{12}A_{22}^{-1}A_{21} + A_{12}A_{22}^{-1}GA_{22}^{-1}A_{21}} & \mathbf{A_{12}A_{22}^{-1}G} \\ \mathbf{GA_{22}^{-1}A_{21}} & \mathbf{G} \end{matrix}$$

DOI: 10.3920/978-90-8686-940-4_310, © E.C.G. Pimentel *et al.* 2022

Where A is the numerator relationship matrix, G the genomic relationship matrix and subscripts 1 and 2 stand for non-genotyped and genotyped animals, respectively. For the sake of clarity matrix G was set equal to A_{22}. Matrix H was subsequently decomposed in H=TDT'. Breeding values of all animals can be expressed as the product of T by the vector containing breeding values of base animals and mendelian sampling terms of animals with known parents (Kennedy *et al.*, 1988). Matrices H and T were computed for two genotyping scenarios and three scenarios with respect to the MGS of animal 10 when setting up A:

- using the correct pedigree (Table 1), in which animal 3 is the sire of dam 9;
- assigning a wrong sire (animal 2) to dam 9;
- assigning a missing sire to dam 9.

Matrix G was the same in all cases, i.e. equal to A_{22} with the correct pedigree. This way, G always contains the true relationship information, eventually not available in the pedigree.

Real data. Data from the December 2021 run of the German-Austrian routine Single-Step evaluation for conformation traits in Fleckvieh were used. Total number of animals in the pedigree was 4,734,659, from which 1,824,625 had an observation for udder score, for example. Missing pedigree records were assigned to unknown parent groups (UPG), defined according to origin, sex and birth year. Modifications in H to account for UPG are described in Macedo *et al.* (2020). The number of genotyped animals was 401,802. Matrix G^{-1} was set up using the algorithm for proven and young (APY) with 32,866 animals in the core set. Mixed model equations were solved using the software package MiX99 Release XI/2019 version 19.1129 (MiX99 Development Team, 2019). Estimated breeding values (EBV), parent averages (EPA) and mendelian sampling terms (EMS) from the routine run were used as reference and are hereafter referred to as the results obtained with the original pedigree. Ten genotyped animals that had a non-genotyped dam and a genotyped MGS were chosen, such that their genomic relationship coefficient to their MGS were at least 0.24. The MGS of five of them were replaced by UPGs and the other five by some non-genotyped bull born on close to the same year as the original MGS. Analyses were performed again, and results will be referred to as the ones with the modified pedigree. All EBVs were scaled to have a mean of 100 and a standard deviation of 12.

Results

Example pedigree. The row of matrix T corresponding to animal 10 is shown in Table 2 for all simulated scenarios using the example pedigree of Table 1. When the correct pedigree is used to set up A, the 10th row of T contains 0.50 for each parent and 0.25 for each grandparent of animal 10. In the scenario I, an

Table 1. Example pedigree with two genotyping scenarios I and II.

Animal	Sire	Dam	Is genotyped (I)	Is genotyped (II)
1	0	0	Yes	Yes
2	0	0	No	No
3	0	0	Yes	Yes
4	0	0	No	No
5	0	0	No	No
6	0	0	No	No
7	1	4	Yes	Yes
8	2	5	No	Yes
9	3	6	No	No
10	7	9	Yes	Yes

Table 2. Coefficients of the matrix T corresponding to animal 10 for different scenarios.

	Animal									
	1	2	3	4	5	6	7	8	9	10
Scenario I:										
Right MGS	0.25	0.00	0.25	0.25	0.00	0.25	0.50	0.00	0.50	1.00
Wrong MGS	0.25	0.25	0.23	0.25	0.00	0.23	0.50	0.00	0.47	1.00
Missing MGS	0.25	0.00	0.25	0.25	0.00	0.23	0.50	0.00	0.47	1.00
Scenario II:										
Right MGS	0.25	0.00	0.25	0.25	0.00	0.25	0.50	0.00	0.50	1.00
Wrong MGS	0.25	0.20	0.24	0.25	-0.06	0.24	0.50	-0.10	0.48	1.00
Missing MGS	0.25	0.00	0.25	0.25	0.00	0.23	0.50	0.00	0.47	1.00

additional coefficient of 0.25 to animal 2 appears when it is wrongly assigned as the MGS of 10, whilst the coefficient to the true MGS is still 0.23 due to the information available in G. This means that there could be almost a full contribution from the right MGS plus a full contribution from the false MGS to the breeding value of animal 10. Final effective contributions will of course depend on the structure of phenotypes and the availability of mendelian sampling information.

When the MGS is set to missing the coefficient to the true MGS (animal 3) is still 0.25, again because this information is available in G. In scenario II animal 8 is also genotyped. The coefficient to the wrongly assigned MGS drops to 0.20 and the coefficients to animal 8 and its dam are no longer 0. This means that the extent to which the information from the wrong MGS to the breeding value of 10 can be transmitted depends on which other animals in the pedigree are genotyped, i.e. on how much and which information is available in G.

Real data. Results from the tests with real data are presented in Table 3. In the cases where the MGS was assigned to a wrong bull, EBVs from the runs with the original and the modified pedigree did not differ much.

Table 3. Estimated breeding value (EBV), parent average (EPA) and mendelian sampling term (EMS) from the real data with the original and the modified pedigree.

Type of modification	Original pedigree			Modified pedigree		
	EBV	EPA	EMS	EBV	EPA	EMS
Wrong MGS	117.00	112.28	4.72	117.24	109.67	7.57
Wrong MGS	115.04	114.40	0.64	115.37	111.65	3.72
Wrong MGS	110.47	115.30	-4.83	111.05	111.28	-0.22
Wrong MGS	131.09	119.62	11.47	130.95	115.00	15.95
Wrong MGS	130.06	127.23	2.83	129.65	119.81	9.84
Missing MGS	117.50	115.83	1.67	118.80	108.93	9.87
Missing MGS	113.22	114.16	-0.94	118.43	113.33	5.10
Missing MGS	114.52	114.28	0.24	119.52	111.46	8.06
Missing MGS	132.83	125.82	7.01	135.78	121.56	14.21
Missing MGS	130.81	117.93	12.88	135.73	118.50	17.23

Due to the lower genetic level of the non-genotyped bulls assigned as wrong MGS compared with the original genotyped MGS, EPA were considerably lower with the modified pedigree. This consequently resulted in considerably larger EMS. When the MGS was set to missing, EBVs from the run with the modified pedigree were overestimated by a quarter or even close to half a standard deviation. The EMS was also overestimated, and this time not only due to lower EPA with the modified pedigree, as illustrated in the last row of Table 3.

Discussion

The exercise with the small example showed that the EBV of an animal may receive two contributions from the MGS when the information about it in A and G do not match. In scenario I, the amount contributed by the wrong MGS was 0.25, making it a full additional MGS contribution. Scenario II showed that depending on the structure of the genotyped population the amount contributed by the wrong MGS may decrease. We did the same exercise with other example pedigrees and other genotyping scenarios and observed that the extra contribution from the wrong MGS may become as low as 0.02 (data not shown). This could explain the small differences in EBV observed with the real data for wrong MGS. Nevertheless, differences in EMS were large and may well depict a common phenomenon in practical applications. A wrong MGS record would only remain in pedigree when a conflict test cannot be done, and the genetic level of such ungenotyped bulls should be usually low.

When the true MGS is genotyped but could not be unambiguously identified in a discovery trial, this information is missing in A but is available in G. Therefore, the coefficient to the true MGS in T was still 0.25 in the small example even though it was set to missing. In a model with UPG, final EBVs are the summation of the estimated animal effects and group solutions weighted by corresponding group contributions. If the information from the true MGS is accounted for in G, the extra contribution from an UPG supposed to replace him will cause information from the MGS being transmitted twice, incurring upward bias in the EBV. Results from the real data were in agreement with this expectation. There was not only a biased partition into EPA and EMS, but a notable bias in the EBV themselves.

The observed patterns of overestimation of EMS of animals with wrong or missing MGS could be at least partly an explanation for the inflation in prediction of young animals often reported in the literature (e.g. Tsuruta *et al.*, 2019). Further studies will be conducted to investigate the cumulative effect of the patterns observed here and its potential implications.

311. An alternative method to consider a reference population in Single-Step SNP BLUP model without separating genomic terms

T. Osawa[1*], T. Baba[2], Y. Masuda[3], T. Kawahara[2] and Y. Goto[2]

[1]National Livestock Breeding Center, Nishigo-mura, Fukushima, 961-8511, Japan; [2]Holstein Cattle Association of Japan, Hokkaido Branch, Sapporo, Hokkaido, 001-0015, Japan; [3]Rakuno Gakuen University, Ebetsu, Hokkaido, 069-8501, Japan; t0ohsawa@nlbc.go.jp

Abstract

This study proposed an alternative method to consider a reference population in the mixed model equations (MME) of single-step SNP BLUP (ssSNP-BLUP) model without separating genomic terms to estimate SNP effects. We adopted the preconditioned biconjugate gradient stabilized method to solve MME because this model was a nonsymmetric linear system. Overall conformation score in the first lactation for Japanese Holsteins was used to compare the original and modified ssSNP-BLUP models. Genotyped animals included in the dataset were 37,197 cows, 5,352 sires, 3,973 young bulls and 88,058 heifers. Three reference populations were defined as sires, cows and both. Our method can consider the reference population in the ssSNP-BLUP without separating genomic terms. The contribution of young animals to genomic predictions was small, and predictions varied when only sires or cows were considered in a reference population. On the other hand, considering the reference population may reduce the overestimation of the predictions.

Introduction

Currently, genetic evaluations of dairy cattle in many countries include large-scale SNP marker information, known as genomic evaluation. Most countries have applied a multi-step model for the genomic evaluation of dairy cattle (VanRaden., 2008), which utilizes deregressed estimated breeding values (EBV) obtained via prior conventional genetic evaluation based on pedigree information. The multi-step model is feasible to implement in conventional genetic evaluation systems. A major advantage of the multi-step method is its low computational cost. It uses only selected genotyped animals such as proven sires and cows with their own records as reference population to estimate SNP effects. However, the separate steps of estimating SNP effects and EBV during conventional evaluation cannot fully account for genomic preselection; therefore, genomic EBV (GEBV) can be biased (Patry and Ducrocq, 2011). In contrast to the multi-step model, the single-step genomic BLUP (ssGBLUP) model can evaluate genotyped and non-genotyped animals jointly, thus providing unbiased predictive value (Aguilar *et al.*, 2010). The ssGBLUP integrates the genomic relationship matrix (G) and the pedigree relationship matrix (A) into the hybrid matrix and replaces the pedigree relationship matrix in the mixed model equations (MME) of BLUP. On the other hand, Liu *et al.* (2014, 2016) developed a single-step SNP BLUP (ssSNP-BLUP) model equivalent to ssGBLUP in theory. The model does not require the constructions of G and its inversion and can estimate GEBV and SNP effects simultaneously. Liu *et al.* (2014) proposed a computing strategy by separating genomic terms from the MME of ssSNP-BLUP and solving two separate sets of equations. They also showed how to consider reference animals, as defined in the multi-step model by expanding the equations associated with genomic term. However, since the calculation of the two separated equations is repeated alternately, the program may not be easy to implement for complex models.

The objectives of this study were to propose a method that considers a reference population for ssSNP-BLUP model without separating the genomic terms to estimate SNP effects and compare the predictions using different reference populations.

Materials & methods

Equation for original ssSNP-BLUP model (ssORG) by Liu *et al.* (2014) can be written as follows,

$$\begin{bmatrix} \mathbf{X'R^{-1}X} & \mathbf{X'R^{-1}W_1} & \mathbf{X'R^{-1}W_2} & \mathbf{0} \\ \mathbf{W_1'R^{-1}X} & \mathbf{W_1'R^{-1}W_1} + \sigma_u^{-2}\mathbf{\Sigma^{11}} & \mathbf{W_1'R^{-1}W_2} + \sigma_u^{-2}\mathbf{\Sigma^{12}} & \sigma_u^{-2}\mathbf{\Sigma^{1g}} \\ \mathbf{W_2'R^{-1}X} & \mathbf{W_2'R^{-1}W_1} + \sigma_u^{-2}\mathbf{\Sigma^{21}} & \mathbf{W_2'R^{-1}W_2} + \sigma_u^{-2}\mathbf{\Sigma^{22}} & \sigma_u^{-2}\mathbf{\Sigma^{2g}} \\ \mathbf{0} & \sigma_u^{-2}\mathbf{\Sigma^{g1}} & \sigma_u^{-2}\mathbf{\Sigma^{g2}} & \sigma_u^{-2}\mathbf{\Sigma^{3g}} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{u}}_1 \\ \hat{\mathbf{u}}_2 \\ \hat{\mathbf{g}} \end{bmatrix} = \begin{bmatrix} \mathbf{X'R^{-1}y} \\ \mathbf{W_1'R^{-1}y} \\ \mathbf{W_2'R^{-1}y} \\ \mathbf{0} \end{bmatrix} \quad (1)$$

where y is a vector of observations, $\hat{\mathbf{b}}$ is a vector of fixed effects, subscripts 1, 2 and g refer to groups of non-genotyped, genotyped animals and SNP effects, respectively, $\hat{u}_1$ and $\hat{u}_2$ are vectors of additive genetic effects of the non-genotyped and genotyped animals, respectively, $\hat{\mathbf{g}}$ is a vector of SNP effects, X is a design matrix for fixed effects, W_1 and W_2 are design matrices for additive genetic effects of non-genotyped and genotyped animals, respectively, R is $\sigma_e^2\mathbf{I}$, σ_u^2 and σ_e^2 are an additive genetic and residual variance.

$$\Sigma = \begin{bmatrix} \mathbf{\Sigma^{11}} & \mathbf{\Sigma^{12}} & \mathbf{\Sigma^{1g}} \\ \mathbf{\Sigma^{21}} & \mathbf{\Sigma^{22}} & \mathbf{\Sigma^{2g}} \\ \mathbf{\Sigma^{g1}} & \mathbf{\Sigma^{g2}} & \mathbf{\Sigma^{gg}} \end{bmatrix} = \begin{bmatrix} \mathbf{A^{11}} & \mathbf{A^{12}} & \mathbf{0} \\ \mathbf{A^{21}} & \mathbf{A^{22}} + \left(\frac{1}{k} - 1\right)\mathbf{A_{22}^{-1}} & -\frac{1}{k}\mathbf{A_{22}^{-1}Z} \\ \mathbf{0} & -\frac{1}{k}\mathbf{Z'A_{22}^{-1}} & \frac{m}{1-k}\mathbf{I} + \frac{1}{k}\mathbf{Z'A_{22}^{-1}Z} \end{bmatrix} \quad (2)$$

where A^{ij} are submatrices of the inverse of the pedigree relationship matrix, consisting of non-genotyped (1) and genotyped (2), k is the proportion of the additive genetic variance due to the residual polygenic effects (k was set to 0.1 in this analysis), and m is $2\Sigma p_j\,(1 - p_j)$, with p_j being the observed allele frequency of the j^{th} SNP marker and Z is a design matrix of regression coefficients on genotyped animals at all SNP markers (2-$2p_j$, 1-$2p_j$ or -$2p_j$ for genotype AA, AB, or BB of the j^{th} SNP marker).

Single-Step SNP BLUP model with the reference population. Liu *et al.* (2014) described the genomic term to estimate SNP effects with the reference population as follows.

$$\hat{\mathbf{g}} = \frac{1}{k}\frac{1-k}{m}\mathbf{IZ'FA_{22}^{-1}}\hat{\mathbf{a}}_2 \quad (3)$$

$$\hat{\mathbf{a}}_2 = \hat{\mathbf{u}}_2 - \mathbf{Z}\hat{\mathbf{g}} \quad (4)$$

where F is a filter matrix which is *diag*{1,0,0,1, … 1,1,1,0} to define genotyped animals as reference (=1) or not (=0). Substituting Equation 4 into Equation 3:

$$\hat{\mathbf{g}} = \frac{1}{k}\frac{1-k}{m}\mathbf{IZ'FA_{22}^{-1}}(\hat{\mathbf{u}}_2 - \mathbf{Z}\hat{\mathbf{g}}) \quad (5)$$

Equation 5 can be rearranged as follows:

$$\left[-\frac{1}{k}\mathbf{Z'FA_{22}^{-1}} \quad \frac{m}{1-k}\mathbf{I} + \frac{1}{k}\mathbf{Z'FA_{22}^{-1}Z}\right]\begin{bmatrix}\hat{\mathbf{u}}_2 \\ \hat{\mathbf{g}}\end{bmatrix} = \mathbf{0} \quad (6)$$

Replace $\mathbf{\Sigma^{g2}}$ and $\mathbf{\Sigma^{gg}}$ in Equation 2 by Equation 6 as follows:

$$\mathbf{\Sigma^{g2}} = -\tfrac{1}{k}\mathbf{Z'FA_{22}^{-1}} \text{ and } \mathbf{\Sigma^{gg}} = \tfrac{m}{1-k}\mathbf{I} + \tfrac{1}{k}\mathbf{Z'FA_{22}^{-1}Z} \quad (6)$$

Therefore, the equation of ssSNP-BLUP model with reference population (ssRP) is a nonsymmetric linear system.

Solving algorithm. ssORG is applicable with the preconditioned conjugate gradient method. However, ssRP results in a nonsymmetric linear system, and we adopted the preconditioned biconjugate gradient

stabilized method (Van der Vorst, 1992). The calculation programs introduced an 'iteration on data' algorithm (Strandén and Lidauer., 1999 and Tsuruta *et al.*, 2001) and used 10 OpenMP threads. The preconditioner matrix combined the Jacobi preconditioner and a second-level diagonal preconditioner (Vandenplas *et al.*, 2019). Assuming that Equation 1 is written as Cx = b, the convergence criterion is defined as $\|b - Cx\|^2 / \|b\|^2 < 10^{-14}$, which $\|\cdot\|$ is the 2-norm. In addition, the average of the last 30 iteration rounds must be less than 10^{-14} in the biconjugate gradient stabilized method.

Data. We used overall conformation score in the first lactation for Japanese Holsteins. The additive genetic variance, residual variance and heritability of the trait were 0.685, 1.852 and 0.27, respectively. The dataset comprised 762,650 cows with record and 8,745 sires with daughters; of those, 37,197 cows and 5,352 sires were genotyped. The dataset also included 88,058 genotyped heifers and 3,973 genotyped young bulls. After the quality control, 39,756 SNP markers were considered in this study. We used three reference populations: sires with daughters (ssRP_S), cows with the record (ssRP_C) and ssRP_SC with both of them.

Results

In ssORG, 821 iterations were needed to stratify convergency criteria, and the total computing time was 94 minutes. For ssRP_S, ssRP_C and ssRP_SC, although the number of iterations was less than ssORG (424 to 600), the total times was slightly longer (106 to 140 minutes).

Correlations and regression coefficients. Pearson correlations in the solutions between ssORG and ssRP and regression coefficients of ssORG on ssRP for SNP effects and GEBV for genotyped sires, cows, young bulls and heifers are showed in Table 1. Correlations in ssRP_SC were closed to 1.0, but ssRP_S and ssRP_C were lower than ssRP_SC. Therefore, although the contribution of young animals to the predictions was small, the composition of reference population affected the predicted values. Since the regression coefficients were smaller than 1.0 for almost any combinations, considering reference population may reduce the overestimation of the predictions.

Genetic trends of genotyped animal. Genetic trends of genotyped sires and young bulls for ssORG and ssRP are shown in Figure 1. Similar trends were obtained for both sires and young bulls in ssORG, ssRP_S and ssRP_SC. However, the genetic trends of ssRP_C were flattened in older generations of sires and young bulls, compared to other reference populations.

Table 1. Correlations between ssORG[1] and ssRP[2] and regression coefficients of ssORG on ssRP for SNP effects and GEBV for genotyped sire, cows, young bulls and heifers.

		Correlations			Regression coefficients		
Items	**n**	**ssRP_S**	**ssRP_C**	**ssRP_SC**	**ssRP_S**	**ssRP_C**	**ssRP_SC**
SNP effects	39,756	0.531	0.790	0.967	0.384	0.740	0.950
Sires	5,332	0.979	0.975	0.999	0.979	0.881	1.001
Cows	37,197	0.894	0.962	0.995	0.838	0.931	0.987

[2] Single-step SNP BLUP model with reference populations (S=sires, C=cows and SC=sires and cows).

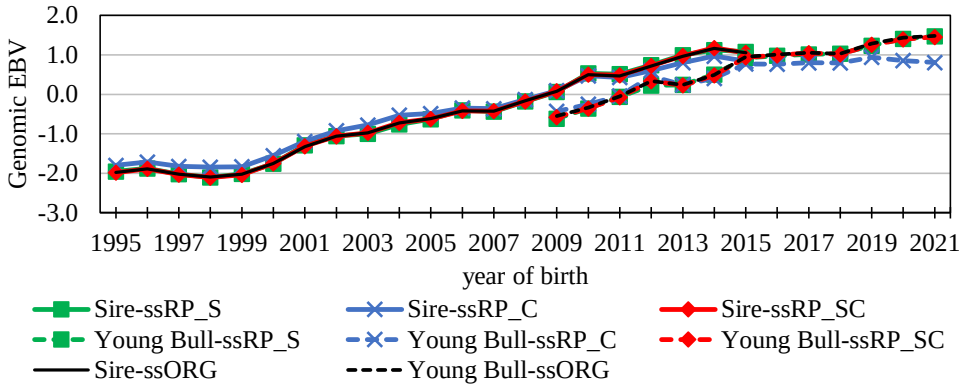

Figure 1. Genetic trends of genotyped sires and young bulls by models. ssORG = Original single-step SNP BLUP model, ssRP = Single-step SNP BLUP model with reference populations (S=sires, C=cows and SC=sires and cows).

Discussion

The proposed method can consider the reference animals without separating the genomic term from the MME in ssSNP-BLUP. This model is easily extensible to complex models e.g. multi-trait and random regression models (results is not shown). In addition, this method can be helpful to understand the influence of the reference population on GEBV and SNP effects in the single-step method. In the results of this analysis, although the contribution of young animals to both GEBV and SNP effects was small, the predictions varied greatly when only sires or cows were considered as reference population. Thus, the composition of the reference population may also need to be carefully considered in the single-step methods. Considering the reference population may reduce the overestimation of the predictions. However, the genetic trends were flattened when only cows were considered in reference population. This may be because the fact that genotyped cows were only relatively new generations. Further studies are needed to investigate the prediction accuracy using the method.

312. Accuracy of pedigree and genomic predictions of meat quality in a multi-breed cattle using single and two step model

S. Naderi[1], R. Evans[1*] and D.P. Berry[2]

[1]The Irish Cattle Breeding Federation, Highfield House, Bandon, Co. Cork, Ireland; [2]Department of Animal Bioscience, Animal and Grassland Research and Innovation Centre, Teagasc, Moorepark, Fermoy, Co. Cork, Ireland; revans@icbf.com

Abstract

The objective of this study was to develop single step genomic breeding values (ssGEBV) for meat tenderness, juiciness and flavour and compare with two-step genomic breeding values as well as non-genomic (i.e. traditional) breeding values (EBV); the comparison also involved testing the impact on the accuracy of the (G)EBVs by altering the number of half sibs in the training population. A residual polygenic single step GBLUP and a two-step genomic approach was applied to 5,262 genotyped and phenotyped animals. Including genomic information improved the prediction accuracy and this accuracy also improved as the number of half sib-progeny in the training population increased. Moreover, applying single step genomic approaches were associated with further improvements in prediction performance across all traits.

Introduction

Meat eating quality (MEQ) impacts repeat purchase of meat by consumers; this is particularly important for beef meat which is often more variable in quality than many other meat types. MEQ is often depicted by meat tenderness, juiciness, and flavour. Whereas heterogeneity is often viewed as an inconvenience, animal breeders require variability to achieve genetic gain. Nonetheless, genetic gain eventually translates into phenotypic changes which is a function of how well estimates of genetic merit translate into expected phenotypic differences but also the acceptance of stakeholders that (products from) individuals divergent in genetic merit will truly be reflective in phenotypic differences. Validation of genetic evaluations is therefore key to stakeholder acceptance. The accuracy of estimates of genetic merit can be improved using widely available genomic information. Integrating phenotypic, pedigree and genomic data to achieve high prediction performance is a modelling challenge. Therefore, the objective of the present study was to evaluate alternative strategies of combining these data to predict genetic merit and, by extension, phenotypic performance.

Materials & methods

Data. Tenderness, juiciness and flavour sensory data were available on 5,912 crossbred cattle consisting of 2,137 steers, 2,093 heifers and 1,682 young bulls. The main breed proportion of the animals was Angus (27%), Belgian Blue (5%), Charolais (12%), Holstein-Friesian (4%), Hereford (14%), Limousin (21%) and Simmental (8%). The phenotyped population was constructed to be as diverse as possible with the aim of a maximum of 20 progeny per sire. The generation of the meat sensory data including the standard operating procedures are described in detail by Judge *et al.* (2021) for a subset of the data set used. Each of the three traits were scored on a 1 to 10 scale: 1 = very tough and 10 = very tender; juiciness: 1 = not juicy and 10 = very juicy; beef flavour: 1 = no beef flavour and 10 = very strong beef flavour. Of the 5,912 animals with meat quality phenotypes, 5,262 were genotyped with the International Dairy and Beef genotyping platform version3 (IDBV3; 50,855 SNPs). The number of animals in the pedigree was 95,674.

Estimation of breeding values. Traditional breeding values (EBVs) as well as genomic breeding values (GEBVs) were estimated for three traits using the following linear mixed model:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_312, © S. Naderi *et al.* 2022

$$y = Xb + Wu + e$$

where y is a vector of one of the sensory phenotypes for all animals in training set, X is the incidence matrix for fixed effects, b is the vector of fixed effects consisting of herd-by-date of slaughter, date-by-location of sensory analysis, gender of the animal, the age in months since slaughter of the meat sample, heterosis proportion class, month of analysis and breed proportion, W is the incidence matrix of random (genomic) effects, u is a vector of EBVs or GEBVs for all individuals, and e is a vector of random residuals. For the traditional genetic evaluation, it was assumed that $u \sim N\ (0,\ \boldsymbol{A}\sigma_u^2)$ where σ_u^2 is the additive genetic variance and A is pedigree relationship matrix. For the estimation of GEBV using the GBLUP model, the A matrix was replaced with a genomic relationship matrix. In the single-step GBLUP model, the A matrix was replaced with a H matrix where H was the combined relationship matrix (Christensen *et al.* 2012). The H matrix is constructed by blending the pedigree relationship matrix with the genomic relationship matrix) considering information from non-genotyped and genotyped animals simultaneously. The inverse of H-matrix was calculated according to Christensen and Lund (2010) and Aguilar *et al.* (2010):

$$\mathbf{H^{-1}} = \mathbf{A^{-1}} + \begin{bmatrix} 0 & 0 \\ 0 & \boldsymbol{G_w^{-1}} - \mathbf{A_{22}^{-1}} \end{bmatrix}$$

where A^{-1} was the inverse of the pedigree-based relationship matrix, $\mathbf{A_{22}^{-1}}$ was the inverse of the sub-matrix of the pedigree-based relationship matrix for genotyped animals and G_w was calculated as follow:

$$G_w = (\alpha \times G + \beta \times A_{22})$$

where G_w was the genomic relationship matrix, $\beta = 1 - \alpha$ where α=0.70. For all the computations, the MiX99 software (MiX99 development team, 2020) was used.

The GEBVs from the two-step genomic evaluation are the result of blending the Direct Genomic Value (DGV) which was calculated by multiplying the SNP effects with the animals' genotypes, traditional Parent Average (PA) and the EBV_{ref} from a traditional evaluation including only relationships among genotyped animals. The method for blending three sources of information (i.e. DGV, PA and EBVref.) to calculate the GEBV are described in detail by VanRaden *et al.* (2009).

Training and testing population design. Three different scenarios were explored on a group of validation animals to assess prediction accuracy. First a group of 49 'well' proven sires with at least 25 progeny was identified. To build a validation set, a random 12 progeny from each of the 49 sires was sampled (i.e. 588 animals) with the remaining progeny of these sires, who did not appear in the validation set, being hereafter referred to as the *remaining set*. In the first scenario (S_I), none of the progeny from the well-proven sires were included in the training population. In the second scenario (S_II), a random seven progeny of each well proven sire from the *remaining set* was added to the training set; in the third scenario (S_III), all the *remaining set* progeny were added to the training set; only the phenotypic records of validation set were masked in this scenario.

Prediction accuracy. The correlation between (G)EBV and the phenotypes (following adjustment for all non-genetic effects) of the validation animals was considered to represent the prediction accuracy at the animal level for all three scenarios. In addition, to assess prediction performance at sire level, the correlation between validation sires' (G)EBVs from S_I in which none of their progeny were in training set with their daughter yield deviation (DYD) was calculated. DYD were calculated based on the average yield deviation from the progeny of each sire including all phenotypic records (full data set).

Results & discussion

Validation results from (single)two-step genomic evaluation as well as traditional EBVs for three scenarios at the animal level are presented in Table 1. Including genomic information and applying a single or two step genomic approach improved the prediction accuracy for all three traits compared with the EBVs from the pedigree-based relationship matrix. For example, the prediction accuracy for flavour increased from 0.09 to 0.17 following the incorporation of genomic information into the model and using two-step approach (i.e. S_III) with a similar pattern detected for the two other traits. Further increases in prediction accuracy were observed by implementing the single step genomic approach compared with the two-step method for all three traits and scenarios. Aguilar *et al.* (2010) demonstrated that ssGBLUP is a quick alternative to estimate GEBV when phenotypes, genotypes and pedigree are jointly available arguing that the automatic and proper definition of weighting factors to blend different sources of information were the main advantage of implementing this approach. In addition, Legarra *et al.* (2014) indicated that the appropriate weight to integrate various source of information avoids double counting of contributions emerging from genetic relationships and phenotypic records.

By increasing number of half sibs in the training population (i.e. S_I to S_III), the accuracy increased for all three prediction approaches (i.e. traditional, (single)two-step GEBV). This improvement could be explained by increasing the genetic relationships between training and validation sets but also an enlargement of the training population size. De Los Campos *et al.* (2013) indicated that the genetic relationships between training and validation set as well as training population size were the most important factors affecting prediction performance for GBLUP.

Validation results at the sire level for the three different prediction approaches for S_I in which none of the identified sires' progeny were included in the training population are shown in Table 2. The results demonstrate that incorporating genomic information and applying the (single)two-step genomic approach improved the prediction accuracy for all three traits. For instance, the prediction accuracy for tenderness increased from 0.17 to 0.38 following the inclusion of genomic information in the model and applying a two-step genomic model.

Using single step genomic approaches generated further improvements in prediction accuracies for all three traits. Across all traits, the slope of DYD on (G)EBV of the validation sires where the expectation of the slope was 0.5, improved with the inclusion of genomic information in the model and improvement further when a single step genomic approach was applied compared to a two-step approach indicating ssGBLUP could reduce potential biases.

Table 1. Correlations between the (genomic) estimated breeding value and adjusted phenotype for the three different scenarios at the animal level from three different approaches.

	EBV			Two-step GEBV			Single step GEBV		
Traits	**S_I[1]**	**S_II[2]**	**S_III[3]**	**S_I**	**S_II**	**S_III**	**S_I**	**S_II**	**S_III**
Tenderness	0.03	0.09	0.13	0.09	0.11	0.15	0.11	0.14	0.17
Flavor	0.09	0.14	0.20	0.17	0.18	0.22	0.21	0.21	0.26
Juiciness	0.008	0.06	0.12	0.08	0.10	0.14	0.09	0.10	0.15

[1] S_I: none of the progeny from the well-proven sires were in the training population.

[2] S_II: a random seven progeny of each well proven sire from the *remaining set* was included in the training set.

[3] S_III: all the *remaining set* progeny were included in the training set.

Table 2. Correlations between the (genomic) estimated breeding value and daughter yield deviations (DYD) and the slope of the DYD on the (G)EBV from three different approaches.

Traits	Statistic	EBV	Two-step GEBV	Single step GEBV
Tenderness	Correlation	0.17	0.38	0.42
	Slope	0.12	0.31	0.39
Flavor	Correlation	0.13	0.36	0.40
	Slope	0.10	0.34	0.36
Juiciness	Correlation	0.16	0.34	0.41
	Slope	0.09	0.27	0.32

313. Single-step genomic prediction in small breeds: Finncattle case

A.A. Kudinov[1*], M. Koivula[1], I. Strandén[1], G.P. Aamand[2] and E.A. Mäntysaari[1]

[1]Natural Resources Institute Finland (Luke), 31600 Jokioinen, Finland; [2]Nordic Cattle Genetic Evaluation (NAV), 8200 Aarhus, Denmark; andrei.kudinov@luke.fi

Abstract

Genomic prediction is of great interest in small breeds. When breed-wise populations cannot exchange data, the establishment of a multi-breed evaluation is a tempting option. Single-step genomic prediction is a useful tool when limited data is available. In the current study, we developed a single-step genomic prediction for the small indigenous Finncattle breed with or without data from national major breed Nordic Red Dairy cattle (RDC). The reliability of genomic prediction was assessed using modified Interbull and Legarra and Reverter validation approaches. Inclusion of the RDC data to Finncattle evaluations helped to improve the quality of prediction in traditional and genomic models. The highest prediction reliability for milk and protein was obtained using the multi-breed single-step model.

Introduction

Genomic prediction has been widely used as a two-step procedure in large dairy cattle populations since 2009. The use of DNA markers allows predicting the breeding value of a candidate animal with high reliability at an early age (VanRaden, 2020). However, in small breeds, the use of the two-step genomic prediction approach might be challenging due to the limited data available. Thus, the single-step method (Christensen and Lund, 2010) would be the best way to perform genomic prediction with a limited number of genotyped animals and phenotypic records (Song *et al.*, 2019). A widely reported procedure to increase the power of genomic prediction is the exchange of genomic, phenotypic, or MACE (Multi-trait Across-Country Evaluations, Interbull, Sweden) information between countries (Kudinov *et al.*, 2021a). Naturally, the exchange can only be done with the common breeds and cannot be used when the breed is unique. In such a situation multi-breed evaluation might be the solution. Usually when multi-breed evaluations are used, the solutions for SNP effects are typically estimated by breed as the two-step procedure. The applicability of the multi-breed single-step genomic prediction model has not been studied extensively.

Finncattle (FIC) is the local Finnish breed. Breeding values for FIC have been evaluated by Nordic Cattle Genetic Evaluation (NAV) in the same evaluation with Nordic Red Dairy Cattle (RDC) and Finnish Holstein (Fin HOL, Kudinov *et al.*, 2021b). Multi-breed data is used because many of the herds raise cows from the three breeds in the same facilities and feeding. The current genomic evaluation for RDC animals uses the two-step approach with pure RDC animals. Because genotyping of FIC breed has started only recently, the development of FIC genomic prediction models has become topical. Assuming the benefits and willingness of Nordic countries to run genomic prediction using a single-step model, the development of a multi-breed single-step model was started.

The focus of the current study was to assess the accuracy of genomic prediction for FIC cows with and without RDC phenotypic and genomic information. We performed validation of the model fit by comparing results from approaches suggested by Legarra and Reverter (2018) and modified Mäntysaari *et al.* (2010).

Materials & methods

Data. Pedigree and phenotypic records were obtained from the August 2020 NAV RDC milk and protein evaluations. Pedigree included 4,741,559 RDC, 1,047,697 Fin HOL, 36,133 FIC, and 101,144 other breed animals. There were 137 unknown parent groups (UPG) formed using breed by country by time classes.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_313, © A.A. Kudinov *et al.* 2022

Phenotypic data was presented by 305-day milk and protein first lactation records from 3,468,530 RDC, 811,363 FIN HOL, and 27,810 FIC cows. Genomic data include genotypes from 187 FIC and 35,729 RDC bulls, and 756 FIC and 133,107 RDC cows. Raw genotypes were imputed and edited by NAV and included 46,914 SNP markers that are used in the current national multi-step genomic evaluations.

Statistical models. Single-step GBLUP and pedigree-based BLUP (PBLUP) were used to estimate breeding values. All models used the same pedigree and UPG, but the phenotypic and genomic data differed. Genomic prediction was performed using a single-step GTBLUP (Mäntysaari *et al.*, 2017; Koivula *et al.*, 2021) model with two different datasets: $ssGTBLUP_{FIC+RDC}$ used FIC and RDC data; $ssGTBLUP_{FIC}$ used FIC data only. Corresponding PBLUP predictions used either FIC and RDC data – $PBLUP_{FIC+RDC}$ or FIC data only – $PBLUP_{FIC}$. In the single-step models, UPG were substituted by the same number of metafounders (MF, Legarra *et al.*, 2015). The relationships between MF in the pedigree were modeled using a gamma matrix (Γ) of size 137 as presented in Kudinov *et al.* (2021b). The inverses of pedigree relationship matrix (A) and submatrix for genotyped animals (A_{22}) were built with MF inbreeding coefficients. Genomic relationship matrix (G) was built assuming a base population allele frequency = 0.5 and residual polygenic effect = 30%. Model runs were done with MiX99 software (Strandén and Lidauer, 1999).

The prediction power of the genetic evaluation models was examined using forward prediction validation. In the reduced data, records from 2017-2020 were omitted. The validation used 73 genotyped cows that had no record in the reduced milk and protein data but had records in the full data. Validation reliability of predictions was assessed by two methods: (1) production prediction validation (PPV) – regression of yield deviations (YD) of cows computed with full genomic and phenotypic data on (genomic) estimated breeding values ([G]EBV) computed using truncated data ($[G]EBV_{red}$; $YD - \mu_{[G]EBVred} = b_0 + b_1 ([G]EBV_{red} - \mu_{[G]EBVred})$, where $\mu_{[G]EBVred}$ is mean of $[G]EBV_{red}$). Similar to the Interbull GEBV validation test (Mäntysaari *et al.*, 2010), the YD of cow *j* was weighted by w_j computed as $w_j = ERC_j / (ERC_j + \lambda)$, where $\lambda = (1-h^2)/h^2$;h^2 is heritability of the trait and ERC_j is the effective record contribution (Přibyl *et al.*, 2013), the coefficient of determination (R^2) from the regression equation was adjusted by mean of the weights (R_w^2); (2) Linear-regression validation (LRV, Legarra and Reverter, 2018) of [G]EBV computed using the full data on $[G]EBV_{red}$ using formulae $[G]EBV - \mu_{[G]EBVred} = b_0 + b_1([G]EBV_{red} - \mu_{[G]EBVred})$.

Results & discussion

Table 1 presents validation results for the first lactation milk yield in 73 FIC cows obtained using the PPV and LRV approaches. In the PPV approach, the highest validation reliability (R_w^2) was obtained for the $ssGTBLUP_{FIC+RDC}$ model (0.52), as expected. Elimination of the RDC data from the single-step model ($ssGTBLUP_{FIC}$) led to a 0.12 decrease in R_w^2 (0.40). In both data scenarios, the single-step models showed higher validation reliabilities than their corresponding animal models. The increase was 0.12 and 0.07 for RDC+FIC and FIC data, respectively. The regression coefficient (b_1), indicating the bias, was over 1.0 for the $ssGTBLUP_{FIC+RDC}$ model due to underprediction of GEBV differences by the reduced data. In the LRV approach, the b_1 coefficient behaved like in PPV and the value was over one (1.05) in the $ssGTBLUP_{FIC+RDC}$ model. The highest correlation between the full and the reduced data predictions was observed in $ssGTBLUP_{FIC+RDC}$ suggesting a higher predictive ability of the model compared to the other methods. For protein (Table 2), in general, the R_w^2 values were higher than in milk. The b_1 coefficients were over one in PPV for both genomic models (1.07 and 1.03). In the LRV approach, b_1 was close to one in all models and the highest coefficient of correlations (*cor*) were in models with genomic data (0.83 and 0.78). The *cor* values for milk and protein were alike.

The addition of RDC phenotypic data to FIC evaluations improved the prediction reliability of the FIC traditional model. Further augmentation of the model by FIC and RDC genotypes enhanced prediction even further.

Table 1. Results from validation test in 73 FIC cows for 305d first lactation milk.

	PPV[2]			LRV[3]		
Model	b_0 **(kg)**	b_1	R_w^2	b_0 **(kg)**	b_1	*corr*

ssGTBLUP$_{FIC}$	-0.11	1.03	0.49	0.14	0.98	0.78
PBLUP$_{FIC+RDC}$	-2.09	1.00	0.44	-0.23	0.98	0.72
PBLUP$_{FIC}$	0.19	0.98	0.42	0.32	0.97	0.71

[1] b_0 = the bias; b_1 = the regression coefficient; R_w^2 = the coefficient of determination from PPV adjusted by the ERC; *corr* = coefficient of correlation.
[2] Prediction of full data YD by reduced data [G]EBV using linear model $YD - \mu_{[G]EBVred} = b_0 + b_1([G]EBVred - \mu_{[G]EBVred})$.
[3] Prediction of full data [G]EBV by reduced data [G]EBV using linear model $[G]EBV - \mu_{[G]EBVred} = b_0 + b_1([G]EBVred - \mu_{[G]EBVred})$.

Both PPV and LRV approaches gave similar results for the analyzed data. The unfit of the PPV for complex data sets (low heritability, indirect genetic values) discussed in Legarra and Reverter (2018) was not applicable for our research. However, the performance of the LRV approach is computationally less challenging compared to PPV and could be prioritized. Implementation of the ssGTBLUP model for FIC and RDC Test-Day data is the next development step. In the analysis of the test day data, the LRV approach allows a straightforward way to perform prediction validation.

Conclusions

A multi-breed single-step model for FIC and RDC was successfully used in genomic prediction using 305-day first lactation milk and protein data. The genomic model with FIC and RDC data showed higher prediction reliability than using FIC data only.

314. Challenges to implement an interim genomic prediction for young animals in Wallonia, Belgium

K. Wijnrocx[1*], R.R. Mota[1,2], M. Dufrasne[3] and N. Gengler[1]

[1]University of Liège – Gembloux Agro-Bio Tech, Passage des Déportés, 2, 5030 Gembloux, Belgium; [2]Council on Dairy Cattle Breeding, Northview Dr 4201, Bowie, MD 20716, USA; [3]Walloon Breeders Association, rue des Champs Elysées 4, 5590 Ciney, Belgium; katrien.wijnrocx@uliege.be

Abstract

Official Walloon genomic evaluation for the Holsteins is performed three times a year for several traits, by using a single-step GBLUP model, with a 'Bayesian' integration comprising both local and foreign breeding values. The need of a system to provide in between evaluations for young animals was stressed out by breeders. This study gives an overview of the method developed, it describes the challenges of its practical implementation, and finally it proposes some improvements. We identified that a crucial step for the correct interim values estimation is the polygenic term, which requires a deep pedigree knowledge.

Introduction

Official genomic evaluations for the Holstein population in the Southern part of Belgium (Walloon region) are performed for production, conformation, udder health and functional traits since 2015. Nearly all traits are submitted three times a year to the Interbull Centre (https://interbull.org/index, Uppsala, Sweden), which generates a Genomic Multiple Across Country Evaluation (GMACE) with local genomically enhanced breeding values (GEBVs). As outlined by Vandenplas *et al.* (2014) and Colinet *et al.* (2018), the Walloon local genomic evaluations are based on pseudo single-step GBLUP model (ssGBLUP) that used a 'Bayesian' integration of local Walloon breeding values. This method adds MACE values and are able to avoid double-counting by the subtraction of the Walloon contribution from MACE. By having evaluations only three times a year this generates a delay up to 4 months between the genotyping of an animal and its official GEBV evaluations. For example, an animal genotyped after the Interbull deadline has to wait for the next official evaluation to get its own GEBV. Thus, an interim system to perform genomic evaluations for young animals is of interest for breeders that will be able to make earlier selection decisions. Several authors have proposed different solutions this issue. A study of Lourenco *et al.* (2015) described an indirect method for the prediction of the GEBV of young animals by using ssGBLUP analyses. This method calculates the GEBV through the weighted combination of direct genomic value (DGV) and parent average (PA), which they adapted by including an algorithm and SNP effects blending and tuning (Lourenco *et al.*, 2018a). This approach however still generated some issues such as animals with records, and the weighing factor calculation.

An alternative approach was proposed by Pimentel *et al.* (2019), in which the GEBVs are directly split into a SNP based part and a polygenic part. Both parts were estimated separately, and then combined afterwards. The SNP part was estimated by using a 'SNP model' on the residual GEBVs from reference animals from ssGBLUP. These SNP effects were used subsequently to compute DGV, and the 'residual' term was the polygenic part. This approach however had some problems to transmit the polygenic term from reference animals to young animals especially when the distance between genotyped animals and selection candidates is not very close, i.e. when direct ancestors are not genotyped. Therefore, Mota *et al.* (2019) proposed an alternative where they combined the best of both methods to obtain an interim prediction for young Holstein animals in Wallonia. The new method was validated, and a test implementation was done by the Walloon Breeders Association (AWE). Some inconsistencies have arisen and resulted in low correlations between the predicted and calculated interim values. This manuscript will give a short outline

of the method of Mota *et al.* (2019), its implementation by AWE, and challenges and necessary adjustments needed for practical use.

Materials & methods

Partitioning of the GEBVs and generation of polygenic terms. The modified approach that was proposed by Mota *et al.* (2019) followed the derivation of ssGBLUP by Christensen and Lund (2010) to split GEBV into genomic (DGV) and polygenic (PG) parts as described previously by Pimentel *et al.* (2019). In contrast to Pimentel *et al.* (2019), PG were extracted at first, and only then DGV were calculated. This step can be derived as follows: let's call û the vector of available genetic values (EBV respectively GEBV). Each of these values will represent the full genetic variance, and even for the non-genotyped animals, their PG can be approximated through $\hat{\mathbf{a}} = \mathbf{Cov(a,u)}\left(\mathbf{Var(u)}\right)^{-1}\left(\hat{\mathbf{u}} - \mathbf{1}\hat{\mathrm{m}}\right)$ where û is as aforementioned, and m̂ is a constant. The matrix $\left(\mathbf{Var(u)}\right)^{-1}$ should be equal to $\mathbf{H}^{-1}$ as defined by Legarra *et al.* (2009) and Christensen and Lund (2010). The covariance matrix Cov(a,u) needs to express the variance ratio between the variance explained by PG, hereafter called σ^2_a and the total genetic variance σ^2_u.

An alternative approach would be to write this hypothetical mixed model as $\hat{\mathbf{u}} = \mathbf{1}\hat{\mathrm{m}} + \mathbf{Z}\hat{\mathbf{a}} + \mathbf{e}$. The associated theoretical correct decomposition of the total (co)variances would be $\mathbf{Var(u)} = \mathbf{ZVar(a)Z'} + \mathbf{Var(e)} = \mathbf{ZAZ'}\sigma^2_a + \mathbf{G}\sigma^2_e$. Therefore, the model would be:

$$\begin{bmatrix} \mathbf{1'G^{-1}1} & \mathbf{1'G^{-1}Z} \\ \mathbf{Z'G^{-1}1} & \mathbf{Z'G^{-1}Z} + \mathbf{A^{-1}}k \end{bmatrix} \begin{bmatrix} \hat{\mathrm{m}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{1'G^{-1}\hat{u}} \\ \mathbf{Z'G^{-1}\hat{u}} \end{bmatrix} \text{with } k = \sigma^2_e / \sigma^2_a \quad (1)$$

and perfectly equivalent to:

$$\hat{\mathbf{a}} = \sigma^2_a \mathbf{AZ'}\left(\mathbf{ZAZ'}\sigma^2_a + \mathbf{G}\sigma^2_e\right)^{-1}\left(\hat{\mathbf{u}} - \mathbf{1}\hat{\mathrm{m}}\right) = \mathbf{AZ'}\left(\mathbf{ZAZ'} + \mathbf{G}k\right)^{-1}\left(\hat{\mathbf{u}} - \mathbf{1}\hat{\mathrm{m}}\right) \text{ with } k = \sigma^2_e / \sigma^2_a \quad (2)$$

where

$$\hat{\mathrm{m}} = \left(\mathbf{1'}\left(\mathbf{ZAZ'} + \mathbf{G}k\right)^{-1}\mathbf{1}\right)^{-1}\left(\mathbf{1'}\left(\mathbf{ZAZ'} + \mathbf{G}k\right)^{-1}\hat{\mathbf{u}}\right) \quad (3)$$

In these equations, 1 is a vector of ones, A is the pedigree-based relationship matrix among known animals, G represents the hypothetical genomic relationships between all animals; m̂ is BLUE estimate of the overall mean; â is the vector of the PG values for all animals, which are to be estimated; $\boldsymbol{\sigma^2_e}$ is the residual variance (which is the genetic variance associated with the SNP effects (DGV)); σ^2_a is the genetic variance (explained by pedigree and therefore due to PG); Z is the incidence matrix linking â to û. The overall GEBV mean was added to the model to avoid a mean shift in the indirect predictions (Lourenco *et al.*, 2018b). It can be shown that these mixed model equations are a close approximation of the theoretically correct equations deriving polygenic contributions to GEBV. The proportion of additive genetic variance explained by SNPs was defined by our routine genomic evaluations, i.e. currently 60% for production and 65% for other traits. Therefore, $k = \sigma^2_e / \sigma^2_a = 0.60\sigma^2_u / 0.40\sigma^2_u$ or $0.65\sigma^2_u / 0.35\sigma^2_u$.

Solving (1) is not trivial therefore we solve these alternative equations:

$$\begin{bmatrix} \mathbf{1'1} & \mathbf{1'Z} \\ \mathbf{Z'1} & \mathbf{Z'Z} + \mathbf{A^{-1}}k \end{bmatrix} \begin{bmatrix} \hat{\mathrm{m}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{1'\hat{u}} \\ \mathbf{Z'\hat{u}} \end{bmatrix} \text{with } k = \sigma^2_e / \sigma^2_a \quad (4)$$

where G was considered equal to an identity matrix and therefore all links between û considered pedigree based and â estimated in an equivalent approach as if this penalized regression $\hat{\mathbf{a}} = \mathbf{AZ'}\left(\mathbf{ZAZ'} + \mathbf{I}k\right)^{-1}\left(\hat{\mathbf{u}} - \mathbf{1}\hat{\mathrm{m}}\right)$ was used. The use of this approach that allowed the combination of both EBV and GEBV in û. After solving this model using all available solutions (i.e. for genotyped and non-genotyped animals) from the ssGBLUP

system, the vector $\hat{\mathbf{e}}$ for genotyped animals (i.e. reference animals) is considered equal to the vector of DGV ($\hat{\mathbf{d}}$) as follows:

$$\hat{\mathbf{d}} = \hat{\mathbf{e}} = \hat{\mathbf{u}} - (\mathbf{1}\hat{m} + \mathbf{Z}\hat{\mathbf{a}}) \quad (5)$$

In this adapted procedure, the generation of PG could be done for newly genotyped animals mixing their EBV with EBV/GEBV from relevant ancestors. As of such, GEBV a posteriori combining PG with SNP effects can be generated, which will potentially include non-reference animals own records.

Generation of SNP effects. The second step of the adapted method proposed by Mota *et al.* (2019) was the estimation of the SNP effects. This step applied the proposal of Lourenco *et al.* (2015), based on selection index theory, and reduced GEBV into $\hat{\mathbf{d}}$:

$$\hat{g} = DM'G^{-1}(\hat{d}) \quad (6)$$

where $\hat{g}$ is the vector of SNP effects, D is the diagonal matrix of standard variance weights for SNPs (an identity matrix here), M is a centred genotypes matrix (VanRaden, 2008), G^{-1} is the inverse genomic relationship matrix (MDM') among reference animals, and $\hat{\mathbf{d}}$ is a vector of reference population DGV values.

Implementation by the Walloon breeders association. Practical implementation of the interim genomic predictions for young animals was performed by AWE using a simplified, approximate procedure. This was done because new genotyped animals are constantly added to the population and a full single-step cannot yet be perform on a weekly or monthly basis. The 10k genotypes of young animals were imputed into common SNP list that combines 50k V1 and 50k V2 SNP chips. In the first step, the reduced polygenic term was obtained by using Equation 4. The interim GEBV for a young animal *i* can thus be calculated for each trait of interest as follows:

$$\text{Interim GEBV}_i = \text{mean} + \text{DGV}_i + \text{PG}_i = \hat{m} + \hat{a}_i + m_i\hat{g} \quad (7)$$

Note that $\hat{g}$ is calculated in the Walloon genomic evaluation centre and transferred to AWE, whereas $\hat{m}$ and $\hat{a}$ are calculated by AWE for the set of animals of interest. The vector of m_i representing the centred genotypes for animal *i* are computed by AWE using the allele frequencies used to generate $\hat{g}$.

Validation and mitigation. Pearson correlations were calculated for a set of 150 Holstein animals that had no own records in the previous official Walloon evaluation in order to validate the method. Correlations were calculated between the published GEBV from the current evaluation, and the calculated interim GEBV for these animals by the proposed method. The extraction of a three generations pedigree was found to cause biased results, and thus a full extraction was applied to overcome this issue and to be further used in the SNP effects estimation.

Results

Pearson correlations between the published and interim GEBV for a three generations and full pedigree for conformation traits (loin strength, udder balance, overall rump) and milk yield are shown in Table 1. Correlations for conformation traits were around 0.72 for the three generations pedigree depth, whereas values increased up to 0.87 by full extraction. Likewise, correlations for milk yield increased from 0.93 to 0.97.

Table 1. Pearson correlations between interim and published GEBVs for a subset of 150 young animals (AWE) for a three generation and full pedigree extraction.

Trait	3 generations pedigree	Full pedigree
Loin strength	0.72	0.87
Udder balance	0.72	0.84
Overall rump score	0.72	0.87
Milk yield	0.93	0.97

Discussion

This study demonstrated the challenge that arose when practically implementing interim genomic breeding values using a simplified system. For breeders, this system is of great interest as it allows earlier selection decisions. Our method, after adaptations, correctly implements genetic groups, a problem that was documented in literature (Lourenco *et al.*, 2015; Pimentel *et al.* 2019), since all animals in the pedigree are considered for the interim estimation. However, the implementation demonstrated suboptimal results when using few generations in the pedigree. The full pedigree extraction allows the estimation of less biased GEBVs. This also demonstrated the importance of the correct calculation of the PG term. Indeed, crucial for a correct implementation is a compatible $\hat{m}$ and $\hat{a}$, as calculated by the Walloon genomic evaluation centre (Equation 4) on the full set of animals, and $\hat{m}$ and $\hat{a}$ calculated and used by AWE (Equation 7). Correct calculation of m_i that represents the centred genotypes for animal i was ensured by providing the calculated allelic frequencies to AWE.

This research demonstrated that interim GEBVs can be applied successfully after few adjustments, to ensure the correct approximation of the PG part needed to calculate interim GEBVs. However, more research is necessary to keep improving the system.

315. New insights into the computation of the inverse of the numerator relationship matrix for genotyped animals

A. Maiwashe[1,2]

[1]ARC-Animal Production Institute, Private Bag X2, Irene, 0062, South Africa; [2]Department of Animal, Wildlife and Grassland Sciences, UFS, P.O. Box 339, Bloemfontein, 9300, South Africa; norman@arc.agric.za

Abstract

The revolution in genotyping, sequencing and statistical computing allowed use of big data in animal breeding programmes. Genomic selection (GS) through Single-Step GBLUP (sSGBLUP) is now the gold standard for national genetic evaluation although computational challenges remain. The sSGBLUP requires the inverse of genomic (G^{-1}) and pedigree matrices (A^{-1}_{22}). These matrices are structurally similar and computationally intensive. The objective of this study was to investigate the properties of the lower triangular matrix, T^{-1}, to identify opportunities for enhancing computational efficiency. We observed that the heuristic algorithm of Faux and Gengler to identify sparsity pattern of T^{-1} is consistent with the *d-separation* graph criterion used in causal inference. We further observed that some of non-zero elements of T^{-1} are correlated due to the violation of the causal Markov faithfulness assumption. The linear dependency provides an opportunity for efficient computation.

Introduction

Genomic selection is now commonplace in most national genetic evaluation systems in developed countries with some developing countries following suite (Burrow *et al.*, 2017). This technology has gradually attained some level of maturity but more work is still required on the statistical computing front (Misztal *et al.*, 2014).

Research to ensure that genomic selection is placed on solid theoretical foundation could be categorised into two broad areas: Firstly, the need for reconciliation of the existing quantitative genetic theory and the new theoretical developments especially in relation to the key theoretical assumptions e.g. base population of the genotyped and ungenotyped animals. Secondly, there is a need for development of the computational statistical machinery for efficient and cost-effective prediction of genomic breeding values. This paper focuses on the second line of research i.e. computational efficient statistical methods.

The computation of the inverse of the genomic and pedigree-based matrices has received considerable attention recently due to their integral role in sSGBLUP (e.g. VanRaden, 2008; Misztal *et al.*, 2009; Faux and Gengler, 2013). Other approaches for inclusion of genomic data which do not require the inverse of the genomic matrix have been developed. Faux and Gengler (2013) presented a practical method to compute A^{-1}_{22} which builds on the theory developed by Henderson (1976). This approach is appealing as it is aligned with the existing classical theory of Wright (1921) on causation and correlation.

As a result of recent theoretical development, we now have a good understanding of the properties of the non-zero elements of the inverse of the lower triangular matrix T^{-1} derived from full knowledge of the pedigree. However, our understanding of the properties of T^{-1} is limited when some animals are ungenotyped. The theoretical basis behind the high density of the T^{-1} for the genotyped animals is also less understood. The objective of this study was to investigate the properties of the A^{-1}_{22} and specifically the sparsity pattern of the lower triangular matrix (T^{-1}) in order to identify opportunities for enhancing computational efficiency.

Materials & methods

Current theory. The classical paper of Wright (1921) on correlation and causation has laid a solid foundation for the quantitative genetic theory. This paper presented a key concept of *path coefficient*. Without loss of generality and following the notation of Li (1956), the fundamental equation for computing correlations / covariance from *path coefficients* is $r_{XY} = \sum_i p_{Xi}p_{Yi} + \sum_{i \neq j} p_{Xi}r_{ij}p_{Yi}$. This equation gave rise to Wright's numerator relationship matrix (A) which can be presented as follows: A = TDT′ (Henderson 1976). For a scenario where animals have different sources of information e.g. pedigree data (denoted by 1) and genomic data (denoted by 2), Faux and Gengler (2013) partitioned the numerator relationship matrix as follows:

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \text{ where } \quad A_{22} = \begin{bmatrix} Z & y \\ y' & m \end{bmatrix},$$

Following partitioned matrix theory, the inverse of A_{22} is given by:

$$A_{22}^{-1} = \begin{bmatrix} Z^{-1} & 0 \\ 0' & 0 \end{bmatrix} + \frac{1}{s}\begin{bmatrix} -Z^{-1}y \\ 1 \end{bmatrix}[-y'Z^{-1} \quad 1],$$

where $b = z^{-1}y$ and -b is the last row of T^{-1}. The non-trivial activity in the computation of $\mathbf{A}_{22}^{-1}$ pertains to solving the linear system $b = z^{-1}y$. Faux and Gengler (2013) implemented efficient algorithms that avoids explicit computations involving zero entries through identification of the sparsity pattern of T^{-1}.

Identification of the sparsity pattern of T^{-1}. The heuristic algorithm of Faux and Gengler (2013) to identify the sparsity pattern of the T^{-1} uses pedigree data. The intuition behind this algorithm was briefly described in their paper but the underlying theory was not adequately addressed. In this paper, we appeal to graph theory and the structural causal model framework to provide an alternative basis for identifying sparsity pattern.

We use the toy pedigree example provided in Faux and Gengler (2013) for continuity (Figure 1). In graph theory, the pedigree is an example of a Directed Acyclic Graph (DAG). A DAG represents the underlying causal structure of a closed system. In a DAG, animals are represented by nodes and the causal relationship between them represented by arrows / vertices whose metrical value is given by a path coefficient.

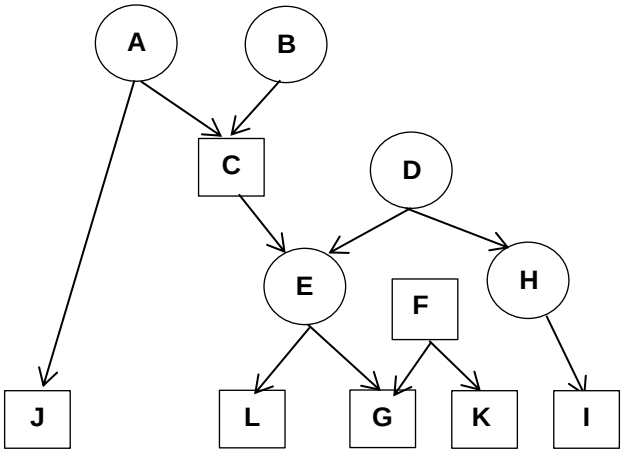

Figure 1. A toy example pedigree (adapted from Faux and Gengler 2013). Circles and squares represent ungenotyped and genotyped animals, respectively.

In a trivial case where all the nodes in a causal network (e.g. pedigree) are known, the covariance between nodes can be computed from the path coefficients and observed covariance. For example, an animal is independent of all other animals in the pedigree conditional on the knowledge of its parents. In a non-trivial case where some of the parents are unknown, as is the case in A_{22}, the notion of conditional independence is generalised through a *Markov blanket* which is a set of all immediate known ancestors of the animal, their offspring and mates. The Markov blanket is identified through a *d-separation* graphical criterion which is a process of traversing the graph to identify a set of animals that blocks all the connecting paths between animals (see Pearl 2010). If animal *X* is *d-separated* from animal *Y* then animals *X* and *Y* are conditionally independent. The set *S* separating *X* from *Y* is a *Markov blanket*. For the example pedigree in Figure 1, a set S = {*C*, *F*, *G*} is a Markov blanket of node *I*. In other words, when animals *D*, *E* and *H* are ungenotyped, animal *I* is conditionally correlated with animals *C*, *F* and *G*. On the other hand, when *H* is genotyped, animal *I* is conditionally uncorrelated with all animals in the pedigree. This example emphasises the fact that the *flow of information* in the pedigree depends on our knowledge of the information on each node.

Computation of path coefficients. The identification of sparsity pattern using *d-separation* indicates that the lack of complete knowledge about the pedigree, as is the case when some animals are ungenotyped, induces statistical covariance among animals. In the example above, animals *C* and *F* are conditionally correlated with animal *I* when its direct ancestors are ungenotyped even though these animals are conditionally uncorrelated based on the pedigree. The induced correlation results in linear dependency among path coefficients. We considered the numerator relationship of the example pedigree in Figure 1 to demonstrate linear dependence between path coefficients.

The linear system to compute the elements of T^{-1} of animal L in Figure 1 is as follows.

$$\begin{bmatrix} a_{cc} & a_{cf} & a_{cg} & a_{ci} \\ a_{fc} & a_{ff} & a_{fg} & a_{fi} \\ a_{gc} & a_{gf} & a_{gg} & a_{gi} \\ a_{ic} & a_{if} & a_{ig} & a_{ii} \end{bmatrix} \begin{bmatrix} b_{cl} \\ b_{fl} \\ b_{gl} \\ b_{il} \end{bmatrix} = \begin{bmatrix} a_{cl} \\ a_{fl} \\ a_{gl} \\ a_{il} \end{bmatrix}$$

Using the observed covariance, the above system is given as follows,

$$\begin{bmatrix} 1 & 0 & 0.25 & 0 \\ 0 & 1 & 0.50 & 0 \\ 0.25 & 0.50 & 1 & 0.06 \\ 0 & 0 & 0.06 & 1 \end{bmatrix} \begin{bmatrix} b_{cl} \\ b_{fl} \\ b_{gl} \\ b_{il} \end{bmatrix} = \begin{bmatrix} 0.25 \\ 0 \\ 0.25 \\ 0.06 \end{bmatrix}$$

Based on the above, $b_{fl} = -\frac{1}{2} b_{gl}$ and the following reduced linear system can be solved to obtain the path coefficients:

Table 1. A_{22} for animals in Figure 1.

	C	F	G	I	J	K	L
C	1	0	0.25	0	0.25	0	0.25
F	0	1	0.5	0	0	0.5	0
G	0.25	0.5	1	0.06	0.06	0.25	0.25
I	0	0	0.06	1	0	0	0.06
J	0.25	0	0.06	0	1	0	0.06
K	0	0.5	0.25	0	0	1	0
L	0.25	0	0.25	0.06	0.06	0	1

$$\begin{bmatrix} 1 & 0.25 & 0 \\ 0.25 & 1 & 0.06 \\ 0 & 0.06 & 1 \end{bmatrix} \begin{bmatrix} b_{cl} \\ b_{gl} \\ b_{il} \end{bmatrix} = \begin{bmatrix} 0.25 \\ 0.25 \\ 0.06 \end{bmatrix}; \text{ with } \begin{bmatrix} b_{cl} \\ b_{gl} \\ b_{il} \end{bmatrix} = \begin{bmatrix} 0.183 \\ 0.269 \\ 0.044 \end{bmatrix} \text{ and, therefore}$$

$$b_{fl} = -\frac{1}{2} b_{gl} = -0.134$$

Results

The results from this study shows that the linear system to obtain the path coefficients required for A^{-1}_{22} exhibit linear dependence as a result of ungenotyped ancestors that explains the observed relationships in the pedigree, A_{22}. For the pedigree considered here, the number of equations in the linear system was reduced from 4 to 3 which seem trivial. The linear dependence was induced by genotyped offspring of the hidden or ungenotyped ancestors of the animal in question. Given that these ungenotyped ancestors may have hundreds or thousands of genotyped offspring, in view of the typical breeding structure in livestock, it could be speculated that the reduction in the linear system could be significant and result in tangible computational efficiency of T^{-1} efficiency.

Discussion

Consideration of the linear system used in the computation of T^{-1} revealed important properties of the path coefficients. The linear dependence among path coefficients induced by functional relations among animals indicate that these are induced statistical correlations to ensure integrity of the linear system. Accordingly, the linear system ensures that the key underlying assumptions, such as closed nature of the causal system, is guaranteed. The results from this study provide important insights into the properties of the linear system which could be useful for computational efficiency in deriving A^{-1}_{22}. The attempt to introduce causal graphical models may stimulate adoption of causal analysis for inference in animal breeding.

Abstract

Female reproductive traits directly impact the profitability of commercial beef herds. The ability to select herd bulls, based on the predicted reproductive performance of their female progeny, has the potential to significantly improve herd productivity. Genomic selection in beef cattle run in the extensive production systems of tropical and subtropical northern Australia is hindered by technical and economic barriers, including the difficulty of obtaining accurate records on reproductive performance of individual females. In this study we present a novel method, Genomic Attribution to Pregnancy and Lactation Status (GAPLS), to predict an individual bull's contribution to six categories of their progeny's 2nd joining pregnancy and lactation status. Using a simulated example and four commercial Brahman datasets, we demonstrate the merit of the method.

Introduction

In extensive production systems of tropical and subtropical northern Australia, uptake of genomic selection has been limited due to practical, financial and management complications associated with collecting individual performance records. In northern commercial cattle herds, following natural syndicate joining, heifers are mustered and grouped based on the result of their 2nd joining pregnancy and lactation status (PLS). Heifers are commonly grouped into six categories in these situations: 1. DNP = Dry and Not Pregnant; 2.WNP = Wet and Not Pregnant; 3. DEP = Dry and Early Pregnant; 4. DMP = Dry and Mid Pregnant; 5. DLP = Dry and Late Pregnant; 6. WEP = Wet and Early Pregnant. When heifers are genotyped, either individually or pooled as a group based on these categories, their DNA profiles become a valuable resource to explore genomic selection strategies for the improvement of fertility traits in beef cattle (Reverter *et al.*, 2016). However, the categorical nature of PLS coupled with departures from normal symmetry (e.g. PLS 3 and 4 not necessarily more abundant than 1 or 6) and the uncertainty about importance ranking of categories (e.g. PLS 2 not necessarily much worse than PLS 5), makes the analytical methodology to explore PLS rather cumbersome.

Here, we present Genomic Attribution to PLS (GAPLS), a novel and intuitive non-parametric proportion-based metric of genomic relatedness of a given individual animal (presumably a sire candidate for selection) across the six PLS categories.

Materials & methods

The basic concept of genomic attribution to PLS (GAPLS). Using the genotypes from individual bulls and a reference population of cows with genotypes and phenotypes for PLS, a genomic relationship matrix (GRM) can be computed as described by VanRaden *et al.* (2008). The GAPLS of a tested bull is defined for each PLS category as its average genomic relationship with the cows having that PLS category divided by its average genomic relationship across all cows. Numerically, for the i^{th} bull, its GAPLS to the j^{th} PLS category (j=1, 2, …6, corresponding to DNP, WNP, … WE, respectively) is computed as follows:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_316, © Y. Li *et al.* 2022

$$\text{GAPLS}_{i,j} = \frac{\frac{1}{N_j}\sum_{k=1}^{k=N_C}[g_{i,k} \times \text{I}(k=j)]}{\sum_{j=1}^{j=6}\left(\frac{1}{N_j}\sum_{k=1}^{k=N_C}[g_{i,k} \times \text{I}(k=j)]\right)},$$

where: N_j = number of cows in the j^{th} PLS category, N_C = total number of cows in the reference population, $g_{i,k}$ = genomic relationship between the i^{th} bull and the k^{th} cow; I(k=j) = an indicator that takes a value of 1 if the k^{th} cow belongs to the jth PLS category, and 0 otherwise. By construction, the GAPLS of the i^{th} bull summed across all 6 j^{th} PLS categories is one.

Simulated example. For simple illustration purposes, consider a situation with 15 cows in the reference population and 2 candidate sires in the testing population (Table 1). The number of cows belonging to the PLS categories 1 to 6 is 2, 1, 3, 4, 1, and 4, respectively (second column of Table 1). Similarly, the genomic relationships between each cow and the hypothetical sires (Sire 1 and Sire 2) are given in the last two columns of Table 1.

In this scenario, the GAPLS of Sire 1 to PLS category 1 is:

$$\text{GAPLS}_{1,1} = \frac{\frac{1}{2}(0.1+0.0)}{\frac{1}{2}(0.1+0.0)+\frac{1}{1}(0.5)+\frac{1}{3}(0.2+0.1+0.1)+\frac{1}{4}(0.2+0.0+0.2+0.1)+\frac{1}{1}(0.0)+\frac{1}{4}(0.5+0.1+0.0+0.2)} = 0.0496$$

Similarly, the GAPLS of Sire 2 to PLS category 6 is:

$$\text{GAPLS}_{2,6} = \frac{\frac{1}{4}(0.3+0.4+0.3+0.4)}{\frac{1}{2}(0.1+0.0)+\frac{1}{1}(0.2)+\frac{1}{3}(0.0+0.1+0.0)+\frac{1}{4}(0.0+0.1+0.2+0.2)+\frac{1}{1}(0.2)+\frac{1}{4}(0.3+0.4+0.3+0.4)} = 0.375.$$

Table 2 presents the average GAPLS values for both sires across the 6 PLS categories based on the original data and after 1000 permutation tests of PLS. Since the first (1= DNP) and last two PLS categories (5=DLP and 6=WEP) indicate poor and good fertility, respectively, therefore Sire 2 would be preferred over Sire 1

Table 1. Hypothetical scenario with 15 cows with pregnancy and lactation status (PLS) and their genomic relationships ($g_{i,k}$) with two testing sires.

Cows		Sire's $g_{i,k}$	
K	PLS	Sire 1 (i = 1)	Sire 2 (i = 2)
1	6	0.5	0.3
2	3	0.2	0.0
3	4	0.2	0.0
4	1	0.1	0.1
5	6	0.1	0.4
6	3	0.1	0.1
7	6	0.0	0.3
8	1	0.0	0.0
9	4	0.0	0.1
10	5	0.0	0.2
11	2	0.5	0.2
12	4	0.2	0.1
13	6	0.2	0.4
14	3	0.1	0.0
15	4	0.1	0.2

because of its highest attribution value for category 6 (0.375). If using completely random data, i.e. a sire has no close relationship with any group of cows of six categories of PLS, the GAPLS of the sire to each PLS category is expected to equal 1/6 = 0.1667. Large deviations of GAPLS will be desirable when selecting sires because the PLS categories are unlikely to be equally represented in real scenarios. As shown in Table 2 (standard deviations in brackets), a robust measure of sampling variation can be quickly computed by permuting the PLS labels while maintaining the genomic relationships fixed.

Real data application. Datasets from four tropical Brahman cattle populations in north Queensland were used for the study. The first three populations contained 829 bulls, of which 114 were from the 2020 season (Bulls_114), 229 from 2021 (Bulls_229), and 486 are to be used in the 2022 mating season (Bulls_486). The fourth population consisted of 795 cows with PLS records. All samples were individually genotyped with 54,791 SNPs (Neogen Australasia GGP TropBeef 50K chip) and later imputed to a higher density of 529,260 autosomal SNPs. A GRM across all animals was constructed, and the GAPLS values of individual bulls were then estimated based on their genomic relationships with the 795 cows.

Results

Genomic relationships between bull and cow populations. The intensity difference in Figure 1A reveals that: (1) The animals in the Cows_795 set were more closely related among themselves than with the 829 bulls from the three bull populations; (2) The two bull populations (Bulls_114 and Bulls_229) had a closer relationship with each other than either had with the third bull population (Bulls_486); (3) The relationship between bulls and the cow population (Cows_795) was stronger for the Bulls_114 and Bulls_229 than for the Bulls_486.

GAPLS estimates for three bull populations. The closer genomic relationships between the first two bull populations (Bulls_114 or Bulls_229) and the 795 cows, allowed for large variations in average GAPLS values (Table 3, columns 2 and 3) in these two bull populations (ranging from 0.139 to 0.182 and 0.139 to 0.194, respectively). In comparison, the bull population Bulls_486 had a much narrower range (0.159-0.172). Accordingly, the standard deviations (STDs) of the GAPLS in the first two bull populations were also consistently larger than those in the third bull population. When clustering bulls based on their GAPLS values (Figure 1B), it is easy to identify the bulls with distinguished value differences (color gradient) across the six categories. For example, selecting the desirable bulls with the highest GAPLS values for 6_WEP (red color) and the lowest values for 1_DNP (green color).

Table 2. Average genomic attribution to pregnancy test outcome (GAPLS) values across the six PLS categories for the two sires after 1000 permutations of six PLS values.

PLS Category	Sire 1 (STD[1])	Sire 2 (STD)
1_DNP	0.0496 (0.115)	0.0536 (0.096)
2_WNP	0.4959 (0.137)	0.2143 (0.125)
3_DEP	0.1322 (0.100)	0.0357 (0.082)
4_DMP	0.1240 (0.098)	0.1071 (0.081)
5_DLP	0.0000 (0.144)	0.2143 (0.126)
6_WEP	0.1983 (0.091)	0.3750 (0.079)

[1] STD = standard deviation.

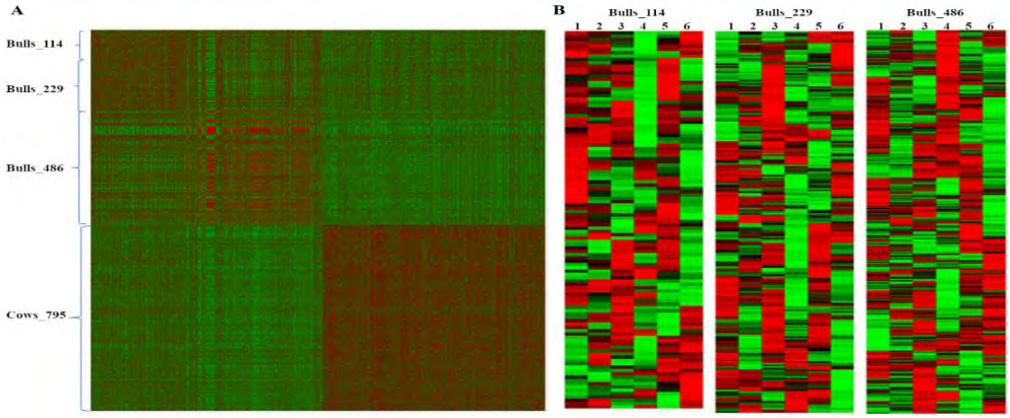

Figure 1. (A). Pairwise genomic relationships between animals of different populations. Each off-diagonal dot represents a genomic relationship matrix element between two animals. The red intensity represents closeness between animals. (B). Heatmap of individual bull's GAPLS values across six categories within each bull population.

Table 3. Average values of bull's genomic attribution to pregnancy and lactation status (GAPLS) across the six PLS categories for three bull populations.

Population	Bulls_114	Bulls_229	Bulls_486
PLS category	Mean (std)	Mean (std)	Mean (std)
1_DNP	0.182 (0.0572)	0.170 (0.0521)	0.172 (0.0463)
2_WNP	0.169 (0.0451)	0.161 (0.0436)	0.159 (0.0299)
3_DEP	0.176 (0.0567)	0.194 (0.0676)	0.178 (0.0499)
4_DMP	0.139 (0.0636)	0.139 (0.0608)	0.159 (0.0514)
5_DLP	0.178 (0.0594)	0.171 (0.0626)	0.170 (0.0461)
6_WEP	0.156 (0.0709)	0.165 (0.0675)	0.163 (0.0513)

Discussion

Genomic prediction for a phenotype like PLS, with six arbitrary categories, is challenging because traditional GBLUP models are inadequate. Firstly, it is hard to interpret the biological significance of a single GEBV that is obtained after treating the six PLS categories as a continuous trait. Secondly, how to define the scoring system for the six categories is open for discussion. For instance, if categories are coded from worst to best for fertility, WNP could be coded as 2 or as 5 and this has a significant impact on GBLUP results (Li *et al.* 2021). The newly proposed GAPLS provides an effective way of assessing individual sire's genomic contributions to six categories of PLS by using the standard GRM values between sires and the cows with PLS records. The merits of the method include: (1) results are easy to interpret, promoting adoption by commercial producers wanting to improve the reproductive performance of their herds; (2) the GAPLS method will not be influenced by the phenotype scoring system allowing producers to tailor selection strategies to their production system; (3) The population variation of GAPLS values will truly reflect the degree of relatedness between testing and reference populations; and, (4) The method could easily be extended to any phenotype of a categorical or ordinal nature.

Abstract

Dense genome-wide SNP chips allow computation of genomic relationships through different methods, either based on identity by state (IBS) or identity by descent (IBD). The latter have shown to increase the accuracy of both estimated relationships and predicted breeding values. Yet, it is unclear which approach would achieve higher performance in real data with a pedigree constrained to a few generations. Here we compare the performance of genomic models based on IBS (G_{IBS}) and IBD (G_{IBD}) for meat quality traits in an F2 crossbred pig population by estimating their predictive ability through cross-validation, compared with the pedigree model. The genomic based covariances had higher predictive ability when compared to A_{22}. A scarce increment in the predictive ability was found with G_{IBS} when compared to G_{IBD}, most likely due to the former method recovering relationships among founder animals.

Introduction

Prediction of breeding values (BV) in livestock genetic evaluation requires phenotypes and the pedigree through the inverse of the additive relationship matrix A. These relationships constitute twice the expected proportion of alleles identical by descent (IBD) shared by pairs of individuals. The availability of molecular markers allows estimating the so-called genomic relationship matrix G (VanRaden, 2008), which is used to estimate the genomic BV (GEBV). Different methods have been proposed to estimate genomic relationships (VanRaden, 2008; Yang *et al.*, 2010), being VanRaden's (2008) the most widely used. In this method, elements reflect the estimated proportion of alleles that are identical by state (IBS) between two individuals, as a deviation from the expected proportion of alleles shared in the population (Vela-Avitúa *et al.*, 2015). Alternative methods have been developed based in the proportion of the genome that is IBD among pairs of individuals. Han and Abney (2011, 2013) proposed a Hidden Markov Model for estimating the probability of IBD between pairs of individuals within a known pedigree. The method takes account of inbreeding and LD among markers. IBD based methods using genomic information have increased the accuracy of estimated relationships and predictions of breeding values (García-Baccino *et al.*, 2016; Jurcic *et al.*, 2021). The use of IBD assumes that the pedigree is complete. Unfortunately, it is not straightforward to think there will be an advantage of IBD over IBS in terms of predictive ability when the pedigree has low depth when using real population data. Therefore, this study compares estimates of predictive abilities through cross-validation, using IBD and IBS from records of meat quality and carcass composition of crossbred pigs with a pedigree constrained to a few generations.

Materials & methods

The experimental pig population was bred at the Michigan State University Swine Teaching and Research Center, East Lansing, MI. The pedigree and genotypes were available for three generations (F_0, F_1 and F_2) of a cross of Duroc × Pietrain. Briefly, the F_0 was formed by mating 16 Pietrain sows by artificial insemination to 4 Duroc boars. 6 males and 51 females were selected from F_1 as parents of the F_2 generation. F2 Pigs (n=948) from both sexes had phenotypes for 20 meat quality and carcass composition traits. The phenotypes were classified within five groups: primal cut weight, carcass measures, meat quality, laboratory analysis

and sensory panels analyses. Genotyping and editing procedures were previously reported by Casiró *et al.* (2017) and consisted of SNP data from two chips with different densities. All F_0 and F_1 animals, as well as 336 F_2 pigs were genotyped with the Illumina PorcineSNP60 BeadChip, which contained approximately 62,000 SNP. Additionally, 612 F_2 animals were genotyped at a lower density (8,836 SNP) using the GeneSeek Genomic Profiler – Porcine LD (GGP-Porcine LD, GeneSeek a Neogen Company, Lincoln, NE). The procedure for editing genotypes involved removing SNP with missing genotypes in all animals and those with Mendelian inconsistencies. Then, all missing genotypes in the 60K chip as well as those not scored in the low-density chip were imputed using the software FImpute with default parameters (Sargolzaei *et al.*, 2014). After the imputation, we additionally removed SNP with MAF<0.05, resulting in a dataset with records from 1,015 pigs having a genotype of 42,087 SNP each.

Relationship matrices. Three different methods were employed to estimate the relationship matrices. The first one was the additive relationship matrix A calculated with 1,037 animals contained in the pedigree and including the 1,015 genotyped animals. Only the submatrix A_{22}, with the additive relationship between genotyped individuals was used in this study. The second was the IBS method of VanRaden (2008) (G_{IBS}). Briefly, genotypes were expressed as allelic dosage and stored in standardized marker matrix M, with dimensions *n* (number of individuals) by *m* (number of loci). From here, G_{IBS} was computed by multiplying Z (the standardized marker matrix) by its transpose. The resulting matrix contains the estimates of the realized genomic relationships between any pair of pigs. The third was an IBD method proposed by Han and Abney (2011, 2013) and implemented in the 'IBDLD' v3.38.1 software. The algorithm employs a Hidden Markov Model for estimating the probability that a pair of individuals at a locus are IBD, given genomic and pedigree information. The output of the program is an empirical kinship coefficient per chromosome between pairs of individuals. Then, the actual genomic relationship between pairs of individuals for a genome of length *L* is calculated as twice the kinship coefficient weighted by the length of the chromosome. Because the resulting genomic relationship matrix may be indefinite, it was necessary to compute the nearest positive definite matrix (Cheng and Higham, 1998), and the latter was used as the IBD genomic relationship matrix (G_{IBD}) in all analyses.

Statistical model. For each character a single trait animal model was fitted to the data using the gwaR package in R (https://github.com/steibelj/gwaR) as y = Xb + Zu + e. In this model, *y* is the vector containing the phenotypes, *X* is the incidence matrix relating records to the vector of fixed effects b, which includes the sex, slaughter group and the carcass weight as a covariate. Matrix Z relates the records in *y* to the random vector of additive genetic effects u, and e is the vector of random errors distributed as $e \sim N(0, I\sigma_e^2)$, where I is the identity matrix and σ_e^2 is the error variance. The distribution of BV was assumed to be $u \sim N(0, G\sigma_u^2)$, where G is one of the relationship matrices A_{22}, G_{IBS} or G_{IBD} and σ_u^2 is the additive genetic variance. As the models only differed in the relationship matrix used for specifying the covariance of BV, we will call these models as A_{22}, G_{IBS} and G_{IBD} hereafter.

Estimating predictive ability through cross-validation. For each trait the models A_{22}, G_{IBS} and G_{IBD} were compared by estimating the predictive ability as the correlation between predicted and observed phenotypes through a 5-fold cross-validation procedure with in-house developed functions written in R. The process consisted of randomly splitting the full dataset for each trait into 5 subsets; in each iteration, the animal's phenotypes were hidden from one subset ('test set') and the phenotypes of the 4 remaining ones were used to train the model ('training set'). As an outcome of each iteration, we obtained estimates of variance components and the solutions for all fixed and random effects of the model. We used these to predict the phenotypes of the animals in the test set as $y2 = \mathbf{x}'\hat{\boldsymbol{b}} + \hat{u}$. Once the 5 iterations were finished, the Pearson correlation coefficient ($r_{(y1,y2)}$) between the observed uncorrected (*y1*) and predicted (*y2*) phenotypes was calculated. The procedure was replicated 300 times, and all replicates (n=213) in which

the Newton-Raphson algorithm converged (to maximum of 50 iterations) with the three models were used for comparison.

Results

For all the models, the predictive ability was high for traits within the primal cut weight group (0.80-0.87), from low to moderate for the group's carcass measures, meat quality and laboratory analyses (0.34-0.70), and low for the traits in sensory panel group (0.21-0.40). In terms of selection models, the predictive ability of G_{IBS} and G_{IBD} were higher when compared to A_{22} in 18 out of 20 traits from carcass measures, meat quality, laboratory analyses and sensory panel. The increment in predictive ability obtained by using genomic relationship matrices with respect to A_{22} was more noticeable in the meat quality group, which ranged from 14 to 37%. It was of lesser importance in the primal cut weights, where the increment varied from 0.6 to 4%. Comparing the performance between G_{IBS} and G_{IBD}, a slight increment in the $r_{(y1,y2)}$ for 14 traits was obtained when fitting G_{IBS} with respect to G_{IBD}, ranging from 0.1 to 5.5%.

Discussion

Predictive ability was greater with genomic models when compared to A_{22}. The result agrees with those from stochastic simulations (Forneris *et al.*, 2016; Vela-Avitúa *et al.*, 2015) or real data (Jurcic *et al.*, 2021; Meuwissen *et al.*, 2014), though some of these investigations employed different IBS or IBD approaches to set up the relationship matrices. The improved performance of genomic matrices over A_{22} may be due to a better capture of the Mendelian sampling term (Daetwyler *et al.*, 2013). In addition, de los Campos *et al.* (2013) found that the predictive ability depends on the extent to which the marker genomic relationship describes the realized genetic relationship at the unobserved causal loci. Other authors have highlighted the importance of information of relatives on the prediction of genomic models. Habier *et al.* (2010) and Clark *et al.* (2012) have found that prediction accuracy is reduced when relationships between individuals from the training and test sets are distant or animals are unrelated. In our study, the choice of animals from the training and test sets was random and the range of relationships between individuals in generation F_2 ranged from 0 to 0.75, -0.276 to 0.9, and -0.26 to 0.92, for A_{22}, G_{IBS} and G_{IBD}, respectively. By randomly picking animal records for cross-validation, the predictive ability is higher than when the sampling is constrained using criteria such as family and relatedness (Daetwyler *et al.*, 2012). In about 70% of traits predictive abilities were higher with G_{IBS} than with G_{IBD}, while in the remaining traits they performed the

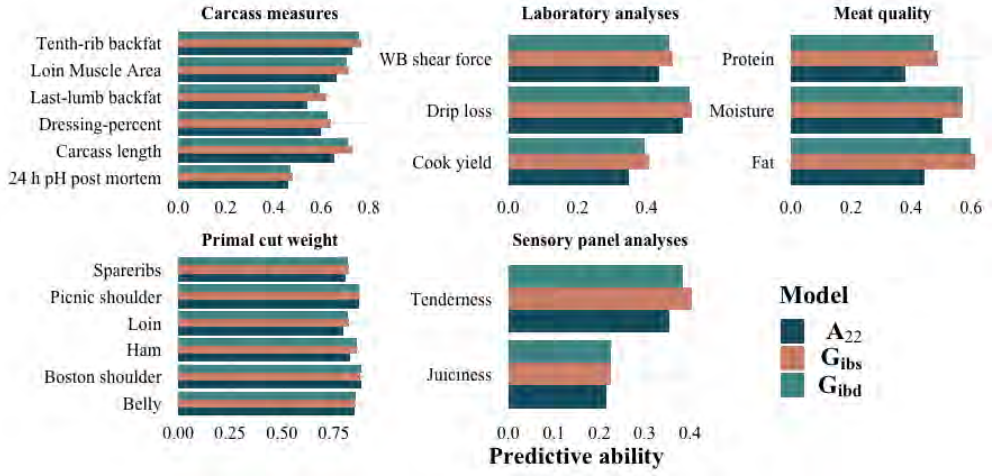

Figure 1. Predictive ability of meat quality and composition traits in F2 pigs using three linear mixed models.

same. The reason may be found in that G_{IBS} displays greater variation in genomic relationships, probably because relationships are referred to a more distant base population, which for an animal model would imply more sources of information with the consequent gain in precision to estimate the BV. Our results revealed sizeable relationships among F_0 animals and thus a deeper pedigree is important for more accurate predictions.

318. Modelling missing pedigree with metafounders and validating ssGBLUP evaluation for Uruguayan Holstein dairy cattle

R.D. López-Correa[1,2*], A. Legarra[3] and I. Aguilar[4]

[1]Universidad de la República, Facultad de Agronomía, Montevideo, Uruguay; [2]Universidad de la República, Facultad de Veterinaria, Montevideo, Uruguay; [3]UMR GenPhySE, INRA Toulouse, Castanet Tolosan, France; [4]Instituto Nacional de Investigación Agropecuaria, Montevideo, Uruguay; rlopez@fagro.edu.uy

Abstract

The objective of this study was to check the quality of single-step GBLUP (ssGBLUP) predictions in Uruguayan dairy cattle, with special focus on the modelling of missing pedigree defined as metafounders (MF). A second objective was to use different estimators to compute relationship matrix among MF (Γ). Five strategies followed to fit unknown parent groups (UPGs) in ssGBLUP were: (1) MF using original Γ; (2) MF with modified Γ based on the median of elements in original Γ; (3) MF bounding base allelic frequencies of markers between 0 and 1 before computing Γ; (4) UPG in A^{-1}; and (5) UPG in H^{-1}. Estimated Γ with restricted allele frequencies gave less biased and more accurate genomic predictions. Future studies are warranted in the definition of Γ and UPGs to improve quality of genomic predictions and understand the origin of bias.

Introduction

Uruguayan dairy herds are creators of genetic progress through selection but are also heavy importers of foreign genetics. Use of genomic predictions is important as producers start using it, so it is important to ascertain the quality of these predictions. Genomic predictions can be done by ssGBLUP but it is challenging to include UPGs due to their specific structure. The use of UPGs in genomic model evaluations may lead to bias in genomic enhanced breeding values (GEBV) and reduce convergence speed in ssGBLUP (Misztal *et al.*, 2013; Tsuruta *et al.*, 2013). The application of MF theory (Legarra *et al.*, 2015; García-Bacino *et al.*, 2017) could be an alternative to fit missing pedigree in a genomic evaluation model and help to overcome bias and convergence problems. However, **Γ** may give estimation problems, for instance when genotyped individuals have a weak bond with UPGs (Lourenco *et al.*, 2020). Another important issue in the Uruguayan genetic evaluation is the restricted capacity to perform large progeny tests. Therefore, we need to define statistics that measure bias and accuracy of genomic predictions. Predictability is a major problem in dairy cattle genomic evaluations, because large differences between GEBV and EBV after progeny test were reported (Bradford *et al.*, 2019). Thus, the linear regression method (Legarra and Reverter, 2018), commonly known as LR, could be a useful tool to assess the predictive ability and accuracy of genomic predictions. The objective of this study was to check the quality of ssGBLUP predictions in Uruguayan dairy cattle, with special attention to the modelling of missing pedigree defined as MF. A second objective was to use different estimators to compute gamma relationship matrix among MF.

Materials & methods

Data. Data consisted of milk yield records from one to five lactations that were used for the Uruguayan Holstein genetic evaluation in April 2021. A total of 1,031,174 records were available for 367,423 cows. The pedigree file included 578,172 animals and was created by tracing back three generations of ancestors of either cows with lactation records or genotyped animals. In total, 18 UPGs were defined based on sex, origin (foreign, national) and birth year. Genotypes for 5,573 animals were available, 3,499 were generated using the ICBF_IDBv3 50k panel and 2,074 genotypes of bulls were provided by international cooperation. After quality control, 39,288 SNPs were analysed. Cows had the largest number of genotypes in the sample (3,275) and more than 95% had at least a single lactation record. They were born between 1993 and 2019, and 263 of the cows had both parents genotyped whereas 1,297 had one parent genotyped. Genotyped bulls

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_318, © R.D. López-Correa *et al.* 2022

(2,298) were born between 1973 and 2019, and 36 bulls had both parents genotyped and 1,181 bulls had one parent genotyped. Most of genotyped animals had both parents known.

Models. Milk adjusted 305-d yield was analyzed in a single-trait repeatability animal model to obtain GEBV using ssGBLUP (Aguilar *et al.*, 2010; Christensen and Lund, 2010). The basic model included fixed effects of herd year season (n=54,274) and age-parity-calving interval-dry period (n=118). The random effects were the additive genetic effect (n=578,190) and the permanent environmental effects (n=423,317). Data included up to five lactation records. Matrix H^{-1} was defined as in Aguilar *et al.* (2010). Genomic relationship matrix (G) was computed by the first method of VanRaden (2008); and blended with default parameters as $G^{*}=0.95\times G + 0.05\times A_{22}$. To make G and A_{22} compatible, we used default tuning in BLUPF90 (Misztal *et al.*, 2018). To fit UPG five methodologies were applied: ssGBLUP with MF using original Γ (MFO model), ssGBLUP with MF using gamma-robust estimator (MFGrob model), ssGBLUP with MF using gamma-complete estimator (MFBou model), ssGBLUP with UPG in A^{-1} (PED model), and ssGBLUP with UPG in H^{-1} (EXA model). For MF models, each UPG was regarded as a MF, i.e. a different ancestral population, and original Γ was computed by generalized least squares using observed genotypes (García-Bacino *et al.*, 2017) and for each MF we calculated the base allelic frequencies. Additionally, the gamma-robust estimator designed Γ with two different values based on the original Γ. The diagonal elements of Γ had the median of all self-relationships, whereas the off diagonals contained the median of all relationships across MF. The complete gamma estimator bounded base allelic frequencies of markers between 0 and 1 before computing Γ. Values in Γ^{-1} were included in the numerator relationship matrix $A(\Gamma)^{-1}$, as previously defined (Legarra *et al.* 2015). The PED model fitted UPGs as a fixed effect into ssGLBUP equations and they were included into the pedigree-based numerator relationship matrix A^{-1} by QP-transformation (Quaas and Pollak, 1981). The EXA model considered UPGs as a random effect into ssGLBUP equations and they were implemented in both A^{-1} and G^{-1} (Misztal *et al.*, 2013).

Validation of genomic predictions. To validate genomic predictions, we used 177 genotyped sires with at least 10 daughters with lactation records (valG). For those sires, we compared their GEBV predicted from the whole dataset ('w') with GEBV predicted from a partial dataset ('p'). The partial dataset removed phenotypes of cows recorded after 2014, so that records of daughters from those sires were not considered. GEBV of sires in valG with the whole dataset used 23,482 lactation records of 14,167 cows, 171 of which were genotyped. All GEBV were expressed in relation to the mean of GEBV for cows born in 2010 and with lactation records. GEBVs obtained with reduced data (GEBVp) and with whole data (GEBVw) were compared using statistics described in the 'LR' method (Legarra and Reverter, 2018). Predictions of GEBV and estimates of UPG effects were obtained by ssGBLUP using BLUP90iod2 program (Tsuruta *et al.*, 2001). The Γ was computed using gammaf90 program from BLUPF90 suite.

Results

Models. The original Γ showed higher extreme values than elements of Γ obtained with gamma complete estimator (Table 1). Using the gamma-robust estimator the self-relationship of MF (diagonal) was 0.776 and relationship between MF (off-diagonal) was 0.641.

Table 1. Statistics of estimated original Γ (MFO) and Γ with restricted allele frequencies (MFBou).

	MFO		MFBou	
	Diagonal values	Off-diagonal values	Diagonal values	Off-diagonal values
Minimum	0.661	-2.371	0.654	-0.259
Median	0776	0.641	0.762	0.5911
Maximum	6.302	1.354	1.478	0.709

Except for MFO, all models converged. However, EXA (average rounds: 86), MFBou and MFGrob (average rounds: 89) converged faster than PED (average rounds: 190).

Validation of genomic predictions. In Table 2, statistics of LR are described for each model, except for MFO. MBou model gave the lowest bias (108). All models had a slope that was far from one and it ranged from 0.672 to 0.699 across models. Correlations between GEBVw and GEBVp were similar for models and doubled the accuracy of GEBVs when using whole data instead of partial data.

Discussion

In this study, we assessed ssGBLUP for the genomic evaluation of Holstein in Uruguay and several methodologies were tested to include UPG in the genomic models. Bias was present in all models. MFBou, MFGrob and EXA models gave better genomic predictions than PED. In contrast, a simulated dairy cattle population, Bradford *et al.*,2019) obtained unbiased and accurate predictions with ssGBLUP and metafounders for the original Γ. Besides, Bradford *et al.* (2019) reported greatest bias and least accuracy for ssGBLUP with UPG for H in a moderate heritability trait. In our study a possible confounding among different UPGs could also happen because of a low number of animals contributing to estimate those UPGs (Misztal *et al.*, 2013). Except for MFO, all models were robust and converged, but overdispersion was observed. The low values of slope could be partly explained by the small number of bulls in the validation set (177 genotyped bulls). Our study showed a greater variation of values in the original Γ than those estimated for dairy cattle (Legarra *et al.*, 2015; Bradford *et al.*, 2019). This implies that in the Uruguayan Holstein genetic evaluation some MF represented very different base populations. The gamma complete estimator computes different values for elements of Γ. Thus, Γ would be a better proxy to reflect relationship between UPGs and we would be able to obtain less bias in genomic evaluations.

Conclusions

We found that ssGBLUP was successfully implemented in the Uruguayan Holstein genetic evaluation. Genomic models that used metafounders with the complete gamma estimator gave less biased and more accurate predictions. However, the origin of bias was not completely understood, so future studies are warranted in the definition of Γ and of UPGs to improve quality of genomic predictions.

319. Estimating metafounder relations for Finnish multibreed beef population

M. Taskinen*, A.-M. Leino, T.J. Pitkänen and E.A. Mäntysaari

Natural Resources Institute Finland, Genomics and breeding, Alimentum, Myllytie 1, 31600 Jokioinen, Finland; matti.taskinen@luke.fi

Abstract

The Metafounder (MF) concept was applied to Finnish beef cattle to harmonize the pedigree and genomic relationships. The multi-breed beef population was divided into MF groups according to available number of genotyped animals. A Gamma matrix (Γ) describing the relations between the MF groups was estimated from genomic information, augmenting the beef breeds with separately calculated allele frequencies from dairy breeds. To match the MF groups with larger number of unknown parent groups used in the breeding value evaluation, a covariance type polynomial fitting was constructed for the Γ matrix. We show that the pedigree relations can be adjusted using the Γ matrix of the MF concept to be, on average, close to the genomic relations.

Introduction

Finland is upgrading its breeding value evaluation scheme for beef cattle from traditional pedigree evaluations into genomic evaluation. As a part of this change, the current evaluation models have been changed from single to multi-breed evaluations since pure-breed populations are rather small in size and cross-breeds that link the populations are common. Further, practically all slaughter records from breeding and commercial herds can be utilized in the breeding value evaluation, improving the accuracy of the evaluations for weight traits through the genetic correlations (Pitkänen *et al.* 2021).

The project aims to build multi-breed, multi-trait single-step genomic evaluations for slaughter, weight and calving traits for pure and cross-bred Aberdeen Angus (aa), Charolais (ch), Hereford (hf), Limousin (li), and Simmental (si) animals. The pedigree structure is complicated and comprises a large number of unknown parent groups (UPG) to consider different genetic base of animals accurately. In such a setting, harmonizing pedigree (A) and genomic (G) relationship matrices according to assumptions of the same scale and equal base populations can be challenging (Christensen, 2012). We aim to obtain this goal by fitting the metafounder (MF) approach (Legarra *et al.*, 2015) to scale the A to fit G. The approach defines the base populations by specific MF groups with a certain level of self-relationships within MF and relationships across MF, contrary to the classical expectation of unknown, non-related base population in the mixed model equations (Schaeffer, 1994). Thereafter, a Gamma matrix (Γ) establishes both the relationships among the descendants of MF and the levels of inbreeding. Therefore, in addition to breed-wise differences, Γ elements should also describe possible changes with time in the MF base populations. This paper illustrates an idea of how to construct MF relations in Γ matrix for building A^{Γ} that is augmented with MF groups.

Materials & methods

In the MF concept, the MF groups replace the UPG in the pedigree. Metafounders fill-in missing parental relations in the pedigree as the MF groups are additionally related through the Γ matrix that is estimated from the genomic information.

Data and pedigree. As a starting pedigree for this work, we used a complete Finnish dairy and beef pedigree (n=10,416,246) from the Nordic dairy and beef routine evaluations because some suckler cows originated from dairy breeds. The pedigree was pruned for the multi-breed beef evaluation with RelaX2 software (Strandén

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_319, © M. Taskinen *et al.* 2022

and Vuori, 2006) by using the pedigree depth of five generations from the animals having either observations or genotypic information or both (n= 378,935). The pruned pedigree comprised 415,344 animals. The UPG (n=98) were created according to country of origin (domestic, foreign), breed group and birth year class. Breed groups of UPG were: aa, ch, hf, li, si, Blonde d'Aquitane, Highland Cattle, other beef breeds, Holstein, RDC and Finncattle, and Other that consisted, for example, of animals with unknown breed information. Animals whose main breed proportion were a minimum of 87.5% were considered pure-breds (aa 11%, ch 14%, hf 20%, li 11%, si 7%). Proportion of F1 animals in the data was 9% and other crosses and breeds 28%.

In total, 7,759 animals were genotyped (aa 1,739, ch 1,492, hf 1,495, li 1,293, si 902, other 838). The group other comprised animals that were not pure-bred. Animals were genotyped with the Euro G MD chip in which around 56 K SNP are accessible for the Nordic partners. The genotype data was cleaned with standard protocols and imputed with the FImpute software (Sargolzaei *et al.*, 2014). The final imputed genotype data comprised 39,608 SNP markers for the beef animals.

Metafounder groups. The grouping of the MFs depends on the number of available genotyped animals for each group. Most of the genotypes of this study were from the five most common pure beef breed animals (aa, ch, hf, li, and si). These breeds also had enough genotyped foreign animals to be able to build separate MF groups according to the country of origin. Because the pruned pedigree included some ancestors of the dairy breeds, three dairy MF groups were formed (RDC, Finncattle (FIC), and Holstein). All other pure- and cross-bred animals were placed to group 'Others'. In addition to breed wise differences, the genotypes should also describe the changes in time in the MF base populations. However, only the five domestic pure-bred MF groups had enough genotyped animals to be able to create more than one birth year classes. All other MF groups comprised a single year-class only.

Estimation of Γ matrix. In this study, information for building the Γ matrix was calculated using Bpop program (Strandén and Mäntysaari, 2020) that estimates allele frequencies (AF) of missing parent groups in a pedigree pruned to certain depth from the genotyped animals for the estimation of the Γ matrix. The pruning depth is here a crucial parameter in the estimation of the Γ matrix as the contribution of the genomic information to the MF groups depends on the distribution of the missing parents in the Γ estimation pedigree. With higher pruning depth most of the missing parents are located further away from the genotyped animals diluting the contribution and shifting the mean birth years of the missing parents of the groups further to the past. Here, the mean birth year of the missing parents determines the temporal location of the MF group.

Because of the low number of genotyped animals, AF were estimated in this study using pruning depth zero, defined as removing all but genotyped parents. This was done for all breed groups except for group Others. As the ancestors of cross-bred animals of the group Others were commonly pure-breds, the cross-bred genotyped animals contributed mostly to the pure-bred MF groups, not to the group Others. Therefore, AF of group Others were estimated from a pedigree that had no parental information at all. This is effectively the same as using the mean AF.

The Γ matrix was calculated from AF using the method of moments (Garcia-Baccino *et al.*, 2017), i.e. from $\Gamma=8 \times \text{var}(AF)$.

Augmenting Γ matrix with the dairy breeds. The Γ matrix was further augmented using blocks derived from AF of the dairy breeds (Kudinov *et al.*, 2020). Only the common SNPs of the Euro G MD chip were used for the off-diagonal blocks. Out of the 39,608 beef SNPs, 37,614 were common with RDC/FIC and 37,288 with Holstein. Furthermore, RDC/FIC and Holstein had 36,995 common SNPs.

Time trend fitting for Γ matrix. The multi-breed, multi-trait breeding value evaluation has more UPG than the Γ matrix constructed above. Especially since all breeds have more than one (birth) year class, whereas only the domestic pure-breds from the five common MF groups consisted of two year classes. In order to obtain matching MF groups for the other birth years, a covariance function fit (Kirkpatrick *et al.*, 1994) was constructed for the Γ matrix:

$$\Gamma = \phi K \phi^{\Gamma} \quad (1)$$

where each row of the ϕ matrix is

$$\phi_i = [0, \ldots, 0, y_i\text{-}d_i, 0, \ldots, 0, 1, 0, \ldots, 0] \quad (2)$$

having a linear time factor coefficient y_i-d_i with a mean birth year y_i of the MF group i and a 'base population year' d_i (described below), and a coefficient 1 for a constant term located on certain columns of the row-vector ϕ_i. The symmetric matrix K contains unknowns of linear time factors, as well as constant terms, and it can be solved using least-squares from:

$$K = (\phi^{\Gamma}\phi)^{-1}\phi^{\Gamma}\Gamma\phi(\phi^{\Gamma}\phi)^{-1} \quad (3)$$

Once the matrix K is solved, more Γ matrix values can be interpolated (and extrapolated) by replacing the years y_i in the Equation 1 with the mean birth years of the UPG of the evaluation. This effectively applies a bilinear function:

$$\Gamma_{i,j}(x,y) = a_{i,j}(x\text{-}d_i)(y\text{-}d_j) + b_{i,j}(x\text{-}d_i) + b_{j,i}(y\text{-}d_j) + c_{i,j} \quad (4)$$

as relation between breeds i and j where x and y are the mean birth years of the groups and $a_{i,j}$, $b_{i,j}$, $b_{j,i}$, and $c_{i,j}$ are corresponding solved unknowns of the K matrix.

A well-known problem in polynomial functions is their poor ability to extrapolate the predictions outside the data range. As the number of genotyped animals was quite small in this study, the polynomial fitting needed further restrictions for the within-breed group relation terms $\Gamma_{i,i}(y,y)$ to prevent them from growing too high in the past. For this, the time derivatives of the within-breed group relations $\partial_y \Gamma_{i,i}(y,y)$ were forced to be zero at the base population years, d_i, by setting the corresponding b terms to zero in the K matrix. In this study, d_i were set to 1988 for all breeds. Furthermore, the time factors of the domestic pure-bred MF groups were shared with the corresponding foreign MF groups in order to be able to fit the time trend of the domestic groups to the foreign groups as well.

Results

For the forthcoming beef cattle single-step evaluations, Γ matrix was interpolated / extrapolated to separate year-classes for all decades starting from 1980 except for the group Others that had only a single year class. Averages of Γ matrix adjusted pedigree relations (A^{Γ}) and genomic relationships (G) were then calculated for groups of genotyped animals. Figure 1 compares the former (left image) with the latter (right) by grouping the genotyped animals to separate year classes, given the breed group comprised enough genotyped animals. The A^{Γ} relations are on average quite close to the genomic relationship values.

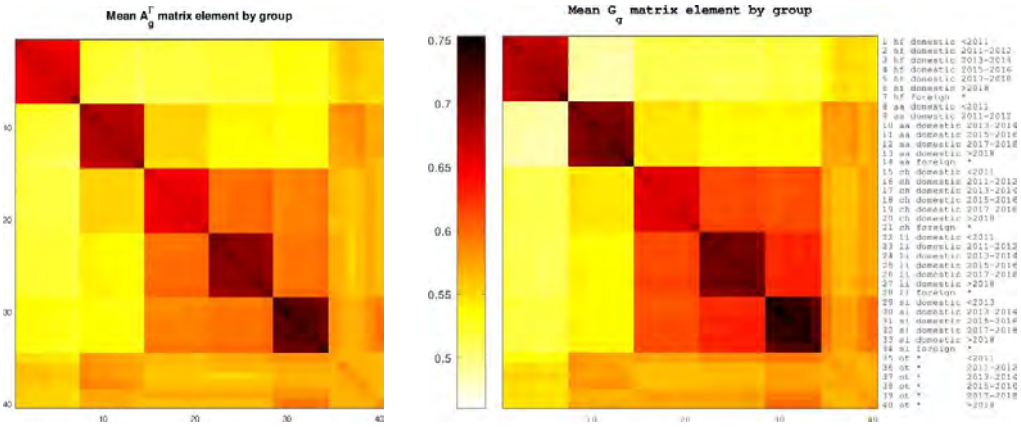

Figure 1. Averages of pedigree relations with metafounders (left) and genomic relationships (right) for genotyped animals by breed groups and year classes.

Discussion

It was shown that the modelling of complicated Γ matrix is possible, and the relationships using the MF concept become, on average, close to the genomic relations. The constructed Γ matrix can be further refined when the number of genotyped animals increases in the near future.

Abstract

For various applications in dairy cattle evaluation, pseudo-phenotype data are needed for cows with own records or bulls with daughters. The purpose of this paper was to develop a GEBV deregression method for the single-step model using all genotype data. A special single-step SNP BLUP model was assumed in this study to deregress GEBV. All animals with own phenotype data and all genotyped animals including young candidates were considered in the GEBV deregression. The same pedigree file as well as the same genotype data were used in the deregression process as the original single-step evaluation. Thanks to the efficient single-step SNP BLUP model, the proposed GEBV deregression should be feasible for analysing millions of genotyped animals. Methodological and technical issues were addressed, and a validation procedure was proposed for the GEBV deregression method. Analysis of real data will be required to verify the developed GEBV deregression method.

Introduction

Pseudo-phenotype of animals are useful data for diverse genetic or genomic analyses. By definition, pseudo-phenotype data should ideally be corrected for all model effects, such as fixed and non-genetic random effects, so that only additive genetic effects and random errors remain in the pseudo-phenotype records. The special property of the pseudo-phenotype data makes genetic or genomic evaluations easier that will be based on the pseudo-phenotype records, because only the additive genetic effects need to be estimated. Daughter yield deviations (DYD, VanRaden and Wiggans 1990; Liu *et al.* 2004) and deregressed proofs (Jairath *et al.* 1998) are two commonly used forms of pseudo-phenotype data. Calculation of DYD for complex statistical models like the random regression test-day model (Liu *et al.* 2004) is technically challenging. In contrast, EBV or proof deregression can be applied to any linear function of estimated breeding values (EBV) to bypass complex evaluation models, such as multi-lactation random regression test-day model or maternal effects model. A single-trait single-effect model can be applied in most cases for the proof deregression. Therefore, the proof deregression provides an easier alternative than the DYD calculation for generating pseudo-phenotypic data. The main objective of this study was to derive deregressed GEBV of a single-step SNP BLUP model (ssSNPBLUP, Liu *et al.* 2014) for bulls with daughters or cows with own phenotypic records using all available genotype data.

Materials & methods

Estimation of breeding values of animals can be understood as a process of regressing phenotype data on additive genetic effects of the animals using pedigree information. The deregression of EBV is to reverse the regression process in the genetic evaluation process (Jairath *et al.* 1998) to obtain the pseudo-phenotype data for the animals with own phenotype records. In literature, many non-iterative deregression methods were proposed. However, the deregression methods on an animal-by-animal basis, termed as scalar deregression, were proven to be only sub-optimal by Calus *et al.* (2016). The iterative deregression method (Jairath *et al.* 1998), also called matrix deregression, uses the pedigree and was demonstrated to be accurate and the deregression process was proven to be reversible (Mark *et al.* 2002; Calus *et al.* 2016).

A GEBV deregression method for the single-step SNP BLUP model. The deregression of conventional EBV (Jairath *et al.* 1998) makes use of the inverse of numerator relationship matrix A. Masuda *et al.* (2021) suggested using the inverse of the unified genomic relationship matrix H for deregressing GEBV of the single-step GBLUP model (Misztal *et al.* 2009). The idea of using H^{-1} for the GEBV deregression had also been independently proposed by Esa Mäntysaari and Zengting Liu of the Interbull working group Genomic-free EBV for MACE in 2019. A major concern of the GEBV deregression using the H^{-1} matrix was raised because of a fast-increasing, large number of genotyped cows seen in many countries like the United States and Germany. Therefore, we propose here a GEBV deregression method assuming the single-step SNP BLUP model (ssSNPBLUP, Liu *et al.* 2014) that can efficiently utilize all genotype data of up to millions of genotyped animals. For deregressing GEBV of the single-step genomic evaluation, we assume a special ssSNPBLUP model:

$$y = \mu 1 + u = e \tag{1}$$

where y is a vector of deregressed GEBV of animals with own phenotype data, 1 is a vector of 1s, μ is a general mean, u is a vector of GEBV for the animals with own phenotype data or for genotyped animals, and e is a vector of residuals. Denote σ_u^2 as additive genetic variance. The deregressed GEBV y are unknown and will be estimated. We assume that:

$$[var(\mathbf{e})]^{-1} = \mathbf{D}\sigma_e^{-2} = diag\{n_i\}\sigma_e^{-2} \tag{2}$$

where D is a diagonal matrix containing effective daughter contribution (EDC) of bulls with daughters or effective record contribution (ERC) of cows with own phenotype records on the animal-model basis, n_i is EDC or ERC for animal i, $i = 1, \ldots, n$, and n is the number of animals with phenotype data. σ_e^2 is residual variance. We use genotype data of all animals, including culled animals or young animals, for the GEBV deregression. In addition, all animals with any source of phenotype data are included in the deregression process. The definition of animals with own phenotype data depends on the applied single-step model. For the single-step evaluation with phenotype data coming exclusively from one country or population, the animals with own phenotype data are usually domestic cows with own phenotypic records. In the single-step evaluation without foreign phenotype data, bulls with daughters are not considered as animals with own phenotype data here rather as ancestors, because their domestic daughters are treated as animals with own records.

Mixed model equations for the GEBV deregression. As stated above for the single-step evaluation without foreign phenotype data, all cows with own phenotype data as well as all genotyped animals are treated as animals with data in the GEBV deregression. We denote the number of non-genotyped animals with own phenotype n_{NP}. Let n_T be the total number of genotyped or phenotyped animals. As usual, we define non-genotyped or genotyped animals as Group 1 or 2, respectively. Ancestors of the genotyped animals (Group 2) or phenotyped and non-genotyped animals (Group 1) are denoted as Group 0. Unknown parent groups (UPG) for the special ssSNPBLUP model (1) are set up via the Quaas-Pollak transformation according to Vandenplas *et al.* (2021a). We use matrix Q_2 to assign the genotyped animals to their UPG. Furthermore, we use a diagonal matrix for ERC for the non-genotyped animals with phenotype data (Group 1):

$$\mathbf{W}_1 = diag\{n_{11} \quad n_{21} \quad \cdots \quad n_{n_{NP}1}\} \tag{3}$$

Likewise, ERC for the genotyped animals of Group 2 are represented with a diagonal matrix as well:

$$\mathbf{W}_2 = diag\{n_{12} \quad n_{22} \quad \cdots \quad n_{n_g 2}\} \tag{4}$$

If a genotyped animal has no phenotype, e.g. a young calf, then its ERC is 0. Under the assumption of known SNP effects available, right hand side (RHS) of GEBV for all the genotyped animals can be modified prior to the deregression process, following the idea of Vandenplas *et al.* (2021b). Mixed model equations without the SNP effects are given in Equation 5 for the GEBV deregression.

$$\begin{bmatrix} \mathbf{1}'\mathbf{W}_1\mathbf{1} + \mathbf{1}'\mathbf{W}_2\mathbf{1} & \mathbf{0} & \mathbf{0} & \mathbf{1}'\mathbf{W}_1 & \mathbf{1}'\mathbf{W}_2 \\ & \lambda\mathbf{A}^{tt} + \lambda(\frac{1}{k} - 1)\mathbf{Q}_2{}'\mathbf{A}_{22}^{-1}\mathbf{Q}_2 & \lambda\mathbf{A}^{t0} & \lambda\mathbf{A}^{t1} & \lambda\mathbf{A}^{t2} - \lambda\left(\frac{1}{k} - 1\right)\mathbf{Q}_2{}'\mathbf{A}_{22}^{-1} \\ & & \lambda\mathbf{A}^{00} & \lambda\mathbf{A}^{01} & \lambda\mathbf{A}^{02} \\ & & & \mathbf{W}_1 + \lambda\mathbf{A}^{11} & \lambda\mathbf{A}^{12} \\ & symm. & & & \mathbf{W}_2 + \lambda(\mathbf{A}^{22} + \left(\frac{1}{k} - 1\right)\mathbf{A}_{22}^{-1}) \end{bmatrix} \times \begin{bmatrix} \hat{\mu} \\ \hat{\mathbf{t}} \\ \hat{\mathbf{u}}_0 \\ \hat{\mathbf{u}}_1 \\ \hat{\mathbf{u}}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{1}'\mathbf{W}_1\mathbf{y}_1 + \mathbf{1}'\mathbf{W}_2\mathbf{y}_2 \\ -\lambda\frac{1}{k}\mathbf{Q}_2{}'\mathbf{A}_{22}^{-1}\mathbf{Z}\hat{\mathbf{g}} \\ \mathbf{0} \\ \boldsymbol{\Delta}_1 \\ \boldsymbol{\Delta}_2 + \lambda\frac{1}{k}\mathbf{A}_{22}^{-1}\mathbf{Z}\hat{\mathbf{g}} \end{bmatrix} \tag{5}$$

where $\hat{\mathbf{g}}$ is a vector of SNP effect estimates assumed to be known without error, t denotes additive genetic effects of UPG, Z is a design matrix of order $n_g \times m$ containing all genotypes, n_g is the number of the genotyped animals of Group 2, m is the number of SNP markers fitted, and A_{22} is pedigree relationship for the genotyped animals, k is the proportion of residual polygenic variance not explained by the SNP markers, $\lambda = \sigma_e^2/\sigma_u^2$ is the variance ratio. RHS for the non-genotyped animals with own phenotypes (Group 1) or the genotyped animals (Group 2) are respectively:

$$\boldsymbol{\Delta}_1 = \mathbf{W}_1\mathbf{y}_1 = \{n_{i1}y_i\} \tag{6}$$

$$\boldsymbol{\Delta}_2 = \mathbf{W}_2\mathbf{y}_2 = \{n_{i2}y_i\} \tag{7}$$

where n_{i1} or n_{i2} represent EDC or ERC of the i-th animal of Group 1 or 2, respectively.

Following the idea of the iterative deregression method by Jairath *et al.* (1998), the input GEBV of the n_T animals with either own phenotype or genotype data must be kept unchanged when solving Equation 5, only GEBV of the ancestors (Group 0 animals), the unknown parent groups, and the general mean need to be estimated.

When the solutions of Equation 5 are converged, RHS for the non-genotyped animals with own phenotype data (Group 1) are calculated as:

$$\Delta_1 = \mathbf{W}_1\mathbf{1}\hat{\mu} + \lambda\mathbf{A}^{10}\hat{\mathbf{u}}_0 + (\mathbf{W}_1 + \lambda\mathbf{A}^{11})\hat{\mathbf{u}}_1 + \lambda\mathbf{A}^{12}\hat{\mathbf{u}}_2 \tag{8}$$

RHS for the genotyped animals (Group 2) are computed with:

$$\Delta_2 = \mathbf{W}_2\mathbf{1}\hat{\mu} + \lambda\mathbf{A}^{20}\hat{\mathbf{u}}_0 + \lambda\mathbf{A}^{21}\hat{\mathbf{u}}_1 + \left(\mathbf{W}_2 + \lambda\left(\mathbf{A}^{22} + \left(\tfrac{1}{k} - 1\right)\mathbf{A}_{22}^{-1}\right)\right)\hat{\mathbf{u}}_2 - \lambda\tfrac{1}{k}\mathbf{A}_{22}^{-1}\mathbf{Z}\hat{\mathbf{g}} \tag{9}$$

If animal *i* with own phenotype is not genotyped, its deregressed GEBV is:

$$\hat{y}_i = \Delta_{i1}/n_{i1} \tag{10}$$

Otherwise, if the animal *i* with phenotype data is genotyped, its deregressed GEBV is:

$$\hat{y}_i = \Delta_{i2}/n_{i2} \tag{11}$$

where Δ_{i1} or Δ_{i2} are the i-th element of Equation 8 or 9 corresponding to animal *i*, respectively. Because animals without own phenotype data have zero EDC or ERC, only animals with own phenotype data have a deregressed GEBV.

A validation of the GEBV deregression method for the single-step evaluation. A designated genomic evaluation based on the special single-step SNP BLUP model 1 needs to be conducted for validating the proposed GEBV deregression method. The input pseudo-phenotype data for the validation study are the deregressed GEBV for all animals that had own phenotype data in the original single-step evaluation. All genotyped animals that have been evaluated in the original single-step model must be included in this validation, too. For genotyped animals without own phenotypes, e.g. young candidates, their phenotype data are treated as missing in the validation study, because those genotyped animals without own phenotype records have no defined deregressed GEBV. The SNP effect estimates from the original single-step evaluation must be assumed to be known without error. Mixed model Equation 5 can be solved as a pure conventional model. After the solutions of Equation 5 are converged, GEBV of all the animals with phenotype or genotype data are compared to the original single-step genomic evaluation. If the GEBV from the validation evaluation are equal to those from the original single-step evaluation, then the GEBV deregression process is proven to be correct and the GEBV degression process is verified to be reversible.

Results & discussion

Generation of accurate pseudo-phenotype data is required by numerous statistical analyses in animal breeding. We have developed a GEBV deregression method for single-step evaluation based on a single-step SNP BLUP model (Liu *et al.* 2014). All animals with phenotype data and all animals with genotypes, including genotyped young candidates, must be considered in the GEBV deregression process as in the original single-step evaluation. We use the SNP effect estimates from the original single-step evaluation for the deregression process. Thanks to the high efficiency of the ssSNPBLUP model, this GEBV deregression method is feasible for handling millions of genotyped animals.

One major concern about the deregressed GEBV is that they may lead to an inflation of the conventional MACE evaluation. This inflated variance of evaluation can be avoided if we can exactly reverse-engineer the single-step evaluation in the GEBV deregression process. Obviously, the single-step evaluation and the following GEBV deregression must not include foreign bulls' phenotype data for the purpose of submitting national deregressed GEBV of bulls to the current conventional MACE evaluation.

In this study we made only a theoretical contribution to the topic of GEBV deregression for the single-step model. The proposed deregression method must be verified by applying a reversibility test to filed data.

321. Variance component estimation for single-step genomic BLUP for Australian terminal sire sheep

P.M. Gurman[1*], L. Li[1], A.A. Swan[1], N. Moghaddar[2] and J.H.J. van der Werf[2]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]University of New England, NSW 2351, Australia; pgurman@une.edu.au

Abstract

Many national genetic evaluation systems have transitioned to single-step genomic BLUP (SS-GBLUP) for breeding value estimation utilising variance components estimated from pedigree-based REML. The genomic and numerator relationship matrices are often weighted in SS-GBLUP by a parameter λ, that minimises bias and increases accuracies and is set to 0.5 in Australian sheep analyses. This study estimates variance components from genomic relationship matrices weighted by λ ranging from 0 to 1 by genomic REML. The impact of using these variances for each λ was then examined in SS-GBLUP models via cross-validation metrics. Data on terminal sire sheep in Australia were analysed using univariate models for carcase and live weight traits. We found that the maximum log-likelihood was estimated at lambda values between 0.5 and 0.875, while cross-validation results suggest that increasing accuracies can be achieved with increasing λ towards one and no significant change to bias using estimated variance components.

Introduction

National genetic evaluations have largely transitioned to single-step genomic BLUP where sufficient genotypes are available. This transition occurred for Australian sheep in 2017 (Brown *et al.*, 2018). Variance components for these analyses have often reused the same components that were derived from, and used in pedigree-based BLUP analyses. Further, it was identified that blending the genomic relationship matrix (G) with part of the numerator relationship matrix (A_{22} for genotyped animals) ($\lambda G + (1 - \lambda)A_{22}$) helped to increase accuracy and reduce the bias that was observed when including genomic data (McMillan and Swan, 2017; Zhang *et al.*, 2017), either correctly weighting the genomic and pedigree information, or underutilising the genomic information. Recent studies have investigated using either sampling-based methods or genomic REML (GREML) based methods to fit two effects simultaneously to examine how the variance partitions between the two effects (with the ratio between the two effects being λ), a pedigree-based genetic effect using the numerator relationship matrix and a genomic-based genetic effect using the single-step relationship matrix H (Samaraweera *et al.*, 2021; Torres-Vázquez *et al.*, 2021). This study investigates the impact of G constructed for a range of λ values on variance component estimates, log-likelihood values, and SS-GBLUP cross-validation metrics to determine what is the optimal value of λ for use in SS-GBLUP analyses.

Materials & methods

Data for 9,688 terminal sire sheep were extracted from the Sheep Genetics LAMBPLAN terminal sire analysis, along with pedigree information on their ancestors. These animals were selected for simultaneous phenotypic recording for carcase and live weight traits including intramuscular fat (IMF, %), shear force (SF5, newtons), carcase eye muscle depth (CEMD, mm), carcase c-site fat (CCFAT, mm), carcase weight (CWT, kg) and post-weaning weight (PWT, kg). These animals are mostly from the Sheep Cooperative Research Centre Information Nucleus Flock (van der Werf *et al.*, 2010) and the Meat and Livestock Australia Resource Flock populations which form the genomic reference population for Australian sheep, so all animals were genotyped and were recorded for all phenotypes Phenotypes were pre-adjusted as part of routine evaluation for combinations of birth type, rearing type, age of measurement, age of dam, and hot carcase weight, depending on the trait. Contemporary groups for IMF, SF5, CEMD, CCFAT, and CWT

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_321, © P.M. Gurman *et al.* 2022

were based on kill group, while PWT was based on breed, flock, management group and sex. A breed-adjusted genomic relationship matrix was constructed (Makgahlela *et al.*, 2013), which utilised multiple sets of allele frequencies to reduce breed level misalignment between pedigree and genomic relationship matrices.

Univariate variance component estimation was performed using MTG2 (Lee and Van der Werf, 2016). The model used was $y = X\beta + Zu + ZQg + Zm + \varepsilon$ where y is the vector of pre-adjusted phenotypes for fixed effects; X is the design matrix for the fixed effects (contemporary groups); β is the vector of contemporary group solutions, Z is the design matrix for the random effects associated with breeding values for individual animals (animals with records by breeding values), which in this case is I; u is the vector of random additive genetic effects with $N(\mathbf{0}, \boldsymbol{G}_w\sigma_a^2)$; G_w is the weighted G $G_w = \lambda G + (1 - \lambda)A_{22}$); Q is the matrix of genetic group proportions, defined by the breed of origin from the pedigree; g is the vector of random genetic group effects with $N(\mathbf{0}, \boldsymbol{QQ}'\sigma_g^2)$; M is the design matrix for the random maternal permanent environment effects; m is a vector of random maternal effects only fitted for two weight traits (CWT and PWT) with $N(\mathbf{0}, \boldsymbol{MM}'\sigma_m^2)$ and ε is the vector of residuals effects with $N(\mathbf{0}, \boldsymbol{I}\sigma_e^2)$. All random effects were fitted as an animals by animals matrix, to accommodate MTG2. For GREML, the value of λ was varied between 0 and 1 in steps of 0.05.

The single-step cross-validation was performed as a 5-fold analysis. The 9,688 animals were randomly allocated into one of the five folds, stratified by breed and sire family. This process was repeated five times resulting in five replicates of five-folds and 25 SS-GBLUP analyses, where the phenotypes for the validation animals were removed from the analysis and EBVs calculated. These cross-validation analyses followed the same model as the GREML analyses, except that the inverse of the appropriate joint relationship matrix, H^{-1}, was used instead. Five cross-validation metrics are presented, for which we define the following for the validation animals: y^* as the phenotypes adjusted for contemporary group solutions from the model with appropriate λ; $\hat{u}_p$ as the EBVs from the partial analyses (data removed for the validation animals); $\hat{u}_w$ as the EBVs from the whole analyses (data retained for the validation animals), K as the subblock of H for the validation animals, and $\sigma_{a,\infty}^2$ as the genetic variance at equilibrium in a population under selection, assumed for simplification to be σ_a^2 and h is the square root of the heritability. Traditional accuracies were calculated as $cor(y^*, \hat{u}_p)/h$ and the dispersion as the regression of phenotype on EBV. Metrics based on Legarra and Reverter (2018) using the method LR (from 'linear regression') were also calculated: LR accuracies as:

$$\sqrt{\frac{cov(\widehat{\mathbf{u}}_p, \widehat{\mathbf{u}}_w)}{(diag(\boldsymbol{K}) - \bar{\boldsymbol{K}}) \times \sigma_g^2}};$$

LR bias as $(\overline{\widehat{\boldsymbol{u}}_p} - \overline{\widehat{\boldsymbol{u}}_w})/\sigma_a$ and LR dispersion as $cov(\widehat{\boldsymbol{u}}_p, \widehat{\boldsymbol{u}}_w)/var(\widehat{\boldsymbol{u}}_p)$.

Results

The variance components estimated for each value of λ are presented in Figure 1, along with a vertical dotted line at the value of λ where the maximum log-likelihood value was observed, between 0.5 and 0.85 across the six traits. The genetic variance increased from a pedigree only model (i.e. λ=0), reaching a peak around λ=0.25 and decreasing as λ continued to increase. The residual variance followed an inverse pattern to the genetic variance. For most traits, the maximum log-likelihood was observed at the λ value where the genetic variance was similar to that observed at λ=0. It should also be noted that the genetic group variances were not, as is often assumed, equal to the genetic variances. For IMF, SF5 and CEMD, the ratio of genetic group variance to the genetic variance was between 0.06 and 0.6, while for the two weight traits (CWT and PWT) the ratio was between 1.97 and 4.4. The only trait where the ratio crossed one over the range of λ was CCFAT, which was between 0.76 and 1.52.

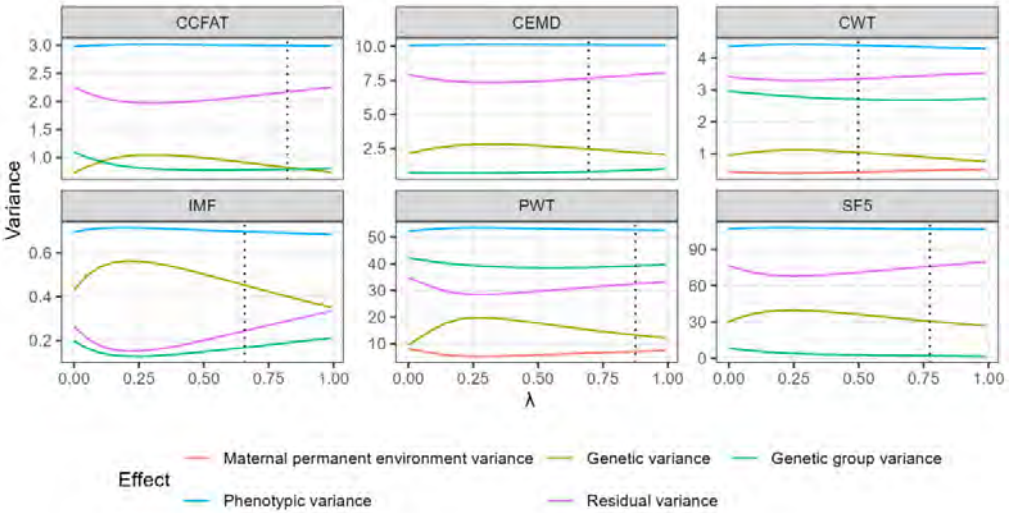

Figure 1. Variance components estimated for each value of λ. Vertical dotted lines indicate the λ value where the optimal log-likelihood value was estimated. Trait abbreviations are defined in the Materials & methods.

For the cross-validation analyses (Figure 2), both the phenotypic and LR accuracies show a mostly linear increase as the value of λ increases, although for λ values <0.3 for some traits a slight increase in accuracy is observed. For most traits except CWT, slight increases in traditional dispersion were observed as λ increased. This was not observed in the LR dispersions, with these dispersions being consistent over the range of λ. Finally, the LR biases were largest for CWT, CCFAT and PWT, though the latter decreased slightly at higher values of λ. No significant patterns concerning λ were observed.

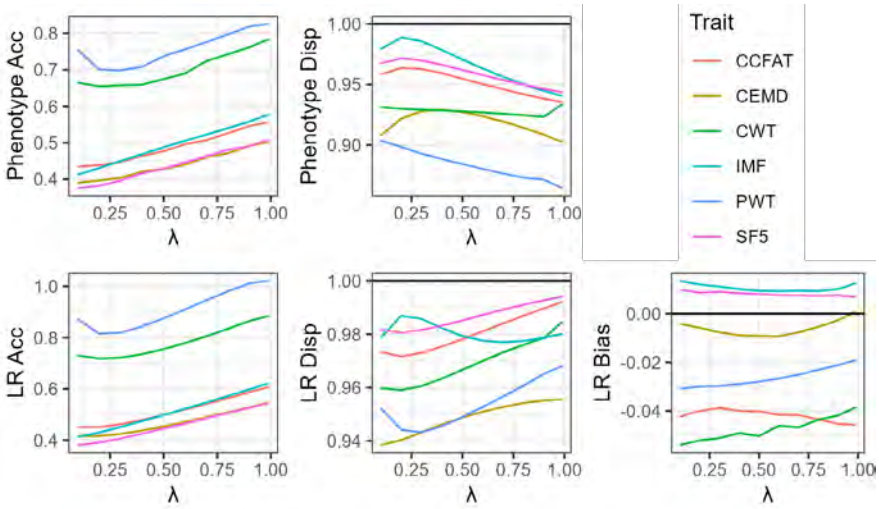

Figure 2. Cross-validation metrics calculated as the mean of the metric within each cross-validation group. Trait abbreviations are defined in the Materials & methods.

Discussion

Of note here is that the log-likelihood results and the cross-validation results provide different indications to the optimal model, due in part to the decreasing genetic variances as λ approaches one. Methods for accommodating individual λ values per trait optimally have been developed by Meyer in a paper submitted to this congress. It is unclear why the highest genetic variances were estimated around λ=0.25 which warrants further investigation. A more diverse set of traits would need to be studied to determine if the estimated heritabilities always decrease with high λ. These results would also need to be verified in models that utilise other methods for aligning A and G, e.g. metafounders and other scaling parameters (Christensen, 2012; Legarra *et al.*, 2015) and in other datasets, including for different traits and different genomic structures. The genetic group variances estimated here are of note, suggesting that where genetic groups are fitted as random, variances should be estimated for this effect and used in SS-GBLUP.

This paper finds that while log-likelihood values presented here suggest that individual λ values per trait are optimal, cross-validation suggests that using only genomic information is optimal if variance components are used that were estimated for the G used in SS-GBLUP. Further work is warranted to validate these results in other datasets.

Abstract

Single step genomic best linear unbiased prediction (HBLUP) has been widely used in livestock breeding. The HBLUP method (e.g. BLUPf90) requires hyper-parameters to combine genomic and pedigree relationships and these should be adequately initialised to maximise the accuracy of genomic prediction. In this study, we assess the performance of HBLUP, using various values of hyper-parameters in simulated genomic data. We show that the tuning parameter (tuning GRM relative to the pedigree-based numerator relationship matrix) considerably increases prediction accuracy, confirming previous studies. The scale factor, α, which scales the allele effect size by its frequency, also affects accuracy and the optimal scale factor can vary for each trait. In conclusion, fine-tuning the hyper-parameters of HBLUP is necessary to maximize prediction accuracy and the scale factor should be considered.

Introduction

Single step genomic best linear unbiased prediction uses a H-matrix that is a harmonised matrix of a pedigree-based numerator relationship matrix (NRM) and a genomic relationship matrix (GRM). The method is known as HBLUP. The H-matrix allows us to use the information of non-genotyped individuals in genomic prediction, using a data augmentation technique (see Legarra *et al.* 2009; Misztal *et al.* 2009). HBLUP has been widely used in the genetic evaluation of livestock (McMillan *et al.* 2017).

In HBLUP, there are several (hyper) parameters that can determine the performance of HBLUP.

Firstly, blending is important because it ensures GRM being a positive definite matrix (VanRaden 2008) thereby avoiding numerical problems in HBLUP (Legarra *et al.* 2009). Secondly, tuning is important because it adjusts the scale of GRM relative to that of NRMbefore inverting. Given that GRM is based on samples in the last few generations (genotyped individuals) whereas pedigree has been recorded from the founders, tuning can correct for this scale difference (Legarra *et al.* 2009; Miztal *et al.* 2009). Thirdly, parameters required to construct GRM may be important. A pairwise genomic relationship is the product of scaled genotypic coefficients of two random individuals (VanRaden 2008; Yang *et al.* 2010). Speed *et al.* (2012) generalised these forms, introducing a scale factor (α) that can determine the genetic architecture of a complex trait (aka heritability model).

In this study, we investigate the hyper-parameters required to estimate GRM to see how they affect the accuracy of HBLUP. First, various values of tuning and blending hyper-parameters were applied and compared to assess the performance of HBLUP, using simulated data with various scenarios of the historical population. In the analyses, we used the direct average information algorithm (Lee *et al.* 2006; Yang *et al.*

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_322, © M. Neshat *et al.* 2022

2011) that is robust to non-positive definite GRM so that we can assess all sorts of blending values including blending = 1. This is followed by exploring various values for the α of GRM that can determine the genetic architecture of a complex trait (heritability model).

Materials & methods

Simulated data. QMSim software (Sargolzaei *et al.* 2009) was used to simulate the historical population for 100 generations. In each generation, 50 males and 500 females were randomly selected and mated, generating 1000 offspring. Nine thousand biallelic markers in total were simulated, which were equally distributed across 30 chromosomes. Phenotypes were simulated for a complex trait, varying the scale factor (α=0 or -0.5) (Gowane *et al.* 2019). For the HBLUP analyses, the last five generations were recorded for phenotype and pedigree (n=5,000) and the last two generations were genotyped (n=2,000). To assess HBLUP accuracy, 1000 individuals were randomly selected from the last two generations as the target dataset, and the remaining 4,000 samples (1000 genotyped and 3,000 ungenotyped) were used as the discovery dataset.

Bending and tuning of GRM in HBLUP. The blending process can adjust the GRM to be a positive definite matrix (Legarra *et al.* 2009, Misztal *et al.* 2009). The adjusted GRM, referred to as $G_{blended}$, can be expressed as:

$$G_{blended} = \theta G + (1-\theta)A_{22} \quad \forall\ 0 \leq \theta \leq 1 \tag{1}$$

where θ is a positive coefficient to achieve a balance between GRM and the part of NRM (A_{22}) that is corresponding to the numerator relationships between the genotyped individuals.

Subsequently, the tuning process can be applied to adjust the scale of the GRM relative to that of the NRM. Following Legarra *et al.* (2014), the adjusted GRM is tuned as

$$G_{tuned} = \beta G_{blended} + \omega \mathbf{J} \tag{2}$$

where J is a matrix with the same size of GRM, and all elements are equal to one, and ω and β are computed as:

$$\omega = \frac{(I A_{22}\, I - I \hat{G} I)}{n^2} \qquad \beta = \frac{\frac{\left[\sum_{i=1}^{n} A_{22_{i,i}} - I' A_{22} I\right]}{n}}{\frac{\left[\sum_{i=1}^{n} G_{i,i} - I' G I\right]}{n}} \tag{3}$$

where I is an array with the size of $n \times 1$ and all values equal to one.

Genomic relationship matrix (GRM) and scale factor (α). It is assumed that the relationship between genetic variance and allele frequency can change depending on the evolutionary forces such as selections, mutation, migrations, and genetic drift. In the following equation, we can see that the variance of the ith genetic variant (v_i) is a function of the allele substation effect (β_i) and the allele frequency (p_i), which can be written as (Momin *et al.* 2021)

$$Var(v_i) = 2p_i(1-p_i)^{1+2\alpha} \times {\beta_i}^2 \tag{4}$$

where α is the scale factor that can determine the relationship between genetic variance and allele frequency, i.e. the genetic architecture of a complex trait. In the infinitesimal model (Falconer and Mackay 1996), α is assumed to be zero for all traits. An alpha value of -0.5, assumes that the genetic variance of the causal variant has a uniform distribution across tits minor allele frequency spectrum. However, it has been

reported that the value of α can vary, depending on trait and population (Momin *et al.* 2021; Speed *et al.* 2017; Speed *et al.* 2012). The generalised form of the GRM with the hyper-parameter of alpha (Speed *et al.* 2012) can be written as

$$G_{ij} = \frac{1}{d}\sum_{l=1}^{L}\left[(x_{il} - 2p_l)(x_{jl} - 2p_l)\right][2p_l(1-p_l)]^{2\alpha} \quad (5)$$

where G_{ij} is the genomic relationship between the i^{th} and j^{th} individuals, the number of SNPs is L and d is the expected diagonals and computed as:

$$d = L \cdot \mathbb{E}[(x_{il} - 2p_l)^2[2p_l(1-p_l)]^{2\alpha}] \quad (6)$$

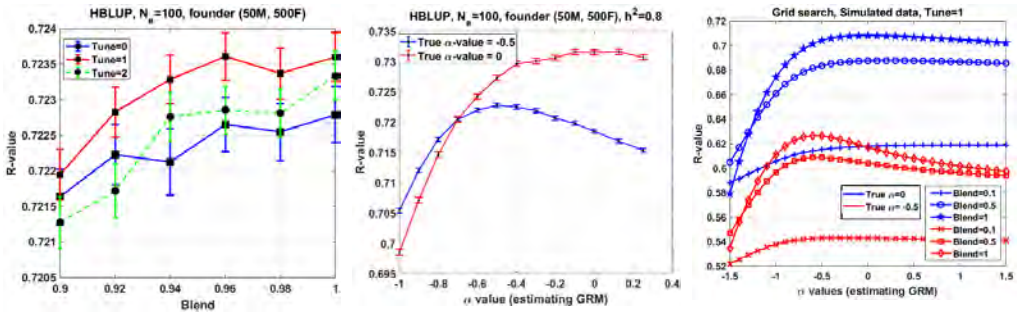
Statistical models. In this paper, we used genome-based restricted maximum likelihood (GREML) and HBLUP, based on linear mixed models, to predict individual breeding values (Gao *et al.* 2012).

Results

Figure 1a shows that the tuning process significantly improves the prediction accuracy (Pearson corelation coefficient (R-value) between true and estimated breeding value), confirming previous studies. Blending with θ<1 is not really improving the performance of HBLUP. The tuning parameter (tune=1, Eq. 3) based on Legarra *et al.* (2009) performed better than tune=2 (Eq. 3 except for β=1). Figure 1b shows that the choice of the α value (scale factor) is important and an optimal α can improve the prediction accuracy. As expected, the highest prediction accuracy is achieved when using the true α value. As shown in Figure 1c, the best configuration of the hyper-parameters could be obtained, using a grid search that considered blend, tune and alpha (scale factor) simultaneously.

Discussion

A blending strategy was not effective in improving the accuracy of HBLUP for various historical population scenarios (result not shown) although one study reported that blending could increase the prediction accuracy in dairy cattle (Gao *et al.* 2012). The second observation was that the tuning methods on the H-matrix could significantly increase the prediction accuracy. We compared three tuning methods



(a) **(b)** **(c)**

Figure 1. HBLUP accuracy and hyper-parameters. (a) The HBLUP accuracy (R-value) improves when using tune=1 (Equation 3) or tune=2 (Equation 3 except β=0 Vitezica *et al.* 2011). However, blending (θ<1) would not increase the accuracy for this simulated dataset. The error bars are 95% CI over 3,000 replications. (b) The HBLUP accuracy increases when using the true α values used in the simulation. The error bars are 95% CI over 3,000 replications. (c) The HBLUP accuracy for a single simulation replicate using a grid search method where the prediction accuracy was measured from 5-fold cross validation.

including tune=1 (based on Legarra's method (2009)), tune=2 (based on Vitezica *et al.* 2011), and tune=0 (i.e. without tuning). It is well known that alpha can vary across populations and traits (Momin *et al.* 2022). We show that the effect of α on the HBLUP accuracy was considerable. Our findings confirm that fine-tuning the hyper-parameters of HBLUP is necessary where the scale factor, a novel hyper-parameter in the context of HBLUP, should be considered. It is recommended that a grid search or similar optimisation algorithm should be used to find the best configuration for these hyper-parameters including blending, tuning and alpha.

Abstract

Predictive abilities of single-step (SS) and multi-step (MS) evaluations were compared using current and truncated domestic phenotypes for U.S. yield traits. Accuracy from SS was several percentage points higher than MS to predict either MS or SS current genomic estimated breeding values (GEBV) of 2,619 Holstein and 345 Jersey bulls from 4-year earlier data. Regressions for GEBV were close to 1.0 and similar for MS and SS for all traits and both breeds. Accuracy advantages of SS have increased since a previous study, perhaps indicating more bias from genomic preselection in MS. The MS methods put too much weight on pedigree evaluation, whereas the SS model had no polygenic effect and was more stable because new phenotypes have little influence on marker effects. Further testing will include more traits, foreign data from Interbull, and crossbreds to determine the potential to use SS methods.

Introduction

Most dairy cattle genomic evaluations still use MS methods, but recent research has improved both efficiency and accuracy of SS methods, and genomic preselection may increasingly bias MS methods. This study compares SS methods to official MS methods applied to the current or truncated domestic U.S. yield records. Previous reports (Masuda *et al.*, 2018a,b) included only Holstein records and less recent data than in the all-breed dataset now available. Masuda *et al.* (2018a) predicted 2015 protein daughter yield deviations from 2011 truncated Holstein phenotypes. They found little difference between SS and MS accuracy and regressions when unknown parent groups were applied only to pedigree but not to genomic relationships. Those earlier comparisons reported R^2 of 52% for SS and 51% for MS with corresponding regressions of 0.78 for SS and 0.81 for MS. Masuda *et al.* (2018b) compared SS vs MS trends and observed underestimation for the latter due to preselection in traditional PTA, especially for young bulls. The authors predicted that differences would further increase for genotyped bulls with the accumulation of preselection bias over the years, which would become more evident with shorter generation intervals and more recent data. Thus, comparisons were updated to determine if the theoretical advantages of SS (Aguilar *et al.*, 2010) now give larger actual advantages over MS when applied to national data.

Materials & methods

Genotypes were available from 5.1 million purebreds; genotypes of crossbreds were excluded from both SS and MS methods. The SS GEBV were estimated using APY method with 45,000 core animals: 15,000 each for Holstein (HO) and Jersey (JE) and 5,000 each for Ayrshire, Brown Swiss, Guernsey, with genotypes and phenotypes for all 5 breeds together (Cesarani *et al.*, 2022). The MS GEBV used current official methods with separate marker effects for each breed. During iteration, the MS used 0.6 million genotyped animals that had phenotypes or descendants with phenotypes, and the SS used 3.9 million genotyped animals that had phenotypes, descendants with phenotypes, or non-genotyped parents; for efficiency GEBVs of the remaining animals are computed only after convergence. Phenotypes were 305-d milk, fat, and protein lactation records solved in multi-trait models in SS and the first step of MS followed by single-trait marker effects in MS. The complete dataset included 99 million lactations beginning in 1960 for MS, whereas SS used a subset of lactations beginning in 2000. For both SS and MS, the complete dataset included calving

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_323, © R.R. Mota *et al.* 2022

dates up to June 2021, while the reduced dataset included calving dates only to June 2017 after truncating the last 4 years. The EBV from Interbull were not included. Thus, validation comparisons were limited to 2,619 U.S. HO and 345 U.S. JE bulls that had ≥100 daughters in the complete but no daughters in the reduced dataset. Other breeds had fewer than 25 such bulls and are not reported here. The unknown parent groups defined for MS were also used in SS but were not optimal after removing the first 40 and last four years of phenotypes; MS software automatically condenses groups outside the minimum and maximum year with phenotypes for each trait. The final GEBVs from both SS and MS were predicted from the earlier SS and MS GEBVs with simple regressions and with extra regressions (SS+ and MS+) on birth year and pedigree EBV from the respective SS or MS evaluation (VanRaden, 2021). Direct genomic values (DGV) from the MS evaluation were also examined because the SS did not include a polygenic effect and thus effectively only solved for a DGV. A MS evaluation with only 1% polygenic variance and no extra weight on pedigree EBV in the final blending step was computed for comparison.

Results

The pedigree models using SS or MS software had similar correlations of initial with later EBV as expected. The correlations ranged from 0.58 to 0.73 and were consistent with the large gain in reliability (REL) when bulls became proven. The GEBV correlations were much higher than for EBV as expected. Correlations from SS were higher than MS model for all traits and both breeds but correlations of the DGV from MS software were higher than from SS for traits of HO (Table 1). Regressions for pedigree models were all below the desired value of 1.0 and were similar using MS or SS software. Genomic preselection can reduce the regressions on pedigree EBVs because selection intensity may be much higher for animals with lower EBV, whereas GEBVs should be much less biased by preselection. Regressions for GEBV were close to 1.0 and similar for MS and SS for all traits and breeds. Regressions were also close to 1.0 for the MS DGV for HO but were lower for JE (Table 2). The standard deviations (SD) were similar for pedigree EBVs from MS and SS software, as expected. The SD were higher from final than truncated EBVs, also consistent with the large gains in EBV REL. The final GEBV had higher SD than the truncated GEBV in the SS and MS models, as expected.

Table 1. Squared correlations (×100) of final and truncated EBVs within the same evaluation system.

Breed	Trait	Genomic EBVs			Pedigree EBVs	
		MS	SS	MS DGV	MS	SS
Holstein	Milk	74	81	93	37	34
	Fat	78	83	95	42	34
	Protein	75	83	94	45	37
Jersey	Milk	78	83	86	53	45
	Fat	70	78	78	39	34
	Protein	73	83	80	49	46

Table 2. Regressions of final on truncated EBVs within the same evaluation system.

Breed	Trait	Genomic EBVs			Pedigree EBVs	
		MS	SS	MS DGV	MS	SS
Holstein	Milk	0.95	0.96	0.97	0.75	0.72
	Fat	0.96	0.96	0.95	0.85	0.76
	Protein	0.91	0.95	0.94	0.80	0.73

Predictions of final MS or SS GEBV or DYD using truncated GEBV from the other software or with extra regressions provides more information about the benefits and biases, with results for milk shown as an example (Table 3). The reduced SS had higher R^2 than the reduced MS GEBV to predict either the MS or SS final GEBV for both HO and JE breeds; differences in R^2 were larger when predicting SS than MS. The extra regressions improved MS+ predictions compared to MS more than SS+ compared to SS, indicating smaller biases in SS as desired. The extra regressions were significant in SS but smaller in magnitude. The R^2 for MS+ and SS+ were very similar with the extra regressions included. The b_1 regression estimates were a little closer to 1.0 for MS than for SS in both breeds, but the MS+ estimates were very high for b_1 as previously shown (VanRaden, 2021) with the extra regressions included.

The SS and MS final GEBVs for milk were correlated by 0.98 and the reduced GEBVs were correlated by 0.96 for the 2,619 U.S. HO bulls that had ≥100 in 2021 but no daughters in 2017. The pedigree EBV from SS and MS software were correlated by 0.99 for final and 0.96 for the reduced EBV. Those differences are likely due to the known biases detected by the extra regressions, inclusion of polygenic effects, and slight differences in input records. The corresponding correlations for the 345 JE bulls were 0.98 for final GEBVs, 0.94 for reduced GEBVs, 0.98 for final EBVs, and 0.98 for reduced EBVs.

Genetic trend estimates were similar for MS and SS; correlations of birth year with GEBV for HO were 0.28 and 0.17 with reduced and final MS vs 0.29 and 0.16 with reduced and final SS. Correlations in the final data may be lower because the young bulls were highly selected. To predict later MS or SS GEBVs, the extra regressions showed that parent average (PA) should be subtracted from the reduced MS GEBVs and that the birth year trend was steeper in young bulls than proven bulls. The trend was also too steep and of same magnitude in the reduced SS GEBVs. With SS, the extra regression on PA was positive to predict MS GEBV but near 0 to predict SS GEBV. When comparing only bulls with 1000 daughters, 5 of the 10 largest differences of SS – MS were clones of famous bulls. Clones have identical DGVs, but their polygenic effects differ slightly due to being modelled as full sibs in the MS model. Thus, their GEBVs and daughter counts are copied to the clones in the official system. Different methods may be needed when using a genomic relationship matrix because clones make the matrix singular. The SS and MS GEBVs had small differences for the highest ranking HO bulls for net merit with >1000 daughters, indicating little bias after bulls are widely used. Biases may occur with early daughters from highly selected mates. The selection and mating patterns for HO may be more extreme and cause more biases than for JE or smaller breeds. The MS model with 1% polygenic variance and no extra weight on pedigree EBV gave GEBV more similar to SS with correlation increased to 0.97, nearly identical prediction R^2, and b_1 slightly closer to 1.0 than SS. Thus, previous revisions to the MS model to reduce overprediction of young animals (i.e. 10% polygenic variance and extra weight on PA) were a main difference between MS and SS predictions.

Table 3. Squared correlations (x100) and regressions to predict final MS and SS GEBV and MS DYD for milk from truncated MS and SS GEBV or with extra regressions on birth year and PA included (SS+ and MS+).

Breed	Predict:	Squared correlation from 2017:				Regression (b1) from:			
	2021	MS	SS	MS+	SS+	MS	SS	MS+	SS+
HO	MS	74	76	80	79	0.95	0.90	1.41	1.00
	SS	74	81	83	85	0.99	0.96	1.58	1.15
	DYD	60	63	69	68	0.93	0.90	1.52	1.08
JE	MS	78	80	80	81	1.05	0.96	1.47	0.96
	SS	74	83	79	84	0.99	0.95	1.58	1.09
	DYD	66	72	71	73	0.98	0.93	1.51	1.01

Discussion

The higher R^2 of SS to predict later MS or SS GEBV or DYD indicates better predictive ability than official MS for both HO and JE, but the b_1 regressions were a little closer to 1.0 for MS than for SS. The SS model without a polygenic effect may be too rigid and adapts less to new data of individual animals in large populations. Instead, new animals adjust the marker effects just a little, but their final GEBV mostly reflects the same historical marker effects they had when younger. For HO, the MS DGV were even more consistent than the SS GEBV. The earliest MS models in 2008 also used no polygenic effect but since 2010 have assumed 10% variance to avoid overprediction and obtain b_1 closer to 1.0. The MS model may now be assigning too much variance to the polygenic effect because recent enhancements and additions to the marker list should account for more of the genetic variance, but the SS model assigns too little polygenic variance (0%). Tests of German and Nordic SS models have assigned 30% polygenic variance to all traits (Alkhoder and Liu, 2021; Andersen *et al.*, 2021). The U.S. MS model has put extra emphasis on pedigree EBV in the final blending step; those weights were decreased from 15 to 10% for yield traits in August 2021. Other model changes may be needed to prevent overprediction of final genetic trend that occurred in both the MS and SS GEBVs of young bulls. Negative values for the b_0 intercept are also a problem but were not yet compared in this validation. Future comparisons will include foreign data and more traits. Comparison of MS and SS results should lead to better understanding and improvements to both systems. The SS software could simplify and improve multi-trait modeling. Switching the current run flow to SS software for all the traits will take some effort and more computation but could be worthwhile.

324. Large-scale multiple-trait single-step marker model implementation

B.L. Harris*, R.G. Sherlock and M.A. Nilforooshan

Livestock Improvement Corp. LTD., Private Bag, 3016, Hamilton, New Zealand; bevin.harris@lic.co.nz

Abstract

An approach to solve large-scale multiple-trait single-step marker models is discussed. The approach uses a block-diagonal Jacobi preconditioned matrix within a preconditioned conjugate gradient solver. This approach has successfully been used for single-trait single-step marker models containing 10s of millions of animals in the pedigree and 100s of thousands of genotyped individuals. This study used data from the New Zealand national genetic evaluation for the milk production traits, combined with bovine SNP markers from Livestock Improvement Corporation. The multiple-trait models took approximately 2.5 times longer to converge than the single-trait first lactation models and required approximately two times the number of iterations. The true multiple-trait genomic breeding values had high correlations with approximated multiple-trait genomic breeding values calculated using selection index method that combined single-trait genomic breeding values. There was re-ranking of elite sires, even though the correlations between true and approximate multiple-trait genomic breeding values were high, suggesting that implementing multiple-trait single-step marker models would be worthwhile.

Introduction

In most livestock breeding programs, it is common to use genomic data consisting of thousands of single nucleotide polymorphisms (SNPs) within genetic evaluations to produce genomic breeding values (GBVs). More recent genomic evaluation methods allow the simultaneous modelling of genotyped and non-genotyped animals. There are two equivalent methods: single-step genomic BLUP (ssGBLUP), which directly estimates the genomic breeding values and single-step SNPBLUP (ssSNPBLUP) that directly estimates the random SNP effects. Both methods are computationally intensive for large-scale evaluations with 10s of millions of animals in the pedigree and 100s of thousands of genotyped individuals in the analysis. The computational demands and short turnaround times (<7 days) required by breeding programs to produce GBVs have limited the large-scale genomic evaluation to single-trait analyses.

It would be useful to obtain multiple-trait (MT) GBVs from large-scale genomic evaluations. Multiple-trait genomic evaluation of the animals enables the use of all available information on several traits to obtain more accurate and timely genomic evaluations. This is particularly useful for low heritable traits such as fertility measures in dairy cattle. Another advantage of MT genomic analysis is obtaining unbiased estimates for traits measured only on animals selected based on a correlated trait. For example, the evaluation of dairy cows' second lactation production yields occurs after the selection has been applied to the first lactation yields.

For this study, we used ssSNPBLUP despite ssGBLUP approach having better convergence properties (Vandenplas *et al.*, 2018). The size of the genomic component of the mixed model equations (MME) for ssSNPBLUP is determined by the number of SNP markers rather than the number of genotyped individuals as in ssGBLUP. In most large-scale applications, the number of genotyped individuals is far greater than the number of SNP markers used in the analysis, allowing ssSNPBLUP to have a lower memory requirement. The lower memory requirement was advantageous for our computing environment. We used a set of equations that include a specialised pre-conditioned conjugate gradient (PCG) (Vandenplas *et al.* 2018 and Mäntysaari *et al.*, 2020) for solving the MME, which overcomes the poorer convergence properties of ssSNPBLUP.

The purpose of this study was first to evaluate the computational feasibility of MT ssSNPBLUP by extending a specialised PCG solver with a block-diagonal Jacobi pre-conditioned matrix to multiple traits. The specialised PCG had been successfully used to solve large-scale single-trait models in New Zealand multibreed dairy-cattle genomic evaluation. The second purpose was to determine the accuracy of selection index procedures used to combine single-trait GBV to approximate MT GBVs. This quantifies the accuracy loss using single-trait analyses compared to MT analyses.

Materials & methods

Data used in this study was from the New Zealand national dairy cattle genetic evaluation in December 2021 and was combined with bovine SNP markers from Livestock Improvement Corporation. The data included 32 million animals in the pedigree from multiple breeds and crosses. Most animals were Holstein-Friesian, Jersey, or their crosses, with Ayrshire's being the next largest breed group. Approximately 200k genotypes were included in the analysis, with males accounting for 5% and females 95% of the genotypes. Phenotypic records for milk, milk fat and protein yields from lactations 1- 6 were used in the milk production models. Lactations 1, 2 and 3-6 were considered as distinct traits for each yield phenotype.

The ssSNPBLUP generic model statement for all models and each trait was:

$$y = Xb + Z_g M_g m + Z_n u_n + Za + Zp + e \quad (1)$$

where y is the phenotype vector, X and Z are incidence matrices, Z_g and Z_n are rows of Z corresponding to genotyped (g) and non-genotyped (n) animals, M_g is the SNP marker matrix with each column centred to have a mean of zero, m is the vector of SNP marker effects with each column is centred to have mean of zero, b is the vector of fixed effects including hybrid vigour, genetic groups, and breed covariates, u is the vector of genomic breeding values for non-genotyped animals, a is the vector of polygenic effects, p is the vector of permanent environment effects, and e is the random residual effect. The model includes the polygenic effects because we assume that the SNPs do not capture all the genetic variance.

The models included fixed effects for contemporary-group (herd-year-age-season) and covariates for hybrid vigour, breed proportion, age at calving and the stage of lactation, and genetic groups for animals with missing parents. The genetic groups were assigned by sex of missing parent and birth year (in 5-year blocks). The genetic groups were fitted directly as fixed effects and not via the numerator relationship matrix. The MME were set up using the approach outlined by (Fernando *et al.*, 2016). The MME requires the inverse numerator relationship matrix for non-genotyped animals, containing >31 million animals. This inverse can be done efficiently (Fernando *et al.*, 2016) using sparse Cholesky decomposition and is suitable for large-scale parallel computing implementations. The Cholesky decomposition was pre-calculated before solving the MME.

The single-trait ssSNPBLUP models were solved using a specialised PCG solver with a block-diagonal Jacobi preconditioned matrix. The blocks in the pre-conditioner matrix were associated with the major factors fitted in the model: fixed effects, SNP marker solutions, animal genomic breeding values for non-genotyped animals, polygenic breeding values, and permanent environmental effects. The blocks contained the matrix inverses for each block. The strategies to obtain the matrix inverses involved Cholesky decomposition for the breeding value blocks and direct inverses for the other blocks with equation absorption. An extension of the block-diagonal Jacobi pre-conditioned matrix to multiple traits is straightforward. The blocks for the SNP marker solutions, non-genotyped animal genomic breeding values, polygenic breeding values and permanent environment effects included all the MME elements for all the traits. The multiple-trait block for the permanent environment effects has values only on

the diagonals of trait sub-blocks, allowing the entire block to be inverted directly and efficiently using a simple recursive Schur algorithm. The multiple-trait block for the fixed effects is a series of single-trait sub-blocks because of the zero error covariance among the traits associated with fixed effects. The block of equations for MT SNP marker random effects within the MME and its inverse was computed separately before the PCG solver.

The accuracy of MT GBV was compared with the accuracy of the approximate MT GBV derived from single-trait GBVs. A selection index approach was used to compute the approximate MT GBV. This approach is based on VanRanden (2001) to avoid double accounting of non-independent sources of information from each single-trait analysis in the approximate MT GBV. Comparisons were made by correlating the true and the approximate MT GBV and regressing the approximate MT GBV on the true MT GBV.

All the analyses were run on an Amazon r5d.24xlarge EC2 server with 48 Intel Xeon cores and 768 Gb of memory.

Results

The MT models all had ~300M equations and ~246M phenotypic records. The single-trait first lactation analyses all had ~99M equations and used ~60M phenotypic records. Table 2 provides the solving times in minutes and the number of iterations required to solve the equations using the specialised PCG solver with a block-diagonal Jacobi preconditioned matrix. The standard PCG convergence metric was used (Shewchuk 1994), with the convergence criterion set to $<10^{-11}$. For comparison, a traditional MT BLUP model for milk yield with no SNP markers took 504 iterations and 956 minutes to solve with the specialised PCG solver. The results from a comparison of true and approximate MT GBV for genotyped sires enrolled in the national genetic evaluation using linear regression across breeds are in Table 3. Figure 1 illustrates the convergence behaviour for multiple and single-trait (1st lactation) milk yield ssSNPBLUP.

Table 1. The number of iterations and time to solve the multiple (lactations treated as 3 traits) and single-trait (1st lactation) analyses.

	Multiple trait		Single trait	
Phenotype	**Number of iterations**	**Solving time (min)**	**Number of iterations**	**Solving time (min)**
Milk	1,391	4,320	924	1,435
Fat	1,120	4,143	746	1,269
Protein	1,221	3,972	801	1,275

Table 2. A comparison of true and approximate multiple-trait GBV for genotyped sires enrolled in the national genetic evaluation.

Phenotype	Trait	Correlation	Slope	Intercept
Milk	All[1]	0.987	0.97	-59.6
Fat	All[1]	0.985	1.00	-1.77
Protein	All[1]	0.989	0.96	-1.44

[1] Weighted average of all lactations.

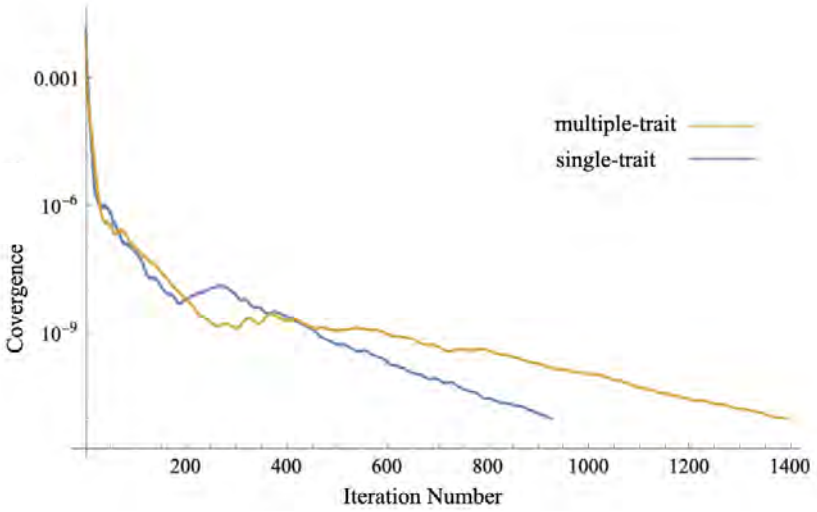

Figure 1. Convergence behaviour for multiple (lactations as 3 traits) and single-trait (1st lactation) milk yield ssSNPBLUP.

Discussion

Solving large-scale ssSNPBLUP models using PCG solvers is complex. A single trait model using a diagonal pre-conditioner matrix can take 10s of thousands of iterations and show poor or erratic convergence behaviour. The use of specialised PCG solvers can reduce the number of iterations and avoid erratic convergence behaviour. In this study, we extended the use of a block-diagonal Jacobi preconditioned matrix from a single trait to multiple traits. The convergence of the MT analyses achieved convergence with only ~50% increase in the number of iterations compared to the single-trait ssSNPBLUP models and ~2.5-fold increase in the number of iterations compared to the traditional MT BLUP model for the corresponding traits. The MT models took approximately 3 days to converge with no prior solutions. An elapsed time of 3 days is a good result. It is feasible to parallelise analyses for different phenotypes across several servers and achieve a 7-day turnaround for timely breeding decisions. More time reductions may be achieved by using prior solutions to reduce the number of iterations. Further work is required to test the effectiveness of prior solutions within ssSNPBLUP MT models.

The approximate MT GBVs were unbiased and highly correlated with the true MT GBVs. Even though the correlations were high, elite sires re-ranked. Thus, the use of true MT GBVs would be advantageous for genomic selection and genomic pre-screening.

325. An iterative method for deregressed proof in single-step genomic BLUP and its application to a dairy cattle population

Y. Masuda[1*], Z. Liu[2] and P. Sullivan[3]

[1]Rakuno Gakuen University, Bunkyodai-Midorimachi 582, 069-8501 Ebetsu, Japan; [2]IT solutions for animal production (vit), Heinrich-Schroeder-Weg 1, 27283 Verden, Germany; [3]Lactanet, 555 Boul des Anciens-Combattants, Sainte-Anne-de-Bellevue, Quebec, Canada; yutaka@rakuno.ac.jp

Abstract

The objective of this study was to describe an iterative algorithm to deregress genomically-enhanced breeding values (GEBV) in single-step genomic BLUP (ssGBLUP). The method is an extension of the previous work by the first two authors, who gave a deregression method in singe-step SNP BLUP. The inverse of the unified relationship matrix (H^{-1}), which is a function of the inverse of genomic relationship matrix (G^{-1}) and the inverse of the additive relationship matrix (A^{-1}), was considered in the deregression method. Effective daughter contribution (ERC) for bulls or effective record contribution (ERC), which are functions of reliability of GEBV, should be used as weights on deregressed proof. The deregression algorithm consists of a series of matrix-vector multiplications, and the number of iterations is expected to be limited. The computational cost of this approach was discussed. Further research is needed to confirm the 'reversibility' of deregressed GEBV.

Introduction

The pedigree-based estimated breeding values (EBV) are often 'deregressed' to give pseudo-phenotypes for further genetic analyses, including international dairy sire evaluation, so-called multiple across country evaluation (MACE), genome-wide association study, and routine genomic evaluation using 'multi-step' methods. In dairy cattle, the multi-step methods optionally use MACE EBV as external information to improve the reliability of genomically-enhanced breeding values (GEBV) for genotyped animals. Accurate deregression methods are required to sustain the entire routine genetic and genomic evaluations system at the domestic and international levels.

Recently, some countries implemented a 'single-step' approach combining all available phenotypes, pedigree, and genotypes in a single system of mixed model equations, which provides GEBV for all genotyped and non-genotyped animals. Two classes of models have been suggested: single-step genomic BLUP (ssGBLUP; Aguilar *et al.*, 2010; Christensen and Lund, 2010) and single-step SNP BLUP (ssSNPBLUP; Liu *et al.*, 2014). The ssGBLUP model uses the inverse of unified relationship matrix (H^{-1}), which includes the inverse of genomic relationship matrix (G^{-1}), together with the inverse of additive relationship matrix (A^{-1}). Pedigree-based deregression methods (e.g. Jairath *et al.*, 1998) can be extended to account for the genomic relationships to give unbiased pseudo-phenotypes.

The objective of this study was to show an iterative algorithm to deregress GEBV in ssGBLUP. For ssSNPBLUP, Liu and Masuda (2021) comprehensively discussed how the deregression can be applied.

Materials & methods

Deregression model. For a particular trait, the deregression is based on the following model:

$$\mathbf{y} = \mathbf{1}\mu + \mathbf{u} + \mathbf{Q}\mathbf{t} + \mathbf{e} \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_325, © Y. Masuda *et al.* 2022

where y is a vector of deregressed GEBV (dGEBV), μ is the overall mean, u is a vector of GEBV, t is a vector of unknown parent groups (UPG), e is a vector of residuals, and 1 is the vector of ones, and Q is a matrix relating UPG to dGEBV. The additive genetic variance (σ^2_u), the residual variance (σ^2_e), and the variance ratio ($\lambda = \sigma^2_e/\sigma^2_u$) are assumed to be known.

Three groups for animals are assumed: group 1 is for non-genotyped animals with the phenotype(s), group 2 is for genotyped animals regardless of whether phenotyped or not, and group 0 for the ancestors of the animals in groups 1 and 2 (i.e. animals without genotypes and phenotypes).

A vector, u* = u + Qt, is split into three groups. Let

$$\theta = \begin{bmatrix} \mathbf{u}_0^* \\ \mathbf{u}_1^* \\ \mathbf{u}_2^* \\ \mathbf{t} \end{bmatrix} = \begin{bmatrix} \mathbf{u}_0 + \mathbf{Q}_0\mathbf{t} \\ \mathbf{u}_1 + \mathbf{Q}_1\mathbf{t} \\ \mathbf{u}_2 + \mathbf{Q}_2\mathbf{t} \\ \mathbf{t} \end{bmatrix},$$

where Q_0 is Q for group 0, Q_1 for group 1, and Q_2 for group 2. The inverse of additive relationship matrix for θ is

$$\mathbf{A}^* = \begin{bmatrix} \mathbf{A}^{00} & \mathbf{A}^{01} & \mathbf{A}^{02} & \mathbf{A}^{0t} \\ \mathbf{A}^{10} & \mathbf{A}^{11} & \mathbf{A}^{12} & \mathbf{A}^{1t} \\ \mathbf{A}^{20} & \mathbf{A}^{21} & \mathbf{A}^{22} & \mathbf{A}^{2t} \\ \mathbf{A}^{t0} & \mathbf{A}^{t1} & \mathbf{A}^{t2} & \mathbf{A}^{tt} \end{bmatrix}.$$

After applying QP-transformation (Misztal *et al.*, 2013), the inverse of unified relationship matrix with genotyped and non-genotyped animals is defined as

$$\mathbf{H}^* = \begin{bmatrix} \mathbf{H}^{00} & \mathbf{H}^{01} & \mathbf{H}^{02} & \mathbf{H}^{0t} \\ \mathbf{H}^{10} & \mathbf{H}^{11} & \mathbf{H}^{12} & \mathbf{H}^{1t} \\ \mathbf{H}^{20} & \mathbf{H}^{21} & \mathbf{H}^{22} & \mathbf{H}^{2t} \\ \mathbf{H}^{t0} & \mathbf{H}^{t1} & \mathbf{H}^{t2} & \mathbf{H}^{tt} \end{bmatrix} = \mathbf{A}^* + \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & (\mathbf{G}^{-1} - \mathbf{A}_{22}^{-1}) & -(\mathbf{G}^{-1} - \mathbf{A}_{22}^{-1})\mathbf{Q}_2 \\ \mathbf{0} & \mathbf{0} & -\mathbf{Q}_2'(\mathbf{G}^{-1} - \mathbf{A}_{22}^{-1}) & \mathbf{Q}_2'(\mathbf{G}^{-1} - \mathbf{A}_{22}^{-1})\mathbf{Q}_2 \end{bmatrix} \quad (2)$$

where A^{-1}_{22} is the inverse of the additive relationship matrix for genotyped animals. The above matrix, H^*, can be modified to support random UPG, metafounders (Legarra *et al.*, 2015), alternative UPG models (Masuda *et al.*, 2022), and simplified G^{-1}, e.g. generated by the algorithm for proven and young (APY) or the Woodbury formula (Misztal *et al.*, 2014; Mäntysaari *et al.*, 2017).

Iterative algorithm. The system of mixed model equations under model (1) is

$$\begin{bmatrix} \mathbf{1}'\mathbf{W}_1\mathbf{1} + \mathbf{1}'\mathbf{W}_2\mathbf{1} & \mathbf{0} & \mathbf{1}'\mathbf{W}_1 & \mathbf{1}'\mathbf{W}_2 & \mathbf{0} \\ \mathbf{0} & \lambda\mathbf{H}^{00} & \lambda\mathbf{H}^{01} & \lambda\mathbf{H}^{02} & \lambda\mathbf{H}^{0t} \\ \mathbf{W}_1\mathbf{1} & \lambda\mathbf{H}^{10} & \mathbf{W}_1 + \lambda\mathbf{H}^{11} & \lambda\mathbf{H}^{12} & \lambda\mathbf{H}^{1t} \\ \mathbf{W}_2\mathbf{1} & \lambda\mathbf{H}^{20} & \lambda\mathbf{H}^{21} & \mathbf{W}_2 + \lambda\mathbf{H}^{22} & \lambda\mathbf{H}^{2t} \\ \mathbf{0} & \lambda\mathbf{H}^{t0} & \lambda\mathbf{H}^{t1} & \lambda\mathbf{H}^{t2} & \lambda\mathbf{H}^{tt} \end{bmatrix} \begin{bmatrix} \hat{\mu} \\ \widehat{\mathbf{u}_0^*} \\ \widehat{\mathbf{u}_1^*} \\ \widehat{\mathbf{u}_2^*} \\ \hat{\mathbf{t}} \end{bmatrix} = \begin{bmatrix} \mathbf{1}'\mathbf{W}_1\mathbf{y}_1 + \mathbf{1}'\mathbf{W}_2\mathbf{y}_2 \\ \mathbf{0} \\ \mathbf{W}_1\mathbf{y}_1 \\ \mathbf{W}_2\mathbf{y}_2 \\ \mathbf{0} \end{bmatrix} \quad (3)$$

where $\mathbf{y}_1$ is $\mathbf{y}$ for non-genotyped animals, and y_2 for genotyped animals. The weight matrices are W_1 = diag$\{n_{i1}\}$ and W_2 = diag$\{n_{i2}\}$, where n_{i1} (n_{i2}) is effective record contribution (ERC) of i-th non-genotyped (genotyped) animal. If an animal has no phenotype(s), the weight is set to 0.

This system of equations includes all genotyped animals considered in the original genetic evaluation because G^{-1} ties a genotyped animal to the other through the precise relationships among genotyped animals. The deregression method is based on the animal model, and y includes cows with phenotypes(s) only. For bulls, dGEBV are computed as Liu and Masuda (2021).

Following Jairath *et al.* (1998), dGEBV for cows (y_1 and y_2) can be available using an iterative method shown below.

1. Put $\hat{\mu} = 0$, $\widehat{\mathbf{u}_0^*} = \mathbf{0}$, $\widehat{\mathbf{u}_1^*} = \mathbf{0}$, and $\widehat{\mathbf{u}_2^*} = \mathbf{0}$.
2. Calculate $\widehat{\mathbf{u}_1^*} = \mathbf{u}_1 - \mathbf{1}\hat{\mu}$ and $\widehat{\mathbf{u}_2^*} = \mathbf{u}_2 - \mathbf{1}\hat{\mu}$, where u_1 (u_2) is a vector of GEBV, obtained by the original genetic evaluation, for non-genotyped (genotyped) animals.
3. Solve
$$\begin{bmatrix} \mathbf{H}^{00} & \mathbf{H}^{0t} \\ \mathbf{H}^{t0} & \mathbf{H}^{tt} \end{bmatrix} \begin{bmatrix} \widehat{\mathbf{u}_0^*} \\ \hat{\mathbf{t}} \end{bmatrix} = \begin{bmatrix} -\mathbf{H}^{01}\widehat{\mathbf{u}_1^*} - \mathbf{H}^{02}\widehat{\mathbf{u}_2^*} \\ -\mathbf{H}^{t1}\widehat{\mathbf{u}_1^*} - \mathbf{H}^{t2}\widehat{\mathbf{u}_2^*} \end{bmatrix}.$$
4. Calculate
$$\mathbf{z}_1 = \mathbf{W}_1\mathbf{y}_1 = \mathbf{W}_1\mathbf{1}\hat{\mu} + \lambda\mathbf{H}^{10}\widehat{\mathbf{u}_0^*} + (\mathbf{W}_1 + \lambda\mathbf{H}^{11})\widehat{\mathbf{u}_1^*} + \lambda\mathbf{H}^{12}\widehat{\mathbf{u}_2^*} + \lambda\mathbf{H}^{1t}\hat{\mathbf{t}}$$
$$\mathbf{z}_2 = \mathbf{W}_2\mathbf{y}_2 = \mathbf{W}_2\mathbf{1}\hat{\mu} + \lambda\mathbf{H}^{20}\widehat{\mathbf{u}_0^*} + \lambda\mathbf{H}^{21}\widehat{\mathbf{u}_1^*} + (\mathbf{W}_2 + \lambda\mathbf{H}^{22})\widehat{\mathbf{u}_2^*} + \lambda\mathbf{H}^{2t}\hat{\mathbf{t}}$$
And
$$m = \mathbf{1}'\mathbf{W}_1\mathbf{y}_1 + \mathbf{1}'\mathbf{W}_2\mathbf{y}_2 = \mathbf{1}'\mathbf{z}_1 + \mathbf{1}'\mathbf{z}_2.$$
5. Calculate $\hat{\mu} = m/(\mathbf{1}'\mathbf{W}_1\mathbf{1} + \mathbf{1}'\mathbf{W}_2\mathbf{1})$.
6. Go to Step 2 until convergence is reached.
7. After the convergence, calculate dGEBV as $\mathbf{y}_1 = \mathbf{W}_1^{-1}\mathbf{W}_1\mathbf{y}_1 = \mathbf{W}_1^{-1}\mathbf{z}_1$ and $\mathbf{y}_2 = \mathbf{W}_2^{-1}\mathbf{W}_2\mathbf{y}_2 = \mathbf{W}_2^{-1}\mathbf{z}_2$.

Evaluation of computing cost using real data. The first author evaluated the deregression cost for GEBV of the udder score in Japanese Holstein. Data included more than 750,000 phenotypes, 157,000 pedigree animals, and 120,000 genotypes with 45,724 SNP markers. A single-trait ssGBLUP model, similar to the traditional animal model used in national genetic evaluation, was applied. The QP-transformed $\mathbf{H}^*$ (2) with 29 UPG was formed. The system of mixed model equations was solved by PCG using BLUP90IOD2 (Lourenco *et al.*, 2020). The ERC for each cow (Liu *et al.*, 2017) was calculated based on the reliability of GEBV; the reliability was calculated the posterior variance of GEBV using a Gibbs sampler. A custom software was developed for deregression.

Results & discussion

The current method is useful for a population with the ssGBLUP evaluations because pre-calculated $\mathbf{G}^{-1}$ and the other part of $\mathbf{H}^*$ are immediately available. The algorithm consists of a series of matrix-vector multiplications. Therefore, the number of iterations should be limited to get convergence. Although step 3 needs to solve a system of sparse equations, it can be solved inexpensively by typical iterative solvers, e.g. preconditioned conjugate gradient (PCG). Alternatively, the matrix factorization is feasible to solve the equations if the order of equations is small enough.

In ssGBLUP with real data, PCG required 607 rounds in 30 minutes to get converged. The Gibbs sampler generated 3,000 samples to compute the variance of GEBV within 12 hours. The deregression algorithm took a few minutes to be converged. The total computing cost for deregression is expected to be much lower than the original single-step evaluation. There are two possible concerns in deregression in practice. First, the reliability computation is a possible bottleneck. A new algorithm to approximate the reliability of GEBV in ssGBLUP (Bermann *et al.*, 2021) should remove the issue. Second, some UPG models in ssGBLUP would be unstable in solving mixed model equations. The options include refinement of UPG definition, alternative UPG models, or random UPG.

The deregressed proof should be reversible (Mäntysaari *et al.*, 2011) in the sense that the recalculated evaluations using dGEBV as phenotypes are identical to the original genomic evaluations. To ensure reversibility, Liu and Masuda (2021) suggested that a deregression formula should include all animals with the phenotype(s), all genotyped animals, the same pedigree animals used in the original single-step evaluation.

A deregression approach was derived from ssSNPBLUP by Liu and Masuda (2021). In theory, their method is applicable to GEBV calculated from any single-step model. However, both methods have not been tested for reversibility with real data. Further research is needed to verify reversibility and computational feasibility for both ways.

Acknowledgements

The first author thanks the Holstein Cattle Association of Japan (HCAJ) for providing us with the phenotypes, pedigree, and genotypes. Toshimi Baba (HCAJ Hokkaido Branch) is acknowledged for the initial preparation of phenotypic data.

326. Efficient approximation of reliability for genomic breeding values in large systems

H. Eding

CRV Animal Evaluation Unit, Wassenaarweg 20, 6843 NW Arnhem, the Netherlands; herwin.eding@crv4all.com

Abstract

This paper presents a simplified procedure to obtain approximations of genomically enhanced breeding value (GEBV) reliabilities. This procedure assumes direct genomic reliabilities are known from genomic validation studies and are roughly equal for all genotyped animals. Direct genomic reliabilities form an upper limit to the information added by genotyped relatives to ungenotyped animals. The concept of 'genotype confidences' is introduced to limit the propagation of EDC from genotyped relatives, such that the genomic EDC do not exceed the number of EDC corresponding to the direct genomic reliabilities. The algorithm, if implemented in a routine evaluation, only adds marginally to the runtime of an evaluation. The method is illustrated in a comparison with GEBV reliabilities from a routine evaluation using pseudo records.

Introduction

The Interbull working group for genomic reliabilities published a bulletin in 2017 (Liu *et al.*, 2017) in which a protocol was proposed to estimate GEBV in a single step evaluation. One attractive facet of this protocol was the fact that it treated genomic data as an addition to conventional sources of data (own, offspring records, pedigree), potentially avoiding the necessity to completely redesign reliability estimation software.

The Interbull protocol encompassed six separate steps:

1. Calculate SNP reliabilities
2. Derive DGV reliabilities
3. Adjust DGV reliabilities
4. Calculate genomic gain => EDC_{add} = $EDC_{dgv} - EDC_{conv}$
5. Propagation => EDC^*_{add} = prop(EDC_{add})
6. Calculate final reliabilities => EDC_{final} = $EDC_{conv} + EDC^*_{add}$

Where EDC_{add} are the difference in expected daughter contributions (EDC), due to genomics, observed in genotyped animals. EDC^*_{add} contain these differences for all animals, after propagation (VanRaden and Wiggans, 1991).

Step 1 approximates the reliability of each SNP-allele of each SNP in a external program running a Bayesian analysis (*cf* Zaabza *et al.* 2021). These are then used as input in step 2 to derive DGV-reliabilities which are subsequently adjusted for (reference-)population means in step 3 after which the EDC added by the genomic information extracted in step 4 by subtracting the EDC_{dgv} from EDC_{conv}, where the latter is the EDC of a BV estimate without genomic information (a conventional EBV). In step 5 the vector with EDC_{add} (containing added EDC for genotyped animals only) is sent off to a propagation subroutine, which calculates the spread of genomic information in the wider population with non-genotyped animals. After this step we have EDC_{add} for all animals in the evaluation (EDC^*_{add}). In step 6 we can derive the final GEBV reliability by adding EDC^*_{add} to EDC_{conv} and back-transforming these EDC to a reliability.

Steps 1 to 4 result in EDC_{add} for genotyped animals. In the original proposal, steps 1 to 4 rely on external programs and procedures. Moreover, the Bayesian methods (Zaabza *et al.* 2021) implemented in the

DOI: 10.3920/978-90-8686-940-4_326, © H. Eding 2022

software proved to be too time-consuming, making this protocol not very attractive for routine evaluations. However, information about EDC_{add} for traits are already available from our GEBV validation work flow (Stoop *et al.*, 2014). Using this information allows to skip these steps and save much time during evaluation. Hence a GEBV reliability approximation, corresponding to the original intent of the Interbull protocol, but relying on already available EDC_{add} data is proposed.

Materials & methods

It may be noted that the key steps in the Interbull protocol are step 4-6: Calculate EDC_{add} for genotyped animals, propagate to ungenotyped animals and calculate final reliabilities from (propagated) added EDC and conventional EDC. Hence, our implementation was built around these key steps.

Basic algorithm. The implementation consists of the following steps:

1. Calculate conventional reliabilities, transform to EDC.
2. Calculate SNP 'genotype confidences'.
   a. Set genotyped animals to rate of imputation;
   b. Propagate genotype confidence.
3. Calculate DGV reliabilities for all animals; transform to EDC.
4. Sum conventional and genomic EDC to obtain final EDC; transform to GEBV reliabilities.

Conventional reliabilities are calculated using standard algorithms such as the method for calculating multi-trait EDC (MT-EDC) and transforming these to reliabilities of traits in a multi-trait evaluation devised by Liu *et al.* (2001).

Direct genomic reliability. The reliability of a single genotype is derived from validation results in the following manner: GEBV validation is performed on data of a group of validation animals; typically candidate animals without progeny or observations, only a genotype. In the GEBV validation procedure deregressed proofs (DRP) for a trait are used as the phenotype which the breeding values (BV) are predictor:
DRP = b0 + b1 BV

The regression is performed twice: Once on conventional EBV, usually PA, and once on genomic breeding value (GBV). The realized R^2 of these regressions can be interpreted as reliabilities of PA en GBV in predicting the DRP. The difference in R^2 is a measure of the information added by the genotype. The exact amount of information added by the genotype can be calculated by transforming the R^2 into EDC, given the heritability of the trait under consideration:

$$DRP = b0 + b1\ PA \quad => R^2_{PA} \quad => EDC_{PA}$$

$$DRP = b0 + b1\ GBV \quad => R^2_{GBV} \quad => EDC_{GBV}$$

And

$$EDC_{GBV} - EDC_{PA} = EDC_{geno}$$

The variable EDC_{geno} is subsequently transformed back to a reliability R^2_{geno} which is the mean reliability of the direct genomic effect for a particular trait. It is assumed that R^2_{geno} for a trait is approximately equal for all genotyped animals.

Genotype confidence. Since propagation is aimed at modelling the information on unknown genotypes of ungenotyped animals, given genotyped relatives, the concept of 'SNP genotype confidence' (R^2_{SNP}) is introduced. The genotype confidence of genotyped animals is set to the 'rate of imputation' (typically nearly 1). For ungenotyped animals genotype confidences are initially set to zero. Genotype confidences are transformed to EDC using an arbitrary h^2 and propagation is performed. The resulting vector is back transformed to genotype confidences R^2_{SNP}, which are (very nearly) 1.0 for genotyped animals (particularly those with many genotyped offspring) and <1.0 for ungenotyped animals with few genotyped relatives. The reliability of the DGV for each (genotyped or ungenotyped) animal *i* for a trait *t* is: $R^2_{DGV,it} = R^2_{SNP,i} \times R^2_{geno,t}$

Transforming R^2_{DGV} to EDC for each animal and all traits gives EDC^*_{add} (propagated added EDC) which are added to the EDC from conventional information (EDC_{conv}): $EDC_{final} = EDC^*_{add} + EDC_{conv}$ => R^2_{final} (GEBV reliability)

Results

As an illustration of the quick approximation proposed the genomic reliabilities are presented from an evaluation of the traits Milking Speed and Temperament. The results are from two types of evaluation: (1) a routine genomic pseudo-record evaluation (rel PSR GEBV); and (2) a single step SNP BLUP evaluation using the method described above (rel SNPBLUP). Both evaluations consisted of 7,300,000 pedigreed animals, 4,770,000 with phenotypes, 624,000 of which were genotyped for a panel of 37,998 SNP.

Reliabilities showed good agreement from 2010 onwards. This coincides with the moment genotyping of the dairy population in the Netherlands became more common. Before 2010 we see higher reliabilities from the SNPBLUP evaluation. These were caused by propagation of genomic EDC from genotyped animals to ungenotyped relatives and agrees with the implicit imputation in a SNPBLUP evaluation, which means that for ungenotyped animals at least some genotype information is available. Total runtime for the reliability estimation was 19:25 minutes, of which 18:40 minutes were taken up by conventional reliability calculations.

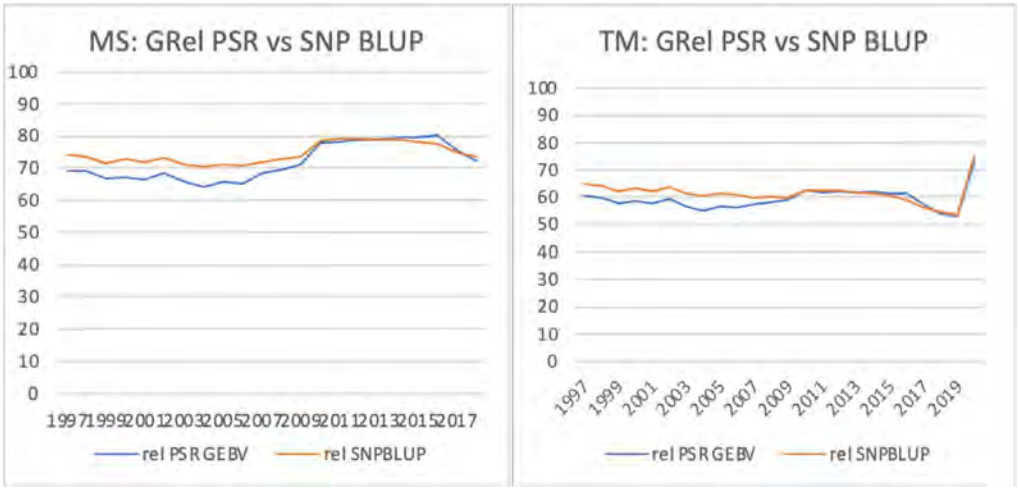

Figure 1. Genomic reliabilities for HF bulls (by birth year) with a conventional reliability >45% evaluated in a single step SNP BLUP run using the quick approximation and a genomic pseudo-record run.

Discussion

The algorithm described above is quick and adds marginally to the run time of conventional reliability calculations (in testing we found 1 to 7 minutes of extra runtime, where the total reliability estimation took 0:19 for the MS/TM evaluation shown above to 52:00 hours for our Fertility evaluation). It relies on few outside parameters: rate of imputation and direct genomic reliabilities for traits in the evaluation, obtained from genomic validation.

Direct propagation of EDC_{add} gives undesirable results in that a (ungenotyped) sire with many genotyped offspring receives added EDC >> EDC_{geno} after direct propagation, which is incorrect since EDC_{geno} is an upper limit of what a known genotype can contribute to the genomic reliability. Hence the necessity of the concept of genotype confidence, which can be interpreted as the reliability with which the genotype of an animal is known. Genotype confidences preclude the need to approximate the genomic reliability of each imputed animal explicitly, which would be costly in time and computer resources.

The use of genotype reliabilities to add to genomic reliabilities has precedent. From 2014 onwards CRV Animal Evaluation Unit estimates GEBV using a pseudo-record approach, in which extra traits are fitted, correlated to existing traits, whose observation is the DGV from the stand-alone GSEL estimation of DGV (Stoop *et al.* 2014). These pseudo-traits are fitted with a heritability of (nearly) 1.0 and a genetic correlation between existing and pseudo-trait that is the square root of the direct genomic reliability estimated from validations. This approach results in GEBV reliabilities with an increase in EDC proportional to the direct genomic reliability.

The algorithm was tested during prototyping to ensure results were as expected. Results of this approximation have not been formally validated yet. Though results show good agreement with other types of analysis, it must be realized this method is an approximation. Use of this method is recommended until efficient, more formal methods to derive genomic reliabilities (e.g. Bermann *et al.*; 2022) become operationally available.

327. Evaluating the suitability of subjectively defined base populations

J. ten Napel[1*], J. Vandenplas[1], M. Calus[1], I. Strandén[2], M. Lidauer[2] and R. Veerkamp[1]

[1]*Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands;*
[2]*Natural Resources Institute Finland (Luke), Jokioinen, Finland; jan.tennapel@wur.nl*

Abstract

Defining multiple base populations for a genetic evaluation is subjective and there is generally no feedback on the suitability of the defined base populations prior to model validation. We present a number of statistics that can be used to evaluate defined base populations. Application of these statistics to one simulated and two practical datasets showed that in practical datasets the number of base animals per base population was in one case very low. In many cases the available genotype information for different base populations was coming from exactly the same genotyped animals. Both issues are likely to complicate genomic evaluation. A tool to estimate these statistics is available in the MiXBLUP software suite.

Introduction

Any pedigree contains founder animals with unknown parents. There may be other animals with unknown parents because of incorrectly or not recording parents at birth, or uncertainty about the sire in case of unobserved matings or use of pooled semen. We refer to these animals as base animals. In genetic evaluations, we generally assume that these base animals are sampled from an infinite population, so we consider them to be genetically unrelated. If base animals originate from various populations or different generations within the same population, we may define several base populations, based on an expected difference in genetic level, due to origin or selection history. Criteria often used for defining base populations are breed, line within breed, sex, years of birth and selection path (Quaas and Pollak, 1981; Mrode, 2014: 55), but the result is subjective. Legarra *et al.* (2015) suggested to use genomic information to take into account that base populations are finite in reality, and that genetic relationships may exist within and across base populations. Such related base populations are referred to as metafounders (MF). In contrast to MF, base populations that are assumed to be unrelated are referred to as unknown parent groups (UPG). Defining multiple base populations is aimed at minimizing bias in genetic trend and estimated breeding values of selection candidates and reducing the mean square error of the evaluation (Foulley *et al.*, 1990). Whether the definition used is effective, depends on the true differences in genetic level and the precision with which genetic level of each base population is estimated. For MF, it also depends on the amount and quality of genomic data available to estimate genetic relationships within and between MF. In practice, the appropriateness of the defined base populations can only be assessed by extensive model validation. The aim of this paper is to present a number of base population statistics that can help to evaluate the suitability of defined base populations prior to any model validation.

Materials & methods

Description of datasets. The base population statistics are illustrated with three example datasets (Table 1). Dataset A is a simulated set of data, which was used in the study of Van Grevenhof *et al.* (2019) that recommended the use of MF. Dataset B is a subset of a routine genetic evaluation and consists of purebred pigs of a single line, their crossbred progeny and ancestors of dams of crossbred pigs., In dataset B, base populations were defined by line and one or more years of birth. Dataset B had a history of poor convergence when using UPG. Dataset C is a set of a routine evaluation of trout using UPG, defined by breeding population. Each founder animal was assigned to a single base population in dataset A and B, but to two in dataset C.

Table 1. Descriptive statistics of example datasets.

	Dataset A	Dataset B	Dataset C
Lines + crosses, N	3 + 2	4 + 3	1 + 0
Animals in pedigree, N	51,500	421,511	385,200
Generations in pedigree, N	8	42	12
Animals genotyped, N	9,250	72,854	6,351

Base population statistics. We introduce three base population statistics, which all include the parameters c_{ij} and q_{ij}. We define a genomic base population which consists of all genotyped animals with a path of non-genotyped ancestors to a base population. Genotyped animals that are descendants of two genotyped parents are not included as they do not provide genotype information to a base population. Now c_{ij} quantifies the width of the path of non-genotyped ancestors to the base population and hence is the genomic contribution of the genomic base animal *j* to base population *i*. If c_{ij} is lower than 1, then animal *j* has genotyped ancestors. The parameter q_{ij} is the fraction relating the contribution of base population *i* to the total genetic value of the animal *j* and is an element of the Q matrix in QP transformation (Quaas and Pollak, 1981). If q_{ij} is lower than 1, then animal *j* is related to multiple base populations.

The first statistic quantifies the amount of genotype information available for each base population. Imputation of non-genotyped animals from genotyped descendants only using pedigree relationships causes loss of information, because the genotype information has to be distributed to two parents in every generation without genotypes. We therefore introduce equivalent number of base animals genotyped for a base population (Neq_i). It is calculated as:

$$Neq_i = \sum_{j=1}^{N} c_{ij} q_{ij} * \left(\frac{1}{2}\right)^{gener_j} \quad (1)$$

where *N* is the number of animals in the genomic base population and $gener_j$ is the maximum number of generations between animal *j* and base population *i*.

The second statistic quantifies uniqueness of genotype information and is the extent to which the same genotype information was used for a pair of base populations, which we call auto-similarity of one base population to the other. To illustrate the concept, imagine 24 balls, 8 red, 8 blue and 8 orange. The balls are placed in two bowls, so the first bowl contains 5 red and 4 blue balls. The second contains the remaining 3 red, 4 blue and 8 orange. The similarity of bowl one to bowl two is 3 red + 4 blue over 9 balls is 0.78. The similarity of the second bowl to the first one is 3 red + 4 blue over 15 balls is 0.47. The colours in the illustration are genotyped animals, the bowls are base populations and the number of balls of the same colour in the same bowl is *q*. So auto-similarity of base population *i* to *j* ($AS_{i\ to\ j}$) is calculated as:

$$AS_{i\ to\ j} = \frac{\sum_{k=1}^{N} c_{ik} \min(q_{ik}, q_{jk})}{\sum_{k=1}^{N} c_{ik} q_{ik}} \quad (2)$$

An $AS_{i\ to\ j}$ of 0 means that genotype information available to two base populations is independent. A value of 1 means that genotype information available is identical.

The third statistic quantifies the proximity of genotype information and is the weighted average number of generations between base animals in a base population and the genomic base population. It is calculated as:

$$\delta Gener_i = \frac{\sum_{j=1}^{N} c_{ij} q_{ij} gener_j}{\sum_{j=1}^{N} c_{ij} q_{ij}} \quad (3)$$

δGener differentiates between many remote genotyped descendants and fewer proximate ones for a given *Neq*.

Results

The number of base animals as a proportion of the total number of animals in the pedigree was similar across datasets (0.5-2.0%). The number of defined base populations varied enormously across datasets and ranged from 3 to 212 (Table 2). Also, the number of base animals per base population varied considerably between datasets and within Dataset B (Figure 1).

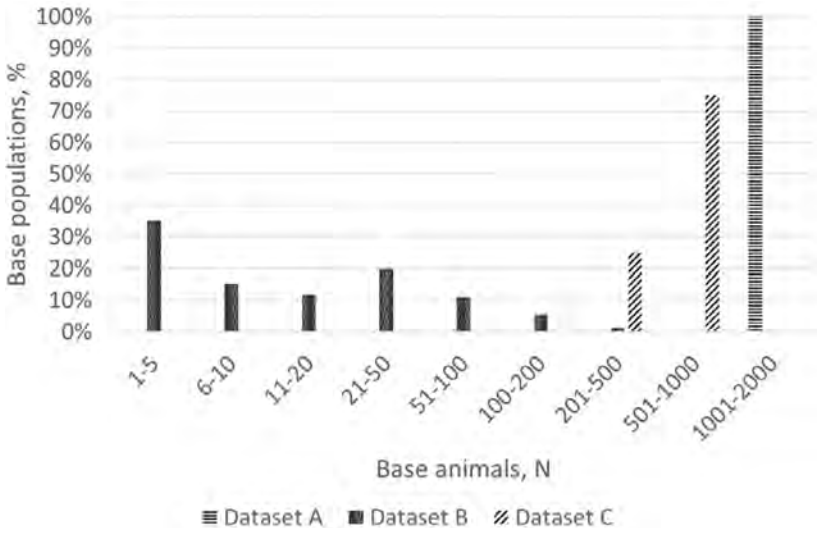

Figure 1. Histogram of number of base animals per base population.

Table 2. Statistics of base populations.

	Dataset A	Dataset B	Dataset C
Base populations, N	3	212	8
Base animals in total, N	1,030	5,702	2,028
Base populations without a link to genotypes, %	0%	47.5%	50.0%
Base populations Neq[1] <0.05	0%	43.5%	0%
Average non-zero Neq[1]	9.5	8.0	5.3
Range non-zero Neq[1]	9.4-9.6	1.0-27.0	1.0-9.5
Average AS[2] across pairs of base populations	0.06	0.07	0.14
Full AS[2] with at least one other base population, %	0.0%	43.9%	50.0%
Average size of genomic base population[3] per base population	2,247	12.2	507
Average δGener[4]	8.4	25.7	8.3

[1] Neq: amount of genotype information expressed as equivalent number of base animals genotyped (Equation 1).

[2] AS: auto-similarity of genotype information of a base population to another and is a measure of the extent to which the same genotype information was used for both base populations (Equation 2).

[3] Genomic base population: genotyped animals with a path of non-genotyped ancestors to the base population.

[4] δGener: number of generations between genomic base population and base animals (Equation 3).

In dataset A, all base populations were well-linked to genotyped animals (Table 2), whereas in datasets B and C, half the base populations had no genetic link to a genotyped animal. The average of non-zero Neq was similar across datasets, but variation was larger in datasets B and C. Of all base populations in datasets B and C, 43.9 and 50% had an AS of 1 with at least one other base population, meaning that their available genotype information was based on the same information (Table 2). In dataset A, there were no pairs of base populations with full AS. In datasets A and C, average δGener was 8.4 and 8.3, respectively. In dataset B, there were five clear clusters with a δGener of 0, 18, 24, 33 and 39 generations.

Discussion

The statistics presented quantify amount, uniqueness and proximity of genomic information for base populations and were useful for evaluating definitions of base populations to be fitted either as UPG or MF.

All studied datasets represented well-recorded populations with 98% or more of pedigree records being complete. Defining base populations based on an expected or *a priori* known difference in genetic level is only meaningful if these true differences can be estimated, so base populations should be defined to be sufficiently large.

The history of poor convergence when adding UPG to the model for dataset B is most likely caused by the large number of base populations with a small number of base animals (Figure 1). Poor connection of MF with genotyped animals, and pairs of MF with full auto-similarity (dataset B and C) will cause the gamma matrix of relationships within and between MF to be singular. If the gamma matrix (or Q'Q in QP transformation) is close to singularity, so is the coefficient matrix of the evaluation, which is known to slow down convergence when solving equations with a conjugate gradient method.

Another issue is the very deep pedigree of dataset B, in some cases, 30 generations of ancestors before the first animals with a genotype. The reasoning was not to lose any known pedigree relationships by removing generations of ancestors from the pedigree. For such data, the challenge is to reduce the number of generations in the pedigree without losing genetic relationships. A solution may be to define a set of base animals two or three generations before the first animals with data or genotypes and use pedigree records of ignored ancestors to construct relationships between these base animals, similar to MF.

Abstract

For single-step genomic best linear unbiased prediction, the use of so-called metafounders provides a coherent approach for combining pedigree and genomic relationships. Here, maximum likelihood estimation of metafounder parameters is presented. For one breed, the maximum likelihood estimate of metafounder parameter can be determined by solving a cubic equation. For multiple breeds, we provide an expression for the likelihood function, and for numerical maximisation of this function using gradient methods, we express the metafounder relationship matrix as a function of partial relationship matrices and metafounder parameters.

Introduction

Single-step genomic best linear unbiased prediction (ssGBLUP) is a methodology for genomic evaluation with partially genotyped populations, i.e. some individuals are genotyped and others are not, and phenotypes may be recorded in both subsets (Legarra *et al.*, 2014). The core idea in ssGBLUP is the construction of a relationship matrix across all individuals that combines genomic and pedigree relationship matrices. For the combined relationship matrix, the concept of metafounders (Legarra *et al.* 2015, Garcia-Baccino *et al.* 2017) provides a coherent approach to make genomic and pedigree relationships relative to the same base population and therefore compatible. With metafounders, the combined relationship matrix is

$$\mathbf{H}_{\Gamma}^{-1} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{G}^{-1} - (\mathbf{A}_{\Gamma})^{-1} \end{bmatrix} + (\mathbf{A}_{\Gamma}^{full})^{-1}$$

where G = MM^{T} / (k/2), with matrix M containing genotypes coded as -1, 0, 1, and k being the number of markers, $\mathbf{A}_{\Gamma}^{full}$ is the pedigree relationship matrix for all individuals with relationships among base individuals defined by metafounder parameters in matrix Γ, and A_{Γ} is the submatrix of $\mathbf{A}_{\Gamma}^{full}$ for genotyped individuals. Further details on metafounders and the computation of these matrices can be found in Legarra *et al.* (2015).

The matrix Γ contains parameters determining the relationships among base populations, within breeds (diagonal elements) and between breeds (off-diagonal element). The objective of this paper is to present methods for maximum likelihood estimation of these parameters, first for a single breed, and second for multiple breeds.

Maximum likelihood estimation of metafounder parameter for a single breed

For a single breed, the pedigree relationship matrix for genotyped individuals $\mathbf{A}_{\gamma} = \mathbf{A}(1-\gamma/2) + \gamma\mathbf{1}\mathbf{1}'$ where $\gamma \in [0;2[$ is the metafounder parameter, and A is the usual pedigree relationship matrix for genotyped individuals. Inference about g is from the observed marker genotypes M.

A model for observed marker genotypes is that $\mathbf{m}_j \sim N(2p_j - 1, 2p_j(1-p_j)\mathbf{A})$, $j = 1,\ldots,k$ are independent, where m_j are columns in M, and allele frequencies $p_j \sim N(0.5, \sigma_p^2)$, $j = 1,\ldots,k$ are independent. The metafounder parameter $\gamma = 8\sigma_p^2$. An expectation-maximisation (EM) algorithm can be derived for this

CC BY

DOI: 10.3920/978-90-8686-940-4_328, © O.F. Christensen and A. Legarra 2022

model, but the resulting algorithm involves numerical maximisation for the M-step and numerical integration for the E-step, and the algorithm as a whole becomes computationally troublesome to use in practice, and is not presented here. Computationally more feasible algorithms that approximate this EM-algorithm can be constructed, for example the one presented by Garcia-Baccino *et al.* (2017), but the statistical properties of these are not known.

Another approach, suggested by Christensen (2012), consists of studying the marginal distribution of m_j (integrating allele frequency p_j) and approximating this by a multivariate normal distribution with the correct marginal mean and marginal variance-covariance matrix, i.e. $\mathrm{m}_j \sim N(0,0.5\mathrm{A}_\gamma)$. Maximum likelihood estimation for this approach is presented here.

The joint density of $\mathrm{M} = [\mathrm{m}_1,\ldots\mathrm{m}_h]$ is

$$f(\mathbf{M}) \propto \prod_{j=1}^{k} \det(0.5\mathbf{A}_\gamma)^{-1/2} \exp(-\mathbf{m}_j'(0.5\mathbf{A}_\gamma)^{-1}\mathbf{m}_j / 2)$$

where a proportionality constant is ignored. Using that the product of exponential terms is the exponential of the sum, and $\sum_j \mathbf{m}_j'(0.5\mathbf{A}_\gamma)^{-1}\mathbf{m}_j = \mathrm{Tr}((0.5\mathbf{A}_\gamma)^{-1}\mathbf{M}\mathbf{M}')$, likelihood function is

$$L(\gamma) \propto \det(0.5\mathbf{A}_\gamma)^{-k/2} \exp(-(1/2)\mathrm{Tr}((0.5\mathbf{A}_\gamma)^{-1}\mathbf{M}\mathbf{M}'))$$

Taking logarithm of the likelihood function, introducing the notation $\mathbf{G} = \mathbf{M}\mathbf{M}' / (k/2)$, and ignoring constants, we obtain the log-likelihood function

$$\ell(\gamma) = -(k/2)\log(\det(\mathbf{A}_\gamma)) - (k/2)\mathrm{Tr}((\mathbf{A}_\gamma)^{-1}\mathbf{G})$$

Using formulas from Henderson and Searle (1981), we obtain:

$(\mathbf{A}_\gamma)^{-1} = \mathbf{A}^{-1} / (1-\gamma/2) - \mathbf{A}^{-1}\mathbf{1}\mathbf{1}'\mathbf{A}^{-1}\gamma / ((1-\gamma/2)(1-\gamma/2+\gamma\mathbf{1}'\mathbf{A}^{-1}\mathbf{1}))$ and
$\det(\mathbf{A}_\gamma) = \det(\mathbf{A})(1-\gamma/2)\ (1+\gamma\mathbf{1}\ \mathbf{A}\ \ \mathbf{1}/(1-\gamma/2)) = \det(\mathbf{A})(1-\gamma/2)\quad (1-\gamma/2+\gamma\mathbf{1}\ A\ \ \mathbf{1})$.

Inserting those into the log-likelihood function, and using short-hand notation $a = \mathbf{1}'\mathbf{A}^{-1}\mathbf{1}$, $b = \mathrm{Tr}(\mathbf{A}^{-1}\mathbf{G})$ and $c = \mathrm{Tr}(\mathbf{A}^{-1}\mathbf{1}\mathbf{1}'\mathbf{A}^{-1}\mathbf{G})$, we obtain

$$\ell(\gamma) = -\frac{k(n-1)}{2}\log(1-\gamma/2) - \frac{k}{2}\log(1-\gamma/2+\gamma a) - \frac{k}{2}\frac{b}{1-\gamma/2} + \frac{k}{2}\frac{c\gamma}{(1-\gamma/2)(1-\gamma/2+\gamma a)}$$

The maximum likelihood estimate is obtained by differentiating $\ell(\gamma)$ and setting equal to zero, where we note that the $k/2$ in front of each term in the expression can be ignored,

$$0 = \frac{(n-1)/2}{1-\gamma/2} - \frac{-1/2+a}{1-\gamma/2+\gamma a} - \frac{b/2}{(1-\gamma/2)^2}$$
$$+c\frac{(1-\gamma/2)(1-\gamma/2+\gamma a) - \gamma\left((1-\gamma/2)(-1/2+a) - (1-\gamma/2+\gamma a)/2\right)}{(1-\gamma/2)^2(1-\gamma/2+\gamma a)^2}$$

Multiplying by $(1-\gamma/2)^2(1-\gamma/2+\gamma a)^2$ on both sides of the equation followed by some algebraic manipulations we obtain a cubic equation

$$e_3\gamma^3 + e_2\gamma^2 + e_1\gamma + e_0 = 0$$

where $e_3 = -n(-1/2+a)^2/2, \quad e_2 = (n(-3/2+a)+a-b(-1/2+a)+c)(-1/2+a),$
$e_1 = (n-1)(-3/2+2a)-(-1+2a)(-3/2+a+b)$ and $e_0 = n-2a-b+2c.$

Solving a cubic equation, first requires the computation of the discriminant

$\Delta = 18e_3e_2e_1e_0 - 4e_2^3e_0 + e_2^2e_1^2 - 4e_3e_1^3 + 27e_3^2e_0^2$. If $\Delta>0$ then there are three distinct real roots, and if $\Delta<0$ then there is only one real root (and two complex roots). Following the computation of the discriminant, root(s) need to be computed, it needs to checked whether root(s) are within the interval [0;2[, and investigated which root (or possibly the boundary value 0) is the maximum.

Maximum likelihood estimation of metafounder parameters for multiple breeds

Here, we present maximum likelihood estimation for multiple breeds or genetic origins.

The columns of the genotype matrix M are assumed independent and distributed as $m_j \sim N(0,0.5A_\Gamma)$, where

$$\boldsymbol{\Gamma} = \begin{bmatrix} \gamma_{b_1} & \cdots & \gamma_{b_1,b_r} \\ \vdots & \vdots & \cdots \\ \gamma_{b_1,b_r} & \cdots & \gamma_{b_r} \end{bmatrix}$$

is a symmetric positive definite matrix with all $\gamma_b<2$, and A_Γ is the metafounder relationship matrix. Then the joint density of M = [m1,…m_p] is

$$f(\mathbf{M}) \propto \prod_{j=1}^{k} \det(0.5\mathbf{A}_\Gamma)^{-1/2} \exp(-\mathbf{m}_j'(0.5\mathbf{A}_\Gamma)^{-1}\mathbf{m}_j/2),$$

where proportionality constants have been ignored. Using that the product of exponential terms is the exponential of the sum, and that $\sum_j \mathbf{m}_j'(0.5\mathbf{A}_\Gamma)^{-1}\mathbf{m}_j = \mathrm{Tr}((0.5\mathbf{A}_\Gamma)^{-1}\mathbf{M}\mathbf{M}')$, the likelihood function is

$$L(\boldsymbol{\Gamma}) \propto \det(0.5\mathbf{A}_\Gamma)^{-k/2} \exp(-(1/2)\mathrm{Tr}((0.5\mathbf{A}_\Gamma)^{-1}\mathbf{M}\mathbf{M}'))$$

Taking logarithm of the likelihood function, noting that $\mathbf{G} = \mathbf{M}\mathbf{M}'/(k/2)$, and ignoring constants, we obtain the log-likelihood function

$$\ell(\boldsymbol{\Gamma}) = -(k/2)\log(\det(\mathbf{A}_\Gamma)) - (k/2)\mathrm{Tr}((\mathbf{A}_\Gamma)^{-1}\mathbf{G})$$

Maximum likelihood estimates of metafounder parameters can then be obtained by numerical maximization of this function.

For numerical maximization using gradient methods, derivatives of the log-likelihood function are needed. From the definition of A_Γ it can be shown using proof by induction that

$$\mathbf{A}_\Gamma = \sum_b \mathbf{A}^b(1-\gamma_b/2) + \sum_{b,b':b'>b} \mathbf{A}^{b,b'}((\gamma_{b'}+\gamma_b)/2) - \gamma_{b,b'})/4 + \sum_b \mathbf{C}^b\gamma_b + \sum_{b,b':b'>b} \mathbf{C}^{b,b'}\gamma_{b,b'}$$

With A^b being the breed b specific partial relationship matrix, $A^{b,b'}$ being the breeds b, b' segregation partial relationship matrix, matrix C^b having entries $C^b_{i,i'} = f_i^b f_{i'}^b$, and matrix $C^{b,b'}$ having entries $C^{b,b'}_{i,i'} = f_i^b f_{i'}^{b'} + f_i^{b'} f_{i'}^b$. Further details about partial relationship matrices can be found in Garcia-Cortes and Toro (2006). From this expression for matrix A_Γ derivatives with respect to metafounder parameters can be obtained.

Discussion

We have here presented maximum likelihood estimation of metafounder parameters. With genotypes on one breed, the parameter can be estimated by solving a cubic equation, whereas with genotypes on several breeds, numerical maximisation of the likelihood function is required for estimating parameters. Therefore, we have a theoretically based procedure for estimating metafounder parameters in simple cases with one or few breeds/ populations.

More challenging cases with large number of populations or genetic origins exist. In particular, for dairy cattle genetic evaluation, pedigree usually is incomplete with unknown parents of certain groups of individuals, e.g. due to imported bulls or incomplete pedigrees, and can be handled using so-called unknown parent groups. For metafounder approach this provides a challenge because number of unknown parent groups is large, making the number of parameters in Γ matrix prohibitively large, and either a reduction in number of unknown parent groups, as in Kudinov *et al.* (2020), or a parameterisation of Γ using fewer parameters, as in Koivula *et al.* (2021), needs to done.

329. Exploring the statistical nature of independent chromosome segments

M.K. Hollifield*, M. Bermann, D. Lourenco and I. Misztal

University of Georgia, Department of Animal and Dairy Science, Athens, GA 30602, USA; marykate.hollifield@uga.edu

Abstract

Previous research in genomics developed the concept of independent chromosome segments and suggested that genomes are a composite of chromosome segments derived from preceding generations. The number of independent chromosome segments (M_e) was posited as $4N_eL$, a function of effective population size (N_e) and genome length in Morgans (L). The objective of this study was to investigate the statistical nature of independent chromosome segments. In a simulated population, N_a animals were selected randomly as founder animals. For all animals, the genome was split into N_s equal-sized segments. For each specific location, segments of non-founders were assigned the most similar segment of one founder. Genomic analyzes estimated the value of the segments, and breeding values were a sum of all segments for a specific animal. Accuracies were maximized at N_a=N_e, N_s=4L, but they were not as high as in GBLUP, suggesting that the current choice for segments is an approximation.

Introduction

The genome is inherited in large segments from each parent and is a mosaic of ancestral segments that are broken in each generation (MacLeod, 2005; Pääbo, 2003). Genomic selection works by estimating independent chromosome segment effects (Goddard, 2009). Hypothetically, for populations with small effective population size (N_e), the estimated number of independent chromosome segments (M_e) is $4N_eL$, where L is genome length in Morgans (Stam, 1980). Experimentally, M_e has been related to the eigenvalues of the genomic relationship matrix (G), as the dimensionality of genomic information is approximately $4N_eL$ (Pocrnic *et al.*, 2016). Predictions are accurate using computing algorithms that assume a limited dimensionality of G (Misztal *et al.*, 2014a).

Stam (1980) defined the number of chromosome segments as a random variable, i.e. of statistical nature, and showed that segments are of different sizes but with a mean of $1/4N_e$. Ignoring the physical properties of the segments and exploring their statistical nature, the genome could be possibly divided into equal-sized segments, and each unique segment could be assigned a value. If the additive value of each segment is known, can genomic prediction be based solely on those segments? Conceptually, chromosome segments effects are additive; thus, an animal's breeding value is composed of a sum of these effects (Misztal *et al.*, 2020). In this study, we assume that the segments are distributed in N_e animals for a population, and the number of segments is equal to the genome size divided by 4L. Then, we estimated the effects of individual chromosome segments to assess if all additive genetic information can be composed in $4N_eL$ independent chromosome segments of equal size.

Materials & methods

Data. Data were simulated using QMSim (Sargolzaei and Schenkel, 2009). The population contained 20,000 animals and ten non-overlapping generations. Each generation included 2,000 animals with N_e equal to 20. One polygenic trait was simulated with a heritability of 0.3. The last three generations were genotyped, and each genome contained ten 1 M long chromosomes, for a total genome length of 10 M and 50,000 SNP.

Models and computations. A group of animals was selected to generate conceptual independent chromosome segments. Hereinafter, these animals will be referred to as 'founder' animals. The founder animals were selected from the genotyped animals in the last three generations. Each animal's genome composed of 50,000 SNP was split into discrete segments. To test the effects of the theoretical $4N_eL$ independent chromosome segments, N_e (20) founder animals and 4L (40) segments per animal were analyzed. This study conducted two main analyses: (1) founder animals were selected randomly or by the least related animals in the population; and (2) various numbers of segments and founder animals were compared.

The chromosome segments of each animal were denoted as p_{ij}, where p is the j^{th} segment of the i^{th} animal. To analyze the behavior around $4N_eL$ segment effects, the number of segments per animal (N_s) varied while the number of founder animals (N_a) remained fixed to N_e (20). Similarly, N_s was fixed to 4L (40) as N_a varied. Each segment of each non-founder animal was assigned to a founder animal segment that was the most similar. Only the effects of the founder animal's chromosome segments were tested to evaluate independent chromosome segment effects. Altogether, there were N_aN_s segment effects total, and the ij^{th} segment effect was numbered as $(i-1)N_a + j$. The similarities per non-founder segment were calculated by $min\ (\Sigma \mid p_{kj} - p_{lj} \mid)$, where k is the founder animal with the minimum sum of the SNP codes in segment j for non-founder animal l. The effects of the hypothetical independent chromosome segments were estimated using:

$$y = 1'\mu + Z_s s + e \quad (1)$$

where y is a vector of phenotypes, Z_s is an incidence matrix relating the assigned founder animal segments to all animals, s is a random vector of estimated segment effects, and e is a random vector of errors.

Accuracies were computed to investigate the theoretical number of $4N_eL$ independent chromosome segments containing all genetic information in a population. Accuracies were calculated for animals in the last generation by *cor* (TBV, $Z_s\hat{s}$), where $Z_s\ \hat{s}$ is a vector of breeding values based on segments and TBV is a vector of the true breeding values outputted by QMSim. Accuracies of segment effects were compared with the true accuracy (i.e. *cor* (TBV,GEBV)). GEBV were computed using GBLUP in the BLUPF90 software suite (Misztal *et al.*, 2014b), whereas $\hat{s}$ and $Z_s\hat{s}$ were computed using in-house software written in Fortran.

Results

Accuracies of estimated chromosome segment effects with random and the least related animals as founder animals are shown in Figures 1 and 2. In Figure 1, N_a is fixed to N_e (20), and in Figure 2, N_s is fixed to 4L (40). It was hypothesized that accuracy is maximized with $4N_eL$ chromosome segments, which aligns with the theory that there is no new genetic information if $4N_eL$ independent chromosome segments are explained (Pocrnic *et al.*, 2019).

The purple lines in Figure 1 and 2 indicate where $4N_eL$ chromosome segment effects are estimated and are close to where accuracy is maximized and begins to plateau or decrease. The maximum accuracy of segment effects was 0.69 for both random and least related founder animals, and the accuracy of GBLUP was 0.90. The results suggest that 4L segments of N_e founder animals contain all additive information in the population. However, the accuracy of GBLUP is greater than that of the chromosome segment effects, suggesting that the chromosome segments do not account for all genetic variation as they were calculated. It was presumed that if the least related animals in the population were used as the founder animals, more ancestral segments would be accounted for than randomly chosen founder animals, and accuracy would be greater. Similar to the initial proposition of APY, the core was defined as the 'proven' animals with their own phenotypes and progeny phenotypes, hence the animals with the most information and greatest genetic

impact on the population (Misztal *et al.*, 2014). Core animals have since been redefined, and random animals are appropriate to use as core and produce the same accuracy as the previous definition (Bradford *et al.*, 2017).

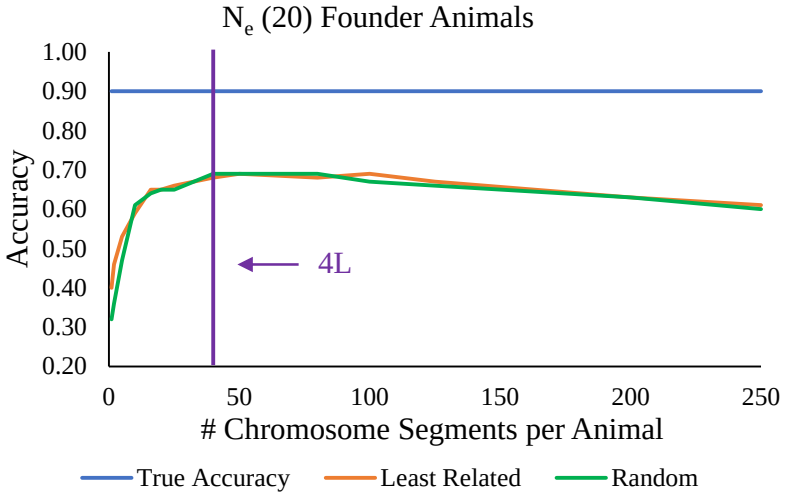

Figure 1. Accuracies of chromosome segment effects with random and least related founder animals. The number of founder animals is fixed to N_e (20). Accuracies of chromosome segment effects were calculated by correlating the TBV and the estimated segment effect. The true accuracy was calculated by correlating the TBV and GEBV. The purple line represents $4N_eL$ independent chromosome segments.

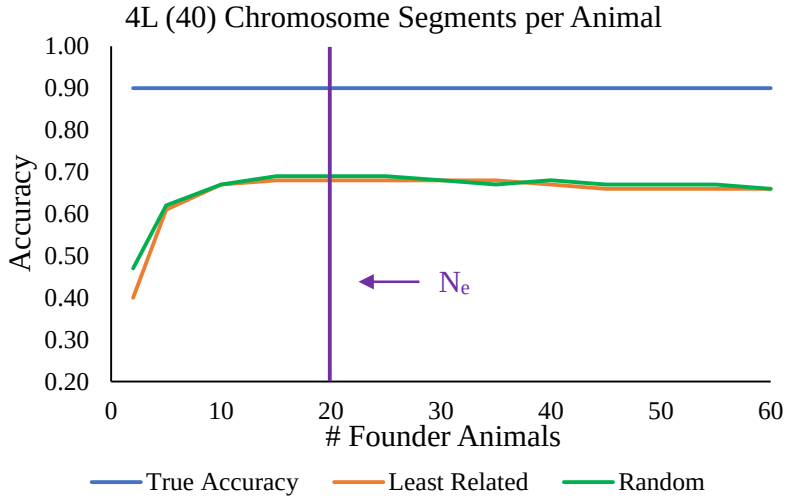

Figure 2. The number of chromosome segments per animal is fixed to 4L (40). The methods and components are the same as in Figure 1.

As aforementioned, DNA is inherited from ancestors as contiguous blocks formed by recombination throughout the evolution of the population (Pääbo, 2003). Biologically, In violation of present concepts of physical chromosome segments, this study used constant segment size, and recombination was not considered. A follow-up study will assume haplotypes following the physical properties of segments. The results presented indicate some agreement with expectation, but it is not complete, perhaps haplotypes better fit the definition.

Discussion

Approximately $4N_eL$ chromosome segments contain almost all the genetic information that can be explained in a population. It is important to notice that M_e is a statistical concept, and the way those M_e segments are physically organized in haplotypes depends on linkage disequilibrium. Further investigation is needed on the definition and characteristics of physical chromosome segments. If each segment has an additive value and can be ranked, genomic predictions can potentially be based on segments alone. By using the concepts of limited dimensionality and independent chromosome segments, overlapping information in a population can be removed, reducing computing time and data storage space for genomic evaluations.

330. Including local genomic breed proportions in genomic predictions for crossbred

J.H. Eiríksson*, G. Su and O.F. Christensen

Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark; jonh@qgg.au.dk

Abstract

Genomic evaluations for crossbred animals introduce challenges not encountered for purebred animals. We propose to include effects of local breed proportions (LBP) based on detected breed of origin of alleles in a genomic model for crossbred dairy cows. We tested different segment length for modelling the LBP: 1, 20, 100 and 500 markers, for genomic prediction based on data of first lactation protein yields of 5,176 Danish crossbred dairy cows with contribution from three dairy breeds. The models that included LBP had slightly higher cross-validation predictive ability, 0.390 for all segment lengths compared with 0.385 for a model without LBP effects. The LBP models also had less dispersion bias. Inclusion of LBP in genomic predictions can therefore improve predictions even when considering the local effects in segments of hundreds of markers.

Introduction

Genomic evaluations for crossbred introduce challenges not encountered in genomic evaluation within the pure breeds. Among those challenges is the lower level of linkage disequilibrium between markers and quantitative trait loci across breeds than within breed levels (Ibánēz-Escriche *et al.*, 2009), genetic background (Falconer, 1989), and breed segregation, i.e. the additional genetic variation in offspring of crossbred parents (Christensen *et al.*, 2015).

Models that split the breeding values of crossbreds into breed specific terms and account for breed origin of alleles (BOA) can in principle account for the different linkage between breeds (Ibánēz-Escriche *et al.*, 2009). However, these models do not always result in more accurate predictions than models assuming common marker effects (Sevillano *et al.,* 2017). Applications of BOA models (e.g. Sevillano *et al.* 2017) have generally not accounted for the breed segregation term which Christensen *et al.* (2015) presented in their derivation of the models for three-way crosses.

For BOA models with training on purebred data, intercepts for correction of breed levels are necessary for the prediction of breeding values of crossbreds (Eiríksson *et al.*, 2021) and might not be readily available from the genomic evaluations of purebred. Phenotypes of crossbreds along with BOA information could give more precise estimates of the breed level intercepts than purebred information alone. Additionally, BOA could give information on the local breed proportions (LBP), i.e. the contribution of the breeds to different regions of the genome, which can vary in offspring of crossbred animals and similarly to the breed segregation term. The LBP can be considered at individual marker level, or for a number of consecutive markers because of the high correlation between BOA of proximate markers.

Therefore, the objectives of this study were to compare predictive ability of genomic models including global genomic breed proportions (GBP) with a model that additionally includes local breed proportions (LBP) for genomic prediction for crossbred cows. We considered different segment lengths for the LBP model (LBPM).

Materials & methods

Data. Single nucleotide polymorphism (SNP) genotypes from the EUROG MD custom chip and phenotypes of 305-day first lactation protein yields of 5,176 Danish crossbred dairy cows from 74 herds were used in this study. These cows were crosses of Holstein (H), Jersey (J) and Nordic Red Dairy Cattle (R) in various combinations. We imputed the genotypes to a set of 50,684 markers, to fill in missing genotypes, and phased them to two haplotypes using FImpute (Sargolzaei *et al.*, 2014), for the genotyped crossbred and 2,500 genotyped animals from each of the pure breeds. We detected BOA using the AllOr method (Eiríksson *et al.*, 2021) with a purebred reference genotypes of 2,500 cows from each of the breeds, a segment length of 100 SNPs and shifting five SNPs between rounds in the method.

For investigating crossbreed-specific genetic effects, we constructed a corrected phenotype, i.e. corrected for both fixed effects and genomic estimated breeding values computed from purebred information. We calculated the corrected phenotype as:

$$y^* = y - \hat{a}_{BOM},$$

where y is a vector of phenotypes of first lactation 305-day protein yields that were corrected for herd-year and calving age effects, and $\hat{a}_{BOM}$ is a vector of genomic estimated breeding values. The $\hat{a}_{BOM}$ were calculated with a breed of origin model using solutions from each of the three purebred genomic evaluations, as described in Eiríksson *et al.* (2021), but without the intercepts for breed level corrections. The estimated effects from purebred evaluations, i.e. estimated marker effects and residual polygenic effects, were from the February 2021 run of the genomic evaluations of the three pure breeds from the Nordic Cattle Genetic Evaluation.

Models. We compared models with and without including local breed proportion effects.

The GBP model (GBPM) included regressions on global breed proportions and genomic breed heterozygosity rates:

$$y^* = 1u + f_H c_H + f_J c_J + k_{H,J} h_{H,J} + k_{H,R} h_{H,R} + k_{J,R} h_{J,R} + e \quad (1)$$

where u is an intercept, 1 is a vector of ones, f_b contains global proportions of alleles assigned to breed b (b=H, J, R), c_b is a regression coefficient on breed proportions, $k_{b,b'}$ contains genomic breed heterozygosity rate, i.e. proportion of loci with alleles assigned to two different breeds, b and b', $h_{b,b'}$ is the regression coefficients on genomic breed heterozygosity, and e is the random residual $e \sim N(0, I\sigma^2_e)$. The values in f_b were calculated as $f_{i,b} = \Sigma_j (x_{b,i,1,j} + x_{b,i,2,j})/(2m)$, where $x_{b,i,g,j}$ is 1 for marker j with allele on haplotype g assigned to breed b, 0 if the allele is assigned to another breed, and a value between 0 and 1 if the allele was not assigned to definite breed and m is the number of markers. Note that since $f_H + f_J + f_R = 1$, one of the global breed proportion effects can be left out of the model, given that an intercept is included. The values in $k_{H,J}$ were calculated as $k_{i,b,b'} = \Sigma_j (x_{b,i,1,j} \circ x_{b',i,2,j} + x_{b',i,1,j} \circ x_{b,i,2,j})/m$ where $\circ$ denotes element wise multiplication.

The LBPM additionally included random LBP effects:

$$y^* = u + f_H c_H + f_J c_J + k_{H,J} h_{H,J} + k_{H,R} h_{H,R} + k_{J,R} h_{J,R} + Z^*_H p_H + Z^*_J p_J + Z^*_R p_R + e \quad (2)$$

where $Z^*_b = Z_b - f_b 1'$, with Z_b containing the local breed proportions, i.e. the proportion of alleles on a segment that were assigned to breed b. Furthermore, p_b is a vector with random effects of local proportion of breed b, with $p_b \sim N(0, I\sigma^2_{p,b})$, where $\sigma^2_{p,b}$ is the variance for segment LBP effect for breed b (similar to SNP variance for SNP-BLUP).

An equivalent model of the LBPM is to construct relationship matrices for the local effects, which is computationally more efficient for short segments. The LBPM with relationship matrix is then:

$$y^* = u + f_H c_H + f_J c_J + k_{H,J} h_{H,J} + k_{H,R} h_{H,R} + k_{J,R} h_{J,R} + v_H + v_J + v_R + e \quad (3)$$

where v_b is a vector of local breed proportion animal effects with, $v_b \sim N(0, Q_b \sigma^2_{v,b})$ where $Q_b = Z^*_b Z^{*\prime}_b / (\mathrm{tr}(Z^*_b Z^{*\prime}_b)/n)$ where tr stands for trace and n is number of animals.

Implementation. We estimated the variance components for LBPM with segment length of 500, 100, 20, and 1 SNPs. For the 1 SNP estimation we constructed a relationship matrix and added a low value, 0.0001, to the diagonal of Q_b to make it invertible. We used the AI-REML procedure from the DMU package (Madsen and Jensen, 2013) for variance component estimation.

We tested the predictive ability of the LBPMs and GBPM using five-fold cross validation, where we randomly split the herds into five groups, and made the prediction for animals in each group based on records from the other four groups. For all models, the predictions $\hat{y}$ included all the effects in the model plus $\hat{a}_{BOM}$. We compared the predictions with y, i.e. the phenotypes corrected for fixed herd-year and calving age effects.

Results

The genomic breed proportions according to the BOA assignment were 49% H, 15% J, and 36% RDC. According to the results from GBPM, a 10% increase in genomic breed heterozygosity increased protein yield by 1.6 kg (SE=1.0), 1.7 kg (SE=0.4), and 2.5 kg (SE=1.1), for H/J, H/R and J/R respectively. For the LBPMs, the local breed proportion effects together explained around 2% of the variance in y^*, with the highest proportion for the shortest segments (Table 1). The variance related to H proportions was the largest, ranged from 20.8 to 25.8, compared with the variances for J and R proportions, which ranged from 5.0 to 5.7 and 3.1 to 4.8, respectively (Table 1). The predictive ability of the models from the cross-validation was equal for all LBPM, and 0.005 higher than the correlation from GBPM (Table 1). The LBPM had less dispersion bias than GBPM, irrespective of segment length.

Discussion

The $\sigma^2_{v,H}$, $\sigma^2_{v,J}$, and $\sigma^2_{v,R}$ estimates are dependent on the breed composition in the datasets. Local breed proportions are for example constant throughout the genome of F1 animals, which were around 30% of our data, and they do therefore not contribute to this variance. Alternative standardization of the LPM relationship matrices, e.g. based on setting the expected diagonal values for a specific type of cross to be 1, could give estimated variances that do not suffer from this. However, in our study that would make

Table 1. Variance components for breed proportions as well as prediction accuracy and dispersion bias for first lactation protein yield.

Model[3]	Segm. length	Variance				Cross-validation	
		$\sigma^2_{v,H}$	$\sigma^2_{v,J}$	$\sigma^2_{v,R}$	σ^2_e	Cor($\hat{y}$,y)	b_1[2]
GBPM						0.385	0.880
LBPM	500	20.8[1]	5.0[1]	3.1[1]	1,578.7	0.390	0.901
LBPM	100	24.8[1]	5.6[1]	4.8[1]	1,572.8	0.390	0.901
LBPM	20	25.7[1]	5.7[1]	4.7[1]	1,571.9	0.390	0.901
LBPM	1	25.8	5.7	4.8	1,571.6	0.390	0.901

[1] Calculated as $\sigma^2_{v,b} = \sigma^2_{p,b} * \mathrm{tr}(Z^*_b{}' Z^*_b)/m$.

[3] GBPM = global breed proportion model, LBPM = local breed proportion model.

comparison across segment lengths skewed. The estimated variances suggest that there is variation related to LBP in the data and the magnitude is about 1-2% of the phenotypic variance and around 5% of the additive genetic variance.

The improvement in predictive ability from LBPM compared to GBPM was marginal in our study (Table 1). However, improvement in prediction was not expected for all the animals in the data, LBP could be more important for groups with few or no F1 animals. Additionally, the training set for estimating LBP effects was not large, only around 4,000 animals for estimating LBP effects for the three breeds. The relatively small difference in variance explained and predictive ability between alternative segment lengths suggests that local breed proportion effects can be included for longer segments, e.g. 100 SNPs, and therefore reduce the number of parameters without compromising accuracy.

The Q_b matrices in Equation 3 have similar structure as the genomic breed-segregation partial relationship matrix presented by Christensen *et al.* (2015). Both have off-diagonal indicating if animals share origin in fewer or more loci than that is expected based on breed proportions. Christensen *et al.* (2015) only considered three-way crosses with the same terminal sire breed and the diagonal of the breed-segregation partial relationship matrix is therefore constant, equal to 0.5. In our case, with crossbred animals of varying breed compositions, the diagonal elements were highly variable, but with the average equal to one because we standardized the matrix with the trace.

Detected BOA has to our knowledge not before been applied to model heterozygosity in crossbreds. If BOA information is available, modelling heterozygosity in this way is simple, and can be simpler than having to rely on pedigree information.

The LBPM presented here is an add-on to the BOA model with training in purebred population (Eiríksson *et al.* 2021). A potential complication with the application of the BOA model in that paper is that the intercepts for correction for breed level differences may not be available from routine genomic evaluation. The global breed proportion effects could be used for accounting for breed levels in that model. Other authors have presented BOA models with training in both purebreds and crossbreds (Karaman *et al.*, 2021) without accounting for breed segregation. Whether the inclusion of local breed proportion effects in those models improves prediction is an interesting area for further development.

Inclusion of LBP effects can moderately increase the predictive ability and reduce bias even when the local effects are considered in segments of hundreds of markers. They should therefore be considered in future development of models for genomic prediction for crossbred.

331. Investigating the impact of APY core size and definition in single-step GBLUP evaluations

R. Abdollahi-Arpanahi*, D. Lourenco and I. Misztal

Department of Animal and Dairy Science, University of Georgia, Athens, GA 30602, USA;
rostam.abdollahi@uga.edu

Abstract

Algorithm of proven and young (APY) uses a subset of genotyped individuals as a core and remaining genotyped individuals as noncore for creating a sparse approximation of the inverse of a large genomic relationship matrix. This study aimed to investigate eight core definitions based on relatedness and distribution across generations, with six different core sizes, to explore the prediction accuracy of APY. The dataset consisted of 357K Duroc pigs, with 111K genotypes, and phenotypes for three production traits. When the core size was equal to the number of largest eigenvalues explaining 50% of the variation of G (eigen50; n=160), the core based on most popular animals or evenly sampled across the pedigree delivered the highest prediction accuracy. As the core size increased to the number of eigenvalues explaining 99% of the variation in G (eigen99; n=7,320), the prediction accuracy of all core types was nearly identical to the regular ssGBLUP.

Introduction

Inverting the genomic relationship matrix for larger than 150K genotyped individuals is a barrier for application of Single-step genomic BLUP (ssGBLUP) (Fragomeni *et al.*, 2015). Misztal *et al.* (2014) proposed the 'algorithm for proven and young animals' (APY) based on genomic recursions to create a sparse approximation of the inverse of G to enable large-scale single-step genomic BLUP (ssGBLUP) evaluations. In APY, genotyped animals are partitioned into two groups of core and noncore. The GEBV of noncore animals is conditioned on the GEBV of core animals. The computing cost of APY G^{-1} is cubic with the number of core animals and linear with the number of noncore. The core size depends on the dimensionality of G, which has been addressed by the eigenvalue decomposition of G (Pocrnic *et al.*, 2016). However, the choice of core animals is still a question that requires further research. Therefore, this study aimed to assess the performance of eight core types in six different core sizes, based on the eigenvalue decomposition of G, on the prediction accuracy of ssGBLUP using 111k genotyped Duroc pigs.

Materials & methods

Data structure. We used a Duroc pig dataset consisted of 357,220 pedigreed animals, of which 111,583 were genotyped for 32,824 SNP markers after the quality control. Data were collected from 2012 to 2021. Studied traits included average daily gain at nursery (ADGn, n=221,955), average daily gain at finishing (ADGf, n=195,946), and backfat (BF, n=195,967). The descriptive statistics of studied traits can be found in Table 1.

Model and analysis. The statistical model for genetic evaluations was as follow:

$$y_t = Xb_t + W_1l_t + W_2c_t + W_3a_t + e_t \quad (1)$$

where y_t is the vector of observations for trait *t*; *t* refers to ADGn, ADGf, and BF; b_t is the vector of fixed effects; $\mathbf{l}_t \sim MVN(0, \mathbf{I}\sigma_l^2)$, $\mathbf{c}_t \sim MVN(0, \mathbf{I}\sigma_c^2)$ and $\mathbf{a}_t \sim MVN(0, \mathbf{H}\sigma_a^2)$ are the vectors of random effects for litter, pen, and direct additive genetic effects, respectively; e_t is the vector of residuals. The X, W_1, W_1, and W_1 are design matrices for the effects in l_t, c_t, and a_t, respectively. Here σ_l^2, σ_c^2, and σ_a^2 are variances of litter

DOI: 10.3920/978-90-8686-940-4_331, © R. Abdollahi-Arpanahi *et al.* 2022

size, pen effects, and additive genetic affects; H is the (co)variance matrix between animals constructed by integrating pedigree and genomic relationship matrix (Aguilar *et al.*, 2010). We used ssGBLUP with APY to compute GEBV. For more detailed description of APY see Misztal (2016). The ssGBLUP was run in a multiple-trait animal model framework.

Direct additive genetic and litter effects were fit for three traits, pen effect was fit for ADGf and BF traits. The fixed effects were gender for three traits, heard-year-week for ADGn, barn for ADGn and BF. Age of weighting was considered as a covariate for ADGn and ADGf.

Core sizes. At first, the G matrix was constructed, then singular value decomposition has been applied. Then, six core sizes equal to 160, 700, 1,363, 2,344, 7,320, 10,000 individuals were chosen according to the number of largest eigenvalues explaining 50, 80, 90, 95, 99 and >99% of the variation in G.

Core definitions. Eight core types were defined including: (1) most popular animals (MPA): Animals with higher than specific number of progeny (>400, >125, >35, >30, >20), both parents known and own performance record; (2) least popular males (LPM): Males with both parents known, without progeny, and without own performance record; (3) least popular females (LPF): Females with both parents known, with neither progeny nor own performance record; (4) random set (Rnd): Core animals were randomly sampled from all genotyped animals; (5) evenly distributed across pedigree (Ped): Animals were ordered in genealogical order, then core animals were evenly sampled across pedigree; (6) within family selection (Fam): from each full-sib family only one progeny was randomly assigned to core group; (7) unrelated animals (Unrel): animals with genomic relationship less than a threshold (<0.10, <0.15, <0.20, <0.22, <0.27) were chosen; (8) QR decomposition: The genotype matrix (Z) was decomposed into a product Z= QR according to QR factorization (Golub and Van Loan, 1996).

The direct inverse of G using all genotyped animals in ssGBLUP was used as the baseline (Regular ssGBLUP).

Prediction accuracy. The prediction accuracy of each scenario was estimated for 17,594 young, genotyped pigs born in 2020 as follows:

$\widehat{acc}_{PA} = \frac{corr(\mathbf{y_{adj}}, GEBV)}{\sqrt{h^2}}$, where y_{adj} is the vector of adjusted phenotypes for all non-genetic effects.

Results & discussion

Core definitions. The prediction accuracy using ssGBLUP with direct inversion of G (i.e. the baseline) was 0.85, 0.80, and 0.77 for ADGn, ADGf and BF, respectively. When the number of animals in the core was equal to eigen99, all core types delivered similar prediction accuracy and slightly less than the baseline (Figure 1). When the core size was less than the number of largest eigenvalues explaining 90% of the variation of G, the MPA delivered the highest prediction accuracy, and the QR and Unrel attained the lowest compared to other core definitions (Figure 1). The results showed that by increasing the core size, the difference among various core definitions faded. They were nearly identical as the number of animals in the core increased to a value equal to the number of largest eigenvalues explaining 99% of the variation in G.

The correlation between GEBV obtained from the regular ssGBLUP and APY ssGBLUP with the core size corresponding to eigen99 was greater than 0.99. In Rnd, Ped, Fam, Unrel core definitions, genotyped animals are distributed well across the generations. Misztal (2016) pointed out that the prediction performance of APY depends on how well core animals represent the independent chromosome segments

(ICS). It has been indicated that core definitions representing all generations and maximizing the number of genotyped offspring would deliver the highest predictive ability (Ostersen *et al.*, 2016; Vandenplas *et al.*, 2018). Including animals from all generations in the core set was also proposed by Bradford *et al.* (2017).

QR core showed the lowest GEBV correlation with regular ssGBLUP (0.992) at eigen99, and it needed the largest number of iterations to reach convergence. Opposite to Rnd and Ped core definitions, the QR core included old animals born from 2012 to 2016. Hence, unequal distribution of core animals across years/generations would result in slightly less accurate GEBV (Vandenplas *et al.*, 2018). It is important to include animals from all generations in the core set.

Regardless of trait and core definition, the accuracy of APY increased 33% from eigen50 to eigen80, 12% from eigen80 to eigen90, and 8% from eigen90 to eigen99. The improvement in the prediction accuracy by increasing the core size from eigen99 to 10,000 animals was negligible (< 1%). When the core size was determined based on eigen99, the difference between prediction accuracy using APY and regular ssGBLUP for ADGn, ADGf, and BF was 0.007, 0.008, and 0.007, respectively.

Core size. We found that when the core size was less than the number of largest eigenvalues explaining 95% of the variation in G, the choice of core animals was critical to accurately predict GEBV using APY ssGBLUP. However, as the core size increased to the number of largest eigenvalues explaining 99% or greater than 99% of the variation in G, all core types converged to similar prediction accuracy. Pocrnic *et al.* (2016) showed that the core size in APY ssGBLUP required to predict GEBV as accurate as the regular ssGBLUP with direct G inverse is related to the dimensionality of G. The effective dimensionality of G is dependent on the minimum number of ICS in the population, number of SNP markers, and number of genotyped animals.

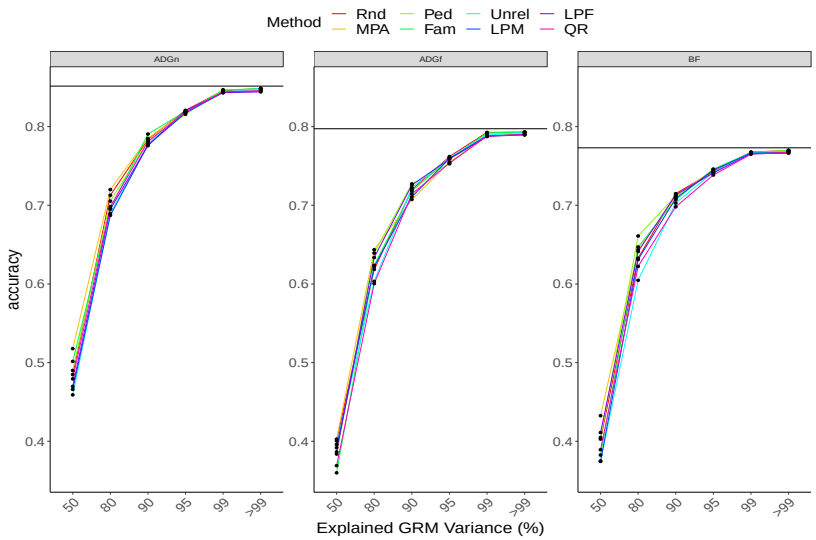

Figure 1. Prediction accuracy of genomic estimated breeding values (GEBV) from different core definitions and sizes in APY ssGBLUP for Average daily gain at nursery (ADGn), average daily gain at finishing (ADGf), and backfat (BF). The core sizes were determined based on the number of largest eigenvalues explained 50% (n=160), 80% (n=700), 90% (n=1,363), 95% (n=2,344), 99% (n=7,320) and >99% (n=10,000) of the variation in G. The solid black line is the prediction accuracy derived using the regular ssGBLUP as the baseline.

To conclude, the core size is more important than the core definition. Randomly sampling the core from the pool of genotyped animals or evenly selecting animals across generations with the size equal to the number of largest eigenvalues explaining 99% of the variation in G is adequate for accurately predicting GEBV using APY ssGBLUP.

Abstract

Different strategies were compared for defining core animals in the APY algorithm using either simulated or real data: random; youngest; rank based on the contribution to the genomic relationship matrix. The selection of animals with the lowest rank according to their contribution to the G matrix provided slightly higher accuracies, especially in the simulated data. In real data, particularly for larger sizes of core animals, the criteria of choice appear less important, confirming results of earlier studies. Data considered in the present work were characterized by a complete pedigree. Thus, the key contributors approach for core definition could also be tested under these conditions and with large datasets.

Introduction

Single-step GBLUP (ssGBLUP) has enabled genomic selection (GS) application in farm animal populations where only a portion of the animals in the pedigree are genotyped. The standard ssGBLUP requires the inversion of the genomic relationship matrix (G), which is computationally feasible for up to 150,000 genotyped individuals (Bradford *et al.*, 2017). However, after more than ten years of GS, the number of genotyped animals has passed the one million mark in some cattle populations (https://queries.uscdcb.com/Genotype/counts.html). An option to face this challenge is using the Algorithm for Proven and Young (APY), where genotyped animals are divided into core and noncore, with only the portion of G corresponding to the core animals directly inverted (Misztal *et al.*, 2014). Pocrnic *et al.* (2016) showed that the APY method is able to provide the same GEBV accuracies of the standard ssGBLUP when the number of core animals corresponds to that of independent chromosome segments (M_e) segregating in the population. The M_e is defined as $4N_eL$ (Stam, 1980), where N_e is the effective population size and L is the genome length in Morgans. This number can be approached by the number of eigenvalues explaining 98% of the variance of G (Pocrnic *et al.*, 2016). In general conditions, a random choice of core animals seems to be the best option (Bradford *et al.*, 2017; Fragomeni *et al.*, 2015). Although the random choice of core animals is widely accepted and used in APY ssGBLUP evaluations, some studies have systematically investigated ways to identify core animals (Bradford *et al.*, 2017; Ostersen *et al.*, 2016). In this work, we applied the concept of key contributors (Neuditschko *et al.*, 2017) to identify animals that affect the (co) variance structure of G. This approach is based on the eigenvalue decomposition of G, and the resulting key contributors were used as core animals in APY ssGBLUP.

Materials & methods

Data. Two data sets were used. The first was a simulated data set generated for the XVII QTL MAS workshop (Usai *et al.*, 2012). It consisted of a population with 4,100 individuals (100 males), spread into five generations with a genome of 5 chromosomes, each carrying 4,000 equally spaced SNPs. A complete pedigree was available. Three phenotypes were also available for females, with heritabilities of 0.35, 0.35, and 0.50, respectively.

The second was a real data set of 136k milkability records of Italian Simmental cattle (Cesarani *et al.*, 2021). A total of 11,636 animals were genotyped with 42,141 SNPs. Genotyped cows born from 2017 to 2019 were considered as the validation population. Scenarios are represented in Table 1.

DOI: 10.3920/978-90-8686-940-4_332, © N.P.P. Macciotta *et al.* 2022

Statistical analysis. Using the simulated data, two multivariate statistical analyses were performed to derive the contribution of each animal to G (G_{contr}). The first was a principal component analysis (PCA). G_{contr} was calculated as:

$$G_{contr} = \sum_{i=1}^{i=k} \left(\frac{a_{ij}}{\sqrt{\lambda_i}} \right)^2 \quad (1)$$

where a is the coefficient of the i-th eigenvector for the j-th animal; λ is the i-th eigenvalue; k is the number of retained eigenvectors. The second was a Multivariate Factor Analysis (MFA). In this case, G_{contr} was calculated as:

$$G_{contr} = \sum_{i=1}^{i=k} {l_{ij}}^2 \quad (2)$$

where l is the loading of the i-th rotated factor for the j-th animal; k was defined before. In factor terms, the G_{contr} is equivalent to the communality for each animal.

Four strategies were then compared for structuring the genetic (co)variance between individuals:

1. BLUP using the average relationship matrix (A);
2. ssGBLUP, using the inverse of the realized relationship matrix (H) (Aguilar *et al.*, 2010);
3. $ssGBLUP_{APY}$, with the APY algorithm and three core sizes (10, 20, 30%).

Four criteria for choosing the genotyped (ssGBLUP) and the core ($ssGBLUP_{APY}$) animals were tested: (1) random; (2) the best for G_{contr}; (3) the bottom for G_{contr}; (4) the youngest. For criteria 2 and 3, G_{contr} was calculated using either PCA or MFA. Thus, 1000 (random, best, bottom, youngest) animals were genotyped among the 4,100 available for ssGBLUP; among them, 10, 20, 30% were selected as core in $ssGBLUP_{APY}$.

For the ssGBLUP applied to real data, 10, 20, and 30%, of genotyped animals were considered (321 candidate cows plus other animals). In $ssGBLUP_{APY}$, all genotyped animals were considered and three different core sizes (10, 20, and 30%) were tested. Genotyped or core animals in the two methods were chosen according to the four criteria used in simulated data.(Table 1).

Validation was assessed by calculating the correlation between (G)EBV and true breeding values of the validation population (simulated data), or by the correlation between (G)EBV when proven and (G)PA of candidates when born (real data).

Results

Accuracies of (G)EBV for the simulated data are reported in Figure 1. For all the three traits, smaller values were showed by BLUP compared to genomic model. For ssGBLUP and $ssGBLUP_{APY}$, the choice of bottom G_{contr} animals yielded higher accuracies.

Table 1. Data structure for the different scenarios of GS.

Data	Scenario	Genotyped	Validation	Core size
Simulated	ssGBLUP	1000	1000	
	$ssGBLUP_{APY}$	1000		100, 200, 300
Real	ssGBLUP	1,164, 2,327, 3,491	321	
	$ssGBLUP_{APY}$	11,636		1,164, 2,327, 3,491

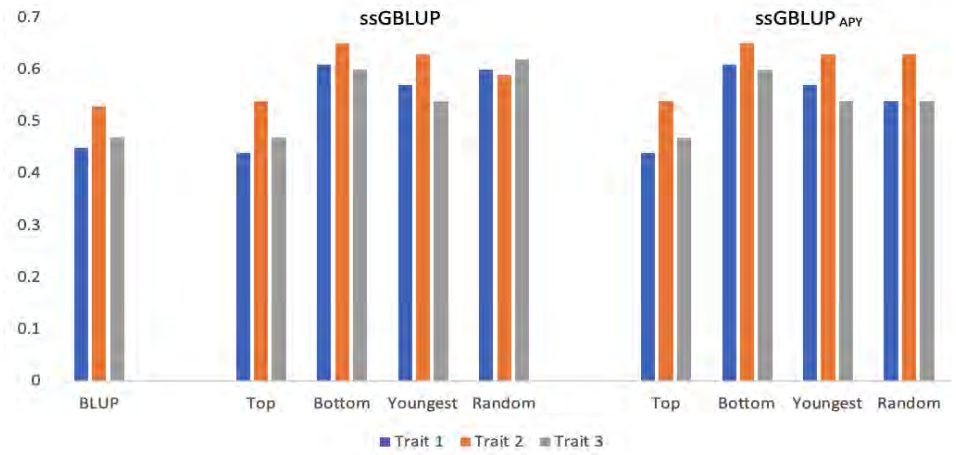

Figure 1. Accuracies of (G)EBV predictions for simulated data under different models and strategies of choice of core animals.

Figure 2 reports results for the real data. Also in this case, as expected, BLUP showed the lowest prediction accuracy. An improvement of accuracy can be observed as the proportion of genotyped animals increases. A clear pattern of the strategy used for choosing core animals cannot be detected. In the core animal size 10% scenario, slightly better accuracies can be observed for the random choice, whereas for larger core sizes (i.e. 20 and 30%), youngest or bottom G_{contr} animals provided larger values. As expected, using all genotyped animals (i.e. $ssGBLUP_{APY}$) provided better results than ssGBLUP.

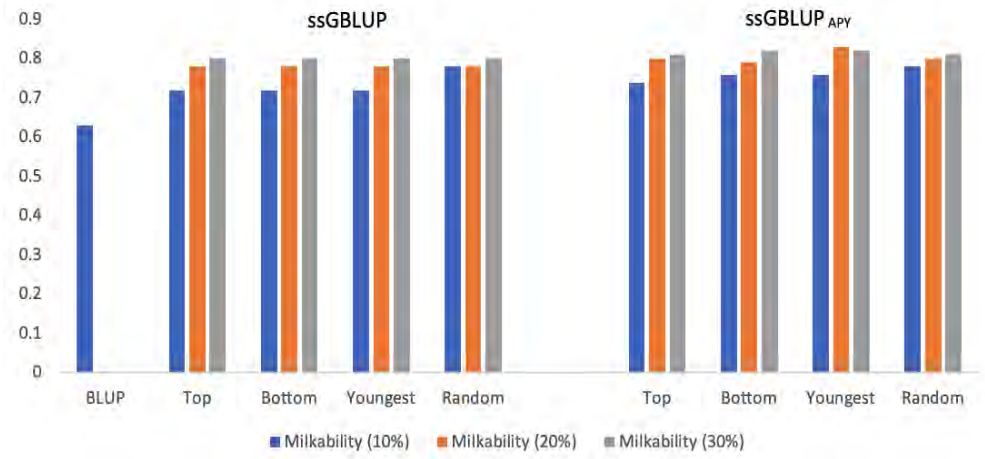

Figure 2. Accuracies of (G)EBV predictions for real data under different models and strategies of choice of core animals.

Discussion

The optimization of genotyping strategies and the definition of core animals have been widely investigated in livestock. Theoretically, to maximize the reliability of genomic predictions, genotyped animals should represent all the independent chromosome segments existing in the population (Misztal, 2016). Previous studies have found no basic differences among criteria used to define core animals, and random selection was the better option (Bradford *et al.*, 2017; Fragomeni *et al.*, 2015). In the present study, the use of different strategies either in ssGBLUP or in ssGBLUP$_{APY}$ resulted in differences, even if small, in genomic prediction accuracies. Among the various methods, the selection of animals with the lowest rank according to their contribution to G evaluated by PCA provided slightly higher accuracies, especially in the simulated data. However, the core sizes used in this study were smaller than the ideal number specified as M_e or the number of eigenvalues explaining 98% of the variance of G. In such a case, different core definitions may result in different accuracies. In real data, particularly for larger sizes of core animals, the criteria of choice appear less important, confirming results of earlier studies. Bradford *et al.* (2017) pointed out that the core definition may be important in the case of incomplete pedigrees. Data considered in the present work were characterized by a complete pedigree. Thus, the key contributors approach for core definition could also be tested under these conditions and with large datasets.

Abstract

Accurate genomic predictions underpin the success of genomic selection-based breeding programs. Therefore, efforts to compute and improve prediction accuracy (ACC) are imperative. Here we use theoretical expectations and simulation to highlight the linear relationship that exists between ACC and phenotypic differences in pre-defined percentiles. We found that an ACC of 0.4 yielded a phenotype difference of one standard deviation (SD) units between the top and bottom quartiles. In addition, a seemingly moderate increase in ACC of 0.05 (absolute value) translates into an increase of 0.127 SD units between top and bottom quartiles and to a 2.54 SD units' difference when extrapolated to a perfect ACC. These theoretical expectations were validated with results from a dataset of 3,408 Australian Angus steers with genomic predictions for a range of feedlot and carcase traits. We conclude that moderate predictions accuracies of ~0.4 are sufficient to effectively draft animals into quartiles.

Introduction

In the last decade there has been a tremendous research effort aimed at boosting the accuracy (ACC) of genomic predictions (GEBVs), by exploring alternative analytical models, genomic relationship matrices, numerical approaches and uses of functional biology information. To name a few recent examples from livestock, Moghaddar *et al.* (2021) showed that using prioritized genetic markers and accounting for different allele frequencies in reference populations resulted in a slightly higher ACC. Similarly, Hidalgo *et al.* (2021) concluded that including genomic information in training sets provided an increase in ACC, while Brito Lopes *et al.* (2020) showed that an artificial neural network can provide superior genomic predictions.

However, one common finding among these studies is that the observed increase in prediction ACC is seemingly and deceptively small, ranging from 0.02 to 0.08 (absolute value). Clouding the impact of these small improvements is the difficulty in translating ACC values into tangible measures for seedstock and commercial producers.

Therefore, the objective of this study was to develop theoretical expectations, along with simulation studies and results from real data, to explore the relationship between prediction ACC, ACC changes, and phenotypic differences on the ability of predictions to distinguish extreme performing individuals.

Materials & methods

Expectations under standard normal distribution theory. We are interested in the average value beyond a nominal percentile threshold T:

$$\mathrm{E}[x/x > T] = \frac{1}{\sqrt{2\pi}} \int_T^{\infty} x e^{\frac{-x^2}{2}} dx = -\frac{1}{\sqrt{2\pi}} \int_T^{\infty} e^{\frac{-x^2}{2}} d\left(\frac{-x^2}{2}\right) = \frac{1}{\sqrt{2\pi}} e^{\frac{-T^2}{2}} \quad (1)$$

The above expression needs to be divided by the cumulative density of the percentile in question. Five percentile splits will be considered to divide the data into equal parts, including: 50% (halves), 33% (thirds),

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_333, © A. Reverter *et al.* 2022

25% (quarters), 20% (fifths) and 10% (tenths). For each percentile split, the value of interest is the expected difference, in standard deviation (SD) units, between the top and bottom percentile.

Simulation of correlated normal random variables. To explore the relationship between ACC and phenotypic differences in pre-defined percentile splits we simulated a series of bivariate standard normal variables with a given correlation and for n=10,000 animals. In this setting, the two variables were intended to represent the true and predicted genetic values while the correlation indicated ACC. Nineteen ACC values were explored from 0.05 to 0.95 using 0.05 increments. Each simulation scenario was repeated 100 times and at each time, animals were ranked based on the prediction and the difference in true value between the top and bottom percentile, for the five percentile splits, was recorded.

Validation with real data. To validate the findings yielded by the simulation, we interrogated the data from the study of Alexandre *et al.* (2021) which was based on a population of 3,408 Australian Angus steers with GEBVs for two feedlot and five carcase traits: average daily gain, average daily dry matter intake, carcase weight, eye muscle area, marbling score, ossification score and subcutaneous rib fat depth. Seven year of birth cohorts were represented in the data and each was used in turn as validation samples to generate seven average ACC values for each phenotype and where ACC was computed as the correlation between the GEBVs and the adjusted phenotype divided by the square root of heritability. The 49 ACC values (from seven traits by seven validation cohorts) averaged 0.43 and ranged from 0.08 to 0.76. In each case, adjusted phenotypes from the validation sample were sorted according to the GEBVs and the difference between the top and bottom percentile expressed in SD units.

Results

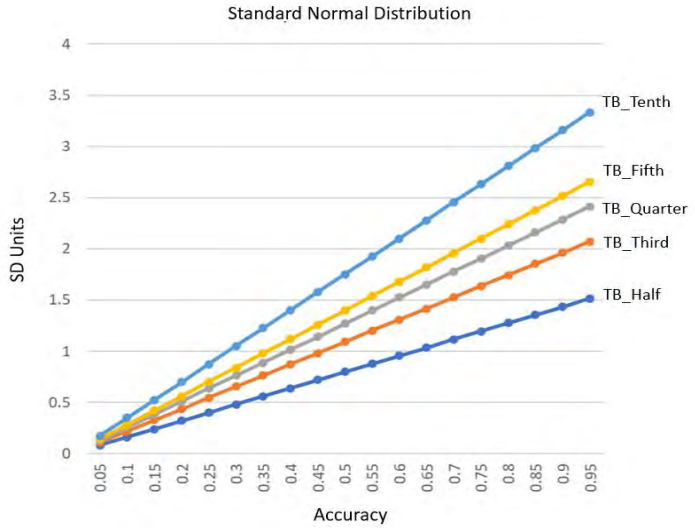
Simulation study. Table 1 presents the theoretical thresholds and expected values from a standard normal distribution and five percentile splits. At 50% percentile, corresponding to category 'Half', the threshold is zero and values above zero are expected to average 0.797 SD units. The difference between the top and bottom half is then twice 0.797 or 1.595 SD units. Similarly, at 10% percentile, corresponding to category 'Tenth', the threshold is 1.282 and values beyond this threshold average 1.754 and the expected difference between the top and bottom 10% equals 3.509 SD units. Figure 1A illustrates the difference in true value, averaged over 100 simulations, between the top and bottom (TB) for each percentile (TB_Half, TB_Third, TB_Quarter, TB_Fifth and TB_Tenth) and at each simulated value for the correlation between the true and the predicted value.

Real data validation. Figure 1B presents the equivalent results based on the real dataset for the five percentiles and 49 ACC values available. Overlaid in Figure 1B are the regression equations with a restriction of zero intercept and their corresponding goodness of fit based on the R^2 coefficient.

Table 1. Theoretical thresholds (T) and expected mean values ($E[x>T]$) for five percentile categories from a standard normal distribution.

Category	Percentile, %	Threshold, T	$E[x>T]$	Expected difference top – bottom
1 Half	50%	0.000	0.797	1.595
2 Third	33%	0.431	1.090	2.181
3 Quarter	25%	0.674	1.270	2.541
4 Fifth	20%	0.841	1.399	2.798
5 Tenth	10%	1.282	1.754	3.509

(A)



(B)

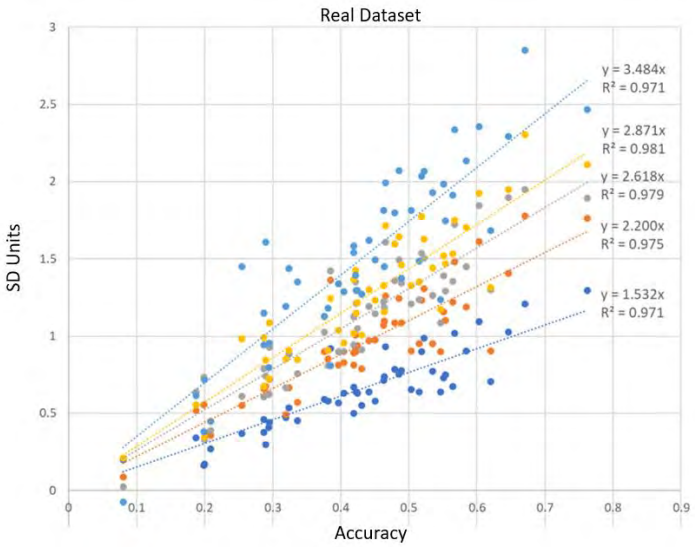


Figure 1. Simulation based on a standard normal distribution (A): difference in true value between the top and bottom for each percentile split with 19 values of accuracy, increasing stepwise, between the true and the predicted value. Real dataset (B): difference in adjusted phenotypes in standard deviation units between the top and bottom for each percentile for 49 accuracy values (from seven traits by seven validation cohorts).

Discussion

While efforts to increase the accuracy of genomic predictions should continue, genomic-based technologies are already allowing commercial beef producers to predict the genetic merit of individual animals of unknown pedigree with increased ease and accuracy (Hine *et al.* 2021).

The expected difference between the top and bottom percentile (Table 1, last column) indicates what could be achieved with perfect ACC. This expected maximum difference can be interpreted as the linear regression of phenotypic difference on ACC (Figure 1). Therefore, a seemingly moderate increase in ACC of 0.05 (absolute value) can translate into an increase of 0.05 × 2.5410 = 0.127 SD units between top and bottom quartiles and 0.05 × 3.5088 = 0.175 SD units between the top and bottom deciles.

The simulation study revealed the perfect linear relationship that is expected between prediction accuracy and phenotypic differences in pre-defined percentiles (Figure 1A). At ACC = 0, animals are ranked at random and the expected difference in any percentile is zero. A prediction accuracy of 0.4 can discriminate a difference of 0.64, 0.87, 1.01, 1.12, and 1.40 SD units respectively for 50, 33, 25, 20 and 10% percentiles. Because of linearity, these differences half and double for prediction accuracies of 0.2 and 0.8, respectively.

Using the real dataset (Figure 1B), the range of ACC values from 0.08 to 0.76 allowed us to confirm expectations with high precision. With an R^2>97% in all cases, the fitted regression models were very closely aligned with the expected values (last column of Table 1): 1.532 vs 1.595, 2.200 vs 2.181, 2.618 vs 2.541, 2.871 vs 2.798, and 3.484 vs 3.509 for 50, 33, 25, 20 and 10% percentiles, respectively.

In real units, when applied to the real data, and for the case of carcase weight with a SD of 31.09 kg (Alexandre *et al.* 2021), the average ACC value 0.43 is expected to identify a difference of 0.43 × 2.541 × 31.09 = 33.97 kg between the top and bottom quartiles, and a difference of 0.43 × 3.5088 × 31.09 = 46.91 kg between the top and bottom deciles. Similarly, an ACC increase of 0.05 translates in an increase in discrimination power between top and bottom quartile or decile of 3.95 and 5.44 kg of carcase weight, respectively.

In conclusion, we have shown that the linear relationship that exists between prediction accuracy and predefined differences in actual phenotype allows for the interpretation of accuracy values in a tangible form for scientists and producers. While only proven animals with lots of relatives will attain ACC>90% for a trait of interest, seemingly small ACC maybe sufficient to draft commercial animals in a cost-effective manner.

Abstract

This study examined ways to correct for environmental effects and effectively utilize all the available performance records in Ethiopian smallholder dairy production systems. Modelling contemporary groups based on villages rather than the usual herd resulted in proper correction for environmental effects and gave higher (0.18 vs 0.12) heritability estimates for milk yield. Besides, in such production systems farmers tend to milk cows for several later lactations and performance records are a scarce resource. Thus, the use of a multiple-trait single-step genomic prediction model that considered 1st and 2nd plus later lactations as two distinct but correlated traits, gave the highest standard deviation of genomic enhanced breeding values (1.365 vs 0.840 kg/d) and better reliability of genomic prediction than univariate models.

Introduction

In the developing countries, most dairy production occurs in smallholder production systems, where herd sizes are small and are with little or no routine systems for capturing performance and pedigree data (Kosgey and Okeyo, 2007). With the advent of genomic selection and the recent successful incorporation of genomic information into breeding schemes, the reliance on very large populations of phenotyped animals has been somewhat relaxed. Therefore, the use of genomic relationship matrix for genotyped animals or the combination of genotypic information with pedigree information applying the single-step GBLUP (ssGBLUP) approach presents unique opportunities to overcome the limiting data and other infrastructural problems. The reliability of genomic prediction among others, depends on the heritability of the trait and the statistical method used to estimate the single nucleotide polymorphism (SNP) effects in the reference population. Further, in tropical dairy herds, farmers tend to milk their cows for up to five or more lactations. In such production systems, accurate estimation of the genetic merit of animals relies on our ability to effectively utilize all the available performance records fitting appropriate statistical models. The main objectives of this study were therefore to develop a single-step genomic prediction model where 1st and 2nd plus all later lactations were considered as distinct but correlated traits and to estimate the accuracy of predicting breeding values.

Materials & methods

Data. Data for this study was obtained from the Ethiopian national dairy cattle performance recording, extracted from the International Livestock Research Institute (ILRI) database (https://www.adgg.ilri.org/uat/auth/auth/login) for cows registered in the Luke ICI project and African Dairy Genetic Gain (ADGG) program from 1990 to 2020. The raw data consisted of 272,447 test-day (TD) milk observations for cows milking from 1 to 10 lactations. Prior to analyses, the data was edited to include cows with age at first calving ≥18 months, milk yield between 1 and 40 liters, and records from 5 to 365 days in milk (DIM). Calving seasons were divided into three, Long dry (October to February), Short rainy (March to May) and Long rainy seasons (June to September), respectively. Cow contemporary groups was tailored to dairy farming practice in the Ethiopian highlands. Thus, contemporary groups were specified by village × calving

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_334, © E. Negussie *et al.* 2022

year × calving season (VYS) classes. Although, the data included records of cows up to 10 lactations, to make effective use of all available TD records, the whole data was divided into two distinct traits including 1st and 2nd plus later lactations. The final edited data consisted of 152,133 TD milk records from 17,501 dairy cows in 6,140 herds located within 544 villages with more data came from recent years (after 2010). The pedigree included 21,501 animals. For estimation of variance components (VCE), a sample of the data was extracted. To avoid selection bias, cows with later lactation records were required to have valid first lactation records and sampled herds had to have at least 5 first calvers per calving year. There were 56,770 and 33,506 observations in 1st and 2nd plus later lactations in the data for VCE.

Genotypes. Genotypic data were available on 5,146 animals which were genotyped by the ADGG program with the GeneSeek Genomic Profiler (GGP) Bovine 50K chip. About 47,843 SNPs were returned from the laboratory and after the edits (Aliloo *et al.*, 2018), 40,581 SNPs were made available for analysis. These were imputed to the Illumina HD chip (686,052 SNPs) using a reference population consisting of crossbred cattle from a previous East Africa Dairy Genetics Gain project and several European Holstein-Friesian, Jersey, Guernsey, and Ayrshire purebred animals (Aliloo *et al.*, 2018). Of the 17,501 animals in the final data, 5,119 were genotyped and 2,140 cows were genotyped and phenotyped.

Model. For estimation of variance-covariance components and associated genetic parameters, a multiple-trait repeatability TD animal model, where 1st and 2nd plus later lactations (2+) were considered as two different traits, was fitted. The model in matrix form can be described as follows:

$$\begin{bmatrix}\mathbf{y}_{i1}\\ \mathbf{y}_{i2+}\end{bmatrix} = \begin{bmatrix}\mathbf{X}_{i1} & 0\\ 0 & \mathbf{X}_{i2+}\end{bmatrix}\begin{bmatrix}\boldsymbol{\beta}_{i1}\\ \boldsymbol{\beta}_{i2+}\end{bmatrix} + \begin{bmatrix}\boldsymbol{\Phi}_{i1} & 0\\ 0 & \boldsymbol{\Phi}_{i2+}\end{bmatrix}\begin{bmatrix}\boldsymbol{\lambda}_{i1}\\ \boldsymbol{\lambda}_{i2+}\end{bmatrix} + \begin{bmatrix}\mathbf{Z_1}_{i1} & 0\\ 0 & \mathbf{Z_1}_{i2+}\end{bmatrix}\begin{bmatrix}\mathbf{htd}_{i1}\\ \mathbf{htd}_{i2+}\end{bmatrix} + \begin{bmatrix}\mathbf{Z_2}_{i1} & 0\\ 0 & \mathbf{Z_2}_{i2+}\end{bmatrix}\begin{bmatrix}\mathbf{pe}_{i1}\\ \mathbf{pe}_{i2+}\end{bmatrix} + \mathbf{Z_3}_{i2}\mathbf{pe2L}_{i2+} + \begin{bmatrix}\mathbf{Z_4}_{i1} & 0\\ 0 & \mathbf{Z_4}_{i2+}\end{bmatrix}\begin{bmatrix}\mathbf{a}_{i1}\\ \mathbf{a}_{i2+}\end{bmatrix} + \begin{bmatrix}\boldsymbol{\varepsilon}_{i1}\\ \boldsymbol{\varepsilon}_{i2+}\end{bmatrix} \quad (1)$$

where y_{i1} and y_{i2+} are the vectors of TD milk yield observations, β_1 and β_{2+} are the vectors of fixed effects consisting of VYS classes, calving age classes, and breed group, λ_1 and λ_{2+} are vectors of the regression coefficients for the fixed lactation curves modelled by 4th order Legendre polynomials plus the Wilmink term, which were nested within calving season classes; htd_{i1} and htd_{i2+}, pe_{i1} and pe_{i2+}, $pe2L_{i2+}$, a_{i1} and a_{i2+}, and e_{i1} and e_{i2+} are vectors of random effects of herd-test-day, permanent environmental effects nested within lactation and across traits, permanent environmental effects within later lactations (2 to 10 lactations) to model repeatability across later lactations, additive animal genetic effects, and residual effects respectively. The design and coefficient matrices X, Φ, Z_1, Z_2, Z_3 and Z_4 related observations to fixed β and l effects and random htd, pe, pe2L and a effects, respectively. Variance components were estimated using BLUP animal model and the average information algorithm.

Genomic prediction. A multiple-trait single-step genomic prediction model (ssGBLUP_mt) where 1st and 2nd plus all later lactations were considered as two distinct traits as described in Equation 1 was developed. Relationships between animals were described by the H matrix that combines the marker-based (G) and pedigree-based (A) relationship matrices. The H matrix was built by blending the G matrix with 10% of the residual polygenic effect.

Model comparison and validation. For validation purposes, the ssGBLUP_mt model was compared against univariate BLUP (pBLUP_univ) and univariate single-step genomic prediction (ssGBLUP_univ) model. The univariate models considered all TD milk observations of the data as the same trait and included the same model effects as specified in Equation 1 for y_{i1}. Model comparisons were made in terms of correlations between and standard deviation (SD) of estimated breeding values (EBV) and genomic enhanced breeding values (GEBV). Predictions were carried out using the MiX99 software (Strandén *et*

al., 2018). In addition, forward validation was used to assess the accuracy of predicting breeding values for candidate animals with only genotype information. For this, milk records of cows born in 2015 and afterwards (2,872 cows with total 23,575 records) in the genomic prediction system were excluded. The reliability of genomic predictions for the candidates whose records were excluded was computed as squared correlation coefficient between the candidates' GEBV and their yield deviations (YD) divided by $\sqrt{h^2}$. The degree of under or over-prediction was estimated by regressing their GEBV on their YD.

Results

Average test-day milk production. The overall mean (±SD) for TD milk in 1st and 2nd plus later lactations in smallholder cows in Ethiopia were 10.6 (5.4) and 11.0 (4.6), respectively. The lactation curves for TD milk nested within calving seasons in Figure 1 shows that cows calving in the long rainy season peaks higher than those that calved in the two other seasons. In addition, Figure 1 towards the end of the lactation curve shows unrealistic upward trend when TD milk observations beyond 350 DIM were included in the analyses.

Variance components. The estimates of heritability from the multiple-trait model for the 1st and 2nd plus later lactations were 0.18 and 0.17, respectively. The repeatability of TD milk yield in 1st and 2nd plus later lactations were 0.67 and 0.57, respectively. Genetic correlation between 1st and 2nd plus later lactations was 0.87 and repeatability across later lactations was 0.34.

Animal evaluation and validation of genomic prediction. Table 1 presents the comparison between pBLUP_univ, ssGBLUP_univ and ssGBLUP_mt animal evaluations in terms of correlations between models and SD of (G)EBVs. For cows with at least 5 TD milk observations, the SD of breeding values was 0.97 liters for ssGBLUP_mt, whereas it was 0.59 liters when applying the ssGBLUP_univ and was as low as 0.57 liters when applying pBLUP_univ model. The SD of (G)EBVs in bulls were higher than those in cows and were 1.37 liters, 0.91 liters and 0.84 for the ssGBLUP_mt, ssGBLUP_univ and pBLUP_univ models, respectively. For cows with observations, the correlations between pBLUP_univ and ssGBLUP_mt, and between ssGBLUP_univ and ssGBLUP_mt models were 0.87, and 0.89, respectively. Whereas for bulls, the correlations between pBLUP_univ and ssGBLUP_mt, and between ssGBLUP_univ and ssGBLUP_mt models were 0.88, and 0.89, respectively. Validation reliabilities for 2,872 validation cows was 0.078 for

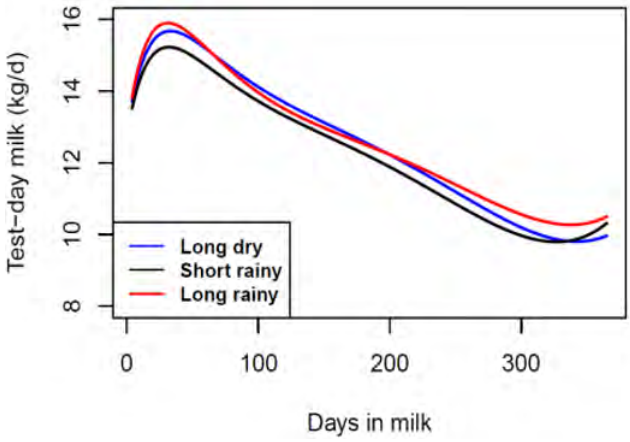

Figure 1. Lactation curves of cows nested within calving seasons in smallholder dairy herds for TD milk data from 5 to 365 days in milk.

Table 1. Correlations between pBLUP_univ, ssGBLUP_univ and ssGBLUP_mt models and their corresponding standard deviation of EBVs and GEBVs.

Models	Correlations[1]		Standard deviation of G(EBV)	
	Cows[2]	Bulls[3]	Cows[2]	Bulls[3]
pBLUP_univ	0.87	0.88	0.57	0.84
ssGBLUP_univ	0.89	0.89	0.59	0.91
ssGBLUP_mt			0.97	1.37

[1] Pearson correlations between ssGBLUP_mt GEBVs and pBLUP_univ EBVs, and between ssGBLUP_mt GEBVs and ssGBLUP_univ GEBVs.

[2] Cows = 10,277 cows >5 TD milk records.

[3] Bulls = 106 bulls >5 daughters.

pBLUP_univ model. Whereas it was 0.091 and 0.101 for the ssGBLUP_univ and ssGBLUP_mt models, respectively. The coefficient from the regression of predicted candidates (G)EBVs on candidates YD was 0.77, 0.87 and 0.87 for the pBLUP_univ, ssGBLUP_univ and ssGBLUP_mt models, respectively.

Discussion

The average daily milk yield from most tropical dairy production systems is reported to be about 6.4 litres (Makau *et al.* 2020). The estimates from this study for the 1st and 2nd plus later lactations is slightly higher but it is close to those reported by (Mrode *et al.* 2021) for the high-grade cows from Tanzania. Estimated heritability from the ssGBLUP_mt model was much higher than 0.12 reported earlier on part of same data. The genetic correlation estimated between 1st and 2nd plus later lactations was lower than unity indicating that milk yield in 1st and later lactations are indeed distinct traits. Thus modelling 1st and 2nd plus later lactations as different but correlated traits is one logical way forward. The ssGBLUP_mt model had the highest SD of GEBVs offering much more variability with greater options for identifying the best animals for breeding. The lower than unity correlations between the three models for both cows and bulls indicate a possible re-ranking of top cows and bulls. As expected, the validation reliabilities of ssGBLUP models were higher than pBLUP. Gains of 0.013 and 0.011 on validation reliability were achieved by using ssGBLUP_mt model. These values are slightly lower than those reported by Mrode *et al.* (2021) and could possibly be due to slightly lower number of genotyped animals with data included or due to the variance components used. Therefore, it is expected that as and when all the genotyped animals get sizable phenotypic records the situation will improve.

Abstract

Due to rising shearing costs and fluctuations in wool prices, developing composite sheep breeds that shed their wool annually has gained interest. Pooling DNA of progeny is a cost-efficient alternative to estimate genomic breeding values (GEBV) of sires. The aim of the study was to measure the correlation between sire GEBV obtained by pooling and mean sire progeny phenotype scaled by the heritability. Wool shedding records on lambs and adults from a composite flock were analysed, and a total of 48 sires and 48 pools were genotyped. Pools were constructed using partitioning around medoids. The correlation between genomic and pedigree relationships was 0.83±0.02. Accuracy of GEBV for sires was 0.41 (0.14-0.62) while the correlation between GEBV and EBV obtained from pedigree best linear unbiased prediction was 0.79 (0.65-0.88). In conclusion, GEBV of sires obtained by pooling allele frequency of their progeny and pedigree EBV were consistent.

Introduction

Rising shearing costs coupled with considerable variation in wool prices have resulted in an increased interest in the use of breeds and their crosses that shed their wool annually. Crossbred lines (composites) that partially or fully shed their wool have been developed by introducing hair genetics (Wiltshire Horn, Dorper, Katahdin) into wool flocks (Johnson *et al.*, 2007; Pollot, 2010; Vargas Jurado *et al.*, 2016).

Wool shedding (WS) is commonly assessed using discrete categories and animals are assigned to them based on their extent of shedding. The number of categories is usually not standard (Pollot, 2010; Matika *et al.*, 2013; Vargas Jurado *et al.*, 2020). Despite the ordinal nature of WS and differences in scoring systems, heritability of WS ranged from 0.26±0.06 (Pollot, 2010) to 0.83±0.06 (Matika *et al.*, 2013). Still, inclusion of WS in routine genetic evaluation is limited. Similarly, genomic analyses of WS either through marker-assisted selection or genome-wide association studies have not been extensive (Johnson *et al.*, 2007; Matikka *et al.*, 2013).

The cost of genotyping has been an impediment to uptake of genomics in sheep (Rupp *et al.*, 2016). Using pooled allele frequencies for the prediction of the genetic merit has been shown to be an economic and reliable alternative to the use of individual genotypes (Bell *et al.*, 2018; Alexandre *et al.*, 2019; Vargas Jurado *et al.*, 2021). In this context, the aim of this study was to estimate sire genomic breeding values (GEBV) using their individual genotypes along with pooled allele frequency and WS scores of relatives, and to estimate prediction accuracy.

Materials & methods

All animal use was approved by the U.S. Meat Animal Research Center (USMARC, Clay Center, Nebraska, USA) Institutional Animal Care and Use Committee.

Data. Phenotypic records were obtained from a crossbred flock composed of five lines resulting from crosses of Romanov, Katahdin, and White Dorper sheep (Vargas Jurado *et al.*, 2016). Wool shedding was

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_335, © N. Vargas Jurado *et al.* 2022

visually assessed using a 9-point scoring system, from zero to eight, where zero and one represented animals with less than 25% wool coverage, two to six represented animals between 25 and 75% wool coverage and seven and eight represented animals with more than 75% wool coverage. A total of 4,767 records from lambs at approximately 170 (SD 12.0) d of age and 3,345 repeated records from 1,527 adult ewes (1, 2, 3, or 4 yr old). While some sires had a lamb record, none had adult wool shedding records. The pedigree consisted of 9,682 individuals and eight genetic groups based on genetic line.

Pools and genotypes. Because of the ordinal nature of wool shedding, individuals were allocated to pools using partitioning around medoids by constructing a distance matrix based on pedigree relationship, contemporary group (line by year of birth), birth and rearing type, weaning weight, and age of dam. These variables were included because they significantly defined variation in WS (Vargas Jurado *et al.*, 2016). A total of 3,038 individuals were allocated to 48 pools. The average number of individuals in a pool was 63.3 (SD 14.8). A total of 48 sires were sampled from the population. Sires and pools were genotyped using the Illumina Ovine 50k chip. For sires and pooled genotypes, fixed markers were removed (i.e. minor allele frequency <0.05). The progeny of sires forming the pools were not individually genotyped.

Variance components and breeding values. Variance components and pedigree best linear unbiased prediction (BLUP) EBV were obtained by fitting a bivariate threshold model where:

$$y_{ij} = k \Leftrightarrow \tau_{j(k-1)} < u_{ij} < \tau_{jk}, \quad (1)$$

where y_{ij} was the j^{th} ordinal trait (j =1, 2 for the lamb and adult WS measurements, respectively) for the i^{th} individual taking values in one of K = 9 possible WS categories (k = {0, 1, …, 8}), τ_j was the vector of thresholds for the j^{th} trait, and u_{ij} was the underlying liability for wool shedding (latent Gaussian variable). In Equation 1 it was further assumed that:

$$\mathbf{u} = \begin{bmatrix} \mathbf{u}_1 \\ \mathbf{u}_2 \end{bmatrix} = \begin{matrix} \mathbf{X_1\beta_1} + \mathbf{Z_1a_1} \\ \mathbf{X_2\beta_2} + \mathbf{Z_2a_2} \end{matrix} + \mathbf{Wc} + \begin{matrix} \mathbf{e}_1 \\ \mathbf{e}_2 \end{matrix} \quad (2)$$

where β_j and a_j were vectors of fixed and additive genetic effects, respectively, and X_j and Z_j were incidence matrices relating to fixed and additive effects, respectively, for the j^{th} trait. W and c corresponded to the vector of permanent environmental random effects and its incidence matrix for adult WS. Fixed effects for lambs included sex and age of dam while for ewes included age at scoring. For both traits contemporary group and birth and rearing category were also included as fixed effects. Residuals were assumed to be Normally distributed and correlated between traits. Random effects in Equation 2 were assumed to follow a normal distribution with zero mean. Additive genetic effects accounted for pedigree relationships and were assumed to be correlated between traits. Permanent environmental effects were uncorrelated to additive genetics effects. The model described by equations 1 to 2 was fitted using the rjmc module in DMU (Madsen *et al.*, 2014). A total of 55,000 samples were produced with 5,000 used as burn-in and a thinning interval equal to five.

Sire and pool GEBV were obtained using genomic BLUP (GBLUP) with a hybrid genomic (G) matrix, containing individually genotyped sires and pool allele frequencies (Vargas Jurado *et al.,* 2021). Pedigree relationships among sires, between sires and individuals in pools, and among individuals within a pool were combined into an average relationship matrix (Ā). Accuracy of GEBV was determined as: (1) the correlation between sire (and pool) GEBV and EBV; and (2) the correlation between GEBV and mean progeny phenotype (for sire families). Lastly, a neighbour joining tree was constructed using sire and pool genotypes (separately) based on Euclidean distance. Nodes were labelled based on their GEBV (below or above the mean).

Results

Heritability of lamb and ewe WS were 0.51±0.03, 0.52±0.03, respectively. The repeatability of ewe WS was 0.61±0.02. The correlation between lamb and adult WS was 0.80±0.02. The overall correlation between elements of G and Ā was 0.85±0.02. Correlations between entries of G and Ā corresponding to relationships among sires, among animals within a pool, and between sires and pools were 0.91±0.01, 0.67±0.03, and 0.66±0.03, respectively. Moderately high correlations between sire and pool GEBV with lamb or adult EBV were found (Table 1).

The accuracy of GEBV measured as the correlation (scaled by $\sqrt{h^2}$) between mean progeny phenotypes (uncorrected) and sire GEBV was 0.41 (confidence interval: 0.14-0.62). Individual sires and pools clustered relatively well on the estimated phylogenetic tree based on whether their GEBV value was above or below the mean (Figure 1).

Discussion

With no genotypes available on individuals forming pools, GEBV and EBV in progeny could not be compared. Therefore, the focus was on the concordance between genomic and pedigree relationships: (1) among sires; (2) among progeny averages within a pool; and (3) between sires and progeny averages within pools. The high concordance in these comparisons (0.52-0.79) was likely due to genomic relationships between sires and pools representing the average of the true relationships in the population (Vargas Jurado *et al.*, 2021). Clusters of sires and pools based on genomic information distinctly showed groupings of individuals with better (or worse) than average performance (GEBV). Furthermore, the clustering methodology showed the value of combining pedigree and systematic environmental effect levels in constructing pools.

Assuming a Gaussian trait and 10 half-sib progeny per sire, accuracy is approximately 0.77. Correlations between EBV, derived from pedigree BLUP and a threshold model, and GEBV were moderately high (0.52 to 0.79) even though WS was a categorical trait with a markedly non-Gaussian distribution (Vargas Jurado *et al.*, 2020). Moreover, the accuracy of GEBV (scaled by $\sqrt{h^2}$) was moderate. Such was encouraging given that uncorrected progeny phenotypes were used to calculate accuracy due to challenges in adjusting the underlying Gaussian liability for WS. Fixed effects adjustments on liability will be considered in the future.

Based on these results, pooling provides an alternative for estimating the genetic merit of sires, even for non-Gaussian traits, especially when economic constraints do not allow for individually genotyping progeny. Moreover, the moderate accuracy of pool GEBV highlights the possibility of using 'average' GEBV as benchmark for comparing the genetic merit of different flocks. Furthermore, these accuracies are comparable to pedigree-based evaluations with a complete pedigree and performance records (Vargas Jurado *et al.*, 2021).

Table 1. Correlation (confidence interval[1]) between sire or pool genomic breeding values[2] with ewe or lamb estimated breeding values from pedigree[3].

	Trait EBV	
Category	**Ewe**	**Lamb**
Sire	0.79 (0.65, 0.88)	0.68 (0.49, 0.80)
Pool	0.52 (0.28, 0.70)	0.56 (0.33, 0.73)

[1] Asymptotic approximation given by Park and Lee (2001).

[2] Estimated from genomic BLUP (GBLUP) with a hybrid G matrix.

[3] Estimated from multiple trait pedigree BLUP.

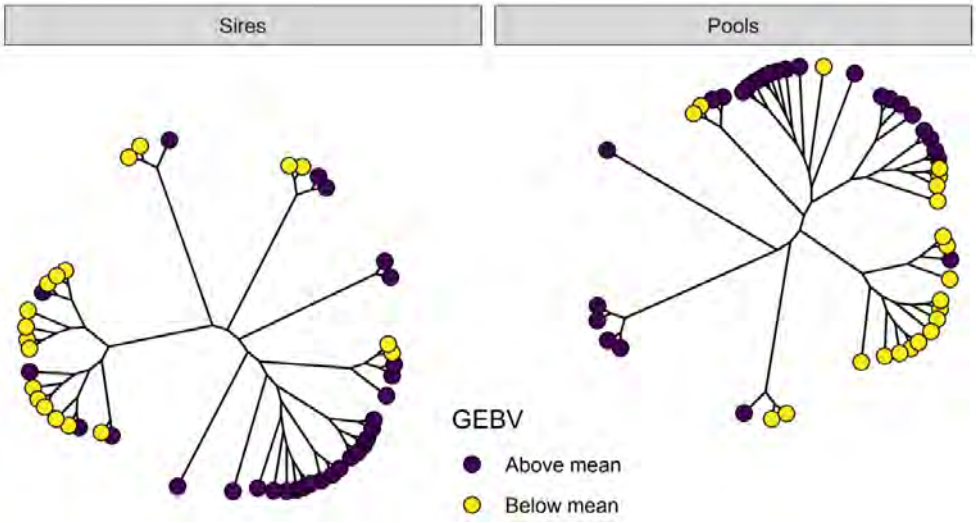

Figure 1. Neighbour joining tree using sire and pool genotypes and a Euclidean distance matrix. Colouring of the nodes was based on genomic breeding values obtained from genomic best linear unbiased prediction with a hybrid genomic relationship matrix.

A key application of pooling is that performance data lacking associated pedigree information can still be used. This may be particularly relevant to integrate data from commercial settings, such as that available from feedlots and abattoirs, into routine genomic evaluation.

Abstract

Genetic evaluation databases accumulated vast amounts of genomic information that are skyrocketing computational needs for standard genomic evaluation models due to their cubic computational complexity. Several scalable approaches have been proposed, such as the Algorithm for Proven and Young (APY), where genotyped animals are usually randomly partitioned into core and noncore subsets to obtain sparse approximation of the inverse of genomic relationship matrix. Here we show a deterministic optimisation of the core set using a sequential sampling approach. We test this optimisation on a large pig dataset. Our results confirm that the APY is robust and that the size of the core set is critical. Our results further show that the stability of APY can be enhanced with an optimal spread of core animals across a given domain of genotyped animals. We discuss possibilities of an alternative optimisation based on the Nearest Neighbours Gaussian Process that also results in a sparse inverse.

Introduction

In the era of genomics, computational burden is inevitable with the standard genomic evaluation models, predominately due to the cubic cost of inverting the dense genomic relationship matrix. Several scalable genomic approaches have been proposed, such as reparametrizing the models with marker effects, inducing sparsity in the inverse, or dimensionality reduction. The Algorithm for Proven and Young (APY) is one of the approaches, where genotyped animals are usually randomly partitioned into core and noncore subsets. The core animals then form the dense part of the inverse, while the non-core animals are conditionally independent given the core animals and form the diagonal part of the inverse. While the APY provides a good approximation of the full standard model, random partitioning can make results unstable, possibly affecting accuracy or even reranking animals (Misztal *et al.*, 2020). In this contribution we: (1) show application of optimal core construction using conditional sequential sampling algorithm on a large pig dataset; and (2) discuss alternative core construction using the Nearest Neighbours Gaussian Process (NNGP).

Materials & methods

Phenotypic data on 42,868 animals collected from 1999 to 2021, for a moderately heritable trait measured on purebred (33,544), crossbred (114) and backcross (9,210) pigs were provided by PIC (a Genus company, Hendersonville, TN, USA). Genomic information was available for 49,788 pigs, including all animals with phenotypes, and consisted of 42,707 single-nucleotide polymorphism markers. Validation subset included 478 phenotyped and genotyped youngest animals born in 2021 (their phenotypes were removed from the analysis). We used GBLUP in the following model $y = Xb + Za + Wc + e$, where y is a vector of phenotypes, b is a vector of contemporary group fixed effects, a is a vector of random animal effects with $a \sim N(0, G\sigma_a^2)$, c is a vector of random litter effects with $c \sim N(0, I\sigma_c^2)$, e is a vector of random residuals with $e \sim N(0, I\sigma_e^2)$, X, Z, and W are corresponding design matrices, G is the genomic relationship matrix with added I0.01 to enable inversion, and σ_a^2, σ_c^2, and σ_e^2 are respectively known additive, litter and residual variances. The model was run using BLUP90IOD software (Tsuruta *et al.*, 2001), either with the full inverse of G or with the APY inverse of G as defined in Misztal *et al.* (2014). For the APY we applied two core selection strategies: (1) strategy where the core animals were randomly sampled among all the genotyped animals;

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_336, © I. Pocrnic *et al.* 2022

and (2) optimised core selection strategy where we iteratively selected core animals with the largest variance conditionally to previously selected core animals (Pocrnic *et al.*, 2021). For the random strategy, sampling was replicated five times to manifest potential instability of genetic evaluations and we present the mean ±95% CI. The number of core animals was the same in both strategies and was based on the number of eigenvalues that explained from 10 to 99% of the variation in G (Pocrnic *et al.*, 2016). We compared strategies based on the correlations between genomic estimated breeding values (GEBV) obtained with the full inverse and GEBV obtained by each APY strategy. Furthermore, we assessed the predictive ability for the validation animals as correlations between their GEBV and phenotypes adjusted for the fixed effects in the model. To gain insight into the behaviour or the algorithms, we have visualised population structure with a non-linear dimension reduction technique called Uniform Manifold Approximation and Projection (UMAP; McInnes *et al.*, 2020).

Results

The size of the core set in the APY ranged from 8 to 8,348 animals and corresponded to the number of eigenvalues that explained from 10 to 99% of the variation in G. Figure 1 shows that correlations between GEBV obtained with the full and APY inverse of G were almost a linear function of the percentage of explained variation. Both optimised and random core selection methods performed equally well when the number of core animals was equal to the number of eigenvalues explaining more than 98% of variation in G. The difference between the methods was larger in the validation population (Figure 1B), than in the entire genotyped population (Figure 1A). There was more uncertainty with random core sampling when the number of core animals was low, especially in the validation population (Figure 1B).

As expected from previous studies (Pocrnic *et al.*, 2016), the predictive ability was largely determined by the number of core animals (Figure 2), but with no difference between the APY and full inverse when the number of core animals was equal to the number of eigenvalues explaining more than 98% of variation in G. Also, differences between 90 to 99% were minimal. In this sense, the optimised core selection achieved

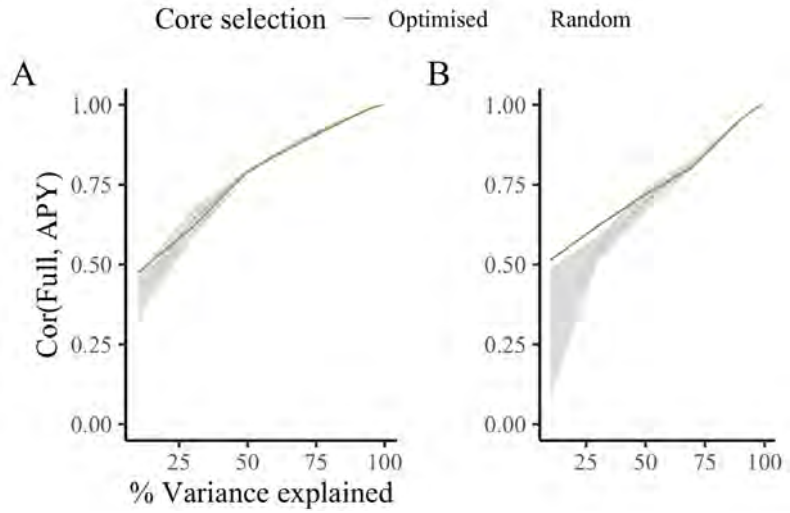

Figure 1. Correlation between GEBV obtained with the full and APY inverse of the genomic relationship matrix for all genotyped (A) and validation animals (B). APY is based on the optimised or random (mean ± 95% CI) core selection, with the number of core animals defined as the number of eigenvalues that explained certain percentage of variance.

the same satisfactory predictive ability as the random selection when the number of core animals was large, but also achieved notable improvements when the number of core animals was smaller. This improvement can be demonstrated by comparison with a large confidence interval in the random sampling strategy for a small number of core animals. This interval reduces as the core gets larger. The apparently higher predictive ability of random core selection with the larger core subsets (>95%) was due to rounding and was always less than 0.005, compared to optimised core selection.

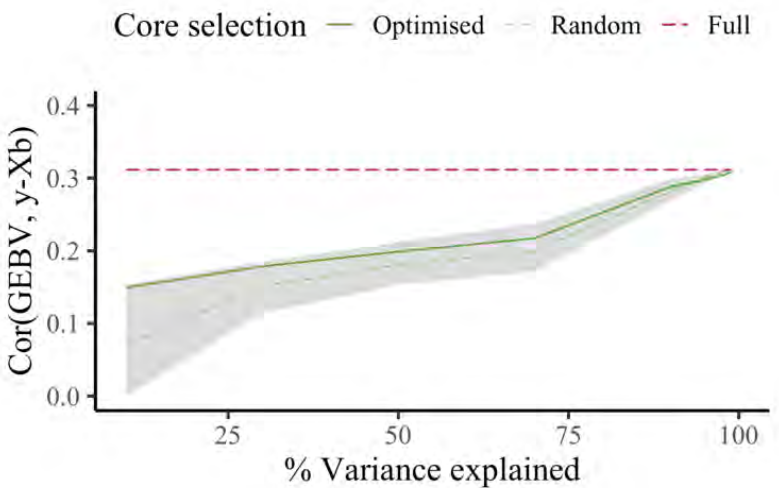

Figure 2. Predictive ability for validation animals. Predictive ability is the correlation between GEBV obtained with the full or APY inverse of the genomic relationship matrix and phenotypes adjusted for fixed effects. APY is based on the optimised or random (mean ± 95% CI) core selection, with the number of core animals defined as the number of eigenvalues that explained certain percentage of variance.

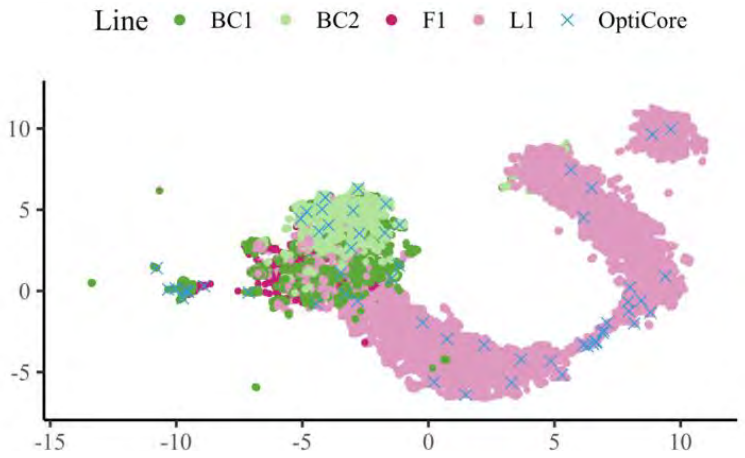

Figure 3. Uniform Manifold Approximation and Projection for purebred (L1), crossbred (F1), and backcross (BC1, BC2) pigs, with first 60 optimally selected core animals.

The UMAP demonstrates several clusters in the population. For example, Figure 3 shows the UMAP for the entire genotyped population, in which purebred animals (L1) cluster into three groups and the majority of crossbreed animals (F1, BC1, and BC2) are closely positioned to one of these clusters. Optimised core set spreads correspondingly.

Discussion

We have demonstrated that the APY is robust, largely dependent on the size of the core set and can be further enhanced by an optimal spread of core animals. While the optimised core selection strategy can introduce stability in the predictive ability (accuracy), especially when the core size is less than optimal, it also introduces additional computing cost compared to random sampling strategy. The optimised strategy builds upon sequential sampling algorithm and results in the spread of core animals far away from each other in a covariance sense. From that viewpoint, the additional computing cost could be justified in several cases, specifically when the genotyped population consists of multiple breeds, lines, and/or crossbred animals. In that sense, the optimised core selection strategy can be further extended towards building a unique core set for each animal based on the NNGP methodology, which recently gained popularity for its ability to deal with large-scale applications in spatial statistics (Datta *et al.*, 2016). While the strategy we presented is depended on application through the APY, the extension into NNGP leads to a sparse inverse through a sparse Cholesky factor (e.g. Faux *et al.* 2012; Finley *et al.*, 2019) and as such could substitute the APY-based inverse matrix when convenient. If n is the total number of genotyped animals, the computational complexity of the full inverse is $O(n^3)$ that is reduced to $O(m^3+2m^2(n-m))$ in the case of the APY or $O(nm^3)$ in the case of the NNGP, where m is either the number of the core animals in APY or the nearest neighbours in NNGP, and assuming $m << n$. On top of the computational complexity for the inversion itself, optimised strategy for APY and NNGP introduce additional computing cost of finding optimal core animals or nearest neighbours. Our future research will investigate faster alternatives for finding optimal set of core animals and nearest neighbours as well as assessing the practical benefit of proposed strategies within complex population structures. Furthermore, we will consider situations in which there is a benefit of using a set of nearest neighbours to form a sparse NNGP inverse relationship matrix rather than being fitted as a core in APY.

Abstract

With the widespread adoption of genotyping by Angus breeders, the American Angus Association has now more than one million animals genotyped. Genomic evaluations are conducted weekly with single-step genomic BLUP (ssGBLUP) using the algorithm for proven and young (APY). A set of high accuracy core animals has been used since the implementation of ssGBLUP in 2017. We investigated changes in genomic EBV (GEBV) and convergence behavior with different sets of core animals. Data from the routine growth genetic evaluation were used, and GEBV from different sets of core animals were compared with the original set defined in 2017. The rank correlation of breeding values was ≥0.99, and the number of rounds was 57% smaller with an updated random core set. Maximum changes in breeding values were at most 1.31 genetic standard deviations of the traits investigated. The core animals in the official evaluations were successfully updated in May of 2021.

Introduction

Single-step is the standard method for beef cattle genetic evaluations in the USA. The American Angus Association (AAA) first released ssGBLUP (Aguilar *et al.*, 2010; Lourenco *et al.*, 2015) genomically enhanced EPD for its national cattle evaluation in July 2017, for this paper we will describe the estimates of animals' genetic merit as GEBV. At the time of the implementation, a total of 350,000 genotyped animals were available, and APY (Misztal *et al.*, 2014a; Misztal, 2016) was used to obtain the inverse of the genomic relationship matrix (G). In APY, the genotyped animals are partitioned into core and non-core sets. A sparse representation of G^{-1} is then possible without directly inverting G, enabling ssGBLUP evaluations for many genotyped animals. For the AAA evaluations, the set of core animals was chosen in 2016/2017 based on trait accuracy and has not changed since.

The adoption of genomic selection has been very successful in the Angus breed in the USA since 2017, and AAA breeders have now genotyped more than one million animals. It took about ten years (2008-2018) to reach 500 thousand genotyped animals but only three more years to reach the one million mark (2018-2021). At such a fast-genotyping pace, one question is whether updating the set of core animals in APY overtime is necessary to accurately represent the whole genotyped population. The follow-up question is about the benefits and potential downsides of making such a change on a national scale. Therefore, our objective was to investigate the impact of updating the core animals in APY ssGBLUP on GEBV and convergence behavior for the AAA evaluations.

Materials & methods

Data and model. A dataset for animals born up to 2019 was extracted from the American Angus Association (AAA) database. Phenotypes were available for birth weight (BW; n= 9,202,115), weaning weight (WW; n= 9,710,750), and post-weaning gain (PWG; n=4,723,244). There were 11,843,831 animals in the pedigree of which, 924,968 were genotyped at 39,773 markers after quality control. We used the same growth model as the AAA official evaluations: $y_t = Xbt + W_1u_t + W_2mat_t + W_3mpe_t + e_t$. Where t refers to traits (BW, WW, and PWG); y is the vector of phenotypes; b_t is the vector of fixed contemporary groups; u_t,

mat_t, and mpe_t are the vectors of random additive direct, maternal, and maternal permanent environmental effects, respectively; e_t is the vector of residuals. The u_t and mat_t were present for BW, u_t, mat_t, and mpe_t for WW and, only u_t for PWG. The matrices X, W_1, W_2 and W_3 are the incidence matrices for the effects in u_t, mat_t, and mpe_t, respectively.

Genetic evaluations at the AAA are performed using ssGBLUP (Aguilar *et al.*, 2010) with APY (Misztal, 2014a; Misztal, 2016). The derivations and the final form of the APY G^{-1} can be found in the cited references. The number of core animals in APY is determined based on the number of eigenvalues explaining 98-99% of the variance in G (Pocrnic *et al.*, 2016).

Core animals in APY. The core animals chosen for the implementation of ssGBLUP in 2017 contain 19,019 high accuracy (HA) animals born up to 2016 (mostly up to 2015). Different sets of randomly sampled core animals were compared to the HA core. To investigate the impact of choosing core animals from different generations, we randomly sampled four sets of 19,019 genotyped animals born up to 2010 (Y1), 2015 (Y2), 2017 (Y3), and 2019 (Y4). It is worth noting that scenario Y2 is a random sample of contemporaries of those animals used in the HA core, and Y4 represents a core sample taken from the whole genotyped population (born up to 2019). To investigate the impact of the number of core animals on GEBV changes, four more scenarios were tested by randomly choosing 10,000 (S1), 25,000 (S2), 30,000 (S3) and 35,000 (S4) core animals from the whole genotyped population. All analyses were performed using the BLUPF90 family of programs (Misztal *et al.*, 2014b). Correlations and absolute changes in GEBV (i.e. changes are expressed in genetic standard deviation (SDa) units) were used as metrics to investigate the impact of changing the core animals. Additionally, the number of rounds to convergence were used to evaluate the convergence behavior with different core animals in APY.

Results

Correlations and changes in GEBV presented here were investigated by contrasting the tested scenarios to the current evaluation (HA). This is because, in practice, critical changes to the current system potentially affect breeders. The GEBV correlations for all animals were ≥0.99, whereas, for genotyped animals, they were ≥0.98 across all scenarios.

Changes in GEBV. Table 1 shows the mean and maximum absolute changes in GEBV across different scenarios. The changes are presented in SDa units to allow easy comparison across traits. The SDa for the traits investigated is 5.38 for BW lbs, 31.41 lbs for WW and 28.08 lbs for PWG. For BW, the biggest change was 1.31 SDa, whereas for WW and PWG the biggest changes were 1.29 and 1.21, respectively. Overall, the largest changes were identified for animals with lower accuracy, genotyped animals, animals that changed from core to noncore and vice versa, and animals with many young genotyped progeny in the core.

Convergence. Table 1 shows the number of rounds to solve the system of equations in ssGBLUP with preconditioned conjugate gradient and iteration on data. The number of rounds to convergence was the largest with the oldest set of core animals (Y1), and rounds decreased with core samples more representative of the whole population (Y4). Memory usage increased with the number of core animals (from 109 GB in S1 to 281 GB in S4), which indicates the availability of restricted memory is a limiting factor when expanding the number of core animals.

Sum of elements of G for core animals (G_{cc}). The sum of all G_{cc} elements is in Table 1. Values were greater for Y1 and HA but decreased as more recent genotyped animals were included in the core. A correlation of 0.81 was observed between the number of rounds to convergence and the sum of G_{cc} for the scenarios based on different generations.

Table 1. Mean and maximum absolute GEBV changes[1], number of rounds to convergence, and statistics of G_{cc} across all scenarios and traits.

Scenario	N	BW		WW		PWG		Rounds	Sum(G_{cc})
		Mean	Max	Mean	Max	Mean	Max		
HA	19,019	-	-	-	-	-	-	3,449	1,008,639
Y1	19,019	0.02	1.31	0.02	1.21	0.02	1.08	4,643	2,662,809
Y2	19,019	0.01	1.05	0.02	1.23	0.01	1.21	3,904	477,087
Y3	19,019	0.01	0.93	0.02	1.29	0.01	1.03	3,120	152,131
Y4	19,019	0.01	1.27	0.02	0.89	0.01	0.86	1,981	24,067
S1	10,000	0.02	1.31	0.03	1.18	0.02	1.07	1,820	11,185
S2	25,000	0.01	0.82	0.02	1.24	0.01	1.07	2,059	37,864
S3	30,000	0.01	1.09	0.02	0.90	0.01	0.97	2,124	43,758
S4	35,000	0.01	1.07	0.02	1.09	0.01	0.77	2,188	59,150

[1] Changes are calculated as the absolute difference in GEBV from the official evaluation (HA) and expressed in SDa units.

Discussion

Changes in the set of core animals only marginally affected the ranking of animals, as the correlations are ≥0.99 regardless of the core choice, as long as the number of core animals explains at least 98% of the variation in G (Misztal *et al.*, 2020; Hidalgo *et al.*, 2021). In beef cattle in the US, even if the ranking of animals remains unchanged, changes in GEBV or expected progeny difference (EPD) are critical because breeders pay close attention to the actual EPD, especially on popular sires.

Changes in GEBV. The largest changes in GEBV observed in this study were slightly over one SDa. Similar findings were reported by Misztal *et al.* (2020) when they investigated core-dependent changes in APY across different populations. The authors reported smaller maximum changes in GEBV compared to our study, but this is likely because in our study, the baseline for comparison is a core set that was created in 2017 (HA). Therefore, the differences between the core sets were larger. Increasing the core size did not reduce the changes in GEBV (Table 1). Misztal *et al.*, 2020 reported that differences are minimized as the core size increases due to the reduction in the Mendelian sampling error in the APY formula. However, this was shown comparing pairs of core sets randomly sampled from the whole population, which was not the comparison made in our study. Expanding the tests to other traits published by the AAA, and with repeated random core samples (results not shown), the magnitude of the changes in GEBV was always similar, with the average absolute changes close to zero and maximum changes around one SDa for any given trait. These changes are not negligible in the context of the AAA evaluation. Still, individual changes were often on lower-accuracy animals or animals with many recent genotyped progeny. This would indicate a set of core animals that is more representative of the whole genotyped population is beneficial for the evaluation.

Convergence. The convergence rate was much improved with an updated sample of core animals. It is clear from Table 1 that randomly sampling core animals from the whole genotyped population yields the best convergence results. For instance, comparing core animals born up to 2010 (Y1) to the set sampled from the whole population (Y4), the number of rounds needed to reach convergence was reduced by 57%, which can dramatically reduce computing time for routine evaluations. Scenarios S1-S4 indicate that a smaller number of core animals results in a smaller number of rounds, as well as less memory usage, but caution is needed as we need to guarantee that a minimum number of core animals is used to explain 98-99% of the variation in G.

The change in convergence behavior seems to be linked with the condition of the blocks that form G and APY G^{-1}. The results in Table 1 show an association between the sum of the elements of G_{cc} and the convergence rate.

The AAA has recently (May 2021) updated the set of core animals used in routine evaluations to better represent the whole genotyped population. Across all genetic evaluations conducted, correlations between GEBV for all animals were always ≥0.99. The core update reduced the number of rounds to convergence by 43%, on average, across all traits. This greatly reduced the computing times of routine genetic evaluations without compromising the quality of the predictions. Despite some large individual changes, the update was well received by the AAA membership, and future research will determine when the next update will be needed.

338. A critical aspect when using APY inversion with Single-Step GBLUP

C. Edel*, E.C.G. Pimentel, R. Emmerling and K.-U. Götz

Bavarian State Research Center for Agriculture (LfL), Institute of Animal Breeding, Professor-Dürrwaechter-Platz 1, 85586 Poing-Grub, Germany; christian.edel@lfl.bayern.de

Abstract

If the algorithm for proven and young (APY) is used to invert the genomic relationship matrix within the framework of Single-Step genomic evaluations, critical side-effects on genomic EBV can occur. Here we demonstrate that if parent animals are not included in the APY-core, their Mendelian sampling deviations are missing in the EBV of their offspring. Additionally, a critical downward bias in genomic predictions for some animals can occur under specific but not uncommon conditions. We illustrate some of the mechanisms involved using a small example and define the circumstances under which a downward bias will occur. Based on this definition, we selectively omit a small group of genotyped animals from the APY-core of the routine evaluation for protein yield in dual-purpose Fleckvieh to demonstrate the resulting effects on their Single-Step predictions.

Introduction

APY was proposed as a method to approximate genomic predictions when the genomic relationship matrix G involved is too large for direct inversion (Misztal *et al.*, 2014). With APY, only a submatrix of G corresponding to a group of core animals is inverted explicitly and the remaining parts of the APY-inverse of G are then derived using recursions. Originally proposed as an 'algorithm for proven and young' with proven animals defined as core, several investigations have suggested that the choice of the core animals is of little relevance, if the core size is sufficiently large (Misztal, 2016; Pocrnic *et al.*, 2016). In April 2021 we established Single-Step methodology using APY as routine-evaluation for all traits in dual-purpose Fleckvieh and Brown-Swiss within the German-Austrian joint evaluation. During the implementation of the new system, we observed that Single-Step proofs of genomic young bulls (genotyped bulls with genotyped offspring but no daughter proofs, GYB) showed remarkable differences depending on whether they were included in the APY-core or not. Further investigation confirmed that proofs of GYB not included in the APY-core tend to be underestimated and that the degree of underestimation increased with the size of their respective offspring group. Since the consistency of proofs of the most widely used genomic young bulls is a key-parameter for the acceptance of genomic predictions in practical breeding programs, this aspect had to be investigated in more detail.

Methods

Example pedigree. To illustrate the mechanisms involved we will refer to a small example pedigree shown in Table 1. Scenarios A and B represent different situations with respect to animals being assumed to be genotyped (gt) and/or member of the APY-core. For each scenario the corresponding combined covariance-matrix H of true breeding values for gt and non-gt animals is calculated (Legarra *et al.*, 2009). To allow for a clearer interpretation, in all these calculations matrix G is replaced by the corresponding submatrix $A_{gt,gt}$ of the standard numerator relationship matrix A, applying APY-recursion depending on the respective scenario. Final matrix H for each scenario is decomposed to give H = TDT', where T is a lower triangular matrix and D is a diagonal matrix of individual Mendelian variances. In this context each row *i* of T illustrates how each breeding value *i* is a function of Mendelian sampling (MS) terms of animals 1:*i*. Likewise, each row *i* of T^{-1} illustrates how each MS-term *i* is a function of breeding values of animals 1:*i*. Multiplication TDT' can be done sequentially by calculating outer products of the respective row/column *i* of T times scalar $d_{i,i}$ and then summing up all partial matrices, thereby illustrating animal *i*'s contribution

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_338, © C. Edel *et al.* 2022

to the final matrix H. The same applies for the inverse $H^{-1} = (T')^{-1}D^{-1}T^{-1}$. In the case of A^{-1} this calculation of partial matrices provides the theoretical background of Henderson's rules for the inverse of the numerator relationship matrix.

Real data. Data from the August 2021 routine-run of the German-Austrian Single-Step evaluation for protein yield in Fleckvieh were used. Total number of animals in the pedigree was 16,864,007, from which 13,417,282 had at least one test-day observation for protein yield. The number of genotyped animals was 370,123. Matrix G^{-1} was set up using APY with 26,724 animals in the core set. Estimated breeding values (EBV) from the routine run were used as reference. We then selected 50 genotyped GYB (GYB50) and omitted them from the APY-core. GYB50 were selected by the following criteria:

- GYB with a large group of genotyped offspring in the evaluation system, that were produced from mating with non-gt females (23-267 matings, average is 66).
- Non-gt females mated to the GYB had to show on average a positive MS (3.0-5.2 kg, average is 3.7 kg). MS-terms used as criteria were calculated from conventional EBV (additional run) without the use of genomics.

To keep the size of the APY-core constant, we replaced the GYB50 by 50 other gt bulls of the same cohort (without genotyped offspring). Finally, we compared the resulting EBV (EBV_{drop}) to the reference (EBV_{ref}). All results shown are EBV on the natural scale (protein-yield, kg). Genetic standard deviation of the trait is 16.4 kg.

Results & discussion

Example pedigree. Rows of matrix T corresponding to animals 5, 7 and 8 (GYB, mate, offspring) for scenarios A and B are given in Table 2. Scenario 'Base' refers to a situation where all animals are gt and in the APY-core. Recall that for ease of interpretation we used submatrix $A_{gt,gt}$ instead of G, so in this case H=A. With sire 5 and dam 7 genotyped but omitted from the APY-core (scenario A), MS-terms of 5 and 7 no longer contribute to the breeding value of offspring 8. If there is no information available to estimate MS-terms for animals 5 and 7 this will have no effect on the estimates of their offspring. However, in a dairy cattle situation, cow 7 will most likely provide information to estimate her MS from her own performance. In this situation, her estimated MS-term will be missing in the parent-average part of EBV of offspring 8. If mate 7 is assumed to be non-gt (scenario B), it is no longer part of the APY-recursion. In scenario B GYB 5 will still not contribute to the BV of animal 8 while the MS of dam 7 will make a contribution, which is slightly higher than expected. Row 7 of Matrix T now additionally includes a negative coefficient of the MS of dam 7 to her mate (GYB 5), contributing to a negative correlation between the MS-terms of animals 5 and 7 in the final matrix. Since GYB 5 has no information to estimate his own MS but mate 7 provides her

Table 1. Example pedigree with two scenarios A and B.

Animal	sire	dam	sex	isGT (A)	isCore (A)	isGT (B)	isCore (B)
1	0	0	m	1	1	1	1
2	0	0	m	1	1	1	1
3	0	0	f	1	1	1	1
4	0	0	f	1	1	1	1
5 (GYB)	1	3	m	1	0	1	0
6	1	4	f	1	1	1	1
7 (mate)	2	4	f	1	0	0	0
8 (offspring)	5	7	m	1	0	1	0

own performance, parts of her MS-estimate will be transferred to GYB 5 but with an opposite sign. This will be the case with every additional non-gt dam mated to the non-core GYB. Assortative mating to a group of superior dams would then result in downward bias in the EBV of the GYB.

As mentioned in the introductory section, initial observations of this phenomenon suggested that there should be an additional effect that scales the bias produced by assortative mating to the number of offspring produced by such matings. Recalling Henderson's rules for setting up A^{-1}, outer products of the rows of matrix T^{-1} (Table 3) will provide the coefficients each animal will contribute to the respective elements of the final inverse. The most prominent aspect here is the deficiency found in the term that offspring 8 provides to the diagonal element of its sire 5 (-0.12^2 instead of -0.50^2). This deficiency is only partly compensated by the non-regular diagonal contribution of dam 7 to the diagonal element of her mate 5 (0.20^2). Since a similar deficiency will be present in every additional offspring's contribution to the final diagonal element of its sire, this will produce an increasing inconsistency with respect to the MS variance assigned to the sire in the final matrix. Thus, the bias in the MS estimate of the GYB, that was produced by assortative mating will increase with the number of such matings.

Real data. Table 4 summarizes the changes observed in routine Single-Step EBV when selectively omitting GYB50 from the APY-core. Results show a downward bias in EBV_{drop} for GYB50 as well as a reduced model fit. In contrast, a systematic bias is mostly absent in the results of all other groups shown. In GYB50 the downward bias in EBV_{drop} is highly correlated to the size of the offspring group of the GYB produced by matings to ngt females as illustrated in Figure 1.

Table 2. Rows of T corresponding to animals 5, 7 and 8 for scenarios Base, A and B.

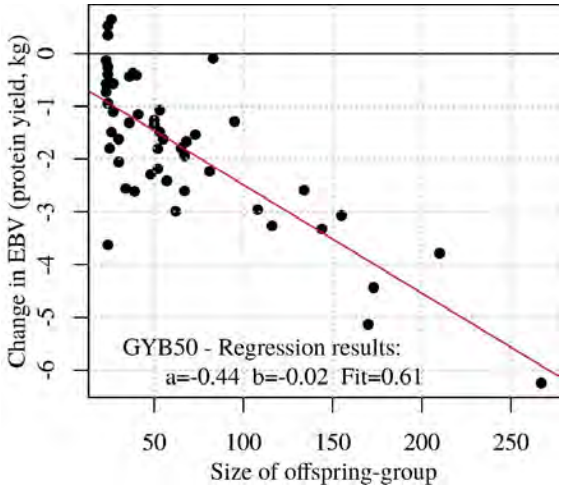

Figure 1. Change in EBV of GYB50.

Conclusions

We have demonstrated that by omitting a gt parent from the APY-core its MS deviation will be absent in the EBV of its offspring. By assigning an APY-core of sufficient size, this deficiency might be partly compensated by the additional information provided by the G matrix. Therefore, in genomic evaluation systems, it might not be as pronounced as illustrated here with the small pedigree example using $A_{gt,gt}$ instead of G. However, if a superior GYB that was systematically mated to superior but non-gt dams is not considered in the APY-core, a systematic downward bias in its EBV will be observed, that will increase with the number of such matings. Since offspring EBV will not be biased accordingly, an increasing discrepancy between average EBV of unselected offspring and their average mid-parent EBV will be the consequence. The situation described here is not uncommon in practical breeding programs where the consistency of proofs of the most popular genomic young bulls is of high importance. Therefore, a random choice of APY-core animals should be avoided, irrespective of additional considerations about the core-size. Although not 'proven' in a strict sense, GYB should be included in the APY-core to prevent strong effects on their genomic EBV.

Abstract

Genomic predicted breeding values (GPBV) to select animals in breeding programs are nowadays routinely adopted by most commercial livestock production systems. Accuracy of the GPBV (defined here as their correlation with the true phenotypes) has a theoretical limit of $\sqrt{h^2}$ that is achieved when, among other factors, available SNPs are in sufficient LD with the QTL. However, even under such assumptions, realized accuracies of GPBV remain generally below $\sqrt{h^2}$, because allele frequencies and LD patterns differ between reference and target populations (particularly noticeable across generations), resulting in the so-called erosion of SNP effects and consequently, erosion of the accuracy of the GPBV. We present here a measure to quantify the erosion of the GPBV's accuracy through the genomic correlation between reference and target populations and validate this measure through simulations.

Introduction

Nowadays, GPBV are routinely used for the selection of animals in many commercial livestock breeding programs. The accuracy of GPBV is therefore a very important factor for the success of a breeding program. However, realized accuracies of GPBV remain below the theoretical maximum ($\sqrt{h^2}$), even when the reference population is sufficiently large, and SNPs included in the model are in sufficient LD with the QTL. That is particularly noticeable over generations, as we observe the so-called erosion of SNP effects accompanied by the erosion of the GPBV's accuracy. Erosion occurs mostly due to differences in LD patterns and allele frequencies between reference and target populations; for example, if in the reference population a SNP is in strong LD with the QTL, a large effect will be assigned to it. However, if due to segregation over the generations, the LD between this SNP and the QTL becomes weaker in the target population, an effect closer to zero should be assigned to this SNP. The decay in prediction accuracy due to differences in allele frequencies and LD patterns, specially over generations, is a topic widely known and discussed by animal breeders and quantitative geneticists (Daetwyler *et al.*, 2008; Habier *et al.* 2013; Wientjes *et al.*, 2015, 2016; Pszczola and Calus, 2016; van den Berg *et al.*, 2019; Dekkers *et al.*, 2021). Quantifying the erosion at the individual SNP level is in fact, a difficult and unresolved task. It is, however, more tractable to quantify the erosion of the accuracy of the GPBV through a metric based on the genomic correlation between reference and target populations, which we present in this paper and validate through simulations.

Materials & methods

Consider the genomic model $y_1 = X_1\beta + M_1\alpha + \varepsilon_1$, in which y_1 are the phenotypes measured in the reference population, β are the fixed effects and X_1 their design matrix in the reference population, M_1 is the (centred) SNP-genotypes matrix of the reference population, $\boldsymbol{\alpha} \sim N(\mathbf{0}, \boldsymbol{I}_m\sigma^2_\alpha)$ are the SNP effects, and $\boldsymbol{\varepsilon}_1 \sim N(\mathbf{0}, \boldsymbol{I}_n\sigma^2_\varepsilon)$ are the random residuals. Solving Henderson's mixed model equations (HMME) (Henderson *et al.*, 1959), we have the estimates $\widehat{\boldsymbol{\beta}} = [\boldsymbol{X}_1'(\boldsymbol{M}_1\boldsymbol{M}_1'\sigma^2_\alpha + \boldsymbol{I}_n\sigma^2_\varepsilon)^{-1}\boldsymbol{X}_1]^{-1}\boldsymbol{X}_1'(\boldsymbol{M}_1\boldsymbol{M}_1'\sigma^2_\alpha + \boldsymbol{I}_n\sigma^2_\varepsilon)^{-1}\boldsymbol{y}_1$ and $\widehat{\boldsymbol{\alpha}} = \boldsymbol{M}_1'(\boldsymbol{M}_1\boldsymbol{M}_1'\sigma^2_\alpha + \boldsymbol{I}_n\sigma^2_\varepsilon)^{-1}\boldsymbol{y}_1^*\sigma^2_\alpha$, such that $\boldsymbol{y}_1^* = \boldsymbol{y}_1 - \boldsymbol{X}_1\widehat{\boldsymbol{\beta}}$. Finally, the fitted breeding values for the n_1 animals in the reference population are $\widehat{\boldsymbol{g}}_1 = \boldsymbol{M}_1\widehat{\boldsymbol{\alpha}}$, and let M_2 be the (centred) SNP-genotypes matrix of the target population, the GPBV for the n_2 animals in the target population are $\widetilde{\boldsymbol{g}}_2 = \boldsymbol{M}_2\widehat{\boldsymbol{\alpha}}$.

Theoretical limit of GPBV's accuracy without accounting for erosion. Our interest lies on the accuracy of the GPBV, i.e. on $R = \widehat{cor}(\tilde{\boldsymbol{g}}_2, \boldsymbol{y}_2^*)$, such that $\boldsymbol{y}_2^* = \boldsymbol{y}_2 - \boldsymbol{X}_2\hat{\boldsymbol{\beta}}$. Using Fisher's z-transformation on R, we have that $Z = log\left(\frac{1+R}{1-R}\right) \sim N\left(log\left(\frac{1+\rho}{1-\rho}\right), \frac{4}{n_2-3}\right)$, with ρ being the true accuracy, i.e. $\rho = \sqrt{h^2}$.

By reversing Fisher's z-transformation $R = \varphi(Z) = \frac{e^Z-1}{e^Z+1}$ is a function of Z, and using Jensen's inequality we show that:

$$E[R|\text{no erosion}] = E[\varphi(Z)|\text{no erosion}] \leq \varphi(E[Z]|\text{no erosion}) = \frac{e^{E[Z]}-1}{e^{E[Z]}+1} =$$
$$\left[e^{log\left(\frac{1+\rho}{1-\rho}\right)} - 1\right] \Big/ \left[e^{log\left(\frac{1+\rho}{1-\rho}\right)} + 1\right] = \rho = \sqrt{h^2}. \quad .$$

Theoretical limit of GPBV's accuracy accounting for erosion. We hypothesized that the genomic correlation between reference and target populations (r) affects linearly the mean of the z-transformed correlations, resulting in $Z = log\left(\frac{1+R}{1-R}\right) \sim N\left(r\ log\left(\frac{1+\rho}{1-\rho}\right), \frac{4}{n_2-3}\right)$.

Using Jensen's inequality again we show that, under our hypothesis:

$$E[R|\text{erosion}] \leq \frac{\left(1+\sqrt{h^2}\right)^r - \left(1-\sqrt{h^2}\right)^r}{\left(1+\sqrt{h^2}\right)^r + \left(1-\sqrt{h^2}\right)^r} \underset{r\to 1}{\longrightarrow} \sqrt{h^2}.$$

Erosion of the GPBV. We consider the erosion of the GPBV (δ_{GPBV}) as the difference between $\sqrt{h^2}$ and the theoretical limit of GPBV's accuracy accounting for erosion, scaled by $\sqrt{h^2}$,

$$\delta_{GPBV} = 1 - \frac{E[R|\text{erosion}]}{\sqrt{h^2}} \quad (1)$$

Genomic correlation between populations. Let M be a (centred) SNP-genotypes matrix ($n \times m$), with singular-value decomposition (SVD) $\left(\sum_{j=1}^{m} 2p_j(1-p_j)\right)^{-1/2}\boldsymbol{M} = \boldsymbol{UDV'}$, such that p_j's are the alleles frequencies. In this SVD, D is a diagonal matrix of the $k = rank\ (M)$ singular-values, and $U_{n\times k}$ and $V_{m\times k}$ are matrices of unitary eigen-vectors relative to the individuals and to the SNPs, respectively. Knowing that components in D^2 explain the variation of the whole system M, each U_{ik} explains the contribution of the i-th individual to the k-th component, and each V_{jk} explains the contribution of the j-th SNP to the k-th component. To obtain the genomic correlation between reference and target populations (r), we need to quantify the different contribution of the SNPs to the system's variation in the two populations. To do so, we perform the aforementioned SVD on M_1 and M_2, then build a matrix $\boldsymbol{T} = \sqrt{(n_2/n_1)}\boldsymbol{V}_2'\boldsymbol{V}_1\boldsymbol{D}_1$ which correlates the contributions of the SNPs in both populations, while correcting for the different population sizes, weighting these correlations by the singular-values on the reference population. Next, we obtain the SVD $T = U_T D_T V_T$, and perform the linear regression $D_T \sim D_2$ with a quadratic term, i.e. we fit $d_{Ti} = a + bd_{2i} + cd_{2i}^2$. Finally, we obtain the genomic correlation between reference and target populations as $r = a + b + c$.

Simulation study. We simulated 50K SNPs and additive phenotypes for h^2 = 0.05,0.15,…,0.9,0.95, using 2K SNPs as QTL. A base reference population of 5,000 individuals was used to estimate variance components using REML (Patterson and Thompson, 1971) and SNP effects â (solving HMME). Using â we obtained the GPBV for three different target populations (1000 individuals each) with increasing generation distances (one, five, and ten) from the reference population. Then we compared our theoretical measures $E[R|\text{erosion}]$ and δ_{GPBV} with the realized prediction accuracies ($R = \widehat{cor}(\tilde{\boldsymbol{g}}_2, \boldsymbol{y}_2^*)$) and erosion ($\hat{\delta} = 1 - R/\sqrt{h^2}$).

Results

In Figure 1 we observe that as the generation distance between reference and target populations increases, the relationship $d_{2i} \times d_{Ti}$ moves further from the identity line and becomes more quadratic, resulting in

decreasing genomic correlations as the generation distances increase: r = 0.49, r = 0.42 and r = 0.33 for target populations respectively one, five and ten generations apart from the reference population.

In Figures 2 and 3 we observe that our theoretical curve $E[R|\text{erosion}]$ accurately fits the realized $\hat{h}^2$ and $R = \widehat{cor}(\tilde{\boldsymbol{g}}_2, \boldsymbol{y}_2^*)$, and that δ_{GPBV} is quite accurate to assess the erosion. For extreme h^2 (<0.1 and >0.85) however, there is still a small over expectation for R, which results in δ_{GPBV} being lower than the observed $\hat{\delta}$. Low heritability traits (h^2<0.2) also present a large $Var(\delta)$, indicating that precise assessment of erosion may be difficult for such traits.

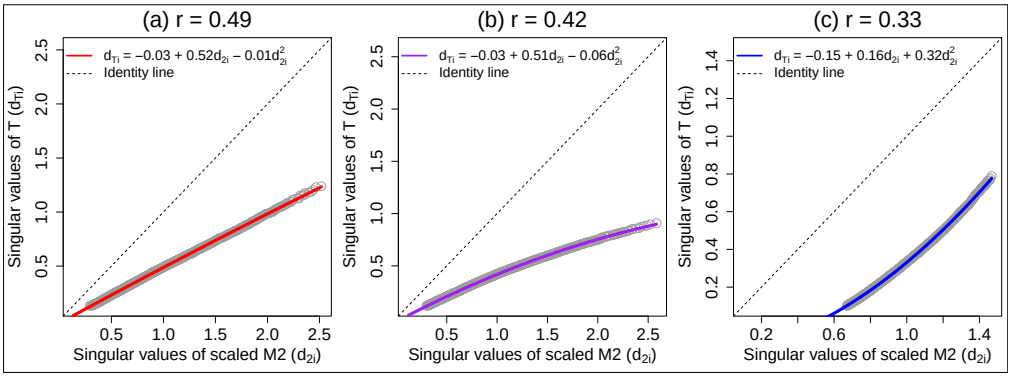

Figure 1. Singular values of the scaled M_2 (d_{2i}) vs singular values of $\boldsymbol{T} = \sqrt{(\boldsymbol{n_2}/\boldsymbol{n_1})}\boldsymbol{V_2'V_1D_1}$ (d_{Ti}), and estimated coefficients fitting the model $d_{Ti} = a + \text{bd}_{2i} + cd_{2i}^2$ for the target populations (a) one, (b) five, and (c) ten generations apart from the reference population.

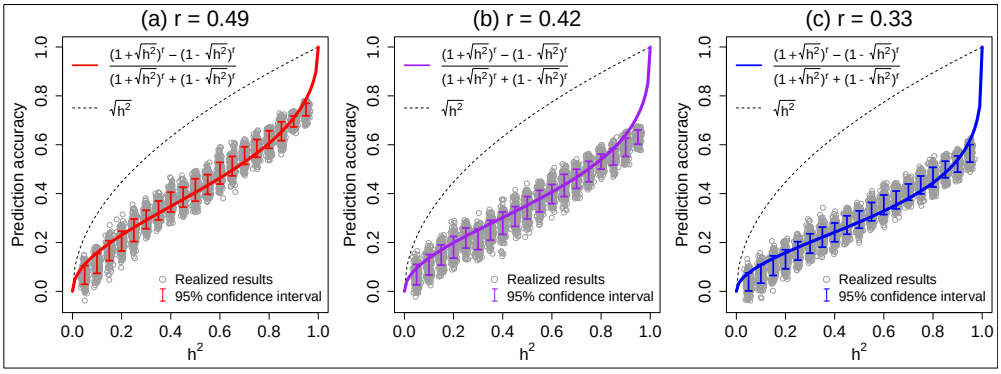

Figure 2. Theoretical $E[R|\text{erosion}]$ (full coloured line) and $E[R|\text{no erosion}]$ (dashed line), and the realized results for the target populations (a) one, (b) five, and (c) ten generations apart from the reference population.

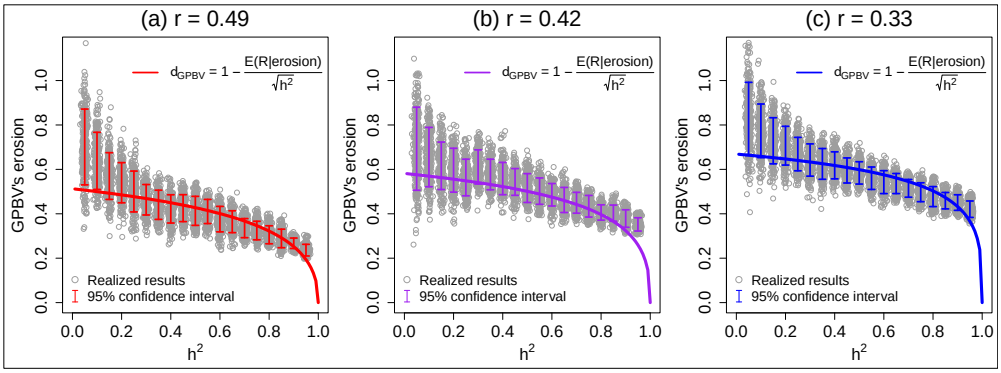

Figure 3. Theoretical erosion (δ_{GPBV}) and realized results for the target populations (a) one, (b) five, and (c) ten generations apart from the reference population.

Discussion

We hypothesized that once we know the genomic correlation between reference and target populations (r), we can define the maximum accuracy of the GPBV as

$$E[R|\text{erosion}] \leq \frac{(1+\sqrt{h^2})^r-(1-\sqrt{h^2})^r}{(1+\sqrt{h^2})^r+(1-\sqrt{h^2})^r} \underset{r\to 1}{\longrightarrow} \sqrt{h^2},$$

and the results obtained with our simulations support this hypothesis. The measure we defined to quantify the erosion of the accuracy of the GPBV ($\delta_{GPBV} = 1 - E[R|\text{erosion}]/\sqrt{h^2}$) was also quite accurate, although it may be imprecise or underestimated for low heritability traits (h^2<0.2). One important element for calculating $E[R|\text{erosion}]$ and δ_{GPBV} is the genomic correlation r, a single value capable to summarize all the information about the differences in allele frequencies and LD patterns observed in both the reference and target populations. Although computationally costly for large populations and dense genotype data, our results indicate that the genomic correlation r obtained with the SVDs of genomic matrices is trustworthy. This work focused on the calculus of $E[R|\text{erosion}]$ and δ_{GPBV}, and did not explore the underlying meaning of the values of the coefficients a, b, and c that compose r, i.e. how allele frequencies, LD patterns, number of SNPs and population sizes affect each of these coefficients, but we do understand that such a study is relevant.

340. Model building pipeline to maximize the accuracy of breeding values prediction

J. Jenko[1*] and Ø. Nordbø[2]

[1]Geno SA, Storhamargata 44, 2317 Hamar, Norway; [2]Norsvin R&D, Storhamargata 44, 2317 Hamar, Norway; janez.jenko@geno.no

Abstract

To maximize the accuracy of selection, models used for the prediction of breeding values need to correct phenotypes for all known important environmental effects. We have developed a pipeline where a fixed part of the model is built automatically, and the proposed models are validated in terms of accuracy and bias of their predictions. After the best model for a single trait is selected, genetic correlations are estimated between all the combination of traits and the optimal multitrait models are proposed. We have tested the model building pipeline on the development of single step genomic predictions for a conformation data set with repeated records on the Norwegian Red dairy cattle breed. The comparison between the single step genomic predictions using the old multitrait models and the new multitrait models averaged over nineteen traits showed a relative increase of 26% (from 0.62 to 0.78) in the accuracy of predictions.

Introduction

Accuracy of selection is among selection intensity, genetic variation, and generation interval one of the four components influencing genetic improvement of a population (Falconer, 1996). For a trait with a single record per individual the accuracy of prediction is a square root of heritability. When multiple measurements are taken on the animal for a single trait, the breeding value is predicted from the mean of these records. Repeated records enable estimation of resemblance between records due to the permanent environmental factors (Mrode, 2014). This is decreasing the variance within the individual which leads to an increase in the accuracy of prediction. The gain in accuracy of prediction is increasing with more records, but the marginal benefit in precision is decreasing.

Before variance component estimation and prediction of breeding values, phenotypes have to be corrected for all known important effects. The decision whether the effect is included into the model is often based on F-test where the simple and alternative models are compared. Other criteria like coefficient of determination and adjusted coefficient of determination can be used as well. Finally, models can be validated for their prediction accuracy.

Conformation traits have been part of the breeding goal from the very beginning of the breeding program for Norwegian Red dairy cattle in the nineteen sixties. The importance of conformation traits in breeding goal has increased from around 10% in the beginning to almost 30% in the 2020. Back in the history phenotypes for exterior traits in Norwegian Red dairy cattle were only collected on the first lactating cows. However, since 2014, repeated recording of conformation traits on cows in the first five lactations were collected and the starting point of the current work was to utilize the repeated records into the routine genomic evaluations. To increase the accuracy of predictions furthermore, new multitrait models will be built to utilize information from genetically correlated traits.

Materials & methods

Data. The data comprised of twenty-four traits collected between 1988 and 2021. There were 646,291 records collected on 585,306 cows, from which 16,924 were genotyped. Only cows in the first five lactations were recorded. At the time of recording the majority were in the first lactation (545,518) followed by

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_340, © J. Jenko and Ø. Nordbø 2022

the cows in the second (59,827), third (32,156), fourth (6,006), and fifth (2,784) lactation. The data were recorded on 22,036 herds. There were seven traits that were standardized since they have changed the scale of recording from 1-3 to 1-9 in 2014. To keep the phenotypic variance constant, phenotypes recorded in 2014 or later were standardized for heterogenous variance due to the lactation number. Except stature and supernumerary teats all the traits were also standardized for heterogenous variance due to the classifier and the year of taking the scoring.

Model development and estimation of variance components. To build the fixed part of the model and estimate the variance components, only data recorded after 2011 from herds with at least 100 recordings for stature were used. Furthermore, only data recorded between 14 and 305 days in lactation were kept. This gave 68,227 records collected from 440 herds. Fixed part of the model was built with an inductive approach. Here, the effects were included in the fixed part of the model only if they have passed the inclusion criterion for a specific scenario. Three different inclusion criteria were set for the four optimization parameters. The four optimization parameters were: (1) R square or the proportion of the variance explained; (2) Adjusted R square, which in comparison to R square penalizes for addition of extra variables; (3) *P*-value that compares the reference and alternative model using the F-test; and (4) Gain by loss which is the relative change in residual sum of squares between the reference and alternative model per change in degrees of freedom between the reference and alternative model. Each of the optimization criteria was tested with three inclusion criteria. R square and adjusted R square with 0.1, 0.01, and 0.001, *P*-value with 0.01, 1×10^{-5} and 1×10^{-10}, and Gain by loss with 0.01, 0.001, and 1×10^{-4}. If the tested effect passed the inclusion criterion for the optimization parameter and its effect was the biggest among all the effects, it was included in the model. By default, each model had already included the fixed effects of herd-five-years and year-month of calving. The inclusion of the other twelve candidate effects (number of days since calving, barn type, recording version, feeding system, milking system, classifier, lactation number, time since milking within time from calving, heterozygosity, year of recording, hours since milking, and age at calving) was tested in a sequential order so that the most important effect was included first. If a linear covariate was included in the model, the squared covariate was also tested. The same was done for cubic covariate if the squared covariate was included in the model. Once none of the effect was passing the inclusion criterion, the model building was finished. Finally, two and three-way interactions were tested and included in the model if passing the inclusion criterion for the optimization parameter. With this approach twelve models were developed for each of the twenty-four traits and variance components were estimated using DMU 6 (Madsen and Jensen, 2013).

Cross-validation of alternative models. The proposed models were then tested for the accuracy of prediction using a cross-validation approach. Here 269,114 records collected on 226,485 cows after the year 2005 were used. First estimated breeding values (EBV) using a single step genomic approach on this complete data set were calculated with the DMU 6 (Legarra *et al.*, 2014; Madsen and Jensen, 2013). Then, phenotypes of 6,841 cows that were genotyped and were not included in the variance component estimation were masked and EBV using the single step genomic approach were calculated again. Finally, yield deviations (YD) were estimated from the complete data set and correlated with the EBV from the data set with masked phenotypes. This was done on the animals with masked phenotypes only. The model with the highest accuracy and the lowest bias was then selected for the construction of multitrait models.

Estimation of variance-covariance parameters and construction of multitrait models. The variance-covariance parameters were estimated on the bivariate models across all the twenty-four traits. Traits with high genetic correlations were then combined into six multitrait models. Some traits were included in more than one multitrait model to increase the accuracy of prediction for the traits in a particular multitrait model.

Cross-validation of final multitrait models. The accuracy of predictions of the newly developed multitrait models were finally compared with the accuracy of predictions from the old multitrait models. This was done with masking of the phenotypes from the youngest 5,000 genotyped cows. The YD calculated from the complete data set and EBV from the masked data set were calculated using the MiX99 software (MiX99 Development Team, 2019). The obtained YD and EBV were correlated (Cor) and corrected for the heritability to estimate the accuracy of prediction (Acc) using the following equation:

$$Acc = Cor(YD,EBV) / (n /(n + (\sigma_e / \sigma_a)))^{0.5} \quad (1)$$

where n is the mean number of observations for each animal with masked phenotype, σ_e is the error variance and σ_a is the additive variance. Error and additive variances estimated from the new models were used when estimating the accuracy for both old and new models.

Results

The heritability and prediction accuracy from old and new multitrait models are presented in Table 1. Out of twenty-four traits breeding values for nineteen traits were predicted with both old and new models.

Most of the traits have moderate heritability spanning from 0.14 to 0.31. Only teat length and stature have high heritability of 0.41 and 0.58, respectively. The prediction accuracy has increased for all the traits when the new multitrait models were used. Average accuracy when the old multitrait models were used for predictions was 0.62 where a minimum accuracy of 0.45 was achieved for rear legs rear view and a maximum accuracy of 0.72 was achieved for stature. Average accuracy when the new multitrait models were used for predictions was 0.79 where a minimum accuracy of 0.60 was achieved for rear legs rear view

Table 1. Prediction accuracy for the conformation traits of Norwegian Red dairy cattle with previous and current multitrait models (old/new multitrait model).

Trait	Previous heritability	Current heritability	Accuracy previous model	Accuracy current model
Stature (1./1.)	0.41	0.58	0.72	0.89
Rump angle (1./2.)	0.19	0.28	0.64	0.87
Body depth (1./3.)	0.14	0.19	0.53	0.77
Chest width (1./3.)	0.11	0.15	0.53	0.74
Rump width (1./3.)	0.22	0.30	0.61	0.80
Rear legs rear view (2./1.)	0.08	0.14	0.45	0.60
Rear legs side view (2./1.)	0.09	0.17	0.62	0.70
Foot angle (2./1.)	0.09	0.14	0.64	0.71
Udder balance (3./4.)	0.11	0.17	0.68	0.85
Rear udder width (3./4.)	0.13	0.17	0.71	0.81
Rear udder height (3./4.)	0.11	0.16	0.70	0.83
Rear teat placement (4./5.)	0.22	0.26	0.69	0.83
Fore udder attachment (4./4.)	0.12	0.17	0.51	0.63
Front teat placement (4./5.)	0.18	0.27	0.70	0.79
Central ligament (5./5.)	0.10	0.14	0.54	0.64
Supernumerary teat (5./6.)	0.21	0.17	0.56	0.95
Teat thickness (5./6.)	0.20	0.29	0.64	0.82
Teat length (5./6.)	0.27	0.41	0.71	0.86
Udder depth (5./4.)	0.25	0.31	0.68	0.83

and a maximum accuracy of 0.95 was achieved for supernumerary teat. This means that on average the new multitrait models increase the prediction accuracy for 26% (from 0.62 to 0.79). Correlations between the predicted breeding values from old and new models were from 0.78 to 0.97.

Discussion

Three main reasons for the increase in the accuracy of predictions with the new models exist. The first one is the inclusion of phenotypes from multiple lactations instead of only the first one. As mentioned earlier this enables estimation of resemblance between records due to the permanent environmental factors and decreases the variance within the individual which leads to an increase in the accuracy of predictions (Mrode, 2014). The second reason is a better correction of phenotypes for all known environmental effects. Old models were all correcting traits for the same fixed effects. Model development pipeline corrected phenotypes only for the important known effects and different fixed effects were included in the different models. Using the cross-validations we have compared the proposed models and selected the model that is maximising prediction accuracy and minimising bias. The third reason is the optimal construction of multitrait models. The old models were built so that trait describing the same part of the cow exterior were combined into a multitrait model. The new multitrait models were constructed so that traits with high genetic correlations were combined into a single multitrait model.

The new multitrait models for the prediction of breeding values for exterior traits were sent for Interbull test in August 2021. After their approval they were successfully implemented in the routine genetic evaluations for the Norwegian Red dairy cattle in December 2021. Given the improved accuracy of genomic predictions with new, updated models, we expect to see an increased genetic gain in the coming years.

Abstract

The objective of this study was to evaluate genomic prediction using a breed origin of alleles (BOA) model for a multi-breed Irish beef cattle population. Our BOA model uses one matrix with allele counts for each breed to predict breed-specific marker effects, enabling to use crossbred and purebred animals in the reference population. Pedigree-based best linear unbiased prediction (PBLUP), a genomic model assuming a homogeneous population (SNP-BLUP) and BOA model were compared. Accuracy was estimated as the correlation between breeding values and corrected phenotype divided by the square root of heritability. The accuracy of predictions using BOA increased by 82 and 42% for crossbred and purebred animals, respectively, compared with PBLUP, and improvements of BOA over SNP-BLUP were of 6% for crossbred animals.

Introduction

Genomic prediction (GP) has been rapidly implemented in cattle due to its ability to accurately predict the genomic values of selection candidates early in life. Accuracy of genomic prediction relies on the linkage disequilibrium (LD) between genetic markers, usually single nucleotide polymorphisms (SNPs), and causal mutations. The stronger the LD, the more accurately will be the prediction of the direct genomic breeding values (DGVs). The effects of causal mutations captured by the SNPs is not consistent across distantly related populations due to differences in LD patterns. Additionally, some causal mutations may not segregate in all breeds, or the allelic effects of causal mutations may differ in different breeds due to epistasis and differences in allele frequencies (Goddard *et al.*, 2018). Therefore, multiple breed evaluation might benefit from a common multi-breed reference population when the models consider the differences in LD and/or marker effects among the involved breeds. The breed origin of alleles BOA model (Karaman *et al.*, 2021) predicts breeding values based on breed-specific marker effects estimated with purebred and crossbred data, allowing for accounting for correlations between the SNP effects of the different breeds. The application of BOA model can be advantageous in multi-breed populations to the extent that the breeds are distantly related. Otherwise, a joint analysis of all available data can be highly competitive. The Irish beef cattle population is a multi-breed population involving around 40 breeds, with some of them being dairy breeds. Therefore, it is expected that accounting for breed-specific marker effect would be more accurate than assuming homogeneous marker effects across the breeds. The objective of this study was to compare accuracy of predictions from a pedigree-based model (PBLUP) or using genomic information in a joint analysis (SNP-BLUP) or BOA model for the Irish beef cattle population.

Materials & methods

Data. The data used in the present study belongs to an Irish cattle multi-breed population (ICBF, http://www.icbf.com). We kept as main breeds the four pure breeds which contributed the most to the crossbred genotyped animals in the population. The pure breeds were Limousin (LM), Charolais (CH), Angus (AA) and Holstein (HO). For BOA estimation, as a fifth group, we kept five breeds that followed the main and treated them as an 'others' (OT) group. We selected genotyped crossbred animals for estimating BOA with more than 85% of the four main breeds (166,925 animals). Carcass weight (kg) data were available on 10,159,493 animals born between 2000 and 2020 slaughtered between 300 and 1,277 days of age. Purebred

animals from minor breeds and animals without registered sire were removed, resulting in 9,947,707 phenotypic records. After quality control, 46,983 SNPs remained available. The pedigree contained 16,120,121 animals born between 1950 and 2021.

Breed origin estimation. We used the AllOr method (Eiríksson *et al.* 2021) to infer breed origin to each SNP allele. We included a donor genotype library with purebred animals of main breeds and OT, and we also included a pedigree file obtained by tracing the genotyped crossbreds back. On average, 96.95% of the alleles were assigned a breed of origin. The alleles not assigned to a particular breed were defined as coming from the OT group.

Prediction of breeding values. The phenotypes for the whole population were pre-corrected for the following non-genetic effects (*fixed*: birth year; type of birth; factory of slaughter; and age at slaughter linear, quadratic and cubic; *random*: contemporary group of herd of slaughter (CG1) and prior to slaughter; and dam permanent environment). Then, we selected a subset (as explained later in the validation subsection) to run PBLUP, SNP-BLUP and BOA models. For PBLUP we traced three generations back the pedigree of animals in the subset.

Models. PBLUP and SNP-BLUP models

$$y^* = 1u + Xb + Zu + e \quad (1)$$

where y* is a vector of adjusted phenotypes of all animals, 1 is a vector of 1s, μ is the overall mean, X is the matrix of breed proportions computed from BOA assignments, b is the vector of fixed breed effects, and e is the vector of random residuals. Random residuals were assumed to follow a normal distribution, $e \sim N(0,\sigma^2_e)$, where σ^2_e is the residual variance. Z and u changes depending on the model. For PBLUP u is a vector of EBVs, distributed as $u \sim N(0,A\sigma^2_g)$, where σ^2_g is the additive variance, and A is the numerator relationship matrix, Z relates phenotypes to animals. For the SNP-BLUP model, u is the vector of SNP effects and Z is the matrix of centered genotypes based on current allele frequency.

BOA model

$$y^* = 1u + Xb + Z_{CH}u_{CH} + Z_{LM}u_{LM} + Z_{AA}u_{AA} + Z_{HO}u_{HO} + Z_{OT}u_{OT} + e \quad (2)$$

where y*,1, μ, X, b, and e were as described in Equation 1, Z_{CH}, Z_{LM}, Z_{AA}, Z_{HO}, and Z_{OT} are the matrices of breed-specific content of SNP for CH, LM, AA, HO and OT, u_{CH}, u_{LM}, u_{AA}, u_{HO} and u_{OT} are vectors of SNP effects for CH, LM, AA, HO, and OT, respectively. The Z matrices were formed by assigning each allele to a certain pure population for which the expected probability is the highest. The entry at a locus in an Z matrix, for instance, Z_{CH}, were the number of '*A*' alleles (0, 1 or 2) originating from CH for an animal. Consequently, if an animal had '*aa*' genotype or had no allele originating from CH, the corresponding entry in Z_{CH} was zero. The Z matrices were centered prior to analysis. The analysis assumed correlations between SNP effects of the different breeds as follows: a multivariate normal distribution was assigned for the vectors of SNP effects: $[u'_{CH}, u'_{LM}, u'_{AA}, u'_{HO}, u'_{OT}]' \mid B \sim N(0,B \otimes I)$, where I is an identity matrix, and B is as in (Karaman *et al.*, 2021). Briefly, the diagonals are the breed-specific SNP variances and off-diagonals are covariances.

The PBLUP analysis was performed in DMU (Madsen *et al.*, 2014). The SNP-BLUP and BOA analyses were written and carried out in Julia software (Bezanson *et al.*, 2017).

Validation. The validation animals were selected from the whole population, using paternal half-sib families in which more than half of the animals were born after 2018. For SNP effects estimation we used a subset of animals in CG1 with >10 animals (28,138 animals) and we removed animals in the validation that were included in this subset. We kept 30,234 animals for validation, of which 24,805 were crossbred and 5,618 were purebred. Estimated breeding values were calculated as the summation of the breeding value and breed effects × breed proportions for each animal. The prediction accuracies were calculated as the correlation between adjusted phenotype (y*) and DGV divided by the square root of the heritability. We obtained a bootstrap sample to obtain 10,000 samples that were used to calculate accuracies, standard errors and to make the comparisons between the models with a paired t-test.

Results

Figure 1 shows the prediction accuracies obtained with PBLUP, SNP-BLUP and BOA.

Based on the validation procedure, gains in prediction accuracy with SNP-BLUP over PBLUP were in 72 and 38% for crossbred and purebred animals, respectively, and gains in prediction accuracy with BOA over PBLUP were 82 and 42% for crossbred and purebred animals, respectively. Regarding SNP-BLUP and BOA, there was no significant improvement in accuracy of purebred animals, but improvements of 6% for crossbred animals. Additionally, posterior distribution of B from BOA were used to calculate the correlation of SNP effects among the breeds. Correlations ranged from 0.45 (HO – LM) to 0.89 (HO – OT).

Discussion

The increases in accuracies when including genomic data were observed for both crossbred and purebred animals. Further improvements were obtained when using BOA. In general, the correlations between SNP effects of the OT group and the four main breeds were higher than between the main breeds (results not given). The estimates of high correlations between the SNP effects of the breeds may occur for different reasons: (1) there were five breeds combined in the OT group (beef and dairy breeds) which may lead to problems in assignments of alleles; (2) unassigned alleles were included in the OT group; (3) the imputation of genotypes was carried out jointly in a multi-breed setting for the entire population which might lead to errors in genotypes, and therefore in predictions using BOA. It has been shown that errors in assignments

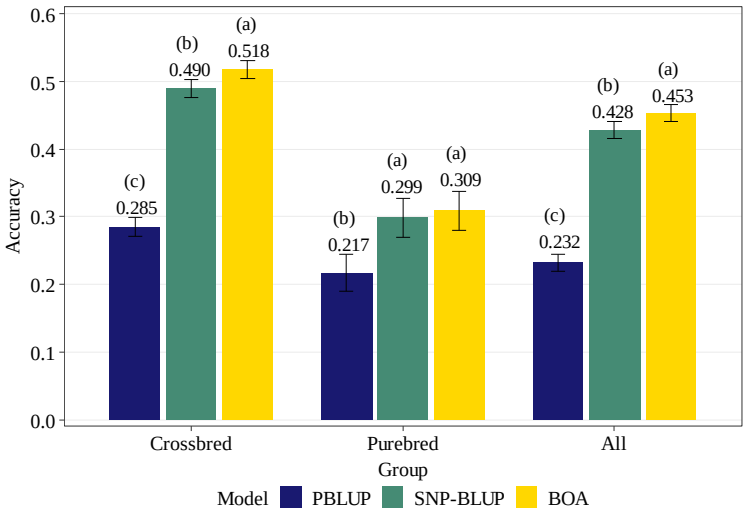

Figure 1. Accuracies and standard errors for validation animals.

of alleles lead to an increase in the correlation of SNP effects between the breeds (Guillenea *et al.*, 2022). Even with correlations higher than expected, the BOA model outperformed PBLUP but more importantly, also out-performed the SNP-BLUP model for animals of the Irish cattle population. Similar results were reported in a simulation study comparing BOA with a model that combines the genomic information of the different breeds (Karaman *et al.*, 2021). The Irish beef cattle evaluation is a very large diverse population in which the vast majority of the animals are crossbred and due to the levels of older phenotypes most are non-genotyped. This implies that a model needs to be developed that can handle both situations. We are currently working on an extension of the BOA model to implement it in populations where some animals are non-genotyped, in a combination of the BOA model with a single-step SNPBLUP model (Liu *et al.*, 2014).

Abstract

Systematic crossbreeding strategies between dairy cattle breeds in dairy herds are becoming more and more attractive to farmers, and this leads to a request for genomically enhanced breeding values for crossbred females in the dairy herds. Accurate genomic prediction of crossbred animals can be achieved if the genotypic and phenotypic data of the breeds involved in the crossbreeding are available to form reference populations, to estimate marker effects. However, sharing genotype and phenotype data between breed populations may be an issue due to privacy and competition. This study investigated genomic prediction of two-breed and three-breed rotational crossbred dairy cattle using summary statistics and a breed-origin of alleles model. The results indicate that the approach can yield almost as high prediction accuracies as having full information from the pure breeds.

Introduction

Crossbreeding between dairy cattle breeds and using genomic testing to predict genomically enhanced breeding values (GEBVs) on future replacement heifers in dairy herds are becoming more attractive to farmers (Magne and Quenon, 2021; Thomasen *et al.*, 2020), and this leads to a stronger request from dairy farmers for predicting GEBVs for crossbred dairy cattle (Clasen *et al.*, 2021).

Previous studies have shown that combining genotype and phenotype data from multiple breeds and crossbreds in a joint reference population can yield higher prediction accuracies for crossbred animals than prediction based on single breed or crossbred reference populations (e.g. Vandenplas *et al.*, 2018). Assuming homogeneous SNP effects across breeds and crossbreds may, in a multi-breed prediction model, not be the best approach if the structure of linkage disequilibrium (LD) and effects of quantitative trait loci (QTL) differs between the crossbred animals and their purebred ancestors (Vandenplas *et al.*, 2016). Instead, assuming heterogeneous SNP effects by tracing each allele back to its breed-origin (BOA) may potentially yield higher genomic prediction accuracies for crossbred animals (Karaman *et al.*, 2021).

Sharing genotype and phenotype data between breeding organisations or foreign countries is difficult due to privacy restrictions and competition (Tenopir *et al.*, 2011). This issue makes genomic prediction for crossbred animals less accurate if the prediction relies on data from reference breeds outside the organisation, that cannot be obtained. A possible solution is to perform genomic prediction based on a meta-analysis of summary statistics including predicted allele substitution effects of single nucleotide polymorphism (SNP) markers and their prediction error (co)variances (Vandenplas *et al.*, 2018). Such an approach is widely used in human genetics (e.g. Maier *et al.*, 2018).

The aim of this study was to investigate the efficiency of using summary statistics as alternative to having full data from purebreds for genomic prediction in two- and three-breed rotational crossbreeding systems using a BOA model.

Materials & methods

Simulated populations. Three base breed populations of 1,050 Danish Holstein (HOL), 1,050 Red Dairy Cattle (RDC), and 220 Danish Jersey (JER) were simulated based on real genotype data (Karaman *et al.*, 2021). Only the first five first chromosomes (12,664 SNPs) were used in the simulation to reduce the computational demand. Among them, 500 SNPs were randomly chosen as QTL. Twelve generations were simulated by randomly mating 1000 females to 50 males within the HOL and RDC population in each generation. Correspondingly in the JER population, 200 females were randomly mated to 20 males. The population sizes and gender distributions were kept constant in each generation. Additionally, two crossbred populations were simulated based on the purebred populations. A three-breed rotational crossbreeding system was used to produce a crossbred population consisting all three purebreds (MIX) by initially mating HOL females to JER males in the first generation, and then alternating between mating crossbred females to RDC, HOL, and JER males. A two-breed rotational crossbreeding system was used to produce a population consisting of crossbred animals between JER and HOL (JXH) starting by mating HOL females to JER males in the first generation, and then alternating between mating crossbred females to HOL and JER sires. Both crossbred populations were simulated for 12 generations resulting in 1,050 animals per generation and all animals being sired by a HOL male in the last generation. Thus, the average genomic breed proportions in generation 12 were 57.3% HOL, 28.2% RDC, and 14.5% JER for the MIX population, and 66.7% HOL and 33.3% JER for the JXH population.

Each breed population had breed-specific allele substitution at the 500 QTL. Computed from the genetic variances and co-variances in the base populations, the genetic correlations between the breeds were 0.87 between HOL and RDC, 0.62 between HOL and JER, and 0.68 between RDC and JER. Heritabilities of the simulated trait were around 0.4 for the three breeds.

The reference populations consisted of animals from generations 9, 10, and 11. Joining all pure breeds and crossbred populations in a combined reference gave a total of 13,260 animals. The average genomic breed proportion of the animals in the combined reference population were 42.2% HOL, 31.6% RDC, and 26.1% JER. The animals in the test populations were all from generation 12.

Breed-origin-of-alleles model. The SNP effects were estimated for each breed as follows:

$$y = 1\mu + Xb + M_1\beta_{HOL} + M_2\beta_{RDC} + M_3\beta_{JER} + e \quad (1)$$

where y is the vector of phenotypes, 1 is a vector of 1s, μ is the overall mean, X is the matrix of (centred) estimated genomic breed proportions computed from genomic data, b is the vectors of fixed breed effects, and M_1, M_2, and M_3 are the column-centred matrices of breed-specific allele content of SNPs for HOL, RDC, and JER, respectively, βs are vectors of SNP effects for HOL, RDC, and JER, respectively, and e is a vector of residuals. We used a Bayesian approach to estimate the dispersion and location parameters and assigned a normal distribution prior to the vectors of SNP effects for each breed: $\beta_i|\sigma^2_{\beta i} \sim N(0, I\sigma^2_{\beta i})$, where *i* stands for the breeds HOL, RDC and JER. Residuals were *a priori* assumed to follow a normal distribution, $e \sim N(0,R)$ where R was a diagonal matrix of residual variances.

The GEBVs were predicted using SNP effects estimated from the combined reference population. In predicting GEBVs for crossbred animals, alleles of each SNP were traced back to their (known) breed of origin, and the SNP effect from the respective breeds. The GEBVs for pure breeds were predicted by multiplying SNP effects with the corresponding allele counts. Additionally, for prediction of GEBVs in crossbred animals, the fixed breed effects were multiplied by genomic breed proportions. Prediction accuracies were calculated as the correlation between the simulated genetic value and the predicted GEBVs.

Summary statistics. If only summary statistics were available for a certain breed, the prior distribution assigned to the SNP effects of the breed was reformulated using the results from a separate analysis of that individual breed. The mean and variance of the prior distribution of the SNP effects was set to the estimated SNP effect and its posterior variance from the separate analysis. The number of animals and their mean phenotypes was used to update the prior for the fixed breed effects.

Scenarios. We investigated different combinations of information sources, including full genotype and phenotype data, only summary statistics, or no data available from the pure breed populations (HOL, JER, and RDC) using the BOA approach. The crossbred populations (MIX and JXH) always had phenotype and genotype information available. All of the analyses were carried out in scripts written in Julia and were replicated 25 times. The prediction accuracies of the different scenarios were compared by a paired t-test using a significance level of $P<0.05$ within test populations.

Results

Within all test populations, using summary statistics from the pure breeds yielded slightly (0.021-0.046) lower prediction accuracies compared with using full genotype and phenotype data, while having no information from the pure breeds yielded much (0.086-0.224) lower prediction accuracies as shown in Table 1. Replacing full data with summary statistics from JER had no or little effect on the prediction accuracies for any of the test populations except JER. When only summary statistics or no information was available from either JER or RDC reference populations or both, the prediction accuracies decreased more for the RDC test population than JER.

Discussion

Our results show that all breeds represented in a crossbreeding system should be included in the reference population to obtain higher prediction accuracies. In the situation when full genotype and phenotype data is not available from all or some of the breeds, using summary statistics can yield prediction accuracies almost as high as when full data is available. Furthermore, using summary statistics to run prediction models does not require a large amount of data, which makes it more practically feasible.

Table 1. Prediction accuracies for Danish Holstein (HOL), Danish Jersey (JER), Swedish Red (RDC), three-breed rotational crosses (MIX) and JER × HOL rotational crosses (JXH) in different scenarios including full phenotype and genotype data (F), summary statistics (S), or no information (-).[1]

[1] Accuracies within test population without common subscripts differ significantly ($P<0.05$).

The sizes of the crossbred reference populations in this study were as large as for HOL and RDC, which is probably optimistic since number of (genotyped) crossbred dairy cattle is small in most dairy cattle populations. Using summary statistics from JER (which had a smaller population size) had little or no effect on the prediction accuracies, compared with having full information from JER, because there were relatively more animals involved with JER genes in the crossbred reference populations than in the purebred JER reference. Furthermore, all animals in the MIX and JXH test populations were HOL-sired, making the information from the RDC and JER reference populations less important than HOL in predicting GEBVs for the crossbred animals. Assuming smaller crossbred reference populations with various breed combinations in the real-life situation, information from purebreds will be more important than indicated in this study.

A main reason for crossbreeding in dairy cattle is utilizing the benefits of heterosis effects (Sørensen *et al.,* 2008), which were ignored in the simulation of phenotypes and estimation of GEBVs in this study. Heterosis is caused by non-additive effects: dominance effects between alleles at the same loci and epistatic effects between alleles at different loci. Ignoring the non-additive effects may cause some biasedness of the genomic prediction (Su *et al.,* 2012). Therefore, if the current model should be applied to routine genomic breeding evaluation, non-additive effects should be considered in the model.

343. Subsetted orthogonal data augmentation for fast parallel implementation of Bayesian models for whole-genome analyses

L.H. Chen and G.S. Plastow*

Department of Agricultural, Food and Nutritional Science, Livestock Gentec, University of Alberta, Edmonton, AB T6G 2H1, Canada; plastow@ualberta.ca

Abstract

A novel subsetted orthogonal data augmentation (SODA) approach was proposed for fast parallel implementation of Bayesian linear regression models for whole-genome analyses. Performance was evaluated using a simulated data set from the QTL-MAS XIV workshop. Computing speed, convergence, and genomic prediction accuracy and bias were compared to those using a regular Gibbs sampling algorithm and the original orthogonal data augmentation (ODA). Results showed that the SODA approach required less time and number of operations to compute per CPU than the ODA and regular algorithms. The SODA algorithm converged faster and had larger effective sample size than the ODA algorithm. Genomic prediction accuracy and bias were similar among different approaches. The proposed SODA approach will be especially useful when the number of markers is very high, where a regular algorithm or the ODA approach are infeasible or takes too long to complete.

Introduction

Bayesian linear regression models have been widely used for whole-genome analyses including genome-wide association studies and genomic prediction (Mewwissen *et al.*, 2001; Gianola, 2013). Estimates for the unknown model parameters are usually obtained via a specially designed MCMC sampling approach, such as a Gibbs sampler. The MCMC sampling procedure is computationally demanding and cannot be easily parallelized to take advantage of modern computers with multiple CPUs. Ghosh and Clyde (2011) proposed an orthogonal data augmentation (ODA) approach without changing the posterior distributions of the model parameters of interest. Zhao *et al.* (2020) adapted the ODA approach to implement a parallel sampling algorithm for genomic prediction using Bayesian linear regression models. Although computing time was shortened by several magnitudes with HPC of hundreds of CPUs, the ODA approach suffered from slow convergence issues. The ODA approach requires computation of a matrix product between the transposed and original design matrix, and Cholesky decomposition of the resulting matrix. It may become infeasible when a very high-density marker panel or whole-genome sequence is used.

One solution is to augment subsets of the design matrix instead of the full matrix. Such an approach has the potential to reduce computing time and improve convergence due to smaller number of augmented phenotypes. It is also feasible when using very high density or whole-genome sequence markers. The objective of this study was to evaluate the performance of a novel subsetted orthogonal data augmentation (SODA) approach and compare it with the ODA approach as well as the regular Gibbs sampling approach for genomic prediction using Bayesian linear regression models.

Materials & methods

Bayesian linear regression models. For simplicity and without loss of generality, the Bayesian linear regression model with a general mean, additive marker effects, and a residual term can be written as:

$$y = 1\mu + Xa + e \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_343, © L.H. Chen and G.S. Plastow 2022

where y is a vector of phenotypes for n individuals, μ is the general mean, X is an n × p matrix of marker genotype covariates (coded as 0,1,2), a is a vector of additive marker effects, and e is a vector of residuals. Elements of X are standardized as $\left(x_{ij} - 2p_j\right)/\sqrt{2p_j(1-p_j)}$, where p_j is the allele frequency at marker j. μ follows a flat prior distribution; $e|\sigma_e^2 \sim N(0, \sigma_e^2)$ with $\sigma_e^2|v_e, s_e^2 \sim \chi^{-1}(v_e, s_e^2)$. Prior distribution for marker effects varies with different Bayesian Alphabet models (Gianola, 2013). For a BayesR model as proposed by Erbe *et al.* (2012), $a_j|\pi, \sigma_a^2 \sim \pi_1\delta_0 + \pi_2 N(0, \lambda_2\sigma_a^2) + \pi_3 N(0, \lambda_3\sigma_a^2) + \pi_4 N(0, \lambda_4\sigma_a^2)$, where π is the probability following a Dirichlet distribution:

$$\frac{1}{Beta(\alpha)}\prod {\pi_k}^{\alpha_k - 1},$$

δ_0 is a point mass at zero, σ_a^2 is a common variance, and λ_k is a scaling factor taking values 0.0001, 0.001 or 0.01 as suggested by the author. σ_a^2 can be estimated from data by giving it a prior distribution, $\sigma_a^2|v_a, s_a^2 \sim \chi^{-1}(v_a, s_a^2)$. To facilitate computation, an indicator variable I_j is introduced to indicate which mixture distribution a_j is currently sampled from. I_j follows a categorical distribution $\prod \pi_k^{[I_j=k]}$, where $[I_j = k]$ evaluates to 1 if $I_j = k$, and 0 otherwise.

Regular Gibbs sampling algorithm. A regular Gibbs sampling algorithm can be used to construct a MCMC chain by sampling from the full conditional posterior distributions of the unknown model parameters. The most computationally expensive part of the Gibbs sampling algorithm is for the sampling of marker effects, which must be sampled one after another. As described by Erbe et. al. (2012), sampling of marker effect a_j can be proceeded by first sampling I_j from a categorical distribution with $p(I_j = k|\Theta_{-j}, y)$, followed by sampling a_j from $f(a_j|y, \Theta_{-j}, I_j)$, where Θ_{-j} denotes all parameters except a_j and I_j.

$$p(I_j = k|\Theta_{-j}, y) = \frac{\pi_k f(y|\Theta_{-j}, I_j = k)}{\sum \pi_k f(y|\Theta_{-j}, I_j = k)} \text{ with}$$

$$f(y|\Theta_{-j}, I_j) \propto [I_j = 1] + [I_j = k, k \neq 1](x'_j x_j \frac{\lambda_k\sigma_a^2}{\sigma_e^2} + 1)^{-\frac{1}{2}} exp\left\{\frac{\left(x'_j y^*\right)^2}{2\sigma_e^2\left(x'_j x_j + \frac{\sigma_e^2}{\lambda_k\sigma_a^2}\right)}\right\} \quad (2)$$

where y^* is the vector of phenotype corrected for all effects except effect of marker j.

$$f(a_j|y, \Theta_{-j}, I_j) = [I_j = 1]\delta_0 + [I_j = k, k \neq 1]N\left(\frac{x'_j y^*}{x'_j x_j + \sigma_e^2/\lambda_k\sigma_a^2}, \frac{\sigma_e^2}{x'_j x_j + \sigma_e^2/\lambda_k\sigma_a^2}\right) \quad (3)$$

Orthogonal data augmentation (ODA). Following Ghosh and Clyde (2011) and Zhao *et al.* (2020), the observed design matrix in (1) including the intercept, W_o, can be augmented with a $(p + 1) \times (p + 1)$ matrix W_a, so that:

$$[W_o' \quad W_a'] \begin{bmatrix} W_o \\ W_a \end{bmatrix} = D,$$

where D is a diagonal matrix. It was shown that by choosing the largest eigenvalue of $W_o'W_o$ as the diagonals of D, a real matrix, W_a, was guaranteed to exist. W_a can be obtained via singular value decomposition or Cholesky decomposition of $dI - W_o'W_o$. Zhao *et al.* (2020) applied the ODA approach to implement a parallel Gibbs sampling algorithm for genomic prediction. With orthogonal data augmentation, Equation 2 and 3 become:

$$f(y|\Theta_{-j}, I_j) \propto [I_j = 1] + [I_j = k, k \neq 1](\frac{d\lambda_k\sigma_a^2}{\sigma_e^2} + 1)^{-\frac{1}{2}} exp\left\{\frac{\left(x'_j y\right)^2}{2\sigma_e^2\left(d + \frac{\sigma_e^2}{\lambda_k\sigma_a^2}\right)}\right\} \quad (4)$$

$$f(a_j|y, \Theta_{-j}, I_j) = [I_j = 1]\delta_0 + [I_j = k, k \neq 1]N\left(\frac{x'_j y}{d + \sigma_e^2/\lambda_k\sigma_a^2}, \frac{\sigma_e^2}{d + \sigma_e^2/\lambda_k\sigma_a^2}\right) \quad (5)$$

Computation for (4) and (5) can be conducted simultaneously for all markers, and therefore, can be implemented in parallel on a modern computer with multiple CPUs.

Subsetted orthogonal data augmentation (SODA). The original genotype covariate matrix can be arbitrarily subsetted into equal or similar sized blocks, X_{o1}, X_{o2}, …, X_{om}. Each block X_{ot} can be augmented with an augmenting matrix X_{at} so that:

$$[X'_{ot} \quad X'_{at}] \begin{bmatrix} X_{ot} \\ X_{at} \end{bmatrix} = D_t,$$

where D_t is a diagonal matrix. With subsetted orthogonal data augmentation, Equation 2 and 3 become:

$$f(y|\Theta_{-j}, I_j) \propto [I_j = 1] + [I_j = k, k \neq 1]\left(\frac{d_j}{\sigma_e^2/\lambda_k\sigma_a^2} + 1\right)^{-\frac{1}{2}} exp\left\{\frac{\left(x_j' y^*\right)^2}{2\sigma_e^2\left(d_j+\sigma_e^2/\lambda_k\sigma_a^2\right)}\right\} \quad (6)$$

$$f(a_j|y, \Theta_{-j}, I_j) = [I_j = 1]\delta_0 + [I_j = k, k \neq 1]N\left(\frac{x_j' y^*}{d_j+\sigma_e^2/\lambda_k\sigma_a^2}, \frac{\sigma_e^2}{d_j+\sigma_e^2/\lambda_k\sigma_a^2}\right) \quad (7)$$

Computation for (6) and (7) can be done simultaneously for markers within the same block.

Data analysis. Simulated data from the 14th QTL-MAS workshop was used to evaluate performance of the three algorithms. Details of the data set was described by Szydlowski and Paczynska (2011). Briefly, 2,326 individuals with phenotypes and genotypes on 10,031 markers were used as training population, and 900 individuals with genotypes only were used for validation.

The number of blocks in the SODA approach ranged from 2 to 150. Number of computational operations, computing time, convergence of the MCMC chain, and accuracy and bias of genomic prediction were compared. A program was written in Fortran 2018 with OpenMP. The program was run on a dedicated HPC node with 24 Intel Platinum 8160F Skylake CPU cores @ 2.1Ghz and 187G RAM. For each scenario, the Gibbs sampling steps were run for a MCMC chain length of 50,000. Computing time was recorded as wall clock time from start to the end of running the program. Convergence of the MCMC chain was diagnosed using Geweke diagnostic in the R CODA package. This was done by dividing the first half of the chain into multiple bins and testing the equality of sample means from each bin and the last half of the chain. Lagged autocorrelations were also computed to evaluate the effective sample size of the MCMC chain. Accuracy of genomic prediction was calculated as correlation between genomic estimated breeding values and the true genetic values for the validation population. Bias of genomic prediction was evaluated by regressing true genetic value on genomic estimated breeding value for the validation population. The computer program used in this study can be downloaded for research use from https://github.com/liuhong-chen/SODABayes.

Results & discussion

The number of computational operations per CPU as a percentage of that required by the regular Gibbs sampling algorithm were determined (Figure 1). The ODA algorithm requires around 20% of the operations per CPU of the regular algorithm with 24 CPUs, while the number of operations for the SODA algorithm decreases with increasing number of blocks. The decreased number of operations for the SODA algorithm was due to smaller number of augmented phenotypes. Computing time decreased from 1,150 s for the regular algorithm to 478 s for the ODA algorithm and to a minimum of 168 s for the SODA algorithm with 16 blocks (Figure 1). The decreased computing time was due to reduced number of operations. Computing time increases for the SODA algorithm after reaching the bottom at around 16 blocks. The increase of computing time was due to increased overhead cost of the multi-threaded OpenMP program. The results suggest that the SODA algorithm with the studied data set can be 6.8 and 2.8 times faster compared to the regular algorithm and the ODA algorithm, respectively. To achieve an optimum computing performance,

the number of blocks needs to be chosen to balance the computational operations and overhead costs. The relative overhead cost is expected to decrease with increasing number of phenotypic observations and the number of marker loci as the threads will have more computational work.

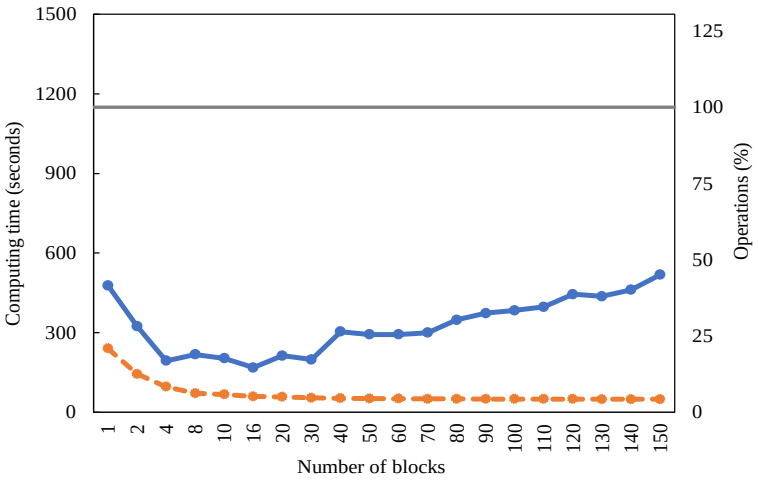

Figure 1. Comparison of number of operations per CPU (orange dotted line) and computing time (blue solid line). The flat grey line indicates number of operations and computing time for the regular Gibbs sampling algorithm.

Geweke convergence diagnostic results indicated that the regular Gibbs sampling algorithm took about 2,000 samples to converge, while the ODA and SODA with 16 blocks required around 24,000 and 12,000 samples, respectively, to converge. Lagged autocorrelation decayed fastest for the regular algorithm, and slowest for the ODA algorithm. Autocorrelation for SODA algorithm with 16 blocks was similar to that of the regular algorithm.

Accuracy and bias of the genomic estimated breeding values were similar for the regular, ODA, and SODA algorithms.

Conclusions

A subsetted orthogonal data augmentation approach was proposed for fast parallel implementation of Bayesian linear regression models. The proposed approach is superior to the original augmentation approach in terms of computing speed and convergence and should be feasible even when a very high-density marker panel or sequence is used.

Abstract

A stochastic simulation package of breeding programs was developed in Julia to evaluate gene editing assisted selections (GEAS). Its generic design makes it to be a general-purpose breeding program simulator. The package can take real or simulated haplotypes of founder populations. It then drops the genotypes through arbitrary multi-trait breeding schemes. Traits can be continuous and binary. The number of genes and the distribution of their effects must be specified. Breeding value estimates (EBV) are obtained from SNP-BLUP by default. Known QTL may be emphasized by treating them as fixed effects in the EBV. GEAS can also incorporate other EBV estimation methods. Gene-editing of known QTL is an option for the breeding programs. Calculations are parallelized wherever possible for computational speed. Early simulation results show significantly genetic gain improvement by applying gene-editing in breeding programs. GEAS is easily maintained and extended, thanks to Julia features.

Introduction

Gene editing technology (e.g. Wargelius A., 2019) is becoming increasingly mature and accurate. It is a powerful tool to produce more productive, functional, and disease resistant farm animals. Increased disease resistance can greatly improve animal welfare. Whilst its technology and legislation are still under development, it is important to perform computer simulation studies to explore optimal strategies to make use of gene-editing.

Softwares that simulate gene-editing schemes, e.g. Jenko *et al.*, 2016, Gaynor *et al.*, 2020 are usually R based, which limits speed and ability to deal with large datasets. Moreover, simulation programs that can easily setup various scenarios and easily maintained and extended are needed, to deal with the many ways to apply gene editing techniques in breeding. Contrary to some other gene editing scenarios, we will assume here that embryos are edited instead of mature individuals.

The GEAS stochastic simulation package aims to evaluate a multitude of gene edit assisted selection programs. The application described below is adapted to fish breeding schemes, but the approach is general. The generic design made the package useful to evaluate conventional breeding schemes of sexually reproducing diploid organisms. The GEAS package, which is written in Julia (https://julialang.org), parallelizes calculations wherever possible. Traits may be continuous (e.g. a production trait) or binary (e.g. a disease resistance trait) in nature. The breeding population structure and gene makeups may be specified by users. Gene editing is applied to known genes. The interface of the package takes in a base population either from real data or a base population simulator. GEAS is easy to maintain and expand, thanks to Julia language features.

Materials & methods

GEAS was designed to evaluate gene editing assisted selection. It can, however, also simulate traditional (genomic selection) breeding schemes. A brief overview of the design and many features of the package is described below (Figure 1).

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_344, © X-J. Yu *et al.* 2022

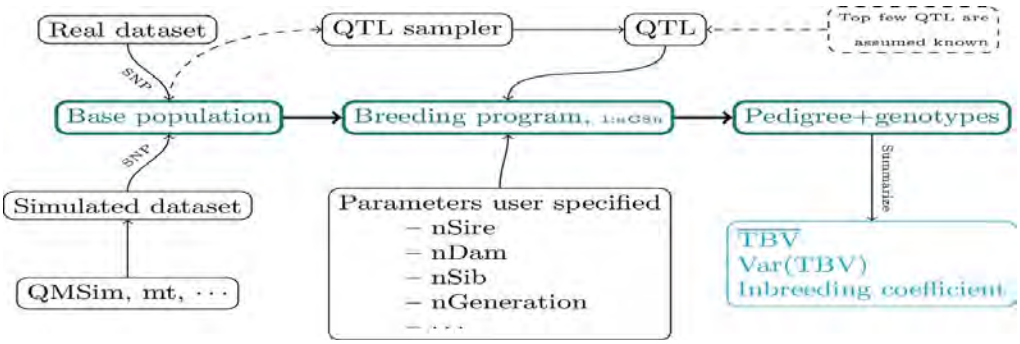

Figure 1. The design of the GEAS package.

The program starts from a founder population. QTL are sampled from the founder genotypes. The founder population genes flow then through a breeding program defined by a dictionary of parameters. The resulting pedigree and genotypes are stored for downstream evaluations.

Genotypes of a founder population can be obtained from real data. They can also come from a base population simulator. The program can automatically download and update base-population simulators such as QMSim, and MaCS. Other simulators can also be integrated into GEAS.

The number of crossovers that occur on a chromosome are sampled from a Poisson distribution with parameter the length of the chromosome in Morgan. It is by default 10^8 base pairs per Morgan. Offspring haplotypes are created in parallel over individuals. That is the number of individuals simultaneously generating equals the number of threads available to the program.

QTL are sampled from the available SNPs in the founder population. The number, and distribution of the QTL effects are specified by the users. QTL can be sampled independently for each trait. In this case, each trait can have different numbers of QTL with a different distribution. QTL can also be pleiotropic and have a multi-variate normal distribution. The QTL with the largest effects are recorded and are candidates for gene editing.

GEAS was designed primarily to mimic fish breeding schemes, with the potential to integrate gene-editing methods. Two traits are simulated by default. One of them is a continuous trait (e.g. production). The other one is a binary trait (e.g. disease resistance). The offspring in each generation may be split into two groups. Group I stays in the nucleus of the breeding program. Group II serves as test individuals (typically challenge tested for a disease). In case of the challenge test, the default survival rate is 50% to maximize the variance of the records. The genotypes of both groups, together with specified traits from group I and II, respectively, are recorded for genetic evaluation. More groups can be added together with a specification of their recorded traits.

SNP-BLUP is the default genomic breeding value (GEBV) prediction method. It uses single trait analyses and the genotypes of all generations. The model for the single trait analyses is:

$$y_{ij} = \mu + f_j + \sum_{k=1}^{n_{\mathrm{SNP}}} \mathrm{SNP}_{ijk} \cdot a_k + e_{ij}$$

That is, individual *i*'s phenotype in generation *j* is modeled by a generation effect f_j, sum of SNP genotypes (SNP_{ijk}) times their effects and a residual. The cyan part is the GEBV of this individual.

The SNP effects, $\widehat{a_k}$, estimated from the challenge group are used to calculate the GEBV of individuals in the production group. A combined index is then calculated for everyone in the production group using economic weights provided by the user. The individuals with top indices are selected as parents for the next generation. They are randomly mated.

For known QTL, users can choose whether to edit them in the breeding generations. The editing is one QTL a generation, in descending order of the alleles' absolute effect sizes. All the embryos/offspring born in the nucleus (group I) are assumed edited for the beneficial QTL allele with a default efficiency of 100%. A lower editing efficiency or fraction of edited offspring may also be specified.

As an alternative to editing, the known QTL may be emphasized in the SNP-BLUP breeding value estimation procedure. This is achieved by: (1) adding the known QTL to the SNP-set used for genetic evaluation; and (2) treating the known QTL as fixed effects instead of as random effects that are severely regressed back to 0. The latter is realized by not adding the λ term, i.e. the variance ratio of the error variance to the SNP variance, to the corresponding SNP's diagonal in the mixed model equations, which implies that the SNP is fitted as a fixed effect.

The GEAS package was written in the Julia language. It is easy to modify, maintain, and extend. This combined with its high computational speed makes the overall efficiency higher than e.g. that of C, or Fortran. Its speed is as fast as C, or Fortran implementations. The program also provides a web interface for end users to ease the design of breeding programs.

The software is freely available on https://github.com/xijiang/GEAS.jl. It is a standard Julia package which can be installed locally. Its documentation is also provided on the website.

Results of example simulations

In an example breeding scheme, three breeding strategies were compared using the same founder population. They are: (1) GEBV estimation with SNP-BLUP; (2) treat all known QTL as fixed effects; (3) edit known QTL (one in each generation). The QTL scenarios were: (1) small number of QTL, 500; and (2) large number OF QTL 5,000, which were combined with QTL effects distributed as either normal or Laplacian distribution. Each scenario had 30 repeats. In each generation, 100 sires and 200 dams were randomly mated to produce 40 sibs. 30 of them were challenged. The rest 10 were evaluated and selected for the next generation.

Figure 2 left-panel shows the results of 5,000 Laplacian QTL. Gene-editing gave the maximal TBV improvement. Traditional SNP-BLUP gave the least. Similar results were obtained with other scenarios. Figure 2 right-panel compared the genetic improvement with gene editing in four scenarios. It shows that the fewer QTL, the higher genetic improvement in the first 10 generations. Distributions with extreme QTL effects (Laplacian) showed more improvement for gene editing effects. A population with 5,000 Laplacian distributed QTL has similar traditional selection and gene editing effects as a population with 500 normally distributed QTL.

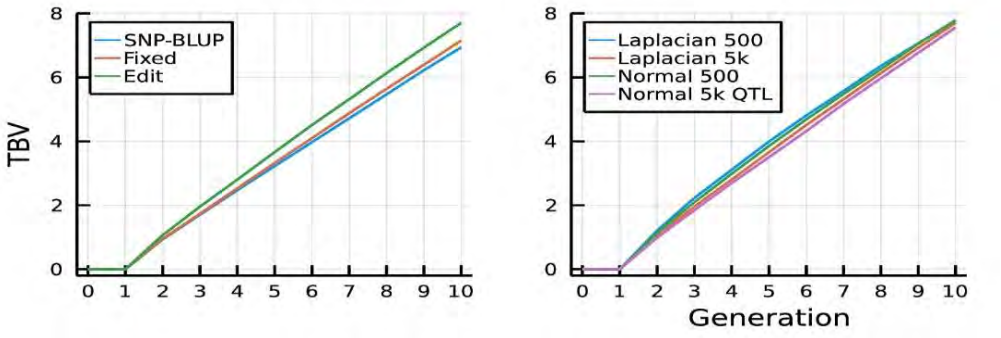

Figure 2. A comparison of different selection methods and genetic architectures.

Discussion

We have developed a new breeding program simulator. This package is fast, easy to maintain and extend. It also utilized many features of modern computer languages. More documentation and demonstrations can be found at https://github.com/xijiang/GEAS.jl.

A preliminary simulation study showed significantly enhanced breeding progress due to gene editing technology. Gene editing gave an extra genetic progress of about 8 to 14% over ordinary SNP-BLUP in our scenarios, even if only one QTL was modified per generation. Emphasizing known QTL also resulted in more genetic improvements of 2-3%. Gene-editing will require, however, precisely positioned causative mutations, which are therefore important.

The current version of GEAS provides many possibilities for alternative scenarios. In the future, we will simulate more scenarios of breeding related to gene editing with GEAS. Meanwhile, more functions will be integrated. Multi-allelic QTL may be a future option. The web interface will be more fledged for a better user experience. The breeding part will have more alternative breeding value estimation methods.

345. A database structural improvement for efficient trait variation curation in animal QTLdb and CorrDB

Z-L. Hu, C.A. Park and J.M. Reecy*

Department of Animal Science, Iowa State University, 2255 Kildee Hall, Ames, IA, USA; jreecy@iastate.edu

Abstract

In livestock genetics studies to improve production traits, the importance of accurately identifying and recording traits of interest cannot be overemphasized. However, it has been a challenge to consistently and unambiguously name and compare traits of interest that span time and geographic locations and are evaluated by different people. While the Animal Trait Ontology for Livestock, Clinical Measurement Ontology, Livestock Product Trait Ontology, and Vertebrate Trait Ontology, among others, provide good frameworks for using controlled vocabularies, building concept hierarchies, and defining relationships between terms, gaps still remain as to what level of granularity should be documented. This is important to efficiently use available resources for effective data curation. In the Animal QTLdb and CorrDB, we have introduced an approach to extend livestock trait ontologies for practical data curation that allows effective capture of trait variations while keeping complexities to a manageable level.

Introduction

The volume of genotype-to-phenotype data from livestock animal genomics studies has been increasing explosively over the past 20+ years, owing to continued progress in sequencing and genotyping technologies. For example, the cattle QTL and association data curated into the Animal QTLdb has increased 330-fold over the past 15 years (Figure 1). Trait ontology development using Vertebrate Trait Ontology (Park *et al.* 2013), Livestock Product Trait Ontology (Park *et al.*, 2021), and Clinical Measurement Ontology (Shimoyama *et al.*, 2012) has been an ongoing part of Animal QTLdb and CorrDB developments (Hu *et al.*, 2007, 2013, 2016, 2019). The increase in incoming data presents challenges for Animal QTLdb and CorrDB data curation, not only due to an increase in workload, but also due to a need to accommodate more diverse data formats, methods of data detection and analysis, and degree of trait data granularity in each new experiment. For example, for the most common trait, Average Daily Gain (ADG), many use cases have been identified in different species, such as in cattle (ADG in cows, heifers, on test, pre-weaning, post-weaning), pigs (120-210d, 120-240d, 21-120d, 21-210d, 21-240d, 21-46d, 210-240d, 30-100kg, 46-120d, 46-210d, 46-240d, BirthTo30kg, pre-weaning, post-weaning), and sheep (3-6Mos, 6-12Mos, 6-9Mos, 9-12Mos, BirthTo3Mos, BirthTo6Mos, pre-weaning, WeaningTo6Mos, WeaningTo9Mos). Clearly, numerous additional variants are possible, depending on study criteria such as age (time), weight, and/or production management stage. The combined use of these factors can vastly increase the number of different ADG terms. Previously, we developed a scheme to accommodate 'sibling traits' (Götz *et al.*, 2012) modified from their base trait (e.g. ADG) in order for reported QTL/associations to have a proper trait name to link to (Hu *et al.*, 2019). This conceptual design was implemented in the QTLdb curator environment and it worked fine, except that the number of such sibling traits quickly exceeded what could be easily managed. The problem was more obvious when a curator needed to choose a trait from a daunting lengthy list of (sibling) traits. When it came to recording the sibling traits as part of a trait ontology hierarchy, concerns arose, such as continually growing trait lists, possibilities of sibling traits as children of base traits, etc. (Figure 2a). To solve these problems, we have envisioned a 'trait variant' structure for practical use in the Animal QTLdb and CorrDB curator tools environment. Here we report the initial steps toward this effort.

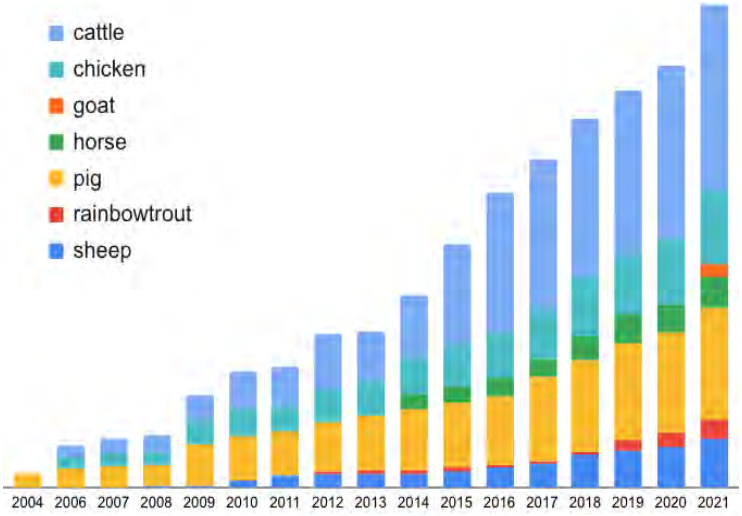

Figure 1. QTL/association data growth in the Animal QTLdb. Data counts were transformed for better visualization of scale. For the actual data counts please refer to https://www.animalgenome.org/QTLdb.

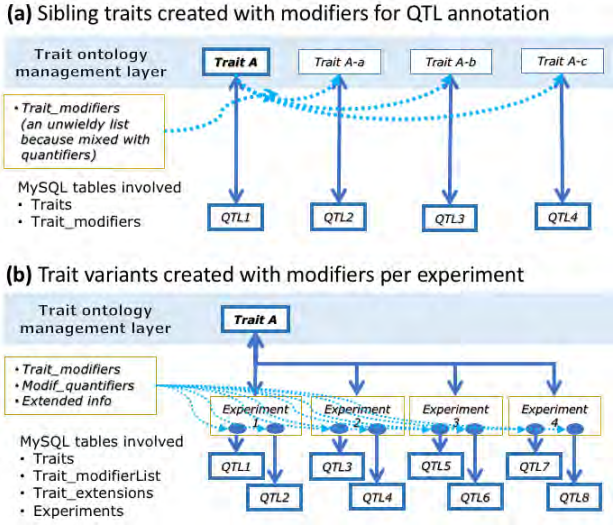

Figure 2. Conceptual data structure differences between 'sibling traits' ['modified'] as part of ontology extensions (a), and 'variant traits' [modified with extended info] created at the experiment level (b), and their use in QTL data annotations.

Results

Approach. A trait term may be 'modified' by another term, as a property, to produce an extension of the trait term as a new term. Examples of such extensions include muscle pH (pH) measured at 24hr or 48hr post-mortem, or in different muscles, such as biceps femoris or semimembranosus; milk yield (MY) measured daily or cumulatively up to 305 days of calf age, or MY compared between the first and second parities, etc. In these cases, if we call pH or MY the base trait, then base traits with additional properties

are modified traits. In order to bring the modifier terms to a manageable level in the trait data curation environment, we use additional terms to extend the context of a modifier. Examples of such terms can be number of days (time) in ADG measurements, parity number in MY measurements, etc. The extended names of traits incorporating the base trait in addition to the relevant modifiers are called trait variants (Figure 2b).

Implementation. By limiting modifiers to some major terms, we were able to create a relatively short list of modifiers (Analysis, Anatomy location, Environment, Herd, Instrument, Measurement, Parity, Pedigree, Stage, Time) for a pull-down menu in the curator tool (Figure 3). Each of the modifier terms has its own list of relational terms to further define its context (e.g. age, before, after, by, during, etc. for 'time'; above, anterior, at, below, dorsal, posterior, by, in, etc. for 'anatomy locations'; and so on). In the QTLdb data curation environment, multiple modifiers can be applied to a base trait. (An example with multiple modifiers is meat color lightness measured 24hr post-mortem on the semimembranosus using the CIELAB method.) This has helped to cover most, if not all, trait variants we have encountered so far. Under this management scheme, our goal is to use a set of terms over time for consistency. This implementation has improved ease of use for QTLdb/CorrDB curators by limiting the long list of sibling traits. Since we implemented the creation and management of trait variants at the experiment level (details entered once for each publication; Figure 3), it essentially moved the trait variant management out of the trait ontology term management realm (for the database as a whole; Figure 2b). The use of more MySQL tables in this implementation (Figure 2a versus Figure 2b) reflects our emphasis on the concept partitioning, compartmentalization, and relationship building, which directly result in a reduction in human effort while leaving the computer/database to handle the complexities.

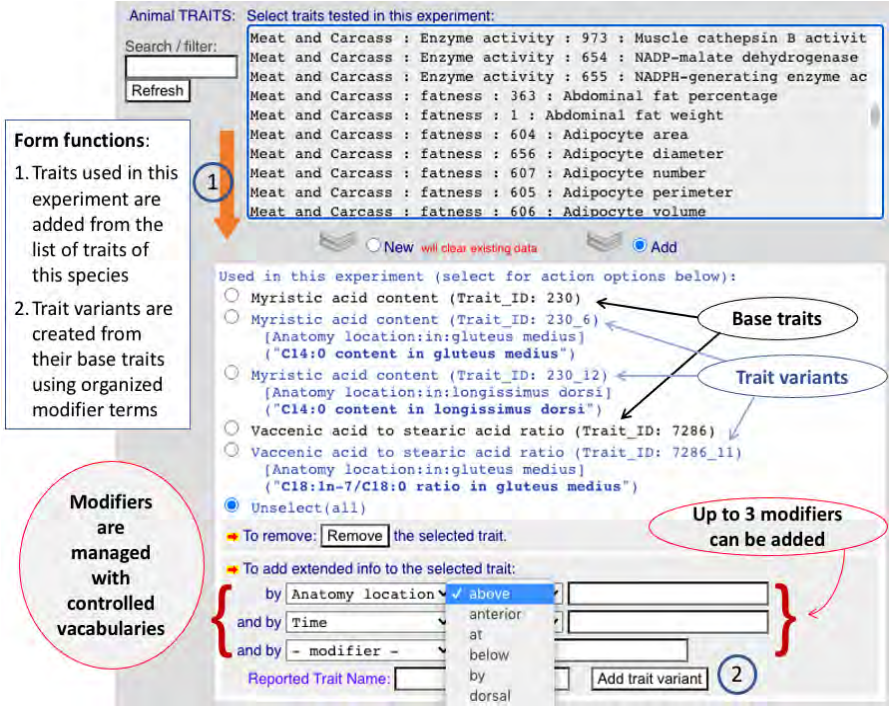

Figure 3. A web form from the implementation of the trait-variant concept showing how trait variants are created from their base traits using modifiers as controlled vocabularies.

Discussion

Our approach effectively helped reduce the lengthy list of 'modifiers' for practical use in the data curator environment, while increasing the trait term modifier system, which can be handled in the database backend once computer programs are developed. As such, this study provided a path for ontology developments by using proper concept partitioning approaches.

As with the development of trait ontologies, the trait variant system may also be subject to future developmental improvements. Because a trait term modifier system will be used well into the future and across species, its stability is important in order to ensure consistent and stable development down the road. For example, properly defining 'base traits' and 'modifiers' is important at the onset. For instance, 'MY' and '305-day MY' may be nearly interchangeable concepts, since 305-day MY is typically the default measurement standard in dairy production throughout the world. In situations like these, careful consideration is needed to weigh the advantages and disadvantages and in order to establish the most appropriate basic trait and its modifiers.

Because we implemented the creation of trait variants at the experiment level (Figure 3), curators must repeat the creation of a trait variant for each and every experiment in which it is used. This may necessitate future improvements regarding how trait variants created in one experiment may be reused in another experiment when traits are defined similarly in both experiments.

346. Efficient algorithms to identify duplicated genotypes in large datasets

M.H. Ferdosi[1*], S. Masoodi[2] and M. Khansefid[3]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]Computer Engineering Group, University of Payam Noor, Tehran, Iran; [3]Agriculture Victoria, AgriBio, Centre of AgriBioscience, 3083, Bundoora, Australia; mferdos3@une.edu.au

Abstract

In this paper, we introduced two novel algorithms to identify duplicated genotypes. The runtime of these algorithms was compared with the widely adopted Exhaustive Search algorithm using simulated data. We found that both new algorithms could significantly reduce the execution time. Further, the optimised Matrix Algebra Approach algorithm was faster than the Dis-Similarity lookup table and could improve the performance nearly 34 times compared to Exhaustive Search.

Introduction

Thousands of farm animals are routinely genotyped with Single Nucleotide Polymorphism (SNP) panels every month in Australia. These new genotypes are continuously added to the genomic datasets for use in genomic evaluation or parent identification. To ensure data integrity, efficient algorithms and programs are needed to assess the quality of the data in large genomic datasets. Checking for mislabelled and duplicated genotypes is the first quality control step when new genotypes are added to a dataset or combined with genomic datasets. Identifying and removing repeated genotypes is also critical before imputation and haplotype phasing. Previously developed algorithms often use fingerprinting methods to identify duplicate genotypes with an approximate approach (Jin *et al.*, 2017). In this paper, we proposed two efficient and deterministic algorithms to identify duplicated genotypes that could also handle missing and wrong genotypes.

Materials & methods

Simulated genotypes. Genotypes were simulated using QMSim V1.10 (Sargolzaei and Schenkel, 2009). Thirty chromosomes, each with 333 SNPs and a length of 100 centimorgans were simulated for 10 generations. Hence, in total 9,990 SNPs were simulated which was marginally more than Illumina BovineLD v2.0 BeadChip with 7,931 evenly spaced SNPs (recommended SNP-chip for cost-effective genotyping of cows in commercial herds). In each generation, 20 males were mated with 400 females. The genotypes across all generations (8,000 individuals) were used in this study. The genotypes of 16 individuals (every 500th animal) were duplicated. In the next step, two percent genotyping error and missing SNPs were added to the genotypes at random using R (R Core Team, 2021). The genotypes were stored in an integer matrix in which each element was 0, 1, 2 or 5, representing *aa*, *ab*, *bb* or a missing genotype, respectively.

We compared four methods for identification of duplicated genotypes.

Exhaustive search (ES). In this method three nested loops were used to check every pair of individuals. The algorithm stopped the computation, and the two individuals were considered different when the error threshold (10 percent) between the genotypes was reached. We considered this algorithm as the base method to identify duplicated genotypes.

Matrix algebra approach (MAA). This method is an extension and modification of the previously described method to identify opposing homozygotes by Ferdosi and Boerner (2014). Suppose M is an integer matrix of 0, 1, 2 and 5, for *aa*, *ab*, *bb* and missing genotypes, respectively. The rows contain the genotypes for the individuals and the columns are associated with the markers. Therefore, $M_{n\times m}$ is the matrix of genotypes, where *n* is the number of individuals and *m* is the number of markers. In the first step, a Boolean matrix for each genotype class (i.e. 0, 1, 2 and 5) should be constructed. For example, for *aa* (i.e. 0) genotypes, we need a matrix (Z matrix in Equation 1) with 1's and 0's; 1's for the presence of *aa* and 0's otherwise.

$$\begin{aligned}\mathbf{R} &= 1-(\mathbf{M}/5)\\ \mathbf{Z} &= -((\mathbf{M}-2\mathbf{J})/2)\circ\mathbf{R}\\ \mathbf{O} &= (\mathbf{J}-(\mathbf{M}-\mathbf{J})\circ(\mathbf{M}-\mathbf{J}))\circ\mathbf{R}\\ \mathbf{T} &= (\mathbf{M}/\mathbf{2})\circ\mathbf{R}\\ \mathbf{S} &= \mathbf{Z}\mathbf{Z}^{\mathrm{T}}+\mathbf{O}\mathbf{O}^{\mathrm{T}}+\mathbf{T}\mathbf{T}^{\mathrm{T}}\end{aligned} \quad (1)$$

where ∘ is the Hadamard product; R is a Boolean matrix in which each element is 0 or 1 corresponding to a missing or non-missing genotype, respectively. Z, O and T are incidence matrices containing 0's and 1's for presence of *aa* (i.e. 0), *ab* (i.e. 1) and *bb* (i.e. 2) genotypes in the M matrix, respectively. J is the matrix of ones and S is the similarity matrix that shows the number of common SNPs between two individuals. Individuals with high level of similarity (>90% of genotypes) were considered as duplicated samples. The key point for optimisation of the MAA algorithm is that Z, O and T matrices are Boolean and their cross products is symmetric. Finally, the $1-\left(\frac{\mathbf{S}}{\mathbf{R}\mathbf{R}^{\mathrm{T}}}\right)$ matrix shows the proportions of SNPs varying between individuals.

Dis-similarity lookup table (DSLT). Firstly, a Dis-Similarity Lookup Table (L) was calculated. This table of dimensions 256 × 256 consists on each axis all the combinations of four SNPs (0000, 0001, 0002, 0005, 0010, …, 5555) and the values stored are the numbers of elements different between the four combinations of SNPs (0, 1, 2, 5). For example, the dissimilarity between 0000 and 0012 is 2. The error per SNP was calculated by dividing one by the total number of SNPs, such that when accumulated across all SNPs the maximum value is one. For example, the table value when the marker matrix contains 20 SNPs between 00 and 12 is 0.05. For computational simplicity, the marker matrix was packed, P, such that each four adjacent SNPs for an animal were combined into a single number between 1 and 256. The proportion of dissimilarity between two genotypes was then calculated as

$$Mismatch_{i,j} = \sum_{n=1}^{n=N\vee m>T} \mathbf{L}\left(\mathbf{P}_{i,n},\mathbf{P}_{j,n}\right) \quad (2)$$

where *T* is the threshold for the number of mismatching genotypes, *N* is total number of segments and *m* is the number of mismatches up to the n^{th} segment. Finally, it is possible to exit this summation early if mismatch is greater than some threshold *T* (10% of segments).

Matrix algebra approach optimised (MAAO). This approach optimised the MAA algorithm further by firstly checking the 1/5 of the markers to identify the individuals which were different in at least 10% of total number markers (i.e. unduplicated genotypes). Subsequently, for the potentially duplicated individuals, all markers were checked to confirm the similarity between genotypes was greater than 90%. Hence, the algorithm did not assess all markers if the number of dissimilar markers was above the threshold in the subset of markers.

All algorithms were implemented in C++ and parallelised with OpenMP Version 5 (OpenMP Architecture Review Board, 2018).

Comparison of algorithms. The speed of the algorithms was compared using the simulated genotypes. The runtime of the different methods was measured for 500, 1000, 1,500, …, and 8,000 individuals. The codes were compiled with GNU Compiler Collection version 11 and tested on a Linux system with 64 GB of random-access memory (DDR4 2400) and Intel Central Processing Unit (CPU; Intel Core™ i7-7700K Processor, 4 cores × 4.2 GHz).

Results & discussion

Figure 1 shows the logarithm of elapsed time to identify duplicated genotypes. Both MAA and DMS algorithms were faster than the ES method, especially when the genotypes of 8,000 individuals were checked for duplicates. DMS was around 14 times, MAA was around 10 times and OMAA was around 34 times faster than ES method (all single thread). The MAA and DMS could extract information from the raw genotypes, allowing less computation during pairwise comparison. This optimisation was more obvious in DMS algorithm. Multi-threading with quad-core CPU has similar effects on MAA and DMS algorithms and increased their performances nearly 3.8 times but increased the ES method's performance almost 4.8 times because the ES method did not require any initial optimisations and could benefit from vectorisation more effectively.

Conclusions

In this article, we presented two novel deterministic algorithms for identification of duplicated genotypes. The performance of these methods can be improved further by identifying the duplicated genotypes with an approximate approach. We reported preliminary results in this paper, and further study is required to compare these algorithms to identify duplicated genotypes with the previously developed algorithms such as 'Genetic Relationship and Fingerprinting' as well (Jin *et al.*, 2017).

Abstract

Measuring recombination rate and identifying hotspots requires reliable crossover detection, which is dependent on accurate phasing and genotyping. Given the low number of crossover events that occur at meiosis even low levels of genotyping and phasing errors can frustrate detection. We outline a pipeline for phasing and crossover detection and evaluate the performance across simulated populations, which contain from 0 to 9% genotyping errors. We present a novel algorithm for genotype correction in pedigreed populations, genoFix, which combines a Bayesian network estimation of Mendelian errors with an empirical LD approach. The algorithm typically achieved a precision of >90% and recall of >80% at 1% error for a chicken population with broiler-type haplotype diversity and was still effective even at atypically high rates of diversity, using populations simulated from randomized founders. Correction of genotyping errors improved both phasing accuracy and crossover detection.

Introduction

Genotyping errors (GEs) lead to downstream errors in phasing and crossover detection. Existing approaches like PedCheck can predict single Mendelian errors using likelihood odds ratios (O'Connell and Weeks, 1998) which can be masked or corrected. Bayesian Network models (BNs) are an attractive approach to modelling the Mendelian probability of genotype inheritance and SoftCSP (Sanchez *et al.*, 2007) describe a weighted constraint networks approach to the detection of GEs and their correction with BNs. GEs can also be identified and corrected based on linkage disequilibrium (LD) probabilities (Wang *et al.*, 2019), which could be a complementary approach to the Mendelian inheritance approach. We present the genoFix algorithm which combines both these approaches. We demonstrate that the subsequent reduction in GEs improved the accuracy of phasing and crossover detection.

Methods

There are four key stages in the workflow (Figure 1a). We simulated two genotype populations from two founder groups, the first set of founders had broiler type (BT) haplotype diversity and the second had high haplotype diversity. Each population was seeded from 405 founder haplotypes across 13 levels of genotyping error between 0-9%. The first 5,000 snps on chromosome 1 of simulated datasets were corrected using the novel algorithm genoFix and the performance evaluated. We then phased haplotypes for both uncorrected and genoFix corrected genotypes using AlphaImpute2 and evaluated the impact of GE and genoFix correction on phasing. Recombination was detected using the xOverDetect algorithm. We evaluate the impact of GE and genoFix on the accuracy of crossover prediction.

Simulating genotypes. All simulated populations were generated from phased founders using the qGsim package (github.com/andreaskranis/quickgsim). To simulate the BT population, we used a complete three generation pedigree of 3,902 chickens genotyped with a 50K SNP chip and phased with AlphaImpute2 (Whalen and Hickey, 2020). From the third generation 405 phased haplotypes were selected as founders. A population of 7,802 chickens was generated by dropping the founders' haplotypes onto a 5-generation real pedigree. The number of simulated crossovers was randomly sampled from a Poisson distribution with a mean equal to the size of chromosome in morgans and resampled if zero. Crossover locations were

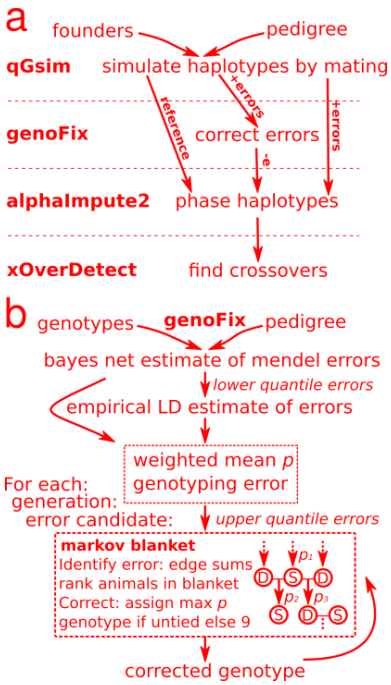

Figure 1. Overview of (a) workflow stages for crossover detection and (b) the main steps in the genoFix algorithm for identifying and correcting genotype errors.

uniformly and randomly distributed across the genome. Datasets with simulated errors were created for GE from 0-9%. Haplotypes, genotypes and crossovers were exported from qGSim before and after errors were introduced so that an exact reference for calculating performance were retained for each dataset. The simulation was repeated for a high haplotype diversity founder set by randomising the phasing of heterozygous SNPs among the founders.

Correcting genotype errors. We developed genoFix (github.com/andreaskranis/genofix) using a combined Mendelian and Empirical LD approach (Figure 1b) for estimating the probability of a genotype error P(E). All parameters listed below were used across all datasets and selected based on parameter grid searches to maximise f-score based on the 1% GE dataset. BNs were implemented using pgmpy (Ankan and Panda, 2015). We constructed Markov blankets for each animal from all breeding pairs and their offspring and include two back generations from the pedigree. For each blanket a BN was constructed for all ancestors where the conditional probability tables on nodes were calculated from Mendelian inheritance probabilities. Missing genotype values and upper terminal nodes in the blanket assume probabilities from the populations' allele frequency. This was then used to calculate the genotype state probabilities P(G) for a given SNP in an animal from the ancestors. An offspring derived P(G) was calculated from mean P(G) of Mendelian inheritance across all children. The final Mendelian SNP P(G) is the product of these ancestor and offspring estimates. We estimated P(E) as the difference between the maximum probability for a genotype and the observed probability. An empirical based LD was estimated for SNPs using a sliding windows of 9 SNPs around each SNP. Observations from the upper 20% quantile of predicted Mendelian errors were excluded from empirical calculations. For a given SNP the empirical observation were calculated as the weighted sum of genotypes combinations observed in the outermost window and inner nested windows. The weight function was defined for a window (W) where W_n is the observed set and W_o is the outermost

window. Observations are calculated for a SNP window by summing over the weighted observations of all symmetric inner windows down to a minimum window size of three (Equation 1).

$$empiricalobservations = \sum_{n=1}^{|W_o|} obs\,(W_n) \times \frac{1}{|W_o| - |W_n|} \quad (1)$$

We observed that true GEs indirectly increase the P(E) estimates on surrounding nodes in a blanket. In order to discriminate these direct and indirect effects we implemented a graph based ranking system where the rank of a node (SNP in an individual) is the sum of P(E) weights on incoming and outgoing edges (pedigree inheritance). We evaluate only the upper 40% quantile of P(E) estimates, and flag SNPs as errors if they rank first within a Markov blanket and have a P(E) value >0.6. If the most probable genotype state has a P(G) that is 1.4 times greater than the next state we correct the genotype, else we label it as unknown. Iterative correction proceeds per generation, such that each generation corrected includes genoFix corrections from the previous generations. BN calculations run in parallel on GPU and CPU and are scalable for high performance compute.

Phasing and crossover detection. For pedigree assisted phasing of haplotypes with AlphaImpute2 we used a conservative peeling threshold of 0.99, 100 SNP phasing consensus window, 20 phasing cycles, 400 phasing particles and specified % error. We developed xOverDetect to identify crossovers in phased data. A fault-tolerant mode evaluates support for SNP blocks flanking a crossover, requiring >2 heterozygous SNPs and >1% heterozygosity.

Results

We observed that at broiler type (BT) heterogeneity levels, as found in a typical chicken breeding line, genoFix can reduce errors in genotyping array data (Figure 2a,c). At 1% GE the algorithm has 97% precision and 84% recall. The high precision value results in <0.05% of new errors introduced by genoFix (Figure 2b). Figure 2b,d shows the same accuracy statistics for a simulated dataset with atypically high heterogeneity levels, designed to explore the upper tolerance of the algorithm, and its dependence on LD. At 1% GE high heterogeneity reduces the performance to 91% precision and 43% recall. In both dataset precision is more stable across higher error levels than recall. GEs below 1% suffer a small penalty in both precision and recall, which is due to fixed parameters that were optimized for 1% GE.

The reduction in GEs due to genoFix improves the downstream accuracy of AlphaImpute2 (Figure 2e,f). This was critical for datasets of >4% GE where phasing accuracy decreases rapidly. GenoFix was still able to reduce GE for these datasets. At all GE levels >1% genoFix improved phasing and reduced both false positives (fp) and false negatives (fn) crossovers (Figure 3a,b). Error tolerance in crossover detection reduced fp but with a resulting increase in fn. The fp rate in crossover detection after genoFix was slightly increased For GEs at 0.5 and 0.75% with marginal or little improvement in fn rate. This reflects the penalty to genoFix precision and recall when using parameters optimized for 1% GE.

Discussion

In these datasets accurate phasing with AlphaImpute2 required GEs below a critical 4% (Figure 2). GenoFix was able to improve the genotyping accuracy of datasets and rescue simulated genotype arrays with >4% error, even in a population with high heterogeneity. Crossovers are rare but strongly localized in the genome (Groenen *et al.*, 2009), with a median vertebrate rate of less than one crossover per Mb (Wilfert *et al.*, 2007). At these rates fp are highly problematic and even 3% GEs could add unacceptable noise (~one fp per 5Kb) to hotspot analysis. High GE rates require large sample populations to achieve adequate signal-to-noise ratios for lower intensity hot-spots. The genoFix was able to improve the accuracy of crossover detection for simulated datasets with >0.75% GE. Genotype correction was shown to be a valuable step within the phasing and crossover detection workflow.

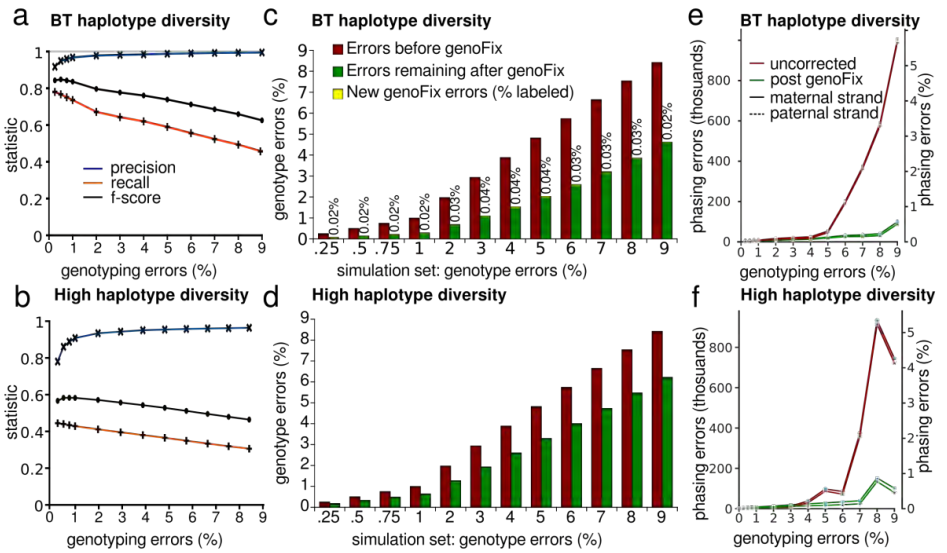

Figure 2. Evaluation of genotype genoFix correction of simulated datasets generated from BT (a,c) and high haplotype diversity (b,d) founders. For both dataset (a,b) precision and recall for genotype correction and (c,d) errors before and after genoFix. Finally, impact of genotype correction on alphaimpute2 phasing accuracy for simulated datasets for (e) BT founders and (f) high haplotype diversity founders.

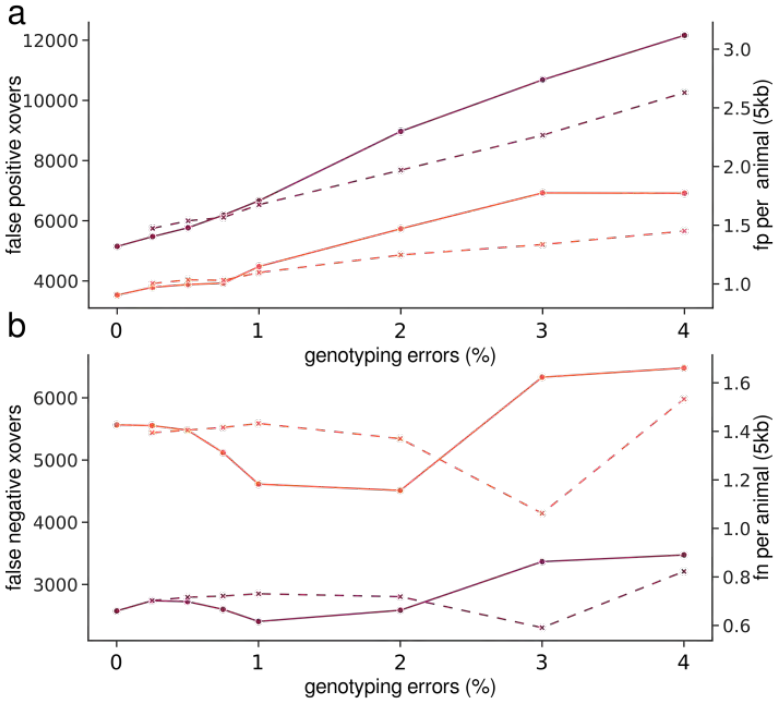

Figure 3. Crossover detection accuracy between 0-9% simulated GEs, before and after genoFix correction. Data is simulated from BT founders. (a) False positives (fp) are crossovers predicted that are not overlapping real crossovers. (b) False negatives (fn) are real crossovers that are not overlapping predicted crossovers.

348. A phasing algorithm targeted at dairy cattle populations having genotyped ancestors with many genotyped offspring

M. Dahl* and O.F. Christensen

Center for Quantitative Genetics and Genomics, Aarhus University, 8830 Tjele, Denmark; mdahl@qgg.au.dk

Abstract

In dairy cattle, the prevalence of genomic testing is now widespread, and commonly both sires and many offspring in the form of children, grandchildren, and great-grandchildren, are genotyped. Calling phases from genotypes is useful for several reasons, in particular for construction of haplotypes and imputation of missing genotypes. In this paper, we present a new computationally efficient method to call phases of grandfathers and great-grandfathers when enough genotyped offspring are present. The method consists of first identifying shared haplotypes between ancestor and offspring, followed by phasing segments based on homozygote genotypes in offspring, and finally merging haplotype segments to call entire ancestral haplotypes. The implementation is based on using bit vectors and fast binary computations. Results show that the method is effective in finding shared haplotypes to be used for phasing.

Introduction

Phasing using homozygotes in relatives and offspring has explored by others. Kong *et al.* (2008) introduced Long Range Phasing (LRP) that phases based on likely identity by descent (IDB) segments of the chromosome, using homozygote markers of fixed length genotype segments, to call paternal and maternal alleles using surrogate parents. The method is implemented in AlphaPhase (Hickey *et al.* 2011, Money *et al.* 2020). Using offspring for phasing was presented in Ferdosi *et al.* (2014) and Nettelblad (2012). They both show that very accurate phasing can be done on parents when enough genotyped offspring are present.

The aim of our paper is to present a computationally efficient method using likely IBD segments to call phases of grandfathers and great-grandfathers when enough genotyped offspring are present.

Materials & methods

Under the assumption of one recombination per meiosis, the average length of a recombination-free sequence of markers passed from an ancestor is half the size of the shared haplotypes. These recombination-free sequences can be used for phasing. The method presented here, is based on identifying parts of the inherited chromosome in offspring, where a haplotype segment from an ancestor is inherited and no recombination has taken place. After ancestor haplotypes have been computed, the offspring genotypes are used to do internal phasing of the called haplotypes. This is done by the following sequence of operations:

1. Identify likely shared haplotypes between ancestor and offspring, using opposing homozygotes, allowing for small percentage of errors.
2. Split the chromosome into segments of equal length.
3. For each segment extract genotype segment from all offspring where segment is fully contained in likely shared haplotype. Set minimum requirements for number of offspring.
4. Split offspring genotype segments into two recombination free groups.
5. Use these two groups to call phase on the ancestor haplotypes.
6. Do internal phasing of identified haplotype segments using heterozygotes in the called haplotype segments.

Test data was generated using QMSim (Sargolzaei and Schenkel 2009). A chromosome with 3,273 markers was created, i.e. as chromosome one on the Illumina BovineSNP50 BeadChip v3. A nucleus population

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_348, © M. Dahl and O.F. Christensen 2022

producing bulls and a production population of cows was created. Then 10 generations of dams in the production population were mated to 10 generations of sires from the nucleus population. Offspring in generation 10 was used for phasing, for grandfather phasing generation 9 sires were used, for great-grandfathers, sires in generation 8 were used. Random positions in genotypes were removed or changed to simulate missing genotypes and genotyping errors.

Step 1: identifying shared haplotypes. Genotypes coded as 0,1,2. Parameters: segment length 8; minimum length 24 SNPs; error window size 16; max errors in window 3; min no opposing length 80; max. error percentage 3.0%. Method: split genotypes in segments of a length that enables fast computation – in this example 8; compute opposing and comparisons; merge no opposing; remove too many opposing and too short; recursive computation of longest shared no opposing that has less than 3% errors.

Fast identification of shared haplotypes is important for obtaining acceptable runtimes. The method stores genotypes as three bit vectors aa, bb and ab, i.e. a bit set mark whether the genotype has AA, BB or AB SNP in the bit position. This enables use of binary instructions and, or, not or x or, when comparing genotypes. These instructions are very fast in most programming languages. Opposing homozygotes between two genotypes can be computed as the number of bits set in the expression: $((aa_1 \text{ and } bb_2)$ or $(aa_2 \text{ and } bb_1))$.

The method is as follows: (1) split the two genotypes into segments with fast binary instructions for fast computing; (2) create arrays of aa, bb, and ab bit segments for all genotypes; (3) do a pairwise comparison between segments by computing number of opposing and number of SNPs present in both genotypes; (4) merge adjacent segments with zero opposing homozygotes; (5) set an error window size and the maximum allowed number of errors in the window; (6) scan all adjacent segments with non-zero opposing homozygotes. If adjacent segments with the length of the window or less, contain more than the maximum allowed number of errors, then remove the adjacent segments from the array; (7) set a minimum length of pairwise shared no opposing haplotypes between the two genotypes and a maximum error percentage; (8) group segments into groups of adjacent segments. Remove all groups with a total length less than the minimum length; (9) for the remaining groups, compute the maximum length of no opposing homozygotes using elements in the group that have fewer errors than the maximum error percentage. This can be done by recursion. Return the longest identified. The method is illustrated in Figure 1.

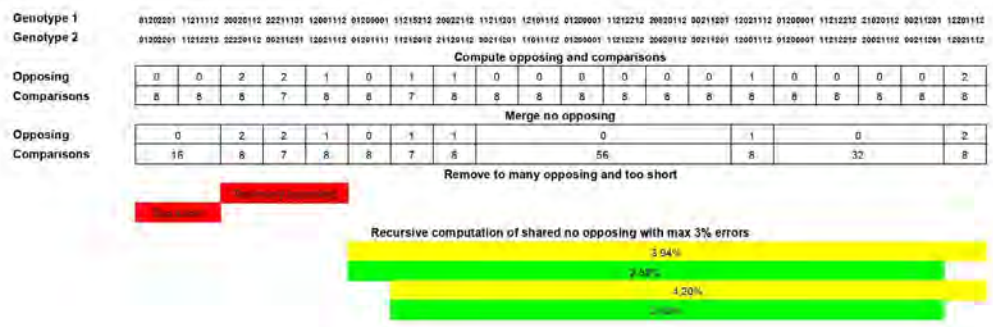

Figure 1. Identification of long shared no opposing SNPs between two genotypes.

Steps 2 to 5: phasing segments based on homozygotes in offspring. Following step 1, all pairs of offspring and sire have had their shared haplotypes computed. An offspring and a sire may share haplotypes from a shared common ancestor. These can be mistaken as the inherited haplotype. To decrease the possibility of this, we chose segments that are sufficiently long. In the experiments presented here, the simulated genotypes were split into 12 segments. Offspring where an ancestor is grandfather or great-grandfather more than once will not be used for phasing. To get variation, pedigrees of all the offspring must have the grandfather or great grandfather as the only ancestor common in offspring pedigrees.

For each of the segments the method does the following: (1) find all elements where the segment is entirely in the shared haplotype and enough offspring exist – store them; (2) split them into the two largest groups that split, around the heterozygotes in the ancestor's genotype. Allow for errors; (3) call phases using homozygotes in the two groups and homozygotes in the ancestor. Allow for errors. In steps 2 and 3 fast bit operations are used.

Step 6: internal phasing of the computed haplotype segments. The haplotype segments phased in step 2 to 5 has no internal phase. In this section a method to call internal phase is described.

The method consist of: (1) Ensure that all haplotype segment pairs have 3 heterozygotes, by doing the following: In all ancestor haplotype pairs with less than 3 heterozygotes, delete heterozygote calls; Merge all homozygote haplotype pairs to an adjacent segment pair. (2b) For each pair of adjacent haplotype segments, called left segment and right segment: Find the three rightmost heterozygote positions in left haplotype pair; Create two short haplotypes with three heterozygote positions; Similar for the right haplotype pair. (3) Find the internal phase of left and right haplotype pair making a vote between all offspring segments that contains all the positions in the two short haplotypes from the left and right haplotype pair.

The proposed method was implemented in a Python3.10 program where bit-vectors are stored in a byte array, that support fast binary computations.

A test was run on a HP notebook (Intel i7-8,565U CPU – 16GB RAM, cache size 8,192 KB). On that hardware on average 1,468 genotype comparisons per second were executed, during the test run. Parameter's settings in program test were as follows. Missing marker percent in genotypes: 3%; Genotype SNP count: 3,273; Error window size: 272: Max opposing count in window: 6; Min no opposing length: 648; Max errors percent: 1% for 0.1 SNP error pct, 2% for 1% error pct.

Results

It is clearly seen that the identified shared haplotypes can be used to call haplotype segments in grand- and great-grandfathers while correcting genotyping errors (Table 1 and 2). In most cases the shared haplotypes can be used for calling the entire haplotype.

Table 1. Phasing of grandfathers.

Simulated offspring	Random SNP call percentage	Phased great grandfathers	Haplotype calls	Haplotype call percent	Haplotype error percent	Haplotype segment calls	Haplotype segment call percent	Haplotype segment error percent	Missing haplotype segment phases
50	0.1	1000	1,988	99.569	0.077	24,000	99.572	0.051	6
200	0.1	100	200	99.552	0.211	2,400	99.557	0.073	0
50	1.0	999	1,954	99.241	0.471	23,976	99.241	0.342	22
200	1.0	100	196	99.197	0.603	2,400	99.203	0.319	2

Table 2. Phasing of great-grandfathers.

Simulated offspring	Random SNP call percentage	Phased great grandfathers	Haplotype calls	Haplotype call percent	Haplotype error percent	Haplotype segment calls	Haplotype segment call percent	Haplotype segment error percent	Missing haplotype segment phases
100	0.1	1000	1,982	99.562	0.137	24,000	99.564	0.051	9

Discussion

A new and computationally fast method for identifying shared haplotypes between genotype individuals is presented, and we have shown that the method is effective in finding shared haplotypes that can be used for phasing. Future work involves an extensive comparison with other software, in particular AlphaPhase (Hickey *et al.* 2011, Money *et al.* 2020) and Fimpute (Sargolzaei, Chesnais and Schenkel (2014). Preliminary investigations show that our algorithm is superior in terms of both speed and accuracy compared to AlphaPhase, but memory usage should also be a criterion for comparison.

Abstract

Genotype imputation has enabled selecting and using many more loci in research and prediction for much less cost than genotyping all individuals with the same array density or technology. Genotyping arrays are updated often to include new QTLs or higher-effect markers and applied to new animals without re-genotyping all previous or reference animals. That may require imputing the new loci from less-dense to higher-density arrays and from descendant genotypes to ancestors in the opposite direction of normal reference and target populations. Routine expansion and recycling of haplotype libraries and updating only individuals expected to change can speed imputation for routine predictions. This study compared imputation strategies for 78,964 loci of 4.6 million Holsteins. Sequence imputation is more challenging due to higher error rates and more complex variants, but new techniques could make sequencing cost-competitive with arrays for routine predictions.

Introduction

Genotypes at thousands of loci are combined into genomic relationships, and genomic predictions are usually obtained by multiple regression of phenotypes on genotypes. Solutions require replacing any unknown genotypes using allele frequencies, imputed genotypes, allele content (dosage), or genotype probabilities (Zheng *et al.*, 2011). Unknown phenotypes usually are easy to exclude from models but can also be 'imputed' to reduce computation using the same canonical transformation as when all traits are measured (Ducrocq and Besbes, 1993). Unknown genotypes can be imputed using pedigrees and a linear model one locus at a time from observed genotypes (Gengler *et al.*, 2007). Similar algebra uses pedigree relationships to linearly impute genomic relationships for ungenotyped animals from genotyped animals in single-step predictions (Aguilar *et al.*, 2010) and can improve marker effects by including phenotypes of ungenotyped parents, for example. More accurate haplotype-based imputation uses allele patterns across linked loci such as in long-range phasing or hidden Markov models and high-quality genome reference assemblies. This nonlinear imputation restricts genotype dosage to the range of homozygous reference to homozygous alternate (usually 0 to 2), whereas dosages from linear imputation can exceed the valid range. Known genotypes, pedigrees, and phenotypes could be used to impute the missing genotypes; however, accuracy is usually high by imputing genotypes just once without using the phenotypes, which often have low heritability and low correlations with individual genotypes. Accuracy is sometimes higher with multi-breed than single-breed imputation or using two steps instead of directly imputing all variants from the lowest density (VanRaden *et al.*, 2013). Imputation strategies for large datasets must balance accuracy with computing costs and adapt to properties such as array densities, sequence depth, error rates, and population structure in the input data. Imputation methods developed in animal breeding are often hundreds of times faster than from human genetics but with similar accuracy, especially with pedigree available (Sargolzaei *et al.*, 2014; Miar *et al.*, 2017). By processing in birth date order, most progeny haplotypes can be quickly selected from the two haplotypes of each genotyped parent or grandparents instead of from a long list of population haplotypes. This study provides a speed and accuracy comparison and a brief overview of genotype imputation strategies.

Materials & methods

Microarray genotypes for 78,964 SNPs of 4.6 million Holsteins were imputed using Findhap version 3 either with no prior haplotype library or by obtaining priors from genotypes of a subset population that included 369,063 bulls plus their 73,813 dams, followed by one iteration including all animals. About 30,000 newly genotyped animals are imputed weekly using the prior haplotype library from the previous monthly update. The weekly imputation is nearly as accurate as the full monthly, with prediction correlations near 1.0 in larger breeds (Wiggans *et al.*, 2015). Each month the whole file is reprocessed to add about 120,000 new genotypes, update about 5,000 previous animals whose genotype or pedigree changed and obtain priors for the next weekly and monthly updates. Only the new and changing animals get their haplotype numbers updated, but any missing alleles within each haplotype can be filled by the added data and improve the imputed genotypes of other animals. The maximum length of haplotypes processed was reduced recently from 700 to 250 SNPs to speed imputation and limit the memory needed. The list of usable SNPs is updated about once per year. Routine evaluations with expanding reference populations must decide how frequently to reimpute all genotypes, such as when new QTLs are added or which animals to update, for example, only the most recent or those whose pedigrees change. Such strategies were compared using Holstein genotypes from the Council on Dairy Cattle Breeding (CDCB) database that included 48 different arrays ranging from <3,000 to >600,000 usable markers.

Results

Imputation using no prior haplotype library and four iterations would take 24 days with 30 processors and up to 500 Gb memory. Time was reduced to nine days by first obtaining a prior haplotype library from only the bulls' and dams' genotypes. Each week, about one hour is required to impute genotypes of new animals using the previous month's haplotype library. About 10 hours are required once per month to reprocess the whole file and include the new animals. Input genotypes averaged 72% unknown, whereas only 0.03% were still unknown after imputation, and 1.7% were half known with one allele still missing. Allele frequencies are later substituted for the missing alleles when estimating SNP effects. The list of 78,964 SNPs includes about 80 known QTLs already genotyped plus locations of six more discovered QTLs expected to be available on future arrays to allow imputing those without starting the imputation from scratch. Some recently selected high-effect SNPs from the high-density (HD) array are genotyped for only about 5,000 animals (0.1% of the population) currently. Still, imputation fills nearly all (>99%) of the missing alleles. Other SNPs from the HD array, especially on the X chromosome, were added to fill gaps when converting to the ARS-UCD1.2 cattle reference map (Rosen *et al.*, 2020). Such SNPs and QTLs are provided to genotyping laboratories and included when designing their future arrays.

Discussion

Advances in imputation allow combining various datasets, but highly accurate prediction may require identifying more of the QTLs and genotyping those in both the reference and candidates for selection instead of relying on markers. Array genotypes are typically so accurate that animal and plant breeders rarely store their quality scores based on distance from cluster centroids, for example. Uncertain genotypes are instead set to missing, and markers or samples with high missing or error rates are not used so that a low, uniform error rate of 1% or less may be assumed for all array genotypes remaining. That strategy allows efficient computation and storage of input data, but output files are much larger after imputation and include many uncertain genotypes. Sequence genotypes often are less accurate due to more read errors and both alleles not being observed across the whole genome, such as in regions with low coverage or where alignment to the reference assembly is challenging. Imputation to sequence can discover better markers or QTL, but high accuracy is needed for imputed sequence variants to outcompete highly linked array genotypes directly measured in the reference population. Rare or less frequent alleles may have poor imputation accuracy and may thus not improve prediction even if their actual effects are larger than

nearby genotyped markers (Zhang *et al.*, 2018). For example, the best linked marker from an array may be correlated by 0.97 with the true QTL but have nearly 100% correct genotypes compared to only 95% correctly imputed QTL genotypes for animals not sequenced. Reference cows may contribute much less to the reliability of prediction or marker selection if their sequence genotypes are imputed from only 6,000 to 20,000 usable SNPs and their individual phenotypes have low heritability. To obtain the gains in prediction accuracy expected from larger reference populations, well-designed genotyping strategies and accurate imputation are needed (Judge *et al.*, 2017).

Variant calling, phasing, and imputation can be combined so that each sample has only two haplotypes per region, and sequence read errors are suppressed instead of called as additional variants. Only two alleles are reported with array genotypes, whereas multiple alleles up to seven often are reported at the same locus in sequence data. Using such variants may require software redesign to exclude the less common alleles or track allele definitions within locations within chromosomes. A location can have all four bases (A, C, G, T) as SNPs plus multiple insertions and deletions of varying lengths. Copy number variants are harder to define, call, and impute than SNPs or indels and have not yet contributed much to genomic prediction (Chen *et al.*, 2021) despite some large, known effects. Standard variant call format (vcf) can require much space and be difficult to read: 'Do not write home-brewed VCF parsing scripts – it never ends well' (GATK Team, 2021). Simpler file formats may be possible that more languages could read with code of the user's choice. When merging separate vcf files, information about less common alleles can be lost for variants not reported if all samples in a single file are homozygous for the reference allele or if many samples have insufficient coverage to detect the allele. Instead of merging all raw sequence data, vcf files could each include and report genotypes and read depth at an agreed list of common locations. This strategy is like all genotyping arrays that include a standard set of 6,000 or 50,000 markers to simplify later merging with other arrays or files. The genomic vcf (gvcf) format instead takes more space to store approximate read depth for all genomic locations.

Low-coverage sequencing could soon become less expensive than arrays, allowing for genotyping many more variants with high accuracy in populations with good sequence reference panels available (Rubinacci *et al.*, 2021) and can also be used in developing those reference panels (VanRaden *et al.*, 2015). Methods to account for read errors in low-coverage data are needed (Ros-Freixedes *et al.*, 2020), and some of the read error bias can be overcome by aligning to both the reference genome and the alternate genome simultaneously (VanRaden *et al.*, 2019). The posterior genotype probabilities reported in vcf usually assume prior probabilities of 0.25, 0.5, and 0.25 and could be recalculated with actual genotype frequency priors (p^2, 2pq, and q^2) to obtain better dosage estimates. Distributed processing works well for arrays with accurate genotypes at predefined locations, but centralized processing may be needed for low-coverage sequences instead of sending imputed genotypes and updating those as reference populations improve and more breeds are added. Storage is a much bigger issue with raw sequence data and many rare alleles detected as more samples are sequenced. Genotypes could be stored for only the alternate alleles instead of storing all the homozygous reference genotypes. Similarly, referential compression can produce cram rather than bam files by storing only the differences of the raw reads from the reference assembly (Shi *et al.*, 2019). Larger populations have been genotyped for humans than livestock, and >300 million sequence variants have been imputed for >20 million humans (TOPMed Imputation Server, 2021). In animal genetics, the goal is not to routinely store or impute more variants but to identify the most useful variants that improve prediction at a reasonable cost. Advances in genotyping and imputation will continue to make genomic selection more affordable and accurate in future livestock populations.

350. Imputation of low coverage sequence data by utilization of pre-phased reads and HBimpute

T. Pook* and J. Geibel

University of Göttingen, Center for Integrated Breeding Research, Animal Breeding and Genetics Group, Albrecht-Thaer-Weg 3, 37075 Göttingen, Germany; torsten.pook@uni-goettingen.de

Abstract

The generation of high-quality genomic data for large populations is an incremental part of animal breeding. In this work, we are proposing an extension for the imputation software HBimpute, which was originally developed for low coverage sequence data from inbred lines in plant breeding. For this, sequencing reads of animals are phased based on genomic information from the sire to generate two 'pseudo'-inbred individuals that are separately processed in the imputation pipeline. The performance of the approach is demonstrated using a simulated data set of 520 chickens from a crossbreeding scheme. Absolute discordance rates to the real simulated genotype are much smaller (0.0303) than for state-of-the-art software using genotype calls (Beagle 5: 0.0887) or genotype likelihoods (0.0564). In particular, performance for rare variants is better than in traditional software.

Introduction

In the last decade, genotyping has been shown to be an incremental part of animal breeding. With the increasing availability of genotyping arrays, large-scale genotyping of breeding populations in various livestock species has become possible. Genotyping in animal breeding nowadays is usually done via SNP arrays and only selected animals are sequenced to use those animals as a reference panel for imputation to sequence level marker density (Bouwman *et al.*, 2018). Although the cost of sequencing substantially dropped in the last few years, costs and bioinformatic processing times are still too high for use in routine breeding programs. Cost reduction may be achieved by low-depth sequencing, which however is error-prone for heterozygous variants. Recently, Pook *et al.* (2021) suggested a new imputation approach for the imputation of inbred material in plant breeding that was sequenced at low coverage, yielding substantial improvements by the use of haplotype blocks from the software HaploBlocker (Pook *et al.*, 2019) and utilizing local read-depth in the imputation algorithm. This approach, however, is not directly applicable in animal breeding, as the identification of haplotype blocks requires accurate phase information, which is usually not given in livestock populations.

In this work, we propose an extension of the work of Pook *et al.* (2021) to perform read-phasing in advance of the variant calling. The key idea of the approach is to use genomic information from the sire animal that was sequenced with high sequencing depth, as the number of sires in animal breeding is usually limited. On the contrary, the number of dams in animal breeding is usually high, making approaches for pre-phasing in trios (Koren *et al.*, 2018) not applicable.

Materials & methods

Materials. Genotypic data was generated via simulations with the MoBPS software (Pook *et al.*, 2020) based on a real dataset of 40 broiler chickens (subset of Geibel *et al.* 2021) with 319,479 SNPs on chr20, simulated with a size of 2.32 Morgan. To mimic the genetic architecture of a crossbreeding scheme with different gene pools, two gene pools with 10 roosters and 250 hens each were generated. Next, 25 generations of mating within the respective pool were simulated. Subsequently, the actually used animals were obtained by mating a sire from the first gene pool with a dam from the second gene pool. Low coverage sequence data was simulated to use reads with a length of 2×150 base pairs with a target coverage of 1X. Additionally,

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_350, © T. Pook and J. Geibel 2022

calling errors with a frequency of 0.02 were simulated. Haplotypes of the sires were assumed to be perfectly known. The interested reader is referred to https://github.com/tpook92/MoBPS for scripts and details of the simulation.

Methods. HaploBlocker (Pook *et al.*, 2019) requires imputed and phased data. As in particular the phasing accuracy in traditional imputation software in low coverage sequence is far below what is needed for HaploBlocker, HBimpute cannot be directly applied. The core idea of our pipeline is the utilization of a typically small number of sires in animal breeding programs, allowing for the generation of high quality data of one of the parents of each animal. Based on this, each generated read for an animal is evaluated if the corresponding haplotype matches with one of the two haplotypes of the sire animal. Subsequently, the reads of an animal are split into two groups based on whether they correspond to a sire haplotype or not.

Instead of using the genotype of the animal itself in the imputation, two 'pseudo'-inbreds are generated by performing the SNP calling for the reads of the two haplotypes separately. Subsequently, the HBimpute pipeline as suggested in Pook *et al.* (2021) was applied.

Results of our imputation pipeline are compared against different versions of the imputation software Beagle (Browning *et al.*, 2018; Browning and Browning, 2013) using genotype hard calls (GT), genotyped likelihood (GL), or the same 'pseudo'-inbred panel as used in our suggested HBimpute pipeline. Other methods that are specifically designed for the imputation of low coverage sequence data are not presented in this manuscript as they were not suited for the available data structure. For example, QUILT (Davies *et al.*, 2021) requires a reference panel that includes haplotypes from both parents, and GLIMPSE (Rubinacci *et al.*, 2021) performed substantially worse in general in all considered tests.

Results & discussion

Quality of the pre-phasing. After pre-phasing, genotype calls for 55.1% of all cells of the genotype matrix were obtained. Note here that on average more genotype calls for the haplotype stemming from the sire were obtained as e.g. regions of identity-by-state between sire and dam haplotype are automatically assigned to the sire haplotype. The average read-depth for the sire haplotype is 1.13X compared to 0.66X for the dam haplotype with genotype calls for 65.4 / 44.8% respectively. 10.5% of all reads are not assigned to either parents. Of all assigned reads stemming for the sire, 93.7% are correctly assigned to the sire haplotype, while only 56.2% of the dam reads are assigned to the dam haplotype (overall 74.8% correct assignment).

Performance of the imputation methods. Overall, our suggested HBimpute pipeline yielded the best imputation performance both in terms of correction / imputation accuracy (0.397) and discordance rates between the imputed and the underlying real dataset (0.0303; Table 1). The use of GT led to substantially worse results, as the low number of reads per variant makes the calling of heterozygous variants challenging. Although this is slightly improved when using GL information in Beagle 4.1, overall imputation performance is still substantially worse than in HBimpute. The use of Beagle 5.0 GT with the use of our pre-phasing method and 'pseudo'-inbreds performed much better than all considered standard Beagle pipeline (0.378; 0.0359), thus indicating the potential of pre-phasing based on sire information.

Imputation quality based on the allele frequency. When analyzing the performance of the different imputation pipelines based on the frequency of the alleles, we observed that both HBimpute and Beagle 5.0 GT with pre-phasing perform well on all allele frequencies, while Beagle 4.1 GL seems to have a strong bias towards the more common variant, with even lower error rates for alleles with a frequency higher than 0.6 (Figure 1), thus indicating that pre-phasing is particularly useful for the imputation of rare variants.

Table 1. Performance of the different imputation pipelines based on imputation accuracy and discordance rates of the imputation.

Imputation method	Imputation accuracy	Discordance rate	Share heterozygosity
HBimpute	0.397	0.0303	0.190
Beagle 4.1 (GL)	0.304	0.0564	0.127
Beagle 4.1 (GT)	0.341	0.0812	0.082
Beagle 5.0 (GT)	0.317	0.0887	0.085
Beagle 5.0 (GT) + pre-phasing	0.378	0.0359	0.195

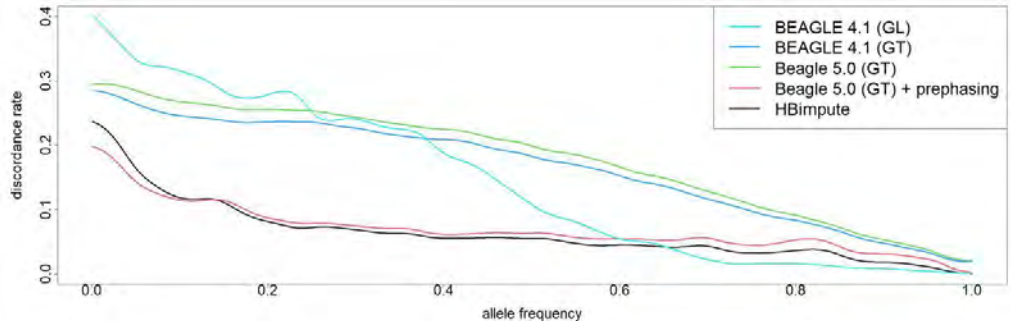

Figure 1. Discordance rates of the imputation depending on the used imputation pipeline.

When comparing the performance within HBimpute based on the number of reads available, we observed discordance rates of 0.0452 when having no reads, 0.0232 when having exactly one read available, 0.229 when having two reads, and 0.228 when having three or more supporting reads. When instead of comparing the discordance of the genotype, the qualities of the two haplotypes of an animal were analyzed separately, we observe discordance rates of 0.0199 for the sire haplotype and 0.0465 for the dam haplotype, indicating a much higher quality of the sire haplotype. A potential reason for this is that wrongly assigned reads to the sire do not negatively impact the pipeline as they are usually assigned based on IBS while bad-quality reads are preferentially assigned to the dam haplotype.

Imputation quality based on the number of used reads. In addition to the genotype call itself, HBimpute is also providing information on the number of reads used to make the call. This can both be seen as a quality indication and tool for the detection of copy number variation. In regions without available haplotype block or own read, discordance rates are 0.130 compared to 0.028 / 0.023 / 0.021 / 0.018 when having at least 1 / 10 / 50 / 250 supporting read. For the sire haplotype only 4.5% of all calls are using less than 10 reads while for the dam haplotype 17.1% of all calls are done with low read support. As only 10 different sires were used in the generation, haplotypes naturally occur in higher frequency.

Conclusions

Our suggested pipeline enables the use of HBimpute for non-inbred genetic material. By this, and in contrast to other imputation approaches, our approach is able to utilize the local read-depth and phase information from the sire animal. Thus, neither genotype information from the dam nor high sequencing depth for the individual itself is required to obtain high quality genomic data. By this, low coverage sequence could become a cost effective alternative to genotyping arrays with the additional benefits of a higher number of markers and detection of copy number variation when the number of sires in a breeding scheme is limited.

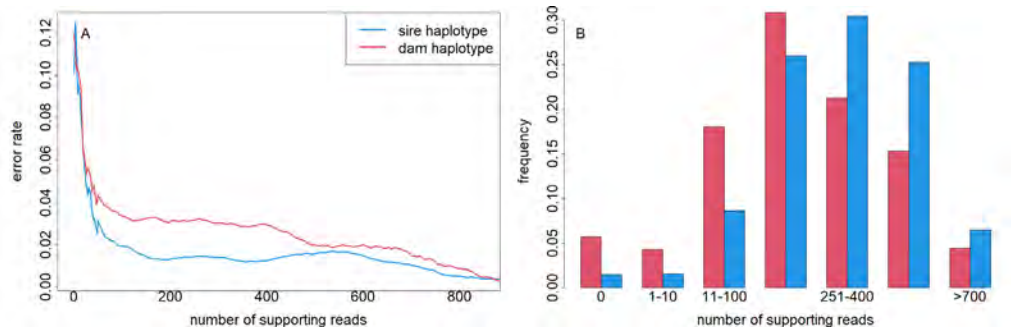

Figure 2. Discordance rate depending on the number of reads used in the HBimpute step (A) and frequency of the read-depth (B) depending on the sex.

It should still be noted that at this stage our method was only evaluated with simulated data and further development of the pre-phasing pipeline is needed to, e.g. run multiple iterations of our pipeline and use the imputed panel of the previous iteration to improve the pre-phasing. Thus, this should be seen as a proof-of-concept, but further evaluation on real data is required.

351. Quantitative trait simulation using MeSCoT software

V. Milkevych*, E. Karaman, G. Sahana, L. Janss, Z. Cai and M.S. Lund

Center for Quantitative Genetics and Genomics, Aarhus University, Tjele, Denmark; vimi@qgg.au.dk

Abstract

This work represents MeSCoT, a software dedicated to complex trait simulation through the mechanistic modelling of genes interactions. The software provides an innovative framework to study molecular mechanisms of gene-by-gene and gene-by-environment interactions. It closely imitates the basic *in vivo* mechanisms of complex trait realization and allows a detailed simulation of genes' regulatory interactions for variable genomic architectures. The MeSCoT software is scalable and well documented (https://genetics.ghpc.au.dk/vimi/mescot/).

Introduction

Quantitative (or complex) traits represent majority of traits that are of economic importance in agriculture (Goddard and Hayes 2009). Genetic variation of such traits is determined by a large number of loci and is related to a specific genomic architecture. The current approaches of breeding value prediction of a complex trait involve all genotyped single nucleotide polymorphisms (SNPs), regardless of their statistical significance (Meuwissen *et al.* 2001), and understanding of a genetic architecture that underlies quantitative traits could help improving statistical models for better predictive ability (Suravajhala *et al.* 2016).

This study represents a novel mechanistic approach to *in silico* quantitative trait simulation implemented within MeSCoT (Mechanistic Simulation of Complex Trait) software (Milkevych *et al.* 2021). The approach imitates core *in vivo* mechanisms of complex trait formation and quantitatively maps genotypic and phenotypic variation into the molecular mechanisms of gene expression. The software delivers a computational framework for $G\times G$ and $G\times E$ interaction studies as well as for verification of novel and existing statistical methods in quantitative genetics

Implemented models and algorithms allow detailed simulation of genes regulatory interactions for variable genomic architectures and generates extensive omics data. In addition to mechanistic models, the software includes the novel single-nucleotide polymorphism and omnigenic genetic models (Boyle *et al.* 2017). These models allow detailed studies of impact of genetic and phenotypic variance on gene regulation and, hence, can help reveal molecular mechanisms linking the heritability and variation in molecular traits.

Methods

Implemented models. A number of detailed mechanistic models constitute the computational framework implemented within MeSCoT software, in particular: the model of genes regulatory interactions, single-nucleotide polymorphism model, genotype by environment interaction model, and a model for genomic network geometry. The detailed mathematical formulation of these models as well as implemented numerical methods and algorithms can be reviewed in (Milkevych *et al.* 2021).

Simulation workflow & software interface. The schematic overview of MeSCoT simulation workflow and data depicted in Figure 1A; Figure 1B and 1C show the MeSCoT input and output interface respectively; adapted from (Milkevych *et al.* 2021).

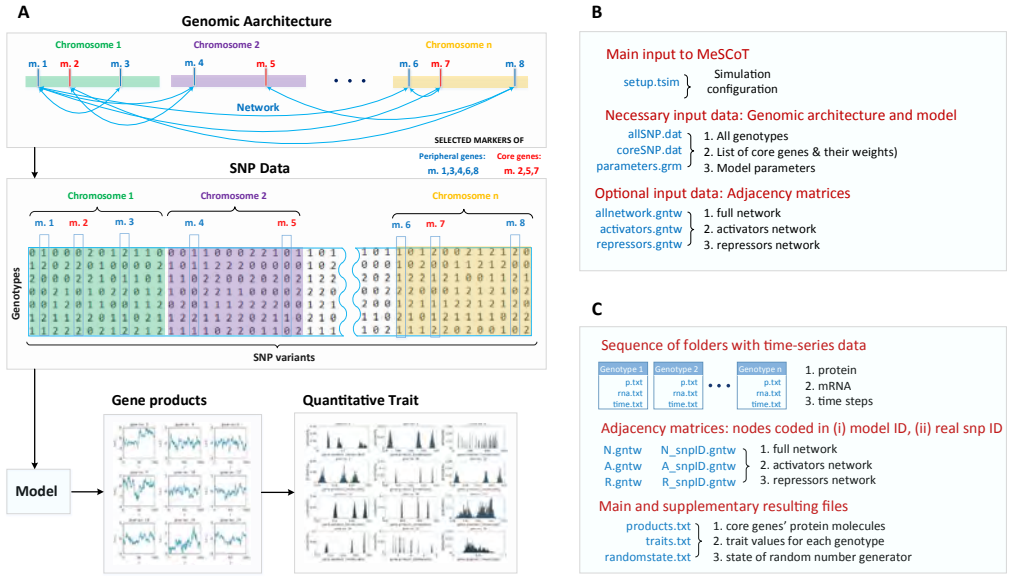

Figure 1. Simulation workflow & software interface. (A) The schematic overview of MeSCoT simulation workflow. The shaded areas depict distinct workflow components: data blocks and functional units. The black arrows represent information flows. The 'Genomic Architecture' is a data block of prior information regarding a modelled complex trait, such as peripheral and core genes (markers colored in blue and red respectively), their locations and network relations (blue arrows). The prior information is used to build a data file consisting the combined information for all genotypes (SNP variants) in population, the shaded area named 'SNP Data File'. The computational unit ('Model') utilizes the genomic and network information to produce 'Gene products' data that can be further used for the trait calculations, depicted within 'Quantitative Trait' area. (B) MeSCoT input interface. C) MeSCoT output interface. Blue color indicate different types of files and folders; black color describes a function and purpose of files; red color marks different interface groups.

Data used for the case studies. For the case studies we use a trait with a pure artificial genomic architecture determined by *in silico* generated genomic network. We simulated the genotypic data for 5,000 individuals completely at random, by sampling allele counts from {0,1,2} for 50 SNP loci. Among the simulated SNPs, 12 were set to be core genes (Boyle *et al.* 2017) with equal contributions to the trait phenotype. The rest of the SNPs were taken as peripheral genes.

Results & discussion

Genomic network. The MeSCoT software allows *in silico* networks simulation. The network data (data files representing adjacency matrices) was produced once and subsequently reused in all simulation studies. The resulting network geometry represented in terms of a directed graph is depicted in Figure 2A; adapted from (Milkevych *et al.* 2021).

Expression data. The detailed dynamics of mRNA and protein concentrations for all genes involved in the regulatory network is covered by MeSCoT functionality. As a result of the case study, the standardized expression level profiles for core genes (from the network depicted in Figure 2A) are depicted in Figure 2B.

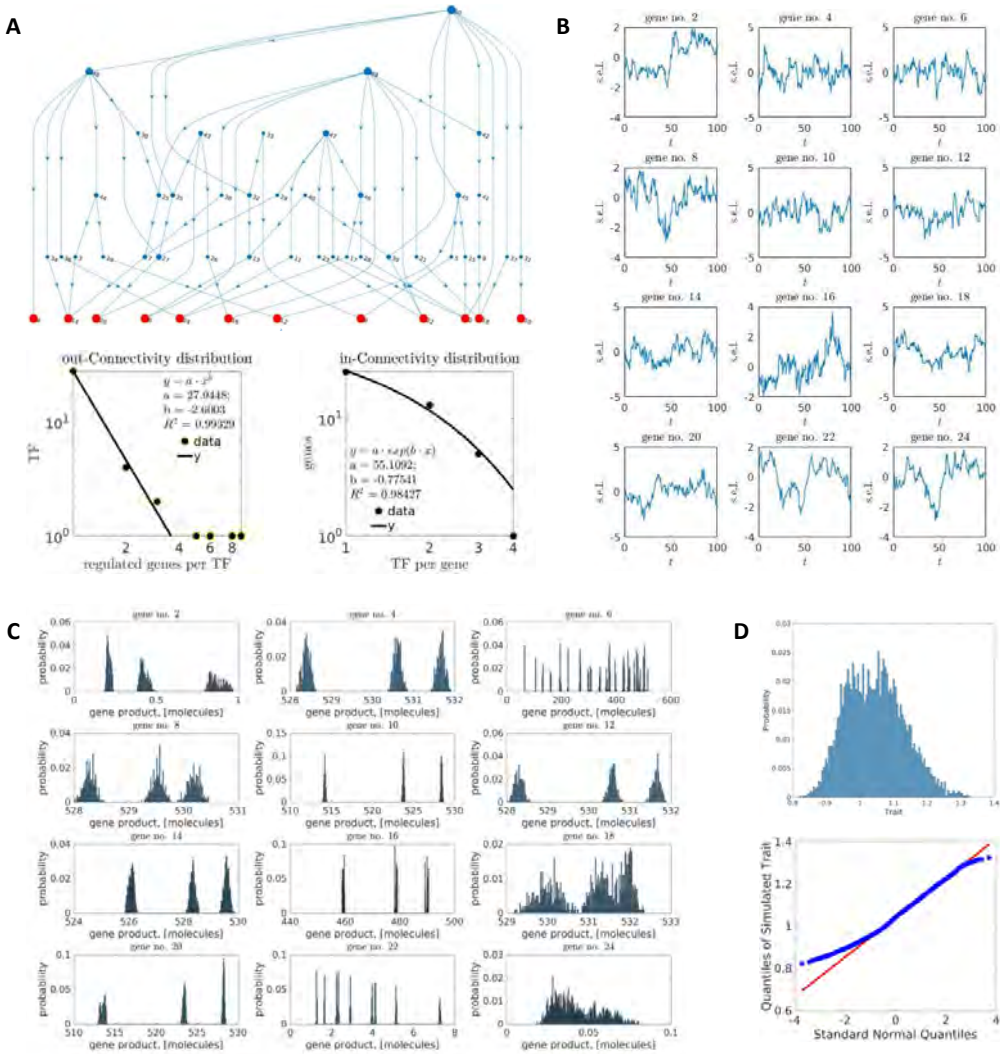

Figure 2. The results of the case study. (A) Simulated genomic network and its connectivity properties (log-log representation). The size of blue dots is proportional to the graph's nodes degrees; red dots indicate the core genes; nodes labels (numbers) correspond to SNP identity numbers in the genotypes data file; arrows indicate the directions of regulatory interactions; TF stands for transcription factor. (B) Standardized expression data for core genes. The expression level profiles were generated using mRNA concentration data of reference genotype; *s.e.l.* is standardized expression level; *t* is time in minutes. (C) Distributions of core genes' products (proteins concentrations); the distributions were generated for the population consisting of 5,000 distinct genotypes. (D) Distribution of simulated genotypic values (traits, expressed as normalized values). The distribution was generated for population consisting of 5,000 distinct genotypes; the trait values were calculated using the normalized values of protein concentrations.

Gene-by-gene interactions. The software allows extensive analysis of $G \times G$ interactions. Core genes' products form complex patterns, such as segregated distributions of protein molecules in Figure 2C. These patterns, as we believe, are due to the interplay between the genomic differences in population and the geometry of the genomic architecture (network, Figure 2A).

Cumulative contribution of all normalized core genes' products is visualized in Figure 2D where the result is represented as the probability distribution of simulated genotypic values upon 5,000 individuals. For the assumed genomic architecture and the study genotypes, the trait approach a normal distribution (Figure 2D). The trait distribution represented as a combination of minor distributions related to the individual core genes' products (Figure 2C).

Multi-trait case. While the current version of the software is able to simulate a multi-allelic QTL, the multi-trait functionality is under development.

Web resources. The software (executables for Linux and Windows platforms) as well as the necessary documentation with examples are freely accessible via the MeSCoT supporting web site: https://genetics.ghpc.au.dk/vimi/mescot.

Abstract

Selection of individuals that are genetically less susceptible to infection, less infectious once infected and who recover more quickly, offer an effective and long-lasting way to reduce the incidence and impact of infectious diseases in farmed animal populations. To date, however, genetic evaluations for these underlying host traits has been hampered by a lack of numerical tools capable of estimating them from available data. This paper introduces a new software tool called SIRE 2.0 which is able to estimate breeding values for polygenic susceptibility, infectivity and recoverability from diverse types of individual-level data. A simulation study is carried out to first validate SIRE 2.0, and then the dependency of prediction accuracies (PAs) on various factors is investigated. These, together with analytical expressions for PAs, indicate that SIRE 2.0 can reliably estimate genetic parameters for all three traits and provide insight into associated data requirements.

Introduction

The speed and severity with which a disease spreads in a population depends on three separate (but potentially correlated) epidemiological host traits: susceptibility, infectivity and recoverability (Pooley *et al.*, 2020, Bijma *et al.*, 2021). Recent research indicates that genetic improvement of all three traits simultaneously, rather than just susceptibility, would be substantially more effective at disease control (Tsairidou *et al.*, 2018, Bijma *et al.*, 2021, Doeschl-Wilson *et al.*, 2022). SIRE is an existing software tool (Pooley *et al.*, 2020) that estimates the contributions from fixed effects (e.g. SNP or vaccine effects) to these traits from various types of individuals' disease records (e.g. disease diagnostic test results or times of infection and/or recovery/death). This paper introduces SIRE 2.0, which incorporates additive genetic contributions into the model (and so builds on previous efforts, e.g. Anacleto *et al.*, 2015). These account for correlations in trait values between individuals through a relationship matrix (e.g. susceptible parents are more likely to have susceptible offspring), and between the traits themselves (e.g. more susceptible individuals may, on average, be more infectious).

Materials & methods

The genetic-epidemiological model. The system is assumed to consist of one or more closed 'contact groups'. The dynamics within each contact groups is represented by an SIR (or SI) compartmental model, with individuals classified as being either susceptible to infection (S), infected and infectious (I), or recovered/removed/dead (R). The force of infection (i.e. the probability per unit time of individual j becoming infected) is given by $\lambda_j = \beta e^{G_z} e^{g_j} \Sigma_i e^{f_i}$ and the time taken for individual j to recover after being infected is taken to be gamma distributed with mean $w_j = 1/(\gamma e^{r_j})$ and shape parameter k_{sh}. Here β and γ are population average transmission and recovery rates, g_j, f_j and r_j represent fractional deviations in the susceptibility, infectivity and recoverability for individual j, and the sum i goes over all infected individuals sharing the same contact group as j at any given point in time. Finally, G_z is a random effect (for group z with standard deviation σ_{GE}) which accounts for group-specific factors that influence the overall speed of an epidemic in one contact group relative to another (e.g. animals kept in different management conditions or environmental variation). The individual-based fractional deviations are parameterised in the following

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_352, © C.M. Pooley *et al.* 2022

way: $g=Xb_g+a_g+\varepsilon_g$, $f=Xb_f+a_f+\varepsilon_f$, $r=Xb_r+a_r+\varepsilon_r$, where g, f and r are vectors (containing information for all the individuals) that are decomposed into fixed effects b_g, b_f and b_r, where X is a design matrix (e.g. to account for sex differences in the traits or vaccination status), additive genetic contributions (a_g, a_f, a_r) that account for the correlations in trait values between different individuals (these are multivariate-normally distributed with zero mean and covariance matrix $A\otimes\Omega$, where A is the pedigree/genomic relationship matrix and Ω is a 3×3 covariance matrix that characterises potential correlations between traits). Finally, the residual contributions (ε_g,ε_f,ε_r) account for all other variation (these are also multivariate normal with zero mean and covariance matrix $I\otimes\Psi$, where I is the identity matrix reflecting the fact that residuals are assumed to be uncorrelated between individuals and Ψ is a 3×3 covariance matrix that characterises environmental correlations between traits). The total phenotypic covariance matrix is given by $\Theta=\Omega+\Psi$.

Software tool. The model from the previous section has been implemented in SIRE 2.0 (Pooley *et al.*, 2022) which uses an efficient Markov chain Monte Carlo (MCMC) algorithm to draw samples from the posterior. A graphical interface takes as input any combination of information about individuals' infection and recovery times, disease status measurements and disease diagnostic test results. The A matrix is specified (either from a pedigree or using a genomic relationship matrix), along with other fixed effects (if included), as well as details of which individuals belong in which contact group. A range of prior specifications can be made on different model parameters. The outputs consists of posterior trace plots for model parameters, distributions, visualisation of infection and recovery times, dynamic population estimates and summary statistics (means and credible intervals) as well as MCMC diagnostic statistics. Files containing posterior samples of parameters and events can be exported for further analysis.

Results

A simulation study was performed to first validate SIRE 2.0 and then explore factors affecting prediction accuracies for the additive genetic contributions to the traits. A simple half-sib population structure is assumed: Q unrelated sires are each randomly mated to P unrelated dams to produce P offspring (giving a total of $U=Q\times P$ individuals in the next generation). These individuals are randomly allocated across contact groups each containing N individuals. A randomly selected index case in each group is infected to instigate an epidemic. Simulated datasets are generated using a modified Doob-Gillespie algorithm (Pooley *et al.*, 2020).

Validation. We begin by looking at what might be considered a 'typical' scenario using the following parameters: $Q=100$, $P=20$, $N=10$, $\beta=0.05$ and $\gamma=0.1$ (corresponding to basic reproductive ratio $R_0=\beta N/\gamma=5$), $k_{sh}=3$, and $\sigma_{GE}=0.25$ (values for covariance matrices are shown in Figure 1). For simplicity no fixed effects are included. In total 20 exemplar datasets were generated (to account for system stochasticity) each of which consisted of the disease status of individuals periodically checked every $\Delta T=2$ time units up until $T_{max}=40$. Figure 1 shows tornado plots for posterior distributions inferred using SIRE 2.0. We find that, for the most part, the true parameter values lie within the 90% credible intervals indicating that inference is able to successfully capture these values. Based on the data from the $U=2000$ individuals used here we find the susceptibility Θ_{gg}, infectivity Θ_{ff}, and recoverability Θ_{rr} can be estimated with good precision, with slightly poorer estimates obtained for heritabilities h^2 and genetic correlations.

Prediction accuracies (PAs). The PAs are defined as correlations between the posterior means of the additive genetic components (a_g, a_f, a_r) and their true (usually unknown) values. Taking a best case scenario in which infection and recovery times are exactly known (along with simplifying assumptions including that traits are uncorrelated), analytical expressions for PAs can be derived using a maximum likelihood approach (not shown):

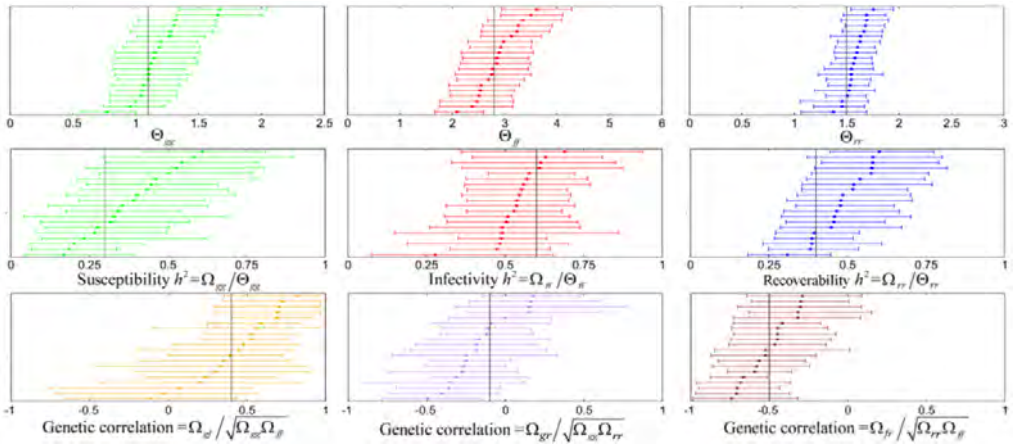

Figure 1. Tornado plots of posterior distributions for 20 replicated datasets (circles represent posterior means, error bars give 90% credible intervals and true parameter values indicated by the vertical black lines).

$$\alpha_g = \left[1+\frac{4N}{P\Omega_{gg}(N-1)}\left(1+\Theta_{gg}+\frac{1}{N}\Theta_{ff}\right)\right]^{-\frac{1}{2}},$$
$$\alpha_f = \left[1+\frac{4N}{P\Omega_{ff}\log(2N)}\left(1+2\Theta_{ff}+\frac{3}{\log(2N)}\Theta_{gg}\right)\right]^{-\frac{1}{2}},$$
$$\alpha_r = \left[1+\frac{4}{P\Omega_{rr}}\left(\frac{1}{k_{sh}}+\Theta_{rr}\right)\right]^{-\frac{1}{2}}. \quad (1)$$

Figure 2 shows results for these expressions under a variety of scenarios, and they are compared to posterior predictions using SIRE 2.0 on simulated data (the baseline set of parameters used were $\Omega=\Psi=I/2$, i.e. a heritability of 0.5 on all traits with no correlations, with others parameters as before): (a-b) shows that if the phenotypic variance in a trait is small then so is the corresponding PA (note for equal variance, recoverability has the highest PA, followed by susceptibility, with infectivity having the lowest). (c) Introducing correlations between any of the traits (in this case between infectivity and recoverability) increases PAs, especially for infectivity (hence Equation 1 represents a lower bound). (d) Varying the number of individuals per epidemic group N (for fixed overall number of individuals U) has little effect on the PA for susceptibility and recoverability, but has a marked effect on reducing the PA for infectivity as N becomes large (i.e. many small contract groups provide more information). (e) Increasing the number of sire offspring P (for fixed U) increases the PAs. In this case the simulated data includes only recovery times, and this leads to a shift to the right in the symbols with respect to the analytical results reflecting a reduction in statistical power (e.g. P would need to be ~10 times larger for an equivalent infectivity PA, although this factor is smaller for the other two traits). (f) This looks at varying the time-step ΔT at which disease diagnostic tests are made. We find that PAs are only marginally reduced even when ΔT is relatively large, indicating that precise measurements of infection and recovery time are not required.

Discussion

This paper introduces the software tool SIRE 2.0 which allows, for the first time, estimation of additive genetic contributions to susceptibility, infectivity and recoverability (as well as the genetic covariance matrix) from different types of real-world epidemiological data. Analytical expressions reveal that large additive genetic variation in these traits correspond to high PAs (supporting the effective use of selective breeding). Based on the empirical observation of super-spreaders (relatively few individuals causing most infections) it is known that phenotypic variation in infectivity is high, but as yet it is not clear to what extent

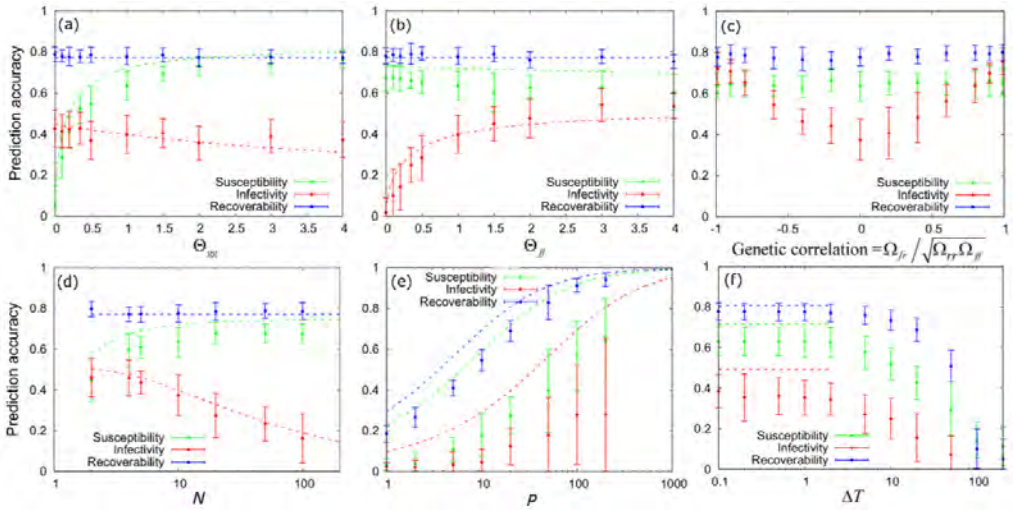

Figure 2. Prediction accuracies for susceptibility, infectivity and recoverability (circles with error bars give the mean and standard deviation of numerical estimates obtained from 20 simulated datasets, dashed lines from Equation 1).

that variation is environmental or genetic-based. The next version of the software SIRE 2.1 is currently under development to allow for arbitrary specification of the compartmental model, e.g. to allow for a latent state, or the possibility of accumulation of pathogens in the environment. These extensions will open up the possibility of applying this tool to a wider range of experimental or field data, as exemplified in Doeschl-Wilson *et al.* (2022) and Prentice *et al.* (2022).

353. iVPSV: an intuitive visualisation platform for structural variation data

H. Jung[1*], B. Jeon[2], B. Hayes[1] and E. Ross[1]

[1]Queensland Alliance for Agriculture and Food Innovation, The University of Queensland, Australia; [2]Deaprtment of Communication and Arts, The University of Queensland, Australia; hyungtaek.jung@uq.edu.au

Abstract

Visual validation is an essential step to minimise false-positive predictions from structural variants (SVs) detection but a difficult task in life sciences. We present a Graphical User Interface (GUI)-based intuitive Visualisation Platform for Structural Variation (iVPSV), a free standalone desktop application software with Python support, that makes manipulating commonly used SV files more accessible to biologists with a simple mouse click. It enables them to perform end-to-end reproducible visual validation by facilitating the rapid discovery and identifying/navigating target regions/sequences (or user's interest) in SVs datasets for novice users. iVPSV can also create images (including summary reports) that display the read depth/contexts and sequence alignments necessary to adjudicate purported SVs across samples and the short and long-read sequencing technologies with multiple vcf and bam files. This specific benefit allows iVPSV to seamlessly integrate visual and interactive representations of SV files, supporting a wider scope of bioinformatics applications in the life sciences.

Introduction

Structural variation (SV), which includes mobile elements, is a fundamental genomic alteration that usually refers to a change of over 50 bp nucleotide fragments, including insertion, deletion, inversion, translocation and duplication (Sudmant *et al.*, 2015). While a considerable number of studies have provided state-of-the-art SV discovery tools, only limited investigations have been made for visualisation (Belyeu *et al.*, 2021; Nattestad *et al.*, 2021).

With the broad implementation of Next Generation Sequencing (NGS) technologies in the life sciences, the importance of visualisation for understanding biological phenomena is an increasingly important aspect in the genomic revolution. However, many of the available tools for SV visualisation are targeted for short-read alignments which cannot cover large compound SVs on several genomic loci. However, advances in long-read sequencing (Sedlazeck *et al.*, 2018; Jung *et al.*, 2019) have shed light on examples where visualising the portions of reads that maps to different parts of the reference is crucial. When a read is over 10 kb long, it can cover a wide-range of complicated SVs on the genome, but that context is easily lost using IGV (Robinson *et al.*, 2001), or other existing reference-centric viewers without adding a read-based perspective and showing all relevant reference loci (Nattestad *et al.*, 2021).

In recent years, other visualization tools have tackled some challenging aspects of validating structural variant calls. In particular, svviz (Spies *et al.*, 2015) has used realignment against a putative structural variant allele to better evaluate the evidence, SV-plaudit (Belyeu *et al.*, 2018) and SVCurator (Chapman *et al.*, 2019) have enabled crowd-sourced curation of structural variants. In addition, Ribbon (Nattestad *et al.*, 2021) has offered an interactive online SV visualisation tool along with other genomic features, and Samplot (Belyeu *et al.*, 2021) has provided a platform for structural variant visual validation and automated filtering including a machine learning package that dramatically decreases the number of false-positive without human review. Even with these very useful approaches, more complex patterns of structural variation remain hard to represent due to the lack of embedded visualisation step requires other third-party

visualisation tools such as IGV (Robinson *et al.*, 2011) which is primarily built for short reads as well as for multiple vcf and bam files. Unfortunately, the true power of long reads is hidden when the tools we use are built for short reads. Furthermore, many existing SV visualisation tools require higher-order computational infrastructure (high-performance computing facilities and Cloud computing), lack GUIs and minimise the true power of long reads in visualisation, making them inaccessible to many researchers, and cumbersome for even experienced biologists. A more flexible approach including the acceptance of multiple vcf and bam files can be helpful by showing the full picture of alignments from both the reference and read perspective, allowing researchers to explore and communicate about complex variation in a more intuitive way. Thus, we have addressed this problem by creating iVPSV an interactive and intuitive visualization tool that displays alignments along with both reference and query sequences, along with variant calls, genes and other genomic features.

Materials & methods

iVPSV can be used by sophisticated data scientists and non-technical users who need an intuitive interface. The original intent for producing iVPSV was to reduce reliance on any command lines/scripts or web-based platforms, by creating a standalone lightweight program with substantially reduced computation demands. iVPSV provides key benefits in convenience, accessibility, and reproducibility because it does not include any heavyweight genome/transcriptome assembly, mapping and clustering workflows. iVPSV can execute and pre-analysed SV VCF files by filtering parameters on a user's desktop with the help of many packages (Table 1). While it mainly focuses on point-and-click analysis for less technical users, the Help function could provide an interactive experience for monitoring and iterating on an executed code.

Please note that iVPSV, a self-contained program, includes all necessary dependencies and executable packages. Simply unzip the folder and double-click iVPSV.exe after downloading the program.

Results

For user-friendliness and convenience, iVPSV was developed with five work modules covering different aspects of data visualisations, including post-processing, parsing, filtering, generating results, and help (Figure 1).

In addition, further assistance and information can be obtained via Help to improve processes and performance.

Table 1. Software packages integrated into iVPSV and their applications.

Software	Application
Python packages	
PyQt5 (https://pypi.org/project/PyQt5/)	PyQt is a Python binding of the cross-platform GUI toolkit Qt.
gffutils (https://github.com/daler/gffutils)	gffutils is for working with and manipulating the GFF and GTF format files typically used for genomic annotations.
PyVCF (https://pyvcf.readthedocs.io/en/latest/#)	PyVCF is for parsing variant call format by mimicking the csv module in the Python stdlib, as opposed to more flexible serialisation formats like JSON or YAML.
JavaScript Library	
D3.js (https://d3js.org/)	D3.js is for producing dynamic, interactive data visualisation with HTML, SVG and CSS.
jQuery	jQuery is for simplifying HTML DOM tree traversal, manipulation, event handling, CSS animation, and Ajax.

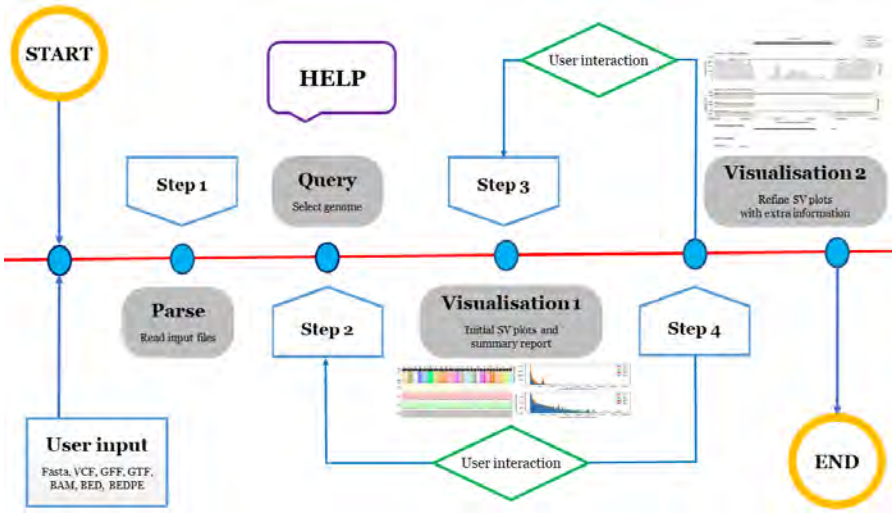

Figure 1. iVPSV workflow and data structures.

Discussion

iVPSV is implemented in Python and available under the MIT license and works on Windows, Linux and Mac systems. This package is also available on the PyPI python package manager. The current code runs under Python 3.7+ and JavaScript Library. Other dependency includes gffutils, PyVCF, PyQt5, D3.js, and jQuery (Table 1). We aimed to create a flexible, educational and user-friendly tool combining multiple features to visualise structural variant data. In the future, we will continue to update with new fast and easy GUI support including new embedding methods such as pan-SV visualisation, with low resource requirements and both multithread and cluster computing support, making these methods suitable for running on standard desktops in laptops. The future version of iVPSV will also include additional integration points allowing us to intersect, merge, count, complement, and shuffle genomic intervals from multiple files in widely-used genomic file formats.

Abstract

Various Bayesian methods have been developed to improve genetic prediction of complex traits. Although Bayesian methods such as Bayes-B have been proven to outperform genomic best linear unbiased prediction for prediction of complex traits, especially those that have major genes, they are usually implemented using Markov chain Monte Carlo, which is time consuming and has convergence issues when the number of markers is greater than the number of individuals. To address this issue, we developed a computationally efficient variational Bayes (Bayes-VB) method that can flexibly partition the whole genome markers into many groups. Our approach can improve the accuracy of genomic predictions compared to Bayes-B and is much faster, as illustrated here for growth rate of pigs under a disease challenge.

Introduction

Genomic prediction using high-density single nucleotide polymorphism (SNP) markers has been widely used in livestock animals. The standard model used for genomic prediction is the genomic best linear unbiased prediction model (GBLUP), which assumes that all SNP effects are drawn from the same normal distribution (VanRaden, 2008; Meuwissen *et al.*, 2001). Various Bayesian methods for genomic prediction have also been developed based on other prior distributions of SNP effects. One of these methods is Bayes-B, which assumes SNP effects follow a mixture of a heavy-tailed distribution and a spike distribution at zero (Meuwissen *et al.*, 2001). Although methods such as Bayes-B have been proven to outperform GBLUP for prediction of phenotypes with major QTL (Moser *et al.*, 2015; Yin *et al.*, 2020), it has several computational drawbacks. First, the Markov chain Monte Carlo (MCMC) used to implement these methods are time consuming. Second, the Bayesian model has difficulty converging when the number of markers is larger than the number of animals (Yin *et al.*, 2020). Last, the SNP effects are assumed to be independently and identically distributed in these Bayesian models. However, because of linkage disequilibrium (LD) between SNP markers, effects of markers that are close to each other may not be independent and, thus, tend to have similar effects and are more likely to follow the same distribution (Yang and Tempelman, 2012). Zeng *et al.* (2018) developed a method called Bayes-N to account for the dependence of effects for SNPs that are closely linked by grouping SNPs, which improved prediction accuracy compared with Bayes-B in simulated data. However, this method is still computationally demanding. To address these issues, we developed a Bayesian method (Jiang, 2018, available at https://sites.google.com/view/ssgp/home?authuser=0) that can account for the dependence of markers by flexibly partitioning the whole genome markers into a large number of groups based on proximity. The method was evaluated using data from a natural polymicrobial disease challenge model in pigs.

Materials & methods

Data. Data on 3,205 wean-to-finish pigs were available from a natural disease challenge model (see Cheng *et al.*, 2020, for details). Pigs were provided by seven companies, and each company was represented once each cycle (one batch per company per cycle) for a total of seven cycles. All animals were genotyped with a 650 k SNP chip. In total, 435,172 SNPs that passed quality control for all seven cycles, as described by

Cheng *et al.* (2020), were utilized for analysis. Average daily gain in the challenge nursery (cNurADG) and finisher (FinADG) were used to compare the accuracies of the different genomic predictions. Phenotypes for pigs that died were imputed and expanded as described by Cheng *et al.* (2020). These two traits reflect different underlying genetic architectures, as a major QTL was identified for cNurADG in the major histocompatibility (MHC) region that explained about 12.8% of genetic variance. In contrast, a relatively larger polygenic contribution to genetic variance was observed for FinADG, with the MHC region explaining only 2.7% of genetic variance (Cheng *et al.*, 2021).

Statistical model. The following statistical model was used:

$$\mathbf{y} = \mathbf{Xb} + \sum_{h=1}^{p} \mathbf{K}_h \mathbf{u}_h + \mathbf{e} \quad (1)$$

where y is phenotype; X is the design matrix for fixed effects; b is a vector of fixed effects, including batch (50 batches), mortality (1 for died; 0 for survived), and entry age, $\mathbf{b} \sim N(\mathbf{0}, \mathbf{I}\sigma_b^2)$, where σ_b^2 is the variance for the 'fixed effects', which was assigned a large value (e.g. 1e8); p indicates the number of groups of random marker effects; K_h is the design matrix, i.e. the genotypes for markers in group h; u_h is a vector of random marker effect for the h^{th} group, assumed to follow a normal distribution, with each group having its own variance component ($\sigma_{u_h}^2$), $\mathbf{u}_h \sim N(\mathbf{0}, \boldsymbol{I}\sigma_{u_h}^2)$; e is the vector of residual effect, assumed to follow a normal distribution, $\mathbf{e} \sim N(\mathbf{0}, \boldsymbol{I}\sigma_e^2)$. Residual variance is further assumed to follow an inverse-gamma distribution with two parameters (shape parameter c_0 and scale parameter d_0) and marker effect variance is assumed to follow a half-Cauchy distribution with group-specific parameters A_h, following Polson and Scott, (2012). In this study, the random effects of pen (437 unique pens in the challenge nursery and 262 in the finisher) and litter (1,119 litters) were also fitted by treating them as pseudo markers that were fitted in two extra groups.

Algorithms for model fitting. A variational Bayes (VB) (Beal, 2003) algorithm that approximates target distribution with a factored distribution that omits dependencies present in the target distribution was used to fit the model. To speed up the convergence, the parameter expanded method was applied to VB iterations (Jaakkola and Qi, 2007) by expanding the model by introducing auxiliary variables (c_h) to each group of SNPs: $\tilde{\mathbf{u}}_h = \mathbf{u}_h / c_h,\ and\ \tilde{\sigma}_{u_h}^2 = \sigma_{u_h}^2 / c_h^2$. After all parameters are updated in each iteration, the variational lower bound is maximized with respect to c_h, and u_h and $\sigma_{u_h}^2$ are then updated again using $\mathbf{u}_h = c_h \tilde{\mathbf{u}}_h, and\ \sigma_{u_h}^2 = c_h^2 \tilde{\sigma}_{u_h}^2$. In such a way, the strong coupling between variables in the original model was reduced.

Genomic predictions. Predictions from Bayes-VB were compared with those from GBLUP and Bayes-B. For Bayes-VB, the whole-genome markers were split into groups by an equal number of 200, 400, 600, 800, 1000, or 2,000 SNPs. The GBLUP and Bayes-B methods were implemented as described by Cheng *et al.* (2020) and Cheng *et al.* (2021), respectively, with the latter using an MCMC of length 50,000, with the first 5,000 iterations discarded as burn-in. Samples were saved at every 100th iteration of the chain. A prior probability of 0.1% of a SNP having a non-zero effect was used for the Bayes-B model. A seven-fold (each cycle was used as one fold) cross validation strategy was employed for genomic predictions of cNurADG and FinADG using the three methods, with data from six cycles used for training and the remaining cycle for prediction. The prediction accuracy was evaluated using the Pearson's correlation in the validation population between the genomic predictions and phenotypes adjusted by estimates of the fixed effects of batch, mortality, and entry age and the random effects of pen and litter from a GBLUP analysis of the full data set. Unbiasedness was assessed as the regression coefficient of adjusted phenotypes on genomic predictions in the validation population. The processor used for all analyses was a 3.00 GHz Intel Core i7 with 64 GB of memory.

Results

In general, for both cNurADG and FinADG, accuracies increased and then decreased with an increase in partition size regarding the number of SNPs. The optimal group size was 600 SNPs for cNurADG and 800 SNPs for FinADG, based on prediction accuracy. Comparison of prediction accuracies using Bayes-VB vs using GBLUP and Bayes-B are shown in Figure 1. For cNurADG, accuracies were higher for Bayes-VB and Bayes-B than for GBLUP for most cycles, except for cycle 2. Bayes-VB outperformed Bayes-B for all cycles. On average, the accuracy for Bayes-VB was 15 and 38% higher than for Bayes-B and GBLUP, respectively. For FinADG, similar to cNurADG, both Bayes-VB and Bayes-B outperformed GBLUP for most cycles (except for cycles 1 and 7). However, Bayes-VB only outperformed Bayes-B for cycles 2 and 5. On average, the accuracy for Bayes-VB was 4% lower than for Bayes-B but 10% higher than for GBLUP. Additionally, Bayes-VB resulted in slightly less bias than Bayes-B. Regarding computational time, Bayes-VB (using the optimal group size) was 76 times faster than Bayes-B (5 vs 380 min) for cNurADG and 54 times faster (5 vs 270 min) for FinADG.

Discussion

The optimal partition of the whole genome markers may be affected by two main factors, the LD decay pattern and the distribution of QTL. In this study, the optimal group size by number of SNPs was 600 SNPs for cNurADG and 800 SNPs for FinADG. This is more or less in agreement with the LD decay pattern in this pig population. The distribution of QTL may also play a role, i.e. a major QTL was found for cNurADG but was not so obvious for FinADG, which resulted in the difference in optimal group size (600 vs 800 SNPs) for cNurADG and FinADG. Even though an appropriate group size that matches LD length was used, these markers in the same group were not strongly associated with a major QTL for FinADG, thus not contributing to prediction accuracy. Previously, Zeng *et al.* (2018) used simulated data to demonstrate that modeling the dependence of effects of SNPs closely linked in the prior will improve the ability of SNPs close to a QTL to jointly capture its effect. The effect of model choice on prediction accuracy also depends on genetic architecture of a trait studied. Using simulation, Coster *et al.* (2010) reported that variable selection methods using Bayesian regression, such as Bayes-B, increased in accuracy when the number of QTL decreased. Our Bayes-VB method was also affected by the genetic architecture of a trait, as the increase in accuracy from Bayes-VB over GBLUP was greater for cNurADG (38%), which has a major QTL (MHC), than for FinADG (10%), which is not controlled by a major QTL. Interestingly, Bayes-B showed similar improvements in accuracy over GBLUP for cNurADG (20%) and FinADG (16%). This suggests that Bayes-VB is more affected by the genetic architecture of the trait analyzed than Bayes-B but further validation study is needed. In practice, a cross-validation strategy can be used to find the optimal group size using training population. The whole genome can also be split by haplotypes (unequal group size).

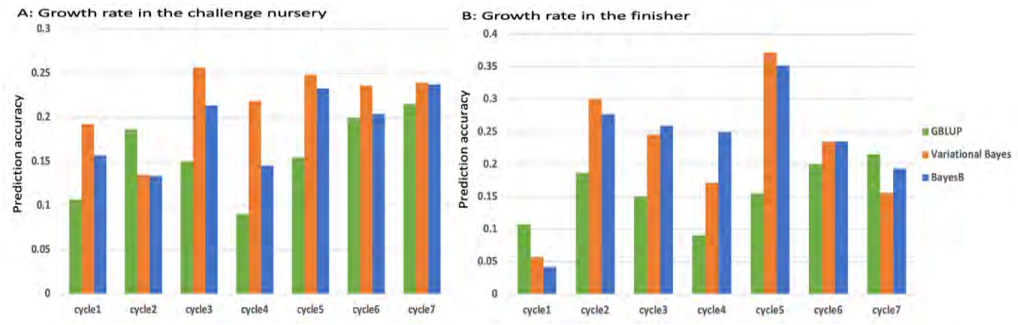

Figure 1. Comparison of genomic prediction accuracies using GBLUP, variational Bayes, and Bayes-B for growth rate in the challenge nursery and finisher for each cycle.

Conclusions

A computationally efficient method that can account for dependence of markers by flexibly partitioning the whole genome markers into a large number of groups was successfully developed.

355. Additions to the BGLR R-package: a new function for biobank size data and Bayesian multivariate models

P. Pérez-Rodríguez[1*] and G. de los Campos[2,3,4*]

[1]Colegio de Postgraduados, CP 56230, Montecillos, Estado de México, México; [2]Department of Epidemiology & Biostatistics, Michigan State University, USA; [3]Department of Statistics & Probability, Michigan State University, USA; [4]IQ – Institute for Quantitative Health Science and Engineering, Michigan State University, USA; perpdgo@gmail.com; gustavoc@msu.edu

Abstract

The BGLR R-package implements single-trait shrinkage and variable selection models that are routinely used for genomic prediction. The software was first released in 2014 and has been successfully adopted by researchers, with over 1000 monthly downloads from CRAN mirrors. We have recently implemented two additional functions to the package: BLRXy() and Multitrait(). The first function is optimized for genomic prediction problems involving a very large sample size (biobank-size data). The second function implements shrinkage and variable selection models for multi-trait models with structured or unstructured (co)variance matrices. In this note we describe the new functionality added to BGLR, present examples, and benchmarks.

Introduction

The BGLR function of the homonymous R-package (Pérez and de los Campos, 2014) implements Bayesian shrinkage and variable selection models for parametric and semi-parametric regressions (e.g. de los Campos *et al.*, 2013; Meuwissen *et al.*, 2001). The software was originally tailored for single-trait regressions involving many more covariates (p) than sample size (n, i.e. $p>>n$). Many modern data sets, including data from human biobanks and large-scale genomic evaluations, can have a very large sample size (hundreds of thousands of individuals with phenotype and genotype records). In some of these data sets sample size can vastly exceed the number of predictors. In such settings computational performance and speed can be improved by implementing algorithms using summary statistics ($y'y$, $X'X$, and $X'y$) as opposed to algorithms that use phenotypes (y) and incidence matrices (X) directly for computations as it is the case of the BGLR() R-function. Thus, to offer efficient software for biobank-sized data we added to the BGLR package the BLRXy() function which generates posterior samples using summary statistics as inputs; the function has a much faster performance than BGLR when $n>>p$. The second major addition we recently made was the extension of BGLR to multi-trait models. The function Multitrait() implements the same models implemented in the BGLR() function for systems of traits with structured and un-structured (co) variance matrices. In this paper we present new updates for the BGLR package for fitting univariate models for large-sample-size problems and multiple trait models.

Materials & methods

New algorithms for single-trait models when n>>p. Consider a linear regression model of the form: $y = X\beta + \varepsilon$, where $y = (y_1, y_2, \ldots, y_n)'$ is a vector of phenotypes, $\boldsymbol{X} = \{x_{ij}\}, i = 1, \ldots, n; j = 1, \ldots, p$ is a matrix of genotypes, $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)'$ is a vector of model effects, and $\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_n)'$ is a vector of error terms. Under Gaussian assumptions, $\varepsilon_i \sim NIID(0, \sigma_\varepsilon^2)$, the likelihood function is $p(\boldsymbol{y}|\boldsymbol{\theta}) = (2\pi\sigma_\varepsilon^2)^{-\frac{n}{2}} exp\left\{-\frac{1}{2\sigma_\varepsilon^2}(\boldsymbol{y}-\boldsymbol{X\beta})'(\boldsymbol{y}-\boldsymbol{X\beta})\right\}$. Expanding the quadratic form, we can express the likelihood as a function of summary statistics $p(\boldsymbol{y}|\boldsymbol{\theta}) = (2\pi\sigma_\varepsilon^2)^{-\frac{n}{2}} exp\{\boldsymbol{y'y} + \boldsymbol{\beta X'X\beta} - 2\boldsymbol{\beta' X'y}\}$. Since data enters in the posterior distribution only through the likelihood, one can generate posterior samples using computations that are based on the summary statistics ($y'y$, $X'X$, and $X'y$. Sampling from the posterior distribution using algorithms that use the original data {y, X} requires using operators with complexity $O(n)$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_355, © P. Pérez-Rodríguez and G. de los Campos *et al.* 2022

(here n represent sample size); these computations must be repeated for each effect in the model, leading to an algorithm with complexity $O(np)$ per cycle of the sampler. This approach, used in the BGLR() function, does not scale well for problems with $n >> p$. The BLRXy() function generate samples from the posterior distributions using the sufficient statistics {$y'y$, $X'y$, and $X'X$} as inputs; the algorithm has a complexity $O(p)$.

Multitrait models. The other addition we made was the implementation of shrinkage and variable selection methods for multi-trait regressions. The Multitrait() function implements models similar to those implemented in BGLR() for multi-traits models. The function has an user interface and a design similar to that of BGLR(). The response is specified using a matrix (observations in rows, traits in columns, missing values allowed). Predictors are specified using a list, as in BGLR, the user can include more than on term in the linear predictor. Each term can be either a multivariate linear regression (XB) or a matrix (U) of random intercepts (aka 'random effects'). For regression coefficients users can use flat priors ('FIXED'), IID Gaussian priors ('BRR'), or a prior from the spike-slab family (with a points of mass at zero and a multivariate gaussian slab, 'SpikeSlab'). All the priors, and distribution of the error terms, have (co)variance matrices as hyper-parameters. The Multitrait() function offers three specifications for priors on (co) variance matrices: unstructured (in which case and Inverse Whishart prior is used), recursive model, and factor-analytic structure (examples are provided below).

Results

Fitting genomic regressions to biobank-sized data using BLRXy(). We benchmarked the BLRXy() function against BGLR() for a linear regression model of the form $y = X\beta + \varepsilon$, with a Gaussian prior for effects, over a grid of values of sample size (from 10,000 to 250,000) and number of predictors (from 500, to 10,000). Since BLRXy() generates samples using summary statistics {$X'X$, $X'y$, $y'y$}, once these statistics are computed, the time it takes to collect a sample for all the parameters, does not depend on sample size. The left panel in Figure 1 shows the time it takes for BLRXy() to collect 1000 samples from the posterior distribution. The time grows exponentially with the number of predictors, for 10,000 predictors (e.g. SNPs), BLRXy() generates 1000 posterior samples in less than 1.5 minutes. Panel B in Figure 1 shows the time required by BLRXy() to collect 1000 samples relative to the time used by BGLR(). For problems involving $n \sim p$, the algorithm implemented in BLRXy() is approximately twice as fast than BGLR. However, for problems involving $n>p$ the proposed algorithm is one (e.g. 32 times faster, 1/0.032) or two orders of magnitude faster (e.g. 333 times faster, 1/0.003). The code is efficient when $n>p$ and this is the scenario that we want to emphasize in the benchmark.

Multi-trait genomic regression using the Multitrait() function. The scripts presented below shows three of the simplest models that can be fitted using Multirtait(): (1) Panel A shows how to fit a linear regression with a Gaussian prior; (2) Panel B presents an example of a multi-trait pedigree model, finally; (3) Panel C shows a model combining SNPs and pedigree information. By default, since the prior on (co)variance matrices were not specified, the software uses un-structured Inverse-Wishart priors. The Multitrait() function saves samples from the posterior distribution and returns estimates (posterior means and SDs). Samples from the posterior distribution are saved in files with a pre-fix specified in the argument 'save_at'. The estimated error (co)variance matrices, the corresponding posterior SD as well as the prior hyper-parameters used can be retrieved using (exemplifying with fmG) fmG$resCov. Predictions can be retrieved using fmG$ETAHat (this returns a matrix with predictions for observations in rows and traits in columns). Estimated effects can be retrieved using fmG$ETA[[1]]$beta and fmP$ETA[[1]]$u. The entries of fmG$ETA also include the estimated (co)variance matrices and the prior hyper-parameters used.

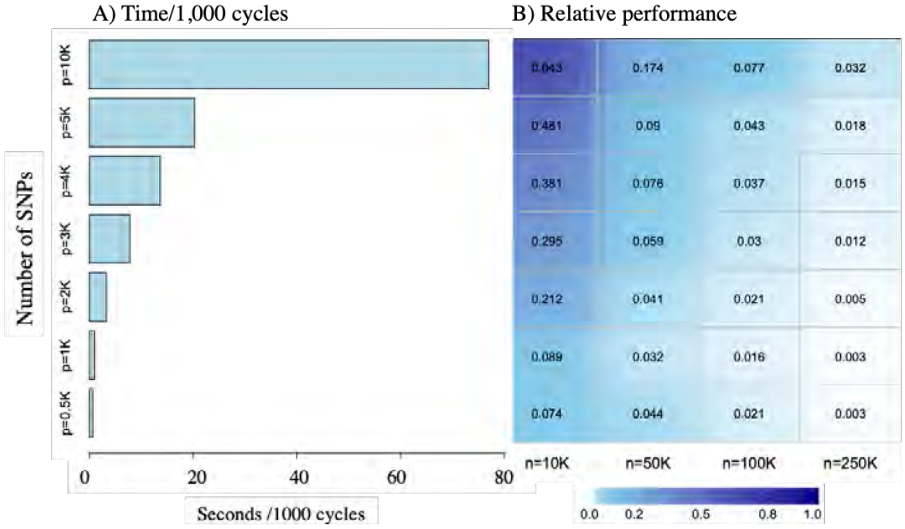

Figure 1. Computational performance BLRXy() and BGLR(). (A) Seconds needed for BLRXy() to generate 1000 posterior samples for a linear model of the form $y = X\beta + \varepsilon$; (B) Time used by BLRXy() to generate 1000 posterior samples, relative to the time used by BGLR() by sample size and number of predictors.

```
library(BGLR); data(wheat); A=wheat.A; X=scale(wheat.X); Y=wheat.Y
#A: Genomic regression
LP1<-list(list(X=X,model='BRR'))
fmG<-Multitrait(y=Y,ETA=LP1,
    nIter=10,000,burnIn=5,000,
    saveAt='snps_')
#B: Pedigree regression
LP2<-list(list(K=A,model='RKHS'))
fmP<-Multitrait(y=Y,ETA=LP2,
      nIter=10,000,burnIn=5,000,
      saveAt='ped_')
#C: Pedigree+SNPs
LP3<-list(list(X=X,model='BRR'),list(K=A,model='RKHS'))
fmG<-Multitrait(y=Y,ETA=LP3, nIter=10,000, burnIn=5,000, saveAt='pg_')
```

We benchmarked the Multitrait() function using a simple model of the form $y = X\beta + \varepsilon$ with a Gaussian prior for marker effects over a grid of values of the number of SNPs (1000 to 10,000), sample size (10,000 to 200,000) and traits (either two or four). The results are summarized in Figure 2.

Discussion

We have presented two important updates that we recently made to the BGLR package. We recommend using the BLRXy() (instead of BGLR()) for problems where sample size exceeds the number of predictors ($n > p$). In the case ($p > n$), it is better to use BGLR. One disadvantage of BLRXy() is that it requires more RAM memory than BGLR() because it requires $X'X$. The Multitrait() function fits for multiple-trait analyses using shrinkage and variable selection priors. Due to space restrictions, we presented only a very small set of the options that these functions offer. The Github repository at https://github.com/gdlc/bglr includes additional examples not covered here, such as models for variable selection.

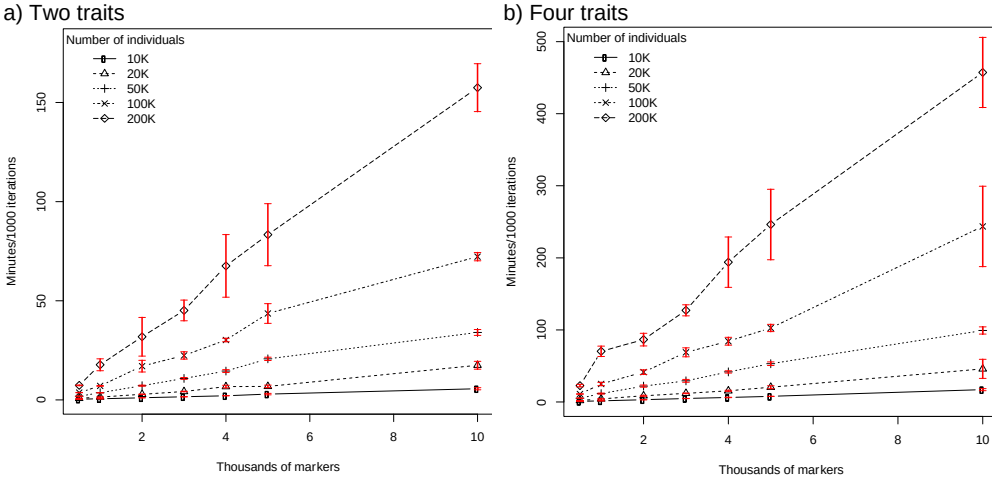

Figure 2. Average time (in minutes) to generate 1000, posterior samples by thousands of SNPs (x-axis) and sample size (K=1000), and number of traits (two or four, in the left and right panels). Intervals correspond to mean ± SD of computing times.

Abstract

We introduce the *SFSI* (Sparse Family and Selection Indices) R-package that offers tools for the solutions to penalized selection indices. We demonstrate how the package can be used to solve three selection index problems: (1) derivation of a selection index using high-throughput phenotype data (crop imaging); (2) single-trait; and (3) multi-trait sparse genomic prediction.

Introduction

The *SFSI* R-package solves penalized regression problems, including LASSO (Tibshirani, 1996), Ridge-Regression (Hoerl and Kennard, 1970), and Elastic Net (Zou and Hastie, 2005). There are several well-established packages available to fit penalized regressions including *glmnet* (Friedman *et al.*, 2010), *lars* (Hastie *et al.*, 2013), and *penalized* (Goeman, 2010). However, unlike other packages, *SFSI* takes as inputs covariance matrices and covariance vectors as opposed to a response vector and a matrix of predictors, which are the standard inputs of other packages. This seemingly small difference enables *SFSI* to solve a variety of problems that cannot be readily solved using standard packages for penalized regressions.

We developed early versions of the package to solve penalized selection indices for indirect selection for a breeding objective using high-dimensional traits (e.g. high-throughput phenotypes) as predictors. We first introduced these methods in Lopez-Cruz *et al.* (2020) and labeled this methodology as sparse selection index (SSI). It turns out that an objective function with the same structure can be used to obtain a sparse solution for genomic prediction. In Lopez-Cruz and De Los Campos (2021), we showed how this approach can be used to produce genomic predictions that rely on information from subsets of the data available for model training.

In the 'Methods' section of this study, we describe the methods implemented in *SFSI* and show how they can be used to derive penalized selection indices for mass selection and sparse single- and multi-trait genomic prediction. Subsequently, in the 'Results' section, we present applications based on real data. We close the article with a discussion on the advantages and limitations of SFSI.

Materials & methods

Consider a linear regression where a response vector, $y = \{y_1, \ldots, y_n\}$, is regressed on p predictors, $\mathrm{X} = \{x_{ij}\}$ (an $n \times p$ matrix), using a model of the form $y = \mathrm{X}\beta + \varepsilon$, where $\beta = \{\beta_1, \ldots, \beta_p\}$ is a p-vector of regression coefficients and $\varepsilon = \{\varepsilon_1, \ldots, \varepsilon_n\}$ is an n-vector of random error terms. In penalized regression, the coefficients are derived by minimizing an objective function that includes the residual sum of squares, $RSS = (y - \mathrm{X}\beta)'(y - \mathrm{X}\beta)$, plus a penalty function which often is the L1-norm: $\sum_{j=1}^{p} |\beta_j|$ (LASSO), the squared L2-norm: $\sum_{j=1}^{p} \beta_j^2$ (Ridge Regression), or a linear combination of the two (Elastic Net). The Elastic Net penalized RSS problem can be expressed as:

$$\hat{\beta} = arg\ \underset{\beta}{min}\left\{\tfrac{1}{2}\beta'\Sigma\beta - \Gamma'\beta + \lambda \mathrm{F}(\beta)\right\} \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_356, © M. Lopez-Cruz *et al.* 2022

where $\Sigma = X'X$, $\Gamma = X'y$, λ is a penalization parameter, and $F(\beta)$ is a penalty function on β given by $F(\beta) = \alpha \sum_{j=1}^{p} |\beta_j| + \frac{1}{2}(1-\alpha)\sum_{j=1}^{p} \beta_j^2$, with α being a number between 0 and 1 controlling the weights of the L1 and L2 penalties. Upon standardization, matrices Σ and Γ can be interpreted as method-of-moments estimates of the covariance matrix of the predictors, and the covariance matrix between predictors and the response, respectively.

In the SFSI package the functions lars2 and solveEN can be used to obtain estimates by solving the optimization problem in Equation 1 taking Σ and Γ as inputs via the Least Angle Regression (Efron *et al.*, 2004) and the coordinate descent algorithm (Friedman *et al.*, 2010), respectively. The fact that we use Σ and Γ as inputs gives *SFSI* great flexibility in terms of the problems that can be solved with it. We provide examples in the following sections.

Application 1: Sparse selection indices for mass selection. A selection index (SI, Hazel, 1943) predicts the genetic value (g_i) of a selection candidate for a breeding objective (y_i) as a weighted sum of p indicator (i.e. measured) traits, $\boldsymbol{x}_i = \{x_{i1}, \ldots, x_{ip}\}$, as $\hat{g}_i = \boldsymbol{w}'\boldsymbol{x}_i$. In a standard SI the weights, $\boldsymbol{w} = \{w_1, \ldots, w_p\}$, are derived by minimizing the mean squared prediction error, $MSPE = \frac{1}{2}\mathbb{E}(g_i - \boldsymbol{w}'\boldsymbol{x}_i)^2 = \frac{1}{2}\boldsymbol{w}'\mathbf{P}_x\boldsymbol{w} - \mathbf{G}'_{xy}\boldsymbol{w}$, wh, where P_x is the phenotypic (co)variance matrix of the measured traits, and G_{xy} is a vector with genetic covariances between the selection objective and each measured trait. The SI methodology was originally developed for problems involving a small number of measured traits. High-throughput technologies can produce thousands of indicator traits (e.g. imaging, sensors, gene expression). This can lead to over-fitting and thus poor accuracy of indirect selection. To address this problem, we (Lopez-Cruz *et al.,* 2020) developed a sparse selection index (SSI) which derives the weights using:

$$\hat{\boldsymbol{w}} = arg\ \underset{\boldsymbol{w}}{min}\left\{\frac{1}{2}\boldsymbol{w}'\mathbf{P}_x\boldsymbol{w} - \mathbf{G}'_{xy}\boldsymbol{w} + \lambda F(\boldsymbol{w})\right\} \quad (2)$$

Above, $F(_w)$ is a penalty function such as the one in Equation 1. To derive an SSI, one needs to: (1) obtain estimates of P_x and G_{xy}; (2) derive the weights $\hat{\boldsymbol{w}}$ by solving Equation 2 (this can be done using the SFSI); (3) evaluate the SSI for the selection candidates, $\hat{\boldsymbol{g}} = \mathbf{X}\hat{\boldsymbol{w}}$, where $X = \{x_{ij}\}$ is the $n \times p$ matrix containing all the measured traits. Once P_x and G_{xy} have been estimated, steps (2) and (3) can be implemented using the following script:

```
fm = solveEN(Px, Gxy, lambda=lambda)
gHat = fitted(fm, X)
```

Application 2: Sparse genomic prediction. In genomic prediction (Meuwissen *et al.*, 2001) via GBLUP the genetic merit of selection candidates (TST=testing) is predicted as a weighted sum of the values of individuals in a training set (TRN=training, y_{TRN}). Indeed, $\hat{\boldsymbol{g}}_{\text{TST}} = \mathbf{W}\boldsymbol{y}_{\text{TRN}}$,, where $\mathbf{W} = \mathbf{G}_{\text{TST,TRN}}(\mathbf{G} + \theta\mathbf{I})^{-1}_{\text{TRN}}$ is an $n_{\text{TST}} \times n_{\text{TRN}}$ matrix of weights with $G_{\text{TST,TRN}}$ being the genetic relationships matrix (GRM) between TST and TRN individuals, $(\mathbf{G} + \theta\mathbf{I})_{\text{TRN}}$ a diagonal-displaced GRM of the TRN set, and $\theta = \sigma^2_\varepsilon / \sigma^2_g$ the residual/genetic variances ratio. GBLUP predictions can be shown to be equivalent to a standard SI where the 'measured traits' are the phenotypes measured in the TRN individuals (Lopez-Cruz and de los Campos, 2021).

The presence of imperfect LD between markers and QTL, non-additive effects, and population structure can make a GBLUP sub-optimal. To deal with this, Lopez-Cruz and de los Campos (2021) proposed an SSI in which the prediction of the i_{th} TST individual is a weighted sum of a subset of the data from the TRN set. Sparsity was achieved by deriving weights using:

$$\widehat{\boldsymbol{w}}_i = arg\ \underset{\boldsymbol{w}_i}{min}\left\{\frac{1}{2}\boldsymbol{w}_i'(\mathbf{G}+\theta\mathbf{I})_{\text{TRN}}\boldsymbol{w}_i - \mathbf{G}_i'\boldsymbol{w}_i + \lambda F(\boldsymbol{w}_i)\right\} \quad (3)$$

where $\mathbf{G}_i = \mathbf{G}'_{\text{TST}(i),\text{TRN}}$ is the i^{th} row of $G_{\text{TST,TRN}}$. These sparse genomic predictions are obtained following the steps: (1) derive the matrix G; (2) estimate the variances ratio θ; (3) determine $G_{\text{TST,TRN}}$, $(G + \theta I)_{\text{TRN}}$, and y_{TRN} from data; (4) derive the weights $\widehat{\boldsymbol{w}}_i$ for each TST subject by solving n_{TST} times the problem in Equation 3 to get $\widehat{\mathbf{W}} = \{\widehat{w}_{ij}\}$; (5) obtain the predictions $\widehat{\boldsymbol{g}}_{\text{TST}} = \widehat{\mathbf{W}}\boldsymbol{y}_{\text{TRN}}$. After obtaining G and θ, steps (3)-(5) can be implemented (for a TST and TRN set indexed with integers vectors) using the *SSI* function as

```
fm = SSI(y,K=G,theta=theta,trn=TRN,tst=TST,lambda=lambda)
gHat = fitted(fm)
```

Application 3: Multi-trait sparse genomic prediction. In a multi-trait genetic model for s traits, $\boldsymbol{y} = \{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s\}$, the (co)variance of the genetic, $\boldsymbol{g} = \{\boldsymbol{g}_1, \ldots, \boldsymbol{g}_s\}$, and residual, $\boldsymbol{\varepsilon} = \{\boldsymbol{\varepsilon}_1, \ldots, \boldsymbol{\varepsilon}_s\}$, terms take the form var(g) = K ⊗ G and var(ε) = R ⊗ I, respectively. Here, K and R are $s \times s$ within-subject genetic and error (co)variances matrices, and ⊗ denotes the Kronecker product. Thus, a small modification of the script presented above can be used derive SSIs for multi-trait problems. After computing G, K and R, step (4) in the single-trait case is performed by replacing G by K ⊗ G, I by R ⊗ I, and making $\theta = 1$. For three traits, y_1, y_2, y_3, this is implemented as:

```
y = c(y1,y2,y3)
KG = kronecker(K,G)
RI = kronecker(R,diag(nrow(G)))
fm = SSI(y,K=KG,theta=1,D=RI,trn=TRN,tst=TST,lambda=lambda)
```

Results & discussion

In the following section we present an application using real data generated by the Pig Improvement Company (PIC, https://www.pic.com). We use this data to illustrate the implementation of the sparse genomic prediction presented in Application 2 in *Methods* section.

The data set comprises weight gain records for n=22,872 pig genotypes and a GRM G constructed from 34,373 SNP markers. We performed sparse predictions for a random 20% (n_{TST}=4,574) of the data using the remaining 80% (n_{TRN}=18,298) for model training. We used 100 different values of λ as in Lopez-Cruz and de los Campos (2021). The accuracy of the predictions $\widehat{\boldsymbol{g}}_{\text{TST}} = \widehat{\mathbf{W}}\boldsymbol{y}_{\text{TRN}}$ was evaluated as the correlation between $\boldsymbol{y}_{\text{TST}}$ and $\widehat{\boldsymbol{g}}_{\text{TST}}$. We also derived the GBLUP (i.e. the SSI with λ=0) using sub-samples consisting of 10, 20, …, 100% of the TRN set. We performed a total of 100 TRN-TST random partitions.

The results in Figure 1A show the prediction accuracy achieved by the SSI as a function of the sparsity of the index (i.e. the number of support points, that is the number of training data points with non-zero weight in the SI). As a reference, the boxplots in the same plot show the prediction accuracy achieved by the GBLUP for the same number of support points selected at random. The results show that including a sparsity-inducing penalty into the genomic prediction framework can provide sparse solutions with the same accuracy while using a reduced number of support points relative to the non-sparse approach. However, the best prediction accuracy achieved in this application was comparable to that of a GBLUP using the maximum sample size available. For other data sets, we have reported results where the SSI gave moderate gains in prediction accuracy (5-10%) over the GBLUP (Lopez-Cruz and De Los Campos, 2021).

Computational considerations: computational cost of implementing these applications depends on the type of the problem. For Application 1, the computational burden is due to the calculation of genetic covariances

G_{xy} (in Equation 2) because this requires fitting a sequence of bi-variate mixed models (as many measured traits). Computing the weights in this problem is not computationally demanding because the weights are solved only once. For Applications 2 and 3, the computational cost of computing an SSI for n_{TST} subjects become expensive as it involves solving n_{TST} penalized problems. However, this type of SSI allows solving each penalized problem independently and, therefore, it can be fully parallelized. The computational time of solving one penalized regression depends on the TRN set size and the value of λ. In a Linux-based system (2.4 GHz Intel Xeon Gold processor, 32 GB of RAM), solving one penalized problem in Equation 1 using n_{TRN}=10,000 training individuals takes on average 2.1 seconds for a very sparse (large λ) model, and around 8.01 seconds for a less sparse (smaller λ) model (Figure 1B).

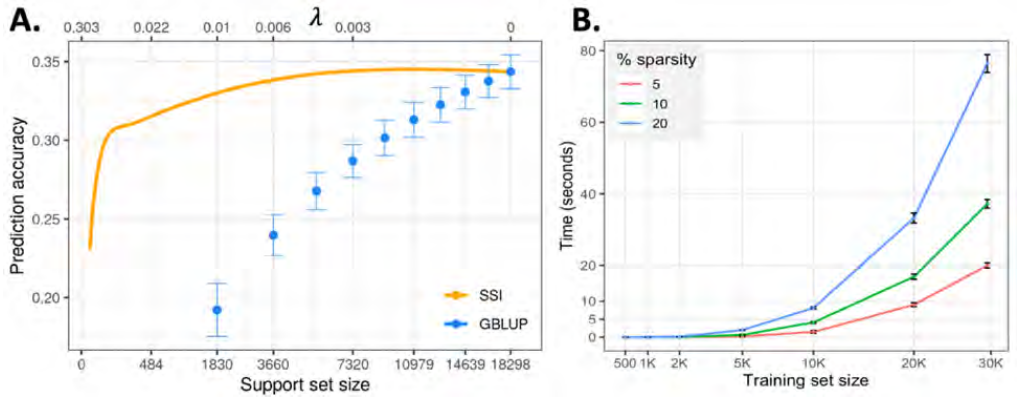

Figure 1. (A) Prediction accuracy of the SSI (orange line) versus the average number of support points given by the value of λ (top x-axis). Blue boxplots correspond to the accuracy of the GBLUP trained with 10, 20, ..., 100% of the TRN set (n_{TRN}=18,298). (B) Average computational time of solving one penalized problem (Equation 1) with the solveEN function by TRN set size and value of λ. Σ ($p \times p$) matrix) and Γ(p-vector) were sampled 100 times from the G matrix for 29,473 subjects used in Lopez-Cruz and de los Campos (2021), for p=500, 1K, 2K, 5K, 10K, 20K, and 29,472. The value of λ was chosen such that the model produced 5, 10 or 20% of sparsity (ratio between number of support points and p).

357. INTERGEN: an efficient and flexible tool for large-scale genetic evaluation of complex animal and plant populations

V.S. Junqueira[1], G.S. Campos[2,3] and F.F. Cardoso[3*]

[1]Bayer Crop Science, Research and Development, BR 452, 38407-049 Uberlândia, MG, Brazil; [2]Departamento de Zootecnia, Universidade Estadual Paulista 'Júlio de Mesquita Filho', Via de Acesso Prof. Paulo Castellane s/n, 14884-900 Jaboticabal, SP, Brasil; [3]Embrapa Pecuária Sul, CP242, 96401-970 Bagé, RS, Brazil; fernando.cardoso@embrapa.br

Abstract

The INTERGEN package contains a wide range of statistical analyses useful for routine genetic evaluations. The package has been under constant development for enabling new models, increasing speed, and improving the efficiency of solving mixed model equations for genetic evaluations. The package was initially developed to perform Bayesian analyses, reaction norm models, multi-breed, and animal models with parentage uncertainty. More recently, it was expanded in version 1.4 to include Best Linear Unbiased Prediction (BLUP) with (or not) genomic information, approximate accuracies, and Iteration on Data (IOD) methods.

Introduction

The INTERGEN package is a collection of Fortran 90/95 routines useful for breeding and genetics analyses. This package contains a wide range of relevant statistical analyses and is currently available in three binaries. The first binary contains functionalities for conducting Bayesian analyses such as parentage uncertainty under multiple sire mating, multi-breed analysis, genotype-by-environment interaction, heterogeneity of residual variances, robustness analysis, genetic merit estimation including (or not) genomic information using mixed model equations, reduced animal model, reaction norm models, and normal prior for fixed effects. The second binary contains routines for approximate accuracies with (or not) genomic information for direct and maternal effects. A third binary is focused on estimating the genetic merit using Iteration on Data (IOD) method.

Materials & methods

The initial development of INTERGEN targeted a novel implementation of a series of analyses for studying genotype-by-environment using reaction norm models with unknown covariates in multi-breed populations with uncertain paternity (Cardoso, 2008). The initial software used several modules (SPARSEM, SPARSEOP, IOUNF, DENSEOP, and Gibbs) from Misztal (1999) useful for handling mixed models (e.g. building, in-memory storage, and solving) using Fortran 77/90 (Misztal 1999, 2002) as starting point. Subsequently, a set of non-public modules, subroutines, and functions were developed to enable below statistical models useful to handle the diversity of management situations found worldwide in livestock genetic evaluations, including:

- animal model with parentage uncertainty and multiple sire mating schemes;
- multi-breed populations;
- heavy-tailed structural models for robust and heterogeneous residual variances;
- reaction norm models with unknown covariates; and
- reduced animal model.

These implementations were made using the MCMC method via Gibbs and Metropolis-Hastings sampling. To our knowledge, no other software combines all these implementations with flexible model specification. Over the past decade, the INTERGEN package has been under constant development for handling

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_357, © V.S. Junqueira *et al.* 2022

additional models commonly used in routine genetic evaluations worldwide. These implementations are listed below:

- use of normal priors for fixed effects;
- mixed-model solutions (BLUE/BLUP) using in-memory equations (Misztal *et al.* 2002);
- threshold models (Gianola 1982);
- genomic module for single step GBLUP (ssGBLUP) models (Aguilar *et al.* 2010);
- routines for calculation of approximate accuracies (Misztal *et al.* 1993, 2013);
- solutions of mixed-models with Iteration-On-Data (IOD) using Preconditioned Conjugate Gradient (PCG) (Misztal 1999; Strandén and Lidauer 1999).

Currently, the INTERGEN package supports analysis using phenotypes, genotypes, and pedigree information. The software is flexible enough to handle complex models including multi-trait (non)correlated traits with additive, maternal, and non-additive effects. Three binaries that made up the software toolkit are: intergen1.4, the most complete option as it contains the majority of the functionalities for running Bayesian analysis and mixed-models considering a wide range of model effects; intergenacc, focused on estimating approximate accuracies; and, finally, intergeniod, relies on IOD methods to solve mixed model equations.

Genomic module. The genomic module contains a mix of sparse and dense matrices depending on the operation step aiming to optimize computing time and performance. The most time-consuming steps of matrices operations (multiplication and inversion) of this module were developed for using parallel programming in a combination of Intel MKL routines and OpenMP.

Computing environment. Intergen is available as a binary compiled under Unix (Linux and Mac) and Windows systems. The compilation of Fortran modules and subroutines are automated through Makefiles (GNU Make 4.2.1). Compilations are currently being done using Intel Ifort (Version 19.1.3.304).

Results

The statistical analyses implemented in INTERGEN have been used routinely for genetic evaluations in Brazil, being the official tool for statistical inference, variance component and genetic merit estimation in Pampaplus (Hereford and Braford) and PROMEBO (Angus, Brangus, Braford, Charolais, Devon and Hereford) programs over the past 6 years. In addition to this commercial use, several research publications have been published over the years in a wide range of species using the package.

As an example, a summary of the performance of the software using phenotypes, genotypes, and pedigree from an Angus dataset for estimating mixed model solutions, exact accuracies (direct inversion of the coefficient matrix), and approximate accuracies are presented in Table 1. Correlation between matrix solving and IOD solutions was 0.99.

The overall correlation between exact and approximate accuracies using Angus weaning weight phenotypes, genotypes, and pedigree was 0.97 and distributions can be seen in Figure 1. Note that approximate accuracies follow a similar trend as exact accuracies.

Discussion

INTERGEN package is freely available for research purposes and as an alternative for commercial genetic evaluations in animals and plants. The list of functionalities of the package is long and detailed information is fully presented in its manual (https://ainfo.cnptia.embrapa.br/digital/bitstream/item/202597/1/DT-153-online.pdf) to enable complex modeling required for running routine genetic evaluations and for research statistical-genetics analyses. The approximate accuracies (intergenacc) and IOD solutions (intergeniod)

Table 1. Description of the dataset used for evaluating the performance for mixed model solutions (GEBV), exact accuracy and approximate accuracy estimation for different beef cattle traits. A total of 5,588 genotyped samples and 106,121 SNPs were used in the analysis.

have very high correspondence to accuracies and solutions obtained by inverting the mixed model equations, being a suitable alternative for large-scale genetic evaluations involving millions of animals and equations.

Software distribution

INTERGEN package is distributed for Linux, Mac, Windows platforms (https://arquivos.cppsul.embrapa.br/downloads/intergen/). The package is free for research purposes but should be cited in publications. The intergenacc and intergeniod are available upon research or commercial agreement. The terms of conditions for commercial use (e.g. routine genetic evaluations) can be obtained from Labegen, Embrapa Pecuária Sul, Bagé, Rio Grande do Sul, Brazil (fernando.cardoso@embrapa.br).

Abstract

The software package MiXBLUP 3.0 allows to efficiently estimate (genomic enhanced) breeding values in livestock using various linear mixed effect models. MiXBLUP aims to be user-friendly while supporting efficient algorithms for solving large genomic evaluations. Originally developed for pedigree-based models, MiXBLUP has been extended to four different approaches for single-step genomic evaluations, allowing simultaneous analyses of all information for both genotyped and ungenotyped individuals. For all approaches, shared-memory parallelism is supported using tailor-made procedures and parallel libraries. It has been tested on some of the largest genomic datasets in the world. The software is developed by Wageningen University and Research in collaboration with the Natural Resources Institute Finland (Luke).

Introduction

During the last decades, the mixed model equations have been used for estimating breeding values in livestock using phenotypes at the traits of interest, together with pedigree. With the advent of genomic selection, the traditional mixed model has been extended to analyse simultaneously phenotypic, pedigree, and genomic information (Legarra *et al.*, 2014). Such models are commonly called single-step genomic models. Currently, genomic information used in routine evaluations contains the genotypes of several (hundred) thousand animals for around 50 thousand single nucleotide polymorphisms (SNP). The integration of such genomic datasets with large numbers of genotyped animals led to new challenges for solving the mixed model equations. Therefore, several approaches for solving the single-step models have been proposed in the literature and implemented in software for large genomic evaluations in livestock (e.g. Mäntysaari *et al.*, 2020).

Since 2006, the MiXBLUP software has been developed for breeding value estimation in commercial genetic programmes. It supports modern developments, such as complex models (e.g. random regression models) or linear-threshold models. With the advent of genomic selection, MiXBLUP has been continuously developed since 2014 to support the use of genomic information through four different single-step genomic approaches. This work aims to present the state-of-the-art of MiXBLUP for large genomic evaluations in animal breeding.

MiXBLUP and its components

MiXBLUP philosophy. The aim of developing MiXBLUP is to utilize efficient computing strategies for solving mixed model equations, while being easy to install and easy to use, even for sophisticated models. For example, MiXBLUP supports a wide range of input files and generates files in the required format for the solvers. So, various formats for the SNP genotype files are supported. When the genotype files are text files, they may contain marker alleles or marker genotypes. The marker alleles or genotypes may be in space-separated or in dense format. MiXBLUP now supports the Plink 1 binary format that requires less memory than text files by taking advantage that only two bits (instead of one byte) are needed to store a biallelic SNP genotype (Chang *et al.*, 2015). Due to this advantage, the Plink 1 binary format is also supported by other programs of the software package MiXBLUP described hereafter.

Being a versatile software, MiXBLUP is used in breeding programmes for cattle, pigs, poultry, sheep, horses, fish, goats, and dogs (ten Napel *et al.*, 2021).

Models supported for breeding value estimation. The statistical method commonly used for routine genetic evaluation is the so-called Best Linear Unbiased Prediction (BLUP). Briefly, a univariate animal model is as follows:

$$y = Xb + Wa + e,$$

where y is the vector of phenotypes, b is the vector of fixed effects, a is the vector of additive genetic effects, and e is the vector of residuals. The incidence matrices X and W relate the phenotypes to the fixed effects and additive genetic effects, respectively.

It is assumed that e follows a multivariate normal distribution, $MVN(0, R\ \sigma_e^2)$ with R being a diagonal matrix, and σ_e^2 being the residual variance, and that a follows a multivariate normal distribution $MVN(0, H\ \sigma_a^2)$ with σ_a^2 being the additive genetic variance. Traditionally, the H matrix was equal to the pedigree-based relationship matrix (A). In single-step genomic BLUP, the H matrix is a relationship matrix that includes the genomic relationship matrix (G) for genotyped animals and modified pedigree relationships for other animals.

Due to limitations related to the computation of G and its inverse (G^{-1}) when the number of genotyped animals is large, some methods were proposed to approximate G^{-1}, such as the algorithm for proven and young animals (APY; Misztal *et al.*, 2014), or to compute G^{-1} implicitly using the Woodbury matrix identity (Mäntysaari *et al.*, 2017). Such models that rely on G will hereafter be referred to as single-step genomic BLUP (ssGBLUP). Another proposed approach to avoid the computation of G or G^{-1}, is to augment the solution vector of the mixed model equations with SNP effects. The SNP effects can be fitted explicitly or implicitly in the underlying model as random effects (e.g. Liu *et al.*, 2014). Such models will hereafter be referred to as single-step SNPBLUP (ssSNPBLUP).

In addition to the original ssGBLUP for which G is explicitly inverted, the software MiXBLUP supports two ssGBLUP-based and one ssSNPBLUP approaches. For all approaches, a residual polygenic (RPG) effect that considers the part of the additive genetic effects not explained by the genomic data (Mäntysaari *et al.*, 2020) can be fitted.

First, MiXBLUP supports the algorithm for proven and young animals (APY; Misztal *et al.*, 2014). This algorithm approximates G^{-1} by dividing the genotyped animals into a limited set of so-called core animals, and the remaining genotyped animals are noncore. The computation of $\mathbf{G}_{APY}^{-1}$ involves the inversion of a genomic relationship submatrix among the core animals and the recursive computation of other coefficients for noncore animals.

Second, MiXBLUP supports the computation of the so-called T matrix, needed for an implicit inversion of G using the Woodbury matrix identity (ssGTABLUP; Mäntysaari *et al.*, 2017). Briefly, when an RPG effect is fitted, G has the form $G = ZBZ' + wA_{gg}$, where Z is a matrix of centered SNP genotypes, B is a diagonal matrix with diagonal entries scaling the genetic variance, w is the proportion of the RPG effect, and A_{gg} is the pedigree-based relationship matrix among genotyped animals. According to the Woodbury matrix identity:

$$G^{-1} = 1/w\ A_{gg}^{-1} - TT' \quad (1)$$

where $T = 1/w\ L^{-1}\ Z'A_{gg}^{-1}$, with L being the Cholesky factor of $K = (1/w\ Z'\ A_{gg}^{-1}Z + B^{-1})$.

In practice, G^{-1} is not computed explicitly, because the MiXBLUP iterative solvers only require its multiplication by a vector, which can be computed efficiently in multiple parts by using the matrices A_{gg}^{-1} and T (Mäntysaari *et al.*, 2017).

Third, MiXBLUP supports the ssSNPBLUP system proposed by Liu *et al.* (2014). This system has the specificity that the random SNP effects are not explicitly fitted in the model. Indeed, the solution vector that includes traditionally fixed and random effects is augmented with the SNP effects, and an inverse of the (co)variance matrix associated with the random additive genetic and SNP effects is derived. It has been shown that the absorption of the equations associated with the SNP effects results in the ssGTABLUP system (Mäntysaari *et al.*, 2020).

The MiXBLUP software provides several options for modelling base populations, such as the concept of metafounders (Legarra *et al.*, 2015), and genetic groups. Different options for scaling genomic relationships to the same base as pedigree-based relationships are also available.

Data processing. Since the users can provide a wide range of data file formats, MiXBLUP will first convert all data files in a format that its two solvers and other programs can read. Indeed, once converted, MiXBLUP will call different parallel programs for computing the various matrices required by the solvers. For example, MiXBLUP will call the program calc_grm, which has an important role in single-step genomic evaluations because it computes relationship matrices for single or multiple, related or unrelated base populations.

Two different solvers. The MiXBLUP software supports two different solvers. The default solver is derived from the MiX99 software (Lidauer *et al.*, 2019). This software was initially developed for pedigree-based genetic evaluations by the National Resources Institute Finland (Luke). With the advent of genomic selection, specifically the single-step models, both software MiX99 and MiXBLUP were adapted for using genomic information simultaneously with pedigree and phenotypic information. The MiX99 software is optimized for solving pedigree-BLUP, ssGTABLUP, and ssGAPYBLUP.

Recently, a solver called hpblup (Vandenplas *et al.*, 2020) was developed within the consortium Breed4Food and added to MiXBLUP. This program was specifically developed and optimized for solving the ssSNPBLUP system of Liu *et al.* (2014).

Computations. For efficient computations, both solvers support shared-memory parallelism through the OpenMP API (www.openmp.org) and various parallelized libraries. Furthermore, both solvers use the preconditioned conjugate gradient (PCG) algorithm as an iterative method. The program hpblup also supports a two-level PCG algorithm for efficiently solving the ssSNPBLUP linear system (Vandenplas *et al.*, 2020).

The main computational cost of a PCG iteration is the multiplication of the coefficient matrix of a system of equations by the so-called direction vector. For both solvers, this multiplication is performed in three main steps (in different orders for each solver). The first step is the multiplication of the least square part of the coefficient matrix by a vector; the second step involves all multiplications of matrices related to pedigree information, and the third step involves all multiplications of matrices related to genomic information. This third step is usually the most computationally expensive for large evaluations, and shared-memory parallel computing has been implemented in both solvers to improve their efficiency. For ssGAPYBLUP and ssGTABLUP, the computations related to genomic information mainly rely on parallel libraries, such

as the Intel Math Kernel Library. For ssSNPBLUP, a tailor-made parallel procedure has been developed for the multiplication of the genotype matrix by another matrix, while keeping the genotype matrix in the Plink 1 binary compressed format (Vandenplas *et al.*, 2020). More details in the different computations of both solvers can be found in Strandén *et al.* (1999), Mäntysaari *et al.* (2017), Lidauer *et al.* (2019), and Vandenplas *et al.* (2020).

Other programs. In addition to the two solvers, MiXBLUP also includes other programs such as calc_grm, MiXPRED, and reliabilities.exe. The program calc_grm is a program for computing pedigree and genomic relationship matrices, their inverses, or some related matrices, such as $\mathbf{G}_{APY}^{-1}$ and T. This program is also used for converting a text genotype file into Plink 1 binary files, and *vice versa*. The program MiXPRED allows the computation of interim GEBV of newly genotyped animals based a decomposition of the GEBVs obtained from a previous single-step evaluation into its different components, namely the direct genomic breeding values, the residual polygenic effects, and if fitted, other effects such as the genetic groups. The program reliabilities.exe allows the computation of approximated reliabilities for all animals in an evaluation, based on the algorithm of Tier and Meyer (2004).

System requirements and availability. The MiXBLUP software is available for Microsoft Windows and Linux/Unix environments and can be downloaded from the website www.mixblup.eu. MiXBLUP works with a license, which can be ordered through its website. More information can be found on www.mixblup.eu.

Abstract

Precision livestock farming tools, such as sensor and automation techniques, enable animal breeders to define novel traits. New challenges are data storage and handling and the development of genetic evaluation. Traditionally, the development of genetic evaluation for novel traits requires several steps, i.e. data curation, trait definition, variance component estimation (ASReml), genetic evaluation (MiXBLUP), and validation of the estimated breeding values (EBVs), requiring many iterations to optimize the genetic evaluations. We combined these steps in a cloud solution to make this entire process more efficient. An experiment was run with 1,782,373,113 daily milk yield records of 1,120,550 cows, all the way from data curation to trait definition and validation of the EBV. The resulting wall-time, i.e. elapsed actual time from start to finish of the entire process, was ~23 hours. The flexible cloud solution can be easily modified or adapted to develop novel traits.

Introduction

The increasing use of sensor and automation technology in livestock farming, for example, to monitor animal health and welfare in cows (Smith *et al.* 2006; Matthews *et al.* 2016; Ouweltjes *et al.* 2021), enable the development of new phenotypes and (complex) traits. The data these sensors generate can be both unstructured non-relational data, including camera or video images, and (non-standardized) structured data, like relational databases (Structured Query Language-SQL). Moreover, sensors are recording in real-time and generate large volumes of data, particularly when recording is done over a long period of time. Big data lakes have emerged as cloud infrastructures that effectively manage these data types, where it is needed to store, manage, access, and process large volumes of a wide range of structured, semi-structured, or unstructured data sources in raw format. In addition, different tools and resources are available in the cloud environment that can interact with such a data lake storage. Such tools and resources include platforms to transform, filter, and structure the data sources, making the cloud environment in combination with a data lake storage both flexible and scalable. Data lake storage can utilise the potential of large volumes of sensor data (Schokker *et al.* 2020). In animal breeding programmes, the challenge lies in utilizing these (novel sensor) data sources to identify the best parents for the next generation. Going from raw (sensor) data to genetic evaluation involves many steps. These pre-processing steps include reading in the data, followed by filtering, transforming, joining and aggregating the data, and writing the output (Gengler 2019). The genetic evaluation includes steps like generating subsets of the data to estimate genetic parameters, and predict breeding values (EBV) and their reliabilities. These downstream steps are performed with different software packages, often in different computing infrastructures. Also, after the final EBV validation, the whole process often has to start again with model adjustments or different data curation. In this study, we combined the entire process in a single cloud environment, linking all the different steps from pre-processing up to the genetic evaluation. As a feasibility experiment, we applied the pipeline to 1,782,373,113 daily milk yield records of 1,120,550 cows to define and evaluate a resilience trait.

Materials & methods

Design of cloud environment. We designed and built a custom-made cloud solution that suited our needs to perform all required steps to get from raw (sensor) data to genetic evaluation in a single cloud environment (Figure 1). The focus of this paper is on the infrastructure of this cloud solution.

Within the cloud-environment we employed a BLOB (binary large object) storage because this has tiered flexible storage and scale-up on performance-driven computing. This BLOB storage was linked to other data analytics resources, i.e. Databricks and our customised Docker containers for variance component estimation, genetic evaluation, and validation of the estimated breeding values. Databricks is an Apache Spark-based analytics service designed for data science and data engineering (Zaharia *et al.* 2016), and therefore, well-equipped to handle the nearly two billion milk yield records. Within the Databricks platform, we generated a pre-processing script for the raw (milk yield) data. Such an Extract, Transform, and Load (ETL) procedure is crucial for an easy and flexible scale-up of the process. This whole ETL procedure was written in Python (v3.7.3) and uses Apache Spark (v3.1.1) in the background for efficiency. For the subsequent genetic evaluation, we have used container technology, i.e. Docker.

Experiment. We intended to build the cloud solution for an existing genetic evaluation, so we used the dairy cattle dataset described by Poppe *et al.* (Poppe *et al.* 2020) as a case study. This dataset contained 1,782,373,113 milk yield records from 1,120,550 cows. Additionally, we used the pedigree and date of birth for those animals, which were necessary to curate a dataset for breeding value estimation. We calculated a potential resilience indicator trait from the milk yield records: natural log of the variance of deviations from the lactation curve, as defined by Poppe *et al.* (Poppe *et al.* 2020). This resilience indicator described the fluctuations in a frequently measured trait, here milk yield. This highly frequent sensor and automation data correspond to the developments in data collection. The ETL procedure was set-up in such a way to easily modify the criteria for filtering the data, including: (1) the milking system (automated or conventional); (2) parity (1, 2, >3); (3) breed; and (4) breed percentage.

Pre-processing. The whole pre-processing, i.e. ETL procedure, was performed within Databricks (https://azure.microsoft.com/en-us/services/databricks/), which we deployed on a computer cluster. We set the cluster with the following specification: the driver and workers all had 56 GB Memory and 16 cores, where

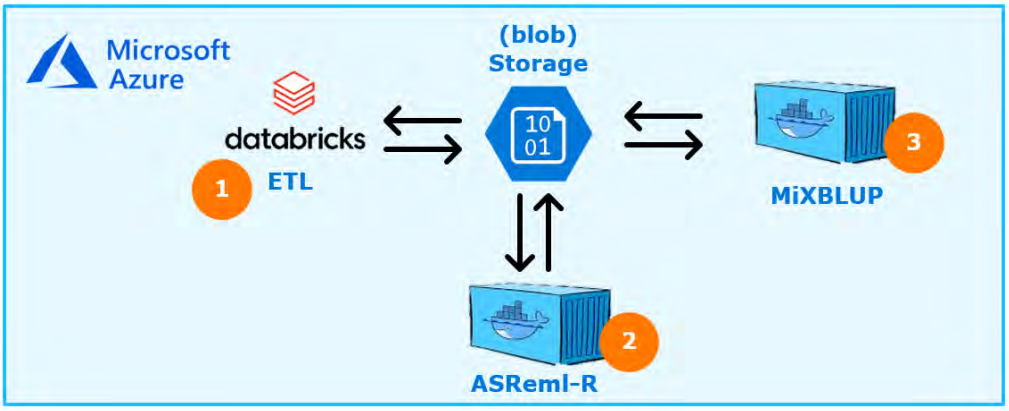

Figure 1. Schematic overview of the infrastructure and resources used in our cloud environment, i.e. Microsoft Azure. Four different modules could interact with the central BLOB (binary large object) storage: (1) pre-processing via Databricks; (2) Docker container with ASReml-R software; and (3) Docker container with MiXBLUP software.

the number of workers may vary from a minimum of 2 to a maximum of 8. Applying the data editing steps using the ETL procedure resulted in 352,871 cows with a resilience trait for at least one of the three lactations in the experiment.

Estimation of genetic parameters. For the estimation of the variance components, first a dedicated Docker (https://www.docker.com/) container was setup within our environment that could communicate via the central (blob) storage. This first Docker container, with Linux operating system, had installed ASReml-R (v4.1.0.110) (Butler *et al.* 2017), and for calculations we used a virtual machine with 2 GPU and 4 CPU cores with 112 GB Memory. Variance estimation is known to be computational intensive, therefore the pre-processed dataset, i.e. 352,871 cows, was split into five random subsets. We obtained five estimates for the heritability and genetic correlations among the three lactations.

Genetic evaluation. In the second Docker container, also with Linux operating system, we installed MiXBLUP v2.2 (ten Napel *et al.* 2017). For the calculations, we used a virtual machine with 4 CPU cores and 16 GB Memory. The model used in MiXBLUP was the same as the model used in ASReml-R. Now the full dataset, i.e. 1,120,500 cows, could be used for the final EBV calculation. From the full pedigree, we build a tailored pedigree starting with the cows present in the pre-processed data and adding five generations of male and female ancestors. We analysed the data using a statistical model with herd-year-season and lactation length as fixed effects, and cow as a random effect (Poppe *et al.* 2020).

Results

For the pre-processing step (ETL procedure) the parameters were set to include automated milking system, parities 1, 2, >3, and the breed Holstein-Friesian with a breed percentage of >75%. The wall-time, the elapsed time from the beginning to the end of the entire process, was approximately 23 hours. Table 1 shows the wall-time for each specific step.

Discussion

We demonstrated that by using a cloud solution we can go from (raw) sensor data to a trait of interest and perform the accompanying genetic evaluation and validation in approximately 23 hours, when processing a very large dataset of more than 1.7 billion milk records from more than 1,000,000 cows. Our results are promising, especially because the expanded use of sensors in the livestock sector will generate an ever-increasing volume of data, either unstructured or structured. This procedure will allow quick alterations in the pre-processing of the data to be tested and validated, therefore, optimizing the time to the final implementation of genetic evaluations using sensor data. The gain is in the generic tools for the data pre-processing and then the 'easy push of a button' for variance component estimation and breeding value estimation, something that often requires a lot of manual work. Our cloud solution enables scalability and flexibility in the cluster computing environment. Examples for scalability include upscaling and downscaling of IT requirements when needed. The flexibility allows easily sharing data, scripts, and results with your collaborators. Implementing the genetic evaluation and validation software in our cloud infrastructure, while avoiding data transferring from one system to another was challenging. Moreover, due

Table 1. Wall-time for each step.

Step	Wall-time (h)
Pre-processing	6
Estimation of genetic parameters	16.5
Genetic evaluation	0.5

to the nature of the cloud infrastructure, it becomes possible to run various genetic evaluations in parallel. For example, estimating breeding values with different models and calculating approximate reliabilities and yield deviations. Another possibility is to run the pre-processing procedure on different clusters, simultaneously, where small but relevant changes in the script can change the outcome of the feature of interest, e.g. specifying the number of parities to include, or what genotype to focus on, or specifying a period in time. These proposed workflows could decrease the wall-time, thus making this process more efficient.

360. Indirect genomic prediction reduces computational costs in large-scale single-step evaluations

I. Strandén[1*], J. ten Napel[2], R.F. Veerkamp[2], R. Evans[3], S. Naderi[3], E.A. Mäntysaari[1] and J. Vandenplas[2]

Abstract

Computing time and memory requirements increase with single-step methods to estimate genomic breeding values when the number of genotyped animals increases. Computational costs can be reduced by omitting genotypes of animals without phenotype and progeny, often the candidate animals for selection. Indirect prediction of a candidate animal GEBV can be based on the animal's genotype and SNP marker solutions (DGV). Alternatively, the sum of DGV and residual polygenic (RPG) effect can be computed, denoted GRV (Genomic and Residual polygenic Value). We applied indirect genomic prediction for a 6 trait calving difficulty evaluation. There were 1.50 million genotyped animals of which 36% were considered candidate animals. Based on our results, DGV showed high accuracy but also bias due to omitting the RPG effect. The GRV prediction had high accuracy and low bias. Computing time was reduced by 33%.

Introduction

Practical implementation of single-step genomic BLUP (ssGBLUP; Aguilar *et al.* 2010; Christensen and Lund 2010) has met many challenges (e.g. Mäntysaari *et al.* 2020; Misztal *et al.* 2020). Continual increases in volumes of genotyped animals also increase the computational costs. A practical aspect seldom considered is the efficient calculation of genomic estimated breeding values (GEBV) for genotyped animals without own and progeny information, so called candidate animals. Excluding these genotypes in the evaluation and estimating their GEBVs afterwards may reduce computational costs (Tsuruta *et al.* 2021). Including these genotypes in the routine evaluation may even be undesirable (Koivula *et al.* 2018). Liu *et al.* (2016) presented formulas for predicting GEBVs of genotyped candidate animals when the model has a residual polygenic (RPG) effect. The aim of this study was to compare the performance of approaches for indirect estimation of GEBV for genotyped candidate animals.

Materials & methods

The ssGTABLUP approach. Mäntysaari *et al.* (2017) presented an efficient computational approach for ssGBLUP named ssGTABLUP where the genomic relationship matrix has the form $\mathbf{G}_C = \mathbf{G}_0 + \mathbf{C}$. Here, $\mathbf{C} = w\mathbf{A}_{gg}$, w is the RPG proportion and $\mathbf{A}_{gg}$ is the pedigree-based relationship matrix among the genotyped animals. The genomic part is $\mathbf{G}_0 = \mathbf{ZBZ}'$ where Z is an $n \times m$ matrix of centered marker genotypes, B is an $m \times m$ diagonal scaling matrix, n is the number of genotyped animals and m is the number of SNP markers. In the VanRaden (2008) method 1, the centering uses base population allele frequencies $p_i, i = 1, \ldots, m$ and the scaling matrix is $\mathbf{B} = \mathbf{I}\frac{1-w}{k}$ with the scaling constant $k = 2\sum_{i=1}^{m} p_i(1-p_i)$.

The $\mathbf{G}_C^{-1}$ matrix in the model equations (MME) can be calculated as $\mathbf{G}_C^{-1} = \frac{1}{w}\mathbf{A}_{gg}^{-1} - \frac{1}{w^2}\mathbf{A}_{gg}^{-1}\mathbf{ZK}^{-1}\mathbf{Z}'\mathbf{A}_{gg}^{-1}$ where $\mathbf{K} = \frac{1}{w}\mathbf{Z}'\mathbf{A}_{gg}^{-1}\mathbf{Z} + \mathbf{B}^{-1}$ is a symmetric positive definite matrix. In practice, iterative methods can be used to solve the MME where the $\mathbf{G}_C^{-1}$ matrix is not explicitly computed and the needed product $\mathbf{G}_C^{-1}\mathbf{v}$ is computed efficiently (Mäntysaari *et al.* 2020).

Let vector $\mathbf{u}_g$ ($\mathbf{u}_n$) have the single-step estimates for the genotyped (non-genotyped) animals. Assuming an RPG effect, the GEBVs for non-genotyped and genotyped animals can be decomposed as (Fernando *et al.* 2014; Fernando *et al.* 2016; Liu *et al.* 2016):

$$\mathbf{u} = \begin{bmatrix}\mathbf{u}_n \\ \mathbf{u}_g\end{bmatrix} = \begin{bmatrix}\mathbf{A}_{ng}\mathbf{A}_{gg}^{-1}\mathbf{Zg} + \boldsymbol{\epsilon} + \mathbf{d}_n \\ \mathbf{Zg} + \mathbf{d}_g\end{bmatrix} = \begin{bmatrix}\mathbf{A}_{ng}\mathbf{A}_{gg}^{-1}\mathbf{Zg} \\ \mathbf{Zg}\end{bmatrix} + \begin{bmatrix}\boldsymbol{\epsilon} \\ \mathbf{0}\end{bmatrix} + \begin{bmatrix}\mathbf{d}_n \\ \mathbf{d}_g\end{bmatrix} \quad (1)$$

where $\mathbf{A}_{ng}$ is the pedigree-based relationship matrix between the non-genotyped and genotyped animals, ε is the imputation residual, vector: $\mathbf{d} = \begin{bmatrix}\mathbf{d}_n \\ \mathbf{d}_g\end{bmatrix}$ corresponds to RPG, the part of the genetic effects not explained by the genomic data (Christensen and Lund 2012). Thus, genotyped animal GEBV has two components: (1) Zg, that is the direct genetic value (DGV) due to the marker effects; (2) d_g, that is the breeding value due to the RPG effect.

Indirect GEBVs of genotyped animals without own and progeny information. Computational costs in any ssGBLUP can be reduced using a two-step algorithm: (1) calculate GEBV without the candidate animals; (2) predict GEBV of the candidate animals. According to Equation 1, we need to compute $\hat{\mathbf{u}}_c = \mathbf{Z}_c\hat{\mathbf{g}} + \hat{\mathbf{d}}_c$ where subscript *c* refers to the candidate animals. The marker solutions can be easily calculated in ssGTABLUP after solving the MME using the formula $\hat{\mathbf{g}} = \frac{1}{w}\mathbf{K}^{-1}\mathbf{Z}'\mathbf{A}_{gg}^{-1}\hat{\mathbf{u}}_g$ (Liu *et al.* 2014).

Calculation of DGV for a candidate animal is straightforward but the RPG effects $\hat{\mathbf{d}}_c$ are unknown. According to Liu *et al.* (2016), $\hat{\mathbf{d}}_c = \mathbf{A}_{cg}\mathbf{A}_{gg}^{-1}\hat{\mathbf{d}}_g$ where $\hat{\mathbf{d}}_g = \hat{\mathbf{u}}_g - \mathbf{Z}\hat{\mathbf{g}}$ and $\mathbf{A}_{cg}$ is the pedigree-based relationship matrix between the genotyped candidate animals and the genotyped animals already included in the single-step evaluation. Calculation of $\hat{\mathbf{d}}_c$ can be done in two steps. First, $\mathbf{x} = \mathbf{A}_{gg}^{-1}\hat{\mathbf{d}}_g$ which can be done efficiently using sparse matrices (Strandén *et al.* 2017). Second, $\hat{\mathbf{d}}_c = \mathbf{A}_{cg}\mathbf{x}$ which can be computed efficiently (Colleau 2002) using the full pedigree-based relationship matrix times vector product:

$$\begin{bmatrix}\mathbf{b}_n \\ \mathbf{b}_g \\ \hat{\mathbf{d}}_c\end{bmatrix} = \begin{bmatrix}\mathbf{A}_{nn} & \mathbf{A}_{ng} & \mathbf{A}_{nc} \\ \mathbf{A}_{gn} & \mathbf{A}_{gg} & \mathbf{A}_{gc} \\ \mathbf{A}_{cn} & \mathbf{A}_{cg} & \mathbf{A}_{cc}\end{bmatrix}\begin{bmatrix}\mathbf{0} \\ \mathbf{x} \\ \mathbf{0}\end{bmatrix}.$$

Data and models. The data and associated variance components were extracted from the 6 trait calving difficulty evaluation for Irish beef cattle performed by ICBF. There were 9.54 million animals in the pedigree file of which 5.76 million had a data record. There were 50,240 SNP markers available from 1.50 million genotyped animals. The animals had been genotyped using the Illumina Bovine SNP50 Bead Chip (Illumina, San Diego, CA). The MME had 123.32 million unknowns of which 114.50 million were additive and maternal genetic effects.

Study design. GEBVs were estimated with two data sets. The full data had all genomic information. In the reduced data, genomic information from the candidate animals were removed. There were 533,116 candidate animals, i.e. the reduced data had 965,868 genotyped animals. For both evaluations, the genomic relationship matrix was based on VanRaden method 1 with a 20% RPG proportion. The Z matrix was centered using base population allele frequencies estimated by the Bpop program (Strandén and Mäntysaari 2020).

Candidate animal GEBV was estimated by three approaches: (1) PA: mean of parent GEBVs; (2) DGV: $\mathbf{Z}_c\hat{\mathbf{g}}$ using estimated SNP marker effects $\hat{\mathbf{g}}$ from the reduced data analysis; and (3) GRV: formula $\mathbf{Z}_c\hat{\mathbf{g}} + \mathbf{A}_{cg}\mathbf{A}_{gg}^{-1}\hat{\mathbf{d}}_g$. Comparison of these candidate animal GEBV with the full data GEBV for the direct and maternal effects was based on a Pearson correlation, linear regression, and level bias for each trait separately. Regression was from the full data GEBV on the reduced data GEBV. Level bias for trait *j* was defined as average of $(\hat{\mathbf{u}}_c - \hat{\mathbf{u}}_{c,full})/\boldsymbol{\sigma}_j$ where $\hat{\mathbf{u}}_c$ and $\hat{\mathbf{u}}_{c,full}$ are GEBV from the reduced and full data analysis, respectively, and σ_j is genetic standard deviation of the trait.

Solver. The ssGTABLUP MME were solved using preconditioned conjugate gradient (PCG) iteration by MiX99 software with 10 CPU threads (Strandén *et al.* 2018). The PCG method was assumed to be converged when $\sqrt{(\mathbf{Cs}^{[k]}-\mathbf{r})'(\mathbf{Cs}^{[k]}-\mathbf{r})/\mathbf{r}'\mathbf{r}} < 10^{-7}$ where C is the coefficient matrix of MME, $\mathbf{s}^{[k]}$ is vector of solutions at round *k*, and r is the MME right-hand side vector.

Results

Preprocessing and solver computing times were reduced effectively in the same proportion as the number of genotyped animals used in the full vs reduced data (Table 1). For the non-candidate animals and both the direct and maternal effects, correlations in GEBV between the full and the reduced evaluations were between 98.9 and 99.8% for the genotyped animals and between 99.0 and 99.6% for the non-genotyped animals across traits. The indirect GEBVs approximated by GRV gave the highest correlations, the lowest level biases, and no over- or under-dispersion (i.e. regression coefficient close to: (1), across all traits and genetic effects (Table 2 and 3). In comparison, DGV had correlations close to 1 (on average 0.97), but the regression coefficients indicated under-dispersion and level biases were higher.

Discussion

Computing time was reduced effectively by omitting genotypes of candidate animals because their number was large. In the indirect GEBV prediction, DGV showed high accuracy but consistent bias due to omitting the RPG contribution. In contrast, GRV gave high correlations and low bias. When the RPG weight is smaller than in our study (e.g. 5%), DGV and GRV are likely to give similar values. The GRV approach can also be used in intermediate GEBV prediction of newly genotyped animals when the full data single-step evaluations are performed at longer intervals such as once every 4 months.

Table 1. Statistics of solving ssGTABLUP using the full and reduced data.

Data	Pre time[1]	RAM[2]	N[3]	Solver time	Indirect time	Total time
Full	9.6h	592	665	12.2h	-	21.8h

361. Accounting for trait-specific genomic and residual polygenic covariances in multivariate single-step genomic evaluation

K. Meyer

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, Armidale, 2351, Australia; kmeyer@une.edu.au

Abstract

For multivariate, single-step genomic best linear unbiased prediction analyses fitting a breeding value model, it is often assumed that the proportions of total genetic variance accounted for by genomic markers and residual polygenic effects are the same for all traits. Different covariance matrices for the two types of genetic effects are readily taken into account by fitting them separately. However, this can lead to slow convergence rates in iterative solution schemes. We propose an alternative computing strategy which – exploiting a canonical transformation – allows for trait-specific covariances whilst directly fitting total genetic effects only. Its effects on convergence rates and gains in accuracy and bias of genomic evaluation compared to analyses assuming proportionality of covariance matrices are examined using a small simulation study. Results show comparatively little improvement in accuracies but worthwhile reductions in overdispersion of predicted genetic merits for genotyped individuals without phenotypes.

Introduction

With the advent of genomic evaluation, it was quickly recognised that the single nucleotide polymorphism (SNP) markers available do not necessarily explain all genetic variation. This can be accounted for by adding a 'residual polygenic' (RPG) effect to the model of analysis fitted (e.g. Jensen *et al.*, 2012). For univariate single-step analyses fitting a breeding value model (ssGBLUP) an equivalent alternative is to replace the genomic relationship matrix, G, with λG + (1 – λ)A_{22}, its weighted average with A_{22}, the submatrix of the numerator relationship, A, for genotyped animals and $\lambda \in [0,1]$ the proportion of the genetic variance attributed to SNP effects. This is readily extended to multivariate analyses if it can be assumed that Σ_G and Σ_A, the covariance matrices due SNP and RPG effects, are proportional.

This paper describes a computing strategy for ssGBLUP exploiting a transformation to canonical scale to avoid fitting a separate RPG effect when this does not hold, i.e. when $\Sigma_G \neq \Sigma_A$ (for c a constant). In addition, a small simulation study is presented to evaluate the potential advantages of accounting for trait-specific weighting of the two sources of genetic variation.

Computing strategy

Consider a multivariate linear mixed model for t traits:

$$y = Xb + Zu + e \tag{1}$$

with y, b, u and e denoting the vectors of observations, fixed effects, additive genetic effects and residuals and design matrices X and Z. Let genetic effects be ordered by traits within individuals so that u can be partitioned into parts for n_1 non-genotyped (u_1) and n_2 genotyped (u_2) individuals. This gives the mixed model equations (MME)

$$\begin{bmatrix} X'R^{-1}X & X'R^{-1}Z \\ Z'R^{-1}X & Z'R^{-1}Z + A^{-1} \otimes \Sigma_U^{-1} + \Delta \end{bmatrix} \begin{bmatrix} \hat{b} \\ \hat{u} \end{bmatrix} = \begin{bmatrix} X'R^{-1}y \\ Z'R^{-1}y \end{bmatrix} \tag{2}$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_361, © K. Meyer 2022

with $\Sigma_U = \Sigma_G + \Sigma_A$ the matrix of (total) genetic covariances between traits and the non-zero block of Δ containing the 'add-on' for genotyped individuals, arising from the inverse of the joint relationship matrix for genotyped and non-genotyped individuals, H (Aguilar *et al.*, 2010).

$$\Delta = \begin{bmatrix} 0 & 0 \\ 0 & \Delta_G - \mathrm{A}_{22}^{-1} \otimes \Sigma_U^{-1} \end{bmatrix} \tag{3}$$

For $\Sigma_G = c\Sigma_A$,

$$\Delta_G = (\lambda \mathrm{G} + (1-\lambda)\mathrm{A}_{22})^{-1} \otimes \Sigma_U^{-1} \tag{4}$$

i.e. a single matrix inverse of size $n_2 \times n_2$ suffices to obtain Δ_G. More generally, however, when $\Sigma_G \neq c\Sigma_A$, Δ_G is not separable and

$$\Delta_G = (\mathrm{G} \otimes \Sigma_G + \mathrm{A}_{22} \otimes \Sigma_A)^{-1} \tag{5}$$

so that the inverse of a matrix of size $tn_2 \times tn_2$ is needed. This can impose a considerable computational burden and become prohibitive for larger numbers of traits or genotyped animals.

Canonical transformation. For two conforming, symmetric matrices, Σ_1 positive definite and Σ_1 positive semi-definite, there exist a matrix Q so that $\mathrm{Q}\Sigma_1\mathrm{Q}' = \mathrm{I}$ and $\mathrm{Q}\Sigma_2\mathrm{Q}' = \mathrm{D}$ with D a diagonal matrix with elements, d_k, equal to the eigenvalues of $\boldsymbol{\Sigma}_1^{-1}\boldsymbol{\Sigma}_2$ (Anderson, 1958) and I an identity matrix. Q defines the so-called transformation to canonical scale which has seen considerable use to simplify multivariate linear mixed model analyses (e.g. Ducrocq and Besbes, 1993; Meyer, 1985). For $\mathrm{Q}\Sigma_G\mathrm{Q}' = 1$ and $\mathrm{Q}\Sigma_A\mathrm{Q}' = \mathrm{D}$, we can factor Δ_G into three terms:

$$\boldsymbol{\Delta}_G = [\mathbf{I} \otimes \mathbf{Q}'](\mathbf{G} \otimes \mathbf{I} + \mathbf{A}_{22} \otimes \mathbf{D})^{-1}[\mathbf{I} \otimes \mathbf{Q}] \tag{6}$$

with the middle term in Equation 6 the inverse of a matrix comprised of n_2^2 blocks of size $t \times t$ which are diagonal. Reordering the levels of u_2 and Δ_G according to animals within traits, denoted by superscript '*', results in:

$$\boldsymbol{\Delta}_G^{\star} = [\mathbf{Q}' \otimes \mathbf{I}](\mathbf{I} \otimes \mathbf{G} + \mathbf{D} \otimes \mathbf{A}_{22})^{-1}[\mathbf{Q} \otimes \mathbf{I}] \tag{7}$$

In this formulation, the middle term is block-diagonal with t blocks $(\mathbf{G} + d_k\mathbf{A}_{22})^{-1}$. Hence the $t(t+1)/2$ submatrices of $\boldsymbol{\Delta}_G^{\star}$ ($\boldsymbol{\Delta}_{G,ij}^{\star}$ for traits i and j) can be obtained as linear combinations of $r \leq t$ inverses of the individual blocks of size $n_2 \times n_2$, with r the number of distinct values d_k. For q_{ij} denoting the ij-$^{\text{th}}$ element of Q,

$$\boldsymbol{\Delta}_{G,ij}^{\star} = \sum_{k=1}^{t} q_{ki}\, q_{kj} (\mathbf{G} + d_k\mathbf{A}_{22})^{-1} \tag{8}$$

Following Mäntysaari *et al.* (2017), we can use the Woodbury matrix identity to compute the inverses required. For G = MM'/s with M the matrix of centred marker counts and s a scalar,

$$\begin{aligned} (\mathbf{G} + d_k\mathbf{A}_{22})^{-1} &= [\mathbf{A}_{22}^{-1} - \mathbf{A}_{22}^{-1}\,\mathbf{M}\,(s\,d_k\mathbf{I} + \mathbf{M}'\,\mathbf{A}_{22}^{-1}\,\mathbf{M})^{-1}\mathbf{M}'\,\mathbf{A}_{22}^{-1}]/d_k \\ &= [\mathbf{A}_{22}^{-1} - \mathbf{A}_{22}^{-1}\,\mathbf{M}\,\mathbf{E}\,(s\,d_k\mathbf{I} + \mathbf{T})^{-1}\,\mathbf{E}'\,\mathbf{M}'\,\mathbf{A}_{22}^{-1}]\,/d_k \end{aligned} \tag{9}$$

with T and E the matrices of eigenvalues and eigenvectors of $\mathbf{M}'\mathbf{A}_{22}^{-1}\mathbf{M}$, respectively. Matrices $(s\,d_k\mathbf{I} + \mathbf{T})$ are diagonal and thus trivial to invert. This facilitates efficient evaluation of the r diagonal blocks required through a single eigen-decomposition of a matrix of size $m \times m$, with m the number of markers.

Calculations can be implemented using either ordering of u_2. We assume animals within traits in the following. This allows for the direct use of highly optimised library routines for dense matrix calculations to evaluate the inverses required. For analyses forming the MME in core, multiplication with Q⊗I can be integrated into the design matrix Z, in the same way as for a transformation to principal components (Meyer *et al.*, 2015). Alternatively, using an iterative scheme to solve the MME, a product $\mathbf{\Delta}_G^\star \mathbf{r}_2^\star$ is required for each iterate (with $\mathbf{r}_2^\star$ the part of the vector of directions corresponding to $\mathbf{u}_2^\star$). This product is readily obtained by first forming $\mathbf{s}_2^\star = (\mathbf{Q} \otimes \mathbf{I})\mathbf{r}_2^\star$, then multiplying with the inverse diagonal blocks, yielding $\mathbf{t}_2^\star = (\mathbf{I} \otimes \mathbf{G} + \mathbf{D} \otimes \mathbf{A}_{22})^{-1}\mathbf{s}_2^\star$ and finally calculating $(\mathbf{Q}' \otimes \mathbf{I})\mathbf{t}_2^\star$.

Materials & methods

Data for three traits recorded on 21,000 animals in eight generations with heritabilities of 0.30, 0.25 and 0.10, respectively, and genetic correlations of 0.70 were generated using AlphaSim, version 1.05 (Faux *et al.*, 2016). Genotypes were constructed sampling 125 quantitative trait loci and 32,000 SNP markers. Subsequently, RPG effects were sampled for the given pedigree structure and added to the respective records and breeding values. Variances for RPG effects were chosen to yield variance ratios of magnitude 0.90, 0.85 and 0.20. Only marker information for 10, 30, 40 and 50% of randomly chosen individuals in generations five to eight was retained.

Genomic relationship matrices were build using Method 1 of Van Raden (2008), eliminating SNP with minor allele frequencies less than 2% and centering allele counts using 'observed' frequencies. To align G with A_{22} these were augmented by αJ with $\alpha = \mathbf{1}'(\mathbf{A}_{22} - \mathbf{G})\mathbf{1}/n_2^2$ for 1 and J a vector and a matrix, respectively, with all elements equal to unity (Vitezica *et al.* 2011). Estimates of variance components were obtained by restricted maximum likelihood (REML), fitting overall means as the only fixed effect. Trait-specific covariance matrices Σ_G and Σ_A were estimated by splitting u into parts explained by markers, g, and RPG effects, a and fitting these separately, assuming they were distributed as H⊗Σ_G and A⊗Σ_A, respectively, with Cov(g,a')=0. This was contrasted with analyses assuming $\Sigma_G = c\Sigma_A$ which fitted u with $\mathbf{\Delta}_G = (\lambda\mathbf{G} + (1-\lambda)\mathbf{A}_{22})^{-1} \otimes \mathbf{\Sigma}_U^{-1}$ and estimated λ by quadratic approximation of its profile likelihood. Analyses were carried out both in- and excluding records for the last generation.

To evaluate the impact on convergence behaviour, MME were also solved using iteration on data. This was done fitting either both g and a (FULL) or u (JOINT), and considering Σ_G and Σ_A to be either proportional (SINGLE λ) or trait specific (VARIED λ). Summary statistics calculated were means and standard deviations across 30 replicates for estimates of λ, i.e. the ratios of diagonal elements of Σ_G to Σ_U, and correlations (ρ) between and linear regressions (β) of true on predicted total breeding values (EBV), for genotyped individuals in the last generation.

Results & discussion

Means and standard deviations of summary statistics for VARIED λ and SINGLE λ together with corresponding values for analyses fitting single, fixed values of λ=0.50 (FIX λ=0.50) or λ=0.95 (FIX λ=0.95) are contrasted in Table 1 (analyses including all phenotypes). In spite of substantial differences in individual λ, improvements in ρ allowing for trait-specific values over those estimating a single value were modest. Similarly, deviations of β from the expected value of unity were only slightly reduced. Only for trait three and FIX λ=0.95 was a sizeable impact on ρ evident. Omitting phenotypes for generation eight (detailed results not shown) resulted in lower levels of ρ overall but yielded only slightly bigger improvements for VARIED λ over SINGLE λ than above. However this was accompanied by a drop of about 0.1 (from 0.984 to 0.874) in mean β for SINGLE λ for trait three, i.e. a marked increase in over-dispersion of EBVs.

Table 1. Means ($\bar{x}$) and standard deviations (sd) for estimates of variance ratios (λ), correlations (ρ) between and regressions (β) of true on predicted breeding values.

		VARIED λ			SINGLE λ			FIX λ=0.95			FIX λ=0.50

Additional univariate analyses (not shown) evaluating the profile for ρ and β over the whole range of λ showed that values were rather robust against considerable deviations of λ from their estimated, 'optimal' values. Similarly, literature results emphasised the insensitivity in ranking of ssGBLUP predictions of genetic merit against choices of λ (e.g. McMillan and Swan, 2017).

Whilst resulting in the same predicted breeding values, attempts to split u into its parts, g and a, (FULL) were clearly detrimental for convergence rates of iterative solution schemes. Means and ranges (in brackets) for the number of iterates required to solve the MME for VARIED λ were 1,036 (631-6,573) and 187 (141-263) for FULL and JOINT, respectively, i.e. JOINT reduced numbers of iterates required on average by about 80%. The highest numbers of iterates for the combination of FULL and VARIED λ were required for samples with individual λ close to unity (or zero), reflecting their effects on the condition number of the coefficient matrix in the MME. Corresponding numbers for SINGLE λ were 663 (563-818) and 152 (122-190).

Conclusions

Use of a canonical transformation facilitates trait-specific weighting of genetic covariances explained by genomic markers and RPG effects in ssGBLUP analyses, directly fitting total breeding values only. However, simulation results suggest that the resulting gains in accuracy of prediction compared to estimating a single, overall value of λ tend to be limited. Accommodating individual λ appeared to be most beneficial for a scenario with the values spanning almost the whole range of $[0,1]$ and in predicting breeding values for genotyped individuals without phenotypes. In practical applications, the trade-off between potential gains and additional computational demands need to be carefully assessed.

Abstract

In this study, the performance of weights for multi-step reliability calculation was examined by 4 approaches: two Interbull methods, single-trait reverse reliability (ST-REV), and multiple-trait reverse reliability (MT-REV). We concentrated on weights for genotyped animals and used 305-d milk yield data in the first 3 lactations in Nordic (Danish, Finnish, and Swedish) Holstein dairy cattle. We compared reliabilities in a classical pedigree-based animal model to the back-calculated reliabilities. Correlations between the pedigree-based animal model reliabilities and the back-calculated reliabilities were high for all approaches (>0.90). However, gains from 0.02 to 0.11 on correlations between the classical and the back-calculated reliabilities were achieved using MT-REV compared with ST-REV and the Interbull methods. The MT-REV outperformed the ST-REV (higher correlations and smaller MSE) mainly for traits with many missing records. However, ST-REV and MT-REV yielded similar results for traits with few missing phenotype records.

Introduction

The total number of daughters of a bull has been used as a weighting factor in some routine genetic evaluations of dairy sires. However, the effective number of daughters does not account for factors such as the number of lactations of each daughter, daughter dam information, and contemporary group (CG). Interbull proposed a procedure to calculate weighting factors to use in international genetic evaluations (Interbull, July 2000 mimeo). The Interbull procedure consists of 2 steps: (1) calculating animal model reliability based on the animal's own performance; and (2) using the reliability of progeny to calculate a weight for each bull. Fikse and Banos (2001) developed new weighting factors based on daughter information for the application in MACE. In their study, they used the number of effective daughter contributions (EDC) instead of the number of daughters. Effective record contributions (ERC) can be obtained as a linear transformation of EDC. Taskinen *et al.* (2014) developed an iterative method for calculating ERC: so-called reverse reliability approximation. The authors applied their method for single-trait estimation. The types of weights used for de-regressed proofs (DRP) are important when either an approximate procedure is used to regress EBV or when individual reliabilities of final EBV are computed based on the prediction error variance of the model (Calus *et al.*, 2016). In this study, we present and test a multiple-trait reverse reliability approximation method to calculate ERCs. Our objective was to compare the performance of the different methods for calculating EDC/ERC.

Materials & methods

Interbull method 1. Interbull method 1 (IB1) uses a sire model and contains 2 steps. The first step consists of calculating reliability based on the animal's own performance records. This step accounts for the most important factors affecting reliability, including the proportion of genetic variance, repeatability of the trait, and the CG information. Step 2 calculates a weight for each bull using the calculated reliability of its progeny. EDC provides a measure of the precision of the daughter used to compute the bull's DRP. The formula for the computation of EDC, which includes the performance of the dam of daughter k of bull i, is: $\text{EDC}_i = \sum_k \frac{\lambda r^2_{k(o)}}{4 - r_{k(o)}(1 + r^2_{dam(o)})}$, where the summation is over all k daughters of the bull, $\lambda = \frac{4-h^2}{h^2}$, $r^2_{dam(o)}$, is the

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_362, © H. Ben Zaabza *et al.* 2022

reliability of the dam's own performance, and $r^2_{k(o)}$ is the reliability of animal *k*'s own performance computed as:

$$r^2_{k(o)} = \frac{n_k h^2}{1+(n_k-1)r^2_k}$$

where r^2_k is the reliability of the animal's records and n_k is the number of lactations of daughter *k* of the sire, adjusted for the CG size.

Interbull method 2. Interbull method 2 (IB2) is an extension of Interbull method 1 (IB1), where the animal model is used instead of the sire model. Thus, $\text{EDC}_i = \sum_k \frac{\lambda r^2_{k(o)}}{1-r_{k(o)}}$ and $\lambda = \frac{1-h^2}{h^2}$.

Single-trait reverse reliability estimation. Single-trait ERC calculation is based on so-called reverse reliability estimation (Taskinen *et al.* 2014), approximating ERC from a given reliability value by reversing the Harris and Johnson (1998) method. The original algorithm estimates animal model reliability using ERC. The reverse reliability estimation estimates $\widehat{\text{ERC}}$ that gives the same prediction error variance PEV as the original PEV*, where the asterisk stands for the initial value of prediction error variance calculated by the Tier and Meyer (2004) method when only a subset of (genotyped) animal reliabilities and their full pedigree are available.

Multi-trait reverse reliability estimation. This approach reverses the Tier and Meyer (2004) method. In the original Tier and Meyer (2004) algorithm, animal model reliabilities are approximated using ERC. In the reverse estimation approach, approximate $\widehat{\text{ERC}}$ are calculated that give the same prediction error variances PEV as the original PEV*. When the PEV* is from the full data with records on all animals, but ERC is solved for only a subset of (genotyped) animals, the approach automatically includes the information from the non-genotyped relatives of the genotyped animals. The calculation of $\widehat{\text{ERC}}$ involves the accumulation of information from progeny and parents using pedigree information as in the original Tier and Meyer approach. In the Tier and Meyer reliability estimation, each animal will receive a n_t by n_t prediction covariance matrix having the diagonals (PEV) used in the estimation of the reliabilities. However, in the reverse reliability estimation, with a given ERC^k for all animals, we estimate PEV^k, and if it does not correspond to PEV*, we search for a new ERC^{k+1} that will give PEV^{k+1} closer to PEV*. The approach needs to be repeated iteratively. The new $\text{ERC}^{[k+1]}$ was solved animal-wise from a non-linear equation:

$$\left\{\left(\mathbf{G}_i^{-1} + \mathbf{E}(\mathbf{c})\mathbf{R}_0^{-1}\mathbf{E}(\mathbf{c})\right)^{-1}\right\}_{jj} = \{\mathbf{y}\}_j$$

where $\{y\}$ are the original PEV* of animal *i* and trait *j*, $\mathbf{G}_i^{-1}$ contains $\mathbf{G}_0^{-1}$ and contributions from animal's offspring and ancestors, and R_0 is the between-trait residual variance-covariance matrix recorded for animal *i*. Animals may have missing observations for some traits, leading to missing ERC and a missing ERC pattern. For these ERC 'patterns', submatrices of R_0 were used by omitting rows and columns corresponding to the missing observations. The ERC values are in the diagonal E(c) matrix, $\{\mathbf{E}(\mathbf{c})\}_{jj} = \sqrt{\mathbf{c}_j}$, where c_j is the ERC for trait *j* to be solved. We implemented a Newton-Raphson based algorithm for solving the ERC_{rev}. See Ben Zaabza *et al.* (2022) for more details.

Performance of different methods for calculating EDC/ERC. The obtained ERC can be checked by back-calculating the reliability for animals by using an animal model. The model only contains an intercept and a genetic effect. The observations can have any value, and ERC are used as weights. The reliabilities for the model should be approximately the same as those used as input in ERC calculation.

Data. We applied the methods in Nordic (Danish, Finnish, and Swedish) Holstein Dairy cattle data, which had 8.10 million first, 5.97 million second, and 3.72 million third lactation 305-d milk yield records from 8.28 million Nordic Holstein dairy cows. The pedigree comprised up to 11 million animals, of which 274,145 were genotyped for 46,342 SNP markers.

Results & discussion

The correlations between approximate animal model reliabilities and back-calculated reliabilities are given in Table 1.

For Interbull method 1, correlations ranged from 0.969 for the first lactation to 0.937 for the third lactation. For Interbull method 2, however, they were between 0.921 for the first lactation and 0.883 for the third lactation. The correlations between reliabilities from ST-REV and back-calculated reliabilities ranged from 0.977 for first lactation to 0.958 for third lactation. An improvement of 0.02 was observed in the correlations between approximate animal model reliabilities and back-calculated reliabilities from MT-REV as compared to the ST-REV method. With Interbull method 1(2), MSE ranged from 0.099(0.0187) for the first lactation to 0.0214(0.0321) for the third lactation. With ST-REV (MT-REV), MSE ranged from 0.0081(0.0012) to 0.0107(0.0018), indicating that MT-REV outperformed ST-REV, especially for lactations 2 and 3. This could be expected because there were more missing observations in second and third lactations. The MT-REV also outperformed the Interbull method 1 and 2. This can be explained by the fact that the MT-REV method allows to account for information from non-genotyped animals using the pedigree relationship structure and the multi-trait covariance structure. Quite contrary, when both the sire and its daughter are genotyped, the use of the Interbull methods will lead to a double counting of the daughter record information. The MT-REV attempts to account for that double counting of information.

Conclusions

The performances of four methods for calculating EDC/ERC were compared in 305-d milk yield data in the first 3 lactations in Nordic Holstein dairy cattle. Our results indicate that ERC can be approximated satisfactorily for genotyped animals using a multiple-trait reverse reliability method, which outperformed the single-trait reverse reliability method mainly for traits with many missing records.

Table 1. Correlation (r), maximum difference (max), and mean-squared error (MSE) between the original reliabilities and the back-calculated reliabilities using the Interbull method 1 (IB1), Interbull method 2 (IB2), single-trait reverse reliability estimation (ST_REV), and multi-trait reverse reliability estimation (MT_REV).[1]

363. JWAS version 2: leveraging biological information and high-throughput phenotypes into genomic prediction and association

H. Cheng[1*], R. Fernando[2], D. Garrick[3], T. Zhao[1] and J. Qu[1]

[1]Department of Animal Science, University of California Davis, Davis, CA 95616, USA; [2]Department of Animal Science, Iowa State University, Ames, IA 50010, USA; [3]School of Agriculture, Massey University, 4442, Palmerston North, New Zealand; qtlcheng@ucdavis.edu

Abstract

The initial release of JWAS was developed as an open-source software tool for single-trait or multi-trait linear mixed models including those used for genome-enabled prediction or genome-wide association studies. We have now made extensive updates to JWAS to incorporate new features to accommodate high-throughput phenotypes and biological information useful in bridging the gap between DNA sequence and phenotypic information. The new features include but are not limited to: (1) incorporating high-throughput phenotypes by simultaneous modeling of thousands of traits or through time-series (longitudinal trait) models; (2) using functional annotation information as a-priori biological knowledge; (3) extending mixed models to multi-layer neural networks that can accommodate intermediate omics data. This latest version of JWAS (version 2) is developed for researchers in both industry and academia to take full advantage of new information such as high-throughput phenotypes, functional annotations, and multi-omics data as they become increasingly available in this decade.

Introduction

The release of the USDA blueprint for animal genomics (2008-2017) triggered the development of many statistical methods to improve genetic progress as well as the implementation of these methods in software tools such as JWAS. The initial version of JWAS (Cheng *et al.*, 2018) was an open-source software tool for single-trait or multi-trait analyses accommodating those models used for genome-enabled prediction and genome-wide association studies, with either complete or incomplete genomic data, i.e. 'single-step' methods (Legarra *et al.,* 2009; Fernando *et al.,* 2014; Fernando *et al.,* 2016). A portfolio of Bayesian regression models including variable selection and shrinkage estimation methods were implemented in JWAS to provide broad scope of analyses.

With the development of high-throughput sequencing and phenotyping technology, the USDA blueprint in animal genomics for the next decade (2018-2027) (Rexroad *et al.*, 2019) has identified several areas requiring more advanced usage of genomic information for animal production. Thus, there was a need to develop statistical methods and tools that could incorporate high-throughput phenotyping, multi-omics data, and biological information such as functional annotations for genomic analyses. Extensive additional updates to our JWAS package were required to accommodate the issues identified in the new blueprint for improved utilization of genomic information. The availability of powerful and efficient statistical methods implemented in extensible software tools that can accommodate the advancing state of the art would have impacts on a wide range of breeding programs. To fill this gap, we extensively upgraded JWAS and released JWAS version 2. The main objective of this paper is to introduce new features in JWAS for researchers in industry or academia, so they can take full advantage of new information such as high-throughput phenotypes, multi-omics data, and functional annotation of animal genomes as they become increasingly available in this decade.

Materials & methods

A list of features in JWAS is shown in Table 1, and highlighted new features in JWAS version 2 are described below.

Mixed models extended to multi-layer neural networks including intermediate omics data. With the growing amount and diversity of intermediate omics data complementary to genomics (e.g. measures of DNA methylation, gene expression, and protein abundance), there is a need to develop methods to incorporate intermediate omics data into genome-enabled prediction and association studies to enhance conventional genomic evaluation. We have implemented a new method NN-LMM (Zhao *et al.*, 2021a; Zhao *et al.*, 2021b) to model the multiple layers of regulation from genotypes to intermediate omics features, then to phenotypes, by extending conventional linear mixed models to multi-layer artificial neural networks. NN-LMM incorporates intermediate omics features by adding middle layers between genotypes and phenotypes. Linear mixed models (e.g. pedigree-based BLUP, GBLUP, Bayesian Alphabet, single-step GBLUP, or single-step Bayesian Alphabet) can be used to sample marker effects or genetic values on intermediate omics features, and activation functions in neural networks are used to capture nonlinear possibly unknown relationships between intermediate omics features and phenotypes.

Using functional annotation information as a-priori biological knowledge. In addition to phenotypic, genomic, and pedigree data, massive amounts of biological information are being generated by the scientific community. For example, the Functional Annotation of Animal Genome (FAANG) consortium is functionally annotating genomic regulatory elements of domesticated animal species. However, such biological information is not generally considered in genomic prediction that routinely uses phenotypic information along with pedigree and SNP genotypes. We have implemented multi-class models (Wang *et al.*, 2021) in JWAS version 2 to allocate markers into different classes based on biological information and assigning separate priors to markers in these different classes. This is implemented for single-trait or multi-trait analyses.

Table 1. A list of features in JWAS for single-trait or multi-trait analyses.

Fixed class or covariate effects (e.g. age, sex)	
Non-genomic random effects (e.g. litter, pen)	
Use of pedigree information	
Joint fitting of direct and maternal genetic effects permanent environmental effects	
Use of genomic information	
Complete genomic data[1]	Genomic BLUP
	Bayesian Alphabet
Incomplete genomic data[2]	Genomic BLUP
	Bayesian Alphabet
Biological information	multi-layer neural networks[3]
	multi-class models[3]
High-throughput phenotypes	sparse factor models[3]
	random regression models[3]

[1] 'Complete genomic data' indicates that genotypes are available on all individuals.

[2] 'Incomplete genomic data' indicates that genotypes are not available on all individuals ('single-step' analyses).

[3] These new features are described in the Materials & methods section.

Incorporating high-throughput phenotypes by simultaneous modeling of thousands of traits through sparse factor models. Large-scale phenotypic data are becoming increasingly accessible due to advances in high-throughput phenotyping platforms and technologies for multi-omics profiling. Although the incorporation of large-scale phenotypic data into genome-enabled analysis can enhance the power of prediction and association inference, genomic analyses of high-dimensional, highly correlated data are challenging. We have implemented a Bayesian sparse factor model (Runcie *et al.*, 2021) with different prior assumptions on marker effects to simultaneously analyze hundreds to thousands of traits for genomic prediction or GWAS. This Bayesian sparse factor model can effectively reduce a large multi-trait model into a set of parallel single-trait models by introducing the concept of latent traits, i.e. traits that are not directly observed, but can be inferred based on their effects on the observed traits. This model is based on some biologically reasonable assumptions including: (1) a limited number of the latent traits control the majority of variation; (2) each latent trait controls only a subset of the observed traits; (3) each latent trait is controlled by genetics and the environment.

Incorporating high-throughput phenotypes through time-series (longitudinal trait) models. In animal and plant improvement, longitudinal traits may be recorded across several time points on a physiological cycle, and might be jointly analyzed to improve the performance relative to an analysis at one time point. The recent advancement in phenotyping platforms enables acquisition of large-scale non-destructive phenotypes measured at frequent intervals. In pedigree-based analyses, the use of random regression models (RRM) has been a typical approach employed for such analyses of longitudinal traits (Henderson, 1982); Laird and Ware, 1982). We have implemented Bayesian random regression models for marker effects that can accommodate variable selection for the analysis of longitudinal data that would accrue through high-throughput phenotyping.

Results

The JWAS software tool was and is being developed as a single-language software tool that is easy for both champions and novice community members to use, maintain, modify, or extend. In terms of speed, for the same BayesC analysis, JWAS is now faster than the C++ program, GenSel. Further, JWAS is relatively easy to extend: to accommodate categorical traits in JWAS required adding only about 40 lines of code; to extend conventional Bayesian regression methods to single-step analyses required adding one file composed of a few hundred of lines of code and a few minor modifications to the original code.

Discussion

Whole-genome analyses are usually computationally intensive even for data sets of moderate size. Although these analyses can be implemented with most dynamic languages such as R or Python with very readable code that is easy to understand, modify and extend, they are often too slow for real data analyses. Therefore, for computational efficiency, compiled languages such as C, C++, or Fortran have historically been used to implement methods for genomic analyses. In order to make these more accessible, a dynamic language such as R may be used as a user interface to the underlying methods that are written in the compiled language. The problem of using compiled languages, however, is that they are usually hard to understand, modify, extend and maintain, in addition to being difficult to readily deploy across different operating systems. Julia (Bezanson *et al.*, 2017), a relatively new scientific programming language, approaches the computing speed of compiled languages, but retains the benefits of dynamic language.

Abstract

Inverting the mixed model equations (MMEs) in single-step GBLUP for calculating reliabilities is not feasible for large MMEs. We developed a program named ACCF90GS2 for approximating reliabilities of breeding values in single or multiple trait contexts. Two datasets were used to test the software. A small dataset was used to assess the accuracy of the method, whereas a large dataset including 335,325 genotyped animals was used to test the software performance. Correlations between exact and estimated reliabilities were 0.98 for the direct effect and over 0.94 for the maternal.Intercepts and slopes of regression of correct reliabilities from ssGBLUP on approximation reliabilities ranged from 0.01 to 0.04 and from 0.92 to 0.96, respectively. For the large dataset, the total computing time was 20 minutes. The computing cost of ACCF90GS2 increases linearly with the number of genotyped animals and traits. ACCF90GS2 is the newest tool in the BLUPF90 software suite to efficiently approximate reliabilities of breeding values with large-scale genomic data.

Introduction

Single-step GBLUP (ssGBLUP) allows estimating the breeding values jointly for genotyped and non-genotyped animals (Aguilar *et al.*, 2010). For that, ssGBLUP combines the inverses of the numerator relationship matrix (A), the genomic relationship matrix (G), and the numerator relationship matrix for the genotyped animals (A_{22}). When the number of genotyped animals is large, inverting G is not feasible. To overcome this problem, Misztal *et al.* (2014a) introduced the Algorithm for Proven and Young (APY). Although APY makes solving the mixed model equations (MMEs) possible for many genotyped animals, the inversion of the MMEs is still not feasible. Therefore, with extensive data, it is still impossible to obtain the prediction error variances (PEV) for reliability calculation from the diagonal of the inverse of the MMEs. Bermann *et al.* (2022) presented a method based on Liu *et al.* (2017) for approximating the reliabilities of estimated breeding values when APY is used. Bermann *et al.* (2022) showed the efficiency of this method with beef data for various models, but without considering maternal effect, which is common for some beef traits. We developed a program named ACCF90GS2 for approximating reliabilities of breeding values in single or multiple trait contexts that can accommodate models used in genetic evaluations.

Materials & methods

Approximation of reliabilities. We used the method of Bermann *et al.* (2022) for approximating the reliabilities of GEBV. The core of this method is the calculation of the reliabilities for a GBLUP model with APY, hereafter called genomic reliabilities. Their calculation is done by the block-sparse inversion of:

$$\mathbf{G}_{APY}^{-1}\,\sigma_{\mathrm{u}}^{-2} + \mathbf{D}\left(\sigma_{\mathrm{p}}^{2} - \sigma_{\mathrm{u}}^{2}\right),^{-1} \qquad (1)$$

where $\mathbf{G}_{APY}^{-1}$ is the inverse of the genomic relationship matrix calculated with APY, D is a diagonal matrix of effective record contributions (ERC), σ_{u}^{2} is the genetic variance, and σ_{p}^{2} is the phenotypic variance. Note that in the presence of other random effects besides the direct genetic effect, $\sigma_{\mathrm{p}}^{2} - \sigma_{\mathrm{u}}^{2}$ is greater than the error variance. If a maternal genetic effect is present, it can be treated as a direct genetic effect. This involves replacing σ_{u}^{2} in (1) by the maternal genetic variance (σ_{m}^{2}) and calculating ERC with the records linked to

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_364, © M. Bermann *et al.* 2022

the maternal genetic effect. The inclusion of a residual polygenic effect (RPG) in the model is done when constructing $\mathbf{G}_{APY}^{-1}$ as in Masuda *et al.* (2015). If so, the estimated reliability includes the residual polygenic effect.

The implementation of the method of Bermann *et al.* (2021) and the adjustment for maternal effects were as follows. First, we calculated the pedigree reliabilities (rel_{ped}) for direct and maternal effects (Misztal and Wiggans, 1988; Strabel *et al.*, 2001). Second, the pedigree reliabilities were back-solved using a root-finding technique to obtain ERC. Third, we calculated the genomic reliabilities (rel_{gen}) by a sparse inversion of Equation 1; two sparse inversions are needed when a trait has an associated maternal effect. Fourth, we calculated a second set of pedigree reliabilities $\left(rel_{\mathbf{A}_{22}}\right)$ with the method of Harris and Johnson (1998). The ERC for calculating these reliabilities were the same as in the second step but zeroing the ERC for non-genotyped animals. Then, we obtained the ERC for ssGBLUP (ERC_{ss}) as (Liu *et al.*, 2017):

$$ERC_{ss} = \lambda\left(\frac{rel_{ped}}{1 - rel_{ped}} + \frac{rel_{gen}}{1 - rel_{gen}} - \frac{rel_{\mathbf{A}_{22}}}{1 - rel_{\mathbf{A}_{22}}}\right) \quad (2)$$

where $\lambda = \frac{1-h^2}{h^2}$ and h^2 is the trait heritability calculated as $h^2 = \frac{\sigma_u^2}{\sigma_p^2}$ for direct effects and as $h^2 = \frac{\sigma_m^2}{\sigma_p^2}$ for maternal effects. Finally, the ssGBLUP reliabilities (rel_{ss}) were calculated as:

$$rel_{ss} = \frac{ERC_{ss}}{ERC_{ss}+\lambda} \quad (3)$$

The above procedure was repeated for each trait. Afterward, the adjustment proposed by Strabel *et al.* (2001) was used for accounting for multiple traits.

Software implementation. The method described in Bermann *et al.* (2022) and the adjustment for maternal effects were programmed in Fortran 90. We developed a software named ACCF90GS2, which will be included in the BLUPF90 software suite (Misztal *et al.*, 2014b). The software is optimized for parallel computations with OpenMP (http://www.openmp.org) and efficient matrix operations with the Intel Math Kernel Library (MKL; Inter Corporation).

Data. The data for this study was provided by the American Angus Association (St. Joseph, MO). Two datasets were created. A small dataset (Data1) was used to assess the accuracy of the approximation method, whereas a large dataset (Data2) was used to test the computational efficiency of the software. Table 1 shows a summary of each dataset.

Records for birth weight (BW), weaning weight (WW), and post-weaning gain (PWG) were available. In the model, the three traits had herd-year-season as a fixed effect and the direct genetic effect as random. BW and WW had maternal effect, whereas WW also included the maternal permanent environmental effect.

Table 1. Number of animals, animals with records, and genotyped animals for the two datasets.

		Data1	Data2
Animals in the pedigree		172,089	10,213,401
Animals with records		78,641	8,681,659
Genotyped animals	Core	10,523	10,523
	Non-core	9,477	324,802

Results

Statistics for the approximation method are shown in Table 2. The elapsed time for approximating the reliabilities was 0.9 and 20.8 minutes for Data1 and Data2. Note that Data2 is roughly 60 times bigger than Data1. However, the elapsed time for Data2 was 23 times the elapsed time for Data1.

Table 2. Correlation, intercept, slope, and mean absolute change (MAC) between the reliabilities calculated from the inverse of the MMEs and the approximated reliabilities for genotyped animals in Data1.

Trait	Effect	Correlation	Intercept	Slope	MAC
BW	Direct	0.98	0.04	0.93	0.01
	Maternal	0.94	0.03	0.92	0.01
WW	Direct	0.98	0.02	0.94	0.01
	Maternal	0.95	0.03	0.93	0.01
PWG	Direct	0.98	0.02	0.96	0.01

Discussion

The results from Table 2 show that the approximation works well, while the computing time is reasonable. The approximation quality depends on the statistical model, population structure, and genotyping strategy (Erbe *et al.*, 2018). The proposed method assumes that the direct and maternal effects are uncorrelated, which may impact the approximation quality. In this study, the correlations between direct and maternal effects were low (-0.24 for BW and zero for WW). Intuitively, the impact would be more significant when traits are highly correlated.

ACCF90GS2 also allows replacing $\mathbf{G}_{APY}^{-1}$ with a used defined G^{-1} in (1). In such a case, a dense inversion increases the computing cost with the number of genotyped animals and the inclusion of a RPG depends on how the user defined G^{-1}. Further, the program has an option to enhance reliabilities for non-genotyped animals using relatives' genomic information. The procedure derives weights from the single-step reliabilities of genotyped animals and applies them as ERC for non-genotyped animals. Overestimation of reliabilities for genotyped animals is expected, especially when the number of genotyped animals is large (Liu *et al.*, 2017). Consequently, ACCF90GS2 includes tools for adjusting the reliabilities of the genotyped animals. This adjustment is a simple linear regression with parameters given by the user, which optimally should be calculated from cross-validation studies. Other possible adjustments, most likely using relatives' contributions, would be explored for further implementation in ACCF90GS2. As future developments, ACCF90GS2 will include a method for approximating reliabilities of indirect predictions and random regression models.

365. One for all: LMT – the linear models toolbox

V. Boerner

Centre for Quantitative Genetics and Genomics (QGG), Aarhus University, Denmark; vinzent.boerner@gmx.de

Abstract

Developments in hardware resources, external computing devices, third party libraries and languages capacities must be considered if big data applications aim for cutting-edge performance. Legacy code structure can make such considerations difficult or impossible. For addressing these issues, LMT ('linear models toolbox') has been developed as a successor for DMU. LMT is a stand-alone, single-executable, instruction file driven program for genetic evaluation and variance component estimation in multivariate data sets with hundreds of millions of equations. LMT supports a wide range of models including ssSNPBLUP random regression test-day models, metafounders, and explicitly modelled genetic groups. Tested on large scale industry data, LMT decreased the necessary processing time by 93% when compared to DMU, and needed 1.7 hours to process a random regression test-day model with 350 million equations and 250 million observations.

Introduction

Over the last two decades the computing and programming environment where quantitative genetics operates in has seen a dramatic change. Hardware resources are abundant, fast third-party libraries and JIT compilers underpin powerful scripting languages, modern language features are available for easier maintenance and extension, and external computing devices enable unprecedented speed. In some cases, the structure of legacy code may not allow to address these developments efficiently, and only a re-development may enable sufficient performance. This paper describes LMT ('linear models toolbox'), which has been developed from scratch as a successor for DMU (Madsen *et al.* 2014) to address maintenance, interface, layout, and performance issues while maintaining a versatility equivalent to DMU.

Modelling capacity

Linear mixed models consist of a combination of factor structures and variance structures, and the modeling capacity of a linear mixed model software is a function of the supported operations applicable to supported factor and variance structures. Below, LMT's modeling capacity is described using this concept.

Supported variance structures. The most general variance structure supported by LMT is $\Omega_L(I \otimes \Gamma)\Omega_L'$, where Ω_L a block-diagonal matrix of lower Cholesky factors of within factor level co-variance matrices (e.g. an animal specific a genetic co-variance matrix), Γ is a matrix of between factor level co-variances (e.g. the numerator relationship matrix), and I is an identity matrix. Therefore, LMT supports assigning a unique co-variance matrix to every single modelled random factor level. Note that under common assumptions this structure simplifies to $\Gamma \otimes \Sigma$ where Γ is usually set to identity (I), the pedigree derived numerator relationship matrices (A), or a single step relationship matrix (H), and Σ is a co-variance matrix between correlated factors across or within trait.

For Γ, LMT supports I, auto-regressive matrices, externally supplied matrices in sparse or dense format, A, and H matrices for ssGBLUP (H_G Christensen and Lund 2010), ssGTBLUP (H_T, Mäntysaari *et al.* 2017), and ssSNPBLUP (H_S, Liu *et al.* 2014). Pedigree structures supported for building A and H are ordinary pedigrees and probabilistic pedigrees with more than one pair of parents per individual (Perez-Enciso and Fernando 1992), where the latter is a key feature for genetic evaluation in plants, fish and extensive livestock

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_365, © V. Boerner 2022

production systems. Further, diagonal elements of A can be derived in an iterative manner accounting for relationships between founders (VanRaden 1992).

For ssSNPBLUP, LMT supports co-variances between and within markers following structure $\Omega_L(I \otimes \Gamma)\Omega_L'$, where the supported Γ types are those pointed out above. For H_G, H_Γ, and H_S a non-zero polygenic weight can be provided for all H structures, and a single keyword in the instruction file invokes the adjustment of G to A (Christensen *et al.* 2012) for all types of H. By providing a pedigree containing phantom parents for the construction of A, for Γ of type A, H_G, H_Γ, and H_S LMT will automatically absorb the genetic group regression matrix into the respective Γ (Westell *et al.* 1988). Further, if provided with a metafounder co-variance matrix LMT will automatically build a metafounder enhanced numerator relationship matrix (A_{mf}) for all Γ which involve A (Legarra *et al.* 2015).

Supported factor structures. LMT supports the following factor structures: classification variable, real co-variables (e.g. 'weight'), integer co-variables (e.g. 'days in milk'), co-variables nested within classification variables (e.g. 'test day models'), genetic group co-variables, and arbitrary real number design matrices. If co-variables are nominated as integer LMT automatically generates regression tables. Further, regression matrices for genetic group co-variables are generated directly from the assigned pedigree during the model building process. The ability to model genetic groups as a separate factor allows to arbitrarily mix metafounders and genetic groups in the same model. For co-variables LMT understands complex polynomials (e.g. $\sin(x)/\mathrm{sqrt}(x)^3$) and will automatically conduct all necessary expansion to fit a random co-variable to its assigned variance structure.

Supported operations. LMT supports solving linear mixed models for obtaining BLUP and BLUE solutions for the modelled factor levels. Two different solvers are available: a direct solver which factorises the mixed model equation system, and an iterative solver which uses the preconditioned conjugate gradient (PCG) algorithm. Both solvers can be applied to equation systems involving any factor or variance structure, although computational feasibility and resource availability limit the application of the direct solver to medium sized data sets and genomic data included via H_G. The PCG solver can be applied to an unlimited number of equations and genotyped individuals and all types of single step models. LMT also supports the exact calculation of prediction error co-variances. For this operation both the above solvers can be used, calculating exact prediction error co-variances for target factor levels even for large multi-variate ssSNPBLUP models. Approximations of prediction error co-variances can be obtained using LMT's multi-chain prediction error co-variance sampler. Implementing a method described in (Harville 1999), the sampler runs a user-defined number of parallel chains on shared resources. That is, all factor and variance structures are shared between the chains which is a key feature to keep the computing resource requirements manageable when genetic markers are included in the model. Sampling is supported for all factor structures and all variance structures, except H_T and H_S. For estimating variance components, LMT provides a MC-EM-REML module (Harville 2004) and two different Gibbs samplers: a blocked sampler which samples all correlated factors within factor level from their joint conditional posterior distribution, and a single pass sampler which samples all factor levels jointly from their posterior distribution.

Additional features. 'On the fly of everything' is the core concept of LMT, meaning that absolutely everything necessary to run a particular model or job stream is calculated as required without the necessity to utilize or call any additional executable. LMT can accommodate for uploading an arbitrary number of pedigrees, genotype files, external Gs, external Γs, etc. and calculates derivatives of that input on the fly, whether it is diagonal elements of A, A_{mf} or H, or building an arbitrary number of Gs from genotypes.

Model communication

LMT's multi-variate model syntax (LMT-mms) is very closely related to the mathematical linear model notation found in the scientific notation. For putting the maximum amount of information into the equation the concept of specifiers has been developed which extends the model y=Xb+Zu to y()=X()b()+Z()u(), where y, X and Z are column names retrieved from the data file header, b and u are arbitrary user-defined factor names, and the parenthesis are optional specifiers which may contain further information about the response variable, model variable, or factor. Contrarily to other model syntax, LMT-mms maintains an acronym for the factor which is a core feature to allow for unambiguous cross-classification of factors over response variables. Variable specifiers contain all information necessary to build a variable and can be described as a tree diagram. A univariate model fitting a fixed classification variable, a nested continuous co-variables with polynomial expansion, and a genetic group co-variable can be written in LMT-mms as:

weight = herdyear×b+age(t(co(p(1,2,3);n(sex))))×c+id(t(gg(myped)))×g,

where 'weight', 'herdyear', 'age', 'sex' and 'id' are column names in the data file, 'b', 'c', and 'g' are user-defined factor names, '1,2,3' in 'age(t(co(p(1,2,3);n(sex))))' are instruction file locations of user-defined polynomials, and 'myped' is a the user-defined name of a user-supplied pedigree. A similar concept applies to the factor specifier which communicates information whether the factor is random and which variance is assigned to it. A bi-variate random regression test-day model using three different polynomials and an automatically generated regression table can be written in LMT-mms as:

milk=hy×b1+dim((t(co(t(i);p(1,2,3);n(id)))))×u1(v(g(1,3,5)))

prot=hy×b2+dim((t(co(t(i);p(1,2,3);n(id)))))×u2(v(g(2,4,6))),

where 'dim' is a column name in the data file, and the specifier in 'u1(v(g(1,3,5)))' assigns the Σ diagonal elements 1,3 and 5 of variance structure with the user-defined name 'g' to factor 'u1'.

Performance

The challenge of developing LMT's software frame was to achieve both, versatility as well as speed, all combined in a single executable. For bench-marking the speed LMT's PCG solver performance was tested with several different industry data sets used for genetic evaluation. Three examples are provided below where the data structures differ with regard to the computationally most demanding operations of the workflow. All runtime parameters provided are indicative.

DanBred ssGTBLUP evaluation for pigs. The data set consisted of 4 traits, about 3 million observations, 1 million animals in the pedigree, and 150,000 animals with 40k marker genotypes. This resulted in an equation system with 4.9 million equations, 4 correlated random genetic effects, 3 other random factors with correlated effects (e.g. birth-litter, service sire, etc.), and an H_T matrix constructed with a polygenic weight of 0.05 and an adjustment of G to A. Transitioning from the DMU tool chain to LMT decreased the total processing time from about 15 hours to less than 1 hour (-93%), and the seconds per solver iteration from 13.18 to 1.8, of which 90% where spent on T-matrix multiplications. Both programs ran on the same hardware and threading resources and used the same convergence criterion.

DanBred ssSNPBLUP evaluation for pigs. The data set consisted of 5 traits, 1.2 million animals in the pedigree, 220,000 animals with 40k marker genotypes, and H was constructed with the polygenic weight of 0.25 and an adjustment of G to A, which resulted in a system with 19 million equations. On an Intel(R) Core(TM) i9-10980XE CPU @ 3.00GHz with 18 cores using a ssSNPBLUP model instead of a ssGTBLUP

model reduced the total runtime from 4.6 hours to 2.1 hours with a convergence threshold $\frac{||Cx_i - b||}{||b||}$<10e-11, and reduced the peak memory requirement from 134GB to 17GB, making the ssSNPBLUP model the most viable solution for a time-critical and memory-aware single step genetic evaluation.

DataGene random regression test-day evaluation for Australian Holstein. The data set consisted of 9 traits (milk, fat and protein in 3 lactations) with a total of 236 million observations and 6.9 million animals in the pedigree. The data were modelled using a random regression test-day model, which resulted in 27 correlated genetic effects, 27 correlated permanent environmental effects, and a system of 355 million equations. On an Intel(R) Core(TM) i9-10980XE CPU @ 3.00GHz with 18 cores the total processing time for the dataset was 1.7 hours with a convergence threshold $\frac{||x_i - x_{i+1}||}{||x_i||}$<10e-5.

Conclusions

With only the AIREML functionality yet to be integrated, nearly all DMU functionalities, spread over 5 different executables, have been successfully integrated into LMT and further functionalities have been added. The achieved performance gains show that generalisation does not contradict performance.

Abstract

BLUPF90 is a flexible software suite that estimates variance components, cross-classified and covariate effects, breeding values, accuracies, and SNP effects, among others. It is based on mixed models and focuses mainly on animal breeding and genetics applications. This collection of software is continually under development to incorporate new methods and algorithms, improve efficiency, and broaden usage. A significant change undergoing BLUPF90 is the merge of variance components and breeding values estimation software. Some of the recent developments include the implementation of *P*-values for SNP effects in single-step GWAS, a new algorithm to approximate reliability or accuracy of GEBV, the inclusion of metafounders or unknown parent groups in ssGBLUP to set the base populations, and several optimizations to speed up computing time with many genotyped animals. BLUPF90 is a resourceful collection of efficient software that handles millions of genotyped animals and dozens of millions of records or individuals in pedigree.

Introduction

The ever-increasing amount of data used in breeding and genetics applications requires efficient software to solve the mixed model equations (MME). In 1997, Ignacy Misztal developed a simple BLUP program to compute solutions for the MME in Fortran 90/95. The simplicity and flexibility of the architecture allowed extensions and improvements by several generations of scholars. Twenty-five years and many contributors later, BLUPF90 became a collection of software that handles virtually all models used in genetic evaluations in animal breeding. This collection includes software for variance components estimation in linear and linear-threshold models, large-scale genetic evaluations using linear and linear-threshold models, exact and approximate computations of accuracies, and general genomic computations. The software supports different models per trait for virtually any number of traits, multiple effects, random correlated and non-correlated effects, random regressions, missing observations, different covariance structures supplied by the user, and extensive genomic data.

Using genomic data stimulated the most comprehensive changes to BLUPF90. This is because the number of opportunities with genomics is endless. A genomic library with well over 200 options was created and encapsulated by nearly all BLUPF90 programs. Those options are mainly related to quality control of genomic data, statistics and visualization, construction and inversion of genomic and pedigree relationship matrices for genotyped animals, and matrix scaling to ensure compatibility in ssGBLUP. Although the primary genomic method implemented in BLUPF90 is ssGBLUP, GBLUP is also supported. Because of the equivalence between GBLUP-based methods and SNP-BLUP, SNP effects are easily computed through backsolving.

BLUPF90 has been in constant progress for 25 years. Some of the most recent developments in this software collection include the consolidation of variance components and breeding values estimation software, implementation of *P*-values for SNP effects in single-step GWAS, a new algorithm to approximate reliability or accuracy of GEBV, the inclusion of metafounders or unknown parent groups in ssGBLUP, and

optimizations to speed up computations with many genotyped animals. This work will present the most critical innovations recently brought to BLUPF90.

Materials & methods

Software consolidation. There are currently 11 free programs in the BLUPF90 software suite (http://nce.ads.uga.edu/html/projects/programs/). Some estimate variance components, and some estimate breeding values. Some are frequentist (REML), and some use Bayesian inference through Gibbs Sampling. This generates questions on which software one should use. To avoid this issue, we recently consolidated the linear, frequentist software into one piece called blupf90plus and the most used Bayesian, Gibbs Sampling into gibbsf90plus. Thus, blupf90plus combines blupf90, remlf90, and airemlf90, whereas gibbsf90plus integrates gibbs2f90, gibbs3f90, thrgibbs1f90, and thrgibbs3f90. In blupf90plus, the default option is breeding values estimation, and variance components estimation (VCE) is turned on by adding OPTION method VCE to the parameter file. For gibbsf90plus, the same software is used for linear and threshold models. These consolidated programs were thoroughly tested with real and simulated populations.

Unknown Parent Groups (UPG) in ssGBLUP. In the BLUP animal model, the mixed model equations (MME) account for UPG using the QP transformation (Quaas and Pollak, 1981). Besides the default QP transformation for A^{-1}, in ssGBLUP, UPG can be assigned to A^{-1}, the inverse of the genomic relationship matrix (G^{-1}), and A^{-1} for genotyped animals (A_{22}^{-1}). This is called the QP transformation for H^{-1} (Misztal *et al.*, 2013). Because pedigree missingness does not affect genomic relationships, UPG can be assigned to A^{-1} and A_{22}^{-1}; this is known as the altered QP transformation for H^{-1} (Tsuruta *et al.*, 2019). The transformations were implemented in the BLUPF90 programs. QP transformation for A^{-1} is the default, whereas the QP for H^{-1} is activated by OPTION exact_upg and the altered QP for H^{-1} needs the previous option along with OPTION TauOmegaQ2 0.0 1.0. All three transformations were tested using US Holstein data for type and production traits with up to 861k genotyped animals.

Metafounders (MF) in ssGBLUP. MF act as proxies for the base animals. Metafounders and UPG are similar concepts; however, metafounders can be related and describe the buildup of coancestry, which is not possible for UPG. With MF, A_{22} is adjusted to G computed with 0.5 allele frequency. Both A^{-1} and A_{22}^{-1} are then modified by a matrix of relationships within and across metafounders (Γ). We developed a software called gammaf90 that computes Γ, and we changed BLUPF90 software to account for MF. When using MF for GEBV estimation, the RANDOM_TYPE in renf90.par should be add_an_meta. Among the free software, only blupf90plus and gibbsf90plus work with MF. The implementation of MF was tested in US Holstein data (861k genotypes), chicken data (107k genotypes), and dairy sheep data (6k genotypes).

Optimizations for large-scale ssGBLUP evaluations. The algorithm for proven and young (APY) was implemented in the BLUPF90 suite in 2015. APY allows the construction of a sparse representation of G^{-1}, making computations with millions of genotyped animals very efficient (Misztal *et al.*, 2014). An efficient algorithm for A_{22}^{-1} was also implemented (Masuda *et al.*, 2017). For blending of G and A_{22}, the initial implementation was inefficient. We recently changed the implementation of Colleau (Colleau, 2002) in BLUPF90 to compute coefficients of A_{22} separately for core and noncore animals. This new implementation was tested with US Holstein data containing 3.4M genotyped animals. Extensive changes in the iteration on data (i.e. iod) programs were also made to improve the computational efficiency in evaluations with extensive data. This included splitting data and pedigree and using different computing cores for parallel i/o.

An efficient algorithm to approximate reliability or accuracy of GEBV. Reliabilities of GEBV can be calculated as a function of prediction error variances (PEV) obtained from the diagonal of the inverse of the

coefficient matrix of MME. This inverse is not feasible with large datasets, and therefore, reliabilities need to be approximated. An algorithm based on Liu *et al.* (2017) was developed that considers the sparsity of APY G^{-1} (Bermann *et al.*, 2021). The algorithm computes weights for pedigree and phenotype contributions, adds the weights to the diagonals of APY G^{-1}, and uses block sparse inversion to compute coefficients for core and noncore animals separately. A brand-new program, accf90GS2, was created to accommodate the new reliability calculations. It is based on accf90 and considers maternal, multi-trait, and repeatability models. Tests included single- and three-trait models using American Angus datasets with up to 335k genotyped animals. An algorithm for the exact reliability of indirect predictions was also recently implemented.

***P*-values for SNP effects in single-step GWAS.** Because of the equivalence between ssGBLUP and ssSNP-BLUP, GEBV from the former can be backsolved to SNP effects. GWAS may use SNP effects or proportion of variance explained by SNP; however, it is usual to present *P*-values to test the statistical significance of SNP on traits of interest. We implemented *P*-values in ssGWAS based on PEV for SNP effects (Aguilar *et al.*, 2019). These GWAS are mathematically equivalent to single-marker regression as implemented in the EMMAX software. Obtaining *P*-values requires OPTION snp_p_value in blupf90 and postGSf90. Testing included US Holstein and American Angus data with 10k and 1.4k genotyped bulls, respectively.

Results

Software consolidation. The consolidation was done successfully, and all the tests resulted in identical solutions between blupf90plus and either blupf90 or remlf90 and airemlf90. The same was observed when comparing gibbsf90plus and its component software. Therefore, the consolidated software is ready for official deployment.

Unknown Parent Groups (UPG) in ssGBLUP. Using the altered QP transformation for H^{-1} resulted in greater reliability and lower dispersion bias than the QP for H^{-1} and A^{-1}. Although the three transformations are implemented, we recommend using the altered QP transformation when applying UPG in ssGBLUP. This may hold in most cases; however, testing is suggested.

Metafounders (MF) in ssGBLUP. The application of MF required new software, gammaf90, to estimate the gamma matrix. Gammaf90 is efficient with virtually any number of genotyped animals and MF; however, an accurate estimation required enough genotyped animals linked to MF. Overall, reliabilities or accuracies and dispersion bias were similar between models with the altered QP transformation in UPG and MF.

Optimizations for large-scale ssGBLUP evaluations. Time to compute the coefficients of A_{22} needed for blending in APY drastically reduced with the new algorithm for core and noncore animals separately. With 3.4M genotyped Holsteins, it took 12 minutes, compared to 41 hours with the previous method. The changes for parallel reading in the iod programs significantly reduced the time to solve the MME. Both modifications were necessary steps towards more efficient software for large-scale evaluations.

Efficient algorithm to approximate reliability or accuracy of GEBV. The new algorithm provided higher correlations (~0.98) with reliabilities based on PEV than the default algorithm (~0.90). The increase in computing time was linear with the number of genotyped animals and traits. It took 11 minutes for a three-trait model with 10M animals in the pedigree and 335k genotypes.

***P*-values for SNP effects in single-step GWAS.** We successfully implemented *P*-values for ssGWAS in BLUPF90. As expected, results were numerically identical to single-marker regression (i.e. EMMAX). Therefore, ssGWAS became a general and efficient QTL detection and test approach. This method can be

used in complex datasets such as those used in animal breeding, where only a proportion of pedigreed animals are genotyped.

Discussion

After 25 years, BLUPF90 became a resourceful collection of efficient software that handles ssGBLUP evaluations with millions of genotyped animals. Breed associations and breeding companies worldwide use this software suite for genomic evaluations in nearly all farm animal species. Academia uses extensively public versions for research. The subsequent updates will focus on further improving efficiency and convergence for large datasets and expanding the methods to increase the usability of the BLUPF90 software suite in animal and plant breeding. Constructive feedback is always welcome.

Abstract

Efficient computational solutions are a continuing concern for genomic predictions in animal and plant breeding. MiX99 was developed for fast solving of large-scale mixed model equations by preconditioned conjugate gradient with iteration on data. MiX99 offers stand-alone tools for pruning pedigree, computing inbreeding coefficients and allele frequencies, constructing and inverting various covariance matrices, calculating reliabilities, etc. In this paper, we describe in a workflow manner the most important programs and features of MiX99 that can be used for carrying out a single-step genomic best linear unbiased prediction based on the T matrix. The workflow is shown with a real dataset, and for each step we illustrate the applied optimization techniques, present the corresponding tools, and describe options in MiX99. Our example demonstrates also the computational load involved in the various steps.

Introduction

The MiX99 software (www.luke.fi/mix99) was developed for fast solving of large mixed model equations (MME) by a preconditioned conjugate gradient (PCG) iteration on data implementation (Strandén and Lidauer, 1999) and evolved to software capable of solving genomic prediction models with a large number of genotyped animals (Strandén *et al.*, 2018). Numerous utilities have been developed that are linked to the core programs. In general, MiX99 has two core parts: the pre-processor *mix99i* and the solver *mix99s* and its parallel version *mix99p*, enabling the users from pre-processing different types of raw data to obtaining the final estimated breeding values (EBV). In addition, MiX99 offers stand-alone tools for users to conduct related data analysis activities such as pruning pedigree, computing inbreeding coefficients and allele frequencies, constructing and inverting covariance matrices, calculating reliabilities, etc.

For the genomic prediction, MiX99 allows fitting the two basic equivalent models, i.e. genomic best linear unbiased prediction (GBLUP) (VanRaden, 2008) and single nucleotide polymorphism BLUP (SNPBLUP) (Strandén and Garrick, 2009). For single-step approaches, MiX99 can be instructed to perform the regular single-step GBLUP (ssGBLUP) (Legarra *et al.*, 2009, Christensen and Lund, 2010), an algorithm for proven and young (APY) (Misztal *et al.*, 2014), a single-step SNPBLUP (ssSNPBLUP) (Liu *et al.*, 2014), or a ssGBLUP implementation without the need to invert the genomic relationship matrix (G) (ssGTBLUP, Mäntysaari *et al.*, 2017) called ssGTABLUP when residual polygenic part is included. Thus, MiX99 allows the use of various linear MME and datasets for genomic prediction, such as single-step multiple trait random regression test-day models (Koivula *et al.*, 2015).

The objectives of this paper were: (1) to describe the most important programs of the MiX99 suite in a chronological workflow order applied for a particular ssGTABLUP evaluation; and (2) to demonstrate some new features of MiX99 within the process.

From raw data to solutions

To illustrate the workflow of running a ssGTABLUP model, a Red Dairy Cattle dataset from Nordic Cattle Genetic Evaluation (NAV) was employed and analyzed. Data comprised of 26.7 million records with 305-day milk, protein, and fat yields from first, second, and third lactations of 4.3 million cows. Pedigree included 5.9 million animals of which 169,779 were genotyped. For each work step, we described the

applied optimization techniques along with the corresponding tools we used in MiX99. In Table 1 we present the summary of the wall-clock time of each computation step. In the example, the pedigree-based relationship matrix A_{22}^{-1} for the genotyped animals was computed to get its diagonals for the preconditioner information. The A_{22} itself was not formed, nor the full inverse stored. Alternatively, A_{22}^{-1} diagonals can be attained faster using Monte-Carlo methods directly on pedigree (see option 2 below).

Estimation allele frequencies of the base population(s) using Bpop. In regular GBLUP, allele frequencies (AF) from an arbitrary base population have been recommended to be used in constructing the G matrix (VanRaden, 2008). The AF can be estimated for multiple base populations using the generalized least squares (GLS) method proposed by (McPeek *et al.*, 2004) and implemented in the *Bpop* program (Strandén *et al.*, 2017, Strandén and Mäntysaari, 2020). For a regular single-step, AF in chosen (earliest) base population can be used in constructing the G matrix. In our example here, however, we used multiple base populations as unknown parent groups (UPG) which were replaced by metafounders (MF, Legarra *et al.*, 2015).

Align G and A matrices and construct the gamma matrix (Γ). The compatibility of G and the numerator relationship (A) matrices is important in single-step methods. One commonly adopted approach is to scale the diagonal and off-diagonal elements of G to have the same average values as those of A (Christensen, 2012). The genomic information processing program *hgTinv* can be used to build various G matrices such as VanRaden 1 and 2 (VanRaden, 2008). Using MF, the UPG are replaced by related and inbred MF individuals. The MF will adjust the A and its part that includes the genotyped animals (A_{22}) matrices to be consistent with G where all AF are equal to 0.5. A covariance matrix of Γ needs to be built to reflect the 'relationships' among MF. The base population AF estimated with *Bpop* can be used in building the Γ matrix as described e.g. in Garcia-Baccino *et al.* (2017).

Compute inbreeding coefficients with RelaX2. Similar to the ordinary A matrix, in the MF approach the inverse of A augmented by the Γ matrix (A^{Γ}) can be constructed when the corresponding inbreeding coefficients are known. Given the input of the original pedigree and the Γ matrix, inbreeding coefficients can be calculated for all animals using the *RelaX2* program (Strandén and Vuori, 2006). It will also provide a new pedigree file with MF.

Predict genomic estimated breeding values (GEBV) with MiX99. Like single-step models with UPG, the MF model can be solved using ssGBLUP (with G_{APY} inverse if requested) or ssGTBLUP. The MiX99 software has two options to compute GEBV in ssGTBLUP:

Table 1. Runtime and CPU use of each program when solving a multiple trait single-step model with 5.9 million animals of which 169,779 were genotyped.

Step	Program	CPU[1] cores	Runtime (hrs:min)	Step	Program	CPU cores	Runtime (hrs:min)
1	*RelaX2*	1	00:21	4	*mix99i*	4	00:10
2	*Bpop*	4	00:09	5	*mix99s*	4	11:09
3	*hgTinv*	4	22:52	6	*apax99* (AM)	4	00:04
	3a) invert A_{22}		16:10	7	*apax99* (20p)	1	00:01
	3b) build T		06:43	8	*snp_blup_rel*	1	00:53[2]

[1] All programs executed in an Intel Xeon 2.8 GHz machine.

[2] Time for one trait.

- **Option 1: Compute matrix T and diagonal of A_{22}^{Γ} matrices with program hgTinv.** Given the input of pedigree, inbreeding coefficients, genotypes, and Γ^{-1}, the *hgTinv* program outputs T, as well as diagonal elements A_{22}^{Γ} (if requested). Once Γ^{-1} and inbreeding are given the rules of Henderson (1976) are used to compute the inverse of numerator relationship matrix for all the animals (A^{Γ}) and for the genotyped animals A_{22}^{Γ}. The advance of ssGTBLUP is that there is no need to compute G^{-1}, but instead an m×n T matrix, where m is the number of markers and n is the number of genotyped animals. If required, *hgTinv* can also generate G^{-1}, $\mathbf{G}_{APY}^{-1}$ *and* $\mathbf{H}_{Liu}^{22}$ from (Liu *et al.*, 2014).
  Compute GEBVs with mix99i and mix99s. To solve the MME and obtain the GEBVs, the files of pedigree, phenotypes, inbreeding coefficients, variance components, and T, are provided to *mix99i*. In the optimal use of ssGTBLUP, the *mix99s* or *mix99p* is asked to perform the computations involving the A_{22}^{Γ}, i.e. the inverse of relationship matrix of genotyped animals through using the pedigree file only and the metafounder information in Γ. While doing this, the iteration convergence can be improved by providing a file with the diagonals of A_{22}^{Γ} for the preconditioner. If high performance is required, this diagonal can be computed by program *iA22diag_make* using Monte Carlo sampling. With the MF approach, the file having the Γ^{-1} matrix must be supplied to *mix99i* using 'iGammaFILE' command. The *mix99i* (pre-processor) and *mix99s* or *mix99p* (solver) need to run sequentially.
- **Option 2: Compute Z and C^{-1} matrices with program T48eig_make.** Given the input of pedigree, genotypes, and Γ^{-1}, the *T48eig_make* program can output the centred marker covariate matrix Z and the C^{-1} matrix, where $\mathbf{C} = \mathbf{Z}'\mathbf{A}_{22}^{-1}\mathbf{Z}/\mathrm{w} + \mathbf{I}\mathrm{d}$, in which d = k/(1-w), w is the proportion of residual polygenic effect and $k = \sum_{l=1}^{m} 2p_l(1-p_l)$ with p_l the AF.
  Compute diagonal of A_{22}^{Γ} with program iA22diag_make. Given the input of pedigree and genotyped IDs, the *iA22diag_make* program outputs diagonal elements of A_{22}^{Γ}.
  Compute GEBVs with mix99i and mix99s. Given the input files of pedigree, phenotypes, inbreeding coefficients, variance components, C^{-1}, Z, Γ^{-1}, and $diag(\mathbf{A}_{22}^{\Gamma})$, similar as in Option 1, GEBVs can be achieved. In this option some of the computations to make the T matrix in option 1 are done within each PCG iteration in *mix99s*. This tends to reduce the total computing time when the model includes more SNPs than the expected number of iterations. Moreover, this approach directly produces the solutions for SNP effects from *mix99s*.

Calculate EBV reliabilities for all animals with mix99i and apax99. Calculation of reliabilities of EBV requires the prediction error variances (PEV). This can be done using exa99. However, for large systems, it is impossible to invert the coefficient matrix of the MME and approximation approaches have to be used. The *apax99* program supports different approaches to approximate EBV reliabilities and provides basic approximation options for GEBV reliabilities. For the given example, we used the method of Jamrozik *et al.* (2000).

Calculate GEBV reliabilities for genotyped animals with snp_blup_rel. In dairy cattle breeding, effective daughter contributions (EDC) or effective record contributions (ERC) has long been adopted as the input to reliability estimation. For single-step models, the ERC for genotyped animals can be computed by *apax99* and thereby be used in the calculation of GEBV reliabilities from SNPBLUP. The a*pax99* program offers options for so-called reverse reliability estimation that give reliability equivalent ERC (Ben Zaabza *et al.*, 2022). Then, given the ERC as weights in SNPBLUP, program *snp_blup_rel* can be used to calculate the GEBV reliabilities for the genotyped animals (Ben Zaabza *et al.*, 2020). EBV reliabilities for the non-genotyped animals can be obtained by returning the genomic added ERC to *apax99* (Ben Zaabza *et al.*, 2022).

Statistical genetics: GWAS

368. Haplotypes affecting pulmonary arterial pressure in Angus cattle

D. Lu[1*], A. Garcia[1], S. Miller[2] and K. Retallick[1]

[1]Angus Genetics Inc., American Angus Association, 3102 Frederick Ave., Saint Joseph, MO 64506, USA;
[2]Animal Genetics & Breeding Unit, University of New England, Armidale NSW 2351, Australia; dlu@angus.org

Abstract

Cattle that have high pulmonary arterial pressure (PAP) and live at high elevations are at risk of high mountain disease, which causes economic loss to Angus breeders. A 2.3 kb haplotype, HapA hereafter, with frequency of 26.99% in the genotyped Angus cattle, was identified at chr7: 90824804- 90827178 and proven to be associated with lower PAP measures at weaning and yearling. Average PAP scores among HapA heterozygotes, HapA homozygotes, and alternate homozygotes were 41.97±7.52, 40.66±6.56, and 44.11±9.25, respectively. Carrying 1 copy and 2 copies of HapA helped lower PAP score by 1.9120±0.1938 (P<0.001) and 2.6620±0.3193 (P<0.001) compared to non-carriers, respectively. While efforts to pin down causal variants for PAP are underway, HapA might be useful for improving the accuracy of PAP breeding value estimates.

Introduction

Pulmonary hypertension, measured by mean pulmonary arterial pressure (PAP), is defined as high blood pressure in the lungs and the right side of the heart, which in cattle is often associated with elevations above 1,524 meters above sea level and indicative of high mountain disease (HMD) (Holt and Callan, 2007). Holt and Callan (2007) estimated that cattle losses due to HMD alone can be averaged around 3-5% of the calf crop, resulting in a financial loss of about US$60 million (McCormick 2011). In May 2020, the American Angus Association and Angus Genetics Inc. (AGI) officially released expected progeny differences (EPD) for PAP in efforts to help Angus breeders make better selection decisions with regard to the trait. With the rapid advancement of DNA and single nucleotide polymorphism (SNP) chip technology, researchers at AGI have been able to explore various approaches to improve the accuracy of PAP prediction, and herein reported a new discovery in our efforts to estimate breeding value for PAP. The objective of this exercise was to estimate effects of haplotypes potentially impacting PAP score in Angus beef cattle.

Materials & methods

Genotypes and imputation. This analysis involved 982,769 animals genotyped with various SNP arrays, namely i50K, HD50K, GGPLD, GGPHD, GGPUHD, AngusGS (hereafter GSv.1 and GSv.2). SNP in GSv.1 fully overlapped with part of GSv.2, thus all animals genotyped with GS.v1 were imputed to GSv.2 for all autosomal SNP. There were various versions of HD50K, of which ZBUv.2 was used as reference panel to impute those genotyped with i50K and other HD50K versions to ZBUv.2 autosomal SNP. SNP in GSv.2 and ZBUv.2 were combined to create a set of 85,134 SNP on 29 autosomes (hereafter 85K). Animals with original and imputed GSv.2, as well as animals with original and imputed ZBUv.2, were imputed to the 85K, which were then used as reference animals to impute GGPLD, GGPHD, GGPUHD animals up to the 85K. Imputation was performed using FImpute v.3 (Sargolzaei *et al.*, 2014). Imputation accuracy in terms of genotype concordance was 99.22-99.85%.

Animals and phenotypes. There were 19,175 animals measured for PAP born between 1993 and 2020, with 59.42% of them born between 2015 and 2020. Pulmonary arterial pressure was measured as described by Holt and Callan (2007). Tests for PAP were categorized into two levels of elevation and different age groups as described in Table 1. Those PAP measured at yearling and at moderate elevation were referred to as moderate PAP (mPAP hereafter). Similarly, PAP measured at high elevation when animals were

Table 1. Description of PAP data.[1]

Elevation	n	AOT	PAP	h^2
Moderate (1,219-1,676 m) – mPAP	5,984	440.52±98.17	42.76±8.35	0.29
High (1,676 m and above) – wPAP	4,572	227.70±39.67	41.45±7.77	0.27
High (1,676 m and above) – hPAP	10,032	424.48±85.62	42.87±7.78	0.40

[1] n = number of records; AOT = age on test; PAP = pulmonary arterial pressure; h^2 = heritability.

424.48±85.62 and 227.70±39.67 days old were referred to as high PAP (hPAP hereafter) and wean PAP (wPAP hereafter), respectively. There were 1,413 animals tested for both wPAP and hPAP. Genetic parameters for PAP were estimated using airemlf90 (Misztal *et al.*, 2014). There were 8,497 animals with both genotypes and PAP measures, including 1,686, 4,032, and 3,266 animals with wPAP, mPAP, and hPAP, respectively. Of the 1,686 animals tested for wPAP, 487 of them were also tested for hPAP.

Methodology. Genomic regions of interest were identified by sliding a six-SNP window across 29 autosomes one SNP at a time, with SNP effect being the average of the window. The process started with estimating genomic breeding values (GEBV) with single-step genomic BLUP (ssGBLUP). The following statistical model was used y = Xb + Zu + e, where y was the vector of phenotypes recorded for mPAP, wPAP, and hPAP; b was the vector of fixed effects of contemporary group, and both the age of the animals, and the elevation fitted as covariates; u was the vector of additive genetic effects and e was the vector of residuals. The matrices X and Z were the incidence matrices for the effects in b and u respectively.

The genomic relationship matrix (G) was constructed as in VanRaden (2008) using allele frequencies from the current genotyped population. To avoid singularity, G was blended with 10% of the pedigree relationship matrix for genotyped animals (A_{22}). Because of the large number of genotyped animals, the algorithm for proven and young (APY) (Misztal *et al.*, 2014) was used to invert G. The number of core animals was based on the number of eigenvalues explaining 99% of the variation in G and it was the same core set as used in the official Angus weekly evaluation. Once GEBV were available, SNP effects were back-solved as described by Wang *et al.* (2012) and used for subsequent analyses. Calculations of GEBV and SNP effects were done using software from the Blupf90 family of programs (Misztal *et al.*, 2014).

A seven-SNP region was selected out of the postGS analysis based on their estimated SNP effect and the extent of linkage disequilibrium (LD) in the region. Effects of all possible haplotypes in the region, including haplotypes of seven, six, five, four, or three consecutive SNP, were estimated in univariate models similar to Equation 1. However, y was now the vector of either mPAP, or wPAP, or hPAP. Fixed effects were extended to include the effect of haplotype coded as categorical zero copy, one copy, or two copies of each haplotype investigated. One haplotype was investigated at a time. The relationship matrix G was replaced with the additive numerator relationship derived from pedigree. Because several haplotypes were tested, running the models through ASReml 4.1 (Gilmour *et al.*, 2015) helped expedite the analyses. Haplotype with the most significant impact on the wPAP, mPAP, and hPAP, as well as displaying the strongest LD among individual SNP, was chosen as a candidate haplotype.

Another statistical model was tested, where wPAP, mPAP, and hPAP were combined into only one trait namely PAP, thus one individual could have more than one PAP measures. The fixed effects included contemporary group, sex, age at test, elevation, and haplotype. Random effects included animal effect, permanent environmental effect to capture variance due to repeated records where animals were tested at both weaning and yearling, and error term. This model was run with ASReml 4.1 (Gilmour *et al.*, 2015).

Results & discussion

Genetic correlations between mPAP and wPAP, mPAP and hPAP, wPAP and hPAP were 0.83, 0.92, and 0.98, respectively. Results from the postGS suggested a 7-SNP segment, chr7: 90689839-90827178, be considered for haplotype analysis. Mean pairwise LD (r^2) in this segment was 0.91±0.08. After testing the effects of all possible haplotypes in the region, the focus has landed on a three SNP segment, chr7: 90824804- 90827178, within the 7 SNP region. Linkage disequilibrium in this three SNP segment was nearly 1.0. There were two main haplotypes in this region, namely HapA and HapB with frequency of 26.99 and 72.99%, respectively, out of 982,769 genotyped animals. Their frequency among the genotyped and PAP tested animals was 32.49 and 67.50%, respectively. HapA with a lower frequency in the population was used as reference haplotype in subsequent analyses. Table 2 presents average PAP score for animals carrying zero copy, one copy, or two copies of HapA. PAP score at weaning was lower than the score at yearling. Animals that carried one copy or two copies of HapA had PAP score consistently lower than those not carrying the haplotype. Genetic correlations of 0.83-0.98 between pairs of PAP traits suggested that they could be collapsed into one trait, whose mean among animals not carrying HapA was 44.11±9.25, decreasing to 41.97±7.52 and 40.66±6.56 in those carrying one copy and two copies of HapA, respectively. According to Holt and Callan (2007), cattle older than 12 months, living at elevation above 1,524 m, are considered normal if PAP score is below 41, however at risk of HMD if PAP score above 49. In the current study, there were 4,578 animals older than 12 months and being raised at altitude above 1,524 m. Of them, 2004, 2020, and 554 animals carried zero copy, one copy, and two copies of HapA, respectively. Among the non-carriers, 418 (20.86%) had PAP above 49. This percentage in the one copy and two copy carriers was 13.02 and 10.83%, respectively. If PAP score greater than 49 is indicative of risk of HMD, non-carriers of HapA were two times more likely to be at risk than HapA homozygotes.

Estimated effects of HapA are presented in Table 3. Carrying HapA significantly decreased PAP score compared to non-carriers. The effect of HapA appeared to be similar among the mPAP and hPAP animals, though slightly smaller in the wPAP animals. Contrasts of PAP score between HapA homozygotes and HapA heterozygotes were also tested and found to be not statistically significant among the wPAP and hPAP groups of animals; However, they were significant among the mPAP animals, as well as when the wPAP, mPAP, and hPAP were collapsed into one trait. In the current study, PAP score spread from a low of 25 to a high of 70, and if a score of 49 is the threshold to determine whether an animal is at risk or not at elevation above 1,524 m, a drop by approximately 2 points might be beneficial to the animal and thus the owner. Specifically, there were 741 individuals being raised at elevation above 1,524 m, older than 12 months of age, and PAP score greater than 49 in this study, and thus were at risk of HMD according to Holt and Callan (2007). Had the non-carriers of HapA carried one copy of the haplotype, the number of animals at risk of HMD would have dropped to 678, a save of 8.5% of the animals.

HapA can be used as a tool to screen animals potentially at risk of HMD. Alternately, SNP surrounding this haplotype region, or the haplotypes could be modelled appropriately when performing the genetic evaluation for PAP. Researchers at AGI are working to find causal variants for PAP specifically in the genomic region identified in this study. Once identified, causal variants can be put on Angus SNP chips for

Table 2. Summary of PAP score in the research population (mean ± SD).

Number of copies of HapA	Wean PAP	Moderate PAP	High PAP	Overall
0	42.08±8.21	44.45±9.55	44.73±9.20	44.11±9.25
1	40.25±6.43	42.16±7.76	42.62±7.62	41.97±7.52
2	38.65±4.38	40.89±7.19	41.39±6.61	40.66±6.56

Table 3. Estimated effects of one or two copies of HapA (Effect ± SE).[1]

HapA	Wean PAP	Moderate PAP	High PAP	Overall
0	0	0	0	0
1	-1.35±0.37*	-2.01±0.29*	-1.89±0.30*	-1.91±0.19*
2	-2.42±0.58*	-2.59±0.50*	-2.75±0.46*	-2.66±0.31*

[1] * = $P<0.001$; HapA 0, 1, 2 – Carrying 0, 1, 2 copies of HapA, respectively.

estimating breeding value for PAP. Yet, the haplotypes need to be validated. More animals need to be PAP tested and genotyped.

Conclusions

Haplotypes affecting PAP score in Angus beef cattle were discovered and found to have significant impact on the research animals. HapA has potential to help increase the accuracy of PAP EPD as a selection tool for Angus breeders, especially those who raise their cattle at high elevations.

Abstract

Global genetic correlations as common estimates of pleiotropy across the genome fail to dissect the absolute level of shared genomic regions and their effects on various traits. Methods in human genetics that try to transfer global estimates to the local scale showed up recently but have not been applied to livestock yet. One of them is LOGODetect, scanning summary statistics for shared genomic regions between two traits. We applied LOGODetect on a sample of German Holstein cattle to identify these regions for milk production, mastitis and claw disease traits and found a certain number of segments with concordant effects and enriched findings on chromosome 14 in the area of the *DGAT1* gene.

Introduction

Dissection of genetic correlation from GWAS summary statistics (Bulik-Sullivan *et al.* 2015) had become a common procedure to quantify the level of shared genetic influence on several traits to quantify pleiotropy (Guo *et al.* 2021). Nevertheless, it does not only fail to unveil the underlying causal mechanisms and exact position of pleiotropic variants in the genome (Visscher und Yang 2016). Moreover, global genetic correlations might also be veiled in their overall dimension as some local correlations can appear in antagonistic directions and global genetic correlations give average estimates across the genome, caching strong local correlations in the absence of any global correlation (Shi *et al.* 2017, van Rheenen *et al.* 2019). SNP-based estimation of global genetic correlation suffers from substantial LD between markers, because non-causal mutations might be raised in their signal even though their trait specific effect is merely LD based (van Rheenen *et al.* 2019). Therefore, common global estimates of genetic correlation cannot be directly transferred to the local scale (Werme *et al.* 2021) and different methods have been developed to deal with this issue. One of them is LOGODetect, a tool to detect shared genomic segments between various traits, that is detached from prior assumptions about the localization of these segments in the genome (Guo *et al.* 2021). So far, this has only been applied in human genetics.

In dairy cattle breeding, several novel health traits are recorded and entered the total merit index in many countries. An in-depth analysis of the genetic correlation might shed some light on the role of pleiotropy for these novel traits and existing production traits. This is peculiar not only because pleiotropy had been detected on a widespread level also in cattle (Xiang *et al.* 2017), but also because of economical, ecological and ethical concerns about livestock production. Therefore, the aim of the present study was to dissect local genetic correlations between milk productions, mastitis and claw diseases applying LOGODetect on a large sample of German Holstein cows.

Materials & methods

We analysed genotypes and phenotypes of 34,497 primiparous Holstein cows with lactation records of milk and health traits between 2015 and 2020, both provided by the national computing centre VIT (Vereinigte Informationssysteme Tierhaltung w.V., Verden). Health traits consisted of mastitis (MAS), claw ulcers (CCU), white line disease (CWL), laminitis (CLA), interdigital hyperplasia (CIH) and digital phlegmon

(CPH). With the formula of Nostitz and Mielke (1995) milk energy yield (MEY) was calculated to obtain a measure of the cow's energetic output via milk production. The cow's farm, year and season of lactation were combined to heard-year-season (hys), where each season contained three months according to the calendric partitioning of seasons. Cows were mostly genotyped with the Illumina Bovine Eurogenomics 10 K chip and then imputed to the Illumina Bovine 50 K SNP BeadChip V2 (Illumina Inc., San Diego, CA) according to the procedure applied in the national genetic evaluation (Segelke *et al.* 2012). 44,126 SNPs remained after filtering out SNPs on gonosomes and those with a MAF below 0.01. We performed a GWAS for all traits with the following mixed linear model that is implemented in GCTA (Yang *et al.* 2011), applying the 'leave-one-chromosome-out' (LOCO) approach according to Yang *et al.* (2014) as

$$y = \mu\,\mathrm{Xb} + g + e$$

Here, y is the vector of raw phenotypes that were standardized for the gaussian traits to facilitate the interpretation of SNP effects but remained coded as 0/1 for the disease traits. The vector b contains the fixed effects including the SNPs effect, the hys, age at first calving or days in milk. X as the incidence matrix for b inherits the SNPs amount of allele copies and further links the trait records to the covariate's effects. g is the polygenic term, accounting for relatedness in the sample with variance $\boldsymbol{g} \sim N(0,\mathbf{G}\sigma_g^2)$ implementing the LOCO-adjusted GRM G and e the residual term with variance $\mathbf{e} \sim N(0,\mathbf{I}\sigma_e^2)$. To decide whether the covariates age at first calving and days in milk had to be included for each trait we performed an ANOVA with the R package car (Fox 2019) and declared a covariate's effect to be significant if it's P-value was below 0.05. Additionally, 20 principal components computed with GCTA (Yang *et al.* 2011) were included as covariates in two different ways, either on a genomewide or chromosomal level. The latter involved only the principal components for the chromosome on which the candidate SNP was located. For subsequent usage, we chose the method where the inflation factor λ_{GC} was closest to unity. A threshold of 0.0000011 (corresponds to a genome wide significance) and 0.0005 (nominal significance) was used to declare a SNP as trait-associated. The GWAS summary data were used as input-data to detect local genetic correlations with LOGODetect, whose application can be taken from Guo *et al.* (2021), following the tutorial on Github (https://github.com/ghm17/LOGODetect). The key point and central output of this method is the scan statistic $Q(R)$. It consists of the SNP effects for both traits within a specified region, multiplied with each other and divided through the sum of LD scores for each of these SNPs. Negative values indicate regions with negative local genetic correlations and vice versa. As it can be seen from this calculation, LOGODetect doesn't give absolute estimates of genetic correlation but identifies regions with significant shared effects on multiple traits (Guo *et al.* 2021).

Results

The number of identified regions between MEY and a health trait varied between two and 20 was highest between MEY and CPH (20). These regions harboured between five (CLA) and 25 (CPH) SNPs, which did not necessarily reach significance in the single trait's GWAS. Two regions were detected in each case for CIH and CCU and four regions for CLA, CWL and MAS respectively. The average segment length was 1,027,368 bp. Regarding the effect directions, it has to be mentioned, that only seven of all 36 identified regions showed a negative sign. Five of them where for CPH and one for CWL and CCU, respectively. $Q(R)$ varied between -5.03 (MEY-CWL) and 14.31 (MEY-CIH), showing that the positive correlation of rising MEY and rising disease cases was about three times higher than the preventive effect of rising MEY on health traits. Figure 1 shows the distribution of concordant effects across chromosomes. Most chromosomes harbour either negative or positive effects except of chromosome 13 and 22, where bi-directional effects on various traits were detected. Located on chromosomes 7, 13 and 14 are regions that show concordant effects on MEY and multiple disease traits. What sticks out is chromosome 14, where positive effects of MEY and all disease traits except of CCU are around the well-known *DGAT1* mutation.

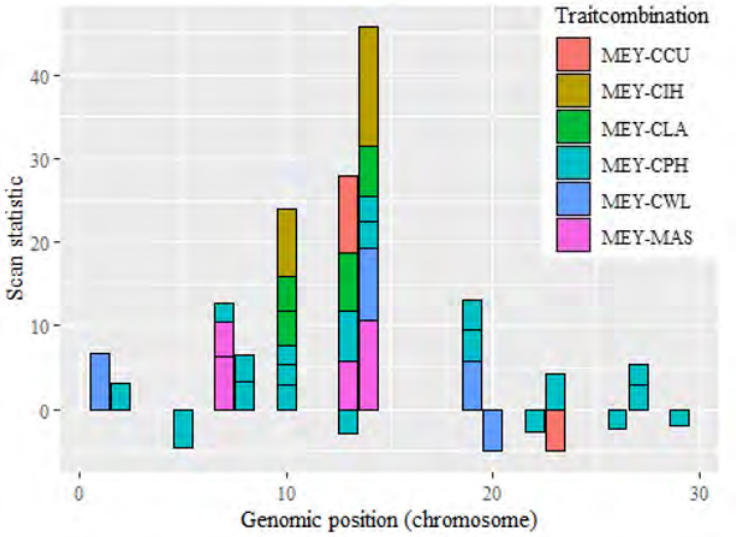

Figure 1. Distribution of genomic regions, which were identified with LOGODetect. Shown is their genomic position and scan statistic.

Discussion

By applying LOGODetect to different trait combinations it was possible to identify segments on the genome with significantly correlated effects on health traits and milk production in German Holstein. These findings are supported by other results that have for example shown pleiotropic effects of *DGAT1* not only on milk production but also on fertility (Oikonomou *et al.* 2009). Yet, the approach is only applicable to two traits simultaneously, making the analysis of multiple trait combinations rather protracted. Nevertheless, because of LD as a weighting factor for the marker effects on both traits, LOGODetect avoids unjustified preference of a sequence that is merely because of linkage in this region and outperforms other tools due to its unbiased and accurate detection of segments inheriting a larger proportion of genetic covariance (Guo *et al.* 2021). Moreover, unlike in other tools that are single SNP based there is no limitation to distinguish between the true SNPs signal and the signal of any neighbouring SNPs (Werme *et al.* 2021). Originally LOGODetect had been developed in human genetics, exhibiting substantially lower LD than livestock. Probably, that's why the choice of the weighting factor might need to be adapted in livestock. Suggestions by Guo *et al.* (2021) were applied here as their optimal choice is computationally expensive. Next to that, LOGODetect compares the null distribution of SNP effects under the assumption of no correlation applying a Monte Carlo approach with currently no existing computationally more efficient method to derive this distribution (Guo *et al.* 2021). What has to be considered is that the present study is limited by the number of markers, as most common variants explain only a small proportion of heritability (Visscher and Yang 2016). In the original methods, the authors suggested a splitting of the genome into independent LD blocks to receive more accuracy in the detection of significant regions (Guo *et al.* 2021). The limited number of markers hindered us to do so as each block would either have consisted of only few markers or would have covered a large part of the genome and neither of these opportunities fits the splitting's intention.

370. Detecting the presence of genomic imprinting for carcass traits in cattle using imputed high-density genotypes

D. Kenny[1], R.D. Sleator[2], C.P. Murphy[2], R.D. Evans[3] and D.P. Berry[1*]

[1]Teagasc, Moorepark, Fermoy, Co. Cork, P61 C996, Ireland; [2]Munster Technological University, Bishopstown, Co. Cork, T12 P928, Ireland; [3]Irish Cattle Breeding Federation, Highfield House, Bandon, Co. Cork, P72 X050, Ireland; donagh.berry@teagasc.ie

Abstract

Genomic imprinting is defined as the silencing of an allele at a given locus, at least partially, based on the sex of the transmitting parent. The objective of the present study was to detect single nucleotide polymorphism (SNP)-phenotype imprinting associations for carcass traits using imputed, high-density genotype data from 23,687 cattle. In total, 51, 226 and 192 SNPs located on six different chromosomes had significant imprinting associations with carcass weight, carcass conformation and carcass fat, respectively. Furthermore, an additional 36, 130 and 100 SNPs demonstrated suggestive imprinting associations with carcass weight, carcass conformation and carcass fat, respectively. Of the SNPs detected herein to have imprinting associations, no SNP was located within 0.5 Mb of a known imprinted gene.

Introduction

Traditional approaches to genetic evaluations assumes that inter-animal genetic and performance differences are due to differences in the DNA sequence of the animals' genomes. The epigenome, which manifests itself as changes in an animal's gene expression and phenotypic performance without an alteration in the underlying DNA sequence, deviates from this assumption (González-Recio *et al.* 2015). Genomic imprinting is a epigenetic phenomenon defined as the differing expression of an allele depending on the sex of the transmitting parent (Reik and Walter 2001). Knowledge of the presence of genomic imprinting has previously been shown to be beneficial in mate allocation programs (González-Recio *et al.* 2015), with the consideration of imprinting effects in genomic evaluations been reported to improve the accuracy of additive genomic breeding values (Nishio and Satoh 2015). The objective of the present study was to detect the presence of genomic imprinting for carcass weight (CW), carcass conformation (CC) and carcass fat (CF) in cattle using high-density genotype data, which, to the best of our knowledge, has not been reported previously.

Materials & methods

Data. After edits, carcass data, along with imputed, high-density genotype data, comprising 618,837 autosomal single nucleotide polymorphisms (SNPs), from 23,687 prime Irish beef cattle were available. The carcass data included carcass weight (CW), carcass conformation (CC; scored 1 [poor] to 15 [excellent]) and carcass fat (CF; scored 1 [thin] to 15 [fat]) information, measured in accordance with the EUROP grading system. All 618,837 SNPs had minor allele frequencies >0.05 and call rates >90%. All 23,687 animals also had call rates >90%. The parental origin of each allele was inferred by phasing the animals' genotypes in FImpute2 (Sargolzaei *et al.* 2014) using pedigree and genotype information from 130,178 animals; these animals included at least one genotyped parent of each animal of interest. Following phasing, four unique genotypes were distinguishable at each locus (e.g. AA, AB, BA and BB; where the first allele of the heterozygotes is paternally inherited and the second is maternally inherited). The four genotypes were then coded to represent additive (i.e. 0 (AA), 1 (AB and BA) and 2 (BB)), dominance (i.e. 0 (AA and BB) and 1 (AB and BA)) and imprinting (0 (AB), 1 (AA and BB) and 2 (BA)) effects.

Genome-wide association analysis. Using the GRAMMAR method outlined by Aulchenko *et al.* (2007a), all carcass phenotypes were pre-adjusted for nuisance variables, fitted as fixed effects, as well as for the direct polygenic effect of the animals *via* a genomic relationship matrix. All phenotypes were adjusted in the GenABEL package in R (Aulchenko *et al.* 2007b) using the following model:

$$y = 1\mu + X\beta + Z\alpha + e \quad (1)$$

where y was the vector of CW, CC scores or CF scores; 1 was a vector of ones; μ was the population mean; β was a vector of fixed effects that included contemporary group, birth herd type (i.e. beef or dairy), dam parity, recombination loss class, whether the animal was born a singleton or a twin and observed heterozygosity; α was a vector of random polygenic effects ($N(0,\mathbf{G}\sigma^2_a)$), where G and σ^2_a are a genomic relationship matrix and the genetic variance, respectively; e was a vector of random residual effects ($N(0,\mathbf{I}\sigma^2_e)$) where I and σ^2_e are an identity matrix and the residual variance, respectively; X and Z were incidence matrices for the fixed and random effects, respectively. Association analyses were then conducted separately for each locus using the following model:

$$e = 1\mu + b_1a_k + b_2d_k + b_3i_k + e_k \quad (2)$$

where e is the vector of corrected phenotypes from Equation 1; 1 was a vector of ones; μ was the population mean; a_k, d_k and i_k were the vectors of additive, dominance and imprinting genotype codes for locus k, respectively; b_1, b_2, and b_3 were the regression coefficients associated with the additive, dominance and imprinting genotype codes, respectively, and e_k was a vector of residuals. To test the significance of the b_3 regression coefficients and to correct for multiple testing, all *P*-values were transformed to q values (Storey and Tibshirani 2003). All SNPs with a q value ≤0.01 were considered significant, while all SNPs with a q value >0.01 and ≤0.05 were considered suggestive. Quantitative trait loci (QTL) regions were defined based on the flanking linkage disequilibrium patterns around the SNPs with significant or suggestive associations. To estimate the start and end positions of the QTL regions, all SNPs within a 0.5 Mb window that were in linkage disequilibrium (r^2 of ≥0.5) with another significantly or suggestively associated SNP on the same chromosome were considered part of a single QTL region. Overlapping regions were merged together and considered single regions.

Results

The associations between the imprinting genotype codes of each SNP and CW, CC and CF are in Figure 1. Fifty-one SNPs, 50 of which were located on *Bos taurus* (BTA) chromosome 2 with one (i.e. rs109356127) located on BTA 19, demonstrated significant (q≤0.01) imprinting associations with CW. In addition, a further 36 SNPs located on BTA 2 (29 SNPs), BTA 10 (one SNP), BTA 11 (one SNPs), BTA 16 (three SNPs), BTA 21 (one SNPs) and BTA 23 (one SNPs) demonstrated suggestive imprinting associations (0.01<q≤0.05) with CW. These SNPs collapsed into five distinct QTL regions located on BTA 2, ranging in length from 8.5 to 387.5 Kb, as well as a QTL region on BTA 16. All lead SNPs (i.e. the SNP with the strongest association) of these regions were intergenic. These intergenic QTL regions detected for CW stretched from 2.590 to 2.826 Mb, from 3.022 to 3.038 Mb, from 3.300 to 3.312 Mb, from 3.326 to 3.713 Mb, and from 4.100 to 4.104 Mb on BTA 2, as well as from 49.938 to 49.943 Mb on BTA 16. In addition to the imprinting associations, 23 SNPs and 41 SNPs on BTA 2 and BTA 6, respectively, demonstrated additive associations with CW, with three SNPs on BTA 2 demonstrating dominance associations with CW.

A total of 226 and 130 SNPs had significant and suggestive imprinting associations with CC, respectively. On BTA 2, 320 SNPs demonstrated either significant or suggestive imprinting associations, from which 23 imprinted QTL regions, ranging from 0.9 to 390.6 Kb in length, were identified. Based on the remaining

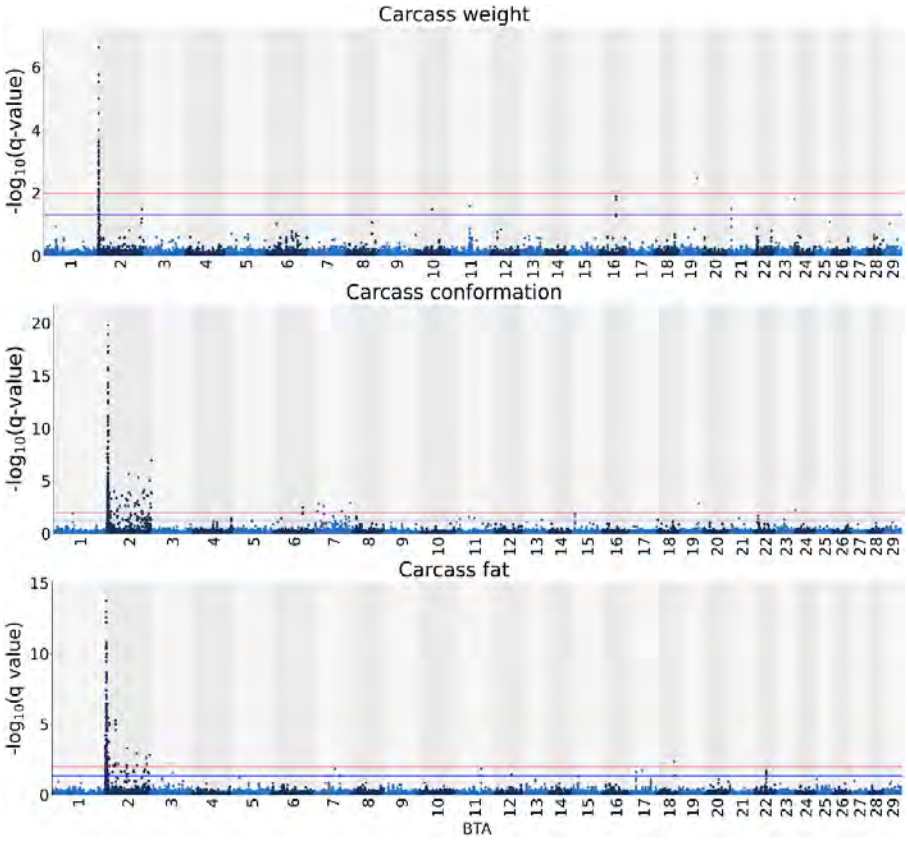

Figure 1 Manhattan plots of the $-\log_{10}$(q values) for imprinting associations with carcass weight, conformation and fat from each *Bos taurus* (BTA) chromosome. Blue and red lines are the thresholds for suggestive and significant associations, respectively.

SNPs demonstrating imprinting associations with CC, additional QTL regions were identified on BTA 4, BTA 6, BTA 8 and BTA 22. The associative lead SNPs of the QTL regions identified for CC included intronic variants of *NIPA1*, *NIAP2*, *IMP4*, *FAM168B*, *UGGT1*, *WDR33*, *BIN1*, *DDX58* and *STAC*, as well as intergenic variants. Furthermore, 12 SNPs on BTA 2 and one SNP on BTA 6 demonstrated additive associations with CC, and 45 SNPs, two SNPs, seven SNPs, one SNP and one SNP on BTA 2, 5, 8, 18 and 19, respectively, demonstrated dominance associations with CC.

Only 191 SNPs on BTA 2, along with a single SNP on BTA 18 (i.e. rs135579718) demonstrated significant imprinting associations with CF, with an additional 100 SNPs, located on eight different chromosomes, demonstrating suggestive associations with CF. The 292 SNPs demonstrating imprinting associations with CF collapsed into 26 distinct QTL regions on BTA 2, as well as into single QTL regions on BTA 7, BTA 18 and BTA 22. The lead SNPs of these regions included intronic variants of *OCA2*, *NIPA1*, *IMP4* and *WDR33*, *MAT2B* and *TAFA4*. Additionally, 161 and two SNPs on BTA 2 and 5, respectively, demonstrated additive associations with CF, with 179 SNPs on BTA 2, two SNPs on BTA 5 and a SNP on BTA 7 demonstrating dominance associations with CF. For all traits, no known imprinting gene was detected within 0.5 Mb of a SNP of interest.

Discussion

Knowledge of the presence of imprinting associations for a trait of interest and consideration of such associations in genomic evaluations can improve the accuracy associated with additive breeding values (Nishio and Satoh 2015). Furthermore, knowledge of the loci at which imprinting associations exist for carcass metrics could be implemented into mating advice programs for genotyped populations to exploit the effects of genomic imprinting in subsequent offspring (González-Recio *et al.* 2015). The presence of SNPs demonstrating imprinting association with carcass traits have been previously reported in cattle (Magee *et al.* 2010; Imumorin *et al.* 2011), although no such analysis has yet been conducted using high-density genotype data. The vast majority of the SNPs detected to have imprinting associations in the present study were located on BTA 2; this is despite the fact that imprinted genes have yet to be validated on BTA 2. Nonetheless, the presence of novel imprinting regions for beef carcass traits, namely CW and kidney, pelvic and heart fat, on BTA 2 was previously reported by Imumorin *et al.* (2011); Imumorin *et al.* (2011) advocates the need for further exploration on this chromosome. Additionally, an ortholog of an imprinted gene (i.e. IWS1) in humans and mice (Gregg *et al.* 2010) was located within 0.5 Mb of the QTL regions in the present study. Further to the fact that most SNPs demonstrating imprinting associations herein were located on BTA 2, genes widely acknowledged to having a key role is the expression of carcass phenotypes, namely *MSTN (Purfield et al. 2019)*, which was located near QTL regions detected herein, are also located on BTA 2.

Abstract

Mastitis is a high prevalence infectious disease in dairy sheep. Even if selection by milk somatic cell score (SCS) has been implemented to increase mastitis resistance, we wonder if rumen bacteria could influence udder inflammatory response. The objectives are to estimate genetic correlations between rumen bacteria and average SCS over lactation (LSCS), and to identify underlying mechanism between traits. 795 Lacaune ewes were studied using metabarcoding (16S rRNA gene) for rumen bacteria characterization and annual SCS records. Two-trait genomic models were used for the parameter estimation and GWAS. Results showed significant genetic correlations, and colocalized QTLs for LSCS and nine bacterial operational taxonomic units (OTUs) on chromosomes 3, 17, and 20. We found a genetic association between resistance/susceptibility to mastitis, using LSCS, and the ruminal bacteria abundance. These preliminary results pave the way for better understanding the biological basis and causalities of an intra-mammary inflammations in sheep.

Introduction

As in cattle, mastitis is one of the most important infectious diseases in small dairy ruminants, due to its high frequency and the price reduction paid to the farmer of up to 10% (95€ per 1000 litres of ewes' milk). The selection was focused on the milk SCS, as a tool to decrease subclinical intra-mammary infections, which is the main problem in dairy sheep. The existence of a genetic basis for mastitis resistance has been demonstrated, and the underlying mechanisms involved such as the *suppressor of cytokine signalling 2* (Socs2) gene (Rupp *et al.*, 2015). Recently, the influence of the rumen microbiome on subclinical ketosis has been demonstrated in cows (Gebreyesus *et al.*, 2020), but no work is available in sheep. Therefore, could rumen bacteria impact on intra-mammary inflammations in sheep? To address this, and after quantifying host control over rumen bacteria we: (1) estimated genetic correlations between rumen bacteria and LSCS; and (2) identified possible underlying mechanisms with genome-wide association analysis (GWAS).

Materials & methods

Animals phenotyping. A total of 795 Lacaune dairy ewes were reared at INRAE Experimental Unit of La Fage (UE 321 agreement A312031, Roquefort, France), between 2015 to 2019. All ewes (weighing 77 kg on average) raised indoors, and fed 93% meadow hay and silage plus 7% of concentrates (on dry matter basis). The daily somatic cell count (SCC) was quantified with a Fossomatic cell counter (Nanterre, France), as part of the official milk recordings of the flock. Then, the average LSCS was calculated as log of somatic cell count, including at least four milk test-days. Rumen sampling of adult ewes between 28 to 133 days in milk was done once per ewe using a vacuum pump and a medical gastric tube. The protocol received approval from the French Ministry of Higher Education, Research and Innovation – Animal Ethics Committee (approval number: APAFIS#6292-2016080214271984 v8). The RNA sequences of the 795 samples were processed with the FROGS 3.0 pipeline, and OTUs with abundances below 0.005% were removed (Bokulich *et al.*, 2013). The resulting abundance table included 2,059 OTUs, but we focused on the 306 OTUs with

heritability significantly different from zero (empirical significant threshold of 0.10 obtained after running 10,000 analyses where OTUs abundancies were shuffling randomly across individuals) using an additive relationship matrix.

Animals genotyping. DNA extraction from blood samples and genotyping were performed for 795 Lacaune ewes. From those ewes, 743 were genotyped using a medium-density SNP chip (Illumina Ovine SNP50 BeadChip, 54,241 SNPs). The remaining 52 ewes were genotyped with a low-density SNP chip (Illumina Ovine SNP15, 16,681 SNPs) and imputed to a medium-density SNP chip genotypes in the framework of the Lacaune dairy sheep genomic selection program (Larroque *et al.*, 2017). SNPs were removed using a call rate <0.99 for SNPs, and <0.95 for individuals, and minor allele frequency <0.05. In total, for the 26 *Ovis aries* autosomal chromosomes (OAR), 35,496 SNPs remained for the analyses, plus one SNP corresponding to the Socs2 gene mutation (OAR3).

Parameter estimation. To estimate the heritability of the 306 rumen OTUs and LSCS, and the genetic correlations between each OTU and LSCS, a two-trait animal model was used:

$$\begin{bmatrix}\mathbf{y_1}\\ \mathbf{y_2}\end{bmatrix} = \begin{bmatrix}\mathbf{X_1} & \mathbf{0}\\ \mathbf{0} & \mathbf{X_2}\end{bmatrix}\begin{bmatrix}\mathbf{b_1}\\ \mathbf{b_2}\end{bmatrix} + \begin{bmatrix}\mathbf{Z_1} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z_2}\end{bmatrix}\begin{bmatrix}\mathbf{a_1}\\ \mathbf{a_2}\end{bmatrix} + \begin{bmatrix}\mathbf{e_1}\\ \mathbf{e_2}\end{bmatrix} \quad (1)$$

where y_1 and y_2 are the vectors of observations for LSCS and one OTU at a time, respectively; b_1 and b_2 are the vectors of fixed effects, b_1 including for LSCS: litter size, number of milking test-day, and b_2 for the OTUs: sampling year, total number of DNA sequences per sample, and three effects nested on year sampling: lactation number, sequencing run, and order-time of sampling; a_1 and a_2 are the vectors of random additive effects; and e_1 and e_2 are the vectors of residual effects. X_1 and X_2 are incidence matrices relating fixed effects to vector y_1 and y_2, respectively; Z_1 and Z_2 are incidences matrices relating the additive effects to vector y_1 and y_2, respectively. The distributional assumptions are $\mathbf{a} \sim N(0, \mathbf{G} \otimes \mathbf{W})$, and $\mathbf{e} \sim N(0, \mathbf{I} \otimes \mathbf{R})$; G is a genomic relationships matrix as $\mathbf{G} = \mathbf{ZZ}'/2\sum p_i(1-p_i)$ (VanRaden, 2008); I is an identity matrix; W and R are the variance-covariance matrices for the random additive and residual effects, respectively. The heritability was estimated as $h^2 = \sigma_a^2/\sigma_y^2$, and the genetic correlations as $r_g = \sigma_{a12}/\sqrt{(\sigma_{a1}^2\sigma_{a2}^2)}$. The variance components were estimated using AIREMLF90 (Misztal *et al.*, 2002). The significance was considered as genetic correlation value greater than the standard error.

Genome-wide association. The GWAS was performed using the two-trait model presented in Equation 1. After solving the single step GBLUP model, all SNP effects were estimated back solving the breeding values estimates as proposed by Aguilar *et al.* (2019) using POSTGSF90 (Misztal *et al.*, 2002). To correct for multiple testing the false discovery rate (FDR) was used as implemented in the p.adjust package in R software. A SNP was considered significant at an FDR of $P<0.10$.

Results

The average heritability estimated for LSCS was 0.39±0.07. Genetic parameters of the 14 rumen bacteria having significant genetic correlations with LSCS are presented in Table 1.

The GWAS for LSCS detected on OAR3 four significant QTLs: in decreasing order of significance, the SNP for Socs gene (129,722,200 bp), SNP rs412514556 (129,423,378 bp), SNP rs425386363 (23,336,791 bp) and SNP rs416770789 (133,977,235 bp). The microbiome GWAS detected 387 significant SNPs for 67 OTUs among the 306 OTUs with heritability significantly different from zero. SNPs were scattered on all chromosomes, with the highest *P*-values and highest number of signals on OAR1, OAR2, OAR3, and OAR5. But, in this study we focus on the OTUs with significant signals located close to the LSCS QTLs on OAR3 (Table 2).

Table 1. Heritability (h^2) and genetic correlations (r_g) between lactation somatic cell score and ruminal bacteria abundance.

Genus	OTU name	h^2 (SE)	r_g (SE)

Ruminococcus	OTU602	Socs	129,722,200	5.70

[1] OTUs with significant genetic correlations with LSCS.

Discussion

The LSCS heritability was greater than the 0.15 reported by Rupp *et al.* (2009), using the whole Lacaune population. Even if the genetic correlations have a high standard error which can lead to spurious ones, most genetic correlations between LSCS and OTUs were positive, meaning that higher bacterial abundance is genetically associated with susceptibility to mastitis. There is also a higher variety of genera within the positive correlations than for the negative correlations where the most frequently associated is *Prevotella*, a bacteria belonging to the *Bacteroidetes* phylum. Zhong *et al.* (2018) obtained *Bacteroidetes* as the most abundant in the group with low SCC, even if they showed that the rumen microbiome in cows was globally stable at different SCC levels. The link between gut bacteria and mastitis is probably not direct but would be through bacterial metabolites absorbed by the host, and which would have pro- or anti-inflammatory properties (Hu *et al.*, 2019). A QTL on OAR3 was detected for *Ruminococcus* OTU602 at the Socs gene position, and the Socs2 genotype known to have more LSCS in milk is associated with highest abundance of OTU602 (results not shown). In contrast, Chuang *et al.* (2021) found that *Ruminococcus* genus was phenotypically reduced in the rumen of cows with clinical mastitis. As well on OAR3, two QTLs were detected, one for *Prevotella* OTU1419 and one for *Lachnospiraceae* OTU1666. The SNP genotype associated with more LSCS in milk is linked with more *Prevotella* OTU1419 abundance, which is contrary with the main genetic correlations for this genus, but on others OTUs. The same SNP genotype associated with mastitis susceptibility is also linked with less *Lachnospiraceae* OTU1666 abundance, which is consistent

with the negative but weak genetic correlation of -0.21 with LSCS. This result on OTU1666 is in agreement with Wang *et al.* (2021) finding that this family is phenotypically associated with anti-inflammatory molecules such as 2-Phenylbutiric acid. But, for the three others OTUs belonging to the *Lachnospiraceae* family, an increase of their abundances is genetically linked with more LSCS. The identification in this study of QTLs on OAR3 common for LSCS and OTUs in addition to the results obtained for genetic correlations, contribute to the hypothesis of a genetic link between rumen bacteria and mastitis. We can conclude that host genetic may influence ruminal bacteria abundances and udder inflammation in sheep via mainly positive genetic correlations, but the underlying metabolic pathways are still difficult to identify with only the identification of bacterial genera. The genetic study of these bacteria's functions is underway in order to unravel the various results obtained at the OTU level.

Abstract

Understanding the biology that underlies artificial selection in animal breeding programs is of significant interest. Recent and ongoing polygenic selection is difficult to map because it does not leave well-defined signatures on the genome. When populations have temporally-stratified genomic data, we can use genome-wide association (GWAS) models to map selection during the sampled period using Generation Proxy Selection Mapping (GPSM). Here, we demonstrate the power of GPSM in two large datasets from American beef cattle populations with 11,759,568 imputed SNPs. We identify ongoing polygenic selection at 294 unique loci. We observe that GPSM has high power to detect minuscule allele frequency shifts over short timescales (<10 years). GPSM loci localized near genes, in annotated epigenetic marks, or in predicted functional genomic regions. We also observed minimal overlap in loci identified by GPSM and other traditional sweep detection methods.

Introduction

While selection occurs on phenotypes or estimated breeding values, the changes observed in a population result from changes in the frequencies of causal variants that underlie the selected trait. Occasionally, a large-effect causal variant is rapidly driven to high frequency in the population, leading to 'selective sweeps' where surrounding neutral genetic variation is reduced (Smith and Haigh 1974). Studies have mapped numerous selective sweeps in livestock species caused by selection on Mendelian traits or large-effect quantitative trait loci (QTL) (Gutiérrez-Gil *et al.* 2015). Selective sweeps at these loci were likely essential components of domestication and breed formation. That said, it is likely that the majority of selection has been on traits that are highly polygenic (Bolormaa *et al.* 2014). Polygenic selection results in subtle allele frequency shifts at hundreds or thousands of causal variants of small effect, which does little to alter surrounding neutral diversity. This makes mapping polygenic selection difficult.

In contemporary livestock populations, we have accumulated large genotypic datasets containing thousands or millions of animals, including influential founder animals. We can leverage these large populations with high-density, temporally-stratified genotypes to detect small directional changes to allele frequency caused by polygenic selection. We use Generation Proxy Selection Mapping (GPSM) to map loci actively responding to polygenic selection. GPSM uses a proxy for the generations that separate an individual from the beginning of a population's pedigree as the dependent variable in a GWAS model. The goal is to detect statistically significant associations between allele frequency and an animal's generation. These associations represent directional allele frequency changes caused by selection (Decker *et al.* 2012; Rowan *et al.* 2021). Simulations in previous work showed that by using a mixed model, GPSM can effectively distinguish selection from drift regardless of effective population size, skewedness of data, family or population structure, and other confounders. We apply GPSM to datasets from two modern American beef cattle breeds, Red Angus and Simmental. Using 11,759,568 imputed genotypes and conditional joint analysis of GPSM results, we can map putative sites underlying ongoing selection for complex traits, allowing us to understand better the biology that underlies selection for production traits.

Materials & methods

Genotype data and imputation. We used assay genotypes from two breed associations, Red Angus (n=46,454) and Simmental (n=90,580), ranging in density from 25K to 770K markers. Genotypes were imputed to a set of 811K SNPs, as described in Rowan *et al.* 2019 (Rowan *et al.* 2019), followed by imputation to 43,214,290 SNPs using the 4,931 animals in Run8 of the 1000 Bulls Project (Hayes and Daetwyler 2019), phased with Eagle (v2.4) (Loh *et al.* 2016) as a haplotype reference. We retained only high quality variants (VQSR Tranche 90) and removed poorly imputed (internal imputation R^2<0.4), or rare (minor allele frequency <0.01) to arrive at a set of 11,759,568 variants. We used genomic coordinates from the ARS-UCD1.2 assembly (Rosen *et al.* 2020) for all analyses.

Generation proxy selection mapping (GPSM). We used the breeder-reported birthdate to calculate the continuous years between an animal's birth and the day we began analyzing data (19 October 2020). We used this value as the dependent variable in GPSM analyses. We used the 811K SNP sets to construct genomic relationship matrices (GRM) for each breed. We used the '--mlma' function in GCTA (v 1.92.3) (Yang *et al.* 2010; Yang *et al.* 2011) to conduct our GPSM analysis using the following model:

$$y = \mu + bx + a + e \quad (1)$$

Here, y is a vector of generation proxies, μ is the sample mean, b is a SNP's regression coefficient, on a vector of animal genotypes x, a is a random vector of polygenic terms, and e is a random error term. We performed this analysis on the full datasets of both breeds, an age-truncated Red Angus dataset (animals born <10 years ago), and a purebred-only Simmental dataset. To refine GPSM signals, we performed a conditional and joint analysis (COJO) (Yang *et al.* 2012), conditioning associations on SNPs with GPSM P-values $<10^{-5}$. Significant COJO SNPs were ones with conditional and genome-wide P-values $<5\times10^{-8}$.

Results

In Red Angus, GPSM detected 2,914 and 9,065 genome-wide significant SNPs (Bonferroni-corrected P-values $<4.29\times10^{-9}$) in the full and birth date-truncated datasets, respectively (Figure 1A & 1B). Our COJO analysis of these GPSM results identified 72 unique lead SNPs in the full dataset and 96 in the truncated dataset (COJO SNPs). Sixteen of these SNPs were identified by both Red Angus datasets. The most striking example of the truncated dataset uncovering unique GPSM associations was on BTA2 near the gene *ARHGAP15*, a major immune function gene in cattle (Noyes *et al.* 2011; Álvarez *et al.* 2016). Both GPSM analyses in Red Angus identified a known pleiotropic QTL for body weight, carcass weight, and sexual precocity on BTA14. Many significant GPSM loci had not been previously identified by other sweep mapping studies (Gutiérrez-Gil *et al.* 2015). The increased power in these datasets uncovered dozens of novel signatures that were not identified by previous GPSM analyses in the same populations (Rowan *et al.* 2021).

In the American Simmental dataset, we performed two GPSM analyses to compare and contrast selection within the purebred Simmental part of the dataset and the entire open herdbook (Animals 5-100% pedigree estimated Simmental). GPSM identified 513 genome-wide significant SNPs in the purebred dataset driven by 18 unique COJO SNPs (Figure 1D). The strongest GPSM signature in purebred Simmental resided on BTA5, near the genes *PMEL* and *ERBB3*. This locus is a known modulator of coat color in European Simmental populations (Mészáros *et al.* 2015). Another selected locus was identified near the gene *KIT,* which contains alleles that control color-sidedness in many mammalian populations (Durkin *et al.* 2012). GPSM in the full Simmental dataset identified significantly more selected loci, 1,008 SNPs and 108 unique associations (Figure 1C). This analysis also identified strong ongoing selection at the same coat color and pattern loci and identified selection on other loci known to affect economically-important quantitative traits.

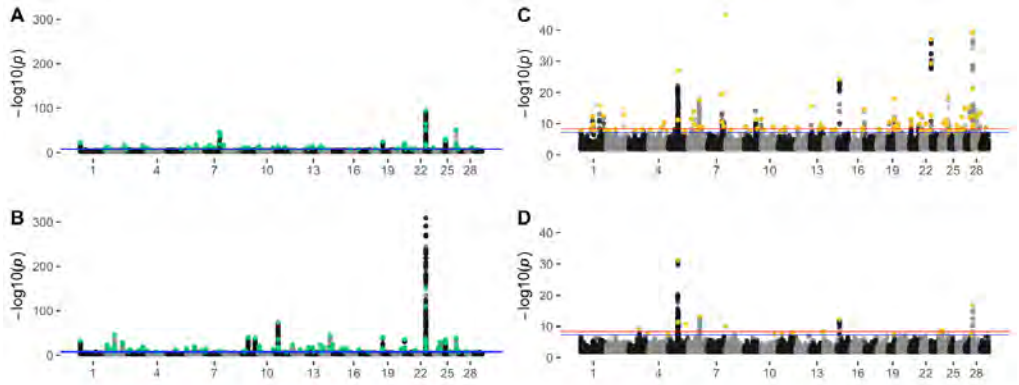

Figure 1. GPSM Manhattan plots for (A) full and (B) young animal truncated Red Angus datasets, and (C) full and (D) purebred Simmental datasets. Colored SNPs were identified as independent associations through COJO analysis. The red line represents Bonferroni significance, and the blue line represents a 5×10^{-8} significance threshold.

We observed only a handful of loci that were under selection in both the Red Angus and Simmental breeds. Red Angus's most significant GPSM signature resided on BTA23 (1-2 Mb), immediately upstream of the gene KHDRBS2. This area was also identified in the Simmental GPSM. However, the selected loci in the region were different, suggesting that depending on the population, selection may be acting on different regulatory variations for the same gene. Across datasets, most GPSM COJO SNPs had a clear candidate gene (Table 1). Many of the selected SNPs with a clear positional candidate gene were immediately upstream of the transcription start sites, suggesting possible selection on *cis*-regulatory variation.

Discussion

Our results show that GPSM, coupled with high-powered livestock datasets can detect very subtle shifts in allele frequency over short time periods, even in the absence of recorded phenotypes. Using a linear mixed model to test allelic associations with a generation, we can explicitly control the population and family structure, which often obscures selection mapping studies. Simulations in previous studies (Rowan *et al.* 2021) indicate that GPSM can effectively distinguish selection from drift and is robust to genotype sampling. The combination of GPSM and sequence-density imputed genotypes lets us map this selection at an extremely high resolution.

Our results suggested that since the initial import of Simmental to America, much selection pressure within the purebred animals has made them appear more similar to Angus animals (solid black-hided). The large sample sizes of our two datasets allowed us to divide them into informative subsets to understand

Table 1. Significant GPSM (COJO and genome-wide $P<5\times10^{-8}$) SNPs and their proximity to annotated genes.

Breed	Subset	COJO SNPs	In gene	Near gene (<50 kb to nearest)	Intergenic
Red Angus	Full	72	17	20	35
Red Angus	Young	96	36	24	36
Simmental	Full	108	32	36	40
Simmental	Purebred	18	6	7	3

how selection operates at very short timescales (Red Angus 'young' animals) or within a specific subset of an open herdbook breed (purebred Simmental). With large or more structured datasets, this subsetted approach to performing GPSM could be informative in understanding how changes to breeding decision-making have impacted the genome over time in a line or family-specific manner (e.g. genomic changes in terminal vs maternal lines). Breeders might also use GPSM results as 'biological priors' in Bayesian genomic prediction approaches. Further, we believe that using putatively selected loci as 'functional annotations' to the genome can add important context to other mapping studies (GWAS, eQTL, etc.).

373. Fine-mapping young-stock survival QTL on chromosome 6 in Nordic Red Dairy Cattle

Z. Cai[1], X. Wu[1], B. Thomsen[2] and G. Sahana[1*]

[1]*Aarhus University, Center for Quantitative Genetics and Genomics, Blichers Allé 20, 8830 Tjele, Denmark;* [2]*Aarhus University, Department of Molecular Biology and Genetics, C.F. Møllers Allé 3, 8000 Aarhus, Denmark; goutam.sahana@qgg.au.dk*

Abstract

A genome-wide association study was carried out for young-stock survival (YSS) in Nordic Red Dairy cattle. The de-regressed proofs for 3,078 bulls for YSS index and four component traits were analyzed. The 50k genotypes were imputed to whole genome sequence level using *run7* 1000 bull genome sequence data. A major QTL on chromosome 6 was identified with rs133470751 as the lead SNP with $-\log_{10}$(*P*-value) equal to 47.02. The lead SNP is located in a gene desert. The post-GWAS analysis for functional annotations of the variants and presence for structural variants in the QTL peak was evaluated for being causal factor.

Introduction

Identification of the genetic variants associated with calf survival in dairy cattle will aid in the elimination of harmful mutations from the cattle population and the reduction of calf and young stock mortality rates (Wu *et al.* 2017). Mortality of cattle causes economic loss for dairy farmers. The cost at rearing period is relatively high compare with early embryonic loss, abortion and stillbirth. Calves and young stock that die during the rearing period result in lost revenue, fewer heifers for replacement, higher veterinarian costs and deteriorating animal welfare. Therefore, it is important for both economy and welfare, to breed for reducing mortality of calves and young stock.

An index for young stock survival (YSS) in calves was included in the Nordic total merit index by the Nordic Cattle Genetic Evaluation (NAV; www.nordicebv.info). The YSS index was calculated based on 4 survival traits: survival from 2 to 30 d for bull calves (BP1) and heifer calves (HP1), from 31 to 184 d for young bull calves (BP2), and from 31 to 458 d for young heifer calves (HP2). Calf death and survival during this period were recorded as 0 and 1, respectively. The YSS index was calculated by combining EBV for BP1, BP2, HP1, and HP2 by NAV (Denmark), which were weighted by their relative economic values and standardized (Carlen 2016).

The combination of genomic information and breeding values for YSS creates an opportunity to identify genomic variants with harmful effects on YSS. Once these variants have been identified, it will be possible to select against them and prevent at-risk matings between carriers. This selection will improve calf survival and reduce the cost per live cattle produced. In this study, we focus to identify the causal variant underlying a major QTL on chromosome 6 in Nordic Red Dairy cattle (RDC).

Materials & methods

Phenotype and genotype data. For genome scan, we used data from 3,078 RDC bulls. The phenotype used was de-regressed proofs for 4 component traits of YSS (i.e. BP1, BP2, HP1 and HP2) and YSS index.

All these RDC bulls were genotyped with Illumina 50k SNP chip; followed by imputed to HD level (777k), and then imputed to whole genome sequence level using *Run7* reference animals from the 1000 Bull Genomes project (BGP). The whole genome sequencing (WGS) reference panel was phased with Beagle4 (Browning *et al.* 2018) and recalled by shapeit2 (Delaneau *et al.* 2011). HD panel was phased using Beagle5

(Browning *et al.* 2018). Both steps of imputation were performed by Minimac4 (Fuchsberger *et al.* 2015). The average imputation accuracy, R^2 from Minimac4, was 91.2% across all minor allele frequency classes. The SNP with a minor allele frequency less than 1% or those deviating from Hardy-Weinberg proportions ($P<10^{-6}$) were removed. Association analysis was carried our using a linear-mixed model approach (Kang *et al.* 2010) using GCTA software (Yang *et al.* 2011). A SNP was declared significant if its *P*-value was less than multiple Bonferroni correction threshold (see Wu *et al.* 2017 for details).

Post-GWAS. To reveal the possible consequence of the variants within the QTL interval, we performed variants annotation using variant effect predictor (VEP) v104 (McLaren *et al.* 2016). The prediction impact with 'HIGH' was retained to check the segregation in the WGS animals from 1000 BGP Run7. The Gene Ontology (GO) (Ashburner *et al.*, 2000) was used to explore the function of identified candidate genes. The precomputed Repeatmasker (Chen 2004) profile was downloaded from NCBI, and checked the presence of the repeat sequence around the lead SNP. Variation in repeats can alter the expression of genes, and changes in the number of repeats have been linked to certain human diseases (de Bustos *et al.* 2016). The flanking 1 Mb region of was compared to the regulatory elements from previous studies (Kern *et al.* 2021). We also examined if chromosomal deletions (Mesbah-Uddin *et al.* 2018) located in or close of the QTL regions could be the causal variants.

Results

Association with component traits of YSS. We detected genome-wide associated SNP, including 9,162 SNP for BP1, 12,173 SNP for BP2, 8,709 SNP for HP1, and 14,096 SNP for HP2. Of the 14,567 SNP that were significant for YSS index, 8,856 SNP showed significant association with BP1, 11,688 SNP for BP2, 8,339 SNP for HP1, and 13,375 SNP for HP2. In addition, there were 8,268 SNP on BTA6, 3 SNP on BTA17, and 266 SNP on BTA23 were associated with both BP1 and HP1. There were 182 SNP on BTA4, 11,655 SNP on BTA6, and 2 SNP on BTA14 associated with both BP2 and HP2. There were 8,400 SNP on BTA6 were associated with both BP1 and BP2; and 8,243 SNP on BTA6 associated with both HP1 and HP2.

Association with YSS. We found a major QTL for YSS at chromosome 6 (Figure 1). The lead SNP of this QTL is 6:38065928 (rs133470751) with $-\log_{10}$(*P*-value) equal to 47.02. The annotation of this variant is intergenic variant. The lead SNP is located at the gene desert (Figure 2). There are several genes in a far distance which are worth to investigate.

Checking variants annotation of the flanking area of lead SNP. We checked the flanking 1 Mb region for high-impact (given by variants effect predictor) of the lead SNP. Two genes with several functionally annotated SNPs showed potential to be causal genes and/or causal variants. *FAM184B* have a stop gained

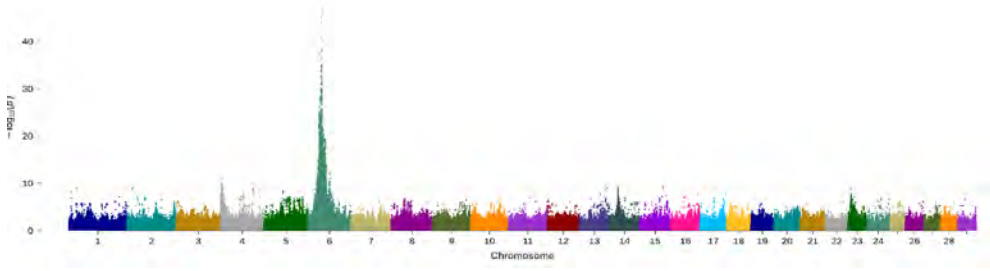

Figure 1. Manhattan plot for association of SNP with young stock survivor in Nordic Red cattle. Red horizontal line indicates genome-wide significance level [$-\log_{10}$(P)=8.5].

variants at 6:37201641. *LCORL* have three frameshift variants at 6:37401110, 6:37401770, 6:37402602 and 6:37403627 and one splice donor variant at 6:37412364. The segregation of these variants in non-Nordic Red WGS animals and Nordic Red WGS animals were listed in Table 1. *LCORL* belong to GO term 'regulation of transcription by RNA polymerase II'. Both genes do not show any clear functional meaning to YSS from GO, KEGG or mammalian phenotype database.

Unveiling the gene desert region around lead SNP. The Repeatmasker profile was downloaded from NCBI, there is a LINE element very close to the lead SNP, which is L2c. The copy in the reference genome is not a full length element, which means it is not active. However, we currently don't have the right dataset, long read sequences, to further investigate the repeat content of this region in our RDC animals. The sequence reads obtained with next generation sequencing platforms are short and simply do not span long repetitive sequences. We checked for the presence of regulatory elements in the flanking 1 Mb region of the lead SNP, and the result showed the region from 38 Mb to 39 Mb contains several regulatory elements even though the region is devoid of genes.

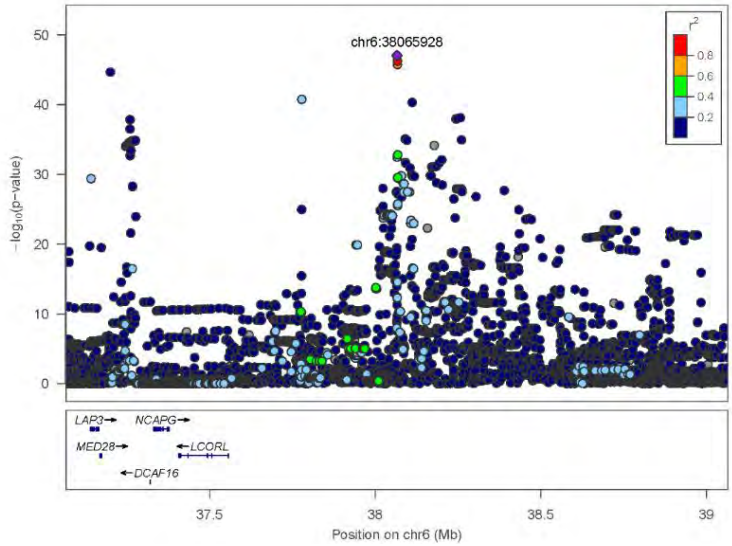

Figure 2. LocusZoom plot (Pruim *et al.* 2010) showing the QTL region on chromosome 6 in Nordic Dairy cattle; colour code is to show the linkage disequilibrium with the lead SNP.

Table 1. The segregation of the high-impact variants located within two candidate causal genes in 1000 bulls genome sequence without and within the Nordic Red cattle (RDC) sequences.

Variants	Gene	All except RDC			RDC		
		HOM-A1	HET	HOM-A2	HOM-A1	HET	HOM-A2
6:37201641	*FAM184B*	0	0	2,913	1	9	153
6:37401110	*LCORL*	2	28	2,882	0	0	164
6:37401770	*LCORL*	643	253	1,996	4	24	136
6:37402602	*LCORL*	0	2	2,916	0	32	129
6:37403627	*LCORL*	2	12	2,892	0	0	162
6:37412364	*LCORL*	1	39	2,866	0	2	160

We fine-mapped a major QTL affecting young-stock survival in Nordic Red dairy cattle. The lead SNP is located in a gene desert, indicating a regulatory variant may be the causal factor for this QTL. The high-impact variants in neighbouring genes were also studied. These variants are included in a custom made SNP array used in routine genotyping.

Acknowledgements

We are grateful to the Nordic Cattle Genetic Evaluation (NAV, Aarhus, Denmark) for providing the phenotypic data used in this study and Viking Genetics (Randers, Denmark) for providing samples for genotyping. This work was supported by research projects funded by the Milk Levy Fund (Mælkeafgiftsfonden, Skejby, Aarhus), Green Development and Demonstration Programme (GUDP) project from the Ministry of Environment and Food of Denmark, Viking Genetics, and NAV. The 1000 Bull Genomes Project is acknowledged for sharing WGS data.

374. Multibreed sequence level genome-wide association study of semen traits in tropical Australian cattle

W.L.A Tan[1*], L.R. Porto-Neto[2], A. Reverter[2] and M.R.S. Fortes[1]

[1]The University of Queensland, School of Chemistry and Molecular Biosciences, 68 Cooper Rd, The University of Queensland, Brisbane, QLD 4072, Australia; [2]CSIRO Agriculture and Food, 306 Carmody Road, Brisbane, QLD 4067, Australia; weiliangandre.tan@uq.net.au

Abstract

Male fertility affects the productivity and profitability of the beef cattle industry. Semen traits such as Percent Normal Sperm (PNS) are heritable indicators of bull fertility. These traits are collected in routine fertility assessments. Genome-Wide Association Studies (GWAS) were conducted in this study, using sequence level data to ascertain regions associated with PNS and two sperm abnormality measures in a multibreed population of 6,422 bulls. We report regions on chromosome 5 that are associated with PNS and Proximal Droplets (PD). Additionally, the X chromosome consistently contains important regions for all traits examined. Downstream analyses are required to identify candidate genes with a causal effect on semen traits.

Introduction

Bull fertility is an important trait for the beef cattle industry globally. However, it has gathered less consideration than its cow counterpart, which has benefited from advancements in biotechnology and selective breeding (Butler *et al.* 2019; Hayes *et al.* 2018). Semen traits are heritable indicators of bull fertility and can be used for genetic improvement (Butler *et al.* 2019). Previous GWAS have identified candidate genes for semen traits (Fortes *et al.* 2013). Genetic variants located through GWAS are often not causal mutations but Single Nucleotide Polymorphisms (SNP) in linkage disequilibrium to causal variants (Tenghe *et al.* 2016). Markers utilised in SNP panels consist of a small subset of common SNPs that segregate in the population. Advancement in next-generation sequencing and imputation methodologies allow animals genotyped with lower density SNP panels to be accurately imputed to sequence level variants (Browning and Browning 2009; Das *et al.* 2016). This preliminary GWAS uses imputed sequence level genotypes to identify regions associated to three semen traits, which may be incorporated in genomic predictions to improve accuracy.

Materials & methods

Animals and phenotypes. A multibreed dataset of 6,422 animals was used in this study. These animals are from two research populations and four stud herds. The two research populations consisted of animal data obtained from the Cooperative Research Centre for Beef Genetic Technologies (Beef CRC), consisting of 1,051 Brahman and 1,819 Tropical Composite (TC) bulls. The other four stud herds consisted of 1,288 Santa Gertrudis bulls, 760 Droughtmasters, 844 Ultra blacks, and 660 Belmont Red Composites. The three semen phenotypes used in this study are PNS (%) and two sperm abnormality measures: Mid-Piece abnormalities (MP, %) and PD (%).

Genotypes, genomic relationships, and GWAS. Animals were genotyped using a commercial 50K SNP chip and imputed to high density (~700K) using a phased reference generated by Eagle 2 (v2.4.1) and imputed using Minimac3 for autosomes and Minimac4 for the X chromosome (Das *et al.* 2016; Loh *et al.* 2016). The same method was used to impute to sequence level. SNPs with imputation r^2>0.8 in Minimac, a call rate >0.9 and a minor allele frequency >0.05 were kept for further analysis, leaving 21,804,882 SNPs, including 233,066 SNPs mapped onto the X chromosome after quality control. A high-density SNP panel (657,563 SNPs for autosomes and 22,775 SNPs for X) was used to build a genomic relationship matrices

(GRM) in GCTA (Yang *et al.* 2011), for the autosomes, which includes the Pseudo – Autosomal Region (PAR), whereas the X chromosome GRM was constructed separately using the non-PAR, as described by Yang *et al.* (2010). The Principal Components Analysis (PCA) was calculated using PLINK1.9 (Chang *et al.* 2015), and GRMs were used to account for genetic structure in the data. GWAS was performed using the Leave One Chromosome Out (LOCO) method in GCTA (Yang *et al.* 2011), as described by Yang *et al.* (2014). The phenotypes were pre-adjusted for their fixed effects (year of birth, breed, property) and covariates (age at measurement, PC1 and PC2). A genome-wide significance threshold of 5×10^{-8} was used, which is a conservative Bonferroni correction. Significant markers were merged into a single QTL region using bedtools (Quinlan and Hall 2010), and genes near each trait's strongest associated region were reported using data from Ensemble (Howe *et al.* 2021).

Results

The summary statistics of each semen trait and heritability is shown in Table 1. The results of the GWAS for each trait are represented in (Figure 1). A total of 100 genes for PNS, 84 genes for PD and 16 genes for MP were located in associated windows.

Table 1. Summary statistics and summary of GWAS results.

Phenotypes[1]	n	Mean	SD	LOCO[2]	h^2 (SE)[3]
PNS	6,055	61.76	27.53	9,677	0.18 (0.02)
PD	6,052	13.50	19.96	2,874	0.15 (0.02)
MP	6,052	11.39	11.04	603	0.13 (0.02)

[1] PNS % of normal sperm, PD % sperm with proximal droplets, MP % sperms with mid-piece abnormalities.

[2] Number of SNPs associated at $P<5\times10^{-8}$ in GWAS.

[3] SNP-derived heritability and standard error.

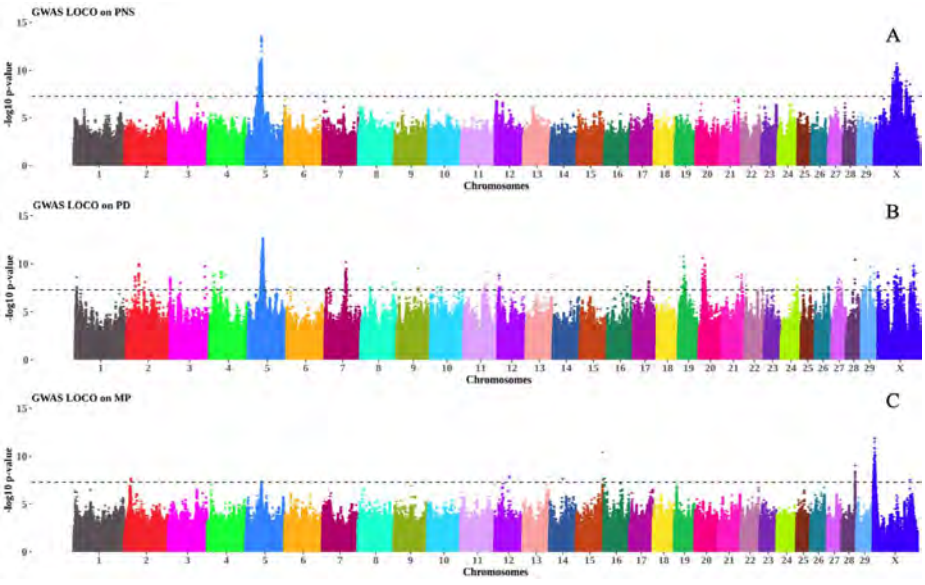

Figure 1. Manhattan plots showing associations identified for all three semen traits. Manhattan plots for PNS, PD and MP are labelled as A B and C, respectively. The inverse log *P*–values for each SNP are plotted along the y-axis for each chromosome on the x-axis. The dotted line represents the genome-wide significance threshold of 5×10^{-8}.

GWAS on PNS. A total of 9,677 significant associations were detected with PNS (Table 1). The largest concentration of SNPs associated with PNS was found between 35.1 Mb to 49.3 Mb at chromosome 5. The strongest genomic association (P=3.18×10^{-14}) for PNS was located at 46.4 Mb at chromosome 5. This highly associated region coded for DYRK2 and CAND1. The largest concentration of SNPs in the X chromosome was located between 58.2 Mb and 111.9 Mb, with the strongest genomic association (P=1.8×10^{-11}) located at 70.5 Mb. A significant SNP was also found at chromosome 12 at 3.83 Mb.

GWAS on PD. A total of 2,874 significant associations were detected for PD (Table 1). As seen in Figure 1, many regions throughout the genome were found to be associated with PD. The largest concentration of SNPs associated with PD was found between 38.7 Mb and 88.9 Mb of chromosome 5. The strongest genomic association (P=1.91×10^{-13}) was located at 46 Mb at chromosome 5. This highly associated region coded for DYRK2 and CAND1. In the X chromosome, several peaks were found at 1.5 Mb, 62.1 Mb and 111.9 Mb, as shown in Figure 1.

GWAS on MP. A total of 603 significant associations were detected for MP (Table 1). The largest concentration of SNPs was located between 2.7 Mb to 8.6 Mb of the X chromosome (Figure 1). The strongest genomic association (P=1.34×10^{-12}) was located at 6.27 Mb of the X chromosome. We did not find any genes in close proximity to this marker.

Discussion

The heritability estimates for PNS reported by Fortes *et al.* (2020) for TC (0.29) and Brahman (0.35) were higher than the 0.18 reported here. Similarly, the heritability estimates for PD reported by Fortes *et al.* (2020) for Brahman (0.35) and TC (0.21) were higher than the 0.15 reported here. Lastly, the heritability estimate for MP was higher than those reported for Brahman (0.07) but lower than those reported for TC (0.21) (Fortes *et al.* 2020). There were two genes in the regions of chromosome 5 that were strongly associated with PNS and PD. The DYRK family of kinases has been associated with rat spermatogenesis and is highly expressed from steps 6 to 11 in spermatids (Sacher *et al.* 2007). The CAND1 protein is highly expressed in the spermatozoa of fertile men (Park and Pang 2021). These regions may affect bull spermatogenesis and morphology. Several regions in the X chromosomes have been consistently associated with all three semen traits in this study. In a GWAS with TC bulls, Fortes *et al.* (2013) reported significant SNPs in the X chromosome, which overlaps with the region reported in this study. The highest association with PNS was located at 39.9 Mb (Fortes *et al.* 2013). Fortes *et al.* (2020) reported Quantitative Trait Loci (QTL) for PNS between 45.2 Mb and 49.7 Mb of the X chromosome in Brahman bulls. However, this QTL did not overlap with the regions reported in this study. Given that this is an across-breed GWAS, certain results that are significant in within-breed GWAS can remain hidden (Fortes *et al.* 2020). Further studies can examine GWAS results within-breeds that could locate breed-specific QTLs. For PD, Fortes *et al.* (2020) reported a QTL between 1.3 Mb and 8.5 Mb of the X chromosome of TC bulls that overlaps with the peak located at 1.5 Mb identified in this study. For MP, the most significant region in the X chromosome located at 6.27 Mb overlaps with the QTL between 4 Mb and 7.3 Mb in Brahman bulls reported by Fortes *et al.* (2020). Mueller *et al.* (2013) previously highlighted that species divergence genes in the X chromosome in mice and humans are highly expressed in the testis. The large number of significant SNPs that map to the X chromosome is consistent with the hypothesis by Mueller *et al.* (2013), which suggested the X chromosome as an intriguing region to look for genes associated with spermatogenesis and male fertility. Fortes *et al.* (2020) highlighted the theories of sex-chromosome meiotic drive or sexual antagonism as a possible explanation for the large number of genes associated with germ-cell development traits, with the latter being the more probable hypothesis in their study. While this hypothesis may plausible in populations with relatively low Minor Allele Frequency (MAF) of QTL SNPs, some markers identified as most significant for each QTL in our study had relatively higher MAF of more than 0.4 and thus this theory would be unlikely

in our context. Further research is still required to ascertain which theory is more probable. Our research uncovered important QTLs for semen traits which warrant further investigation in downstream analyses. If candidate genes with causal effect can be located, incorporation of these genes in genomic predictions may help improve accuracy.

375. Improved genome-wide associations using a breed-specific 200K SNP chip for German Black Pied (DSN) cattle

P. Korkuć[1*], G.B. Neumann[1], D. Arends[1], M.J. Wolf[2], K. May[2], S. König[2] and G.A. Brockmann[2]

[1]Humboldt University Berlin, Albrecht Daniel Thaer- Institute for Agricultural and Horticultural Sciences, Animal Breeding Biology and Molecular Genetics, Invalidenstr. 42, 10115 Berlin, Germany; [2]Justus-Liebig-University of Gießen, Institute of Animal Breeding and Genetics, Ludwigstr. 21, 35390 Gießen, Germany; paula.korkuc@hu-berlin.de

Abstract

The DSN200K chip was specifically designed for German Black Pied cattle (DSN 'Deutsches Schwarzbuntes Niederungsrind') to improve genome-wide association analyses (GWAS) in DSN. Here, we performed GWAS with 2,099 DSN cows and 20 milk performance traits using 131,273 SNPs from the DSN200K chip. We compared those GWAS results to results obtained with the Illumina BovineSNP50 BeadChip (Illumina 50K) and *in silico* randomly generated SNP chips. Those random SNP chips had the same number of SNPs as on the DSN200K chip selected from a prefiltered set of 2.6 million sequence variants. We identified 13-15 times more associated SNPs with the DSN200K chip than with the Illumina 50K and 2.7-3.2 times more than with random SNP chips. With the DSN200K chip, we associated DSN-unique SNPs and SNPs with impact on gene transcripts which could potentially be causal mutations. These SNPs were seldom identified with the Illumina 50K or the random SNP chips.

Introduction

German Black Pied cattle are an endangered dual-purpose cattle breed, which is considered to be one of the ancestor populations of the modern Holstein breed. In order to track DSN-specific sequence variants that could help to conserve the specific genetic diversity of DSN and to allow for genetic improvement, we designed a breed-specific chip for DSN cattle (DSN200K chip) with 182,154 sequence variants (Neumann *et al.*, 2021).

Previous genome-wide association analyses (GWAS) in DSN were performed using genotypes from the Illumina BovineSNP50 BeadChip (Illumina 50K) (Korkuć *et al.*, 2021; May *et al.*, 2019; Meier *et al.*, 2020). The Illumina 50K chip was designed based on commercial breeds (Matukumalli *et al.*, 2009). Only 37K out of all 54K SNPs on the Illumina 50K chip were informative in DSN considering a SNP call rate>0.95 and a minor allele frequency (MAF)>0.05 and thus suitable for GWAS. Due to the ascertainment bias of the chip design, DSN-unique SNPs are missing on this chip. The designed DSN200K chip provides not only a higher density of SNPs but includes also DSN-unique SNPs and SNPs from previous GWAS in DSN. Moreover, it contains also SNPs of general interest such as SNPs with impact on gene functions and SNPs from the Illumina 50K chip. Additionally, SNPs were included that track most haplotype blocks found in DSN.

In this study, we performed GWAS with 2,099 DSN cattle and 20 milk performance traits using 131,273 SNPs from the DSN200K chip. We compared those results to results obtained with the lower-density Illumina 50K chip and *in silico* randomly generated SNP chips having the same number of SNPs as the original DSN200K chip in order to test whether only the number of SNPs or also the selection of SNPs on the DSN200K chip improve GWAS results.

Materials & methods

Genotypes and traits. Genotypes of 2,099 DSN cows from 8 farms in Germany were available from either Illumina 50K (1,473 cows) Korkuć *et al.*, 2021), DSN200K chip (453 cows) or whole-genome sequencing

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_375, © P. Korkuć *et al.* 2022

(173 cows) (Neumann *et al.*, 2021). For GWAS, genotypes were imputed to whole-genome sequencing (WGS) level using 304 sequenced DSN cattle (Neumann *et al.*, 2021) with BEAGLE v5.1 and then reduced to the SNP positions of the DSN200K and the Illumina 50K chip that were also available on the DSN200K chip. SNPs with MAF<0.05 and indels were removed, leading to 131,273 and 33,546 SNPs on the autosomes and chromosome X suitable for analyses on the DSN200K and the Illumina 50K chips, respectively. Milk performance data at 305 days was obtained from 'Vereinigte Informationssysteme Tierhaltung w.V.' as of February 2021. Traits included milk, fat, and protein yield in kilogram and fat and protein content in percent for the first three lactations and the lactation mean when data for all three lactations was available. Only full lactations with at least 270 days in milk were considered.

Genome-wide association analysis. Multiple linear regression models implemented in R were used to test the additive effect of each SNP. For each trait *Y*, the model included covariates for population stratification *ps,* farm *f*, sire *s*, birth year *by*, birth season *bs*, calving year *cy*, calving season *cs*, and age at first calving in days *ac*, together with the SNP genotype *gt* and the residual error *e:*

$$Y = ps + f^{*} + s^{*} + by^{*} + bs^{*} + cy^{*} + cs^{*} + gt + e \quad (1)$$

Population stratification *ps* was estimated using the pairwise population concordance test in PLINK v1.9 which is based on a pairwise identity-by-state matrix. The *P*-value cut-off of 0.0001 resulted in 65 clusters of relatedness. Covariates marked with an asterisk '*' were only included in the model when the difference in Akaike information criterion was ≤-10 between the null model ($Y = ps$) and the null model extended with one of the covariates ($Y = ps + covariate\ x$). To reduce the number of false positives in GWAS, *P*-values of each trait were corrected to an inflation factor of λ=1.3 on autosomes and chromosome X, separately. The number of independent SNPs (n=95,140) was estimated using LD-pruning SNPs with r^2>0.8 using PLINK v1.9 and used to adjust *P*-values for multiple testing with Bonferroni correction. After correction, SNPs were considered as significant when *P*<0.05 or suggestive when *P*<0.1. Associated SNPs within ±5 Mb across all traits were combined to quantitative trait loci (QTLs).

***In silico* random SNP chips.** For the design of the DSN200K chip, a set of 3.1 million quality-controlled sequence variants was used (Neumann *et al.*, 2021) which were filtered for MAF<0.05 and indels. From the left 2.6 million SNPs, 100 random SNP chips with 131,273 SNP positions were generated *in silico* by keeping all 33,546 informative SNPs from the Illumina 50K chip and selecting additional 97,727 SNPs randomly and uniformly across all chromosomes. The SNP distribution across chromosomes on the original and random SNP chips was similar. The mean distance between adjacent SNPs was 19,990±25,439 SD for the original and 19,972±26,148 SD for the randomly generated SNP chips. GWAS was repeated with those 100 random SNP chips as described above.

SNP annotation and haplotype blocks. The SNP selection categories for the design of the DSN200K chip and the estimation of haplotype blocks were thoroughly described in Neumann *et al.* (2021). SNP categories included SNPs from previous GWAS in DSN (Korkuć *et al.*, 2021; May *et al.*, 2019; Meier *et al.*, 2020; Wolf *et al.*, 2021), SNPs with high, moderate or low impact on gene transcripts (e.g. missense mutations) as estimated with Ensembl Variant Effect Predictor, and DSN-unique SNPs.

Results

GWAS with the DSN200K chip identified a total of 163 (131 significantly and 32 suggestively) associated SNPs (Table 1). Those SNPs covered 81 out of possible 87,266 haplotype blocks and could be grouped into 25 QTLs (61 haplotype blocks; 13 QTLs when considering only significant SNPs). The identified associated SNPs were mainly SNPs that were added to the DSN200K chip as significant SNPs from previous GWAS

results. But additional SNPs with high, moderate or low impact on the function of genes and DSN-unique SNPs that are important to identify breed-specific QTLs in DSN were also found. Many of the associated SNPs that had been found already in previous GWAS in DSN, had a potential impact on the gene transcript and/or were DSN-unique.

Only 13 (9 significantly and 4 suggestively) associated SNPs were identified when using the 33,546 SNPs from the Illumina 50K chip which were also present on the DSN200K chip. These were 13-15 times less associated SNPs than with the DSN200K chip while using only 4 times less SNPs. With regard to QTLs, 11 out of 25 would not have been detected when considering only SNPs from the Illumina 50K chip (5 out of 13 QTLs when considering only significant SNPs). Only 12 haplotype blocks were covered by those SNPs (8 when considering only significant SNPs).

GWAS with the randomly generated SNPs chips identified on average 60±8 SD associated SNPs (41±7 SD when considering only significant SNPs) (Table 1). This was around 2.7-3.2 times less SNPs than with the breed-specific DSN200K chip. Also, on average 1.6-1.7 times less haplotype blocks were covered. With regard to QTLs, with the randomly generated SNP chips on average 17±1 SD out of 25 QTLs that were found with the original DSN200K chip could be identified as well (11±1 SD out of the 13 QTLs when considering only significant SNPs). Almost no SNPs with impact on the gene transcripts or unique to DSN were identified with the randomly generated SNP chips.

The QTL with the highest significance using the DSN200K chip was found on chromosome 5 for milk fat content in lactation 1 (Figure 1). The top SNP of this QTL (5:93,516,066, rs211210569) is located in the gene *MGST1* (Microsomal Glutathione S-Transferase 1). This region was found to be as well associated with milk fat content in Holstein (Littlejohn *et al.*, 2016). This QTL would have been missed when considering only significant SNPs from the Illumina 50K chip, but would be likely found with any SNP chip of higher density.

Discussion

Higher density SNP chips (DSN200K and random SNP chips with 137K informative SNPs) identified as expected remarkably more associated SNPs that could be grouped also into more QTLs compared to the Illumina 50K chip. The higher number of associated SNPs in each QTL region improved also their

Table 1. Comparison of GWAS results using different SNP chips.

Chip	Threshold	Number of SNPs[1]				Number of haplotype blocks
		Previous GWAS	VEP impact	DSN-unique	Total[2]	Total[2]
DSN200K	MAF>0.05	1,898	40,120	7,295	131,273	87,266

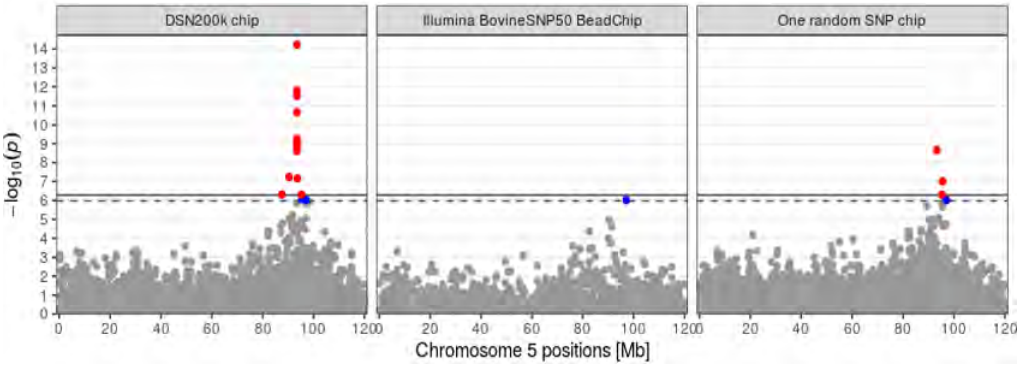

Figure 1. QTL on chromosome 5 for milk fat content in lactation 1 using different SNP chips (red=significant SNPs, blue=suggestive SNPs).

certainty. Furthermore, the carefully designed breed-specific DSN200K chip was better at identifying associated SNPs and QTLs with milk performance in DSN than the randomly generated SNP chips. This was expected, as this chip already contained previously identified SNPs associated with milk performance in a smaller population of 1,490 DSN cows (Korkuć *et al.*, 2021). With regard to SNP categories, SNPs having impact on gene transcripts or breed-specific SNPs were underrepresented on the randomly generated SNPs chips. Because these functional SNPs have a high potential for being causal for economically important phenotypes, they should be included on breed-specific SNP chips. Our findings support the fact that adding significant SNPs from GWAS and SNPs with functional impact or unique to the investigated breed to a custom SNP chip is beneficial for the target breed for future GWAS and genomic breeding. In conclusion, we obtained not only quantitatively but also qualitatively best results with the breed-specific DSN200K chip compared to the lower density Illumina 50K chip and to the randomly generated SNP chips.

Abstract

Understanding the genetic architecture of behavioral traits is of great interest for the livestock sector due to its economic and welfare implications. Therefore, the objective of this study was to perform traditional and weighted single-step genome-wide association studies (GWAS) for yearling temperament (YT) in North American Angus cattle using haplotypes. Approximately 266K YT records and 70K animals genotyped using a 50K single nucleotide polymorphisms (SNPs) panel were used. Pseudo-SNPs from the unique haplotype alleles generated from haplotype blocks with low (0.15), moderate (0.50), and high (0.80) linkage disequilibrium thresholds were used with and without fitting the non-clustered SNPs. Weighted single-step GWAS did not perform better than the traditional single-step GWAS. YT is a highly polygenic trait. The main candidate genes identified are involved in important biological processes and metabolic pathways related to behavioral traits, social interactions, and aggressiveness in cattle.

Introduction

Yearling temperament (YT) in North American Angus is a categorical trait measured on a scale from 1 to 6 for docile and very aggressive animals, respectively, and scored subjectively by farmers/handlers when a one-year-old calf is being processed through the chute and is a measure of cattle behaviour (Northcutt and Bowman, 2010). YT is heritable (heritability ~0.37) and improving cattle behaviour is paramount to the beef cattle industry, due to its relationship with other economically important traits (e.g. carcass end product) as well as animal handling and welfare (Northcutt and Bowman, 2010).

Haplotypes can better capture the linkage disequilibrium (LD) between markers and the quantitative trait loci (QTL) than SNPs and also account for epistatic effects (Hess *et al.*, 2017), which can improve QTL mapping. We have not found reports of haplotype-based GWAS for behavioural traits in cattle, and hypothesized that this approach could provide complementary information to dissect the genetic basis of cattle behaviour.

The traditional single-step GWAS (ssGWAS) consist in using phenotypes from genotyped and non-genotyped individuals to find QTL, however, it assumes that the markers explain similar and small proportion of the total additive genetic variance (Wang *et al.*, 2012). This limitation resulted in proposing the weighted ssGWAS (WssGWAS), in which priorities can be given to regions that explain greater proportions of the additive genetic variance (Wang *et al.*, 2012). Therefore, the objective of this study was to perform ssGWAS and WssGWAS for YT in North American Angus cattle using haplotypes.

Materials & methods

Datasets. No ethical review and approval were needed for this study because all datasets used were provided by commercial breeding operations. The American Angus Association (through Angus Genetics

Inc.; St Joseph, MO, USA) provided YT records for 266,029 animals born between 2001 and 2018 (147,671 bulls, 3,332 steers, and 115,026 females), in which 69,559 of them also had genotypes for 54,609 SNPs. The pedigree dataset included 4,410,551 animals. We have used the YT measured in a scale from 1 to 4 for docile and aggressive animals, respectively, by grouping the classes 4 to 6 (Northcutt and Bowman, 2010). The genotypic dataset was filtered to remove SNPs with minor allele frequency <0.01, call rate <0.90, difference between observed and expected heterozygosity >0.15, located in the non-pseudo-autosomal region of the X chromosome, and animals with call rate <0.90, remaining 42,633 markers and 69,437 animals for further analyses.

Haplotype block construction. First, the SNP genotypes were phased using the FImpute software v.3.0 (Sargolzaei *et al.*, 2014). Then haploblocks were created with LD measured as r^2 using the 'gpart' R package (Kim *et al.*, 2019). The LD thresholds of 0.15, 0.50, and 0.80 were used to create the haploblocks. The total number of blocks was 9,634, 5,617, 2,721 and the total number of SNPs within blocks was 21,784, 12,132, and 5,822 for the LD thresholds of 0.15, 0.50, and 0.80, respectively.

Traditional and weighted single-step GWAS. The ssGWAS consisted in predicting the genomic estimated breeding values (GEBVs) using the single-step genomic BLUP, back solving the GEBVs to the marker effects, and then calculating the percentages of the total additive genetic variance (PTGV) explained by each one of them. The THRGIBBS1f90 software (Misztal *et al.*, 2018) was used to predict the GEBVs for YT considering it as a categorical trait under a Bayesian approach, using the following mixed model:

$$y = Xb + Ww + Zu + e \quad (1)$$

where y is the vector of phenotypic records, b is the vector of systematic effects (age of dam, conception type, and calf age deviation from 365 days as linear covariate), w is the vector of contemporary group (CG) effects with $w \sim N(0, I\sigma_w^2)$, u is the vector of additive genetic effects with $u \sim N(0, H\sigma_u^2)$, and e is the vector of residuals $e \sim N(0, I\sigma_e^2)$. The CG were formed by concatenating birth month and year, birth herd, birth sex, weaning date, weaning herd, weaning sex, creep feeding offered or not, date of temperament measurement, YT measurement herd, sex at the YT measurement, temperament group age deviation, and presence of ultrasound records. X, W, and Z are the known design matrices for the systematic, CG, and additive genetic effects, respectively. H is the matrix that combines the pedigree (A) and genomic (G) relationships, which was computed directly as H^{-1} as suggested by Aguilar *et al.* (2010). A chain of 10,000 iterations with 1000 discarded as burn-in and 10 as thin was used to predict the GEBVs. The POSTGSf90 software (Misztal *et al.*, 2018) was used for post-GWAS analyses. The WssGWAS was performed following the algorithm proposed by Wang *et al.* (2012) using the non-linear A weights proposed by VanRaden (2008). We performed two additional iterations in the WssGWAS beyond the ssGWAS because this value was enough to achieve the convergence of the GEBV accuracy (Wang *et al.*, 2012).

Scenarios evaluated. Eighteen scenarios were defined by combining: (1) ssGWAS or WssGWAS in the second and third iterations; (2) G calculated considering only pseudo-SNPs from unique haplotype alleles derived from haploblocks with LD threshold of 0.15, 0.50, and 0.80; and (3) same as (2) including the non-clustered SNPs (NCSNP) with the respective LD thresholds.

Empirical selection of the candidate regions and functional analysis. First, a probability distribution (Beta or Gamma) was fitted to the PTGV in each scenario, then a quantile with the tail containing the markers that explained the biggest PTGV (top) was defined for further investigation. The candidate regions were selected as the top 0.001% genomic regions and the Biomart tool (www.ensembl.org/biomart/martview/ad1112a783c0e0ae22e6572189d5bead) was used to identify candidate genes overlapping. Gene

ontology biological processes and metabolic pathways were annotated for the genes found using the DAVID platform (https://david.ncifcrf.gov/home.jsp) by the Functional Annotation Tables for each gene.

Results

The WssGWAS did not perform better than ssGWAS, which found the largest number of top 0.001% genomic regions for YT regardless of the LD threshold used, with the PTGV summing up to 4.21% of the total additive genetic variance. As all the top genomic regions found by the WssGWAS scenarios were present in the ssGWAS scenarios, only the results for the latter are presented (Figure 1) and were used to find overlapping genes (Table 1).

Discussion

The fact that WssGWAS did not perform better than ssGWAS indicates the highly polygenic architecture of YT, as ssGWAS assumes the infinitesimal model for the QTL (Wang *et al.*, 2012). A total of 76 genes were identified across all scenarios. The biological processes associated with some of the genes overlapped with the top 0.001% genomic regions are related to neuron projection development (GO:0031175); axonogenesis, visual perception, forebrain development, embryonic eye morphogenesis, and retina development in camera-type eye (GO:0007409, GO:0007601, GO:0030900, GO:0048048, and GO:0060041,

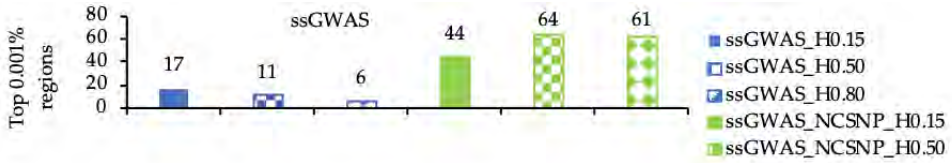

Figure 1. Number of top 0.001% genomic regions for yearling temperament in American Angus cattle found by traditional single-step GWAS (ssGWAS). H0.15, H0.50, and H0.80: only haplotypes from blocks with linkage disequilibrium (LD) thresholds of 0.15, 0.50, and 0.80, respectively; NCSNP_H0.15, NCSNP_H0.50, and NCSNP_H0.80: non-clustered SNPs (NCSNP) from blocks with LD thresholds of 0.15, 0.50, and 0.80, respectively.

respectively); sensory perception of sound and inner ear morphogenesis (GO:00076605 and GO:0042472, respectively); face morphogenesis (GO:0060325); positive regulation of dendrite and dendrite spine morphogenesis (GO:0050775 and GO0061003, respectively); central and peripheral nervous system myelin maintenance (GO:0032286 and GO:0032287, respectively); embryonic neurocranium, brain morphogenesis, and respiratory system development (GO:0048702, GO:0048854, and GO:0069541, respectively); branchiomotor neuron axon guidance, regulation of axon extensions involved in guidance, the semaphorin-plexin signaling pathway involved in axon guidance, and neuron projection extension (GO:0021785, GO: 0048841, GO:1902287, and GO:1990138, respectively). The three main metabolic pathways related to YT are related to Alzheimer disease, axon guidance, and oxytocin signalling pathway (bta05010, bta04360, and bta04921, respectively). In summary, they were mainly related to central and peripherical nervous system and sense organs, which affect social interactions between individuals because they are involved in capturing, decodifying, and reacting to external stimulus (Grandin and Deesing, 2014). Including the non-clustered SNPs and using different LD thresholds to create the haploblocks in the ssGWAS is recommended because it increased the likelihood of finding important genomic regions. The main candidate genes identified are involved in biological processes and metabolic pathways related to behavioural traits, social interactions, and aggressiveness in cattle.

Abstract

Heat stress is a major welfare and economic issue in the swine industry. Genome-wide association studies (GWAS) represent a great tool to investigate the association of candidate genes and quantitative trait loci (QTL) with phenotypes of interest. Therefore, this study aimed to perform GWAS for six indicators of thermotolerance (automatically-measured vaginal temperature; ear, shoulder, rump, and tail temperatures; and respiration rate) in lactating sows to identify genomic regions and candidate genes influencing these traits in commercial Landrace × Large White sows during lactation stage under heat stress conditions. Sixteen genomic regions were identified on chromosomes 1, 2, 3, 5, 6, 7, 8, 10, 12, 13, 14, and 16, with ten of these genomic regions related with known QTL associated with health and production traits. These findings highlight the importance of thermoregulation indicators on the performance and well-being of pigs, and consequently adding such traits to the current selection indexes.

Introduction

Climate change-induced heat stress is considered a major welfare and production issue in the swine industry. Advances in genetic and genomic selection, nutrition, and management have increased pig performance through larger litter sizes (Kemp *et al.*, 2018), with a subsequent higher metabolic heat production (Stinn and Xin, 2014; Cabezón *et al.*, 2017). In general, swine breeding programs rely on a wide number of traits (e.g. litter characteristics, slaughter, and reproduction) integrated into selection indexes. This approach has led to the identification of traits that may assist in the selection of more heat tolerant animals.

Various efforts have been made in the identification of novel phenotypes under non-commercial conditions using simulated heat stress (Graves *et al.*, 2018; Kim *et al.*, 2018). In addition of the development of novel phenotypes, the identification of candidate genes and genomic regions related to thermotolerance traits based on genome-wide association studies (GWAS) is an important step to understand the genetic mechanisms underlying their phenotypic expression. However, there is still a need to further investigate the association of genomic regions and candidate genes with thermotolerance using larger datasets. Therefore, the study objective was to perform GWAS for novel indicators of thermotolerance aiming to identify key genomic regions and candidate genes influencing these traits in commercial Landrace × Large White lactating sows measured under heat stress conditions.

Materials & methods

Animals, phenotypic and genotypic dataset. A total of 1,639 multiparous lactating sows (Landrace × Large White; parity 4.27±1.53) and their litters (11.10±2.33 piglets/litter) were tested. Sows and their litters were housed under commercial production conditions within individual farrowing crates at a commercial sow farm in Maple Hill, North Carolina, USA (34.70738, -77.73653), and novel phenotypes associated with heat tolerance were measured between June 05, 2021 and July 30, 2021. Ear skin temperature (T_{ES}), shoulder skin temperature (T_{SS}), rump skin temperature (T_{RS}), and tail skin temperature (T_{TS}) were collected in

all sows throughout the length of the study, four times a day (at 08:00, 12:00, 16:00, and 20:00 hours) using an infrared temperature gun (Raytek model ST61; accuracy = ±1%; emissivity = 0.98; resolution = 0.10 °C; Raytek Corporation, Fluke Process Instruments, Everett, WA, USA). Vaginal temperature (T_V) was automatically measured in 10 min intervals using calibrated thermochron temperature recorders (iButton model DS1921H, calibrated accuracy ±0.01 °C; resolution = 0.125 °C; Dallas Semi-conductor, Maxim, Irving, TX, USA). Respiration rate (RR) was collected by counting flank movements for 15 s and multiplying by 4 to calculate breaths per minute at 08:00, 12:00, 16:00, and 20:00 hours daily (Johnson *et al.*, 2016; Kpodo *et al.*, 2019). In-barn environmental data were collected throughout the length of the trial using data loggers in each farrowing room (Hobo model #MX1101; data logger temperature/RH; accuracy ±0.20 °C and ±2% RH; Onset; Bourne, MA, USA). Each data logger was placed in 1 of 4 quadrants mounted at sow height to record dry bulb temperature and relative humidity, which were used to calculate dew point (Buck, 1981).

A total of 1,639 animals were genotyped using the PorcineSNP50K (50,703 SNPs) Bead Chip (Illumina, San Diego, CA, USA). Quality control (QC) of genotype data consisted of removing SNPs and animals with call rate below 0.90, and minor allele frequency lower than 0.01, using the BLUPF90 family software (Misztal *et al.*, 2018). After QC, 49,547 SNPs for 1,625 animals were kept for subsequent analyses.

Genome-wide association studies. Variance components and genomic estimated breeding values (GEBV) were estimated implementing repeatability models using the BLUPF90 family programs (Misztal *et al.*, 2018). The model fitted can be described as:

$$y = X\beta + Z_a a + Z_{pe} pe + e \quad (1)$$

where, y is the vector of phenotypic records for T_V, T_{ES}, T_{SS}, T_{TS}, T_{RS}, and RR; β is a vector of fixed effects, including parity, location, time of measurement, body size, scorer of body size, hair density, scorer of hair density; a is the random additive genetic effect assumed to follow $\mathbf{a} \sim N(0, \mathbf{G}\sigma_a^2)$. The G matrix was created based on the first method proposed by VanRaden (2008); p is the vector of random permanent environmental effects; X, Z_a, and Z_{pe} are the incidence matrices; and e is the residual effect assumed to follow $\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2)$.

After estimating the GEBVs, GWAS analyses were performed using the postGSf90 software (Aguilar *et al.*, 2014), considering the variance explained by moving windows of five adjacent SNPs. The GEBVs were back-solved to obtain the SNP effects following the equation:

$$\hat{\mathbf{u}} = \mathbf{Z}'[\mathbf{Z}\mathbf{Z}']^{-1}\hat{\mathbf{a}} \quad (2)$$

where û is the vector of estimated SNP effects for the additive genetic effect; Z is the matrix with genotypes for each SNP, and â is the vector of GEBVs. Genomic windows (±100 kb) were considered relevant if they explained ≥0.5% of the total additive genetic variance of the trait. Positional candidate genes were mapped using the Biomart tool (Kinsella *et al.*, 2011; http://useast.ensembl.org/index.html). Based on the start and end chromosomal positions, important genomic regions were further investigated to understand the biological processes related to the studied traits and to define the most likely functional candidate genes. All candidate genomic regions were searched in the Pig QTL Database (PigQTLdb; Hu *et al.*, 2018) to investigate whether they contained previously reported quantitative trait loci (QTL).

Results

Sixteen genomic windows were associated with the six different studied traits. These genomic regions were in the *Sus scrofa* (SSC) chromosomes SSC1, SSC2, SSC3, SSC5, SSC6, SSC7, SSC8, SSC10, SSC12, SSC13, SSC14, and SSC16, and the maximum proportion of the additive genetic variance explained was 1.16% (T_{ES}). Previously reported QTL within the relevant genomic windows are shown in Table 1. The main QTL are related to health (e.g. immune capacity) and production (e.g. feed conversion). Key candidate genes were found on these genomic regions. Tail skin temperature had the highest number of candidate genes (26 genes in 4 genomic regions), while T_{RS} had the lowest number of candidate genes (one gene in one genomic region). Some genes were commonly found between T_{SS}, T_{ES}, and T_{TS} (*CD209*, *CD320*, *ELAVL1*, *FBN3*, *FCER2*, *KANK3*, *PCP2*, *PRR36*, *TIMM44*, and *XAB2*). Genomic regions were commonly found between T_{ES} and T_{SS} (on SSC2), T_{RS} and T_{SS} (on SSC14), and T_{TS} and RR (on SSC8). =

Discussion

In this study, most of the candidate genomic regions (4) were found to be associated with T_{TS} and T_{SS}. The candidate genes located in these regions have been previously associated with health, feed efficiency, and production QTL, highlighting the importance of thermoregulation on the performance and well-being of animals raised under heat stress conditions. For instance, the gene *CD320* identified for T_{SS}, T_{ES}, and T_{TS} play an important role on reproduction. Mice lacking *CD320* were found to suffer from reproductive loss (Bernard *et al.*, 2018). Another interesting candidate gene (*ELAVL1*) is associated with immune response and was found for T_{SS}, T_{ES}, and T_{TS} (Karginov, 2019). Furthermore, the gene *TIMM44* (T_{SS}, T_{ES}, and T_{TS}) has key functions related to oxidative stress (Steibel *et al.*, 2011). From the sixteen relevant genomic regions, ten are associated with QTL related with health parameters, which shows the importance and relevance of the studied traits on a healthy and productive animal. The amount of candidate genes and genomic windows found to be relevant in this study indicates the complex nature of the studied traits.

Table 1. Previously reported quantitative trait loci (QTL) for related traits within candidate genomic regions.

Trait[1]	Genomic region (Mb)[2]	Related QTL
T_{ES}	SSC2: 70.61-71.56	Immune capacity, disease measurement.
T_{RS}	SSC14: 108.41-108.72	Mean corpuscular hemoglobin concentration, skeletal muscle morphology, response to bacterial infection.
T_{SS}	SSC1: 17.31-17.37	Red blood cell distribution width, blood glucose level.
	SSC2: 70.82-71.56	Blood immunoglobulin amount, disease process measurement, shoulder weight, liver weight.
	SSC3: 137.70-138.15	Disease process measurement, serum creatinine level.
	SSC14: 108.41-108.72	Average daily food intake, mean corpuscular hemoglobin concentration, skeletal muscle morphology, response to bacterial infection.
T_{TS}	SSC5: 62.12-62.20	Blood urea level, meat pH, outer ear area, outer ear prominence, outer ear size.
	SSC6: 149.37-149.50	Feed conversion ratio.
	SSC7: 38.82-39.02	Viable offspring quantity, hemoglobin concentration, blood potassium level.
	SSC8: 69.15-69.62	Disease process measurement, corpus luteum quantity.
T_V	SSC1: 58.45-58.58	Internal adipose amount, food intake rate.
	SSC14: 48.32-48.56	Abdominal fat weight, internal adipose amount, viable offspring quantity.
	SSC16: 21.58-21.70	Belly muscle percentage, outer ear area, immune response.
RR	SSC6: 15.37-15.41	Litter size, social interaction, hair pigmentation, meat pH, body weight, leg conformation.
	SSC8: 69.15-69.62	Corpus luteum number, feet weight, average daily gain, red blood cell count, uterine capacity.
	SSC12: 26.60-26.87	Response to viral infection, disease measurement, stress-related behaviour.

[1] T_{ES}: ear skin temperature; T_{SS}: shoulder skin temperature; T_{RS}: rump skin temperature; T_{TS}: tail skin temperature; T_V: vaginal temperature; and RR: respiration rate.
[2] bp: mega base pairs; SSC: *Sus scrofa* chromosome.

These findings are an important first step to understand the genetic background of close-to-biology indicators of thermotolerance in pigs. Further studies are needed to validate the relevant candidate genes and genomic regions found in this study.

Abstract

Genome wide associate studies (GWAS) aim to identify genomic regions implicated in phenotype expression, but identifying true causative variants is difficult. Pig combined annotation dependent depletion (pCADD) scores may provide a straight-forward method of prioritising causal variants identified by GWAS. This study aimed to test using pCADD to identify candidate variants using loin depth in four pig lines. Three main regions on SSC7, 9, and 16 were identified in both maternal and terminal lines and have been found to be associated with carcass traits in previous studies. Two genomic regions were identified in maternal lines only, with SNPs within *MC4R* and *PIK3C2A* identified as the most likely causative variants. Several of the candidate SNPs have plausible biological links to muscle-related phenotypes, however further work is required to determine whether these are true causal variants.

Introduction

In genome-wide association studies (GWAS), genetic variants are independently tested for statistical association with a phenotype, with the aim of identifying the underlying causal genetic basis of the trait. Identifying true causal variants is difficult, due to high linkage disequilibrium (LD) between variants, a dilemma that is exacerbated in livestock species that have undergone selection for specific traits. While fine-mapping aims to solve this problem, there are many methods to choose from, with varying degrees of complexity. Pig combined annotation dependent depletion (pCADD) is an algorithm that estimates the deleteriousness of a given variant in the pig genome. As demonstrated by Derks *et al.* (2021), incorporating pCADD scores in the GWAS pipeline may provide a simple method for identification of candidate causative SNPs. The objective of this study was to use GWAS and pCADD to computationally identify SNPs that are likely to contribute to variance in pig loin depth, and to explore their biological plausibility by examining the genes in which these SNPs are located.

Materials & methods

Animals and phenotypes. Analyses were performed on 232,057 pigs from the Pig Improvement Company (PIC; Hendersonville, TN, USA). Pigs from two maternal lines (recoded as A and B) and two terminal lines (recoded as C and D) were used in this analysis. Breeding values for loin depth measured via ultrasound were calculated as part of routine genetic evaluations. Breeding values were de-regressed (dEBV) as per VanRaden and Wiggans (1991), and used as phenotypes in GWAS. To account for variation in the reliability of dEBVs, a weighting value based on Garrick *et al.* (2009) was calculated for each individual, and the reciprocal of each weight was used as a residual weighting factor in GWAS.

Genotypes and quality control. Tissue samples were acquired from tails, which were docked within 48 hours of birth, and samples were genotyped using a customized Illumina single-nucleotide polymorphism (SNP) chip, mapped to susScr11.1. SNPs with MAF<0.01 or a call rate <0.95 were removed from further

DOI: 10.3920/978-90-8686-940-4_378, © S. Desire *et al.* 2022

analyses. After quality control, an average of 42,370 (SD 1,514) SNPs were available for each line and used in GWAS analysis. Variants from whole genome sequence datasets were available, imputed via hybrid peeling (Ros-Freixedes *et al.,* 2020), and these SNPs were used to identify candidate SNPs, post-GWAS.

Association analyses. GEMMA software (Zhou and Stephens, 2012) was used to estimate centered genomic relatedness matrices. GEMMAs was also used to apply a series of univariate linear mixed models:

$$y = Xb + u + e, \quad (1)$$

where y is the vector of de-regressed EBVs, the vector β, represents the vector of effect size of each SNP, and X is the incidence matrix relating genotypes with β. The vector $u \sim N(0, G_c\sigma_u^2)$ represents polygenic additive effect with covariance equal to the centred genomic relationship matrix G_c and variance σ_u^2. The vector *e* represents residual error, weighted to account for the variable reliability of de-regressed breeding values. To conservatively account for multiple comparisons in the GWAS, *P*-values were adjusted by Bonferroni correction. A SNP was significant at the genome level if -log10(*P*-value) was greater than -log10(0.05/n), where n represents the number of markers across the genome.

Identifying candidate SNPs. A region spanning 0.5 Mbp up and downstream of each significant SNP was defined as a distinct genomic region. Significant SNPs within 0.5 Mbp of each other were merged into a single region. The GWAS SNP with the highest significance from each genomic region (lead SNP) was identified, and all SNPs in high LD (^{3}0.7) with lead GWAS SNPs were identified from sequence data. We obtained pCADD scores (Groβ *et al.,* 2020) for each of these SNPs, along with their predicted effect, using Ensembl Variant Predictor (VEP). The variant with the highest pCADD score found to be in high LD with a lead SNP is referred to as the seqSNP. The genes harbouring seqSNPs were identified from the Ensembl database.

Results & discussion

The aim of this study was to identify regions associated with loin depth in four pig lines, and to interrogate the candidate causative SNPs, as suggested by pCADD scores. Table 1 lists the strongest associations found within each genetic line, along with a corresponding seqSNP for each region. While SNPs with strong genome-wide associations with loin depth were found for all genetic lines, no common regions were found across all four lines (Figure 1). Of the exonic seqSNPs identified, 11 were missense variants, 8 were synonymous, and one stop-gain. Six of the seqSNPs were intronic and 5 were intergenic.

Table 1. The most highly significant GWAS associations (lead SNPs) for de-regressed EBVs for loin depth in each of four purebred pig lines, and candidate causative SNPs (seqSNPs), identified using pCADD scores.

line	SSC	lead SNP		seqSNP		
		Position (Mbp)	GWAS -log10pvalue	Position (MbP)	pCADD score	Predicted consequence
A	6	45.74	11.14	52.0	34.95	missense
B	2	0.40	18.83	0.8	41.97	synonymous
C	16	34.10	21.55	34.0	43.19	missense
D	5	66.10	27.4	66.2	15.82	intergenic

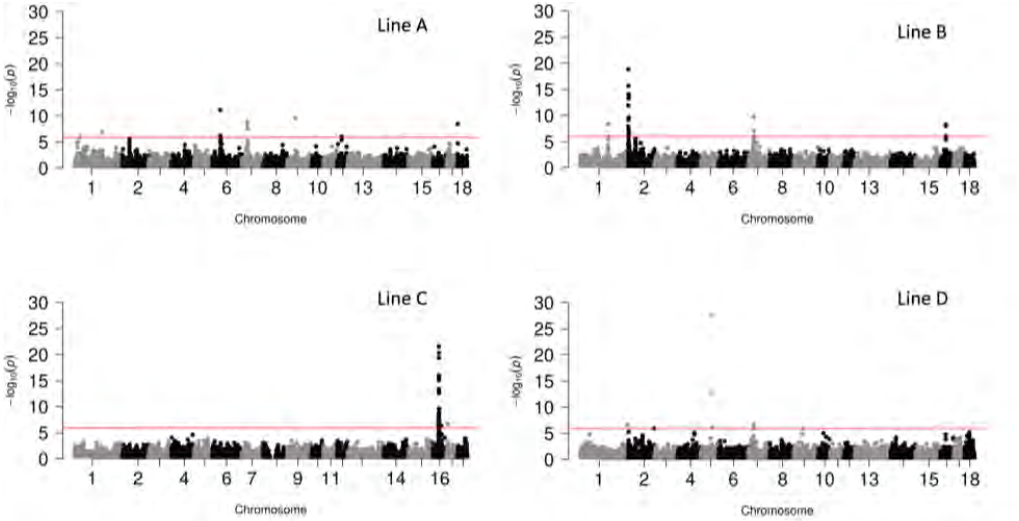

Figure 1. Genome wide plot of −log10 *P*-values (y axis) for association of SNPs with loin depth in four pig lines. The horizontal line indicates the threshold for genome wide significance.

One genomic region on SSC7 (~30 Mbp) was found to be statistically associated with loin depth in both maternal lines, and one terminal line (D). This region has been previously associated with loin muscle area and other body traits in pigs (Zhuang *et al.*, 2019; Bian *et al.*, 2021). Three separate seqSNPs were identified by pCADD scores for this region. Two were missense SNPs located in *GRM4* and *FANCE,* and one was a synonymous variant located in *CPNES*.

One maternal line and both terminal lines shared a large genomic region located on SSC16 (~32-34 Mbp) in common. Two of the seqSNPs identified for this region were located within known genes *ITGA1* and *ARL15*, while the third was an intron variant located in *MAST4*. Several studies have found this SSC16 region to be associated with loin muscle (Zhuang *et al.*, 2019; Bergamaschi *et al.*, 2020) and other body and growth-related traits (Gozalo-Marcilla *et al.*, 2021). In addition, *ITGA* has been shown to be up-regulated in steers with low marbling in the *Longissimus Dorsi* muscle (de las Heras-Saldana *et al.*, 2020). The gene *GRIK4* located on SSC9 (~47.7 Mbp) was implicated in one maternal and one terminal line and has been previously associated with loin muscle depth in pigs (Bian *et al.,* 2021). *MAST4* has not previously been implicated in pig production.

The maternal lines shared two significant genomic regions on SSC1 (~160.7 Mbp) and SSC2 (~41.5 Mbp). The most likely seqSNP identified for these regions within both breeds were missense variants located within the *MC4R* (SSC1), and *PIK3C2A* (SSC2). *MC4R* is a known regulator of feed intake, growth and meat quality traits (Kim *et al.*, 2000). Derks *et al.*, 2021 predicted a missense mutation within *MC4R* to be associated with fat deposition and growth in pigs, while (Reyer *et al.,* 2017) found a SNP near *MC4R* to be statistically linked to lean mass percentage and growth. On SSC2, *PIK3C2A* has been linked to lean meat percentage in pigs (Zhou *et al.*, 2021). Cánovas *et al.* (2010) showed *PIK3C2A* to be downregulated in pigs in a high lipid deposition group, while *PIK3C2A* is up-regulated in the high-marbled Hereford cattle (Roudbari *et al.*, 2020).

The strongest signals in the present study have been replicated elsewhere, supporting the evidence that these regions are important to the genomic control of muscle traits. pCADD identified several candidate

SNPs, some of which were in genes that have plausible biological links to muscle phenotypes, although some were located a considerable distance away from the lead SNP. It is notable that a large proportion (35%) of variants flagged by pCADD in this analysis were missense mutations. CADD was developed to estimate the pathogenicity of SNPs in humans (Kircher *et al.,* 2014), and as such prioritises potentially deleterious variants with protein-coding consequences. Generally, GWAS variants are expected to have small effect sizes, therefore the genes they impact are likely to have a small effect on the phenotype. Further work is required to determine whether the missense variants prioritised in this study have a functional effect on muscle phenotypes. Several intergenic, intronic, or synonymous variants were predicted to be likely candidate variants by pCADD scores. The next step is to perform eQTL analysis on porcine muscle sampled from the genetic lines used in the present study. These data will aid the interrogation of candidate causal SNPs.

379. Multivariate GWAS revealed a critical region on chromosome 4 for developmental and feather growth traits in ducks

E. Tarsani[1*], S. Desire[1], O. Matika[1], K. McIntosh[1,2], A. Rae[2], A. Kranis[1] and K.A. Watson[1]

[1]The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush, EH25 9RG, Midlothian, United Kingdom; [2]Cherry Valley Farms Ltd., Grimsby Road., DN37 7DP, Laceby, United Kingdom; etarsani@exseed.ed.ac.uk

Abstract

Aim of this study was to discover the genetic variants for average daily gain (ADG), body weight (BW) and primary feather length (PRF) traits in Pekin ducks. Using 1,215 ducks and 45 k autosomal SNPs, multivariate and univariate genome-wide association analyses were performed. A total number of 50 markers were identified as common between all analyses and these SNPs were co-localized on chromosome 4. Current findings confirm previously reported findings for growth in ducks while proposing novel genetic loci associated with feather development and growth in ducks.

Introduction

Pekin duck has become the predominant breed used for meat, egg and feather production in the global duck industry. Current literature on duck genome-wide association studies (GWAS) is limited to univariate models conducted on quantitative traits such as growth and carcass traits (Deng *et al.* 2019, Zhou *et al.* 2018, Zhu *et al.* 2019), feeding behaviour (Zhu *et al.* 2019) and egg production (Liu *et al.* 2021) with no multivariate GWAS reported so far in ducks.

The objectives of the present study were to: (1) identify the genetic variants with pleiotropic effects on growth and primary feather length in ducks; and (2) investigate the most plausible pleiotropic genes for the examined traits.

Materials & methods

Data and quality control. Genotypic and phenotypic records were provided by Cherry Valley Farm (CVF). The available data consisted of 1,215 Pekin ducks (n= 298 males and n=917 females) with phenotypic records on average daily gain (ADG) at 27 to 39 days of age, body weight (BW) at 39 days and primary feather length (PRF) at 39 days of age. Animals were genotyped using a 60K Affymetrix SNP array. After quality control (samples: call rate: 0.95, markers: call rate: 0.95, MAF: 0.05 and HWE Fisher exact test *P*-value:10^{-6}) a total number of 1,215 samples and 45,080 autosomal SNPs were retained for further analyses.

Univariate and multivariate association analyses. Data were initially analyzed using linear mixed models fitting effects for sex and hatch as fixed effects and animal as random effects using ASReml (Gilmour *et al.*2015) software. Univariate association analyses using GEMMA (Zhou and Stephens 2012) software were conducted fitting the same models as those used in the variance component analyses. The traits analysed were ADG, BW and PRF.

The multivariate analysis, fitting a multivariate linear mixed model three traits (ADG, BW and PRF), subsequently performed in GEMMA software using same fixed effects as used before. For all analyses, SNPs with FDR *P*-value<0.05 were considered as genome-wide significant. Estimation of the genomic heritability was further implemented via the realized marker information. Finally, the genetic correlation (r_g) was estimated between bivariates i.e. ADG and BW, ADG and PRF, BW and PRF.

Positional candidate genes. We used the SNPs that reached the significance threshold (FDR *P*-value) identified across all analyses to search for positional candidate genes. The search was restricted to SNPs within 50 kb downstream and upstream flanking regions of each significant marker for positional candidate genes using the NCBI database and the ZJU1.0 assembly. Due to the absence of a duck QTL database, we used the orthologues of chicken genes to search the documented role of the genes.

Results

Estimation of genetic parameters. The heritability estimates for additive effects were 0.28±0.04, 0.47±0.04 and 0.17±0.03 respectively for ADG, BW and PRF. The estimates of genetic correlation (r_g) between the ADG and BW was high (0.77) with negative and moderate estimates (-0.21) between ADG and PRF, and low and negative estimates (-0.09) between BW and PRF.

Comparison of genome-wide significant SNPs found by multivariate and univariate analyses. Figure 1 shows the profiles of the SNP *P*-values (expressed as $-\log_{10}$ values) across the three GWAS. Specifically, a total number of 112 genome-wide significant SNPs (FDR *P*<0.05) were detected by ADG univariate analysis and these SNPs were dispersed across nine autosomes (1-4, 10, 14, 15, 19 and 28). For BW univariate analysis, a total number of 138 SNPs across seven autosomes (1, 4, 15, 16, 20, 24 and 28) were found to reach genome-wide significance (FDR *P*-value<0.05). For PRF univariate analysis, a total number of 62 genome-wide significant SNPs (FDR *P*-value) were detected and these markers were located on two autosomes (4 and 18). The multivariate analysis resulted in 119 genome-wide significant (FDR *P*-value<0.05) SNPs across 10 autosomes (1-4, 11, 14, 15, 18, 19 and 28).

Comparison of SNP signals across the four association analyses resulted in fifty common significant markers on chromosome 4. Note that the 50 significant SNPs residing on chromosome 4 were co-localized

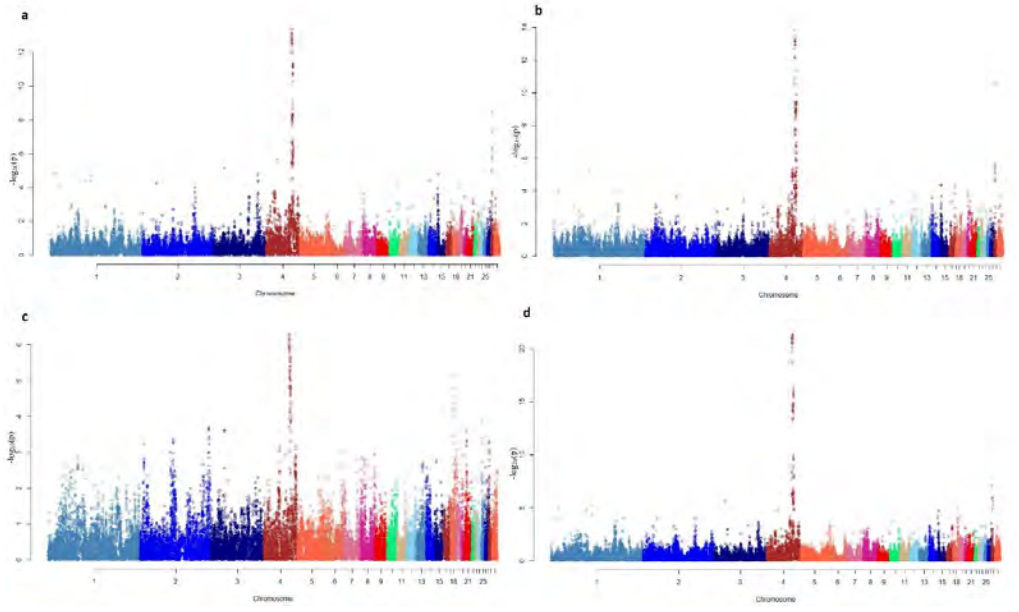

Figure 1. Manhattan plots showing the -$\log_{10}$(*P*-values) of SNPs across the 29 autosomes for average daily gain (ADG) (a), body weight (BW) (b), primary feather length (PRF) and all traits, respectively. Plots were constructed using the gaston R package.

in a region spanning 3,498,371 bp (57,648,845-61,147,216 bp) with high LD (r^2) levels (r^2:0.40-1). From the 50 SNPs, n=28 SNPs were located within 8 genes (*PPARGC1A, KCNIP4, PACRGL, SLIT2, LDB2, FBXL5, CC2D2A and CPEB2*) while the total number of positional candidate genes was 23 (*DHX15, PPARGC1A, ADGRA3, KCNIP4, PACRGL, SLIT2, LCORL, NCAPG, FAM184B, MED28, LAP3, CLRN2, QDPR, LDB2, TAPT1, PROM1, FGFBP2, FGFBP1, BST1, FBXL5, CC2D2A, C1QTNF7 and CPEB2*).

Discussion

Multivariate genotype-phenotype methods are known to increase the statistical power to detect marker-trait associations in the case of shared genetic basis between traits. The present study exploited a multivariate GWAS to identify candidate pleiotropic genetic loci for the ADG, BW and PRF traits in ducks. Our results identified two genes (*FGFBP1* and *FGFBP2*) which are fibroblast growth factors that have been reported to play critical role in embryogenesis and positive regulation of hair and feather development (Mandler and Neubüser 2004). Apart from these candidate pleiotropic genes, our study also supports findings by previous studies for growth traits in ducks. An interesting example is the *PPARGC1A* gene reported to play a role in promoting fatty acid oxidation of breast muscle in ducks (Fan *et al.* 2020). The other gene, *LDB2* has previously been reported as a candidate gene for body size and carcass traits in ducks (Deng *et al.* 2019). The *KCNIP4* gene, a member of potassium channel-interacting proteins has extensive physiological functions and insulin secretion was identified as an important QTL region associated with growth traits in chickens (Cha *et al.* 2021). *SLIT2* has also been reported to be strongly associated with back yield, feet weight, fat and muscle weight traits in chickens (Cha *et al.* 2021).

Several previous GWAS in chickens reported that chromosome 4 is a critical region influencing growth traits (Xu *et al.* 2013). We identified large QTL on chromosome 4 that has markers significantly associated with growth in ducks. Current findings by both univariate and multivariate GWA analyses could dissect the duck genetic architecture and have potential use in breeding programmes.

380. Investigation of genes associated with maternal weaning weight in South African Bonsmara beef cattle

J.J. Reding[1,2*], R.R. Van der Westhuizen[1,2], D.P. Berry[2,3] and E. van Marle-Köster[2]

[1]SA Stud Book and Animal Improvement Association, 118 Henry Street, Westdene, 9300, Bloemfontein, South Africa; [2]University of Pretoria, Department of Animal Science, Lynnwood Road, 0002 Pretoria, South Africa; [3]TEAGASC, Moorepark, Fermoy, Ireland; jason@studbook.co.za

Abstract

Maternal weaning weight (WW_{MAT}), the dam's genetic and permanent environmental components that contribute to the weaning weight of her calf, is a trait of economic importance in extensive beef production systems. Positive genetic correlations between milk yield and WW_{MAT} have been reported. In this study, a genome wide association was performed to search for genes associated with WW_{MAT}. A total of twenty-three significant single nucleotide polymorphisms (SNPs) was identified with a further 103 suggestive SNPs. These SNPs were collapsed into 12 quantitative trait loci (QTL) across eight autosomes with an additional QTL residing on the X-chromosome. Ten different genes were co-located with the detected QTL. Genes identified were either essential in protein ubiquination pathways or were related to mammary morphology and ability to respond to infection by the presence of bacterial species.

Introduction

Milk production in beef cattle is an essential component of calf growth (Mulliniks *et al.*, 2020), especially in extensive systems due to seasonal fluctuations in natural veld quality and low forage availability (Cortés-Lacruz *et al.*, 2017, Mulliniks *et al.*, 2020). Milk yield is influenced by both the calf, through its demand for milk in conjunction with nursing frequency, along with the nutritional, genetic and health status of the cow. Other maternal effects include the maternal ability of the cow to protect the calf, the gestational environment and the transfer of antibodies through colostrum which contribute to calf growth up to weaning (Mulliniks *et al.*, 2020).

Positive genetic correlations between milk yield and maternal weaning weight (WW_{MAT}) have been well documented (Nesengani *et al.*, 2018) and thus warrant investigation into the underlying genetic mechanisms of these traits (Meyer *et al.*, 1994). The majority of single nucleotide polymorphism (SNP) analyses in cattle have focused on traits such as measured milk production, growth and carcass characteristics. Fewer studies have attempted to locate genomic regions associated with WW_{MAT}. Significant SNPs on multiple autosomes were linked to WW_{MAT} in Brahman cattle (Martínez *et al.*, 2017), while Hay and Roberts, (2019) identified a region on *Bos taurus* autosome (BTA) 24 that contributed significantly to the genetic variance of WW_{MAT}.

The South African Bonsmara, classified as a Sanga type, is a composite breed of 5/8 Afrikaner and 3/8 exotic (Milk Shorthorn, Hereford) established through a well-documented crossbreeding program. The breed is the most numerous in South Africa (SA) and is farmed under extensive production systems. In this study, a genome wide association was performed to search for genes associated with WW_{MAT}.

Materials & methods

weighed and the contemporary group in which the calf was weaned. Random effects included are Sire × Herd × Year (SHY), the permanent environmental effect of the dam as well as the direct genetic effect of both the animal and the dam. A total of 1,242,158 weaning weight records are used in the genetic evaluation with an average weaning weight of 216.82 kg. Direct and maternal heritability estimates used are 0.27 and 0.17, respectively.

Estimated breeding values (EBVs) of 3,253 genotyped animals for WW_{MAT} were available, which consisted of 1,498 males and 1,755 females. The genotypes originated from three genotype panels, namely, 1,932 animals on the GeneSeek Genomic Profiler (GGP) 150K (140,113 SNPs), 589 animals on the GGP 80K (76,883 SNPs) and 732 animals on the Irish Cattle Breeding Federation (ICBF) International Beef and Dairy (IDB, 55,445 SNPs) platforms. All SNP locations were based on the ARS-UCD1.2, INSDC Assembly (GCA_002263795.2, Low *et al.*, 2019). Only autosomal and X-chromosomal SNPs with a known position and a call rate of ≥0.90 were retained. Non pseudo-autosomal SNPs on the X-chromosome were assumed homozygous for all male genotypes. All genotypes were subsequently imputed in FImpute v.3 to 134,421 SNPs.

Effective record contributions (ERCs) for each genotyped animal were generated using the reversed reliability approximation method in APaX99 (Lidauer *et al.*, 2017). The estimated breeding values for WW_{MAT} were subsequently deregressed using the Secant method in MiX99 (Strande, 1999) with the generated ERC used as a weighting factor. Only animals with an ERC of ≥0.5 were retained, which resulted in 1,454 animals for WW_{MAT} (median ERC=7.618) being available for the association analysis.

The weighted (by ERCs) deregressed WW_{MAT} EBVs were regressed on each SNP individually using a linear mixed model in WOMBAT (Meyer and Tier, 2012). An intercept term and the allele count per SNP were both included as fixed effects while relationships among animals was accounted using a genomic relationship matrix. The t-test statistic for all SNPs was obtained and SNPs with a $P \leq 1 \times 10^{-7}$ were considered to be genome-wide significant, while SNPs with a $P \leq 5 \times 10^{-6}$ were deemed to be suggestively significant.

The start and end of each quantitative trait loci (QTL) was defined by SNPs 0.5 Mb up and downstream that had an $r^2 > 0.5$ with the significant SNP. Overlapping QTL were consolidated into one QTL. Identified QTL were then explored using ENSEMBL in order to detect candidate genes residing within and Panther (Mi *et al.*, 2017) was used to list the biological and metabolic functions and/or processes of possible genes.

Results & discussion

Twenty-three significant SNPs were identified with a further 103 suggestive SNPs being identified. Fourteen of the significant SNPs were all located on BTA 8, with the remaining SNPs being on BTA 2, 6, 6, 9, 10, 16, 22 and *B. taurus* X-chromosome (BTX). Eleven different genes were co-located with the detected QTL (Table 1). The amalgamated QTL on BTA 8 contains nine significant SNPs that are in high linkage disequilibrium, with most of these being intron SNPs located in the *PCSK5* gene coding region.

DEGS1 was identified by Xu *et al.* (2018) to show differential gene expression in mammary tissue of dairy cattle after infection with *Escherichia coli* or *Streptococcus uberis*. *PCSK5* was reported by Hoac *et al.* (2018) to play a role in embryonic development, hormone regulation as well as bone mineralisation. *PCSK5* was associated with teat scores in Canadian Angus Cows (Devani *et al.*, 2021). These genes may play a role in the morphology of the udder as well as affect milk yield through mediating resistance to infection which would lead to mastitis.

Table 1. Detected quantitative trait loci with the most significant single nucleotide polymorphism and co-located genes.

BTA	Start	End	Distance (kbp)	SNPs in QTL	Genes
2	718140	882990	164.85	5	*HERC2*
6	374487838	37516229	28.39	3	*LCORL*
7	60414842	60452720	37.88	2	*SH3TC2*
8	51745358	51899568	154.21	5	
8	52180527	52333334	152.81	9	*PCSK5*
8	78145059	78145059	0	1	*NTRK2*
9	28257531	28257531	0	1	
9	56836009	56836009	0	1	*EPHA7*
10	2575344	2575344	0	1	
16	27298728	27407724	108.99		*FBXO28, DEGS1*
22	22033915	22033915		1	
X	59554341	59554341	0	1	DCX

Some of the detected genes (i.e. *DCX*, *EPHA7*, *FBXO28* and *SH3TC2)* have not been previously reported to be associated with any traits in beef cattle breeds. The number of genes linked to the posttranslational modification of proteins through ubiquination (i.e. *EPHA7*, *FBXO28* and *HERC2)* is interesting. This process essentially mediates the quantity and quality of various proteins that contribute to cellular homeostasis and influence life activities.

The *LCORL* gene has been identified as a candidate QTL for birth weight, growth and length in beef cattle breeds (McClure *et al.*, 2010; Lindholm-Perry *et al.*, 2011). Lindholm-Perry *et al.* (2013) reported 14 SNPs in the *LCORL* gene region to be associated with muscle and adipose tissue related *LCORL* transcript in crossbred beef cattle. In cows and heifers, an up-regulated expression of *LCORL* in adipose tissue is significantly correlated with average daily feed intake.

HERC2 is involved in protein modification through ubiquination and was only previously reported to be associated with back-fat thickness in the Hanwoo beef cattle breed (Naserkheil *et al.*, 2020). *NTRK2* is a transmembrane signal receptor associated protein. A study on longevity indicated that *NTRK2* plays an important role in the development of reproductive tissues in both female and male beef cattle (Mészáros *et al.*, 2014). The occurrence of multiple adipose and reproductive tissue related genes indicates the complexity and polygenic effect of WW_{MAT}.

Abstract

Traits related to the calving abilities and workability of cows are essential for the dairy economy and the welfare of cows. The main goal of our study was to identify SNPs significantly associated with calving and workability traits, but having in mind the low heritability of those traits and then consequently the lack of genes with very strong individual effects, we also identified significant metabolic pathways and gene ontology terms. The data set originated from the EuroGenomics Holstein-Friesian population. All animals were genotyped or imputed to the Illumina BovineSNP50 BeadChip Version 2. The first step of the analysis was to identify significant SNPs and the second step comprised the estimation of pathway effects using a mixed effect model. The largest number of significant SNPs was detected for direct calving ease and for direct stillbirth Significant KEGG pathways and GO terms were identified.

Introduction

Traits related to the calving abilities and workability of cows are essential both for dairy economics and for the welfare of cows. According to Philipsson *et al.* (1994), in 1994 only five countries – the Nordic countries and Slovenia, considered calving traits in their national selection indices. Nowadays 19 countries carry out routine genetic evaluations of calving and workability. Despite generally low heritabilities, during the last decade, it has been possible to conduct successful selection, resulting in an improvement in calving ease and decrease in stillbirth rate, as demonstrated by Ma *et al.* (2019). Numerous Genome-wide Association Studies (GWAS) for calving performance have been conducted so far. Traits related to handling cows on farms have only recently been subjected to genetic evaluation, which is currently carried out by 14 countries on the international level. So far, only three GWAS results for workability traits have been published by Jardim *et al.* (2018), Marete *et al.* (2018), and Chen *et al.* (2020), indicating that further studies on various populations are needed for a better understanding of the genetic components of workability phenotypes. Consequently, the primary goal of our study was to identify SNPs significantly associated with the direct and maternal components of calving ease, direct and maternal components of stillbirth, cow temperament and milking speed. Having in mind the low heritabilities of all those traits we expect no genes with very strong individual effects, so we defined a secondary goal of the study which was the identification of metabolic pathways and gene ontology terms significantly associated with workability and calving that express a cumulated effect of many genes on a functional scope.

Materials & methods

Material. The analysed data originated from the EuroGenomics Holstein-Friesian dairy cattle population. For each bull, direct calving ease (DCE), maternal calving ease (MCE), direct stillbirth (DSB), maternal stillbirth (MSB), milking speed (MSP), and temperament (TEM), were available in the form of de-regressed breeding values (DRP) corresponding to the Interbull evaluation from April 2020. The majority of individuals (87%) was genotyped by the Illumina BovineSNP50 BeadChip Version 2 containing 54,609 SNPs. Bulls genotyped with other platforms were imputed to the above using the Beagle software. SNP

preselection criteria comprised a minor allele frequency of at least 0.01 and a minimum call rate of 99%. After editing, 46,216 SNPs remained for further analysis.

Genome-wide association study. The following mixed model was used to estimate the additive effects of SNPs:

$$\boldsymbol{y} = \boldsymbol{X\beta} + \boldsymbol{Z_1 g} + \boldsymbol{Z_2 a} + \boldsymbol{\varepsilon} \quad (1)$$

where y represents a vector of DRPs for considered traits; β is a vector of fixed effects representing a general mean with a design matrix X; Z_1 is a design matrix for SNP genotypes, which is parameterized as -1, 0, or 1 for a homozygous, heterozygous and an alternative homozygous SNP genotype, respectively; g is a vector of random additive SNP effects; Z_2 is a design matrix for a residual polygenic effect; α is a vector of random bulls' residual additive polygenic effects, representing the part of additive polygenic variance which is not explained by SNPs; and ε is a vector of residuals with $\boldsymbol{\varepsilon} \sim N\left(0, \boldsymbol{D}\hat{\sigma}_e^2\right)$, where D is a diagonal matrix containing the reciprocal of effective daughter contribution per bull on the diagonal and $\hat{\sigma}_e^2$ representing the residual variance. The covariance structure of g was assumed to be $\boldsymbol{g} \sim N\left(0, \boldsymbol{I}\frac{\hat{\sigma}_a^2}{N_{SNP}}\right)$, with I being an identity matrix and $\hat{\sigma}_a^2$ representing the additive genetic variance of a given trait and $\mathrm{N}_{\mathrm{SNP}}$ is the number of SNPs. $\boldsymbol{a} \sim N(0, \boldsymbol{A}\hat{\sigma}_{a*}^2)$, where A is the numerator relationship matrix and $\hat{\sigma}_{a*}^2$ is a predetermined ratio of genetic variance for each trait. In this study $\hat{\sigma}_{a*}^2 = 0.4 \cdot \hat{\sigma}_a^2$. For testing the hypotheses ($H_0: g_i = 0$ vs. $H_1: g_i \neq 0$), we used the Wald test with the Bonferroni correction for multiple testing.

Functional analysis. To associate SNPs to closest genes, all polymorphisms' coordinates from the Illumina BovineSNP50 BeadChip were remapped to the ARS_UCD1.2 reference genome. SNPs were genomically annotated with the Variant Effect Predictor, with 5,000 bp as the maximum distance between a SNP and its closest gene. The functional information was expressed by pathways defined by the Kyoto Encyclopedia of Genes and Genomes (KEGG) and by Gene Ontology (GO) terms corresponding to the genes marked by SNPs. DAVID was used for the annotation. The estimation of functional effects was based on the following model:

$$\boldsymbol{y}^* = \boldsymbol{\mu} + \boldsymbol{Z}^* \boldsymbol{p} + \boldsymbol{\varepsilon}^* \quad (2)$$

where y^* is the absolute value of the SNP effect for a given trait; p is a random KEGG pathway or GO term effect and ε^* represents the residual term. Z^* is the incidence matrix for KEGG/GO term effects p. It is assumed that $\boldsymbol{p} \sim N\left(0, \boldsymbol{P}\hat{\sigma}_p^2\right)$ and $\boldsymbol{\varepsilon}^* \sim N\left(0, \boldsymbol{L}\hat{\sigma}_{\varepsilon^*}^2\right)$, where P is a covariance matrix of KEGG/GO terms, consisting of the percentage of common genes between them and $\hat{\sigma}_p^2$ represents the KEGG/GO term variance. L is a diagonal matrix with elements equal to 1 (if a SNP was assigned a KEGG/GO term) or 10 (if a SNP was not assigned any functional element), $\hat{\sigma}_{\varepsilon^*}^2$ is the residual variance. For testing the hypotheses $H_0: p_i = 0$ vs. $H_1: p_i \neq 0$, the Wald test with the Bonferroni correction was used.

Results & discussion

Direct calving ease. The largest number of significant SNPs was detected for DCE. GWAS results demonstrated an accumulation of 22 highly significant SNPs on BTA18, distributed across a region spanning 10,225,739 bp. Nine of those SNPs were also reported as associated with direct calving ease by Müller *et al.* (2017) and by Abo-Ismail *et al.* (2017). Significant SNPs were also identified on BTA5, BTA7, BTA17, BTA19, BTA21, BTA25 and BTA29. On the functional scope, we identified seven significant biological processes: cartilage condensation, cell aggregation, artery development, nucleus localization, cardiac myofibril assembly, myofibril assembly, and actin filament-based movement. Microfilament motor

activity was the significant molecular function, while two significant cell components were myosin complex and neuromuscular junction. No significant KEGG pathway was identified.

Maternal calving ease. For the maternal component of calving ease, much fewer significant SNPs (17) were identified than for the direct component (59). The most significant SNPs (8) were scattered over BTAX, from 863,652 bp up to 127,125,130 bp. Among those SNPs, two have already been previously reported by Cole *et al.* (2011) as associated with maternal calving ease and direct calving ease. A significant SNP on BTA6 and BTA20 were reported by Sahana *et al.* (2011). Many of the significant SNPs were reported to be associated with conformation traits, which may indirectly impact calving ease, i.e. body depth, dairy form, rump width, stature, and type. No significantly associated KEGG pathways were identified. Significant GOs represented processes of positive regulation of protein maturation and modulation of chemical synaptic transmission with synapses being associated with cellular components.

Direct stillbirth. 19 out of the 25 significant SNPs overlapped with those that were also significant for DCE. Both traits were characterised by many significant SNPs located mainly toward the end of BTA18, all the other 18 polymorphisms were pleiotropic for DSB and DCE. Five SNPs from BTA18 have already been reported by Höglund *et al.* (2012) and by Müller *et al.* (2017). Another chromosome with multiple significant SNPs is the BTAX, but each of the four polymorphisms points out at a very different location. The similarity of the genetic architecture underlying DSB and DCE revealed by GWAS was also reflected on the functional annotation level, since all eight GO terms significantly associated with DSB were also significant for DCE. There was no significant association of stillbirth with KEGG.

Maternal stillbirth. The largest number (seven) of SNPs significant for MSB was located on BTA9. Six of them also exhibited high effects on MSB. In the literature, none of those significant SNPs was reported. Still, three SNPs located on BTA18 were also significant for the DSB and DCE, five SNPs located on BTA9, BTA18 and BTAX were also associated with MCE. Signalling mediated by cyclic nucleotides was the biological process associated with MSB. The significant molecular function is binding of 1-phosphatidylinositol. MSB was the only calving related trait for which significant KEGG pathways were assigned: PD-L1 expression and PD-1 checkpoint pathway in cancer and Th1 and Th2 cell differentiation. Although at the first glance both pathways seem unrelated to each other – a common feature is their relation to immune response, especially through T-type lymphocytes.

Temperament. All SNPs significant for temperament were located on BTAX but across a long span of 130,498,495 bp. Interestingly, the ATPase copper transporting alpha gene (*ATP7A*) harbouring the SNP with the highest effect on temperament is associated with temperament-related phenotypes of lethargy and hypoactivity in the mouse. Eight GO terms were estimated as significant for temperament, which are related to the processes of gamma-aminobutyric acid secretion and transport, the transmembrane import of calcium ions and glucose into cells as well as the early endosome membrane cell component. The significant KEGG pathways are related to the metabolism of porphyrin, chlorophyll, glyoxylate, and dicarboxylate.

Milking speed. With one exception, all 24 SNPs significantly associated with MSP did not show pleiotropy with other traits considered in this study. The most SNPs (ten) were located on BTA19 with the most significant of them forming two groups. One, close to the beginning of the chromosome, between 7,250,802 bp and 7,717,717 bp harbouring two genes – *ANKFN1* and a novel gene *ENSBTAG00000038823*. The other, close to the end of the chromosome, between 59,364,966 bp and 59,547,890 bp, harbouring a novel gene *ENSBTAG00000048685*. One of the SNPs in the latter group was reported as associated with several udder conformation traits, such as front and rear teat placement, udder attachment, udder cleft, udder depth and height by Cole *et al.* (2011). A group of five highly significant SNPs was also detected on BTA6, three

of them within a short region, spanning 68,984 intergenic bps, close to the *MSX1* gene. A polymorphism on BTA5 was previously reported by Lund *et al.* (2018) as associated with milking speed. Among the 11 GO terms significantly influencing milking speed the biological processes related to hippo signalling and the catalysis of ceramides and glycosphingolipids. Significant GO terms representing molecular functions comprised ligand-gated ion channel activity, phosphoric diester hydrolase activity and voltage-gated calcium channel activity, and binding of calcium ions and 1-phosphatidylinositol. The only significant KEGG pathway comprised the metabolism of degradation of valine, leucine and isoleucine.

Conclusions

Calving traits are low heritable. Their additive genetic component does not typically exceed 10%. Therefore, the presence of single genes with marked effects is not to be anticipated for the traits. However, a surprisingly large overlap was observed between genomic regions, so that many polymorphisms detected as significant in our study have already been indicated by previous analyses listed in the Results & discussion section. This observation is important for carrying out the genomic selection on the traits, especially by incorporating targeted polymorphisms into the evaluation model. Still, from the basic perspective of a better understanding of the genomic background of the phenotypes, traits' low heritabilities indicate that the focus should be moved from single genes to metabolic pathways or gene ontologies significant for the manifestation of calving problems. Such a functionally based approach has not so far been considered neither in the relation to calving nor workability traits.

382. Genomic region-specific association test identifies new loci for carcass traits in Hanwoo (Korean native cattle)

D.J. Lee, D.H. Lee, J.M. Kang, Y.K. Kim, Y.J. Chung and S.H. Lee*

Division of Animal & Dairy Science, Chungnam National University, Daejeon, 34134, Republic of Korea; slee46@cnu.ac.kr

Abstract

Genetic variations in quantitative traits are remarkably complex. Moreover, it is more challenging to detect causative genetic variation because small effects mainly influence quantitative traits. The objective of this study is to search for markers that are significantly involved in carcass traits using missense mutations in which single nucleotide polymorphisms (SNPs) change amino acids. Genomic region-specific association test used missense variants and carcass traits of 16,970 Hanwoo. As a result, 222, 98, 142, and 119 significant SNPs were found in association with carcass weight (CW), backfat thickness (BFT), eye muscle area (EMA), and marbling score (MS), respectively. The most significant marker was the same in the results of CW and EMA, which was located at 19,524,263 on chromosome 14 involving the *PRKDC* gene. Four candidate genes were newly discovered for MS. The SNPs identified in this study will be useful markers for carcass traits in Hanwoo commercial farms.

Introduction

Hanwoo is the native cattle of Korea and has been inhabiting the Korean Peninsula for over 2,000 years. The improvement of Korean beef is cultivated by intensive selection for economic characteristics including meat quantity and meat quality (Edea *et al.* 2018). This was further accelerated by genome-wide panels of single nucleotide polymorphisms (SNPs), enabling the implementation of genome predictions in livestock. In addition, many genome-wide association studies (GWAS) are being conducted to explore quantitative trait loci (QTL) due to SNP information (Kanai *et al.* 2018; Bedhane *et al.* 2019) In previous studies, genetic variation for complex traits has a small effect, which accounts for only a small fraction of heritability (missing heritability problem), which may reduce the power of GWAS studies in complex traits (Weng *et al.* 2011; Dao *et al.* 2022). Koufariotis *et al.* (2014) showed that missense variants in the protein-coding region had the highest proportion in genetic variance explained by SNP according to functional annotation class in dairy and beef cattle. This kind of variants makes changes in both the genetic sequence and the amino acid sequence of the protein, being potential to be harmful or beneficial. This study aims to search for genetic mutations that change the amino acid sequence of proteins in carcass traits by conducting an association analysis using the functional aspects of SNPs in Hanwoo.

Materials & methods

Animals, genotyping, and quality control. Commercial Hanwoo (n=16,970) with an average age of 30.2±1.9 month (born in 2006-2016) were used in this study (Table 1). The animals were slaughtered in 2013-2019 at a commercial abattoir and produced phenotypes (carcass traits). The genomic DNA was extracted from longissimus thoracis muscle samples using a DNeasy Blood and Tissue Kit (Qiagen, Valencia, CA, USA). DNA concentration and purity were determined using a NanoDrop 1000 (Thermo Fisher Scientific, Wilmington, DE, USA). Samples were genotyped using the Bovine SNP50 BeadChip (Illumina Inc., San Diego, CA, USA). Imputation was carried out in 2-step using minimac3 (Das *et al.* 2016). Using the Illumina Bovine HD BeadChip (777K) of 1,295 Hanwoo, the 50K genotype of 16,970 Hanwoo was imputed to a high-density level. After that, it was imputed to the sequence level using whole genome sequence data of 203 Hanwoo. SNPs with R^2<0.6 were excluded in the imputation steps and SNPs on the sex chromosomes were excluded from the analysis. The imputed sequence level data was annotated

using the SnpEff program (Cingolani *et al.* 2012). Genomic coordinates were converted from *UMD 3.1.1* to *ARS-UCD1.2.* Quality control was performed using PLINK1.9 software (Purcell *et al.* 2007) based on the following SNP selection criteria: call rate (CR) higher than 0.90; minor allele frequency (MAF) higher than 0.01; *P*-value for Hardy-Weinberg equilibrium test (HWE) higher than 10^{-4}.

Statistical model. A region-specific genomic data was used by extracting only missense variants from the sequence level data. The phenotypic data on carcass traits were pre-adjusted for fixed effects including growing sites, birth year, season of birth, and slaughter age using a mixed linear model implemented in R software 3.3.1 (R Foundation for Statistical Computing, Vienna, Austria). The adjusted phenotypes and SNP information were subsequently applied for GWAS using a linear mixed model. The linear mixed model can be written as:

$$y = a + bX + g + e \quad (1)$$

Y: phenotype; *a*: the mean term; *b*: additive effect (fixed effect) of the candidate SNP; *X*: SNP genotype indicator variable coded as 0, 1 or 2; *g*: the accumulated effect of all SNPs captured by the genetic relationship matrix (GRM) calculated using all SNPs; *e*: residual.

Results

Genomic region-specific association test. In this study, 28,114 missense variants that met the quality control criteria were used for the genomic region-specific association test. The results are shown in Figure 1. The Bonferroni correction method was used for the significance test (0.05/number of SNPs) in the genomic region-specific association test. In association with carcass weight (CW), back fat thickness (BFT), eye muscle area (EMA), and marbling score (MS), 222, 98, 142, and 119 significant SNPs were found, respectively. Among them, information of the three most significant SNPs based on *P*-value and information of novel marbling genes discovered are shown in Table 2. For the trait of carcass weight (CW), the marker at position 19,524,263 in chromosome 14, located in the *PRKDC* gene, was found to be the most significant. Interestingly, a significant association was detected between the eye muscle area (EMA) and the same SNP. For backfat thickness (BFT), the most significant marker was found at position 107,160,304 in chromosome 2, involving the *ZFAND2B* gene. The most significant marker for marbling score (MS) located in the *ACVR2B* gene at position 11,849,704 in chromosome 22 was also detected. In the case of marbling, one significant SNP was found in each of chromosomes 9, 14, 18, and 19, and they were novel genes that have not yet been identified.

Table 1. Descriptive statistics of phenotypic data in commercial Hanwoo.[1]

Traits	N	Mean	Median	Min.	Max.	SD	CV
CW	16,970	441.21	441.00	159	692	50.89	11.53
BFT	16,970	14.26	14.00	1	48	4.92	34.50
EMA	16,970	95.81	95.00	30	156	12.21	12.74
MS	16,970	5.94	6.00	1	9	1.85	31.14

[1] BFT = backfat thickness (mm); CV = coefficient of variation (%); CW = carcass weight (kg); EMA = eye muscle area (cm^2); MS = Marbling score (1-9); SD = standard deviation.

Discussion

Candidate genes for carcass traits. Several markers in the *NCAPG-LCORL* locus have been reported to be significantly associated with feed intake for weight gain and feed intake in beef cattle (Lindholm-Perry *et al.* 2011). In particular, the SNP c.1326T>G in the *NCAPG* (non-SMC condensin I complex, subunit G) gene identified in this study has also been reported to be a significant SNP associated with height, length, and width of puberty (components of body skeleton size) in the Japanese Black steer and F2 bulls of Charolais × German Holstein cross (Setoguchi *et al.* 2011). The PRKDC gene is important for embryonic development, interferon tau expression, and trophoblast development rate, and it has been reported that PRKDC is required during early bovine embryonic development (Ealy *et al.* 2012). Activin-type II receptor B (*ACVR2B*) is a myostatin-related gene involved in the regulation and signaling of myostatin. Genetic mutations in myostatin in cattle show marked effects on skeletal muscle, resulting in a dual muscle phenotype in certain breeds (Walsh *et al.* 2007).

Abstract

A genome-wide association analysis was performed to identify genomic windows and the underlying positional candidate genes associated with feet and legs malformation (FL) in Nellore cattle. Single Nucleotide Polymorphism (SNP) effects were estimated from 295,031 pedigree records from animals with phenotypes, 12,537 genotypes for FL and 461,057 SNPs from the Alliance Nellore database using the weighted single-step genomic BLUP method. Twelve non-overlapping windows of 20 adjacent SNPs that explained more than 1% of the additive genetic variance were selected for candidate gene annotation. Functional and gene prioritization analysis of the candidate genes identified four genes (*ATG7*, *EXT1*, *ITGA1*, *PPARD*), previously reported in dairy and beef cattle populations, with a known role in skeletal muscle development, aberrant bone growth, lipid metabolism and intramuscular fat deposition. These candidate genes are believed to be associated with the incidence of FL in Nellore cattle.

Introduction

The feet and legs malformation (FL) is a functional binary trait already reported in the literature with a heritability of 0.18 (SE=0.04) and an incidence of approximately 5% in Nellore cattle (Vargas *et al.*, 2017). Animals affected by feet and legs malformations are unable to satisfactorily perform their productive and reproductive functions, which leads to considerable economic losses. The objectives of the present study were: (1) to find SNP windows significantly associated with FL in Nellore cattle using a weighted single-step approach; and (2) to identify positional candidate genes and their potential role in conformational structure of feet and legs.

Materials & methods

Pedigree data of 295,031 Nellore cattle from the Alliance Nellore (www.gensys.com.br), all with phenotypic information, collected between 2001 and 2017 were used in this study. Contemporary groups were defined considering the effects of herd, year and season of birth, sex, management group at weaning and yearling, date of measurement at yearling. Only data from contemporary groups with more than 10 records, variability in the trait and at least 10 genetic links to the main dataset were kept for the analyses.

A total of 12,537 genotyped animals from the genomic reference population of Alliance Nellore, all with their own phenotypes and progeny evaluated for FL, were used for GWAS. Animals genotyped with 50K SNP chip were imputed to 700K using FImpute V3 Software (Sargolzaei *et al.*, 2014) and 6,624 HD genotyped samples as reference. Using QCF90 (Masuda *et al.*, 2019) SNPs from non-autosomal regions, with minor allele frequency <0.02 and a call rate <0.9 were excluded from the analysis. After the quality control, there were 461,057 SNPs left.

GWAS. Programs from the BLUPF90 suite (Misztal, 2020) were used to estimate SNP effects by the weighted single-step genomic BLUP method (WssGBLUP). The observed phenotypes of FL were used as dependent variables in a single-trait threshold animal model:

$$y = Xb + Z_a a + e \quad (1)$$

where y is a vector of underlying liabilities of FL; b is a vector of systematic effects; a is a vector of random additive direct genetic effects; e is a vector of random residual effects, and X and Z_a are incidence matrices that relate the phenotypes in y to the effects in b and a, respectively.

The solutions of SNP effect estimates (û) were obtained as a function of the genomic estimated breeding values (GEBVs) using the formula:

$$\hat{u} = DZ'[ZDZ']^{-1}\hat{a}_g \quad (2)$$

where D is a diagonal matrix with weights, assigned based on SNPs solutions, Z is an incidence matrix of genotypes for each locus, and $\hat{a}_g$ is the vector of GEBVs of the genotyped animals. The û vector and the matrix D were iteratively recomputed using the algorithm proposed by Wang *et al.* (2012). Thus, the weighted genomic relationship matrix and $\hat{a}_g$ were recalculated for the prediction of SNP effects at each iteration. The algorithm was run over three iterations in total.

Gene annotation. The sum of the proportion of variance explained by SNP effects within each non-overlapping window of 20 adjacent SNPs was adopted as the criterion to identify potentially important genomic regions. Windows that explained more than 1% of the additive genetic variance were selected for candidate gene annotation using the .gtf annotation file corresponding to the bovine gene annotation from the ARS-UCD1.2 assembly and the GALLO package (Fonseca *et al.*, 2020). The presence of genes in adjacent 100 Kb windows to the left and right of the main windows was also evaluated, as their effect can be captured by neighboring SNPs due to linkage disequilibrium (O'Brien *et al.*, 2014).

Gene prioritization analysis. A 'trained list' of the top 100 genes associated with relevant trait keywords[1] was created using GUILDify (Guney *et al.*, 2014) and a species-specific (*Homo sapiens*) interaction network. This list of 'trained' genes was used in the ToppGene Suite (Chen *et al.*, 2009) simultaneously with the list of 'test' genes, containing genes located within windows that explained more than 1% of the genetic variance. Gene Ontology terms (molecular function, biological process, and cellular component), human and mouse phenotypes, metabolic pathways, PubMed publications, coexpression pattern and diseases were used to retrieve the functional information for the genes in both lists. The prioritized significant genes were selected based on a multiple correction false discovery rate of 5% ($P \leq 10^{-3}$). This means that these genes have a functional profile that is significantly similar to the functional profile of the list of 'trained' genes.

Results

Twelve windows, located on chromosomes BTA2, BTA3, BTA5, BTA6, BTA14, BTA18, BTA20, BTA22, BTA23, BTA27 and BAT29, explained >1% of the genetic variance of FL. Together, these windows explained 16.37% of the total genetic variance of FL (Figure 1). A total of 35 positional candidate genes for FL were identified, including the genes found 100 Kb upstream and downstream from the windows. The window that harbored the largest number of genes (eight genes) for FL was located on BTA3 and the window that explained the largest proportion of variance (1.7%) was located on BTA27. The candidate gene prioritization analysis identified 4 prioritized candidate genes (*ATG7*, *EXT1*, *ITGA1*, *PPARD*) (Table 1).

[2] Prioritized candidate genes identified by GUILDify and ToppGene analysis.

Discussion

The *ATG7* gene (BTA22) encodes an essential activating enzyme for autophagy and cytoplasmic transport to the vacuole. The autophagy flow is important to preserve muscle mass and maintain the integrity of the myofiber. In beef cattle, increased *ATG7* gene expression was correlated with skeletal muscle growth and body weight during the fattening period, regardless of the muscle evaluated (Nakanishi *et al.*, 2019).

The *EXT1* gene (BTA14) encodes a glycosyltransferase responsible for heparan sulfate (HS) polymerization, related to fibroblast growth factor (Nadanaka *et al.*, 2008). The interaction between growth factors and their receptors is regulated by the amount of HS. A defect in HS biosynthesis due to somatic mutations in *EXT1* can cause a localized break in the negative feedback loop that regulates chondrocyte proliferation and maturation, allowing premature differentiation and therefore aberrant bone growth (Duncan *et al.*, 2001).

Another prioritized candidate gene, *ITGA1* (BTA20), encodes a subunit of the cell-surface receptor integrin α1β1, which acts in the regulation of hepatic glucose and lipid metabolism under conditions of overnutrition *in vivo*. On a high fat diet, mice with the *ITGA1* gene inactivated show severe hepatic insulin resistance and decreased hepatic fat accumulation (Williams *et al.*, 2015). In Korean Hanwoo cattle, the *ITGA1* gene was significantly associated with intramuscular fat deposition (de las Heras-Saldana *et al.*, 2020).

A key role for the *PPARD* gene (BTA23) in controlling the biological processes that drive ruminal epithelial cell development in newborn calves was suggested by Naeem *et al.* (2012). The increase in its expression, in response to an improved nutrition plan, would indicate an important role promoting the use of long-chain fatty acids as a substrate for oxidation in cell membranes during differentiation in ruminal development.

The present GWAS allowed the identification of chromosomal regions associated with feet and legs malformation in Nellore cattle. The role of the prioritized candidate genes in skeletal muscle development (*ATG7*), aberrant bone growth (*EXT1*), lipid metabolism (*ITGA1*, *PPARD*) and intramuscular fat deposition (*ITGA1*) adds to the evidence of the importance of these genes for feet and legs malformation in the studied population. Future investigations on these candidate genes and their causal mutations may contribute to the understanding of the genetic and physiological mechanisms that regulate this trait.

384. Genome-wide association studies for milk yield in *Bos taurus* × *Bos indicus* crossbred cattle in India

M. Al Kalaldeh[1*], M. Swaminathan[2], V. Podtar[2], S. Jhadav[2], V. Dhanikachalam[2], A. Joshi[2] and J.P. Gibson[1]

[1]Centre for Genetic Analysis and Applications, School of Environmental and Rural Science, University of New England, Armidale, NSW 2350, Australia; [2]BAIF Development Research Foundation and Central Research Station, Uruli Kanchan, Pune, Maharashtra 412202, India; malkala2@une.edu.au

Abstract

In India, crossbred dairy cows are used to exploit milk production potential of exotic *Bos taurus* dairy breeds with the adaptation to difficult environments of indigenous *Bos indicus* cattle. A genome-wide association study (GWAS) for milk yield was undertaken to detect effects of indigenous versus exotic origin at a locus, as well as the effects of quantitative trait loci (QTL) in linkage disequilibrium (LD) with single nucleotide polymorphism (SNP) within ancestral breeds. Analyses found a large number of QTL that define ancestral differences between *B. taurus* and *B. indicus*. The most significant between-breed region was on chromosome 5 located between 44 to 55 Mbp, with the positive allele coming from *B. indicus*. The results indicate that evolutionary differences in milk production (in crossbreds) between *B. indicus* and dairy *B. taurus* cattle are due to many causal mutations, some of which appear to have large effects.

Introduction

India is the world`s largest milk producer, with an annual production of 198 million tons, and increasing by approximately 6% each year (DAHD 2021). Half of the country`s milk production comes from cattle, with the largest proportion from crossbreds between *B. taurus* dairy breeds and local *B. indicus* cattle. The only *B. Taurus* breeds known to have been used in crossbreeding are Holstein-Friesian and Jersey.

Gebrehiwot *et al.* (2020) found literature estimates of age of divergence of *B. taurus* and *B indicus* cattle to range from 200,000 to 2 million years, with most estimates in the range of 200,000 to 300,000 years. Given the time since the divergence between *B. taurus* and *B. indicus*, they are likely fixed for different alleles at many loci affecting milk production, and that different loci are involved in current genetic variation within *B. taurus* and *B. indicus*. If any causative loci are segregating in the two sub-species, it is not expected that they are in the same LD with SNP. In crossbred cattle, SNP alleles can be assigned to their ancestral origin based on the inferred origin of the phased haplotypes in which they sit. This provides an opportunity to identify QTL that segregate in crossbred cows that have been fixed (or nearly fixed) for opposite alleles in *B. taurus* versus *B. indicus* breeds, and also identify QTL that segregate within the ancestral populations. The objective here is to undertake a simultaneous GWAS for milk yield in crossbred dairy in India that separate SNP associations into: (1) the effect of indigenous versus exotic origin (i.e. QTL that are fixed or nearly fixed for opposite alleles in the two ancestral populations); (2) the effect of QTL in LD with SNP within indigenous ancestral breed(s); (3) the effect of QTL in LD with SNP within exotic ancestral breed(s).

Materials & methods

Phenotypes and genotypes. The data analysed originate from the Enhanced Genetic Gains program (EGP) of BAIF Development Research Foundation (https://baif.org.in/). Phenotypes are 123,042 test-day (TD) records from 4,968 crossbred (*B. taurus* × *B. indicus*) cows in smallholder herds that have an average of 1.7 milking cows, collected from 6 states between February 2016 and September 2020. Cows were genotyped with the GGP 50k assay and genotypes imputed for 737,073 SNP. TD records were corrected for non-genetic effects using a mixed model as described in (Al Kalaldeh *et al.* 2021).

Assigning breed origin to alleles in crossbred cows. This was undertaken using three steps. (1) Phasing the genotypes of both the reference and crossbred cows using Eagle software (Loh *et al.* 2016). Phasing was based on 676,577 common SNP that had minor allele frequencies (MAF) higher than 1%. The reference dataset includes 101 purebred Indigenous animals from the EGP project, 21 pure Holstein and 21 pure Jersey animals from the HapMap project, and 21 pure Friesian animals from the Scottish Rural University College (SRUC), all genotyped with the high density (HD) SNP array. (2) Assigning ancestral origin (*B. taurus* vs *B. indicus*) to the phased haplotypes of crossbred cows using PCAdmix software (*Brisbin et al.* 2012). (3) Assigning breed origin to SNP alleles in crossbred cows. SNP alleles were assigned to their breed origin based on the inferred origin of the phased haplotypes in which they sit. There are 4 possible combinations of ordered breed origin and 4 possible combinations of SNP genotypes, resulting in 16 different ancestry genotype combinations at each locus.

GWAS. Wombat software (Meyer 2007) was used to perform a simultaneous GWAS regression on the allele count for: (1) breed origin; (2) SNP alleles inherited from the indigenous ancestor; (3) SNP alleles inherited from the exotic ancestor. The allele count for breed origin was based on the number of copies inherited from the indigenous ancestor. The genotypes were coded to breed origin as 0, 1, and 2 for no copies, one copy, or two copies coming from the indigenous ancestor, respectively. To avoid confounding of estimates, genotypes were classified into three groups. Group 1 includes 510,243 genotypes that had minor allele frequency (MAF)>0.01 for alleles of exotic and indigenous origin. Group 2 includes 104,292 genotypes that had MAF<0.01 for alleles of indigenous origin. Group 3 includes 62,362 genotypes that had MAF<0.01 for alleles of exotic origin.

For SNPs in Group 1, GWAS model 1 was:

$$\text{trait}=\text{BC}\times\text{ENV}+\text{SNP}_1+\text{SNP}_2+\text{SNP}_3+\text{G}+\text{herd}+\text{e} \quad (1)$$

For SNPs in Group 2, GWAS model 2 was:

$$\text{trait}=\text{BC}\times\text{ENV}+\text{SNP}_1+\text{SNP}_3+\text{G}+\text{herd}+\text{e} \quad (2)$$

For SNPs in Group 1, GWAS model 3 was:

$$\text{trait}=\text{BC}\times\text{ENV}+\text{SNP}_1+\text{SNP}_2+\text{G}+\text{herd}+\text{e} \quad (3)$$

where trait is the adjusted TD milk records averaged per cow, BC×ENV is the fixed effect of breed composition by environment as defined by Al Kalaldeh *et al.* (2021), SNP_1 is the allele substitution effect for breed origin, SNP_2 is the allele substitution effect for SNP alleles inherited from the indigenous ancestor, SNP_3 is the allele substitution effect for SNP alleles inherited from the exotic ancestor, G is the cow's random additive genetic effect estimated using the genomic relationship matrix, herd is the random herd effect, and e is the random error effect. Due to the degree of correlation between alleles of breed origin, alleles of exotic ancestor, and alleles of indigenous ancestor, which can affect the coefficients and *P*-values, the *P*-values were adjusted for genomic control by dividing the chi-squared test statistics by the genomic inflation factor (lambda). Lambda were 0.91, 1.07, and 0.97 for SNP effects of breed origin, alleles inherited from exotic ancestor, alleles inherited from indigenous ancestor, respectively. After performing GWAS, the false discovery rate (FDR) was calculated to control for multiple SNP testing.

Results

The frequency of indigenous breed origin alleles ranged from 0.30 to 0.40, with an average of 0.36, which is the estimated proportion of *B. indicus* ancestry in the crossbreds. The most prominent region detected for breed origin effect was between 44.8 and 55.1 Mbp on chromosome 5, which included 35 SNP that had FDR<5% (Group 1 results shown in Figure 1). This region has not previously been identified as having a large effect on milk yield. The average difference between *B. indicus* and *B. taurus* SNP genotypes is 0.60 kg/day (8% of average TD yield), with the positive allele coming from *B. indicus*. Considering a conservative FDR of 10%, 14 regions pass the threshold, and at the less conservative FDR 30%, a high proportion of the genome passes the threshold. These results indicate that causal differences between *B. indicus* and *B. taurus* occur at very many loci distributed across the genome. Figure 2 and 3 show Manhattan plots for LD within *B. indicus* and LD within *B. taurus* respectively, with no effects detected at FDR<30%.

Discussion

Many regions differentiating *B. indicus* from *B. taurus* ancestors are detected. However, no regions in LD within *B. indicus* and *B. taurus* are detected. Since only 36% of alleles are assigned to *B. indicus* and 64% to *B. taurus* origin, GWAS for within ancestor LD have substantially lower power than the between breed origin GWAS. For example, the power of GWAS based on LD within *B. indicus* is equivalent to performing a purebred GWAS on approximately 1,800 cows rather than the 4,968 cows analysed here. Also, both Holstein-Friesian and Jersey are known to have been used for crossbreeding in the states sampled in our data, and many different and usually undefined indigenous breeds are known to have been used. Thus, LD may well differ between ancestral breeds within the *B. taurus* and *B. indicus* ancestral origins traced here, further eroding the power of detection of most QTL. Analyses are underway to separate the effects due to LD within Holstein-Friesian versus Jersey ancestors, which is relatively accurately determined based on imputed genotypes. Differentiating alternative *B. indicus* ancestors is not possible because of the large number of ancestral breeds and the low SNP genetic variation among *B. indicus* breeds (Strucken *et al.* 2021).

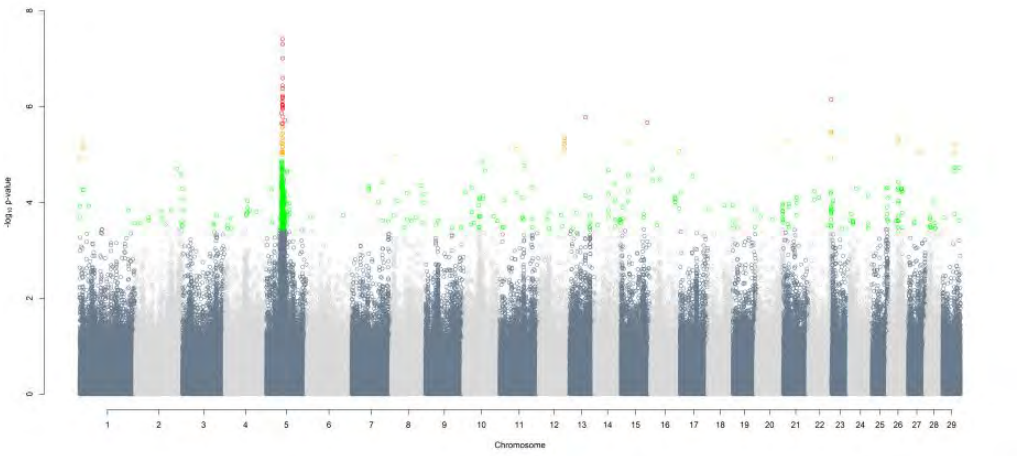

Figure 1. Manhattan plot of SNP effects for breed origin. SNPs passed FDR 5, 10 and 30% are highlighted in red, orange, and green, respectively.

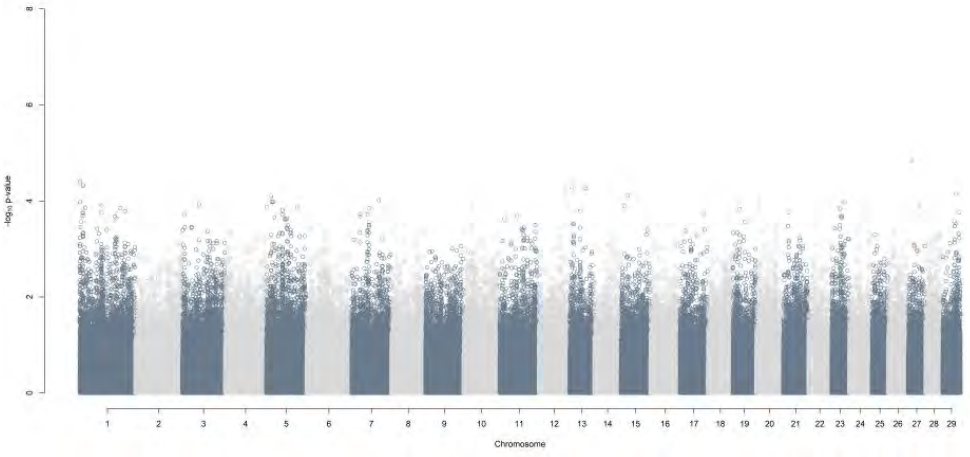

Figure 2. Manhattan plot of SNP effects for SNP inherited from *B. indicus* ancestral origin.

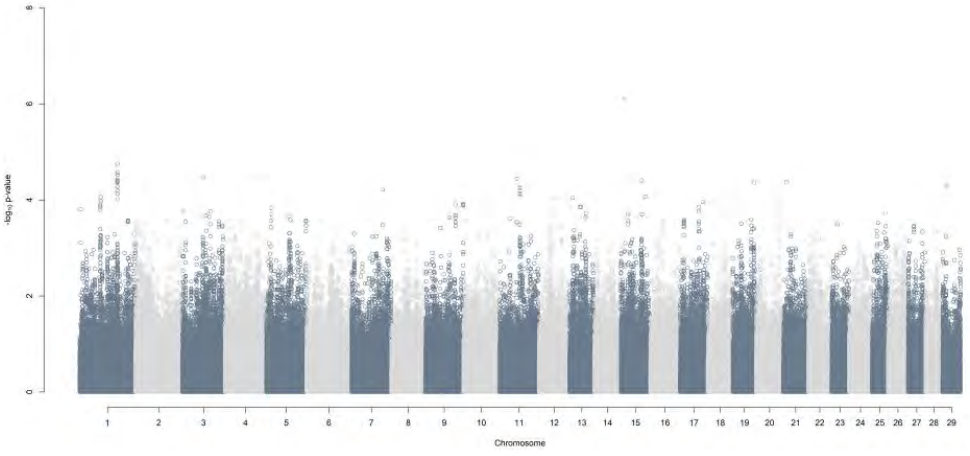

Figure 3. Manhattan plot of SNP effects for SNP inherited within *B. taurus* ancestral origin.

385. Grouping of highly correlated variables improves performance of genomic evaluations

D. Wittenburg* and J. Klosa

Research Institute for Farm Animal Biology (FBN), Institute of Genetics and Biometry, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany; wittenburg@fbn-dummerstorf.de

Abstract

Extensive genetic information enables the identification of genome regions associated with trait expression but this may lead to high model dimensions and the occurrence of dependencies among predictor variables. A grouped penalised regression approach provides a framework to account for these dependencies adequately. Previous studies showed that the overall performance of genomic evaluations improved if genomic markers were grouped according to their strength of interdependence. Here, we investigate different options for grouping taking linkage and linkage disequilibrium into account and additionally considering adjacency between markers. As the extent of dependence is influenced by the family structure in a livestock population, we investigated an empirical and a theoretical measure thereof. Options have been validated with simulated data. Generally, the more groups were determined, the better the performance of the grouped penalisation approach.

Introduction

To investigate the association between genetic and phenotypic variation, genomic markers (such as single nucleotide polymorphisms; SNPs) are used as predictor variables in a statistical model, e.g. $y = X\beta + e$. The $n \times p$ design matrix X contains the genotype codes at p SNPs of n individuals with corresponding regression coefficients $\beta = (\beta_1,\ldots\beta_p)'$. Any fixed or nuisance effects are discarded here for convenience. Due to the (partly) tight linkage of markers, multicollinearity occurs in X. Grouping is a universal strategy to cope with this situation. No matter what the actual grouping technique is (e.g. hierarchical clustering, k-means clustering), it shall employ a measure of association suited to the family structure in a population, which is characterised by non-random mating in livestock. Then, pre-specified groups of highly associated markers can be utilised, for instance, in a grouped penalised regression approach to differentiate genome regions with impact on trait expression (y) from neutral regions. Sparse-group lasso (SGL) has been developed to allow for sparsity of effect estimates between and within groups of predictors (Simon *et al.* 2013; Klosa *et al.* 2021). In an earlier evaluation of penalised regression approaches (Klosa *et al.* unpublished), SGL turned out to be a robust and high-performing method in various scenarios of genetic architecture (differing in heritability, proportion of non-zero effects, etc.). In extension to this, our objective is to investigate suitable options for grouping of markers regarding the family structure and to quantify the impact on the ability to detect trait-associated loci and on the accuracy of genomic prediction with SGL.

Materials & methods

Grouped penalised regression approach. Estimates of genetic effects β captured by SNP markers were obtained with SGL, as implemented in the R package seagull v. 1.1.0, i.e.

$$\min_\beta \frac{1}{2n}\left\|y - X\beta\right\|_2^2 + \alpha\lambda\left\|\beta\right\|_1 + (1-\alpha)\lambda\sum_{l=1}^{L}\sqrt{p_l}\left\|\beta^{(l)}\right\|_2$$

with shrinkage parameter λ>0 and mixing parameter α=0.5. The regression coefficients were grouped into L bins with group size p_l, l=1,…,L. As a baseline approach, a single group of markers was built for each chromosome. Alternatively, involving linkage and linkage disequilibrium (LD) enabled measuring the strength of association between markers more locally. The squared correlation between two columns of X

R.F. Veerkamp and Y. de Haas (eds)

served as an approximation to population LD (in terms of R-squared) between a pair of SNPs; the matrix including all pairwise *observed* correlations was denoted as R_{obs}. The correlation among SNP pairs was also derived theoretically conditional on the genetic information of parents and a linkage map (Wittenburg *et al.* 2021). Hence, this approach was suited to the underlying family structure in the data. The resulting *expected* correlation matrix was termed R_{exp}. Both R^2_{obs} and R^2_{exp} served as a similarity matrix for a clustering procedure in the following step. As a first option, grouping followed a greedy approach with no restrictions ('noc') on the proximity of markers (Wittenburg *et al.* 2021) as implemented in the R package hscovar v. 0.4.2. This way, markers with squared correlation >0.8, no matter if they were located close to each other or not, were grouped into the same bin. As a second option, we applied hierarchical clustering under adjacency constraints (Ambroise *et al.* 2019), provided in the R package adjclust v. 0.6.3. This approach necessitated a banded structure of the underlying similarity matrix, for which we regarded a bandwidth of 10%. Hierarchical clustering required a decision rule for selecting the optimal number of groups. We considered two possibilities: (1) we selected the same number of clusters as obtained with the greedy approach ('adj1') or (2) we applied a slope heuristics *capushe* ('adj2'; Baudry *et al.* 2012), which did not rely on prior information.

Simulation study. A simulation study was conducted resembling a typical family structure in cattle. In total, 100 samples were generated containing 10 half-sib families with 900, 100 and 100 progeny each in the training data, validation data and independent test data, respectively. Two chromosomes, each containing 1,660 SNPs on one Morgan length, were simulated with realistic extent of LD. Scenarios with three or 9 groups of trait-associated and highly correlated loci per chromosome were set up with varying sparsity within such groups (33 or 66% of loci had non-zero effect). Genetic variation explained 30% of the phenotypic variation. The data and more details on the simulation study are available at https://dx.doi.org/10.22000/432.

Using the validation data, we inspected sensitivity and specificity of SGL's selection property resulting from the different groupings of markers. The number of true positive detections was recorded allowing a window of 0.1 centiMorgan (i.e. one to two SNPs) to both sides of the causal variant. The mean squared error (MSE) of regression coefficients provided another measure of performance. Using the independent test data, precision of prediction was determined as correlation between simulated and predicted phenotype.

Results

Grouping based on the expected (observed) correlation matrix with no constraints yielded on average L=1,480 (1,481) groups of markers over all chromosomes, whereas considering adjacency constraints followed by cluster selection with *capushe* resulted in L=26 groups of markers based on both correlation matrices.

Though sensitivity was at a high level with the baseline approach (2 groups of markers) throughout scenarios, the remaining performance criteria were inferior to other options of grouping. With increasing number of groups of markers, we observed the typical trade-off: sensitivity reduced and specificity increased. Additionally, MSE improved. Precision of prediction was almost unaffected by the grouping method chosen. Against our expectation, grouping with adjacency constraints ('adj1') did not improve the performance of SGL in general, only in case of sparse signals (three groups of trait-associated loci and sparsity 33%). All results are summarised in Table 1; bold entries highlight the best outcome in each setting. Since grouping was very similar with R_{exp} and R_{obs}, performance of SGL did not differ in essence and only results with option 'observed-noc' were presented exemplarily in Table 1. Furthermore, as a representative example, Figure 1 displays estimated marker effects in a single repetition. It shows that few regions with

strong effects can be localised best with option 'noc'. Though the number of groups is equal with 'noc' and 'adj1', spurious non-zero effects appeared more often with option 'adj1'.

Table 1. Accuracy-related measures for SGL with different options of grouping SNPs.

Scenario[1]	Grouping option[2]	Sensitivity	Specificity	MSE[3]	Precision
3 groups and sparsity 33%	per-chrom	**0.96**	0.53	1.17	0.49
	expected-noc	0.39	**0.99**	0.57	0.52

	expected-adj1	0.68	0.87	**5.44**	**0.51**
	expected-adj2	0.90	0.47	5.90	0.50
	observed-noc	0.64	**0.90**	5.67	0.50

[1] Number of trait-associated groups per chromosome and percentage of loci with non-zero effect within group.

[2] Per-chrom: one group of markers per chromosome; expected/observed: grouping based on expected/observed correlation matrix; noc/adj: grouping approach without/with adjacency constraints; adj1: number of clusters corresponds to noc; adj2: number of clusters was derived from slope heuristics.

[3] MSE$\times 10^{-4}$ of regression coefficients.

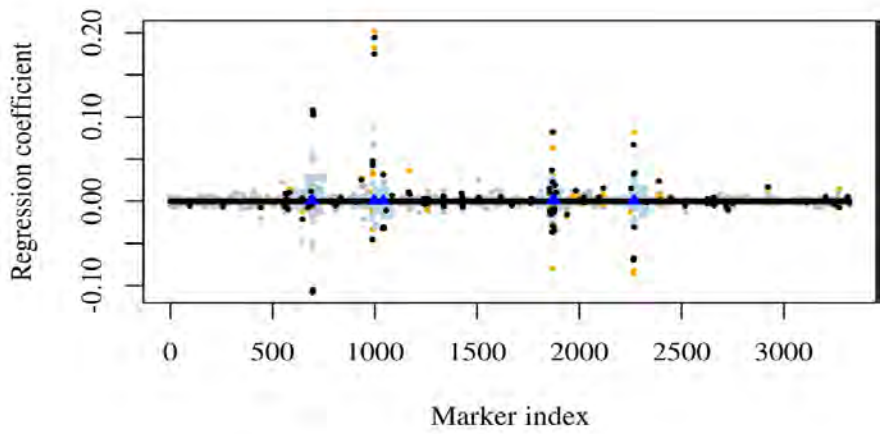

Figure 1. Estimated regression coefficients with sparse-group lasso for a single repetition. Grouping was obtained with greedy approach ('noc', black), hierarchical clustering under adjacency constraints ('adj1' in orange and 'adj2' in lightblue) or chromosome-wise ('per-chrom', grey). Simulated locations of causal variants (three groups with sparsity 66%) are coloured in blue.

Discussion

The aim was to exploit the grouped nature of predictor variables according to the underlying family structure. We worked with the observed and expected correlation between SNP genotypes. By construction, any deviation between observed and expected correlation vanishes with increasing number of families. However, only the expected correlation is able to account for imbalanced family sizes if they exist. Setting up the elements of R_{exp} considers the haplotype distribution within family and its contribution to the population-wide correlation depending on family sizes. We expect that if the number of families is smaller than investigated here or the family design becomes imbalanced, the larger the benefit from R_{exp} compared to R_{obs} will turn out. This study, however, concentrated on the grouping approach. Influences arising from sample and family sizes will be verified in future research.

The SGL is not only able to cope with multicollinearity in X, it can also incorporate different sources of data, such as expression or metabolomics data. In those applications, similar to Boulesteix *et al.* (2017) and Klau *et al.* (2018), predictor variables may be grouped according to their origin and prior knowledge (e.g. gene pathways).

Conclusions

This study showed that considering adjacency for grouping of markers did not improve the performance of SGL *per se*. The number of groups was decisive – in particular, the more groups, the better the specificity of detecting trait-associated loci. Grouping with or without adjacency constraints is applicable to any study design (family structure, SNP panel, etc.) and requires in the simplest case only the observed pairwise correlations between SNP genotypes. Hence, GWAS can rely on all marker information available without prior pruning.

386. A Monte-Carlo approximation of the null hypothesis for genome wide association sing the windows variance approach

D. López-Carbonell[*#], M. Ramírez[#], J. Altarriba, H. Srihi and L. Varona

[†]Instituto Agroalimentario de Aragón (IA2), Facultad de Veterinaria, Universidad de Zaragoza, Calle Miguel Servet, 177, 50013, Zaragoza, Spain; 767339@unizar.es; [#]these authors contributed equally

Abstract

The interest in Genome Wide Association Studies (GWAS) has widely increased over the last few years, and Frequentist and Bayesian methods have been developed. The use of genomic windows has been proposed to gather SNP information. Nevertheless, spurious associations have been detected, which may be attributed to different causes. The aim of this study is to detect these spurious associations and weigh SNP importance to avoid them. This can be reached starting from a real data set, that was analysed using single step GWAS methodology. Thereafter, new simulated data were generated, using statistical simulation, as well as following data and pedigree structure. The same methodology was performed to analyse simulated data. Lastly, real and simulated results were compared in order to distinguish those spurious associations that appear in both simulated and real data, and those who were associated with genetic variance in the trait, which sometimes can be concealed.

Introduction

Genome Wide Association Studies (GWAS) have become a common technique to locate Quantitative Trait Loci (QTL) (Visscher *et al.*, 2017). Some authors have proposed using genomic windows (Sahana *et al.*, 2010) instead of testing significance for each single nucleotide polymorphism (SNP) to avoid the low amount of information provided for each single SNP. This kind of approach is possible due to the equivalence of GBLUP and SNP-BLUP methods (Wang *et al.*, 2012) and some Frequentist (Chen *et al.*, 2017) and Bayesian (Fernando *et al.* 2017; Legarra *et al.* 2018) test have been proposed. However, Li *et al.* (2021) have noticed that the results of the GWAS analysis using genomic windows are strongly influenced by the SNP density. As a result, they have offered two solutions: (1) using windows size of equal numbers of SNP; and (2) using a specific test for each genomic window.

Here we noticed that the results can also be strongly affected by some other causes such as the LD (linkage disequilibrium), the allelic frequencies (AF) or the degree of genetic similarity across individuals within each genomic region (DS). We propose a simple Monte-Carlo approximation in order to take into account all the different possible circumstances.

Materials & methods

Data. The data used in this study consist of 16,320 records of *Pelvis Width* measured by trained classifiers in the Pirenaica beef cattle population and a pedigree of 35,161 individual-sire-dam entries. Additionally, there were 755 genotypes at our disposal generated with Axiom Bovine platform (*Axiom_BovMDv3*) from ThermoFisher Scientific (Waltham, MA USA). The filtering consisted of excluding genotypes with a minor allele frequency lower than 0.05 and a SNP call rate less than 0.90 in the overall population. After this, 31,509 SNP markers were used.

Model of analysis. The data were analysed using the *airemlf90* software (Misztal *et al.*, 2002) with the following model:

$$y = Xb + Wp + Zu + e \quad (1)$$

where b is the vector of systematic effects that include sex -2 levels-, classifier -25 levels- and age in years -9 levels-, p is the vector or random herd-year-season, u is the vector of breeding values and e is the residuals. Later, we used the *postGSf90* software to calculate the percentage of additive genomic variance explained by genomic windows of 12 SNP (approx.. 1 Mb). This process was repeated iteratively 3 times for SNP weighing as suggested by Wang *et al.* (2012).

Simulation. We generated 1000 populations using statistical simulation over the available pedigree. The statistical simulation calculates the simulated breeding values (u_s) and the herd-year-season (p_s) effects with the following multivariate Gaussian distribution:

$$\mathbf{u}_S \sim N(\mathbf{0}, \mathbf{A}\hat{\sigma}_A^2) \quad (2)$$

$$\mathbf{p}_S \sim N(\mathbf{0}, \mathbf{I}\hat{\sigma}_P^2) \quad (3)$$

where $\hat{\sigma}_A^2$ and $\hat{\sigma}_P^2$ are the estimated additive genetic and herd-year-season variances. Furthermore, the simulated data were generated in the phenotyped individuals using the same model as (1), using the estimated systematic effects and residuals sampled from a Gaussian distribution with a mean of 0 and the estimated residual variance. The analysis of each simulated dataset was performed with the same procedure as that of the real one.

Results

The results of the GWAS analysis of the real data set using *postGSf90* software are presented in Figure 1. The results of the analysis identified two genomic regions at BTA6 (bp 64,514,509) and BTA16 (bp 25,796,893), which explains more than 2% of the additive genetic variance. However, when the simulated datasets were analysed (Figure 2), the results showed that the average estimates of the percentage of variance explained by the genomic segments is heterogeneously distributed along the genome, albeit the data sets were simulated under a pure polygenic model.

These discrepancies can be explained by several reasons, such as the patterns of LD, AF, or DS. If we focus on the two highlighted segments of the first analysis, it can be noticed (Figure 3) that the result obtained in the genomic region of BTA6 (2.24%) is clearly higher than all the results generated by the simulated datasets in the same genomic region. In contrast, simulated data sets explained more percentage of variance in BTA16, and 35 of 1000 explained a higher percentage of variance than real data set (2.75%).

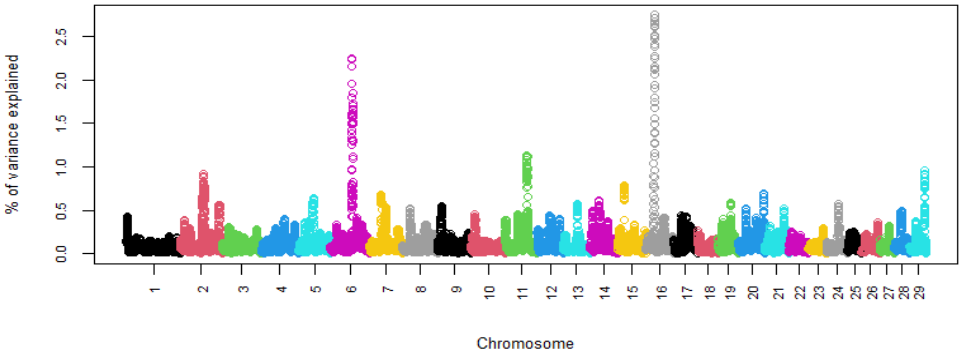

Figure 1. Manhattan plot for the percentage of additive genetic variance explained by windows of 12 SNP in the real dataset.

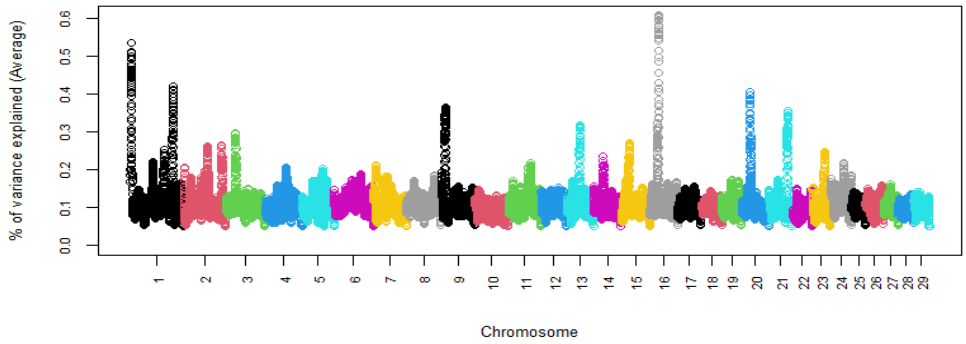

Figure 2. Manhattan plot for the average percentage of additive genetic variance explained by windows of 12 SNP in the simulated data sets.

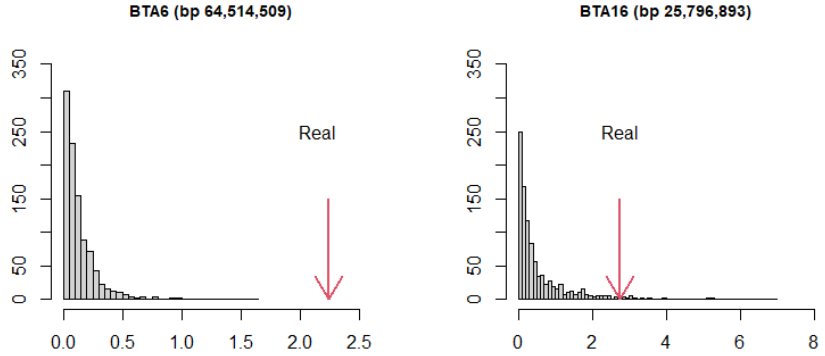

Figure 3. Empirical distribution of the percentage of additive variance explained by the genomic regions of 12 SNP centered at BTA6 and BTA16 in simulated data sets and the percentage of additive variance explained by the same regions in the real data set (red arrow).

Finally, we estimate an empirical *P*-value by using the empirical distribution generated with the simulated datasets at each genomic region. The results are presented in Figure 4.

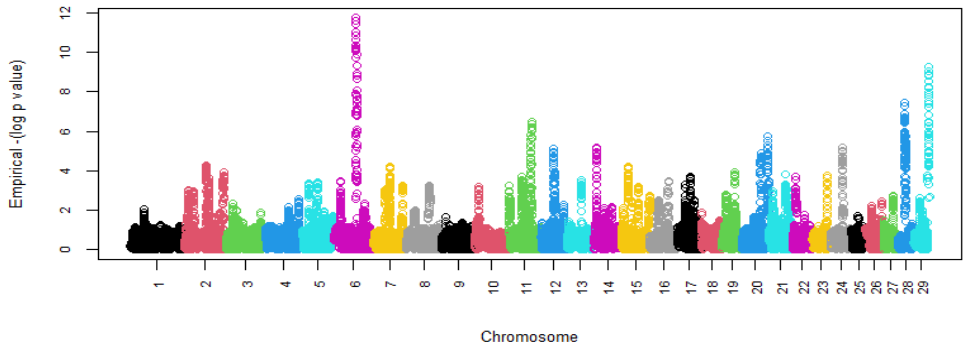

Figure 4. Manhattan plot of empirical log *P*-values using genomic regions of 12 SNP along the autosomal chromosomes.

Having corrected the real data using simulated ones, the results strongly confirmed the QTL detected in BTA6 but showed that the QTL previously identified at BTA16 was spurious and additionally point some other interesting genomic regions at BTA11, BTA12, BTA14, BTA20, BTA24, BTA28 or BTA29 as potentially candidates of carrying genes that affect the additive genetic variation of the trait.

Discussion

We have shown that the results of GWAS study based on the variance explained by genomic segments were not only affected by the genomic density but also by some other circumstances associated with the chip design or the population genomic features. To generate a null hypothesis, we have suggested using statistical simulation, which is based on the fact that breeding values follow a multivariate Gaussian distribution. Therefore, it reflects a pure polygenic model that considers the resemblance among relatives caused by the additive genetic variation. The case study illustrates that the inferences can be strongly modified even when the number of SNP is set to a fixed number.

Abstract

Genomic evaluations in cattle are commonly based on effects of autosomal SNPs, the X chromosome (BTAX) being generally excluded because of its hemizygous state in males. We estimate here the effects of imputed sequence variants of BTAX in six dairy breeds and for 11 complex traits related to milk production, milk composition, mastitis resistance, fertility and stature. We detected QTL in almost all breeds and for almost all traits. They were distributed throughout BTAX and explained between 0.1 and 5.2% of the total phenotypic variance of the trait. In each of these QTL, we identified genes (*GPC3*, *SEPTIN6*, *ZC3H12B*, *COL4A6*, *IDS*, *SLC16A2*, *MIR363*, *HS6T2*, *MAMLD1*, *COL4A6*, *DGKK*, *DDX3X*, *GPC3*, *ERCC6L*, *FRMPD4*, *ENOX2*, *KLHL13*, *HMGB3*, and *CDKL5*) for which the functional link with the studied traits remains to be established. We therefore show here the importance of BTAX in the genetic determinism of complex traits in dairy cattle.

Introduction

Due to its specificity (hemizygous state in males, dosage compensation in females, different genomic relationship matrix), BTAX is often excluded from genetic analyses in cattle. Yet, BTAX is the second largest chromosome of the bovine genome and it is particularly rich in genes. Excluding BTAX from genomic evaluations can thus lead to the loss of a significant part of the genetic variability of traits (Su *et al.*, 2014). To assess the effects of BTAX on dairy traits, we report here results of association analyses from imputed sequences of cows of six French breeds for eleven traits related to milk production, mastitis resistance, fertility and stature.

Materials & methods

Cows and traits. We analysed 236,496 cows from three national (MON, NOR, HOL) and three regional (ABO, TAR, VOS) breeds with 50k genotypes and phenotypes (Table 1). Traits included were milk (MY), protein (PY) and fat (FY) yields; protein (PC) and fat (FC) contents; somatic cell score (SCS) and clinical mastitis (MAST; except for VOS); calving-first insemination interval (ICFI), heifers' (HCR) and cows' (CCR) conception rate; stature (STAT). Phenotypes used were yield deviations (YD) i.e. phenotypes adjusted for non-genetic effects.

Table 1. Features of populations and sequence variants analysed.

Breed	Abbrev.	# 50k genotypes	# HD genotypes	# WGS animals[2]	# variants after filtering[1]	Mean[1] imputation R^2	Mean[1] MAF

Imputation and association analyses. We considered only the X-specific non-pseudo autosomal region (non-PAR) that covers the main part of BTAX (0-133.3 Mbp on the ARS-UCD1.2 reference genome; Johnson *et al.*, 2019). For imputation, males were considered homozygous for all SNPs and pedigree information was not included. HD genotypes of 32,268 SNPs were first imputed from genotypes of 1,147 EuroGMD SNPs with FImpute (Sargolzaei *et al.*, 2014) using animals with HD genotypes as a reference (Table 1). Then, 778,576 sequence variants were imputed using a multi-breed population of 2,712 animals from the RUN8 reference panel of the 1000 Bull Genomes consortium (Bouwman *et al.*, 2018) with Minimac (Howie *et al.*, 2012). Allele dosages were tested in within breed association analyses using GCTA software (Yang *et al.*, 2011). All phenotypes were measured on females, we therefore applied the following model: $y = 1\mu + xb + u + e$, where y is the vector of YD; μ is the overall mean; b is the additive fixed effect of the variant tested; x is the vector of imputed allele dosages; $u \sim N(0,G\sigma_u^2)$ is the vector of random polygenic effects, with G the genomic relationship matrix based on autosomal 50k SNPs, and σ_u^2 is the polygenic variance; $e \sim N(0,I\sigma_e^2)$ is the vector of random residual effects. We analysed variants with a MAF≥0.005 and with a Minimac imputation $R^2 \geq 0.20$ i.e. from 154,966 to 236,011 variants depending on the breed (Table 1). A unique threshold was used corresponding to 5% significance after Bonferroni correction for ~160,000 variants ($-\log_{10}(P)=6.5$). In each breed and trait, variants with significant effects located less than 10 Mbp apart were grouped together to define QTL. Confidence intervals (CIs) of QTL were then determined based on the positions of variants in the upper third of the peak (van den Berg *et al.*, 2016). The percentage of phenotypic variance (σ_p^2) explained by each QTL was calculated for the variant with the most significant effect as $\%\sigma_p^2 = 100.2p(1-p)\alpha^2/\sigma_p^2$, with p the frequency and α the estimated allelic substitution effect.

Results

Association analyses detected QTL in all breeds, except TAR and VOS, and for all traits, except HCR (Table 2). We identified 191 QTL (0 to 10 QTL per breed × trait analysis). For milk traits, we detected QTL in four breeds, the most significant ones being mainly located at the beginning of BTAX for PC and FC and throughout BTAX (~30, 60, 85, 102, 110, 130 Mbp) for MY, PY, and FY (Figure 1). We found a higher number of QTL in national breeds (63, 57, and 63 in MON, NOR, and HOL, respectively) than in regional breeds (8, 0, and 0 in ABO, TAR, and VOS, respectively). The cumulative effects of the QTL per breed explained from 0.1% (ICFI in HOL and CCR in MON) to 5.2% (FY in ABO) of σ_p^2. CIs of the QTL contained 1 to 2,193 variants with significant effects. In total 39,429 unique variants were identified.

Most variants included in CIs were located in intergenic regions (72%) while the other (28%) were in genes or in the vicinity of genes, mainly in introns (20.3%) (Table 3). The best-ranked variants in the peaks i.e. the top 10 and top 1 variants, were more frequently located in genes (37.3 and 47.8%, respectively). Non-intergenic variants ranked first in the peaks were located in 58 different genes. The top 1 variants with the most significant effects ($-\log_{10}(P)\geq 20$) were located in *GPC3* (FC), *SEPTIN6* (PC), *ZC3H12B* (PC), and *COL4A6* (STAT) in MON; *IDS* (STAT) in NOR; and *SLC16A2* (FC) and *MIR363* (PC) in HOL. For fertility traits (ICFI and CCR), the genic top 1 variants of the QTL, detected in national breeds (MON, NOR

or HOL), were located in *HS6T2*, *MAMLD1*, *COL4A6*, *DGKK*, *DDX3X*, *ENSBTAG00000048527*, *GPC3*, *ERCC6L*, and *FRMPD4* genes while for udder health traits (MAST and SCS in ABO, MON, NOR, and HOL), they were located in *ENOX2*, *KLHL13*, *HMGB3*, and *CDKL5*.

Discussion

In mammals, the non-PAR region of BTAX differs from autosomes because of its hemizygous state in males (XY). Mechanisms of dosage compensation occur in females (XX) to inactivate one BTAX copy and therefore ensuring an equal expression of genes located on BTAX in both sexes. Little is known about the complex mechanisms of BTAX inactivation in cows but both copies appear to be equally expressed in the mammary gland at the population level suggesting a random inactivation of either copy (Couldrey *et al.*, 2017). Because of its specificities, BTAX is usually excluded from genetic analyses and few GWAS were conducted in cattle (e.g. Fortes *et al.*, 2020). In the present study, we focused on this particular chromosome to assess the effects of its variants imputed at the sequence level on various complex dairy traits (milk production, udder health, fertility, and stature) in cows from six dairy cattle breeds. After adapting the imputation process (males assumed homozygous and no pedigree) and considering paternal and maternal X chromosomes equally expressed at the population level, we applied the model used for autosomes in association analyses. Except for breeds with the lowest number of cows (TAR and VOS) and for one fertility trait (HCR), we identified QTL for all breeds and traits analysed. As expected, due to the number of cows analysed in each breed, the number of QTL was higher in the largest breeds and these QTL had larger effects. A higher number of QTL with more significant effects was also found for the most heritable traits (milk production, milk composition, and stature). Depending on the breed and on the trait, these QTL explained up to 5.2% of σ_p^2. We also highlighted QTL for less heritable traits that may explain up to 1.3% (fertility) and 1.1% (udder health) of σ_p^2 in some breeds. In particular, for SCS in MON, NOR, and HOL, we found that 0.4, 0.4, and 1.1% of σ_p^2 was explained by 3, 4, and 9 QTL located on BTAX, respectively. These values can be compared to the values we estimated in a previous study for the same trait in MON, NOR, and HOL bulls i.e. 6.3, 0, and 2.6% for 3, 0, and 2 QTL detected on all the 29 bovine autosomes, respectively (Tribout *et al.*, 2020). As illustrated in Figure 1, QTL detected on BTAX presented large CIs. This phenomenon is probably due to the linkage disequilibrium, more extended in the non-PAR region where no recombination occurs in males (Zhang *et al.*, 2020). We show here that dozens of candidate genes are located in X-linked QTL. However, functional links between these genes and traits analysed remain to be established. This study shows the importance of BTAX in the genetic determinism of complex traits in dairy cattle and supports the results of Su *et al.* (2014) who found that markers on BTAX contribute to accuracy of genomic predictions in Holstein breed.

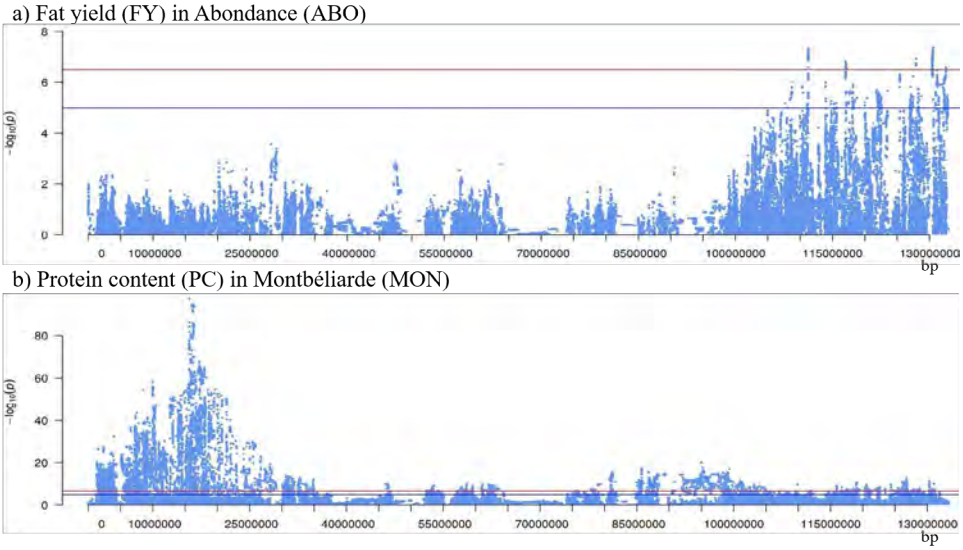

Figure 1. $-\log_{10}(P)$ values plotted against the position of variants on X chromosome.

[1]University of Florida, P.O. Box 110910, 2250 Shealy Dr, Gainesville, FL, USA; [2]University of California, 9500 Gilman Dr, San Diego, CA 92093, USA; frezende@ufl.edu

Abstract

Our objective was to identify genomic regions with pleiotropic effects on carcass and meat quality traits in a multibreed Angus-Brahman population. Data included phenotypes from 2,384 steers, of which 1,038 were genotyped. Single-trait genome-wide association studies were first used to investigate the relevance of additive genetic effects. A second analysis was performed to capture genomic regions with pure direct effects on each trait, removing regions with indirect effects. Four pleiotropic (BTA5, BTA7 and BTA18) and two suggestive pleiotropic regions (BTA10 and BTA19) were identified. Candidate genes encode key players in cell growth, muscle development, lipid metabolism and fat deposition. Functional analysis revealed GO terms directly related to carcass quality, meat quality, and tenderness in beef cattle, including calcium-related processes, and modulation of cell-cell adhesion. These results contribute with novel information about the complex genetic architecture of carcass and meat quality traits in crossbred beef cattle.

Introduction

To attenuate the impacts of tropical and subtropical conditions on growth rate and reproductive performance of Taurine (*Bos taurus taurus*) beef breeds, producers use crossbreeding between European Taurine and Zebu (*Bos taurus indicus*) breeds as a strategy to enhance beef production. In subtropical areas of the United States, Angus-Brahman crosses are preferred for beef production over other Taurine-Zebu combinations.

While carcass quality is the primary factor determining the value of a carcass in the beef industry supply chain, consumers evaluate beef products at purchase time based on visual quality and at consumption time based on sensory quality. These traits are of even greater importance in crossbred cattle used in subtropical and tropical regions for their superior adaptability because they tend to underperform compared to their purebred counterparts.

Many of these traits are challenging and expensive to measure and unavailable until late in life or after the animal is harvested, hence unrealistic to improve through traditional phenotypic selection, but perfect candidates for genomic selection. Before genomic selection can be implemented in crossbred populations, it is important to explore if pleiotropic effects exist between carcass, visual meat quality and sensory meat quality traits. Therefore, our objective was to identify genomic regions with pleiotropic effects on carcass and meat quality traits in a multibreed Angus-Brahman population.

Materials & methods

The cattle population for this study consisted of 2,384 steers from the University of Florida multibreed Angus-Brahman herd born between 1989 and 2018 and raised under very similar management system throughout the years. The breed composition of animals in this unique multibreed population ranged from 100% Angus to 100% Brahman, including all crosses in between them. Phenotypes for marbling (MARB), ribeye area (REA), tenderness (TEND), juiciness (JUIC), color, texture (TEXT) and firmness (FIRM) were analyzed. Genotyping was carried out on 1,038 of the 2,384 animals using the Bovine GGP F250 array,

which contains 221,115 SNP. A total of 125,042 autosomal SNP markers with MAF>0.01 and call rate higher than 90% were included in the genomic analysis.

Variance components, heritabilities, additive genetic correlations, and phenotypic correlations were estimated using single-trait and two-trait single-step genomic best linear unbiased prediction (ssGBLUP). Animal mixed models included the direct additive genetic and residual as random effects, year of birth as a class effect, and age at slaughter as a covariate, except for TEND and FLAV where age at slaughter was not significant. Computations were performed with the *airemlf90* package from the BLUPF90 (Misztal *et al.*, 2009).

Genome-wide scan for pleiotropic effects. Single-trait genome-wide association studies were carried out using the weighted ssGBLUP (WssGBLUP; Wang *et al.*, 2012) procedure to scan for genomic regions with pleiotropic effects on carcass and meat quality traits. First, the relevance of direct additive genetic effects was investigated fitting all fixed and random effects from the variance component models. Second, conditional genome scan fitting all other traits as covariates in the aforementioned model allowed correcting for indirect effects and capturing genomic regions with pure direct effects on the trait under analysis. Genomic windows explaining more than 1% of direct additive genetic variance were considered associated with the analysed trait. Common genomic regions involving overlapping windows associated with two or more phenotypes in both analyses were considered as pleiotropic regions. Additionally, common regions from overlapping windows explaining more than 1% of the direct additive genetic variance for one trait and between 0.9 and 1% of the direct additive genetic variance for another trait were considered as suggestive pleiotropic regions.

Functional analysis. Top 20 SNP markers with the largest absolute estimated effect across two or more traits within each pleiotropic region were used to identify genes with pleiotropic effects. A SNP marker was assigned to a particular gene if it was located within the gene. Genes with a known function directly or indirectly associated with carcass and meat quality traits were defined as candidate pleiotropic genes. Following, GO and pathway enrichment and clustering analyses of all annotated genes within pleiotropic regions were performed.

Results

Estimates of heritabilities, phenotypic and genetic correlations between analyzed traits are presented in Table 1. Heritability estimates for MARB, REA and TEND were moderate, ranging from 0.44 to 0.53, and low estimates were observed for the other sensory panel and visual meat quality traits (0.12-0.19). Ribeye area had consistently the lowest phenotypic correlations with all other traits (-0.01 to 0.10). Positive moderate phenotypic correlations existed between MARB and TEND (0.32), MARB and JUIC (0.32), TEND and JUIC (0.51), and JUIC and COLOR (0.36). Negative moderate phenotypic correlations were estimated between MARB and FIRM (-0.37) and JUIC and FIRM (-0.33). High and favorable additive genetic correlations was observed between MARB and JUIC (0.66) and MARB and FIRM (-0.38), TEND and JUIC (0.64) and TEND and TEXT (-0.53).

The WssGBLUP analyses correcting for indirect effects identified a total of 3,460 non-overlapping 1-Mb genomic windows for MARB, 3,083 for REA, 3,218 for TEND, 3,557 for JUIC, 3,502 for COLOR, 3,315 for TEXT, and 3,341 for FIRM. Out of these, 4, 8, 5, 7, 6, 2, and 5 windows explained more than 1% of the direct additive genetic variance for MARB, REA, TEND, JUIC, COLOR, TEXT, and FIRM, respectively. Four pleiotropic genomic regions and two suggestive pleiotropic regions were identified. The first pleiotropic region on BTA5 (26.7-27.5 Mb) was significantly associated with REA (2.68%) and MARB (1.27%), while the second region (56.2-56.9 Mb) explained a high proportion of the direct additive genetic variance in

Table 1. Heritabilities (h^2, diagonal), phenotypic (above diagonal) and direct additive genetic (cor, below diagonal) correlations between carcass and meat quality traits in a multibreed Angus-Brahman population.[1]

Trait	MARB	REA	TEND	JUIC	COLOR	TEXT	FIRM
MARB	**0.49**	0.19	0.32	0.32	0.03	-0.22	-0.37
REA	-0.03	**0.53**	0.10	-0.03	0	-0.01	0.04
TEND	0.21	0	**0.44**	0.51	0.16	-0.08	-0.17
JUIC	0.66	-0.15	0.64	**0.15**	0.36	-0.01	-0.33
COLOR	-0.19	0.02	0	-0.54	**0.15**	0.23	-0.19
TEXT	-0.30	0.24	-0.53	-0.99	0.02	**0.12**	0.16
FIRM	-0.38	0.24	-0.16	-0.32	-0.22	-0.24	**0.19**

[1] Standard error (SE): $0.04<SE_{h^2}<0.07$ and $0.06<SE_{cor}<0.5$.

REA (4.78%), TEND (2.45%), MARB (2.09%), TEXT (1.55%) and FIRM (1.34%). One genomic region on BTA7 (51.5-52.5 Mb) had effect on MARB (2.24%), TEND (1.63%), and TEXT (1.36%). The genomic region between 61.9 and 62.5 Mb on BTA18 accounted for 2.17 and 1.10% of the genetic variance for COLOR and TEND, respectively. A suggestive pleiotropic region on BTA10 (76.2-77.2 Mb) explained 1.04 and 0.99% of the genetic variance for JUIC and MARB. The suggestive pleiotropic region on BTA19 (27.0-28.0 Mb) explained 1.12 and 0.96% of the genetic variance for TEND and TEXT.

These pleiotropic genomic regions contained about 260 genes with effect across two or more traits. Two candidate genes were identified in the first pleiotropic region on BTA5, seven in the second region on BTA5, one gene in the pleiotropic window on BTA7, and two genes in the pleiotropic region on BTA18. In addition, two genes were mapped in the suggestive pleiotropic region of BTA10, and the region on BTA19 contain four candidate genes. Overrepresented terms for GO Biological Processes within pleiotropic regions included 'Regulation of Apoptotic Process', 'Regulation of Cell Proliferation', 'Linoleic Acid Metabolic Process', and 'Cell Adhesion via Plasma Membrane Adhesion Molecules'. Moreover, overrepresented terms for GO Molecular Functions included 'Iron Ion Binding', 'Calcium Ion Binding', 'Steroid Hormone Receptor Activity', 'DNA Binding', 'Translation Initiation Factor Activity', and 'Transcription Factor Activity'.

Discussion

Heritability estimates for carcass and meat quality traits in the multibreed Angus-Brahman population were generally consistent with values reported in the literature (Mateescu *et al.*, 2014). Examination of direct additive genetic correlations between traits in this study is important to understand the challenges and limitations that could result from the inclusion of any of these traits in selection schemes. The moderate favorable direct additive genetic correlation observed between MARB and TEND was lower than other estimates of 0.40 (Reverter *et al.*, 2003) and 0.61 (Wheeler *et al.*, 2010), but comparable to estimates for purebred Brahman (Riley *et al.*, 2003), reinforcing the long-held belief of a unique fat-tenderness relationship in *B. t. indicus* versus *B. t. taurus* cattle.

The two candidate genes (*CSAD* and *TNS2*) in the first pleiotropic region on BTA5 are directly involved in muscle physiology and lipid metabolism (Wen *et al.*, 2019; Ishii *et al.*, 2013). The second BTA5 region is of particular importance because of its pleiotropic effects on most of the traits under investigation. This region harbors three candidate genes (*LRP1*, *MYO1A*, *NACA*) involved in muscle development, myoblast proliferation, and lipid metabolism (Dato and Chiabrando, 2018; Lv *et al.*, 2019, Berger *et al.*, 2012). Besides the obvious effect on MARB and REA, these genes could also affect TEND, TEXT and FIRM given the impact of muscle fiber diameter and density on these traits (Pearson, 1990, Lv *et al.*, 2019). The region on

BTA7 contains *Protocadherin Beta 1* (*PCDHB1*), which may directly impact marbling, tenderness, and texture. Cadherins are structural proteins that play important roles in cell adhesion and differentiation in several bovine tissues (Martignani *et al.*, 2020), thus could be involved in processes that lead to less tender and visually coarser meat. The suggestive pleiotropic region on BTA10 harbors *SYNE2*, and obvious candidate gene due to its possible role in proteolysis and cell compartmentalization (Zhang *et al.*, 2007).

Many of the biological pathways enriched within these regions were previously reported to be important for carcass quality, meat quality, and tenderness in beef cattle (Leal-Gutiérrez *et al.*, 2019). Numerous genes identified in pleiotropic regions are involved in calcium-related processes such as calcium ion binding, calcium channel, and calcium channel regulator. It was anticipated that calcium and potassium play a major role in meat tenderness because of their contribution to the proteolytic system responsible for muscle contraction and postmortem tenderization. Taken to together, our results contribute with novel information on the complex architecture of direct additive genetic correlation between carcass and meat quality traits in crossbred beef cattle.

389. Sequence-based multi-trait genome-wide association study for linear classification traits in Belgian Blue beef cattle

J.L. Gualdron Duarte[1,2*], A.S. Gori[2], G. Costa Monteiro Moreira[1], M. Georges[1], C. Charlier[1] and T. Druet[1]

[1]Unit of Animal Genomics, GIGA-R, University of Liège, 4000 Liège, Belgium; [2]Walloon Breeders Association (awe groupe), 5590 Ciney, Belgium; jlgualdron@awegroupe.be

Abstract

We performed a genome-wide association study in Belgian Blue beef cattle for 11 traits related to muscular development and height. Phenotypes were available for 14,762 genotyped cows and imputation was performed to the sequence level (11,537,240 variants). A total of 37 genome-wide significant QTL were identified with a single-trait analysis, corresponding to 11 unique pleiotropic QTL. We then used and compared two multiple-trait approaches to combine information from different traits to fine-map the QTL and increase the power. Although these approaches allowed identifying additional QTL, other were lost. Among the identified QTL, four corresponded to previously identified variants having negative effect when homozygous. In addition, three new missense variants in genes related to muscular development and height were identified.

Introduction

Genome-wide association studies (GWAS) are performed to identify variants associated with traits of interest Generally, they are performed with single-trait (ST) approaches although it is not uncommon to identify variants associated with several traits. Multiple-trait (MT) approaches could be advantageous in such cases, by improving the fine-mapping resolution or the mapping power. These MT approaches have a high computational cost and they can thus be applied on a limited number of traits. Bolormaa *et al.* (2014) proposed an approximate MT approach that requires only to perform ST approaches for each trait.

With the implementation of genomic selection in Belgian Blue beef (BBB) cattle, the number of genotyped individuals is continuously increasing, offering the possibility to perform GWAS at increasing power. A series of linear classification traits, related to conformation and muscular development, are routinely recorded on adult females. Such traits are typically correlated and affected by shared variants. Our objective was to conduct a GWAS in BBB cattle for 11 linear classification traits and to assess the benefit of MT approaches (Stephens, 2013), including the indirect approach proposed by Bolormaa *et al.* (2014).

Materials & methods

Genotype imputation. 14,762 cows with phenotypes were genotyped with custom low-density (LD) arrays with 8,576 to 32,318 SNPs or with the Bovine50K genotyping array (MD). To impute genotypes to the sequence level, we relied on a set of 890 bulls genotyped with the BovineHD array and on a sample of 242 whole-genome sequenced bulls. The imputation was achieved in three steps with ShapeIT4.2 (Delaneau *et al.*, 2019) and Minimac4 (Howie *et al.*, 2012), from LD (7,525 SNPs) to MD (28,893 SNPs), from MD to HD (611,322 SNPs) and from HD to whole-genome sequence level (11,537,240 selected SNPs and indels).

Single-trait GWAS. Association was tested with a Linear Mixed Model (LMM) approach implemented in GEMMA (Zhou and Stephens, 2012). The genomic relationship matrix obtained with the MD genotypes was used to capture the polygenic effects and the population structure. Each cow was phenotyped for 11 traits including body length, pelvis length, height, chest width, pelvis width, rib shape, rump, top muscling, shoulder muscling and buttock muscling (side and rear view). Phenotypes were corrected for fixed effects

from the genetic evaluation. The number of independent SNPs was estimated to be equal to 500,000 whereas we determined that 7 independent traits were analysed. Accordingly, we set the significance threshold at 1.43e-8 after application of a Bonferroni correction for 3,500,000 tests.

Multiple-trait GWAS. We first applied the MT approach proposed by Stephens (2013) and implemented in GEMMA. In addition, we used the indirect approach proposed by Bolormaa *et al.* (2014) relying on a score computed from the signed t-values obtained for the SNPs and for each traits (in ST analyses). For one SNP, the score is computed as tVt' where t is the array of t-values estimated for the tested SNP for each of the N traits and V is the N × N correlation matrix between t-values, estimated from all the tested positions. This score is approximately distributed as a chi-squared with N degrees of freedom. For MT analysis, the significant thresholds were modified to 1e-7 and 5e-8 when one or two genome scans were performed (e.g. all traits simultaneously or two groups of six traits).

Results

The ST GWAS analysis identified a total of 37 QTL exceeding the significance threshold. However, several of these QTL co-localized in the same interval, suggesting pleiotropic QTL. All the identified QTL are summarized in Figure 1, where the 37 QTL could be condensed in a set of 11 unique QTL. As illustrated for a QTL on chromosome 19 (Figure 2), high correlations between SNP significance levels for several traits further support the presence of a pleiotropic QTL.

The first MT approach (Stephens, 2013) could not be applied on all traits simultaneously. We used the results from the QTL sharing with the ST approach to define two groups of 6 traits to perform MT analysis. By combining information from several traits, the MT approach helps to identify the causative variants. For instance, three previously identified causative variants are clearly the lead SNP with the MT approach whereas this was not the case for all ST analyses (Figure 2 and 3). The association signals obtained with the second MT mapping approach were highly correlated with those from the first approach (correlations ranging from 0.90 and 0.99) and pointed towards similar sets of causative variants, indicating that the

Figure 1. Heat-map showing association between QTL and traits. The circle sizes indicate strength of association, red borders around circles are used for significant associations, and the colour intensity denotes effect magnitude.

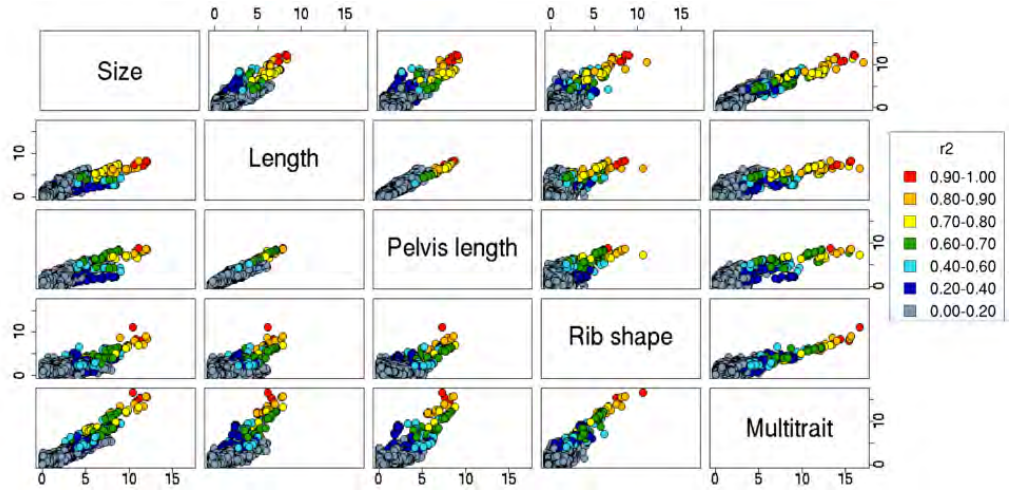

Figure 2. Correlation plot between ST and MT *P*-values (on -log10 scale) for a QTL on chromosome 19. Variants ±2.5 Mb from the QTL are included. The dot colours indicate the linkage-disequilibrium (r^2) between each variant and the lead SNP (on each row, the lead SNP corresponds to the analysis indicated on the diagonal).

indirect approach was a good approximation (although with slightly lower *P*-values). Although both approaches identified respectively two and three new QTL, two and one QTL were no longer significant (on BTA16 and 23). Inclusion of traits not associated with a QTL in MT approaches might thus reduce the power of association. Therefore, the optimal MT approach should not necessarily combine all traits simultaneously. These observations were confirmed by a MT analysis including 11 traits: although the mapping resolution was improved for the most pleotropic effects, the power decreased for some QTL associated with fewer traits (QTLs on BTA16 and 23 were lost). Nevertheless, five new QTL were identified thanks to increased power for pleiotropic QTL (and correction for fewer tests).

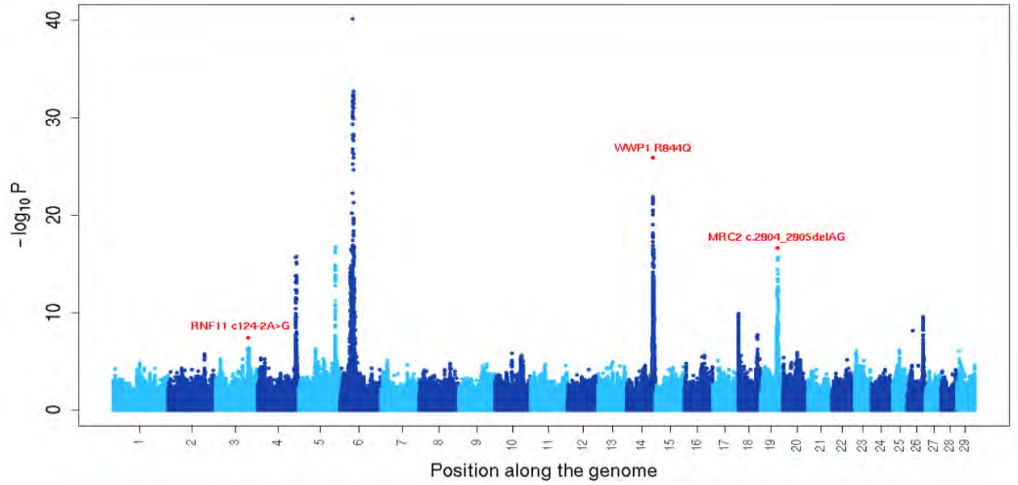

Figure 3. Example of Multiple-trait GWAS. Six traits were included: body length, pelvis length, height, chest width, pelvis width and rib shape. The red points are previously identified causative variants.

Four of the QTL are associated to variants altering the protein sequence previously identified, whereas three additional missense variants in genes related to height or muscular development were also identified.

Discussion

Several QTL detected in this study were previously identified in other studies. For instance, we found QTL on BTA5 (CCND2), BTA6 (LCORL and NCAPG), BTA23 and BTA26 reported for stature in Bouwman *et al.* (2018). In addition to these QTL, four QTL associated with deleterious variants presenting heterozygous advantage (e.g. Gualdron *et al.,* 2020), and other QTL might be more specific to the BBB cattle breed. The association with these recessive deleterious variants are still highly significant although their frequency has been decreasing in the population as a result of selection against carriers.

MT approaches allow obtaining a more precise association signal, in particular when most of the combined traits are associated with the variant. Although fewer tests were performed with such approaches, few new QTL were identified and some ST QTL were even lost, possibly because the MT approach included too many un-associated traits. Finally, the indirect MT approach from Bolormaa *et al.* (2014) was an excellent approximation of the standard MT approach with a lower computational cost. However, the *P*-values obtained with this second approach were less conservative and it remains to be determined whether the higher number of significant results we obtained results in increased power or a higher rate of false positives.

390. Integrating imputed structural variants and tandem repeats in a GWAS for growth and carcass traits in F_2 pig crosses

I. Blaj[1*], J. Tetens[2,3], J. Bennewitz[4], G. Thaller[1] and C. Falker-Gieske[2]

[1]Institute of Animal Breeding and Husbandry, Kiel University, Hermann-Rodewald-Straße 6, 24118 Kiel, Germany; [2]Department of Animal Sciences, Georg-August-University, Burckhardtweg 2, 37077 Göttingen, Germany; [3]Center for Integrated Breeding Research, Georg-August-University, Wilhelmsplatz 1, 37073 Göttingen; [4]Institute of Animal Science, University of Hohenheim, Garbenstraße 17, 70599 Stuttgart, Germany; iblaj@tierzucht.uni-kiel.de

Abstract

Structural variants and tandem repeats are relevant sources of genomic variation but are not commonly used in genome-wide association studies due to challenging identification and genotyping. Here, we profiled these variants via state-of-the-art strategies in the founder animals of four F_2 crosses based on whole-genome sequence data (20×). After imputation, an association study in the F_2 generation was carried out for average daily gain, backfat thickness, meat to fat ratio, and carcass length. 56.56% of the significant variants were not in high LD with previously significantly associated SNPs and small indels identified for the same traits in an earlier study and thus presumably not tagged in a standard association study. Besides proposing specific causative mutations related to *COL21A1, BMP5, BMP2, ISL1*, or *SHANK2*, the findings of this study demonstrate that structural variants and tandem repeats play an important role in biological regulation often via mechanisms driven by long non-coding RNAs.

Introduction

A genome-wide association study (GWAS) is an effective approach to discover phenotype-genotype associations with growing potential when using whole-genome sequence (WGS) data and advanced analytical methods. The common understanding of the term genotype refers to SNPs and possibly small indels (<50 bp), nevertheless additional polymorphisms classes exist such as structural variants (SVs) and tandem repeats (TRs). SVs are described as large-scale (>50 bp) genomic alternations (e.g. deletions, insertions, duplications, inversions, and translocations), while TRs are characterised by their repetitive motifs and highly polymorphic nature. The contribution of SVs and TRs to quantitative trait variation is currently not fully understood as they are not routinely screened for. Therefore, the aim of this study was to conduct a GWAS based on imputed SVs and TRs and to assess their implications for growth and carcass traits in four pooled F_2 pig crosses.

Materials & methods

Data sources. The four F_2 pig populations included in this analysis were entirely genotyped with the Illumina PorcineSNP60 BeadChip and, additionally, WGS data was available for the F_0 (20×) and F_1 (1×) individuals. The following traits were used as phenotypes: average daily gain (ADG), backfat thickness (BFT), meat to fat ratio (MFR), and carcass length (CRCL). A full description of the crosses, as well as, the genomic and phenotypic data was published by Falker-Gieske *et al.*, 2019.

Structural variants and tandem repeats profiling. Using WGS data from the founders, we profiled SVs using three independent callers: smoove v0.2.6 (Brent, 2018), DELLY v0.7.7 (Raush *et al.*, 2012), and manta v1.6.0 (Chen *et al.*, 2016). Further, a high confidence set was obtained with SURVIVOR v1.0.7 (Jeffares *et al.*, 2021) followed by discarding SVs with a genotyping rate <0.8 and QUAL<6,000. Concerning the TRs, we screened all tandem repeats with a motif length of 2-20 bp with GangSTR v2.4.6 (Mousavi *et al.*, 2019)

which we then subjected to a call-level quality control filtering (min DP 10 and quality score >0.8). The final TRs dataset only contained variants with a call rate >0.8.

Imputation step and genome-wide association study. The joint set of curated SVs and TRs were then imputed to the F_2 individuals (n=2,657) based on the low coverage F_1 and F_2 SNP array data using the same imputation strategy we applied in Falker-Gieske *et al.*, 2019 for SNPs and small indels. Beagle 5.2 was employed for phasing, while Beagle 4.0 (Browning *et al.*, 2021) was utilized for imputation as it considered pedigree information. For single trait association analysis, we used GCTA v1.93.2 (Yang *et al.*, 2011) by incorporating the SVs and TRs as genotypes to be tested for association and ADG, BFT, MFR, and CRCL as phenotypes. A genomic relationship matrix was created from the F_2 SNP array data for the mixed linear model 'leave one chromosome out' analysis which also included a cross covariate (4 classes representing each of the 4 crosses). Following this model, imputed SVs and TRs with MAF>0.01 were tested. The significance level for the marker effects was set by the corresponding Bonferroni correction to a *P*-value of 0.05/number of tests.

Results

In the first part of this study, we profiled 13,201 high confidence SVs and 103,730 polymorphic TRs in the founders. These variants were considered for imputation. After MAF filtering on the imputed variants in the F_2 individuals, a final SVs and TRs dataset comprising 54,076 variants was tested for association. From the GWAS results, the following cumulated number of SVs and TRs exceeded the genome-wide significance threshold: 17, 156, 105, and 339 for ADG, BFT, MFR, and CRCL, respectively. Overall, among these, 88 were SVs whereas 529 were TRs. Compared to our previous SNPs and small indels based GWAS study (Falker-Gieske *et al.*, 2019), here we detected additional significant signals on *Sus Scrofa* chromosome 1 (SSC1) and SSC16 for ADG, on SSC16 for BFT, on SSC14 and SSC15 for MFR, and on SSC4, SSC8, SSC9, SSC14 and SSC16 for CRCL. Nevertheless, common GWAS peaks in both studies were localized over all traits on SSC1, SSC2, SSC4, SSC5, SSC7, SSC17, and SSC18. On these chromosomes, we proceeded by prioritizing SVs and TRs based on LD. Therefore, we discarded for each trait all significant SVs and TRs that were in high LD (r^2>0.8) with the previously identified significant SNPs and small indels. The number of non-tagged SVs and TRs were 12 (out of 17) for ADG, 112 (out of 156) for BFT, 89 (out of 105) for MFR, and 237 (out of 339) for CRCL. 388 genes incorporated or lied in the proximity of these prioritized SVs and TRs from which 75.51% were protein coding and 19.33% lncRNA (long non-coding RNA), while the remaining 5.16% were represented by miRNA (microRNA), processed pseudogene, pseudogene, snoRNA (small nucleolar RNA), and snRNA (small nuclear RNA). Table 1 presents the chromosome-wise top three genes (when present) per trait.

[1] * = snRNA; ** = lncRNA.

Many of the highly associated regions overlapped between the traits leading to common candidate genes. *COL21A1* was singled out due to an intronic TR ($(TTTG)_3/(TTTG)_5$, SSC7:29,488,854) causing the top GWAS peak on SSC7 for BFT, MFR, and CRCL. Further, for BFT, MFR, and CRCL, *DST* was associated, whilst for ADG, BFT, and MFR, the genes *AP2A2, ENSSSCG00000012835, SHANK2* were shared. Finally, *U6, ENSSSCG00000044971, HMGCLL1, DAAM2, PRIM2, ENSSSCG00000001612* influenced ADG, BFT and CRCL.

Discussion

Here, we investigated the role of structural variants and tandem repeats in a series of association studies using pooled F_2 pig crosses characterized for growth and carcass traits. The influence of SVs and TRs on quantitative traits and to which extent these variants were tagged by SNPs and small indels from a prior GWAS was addressed. Regarding the latter and assessed across all traits, 56.56% of the highly significant variants were not in high LD (r^2<0.8) with a previously associated variant, demonstrating that part of the molecular mechanisms behind complex traits could be driven by SVs and TRs. Nevertheless, in both GWAS studies many signals coincided leading to overlapping associated genes. An intronic TR variant was identified for *COL21A1* and was proposed as a straightforward candidate for functional validation. In addition, for ADG, BFT, and CRCL, *BMP5* was in the vicinity of the top genes *U6* (snRNA) and *ENSSSCG00000044971* (lncRNA). Similar lncRNA-related mechanisms were found for CRCL with *BMP2* and nearby lncRNAs (upstream: *ENSSSCG00000043546, ENSSSCG00000047884*; downstream: *ENSSSCG00000044805*). Li *et al.*, 2021 indicated that a SNP (rs320706814) was the main cause of the effect on carcass length, however, this variant was not significantly associated nor in LD with the significant SNPs, small indels, SVs or TRs we have identified. The associated genes found for BFT and CRCL on SSC16 (Table 1) indicated the existence of pleiotropic loci which we also detected in the previous GWAS but on SSC7. The peak on SSC16 was led by a lncRNA (*ENSSSCG00000050819*) together with *ISL1* and has not been reported for both traits in the previous GWAS as well as no reports in the region were found for CRCL in the AnimalQTLdb (Hu *et al.*, 2022). *ISL1* is known to regulate pancreatic development and insulin secretion (Yan *et al.*, 2016). The findings related to lncRNAs add to the growing body of evidence indicating that these genes could be involved in different mechanisms of gene regulation as they can control the expression of nearby genes by influencing their transcription (Statello *et al.*, 2021). For SSC2, *SHANK2* was part of the BFT and MFR GWAS peaks due to several highly significant TRs and to one deletion (SSC2:2,753,494, length=-556 bp). *SHANK2* has been associated with the autism spectrum disorder (Lu *et al.*, 2018) that was linked with feeding and eating disorders in humans (Carpita *et al.* 2020). Therefore, the differences in BFT and MFR phenotypes could be a consequence of pig behavioral changes related to feed intake. This study provides an efficient strategy for utilizing existing populations with whole-genome sequence, SNP array, and phenotypic data available to better understand mechanisms behind quantitative traits. Overall, this paper can be regarded as a valuable resource for future studies examining how structural variants and tandem repeats regulate gene expression and ultimately contribute to complex trait variation.

Abstract

We performed single-trait and multi-trait genome-wide association studies (GWAS) to detect quantitative trait loci (QTL) for body length and feed intake in 3,638 Swiss Large White pigs that had genotypes at 43,994 SNPs. Single-trait GWAS (ST-GWAS) revealed two non-overlapping QTL for each trait. Multivariate GWAS implemented with GEMMA software yielded 75 significant SNPs ($-\log_{10}(p)>6$) at the same four QTL. A meta-analysis of summary statistics from the two ST-GWAS resulted in 83 significant SNPs at the same QTL. After including all samples that had at least one phenotype recorded (in total 5,109), the *P*-values of top variants decreased suggesting higher statistical power due to a larger sample size. Fine mapping using imputed sequence variant genotypes confirmed the presence of three previously reported candidate causal variants in *MC4R*, *VRTN* and *BMP2* genes among the most significantly associated variants.

Introduction

Most of the traits considered in pig breeding programs have a complex genetic architecture. Genome-wide association testing between dense markers and phenotypes in reasonably large cohorts is a powerful approach to detect loci underpinning complex traits. Recent investigations suggested that markers associated with complex traits often exhibit pleiotropic effects (Bolormaa *et al.*, 2014). Despite an increasing number of GWAS being carried out in pigs, only a handful of causal variants have been identified.

In this study, we explored and compared single-trait and multi-trait GWAS methods to detect QTL for two lowly correlated traits in the Swiss Large White (SLW) pig breed. The detected QTL were characterized using sequence variant genotypes imputed from a cohort of 421 sequenced animals.

Materials & methods

Input data. Genotypes of 17,006 pigs from different breeds were obtained using 5 Illumina porcine SNP Bead chips with various densities. The physical positions of the SNPs were determined based on the *Sscrofa*11.1 assembly of the pig genome. Using plink (v. 1.9; Purcell *et al.*, 2007), we kept 43,994 unique autosomal SNPs that had minor allele frequency above 1%, less than 10% missing genotypes per variant, and did not deviate from Hardy-Weinberg proportions. We retained only samples that had genotypes for at least 80% of the markers. Sporadically missing genotypes were subsequently imputed and phased for 14,292 Large White pigs using Beagle (v. 5.0; Browning *et al.*, 2018). Using our in-house reference panel of 421 pigs with whole-genome sequence data (average depth of coverage 7.1×, ranging from 2.4× to 37.5×), we imputed the array-derived genotypes up to sequence level. In total 17,600,482 bi-allelic SNPs passing the aforementioned filtering criteria, and 3,638 pigs with phenotype records for the studied traits were used to fine-map the identified QTL.

Phenotypes were available in the form of de-regressed estimated breeding values (drEBV; Garrick *et al.*, 2009). The breeding values of 5,753 SLW pigs were routinely estimated using a BLUP multi-trait multi-breed animal model. Only drEBV with $r^2>0.3$ and in the range of mean ±5 standard deviations were considered, resulting in 3,638 records for body length (BL) and 5,109 for average daily feed intake (ADFI).

Genome-wide association studies (GWAS). We applied linear mixed model-based approaches implemented in the Genome-wide Efficient Mixed Model Association software (GEMMA; v. 0.98.5; Zhou and Stephens, 2014) to detect association between genotypes and phenotypes while considering either one (ST-GWAS) or two traits at a time in a multivariate GWAS (mtGWAS). A centered genomic relatedness matrix was fitted to control for the relationship among the individuals. A score test was applied to obtain the significance level of the association tests.

Results from mtGWAS were compared with those obtained from a meta-analysis (metaGWAS) of summary statistics from ST-GWAS following the approach proposed by Bolormaa *et al.* (2014). The t-values were calculated based on regression coefficients and corresponding standard errors from the ST-GWAS summary statistics. Multi-trait χ^2 statistic was subsequently calculated based on the SNP-based t-values and corresponding variance-covariance matrix. The metaGWAS was calculated on results obtained from individuals that had phenotypes for both traits (n=3,638) as well as for at least one of the traits (n=5,109). The GWAS results were visualized using the qqman package (Turner, 2018), with *suggestiveline* = -log10(1e-06).

Results

Single-trait GWAS. Linear mixed model-based ST-GWAS were performed between two traits (body length and average daily feed intake; BL and ADFI) and microarray-derived genotypes at 43,994 SNPs in 3,638 SLW pigs. The ST-GWAS revealed four major QTL (Figure 1A). The most significant SNPs (Table 1) for BL were MARC0038565 on SSC7 and INRA0052780 on SSC17. The top SNPs at two QTL for ADFI were both located on SSC1 (ASGA0004992 and ASGA0008077).

Low correlation of the de-regressed breeding values (r=-0.06 from 3,638 pigs) and distinct QTL revealed by ST-GWAS indicated that the traits were largely independent. Next, we investigated if multi-trait association methods might increase the power to detect QTL also for seemingly unrelated traits.

Multi-trait GWAS and meta-analysis GWAS. We applied multivariate association testing (mtGWAS) and meta-analysis of ST-GWAS (metaGWAS) to consider both traits (BL and ADFI) simultaneously. Both approaches revealed similar results (Table 2). Both methods discovered the four QTL that were previously shown by ST-GWAS, including the same top SNPs. The metaGWAS yielded 8 more markers above the suggestive significance level ($-\log_{10}(p)>6$) than mtGWAS.

Following our confirmation that both methods provide almost identical results, we took advantage of the fact that the metaGWAS approach does not rely on the availability of phenotypes for all individuals. We conducted the analysis for BL and ADFI in 5,103 pigs including 1,471 animals that had missing phenotypes for BL. The results (Figure 1B) mirrored previous findings and further increased the significance of top marker on SSC1 by on average 17% when compared to first metaGWAS. The significance level of the markers on SSC7 and SSC17 slightly decreased (-0.85%).

Table 1. The most significant markers at QTL detected for two traits.

SNP	rsID	Chr	Position	MAF	Candidate gene

* Single-trait GWAS for body length (BL) and average daily feed intake (ADFI).

[1] Number of individuals = 3.638.

[2] Number of individuals = 5.109.

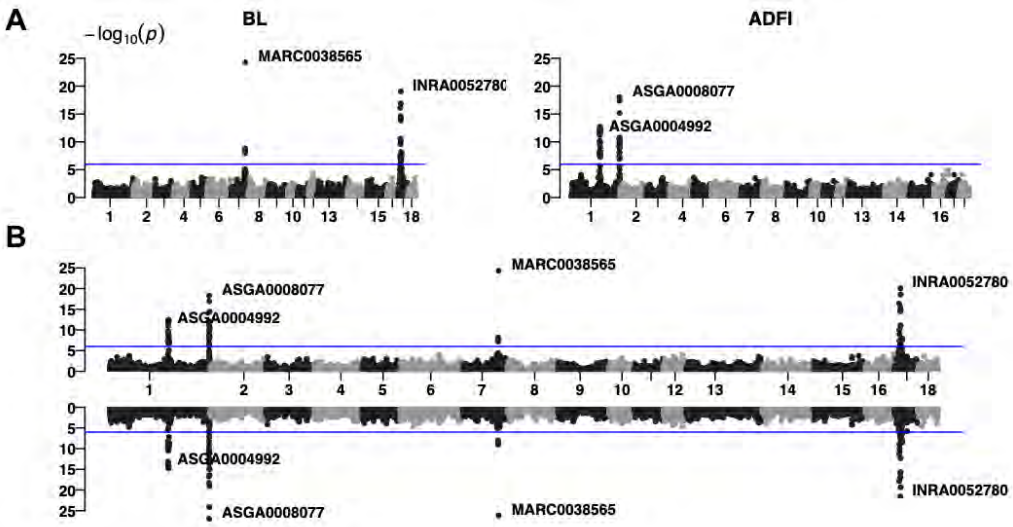

Figure 1. Manhattan plots of (A) ST-GWAS for body length (BL) and average daily feed intake (ADFI) and of (B) mtGWAS (top; n=3,638) and metaGWAS (bottom; n=5,109).

Fine mapping. We considered sequence variants imputed from 421 pigs into our mapping cohort to fine-map the QTL on SSC1 (160 Mbp), SSC7 (98 Mbp) and SSC17 (16 Mbp). All three top sequence-derived SNPs were in high LD with the top array-derived markers as well as with previously described candidate causal variants (rs81219178, rs709317845 and rs320706814 in or nearby *MC4R*, *VRTN* and *BMP2*, respectively). The QTL on SSC17 was strongly associated with BL (*P*-value 5.17E-61) and weakly with ADFI (*P*-value 2.7E-07), unveiling a hitherto undetected potential pleiotropic effect.

Discussion

We compared mtGWAS and metaGWAS of two almost uncorrelated traits and fine-mapped the QTL using imputed sequence variants in 3,638 SLW pigs. Similar to Fang and Pausch (2019), the *P*-values of the top SNPs were lower in multi-trait methods than in ST-GWAS (Table 2). The four QTL described here have been detected in several pig populations and *BMP2* (Li *et al.*, 2021), *VRTN* (Duan *et al.*, 2018), and *MC4R* (Bruun *et al.*, 2006) have been proposed as candidate genes. The QTL on SSC1 (271 Mbp) was found to be associated with backfat thickness (Gozalo-Marcilla *et al.*, 2021). It is close to *FIBCD1*, which is associated with body mass index in human (Pulit *et al.*, 2019). Our sequence-based fine-mapping approach

revealed three previously detected candidate causal variants near *VRTN*, *MC4R* and *BMP2* among the most significantly associated variants. However, the previously reported candidate causal variants were not the top variants. This may indicate sampling bias (Barendse, 2011) or superior association power due to strong LD with adjacent causal variants (Bickel *et al.*, 2011), or that they are not causal but in LD with the true causal variant. Another likely reason could be low accuracy of imputation due to the low marker density in the array panels. Low accuracy of imputation from a marker panel with similar size was reported previously (van den Berg *et al.*, 2019).

Multivariate association testing as implemented with GEMMA requires individual-level genotype and phenotype data and considers only animals with non-missing phenotypes across the traits. To consider all animals, missing phenotypes need to be imputed upfront. In contrast, the meta-analysis of summary statistics that are measured on a various number of individuals in contributing studies is somewhat agnostic to an unbalanced number of animals per trait. We observed an increase in statistical significance when additional individuals (n=1,471) were considered that had phenotypes only for one trait. However, this increase in statistical power is likely higher for correlated traits and pleiotropic variants.

Abstract

In regression models, high collinearity can severely reduce the power to detect associations between individual SNPs and a phenotype. We present a simple algorithm that uses the samples from the posterior distribution of a Bayesian Variable Selection model to identify sets of SNPs (i.e. Credible Sets, CS) that (jointly) are confidently associated with a trait. The proposed method leads to multi-resolution inferences identifying, depending on the degree of collinearity and the LD between the SNPs and causal variants, CSs of variable size. Using simulations, we show that the proposed approach increases power with adequate FDR-control. The method described in this study was implemented in the R language and is available with the BGLR R-package.

Introduction

Modern data sets often include a large number of predictors (e.g. SNPs, gene expression, methylation, milk spectrometry) that cluster in complex ways. For instance, in genomic data, linkage disequilibrium (LD) coupled with high marker density can lead to very high collinearity between SNPs. In genome-wide association studies (GWAS) mapping is done using either marginal association test-statistics or multiple regression models. In multiple linear regression models, high collinearity can reduce the power to detect individual variants associated with QTL. For instance, when Bayesian Variable Selection methods are applied to SNPs in high LD often no individual SNP reaches the posterior probability thresholds that are required to achieve a low false discovery rate (FDR, e.g. $\pi_j = \text{p}(\beta_j \neq 0 \mid data) > 0.95$ which corresponds to a local FDR of 0.05); thus, reducing power or requiring to tolerate a high error rate to achieve high power. At the same time, the joint probability of association of the SNPs in segments harboring causal loci (i.e. for a SNP set) $\text{p}(\beta_1 \neq 0 \text{ or } \beta_2 \neq 0 \text{ or } \beta_s \neq 0 \mid data)$ can be very high, even close to 1. In such situations, we may have strong evidence of an association for a set of SNPs in a chromosome segment and high uncertainty about individual SNP effects.

To address the problem above-described, studies often use window methods whereas statistics (variances, joint probability of association) are produced for chromosome segments instead of individual variants. However, there is no consensus as to how wide these windows should be, whether a fixed or variable window size is needed, and whether non-overlapping or sliding windows are best (Beissinger *et al.*, 2015). In this study, we propose an alternative approach that uses the samples from the joint posterior distribution to identify sets of SNPs with high joint posterior probability of inclusion. When the number of SNPs in the model is large, exploring all possible credible sets (CS) is not feasible. Thus, we designed a forward search algorithm to identify sets of SNPs jointly associated with the outcome. Here, we described the proposed algorithm and evaluate its performance using extensive simulations applied to two large data sets with distinct characteristics.

Materials & methods

The joint probability of association of two SNPs with a phenotype is:

$$p(\beta_j \neq 0 \text{ or } \beta_{j'} \neq 0) = p(\beta_j \neq 0 + p\beta_{j'} \neq 0 - p(\beta_j \neq 0 \text{ and } \beta_{j'} \neq 0$$

Above, β_j and $\beta_{j'}$ are SNP effects in a multiple linear regression model. The above expression can be extended to more than two SNPs. However, evaluating the joint probability of inclusion of more than two SNPs requires evaluating multiple joint probabilities of inclusion of 2, 3, or more SNPs. To avoid performing an exhaustive search for CSs, we propose to use a forward algorithm that builds CSs by adding to an existing CS the SNP that maximizes the joint probability of association of the CS with the phenotype. To simplify computations, at each step of the forward search we maintain a boolean vector $Z = \{Z_s\}$ where $Z_s = \{1$ if at least one element of the CS was active; 0 otherwise$\}$. Using this, at each step of the forward search we decide which SNP to add to the CS by maximizing

$$p(Z_s = 1 \text{ or } \beta_j \neq 0) = p(Z_s = 1) + p(\beta_j \neq 0) - p(Z_s = 1 \text{ and } \beta_{j'} \neq 0) \quad (1)$$

We use the above expression to decide, at each step in the forward search which SNP to add to the CS. Schematically, the algorithm proceeds as follows:

- *Step 1*: Select the SNP with the highest posterior probability of inclusion.
- *Forward search*: Using Equation 1, select the SNP that, when added the current CS, yields the maximum joint probability of inclusion ([1]) of the CS. Add the selected SNP to the CS. Repeat this process until one of the following stopping rules are met.
- *Stopping rules*: At each step stop the forward algorithm: (1) if the size of the CS is larger than a pre-specified maximum size; or (2) if the SNP to be added produces an increase in the probability of association of the CS by less than a pre-specified threshold (e.g. 0.03); or (3) if the joint probability of association of the CS is greater than a pre-specified value (e.g. 0.98).

We implemented the algorithm described above in the R-function findCS(); the function is included in the development version of the BGLR R-package (https://github.com/gdlc/BGLR-R).

Data sets. To evaluate the performance of the proposed algorithm we conducted a simulation study with two data sets (Table 1). The human data set uses ultra-high-density (imputed) SNP genotypes from distantly related individuals from the UK Biobank. The second data set originates from a pig breeding population from the PIC® and includes high-density SNP genotypes from a breeding line. The two data sets have contrasting features and are representative of the challenges that are faced in GWAS applied to data from distantly related individuals and from breeding populations.

Simulation. In both cases, in each MC replicate we simulated one 30 Kbp chromosome segment with three causal variants separated by 10 Kbp. In the human data set, each causal variant explained either 1/12th- or 1/3rd-of-1% of the phenotypic variance. In the pig data set the sample size available does not offer high power to detect very-small effect variants, thus, each causal variant explained either 1% or 1/3rd-of-1% of the phenotypic variance.

Table 1. Data sets used in the simulation study.[1]

Data set	Sample size	# of SNPs	Sample type	LD
Human	100,000*	13.1 million (~4,366 SNPs/Mbp)	Distantly related**	Short span
Breeding (swine)	25,000	43,837 (~15 SNPs/Mbp)	Family data	Long span

[1] Mbp: mega-base-pair; *: we run analyses with N up to 300,000; due to space-restriction we present results up to n=100,0000 only; **: genomic relationship <0.05.

Analysis. We fitted a Bayesian model with a point of mass at zero and a Gaussian slab prior (aka BayesC in animal breeding, Habier *et al.*, 2011) to a chromosome segment consisting of all SNPs within ±500 Kbp (in the human data set, ~4,400 SNPs) or ±5 Mbp (in the pig data set, ~160 SNPs) of the 30 Kbp segment holding the 3 causal variants. We used much shorter segments in the human data set because LD decays very fast in this data set. We fitted models using the BGLR R-package (Perez and de los Campos, 2014); for each simulation scenario, we conducted 300 MC replicates. For each MC replicate we run five chains; then, using the combined samples, we obtained discovery sets by identifying either individual SNPs or CS with a posterior probability of inclusion greater than 0.95, 0.90, 0.80, and 0.50. To make a fair comparison between individual-SNP and CS inference, we considered a SNP in a discovery set to be a true (false) discovery if its distance to the closest causal variant was smaller or equal (larger) than xKbp (x=10, 30, 50, 100, and 500 in the human data set and x=500, 1000, 2,000, and 3,000 in the pig data set). Using this, we computed the false discovery proportion for each MC replicates and mapping resolution. Likewise, we considered that a causal locus was mapped if the distance of it to the closest SNP in the discovery set was smaller than xKbp – we used this to estimate power.

Results

Figure 1 shows the power/FDR curves obtained by data set, method (either single-SNP or CS), sample size, and heritability. Due to space restriction, we only present results for a mapping resolution of 50 Kbp in the human data set and 2 Mbp in the pig breeding data set. In all cases, the CS method achieved higher power than inferences based on individual SNPs. However, a stringent probability cutoff (e.g. >0.95) was needed to achieve effective FDR control. In the human data set, for h^2=0.33% and a mapping resolution of 50 Kbp, the CS method achieved high power with an FDR near 0.1 for N≥30,000. For lower heritability (0.08%) a sample size of ≥100,000 was needed to achieve high power. On the other hand, in the pig breeding data set the mapping resolution that was needed to obtain a good power/FDR performance was much coarser (2 Mbp); this is a direct consequence of lower marker density and the longer span of LD present in this breeding population. In this data set, even with a 2 Mbp mapping resolution, the FDR was high for the low heritability scenario (h^2=0.33%) and sample size <10,000.

Discussion

High LD between SNPs can reduce the power to detect the association of individual variants with a phenotype because collinearity can lead to uncertainty about individual SNP effects. Therefore, when multiple variants are in LD with the same causal variant often multiple variants show elevated inclusion probability with no individual variant reaching the inclusion probability cutoffs that are used in GWAS to achieve adequate FDR control. In these cases, we may have strong evidence supporting the presence of signal variants in a region, without enough evidence to perform individual variant mapping. The credible set algorithm addresses the problem just described. The simulation study showed that the use of CS can lead to a remarkable increase in power relative to individual SNP inferences. In most scenarios, the CS method showed a flat power-FDR curve (Figure 1) which suggests that one should use this method with a stringent probability inclusion cutoff (e.g. 0.95 or 0.98) – lowering the probability cutoff can increase the FDR without much improvement in power. This way, the approach leads to high power with a reasonably low error rate. The size of the CS produced by the proposed algorithm varies, when individual variants reach a high posterior probability of inclusion some CS may contain only one variant; in cases where multiple variants show elevated posterior probability of inclusion with no individual variant reaching the probability cutoff, the resulting CS include multiple variants.

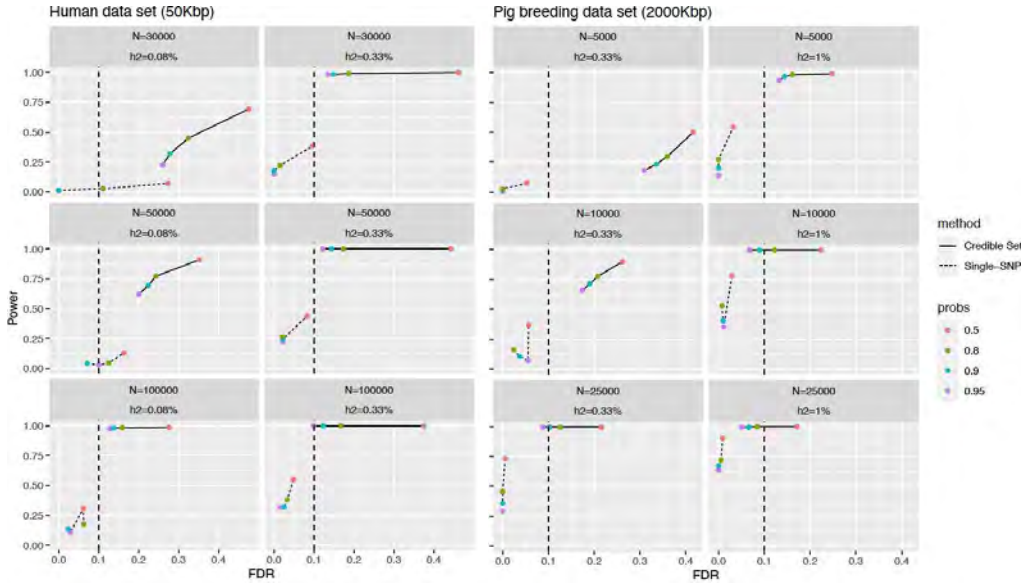

Figure 1. Power-FDR performance by data set, sample size, heritability, and posterior probability threshold used to define credible sets.

Abstract

Phenotypic data for growth traits including birth, weaning and yearling weights and genomic data of 50K SNP markers were collected from 738 Brangus. Multivariate artificial neural networks (ANN) with 1 to 10 neurons models including the inputs from genomic relationship matrix were created and applied with the learning algorithms (Levenberg-Marquardt, Bayesian Regularization and Scaled Conjugate Gradient) and activation functions (tangent sigmoid and linear) for the analysis of growth data. Pearson correlation coefficients were used to evaluate multivariate ANN model performances about genomic prediction in datasets. In multivariate ANN models, the prediction performance of the combination of learning algorithms and activation functions changed for growth traits and there were no superior multivariate ANN models with learning algorithms and activation functions. The application of different activation functions did not make any significant difference on the genomic prediction performance of ANN models with different learning algorithms.

Introduction

The development and use of artificial neural networks (ANN) for artificial intelligence was inspired from the operations of nerve cells (known neurons) in the human brain. The ANN is a statistical modeling of the human brain functions and represents a new generation of information processing systems (Pereira *et al.*, 2009). The learning ability of ANN without using any prior assumption and sophisticated statistical models for linear and nonlinear relationships in the information processing systems is a very attractive feature. Therefore, ANN statistical models have been used to predict genomic values of individuals for complex traits for last decade because complex quantitative traits such as growth and production traits in animal and plant breeding are controlled by a network of numerous genes (Howard *et al.* 2014). This study aimed to compare multivariate ANN models with the learning algorithms (Levenberg-Marquardt (LM), Bayesian Regularization (BR) and Scaled Conjugate Gradient (SCG)) and activation functions (tangent sigmoid and linear) using 1 to 10 neurons models based on the input from G genomic relationship matrix.

Materials & methods

Phenotypes. Phenotypes including birth weight (BW), weaning weight (WW) and yearling weight (YW) as growth traits were from 738 Brangus heifers (3/8 Brahman × 5/8 Angus) from Camp Cooley Ranch in east central Texas, and the Chihuahuan Desert Rangeland Research Center and Campus Farm of New Mexico State University described by Luna-Nevarez *et al.* (2010), and Peters *et al.* (2012). Contemporary groups based on year of birth (2005 to 2007) and calving season (spring or autumn) and dam age were also extracted from database of International Brangus Breeders Association.

SNP marker genotypes and G matrix. SNP marker (53,692 SNP) genotypes were obtained from the BovineSNP50 Infinium BeadChips (Illumina, San Diego, CA). The quality control of SNP markers (Granato *et al.*, 2018) removed the animals having higher than 50% missing data, SNP markers having higher than

5% missing data or lower than 95% call rate and lower than 10% minor allele frequency and resulted in 738 animals with 35,351 SNP markers. The genomic relationship (G) matrix was calculated based on Habier *et al.* (2007) and vanRaden (2008).

Artificial neural networks. The Multi-Layer Perceptron Artificial Neural Network (MLPANN) includes many interconnected neurons which are grouped into an input layer, an intermediate or hidden layer and an output layer. Genomic relationships (g_{ij}) between animals are independent variables and the input neurons in the input layer of the MLPANN. Also, the growth traits are dependent variables and the output neurons in the output layer of the MLPANN. Training process in the MLPANN focus on increasing the estimation accuracy between predicted values ($\hat{y}$) and the phenotypic values (y) using the number of neurons between 1 and 10, learning algorithms (LevenbergMarquardt (LM), Bayesian Regularization (BR) and Scaled Conjugate Gradient (SCG)) and tangent sigmoid and linear activation functions in the hidden layer and producing the multivariate outputs in the output layer.

Cross-Validation and application of MLPANN models. The genotyped animals were partitioned into 10 cross-validation sets by using k-means clustering. The accuracy of phenotypic values of animals was quantified in training and validation sets using the Pearson's correlation coefficient ($r_{y_k,\hat{y}_k}$) between the observed (y_k) and predicted phenotypic ($\hat{y}_k$) values.

MATLAB Neural Network Toolbox (2000) was used to fit the MLPANN models. The learning algorithms were applied by utilizing the functions of trainlm(.), trainbr(.) and trainscg(.) in MATLAB Neural Network Toolbox. The tangent sigmoid and linear activation functions for each learning algorithm were applied by using in MATLAB Neural Network Toolbox, respectively.

Results

Genomic prediction for three growth traits were studied by using multivariate ANN models with 1 to 10 neurons, BR, LM and SCG learning algorithms and Tangent Sigmoid and Linear activation functions. The average Pearson correlation coefficients (accuracies) obtained from 10-fold cross validation datasets were given in Table 1 for training datasets and in Table 2 for validation datasets for growth traits. Table 1 showed that the predictive accuracy results changed from -0.06 to 0.85. The best accuracies for BW, WW and YW were obtained from BR learning algorithm (0.00 to 0.85) and Linear activation function (0.22 to 0.84). However, SCG learning algorithm produced the worst accuracies results (-0.06 to 0.05) regardless of the trait and activation function and there were no big differences among accuracy results from Tangent Sigmoid and Linear activation functions. Table 2 indicated that accuracy results from cross-validation dropped remarkably and changed from -0.09 to 0.16. The best accuracy results (0.06 to 0.16) were obtained from the combination of BR learning algorithm and linear activation function for BW trait. However, learning algorithms and activation functions produced very low and similar accuracy results for BW, WW and YW traits.

Discussion

As seen in Table 1 and 2, the average accuracy results showed that the predictive performance of multivariate ANN models depended tightly on the number of neurons used (architecture of network) in the hidden layer of the network, the type of learning algorithms and activation functions and genetic architecture of growth traits.

In multivariate ANN models, as the number of neurons and the number of output increases, the number of parameters to be estimated also increases. Therefore, genomic relationship among animals could not provide enough information through input neurons to obtain high accuracy from multivariate ANN

models and the predictive performance results from cross-validation datasets were not consistent with increasing number of neurons within each growth trait for different learning algorithm and activation functions.

Abstract

Guide dogs are a class of highly trained working dogs used by individuals with vision impairment to increase independence and quality of life. Through structured breeding programs, genetic improvements can advance their health and performance. Breeding values are a valuable tool that allow for heritable traits of interest to be selected for or against in animal colonies. Three binary health traits from a cohort of 1,097 guide dogs were utilized to construct breeding values to predict phenotypes using genome best linear unbiased predictor (GBLUP) and four machine learning (ML) techniques; support vector machine (SVM), random forest (RF), gradient boosting (GB), and neural network (NN). Across the traits studied, there was not a significant difference between GBLUP and ML performances. These results provide an experimental comparison indicating that ML approaches can construct breeding values at a similar level to the more traditional GBLUP.

Introduction

A variety of breeds are suitable for work as guide dogs which are defined by their ability to complete rigorous training to be selected for working (Fishman 2003). Health conditions can make it more difficult for a dog to pass their training and even preclude them from usage or breeding. The present study investigated data for class II mandibular distocclusion, distichiasis, and acral lick dermatitis traits within a cohort of working dogs. Mandibular distocclusion class II is a case of the mandible being too short and results in a misalignment between the lower and upper teeth. Dogs with the condition can experience difficulty eating, and pain. Treatments can include orthodontics and extractions (Hoyer and Rawlinson 2019). Distichiasis occurs when an extra layer of cilia is present on the margin of the eyelid. Eye irritation and infections can result, with surgical interventions available for severe conditions (Palella Gómez *et al.* 2020). Dogs with acral lick dermatitis often exhibit excessive licking of the extremities due to neuronal, behavioral, or external triggers. Persistent bacterial infections can be common and require medical and behavioral interventions (Paterson *et al.*, 2007).

All of the traits identified present challenges for completing any intensive training regimen, and breeders for guide dogs have incentives to remove genetic causes of these traits from their populations. A method to identify the genetic merit of an individual is breeding values which can be constructed with a variety of techniques. GBLUP was built on the improvement of genetic data over pedigree data used in the BLUP method. A relationship matrix is constructed, which employs the observed genetic similarity to determine the merit of individuals and can be used to predict phenotypes based on the genotypes of animals outside of the training dataset (Clark and van der Werf 2013).

Many different ML techniques have been utilized to construct breeding values in various species of both animals and plants. SVM segregates data into groups using kernels to enlarge the feature space (Suthaharan 2016). Studies have successfully used SVM for breeding values in species from swine to maize (Zhao *et al.* 2020). RF works by constructing individual decision trees, which operate as an ensemble to provide a single output prediction expected to outperform any individual tree (Qi 2012). It is a highly versatile ML approach that has been used extensively for genetic purposes (Naderi *et al.* 2016). GB is similar but continually constructs

DOI: 10.3920/978-90-8686-940-4_394, © J.A. Thorsrud *et al.* 2022

trees to outperform and replace the previous model in the iteration, which makes it useful for bioinformatics (Srivastava *et al.*, 2021). Neural networks aim to artificially replicate how biological neurons work for pattern recognition in high-dimensional data. This approach is flexible but can be computationally costly (Nicholls *et al.*, 2020). In genetics, NN have been used for phenotypic prediction, genome wide association studies, and breeding value construction with success (Liu *et al.*, 2019). The current project aims to identify the effectiveness of ML methods compared to GBLUP in binary classification breeding value creation.

Materials & methods

Genotypes and phenotypes. A total of 1,097 dogs were genotyped from a colony of guide dogs. This included 322 German Shepherds, 578 Labrador Retrievers, 127 Golden Retrievers, and 70 Golden Retriever Labrador Retriever crosses. The animals were genotyped on the Illumina Canine HD beadchip with 220k single nucleotide polymorphisms (SNPs). After the SNP call rate of >0.9, number of alleles <2, and minor allele frequency of >0.03 thresholds were set, 158,895 SNPs remained. A sample call rate of >0.9 cutoff removed 76 dogs. Genotypes were coded as 0, 1, 2 for all models based on the minor alleles. The percentage of dogs with class II mandibular distocclusion was 5.8%, for distichiasis it was 4.9%, and acral lick dermatitis had a percentage of 4.8%.

Statistical methods. Five-fold cross-validation was used to evaluate the models. The dataset was broken into five segments and each segment had a run as the test dataset while the other four were used for training. The models were scored based on the area under the receiving operating characteristic curve (AUROC) to adjust for the high probability of prediction accuracy alone being greater than 90% for all models due to the small percentage of cases. An analysis of variance (ANOVA) test compared the performance of the models across their cross-validations to determine the significance of any differences in performance.

Model creation. For the GBLUP, the efficient mixed-model association algorithm was used to identify the restricted maximum likelihood. The genomic-heritability was calculated for the three traits as well. The GBLUP model creation and testing were done through the SNP and Variation Suite v8.9.0 (Golden Helix, Inc., Bozeman, MT, www.goldenhelix.com).

The scikit-learn python package was used for all ML methods to create and test the models. Multiple versions of the five-fold cross-validation were run with different parameters to determine the optimal settings for each approach. The highest scoring parameters were used in the model included in the analyses. When testing the SVM classifier, the radial basis function kernel proved most accurate for the current dataset. For the RF classifier, the number of trees built before the average was taken, the maximum number of features before splitting a node, the maximum number of levels in a tree, the minimum number of data points before a node split, and bootstrapping were optimized. The maximum depth of regression estimators, maximum leaf nodes, number of boosting stages, and learning rate were the parameters that were set for the individual models while they all performed best with Friedman mean square error for the criterion. A multi-layer perceptron classifier was used for the neural network. The parameters varied for individual models included the learning rate, hidden layers, and hidden units.

Results

Initially, the genomic heritabilities were calculated with mandibular distocclusion, distichiasis, and acral lick dermatitis, propducing values of 0.532, 0.240, and 0.071, respectively. The top-performing model for each ML approach's results are listed in Table 1, along with the results from the GBLUP for the average AUROC and standard deviation. An ANOVA test was used to determine significant differences between the model's AUROC with the *P*-values being 0.182, 0.569, and 0.148 for mandibular distocclusion, distichiasis, and acral lick dermatitis respectively.

Table 1. AUROC average and standard deviation for the models.

	GBLUP	SVM	RF	GB	NN
Mandibular distocclusion	0.811±0.032	0.744±0.084	0.677±0.107	0.699±0.096	0.723±0.097
Distichiasis	0.939±0.040	0.894±0.125	0.906±0.085	0.919±0.078	0.832±0.155
Acral lick dermatitis	0.660±0.067	0.686±0.053	0.631±0.114	0.591±0.053	0.695±0.024

Discussion

For all three traits, there were similar levels of prevalence within the population of five percent. This low rate can make classification problems difficult as the class imbalance can lead to a bias towards the negative. With that, there was not a significant difference in the performance of any of the models in the present study with a trend for GBLUP to outperform the other models. This matches previous work with breeding values using regression methods (Srivastava *et al.*, 2021). The genomic heritabilities for the three traits studied varied, but the impact on model performance matched previous work using classifiers scored by AUROC comparing RF and GBLUP with simulated data (Naderi *et al.* 2016). The genomic heritability for distichiasis also aligned with previous estimates based on pedigrees (Peterson *et al.*, 2015). SVM trended as the highest performing ML model, which may indicate that it is better suited for binary traits compared to regression problems where it was not found to trend higher than GB or RF (Srivastava *et al.*, 2021).

In simulated studies, the number of quality trait loci plays an important factor in the effectiveness of RF in particular (Naderi *et al.* 2016). The usage of NN for association studies and quality trait loci identification could help provide a pipeline to help identify which model would be most appropriate for breeding value construction based on the results (Liu *et al.*, 2019). Other approaches have used RF and GB to subset SNPs which are then used to construct genomic relationship matrices for breeding value construction (Li *et al.*, 2018). This may indicate that a blending of approaches may be needed to maximize the ability to predict phenotypes based on genetic data.

ML models have become an increasingly popular tool across bioinformatics. Research into when different approaches can be more or less effective than other methods can allow researchers to better assist breeders in creating healthier and higher performing animals.

395. Predicting the polled genotype of ungenotyped animals using machine learning methods

A.B. Gjuvsland

Geno, Storhamargata 44, 2317 Hamar, Norway; arne.gjuvsland@geno.no

Abstract

Selection for polled in Norwegian Red cattle started 30 years ago and intensified the last 5 years. The SNP chip includes the (celtic) polled mutation, making selection very accurate for genotyped animals. However, ~85% of calves are ungenotyped and phenotypic horn status has been used to predict the polled genotype. This prediction has low accuracy (r^2=0.69) which limits genetic progress. To improve predictions, a broad set of variables related to horns were extracted from the herd registration system. Data for ~134,000 genotyped animals was used to train and compare different machine learning methods for predicting polled genotype. Gradient boosting machines performed best, followed by random forests, deep neural networks, and generalized linear models. The best gradient boosting machine gave a large improvement in accuracy (r^2=0.87). We have implemented this in the routine evaluations and expect increased accuracy of selection for ungenotyped animals and faster increase in polled allele frequency.

Introduction

The main genetic determinant of horns in cattle is the Polled locus, with the polled allele (*P)* dominant over horned (*p*). However, the genetics of horns is more complex (Grobler *et al.* 2021). Heterozygous polled (*Pp*) animals sometimes develop loose horn-like structures called scurs, and the inheritance and phenotypic expression of scurs is dependent on sex and breed. A number of scurs loci have been mapped on different chromosomes in different breeds (Gehrke *et al.* 2002) and in Norwegian Red cattle (NR), a scurs locus has been identified on BTA5 (Gjuvsland *et al.* 2019)

Historically, most NR were horned, but the celtic *P* allele (Medugorac *et al.* 2012) segregated in the population. In 1990 when selection for polled started the *P*-frequency was 2-3%. With genomics came new possibilities, a haplotype test was developed and later the causal mutation was added to the chip. When large-scale cow genotyping started in 2017, polled was included in the index (current weight 5%). For new-born calfs the *P*-frequency is now ~20%. For genotyped animals the number of P alleles is weighted into the index. However, ~85% of NR calfs are not genotyped and for these the predicted number of *P* alleles is used. Farmers register the phenotypic horn status for new-born calfs, and in each category the mean number of *P*-alleles among genotyped animals has been used for the ungenotyped animals. However, the accuracy of prediction is low, limiting the genetic progress for polled.

The machine learning ecosystem has developed rapidly in the last decade, with methodological breakthroughs and striking applications in many fields. The speed and breadth of development makes it challenging to identify the best algorithm and software for the problem at hand. Automated machine learning (AutoML) aims at automatizing the process of training models, tuning hyperparameters and comparing a wide range of algorithms as much as possible. Several powerful and easy-to-use AutoML packages are now available (Feurer *et al.* 2021, Ledell and Poirier 2020).

The goal of this work was to make a better predictor of polled genotype for ungenotyped animals. The approach taken here to achieve this is to use a wider set of relevant registrations and test a range of machine learning algorithms.

Materials & methods

Dataset. Records from 1,154,254 animals with published breeding values were extracted from the database used for routine evaluations, 134,155 of the animals were genotyped. Each animal in the data set was characterized by birthyear, gender and the variables in Table 1.

Cow features: For cows additional variables were computed: number of calfs (*Noff*), total number of *P* alleles for sires of the calves (*Npnum_sires*), number of calves registered as phenotypically 'Polled' (*Npolloff*) and number of dehorned calves (*Ndhoff*). Two additional variables were derived as: *off_score1=Npolloff-Npnum_sires* and *off_score2=Ndhoff/Noff*.

Herd features: Registration quality varies between herds and some herd variables were defined in an attempt to account for this: within-herd correlation between being registered as horned and being dehorned (*corr_HDH*), within-herd correlation between not being registered as polled and being dehorned (*corr_NPDH*), proportion of herd registered as horned (*rate_H*), proportion of herd not registered as polled (*rate_NP*) and the number of animals (*N_herd*).

Prediction method 1 Registered horn status, category-means. The first method for predicting genetic horn status (*Pnum*) for ungenotyped animals was based on the registered phenotypic hornstatus (*Hornbud*). Within each phenotypic category (Horned, Polled, Unknown) the mean number of *P-alleles* for genotyped animals was used as the predicted number *of P*-alleles for all the ungenotyped animals. This method was used in the routine runs for NR until 2021.

Prediction method 2 Genotypes of parents or male ancestors. Here we computed *Pnum_ped,* the expected number of *P* alleles inherited from the parents (Equation 1) or male ancestors (eq.2, if dam is not genotyped) of an animal. Equation 1 was used for animals with genotyped dams, and Equation 2 for animals with ungenotyped dams.

$$Pnum_ped = 0.5 \times Pnum_sire + 0.5 \times Pnum_dam \quad (1)$$

$$Pnum_ped = 0.5 \times Pnum_sire + 0.25 \times Pnum_mgs + 0.125 \times Pnum_smgd \quad (2)$$

Table 1. Records extracted for all animals in the dataset.

Variable	Description	Values
Pnum	Number of *P* alleles for the animal. NA if not genotyped.	0, 1, 2, NA
Hornbud	Horn bud registered by farmer at birth	horned, polled, unknown
Dehorned	Dehorning registered by veterinarian	0, 1
Dehorned_age	Age (days) at dehorning	integer
Pnum_sire, Pnum_dam, Pnum_mgs, Pnum_smgd	Number of *P* alleles for sire, dam, maternal grandsire and sire of maternal granddam of the animal. NA if relative is unknown or ungenotyped.	0, 1, 2, NA
Hornbud_dam	*Hornbud* for dam of animal	horned, polled, unknown
Dehorned_dam	*Dehorned* for dam of animal	0,1
Snum_sire	Number of scurs alleles for sire of animal	0,1,2,NA

Prediction method 3 Automatic machine learning with all variabless. Here we used automatic machine learning to predict genetic horn status (*Pnum*) from all the other variables. We used the AutoML functionality (LeDell and Poirier, 2020) in the H2O (http://h2o.ai) R-package v3.32.1.1. The following machine learning algorithms were included: generalized linear models with elastic net regularisation, distributed random forests, gradient boosting machines, fully-connected multi-layer artificial neural network and ensemble models. The automl function was run on 20 CPUs for 4 hours and 10-fold cross-validation was used for tuning of hyperparameters and model comparison.

Results & discussion

Distribution of horn bud and dehorning registrations. Phenotypic registrations of horn status (*Hornbud)* and dehorning correspond fairly well with polled genotype. The majority of *pp* animals are registered as horned, while most *Pp* and *PP* are registered as polled (Figure 1). For both *pp* and *Pp* animals there are small, but clear sex-differences in registered horn status, with male calves being registered as horned more often than females. When it comes to dehorning there is a substantial sex-difference for *Pp* animals, with 21.8% of the males and 3.5% of the females being dehorned.

Automatic machine learning. Gradient boosting machines (GBM) outperformed the other methods, while random forests, deep learning networks and generalized linear models had quite similar performance (Table 2). For many applications with complex data types like images, deep learning networks are superior, but for tabular data gradient boosting is often better (Shwarz-Ziv and Armon 2022). In many machine learning use cases an ensemble of all models outperform the best performing single model, but here there is practically no difference between the ensemble and the best GBM. GBMs are complex, non-linear models, but 'variable importance' allows for some interpretability. The best GBM ranks *Hornbud* as the most important variable, followed by *Pnum_sire, Dehorned* and *Hornbud_dam.*

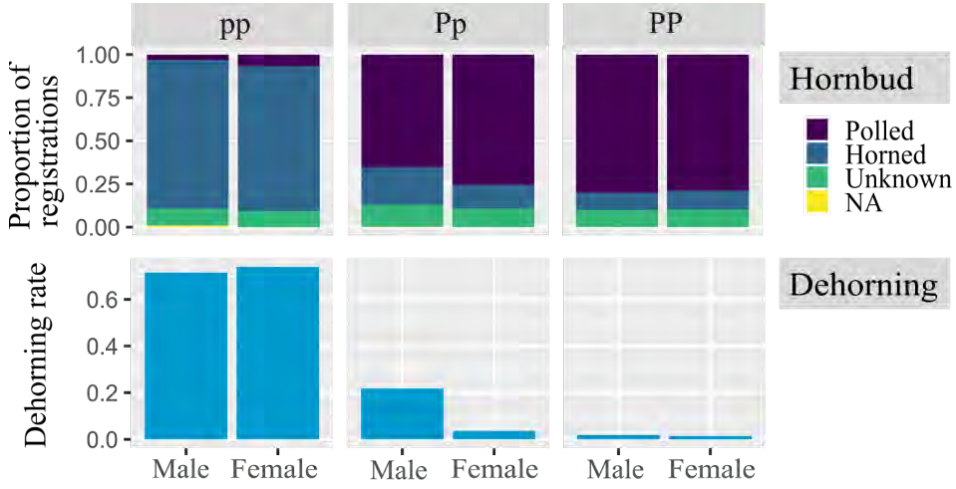

Figure 1. Horn phenotypes conditional on sex and polled genotype for 127K genotyped NR calves (92K females / 35K males) born 2005 or later.

Table 2. AutoML leaderboard.

Best model per algorithm	RMSE
Ensemble of all models	0.2959
Gradient boosting machine	0.2960
Distributed random forest	0.3208
Deep learning[1]	0.3336
Generalized linear model[2]	0.3385

[1] Fully connected multilayer neural networks.
[2] With elastic net regularization.

Comparison of prediction methods. Cross-validation (10-fold) on genotyped animals was used to evaluate and compare the prediction methods. *Pnum* and the predictions are numeric so we used correlation, rather than classification-metrics, to measure accuracy. Prediction of number of *P* alleles by registered horn status (Figure 2 red line) separates (on average) *pp* animals from *Pp* and *PP*, but it is unable to separate *Pp* from *PP* due to dominance. The accuracy, measured as the correlation to the true genotype (black line), is fairly low (cross-validated r^2=0.69). Using the expected number of *P* alleles from the genotype of parents or male ancestors (green line) separates *pp* from *Pp* and *Pp* from *PP*, but the accuracy goes down (r^2=0.61). Prediction with gradient boosting (blue line) separates well between the three polled genotypes and the accuracy increases substantially (r^2=0.87).

Conclusions and implementation

Machine learning with a broad set of variables gives a substantial increase in a prediction accuracy compared to prediction based on registered horn status. The prediction models are trained and validated on genotyped animals, however the practical use in the breeding programme is for predicting polled genotypes of ungenotyped animal. The value of the predictions therefore relies on the genotyped animals being representative for the whole population. We expect the genotyped animals to be representative in many aspects, but when it comes to things like unknown parents and pedigree errors there are systematic

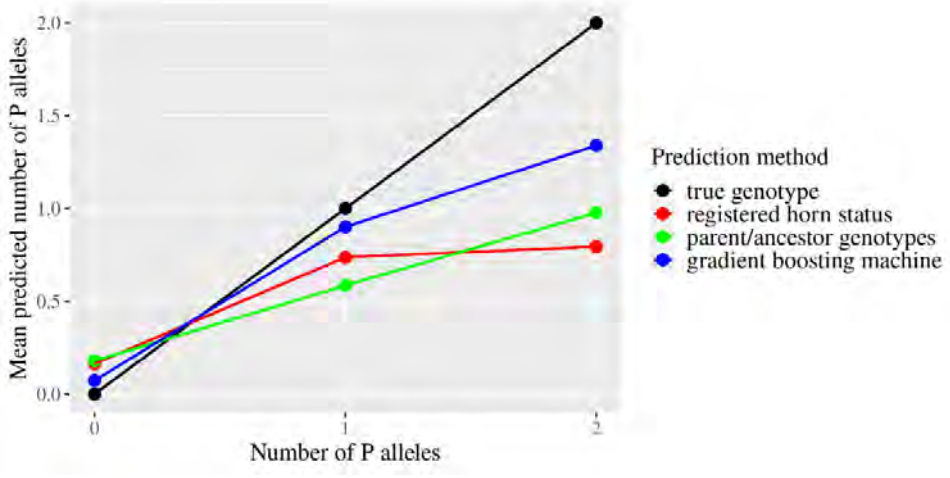

Figure 2. Mean predictions of polled genotype for genotyped animals. True number of *P*-alleles (x-axis) versus the mean predicted number (y-axis) when the genotype is masked in cross-validation.

differences and the prediction accuracy for ungenotyped animals will be lower than observed here. However, considering the low numbers of pedigree errors and unknown parents in the NR population we expect the predictions to be quite accurate for most animals and have implemented the gradient boosting method in our routine evaluations. This will give more accurate selection for polled in particular on the female side where many breeding animals in the herds and dams of potential selection candidates are ungenotyped.

396. A machine learning approach to classify high and low feed efficient or grower mink

A. Shirzadifar, G. Manafiazar, P. Davoudi, D.N. Do, G. Hu and Y. Miar*

Department of Animal Science and Aquaculture, Dalhousie University, Truro, Nova Scotia, B2N 5E3, Canada; miar@dal.ca

Abstract

This study aims at evaluating the feasibility of Machine Learning (ML) algorithms in classification of American mink (*Neovison vison*) into high/low performing groups for three different traits. Average Daily Gain (ADG), Feed Conversion Ratio (FCR), and Residual Feed Intake (RFI) were calculated for 1,088 mink over a period of 105 days. The 10% high and low feed efficient and grower animals were identified. To classify animals into the high/low feed efficient and grower groups based on the recorded features (initial weight and length at the bigining of the test, sex, age, and color-type), five common ML algorithms including Random Forest, Neural network, K-Nearest Neighbors, Logistic Regression, and Decision Tree were employed. The results showed that Random Forest was the most accurate algorithm in classification of 10% high and low ADG, FCR, and RFI groups with the accuracy of 98, 95, and 100%, respectively.

Introduction

Feed is the largest expense to the production of American mink (*Neovison vison*), which is the most widely raised fur-bearing animal in the world. Growth and feed efficiency traits such as Average Daily Gain (ADG), Feed Conversion Ratio (FCR), and Residual Feed Intake (RFI) are economically important traits that could be used to select the animals to increase the profitability of mink farmers (Yi *et al.*, 2018). Selection for growth and feed efficiency traits require substantial labor and resources to continually monitor Daily Feed Intake (DFI) and performance measures over a defined period. Alternatively, Machine Learning (ML) algorithms may potentially to be used to classify animals based on their feed efficiency (Nayeri, *et al.*, 2019). For instance, ML algorithms predicted the RFI class based on the gene expression levels in the liver and duodenum with an accuracy of 87% (Piles *et al.*, 2019). Therefore, the objective of this study was to investigate the feasibility of ML algorithms in classification of mink into high/low performing groups for ADG, FCR and RFI using the available features such as initial body weight, and length at the test bigining, sex, age, and color type.

Materials & methods

Data collection. Daily feed intake and body weight were recorded on 1,088 mink from the Canadian Centre for Fur Animal Research (CCFAR) at Dalhousie Faculty of Agriculture (Truro, NS, Canada) for 105 days from August 1st to November 14th in both 2018 and 2019. Additional information including sex, color type, body length, and age were recorded at the beginning of the experiment. Growth and feed efficiency measures (ADG, FCR, and RFI) were calculated using the following formulas (Jiao *et al.*, 2014):

$$\text{Average Daily Gain (ADG)} = \frac{\text{Final weight-Initial weight}}{\text{Test Period (Days)}} \quad (1)$$

$$\text{Feed Conversion Ratio (FCR)} = \frac{\text{Feed intake}}{\text{Average Daily Gain}} \quad (2)$$

$$\text{Residual Feed Intake} = \text{DFI}_{\text{actual}} - \text{DFI}_{\text{expected}} \quad (3)$$

CC BY

DOI: 10.3920/978-90-8686-940-4_396, © A. Shirzadifar *et al.* 2022

$$DFI_{expected}=\beta_0+\beta_1 ADG+\beta_2 BW^{0.75}+\varepsilon \quad (4)$$

$$BW^{0.75}=\left(\frac{\text{Initial BW+Final BW}}{2}\right)^{0.75} \quad (5)$$

Where β_0 is the intercept; β_1 is the partial regression coefficient of DFI on ADG; And β_2 is the partial regression coefficient of DFI on $BW^{0.75}$; and ε is residual error

Data analyses. The 10, 15, 20, and 25% high and low animals based on their ADG, FCR, and RFI records were identified as high and low groups. The middle group between high and low percentage groups was considered as conventional group and animals among this group were not classified. Five ML algorithms including Random Forest, Neural network, K-Nearest Neighbors, Logistic Regression, and Decision Tree were employed to classify the animals into high/low performing groups for each trait (ADG, FCR, and RFI) using initial body weight and length at the beginning of the test (the first day of test period), sex, age, and color-type. Twenty scenarios were considered for each ADG, FCR, and RFI traits including the combinations of five ML algorithms and four data sets (10, 15, 20, and 25% high/low) to test and find the most reliable scenario for the classification of animals into high and low feed efficiency and grower groups.

Classifier performance evaluators. The performance of ML was evaluated through a 10-fold cross-validation method. For this purpose, data were divided randomly into two parts for training (70% of data) and validation (30% of data), and the process was repeated 10 times. For each fold, the ML algorithms were developed with training data set and evaluated with validation data set. Results were compared with the actual data to evaluate the accuracy, sensitivity, specificity, precision, and F-measure. The ML algorithm performance was then evaluated using two classes including high and low groups based on the confusion matrix. Sensitivity and specificity represent the proportion of real high or low animals that are correctly classified. In precision calculation, the number of actual predicted high animals is divided by the total number of predicted high animals that were classified as true or false (Shirzadifar *et al.*, 2020). F-measure defines the harmonic mean of sensitivity and precision.

Results

The performance measures based on the 10, 15, 20 and 25% high and low ADG, FCR and RFI values were calculated for five different ML algorithms. The results indicated the high accuracy of over 90% in identifying the high and the low feed efficient and grower animals using ML algorithms and five features of initial body weight and length at the beginning of the test period, sex, age, and color-type. The most accurate ML algorithm was Random Forest with the accuracy of 98, 95, and 100% for 10% high/low ADG, FCR, and RFI groups, respectively. The confusion matrices of the Random Forest algorithm for high and low 10% groups are shown in Table 1. To assess the classification accuracy of ML algorithms, the total number of 64 (32+32) animals were used for the 10% high and low groups of ADG, FCR and RFI. Table 1 showed that 32 animals from high ADG group were correctly classified, while one animal from low ADG group was misclassified. There were two animals from low FCR group and one from high FCR group that were classified incorrectly. However, all animals in the high and low groups were correctly identified for the RFI data set.

To further evaluate the algorithms performance, sensitivity, specificity, precision, and F-measure were calculated in addition to accuracy. High accuracy (over 90%) was achieved for the 10, 15, and 20% high and low groups in all ML algorithms. Figure 1. illustrated the statistical measurements achieved by different ML algorithms for the 10% high and low groups.

Table 1. Confusion matrix of Random Forest classification based on the 10% high/low ADG, FCR, and RFI data sets.

		Predicted animal group								
		ADG			FCR			RFI		
		High	Low	Total	High	Low	Total	High	Low	Total
Actual animal group	High	32	0	32	31	1	32	32	0	32
	Low	1	31	32	2	30	32	0	32	32
Total		33	31	64	33	31	64	32	32	64

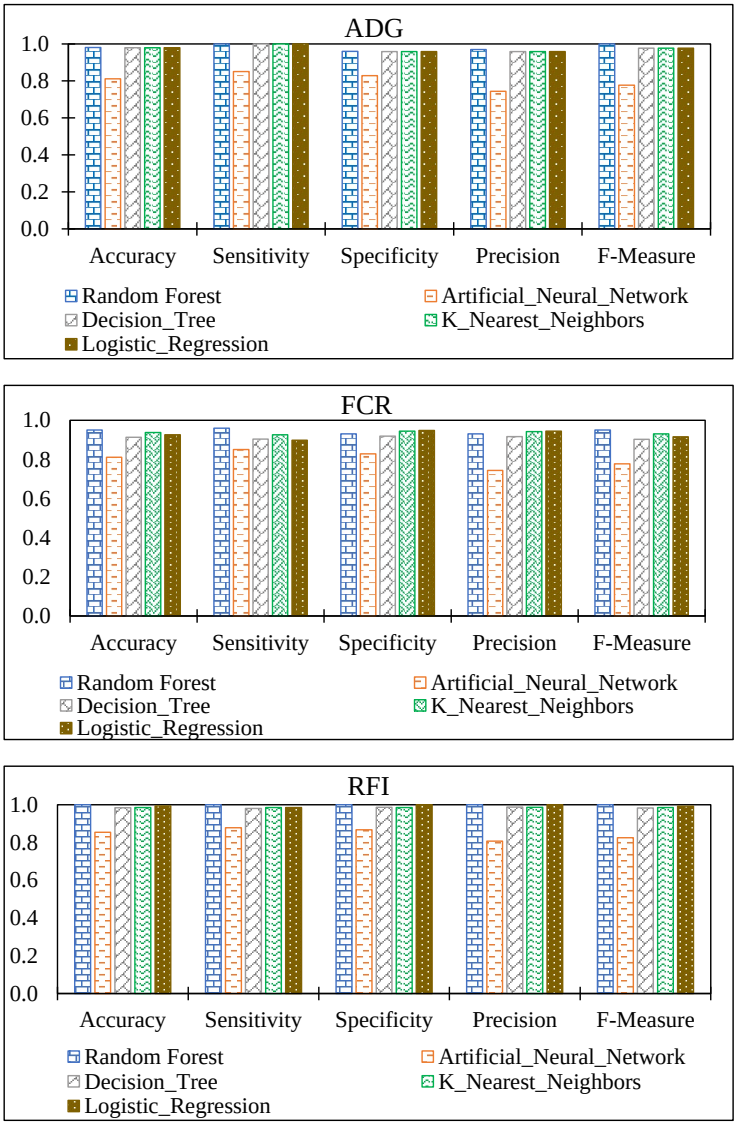

Figure 1. Performance measures achieved by different ML algorithms for the 10% high/low ADG, FCR, and RFI groups.

Discussion

This study demonstrated that ML algorithms were capable of identifying high/low performing mink groups for ADG, FCR and RFI traits based on the features including initial body weight and body length, at the beginning of the test, sex, age, and color-type without relying on expensive and labour intensive measurements. A high level of accuracy in prediction can be attributed to the high correlation between RFI, ADG, and FCR with the features used for prediction Although RF is the best method, all ML algorithms performed quite similarly; therefore, additional data is required to confirm if RF is the most appropriate approach.

Abstract

This study evaluated six machine learning (ML) algorithms in classification of beef cattle into the most and least feed efficient groups using genomic information. Residual Feed Intake (RFI; a measure of feed efficiency) and 50k SNP genotype data for 4,050 animals were included from research and commercial herds in this analysis. A genome-wide association study was performed to determine SNP effects on the phenotypic variation of RFI. Next, SNPs were sorted based on their contribution to phenotypic variation, and six new datasets were created containing 500, 1K, 5K, 10K, 15K, and 20K SNPs. To predict the most and least feed efficient groups, six ML algorithms (Random Forest, Neural Network, K-Nearest Neighbors, Logistic Regression Decision Tree, and Support Vector Machine) were tested. K-Nearest Neighbor, with an accuracy of 61%, was found to be the most accurate algorithm to predict the most and least feed efficient groups.

Introduction

Approximately 55-75% of the total cost beef production is attributed to feed, and feed efficiency has a significant role to play in enhancing profitability and competitiveness for the Canadian beef industry. Residual Feed Intake (RFI), as a measure of feed efficiency, is considered a more appropriate measure since it is independent of body weight, growth and body composition and is a reflection of maintenance requirements. The production of beef cattle with low RFI is desirable as they consume less feed than expected for their body weight and growth. RFI is calculated as the difference between an animal's actual feed intake and its expected feed intake based on the regression of DMI on metabolic body weight and post-weaning ADG of its contemporary over a defined feeding period (e.g. 74-84 days). RFI is, however, limited by a lack of facilities to record daily feed intake on individual animals and costs approximately $1.5-2.5 per animal per day, or more. Machine learning (ML) uses big data to learn from and create new opportunities to reveal any possible pattern associated with data. ML is now being applied increasingly in the medical and engineering fields; however, to date it has had limited uptake in livestock mainly due to the limited number of observations and number of recorded traits. Among the limited number of available reports, Piles *et al.* (2019) employed the Elastic Net algorithm to predict RFI class in swine based on gene expression levels found in the liver and duodenum tissues of 32 high and 33 low RFI pigs with 78% accuracy. Compiling RFI data over 12 years from different commercial and research herds in this study availed us to generate a large dataset and to assess the capabilities of ML algorithms to predict the most and least feed efficient beef cattle.

Materials & methods

Data acquisition. This study included RFI performance data and genomic data (genotyped utilizing the Illumina 50K SNP BeadChip) from 4,050 beef cattle collected over a 12-year (2003-2015) period from research and commercial herds. The RFI value for each animal was calculated across contemporary groups, and animals were sorted based on their RFI values. Animals in the 15% top and bottom of the range based on their RFI values were selected and considered as the most (negative RFI; n=607) and least (positive RFI values; n=607) feed efficient groups making a total of 1,214 animals.

Genomic analysis. The objective of the genomic analysis was to demonstrate to what degree phenotypic variation in RFI is accounted for by the SNPs of a 50k panel, and to choose a set of highly significant SNPs in order to reduce the dimensionality of the dataset for the development of ML algorithms. Using a quality-control procedure, SNPs with frequencies less than 0.05 and call rates less than 0.95 were excluded from the genomic dataset. A total of 42,689 SNPs was considered for further analysis with a mean frequency of 0.54 and a variation of 0.07.

The method of single-step regression was used to detect SNPs, and SNPs associated with RFI using BLUPF90-family software package program. The variance components of RFI were estimated using the following model:

$$y = Xb + Zu + e \quad (1)$$

where y represents RFI, and X is an incidence matrix relating RFI to fixed effects. In this model b is the vector of fixed effects solutions, Z is the incidence matrix that relates animals to each other and to phenotypes, u is the vector of breeding values, and e is the vector of random residuals. Following the estimation of SNP marker effects using model 1 with the data set of 4,050 beef cattle, SNPs were sorted in descending order based on the percentage of the genetic variance accounted for by each SNP. To reduce dimensionality, 6 different sets of SNPs (500,1K, 5K, 10K, 15K, and 20K SNPs) were selected based on their contribution to phenotypic variation in RFI.

Machine learning analysis. Six common machine learning algorithms were used to predict the most and least feed -efficient groups. The algorithms were Random Forest, Neural Network, K-Nearest Neighbors (KNN), Logistic Regression, Decision Tree, and Linear Support Vector Machine. Thirty-six scenarios were tested to predict the highest and lowest RFI groups in a binary formats with the combinations of six ML algorithms and six genomic datasets (500, 1k, 5k, 10k, and 15k and 20K SNPs) to identify the most reliable scenario for classifying the most and the least efficient animal groups.

Classifier performance evaluators. The performance of the ML algorithms was evaluated using a 10-fold cross-validation procedure. Specifically, the data were randomly divided between training (70%; n=848) and validation (30%; n=366) sets, and the process was repeated ten times. For each fold, the ML algorithms were developed using training datasets and evaluated with a validation dataset. Results were compared with observed RFI groups to evaluate the accuracy, sensitivity, specificity, precision, and F-measure. Following that, we evaluated the performance of the ML algorithms using two classes of the most and least efficient animal groups based on the confusion matrix. In the confusion matrix, each row represents an instance in an actual class, while each column represents an instance in a predicted class, or vice versa (Piryonesi *et al.*, 2020). Sensitivity and specificity are the proportion of actual high- or low-efficiency animals correctly classified in each scenario. In precision calculation, the number of actual predicted most efficient animals is divided by the total number of predicted most efficient animals that were classified as true or false (Shirzadifar *et al.,* 2020). F-measure defines the harmonic mean of sensitivity and precision.

Results

Genomic analysis results. Results from the GWAS analysis and individual SNP effect are illustrated in the form of Manhattan plots (Figure 1). For the Manhattan plot, the Y axis represents the negative logarithm of the *P*-value for each single nucleotide polymorphism (SNP), and the X axis is the chromosomal location of the SNP. Each dot on the Manhattan plot signifies a SNP. The top10 highly significant SNPs are located on chromosomes 14, 2, 16, 18, 1, 5, 3, 22, 8 for RFI.

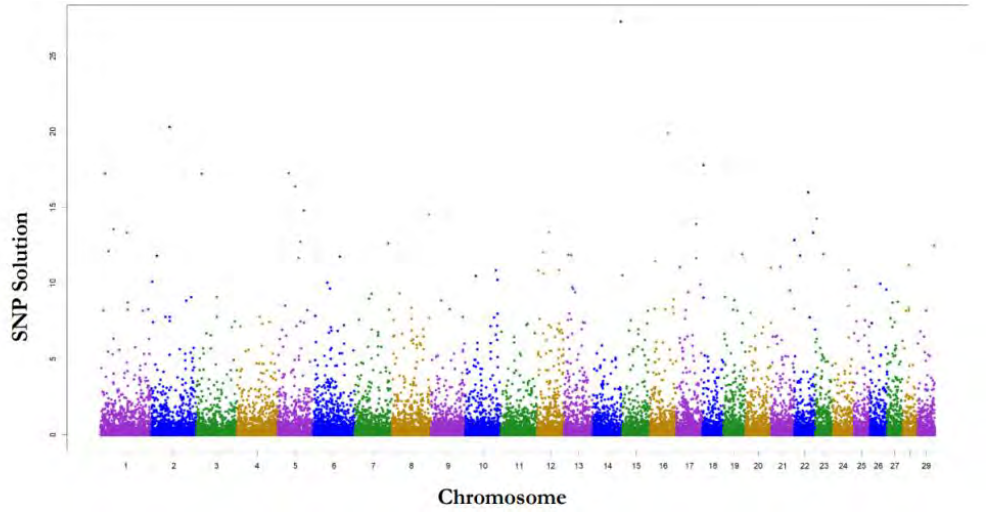

Figure 1. Manhattan plot of single nucleotide polymorphism (SNP) variance explained by each SNP for RFI.

ML algorithm classifier performance results. The performance measures based on genomic datasets including 500, 1k, 5k, 10k, 15k, and 20K SNPs were calculated for six different ML algorithms. The results showed an accuracy of over 53% in identifying the most efficient and the least efficient groups in all selected genomic datasets, excluding logistic regression. On a 15 K genomic dataset, KNN algorithem was the most accurate ML algorithm with an accuracy of 61% (Figure 2.). Nevertheless, the accuracy of the Logistic Regression algorithm decreased dramatically when the numbers of SNPs were increased. To further evaluate the algorithms' performance, sensitivity, specificity, precision, and F-measure were calculated in addition to accuracy. The performance of the KNN algorithm using 15K genomic dataset was the highest among the combination of the other ML algorithms with genomic datasets.

Figure 2 illustrates the statistical measurements of the performance of 15% sorted value for different ML algorithms in 15K dataset. The accuracy, sensitivity, specificity, precision, and F- measure were obtained 61, 60, 64, 61, and 60%, respectively in 15K genomic dataset.

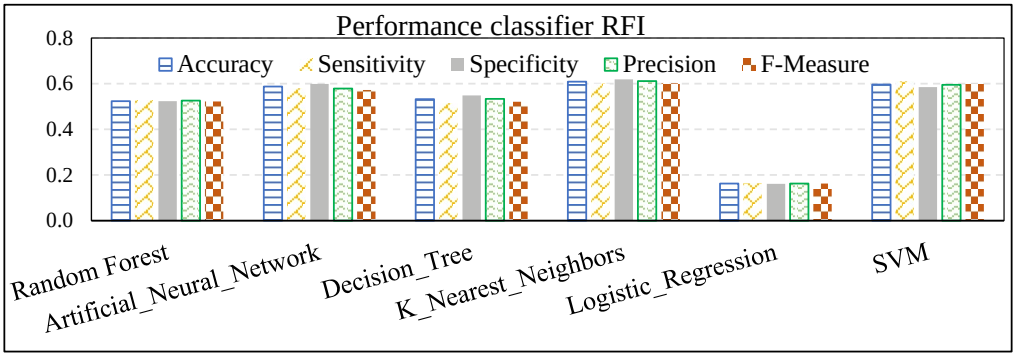

Figure 2. Performance measures for 15% sorted value and different ML algorithms based on RFI.

Table 1 presents the test set validation results (confusion matrix) of KNN analysis for all genomic datasets. It was noted that in classifier performance evaluators, 70% of the dataset were used to develop the model and 30% was selected at random to test the accuracy of the prediction. A total number of 366 animals (183 animals within each group) as a test was used to assess the classification accuracy of ML algorithms using different sets of SNPs, and the results are demonstrated in Table 1. The results based on confusion matrix demonstrated that 15K SNPs had the best predictability such that 101 out of 183 animals were correctly classified in the most efficient group, and 118 out of 183 animals from the least efficient animal group were correctly classified.

Table 1. Confusion matrix of KNN algorithm classifier based on 15% RFI and selected genome datasets.

		Predicted animals											
		500		1K		5K		10K		15K		20K	
		ME[1]	LE[2]	ME	LE	ME	LE	ME	LE	ME	LE	ME	LE
Actual animals	ME	98	85	89	94	90	93	97	86	101	82	95	88
	LE	89	94	66	117	87	96	88	95	75	118	72	111
Total		187	179	155	211	177	189	185	181	176	200	167	199

[1] ME = most efficient.

[2] LE = least efficient.

Discussion

This study demonstrated that KNN algorithms has potential to identify the most and the least efficient animal groups based on genomic information of beef cattle without relying on expensive and hard-to-measure traits such as dry matter intake. The output of this project presents evidence of how new ML-based algorithms have the potential to be used in the livestock breeding industry.

398. Combination of SNP markers for discrimination of a target chicken population using machine learning algorithms

E. Cho, S. Cho, M. Kim, T.K. Ediriweera, D. Seo and J.H. Lee*

Chungnam National University, 99, Daehak-ro, Yuseong-gu, 34134, Daejeon, Republic of Korea; junheon@cnu.ac.kr

Abstract

Identifying target populations using genetic information is a necessary aspect for the conservation of pure breed and discrimination of chickens in the market scenario. In this study, the optimal combination of single nucleotide polymorphism (SNP) markers for discriminating the target chicken breed (the Yeonsan Ogye breed) was presented using high-density SNP chip data. SNP markers specific to the target population were discovered through case-control genome-wide association study (GWAS) and filtered out based on the linkage disequilibrium blocks, and optimal SNP markers were selected by applying a machine learning algorithm. Through the machine learning approach, the identification power of the 38 optimal SNP marker combination for the specific chicken population was confirmed, and the marker combination demonstrated complete accuracies. Hence, the GWAS and machine learning models used in this study can be efficiently utilized to find out the optimal combination of markers that can discriminate target populations using multiple SNP markers.

Introduction

Yeonsan Ogye, characterized by black feathers, skin, and bones, is one of the Korean native chicken (KNC) breeds and is highly regarded as a natural heritage. Generally, the methods for identifying chicken breeds are based on morphological characteristics, but distinguishing them from other breeds with similar morphology is difficult. From this point of view, genetic information can be used effectively for precise identification. Various genetic markers have been developed and used to obtain genetic information, but the most effective tool of genetic markers for discrimination of target breed is single nucleotide polymorphism (SNP) markers. The SNP genotype data can provide rapid and accurate information with selected marker combinations for breed identification. The objective of this study was to select the optimum SNP marker combination to discriminate a target chicken population (Yeonsan Ogye) from other populations using machine learning algorithms.

Materials & methods

Samples and genotypes. A total of three data sets were used in this study: Set 1 and Set 2 for selecting SNP markers, and Set 3 for validation test. Set 1 and Set 2 consisted of 198 populations (3,904 individuals), genotyped with Affymetrix 600K SNP array (Kranis *et al.*, 2013). Set 3 constituted 127 individuals, genotyped with custom 60K SNP array and Illumina 60K SNP array (Groenen *et al.*, 2011). The imputation step was performed before analysis using 60K genotype data. More information on each set has shown in Table 1.

Pre-processing and SNP pruning. Based on the genotype call rate (missing rate ≥10%) and the minor allele frequency (MAF≥0.05), 542,717 SNPs were derived from the merged common SNPs. These SNPs were analysed for case-control genome-wide association study (GWAS) using PLINK 1.9 software. In this analysis, the case group was the Yeonsan Ogye population, whereas the control group was composed of the other populations. Following the case-control test, the linkage disequilibrium (LD) was calculated, and the LD-block based SNP pruning analysis was conducted to select one SNP per each of the 50 LD blocks.

		SYNBREED[3]		3,235	
Validation test	Set 3	Yeonsan Ogye		67	127
		KNC		30	
		Crossbreed of Yeonsan Ogye and White Leghorn		30	

[1] SNP, single nucleotide polymorphism.

[2] KNC, Korean native chicken.

[3] Various other global chicken breeds from the SYNBREED project in Germany (Malomane *et al.*, 2019).

Feature selection. The feature selection by machine learning methods was applied for pruned SNP markers. The feature importance value was calculated through the Random Forest machine learning algorithm. Finally, the optimum SNP marker combination was selected with values higher than the average feature importance value.

Evaluation of the accuracy. To confirm the accuracy for discrimination of the target chicken population, eight different machine learning models were used: Decision Tree, AdaBoost, Support Vector Machine, Quadratic Discriminant Analysis, Random Forest, Linear Discriminant Analysis, K-Nearest Neighbours, and Naïve Bayes. To resolve data imbalance before analysis, only one individual from each group was randomly sampled in the control group consisting of 197 populations. Accordingly, the data set was split into two sets based on the five times repeated K-fold cross-validation (K=10): training set (70%) and test set (30%). We used the 'caret' package in R software to build classification models.

Results

Principal component analysis (PCA) was performed to confirm the genetic distribution trend of the entire population using 600K SNP genotype data. As a result, the Yeonsan Ogye population was remarkably clustered from the SYNBREED populations, as well as the KNC populations (Figure 1). A total of 38 SNPs

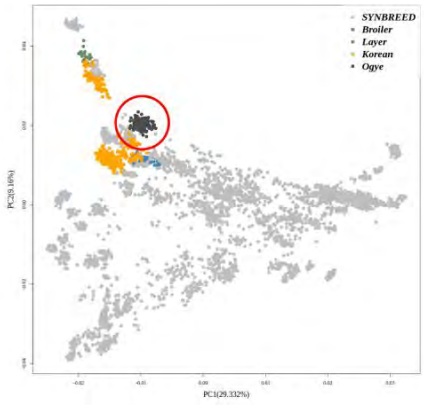

Figure 1. PCA plot based on 600K SNP genotype data. Note that Yeonsan Ogye population (inside red circle) is a distinct population by comparing with the data from Korean breeds and the global SYNBREED populations.

was selected through the SNP pruning and feature selection processes. In the machine learning approach for evaluation of the classification using 38 optimal SNPs, all of the algorithms discriminated the Yeonsan Ogye population precisely (Figure 2). All confusion matrix values (Accuracy, Specificity, Sensitivity, Precision, and F1-score) were also confirmed to be 1.00. In the case of the validation test, the 30 SNPs overlapped with the previously selected markers. Even with these markers, it was possible to sufficiently differentiate the targeted population.

Discussion

Strategies for optimal breed identification are utterly important in livestock conservation and research. The capability to discriminate chicken breeds at the genetic level could increase consumer confidence and protect unique genetic resources. Recently, a large amount of produced genotype data is available as biomarkers in various ways. However, finding optimal SNP markers for identifying targeted populations using high-density SNP chips is still quite complex.

According to previous studies, SNP markers were used for genetic classification based on PCA, *F*-statistics, and genotype frequencies (Suekawa *et al.*, 2010; Wilkinson *et al.*, 2011). In this study, significant markers were obtained based on the GWAS and LD pruning results using 600K high-density SNP chip data. Johnson *et al.* (2010) explained that it is often difficult to determine which genetic markers identified through GWAS are actual causative genes in response to LD. Also, according to Bakshi *et al.* (2016), more effective results were obtained when removing SNPs with strong LD relationships and using them for analysis. In this analysis, it was also demonstrated that the target group was effectively discriminated when the SNP markers were selected in consideration of the LD relationship.

We applied machine learning algorithms to determine efficient marker combinations using preselected SNPs. In previous studies, it was confirmed that machine learning was applied to discover and select SNP markers (Seo *et al.*, 2021; Schiavo *et al.*, 2020). In addition, selecting markers by applying the feature selection technique to the GWAS results can reduce dimensions and overfitting errors, resulting in more accurate predictions (Bermingham *et al.*, 2015).

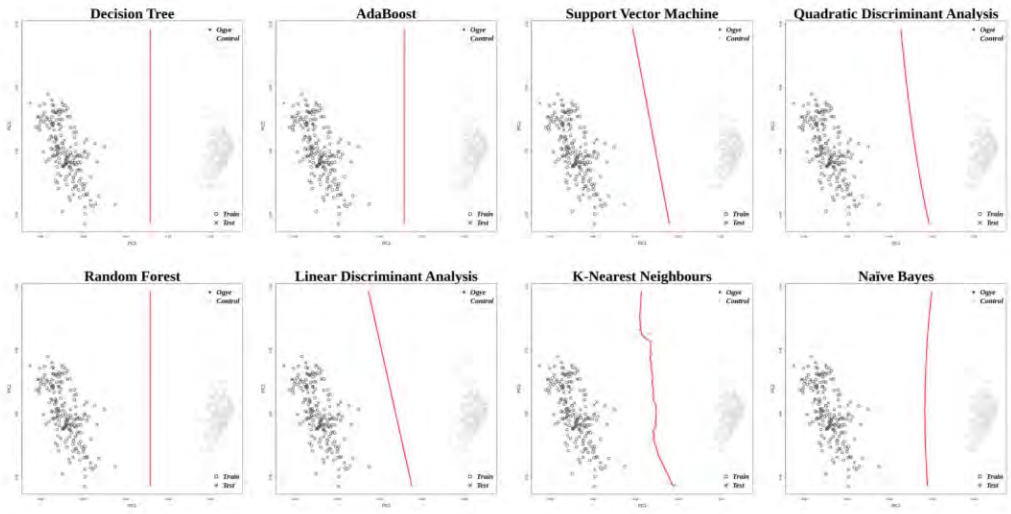

Figure 2. Group clustering trend plot for eight machine learning models using 38 SNPs.

The decisive reason for obtaining such precise results might be that the Yeonsan Ogye was a genetically unique breed. It was verified that the Yeonsan Ogye had an independent gene pool from entirely black chickens in the SYNBREED group such as Cemani and Sumatran from Indonesia, and Silkies from China.

The combinations selected for identification targeting the Yeonsan Ogye pure line showed impressive results in the validation test. The 30 SNPs correctly differentiated KNC and Yeonsan Ogye as in the SNP selection process. In addition, the crossbreed groups between the Yeonsan Ogye and White Leghorn were also clearly distinguished. These marker combinations showed the ability to discriminate the individuals with the same phenotype as those of the purebred Yeonsan Ogye individuals.

Since the breed-specific markers are identified through the pure lines, there is a limitation as an application to breeds that have not been verified under the marker selection process. Of course, although verification analysis was performed on crossbreed in this study, it would be complicated to flexibly react to hybridizations with other breeds other than White Leghorn. Therefore, the accuracy of the discrimination power possessed by the optimal SNP marker combination will be properly recalculated when information composed of more diverse populations is additionally provided.

Identification of populations by combinations of SNP markers can efficiently discriminate different types of populations and confirm their genetic diversity. Ultimately, this can be used as a way to protect the right to use a specific breed population in a society where breeds can secure national competitiveness as a genetic resource.

399. LASSO and SVM: an alternative approach to identify associated genome regions for simple and complex traits in cattle

S. Widmer[1*], F.R. Seefried[2], C. Drögemüller[1] and P. von Rohr[2]

[1]*Institute of Genetics, University of Bern, Bremgartenstrasse 109a, 3012 Bern, Switzerland;*

Abstract

Variable selection via the LASSO regression analysis followed by a classification of phenotypes into two groups of cases and controls using SVM was performed to identify genomic regions associated with phenotypic traits of interest. This approach was successfully validated by identifying previously known genomic associations for two Mendelian traits and a complex polygenic trait in Swiss cattle populations. Furthermore, new associated regions for the trait multiple birth were found in Holstein. Therefore, this approach proved to be a valuable alternative to identify associated genomic regions for inherited traits in livestock.

Introduction

Support Vector Machine (SVM) is a general-purpose classification method (Cortes and Vapnik 1995) and is used in many fields (James *et al.* 2021). For example, it was able to find SNPs associated with the risk for type 2 diabetes in humans and to perform genotype-based predictions of the affection status (Ban *et al.* 2010). SVM classifies data consisting of different groups by separating hyperplanes. The separating hyperplanes are defined by explanatory variables such as SNP genotype effects. This definition makes SVM suitable to analyse data that can be divided into two groups, e.g.: cases and controls. Although SVM can be used for high-dimensional data, it is important to first identify the subset of relevant explanatory variables. It is necessary to select relevant SNPs to avoid overfitting which might impair classification negatively. Least Absolute Shrinkage and Selection Operator (LASSO) performs variable selection in a linear model using a constraint on the norm of the absolute values of the coefficients (Tibshirani 1996). LASSO regularizes the coefficient estimates, shrinks them towards zero and consequently reduces their variance significantly (James *et al.* 2021). Combining LASSO and SVM together with using raw phenotypes instead of predicted breeding values promises a highly computational efficient method.

In this study, we first validated the proposed method as an alternative approach to detect genomic associations for two Mendelian traits: *CNGB3*-related achromatopsia, also reported as Original Braunvieh Haplotype 1 (OH1) (Häfliger *et al.* 2021) and *TWIST2*-related depigmentation known as belt pattern (Awasthi Mishra *et al.* 2017). Subsequently we applied the workflow on stature in Holstein, a complex but well studied genetic trait (Bouwman *et al.* 2018). Finally, the proposed method was used to find new genomic regions associated with the trait multiple birth in Holstein cattle, representing a still poorly understood polygenic trait.

Materials & methods

Phenotypes. The proposed approach was validated using three different datasets of three different Swiss cattle populations (Table 1). The phenotypic and genotypic data were provided by the Swiss cattle breeding organisations. The definition of cases and controls for both monogenic traits achromatopsia and belt was based on phenotypic observations. Regarding the trait stature, cows in first lactation born between 2016 and 2019 with an age at first calving between 730 and 820 days were selected. From the routine conformation scoring, 500 top / bottom cows for measured sacrum height were used to define the groups of cases and controls, respectively. For multiple birth, dams with at least one multiple birth event (mostly twins) were defined as cases and dams with at least 3 singleton calvings as controls.

Table 1. Final datasets per trait and the sizes of the respective case and control groups.

Trait	Population	No. cases	No. controls	No. SNP
Achromatopsia	Original Braunvieh	8	231	670,140
Belt	Brown Swiss	92	1,644	675,828
Stature	Holstein	500	500	680,502
Multiple birth	Holstein	238	919	683,277

Genotypes. Animals were genotyped under the umbrella of genomic selection using different arrays that include between 9k and 850k SNPs. A standard imputation approach was applied, which led to the final datasets (Table 1).

LASSO. LASSO uses the residual sum of squares plus a penalty term to estimate coefficients and to do variable selection in a linear model (Tibshirani 1996). LASSO was described in detail by James *et al.* 2021. The LASSO analyses were carried out using the R-package glmnet (Friedman *et al.* 2010). The parameter λ was estimated using a ten-fold leave-one-out cross-validation. The cross-validation resulted in two different estimates for λ: λ_{min} is the estimate with lowest cross-validation error. Adding one standard error to λ_{min} leads to λ_{1se}. Both estimates of λ were used in the LASSO analyses for all four datasets. LASSO resulted in a smaller set of SNPs compared to the complete marker-set.

SVM. SVM separates two groups of data (such as cases and controls) with the hyperplane that maximizes the distance to the training data of the two groups (Cortes and Vapnik 1995). The separating hyperplane is determined by the training data (James *et al.* 2021) that we defined as a random sample of 80% of the complete dataset. The remaining 20% of the data is used as test data to validate the estimated classification model. A linear kernel was used for classification. For SVM analyses R-package e1071 was applied on the SNPs selected by LASSO for the validation of the variable selection (Meyer *et al.* 2021). The prediction of animals outside the high and low groups is not considered yet.

Results

The results of the LASSO analyses of the four datasets are shown in Table 2. Using λ_{1se} instead of λ_{min} led to a lower number of SNPs selected by LASSO for all datasets.

From the LASSO analysis, the absolute coefficient values were combined using a sliding window approach whereof each window consisted 50 SNPs. Window coefficients are plotted as a function of their chromosomal position (Figure 1). Only windows with a higher impact on the trait and the colocalization of possible candidate genes were considered (Table 3). Therefore, the window coefficients must be higher as the 5-fold standard deviation of all absolute coefficients. For each of the two Mendelian traits, as expected

Table 2. Results of LASSO and SVM analysis for all four traits.

	LASSO No. SNP		SVM rate of correct prediction (%)		SVM F_1 score	
Trait	λ_{min}	λ_{1se}	λ_{min}	λ_{1se}	λ_{min}	λ_{1se}
Achromatopsia	8	5	100	100	1	1
Belt	1,243	420	100	100	1	1
Stature	674	393	100	100	1	1
Multiple birth	232	1	89.7	76.3	0.765	0.035

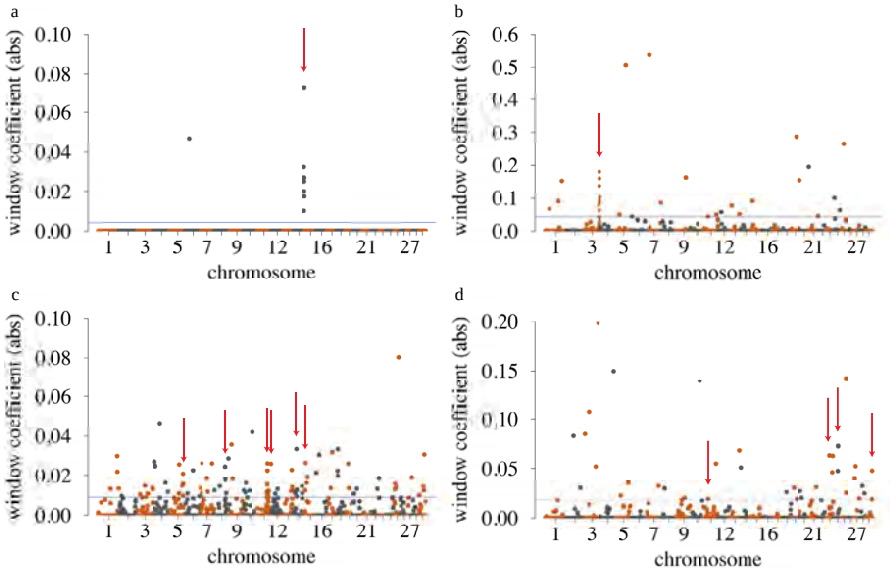

Figure 1. Genome-wide Manhattan plots of the sum of the absolute coefficient values for each window. For (a) achromatopsia and (d) multiple birth λ_{min} was used, while for (b) belt and (c) stature λ_{1se} was used. Red arrows are highlighting the QTL from Table 3 and the blue lines indicate the values of the 5-fold standard deviation of all absolute (abs) window coefficients per trait.

a clear signal was identified on BTA 14 for achromatopsia and BTA 3 for belt, respectively (Figure 1a and 1b). For the trait stature, multiple QTL regions were observed (Figure 1c). Several associated regions were identified for multiple births in Holstein (Figure 1d). The rate of correct predictions from SVM analysis (Table 2) using the test data was 100% (F_1 score=1) for all three validation datasets and for both variants (λ_{1se} and λ_{min}). For the trait of multiple birth, the rate of correct predictions in the test data reached 90% using λ_{min} (F_1 score=0.765).

Discussion

For all four analysed traits, LASSO resulted in a set of SNPs which is considerably smaller compared to the complete marker-set. This forms the basis for the identification of associated genomic regions using raw phenotypes. Using λ_{1se} instead of λ_{min} resulted in a lower number of SNPs selected, as expected from the properties of LASSO. The resulting set of SNPs was used in an SVM classification to group the data into cases and controls and to validate previous results. The rate of correct predictions of SVM for both λ-estimates were comparable and hence λ_{1se} (except for achromatopsia and multiple birth) was favoured because it yields sparser models. Regarding the monogenic recessive disorder achromatopsia, LASSO selected correctly the region of *CNGB3* on BTA 14 (Häfliger *et al.* 2021). For the monogenic dominant inherited belt phenotype, a signal in a window on BTA 3 with *TWIST2* was observed (Awasthi Mishra *et al.* 2017). Concerning stature, two regions on BTA 11 and the signals on BTA 5, 8 and 14 were previously reported as QTL for bovine height in a meta-analysis using the 1000 Bull Genomes project data (Bouwman *et al.* 2018). We propose *MMP13* as a new candidate gene mapping to the region of a QTL found on BTA 15 for stature in cattle, as it influences bone mineralization and growth plate cartilage (Ståhle-Bäckdahl *et al.* 1997). Finally, regarding multiple birth in Holstein, we found multiple associated regions with genes related to the reproduction cycle and oocyte maturation (Table 3). The QTL in the region of *FSHR* and *LHCGR* genes on BTA 11 agrees well with recent findings of GWAS and classical fine mapping approaches

Table 3. Identified associated genome regions with selected candidate genes for the four analysed traits.[1]

Trait	BTA	Start position[2]	End position[2]	Coefficient[3]	Candidate gene[2]
Achromatopsia	14	75,583,503	78,489,957	0.2055	*CNGB3*
Belt	3	117,018,007	118,619,571	0.7183	*TWIST2*
Stature	5	104,712,189	105,942,817	0.0467	*CCND2*
	8	80,544,099	83,316,183	0.0551	
	11	79,311,390	79,594,907	0.0347	
	11	105,098,263	105,220,577	0.0258	
	14	19,996,921	23,379,474	0.0688	*PLAG1*
	15	4,836,530	5,916,553	0.0389	*MMP13*
Multiple birth	11	31,139,464	31,340,099	0.0236	*FSHR, LHCGR*

	24	33,994,132	36,319,363	0.1255	*GATA6, ENOSF1, ADCYAP1*
	29	48,563,749	50,109,725	0.0671	*IGF2, INS, CTSD*

[1] For achromatopsia and multiple birth using λ_{min} and for belt and stature using λ_{1se}.

[2] Using the ARS-UCD1.2 reference assembly.

[3] Sum of all absolute values of the coefficient in the interval (typically more than one window).

using predicted breeding values (Widmer *et al.* 2021). Dichotomizing the quantitative trait by selecting extreme phenotypes as cases and controls helped here to unravel the potential genetic factors important for the expression of the phenotypes of interest. The rates of correct predictions from SVM were 100% for the three validation datasets and 90% for multiple birth (using λ_{min}), respectively. Hence, the validation of the herein applied alternative methods was successful.

In conclusion, using the combination of LASSO variable selection and SVM classification, we were able to detect associated genome regions for simple and complex inherited traits in cattle using raw phenotypes. Therefore, we propose this approach as a valuable and efficient alternative to GWAS based on predicted breeding values.

Abstract

Identifying functional conservation between human and pig genomes is an important challenge in pig model studies. To evaluate it, we predicted conservation scores through fitting a neural network model based on the integration of multi-tissue epigenetic and gene expression profiles. We then integrated the conservation score with chromatin state and human expression quantitative trait loci (eQTL). The average conservation score for promoters was higher than enhancers as expected. The conservation scores for human regions with eQTL were higher than the average level of the whole genome. In addition, eQTLs with higher conservative scores had a smaller effect size than those with lower scores. In conclusion, the model reflected the genome-wide functional conservation between human and pig, which can be easily extended to other species, and could be further utilized to reveal the conserved patterns linked to complex traits.

Introduction

The investigation of genome conservation not only reveals evolutionary evidence (Alföldi and Lindblad-Toh, 2013), but also helps with the integration of genetic findings across different species (Raymond *et al.*, 2020). The genomic conservation between human and domestic pig (*Sus scrofa*), a relevant biomedical model for certain human diseases, is of importance and interest. Previous studies investigated the functional conservation between human and pig based solely on the gene expression profile (Sjöstedt *et al.*, 2020) or the epigenomic profile (Pan *et al.*, 2021), but not all available functional data were integrated simultaneously to quantify the conservation. Kwon and Ernst (2021) developed a neural network model to study human-mouse functional conservation based on multi-omics information and showed that their method can be used to explain the phenotype-associated variation. In this study, we aim to implement a neural network model to evaluate genome-wide functional conservation between pig and human based on the integration of large-scale epigenetic data and gene expression data across multiple tissues.

Materials & methods

The overview of the model development is shown in Figure 1. To define pairs of human and pig regions for training and prediction, we first obtained the pairwise sequence alignment between the human genome (hg38) and the pig genome (Sscrofa11) from the UCSC Genome Browser (Navarro Gonzalez *et al.*, 2021). We then divided the alignment into non-overlapping 50-bp windows, which resulted in 38,961,932 aligned pairs. We randomly paired up human and pig regions included in the aligned pairs to get the same number of unaligned pairs.

For each aligned and unaligned pair, we obtained the corresponding human and pig functional features, including gene expression measured by RNA-seq, chromatin accessibility measured by Assay for Transposase-Accessible Chromatin (ATAC-seq), histone modifications measured by Chromatin Immunoprecipitation sequencing (ChIP-seq), and chromatin state annotations (ChromHMM). Human features were collected from ENCODE (The ENCODE Project Consortium, 2012) and Roadmap Epigenomics Project (Kundaje *et al.*, 2015), and pig features were from https://doi.org/10.6084/m9.figshare.13480425 (Pan *et al.*, 2021). In total, we collected 313 and 312 functional features for human and pig, respectively.

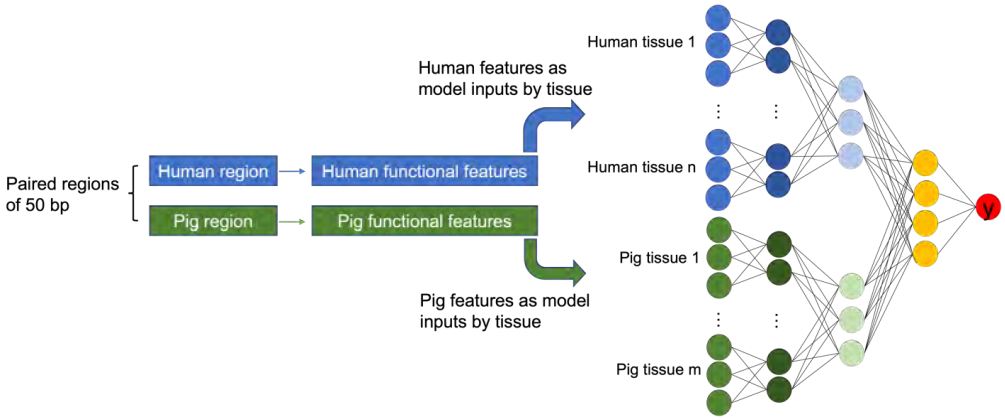

Figure 1. The schematic of the artificial neural network model. The functional features of human and pig in the paired (aligned or unaligned) regions are used as the model inputs by species and tissue, to predict the conservation score (y). When training the model, the response variables (labels) for aligned pairs are coded 1 while those for unaligned pairs are coded 0.

Aligned regions are conservative at the sequence level but not necessarily at the functional level. However, unaligned regions are much less likely to be conservative given different sequence information. Based on this, we presumed the aligned regions to be conservative (coded as 1) and unaligned ones to be unconservative (coded as 0). Thereby a pseudo-Siamese neural network model was trained based on the alignment (1 or 0) as the response variable and corresponding functional features as the predictor variables (Figure 1). To reflect the tissue-specific information in the model structure, the input and first two hidden layers were not fully connected. Instead, the input layer and the first hidden layer were connected by species and tissue, and the first and second hidden layers were connected by species. Although the response variable is binary when training the model, the output was transformed through a sigmoid activation function. Therefore, a continuous conservation score between 0 (not conserved) and 1 (highly conserved), could be predicted for any paired regions based on the functional features.

To predict the conservation score of human regions from even (or odd) chromosomes, and the corresponding paired pig regions, a neural network model was trained based on human odd (or even) chromosomes and paired pig regions. The area under the receiver operating characteristic (ROC) curve was assessed by comparing the predicted results to whether the pairs were aligned or not.

To demonstrate the potential application of the conservative score, we integrated the score with the expression quantitative trait loci (eQTL) in human. The significant loci associated with at least one gene expression from 49 tissues were obtained from the GTEx portal (https://gtexportal.org/home/datasets). We also compared the conservation score and the effect size of eQTLs, which was quantified as log allelic fold change (Mohammadi *et al.*, 2017).

Results & discussion

The predicted conservation scores showed that most of the aligned pairs (~95%) had a small conservation score (<0.2), while only ~0.4% of the aligned pairs had a conservation score greater than 0.8. This indicates that only a small part of the aligned genome between human and pig is functionally conserved. The area under the ROC curve was 0.77, suggesting a decent model prediction.

We next investigated average conservation score for chromatin states in each tissue (Figure 2). Similar results were found for human and pig. The highest average conservation score was found in the strongly active promoters, which was higher than all the scores derived from the enhancers. This result was consistent with the previous finding that promoters are more conservative than enhancers in general (Villar *et al.*, 2015).

The results of the application of the conservative score on human eQTLs are shown in Figure 3. The scores obtained by regions with eQTLs were higher than the average score of the whole genome in all tissues (Figure 3A), which suggests that eQTLs regions were more conservative than genomic regions outside eQTLs. We regressed the eQTL effect size on the conservation score and found that the slope was significantly smaller than 0 for all tissues except uterus and blood (Figure 3B). The negative association between effect size and

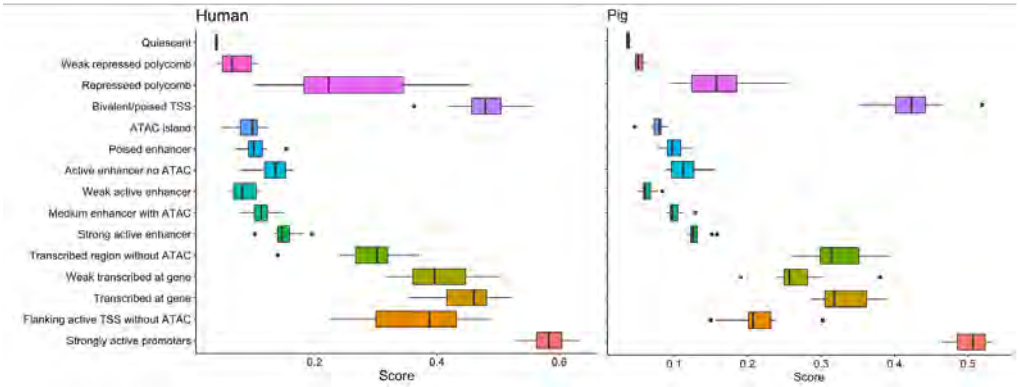

Figure 2. Average conservation scores for different chromatin states across tissues of human (12 tissues) and pig (14 tissues).

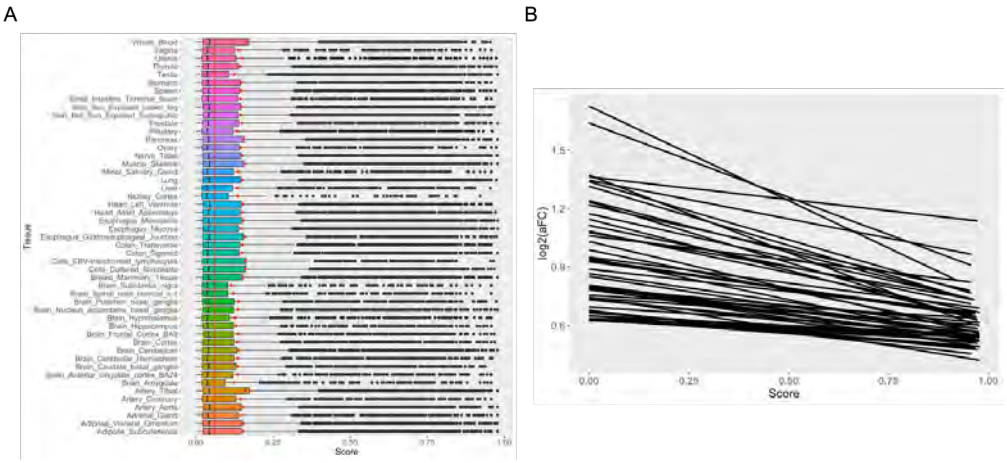

Figure 3. Relationship of conservation scores to human eQTLs. A: Conservation scores on eQTLs across 49 tissues. The red line represents the average score over the whole genome, and the red dot represents the average score of the eQTLs in the tissue; B: Regression lines of the conservation score and eQTL effect size (log_2(aFC) = log allelic fold change) for 49 tissues.

conservation of eQTLs agrees with the previous finding that genomic regions having large effect sizes are less likely to be conservative (Mohammadi *et al.*, 2017).

In conclusion, functional conservation between human and pig predicted by the neural network model had a decent accuracy, and the score reflected the conservation of different chromatin states and eQTLs. The method could be further used to reveal the conserved patterns linked to respective complex traits and diseases between human and pigs, facilitating the recycling information among species. The method can also be easily extended to other species.

401. Using a U-net architecture to develop an automated ultrasound images analysis method in a rabbit breeding program

C. Herbert[1,2*], C. Ribas[2], K. Kashefifard[2,3], L. Flatrès-Grall[2,3,4] and G. Lenoir[2,3]

[1]HYCOLE, 59159 Marcoing, France; [2]GIS Nord Sélection, France; [3]AXIOM, 37310 Azay-Sur-Indre, France; [4]Chrysalide Loïc Flatrès-Grall Kerbastard, 29150 Dinéault, France; caroline.herbert@hycole.com

Abstract

Since 2014, HYCOLE has been using *in vivo* saddle by ultrasound measurements to estimate the animals' carcass yield. The saddle's area measurement was done manually by specialist operators and was time consuming. HYCOLE therefore searched a method to automatically determine the saddle area and its measurement. Deep learning, using a U-net architecture model, was the appropriate answer to this issue. The model was trained in two phases with 4,124 images over 4 years with an associated mask and then, a correlation validation phase was made with a set of 1,410 which were not used in the training phase and also measured manually by a specialist operator. Correlations between the automatically measured criterion (S23auto) and the manually measured criterion (S23ref) were calculated: the rank correlations with the selection criterion are between 0.80 and 0.94 and between 0.86 and 0.96 for the rank correlations between the areas. A genetic evaluation was carried out to validate the trait and automatic measure gave more accurate estimation with higher heritability. S23auto is validated to use in the genetic program and will be add as a data in the « operator » variable from the carcass yield genetic evaluation.

Introduction

Carcass yield is an important economic criterion in meat rabbit production. At HYCOLE, a rabbit breeding company, the improvement of carcass yield by selection is carried out by *in vivo* measurements on the candidates for selection. The surface area of the *Longissimus dorsi* muscle between the 2nd and 3rd lumbar vertebrae is measured on the HYCOLE X male line by ultrasound measurements at 65 and 66 days of age. This estimation of the saddle surface is done manually by an operator. This process is very time consuming and is a limiting factor for the development of the use of ultrasound images for other carcass quality criteria. HYCOLE therefore wanted to automate the estimation of these measurements and validate the method at the genetic level.

To estimate these measures, different approaches were investigated first by algorithmic means, using predefined models with markers coupled to pixel intensity gradients, and then by deep learning means, using neural network architectures such as the U-net (Ronneberger *et al.,* 2015). It is this last method that will be developed in this article.

Materials & methods

Animals. We used ultrasound images of males and females of the HYCOLE male X line for this study. These are animals in closed nucleus, born and raised on the same farm. Three datasets were created to validate the method: a first one composed of 4,124 images with a manual mask dating from 2018 to 2020 for model learning. A dataset of 1,410 images with a manual mask dating from 2018 to 2020 and not used in the training of the model to validate the model with correlations calculation from an expert operator, and a third set of 1,633 images over 2021 to estimate S23auto heritability, phenotypic and genetic correlations. The pedigree file was made with 88,968 animals born between 1998 and 2021 with no missing parents.

Ultrasound measurements. Rabbits were weighed at 65 days of age and then scanned at 65-66 days of age using an Exapad Mini (IMV Imaging; Angoulême, France) equipped with a linear probe of 7.5 MHz.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_401, © C. Herbert *et al.* 2022

Measurements were taken at the level of the *Longissimus dorsi* muscle, between the 2nd and 3rd lumbar vertebrae on the right and left. Two images were recorded for each side of the muscle. Operators who recorded measurements are technicians, trained together and evaluated each year to validate the correlations between their measurements, by analyzing several same images by several operators, to not create biases over the years.

S23ref. The reference areas were estimated using a method developed by HYCOLE (Lenoir and Morien, 2015). All recorded images and images with estimated areas are stored as Joint Photographic Experts Group (JPEG) in grayscale.

S23auto. The automatic image analysis process was developed by HYCOLE using all historical data. First, image pre-processing was performed to ensure that the input images were square to obtain 464×464 pixels images and stored into Portable Network Graphics (PNG) format so that the max-pooling operation worked well. A deep learning model was then created based on the U-net architecture (Ronneberger *et al.,* 2015) and was run under python version 3.8.8 using Tensorflow (Raschka, 2015; Tensorflow.org). The U-net architecture is presented in Figure 1: each blue box corresponds to a multi-channel feature map. The number of channels is denoted on top of the box. The x-y-size is provided at the lower left edge of the box. White boxes represent copied feature maps. The arrows denote the different operations (Ronnerberger *et al.,* 2015).

For model learning phase, out of the 4,124 images (26 batches) available, 80% were randomly selected for the model training phase (3,300 images) which lasted 5 rounds. The remaining 20% (824 images) were used for the model verification phase. A morphological filter is finally applied before the surface calculation to refine the results and eliminate areas that would not belong to the saddle. A second validation of the model was carried out using a batch of 1,410 images (6 batches) for which we already had the measurements, and which had not been used during the learning phase. The model was validated using Spearman correlations by rank correlation between the obtained areas and with the selection criterion on R for each batch (R Core Team, 2018).

Genetic parameters estimation. Genetic parameters were estimated using ASREML 4.2 software (Gilmour *et al.*, 2009; Gilmour and Thompson, 2021) with the restricted maximum likelihood methodology

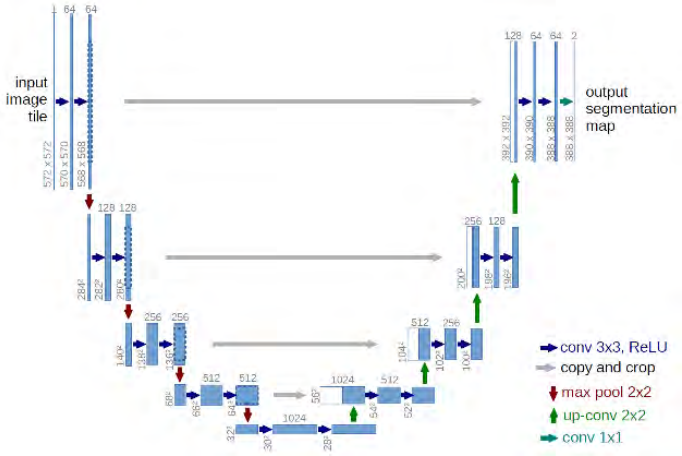

Figure 1. U-net architecture, example for 32×32 pixels in the lowest resolution (Ronnerberger *et al.*, 2015).

applied to a multitrait animal model. Fixed effects were tested at an α-risk of 5% using the Wald test on ASReml (Gilmour *et al.*, 2009; Gilmour and Thompson, 2021). Sex with male and female, batch of control, the ultrasound's operator and the age at weighing were significant for both S23 and were used as fixed effect. The additive animal genetic effect was also added as a random effect.

Results

S23auto development. The learning phase, which is carried out only once, lasted 18 hours. The time spent on a group then, is 10 min (170 animals with 4 photos/animal) from the pre-processing of the image to the opening of the file containing the estimated *Longissimus dorsi* area for each animal. Below, a raw image in Figure 2 and the desired mask during the learning phase and in Figure 3, a raw image and the mask actually produced by the model.

Spearman correlations ranged from 0.80 to 0.94 with the selection criterion and from 0.86 to 0.96 with the measured or estimated areas.

Genetic parameters. The genetic parameters are presented in Table 1. S23auto heritability is high but the standard error is also high and cannot be considered as a difference. Phenotypic and genetic correlations are significatively different from 1 even if genetic correlation is near 1 with correlation respectively at 0.87 and 0.90.

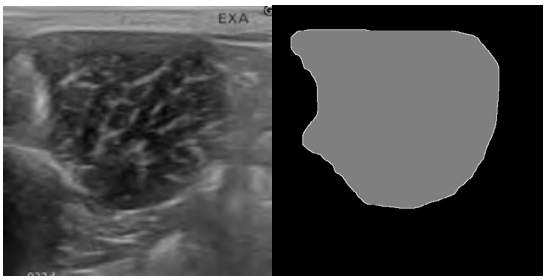

Figure 2. Raw image and desired mask during the model training phase.

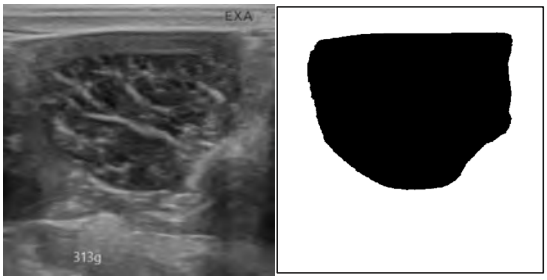

Figure 3. Raw image and mask made during the model validation phase.

Table 1. S23ref and S23auto genetic parameters (heritability on diagonal, phenotypic correlation down to the diagonal and genetic correlation up to the diagonal),

	Animals number	S23ref	S23auto
S23ref	52,472	0.34±0.02	0.90±0.08
S23auto	1,633	0.87±0.06	0.54±0.11

Discussion

S23Auto. Deep learning approach seems to be the best approach for HYCOLE. As Kvam *et al.* (2017) show, this is usable with a large number of images and sufficient image quality. Work on the images' quality will nevertheless have to be carried out in greater depth, as approximately 10% of the images do not pass the quality test. Some common points stand out on the images that do not pass the quality control. The idea is therefore to draw the images manually as before and to make the model relearn by adding these images in order to increase the variability of the model's images quality and to reduce the percentage that do not pass the test. Regarding the mask that came out of the model, we should have three colours on the obtained images: the pixels outside the saddle in black, the pixels inside the saddle in grey and the pixels around the saddle in white. This is not the case after the training phase of the model: the grey colour does not appear, the pixels inside the saddle and its contour are black and those outside the saddle are white. This is the case for all the images that emerge from the model. We do not tried to train the model with only two colours because what was important in our study was to be able to recover the surface of the saddle, which is the case here. Thus, we kept the model as it was.

Genetic validation of S23auto. S23auto and S23ref had very similar values. The carcass yield criteria automatically obtained is well correlated to the one manually developed by Lenoir and Morien (2015). The Spearman correlations show that the rank of the values obtained by manual measurements and by automatic measurements are well correlated and permits to select animals on S23Auto. We should gain in precision when adding new data. Phenotypic and genetic correlations between S23auto and S23ref are close to 1, both approaches are evaluated the same trait. S23Auto heritability is higher than S23Ref even if its standard deviation is also higher.

Conclusions

HYCOLE has developed a deep learning process to estimate the *Longissimus dorsi* area. The Spearman, phenotypic and genetic correlations show that S23Auto and S23ref are the same trait. Automatization permits to get the same *Longissimus dorsi* area or even more accuratly, while reducing a lot the time of measurements. This model has achieved the required objectives. The next work is to improve images quality to reduce the number of images rejected.

402. Machine learning and genetic improvement of animals and plants: where are we?

D. Gianola[1*], J. Crossa[2], O. Gonzalez-Recio[3] and G.J.M. Rosa[1]

[1]University of Wisconsin-Madison, WI 53706, USA; [2]CIMMYT, 56237 Texcoco, Mexico; [3]Instituto Nacional de Investigaciones Agrarias, INIA-CSIC, 28040 Madrid, Spain; gianola@ansci.wisc.edu

Abstract

We give a brief overview of knowledge collected in animal and plant breeding since the term 'machine learning' (ML) surfaced in these fields. ML is used to denote members of a broad 'hyper-class' of methods that have been employed, or are undergoing scrutiny, in genome-assisted animal improvement and phenomics. Our focus is on kernel methods and neural networks and on how machine learning can be employed to construct features or target phenotypes of relevance. Mainly, we summarize our experience with these procedures and give scant references for reasons of space.

Introduction

The borders between predictive inference, statistical learning and machine learning are soft. For instance, best linear unbiased prediction (BLUP) can be viewed as an inferential procedure (estimation of breeding value); as a parameter in a Bayesian setting); a prediction method of yet-to-be observed quantities; as a kernel regression method (kernel= genome or pedigree-derived similarity matrix), or as a single-layer neural network, with an identity activation function and a Gaussian penalty for regularization. The Bayesian alphabet represents linear regression methods where the distinct priors induce different regularization and, thus, prediction machines. If the problem is one of prediction or classification, performance must be evaluated via a replicated cross-validation such that extant uncertainty can be assessed.

It is unclear when 'novel' ML methods started being applied in these fields. A predictive GWAS (genome-wide association analysis) was proposed in 2007 by Gianola's group, using a naïve Bayes classifier for SNP set selection. Reproducing kernel Hilbert spaces (RKHS) regression for genomic prediction made its debut in 2006 and the first application to animal breeding was in 2008. The CIMMYT group led by Crossa extensively studied kernel methods for single and multi-environments, with genotype × environment interaction as an important target. Bayesian Regularized Gaussian neural networks (BNN) were suggested in 2011, and a grouped-neuron architecture (additive and dominance groups) with Monte Carlo sampling of the posterior distribution of connection strengths published in 2012. In 2018, Deep learning (DL) was applied to genomic prediction of human traits and by the CYMMIT group to many different setting and types of plants. ML is being actively investigated in Wisconsin by Rosa and Dorea in connection with leveraging data from sensors, images, spectroscopy and other digital tools to identify and monitor animals, spatially and temporally.

Our experience

Our opinion is that there is no universally best genome-based prediction machine. The performance of the various methods depends on many factors, including genomic structure, sample training and testing sizes, and algorithm (optimization vs sampling). Reinoso-Peláez *et al.* (2022) made 205 comparisons in 34 studies done in the last decade with plants and animals. They used a rank-based Thurstonian method to compare prediction models, as when comparing horses in races. Figure 1 shows that the methods that consistently ranked best in terms of a higher Pearson's correlation between predicted and observed phenotypes were RKHS, BNN, naive Bayes, Bayes A, and Bayes B. In general, RKHS and Bayesian methods seemed to outperform other procedures.

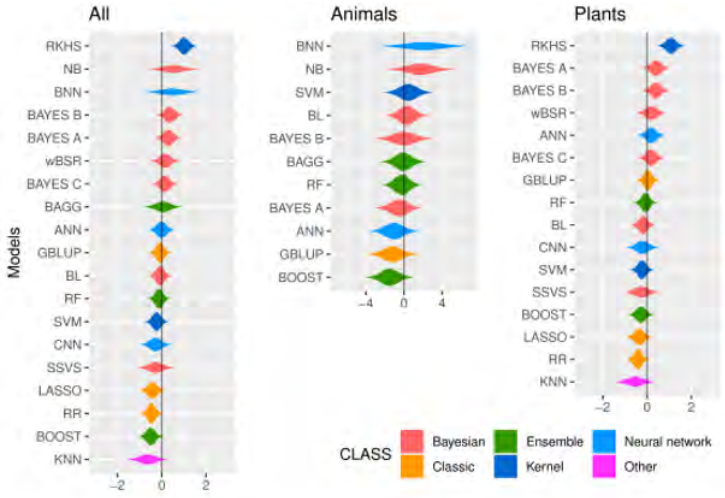

Figure 1. Rank of predictive performance (predictive correlation) of different methods in in 205 comparisons from 34 studies. (with permission of Reinoso-Peláez *et al.* 2022).

CIMMYT extended and applied RKHS methodology in many directions, including multi-kernel fitting, multiple-trait kernels, genotype × environment interaction kernels and deep kernels that, in some sense, are counterparts of deep learners. In multiple-kernel fitting, the basic idea is to create, say, genomic, epi-genomic, meta-genomic or environmental similarity matrices. For instance, such a matrix could represent atmospheric pressure similarity among sites, and another matrix could use some humidity or temperature (or both) index. Interaction kernels are created by Hadamard products. In a single-trait setting, training requires fitting a variance component model. In the multi-trait approaches, one must estimate several covariance matrices. Due to non-orthogonality of kernels, it is difficult to interpret and disentangle the relative importance of the sources of (co)variation.

Neural networks 'resurrected' in the late 80s and early 90s. The appeal of a neural network is provided by one out of many Kolmogorov's theorems. Any continuous function can be approximated by a nested sum of transformed linear combinations of nonlinear functions of inputs and connection strengths. All features of the architecture (number of nested sums, number of terms in the sum, rate coefficients, activation function and statistical distribution of 'residuals') must be learned. Methods of learning have been non-linear least squares for n>p problems, and for n<p situations, empirical Bayes methods and fully Bayesian approaches with Markov chain Monte Carlo sampling have been explored. The use of sampling, instead of optimization, led to improvement of performance (Perez-Rodriguez *et al.* 2012). Zhao *et al.* (2021) run multi-layered neural networks with priors as in the Bayesian alphabet and found a consistent improvement in predictive correlations with both simulated and real data. Figure 2 shows differences between a neural network with 10 layers and an implementation of BayesCπ. An inversion of Fisher's z-transform, implies that a difference in correlations of 0.67 and 0.65 (i.e. 0.02) translates into a difference between 0.81 and 0.73 in a linear scale. The predictive correlation, typically in the 0-1 space, is like a speedometer with an insensitive needle. These results encourage more research on neural networks, or even deep learning, together with Monte Carlo sampling in genome-enabled prediction.

Deep learning (DL), a multi-layered neural network with a new class of algorithms, entered into the picture recently. The CIMMYT group evaluated DL in many different settings (Montesinos-Lopez *et al.*, 2018). DL implementation is challenging. The DL methods do not seem competitive and stable when n<<p, and

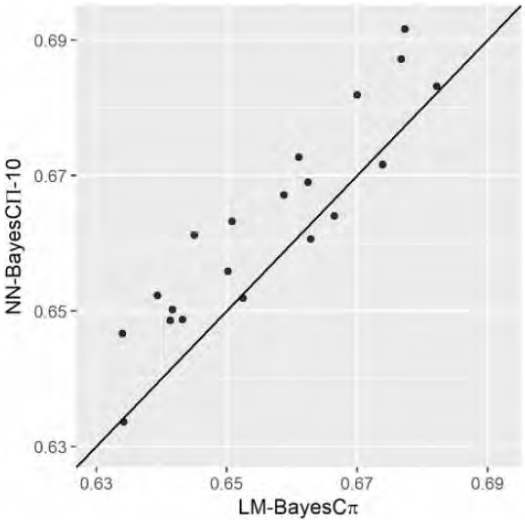

Figure 2. The prediction accuracy of NN-Bayes composed of 10 hidden nodes with BayesCπ priors (NN-BayesCπ-10) versus the linear model with BayesCπ-10 prior (LM-BayesCπ) for the soy dataset. 20 replicates for validation were applied. The diagonal line is used for reference such that a dot above the line represents a validation with higher accuracy for NN-Bayes (Zhao *et al.*, 2021).

there is not much evidence of utility for extracting biological insights from data. The convolutional neural network (CNN) DL topology seems outstanding when inputs are raw images. For this reason, CNNs are being applied in plant science to, e.g. root and shoot feature identification, leaf counting, detecting wheat spikes, and estimating plant morphology and developmental stages. The situation is similar in animal production.

The explosion of ML led to the emergence of 'livestock' prediction analytics. For example, monitoring feed efficiency at the animal level requires measuring individual feed intake, which is extremely difficult. Milk spectrum from mid-infrared spectroscopy has been used to predict milk traits, and it has also been explored as a predictor for other traits such as dry matter intake (DMI). Overall, the use of neural nets improved predictive performance. Image analysis and computer vision systems (CVS) are promising and the power of information has been harvested through DL algorithms. For example, CVS has been used for automated prediction of body weight and body measurements in fish. In a study in Nile tilapia, DL predicted body weight with a predictive R^2 of 0.96.

Conclusions

It seems that SOME machine learning procedures are SOMETIMES better but OFTEN worse than either BLUP or members of the Bayesian alphabet, as there is no universally best method. In genome-enabled prediction DL has not delivered clearly and consistently better results. However, ML and DL offer promise for targets derived from images, sounds, sensors and motion.

The gold standard is single-step genomic best linear unbiased prediction (ssGBLUP). A competing ML procedure should accommodate cross-sectional, longitudinal and multiple-trait settings, and should be as flexible and computable as the gold standard. Kernel methods may meet this challenge. Wisconsin has shown how a more general kernel can be used in lieu of a genomic relationship matrix in ssGBLUP.

CIMMYT proposed a Bayesian multi-trait kernel method: the Gaussian kernel outperformed GBLUP by 10.4, 17.5 and 16.4% in three datasets. There is work going on in extending the multi-trait kernel method to a ssGBLUP setting. The more flexible kernel methods may capture non-additive gene action and accommodate genotype-interactions and may (or may not) outperform the current gold standard.

Defining breeding objectives is crucial. Until buzz terms such as, e.g. eco-system, robustness, resilience, sustainability, etc., are defined precisely and unambiguous metrics are developed, researchers will navigate in a sea of vagueness. AI, ML and DNN may lead to the discovery of more relevant phenotypes. A salutary impact of ML and AI has been to help us take the naïve theory of quantitative genetics less seriously. In ML, heritability and genetic correlations cease to have an existential meaning and become transitional tools that help us go from past and current phenotypes to expected phenotypes.

Current emphasis on 'big data', 'massive computing' and 'visualization' perhaps will diminish basic science education. Students must understand the meaning of a probability distribution, and attain knowledge of experimental design, randomization or causality, before running algorithms (downloading is easy), that somebody else (perhaps a robot) has written. Strong theory and basic biology must continue being taught if animal breeding wishes to maintain a status as a science.

Abstract

Classical methods as genomic BLUP performs well for genomic prediction of polygenic trait, but does not consider interaction between genes or between genes and other information such as host genetic or microbial data. This study aims at comparing several methods including parametric and machine learning methods to predict digestive coefficient using genomic, microbial and both genomic and microbial information. Considering only microbial data led to the best prediction accuracies for digestive coefficients, whereas considering only genomic data performed worst. BLUP, RKHS and GSVM gave the best prediction accuracies except when combined genomic and microbial data was used. Combining microbial and genomic data did not improve prediction accuracies for all traits and methods considered in this study. Thus, considering microbial information is crucial to predict digestive efficiency and interactions between host genetic and faecal microbial information seem to be limited.

Introduction

Genetic evaluation as a sum of additive trait effects using genomic Best Linear Unbiased Predictor (BLUP) method, as defined by Meuwissen *et al.* (2001), is known to be more accurate than other methods for polygenic traits in animal genetics (Zhu *et al.*, 2021; Wang *et al.*, 2019). Nevertheless, some non-parametric machine learning methods allow considering interacting genes, or interaction between microbiota and host genetic and major effect of some gene or OTUs (Operational Taxonomic Unit). The objective of this study was to compare parametric approaches, and machine learning methods that can capture such interactions, in terms of prediction accuracy of digestive efficiency considering microbial data, genomic data, or both information. Indeed, in pigs, earlier studies showed that both host genetic and faecal microbial information contribute to digestive coefficients variability (Déru *et al.*, 2021a).

Materials & methods

Statistical analyses. Corrected phenotypes were predicted using six different methods: BLUP, Least Absolute Shrinkage and Selection Operator (LASSO), Elastic Net (EN), Reproducing Kernel Hilbert Space (RKHS), Support vector Machine using Linear (LSVM) and Gaussian (GSVM) kernel. BLUP (aka Ridge regression) and LSVM are linear methods, which can capture additive polygenic effects of SNP. The major difference between BLUP and LSVM lies in the loss function used for measuring the corrected phenotype prediction error i.e. squared euclidean loss versus epsilon-insensitive loss respectively. EN and LASSO are variable selection methods, which allow considering non-polygenic traits or more important effects of some OTUs. RKHS and GSVM methods are approaches using kernels, which allow considering additive effects and interactions between genes or OTUs. BLUP, LASSO and EN were performed using glmnet R package (Friedman *et al.* 2010), whereas RKHS and SVM were performed using KRMM (Jacquin *et al.*, 2016) and kernlab R packages (Karatzoglou *et al.*, 2004), respectively. Hyperparameters for RKHS and SVM methods were optimised by cross-validated grid-search as in Jacquin *et al.* (2016). For LASSO, the regularization parameter was optimised using the cv.glmnet function with its default values (Friedman *et al.*, 2010). For each trait, the six prediction methods were used with genomic data only, microbial

DOI: 10.3920/978-90-8686-940-4_403, © C. Carillier-Jacquin *et al.* 2022

data only, and combined genomic and microbial information. Microbial data was included in the model as the centered and standardized log abundancies of each OTU (i.e. matrix of 2,399 OTUs for 1,082 animals). Genomic data was the matrix of 48,919 SNP for 1,082 animals and did not include any pedigree information. Combining genomic and microbial data was considered using the concatenation of the matrix of SNP and the matrix of OTUs (i.e. matrix of 51,318 columns (48,919 SNP + 2,399 OTUs) and 1,082 rows (animals)). Considering the largest amount of SNP compare to the amount of OTUs, combining genomic and microbial information could not be ideal for methods that did not reduce the number of variables. For this reason, we also tested combination of microbial data with genomic data reduced to 10,000 SNP selecting equidistant SNP.

Prediction accuracies. Cross validation was used to estimate prediction accuracy, by splitting randomly our population of 1,082 animals into two sets: a training set (722 animals, i.e. 2/3 of the total population) and a validation set (360 animals). Prediction accuracy was estimated for each trait and predicting method for the validation set, as the Pearson correlation between records corrected for diet and batch and predicted traits. Confidence intervals of the Pearson correlation were computed using cor.test function of psych R package (Revelle, 2021).

Data. Data used for 1,082 Large White male pigs feed with a conventional European diet or a high-fiber diet were available (Déru *et al.*, 2021b). Digestibility coefficients of energy (DC_E), and nitrogen (DC_N) were predicted from faecal sampling at 16 weeks of age using near infrared spectrometry (Déru *et al.*, 2021a). Microbial information was obtained from sequencing of the V3-V4 regions of the 16S rRNA contained in the same faecal samples as used for DC predictions. After data curation, the 2,399 operational taxonomic units (OTUs) were kept filtering out OTUs present in less than five samples and with an average abundance lower than 0.001%. Genomic data from the 70K SNP GeneSeek GGP Porcine chip was filtered according to minor allele frequency, call rate, call freq and Hardy-Weinberg equilibrium leading to 48,919 markers available for all pigs.

Results & discussion

Prediction accuracies and confidence intervals estimated in the validation set for DC of nitrogen and energy using the six prediction methods are presented in Table 1. Rankings of the six methods were similar for all DC. Among methods, BLUP, RKHS and GSVM gave better accuracies compared to other methods when considering genomic or microbial information separately. Selection variable methods used in this study (i.e. LASSO and EN) gave the worst prediction accuracies with separate information, and were best when combined microbial and all the genomic information was used. If some genes or OTUs had higher effects on trait than other ones, we expected that these methods outperformed BLUP. We can suppose that all SNP and OTUs seemed to contribute equally to digestive coefficients. LSVM did not performed as well as BLUP, probably due to loss function not adapted to our data. GSVM and RKHS did not outperform BLUP, which could be explained by only few interactions between host genes, between OTUs and between host genetic and microbial information. The better prediction accuracy obtained for BLUP and RKHS in this study is similar to results obtained in other species for a wide range of traits (Wang *et al.*, 2021; Zhu *et al.*, 2019). However, Maltecca *et al.* (2019) have reported similar results with LASSO and RKHS when using microbial data to predict pig growth and carcass traits.

Table 1. Prediction accuracies and confidence intervals for digestive coefficients of energy (E) and of nitrogen (N) with six prediction methods.[1]

		BLUP	LASSO	EN	RKHS	LSVM	GSVM

	E	0.58	0.60	0.59	0.59	0.56	0.59
		[0.43,0.58]	[0.55,0.67]	[0.53,0.66]	[0.52;0.65]	[0.41;0.56]	[0.45;0.59]

[1] BLUP = best linear unbiased predictor; EN = elastic net; GSVM = support vector machine using Gaussian kernel; LASSO = least absolute shrinkage and selection operator; LSVM = support vector machine using linear kernel; RKHS = reproducing kernel Hilbert space.

For all traits, considering only microbial data led to the best prediction accuracies, whereas considering only genomic data performed worst. The decrease in prediction accuracies when using only genomic information compared to using microbial data only can be explained by the large part of variance of DC traits explained by microbial information in these traits (Déru *et al.* 2021c). Compared to the use of microbial data only, Pearson correlations decreased when both microbial and genomic data were analysed jointly except for variable selection methods certainly due to much larger amount of genomic data (48,919 SNP) compared to microbial data (2,399 OTUs). In practice, LASSO and EN were able to select more OTUs than SNP in the model, thus prediction accuracies were close to the ones obtained with microbial data only. When reducing genomic data to 10,000 equidistant SNP, other methods (i.e. BLUP, RKHS and SVM) performed similarly to the selection variable methods. This confirms our hypothesis that the highest amount of SNP compared to OTUs did not allow methods to perform as well as using only microbial data, at least in the case of DC traits where microbial information seem to be preeminent on genomic information to explain the traits.

Comparing DC traits, Pearson correlations obtained for DC of nitrogen using only genomic data were lower to the one obtained for DC of energy, which is not the case when considering only microbial or combined data. This could be explained by a lower contribution of host genetic to DC_N variance, as reported also by Déru *et al.* (2021c) with different approaches.

Conclusions

We conclude that microbial information is crucial to predict digestive coefficients. Machine learning methods did not outperform BLUP, which suggest few interactions between SNP, between OTUs, and between microbial and host genetic information. For further study, it could be interesting to estimate prediction accuracies without filtering out rare OTUs, to evaluate a potential prediction improvement

when combing both data. The interest of random forest variable importance methods could also be used to explore genomic and microbial data combination.

Funding

This study was supported by the Feed-a-Gene European H2020 project. The authors acknowledge the breeding companies Axiom and Nucleus for providing animals and the UEPR phenotyping station staff in Le Rheu for animal raising and data recording.

Abstract

This study investigates non-linear kernels for multi-trait genomic prediction using support vector regression (SVR) models. Phenotypic traits from broiler chickens purebred lines were used. The predictive ability for two carcass traits was assessed according to different single-trait (ST) and multi-trait (MT) models, as well as training strategies. The MT models used performance traits measured *in vivo* (Growth Trait – *Growth* and Feed Efficiency Trait – *FE*) as secondary traits. The proposed (Quasi) multi-task SVR (*QMTSVR*) outperformed the traditional *MTGBLUP* model, improving the predictive ability for the *post-mortem* traits when phenotypes for secondary traits were available. Additionally, the weighted *QMTSVR* accounting for the relative importance of different genomic regions provided a bias reduction on the predicted values.

Introduction

In animal breeding programs, many quantitative traits of economic importance are sex-specific, laborious, time-consuming, or expensive to measure. Hence, strategies that allow rapid, accurate, and resource-efficient predictions are of particular interest to fully explore the potential of genome-enabled selection. In this regard, the interest in multi-trait genomic prediction (MT-GP) for aggregating the complementary information of correlated traits has been largely increased in the last few years (Karaman *et al.* 2018, Gianola and Fernando 2020, Manzanilla-Pech *et al.* 2020).

MT-GP is particularly interesting for carcass traits as they generally require slaughtering the animals for assessing their phenotypic performance; therefore, exploring the information of secondary traits measured on live animals might benefit the genomic evaluation of *post-mortem* traits. In practical applications, the implementation of MT-GP models can be challenging as such methods are computationally intensive and require the knowledge of covariance parameters that are hard to estimate when many traits are analysed jointly. Additionally, most MT-GP models assume only additive effects for the genetic markers, while potential non-linear effects are ignored. In this study, we propose non-linear kernels for aggregating multi-trait genomic information in support vector regression models to overcome these problems.

Materials & methods

(Quasi) Multi-task support vector regression (QMTSVR). In standard support vector regression (SVR) models the ϵ-insensitive loss function is generally optimized by using quadratic programming. Considering the information from multiple correlated traits, the following data augmentation scheme can be proposed for this loss function:

$$arg\ min_{\alpha,\beta}\ \frac{1}{2}\begin{matrix}\boldsymbol{\alpha}^{(1)}-\boldsymbol{\beta}^{(1)\,\mathbf{T}}\\ \boldsymbol{\alpha}^{(2)}-\boldsymbol{\beta}^{(2)}\\ \vdots\\ \lfloor\boldsymbol{\alpha}^{(t)}-\boldsymbol{\beta}^{(t)}\rfloor\end{matrix}\mathbf{Q}\begin{matrix}\boldsymbol{\alpha}^{(1)}-\boldsymbol{\beta}^{(1)}\\ \boldsymbol{\alpha}^{(2)}-\boldsymbol{\beta}^{(2)}\\ \vdots\\ \lfloor\boldsymbol{\alpha}^{(t)}-\boldsymbol{\beta}^{(t)}\rfloor\end{matrix}+\varepsilon\begin{matrix}\boldsymbol{\alpha}^{(1)}-\boldsymbol{\beta}^{(1)\,\mathbf{T}}\\ \boldsymbol{\alpha}^{(2)}-\boldsymbol{\beta}^{(2)}\\ \vdots\\ \lfloor\boldsymbol{\alpha}^{(t)}-\boldsymbol{\beta}^{(t)}\rfloor\end{matrix}\mathbf{1_n}\otimes\mathbf{1_t}-\begin{matrix}\boldsymbol{\alpha}^{(1)}-\boldsymbol{\beta}^{(1)\,\mathbf{T}}\\ \boldsymbol{\alpha}^{(2)}-\boldsymbol{\beta}^{(2)}\\ \vdots\\ \lfloor\boldsymbol{\alpha}^{(t)}-\boldsymbol{\beta}^{(t)}\rfloor\end{matrix}\begin{matrix}\mathbf{y}^{*(1)}\\ \mathbf{y}^{*(2)}\\ \vdots\\ \lfloor\mathbf{y}^{*(t)}\rfloor\end{matrix}$$
$$subject\ to\ \begin{cases}0\le\ \alpha_i^{(t)},\beta_i^{(t)}\ \le C, i\ =\ 1,2,\dots,N\\ \quad[\boldsymbol{\alpha^{(t)}}-\boldsymbol{\beta^{(t)}}]^T\mathbf{1_n}=0\end{cases} \quad (1)$$

CC BY

DOI: 10.3920/978-90-8686-940-4_404, © A.A.C. Alves *et al.* 2022

in which t refers to the number of traits, $\alpha^{(t)}$ and $\beta^{(t)}$ are the vectors of positive Lagrange multipliers related to trait t, 1_t is a t-dimensional vector of ones, $\otimes$ is the Kronecker product, $\left[\mathbf{y}^{*(1)}, \mathbf{y}^{*(2)}, \ldots, \mathbf{y}^{*(t)}\right]^T$ are vectors of observed values for t target variables standardized to the same scale, and $\mathbf{Q}$ is a block symmetric matrix, partitioned into t^2 blocks of dimension $N \times N$. Each block matrix in $\mathbf{Q}$ is computed as $\mathbf{Q}_{mn} = \mathbf{Q}_{nm} = \rho_{mn} exp\left(-\theta_{mn}\mathbf{D}^2 p^{-1}\right)$, where ρ_{mn} is a constant between -1 and 1 for $m \neq n$ (m, n = 1, 2, …, t) or 1 otherwise, θ_{mn} is a block-specific bandwidth hyperparameter for traits m and n, $\mathbf{D}$ is an $N \times N$ Euclidean distance matrix (EDM), and p is an scalar representing the number of markers *loci*. Please notice that the regularization parameter (C) and epsilon value (ε) are assumed to be constant across traits, therefore this model can be considered as a (Quasi) Multi-task Support Vector Regression (*QMTSVR*). The block matrices in $\mathbf{Q}$ can be further expanded to account for the loci-specific variance in each trait combination by building block-specific weighted EDMs ($\mathbf{WD}_{mn}$); this method will be hereinafter termed as *QMTWSVR*. The weighting factors were obtained with a marker-wise genome-wide association study (*GWAS*), performed only on the training population for each trait and normalized by dividing the -log10(p-values) by their maximum value. For $m \neq n$ the weighting factors were found by multiplying the -log10(p-values) computed for the same marker on each trait-specific *GWAS* and rescaled to lie between 0 and 1. Further, in the *QMTWSVR* method, the constant p in $\mathbf{Q}_{mn}$ is replaced with $\sum_{l=1}^{p} w_l^{(mn)}$, in which $w_l^{(mn)}$ is the weighting factor for *locus l* considering the $N \times N$ block for traits m and n.

Phenotypic and genotypic data. The dataset used in this study was provided by Cobb-Vantress Inc. (Siloam Springs, AR) and comprised observations related to broiler chickens from purebred lines, bred in 20 overlapping mating groups. The phenotypic data included observations of two carcass traits (Carcass Trait 1 – *CT1* and Carcass Trait 2 – *CT2*) and two *in vivo* traits (Growth Trait – *Growth* and Feed Efficiency Trait – *FE*). All traits were adjusted for the fixed effects of contemporary group (GC) with at least 5 observations and sex. The number of genotyped animals with observations for *CT1* and *CT2* (the primary traits) was 8,749, being all males. All animals were measured also for *Growth*, whereas a subset of 3,703 animals had phenotypes available for *FE*. The genotypic data were obtained using a moderate-density Illumina (San Diego, CA) chip, containing 60k single nucleotide polymorphism (SNP) markers.

Training and testing populations. The predictive ability of the *SVR* and *QMTSVR* models was assessed by splitting the data into training and testing datasets according to the chronological information of the mating group. The animals from mating groups 1 to 19 (n=8,337) were used for fine-tuning and training the models, whereas the data related to mating group 20 (n=412) was held out as the testing set. Three different training strategies were used: *TS1*, *TS2*, and *TS3*. The *TS1* consisted of using solely the information available for the primary trait on the training set. For the *TS2*, the primary traits (*CT1* and *CT2*) were analysed jointly with a secondary trait in a bi-trait model (*CT1* × *Growth* and *CT2* × *FE*), considering that the observations for both the primary and secondary traits were missing in the testing group. The *TS3* was similar to *TS2*, with the exception that all available observations for the secondary trait were considered for training the models (including those from the mating group 20). The *SVR* models can be summarized according to the training strategies as *SVR-TS1*, *QMTSVR-TS2*, *QMTSVR-TS3*, *QMTWSVR-TS2*, and *QMTWSVR-TS3*. These models were benchmarked with ST and MT genomic best linear unbiased prediction models (*GBLUP* and *MTGBLUP*, respectively), following the same training strategies. The criteria adopted for assessing the methods' predictive ability were the prediction accuracy (*ACC*), root-mean-squared error (*RMSE*), mean absolute prediction error (*MSE*), and inflation factor (b; values closer to one are preferable). For finding an optimal combination within the hyperparameter multidimensional space we used a genetic algorithm (GA) to perform a heuristic search by minimizing the metric 1 – ACC^2 measured in the 19th mating group. All GA-optimized support vector regressions models were fitted using an under development package that wraps the *kernlab* library (Karatzoglou *et al.,* 2004) as backend. The *GBLUP* and *MTGBLUP* models were fitted using the BLUPF90 suite programs (Misztal *et al.*, 2018).

Results

The observed values for the predictive ability metrics varied remarkably according to the trait, model, and training strategy, ranging from 0.41 to 0.63 for *ACC*, 1.52 to 1.78 for *RMSE*, 1.23 to 1.41 for *MAE*, and 0.91 to 1.31 for *b*, considering the *CT1*, and from 0.51 to 0.55 for ACC, 0.26 to 0.27 for *RMSE*, 0.20 to 0.21 for MAE, and from 0.78 to 0.85 for *b*, considering the *CT2* trait (Figure 1). According to those metrics, the *GBLUP* was slightly better than the *SVR* and *WSVR* models for *CT1* (higher *ACC*, lower *RMSE* and *MAE*, and *b* closer to one), whereas for *CT2* the opposite was observed. In general, there was an evident improvement for all predictive ability metrics when using the MT models, especially comparing the *TS1* with *TS3* (Figure 1).

The *QMTSVR-TS3* provided the highest *ACC* for both traits, 0.63 and 0.55 for *CT1* and *CT2*, respectively, which correspond to a relative gain of about 22 and 3.6% compared to the *MTGBLUP-TS3*. Incorporating the prior information for the *loci*-specific variance on the *SVR* models did not improve the overall *ACC* even though this approach was notably successful in reducing the prediction errors in both traits, as evidenced by the lower *RMSE* and *MAE*. Further, weighting the kernel Q according to individual and pleiotropic effects was also important for attenuating the prediction bias, more notably for *CT1*, with the *b* coefficient reducing from 1.31 to 0.96, comparing *QMTSVR-TS3* with *QMTWSVR-TS3* (Figure 1). The necessary time for the GA to find the best hyperparameter configuration was on average 69.13±15.54 (minutes) and 298.91±44.24 (minutes) for the *SVR* and *QMTSVR* models, respectively. This was the time required for the GA to compare 750 specific hyperparameters combinations for each trait and training strategy. The (co)variance components on the *GBLUP* and *MTGBLUP* models were estimated via AIREML, with the algorithm taking on average 871.42±196.66 minutes to converge for the bi-trait analyses.

Discussion

Since early developments by Hernderson and Quaas (1976), multiple-trait analysis has gradually become the state-of-art methodology for the joint selection of many traits. This approach has a solid theoretical base

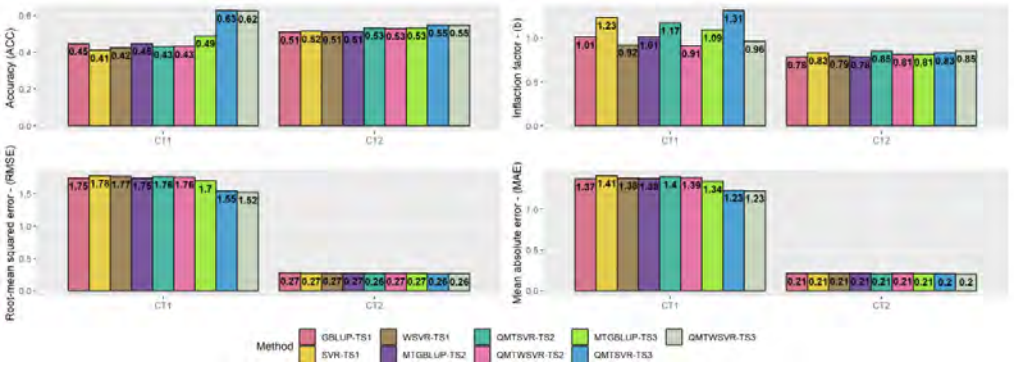

Figure 1. Predictive ability metrics for carcass traits measured in broiler chickens according to different single-trait and multi-trait genomic prediction methods. GBLUP-TS1: Genomic Best Linear Unbiased Predictor using TS1; MTGBLUP-TS2: multi-trait GBLUP considering that the information for the secondary trait (Growth or FE) was available only for the training population. MTGBLUP-TS3: MTGBLUP considering that the information for the secondary trait was available for both the training population and testing population. SVR-TS1: Support Vector Regression; MTQSVR-TS2 and MTQSVR-TS3 are multi-task SVR models with similar training and testing set schemes as in the MTGBLUP model. WSVR and QMTWSVR are similar models but with weighted kernels to reflect genetic architecture.

for pedigree-based selection and is becoming popular for GS over recent years, with different methods and strategies being proposed (Cheng *et al.,* 2018, Karaman *et al.* 2018, Gianola and Fernando 2020, Manzanilla-Pech *et al.* 2020). Here, we presented a simplified approach for expanding the SVR to the MT case under a genomic prediction context. This model shares some computational advantages of the GBLUP (e.g. both are based on $N \times N$ kernels) while being capable of exploring non-linear relationships within and between traits, without any strong assumption for the markers effects. Results showed that the *QMTSVR* improved the predictive ability for the primary traits (*CT1* and *CT2*) when compared to the traditional *MTGBLUP*, especially when the phenotypes for secondary traits were available on the testing population (Table 1). This is a reasonable scenario since broiler chickens are selected before the slaughtering process but after some routinely measured traits are already available, especially growth-related traits.

The burden of the fine-tuning process for the MT-QSVR method was alleviated by assuming some global hyperparameters for all traits analysed jointly, leading to $2 + t[t+1]/2$ hyperparameters to be tuned. A GA was then used for avoiding an extensive grid search. Results suggested that finding an appropriate hyperparameter configuration with the GA for the *QMTSVR* would take less computing time than estimating the *MTGBLUP* (co)variance components with an AIREML algorithm. Similar to what has been proposed for *GBLUP* (Karaman *et al.*, 2018) we further expanded the *QMTSVR* method to account for the relative importance of different genomic regions, by computing trait-specific and pleiotropic weighted Kernels. While this strategy did not imply higher prediction accuracy than the non-weighted counterpart, it was noticed a bias reduction with the *QMTWSVR* method (Figure 1). One must highlight that the weighting factors used in this study were based on a simple marker-wise *GWAS*; thus, further studies using weighting factors derived with more sophisticated methods may provide a better picture of the usefulness of the *QMTWSVR* model. Lastly, future research performing a comprehensive comparison of the proposed approach with other methods and different traits is encouraged.

Abstract

Neural networks have drawn considerable interest for their use in genomic prediction in recent years. As a flexible universal approximator, nonlinearity can be easily accommodated in a neural network, allowing non-additive genetic effects and genotype by environment interactions to be captured. However, SNP effects must be formulated as additive effects for use in genetic improvement. We developed a neural network model for genomic prediction for body weight of pigs. The model consists of two parts: (1) additive effects of SNPs using genomic prediction; and (2) one layer of a feedforward neural network to predict longitudinal body weights based on the SNP effects. By decoupling the prediction of additive SNP effects from the prediction of phenotype, the model is expected to better predict body weight across populations and environments.

Introuction

Genomic prediction has been shown to improve genetic progress by allowing more accurate estimated breeding values (EBV) at an early age (Meuwissen *et al.*, 2001). However, the fundamental assumption of additive models for observed phenotypes, as applied in most genomic prediction models, remains debatable. Over the last decade, there have been multiple attempts to incorporate non-additive genetic effects and genotype by environment interactions (GxE) into genomic prediction. As a universal approximator, neural networks have been shown to improve the accuracy of phenotype prediction in several settings (Waldmann 2018; Gianola *et al.* 2011). Whether neural networks can be used for genomic prediction based on longitudinal trait data, such as body weight, which is a complex quantitative trait with moderate heritability, deserves investigation. Several studies have attempted to integrate non-linear mechanistic models into genetic evaluation of body weight in pigs (Doeschl-Wilson *et al.*, 2007). These mechanistic models usually require specific assumptions of the relationship between latent variables and phenotypes, which may not be valid across populations and environments. Neural networks don't require such assumptions. Against this background, the objective of this study was to develop an assumption-free neural network model for genomic prediction of longitudinal body weights in pigs.

Materials & methods

Neural network model for genomic prediction. Figure 1 illustrates the neural network model with 3 neurons that each consist of a pair of latent variables, b_{ni} and a_{ni}, that model the intercept and slope, respectively, of body weight against centered age. The latent variables are linked to the observed longitudinal body weight of pig_n using an one-layer feedforward neural network, with nonlinearity introduced through the activation function Relu (Stursa and Dolezel 2019). Similar to a random regression model (Jamrozik *et al.*, 1997), each b_{ni}/a_{ni} pair is linked to SNP genotypes using an additive whole-genome prediction model, as linear combinations of an intercept (μ_{ani}/μ_{bni}), a fixed contemporary group effect (CG_{bni}/CG_{ani}), random SNP effects for the slope and intercept ($\delta_{jbni}/\delta_{jani}$), and a residual ($\varepsilon_{bni}/\varepsilon_{ani}$). The number of b_{ni}/a_{ni} pairs is a tunable parameter. Increasing the number of pairs increases the expressive power of the model, but predictive ability may decrease if the size of the dataset is limited. The final predictions of body weight with age are obtained as a weighted sum of the predictions from each b_{ni}/a_{ni} pair, equivalent to an ensemble learning process (Hashem 1997).

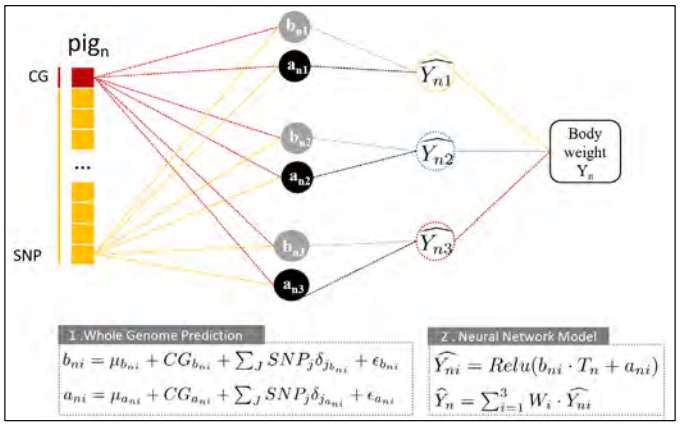

Figure 1. Structure of the neural network model for genomic prediction of body weights based on 3 neurons, each consisting of a pair of latent variables (g and t).

The neural network was built using the Flux.jl package (Innes *et al.* 2018) and trained for 5,000 iterations using the minibatch gradient descent method (Goodfellow *et al.*, 2016) and the ADAM optimizer (Kingma and Ba, 2014). A mean square error loss function that incorporates the L2 regularization (Friedman *et al.*, 2001) was used, which avoids overfitting, since the number of SNPs is typically much larger than the number of records. The model has 4 hyperparameters: the number of neurons, the L2 regularization coefficient λ, the size of the minibatch, and the learning rate of the ADAM optimizer. The first step in applying the model is tuning the hyperparameters, which was based on a grid search by training the model for a given set of hyperparameters and evaluating its prediction accuracy in validation data to identify the set with the highest accuracy.

Application. The model was applied to a dataset of daily body weight records from 79 to 197 days of age from 3,934 purebred boars in 97 contemporary groups. Evaluation of predictions was by forward cross-validation by using the first-born 2,000 boars as the training set and the remaining boars as the test set. To avoid information leakage, tuning of the hyperparameters was conducted by forward cross-validation within the 2,000 training animals, by fitting the model to the first 1000 of the 2,000 training set animals, and computing the accuracy of predictions using data from the second set of 1000 animals. For this purpose, the accuracy of predictions for a given set of hyperparameters was computed for each day of age based on the correlation of predictions with observed body weights adjusted for contemporary group effects for that day of age. Choice of the best set of hyperparameters was based on the average accuracy across days 103 to 153, which is when most pigs had records. The optimal set of hyperparameters was then used to train the model on the full training set of 2,000 and applied to forward-predict the test set. The accuracy of predictions in the test set was computed for each day of age as for tuning. The bias of predictions was computed for each day of age based on the regression coefficient of adjusted body weights on predictions and would be 1 if there's no bias.

Results

The grid search identified the optimal hyperparameters to be 5 neurons, a batch size of 1000, λ=240,000, and a learning rate of 1.0 e^{-5}. Example predictions in the test set at example days are in Figure 2, compared to predictions based on a hierarchical Bayesian model that fits the Gompertz function, similar to Cai *et al.* (2012). The cross-validation accuracy and bias of predictions of body weights for each day are shown in Figure 3. Results from the Bayesian hierarchical model are provided for comparison. The average accuracy

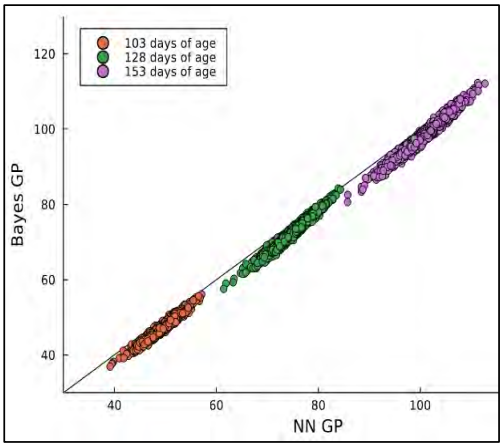

Figure 2. Predictions of body weight (kg) using a Neural Network Model (NN GP) versus the Bayesian method (Bayes GP) at 103, 128, and 153 days of age.

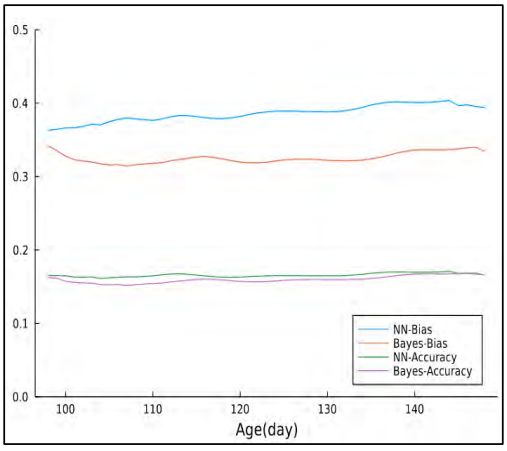

Figure 3. Comparison of bias and accuracy of the Neural Network Model (NN) and the Bayesian method (Bayes).

across days was slightly higher for the neural network model (0.17) than for the Bayesian hierarchical model (0.16). The neural network model also had a lower bias of 0.39 compared to 0.33 for the Bayesian hierarchical model.

Discussion

We found that the neural network model obtained slightly higher accuracy and less bias than the Bayesian hierarchical model that was based on the Gompertz function as the underlying biological model. This may be because the Gompertz function models the S-shaped body weight curve over a longer lifespan, which contains much nonlinearity, compared to the fairly linear part of the curve that our data were obtained in. Nevertheless, the results suggest that the neural network can predict longitudinal data well when trained using properly tuned hyperparameters in the framework of random regression. And indeed,

Sonoda and Murata (2017) previously proved that a neural network using Relu functions could act as a universal approximator. However, because a neural network model is intrinsically a data-driven method, extrapolating predictions, e.g. to other ages, remains problematic. This is less of an issue for mechanistic models. Interpretability of a neural network model is also lacking under most circumstances. However, an appealing feature of the neural network model is that its computing time is much shorter than that of the Bayesian hierarchical model: less than 5 minutes on a Geforce Nvidia 3090 GPU given a specific set of hyperparameters, compared to at least 3.5 hours on an Intel Core i7-9800X CPU for the Bayesian model. But the current grid search requires numerous trials over different combinations of hyperparameters, which is time consuming. More sophisticated hyperparameter tuning methods such as heuristic algorithms need to be investigated to reduce tuning time.

In conclusion, the expressive power of a neural network can be incorporated into genomic prediction using a decoupling 2-step design, enabling the model to capture non-additive genetic effects and G×E, hence increasing the accuracy of predictions and reducing their bias. The predictive performance of the neural network model was comparable to a Bayesian hierarchical model that relies on a mechanistic biological model and associated assumptions. The neural network avoids the possible negative effects of improper assumptions of mechanistic models on predictions, especially under specific scenarios, which supports the broader application of predictions across different scenarios.

Abstract

Microbial composition represents a promising tool in precision farming. In the current paper, we evaluated the power of fecal microbial composition to predict growth performance across swine farming systems. We used different dimensionality reductions to select microbial features to be included in the predictive models, ranging from random selection to selection based on association to data compression using a sparse autoencoder. We compared these methods with a model including all information available. We found that microbial information can predict performances for growth and fat deposition. We found that in most cases, the use of all microbial information resulted in the highest predicting performance regardless of the trait or the populations used for training and prediction. Our results suggest that including all available microbial information might be the best option when using it to predict performance.

Introduction

Previous research used microbiota information to predict livestock performance (Maltecca *et al.*, 2019). In principle, microbiota abundance counts are akin to genomic information in format. Yet, they present peculiar analysis challenges related to their compositional nature and the fact that they are temporally and spatially dependent (Maltecca *et al.*, 2020). This is particularly relevant when transferring microbiota predictions from different settings or experimental designs. Autoencoders are a class neural network used, among other things, to learn an efficient reduced representation of the input data (Pasolli *et al.*, 2016). They are often proposed as a way to denoise data and extract salient descriptors. This paper compares autoencoders vs raw counts as a preliminary step in predicting swine growth parameters using microbiota information in nucleus and terminal systems.

Materials & methods

Experimental design and data collection. Phenotypic records were obtained from a commercial and a nucleus farm operated by The Maschhoffs LLC (now Acuity, Carlyle, IL, USA). The data spanned two connected systems: a Duroc nucleus purebred population (NU) and a terminal commercial crossbred population (TE), both sired by 28 Duroc founding boars. The NU population consisted of 769 Duroc individuals. Individuals were raised in a fixed-time system. Individuals entered performance test at an average of 88 days of age and were taken off-test at an average of 178 days of age. The TE population consisted of 1,141 individuals generated by crossing the Duroc sires with two commercial sow lines. Crossbred commercial individuals were raised in a fixed-weight testing system and harvested at an average weight of 98.8 kg and 97.90 kg for the males and females. In both systems, a contemporary group was defined as the group of animals entering a given facility at the same time. Microbiota composition from all pigs was obtained at off-test. 16S rRNA gene sequencing and quality control of the data were conducted as described by Lu and colleagues (2018). 3,001 OTUs were available for further analyses. Additional details can be found in Maltecca and colleagues (2021).

Phenotypic information. Growth traits were collected in the two populations according to the standards of the respective production systems. Phenotypes for NU individuals were obtained at off-test while at

DOI: 10.3920/978-90-8686-940-4_406, © C. Maltecca *et al.* 2022

market weight for TE individuals. Backfat (BF), average daily gain (ADG), and loin depth (LD) were used for the subsequent analyses.

Training and testing sets. Solutions (either OTUs or compressed representations) were obtained for each trait in one system serving as the training set. These solutions were then used to predict performance in the opposite system serving as the prediction set (i.e. NU to predict TE or TE to predict NU).

Models. Solutions were obtained fitting microbial information with a Bayesian Ridge Regression model (BRR). A preliminary model was fitted to correct for any systematic effects in the data using the BGLR package in R (Pérez and Campos, 2014). The models for NU and TE were similar. In TE, models for each trait included the effects of sire, contemporary group, maternal genetic line, and pen. In the NU population, the models included the effects of sires, contemporary group, and biological litter. Adjusted phenotypes were subsequently used for the microbiota analyses. All microbial models were fitted as implemented by the Python Scikit Learn (Pedregosa et al., 2011). The predictive performance of each model was evaluated through Pearson's correlation coefficient, between microbial predicted values (MPV) and observed phenotypes, as well as root means squared error (RMSE).

Autoencoder. Autoencoders are similar to PCA (equivalent under linear transformation) and have two portions: an encoder and a decoder. The first condense the data to a reduced representation state (bottleneck, or latent space). The second takes the output of the bottleneck to recreate the input. For the predictive part of the model, only the bottleneck is retained and used as input in the subsequent analysis. Based on a preliminary grid search analysis (data not shown), we defined an encoder with three hidden layers, the first with 1,500 inputs, the second with the same number of inputs as OTUs (3,001), and the third (the bottleneck layer) with 400 inputs. A rectified linear unit (ReLU) was used as activator function. The autoencoder was fitted using the Python package Keras (Chollet *et al.*, 2015). The output of the models at the bottleneck was used as a feature vector in the BRR autoencoder model (AUm). These models were compared to models with all features included (ALLm), and models where 400 features were selected based on association of OTUs (MWASm) or randomly (RANm). MPVs in the prediction set were obtained as $X_{ip}m_{it}$ where X_i is the feature matrix of the correspondent model *i*, m_i is the vector of solutions for features of the correspondent model *i,* and t and p correspond to the training or prediction sets. Features were only selected from association (MWASm) in one popopulation, and used to predict the opposite.

Results

Prediction accuracies for all the models traits combinations are reported in Table 1. Predictions were highest for fat deposition and lowest for loin depth for all scenarios. This is in agreement with previous studies (Bergamaschi *et al.*, 2020). Predictions from nucleus training to terminal testing set were higher in most cases than the opposite, except for loin depth that was predicted better from terminal to nucleus (0.08 vs 0.24 in the full model), for the ALLm model, accuracies ranged from 0.08 (NU_TE LD) to 0.36 (NU_TE BF). Models including features selected through association were the second-best performing ones with Pearson's correlations ranging from 0.10 (LD NU_TE) to 0.34 (BF NU_TE).

In most cases, MWASm had less accuracy than ALLm except for LD predicted from NU to TE (0.12 vs 0.08). The autoencoder model was, on average, the third performing one, and it only outperformed the MWASm for only one trait (LD), for which it was better than ALLm for NU_TE (0.10 vs 0.08) and performed the same as MWASm. The scenario with 400 randomly chosen featured was the one that performed worst in all cases, as expected, with correlations ranging from (0.01 to 0.10). Results for RMSE are reported in Table 2. These, for the most part, were in agreement with accuracies. Interestingly the AUm models had, on average, a lower RMSE than the MWASm models. In all cases, ALLm models were the ones with the lowest RMSE.

Table 1. Correlation coefficients, (*r),* between microbial predicted values (MPVs) and phenotypes, for backfat (BF), average daily gain (ADG), and loin depth (LD), for the OTU model (ALLm), autoencoder model (AUm), association OUT model (MWASm) and random OTU (RANm), when predicting from nucleus to terminal (NU_TE) and from terminal to nucleus (TE_NU).

Discussion

In the current paper, we evaluated the power of fecal microbial composition to foretell growth performance across farming systems. We took advantage of an experimental design where the microbial composition of purebred or terminal crosses progeny of 28 Duroc sires was collected during the performance test. We then used this information to investigate how microbial information could be used to predict phenotypes in the nucleus or terminal populations using different methods. In our research, prediction accuracy from TE to NU was higher than the opposite for most traits. Possible reasons for this could be related to a more considerable environmental and genetic variability in commercial settings leading to a broader microbial representation in TE, as well as the difference in sample size in the training populations. Prediction accuracies were larger than zero for all the traits and sizable for most of them, particularly for fat deposition and growth. The use of an autoencoder did not improve the stability of predictions across systems, and the model with all features included was the best performing in all cases. This, in addition to the added computational costs of the model, suggest that including all available microbial information might be the best option when using it to predict performance.

Abstract

Milk production is usually challenging under tropical environments. Heat stress and/or recurrent parasite infestations frequently cause cattle's reduced fitness and productivity. As a way to overcome this challenge, the Gir indicine cattle breed has increasingly been used in crossbred schemes to constitute milk production herds in Brazil and other countries in tropical regions. The Brazilian Dairy Gir Breeding Program was established in 1985, based on a partnership between the Brazilian Agricultural Research Corporation and the Brazilian Association of Dairy Gir Breeders. It was the first breeding program outlined with a progeny test for the improvement of an indicine breed for milk production in the world. Several technical innovations were employed along the time. Now, producers can access genomic predictions for thousands of Gir males and females. Those predictions are used mainly by Brazilian breeders, but also increasingly in other tropical countries from South America, Central America and Asia.

Introduction

India is the world's largest milk producer, responsible for more than 20% of the global production, followed by the United States of America, China, Pakistan and Brazil. A significant part of the global milk production occurs under tropical conditions. European cattle breeds are very successful under temperate or subtropical climates, but struggle to keep good production and reproduction performances in tropical regions, especially because of heat stress and/or recurrent parasite infestations. Thus, better adapted cattle genetics is needed to constitute tropical dairy herds, especially in some parts of Asia, Africa, Central and South Americas.

The Gir indicine breed has been increasingly used in successful crossbreeding schemes to compose dairy herds in the tropics. The initial idea of such crossbreeding schemes was to combine the productivity from one European breed, mainly Holstein, to the rusticity from one indicine breed, mainly Gir. Some breeders in Brazil, though, started selecting purebred Gir for milk production during the last century, with the idea of improving the performance of crossbred production herds. Those breeders later created the Brazilian Association of Dairy Gir Breeders (ABCGIL, from the initials in Portuguese), and stablished a partnership with the Brazilian Agricultural Research Corporation (EMBRAPA), to initiate the Brazilian Dairy Gir Breeding Program (PNMGL, from the initials in Portuguese), back in the 1980s. It was the first breeding program in the world outlined with a progeny test for the improvement of an indicine breed aiming milk production. The objective of this paper was to describe a very successful public-private partnership in Brazil, in which EMBRAPA provides the technology and detachment needed for reliable genetic evaluations,

serving the breeders with information to improve their herds, while breeders provide the data allowing EMBRAPA and partners to continue developing relevant research projects.

Materials & methods

The PNMGL started in 1985 by selecting a group of purebred Gir sires, based on the data available at that time. Semen from those sires were distributed to small holder dairy producers, being used in purebred Gir, Holstein/Gir crossbreds of various genetic compositions or even purebred Holstein cows. EMBRAPA's and ABCGIL's personnel started making systematic visits to those herds in order to keep reproductive and productive records of the resulting female progeny. This progeny test scheme continues until the present day, with a new group of sires being included every year. Together with the purebred Gir genealogical and productive data, recorded by the Brazilian Association of Zebu Breeders (ABCZ, from its Portuguese initials), and the composite Girolando breed genealogical and productive data, recorded by the Brazilian Girolando Association, the progeny test composes the basis for the Brazilian Dairy Gir genetic evaluations. The Dairy Gir Sire Summary published in 2021 included a list of more than 500 bulls, evaluated for up to 26 different traits.

Traits recorded. In the beginning of the program, only milk yield, milk fat and age at first calving were recorded. In 1994, the program started recording 18 linear conformation and handling traits (*body traits*: rump height, heart girth, body length, rump length, pin width, hip width and rump angle; *legs and feet traits*: foot angle, rear legs side view and rear legs rear view; *mammary system traits*: fore udder attachment, rear udder height, rear udder width, udder depth, teat length and teat diameter; *handling traits*: milking ease and temperament). In 1999, milk protein, lactose, total solids and somatic cell count started being recorded. From 2001 biological samples from sires and production cows started being collected for DNA extraction and storage. Some markers of interest, related to milk properties started being analysed and published from 2006 and analyses for genetic diseases were included in 2013. The beta-casein genotype started being published in 2016, allowing some breeders to select their herds for the production of the A2A2 milk. Even though a number of traits are already included and many others still need to be properly recorded, the main selection objective of Dairy Gir breeders in Brazil still is 305 days milk yield.

Methods applied. First sire groups were formed by breeder's choices, based on the information they had from the genetic evaluations of parents, or the milk yield of the dam of the young bull. Along the time, the technical coordination followed the results of each group of sires, while implementing various innovations and rules to the program and the choice of sires to enter the progeny test. The animal model was implemented in 1995, replacing the formerly used sire model. One important rule was included to the group of sires selected in 2008, in which only young bulls from the top 10% dams of each herd, in terms of milk yield Expected Breeding Values ($EBV_{milk\ yield}$), should participate on the progeny test. The last breaking point of the program was the implementation of the genomic selection to the young bulls, that began in the group of sires selected in 2016, after structuring of the Gir genotyped reference population (Boison *et al.*, 2017). From this point, breeders had more accurate information to choose the best young animals within their herds and the program was able to select the most promising animals, amongst all breeders, to compose the groups of sires.

Results

Average milk yield of participating herds has considerably grown since the beginning of the breeding program. The phenotypic trend for this trait in the population can be observed through illustration in Figure 1.

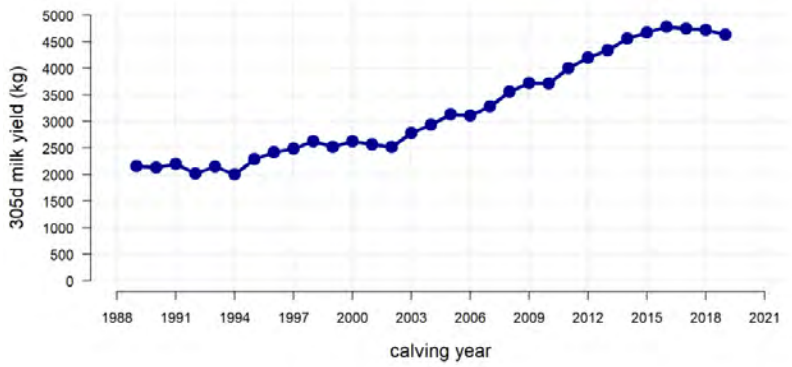

Figure 1. Phenotypic trend for 305 days milk yield since the beginning of the Brazilian Dairy Gir breeding program.

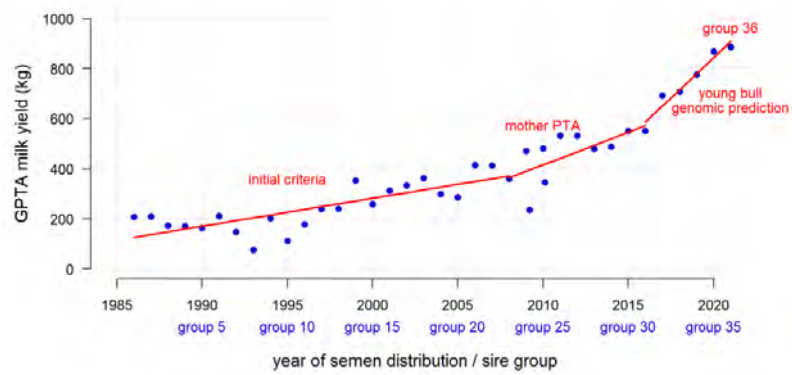

Figure 2. Genetic trend of the groups of sires since the beginning of the PNMGL: effect of change of criteria for the inclusion of young sires.

The impact of two actions taken by que program coordination on the genetic evolution for milk yield can be observed by the change in the slope of the genetic trend indicated by the average genomic values estimated for the groups of sires according to the year they have been included in progeny test (Figure 2).

In Figure 2, the blue dots indicate average genomic predicted transmitting abilities for milk yield of each group of sires. From the year 1985 to 2008 a small rate of genetic evolution can be observed (initial criteria). For this period, the milk yield of the dam was the main criteria used by the breeders to choose young sires to be included in the progeny test. For the second period (2008 to 2016) the mother of the young bull should be among the top 10% dams within the herd. This new rule, as expected, resulted in an increased genetic evolution in the population. For the most recent period observed (2016 to 2021) the increase in the rate of genetic evolution was even bigger. The use of genomic values for the selection of young bulls to be included in the progeny test allowed breeders to include more animals as candidates, by genotyping all born males at a young age. Thus, with better accuracy of genetic predictions and higher selection intensity, the rate of genetic evolution resulted in the program having its best Dairy Gir sires included in recent groups.

Discussion

Despite higher input costs and unfavourable weather conditions, Brazil's milk output is likely to rise by 1.0% year-on-year due to increasing dairy cattle numbers, increased herd sizes, improved genetics, and high yields in large-scale farms (FAO, 2021). Such conclusion from FAO's technical report is in accordance to the results observed in the Brazilian Dairy Gir breeding program, partially presented here. Genetic composition of dairy cattle herds in Brazil and other tropical countries include Gir and Holstein as the main breeds. Girolando is a composite breed formed by these two breeds, largely used for milk production and continually including improved sires and dams from both, Gir and Holstein breeds.

Genetic improvement of Holstein, Girolando and Gir populations have great impact on the milk production and dairy industry in the tropics. Considering the advances recently achieved by the Brazilian Dairy Gir Breeding Program, we can assume that newly obtained sires, and also genomic selected dams, have the potential to cause great improvements for the dairy herds in Brazil and other tropical countries, if the best animals are properly used for reproduction. Actually, exportation of Dairy Gir genetics from Brazil to tropical regions is clearly growing in recent years (unpublished data). Main countries importing Dairy Gir from Brazil are Colombia, Ecuador and Costa Rica. Even India, which is the country of origin of the Gir breed, can greatly benefit from improved Dairy Gir from Brazil.

Research groups should work as closely as possible the production environment, benefiting from the possibilities of obtaining field data and stimulating improved data annotation and collection. As an outcome of this approximation, innovation and technological solutions can be provided, resulting in quality and productivity advances to the sector.

Abstract

Genetic selection for phenotypic plasticity may be a solution to develop sires suitable for a variety of climates. Phenotypic plasticity can be modelled with random regression, where the additive genetic intercept represents production in a baseline environment and the slope of a first order model represents the environmental sensitivity and target of selection for phenotypic plasticity. Dry matter intake (DMI) was modelled as a function of a temperature humidity index (THI). The mean phenotypic trajectory point estimate was negative, indicating DMI decreases as THI increases. However, there was enough additive genetic slope variation for selection to move the population phenotypic slope towards zero and phenotypic plasticity. Selection for plasticity would likely be advantageous for DMI, because additive genetic correlations for DMI between divergent levels of THI (70 to 85) fell as low as 0.50. This indicates selection of sires using data from different environments may be inaccurate.

Introduction

Climate change is a serious issue contributing to increasing average global temperatures and greater variability in climate conditions (Nardone *et al.*, 2010; IPCC, 2007). Heat stress is known to negatively affect cattle (Fuquay, 1981; Nardone *et al.*, 2010) and can be measured by temperature humidity indices (THI). Thus, it is likely prudent to select for cattle adaptable to heat stress conditions.

Phenotypic plasticity represents the degree of sensitivity to an environmental variable and is characterized by stable performance across the environmental continuum (West-Eberhard, 2008). The sensitivity, or degree of change, of additive genetic potential as a function of the environment implies genetic-by-environment interaction (G×E) effects. The degree of environmental sensitivity, or the magnitude of G×E effects, can be characterized by the slope of a linear reaction norm. Individual animal reaction norms capturing the additive genetic component of phenotypic plasticity can be modelled via random regression. Thus, the objectives of this study were to characterize the genetic parameters for dry matter intake (DMI) with respect to THI using random regression models and the extent of G×E in a feedlot population of admixed steers.

Materials & methods

Population and phenotype collection. The study design, ration, and pre-processing details are described in Ahlberg et al. (2019). In total, seven cohorts of animals, comprised of 830 admixed steers, were on trial during all seasons from May 2014 to May 2018. All procedures involving the use of animals were approved by the Institutional Animal Care and Use Committee at Oklahoma State University (protocol AG13-18).

Phenotypes were collected for 70 days after an initial acclimation period. An Insentec system (Hokofarm Group, Marknesse, the Netherlands) was utilized to collect individual feed intake events, which were then summed to obtain daily DMI values. The THI was calculated using a livestock-specific equation (NOAA,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_408, © W. Shaffer *et al.* 2022

1976; Bohmanova *et al.*, 2007), where T_{db} is the dry-bulb temperature and RH is the percent relative humidity.

$$THI = (1.8 \times T_{db} + 32) - (0.55 - 0.55 \times RH / 100) \times (1.8 \times T_{db} - 26) \quad (1)$$

Temperature and humidity data were obtained from the Oklahoma Mesonet Stillwater tower in five-minute intervals. The THI was then calculated according to Equation 1 for each five-minute interval and daily DMI observations were paired with the maximum THI observed for the day to capture the effects of heat stress on feed intake. The THI values were subsequently centred around thermoneutral conditions by subtracting 70 from the THI value. Observations with a centred THI value that was negative were removed from the analysis as the analysis focused primarily on heat stressed conditions.

Statistical model and other computations. Random regression animal models with permanent environment effects were utilized to evaluate the influence of the THI on predictions of estimated breeding values (EBV). The following random regression model was utilized for DMI

$$y_{ijk} = \eta + f_i + \beta_1 x_{ijk} + \beta_2 v_{ijk} + a_j + b_j x_{ijk} + g_j + h_j x_{ijk} + e_{ijk} \quad (2)$$

where y_{ijk} is a DMI observation for an individual, η is the intercept, f_i is the effect of the i^{th} group, β_1 is the effect of a one unit increase of THI on DMI, x_{ijk} is the centred THI value associated with a DMI observation, β_2 is the effect of a one kg increase in initial body weight on DMI, v_{ijk} is the body weight measurement, in kg, associated with a DMI observation, a_j is the additive genetic intercept of animal j, b_j is the additive genetic slope for animal j, g_j is the PE intercept for animal j, h_j is the PE slope for animal j, and e_{ijk} is the residual for a given DMI observation. Notably, the model included heterogeneity of residual variances by group, a covariance between the additive genetic intercept and slope, a covariance between the PE intercept and slope, and a between-group variance. Location (fixed) parameters included the population intercept and slope for the THI covariate and the covariate for initial body weight. Dispersion parameters (random) included the group effect, additive genetic intercept and slope for the THI covariate, PE intercept and slope for the THI covariate, and the residual effect. Analyses were conducted in a Bayesian framework with improper, uninformative priors and posteriors for all parameters were sampled.

Additive genetic variances for various levels of THI and additive genetic covariances and correlations between each pair of THI values were computed as follows:

$$\sigma_{u|x,u|x'} = \text{cov}(a_j + b_j x, a_j + b_j x') = \sigma_a^2 + xx'\sigma_b^2 + (x + x')\,\sigma_{ab} \quad (3)$$

where $\sigma_{u|x,u|x'}$ represents the additive genetic covariance for DMI between THI values x and x'.

Results

Parameter point estimates from the random regression models are in Table 1. The DMI intercept was positive at 5.79 kg DMI, but the population slope was negative, with a decrease of 0.046 kg DMI/ 1 unit THI. The DMI additive genetic intercept point estimate was 2.01 kg DMI^2, the additive genetic slope variance was 0.0078 (kg DMI / 1 unit $THI)^2$, and the additive genetic covariance between the intercept and slope was -0.10 kg DMI^2 / 1 unit THI. Permanent environment variance components were at least one magnitude smaller than their corresponding additive genetic counterparts. Residual variances by group ranged from 2.07 to 3.22 kg DMI^2. The genetic correlation between the additive genetic intercept and slope was negative at -0.66.

Table 1. Posterior median point estimates for model parameters, including lower and upper bounds of 95% highest posterior density credible intervals for daily dry matter intake (DMI) measured as kg. Slope parameters represent the DMI response to the temperature humidity index covariate.

Parameter	Estimate	Lower	Upper
η	5.79	4.88	6.66
β_1	-0.046	-0.053	-0.039
σ_f^2	0.85	0.10	3.92
σ_a^2	2.01	1.54	2.49
σ_{ab}	-0.10	-0.13	-0.07
σ_b^2	0.0078	0.0061	0.0096
σ_g^2	0.27	0.00	0.59
σ_{gh}	-0.0066	-0.03	0.00
σ_h^2	0.0007	0.0000	0.0020
$\sigma_{e_2}^2$	3.221	1.86	4.71
$\sigma_{e_6}^2$	2.231	2.13	2.33
r_{ab}	-0.78	-0.86	-0.69

[1] The largest and lowest residual variance point estimates were for groups 2 and 6, represented by the subscript. Residual variance point estimates for groups 1, 3-5, and 7 were between 2.23 and 3.22.

Point estimates for the DMI additive genetic correlations between different levels of THI are in Figure 1. The genetic correlations between different levels of THI ranged from near one at close intervals of THI to 0.5 as pairwise values of THI diverged.

Discussion

The population mean phenotypic trajectory for daily DMI decreased on average, equating to a mean loss of nearly 0.5 kg DMI per day for every increase of 10 units of THI. Compounded over many days and many head of cattle, this may equate to a substantial decrease in performance in both DMI and average daily gain (Santana *et al.*, 2014). Fortunately, there is sufficient genetic variation with respect to the environmental sensitivity (i.e. the additive genetic slope) for selection to move the mean phenotypic slope towards zero and thus increase phenotypic plasticity. Using empirical rule, 95% of EBVs would be expected to be within the interval of -0.177 to 0.177 kg DMI / 1 unit THI. Given the population phenotypic mean trajectory is

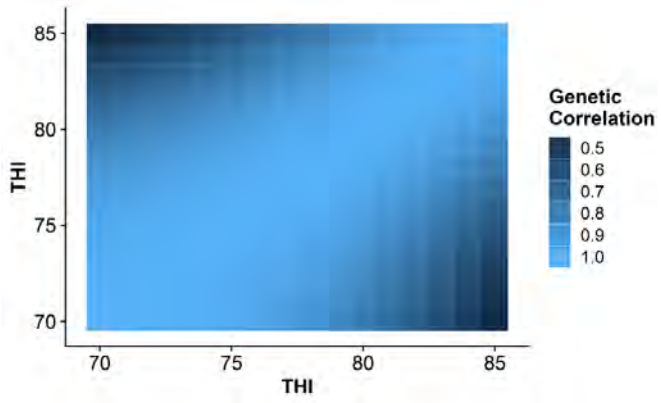

Figure 1. Genetic correlations for dry matter intake between different values of the temperature humidity index (THI).

-0.046 kg DMI / 1 unit THI, this indicates selection can move the population to be more phenotypically plastic on average.

The negative additive genetic correlation between the additive genetic intercept and additive genetic slope indicates selection to increase DMI in non-heat stressed conditions will decrease the slope on average, which is not favourable for phenotypic plasticity given the negative population trajectory. These results agree with the majority of G×E studies using the same THI function, such as Aguilar *et al.* (2009), where similar unfavourable relationships between plasticity and production exist. However, Sungkhapreecha *et al.* (2021) have reported a favourable additive genetic correlation between selection for milk production in non-heat stressed environments and environmental sensitivity to the THI in a Holstein × Thai *Bos indicus* cross and Bradford *et al.* (2016) demonstrated a favourable correlation between the intercept and slope for maternal weaning and yearling weight respective to THI in Angus animals. This may indicate inclusion of *Bos indicus* alleles could shift production under heat stressed scenarios to be favourable.

Given the low genetic correlations for DMI between diverse values of THI, sire EBVs would likely reranked based on the environment they are utilized in. Failure to account for these G×E effects would lead to decreased accuracy in cross-environment selection, thus decreasing the rate of genetic progress. Given the correlations for DMI between different levels of THI are low, selection to increase phenotypic plasticity is advisable.

Abstract

Driven by the diversity of the Afrikaner and Brahman cattle, regarding their diverged origins, different migration routes to South Africa and performance under harsh environmental conditions; this study was designed to investigate genomic differentiated regions that may be evidence of parallel adaptive mechanisms. Across breed, edited genotype data included 83,306 SNPs common for 309 Afrikaner and 523 Brahman animals. Estimation of differentiation and signatures of selection explored two statistical complementary tests i.e. pairwise F_{ST} and FLK. Average F_{ST} was 0.318, showing moderate population structure. Regions of differentiation were located on Chromosomes 1, 6 and 21 with 105 putative candidate genes (65 annotated and 40 unannotated) using F_{ST}, and Chromosomes 4, 6, 11, 12 and 21 with a combined 4,697 candidate genes using FLK method. Shared regions were on Chromosomes 6 and 21, with underlying genes (e.g. SEM4B and SEC11A) responsible for compensatory growth and mammary involution during dry period and environmental heat stress.

Introduction

Different historical origins and divergent routes into South Africa (SA) characterize the Afrikaner and Brahman cattle breeds. The Afrikaner cattle are Sanga type (*Bos taurus africanus*), typically small to medium frame size and have a unique evolutionary adaptation to harsh climatic conditions and the Brahman cattle are Zebu type (*Bos indicus*) medium framed cattle, developed from the Nellore, Gir, Indo-Brazil, Guzerat and Krishna Valley cattle, which themselves originated from Pakistan, India and Brazil (Hartati *et al.*, 2015). The Afrikaner cattle have low susceptibility to endemic diseases, tolerance to trypanosomiasis, and great adaptability to extensive grazing in the arid areas of SA and survive on low quality forage (Scholtz *et al.*, 2016). The Brahman breed is heat tolerant, has resistance against internal and external parasites and can survive on low quality forage. This breed has desirable traits that separate it from other indigenous breeds, such as maintenance of a balance between low birth weight and higher weaning weight and has good mothering abilities. However, the Brahman cattle lacks tolerance against trypanosomiasis (Mattioli *et al.*, 2000).

The Afrikaner and Brahman cattle differ in historical origins and development, as also shown by their phenotypic disparities. However, harsh SA climatic conditions, characterized by dry and extreme weather conditions may have driven selection in both breeds to favour development of parallel adaptive mechanisms at the genome level. There is limited information about the shared genes associated with adaptation between the Afrikaner and Brahman, and the parallel evolution of adaptive mechanisms between these breeds. This information will be useful in breeding programmes to improve their genetic response to environmental stressors. In this study, we explore 2 statistical complementary tests i.e. fixation index (F_{ST}) and marker differentiation (FLK) (Bonhomme *et al.*, 2010) to assess genetic differentiated regions that may be evidence of parallel evolution of adaptive mechanisms due to similar environmental conditions in South African Afrikaner and Brahman cattle breeds.

Materials & methods

Resource population and genotyping. Influential animals explaining the genetic diversity of the breeds were defined by their marginal genetic contributions to the entire population. The ARC-Animal Production ethical committee (APIEC18/03) approved sample collection (hair and semen samples) and genotyping procedures for this study. A total of 373 Afrikaner and 523 Brahman cattle were genotyped for 141,746 SNP markers using GeneSeek Genomic Profiler. Minor allele frequencies (MAF) and call rates (CR) for the individual SNP and animals were edited within and across breeds using Plink v1.9, where markers with MAF<0.02, CR<0.95, and individuals with call rate <0.90 were excluded. Within breeds, the edited data contained 92,291 and 99,086 autosomal SNP, respectively, for 310 Afrikaner and 523 Brahman animals. These data were used to estimate linkage disequilibrium (LD), genetic diversity and haplotype block structure. Across breeds, the edited data contained 83,306 SNP common to both breeds, which were used to detect differentiated regions containing putative selective sweeps.

Statistical analysis. Population admixture was investigated in the Afrikaner and Brahman after selecting 30,000 SNP markers pruned for LD<0.03 using a sliding window of 50 SNP and forward shift of 3 SNP in order to reduce the number of markers in LD. The genetic admixture with cross-validation (CV) for K values ranging from 1 to 3 was performed using Admixture v1.22 default parameters, were SA Limousine breed (Bos taurus) was used as an out-group. Clustering among breeds was visualized with a multi-dimensional (MDS) plot in Plink v1.9. Pairwise F_{ST} statistic was calculated as 1000 kb sliding windows with a step size of 50 kb. Genomic regions with average $F_{ST} \geq 0.2$ were examined further. The FLK statistic, which is a single SNP test that accounts for population size heterogeneity and structure to compute a global F_{ST} for each SNP was used to detect loci differing between breeds. The calculation of FLK exploits a kinship matrix where each chromosome was analysed independently, and the probability of the difference between loci was based on the $\log_{10}$ of probability values (*P*-values).

Ensembl variant effect predictor (VEP) was used to annotate the genome regions harbouring potential signatures of selection. The annotated variants from Ensemble were used for general 'gene to biological pathway' classification in PANTHER 15.0 and the NCBI gene database manual search was conducted to identify the candidate genes underlying signatures of selection.

Results

The Afrikaner cattle showed more ancestral admixture while the Brahman and Limousine had negligible levels of ancestral admixture (Figure 1 left). The separation of Brahman from Afrikaner and Limousine on the 1st MDS coordinate likely reflects more indicine heritage compared to the taurine ancestry of Afrikaner and Limousine breeds, while similarity of Brahman and Afrikaner at the 2nd MDS coordinate could be tracing back the indicine ancestor (Figure 1 right).

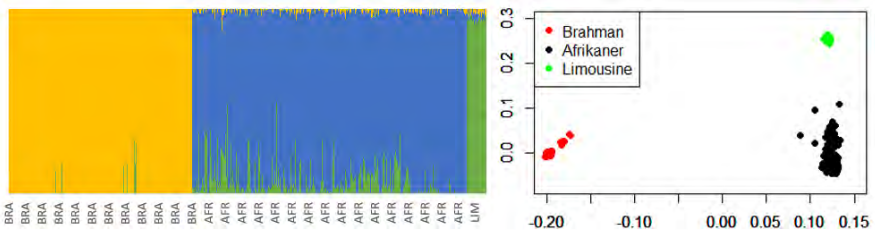

Figure 1. Admixture of the Afrikaner (AFR) and Brahman (BRA) ancestry at K=3 with the Limousine (LIM) as outgroup (left) and the Multi-dimensional plot of the distinct separation of the breeds (right).

Table 1 presents putative signatures of selection that are indicative of differentiation between Afrikaner and Brahman cattle and the number of underlying candidate genes for these breeds.

The average estimated F_{ST} was 0.318, and subsequent regions of differentiation between the breeds were identified in chromosomes 1, 6 and 21, with chromosome 1 having the longer window than 6 and 21. A total of 105 putative candidate genes were revealed with 65 annotated and 40 unannotated genes.

The FLK statistics located regions of differentiation in chromosomes 4, 6, 11, 12 and 21 with a combined 4,697 candidate genes underlying these regions, Chromosome 4 had the longest SNP window that consisted of 1,175 genes, while Chromosome 21 had a shortest window consisting of 814 candidate genes. Shared regions were observed between F_{ST} and FLK analysis on Chromosomes 6 and 21. Candidate genes identified in the shared regions included *FABP2, SEM4B and SEC11A*.

Discussion

Genetic structure and clustering showed some degree of common ancestry between the Afrikaner and Brahman. The levels of ancestral admixture of the Afrikaner versus Brahman and Limousine were previously observed by Makina *et al.* (2016), where ancestral genetic contributions making up the Afrikaner was quantified as 70% African taurine and 28% indicine. Population admixture and clustering for the Afrikaner was consistent with the suggested migration route and point of introgression between its ancestral breeds (African taurine from Egypt and Sudan; and *Bos indicus* breeds from Asia).

Differentiated genomic regions identified a higher proportion of candidate genes associated with adaptation than production in both breeds. For example, *GTPBP8* gene in Chromosome 1, was previously associated with post-partum anoestrus, resumption of ovulation, hormone activity and energy balance in tropical Brahman cattle (Fortes *et al.*, 2014). In terms of parallel adaptive mechanisms, shared regions between breeds and methods located on chromosomes 6 and 21 were underlined by candidate genes such

Abstract

This study was undertaken to estimate the additive genetic variances of milk yield and heat tolerance and the genetic correlation between these effects at different thermal loads as a first step in exploring the possibility of including heat tolerance in selection indices for dairy cattle selection in the sub-Saharan African climate of Tanzania. Data obtained from aWhere, an agricultural weather data platform (http://www.awhere.com) was analysed with 15,703 test day milk records of 9,922 dairy cows collected between 2016 and 2020. Temperature humidity index (THI) was calculated from daily maximal temperatures and daily minimum humidity. Variance components were estimated using a fixed regression model with random regressions on a function of THI for additive genetic and permanent environmental effects modelled with an intercept and a slope. Results suggested that milk yield is antagonistic with heat tolerance, and selection for only increased milk production might reduce heat tolerance in this population.

Introduction

Climate change is expected to have major impacts on livestock, including increased heat stress in animals in many parts of the tropics and in low and middle-income countries (LMICs), where the cost of heat stress abatement measures may be prohibitive (Thorton *et al.* 2021). One alternative approach to mitigating the impact of climate change in dairy cattle, especially in smallholder dairy systems of LMICs which are more vulnerable to the impacts of a changing global climate than other dairy systems would be selection for improved heat tolerance in production traits, to which several authors have demonstrated substantial between animal genetic variation and low to moderate heritability (Ravagnolo and Misztal, 2000; Bernabucci *et al.*, 2014). Using temperature-humidity index (THI), a single value that combines the effects of air temperature and humidity as an indicator of heat load, Ekine-Dzivenu *et al.* (2020) evaluated the effect of heat stress on milk production and described the pattern of response of milk yield to increasing heat load in small holder dairy cattle populations in the sub-Saharan African climate of Tanzania. Results from their study indicated that cows experienced heat stress between THI values of 67 and 76 after which milk loss plateaued. Identifying sires and dams to improve thermotolerance in smallholder farming systems in sub-Saharan Africa in the face of rising temperatures is of vital importance for small holder dairy profitability and will require availability of genetic parameters which is presently lacking. Within the described background, the goal of this study, was to evaluate changes in genetic parameters for milk yield and heat tolerance in small holder dairy cattle population of Tanzania under different THI thresholds as a first step toward including this trait in selection indices for dairy cattle in the region.

Materials & methods

Data. This study was carried out as part of a wider project called African Dairy Genetic Gains (https://www.ilri.org/research/projects/african-dairy-genetic-gains) which is developing and testing a multi-country genetic gains platform using smallholder dairy cattle performance and genomic information. Performance

DOI: 10.3920/978-90-8686-940-4_410, © C.C. Ekine-Dzivenu *et al.* 2022

data consisting of 134,987 test day records of 14,741 cows from 8,735 farms, with pedigree information comprising 67,910 animals were extracted from the International Livestock Research Institute (ILRI) database (https://www.adgg.ilri.org/uat/auth/auth/login) for cows registered on the ADGG project from November 2016 until May 2020 in Tanzania. The Data was subjected to several edits as previously described by Mrode *et al.* (2021). Climate data was obtained from aWhere (http://www.awhere.com), an agricultural weather data platform using GPS coordinates of the farms at 10 km grid cell resolution. This included daily maximum (Tmax, °C) and minimum relative humidity (RHmin, %). Daily THI was calculated by applying the National Research Council (1971) formula as follows:

$$\text{THI} = (1.8 \times \text{Tmax} + 32) - [(0.55 - 0.0055 \times \text{RHmin}) \times (1.8 \times \text{Tmax} - 26.8)] \quad (1)$$

Each THI was calculated using a 4-day average of Tmax and RHmin from measures on the test day and 3 days prior. After production and weather data were merged and duplicate THI values per animal removed, 15,703 records for 9,922 animals remained for analysis.

Genotypes. Genotypic data for this study were from 1,916 cows and bulls genotyped with the GeneSeek Genomic Profiler Bovine 50K chip. These were imputed to the Illumina HD chip using a reference population consisting of crossbred cattle from East Africa and several European purebred animals (Aliloo *et al.*, 2018). After quality control, 681,511 SNPs remained for inclusion in the analysis.

Statistical model. Variance components were estimated using a fixed regression model with random regressions on a function of THI for additive genetic and permanent environmental effects using the Wombat program (Meyer, 2006). The model fitted was as follows

$$y_{ijklmno} = \text{wym}_i + \text{breed}_j + \text{par}_k + \text{age}_l(\text{par}_k) + \text{dim}_m(\text{par}_k) + a_n + \text{aht}_n\,[f(THI)i] + \text{pe}_n + \text{peht}_n\,[f(THI)_i] + e_{ijklmno} \quad (2)$$

where $y_{ijklmno}$ is the o^{th} test-day milk yield of cow n; wym_i is the random effect of the i^{th} combination of ward-year-month of milking; breed_i is the fixed effect of the i^{th} breed group; par_k is the fixed effect of the k^{th} parity; age_l is the fixed effect of the l^{th} age group nested within parity; dim_m is the fixed effect of the m^{th} dim group nested within parity; a_n is the random additive genetic effect of cow n without consideration of heat tolerance (intercept); aht_n is the random additive genetic effect of heat tolerance for cow n (slope); pe_n is the random permanent environmental effects of cow n without consideration of heat stress (intercept); $peht_n$ is the random permanent environmental effect of cow n for heat tolerance (slope); $f(THI)_i$ is a heat stress function for ward-year-month of milking and $e_{ijklmno}$ is the random residual effect. The THI function was defined as follows:

$$f(THI) = \{0, THI \leq THIthreshold\ (no\ heat\ stress)$$

$$THI - THIthreshold, THI > THIthreshold\ (heat\ stress) \quad (3)$$

using various heat stress threshold points (69, 71, 78), previously reported by Ekine-Dzivenu *et al.* (2020) for the same population. Genomic analyses were implemented with single-step genomic best linear unbiased prediction (ssGBLUP) where inverse of the pedigree-genomic relationship matrix H was used for the estimation of genetic parameters. Heritability for production of milk at heat stress levels, genetic correlations between the intercept and slope of the additive genetic effects and between the intercept and slope of the permanent environmental effects was calculated based on Ravagnolo and Misztal (2000).

Results

A summary of the mean, standard deviation, and range of test-day milk yield including a summary of weather data characterizing THI during the period of this study is presented in Table 1. Estimates of genetic parameters for milk yields along the THI gradient are presented in Table 2 and shows a decrease of variance for additive genetic effect of the intercept (9.83±1.21 to 7.52±1.39) but an increase for additive genetic variance for the slope (0.10±0.61 to 2.15±0.95). Covariance between the intercept and the slope for additive genetic effects were negative and ranged from -0.24±0.72 to -2.10±0.93 and correlation ranged from -0.06 to -0.99 but variances and covariance between the intercept and the slope for permanent environmental effects were negligible across THI levels (not shown). Heritability estimates for milk yield showed an increase across THI gradient and ranged between 0.38 to 0.50.

Discussion

Our study detected antagonistic relationships between milk yield (intercept) and thermal tolerance for heat stress (slope) which suggests that selection for increased milk yield disregarding heat tolerance will result in deteriorating heat tolerance in this population. Antagonism between milk production and heat tolerance has also been found in several other studies in cattle (Ravagnolo and Misztal, 2000; Bernabucci *et al.*, 2014; Carabaño *et al.*, 2014). Estimates for permanent environmental variances were very small which might indicate that sensitivity for heat stress is not cow-specific but genetic. It is important to note that not observing animals across the THI gradient due to low retention of cows in the small holder farms may contribute to the low permanent environmental variances observed. The moderate heritability estimates for milk yield over different heat stress levels found in this study show potential to genetically improve

Table 1. Basic description of milk yield and weather data.

411. Genetic analysis of traits needed to optimize improvement in beef cow-calf efficiency in Afrikaner cattle

M.M. Scholtz[1,2*], M.D. MacNeil[1,2,3], M.C. Chadyiwa[1,2] and F.W.C. Neser[2]

[1]Agricultural Research Council, Animal Production, Private Bag X2 Irene 0062, South Africa; [2]University of the Free State, P.O. Box 33009, Bloemfontein, 9300, South Africa; [3]Delta G, 145 Ice Cave Rd., Miles City, MT 39301, USA; gscholtz@arc.agric.za

Abstract

Improving beef cattle productivity will have positive sustainability implications, as it will reduce resource use while improving the economic viability. Achieving optimal cow-calf efficiency is therefore important but measuring it in extensive cow-calf production systems is not easy; however, it is imperative that it should be estimated. In this study data from the indigenous Afrikaner beef breed was used to estimate genetic parameters for the three component traits of cow-efficiency, viz. weaning weight, cow weight and fertility as measured by inter-calving period. The estimates of (co)variance components indicated low to moderate heritabilities for the component traits and the presence of weak genetic antagonisms among the components of cow efficiency. The use of the ratio of calf weight to cow weight should be replaced by an index that includes reproductive performance. Annual cow-calf efficiency can be calculated for every individual, including bulls and those with incomplete records, using their EBV's.

Introduction

The world population is expected to increase dramatically in the coming decades with a commensuration increase in demand for high quality protein products (e.g. beef). This population increase is expected to be mostly in the developing countries of Africa (Bello-Schünemann, 2017). In addition, the beef cattle industry globally faces the challenge to maintain and improve sustainability with the increase in global population. Furthermore, environmental stewardship of beef producers is under scrutiny as many consumers perceive that beef production has an unacceptable environmental cost (Scholtz *et al.,* 2020). Improving production efficiency will have positive implications for sustainability because resource use and greenhouse gas emissions will be reduced whilst improving the economic viability of beef producers (Scholtz, *et al.,* 2013a).

Livestock agriculture is the largest user of land resources in South Africa, where 71% of the surface area is only suitable for extensive livestock farming (Scholtz, *et al.*, 2013b). Consequently, primary beef cattle farming (cow-calf production cycle) is largely extensive. The cow-calf portion of the production cycle (the extensive part in South Africa) accounts for 72% of the energy that is utilized from conception to harvest. (Ferrell and Jenkins, 1982). Improvement of the productivity of beef per unit of feed used over the whole production system would be of significance to beef producers.

Achieving optimal efficiency is therefore a significant goal in beef production. It should be noted that on the farm, an efficient animal would be the one that has minimum maintenance requirements and has the ability to convert available energy (forage) into the greatest possible kilogram of weaned calves, without increasing the mature weight (or the maintenance requirements) of the cow. In spite of the fact that the ratio of calf weight at weaning to cow weight (CW) favours smaller cows, it has long been used as a proxy for efficiency (Dickerson and Grimes, 1947; Frahm and Marshall, 1985; Lemes *et al.*, 2017) and is still used frequently (Thompson *et al.*, 2020; Farrell *et al.*, 2021). Therefore, following from Dickerson (1970), an index (I) of the phenotypes for the three components traits weaning weight (WW), CW and inter-calving period (ICP) is proposed as a metric to evaluate annual cow efficiency:

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_411, © M.M. Scholtz *et al.* 2022

$$I = (365 \times WW) / (ICP \times CW)$$

The objective of this study was to estimate genetic parameters for the component traits in I for the Afrikaner breed, which is indigenous to South Africa.

Materials & methods

The data were extracted from the Integrated Registration and Genetic Information System of South Africa. After being edited, the data comprised of weaning weight records for 29,975 calves, with 19,191 records of cow weights from 8,556 unique cows, and 6,181 records of inter-calving period. Only those cows with at least one recorded measurement of body weight at the time of weaning and their progeny were retained in the dataset for analysis. The pedigree that was used to quantify relationships among animals contained 38,766 records.

Multiple-trait analyses using restricted maximum likelihood methods were implemented using the software of Boldman *et al.* (1995). The linear model for weaning weight contained a linear covariate for age of calf at weaning, a categorical fixed effect for age of dam and sex of calf, random direct and maternal genetic effects, and uncorrelated random effects of the herd-year-season (HYS) in which the calf was weaned and the permanent maternal environment provided by the dam. The linear model for cow weight contained a categorical fixed effect for the age of the cow, a random direct genetic effect, and uncorrelated random effects to account for the herd-year-season in which the cow was weighed and to account for repeated observations. The linear model for inter-calving period contained a categorical fixed effect for the age of the cow when she first calved, a random direct genetic effect, and uncorrelated random effects to account for the herd-year-season in which she first calved. Note that with annual calving and a fixed breeding season, the HYS of subsequent calving events is confounded with the herd-year-season of first calving. Convergence to a global maximum was assumed when the variance of values in the simplex was less than 10^{-9} with confirmation that the parameter estimates were unchanged in independent analyses. Adjusted phenotypes for WW, CW, and ICP were calculated by combining the corresponding EBV with the overall means for the respective traits.

Results

Estimates of the phenotypic and genetic parameters for weaning weight, cow weight and inter-calving period for Afrikaner cattle are given in Table 1.

Table 1. Estimates of genetic parameters for weaning weight, cow weight and inter-calving period of Afrikaner cattle.

Effects	Weaning weight		Cow weight		Inter-calving period	
	VC[1]	%[2]	VC[1]	%[2]	VC[1]	%[2]
Direct genetic	131.1	18±1	923.3	33±2	3,184.7	34±3
Maternal genetic	72.6	10±1				
Permanent environmental	58.5	8±1	383.9	14±1		
Herd-year-season	265.6	33±1	691.2	25±1	2,912.1	31±2
Residual	233.7	32±1	724.2	27±1	3,275.6	35±3
Phenotypic variance	730.0		2,722.6		9,372.4	

[1] Variance component.

[2] Percentage of phenotypic variance.

Estimates of the heritabilities and genetic correlations are given in Table 2. The heritability estimates may differ somewhat from those found in other literature because they include the variance of HYS effects in the phenotype variance. This practice allows for the recovery of genetic variance that is present between the HYS classes which make the prediction of breeding values more accurate. The heritability estimates range from low in the case of weaning weight direct (WWd) and weaning weight maternal (WWm) to moderate / high in the case of cow weight (CW) and inter-calving period (ICP). The high heritability of ICP is somewhat surprising, especially considering that the variance among contemporary groups is included in its denominator.

With respect to genetic correlations the following should be noted: (1) there is a moderate negative genetic correlation between WWd and WWm, (2) WWd is moderately positively correlated with CW, indicating selection for it will tend to result in heavier cows, (3) the correlation between WWm and cow weight is low negative, indicating that cows with more milk will tend to be smaller, (4) the low negative correlation between WWd and ICP may indicate that calves that are heavier at weaning may have shorter ICP's and (5) the correlation between CW and ICP is low negative indicating that lighter cows will have longer ICP's.

The estimated breeding values (EBV) resulting from this multiple trait analysis had average accuracies for WWd, WWm, CW, and ICP of 0.59, 0.46, 0.61, and 0.51, respectively. The rank correlations were also estimated and are presented in Table 3. The negative rank correlation of ICP with WWd (-0.46) and CW (-0.46), indicate that more fertile cows will tend to have greater growth potential.

Due to its commonplace use (e.g. Thompson *et al.*, 2020), the ratio of weaning weight to cow weight is used here as a benchmark. The annual efficiency index (I) that includes ICP ranks animals in a manner that is moderately correlated with this ratio (r =0.5). Thus, using the weaning weight to cow weight ratio will explain approximately 25% of the variation in annual efficiency when differences in the probability of producing a calf are taken into account. The rank correlations for the proposed annual efficiency index with its component traits were 0.47 for weaning weight direct, 0.31 for weaning weight maternal, 0.15 for cow weight, and -0.80 for inter-calving period.

Table 2. Estimates of heritability (on the diagonal) and genetic correlation (above the diagonal).

Trait	Weaning weight direct	Weaning weight maternal	Cow weight	Inter-calving period
Weaning weight direct	**0.18**	-0.32	0.55	-0.17
Weaning weight maternal		**0.10**	-0.22	0.14
Cow weight			**0.33**	-0.19
Inter-calving period				**0.34**

Table 3. Estimates of the rank correlations between the EBV's of the different traits.

Trait	Weaning weight maternal	Cow weight	Inter-calving period
Weaning weight direct	-0.02	0.76	-0.46
Weaning weight maternal	-	-0.13	0.06
Cow weight		-	-0.46

Discussion

The estimates of (co)variance components clearly show the presence of modest genetic correlations among the components of cow efficiency. The direct-maternal correlation for weaning weight was clearly negative in these data and should be included in the genetic evaluation for this trait (Lee, 2002). However, the ranking of animals by either component of weaning weight was essentially unchanged. Conversely, the genetic correlations of ICP with WWd and CW were both larger and thus indicated that more fertile cows (low ICP) would be genetically heavier. Favourable genetic relationships between growth and reproduction have been observed (Kluska *et al.*, 2018; Santana *et al.*, 2012); but significant antagonisms between these traits have also been observed (MacNeil *et al.*, 1984). These genetic relationships indicate the need for multiple trait genetic evaluation and selection indexes to improve biological and economic efficiency, and reduce the environmental impact of beef production.

It is recommended that the use of the ratio calf weight to cow weight needs to be replaced by an index that includes reproductive performance. Because the components of cow efficiency are correlated, additional accuracy can be gained in their genetic evaluation using multiple trait models. The recommended index can be derived from the genetic evaluation for the component traits. One advantage of using the EBV's to calculate annual cow-calf efficiency is that it can be calculated for every individual, including bulls and animals with incomplete records.

Abstract

While genomic tools have been applied to address various questions in livestock of European origin, primarily from temperate and boreal ecological zones, less is known about African breeds, many of which are from tropical regions. Our study focused on indigenous Blackbelly sheep from Cameroon, most of which has a tropical climate. We found that Cameroon Blackbelly sheep are genetically distinct from other African sheep populations and are associated with a single ancestry. Genes found in genomic regions of low diversity suggest biological functions that may be under strong selection, including immune function, pigmentation and fertility. Genomic diversity information from indigenous tropical livestock is a valuable source of information to understand environmental adaptation of animals to local conditions and will also inform the development of new and existing genotyping platforms.

Introduction

An important application of genomic technologies over the last several years has involved the use of genetic diversity patterns to help identify genes and functional gene groups associated with environmental adaptation. This approach has been applied in various livestock species and has led to the identification of candidate genes related to adaptation to high altitude (Friedrich and Wiener, 2020) as well as other climatic and disease factors (e.g. hot or cold temperature, aridity (Wiener *et al.*, 2021; Yurchenko *et al.*, 2018); nematode resistance (Ahbara *et al.*, 2021)).

The Republic of Cameroon is a country in west-central Africa. Most of Cameroon has a tropical climate, with wet and dry seasons. It has a diverse geography, including highlands, low-lying coastal plains and tropical forests, suggesting that autochthonous livestock may be adapted to the local environmental conditions. It has also been estimated that 2/3 of the country is at risk from Animal African Trypanosomiasis, due to tsetse fly infestation (Meyer *et al.*, 2016). Compared to cattle, less is known about this endemic African disease among small ruminants, however, there is evidence that some West African sheep and goat breeds are trypanotolerant (Geerts *et al.*, 2009). Anecdotally, the Cameroon Blackbelly sheep, which is indigenous to Cameroon, has been reported to be tolerant to trypanosomiasis, suggesting that they have been under selection for this trait and that this may have left a signature on their genome. Based on similarities in physical appearance and historical information (Meka zibi II. *et al.*, 2019) as well as genetic findings for other West African sheep (Spangler *et al.*, 2017), it is likely that the genetics of the Cameroon Blackbelly sheep has contributed to sheep breeds of the Caribbean (i.e. Barbados Blackbelly) and elsewhere in the world. Capturing the genetic diversity of indigenous breeds such as Cameroon Blackbelly will facilitate characterisation of the genetic basis of environmental adaptation and disease resistance and also help to ensure that such breeds are adequately represented in new and existing genotyping tools.

Materials & methods

Samples. Ear notch samples from 111 Cameroon Blackbelly sheep were collected from regions across Cameroon. DNA was extracted using a DNAEasy Blood and Tissue Kit. Samples were genotyped using the Illumina Ovine 50K SNP chip. Additional 50K data for 97 other sheep breeds from across the globe was extracted from public databases. For two additional breeds from West Africa, publicly available whole-genome sequence data was down-sampled to provide 11-22K markers on the 50K array. Highly related individuals (first-degree or greater) were removed from the dataset (including 30 Cameroon Blackbelly sheep). Marker positions were based on the OAR3.1 reference genome assembly coordinates.

Population structure. In order to analyse data across breeds, a subset of 12,047 markers was extracted that were genotyped in most of the down-sampled individuals and which met additional criteria (genotype coverage >0.90, minor allele frequency >0.01 and between-marker r^2<0.5). In order to balance the dataset across breeds, a subset of individuals were selected for analysis. For the set of European + Pacific (Australia/ New Zealand) breeds, 250 representative samples were selected using the Corehunter v3.2.1 method with default settings (De Beukelaer *et al.*, 2018). For other breeds with >10 samples (excluding the Cameroon sheep), 10 individuals per breed were selected, again using Corehunter. All individuals were retained from breeds with ≤10 samples and from the Cameroon sheep. The complete dataset comprised 779 individuals, including 81 Cameroon sheep. Subsequent analyses were carried out for only the African breeds (262 individuals, 11,937 markers) and only the Cameroon sheep (81 individuals, 11,976 markers).

Plink 1.9 (Chang *et al.*, 2015) was used to carry out principal components analysis (PCA) on the full dataset. Admixture software (Alexander *et al.*, 2009) was used to estimate ancestry using the complete dataset, the subset of African breeds and only the Cameroon sheep. Assessment of the number of underlying clusters (K) was assessed by the default (5-fold) cross-validation procedure.

Genomic regions of reduced diversity. Normalized heterozygosity values in the Cameroon sheep were identified using the ZHp statistic (Rubin *et al.*, 2012; Rubin *et al.*, 2010) for 45,066 markers with >0.90 genotype coverage in the 81 unrelated individuals. Window averages (ZHp-window) were calculated in 9-SNP sliding windows across the genome (with step size of 1 SNP), such that the statistic was attached to the central marker in each window. Markers in the bottom 0.001of the ZHp-window distribution (lowest level of heterozygosity) were extracted and signatures of selection were identified as groups of markers within 200 kb of each other. Genes underlying the genomic signatures were identified based on the annotation of the OAR3.1 reference assembly.

Results

PCA. The first principal component (PC) of the PCA (Figure 1) explained 29% of the genotype variation while PC2 explained 23%. The separation of individuals/breeds by PCA was strongly associated with geography, with a few exceptions: (1) Pacific breeds clustered with European breeds and (2) some North and South African individuals clustered together, close to Middle Eastern breeds. Higher PC1 values were associated with African breeds, with highest values for the Cameroon sheep. Lower PC1 values were associated with European/Pacific breeds.

Population ancestry. The Admixture analysis of the complete dataset supported K=14 underlying clusters, where West African sheep were primarily associated with a single cluster. Out of the 81 individuals from Cameroon, all except four had ancestry proportions of >70% for this cluster. Outside of West African sheep, this cluster was represented at <13% ancestry except in the Barbados Blackbelly breed, from the Caribbean, where it was represented at ~30%. The Admixture analysis of only African populations (Figure 2) supported K=6 underlying clusters, where one main cluster was represented at high ancestry in the Cameroon sheep (most individuals with ancestry >80%) and also in the other West African sheep (Figure 2). This cluster was

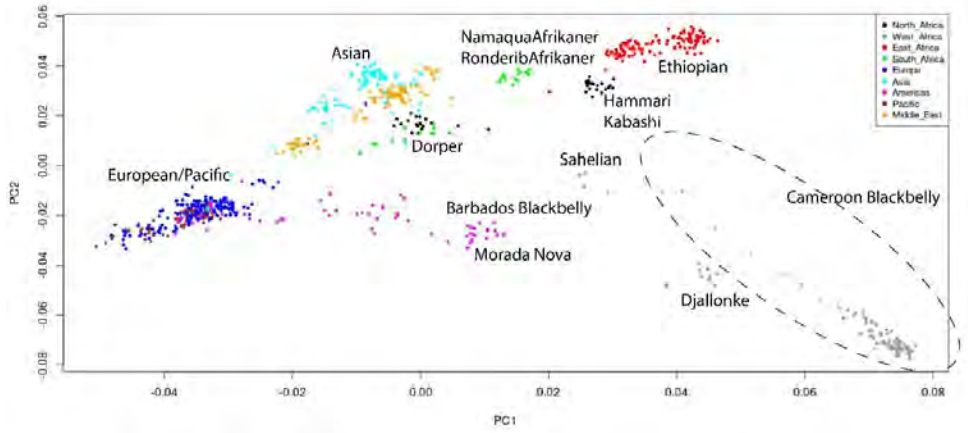

Figure 1. PCA of 779 sheep from across the world, including 81 unrelated Cameroon Blackbelly individuals. Analysis based on 12,047 markers.

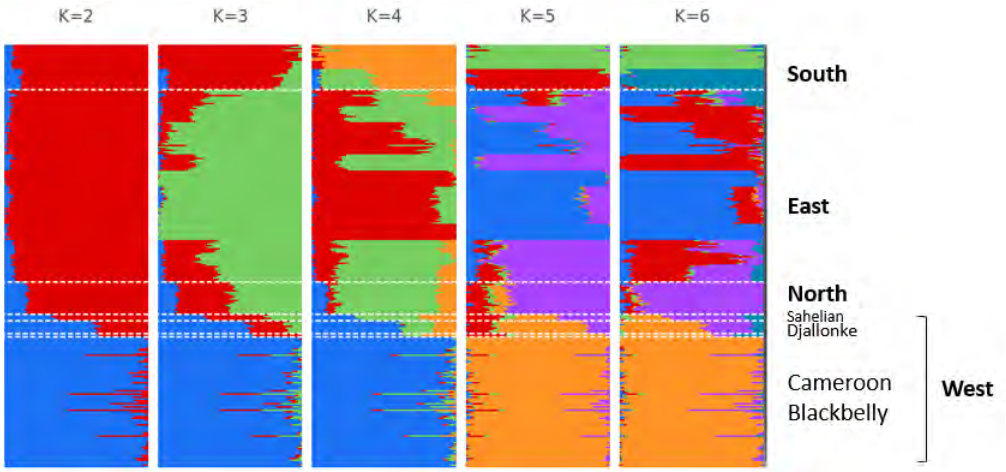

Figure 2. Admixture results for 262 African sheep samples: ancestry proportions for K=2-6 clusters shown on x-axes. North, East, South refer to breeds from those African regions; West African sheep: Cameroon Blackbelly, Sahelian and Djallonke are shown separately.

represented at <6% ancestry in breeds from North, East and South Africa. The Admixture analysis of only Cameroon sheep supported a single underlying cluster (K=1 had the lowest CV error).

Reduced diversity. Twenty-three regions of reduced heterozygosity in Cameroon sheep (lowest values of ZHp) were identified across the genome (OAR1,2,3,4,5,7,9,11,15,17,18 and 23). The most extreme was on OAR3, which overlapped the PUM2 gene (encoding an RNA-binding protein that functions as a translational repressor during embryonic development). The other regions overlapped 10 genes, which include those associated with immune function (IL6R), pigmentation (OCA2) and fertility (SPAG1), suggesting possible functions under selection.

Discussion

Our analysis demonstrates the genetic distinctiveness of West African sheep compared to other African sheep, with separation on both the first and second principal components of the PCA. The ancestry results show that the Cameroon Blackbelly sheep are primarily associated with a single cluster, with limited admixture from other populations. These findings reflect the genetic uniqueness of small ruminants in West Africa and demonstrate the importance of conserving them as a genetic resource and ensuring that indigenous breeds are adequately represented on new and existing genotyping tools. The finding of West African ancestry in Barbados Blackbelly sheep is consistent with previous studies (Spangler *et al.* 2017) and demonstrates the role of human history and migration (e.g. slave trade) in the worldwide distribution of livestock. Additional analysis, including analysis of whole genome sequencing data, will further explore introgression from West African sheep into Caribbean breeds.

Abstract

In sub-Saharan Africa, most poultry production is traditional with birds being raised by smallholders in free-range semi-scavenging conditions. The aim of our project is to extensively characterise phenotypes of chickens raised in typical African farming conditions, by measuring production, immunity and survival characteristics. In total, 2,573 chickens were raised in five batches in the poultry facility at ILRI in Ethiopia. These chickens were phenotypically characterised and sampled across an eight-week period. Traits measured included weekly body weight, growth rate, breast muscle weight in carcass, mortality/survival, and immunological titres. The population of chickens had extensive variance at these phenotypes. For body weight, 65% of the total phenotypic variance was attributed to the individual birds providing an excellent source of variation for identifying potential selection markers. This data will subsequently be used along with whole genome sequencing data of these birds to identify selection targets to underpin future breeding programs.

Introduction

In recent years much progress has been made in identifying selection signatures in the genomes of poultry to improve poultry production. This has been primarily focussed on commercial species used in large farming enterprises in developed nations (Wolc *et al.* 2016), with huge gains made in growth rate and feed efficiency in the past few decades (Zuidhof *et al.* 2014). In Africa, 80% of poultry production is in the form of smallholder farms, where chickens are typically raised in free-ranging semi-scavenging conditions (Sonaiya 2008), but there is limited knowledge of the phenotypic characteristics and genetics of these chickens. Phenotypic characterisation and identification of genomic selection targets is necessary for the genetic improvement of chickens adapted to extensive semi-scavenging conditions.

In this study we aimed to comprehensively characterise the phenotypes of typical African dual-purpose village chickens, raised in simulated semi-scavenging conditions in Ethiopia, focusing on meat production, immunity and survival.

Materials & methods

Bird trials, phenotyping and sampling. A total of 2,573 T4451 Sasso birds, a dual-purpose chicken, were raised in five batches of approximately 500 birds across the span of a year at the poultry facility of the International Livestock Research Institute in Ethiopia. The birds were raised in outdoor, semi-scavenging conditions (feed mainly from scavenging with some supplementation from day 56 of age, for approximately 8 weeks until they reached an average market weight of approximately 1,500 g (except batch 1 which was raised until 1000 g was achieved). Body weight was recorded weekly. At the beginning of the experiment, blood (from wing vein) and cloacal swabs were collected for genotyping and immune phenotyping, and the

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_413, © K.M. Morris *et al.* 2022

sex of the birds was recorded. Across the trial period the health of the birds was monitored, disease episodes (including coccidiosis) were recorded, and the day and cause of death were recorded, when applicable. At the last day of the experiment (day of slaughter), blood, cloacal and buccal samples were collected for additional immune phenotyping. Breast muscle was excised and weighed, and liver, heart, spleen and ileum samples were collected and stored in RNA-later and frozen at -80 °C for future transcriptomic studies.

Immune phenotyping. Blood from 2,573 birds from day 56 and 2,097 birds from the day prior to slaughter, was allowed to coagulate overnight at room temperature prior to removal of serum. Serum samples were stored at -20 °C. The cloacal samples from the same birds were retrieved using floxed swabs that were subsequently placed in 500 µl of PBS and stored at -20 °C. Serum anti-NDV titres were analysed using commercial IDEXX NDV ELISA kits (serum dilution 1:100). Cloacal samples were analysed for total IgA levels using direct in house developed sandwich ELISA.

Statistical analysis. A mixed model was used to assess the impact of the batch, age and sex on body weight and estimate the proportion of variance attributed to individual birds. A fixed effect model was used to examine the impact of the same effects on the other traits. Model analysis was conducted in ASReml-W 4.2.

Results

Data are summarised in Table 1. The data demonstrated that the chickens were phenotypically diverse with extensive variance in body weight, growth rate and breast muscle weight.

The key quantitative traits measured all significantly differed by batch and age, likely due to variation in season across the batches (Table 2). In addition, sex differed significantly for weight-related traits, as

expected, though had less impact on the NDV antibody and IgA titres. The proportion of phenotypic variance in body weight attributed to the individual bird was 65.3% (±0.8%).

Across the five batches, 511 mortalities were recorded for a range of reasons including predation, huddling and disease (primarily coccidiosis infection) (Figure 1), which are common causes of mortality in smallholder African farms. The cause and rate of mortality varied by batch, particularly in terms of predation and diseases.

NDV titres showed extensive variance across the samples, indicating a range in immune response to NDV vaccination (Figure 2). This varied both within and between batch, with titres falling across the test period in batches 1-4 but increasing in batch 5. IgA titres likewise showed strong variance across the dataset. Batch 5 also experienced a large outbreak of the parasitic disease coccidiosis, and NDV titres at the beginning of the experiment were found to be significantly associated with coccidiosis mortality ($P<0.01$).

Discussion

In this study we phenotypically characterised over 2,500 closely monitored chickens raised in simulated semi-scavenging smallholder village conditions in Ethiopia. This includes key production and health traits

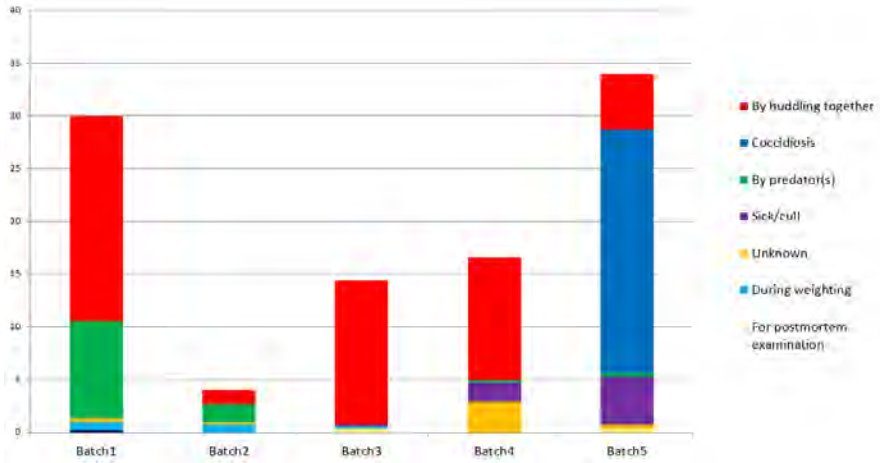

Figure 1. Percent mortalities by batch and cause.

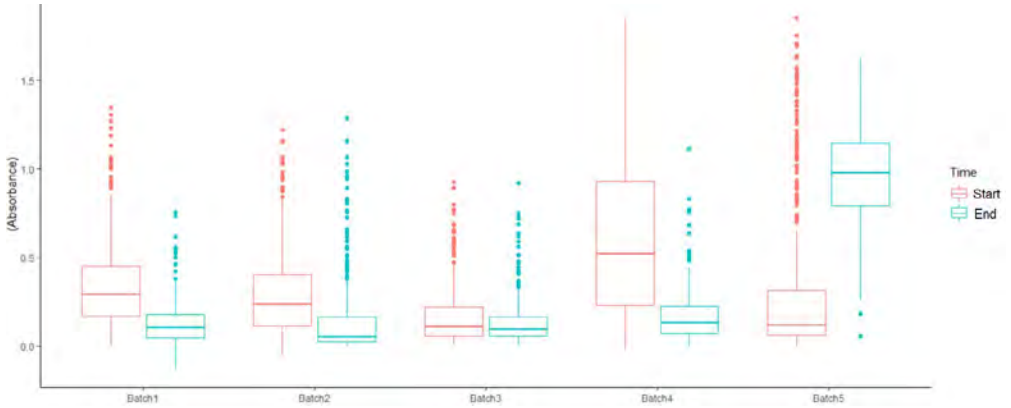

Figure 2. NDV titres of birds at the start and end of the experiment by batch.

including body weight, growth rate, carcass breast weight, disease, mortality, and antibody titres. The analysis of these traits, and selection of chickens adapted to smallholder farm conditions in developing and tropical nations has not achieved the same progress as in the developed world.

We observed extensive variation in the studied traits; we anticipate a proportion of this will reflect genetic variability which can be used for the identification of selection sites for use in breeding programs. Additionally, the substantial number of mortalities observed in this study due to predation and infection will be key for identifying genetic signatures important for survival. These will be critical for African farms as high mortality has been identified as the greatest constraint to poultry production (Sonaiya 2008).

We now aim to genotypically sequence and characterise all of the chickens used in this study. Using the combined phenotypic and genomic data we will identify genes and genomic regions associated with these traits that can be subsequently used as selection targets in breeding programs. In addition, we have identified 48 birds which have the highest and lowest growth and immune trait records, which will be studied using RNA-Seq to further understand the molecular mechanisms underlying these traits. This study will be key for the optimisation of breeding programs and the improvement of poultry in typical smallholder farms in Africa.

Abstract

African dairy production systems are characterized by small herd size and low genetic connectedness between herds. This situation makes it difficult to accurately estimate environmental and genetic effects. We evaluated how accounting for spatial relationship between neighbouring herds impacts genetic evaluation of 305-days milk yield in South African Holstein cattle population. We analysed 305-days milk yield and pedigree data for 98,632 Holstein cows collected between 1957 and 2014 from 1,145 herds. Herd and herd-year effects were modelled as independent, whereas spatial effects were modelled as correlated between regions using the Besag model. The results show a regional variation of estimated breeding values and separation of spatial effect from herd effect. The spatial modelling of herd as random effect showed similar accuracy compared to modelling herd-year. Further studies integrating the genotype-by-environment interactions will be needed to better explore the benefits from spatial modelling in African smallholder dairy farming systems.

Introduction

The significant increase of milk yield in the dairy cattle production sector in developed countries has been associated with selective breeding and herd management strategies (Cole *et al.*, 2020). However, in many low to middle-income countries genetic improvement have led to low or no genetic progress, especially in smallholder dairy production systems, due to a lack of appropriate performance records (Ojango *et al.*, 2019). One of the reasons for this is that African dairy production systems are characterized by small herd size and low genetic connectedness between herds. Such a situation is challenging accurate estimation of environmental and genetic effects (Selle *et al.*, 2020). Genetic evaluation partitions genetic and environmental effects on phenotype, which is critical because similarity between relatives may also be caused by shared environmental conditions. Breeders use statistical models to separate these effects by modelling the genetic effect as random with pedigree or genomic relationships between animals and modelling a herd or herd-season effects as fixed or random contemporary group (Mrode, 2014). Traditionally, the herd effect is modelled by assuming the effect of different farms as independent (Cuyabano *et al.*, 2021). However, nearby farms are likely to have similar climate, soils, management, and even social aspects of production and addressing these aspects with spatial models can improve genetic evaluation (Sæbø and Frigessi, 2004; Cuyabano *et al.*, 2021; Selle *et al.*, 2020).

The aim of this study was to evaluate the impact of modelling regions as correlated effects on genetic evaluation of 305 days milk yield in Holstein dairy cattle population in South Africa.

Materials & methods

The 1,331,015 305-days milk yield (MY305) records from 377,921 South African Holstein cows in 7,121 herds was provided by South African Agricultural Research Council. After the quality control we retained 248,597 MY305 records and a pedigree for 196,778 animals, including 98,632 cows from 1,145 herds. The average number of animals per herd across the whole period was approximately 91 cows per herd (8-2,230).

We used postcodes of the herd's location to assign them to administrative regions. The herds were spread over 46 of the 52 South African regions.

Statistical modelling

The baseline model (G_1) for MY305 was accounting for the overall mean, a polynomial function of age within parity, random effect of herd (h), random additive genetic effect of the animal (a), random permanent environmental (p) and random residual (e): $y = Xb + Z_1h + Z_2a + Z_3p + e;\ h \sim N(0, I\sigma_h^2), a \sim N(0, A\sigma_a^2)$, $p \sim N\left(0, I\sigma_p^2\right)$ and $e \sim N(0, I\sigma_e^2)$ where X is the design matrix associated with the vector of fixed effects b, Z_1, Z_2 and Z_3 are design matrices respectively associated with herd (h), additive genetic effect (a), and permanent environmental effects (p), and A is the pedigree relationship matrix. We also tested a second model (G_2), where the herd effect was replaced by the herd-year effect (hy), $hy \sim N\left(0,\ I\sigma_{hy}^2\right)$. We extended models G_1 and G_2 using an intrinsic conditional auto-regressive (ICAR) model component (Besag, 1974) to account for spatial variation associated with herd's region: (1) $GR_i = G_i + R$, where R is the fixed effect of herd's region and i is the index of the models (i=1,2); (2) $GRU_i = G_i + RU$, where RU is an independent random effect of herd's region; and (3) $GRC_i = G_i + RC$, where RC is a correlated random effect of herd's region via neighbourhood-based covariance matrix (Besag, 1974). We defined scaled (GRC_1) and unscaled ($GRCNS_1$) inverse of the neighbourhood-based covariance matrix using R-INLA package (Rue *et al.*, 2009). The models were fitted using the BLUPf90 suite of programs (Misztal *et al.*, 2018). The AIC criteria was used to select the most parsimonious model. Moreover, accuracies of estimated breeding values (EBV) were calculated as sqrt(1-PEV/σ^2_g) where PEV is the prediction error variance of EBVs and σ^2_g the additive genetic variance.

Results

Variance components. Variance components and heritability estimates are presented in Table 1. Heritabilities in G_1 models were higher than those from G_2 models (Table 1). The additive genetic, permanent environmental, and residual variances were similar between G_1 models. The same trend was observed between G_2 models. However, the additive genetic and residual variance were higher in G_1 models compared to G_2 models due to large difference between herd and herd-year variance estimates. On the other hand, the permanent environment effect was higher in G_2 models than in G_1 models. The herd effect variance was smaller in GR_1 than in model G_1 since the herd effect in model G_1 captured the regional effects.

Table 1. Variance components and heritability[1].

Model	σ^2g	σ^2h	σ^2hy	σ^2pe	σ^2r	σ^2p	h^2

[1] Variances are in 10^3 and standard errors in brackets, σ^2_g: animal additive genetic variance, σ^2_h: herd variance, σ^2_{hy}: Herd-year variance, σ^2_r: regional variance, σ^2_p: phenotypic variance and h^2: heritability.

GRU models had a similar estimate of regional variance as the GRC models and scaling was important to get interpretable estimates (GRCi vs GRCNSi).

Regional effect estimates. Figure 1 presents region estimates using GRC_1 and GRC_2 models. From the GRC_1 model, regions with low estimates (indicated in blue) were observed in the central-western and eastern parts of South Africa (Figure 1, left). Most of the regions with low estimates are neighbouring regions in the semi-arid part of the country with high variability in temperature and precipitations. Regions with medium estimates (indicated in purple) were primarily found in the country's northern, south-central, and south-eastern parts. The few regions with high estimates (indicated in red) were in the country's southwestern and eastern parts. GRC_2 model showed similar observations (Figure 1, right).

Regional variation of estimated breeding values (EBV) and accuracy. Figure 2 presents the regional variation of EBV measured by the standard deviation (SD, left) and prediction error variance (PEV, right). The region in the northern part with a very low SD of EBVs had a very high PEV. Similarly, the region in the western part with a low SD of EBVs had a very high PEV. However, most of the regions in the country with medium to high SD of EBV had low to medium PEV. The same trend was seen for GRC_2 models (results not shown). The few regions with low SD of EBV and high PEV suggest that there was not much information on animals in those regions and the difference in distributions is more due to the amount of information. Considering the EBVs of all animals in the pedigree, similar accuracies were observed across the G_1 and G_2 models (results not shown).

Discussion

The study evaluated the impacts of modelling spatial variation via neighbouring herd's region on genetic evaluation of MY305 compared to treating herds as entirely independent units. The results show that spatial modelling separated spatial effect from herd effect when treated as correlated and did not negatively impact prediction accuracy. Regional distribution of EBVs was observed. A recent study showed that modelling proximity between herds better separated genetic effects from environmental effects and increased

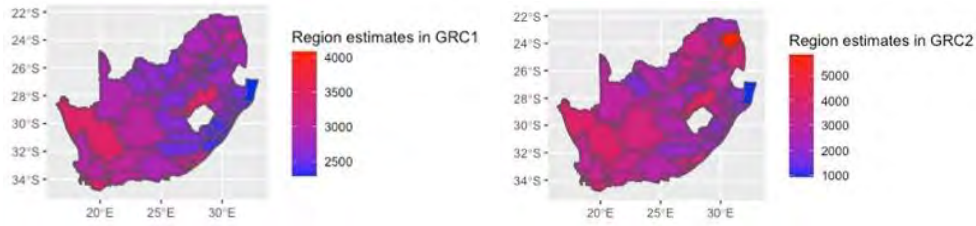

Figure 1. Regional South Africa effect estimates in GRC_1 model (left) and GRC_2 model (right).

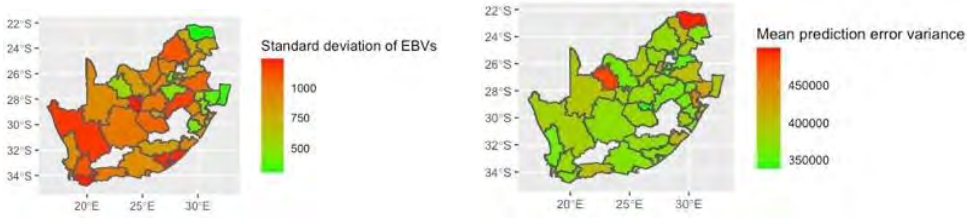

Figure 2. Standard deviation of EBVs (left) and mean of prediction error variance of EBVs (right) in GRC_1 model within south Africa

prediction accuracy in smallholder breeding programmes (Selle *et al.*, 2020). The spatial modelling increases accuracy because it induces environmental connectedness and hence accurately separates a proportion of herd effect that other models may assign to breeding values. Our initial analysis showed that modelling herds using a spatial correlation structure between herd's regions using the Besag model (Besag, 1974) does not increase the prediction accuracy. A recent study on modelling proximity between herds showed increased reliabilities of genomic EBV, but no increase in prediction accuracy of phenotypes (Cuyabano *et al.*, 2021). However, a deeper understanding of data structure, genetic connectedness between herds, the frequent movement of cows between herds, typical to the African livestock production system, is the next important step in this study.

Significant region effects were observed in the present study. These effects are likely due to differences in climatic conditions across regions. To account for large scale environmental effects, Sæbø and Frigessi (2004) modelled veterinary districts as correlated via neighbourhood in genetic evaluation of mastitis resistance in Norwegian Cattle and discovered regional effects in the south-eastern parts of Norway. Despite the benefits from regional modelling in previous studies, coordinate-based models would account more precisely for spatial relationships between farms (Selle *et al.*, 2020; Cuyabano *et al.*, 2021). Furthermore, the current study ignored the genotype-by-environment interaction effect, which are likely significant given the wide range of environmental differences in South Africa.

Conclusions

This study evaluated incorporating region-based spatial effects in genetic evaluation of 305-days milk yield in South African Holstein. Results showed large differences between regions, in some cases more than double, indicating the importance of modelling environmental variation. Further work is required to model environmental variation at a herd level by using a coordinate-based model and possibly expand that model with genotype-by-environment interaction.

415. Testing phenotypes for degree of resilience using fluctuations in milk yield of dairy cows in sub-Saharan Africa

R.D. Oloo[1,2*], C.C. Ekine-Dzivenu[2], J.M.K. Ojango[2], R. Mrode[2], A.O. Mwai[2], and M.G.G. Chagunda[1]

Abstract

Despite the relevance of dairy production in the fight against food insecurity and unemployment in sub-Saharan Africa (SSA), negative effects of climate change and general changes in the production environment pose huge challenges to its profitability. Thus, there is a need to improve resilience capacity of dairy animals to adapt to this changing environment. In the current study, we tested two indicators of resilience, log-transformed variance (LnVar) and Skewness (Skew) of deviation, based on fluctuations in animals' milk yield. Further, we assessed the effects of genotype, agroecological zone, and genotype by agroecological zone (G×E) interaction for these phenotypes. Cows with less than 50% of exotic genetics had higher degree of resilience ($P<0.05$). Cows performing in semi-arid zones had higher resilience capacity compared to those in semi-humid environment ($P<0.05$). G×E did not significantly influence both indicators. The results provide valuable information that would inform dairy cattle improvement initiatives in SSA.

Introduction

An animal's degree of resilience to a disturbance is its capacity to be minimally affected by the perturbation or rapidly return to the state pertained before exposure to the disturbance. The performance of the resilient animal need not be the same as without a disturbance, but rather, the negative change in its performance should be relatively lower compared to non-resilient individuals performing in the same conditions. Dairy production in sub-Saharan Africa (SSA) is still low compared to the demand. As a result, pressure for genetic improvement for milk production is still accumulating. However, in the wake of climate change, general environmental changes and their impact, the focus of dairy production must shift from increased production to efficiency and sustainability of milk production. Sustainable dairy production practices that ensure food security to the growing population and overcome the negative impacts of climate change on dairy cattle need to be adopted. SSA is confronted with environmental disturbances, most of which are causes of nature that cannot be modified in the favor of the cattle through good husbandry practices. Therefore, one robust way into this is through breeding for resilience in dairy cattle to enhance their ability to withstand environmental stressors and maintain optimal production levels. Deviations from the normal performance has been utilized to derive indicators that can quantify the general resilience of the animals (Berghof, *et al.*, 2019; Elgersma *et al.*, 2018; Poppe *et al.*, 2020). However, these methods have so far not been applied in SSA. The current study aimed to test two indicators of resilience based on deviation in milk yield and to assess the effect of genotype, agroecological zone and their interaction on these indicators.

Materials & methods

Data used in this study came from dairy cows from three different herds, each representing one of the following agroecological zones of Kenya: semi-arid arable (SAA), semi-arid pasture-based (SAP), and semi-humid (SH). All the herds are kept under extensive dairy production system with occasional supplementation feeding for the lactating cows. Rotational cross breeding is adopted for two herds performing in the semi-arid regions. The herd in semi-humid zone is made up of a stable intermating population of composite cattle originating from crossbred parents.

Data. The original data set for this analysis contained 2,640 lactations with 62,321 bi-monthly milk yield records of 1,490 multibreed cows from three large-scale dairy farms in Kenya born between January 2000 to December 2017. Data for the first parity were extracted and assessed for quality before the analysis. Cows that had at least two breed types in their genetic make-up based on the information provided by the farmers were used. All cows were required to have 5 or more milk records per lactation and all records were used up to 400 days after calving. To correct for season and year of calving, contemporary grouping of year-season (YS) was done with 17 possible years of calving (2003-2019) and 4 possible seasons. YS groups with less than 5 lactations were excluded from the analysis. After editing the data, 14,278 milk yield records from 745 cows were used for the analysis. These animals were grouped into two genotypic classes based on the proportion of exotic genetics in their breed composition, genotypic class 1 (GC1) (≤50% exotic, n=325) and GC2 (>50% exotic, n=420).

Defining resilience indicators based on fluctuations in milk. The deviations in daily milk yield from the mean production was used to define two resilience indicators: log-transformed variance of deviation (LnVar) and skewness of deviations (Skew). LnVar indicates the impact of the disturbance to the performance of an individual animal. Because resilient animals are less affected by the disturbances in their environments, they have a smaller range of deviation from their average performance. Therefore, they have low variance of deviation. Skew indicates the direction of the deviation and captures the level of severity of the disturbance experienced by an individual animal. Resilient animals have skewness around zero because they have almost equal numbers of negative and positive deviations. The less resilient animals are more influenced by disturbances and thus have more negative than positive deviations which leads to a negative skewness. The LnVar of j^{th} individual was calculated as:

$$ln(variance_j) = ln\left(\frac{\sum_{i=1}^{n_j}(x_{ij}-\bar{x}_j)^2}{n_j-1}\right) \quad (1)$$

where x_{ij} is deviation i of the j^{th} individual, $\bar{x}_j$ is the mean of deviations of the j^{th} individual, and n_j is the number of deviation observations of the j^{th} individual. The skewness of deviation j^{th} individual was calculated as:

$$skew_j = \frac{n_j}{(n_j-1)(n_j-2)}\sum_{i=1}^{n_j}\left(\frac{x_{ij}-\bar{x}_j}{\sqrt{s_j^2}}\right)^3 \quad (2)$$

where n_j is the number of deviation observations of the j^{th} individual, x_{ij} is deviation i of the j^{th} individual, $\overline{\bar{x}}_j$ is the mean of deviations of the j^{th} individual, and s_j is the variance of deviations of the j^{th} individual.

Data analyses. The effects of agroecological zone (environment) and genotype as well as the existence of their interaction in the two resilience indicators was analyzed. A multiple linear regression model with explanatory variables of genotypic class, agroecological zone, genotype by agroecological zone interaction, year-season of calving, day in milk (DIM) class of first day in lactation, DIM class of last day in lactation, age of calving, and squared term of age of calving was used. Analysis of variance was performed prior to fitting linear models to determine the significant factors of variation. The following model was fitted:

$$RI_{ijklmn} = U + G_i + E_j + G_i * E_j + YSC_k + dim.f_l + dim.l_l + Age_m + Age_m^2 + e_{ijklmn} \quad (3)$$

where RI_{ijklmn} is the resilience indicator (LnVar and Skew) measurement for n^{th} animal, U corresponds to the population mean, G_i is the i^{th} genotypic class (i = 1-2), E_j is the j^{th} agroecological zone (j=1-3), $G_i \times E_j$ is the interaction between i^{th} genotypic class and j^{th} agroecological zone, YSC_k is the k^{th} year-season of calving (k=1-53), $dim.f_l$ and $dim.l_l$ are the first and the last DIM classes, respectively of the l^{th} DIM (l=1-10), Age_m and Age_m^2 represent m^{th} age and its squared term, respectively (m=22-60) e_{ijklmn} is the residual error.

Least-square means (LSM) of the genotype classes within the different traits were calculated and contrasted across the 3 different agroecological zones.

Results

The raw average estimate (± standard deviation) for LnVar for the whole dataset was 1.4998±0.8420. The minimum and maximum LnVar values were -1.3587 and 3.8916, respectively. The Skew had a raw mean of -0.05316±0.7186 with a minimum of -2.4986 and a maximum of 3.6525. The significant sources of variation for LnVar were environment, genotypic class, age of the animal, and year season of calving. At population level, GC1 cows had significantly lower LnVar than GC2 cows (P>0.05). This shows that GC1 cows had a higher degree of general resilience than GC2 cows. Agroecological zone influenced LnVar, hence level of general resilience significantly (P>0.001). Animals performing SAA zone had lowest LnVar, followed by those in SAP and SH (P<0.01) (Table 1). Within agro-ecological zones, GC1 had significantly lower LnVar than GC2 cows in SAA (P<0.001) and SH (P<0.05) environments. However, in SAP, there was no significant difference in LnVar for the two genotypes groups (Table 2). The significant sources of variation for Skew were same as those of LnVar except age of the animal and its squared term. However, the skewness

Table 1. Least square mean (± standard error) for log-transformed variance (LnVar) and skewness (skew) of deviation in milk yield at genotypic class and agroecological zone levels.[1]

Variable and level	n	LnVar of deviation	Skew of deviation
% Exoticness			
GC1 (0-50%)	325	0.813±0.257a	-0.0455±0.251a
GC2 (>50%)	420	0.992±0.258b	-0.107±0.252a
Agroecological zone			
Semi-arid arable	352	0.541±0.262a	0.0531±0.256a
Semi-arid pasture-based	169	0.902±0.271b	-0.0721±0.264ab
Semi-humid	224	1.263±0.253c	-0.2099±0.247b

[1] The difference between GC1 and GC2 and among the agroecological zones that are significant at P<0.05 have been shown using different small letters. Similar letter denotes that the difference is not significant. GC1 and GC2 represent genotypic class 1 and genotypic class 2, respectively.

Table 2. Least square means (± standard error) for log-transformed variance (LnVar) and skewness (Skew) of deviation in milk yield of genotypic classes across the three agroecological zones.[1]

Resilience indicator	GC1 (0-50%)	GC2 (>50%)	Pairwise comparison (GC2-GC1)	Significance level
LnVar of deviation				
Semi-arid arable	0.405±0.266	0.678±0.264	-0.2726±0.0808	***
Semi-arid pasture-based	0.92±0.268	0.885±0.299	-0.0345±0.1709	ns

Semi-humid	-0.1706±0.26	-0.2492±0.248	-0.0786±0.1219	ns

[1] The difference between GC1 and GC2 that are significant have been shown. '***', and '*' indicate significant differences at P<0.001, and 0.05, respectively. ns denote not significant. GC1 and GC2 represent genotypic class 1 and genotypic class 2, respectively.

of deviation did not detect differences in resilience between the two genotypic classes. The only significant difference in skew was between the animals performing in SAA and those in SH where the animals in former environment had a positive and a closer to zero Skew signifying more degree of resilience than their counterparts ($P<0.01$). Genotype by environment (G×E) interaction was not significant for both resilience indicators.

Discussion

This study used deviations in milk yield to test two indicators of resilience for cows performing in the tropical environment of sub-Saharan Africa. The LnVar was stronger in showing resilience of the animals than the skew based on its ability to discriminate degree of resilience of cows more efficiently. Similar findings were reported in past studies (Berghof *et al.*, 2019; Poppe *et al.*, 2020). Animals with lower exotic genetic proportion had higher degree of resilience possibly due to the fact that they have a high proportion of Zebu genes in their genetic make-up which could have conferred the adaptation to the local production environments. The environment also affected the degree of resilience of the animals. In particular, animals performing in semi-arid zones, which are known to have many disturbances related to high temperatures and long periods of dry seasons, had better resilience capacity than those in semi-humid zone. Constant exposure of the animals to the disturbances in semi-arid zones could have activated their innate regulatory pathways and bettered their chances to survive environmental adversities in the long run (Colditz and Hine 2016). G×E interaction was not significant for both resilience indicators. This implies that a resilient genotype is capable of performing in a wide range of environments without its resilience capacity being altered. This study has shown the possibility of utilizing the deviations in milk yield to quantify general resilience of dairy cows performing in the tropical environment of SSA, where climate change is already affecting dairy production.

Abstract

Local chickens play an important role in food security, nutrition, and livelihoods in rural Africa but they have limited production performance. We quantified egg production of three Tanzanian chicken ecotypes (n=870) and estimated genetic parameters using genotypes from targeted genotyping by sequencing at 5K SNPs that were imputed to 600K SNPs. Age at first egg (AFE) and the number of eggs laid in consecutive 90-day periods after AFE were analysed. The average AFE was 183.0 days and the mean number of eggs per period ranged from 6.8 to 22.3. Estimates of heritability were 0.04±0.10 for AFE and ranged from 0.04 to 0.46 for egg production per period. Genetic correlations among the egg production traits were >0.91 for most trait pairs but had high standard errors. We conclude that egg-laying performance in local Tanzanian chickens is low but can be improved by selection.

Introduction

Local chickens play an important role in the food security, nutrition, and livelihoods in the rural communities of Africa. In most developing countries, chickens are kept for both meat and egg production (Terfa *et al.*, 2019). Seventy-nine percent of the 4.7 million households in Tanzania are reported to keep local chickens, which comprises 56% of the chickens in the country (Ringo, 2018). Annual egg consumption is 1.5 kg per capita (Ministry of Livestock and Fisheries, 2019), compared to 6.2 in South Africa and 15.2 in the USA. Genetic improvement of local chickens for egg production is one way to increase egg consumption per capita. Tanzania has several local breeds or ecotypes, including Ching'wekwe, Kuchi, Morogoro-medium, Pemba, and Unguja (Lyimo *et al.*, 2013). Whilst these local chicken breeds, require low resource input and are adapted to local conditions, they are characterized by low production performance (Pym *et al.*, 2006; Safalaoh, 1997), which cannot match the growing African population and the change of taste and preference towards animal protein and white meat (Henchion *et al.*, 2017). Knowledge of trait genetic parameters forms the basis for genetic improvement. Several studies have been done on the performance of local chickens, but there have been no reports on the egg-laying performance of the local ecotypes evaluated here, i.e. Morogoro-medium, Chingw'ekwe, and Kuchi, which were chosen based on their diversity and prevalence for a large-scale project on resistance to New Castle disease (Walugembe *et al.*, 2019). The objective of this study was to quantify the egg production of these three ecotypes and estimate the associated genetic parameters.

Materials & methods

Egg production data were collected from 2019 to 2021 (103 weeks) on 870 hens from the local Tanzanian ecotypes Kuchi (n=233), Morogoro-medium (n=352), and Ching'wekwe (n=285). Contrary to commercial layers, which are kept in production for ~1 year, African local chickens have a reproductive life span of three and a half years (Mujyambere *et al.*, 2010). The chickens were offspring of parents described by Walugembe *et al.* (2019). Chicks were tagged, weighed at hatch, and raised as one flock. The birds were

DOI: 10.3920/978-90-8686-940-4_416, © T. Magwaba *et al.* 2022

separated by sex at three weeks of age. Females were separated into individual cages at the point of lay. The birds were vaccinated against Newcastle disease at 3 and 21 days of age and then every 3 months. Gumboro vaccinations were done at 11 and 18 days of age and Fowl Pox vaccination at 8 weeks of age. Deworming was done every 3 months. The birds were genotyped using targeted genotyping by sequencing at 5K SNPs, which were imputed to the Affymetrix chicken 600K SNP chip, as described in Walugembe *et al.* (2022).

The age of each hen at the time of the first egg (AFE, days) was recorded. Eggs were then collected daily and summarized as the total number of eggs laid during each 90-day period, starting from the point of lay, which will be referred to as periods 1 to 8. Records for periods with zero eggs and those that deviated more than three standard deviations from the population mean for each period were removed. Table 1 shows the remaining number of records for each trait and descriptive statistics.

The following univariate linear model was fitted in ASReml version 4.1 (Gilmour *et al.*, 2015) to estimate variance components for each trait: $y = Xb + Zu + e$, where y is the vector of phenotypes, X and Z are incidence matrices for fixed and random effects, respectively, b is a vector for fixed effects, u is a vector of random genetic effects with covariance structure based on the genomic relationship matrix (VanRaden, 2008), and e is a vector of residuals. The fixed effect was the date of hatch (n=26), along with age at a first egg (not included for AFE) and ancestral population proportions as fixed covariates. Ancestral subpopulation proportions were used instead of ecotype because the three ecotypes were found to be made up of two ancestral populations, as described by Walugembe *et al.* (2019). Bivariate models were run to estimate phenotypic and genetic correlations among the first five egg production traits, along with AFE. The last three egg production periods were excluded because of very low heritability estimates.

Results

The mean AFE was 183 days and the mean egg number per 90-day period generally declined with age from 22.3±5.9 in period 1 to 6.8±2.9 in period 8 (Table 1). Estimates of variance components and heritabilities are in Table 2. The estimate of heritability for AFE was 0.04±0.01. Heritability estimates were low for period 1 (0.04±0.09) but then increased to 0.46±0.26 at period 4, after which it decreased again. The average heritability across the periods was 0.14. The estimate of genetic variance was also highest for period 4 (Table 2), while period 5 had the highest phenotypic variance, and period 1 had the highest environmental variance.

Estimates of phenotypic, genetic, and environmental correlations are in Table 3. Estimates of phenotypic correlations were moderate and positive between consecutive periods but close to zero between non-

AFE	-0.24 (0.04)	-0.01 (0.06)	-0.05 (0.06)	-0.14 (0.06)	-0.26 (0.06)	

[1] DNC = did not converge.

consecutive periods. Generally, estimates of genetic correlations were greater than 0.92 among all periods, except between periods 2 and 3 (0.53±1.10). However, all genetic correlation estimates had very high standard errors because of limited numbers of observations, and some did not converge. Phenotypic correlations of AFE were negative with all egg production traits, as expected. Conversely, the number of eggs laid had positive genetic correlation estimates with AFE for each period, except for period 2, but standard errors were again very large.

Discussion

The mean egg production was low, as is expected for local chickens. These results are consistent with the findings of Dana *et al.* (2011) for local ecotypes in Ethiopia. The mean AFE of 183 days is within the range of means for AFE of 166 and 190 days reported by (Mujyambere *et al.*, 2010) and Dana *et al.* (2011), respectively. In the univariate analyses, the effects of hatch date and AFE were significant, but the effect of ancestral proportions was not. The estimate of heritability for AFE (0.04±0.10) was lower than the previous report of 0.37 by Acharya *et al.* (1969) but close to the estimate of 0.06±0.15 reported by Dana *et al.* (2011). Heritability estimates differed between successive egg production periods, which is consistent with Wolc *et al.* (2007). The average heritability across the periods was 0.14, which is lower than that published by Biscarini *et al.* (2010) in their study with commercial layers but close to findings by Tongsiri *et al.* (2019) (0.15±0.10) on Thai native chickens. Estimates of genetic correlations among egg-laying periods were very high, except for periods 2 and 3, which had a genetic correlation estimate of 0.57. The traits with high genetic correlations might be controlled by the same genes. This suggests that egg production across periods can be

improved by the selection of birds with high production at an early age. The estimates, however, had very large standard errors because of small data sizes. More reliable estimates will require larger sample sizes. The phenotypic correlation between egg-laying periods and AFE was negative. The standard errors were low, which indicates that the estimates are reliable. Most of the genetic correlations between periods and AFE were positive and high, except for period 2. However, again, standard errors were very high and more data is needed to draw strong conclusions.

Abstract

Recent studies have highlighted several key advantages of graph genomes over standard linear reference genomes. These advantages include improvements in read mapping rates at divergent loci and the ability to more accurately call structural variants. However, the availability of graph genomes that represent the extensive diversity of livestock species remain limited. To address this limitation, we have incorporated 15 cattle genomes into an expanded cattle graph genome, including 8 completely novel high-quality cattle assemblies from 4 divergent breeds (Holstein-Friesian, N'Dama, Boran and Nelore), each with high contiguity (N50>10 Mb). This graph genome incorporates over 250 Mb (9.5%) of novel sequence across the primary chromosomes, providing a better reference representation of the bovine pangenome and a key resource for the livestock community.

Introduction

Recent studies have highlighted the limitations of single linear reference genomes in genomic studies (Hickey *et al.*, 2020). For example, as larger structural variants (SVs) are absent from the reference genome, they cannot be directly genotyped (Hickey *et al.*, 2020). One solution is to use population-specific genomes, that reduce the impact of allelic bias and allow for the investigation of portions of the genome not present in the other references available (Fakhro *et al.*, 2016).

Even though breed specific genomes are useful for single-population studies, they do not provide a solution for multi-breed studies involving distantly related populations. A viable solution is provided by graph genomes, which incorporate variation on a backbone genome in the form of 'bubbles' in a graph (Hickey *et al.*, 2020). Multiple studies have shown how incorporating short variants present in a population leads to large improvements in the resulting genotype calling (Garrison *et al.*, 2018; Pritt *et al.*, 2018; Crysnanto and Pausch, 2020). However, the largest gain comes from graph genomes incorporating structural variants, which allows for large increases in read mapping, as well as allowing for the genotyping of long or complex structural variants represented in the graph itself (Talenti *et al.*, 2021).

In this study, we generated a total of 8 new, high-quality cattle assemblies of 4 divergent breeds. These highly-contiguous, highly complete assemblies have been incorporated, together with 7 further publicly available assemblies, in the largest cattle graph genome so far generated, that will allow us to investigate SV diversity across the cattle pangenome.

Materials & methods

Genomic DNA for the Boran sample was extracted from monocytes using the nanobind big DNA kit from Circulomics. Genomic DNA for the remaining samples was extracted from whole blood using the Paxgene

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_417, © A. Talenti *et al.* 2022

Blood DNA kit. All samples were sequenced on the Pacific Bioscience Sequel IIe platform using the circular consensus sequencing protocol, which generated high-fidelity (HiFi) sequences. We generated 20-35X genome coverage for each sample with >Q20 quality. Resulting raw reads have been assembled using peregrine (v1.6.3; Porubsky *et al.*, 2020). Genome completeness for each assembly has been calculated using BUSCO (v5.2.2; Manni *et al.*, 2021), Merqury (v1.1; Rhie *et al.*, 2020) and custom scripts used to compute the N50, L50 and %GC.

Generation of the graph genome. All 8 novel assemblies (Table 1) were then aligned together with 7 publicly available genomes: Hereford (ARS-UCD1.2), Brahman (UOA_Brahman_1), Angus (UOA_Angus_1), N'Dama (ROS_NDA1), Ankole (ROS_ANK1), Highland (GCA_009493655.1) and Simmental (GCA_018282465.1). This provided a set of 15 diverse assemblies from third generation sequencing technologies, which will allow for a better comparison of highly complicated regions of the genome.

A graph genome was then generated using the CACTUS pangenome pipeline (v2.0.4; Armstrong *et al.*, 2020), specifying the ARS-UCD1.2 genome as reference, and focusing only on the primary chromosomal sequences (autosomes, X, Y and MT). This generated a reference-based graph in VG format, which can be used for downstream analyses.

Novel portions of sequence. After the generation of the graph genome, we identified the non-reference sequence in the dataset. The total length of the graph was extracted using the vg stats -l commands (Hickey *et al.*, 2020), which returns the size of the graph. We then extracted the novel sequences using the nf-GraphSeq workflow (https://github.com/evotools/CattleGraphGenomePaper/tree/master/detectSequences/nf-GraphSeq) described in Talenti *et al.* 2021. This workflow takes a PackedGraph (pg) graph, and iteratively screens the graph for nodes (i.e. fragments of sequences) not represented in any of the Hereford chromosomes. It then extracts and saves them for each of the assembly considered in the study.

Results

The assembly generation created a set of highly contiguous genomes, with contig N50s ranging from 15 to 56 Mb. Estimated completeness ranged from 95.7 to 95.9% with estimated accuracy ranging from 37.2 to 42.4 (Table 1). These numbers are comparable to other assemblies generated using PacBio HiFi sequencing technologies (Vollger *et al.*, 2020).

Table 1. Metrics of the novel assemblies: genome contiguity (N50 and L50), GC content (%), genome completeness as % of complete universal single-copy orthologs and quality values (QV).

Genome	Contig N50 (Mb)	Contig L50 (N)	GC-content	Completeness (BUSCO)	Accuracy (QV)
Nelore 1	52	20	43.80%	95.7%	38.7
Nelore 2	35	24	43.03%	95.9%	40.7
N'Dama 1	53	18	43.10%	95.9%	41.3
N'Dama 2	14	64	42.89%	95.8%	41.6
Holstein 1	31	27	42.90%	95.9%	42.3
Holstein 2	31	24	42.88%	95.7%	42.2
Holstein 3	56	19	43.03%	95.8%	42.4
Boran 1	49	21	43.77%	95.8%	37.2
ARS-UCD1.2	25	32	/	/	48.7

Following the generation of the 8 new assemblies, we proceeded to generate a graph genome, with the objective of identifying the amount of novel sequence found across the assemblies. The graph included sequences from 15 different assemblies, the largest so far, encompassing multiple *B. taurus* and *B. indicus* genomes, as well as a number of representative genomes of breeds from Africa, South America and Europe. The output graph from the CACTUS pangenome workflow was 2.93 Gb long, over 250 Mb (9.5%) longer than the ARS-UCD1.2 primary chromosomal sequence. As may be expected, the indicine genomes contribute the most to the number of novel fragments of sequence and bases in the graph, with over 50 Mb of novel bases in the non-taurine genomes in over 11 M nodes per genome (Figure 1).

Discussion

Progress in the field of graph genomics has made evident the limitations of single linear genomes. Even though multiple studies have highlighted how incorporating short variants that are specific to a population into a graph genome can lead to an improvement in the resulting genotypes, the biggest gain comes from incorporating large structural variations. Incorporating the large structural variants and novel sequences can help in increasing the number of mapped reads, as well as allowing for the genotyping of otherwise inaccessible variants.

In this context, the generation of new assemblies that capture more of the global cattle genetic diversity becomes most relevant, since it allows us to expand the repertoire of accessible sequence in the cattle pangenome. In this study, we generated a total of 8 new cattle HiFi assemblies from 4 divergent breeds, each with high contiguity and completeness. Over half of these are of non-European taurine ancestry, allowing us to characterise otherwise inaccessible portions of the genomes of these populations. In fact, we successfully identify a total of 250 Mb of novel bases, not represented in the current cattle reference genome.

In conclusion, we successfully generated a large number of new genome assemblies, and combined them successfully in a VG graph, opening up the possibility of investigating the role of large rearrangements in global cattle diversity and their effects on phenotype of interest.

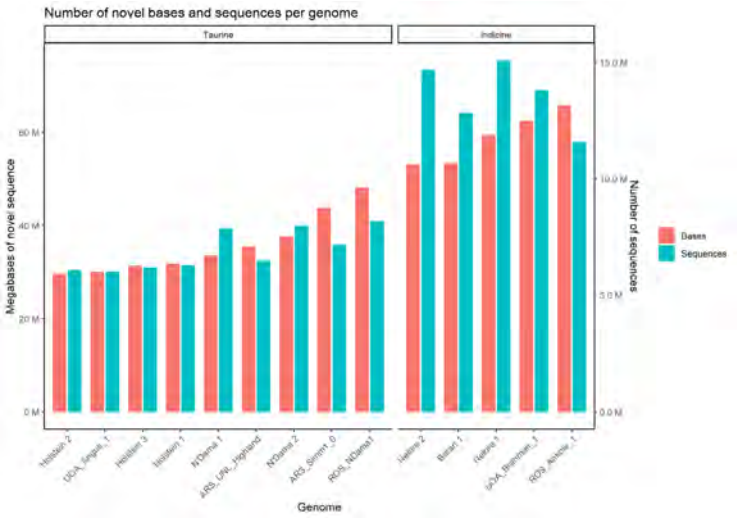

Figure 1. Characterization of the novel sequence identified in the 14 non-Hereford (ARS-UCD1.2) genomes.

Abstract

This study explored the current genetic diversity and structure of Rwanda's dairy cattle population to support the development and use of genomic tools for dairy development and other livestock development initiatives in Rwanda. Dairy cattle in the study (n=1,917) were genotyped at medium density (50K), population structure and diversity analyses were performed. Principal component analysis (PCA), Admixture analysis and measures of expected heterozygosity (He), observed heterozygosity (Ho), minor allelic frequency (MAF) were applied in the study. A dataset of global dairy population of European taurine, African indicus and Zebu breeds (n=250) was used as reference. Results showed Rwanda cattle as a highly admixed population with minor allele frequency of 33% (se=0.001) and 22% (se=0.01) proportion of genes from Jersey Island. The study provides genetic information for future genomic approaches, as well as smallholder farmer-centric decision making tool to enhance productivity and profitability using the Jersey cattle in Rwanda.

Introduction

Genomic selection provides a unique opportunity to optimise genetic gains and breeding potential of animals in the presence of little or no pedigree data records (Thomasen *et al.* 2014) when phenotypes are available. Medium genotyping chips with approximately 50 to 60 thousand single nucleotide polymorphisms (SNPs) have been utilised in global livestock populations for derivation of SNP keys, optimise genetic gains and accuracies of genomic predictions for genomic selection. In Africa, well-structured breeding programs are lacking due to paucity of adequate performance and pedigree data to monitor genetic progress. Therefore, genomic selection in Africa could improve accuracy of selection procedures where data is limited. In addition, productivity gaps of most of the production systems especially, dairy remains significantly high with yield gaps compared to the current levels in advanced economies. The aim of the study was to explore the use of 50-60K SNPs to provide insights to the genetic variation of Rwanda's current dairy cattle population as a smallholder farmer-centric decision making tool to enhance productivity and profitability using the Jersey cattle in Rwanda. We anticipated that the genotyped animals would guide future genomic approaches to support the basis for directional selection for on-farm productivity, genetic progress, healthy and feed-efficient animals that best adapt to the diverse production systems and tropical environment in Africa.

Materials & methods

Jersey cattle of the 'Inka Nziza initiative in Rwanda were selected for genotyping at Geneseek® Neogen, United Kingdom using the Geneseek Genomic Profiler (GGP) 50K SNP array (n=1,917). The Jersey breed of Jersey Island (n=46) were also used as reference population. Other reference breeds were Ankole (Uganda), East African Zebu shorthorn (Kenya), Holstein and non-Island Jersey (West Europe), N'dama (Guinea), Nellore (Brazil), Sheko (Ethiopia), Gir and Sahiwal (India). All SNPs in GGP arrays optimised for use in dairy cattle had the most informative SNPs common to all the platforms for the Illumina Bovine chip®.

Data analyses. Quality control of genomic data was performed using the software PLINK (Purcell *et al.*, 2007) considering the following exclusion criteria: non-autosomal SNP, SNP or those with no chromosomal position, minor allele frequency (MAF)≤0.05, call rate (CR)≤0.90, individuals missing more than 90% genotypes (MIND), genotypes missing more than 10% (GENO) of markers, excluding bi-allelic and singletons SNP sites.

Estimation of genetic diversity level and principal components. The SNP filtering based on the Hardy–Weinberg equilibrium (HWE) was performed as we expected HWE deviations in the studied population due to their large and possible diversity and genetic drift. Genetic relationship between and across-breed populations were plotted using the R function 'tidyverse' and its dependencies (Wickham *et al.*, 2019). Average expected heterozygosity (He) was assessed and observed heterozygosity (Ho) were averaged over loci by computing in PLINK under the assumption of HWE (Purcell *et al.*, 2007). Furthermore, the population genetic structure assessment was performed using ADMIXTURE v1.3 (Alexander *et al.*, 2009) to perform cross-validation iterations with a *k*-fold and the increase in log-likelihood between iterations. We performed K=2 to K=12 as ancestral modes in order to identify the optimal number of ancestral populations by detecting the lowest value of cross-validation (CV) error. Admixture output was visualised as barplots in vegan package in R (Jari *et al.*, 2020). After quality control, the total number of genotyped samples and available markers was 1,907 samples and 17,712 SNPs.

Results

Table 1 shows minor allelic frequency, expected, observed heterozygosity within Rwanda dairy population vs reference population.

Population genetic structure, diversity and ancestry. Results of principal component and admixture analyses confirmed the genetic background of Rwanda cattle as an highly admixed (crossbred) population of European taurine; Holstein and Jersey (West Europe); Jersey (Jersey Island) and African indicine and Zebu (Sahiwal, Ankole) with levels of admixture (K=9, 10 & 11) in all the breeding populations.

Figure 1 shows the PCA in Rwanda in comparison to the global dairy population.

Table 1. Sample frequency, minor allele frequency, expected and observed heterozygosity.[1]

Breed	n	H_e	Std	H_o	Std	MAF	Std

[1] H_e (expected heterozygosity); H_o (observed heterozygosity); MAF (minor allelic frequency).

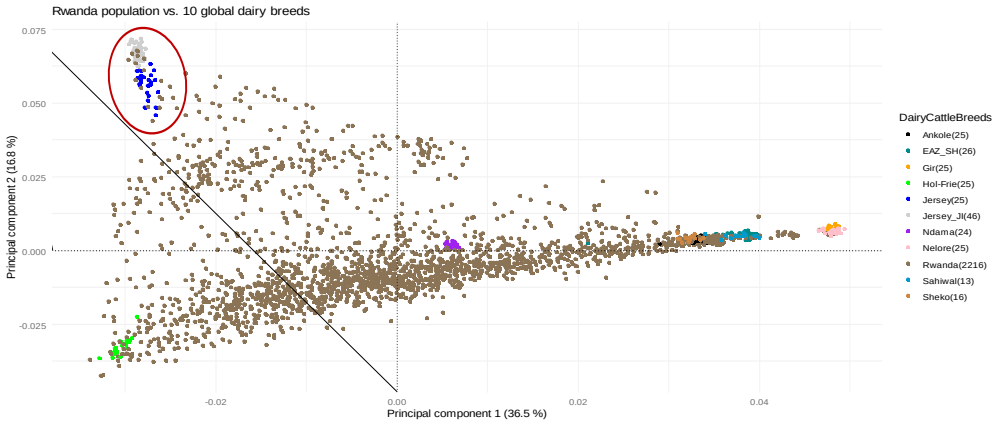

Figure 1. Principal component analysis of Rwanda cattle vs global reference population.

The second principal coordinate vector accounted for 16.8% of the total variation and separated the Island and non-Island Jersey breeds highlighted in the red circle (Figure 1). The first principal coordinate vector accounted for 36.5% of total variation with a significant contribution of European breed (HOL) African *Bos indicus* (NDG), and separated the GIR and NEL breeds. The Rwandan animals dispersed evenly between ANK, SHW, SHK, EAZ-SH and to a lower extent; GIR and NEL breeds. The coefficient of variation (CV) errors for both unsupervised and supervised Admixture learning ranged between 0.60 and 0.65, respectively irrespective of inclusion or exclusion of GIR and NEL breeds. For unsupervised learning, K9 and K11 with NEL and GIR was 0.60. Although not reported here, excluding both breeds had lower but same CV errors at K9 and K11, respectively (0.61; 0.60). For supervised learning with or without GIR and NEL, CV errors were higher than unsupervised learning procedures (K9=0.65; K11=0.64). Figure 2 shows admixture plot at ancestries (clusters) K 9 and 11.

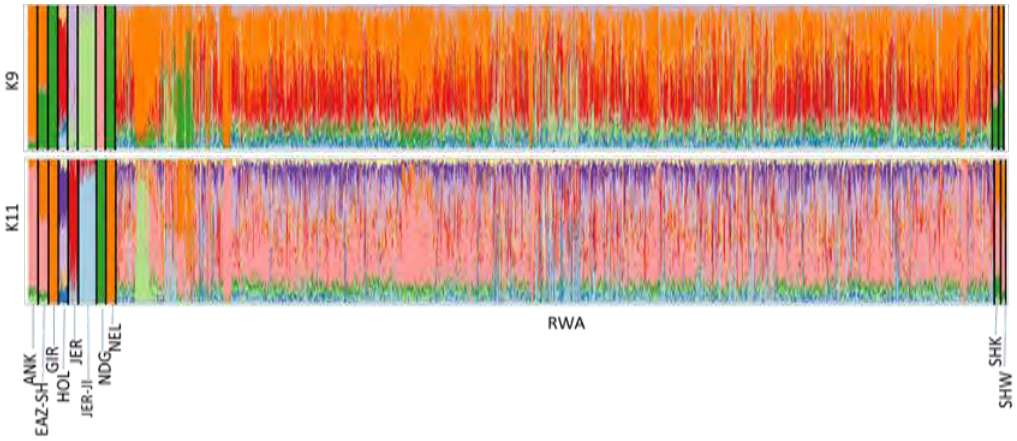

Figure 2. Admixture bar plots showing breed proportions and introgression at selected and assumed ancestry assignment clusters K (9 and 11). Each horizontal bar from left to right, represents Ankole (ANK), East African zebu shorthorn (EAZ-SH), Gir (GIR), Holstein (HOL), non-Island Jersey (JER), Island Jersey (Jersey-JI), N'dama (NDG), Nellore (NEL), Rwanda (RWA), Sheko (SHK) and Sahiwal (SHW).

Average MAF was 34% (±0.0001) and average proportion of exotic Jersey Island exotic genes in the population was ~22% (±0.01) while the greater percentage is of Holstein-Friesian genetics as well as other indigenous African breeds.

Discussion

The Jersey 'Inka Nziza project provided a good platform to assess the genetic diversity of Rwanda's dairy population and generate evidence to support the orientation towards dairy genetics suitable for local production systems. Principal component and admixture analyses confirmed Rwanda cattle as a highly admixed (crossbred) population. The PCA indicated population stratification reflective of sample country of origin, predominantly crossbreds of Holstein breed, followed by Jersey and indigenous breeds of ANK, EAZ-SH, NDG, SHW and SHK. The dispersal of Rwanda animals to the GIR and NEL breed, suggests a contribution of the two breeds albeit to a lower extent. Genetic contributions of N'dama, Gir and European *Bos taurus* breeds have been recently reported in Rwanda (Chagunda *et al.*, 2018). The Holstein-Friesian and Jersey are among the exotic dairy breeds used extensively in pure and crossbreeding in the tropics (Ahunu *et al.*, 1994). Genomic selection has been widely implemented in dairy cattle breeding with the aim to improve performance of purebred animals in developed countries and as well as crossbred cattle (Strucken *et al.*, 2017). By exploring the potential of pure and crossbred animals, there is an untapped potential to select for resilient, productive and ultimately profitable animals by use of genomic tools. Recent studies have demonstrated the opportunities of selection signatures for adaptation traits, disease tolerance parentage assignment and accurate estimation of breed composition (Bahbahani *et al.*, 2017) in cattle in Africa in order to inform future selection of desirable breed traits. The medium-density genomic markers provided insights to the current genetic make-up of Rwanda's dairy cattle population currently practiced in the dairy farming systems. Jersey breed irrespective of the origin showed a diversity of its use within Rwanda. Therefore, we propose that genomic technologies linked to effective dairy breeding systems could close the productivity gaps and more importantly support the development of tools and solutions for use to transform livestock production systems in Africa. This study contributes to a better understanding of the genetic architecture of Rwanda dairy cattle that could best enhance and drive tropical dairy improvement strategies through genomic selection.

419. Estimation of breed admixture levels in Sri Lanka cattle and its relation to performance traits

M. Spoelstra[1*], J. Sölkner[2], H. Bovenhuis[1], B. Babigumira[2], K. Periasamy[3] and C.M.B. Dematawewa[4]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Division of Livestock Sciences, Department of Sustainable Agricultural System, University of Natural Resources and Life Sciences, Vienna, Austria; [3]Animal Production and Health Laboratory, Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, International Atomic Energy Agency, Vienna, Austria; [4]Faculty of Agriculture, University of Peradeniya, Peradeniya 20400, Sri Lanka; mirjam.spoelstra@wur.nl

Abstract

Measuring ancestry levels of local admixed cattle in Sri Lanka provides insight on the most suitable dairy (cross)breeds for the local environment. Performance data of dairy cows (n=197) as well as blood samples for genotyping were collected from two governmental farms in the Kurunegala District in Sri Lanka. Admixture levels were calculated as proportional abundance of the Jersey, Holstein Friesian, and Sahiwal ancestry. The dominance component of heterosis was determined by calculating the abundance of non-homozygous genetic blocks. A mixed linear model was applied to find how performance and admixture levels were associated. For 305-day milk yield, significant predictors were found for Jersey ancestral breed proportion and the dominance component of heterosis for $P<0.05$. Although the feasibility of a crossbreeding program needs to be considered, performance of local Indicine cattle can be improved substantially through crossbreeding with Taurine cattle, mainly through the dominance effects of heterosis.

Introduction

Crossbreeding is a widely used implementation in (sub)tropical countries to increase performance while pertaining favourable characteristics of the indigenous cattle, such as heat tolerance, tick resistance and the ability to perform on low-quality feedstuffs (Galukande *et al.*, 2013). Breeding policies in Sri Lanka have, to large extent, stimulated a continuous grading up of existing cattle using purebred exotic animals (Ministry of Livestock and Rural Community Development, 2010). Continuous upgrading has been reported to decrease performance (Syrstad, 1989) due to a decrease in heterosis as well as the loss of beneficial and necessary key traits, mainly relating to the adaptation of indicine cattle breeds to the local environmental conditions. So far, little research has been performed on breed composition of dairy cattle in Sri Lanka, although identifying admixture levels that correlate with high performance under the local climate(s) of Sri Lanka could substantially improve dairy production.

Materials & methods

Data collection. Phenotypes and blood samples from 197 dairy cows were collected from two governmental farms in Sri Lanka, which were used to estimate the link between performance and admixture level. Phenotypes were collected from 2008 to 2018 and included reproduction data and production data related to milk yield. Ancestry of Sri Lanka cattle were explored in global context and therefore included genotypes of purebred Holstein Friesian, purebred Jersey, local Sri Lankan cattle, purebred Sahiwal as well as several indigenous cattle breeds including Batu Haraka, Thawalam and White cattle. The bulk of genotyping was performed at the laboratories of International Atomic Energy Agency (IAEA) in Seibersdorf (Austria) using an Affymetrix Axiom Bovine chip with a density of 52,518 SNPs. Genotypes of Holstein Friesian and Jersey originated from the International Bovine HapMap Project, genotyped using the Illumina BovineHD chip with a density of 777,962 SNPs (Bovine HapMap Consortium *et al.*, 2009).

DOI: 10.3920/978-90-8686-940-4_419, © M. Spoelstra *et al.* 2022

Data editing, selection and admixture analysis. Genotypes were merged and manipulated in PLINK1.9 (Chang *et al.*, 2015), resulting in a total of 35,284 overlapping SNPs. The merged data was explored using multidimensional scaling in the form of a PCA plot and ADMIXTURE analysis (Alexander *et al.*, 2009). To estimate the locus-specific ancestry in the autosomal chromosomes (n=29), data was phased with SHAPEIT v2 (Delaneau *et al.*, 2012) using a cattle recombination map from the Dryad (Ma *et al.*, 2016). Subsequently, locus-specific ancestry was calculated using the Ghap package (Utsunomiya *et al.*, 2020) where the reference populations (k=3) consisted of Holstein-Friesian (n=30), Jersey (n=30) and Sahiwal cattle (n=29). Admixture levels were calculated as proportional abundance of the Jersey, Holstein-Friesian and Sahiwal ancestry for all the generated genetic blocks per animal. Based on the ancestral haplotypes, the dominance component of heterosis was determined by calculating the abundance of genetic blocks of mixed ancestry, following Khayatzadeh *et al.*, 2018).

Mixed linear model. Admixture levels for locus-specific ancestry and the dominance component of heterosis were included in a mixed linear model to estimate how performance and admixture levels were associated. The model was run for milk yield and number of services per conception, using the lme4 package (Bates *et al.*, 2015) in R (R Core Team, 2020) to investigate the breed effect:

$$y_{ijklmnop} = \mu + \beta_1 HF_i + \beta_2 JR_j + \beta_3 Dominance_k + Parity_l + Farm_m + Cow_n + Year_o + e_{ijklmnop} \quad (1)$$

Where: $Y_{ijklmnop}$ is the dependent variable (305-day milk production, number of inseminations), μ is the overall intercept of the model, $\beta_1 HF_i$ is the fixed effect of the proportion Holstein-Friesian admixture level (i=0 to 1), $\beta_2 JR_j$ is the fixed effect proportion Jersey admixture level (j=0 to 1), β_3Dominance$_k$ is the fixed effect of the dominance component of heterosis defined as the percentage homozygous blocks (k=0 to 1). Parity$_l$ is the fixed effect of the k^{th} number of parity (l=1 to 6, where 6 encompasses the parities 6-10*),* Farm$_m$ is the fixed effect of the m^{th} farm (m=Andigama or Maradawila), Cow$_n$ is the random effect of the n^{th} cow (n=1 to 168), Year$_o$ is the random effect of the birth year of the cow (0 = 2005 to 2019), $e_{ijklmnop}$ is the random residual effect with mean 0 and variance σ^2. The model was tested for significant predictors using the lme4 summary statistics and a type III ANOVA test (Wald chi-square test).

Results

Locus-specific ancestry analysis. The supervised locus-specific ancestry analysis used to infer ancestral populations on haplotype level of the admixed cattle on Andigama and Maradawila farm was visualized using Ghap (Utsunomiya *et al.*, 2020, Figure 1). Main breed components consisted of Pakistan Sahiwal (red) and Jersey (green).

Mixed linear model for 305-day milk yield & number of services per conception. The model for 305-day milk yield indicated significant predictors for parity (P=0.0199), Jersey ancestral breed proportion (P=0.0131) and the dominance component of heterosis (P=8.045e-06) for P<0.05 (Table 1). The Holstein-Friesian breed component was showing a high standard error and was indicated as insignificant (P=0.1425) for P<0.05. Both breed components had a negative effect on milk yield, whereas the dominance component of heterosis increased milk yield substantially. The combination of these two components gives us the estimated milk yield response for full heterosis based on dominance effects at haplotype level.

Based on the results of this analysis, a pure Sahiwal would produce 1,076 kg milk at first parity. A first cross Sahiwal × Jersey would result in an estimated milk yield of 1,839 kg for the first parity on Andigama farm (1,076.47 – (789.22×0.5) + 1,156.85) and 2,076 kg for Maradawila farm (1,076.47 – (789.22×0.5) + 1,156.85 + 237.63). A crossbred Sahiwal × Holstein Friesian (not-significant) would result in an estimated milk yield of 1,871 kg for the first parity on Andigama farm (1,076.47 – (724.61×0.5) + 1,156.85) and 2,109 kg

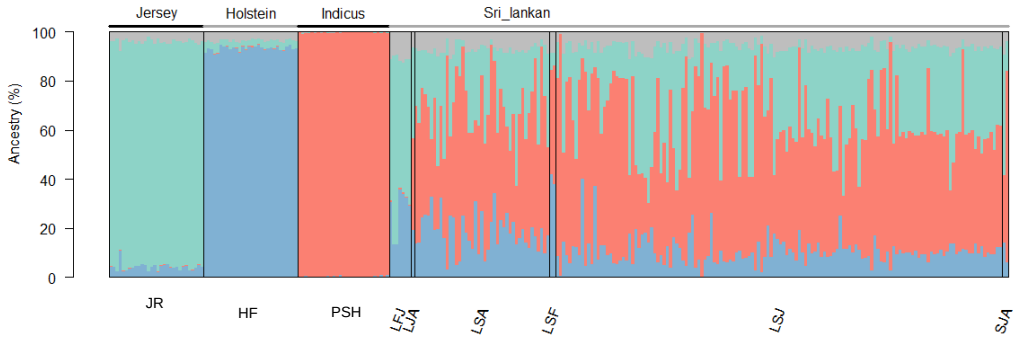

Figure 1. Locus specific ancestry predicted for admixed cattle population based on a reference panel including Jersey (JR: green), Holstein Friesian (HF: blue), and Pakistan Sahiwal (PSH: red). Admixed cattle include crossbred Sahiwal × Jersey × Australian Friesian Sahiwal (SJA); crossbred Sri Lankan Holstein Friesian × Jersey (LFJ); crossbred Sri Lankan Jersey × Australian Friesian Sahiwal (LJA); crossbred Sri Lankan Sahiwal × Australian Friesian Sahiwal (LSA); crossbred Sri Lankan Sahiwal × Holstein Friesian (LSF); crossbred Sri Lankan Sahiwal × Jersey (LSJ).

Table 1. Summary of linear mixed effects model for 305-day milk yield based including the fixed effects: Holstein Friesian proportion; Jersey proportion; parity; farm; and the dominance effect of heterosis.

for Maradawila farm (1,076.47 – (724.61×0.5) + 1,156.85 + 237.63). For the model estimating number of services per conception, no significant predictors were found for $P<0.05$.

Discussion

Our findings suggest that an increased response in performance was mainly caused by the dominance effects of heterosis at haplotype level, indicated by the high correlation between the dominance effect of heterosis and 305-day milk yield. Heterosis effects are generally higher in functional traits with low heritability, such as those accounting for reproduction, survival, and fitness, whereas production traits with moderate heritability (e.g. milk yield and growth) are less affected by heterosis. Interestingly, our results showed a higher influence of heterosis on milk yield than on reproduction (number of services per conception). Since the (timing of) insemination of cows is nevertheless under the influence of the farm management, there might be additional influences that we did not account for. Heterosis effects are generally much larger in

crosses between temperate and tropical breeds (Wakchaure *et al.*, 2015. The large genetic distance between the breeds possibly explains the high influence of heterosis on milk yield in our study.

420. Economic values for skin grade, days to market and number of hatchlings in the Australian saltwater crocodile industry

S. Hermesch[1*] and S.R. Isberg[1,2]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]Centre for Crocodile Research, PO Box 329, Noonamah, Northern Territory 0837, Australia; susanne.hermesch@une.edu.au

Abstract

The saltwater crocodile industry in northern Australia produces skins for high-value leather products. Most eggs are harvested from the wild, providing multiple livelihood benefits to rural and Aboriginal communities in the area. Economic values derived from an independent model for each trait were AU$620.40 for skin grade (a binary trait), AU$-0.95/day for days to market and AU$105.30/hatchling for number of hatchlings per clutch. Economic values were converted to economic weights expressed on the basis of a clutch of the breeding female for a comparison among traits. Based on phenotypic standard deviations of traits, skin grade had the highest emphasis (50%) followed by days to market (38%). Economic values derived in this study should be used to assist management decisions. Setting up structured breeding programs for saltwater crocodiles in northern Australia is less desirable given the wider benefits of harvesting eggs from the wild for rural and Aboriginal communities.

Introduction

The saltwater crocodile industry in northern Australia produces skins for high-value leather products. Saltwater crocodile eggs are collected from the wild, under approved management programs, providing multiple livelihood benefits for rural communities (Fukuda and Webb, 2019, DEPWS, 2020). Harvesting eggs relies heavily on traditional Aboriginal knowledge and royalties are paid for each egg collected, placing economic worth on an apex predator. This sustainable-use model has contributed to full species recovery and conservation of the habitat and co-existing species. Further, the saltwater crocodile industry provides jobs and income to rural communities in remote areas where other income sources are scarce. Fukuda and Webb (2019) also point out 'a key threat, however, to both wild crocodiles and Aboriginal livelihoods, is recent moves by some actors in the fashion industry to stop using wild crocodilian skins.'

The crocodile industry can only provide livelihood benefits to rural communities if it is profitable. Profitability can be increased by improving traits of economic importance. Economic values define economic importance of traits and have been used extensively in animal breeding. However, they may also be used to evaluate alternative management strategies to improve profitability. So far, information about economic values in the crocodilian industry is sparse (Gray *et al.* 2007) and adoption has been hindered by lack of information about input values and specific setup of bio-economic models. The use of independent models (e.g. Amer *et al.* 2014) provides greater flexibility in trait selection for breeding, and management, objectives. The aim of this study was to develop independent economic models to derive economic values for key performance traits in saltwater crocodiles in the Australian context.

Materials & methods

Economic values for skin grade, days to market and number of hatchlings per clutch were derived based on an independent economic model for each trait. The components of these economic models reflect relevant crocodile farming practices which are not widely known and some background information is provided. More detailed information about saltwater crocodile farming and trait definitions was provided by Isberg *et al.* (2005a,b).

Skin grade. Skins are sold on a 'per cm belly width' basis and returns per crocodile increase linearly for every additional cm in belly width. However, the maximum price received is only obtained for first-grade skins and price is substantially reduced depending on the number and location of any imperfections. Skin grade was defined as a binary trait defining whether skins meet requirements for the first grade (1) or were part of the other grades (0). The economic value for skin grade (EVsg) was derived as: EVsg = (Rsg1 – Rsg0) where Rsg1 was the return for first-grade skins and Rsg0 was the average return for skins in the other three grades. The return per first-grade skin was AU$1,504 based on a payment of AU$40/cm and an average belly width of 37.6 cm (Isberg *et al.* 2005b). The average return for skins from the other grades was AU$883.6 based on prices of AU$30, AU$10 and AU$0 per cm for the second, third and fourth skin grades, respectively, which were assumed to represent the same average dimensions and comprise 15, 2 and 3% of skins.

Days to market. Days to market quantifies the number of days from birth until the age when crocodiles reach market size. Market size is determined by belly width, rather than weight, and saltwater crocodiles are slaughtered when they have reached a belly width of 35 to 45 cm. In northern Australia, saltwater crocodiles hatch from January to July and stay in the hatchling facility until the end of each calendar year, when they are moved to the overall grow-out facilities. Days to market therefore encompasses the hatchling phase and the grower phase. The economic value for days to market (EVdays) was: EVdays = - (Vm – Cm – Ch) / days where Vm was the average market value per crocodile (AU$1,380) based on the assumptions of classification and payments of skin grades outlined above, Cm were the marketing costs per crocodile (AU$ 284) and Ch were costs to produce a hatchling (AU$ 107.3), while days was the number of days to reach market size (1,037.8 days).

Number of hatchlings. Despite the Australian crocodile industry relying heavily on wild egg collection with the primary aims of species conservation and rural livelihood benefits, farms often keep a small nucleus of breeding animals. These breeding crocodiles have been removed from the wild as problem crocodiles, as part of the public relations program of promoting living with an apex predator (DEPWS, 2020). However, no performance selection has occurred and there is an opportunity to optimise future breeder selection and increase farm profitability.

Each female produces one clutch of eggs per year, which are then incubated. Breeding pens vary in their stocking density but mainly consist of one male with one to eight females. Others simulate more natural breeding populations with multiple males and multiple females. Each crocodile farm can produce a fixed number of hatchlings each year due to market constraints and an increase in clutch size would lead to cost savings in the number of females required to produce the target number of hatchlings. The economic value for number of hatchlings (EVnh) was: EVnh = Cf / nh – Clh where Cf was the sum of all annual cost of breeding females (Cf), nh was the number of live hatchlings per clutch (nh: 31.25, Isberg *et al.* 2005a) and Clh was additional labour cost for an additional hatchling (AU$0.96). Costs per female included costs for capital (AU$1,122), labour (AU$1,278) and feed (AU$780) based on one female per male in each breeding pen.

Economic weights. Economic values were derived for two traits of growing crocodiles and a trait of breeding females expressed per clutch, which differ in frequency and timing of expression. These differences were considered through discounted genetic expressions (DGE) to convert economic values of traits of growing crocodiles into economic weights of a breeding objective at the time when number of hatchlings per clutch is expressed. The DGE was derived as: DGE = nh × surv / {(1+r)^(days / 365)} where nh was the number of hatchlings per clutch (31.3), surv was the survival rate of hatchlings until slaughter (81%) and r was discount rate (0.07). The economic weight of each trait was multiplied with the corresponding phenotypic standard deviation to express each trait emphasis relative to the sum of these products. In

animal breeding, this illustration of trait emphasis is usually based on genetic standard deviations which are currently not available for these crocodile traits and phenotypic standard deviations were used instead.

Results

The proportion of first-grade skins was assumed to be 0.8 and the standard deviation of this binary trait was derived (Table 1). First heritability and repeatability estimates for the other two traits were moderate to high. Economic weights expressed relative to the phenotypic standard deviation of traits were highest for skin grade (50%) and days to market (38%, Figure 1).

Discussion

Crocodiles are placed into finishing pens when they are appraised to be close to market size. The number and severity of imperfections on the belly skin determines the amount of time they spend in the finishing pens. Environmental influences such as floor surfaces, hygiene practices and prevalence of mosquito-borne viruses may override expression of underlying genetic variation for skin grade. Given the economic importance of skin grade, this trait should be recorded more closely on farms to identify genetic and non-genetic factors affecting the trait.

Skin grade determines the price per cm belly width obtained for each crocodile skin and a higher belly width leads to higher returns. Further, Gray *et al.* (2007) illustrated a payment system which rewarded larger belly width in the first skin grade while prices for belly width in other skin grades remained constant. This type of payment system can be considered when deriving economic values for both skin grades and belly width through a bivariate distribution of crocodile skins across skin grades and belly-width groups,

Table 1. Data statistics, repeatability or heritability (ratio where known) as well as economic values (EV) and economic weights (EW) for saltwater crocodile traits.

Trait	Mean	SD	ratio	EV	EW [4]
	Traits of growing crocodiles				
First-grade skins (1/0) [1]	0.8	0.40		620.40	12,915.70
Days to market (days) [2]	1,037.8	197.77	0.40	-0.95	-19.83
	Trait of the female (clutch)				
Number of hatchlings [3]	31.3	11.45	0.34	100.80	100.80

[1] Data statistics derived for a binary trait and heritability is unknown.
[2] Data statistics from Isberg *et al.* (2005b), heritability presented.
[3] Data statistics from Isberg *et al.* (2005a), repeatability presented.
[4] The discounted genetic expression to convert EVs of traits of growing crocodiles traits to EW expressed per clutch (AU$/clutch) was 20.82.

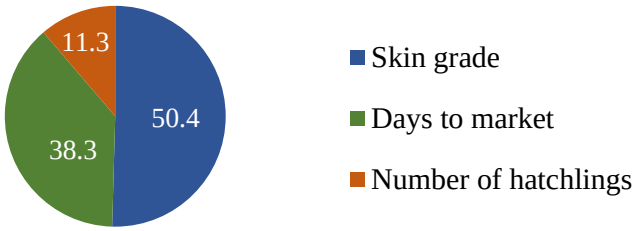

Figure 1. Percentage emphasis of crocodile traits based on phenotypic variation of traits.

as outlined by Hovenier *et al.* (1993) for the univariate case. However, belly width and days to market are associated and trait definitions for belly width and days to market have to ensure that these two traits are independent at both the phenotypic and genetic level. Belly width is similar to market weight in livestock, which is often assumed fixed and not considered separately to days to market in breeding objectives. These considerations need further investigation to model the economic benefits of larger belly width.

Feed costs were not modelled separately and were part of EVdays. Crocodiles require a relatively low amount of feed; e.g. adult breeding crocodiles require only one (females) or two (males) chicken each week. However, costs of feed are not negligible due to high transport and refrigeration costs and should be considered separately as a trait. Of larger consequence is the natural variation of growth rates expressed. Isberg *et al.* (2005b) reported the range in number of days to reach market size to be 634 to 1,859 days. This translates to a difference of 3.4 years in associated production costs, illustrating the potential to improve profitability.

In northern Australia, the majority of eggs to produce hatchlings are sourced from the wild-egg harvest providing income and employment to rural and Aboriginal communities. The cost of wild eggs is similar to the costs of eggs bred in captivity (EVhn) and there is no economic benefit to produce eggs on farms. Given the primary consideration to the income and employment opportunities that wild-egg harvesting provides in northern Australia, economic values derived in this study may best be used to aid management decisions on farms to improve profitability because most farms may not setup a genetic improvement program.

Abstract

Livestock populations can have different genetic backgrounds and may vary in their capacity to respond to environmental changes. Our findings suggest that improved chicken breeds differ in growth performance and phenotypic plasticity (yield stability) when they are introduced into new tropical environments. Dual consideration of productivity and phenotypic plasticity gives opportunities to select or recommend genotypes with optimal performance and wider adaptability for smallholder farmers raising livestock in different agroecologies.

Introduction

Phenotypic plasticity refers to the variation in phenotype (e.g. morphological, physiological, behavioural) which results from complex relationships between a genotype and its environment (s). A genotype that shows high phenotypic variation across environments is termed 'phenotypically plastic' while the one that shows low variation is termed 'robust' or 'stable'. Plastic responses for a quantitative trait surfaces as genotype by environment interaction (G×E) during statistical analysis and can be explained through a 'reaction norm'.

Plasticity is thought to be under genetic control. Some genes control both plasticity and mean phenotype while many others are associated only with plasticity (Sieriebriennikov *et al.*, 2018; Lafuente and Beldade, 2019). Phenotypic plasticity can be incorporated as a selectable trait into an animal breeding programme to develop individuals or populations with wider environmental adaptation (De Jong and Bijma, 2002). Plasticity can also be harnessed to screen candidate breeds for introduction at scale to smallholder farmers in the tropics. The objective of the present study is to exploit the concept of plasticity to select and recommend improved chicken breeds with wider environmental adaptation and higher growth performance.

Materials & methods

We distributed five different chicken breeds into three different agroecologies of Ethiopia. The agroecologies were defined following the approaches by Kebede *et al.* (2021) who applied species and phenotypic distribution models. Species Distribution Models (SDMs), implemented in MaxEnt (Phillips *et al.*, 2006) and similar software, predict distribution of a species based on presence-only data, estimate the contribution of environmental predictors, and help identify environmental predictors associated with habitat suitability and phenotypic differentiation in current and future environments. Agroecologies defined through distribution models give a better estimate of G×E compared to conventional agroecologies defined on agronomic attributes (e.g. length of cropping season) and are more appropriate to evaluate phenotypic plasticity in livestock.

A total of 21,562 improved chickens were raised by 2,547 smallholder households and average live body weight of each flock was recorded. The growth performance and plasticity (yield stability) of the five

R.F. Veerkamp and Y. de Haas (eds)

chicken breeds until 150-days-of-age (LBW150) across three distribution-model-defined-agroecologies (AEI, AEII, and AEIII) was compared by Additive multiplicative interaction model (AMMI) and mixed-effects (REML)/LMM models.

Results

The phenotypic plasticity for LBW150 among different chicken breeds introduced into different environments based on AMMI model is presented in Figure 1. Performance of the five breeds in the different agroecologies is presented against the first environmental principal component (along the x-axis). The plastic responses of the breeds for LBW150 are characterized by changes in magnitude and rank, signifying the presence of G×E. Breeds with gentler slopes in the reaction norm plots (Sasso, SRIR and Potchefstroom Koekoek) indicate these breeds have wider adaptation (are less plastic). Kuroiler breed, shows a steeper slope (more plastic/less stable) and appears to be a better choice to be introduced specifically into agroecology-I (AEI). Differential growth performance of these breeds in conventionally defined agroecologies was shown by other statistical approaches (Lozano-Jaramillo *et al.*, 2019a,b; De Kinderen *et al.*, 2020; Alemu *et al.*,2021) supporting the presence of G×E.

WAASB (Weighted Average of Absolute Scores) biplots on LMM/REML-based analysis for productivity and plasticity are presented in Figure 2. The breeds or agroecologies included in quadrant I are considered unstable breeds or agroecologies with high discrimination ability, and productivity level below the grand mean. We have Horro in quadrant I. Unstable breeds with productivity above the grand mean are included in quadrant II. The only breed which fell into this category is Kuroiler. Breeds withing quadrant III (SRIR and Koekoek) have close to average productivity but can be considered less plastic (stable) due to the lower value of WAASB. The lower the WAASB stability value, the more stable the breed can be considered. The agroecology included in the third quadrant are considered as unfavourable and having low discrimination ability. The breed within quadrant IV (Sasso) is considered highly productive and broadly adapted (less plastic/more stable).

Discussion

The five chicken breeds showed different levels of growth performance and plasticity for LBW150 in three agroecologies defined by distribution models. That was probably due to differences in their genetic backgrounds (e.g. genes influencing plasticity, selection history, levels of inbreeding). AMMI and LMM

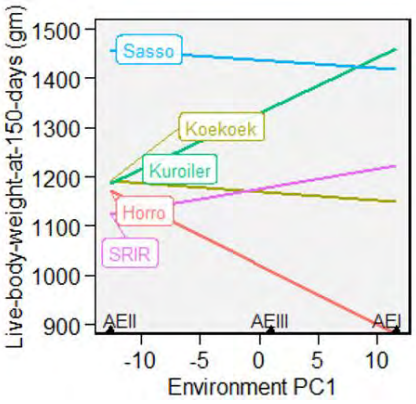

Figure 1. Performance plots showing phenotypic plasticity of five chicken strains for LBW150 against environmental principal component analysed by AMMI model. AEI, AEII, and AEIII, indicate the distance of agroecologies along PC1.

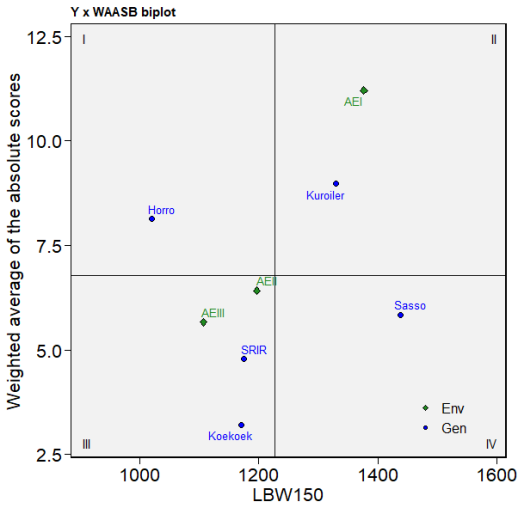

Figure 2. Biplot of LMM analysis for LBW150 showing mean growth performance (x-axis) and plasticity (four-quadrants) of five improved chicken breeds.

detected G×E differently but effectively. But LMM was more sensitive in identifying productive and stable breeds than AMMI. LMM-based models and indexes allowed fitting of random effects and helped generate biplots combining productivity and yield stability. Multi-environment comparison of breeds on productivity and plasticity is essential before new breeds are introduced to suboptimal environments of the tropics. Such comparisons may help identify breeds with high productivity and low plasticity for smallholders.

We recommend that phenotypic plasticity should be harnessed by animal breeders to deal with changes in production environment at present and future scenarios (e.g. climate, health, management levels). In depth studies should be conducted to understand molecular mechanisms controlling plasticity of QTLs. Multi-environment performance models incorporating diverse information (e.g. phenotypic, environmental, and genetic/genomic) should be also developed for comparison of livestock breeds on productivity and plasticity for smallholder systems.

Abstract

Poultry is a crucial sector for the livelihoods and food security of millions of people in Nigeria. Here we present the first large scale whole-genome sequencing analysis on Nigerian indigenous chickens from different agro-climatic conditions, investigating their genetic diversity and adaptation to tropical hot climates. We observe a large genetic diversity but low levels of population differentiation. Selection signature analyses were performed to identify candidate genes in relation to heat-stress adaptation including those specific to extreme hot-humid or hot-arid conditions. These results have important implications for the conservation of genetic diversity and breeding improvement of chickens for thermo-tolerance.

Introduction

Indigenous livestock populations from different geographic regions constitute important genetic resources for conservation as they represent adaptation to local agro-climatic conditions. Native tropical breeds are particularly crucial, as climate change and global warming is forcing many temperate regions to experience tropic-like conditions and such breeds may hold a genetic solution for climate-resilience.

Nigeria is a tropical lowland country, where poultry farming plays a crucial role in the economy and the livelihood of millions. Nigeria has one of the largest stocks of chickens in Africa, but over half of its birds are still raised in extensive backyard farming systems, which are predominantly represented by unimproved indigenous breeds. Even though these local unimproved breeds have poor productivity, they show superior adaptive ability to harsh tropical climates. The Nigerian agro-climate offers an excellent opportunity to dissect thermo-tolerance in chickens, both under hot-humid and hot-arid conditions. Whilst most Nigerian geographic regions experience very high temperatures (except in the high plateaus), the climate varies from very wet conditions in the coastal south (annual rainfall >3,500 mm, temperature up to 32 °C) to substantially dry conditions in the Sahel region of the north-west and north-east (annual rainfall <600 mm, temperature up to 41 °C). The genetic characterisation of these indigenous chickens (IC) is crucial for conservation of genetic and adaptive diversity and for elucidating the molecular mechanisms of environmental adaptation, particularly to heat-stress.

Most of the genetic studies on Nigerian IC were on mtDNA, with none examining whole-genome sequence (WGS) data. Here we examine the genetic diversity in Nigerian IC with WGS data, and explore genomic signatures for positive selection in response to heat-stress.

Materials & methods

Chicken sampling and genome sequencing. Blood samples were collected from 120 village chickens from 14 populations representing different agro-ecological zones (AEZs) (Figure 1). WGS was performed on the Illumina HiSeqX platform at 30x paired-end coverage.

Figure 1. (A) Nigerian agro-ecological map showing sampling locations; (B) details of the studied chicken populations.

Sequence data processing and genomic analysis. Sequence reads were mapped against the chicken reference genome (GRcg6a) using the BWA-mem algorithm. SNP calling was performed following GATK best practice protocol for 'Germline short variant discovery' followed by Variant Calling Score Recalibration (VQSR) for initial filtration. Autosomal SNPs with minor allele frequency >0.05 and genotype quality >15.0 were used for genetic diversity and selection signature analyses (SSA). SSA was performed using Pooled Heterozygosity (*Hp*) (Rubin *et al.*, 2010) and *Fst* (Weir and Cockerham, 1984) approaches in overlapping sliding windows (20 kb size with 10 kb step) with at least 10 SNPs/window.

Results

Nigerian IC show large genetic diversity but low levels of population differentiation. The combined analysis of all samples identified over 17 M SNPs of which 24% (~4.1 M) are novel. This represents an average density of 1 SNP every 62 base pairs. The number of SNPs from different populations varied between 9 M (Jiga) and 12 M (Sanchitagi); variation largely reflecting the number of samples analysed. Nucleotide diversity (pi) – calculated in overlapping windows of 20 kb size and 10 kb steps – was similar across all the populations (0.0031-0.0035). Moreover, a low level of inbreeding (<0.05) was observed for all populations. PCA plots – using 4M LD-pruned SNPs – show overall weak population structure, with most populations clustering together except Degema, DakanKaru and Odenkume (Figures 2A, 2B). Admixture analysis predicted contributions from four ancestral gene pools (Figure 2C) but pairwise *Fst* analyses showed a generally low level of population differentiation (*Fst*<0.05), except in a few cases where moderate differentiation (0.05-0.08) was observed (Figure 2D).

SSA reveals candidate genes for heat-stress adaptations. The climatic conditions of the studied populations showed little variation in annual mean temperature (except populations from the MidAltitude region) (Figure 3A), but large variations in annual rainfall (Figure 3B). SSA was therefore performed in two ways. First, 12 populations (omitting WatKaru and DakanKaru) were combined for *Hp* analysis. The combined analysis allowed reduction of spurious signals from population structure and detection of genomic regions with extreme low heterozygosity (*zHp*<-4) from all the hot-climate populations. These genomic loci and overlapping genes are therefore candidates for heat-stress adaptation, irrespective of humid or arid conditions (Figure 4A). Second, *Fst* analysis was performed among population groups from hot-humid (Degema and Isiokpo) and hot-arid (Jiga and Sabiyal) climates (Figure 3B) to identify candidate regions/genes that show large differentiation (*Fst*>3.5) in relation to heat-stress adaptation under dry and humid conditions (Figures 4B-4D). Selection direction of the *Fst*-sweep regions was decided based on their *Hp* values within groups.

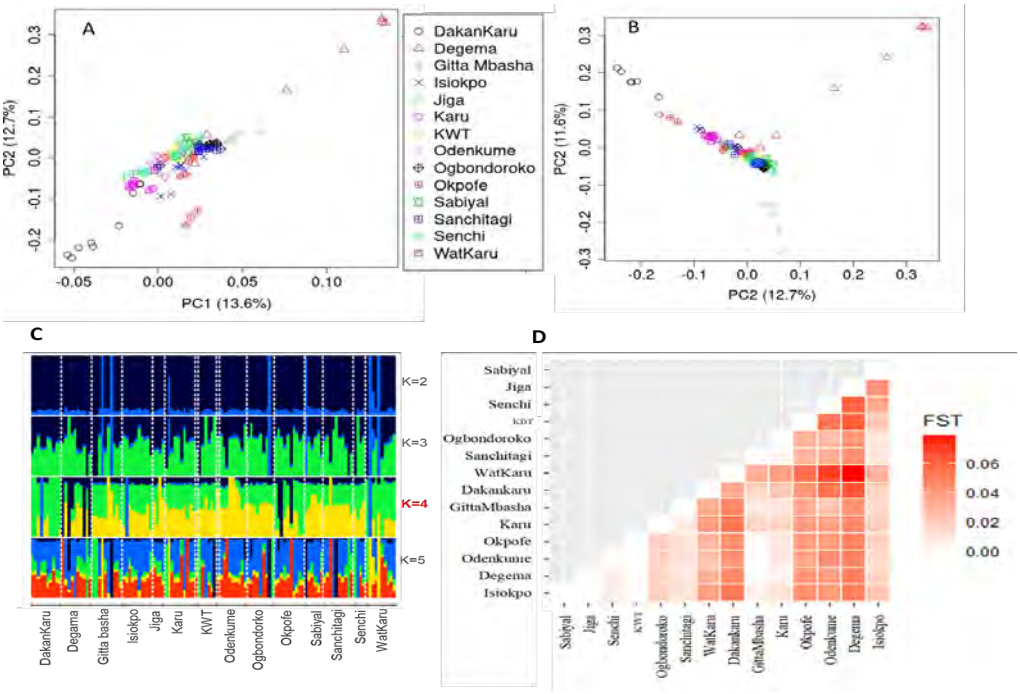

Figure 2. Population genetic diversity. (A & B) PCA plots showing population structure, (C) admixture analyses (K=4 is best prediction); (D) heat map of pairwise *Fst* values.

Discussion

This is the first study performing a large scale WGS analysis on Nigerian IC to assess genetic diversity and identify genomic signatures of adaptive selection in relation to hot climates. Our study shows a large genetic diversity in Nigerian chickens that can be harnessed in breeding programmes for improvement of production and performance traits. The study also dissected candidate genes for general heat-stress adaptation (*Hp* analysis) as well as those important in either humid or arid conditions (*Fst* analysis). The *Hp*-based candidates have highly relevant biological functions associated with thermo-tolerance, e.g. *TSHR* – role in thermogenesis (possibly regulated by epigenetic mechanisms, as fixed in most chickens), *RYR1*-like genes (*LOC11233047* and *LOC101748756*) – involved in hyperthermia, *CYP450*-like genes

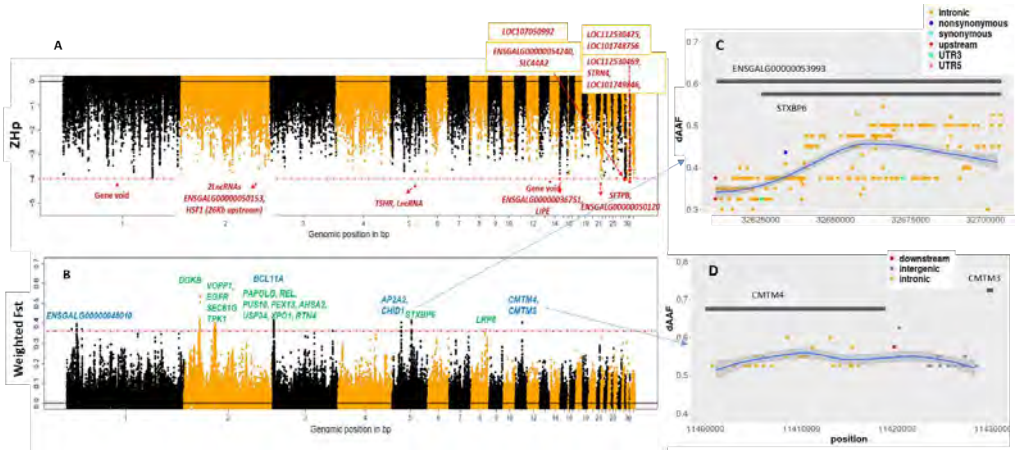

Figure 4. (A) Manhattan plot from *Hp* analysis based on 12 hot climate populations; (B) Manhattan plot for *Fst* analysis between hot-humid and hot-arid groups (candidate genes for humid climate are shown in green and for dry climate in blue); (C) and (D) showing close-up of two selection signature regions from humid and arid regions, respectively (Y axis represents difference in alternative allele frequency between the two groups)

(*LOC11253049* and *LOC101749846*) – roles in oxidative stress response, *SFTPB* – role in respiratory gaseous exchange (affecting heat loss from body), *LIPE* – lipid metabolism, *STRN4* and *SLC44A2* – roles in nervous system processes and immunity, and two lncRNAs with possible cis-regulatory effect on Heat Shock Factor 1 (*HSF1*) gene (Lin *et al.* 2017; Seo *et al.* 2020; Uniprot). The candidate genes associated with hot-arid conditions include: *CMTM3, CMTM4, BCL11A* and *CHID1* – all with roles in immune system development and/or functioning and *AP2A2* and *LRP8* with roles in lipid metabolism (Uniport). Prominent candidates from hot-humid climate include: *DGKB* – involved in many cellular processes including immunity (Zhong *et al.* 2008), *EGFR* – role in converting extracellular cues to appropriate response (Uniprot), *SEC61G* – involved in translocating proteins to Endoplasmic Reticulum, which has an important role in environmental and cellular stress response (Singh *et al.* 2021), *TPK1* – involved in heat and osmo-stress response (Reca *et al.* 2020); *AHSA2* – activator of Heat Shock Protein 90 (*HSP90*) gene (Uniprot), *RTN4* – with many roles including apoptosis, angiogenesis, and immunity (Uniprot). These results will have important implications for breeding improvement to develop heat-tolerant productive breeds for tropical small-holder farming systems.

Part 23

Challenges – delivering genetic progress in systems around the world

423. Impact of industry effort to increase dairy heifer genomic testing in Australia

M. Abdelsayed[1], M.M. Axford[1,2,3*] and G.J. Nieuwhof[1,2]

[1]DataGene Ltd, 5 Ring Road, Bundoora, Victoria 3083, Australia; [2]Agriculture Victoria, AgriBio, Bundoora, Victoria 3083, Australia; [3]School of Applied Systems Biology, La Trobe University, Bundoora, Victoria 3083, Australia; maxford@datagene.com.au

Abstract

The increased use of heifer genomic testing enables further herd improvement on Australian dairy farms. This paper describes pre-competitive, industry efforts to improve the customer experience and increase the rate of heifer genomic testing. Following the implementation of process improvements, the number of females genotyped, annually, more than doubled between years ending 30 June 2020 and 2021. Turn-around time was reduced by two-thirds and 99% of animals now receive results. Process improvements also contribute to the success of activities that increase collaboration and industry extension.

Introduction

Heifer genomic testing delivers value to most Australian dairy farmers as a tool to select replacements, correct pedigree records, control inbreeding and plan mating strategies (Newton *et al.*, 2018). Yet, in 2018/2019, less than 20,000 females (2% of dairy cows) were tested in Australia. An industry-lead initiative began in 2019 to rapidly increase the rate of genomic testing through three work areas:

1. implement a series of process improvements to deliver results more quickly;
2. collaborate with commercial and industry partners to support farmers with clearer and more consistent messages about the value of genomic testing; and
3. develop and deliver communication and extension programs using outcomes from market research activities.

Following the report of collaboration, communication and extension activities presented by Monks *et al.* (2021), the purpose of this paper is to describe the impact of process improvements that delivered an improved customer experience to genomic service providers (customers) and their dairy farmer clients by DataGene.

Materials & methods

In consultation with customers and industry stakeholders, the most important process improvements were prioritised on the basis of likely impact on customer experience. The improvements can be grouped into four areas including faster turn-around time, extending evaluations, systematic correction of data issues and providing secure access to the centralised data repository.

Faster turn-around time. Genetic evaluations were run monthly at the commencement of this work. Accounting for sample transport, processing and lab times, a monthly schedule meant that some animals received results more than two months after samples were collected. This turn-around time did not meet the expectations of customers and so a new target was set for the weekly evaluations of all animals.

Investigators analysed workflows to identify opportunities to improve efficiencies and increase automation during the evaluation schedule. For example, the genetic evaluation team traditionally loaded data from herd recording centres, monthly, with some manual processing required. With automation in place, animal data is now systematically loaded through an application programming interface and quality checked every

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_423, © M. Abdelsayed *et al.* 2022

night from most centres. Provisions are in place for centres that choose to load data, weekly, through an enhanced managed file transfer protocol. In a second example, virtually all genetic evaluation and data quality reports for customers and internal users are now systematically generated as part of the evaluation without manual intervention. Finally, a restructure of the data exchange between genetic evaluation and report delivery systems has reduced the time taken to deliver reports and update all web-based interfaces. A weekly evaluation schedule was then able to be implemented as a result of workflow changes that increased efficiency and reduced manual intervention.

Extend evaluations. Genomic evaluations for animals sired by a Holstein or Jersey sire commenced in Australia in 2011 and 2012 respectively. The project aimed to grow the number of animals that can benefit from genomic testing. Animals sired by the Red breed group (Australian red dairy cattle, Scandinavian red, Ayrshire, Illawarra or Dairy Shorthorn) are the next biggest breed group, comprising 4% of herd-recorded cows in Australia (DataGene (2019/20)).

Building on the work of Van den Berg *et al.* (2020), DataGene scientists implemented a single-step genomic evaluation for four traits for the Red breed group (DataGene, 2021). Traits were selected based on reliability and included milk (L), fat (kg), protein (kg) and somatic cell count (%). When first published in July 2021, average reliability for genotyped females was reported to be 59% for protein (kg) (DataGene, 2021). The National economic index, Balanced Performance Index, is calculated using genomic evaluations for traits where they are available and traditional evaluations for the remainder (DataGene, 2021).

Two other examples where the evaluation has been extended is the calculation of breed-based representation and the reporting of additional haplotypes. Both services deliver additional value to the customer without additional effort as part of the routine evaluation.

Systematic correction of data issues and providing troubleshooting tools. Prior to the commencement of the project, 89% of nominated animals received breeding value results following genomic evaluation. Twenty percent of animals were reported with an inconsistent sire, 10% with an inconsistent dam, 10% without a correct breed, eight percent with an inconsistent birthdate and six percent of samples were rejected for poor quality.

To achieve the target of 95% of animals receiving results, workflows were revised to resolve inconsistent pedigrees where the sire and/or dam could be discovered as part of the evaluation. Importantly, this service is customised to meet the needs of individual customers. The automatic update of pedigree is an 'opt-in' service that service providers can elect to include if it is appropriate for their clients. Secondly, rules were implemented to prevent the changing of a confirmed pedigree, breed or birth date by other parties. This ensures that animals receiving a result don't suddenly fail based on incoming data containing outdated information.

Customers value the ability to quickly detect and resolve an issue related to an animal, genotype or service request with as much capacity for automation as possible. In addition to automatically correcting pedigree, additional static reports and an interactive dashboard with appropriate permissions were built to help customers to troubleshoot issues.

Provide secure access to the centralised data repository to genomic service providers. The number of genomic service providers has doubled since the beginning of the project. By opening access to DataGene's centralised data repository, customers can structure a service according to their business objectives. Previously, customers were limited to supplying data and receiving static reports using file

transfer protocols (ftp) and secure websites. Now, customers can exchange animal data, genotypes and load service requests using a managed file transfer protocol with multiple file loading capacity that can be operated programmatically or by interacting with a user interface. With appropriate security and permissions, customers now have the capacity to load/edit new animals to the centralised data repository, a role that was previously limited to data processing centres.

Results

The turn-around time between data loading and result reporting is a useful metric to monitor as it illustrates the impact of numerous workflow improvements across the system. The mean number of days between loading data and reporting a result has declined from 25 days in June 2020 to 7 days in December 2021 as shown in Figure 1. The steeper decline between quarters ending December 2020 and June 2021 is in line with the transition from monthly to weekly evaluations.

Extending genomic evaluations has increased the number of animals eligible for testing. In the quarter concluding December 2021, four percent of females tested had a sire from the Australian red dairy cattle breed group. This value is identical to the proportion of red dairy cattle animals in the population, indicating a strong, early, uptake of the new evaluations.

In June 2019, June 2020 and June 2021, the proportion of animals receiving results was 89%, 98 and 99% respectively with the most recent two years exceeding the original target of 95%. These results are influenced by the automatic correction of inconsistent pedigree and rules that prevent the over-writing of confirmed animal information. Table 1 shows the proportion of genotyped animals with data warnings or errors and illustrates the impact of process improvements. For example, inconsistent sires were observed in 5% of animals in 2021, compared to 20% in 2020.

Figure 1. Mean days between loading and result delivery.

Table 1. Proportion (%) of genotyped animals with warnings or errors at the time of evaluation.

	Financial year	
Reason	**2020**	**2021**
Inconsistent birth date	8	0
Inconsistent sire	20	5
Inconsistent dam	10	2
Breed unknown or not evaluated	10	1

Discussion

A concerted effort to prioritise and implement substantial system-wide improvements has delivered a faster genomic evaluation service for more animals. The number of females genotyped in the financial year ending 30 June 2021 was more than double that of the previous year. Turn-around time was reduced by two-thirds and 99% of animals now receive results. There is an opportunity to continue to improve service by reducing the turn-around time for animals that arrive with data issues. Additionally, there are opportunities to grow the genomic service by incorporating genomic inbreeding, creating actionable reports using breed-based representation and haplotypes and providing further customer training to optimise their use of the system.

Improving the customer experience is vital to realising results from investment in closer collaboration and stronger communication/extension activities. For example, standardised reporting metrics are regularly shared with commercial and industry partners as they work alongside DataGene to grow awareness and uptake of heifer genomic testing. In a second example, the faster turn-around time and introduction of red breed genomics has attracted farmers to test their heifers for the first time. Farmers that are new to genomic testing have then shared their early experiences in case studies distributed through social and traditional media as part of co-ordinated communication and extension activities organised by DataGene, Dairy Australia and genomic service providers. Success in all three project work areas is vital to realising higher rates of heifer genomic testing.

System-wide process updates that deliver an improved customer experience are expected to lift participation in heifer genomic testing leading to an improvement in heifer selection for the milking herd. More accurate heifer selection means higher rates of genetic gain and faster herd improvement for farmers who choose to utilise heifer genomic testing.

This work was completed as part of the Dairy Australia and DataGene funded project known as 'Accelerating Heifer Genomics'.

424. Weekly national dairy evaluations – a Vietnam-Australia collaboration

G.J. Nieuwhof[1,2*] and L.T. Ong[3]

[1]DataGene, AgriBio, 5 Ring Road, Bundoora, Victoria 3083, Australia; [2]Agriculture Victoria, AgriBio, 5 Ring Road, Bundoora, Victoria 3083, Australia; [3]TMA Solutions, TMA Tower, Quang Trung Software City, District 12, Ho Chi Minh City, Vietnam; gnieuwhof@datagene.com.au

Abstract

A data warehouse and workflow system was built to store the Australian dairy milk recording data and run genetic evaluations. The involvement of a specialised Vietnamese IT firm ensured a systematic approach that, based on detailed requirements as detailed by stakeholders in Business Requirement Documents, led to a system that is maintainable, agile, adaptable and auditable. It is based on the Data Vault modelling technique, designed at several layers and forms the core of the logic and operations, implemented using mainly SQL and C#. Changes were tested in a testing environment before being brought to the production environment. The system evokes specialised statistical programs for imputation and genetic and genomic solvers. Taking advantage of the latest developments in IT as well as the skills of experts, the new system allows for complete weekly runs with a single user operation, compared to monthly runs depending on a team of four previously.

Introduction

Since its establishment in 1982 the Australian Dairy Herd Improvement Scheme (ADHIS) and its successor DataGene have been expanding and improving the genetic evaluations made available to the Australian dairy industry. The system grew organically; extending the number of traits analysed, followed by the introduction of a national breeding objective and its updates.

The frequency of evaluations increased from a few per year, to about 8 in the years leading to 2020, with a jump to weekly runs in 2021. This paper describes how innovations in the storage of data and use of workflows implemented by a specialised IT company enabled this dramatic rise in run frequency, while improving quality and flexibility in a system that is more user-friendly and delivers a better service to stakeholders.

Conventional evaluations. In 2007, after the national dairy database as maintained by ADHIS had grown for over two and a half decades, both in terms of number of animals and number of traits, it was realised that there was a need for a more flexible, faster and easily maintainable database. An important consideration was the ability to continue the exchange of data. It was realised that a system conceived, written, tested, maintained and run by a small group of specialists (trained in genetics rather than IT), may not take full advantage of the latest IT developments and bears the risk that knowledge residing in a single person could disappear altogether.

Genomics. Then genomics appeared and took priority. The advantage of genomics was that it was new, and therefore a more systematic approach could be taken to implement newly written requirements. The genomic evaluation system called GEN, incorporated many of the requirements for a complete new system, such as a relational database, user-friendly user interfaces and automated workflows. But it was only partial; it started by importing conventional breeding values from the old system and its database only held breeding values and genotypes, no phenotypes. GEN was built by a small local company that was specialised in dairy herd recording. It went live in 2010, delivering Australia's first genomic breeding values.

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_424, © G.J. Nieuwhof and L.T. Ong 2022

2010-2019. The introduction of genomics brought with it an increased interest in cows and an emphasis on a high turn-around. Actually running the evaluations required 4 people for 2 weeks who had to first process incoming data and build databases (c++), extract data and start BLUP runs for each individual trait group, and in the case of conformation, each separate breed, build databases of breeding values, extract them again to blend with MACE proofs, import them again and export basic animal data and breeding values to the GEN system. In the meantime the latest genotypes had to be loaded on GEN, so that imputation could be run, followed by marker effect estimation (SNP BLUP) and in a next step DGV calculation and genomic blending (Nieuwhof *et al.*, 2010). Instruction to run this, for the old conventional system spanned over 100 pages of text that had to be copied, line by line to a unix command line and edited. The GEN system had a more friendly user interface but still required some special manual steps, e.g. to run sql queries to create lists of animals qualifying for imputation, the reference set or genomic blending. Both approaches were prone to human error.

In a separate development the Australian dairy industry realised there would be a great advantage in sharing data, rather than each organisation having their own. This project was called Central Data repository (CDR). It was clear that CDR would become the database from which the genetic evaluation system would obtain its data and the two should be developed together.

The new system

Agile Software Development is now considered state-of-the-art for IT projects (Beck *et al.*, 2010, Wikipedia, 2022). Product owners and the development team collaborate to deliver results faster with fewer overheads. Instead of having everything evident on the table, the agile team deliver work in small, consumable increments. Changes are expected and responded quickly during the project life cycle. Agile environments value interaction, results and customer engagement. By applying the Scrum framework (Schwaber and Sutherland, 2020), the development team and Subject Matter Expert (SME) team can plan, work and validate the result through short iterations (or Sprints), which cover two weeks. Daily Scrum meetings are conducted to react to issues and feedback that may cause the project to deviate from its goal.

Data Vault architecture aligns well with the ideas behind Agile as it avoids having all the data models designed at the beginning when there is still a lot of fuzziness. Business entities are broken down to the smallest grain (hubs) connected through links to depict the relationship. Satellites are attached to hubs or links to describe the entity or relationship attributes. New hubs and links are added later as the team has a better understanding of the requirements.

TMA Solutions in Vietnam was engaged to build the new system. Detailed Business Requirements Documents (BRD) were drafted by DataGene staff and other stakeholders. At a high level, the requirement for the new system combining CDR and the genetic evaluation system (now called GESNP) was to create a relational database to store all Australian milk recording and associated data, including genotypes, combined with automated workflows for running of evaluations and reporting. A User Interface (UI) was to be built to allow both internal and external users to access the central database for loading and interrogating data. All the latest (and some historic) breeding values would be available on a website.

The development team first analysed the requirements and a data warehouse, modelled after the Data Vault technique, was designed at several layers. The data model formed the core of the logic and operations. These logics (or workflows) were implemented using mainly SQL and C#. They closely follow the steps of the old and GEN systems. The data warehouse does most calculations and stores intermediate values between steps. For specialised statistical computations (called Black Boxes) the system invokes programs such as FImpute (Sargolzaei *et al.*, 2014) for imputation and MiX99 (MiX99 Development Team, 2016) for genetic analyses (Figure 1). Minimal human input is required and, therefore, minimal risk of human error.

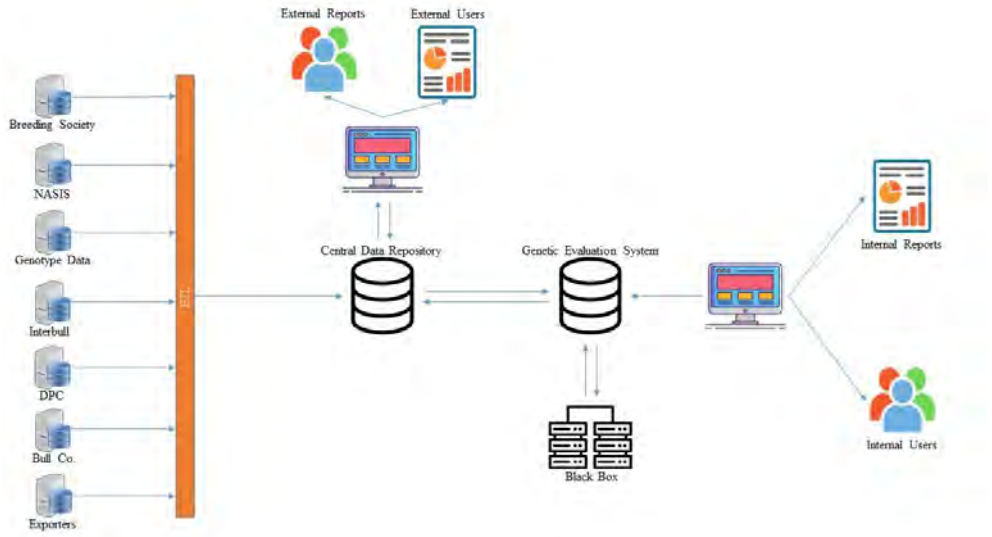

Figure 1. Simplified high-level overview of the CDR/GESNP system.

In its first version, CDR didn't have a lot of features and was mainly for daily data loading from milk recording centres and bull companies. Over time it has completely integrated numerous functions such as bull registration, progeny test reports and genotype services. The system consists of multiple environments for different purposes – pre-production, User Acceptance Testing (UAT) and production. Any changes are first made in the pre-production environment, where they can be tested with dummy data. Secondly, the changes are deployed to UAT, which is very similar to the production environment, to test with actual data. Finally, approved changes go live through periodical production builds. A release note and BRD updates are included to track all the new enhancements in that build.

The main engine of an evaluation run is now called '1-click', although it actually requires six clicks. 1-click runs all steps from initial data extraction to creation of final reports and a report database, in about 3.5 days, without any shortcuts. Prior to the 1-click is a manual exchange of data from CDR to GESNP and the user needs to start imputation with a few clicks on the UI. At the end, the exchange to DataVat for website publication (www.datavat.com.au) is also still a manual process. In incremental steps, and while observing best-practice, these manual steps are being automated.

An important labour reduction is achieved by automatically importing data from the milk recording centres overnight. QA reports can be generated by a few simple clicks on the UI. A typical weekly run consists of:

Wednesday evening:	exchange data from CDR to GESNP
Thursday morning:	run imputation
Thursday midday:	start 1-click
Monday morning:	1-click finishes, QA
Tuesday:	exchange to DataVat, publication of reports

Development is continuous, the next big step is inclusion of the single step genomics for Red Dairy Cattle in the 1-click.

Discussion

The move from a database and workflow system controlled from conception to daily operation by a small group of geneticists to a state-of-the-art IT system is in essence a change in philosophy. While geneticists may at times get frustrated by the new system as it does not allow for quick fixes and requires spelling out of 'obvious' things, in fact the need to think through, document and defend detailed requirements, creates a better system short-term and enables maintenance and upgrades medium and long-term. The approach allows for involvement of stakeholders such as bull companies, breed societies and milk recording centres, as well as non-geneticists within the organisation at both the requirement end and at testing of the final product. IT specialists are very good at checking logic and inconsistencies and they have a better overview of the latest technical developments. Geneticists need to learn to think in terms of requirements, the IT specialists will design and build the solutions.

Conclusions

By engaging an IT firm and going through a systematic approach a new database and workflow system was developed to store Australia's herd recording data and run complete genetic evaluations on a weekly basis. The system is based on solid documentation and independent testing and minimises the risk of human error. Further improvements and expansion will be based on the same philosophy.

Abstract

To facilitate uptake of female genomic testing, this study sought to estimate and quantify the impact of sire pedigree errors in cow populations. In a sample of 1,863 genotyped females, 26% of females had sire pedigree inconsistencies. The most frequent of these were nominating either unknown or incorrect sires. The additional value correcting pedigree added to GEBV-based heifer selection only represented a small percentage of genomic testing benefits, though this increased as the proportion of females with pedigree errors increased. In a separate scenario, heifers incorrectly identified as either herd replacements, or cull animals due to errors in sire pedigree were expected to cost between $AU 84-253 in lost lifetime profit per mis-identified heifer. While numerically the impact of parentage errors was small, given their importance to farmers, developing value propositions for confirming parentage with genomic testing could help increase female genomic testing and improve genetic progress.

Introduction

Genetic progress in Australian dairy systems is influenced by comparatively low uptake of female genomic testing. In 2020, only 4% of herd recorded cows were genotyped compared to 22% in the USA (Monks *et al.* 2021). The two top reasons given by Australian dairy farmers for engaging in genomic testing were parentage verification and identifying herd replacements (Monks *et al.* 2021). The value of using GEBVs to inform replacement decisions has been extensively modelled (i.e. Newton and Berry (2021). However, while Banos *et al.* (2001) showed that cow pedigree errors bias sire EBVs and reduce genetic progress, the impact of parentage errors on female populations or in isolation from GEBV based selection decisions has not been considered. In pasture-based systems where matching dam to calf is difficult, the value proposition for verifying pedigree is expected to be greater. In Australia, it is common practice to artificially inseminate (AI) cows early in the mating period and use natural matings (a bull) in the later part of the mating period and over heifers. Also, currently only ~50% of commercial Australian dairy farms have access to cow EBVs. To foster increased farmer engagement with genomic testing it is important value proposition development reflects actual on-farm scenarios. The aim of this study was to estimate sire parentage error frequency and type in Australian dairy herds and calculate the potential impact of sire error rates in the milking herd to help facilitate increased uptake of genomic testing.

Materials & methods

Estimating pedigree error rate. Parentage discovery completed during genomic testing was used to calculate frequency of discrepancies in cow pedigree. Discrepancies in sires and dams nominated on-farm and discovered (identified) during genomic testing parentage discovery were summarised from individual parentage discovery reports generated for heifer cohorts in 16 Australian dairy herds (no. females = 1,863) by Holstein Australia. Average across-herd discrepancy rates, standard errors and the types of errors are presented.

Impact of pedigree errors. The additional value of correcting pedigree errors in heifer selection candidates adds to GEBV based heifer selection was calculated using a deterministic excel tool developed by Newton and Berry (2020). The tool estimates the net benefit of selecting replacements on GEBVs over parent-average derived (pedigree) EBVs (PA-EBV) in a discrete generation of heifers. It assumes that the selection index is measured in $/cow.year and that selected replacements express their genetic superiority in additional profit upon entering the milking herd. The tool uses the formula described by Visscher *et al.* (2002), to apply an adjustment to sire reliability based on sire pedigree errors enabling comparison of scenarios with and without pedigree errors. Key model assumptions were: heifer GEBV reliability of 0.66, dam and sire EBV reliability of 0.32 and 0.71, respectively, and standard deviation of the national breeding objective of $AU 90. The proportion of heifers retained as replacements ranged from 50-95% while corresponding replacement rates were 17-32%.

To be reflective of more Australian farms, a simplified heifer selection strategy which did not use EBVs was also modelled. An average fertility herd with 70% AI-sired calves and 30% naturally sired calves was used. It was assumed all AI-sired heifer calves are kept as herd replacements and naturally sired heifer calves are sold. One impact of sire pedigree errors is to accidently sell an AI-sired calf or keep a naturally sired calf. As on average, AI-sired calves have superior genetic merit than naturally sired calves (and the national breeding objective is expressed in $/cow.year), this error can be represented as the expected difference in lifetime profit of the 2 calf types. Genetic merit differences in AI and naturally sired calves ranging from $AU 50 to $AU 150 were considered, reflecting differences observed in industry (M. Axford, pers. comm). However, not all sire errors incur a cost in this strategy, i.e. recording the wrong AI sire for an AI-sired calf is a silent error and has a value of $0 as all AI-sired calves are kept. To get the average cost per heifer with wrong sire pedigree and account for the difference in cost of sire errors, the frequency of each sire error type (Table 1.) was multiplied by the cost of that error. This gave a cost weighted by the frequency of errors.

Results

On average, 26% of females submitted for genotyping had discrepancies in sire nomination and verification (Table 1). The most common error, representing 50% of sire errors was an unknown and ungenotyped bull being nominated as the cow's sire. The next most common errors were a sire being nominated on-farm and, a different AI sire (34%) or no matching sire (11%) being identified during parentage discovery. Two percent of all records had no sire nominated and no sire identified during parentage discovery. In total 26 (1.4%) females had incorrectly assigned dams identified during parentage discovery.

As expected, as the proportion of heifers with incorrect pedigree increased, the value that correcting pedigree added to GEBV based heifer selection increased (Figure 1), however was low overall. At lower replacement rates and higher selection intensity, the added value from correcting pedigree was greater. For example, at a sire pedigree error rate of 26%, correcting pedigree added an additional $AU 3.28, 1.44 and $0.26 per heifer identified as a replacement using GEBVs, for replacement rates of 17, 22.5 and 32%,

Table 1. Sire discrepancies (and s.e.) identified from genomic testing (n=1,863 females).

	Recorded and discovered sires				
Nominated sire	valid AI sire	sire nominated[1]	valid AI sire	unknown sire	none
Sire verified	same AI sire	different AI sire	no sire found	no sire found	no sire found
Average (no. cows/ herd)	85.8 (16.9)	10.4 (4.2)	3.3 (2.3)	15.3 (4.7)	1.8 (0.9)
Totals	1,372	166	52	244	29

[1] Nominated sire could be an unknown natural bull or registered AI sire.

respectively. This represents 3, 6 and 0.4% of net-benefit of genomic testing, respectively. In our simplified replacement strategy, incorrectly identifying a heifer as a herd replacement or cull animal based on sire pedigree, is expected to cost between $AU 84 and $253 per heifer with incorrect sire, depending on the genetic merit difference between AI-sired and naturally sired calves (Figure 2). If there was a $AU 100 or more difference in genetic merit of the two calf types, net cost of pedigree errors exceeds $AU 1000 even at relatively low error rates (6%).

Discussion

In the Australian dataset used here, 26% of cows had inconsistencies in sire pedigree, though large variation existed across herds. This is similar to the 20% sire error rate reported for Australian animals genotyped in 2020 (Axford 2022). Both these values are higher than previously reported in the United Kingdom (Visscher *et al.* 2002), though could be influenced by Australia's larger and pasture-based herds. The 2.6%

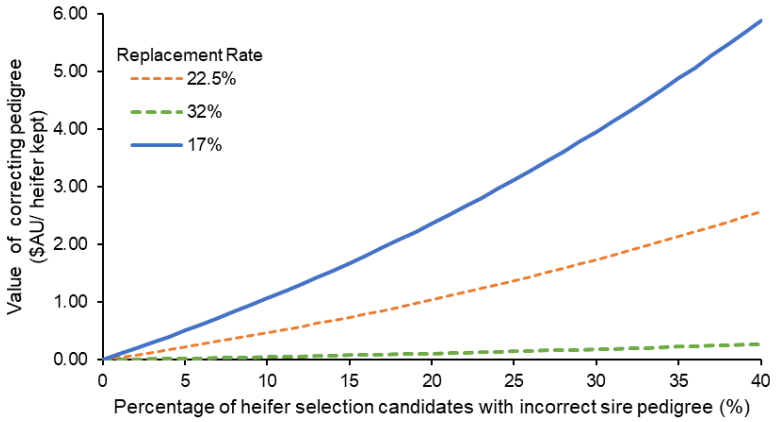

Figure 1. Additional value of correcting pedigree ($AU/heifer retained in the herd) as part of GEBV-based heifer selection decisions for 3 different herd replacement rates.

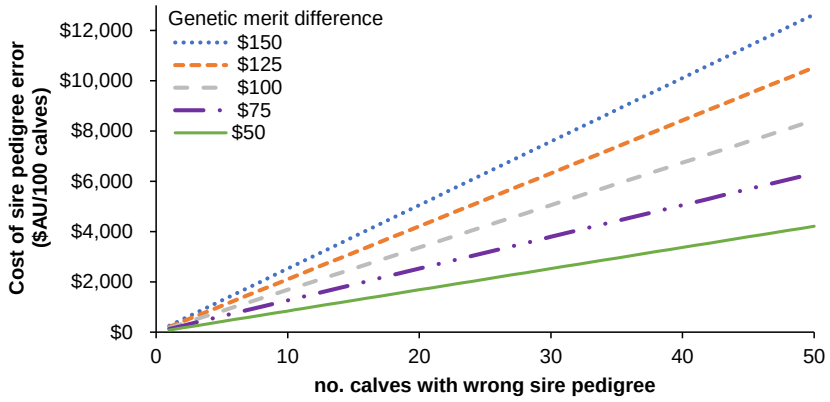

Figure 2. Lifetime cost of sire pedigree error ($AU/100 calves). Different line colours and styles indicate differences in genetic superiority of AI and naturally sired calves.

dam error rate found here is likely lower than the true rate, with few dam genotypes available for parentage verification. This study aimed to value the impact of sire error in cow populations. For an average Australian dairy herd (26% sire error rate, 279 cows, 22.5% replacement rate), the $AU 90 additional value ($AU 1.44 × 22.5% × 279) that correcting pedigree errors added to GEBV based heifer selection was ~6% of the overall value of female genomic testing. This $ value increases as selection intensity or sire pedigree errors increase as pedigree errors reduce accuracy of PA-EBV. Other illustrations of the value of correcting parentage are needed for the ~50% of Australian dairy farmers currently without access to PA-EBVs in their cow herds. Incorrectly identifying a heifer as a herd replacement or cull animal based on sire pedigree could cost an average Australian dairy herd $AU 994 to 2,993 in lost lifetime profit, depending on the genetic merit difference between AI and naturally sired heifers. However, this is less than the expected cost of genotyping at current prices. The full value of having verified pedigree in Australian dairy herds is not captured in these two examples. On-farm, in addition to playing a role in breeding programs, verified pedigree can also lead to 'opportunistic events' like selling surplus heifers into the export market (DataGene, 2021). In the USA, errors in sire pedigree in cow populations have been previously shown to bias sire EBVs, slow genetic trends and decrease genetic correlations in across-country bull comparisons (Banos *et al.* 2001). An opportunity exists to consider a similar study in the Australian population.

Low farmer uptake of female genomic testing is contributing to suboptimal genetic progress. A large industry initiative is currently underway with a target of 300,000 females genomic tested annually by 2025 (DataGene, 2020). Cost of genomic testing still remains a barrier to uptake (Monks *et al.* 2021). The return on investment from genomic testing improves when the information is used multiple times and for multiple purposes. It is therefore important to illustrate multiple uses to farmers and consider alternate value propositions (Newton *et al.* 2021). Aligning research questions to farmer feedback is one strategy to address the challenge of suboptimal genetic progress in female populations. Given the importance farmers place on verifying parentage from genomic testing (Monks *et al.* 2021), future value propositions of genomic testing should consider this aspect, even if numerically small. Extending messages on the value and impact of genomics beyond heifer replacement could help improve farmer uptake of genomic testing resulting in improved genetic progress in Australian dairy systems.

Abstract

Multistep genomic evaluations for US dairy cattle were first implemented in 2009 for Holstein, Jersey, and Brown Swiss dairy cattle breeds. In contrast, the adoption of genomics for Ayrshire and Guernsey is more recent. We investigated the genetic trends, inbreeding levels, and generation intervals since 1975 for the five dairy cattle breeds receiving genomic evaluations. Overall, production traits have increased steadily over time, as expected. Holstein and Jersey have benefited most from genomics, with up to a 6-fold increase in genetic gain in fat yield for Holstein bulls since 2009, nonetheless, with a rise in inbreeding levels. The progress made by breeds other than Holstein and Jersey is still small because of the limited portfolio of bulls available and the lower number of genotyped and phenotyped animals. Expanding the benefits of genomics for those breeds will require more comprehensive adoption of this technology and market incentives.

Introduction

Official genomic evaluations for dairy cattle in the United States were released in 2009 for Holstein (HO), Jersey (JE), and Brown Swiss (BS), 2013 for Ayrshire (AY), and 2016 for Guernsey (GU) (Wiggans *et al.*, 2017). Those evaluations comprise multibreed BLUP followed by single-breed estimation of SNP effects. Genomic PTAs are obtained as the combination of direct genomic value based on markers and parent average. Since the implementation of genomic selection (GS) in the US, it has been documented that genetic trends have changed significantly for the HO breed (García-Ruiz *et al.*, 2016). Genetic trends measure the success or failure of a breeding program and are needed to justify the usefulness of genetic evaluations and, therefore, the rationale behind using new methodologies (Grosu *et al.*, 2013). There are currently over five million genotyped animals in the US evaluation system (https://queries.uscdcb.com/Genotype/cur_ctry.html), but the uptake of genotyping is not even across breeds. Increased reliability and a reduction in generation interval (GI) are known for driving the accelerated rates of genetic gain under GS. There is little documentation of the improvement and changes in breeds other than Holstein (i.e. AY, BS, GU, and JE) in the US since the introduction of genomic evaluations. Reviewing assumptions of genetic progress since the introduction of genomics is crucial for advising breed associations and non-academic stakeholders on how to utilize this technology moving forward. Therefore, the main purpose of this study was to investigate genetic trends in the five breeds receiving genomic evaluations for production, fertility, longevity, and health traits.

Materials & methods

The data for this study were extracted from the National Cooperator Database maintained by the Council on Dairy Cattle Breeding (CDCB, Bowie, Maryland). The data included (Genomic) Predicted Transmitting Abilities (PTAs) of bulls and cows born since 1975 incorporating pedigree, phenotypic and genomic (when available) data from the August 2021 official evaluation. Each breed is in the within-breed base; therefore, individual plots are not directly comparable. We analyzed milk, fat, and protein yield, somatic cell score (SCS), productive life (PL), daughter pregnancy rate (DPR), and livability (LIV). Data were restricted to a

minimum of 10 daughters per bull, and a weighted average for bulls was calculated. Cows had to have at least one calf (Masuda *et al.*, 2018), but their PTAs were not weighted by progeny size. Predicted breeding values (PBV) were calculated by multiplying the stored (G) PTA by two.

Previous studies (García-Ruiz *et al.*, 2016), used the four-path selection model was to calculate genetic trends using selection differentials. Research by Dechow *et al.* (2018) has suggested that the four-path selection model was derived for a closed population; however, through the use of artificial insemination commercial herds are not, in fact, closed. Thus, we generated genetic trends based on bull and cow contributions to genetic improvement. Statistical Analysis Software (SAS Institute, 2016) was used to calculate genetic trends, inbreeding levels, and generation intervals. Average PBV, inbreeding, and generation intervals per year were calculated using PROC MEANS. The PROC REG was used to create a linear model to estimate the breakpoints (priors) to be included in PROC NLIN to fit the best line between the breakpoints. The breakpoints were estimated every five years. This aided in plotting genetic trends for the colored breeds when data were limited and based on only a few observations in a given year. Finally, PROC GPLOT and PROC SGPLOT were used to plot the data over time.

Results

Since 1975, there have been 154,602 bulls with at least 10 daughters with milk records in the US evaluation system. Of those bulls, AY, BS, and GU make up less than 2%, whereas HO and JE represent 86.97 and 8.13%, respectively. Interestingly, BS proportionally has the most genotyped bulls. This is a result of the European Brown Swiss Federation Intergenomics project, which established an international database of genotypes for the Brown Swiss populations. In 2005, slightly more than half of the bulls were genotyped, and in 2017 all bulls were genomically tested. Although the number of genotyped cows has increased throughout the years, they still represented only 19.98% of the total cows born in 2017. Proportionally, the JE breed has genotyped the most cows (8.73%); however, the proportion of cows genotyped is still a stark contrast to the bulls (overall 4.62 vs 24.06%).

The most apparent improvement across all traits was observed for production. Since milk historically received so much emphasis in the selection indexes (52% in 1971) and producers were primarily paid for increased production, this is no surprise. Breeding objectives of dairy industries worldwide have been evolving over the years towards functional traits and away from production traits (Miglior *et al.*, 2005). Overall, genetic trends for milk, fat, and protein were similar for both bulls and cows across all breeds. This is partially due to the high genetic correlations between the three yield traits. Tsuruta *et al.* (2004) reported milk-fat genetic correlations ranging from 0.48-0.69. Fat PBV for AY bulls shows a steady increase (Figure 1). Interestingly, the rate of genetic improvement for production traits accelerated in 2009, even though AY did not receive a genomic evaluation until 2013. This is due to producers genotyping the best AY bulls once genomic evaluations were released for HO and JE in 2009, which impacted all the traits. Ayrshire bulls born in 2016 had a mean PBV of 48.12 kg for fat, whereas the ones born in 2012 (i.e. before GS) had a mean PBV of 14.95 kg. A similar trend is evident for the AY cows. In 2006, PBV for fat yield for AY cows became positive (Figure 1). This again highlights the impact of genotyping bulls used when genomic evaluations were initially released.

Genetic trends for BS bulls and cows are comparable, moving upward, especially since 2009 when BS received genomic evaluations. This was also the point where fat PBV became positive (Figure 1). As GU only began receiving genomic evaluations in 2016, and in this dataset, we only have bulls with at least 10 daughters up to 2016, the inference to be made from this trend regarding the use of genomics is limited (Figure 1). However, since 1975, there has been a significant increase in fat production for GU bulls. As our GU cow dataset extends to 2019, we see increased PBV for fat yield since 2009 (Figure 1). This infers

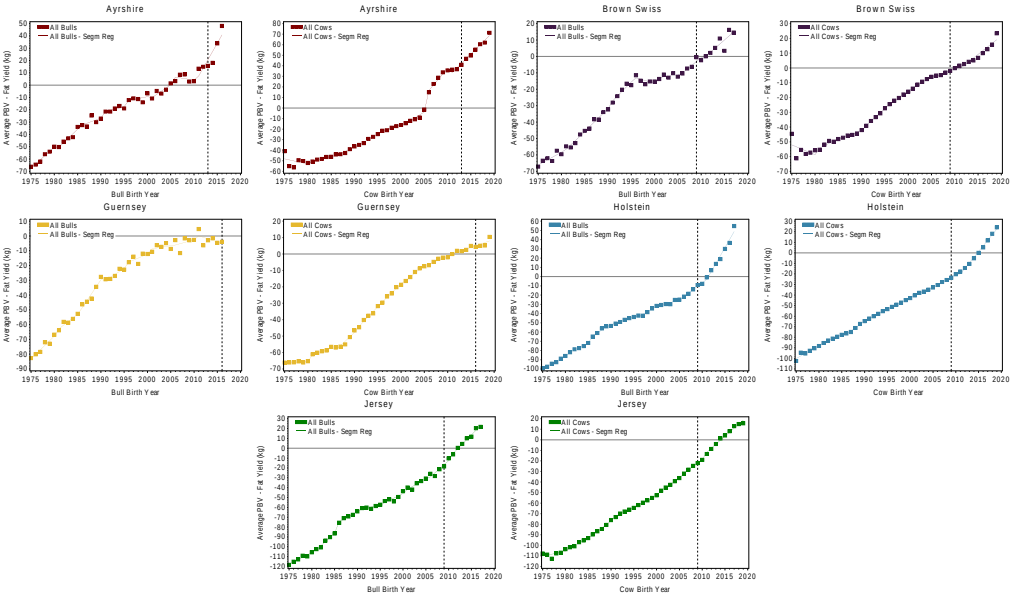

Figure 1. Estimates of genetic change per year from segmented regressions of PBV on birth year for AY, BS, GU, HO and JE bulls and cows for fat yield.

that the best GU were genotyped before receiving a genomic evaluation. Due to a large number of HO bulls and cows, the trends are more defined. HO bulls have potentially made the most progress in the evaluated period. A sharp increase is evident for fat yield since implementing HO genomic evaluations in 2009 (Figure 1). Similarly, fat PBV has increased substantially over time for HO cows (Figure 1). In 2017, JE bulls had an average fat PBV of 21.66 kg. Compared to 2009, this is an increase of 40.04 kg.

Although only fat trends are discussed here, improvements are evident across most breeds for genetic trends. PL increased 4.2-fold for HO bulls since 2009, while JE bulls have increased LIV by 64%. DPR has decreased steadily for JE bulls and cows since 1975; there were 13.98 and 17.97 percentage point reductions, respectively. Because of the increased use of young, genotyped bulls and heifers, a decrease in GI followed the implementation of GS for all breeds, except AY and GU. The GI before and after GS changed from 7.1 to 2.2 years in HO, 7.3 to 3.1 in JE, 8.4 to 5.2 in BS, and 7.6 to 5.3 in AY for sires of bulls. Genomic inbreeding has increased steadily since 2009 for BS cows (6.67-7.82%). The average genomic inbreeding for HO and JE cows in 2019 was 9.1 and 6.4%, respectively. For BS bulls in 2016, genomic inbreeding was extremely high (16.1%); however, it was only one observation and not an average. For HO bulls, the level of genomic inbreeding was 12.73% in 2017, which indicates it would be proper to update GPTA with the genomic inbreeding coefficient. Lastly, JE genomic inbreeding levels averaged 7.22% in 2017.

Discussion

Significant improvements have been made since the implementation of genomic evaluations in the US in 2009. Bulls are making more progress than cows as bulls have more progeny, and a great proportion of bulls (68%) are genotyped versus cows (5%) since 1975. Fat yield increased almost 6-fold for HO bulls between 2009 and 2017. Because of the increased use of young, genotyped bulls and heifers, a decrease in generation interval followed the implementation of GS for all breeds, except AY and GU. As genomic evaluations were only released for GU in 2016, it is too early to see the benefits as clearly as in other breeds. Progress for

smaller breeds will need to be continually monitored to assess the level of genetic progress and to measure the level of genetic gain ten years post-genomic evaluations.

This research provides benchmarks for breed associations to evaluate the updates in genetic evaluations methodology in the genomics era. Genomic information has mainly benefitted Holstein, Jersey and Brown Swiss because the implementation of GS for these breeds happened as early as 2009. Another reason is that HO and JE have larger reference populations and more refined selection indexes. In the short years investigated, there is success in the majority of traits for the breeds other than Holstein. Smaller breeds in the US could significantly benefit from genotyping and phenotyping more of the population and increasing the adoption of genomic methods. This study should be updated in another five years to give these breeds further opportunity to develop.

427. Community based breeding programme for low input beef cattle production systems in the arid region of Argentina

S. Munilla[1,2*], J.M. Tessi[3] and D.O. Maizon[4]

[1]Universidad de Buenos Aires, Facultad de Agronomía, Departamento de Producción Animal, Av. Abstract

In this paper, we describe a community based breeding programme designed for beef cattle production systems that range between a smallholder farm and a traditional cow-calf operation. The design involves a network structure with three nodes: a cooperating node, integrated by farmers that organise themselves into a cooperative, a facilitating node that provides technical support, and a centralised nucleus tier. The program was conceptually developed for the case of farmers in the Los Llanos region, La Rioja province, Argentina. After modelling the typical production system of the region, economically relevant traits were identified and a selection index was developed. Finally, the achievable response to selection was estimated. Based on these calculations and projecting the economic benefit over five years, it was estimated that the program would report a 10.6% increase in the producer's gross margins, as a result of an increase in the average weaning weight due to genetic selection.

Introduction

Low input livestock production systems are typically found in regions with less productive potential and far from large markets, conditions that hamper the introduction of their products into formal trade, the purchase of production inputs and the access to financing. In these regions, relatively smallholder farms with limited infrastructure and low adoption of technologies are the norm. These farms, however, generate a large portion of the income necessary to bear the expenses of the family group.

In these contexts, cooperative animal breeding programmes emerge as one of the best known strategies to increase productivity (Olivier *et al.*, 2002). Cooperative programmes involve community based livestock breeding strategies that arise from the needs of the farmers themselves, are proactive, facilitate the organization of the intervening structures and aim not only to attend management of the genetic resources but also to social, cultural and ecological constraints (Mueller *et al.*, 2015, Table 1)

Community based breeding programmes have been developed all around the world for small ruminants (Kosgey *et al.*, 2006, reviewed some of them; a lot of new experiences have been reported since). However, they have attracted little attention to beef cattle farmers. In this paper, we describe a community based breeding programme designed for beef cattle farmers that range between subsistence smallholders and a traditional cow-calf operation. The program was conceptually developed for the case of beef cattle farmers in the Los Llanos region, La Rioja province, Argentina.

Materials & methods

Breeding programme design. The proposed design is based on the general principles discussed by Mueller *et al.* (2015) for community based breeding programmes. The structure involves a network with three nodes: a cooperating node, integrated by farmers that organise themselves into a cooperative, a

R.F. Veerkamp and Y. de Haas (eds)

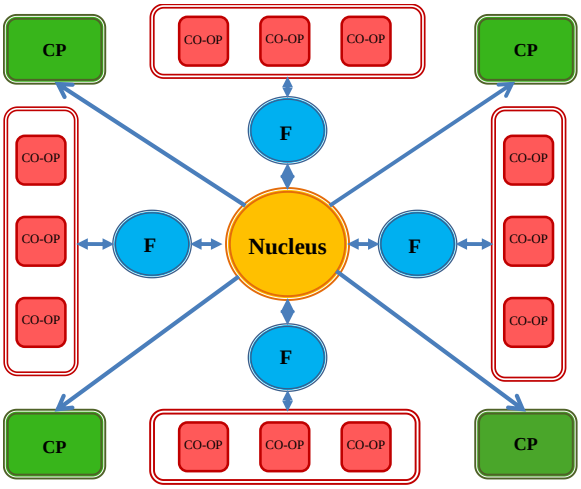
DOI: 10.3920/978-90-8686-940-4_427, © S. Munilla *et al.* 2022

facilitating node, and the nucleus (Figure 1). Co-operators are linked together and with the nucleus through the facilitating node, formed by the professional staffs that provide technical support.

In each production cycle, co-operators transfer to the nucleus the weaned male calves the programme determines. At this point, the selection criterion is based on an intra-herd evaluation coupled with a phenotypic inspection. Once in the nucleus, the young bulls are reared until they are 16-18 months of age, at which time semen is collected from them and subsequently used on cows from the co-operators farms to perform a progeny test. Eventually, this test will provide data on their offspring that will be integrated into the database of a genetic evaluation. With the predicted breeding values, an economic index is calculated and, based on this criterion, outstanding bulls would be ultimately selected to form part of a semen bank. The bank is managed by the nucleus and used to breed back the co-operator's herds via an AI programme.

Case study. Los Llanos, La Rioja province, Argentina, is a typical sample from the arid Gran Chaco biome that comprises about 100,000 km^2 and is framed by mountains ranging 2,000 meters above sea level. It has a dry subtropical climate with annual average temperatures ranging between 17 and 20 °C and rainfall ranging from 500 mm in the east to 300 mm in the west. It is a primary livestock producing region, predominantly dedicated to cattle ranching, characterized by low weaning rates (~50%) and meagre beef yields (~5 kg/ha), mainly associated with the low availability and seasonality of forage and the scarcity of water.

Selection index. To develop an appropriate breeding goal, a cooperative was conceptually created, made up of six cooperating members from the Los Llanos region. Their farms were characterized in terms of both, their productive (management of forage resources, reproductive management of the herd, etc.) and economic (income and expenses, marketing, etc.) factors. Based on this information, a profit equation (Hazel, 1943) comprising three economically relevant traits, birth weight (BW), weaning weight (WW) and mature cow weight (MW), was elaborated. Taking derivatives from the benefit equation with respect to each of these traits, their marginal benefit (or economic weighs) were obtained and finally adjusted by the



F: facilitator; CP: commercial producer; CO-OP: cooperative members.

Figure 1. Community based breeding programme design. F = facilitator; CP = commercial producer; CO-OP = cooperative members.

discounted genetic expressions for terminal sires published by Amer *et al.* (2001, Appendix A) to evaluate the impact that selected bulls would have on this marginal benefit.

Response to selection. Given the selection scheme that derives from the operation of the breeding programme, the response to selection that its potential implementation would generate was calculated. The selection intensity was assessed only for the male's pathway and calculated from the proportion of select bulls in each production cycle. The accuracy, in turn, was that of the progeny testing. Finally, the sire's generation interval was computed by averaging the age of the bulls that make up the semen bank whereas the dam's generation interval corresponded to the average age at which the cows from the co-operators are replaced. For all these calculations, it was assumed that the program was already in place.

Gross margins. The gross margin of each of the six co-operators was calculated and projected over a period of five years. Income derived from the sale of calves (mainly males, as a proportion of the females are retained) and culled cows. In turn, expenses derived from health treatments and veterinary services, labour, and commercialization costs. In addition, feeding costs were calculated relating the grassland area a 400 kg beef cow required in this region and the opportunity cost of this area. It was assumed that over the years the income accrued pulled by increases in the average weaning weight, whereas expenses not directly related to the weight of the calves remained constant.

Results

Table 1 shows the factors that determined the economic values of the selection index proposed for the case study cooperative. The index equation is:

$$\text{Index}(\$) = -0{,}0065 \times \text{EBV}_{BW} + 14{,}95 \times \text{EBV}_{WW} + 0{,}04 \times \text{EBV}_{MW} \quad (1)$$

Notice that the weaning weight is determinant in this index. Then, response to selection was calculated based on this trait.

The response to selection expected per year would be 0.2 genetic standard deviations (σ_A, Table 2). Based on historical data on weaning weight and a presumed heritability of 0.3 for this trait, the genetic standard deviation was estimated as σ_A = 14.4 kg, which represents around 3 kg of annual genetic progress. The

Table 1. Economic values for the traits that compose the selection index.

Trait	Economic weigh ρ	DGE[1]	Economic value $\rho \times$DGE
Birth weight	-0.013	0.500	-0.0065
Weaning weight	32.50	0.460	14.95
Mature weight	2.70	0.014	0.04

[1] DGE = discounted genetic expressions.

Table 2. Response to selection factors.

Pathway	Selection intensity, i	Accuracy, r_{TI}	$i \times r_{TI}$	Generation interval, L	Response to selection, $i \times r_{TI}/L$
Sires	2.097	0.79	23.86	2.50	
Dams	0.000	-	0.00	5.76	
Total			23.86	8.26	0.2 σ_A ~3 kg/yr

projection of the economic benefit over five years indicated a 10.6% increase in the average producer's gross margins.

Discussion

The scale and degree of organization of typical beef cattle farmers in the Los Llanos region, La Rioja province, Argentina, have hindered their involvement in traditional animal breeding programmes. Faced with this scenario, cooperative, community based programmes become an attractive alternative. These programs involve community strategies that arise from the needs of producers and are leveraged on R&D institutions, generally governmental. The link with these institutions is very important, since these programs require great technical, financial and organizational support in their initial stages, as highlighted by Mueller *et al.* (2015).

With that prospect in mind, we designed a community based breeding programme with a centralised nucleus, to which cooperating farmers would contribute by transferring young selection candidate bulls. It was estimated that the implementation of this program would result in a 10.6% profitability increase after 5 years, approximately one generation. Our results are encouraging in terms of the feasibility of a project that would increase the productivity of livestock producers in this region. For this particular case, the National extension service could harbour the nucleus on their local station (INTA, EEA Los Llanos) and provide technical support.

Our analysis did not consider the implementation costs or operating expenses of the cooperative nucleus. However, these expenses could reasonably be covered, once the programme is in place, with the sale of bulls that have been discarded from the selection process and semen straws to other commercial producers in the region. In addition, the programme may also contribute to the more intangible benefit of the conservation and promotion of local animal genetic resources. As it is pointed out in FAO's (2010) 'Breeding Strategies for Sustainable Management of Animal Genetic Resources' guide, these resources contribute to development, food security and poverty alleviation in the regions where they are applied.

428. A participatory approach to review and update the national breeding objectives for New Zealand dairy cattle

B.F.S. Santos[1*], G.M. Jenkins[2], J. Kok[1], K. Stachowicz[1] and P.R. Amer[1]

[1]AbacusBio Limited, PO Box 5585, Dunedin 9058, New Zealand; [2]Beef + Lamb NZ, P.O. Box 5501, Dunedin 9054, New Zealand; bsantos@abacusbio.co.nz

Abstract

The National Breeding Objective (NBO) for the New Zealand (NZ) dairy industry has been updated in 2021 following a major review. The review included farmer/industry stakeholder consultation, updated methodology to calculate economic values (EVs) for some of the important traits, as well as inclusion of new selection traits. Fertility sub-traits and functionality for non-linear traits were incorporated. The review resulted in new EVs being produced for the updated Breeding Worth index (BW2022) which represents the NBO and is expressed in monetary units (NZ$ per lactation). The changes were modelled to determine the impact to the national dairy herd. The outcomes incorporate farmers' preferences for traits with the intention of increasing adoption levels of the national index as the main reference for selection of dairy cattle in New Zealand. This paper summarizes the NBO review, along with the index testing outcomes and specifications for upgrading BW2022.

Introduction

The NBO for the dairy industry had its previous major review in 2012, and since then it has had body condition score (BCS) added as a new trait and been updated annually for some key performance and price inputs. Following discussions within the dairy sector, New Zealand Animal Evaluation Limited (NZAEL), the DairyNZ wholly owned subsidiary that coordinates national genetic improvement initiatives for dairy cattle, initiated a major revision of the NBO starting in 2020.

The review process consisted initially of stakeholder consultations, most importantly, surveying of stakeholders (industry leaders, scientists, service providers, and breeding companies) and farmers. This consultation was a starting point to inform the wider review process. It was followed by a separate farmer survey which used 1000minds software (Hansen and Ombler, 2009) for trait choice trade-offs, along with parallel survey questions to elicit quantitative differences in trait preferences by New Zealand dairy farmers.

This paper presents the outcomes of the NBO review process, including a high-level summary of the methodology used to meet farmers' trait improvement requirements through EVs representing farm profitability. It also includes an estimate of the impact of changes in the NBO to the national dairy herd.

Materials & methods

The consultation was divided into two specifically designed surveys focused on: (1) stakeholders' views; and (2) dairy farmers' views and trait preferences. The online surveys combined socio-demographic, dairy system, and trait preference questions, similar to the methodology used by Martin-Collado *et al.* (2015). The stakeholder survey reached 280 complete responses and the farmer survey 439 complete responses. Principal component (PCA) and cluster analysis (CA) were used to define dairy farmer typologies and their association with respondents' views.

Following the surveys, the NBO model which calculates EVs for several traits independently of each other (DairyNZ, 2021), was updated to incorporate core inputs. This included changes to milk prices, feeding costs, replacement heifer costs, and other parameters that impact profitability of the dairy operation. A

new methodology for fertility EV was developed as the trait was separated out into heifer and cow calving season day (CSD0 and CSD123, respectively), and changed from binary CR42 (% cows calving in first 6 weeks from planned start of calving) to continuous CSD. A new methodology was created to convert residual survival (expressed as the additional average herd age in days) into functional survival (defined as % cows surviving from one parity to the next). Finally, a non-linear model was incorporated for udder overall, a new BW trait where many farmers tend to avoid very bad udders, but do not necessarily want to give up too much progress in other traits to achieve excellent udders.

The changes to BW were modelled to determine the impact of such changes to the national dairy herd through methodology proposed by Zhang and Amer (2021). The analysis was applied to Jersey, NZ Holstein-Friesian, Overseas Holstein and Jersey Holstein-Friesian cross bulls born between 2011 and 2015 in four separate analyses. To be included, bulls had to have at least 50 daughters with production and fertility records, which resulted in a minimum reliability of 85% for milk and 67% for fertility. A minimum reliability threshold of 10% was used for all other trait estimated breeding values (EBVs).

Results

The consultation achieved reasonable coverage of the quite diverse NZ dairy industry, with all farming systems, breeds, and regions participating. There was a lower level of support for the BW index than expected (55% agree with its importance). Fertility and udder traits were stated as the most critical improvement requirements, followed by susceptibility to mastitis and lameness. Environmental traits were also considered important, albeit with substantial variation in stated degree of priority across respondents. On average, farmers are willing to trade-off about 20% of genetic progress in milk solids for progress in Greenhouse gas (GHG) emissions and nitrogen leaching mitigation traits.

Two clusters of farmers were identified according to their preferences for traits (Figure 1). Cluster 1, formed by farmers with strong preference for milk solids, fertility, somatic cell count (SCC), and body condition score; and Cluster 2, formed by those with strong preference for udder, mastitis, and lameness. These preferences were based on intrinsic values and independent of systems, breeds, or region.

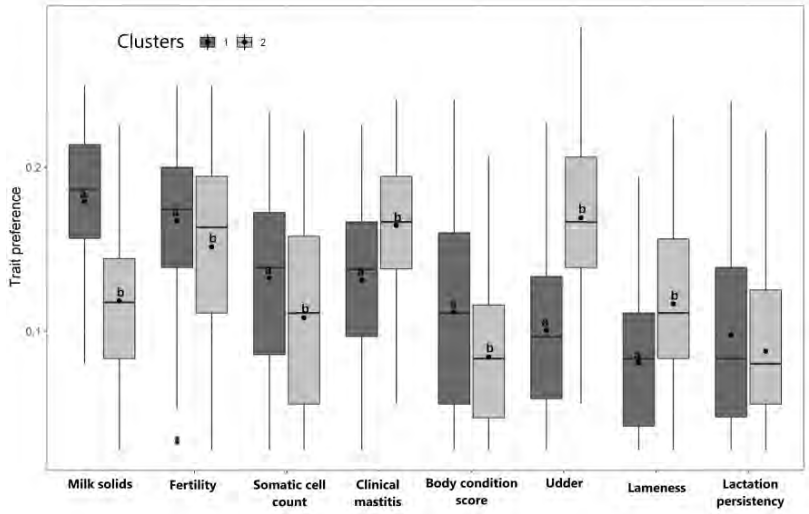

Figure 1. Dairy farmers' clusters based on trait preferences.

The updated trait EVs (BW 2022) are presented in Table 1. The current economic environment, with record high milk prices, resulted in higher emphasis on milk production traits. A small increase in penalty for milk volume (-9.5c/l) resulted from penalties imposed by milk processors and feed costs associated with lactose synthesis. There were no changes implemented for methodology used in the live weight EV calculation, with a further review planned to address the major implications for both within and between breed rankings. The same economic principals were applied, despite the change in the definition of survival, and rising costs of rearing replacement heifers (~NZ$2,000 per heifer), better salvage revenue from cull cows as well as greater loss from culling or death during lactation (impacted by the milk price) were incorporated. The higher SCC penalty is consequence of the increased impact of cell counts on higher value milk and higher replacement costs associated with increased probability of clinical mastitis. There was an increase in the EV of fertility, mostly due to the higher replacement costs, and the separation between heifer and cow fertility traits causing increased effective dispersion in the fertility EBVs. Finally, the increase in BCS EV was largely driven by higher milk prices surpassing the increase in feed costs.

The impact of changes to the NBO were represented both as correlations between trait EBVs and indexes (Table 2 – results averaged from four different breed data sets of bulls), as well as trait responses over a period of 10 years (Table 3).

Discussion

Industry consultation is a powerful tool to improve engagement and to gather direction in the formulation of breeding objectives represented by economic selection indexes. The surveys are not used to establish trait EVs, but rather to identify areas where current EV calculations might be missing true and perceived economic impacts of trait changes. Trait EVs remain strongly influenced by economic modelling, where the impact of each trait is calculated independently. Index formats and gaining a mandate for inclusion of specific traits and economic modelling (e.g. non-linear approaches) and benefited from the industry consultation (Santos *et al.*, 2019).

The consultation indicated that farmers and stakeholder respondents would favour stronger selection effort on functional traits (especially udders), more progress on fertility, and development of national standard auxiliary indexes which address specific industry challenges, e.g. high per cow output systems, once a

Udder over. (score)	-0.56	3.64	-1.11	4.13	-0.98	2.92	-0.13	0.09

day milking, and environmental issues. The non-linear approach to udder overall was well received by stakeholders as it allows poorer bulls to be penalised, but without too much sacrifice in progress in other traits. Correlations between indexes showed that if udder overall had no true value for some farmers, the inclusion of the trait in the BW would cause a loss between 1 and 2% of genetic progress in profitability. The expected improvements in perception and level of support for the national index approach should more than offset these relatively modest impacts.

The framework has been established for incorporation of further changes to BW. The engagement and consultation highlighted under-emphasis on cow functionality as an area of concern relating to the index in use. The BW 2022 has greater weighting on fertility, and udder traits have been included in a way that efficiently penalizes very bad udders. The combination of surveys, rigorous testing, and description of the key input assumptions and methodologies allowed a diverse farmer advisory panel to reach a high level of consensus on the new index.

429. Genetic trends for carcass traits within breeds in a multi-breed evaluation

S.A. Mulhall[1,3*], R.D. Sleator[3], R.D. Evans[2] and A.J. Twomey[1]

[1]Teagasc, Moorepark, Fermoy, Co. Cork, Ireland; [2]Munster Technological University, Bishopstown, Co. Cork, Ireland; [3]Irish Cattle Breeding Federation, Highfield House, Shinagh, Bandon, Co. Cork, Ireland; shauna.mulhall@teagasc.ie

Abstract

The focus of this research is to determine the genetic trends in carcass traits within each of the common sire breeds used in both the dairy and beef populations. Estimated breeding values for carcass weight, carcass conformation, and carcass fat were available on 8,375,561 animals from the national carcass genetic evaluation. Larger genetic gain was observed within breeds for beef sires used on beef dams in comparison to beef sires used on dairy dams for all carcass traits. There was a relatively small genetic gain observed across breed for beef sires used on dairy dams although a significant genetic gain was observed within these sire breeds, suggesting breed substitution.

Introduction

Most genetic evaluations and breeding objectives worldwide for beef traits tend to be on a within breed basis (Johnston *et al.,* 2018). Ireland is relatively unique in publishing national multi-breed genetic and genomic evaluation for carcass traits (Purfield *et al.,* 2019). Furthermore, large diversity exists across beef production systems in Ireland, which include suckler-based systems, where cows rear calves for beef (Hocquette and Chatellier, 2011) and dairy systems, where progeny surplus to replacements are reared for slaughter. Genetic selection for beef traits is included in the four national breeding objectives: the economic breeding index for dairy cows, the dairy-beef index for beef sires used on dairy cows, the terminal index to breed animals for beef production, and the replacement index to breed replacement beef cows. Genetic progress has been observed for a range of species and traits including fertility in cattle (Berry *et al.,* 2016) and carcass traits in broilers (Tavárez and Solis de los Santos, 2016). A potential concern for selection based on multi-breed evaluations, and breeding objectives, is that genetic gain observed is due to breed substitution and that there may be little or no genetic gain achieved within individual breeds. The objective of this analysis was to quantify the genetic gain in carcass traits within each breed, for sires used in dairy and beef herds.

Materials & methods

Data. Estimated breeding values (EBV) for carcass weight, carcass conformation, and carcass fat were available from the September 2020 Irish carcass genetic evaluation, from an existing database managed by the Irish Cattle Breeding Federation (ICBF). This multi-trait and multi-breed evaluation is one of the routine evaluations run by ICBF every two months, using Mix99 software (Strandén and Lidauer, 1999) generated EBV's for 20,236,674 animals.

Data edits. Animals with an unknown sire or dam were excluded; after which data on 14,570,772 animals remained. Animals were defined as either beef or dairy based on their dam breed proportion. Dairy dams were defined as dams with a dairy breed (Holstein-Friesian, Jersey, Ayrshire, Norwegian Red, Montbeliarde, Brown Swiss, Normande, and Rotbunt) composition of ≥87.5%. Beef dams were defined as dams with a beef breed (Aberdeen Angus (AA), Belgium Blue (BB), Charolais (CH), Hereford (HE), Limousin (LM), Simmental (SI), Aubrac, Blonde d'Aquitaine, Piedmontese, Parthenaise, and Saler) composition of ≥45%. Animals whose dams were not defined as either beef or dairy were excluded. The sire of each animal was

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_429, © S.A. Mulhall *et al.* 2022

required to be at least 87.5% of its known breed composition. Progeny sired among the most common breeds were retained. For dairy dams only progeny sired by AA, BB, CH, HE, LM were included and for beef dams on only progeny sired by AA, BB, CH, HE. LM, and SI were retained. To ensure an adequate representation of animals per year; animals born prior to 2002 were not considered further for dairy dams and animals born prior to 2005 to beef dams were not considered further. Number of animals sired by each breed and dam type is presented in Table 1.

Data analysis. The mean of the progeny sire EBVs were estimated for each progeny birth year for carcass weight, carcass conformation, and carcass fat. These means were calculated within sire breed (AA, BB, CH, HE, LM) used on dairy dams, and within sire breed (AA, BB, CH, HE, LM, SI) used on beef dams. These means were also calculated on an across breed basis for both beef sires used on dairy and beef dams. A linear regression model was used to estimate the genetic gain within and across each breed from 2008 to 2018, inclusive, for beef sires used on dairy and beef cows separately. The dependent variables were carcass weight, conformation, and fat score. Birth year of progeny was included as a fixed effect. In an additional analysis, sire breed (AA, BB, CH, HE and LM) for dairy dams, and sire breed (AA, BB, CH, HE, LM and SI) for beef dams, was also included as a fixed effect to identify if genetic trend was due to a breed substitution effect.

Results

Dairy dam × beef sire. A genetic gain of 0.15 kg was observed across the most common beef sire breeds (AA, BB, CH, HE and LM) used on dairy dams for carcass weight for the years 2008 to 2018, inclusive. However, when breed was adjusted to a common breed, the trend in carcass weight increased to 0.62 kg per year. The trend for carcass conformation, and carcass fat, reversed when sire breed was adjusted to a common breed. A 0.04 unit decrease was observed per year in conformation EBV's, however the genetic trend reversed when breed was accounted for showing an increase of 0.05 units per year. Similarly, the trend for carcass fat showed an increase of 0.03 units per year for sire EBVs. However, when adjusted for breed, the genetic trend decreased by 0.03 units per year. Carcass weight increased for AA, BB, CH, HE and LM sires used on dairy cows from 2008 to 2018 (Figure 1); the genetic gain was 0.84, 1.27, 1.27, 1 and 0.88 kg per year, from 2008 to 2018 for AA, BB, CH, HE and LM. For carcass conformation sire EBVs increased by 0.01, 0.06, 0.01 and 0.06 units per year for AA, CH, HE and LM, respectively (Figure 2); BB declined by 0.01 units per year, respectively. Finally, a reduction in carcass fat was observed within all five breeds, AA, BB, CH, HE, LM, which was 0.02, 0.04, 0.01, 0.02, 0.01 units respectively, per year.

Beef dam × beef sire. The linear regression for the most recent 10 years for the most common beef sire breeds (AA, BB, CH, HE, LM and SI) used on beef dams for carcass weight, carcass conformation and carcass fat followed the same trend; irrespective of the inclusion or exclusion of sire breed in the model. Carcass weight improved 1.18 kg per year for beef sires used on beef dams, but was 0.83 kg per year when sire breed was accounted for. Similarly, the trend for carcass conformation increased 0.04 units per year irrespective of accounting for sire breed. Carcass fat reduced 0.01 units per year, however, when adjusted to a common sire breed there was 0.04 unit reduction per year for carcass fat. Genetic gain in carcass weight was 1.25, 1.43, 1.54, 1.13, 1.32 and 1.67 kg for AA, BB, CH, HE, LM and SI, respectively, per year from

Table 1. Number of animals sired by each breed.

Dam type	AA	BB	CH	HE	LM	SI	Total
Dairy	823,708	193,804	75,902	496,922	272,519	-	1,862,855
Beef	549,018	322,677	2,570,992	201,001	2,461,768	407,205	6,512,706

2008 to 2018 (Figure 1). For carcass conformation, the largest genetic gain was observed in the continental breeds BB, CH, LM and SI being 0.05, 0.05, 0.07, and 0.05 units per year respectively, whereas a smaller genetic gain was observed in the more traditional breeds AA and HE being 0.01 units and 0.01 units per year respectively (Figure 2). Similar to the previous analysis on dairy cows, a reduction in carcass fat was observed within breed for AA, CH, HE, LM, SI which was 0.02, 0.02, 0.03, 0.02, 0.02 units respectively per year, except BB which remained constant for the years 2008 to 2018.

Discussion

Genetic gain for each of the carcass traits was achieved within each of the sire breeds used on both the dairy and beef dam populations with the exception of conformation in BB sires used on dairy dams. A slight reduction in carcass conformation for BB sires used on dairy cows suggests selection within the breed has put higher emphasis on other traits, such as calving traits.

The genetic gain was larger in beef sires used on beef cows compared to the gain in beef sires used on dairy cows. The poorer genetic gain for carcass traits in beef sires used on dairy cows relative to beef cows is likely due to the higher selection emphasis on calving traits which is known to be negatively correlated (Berry

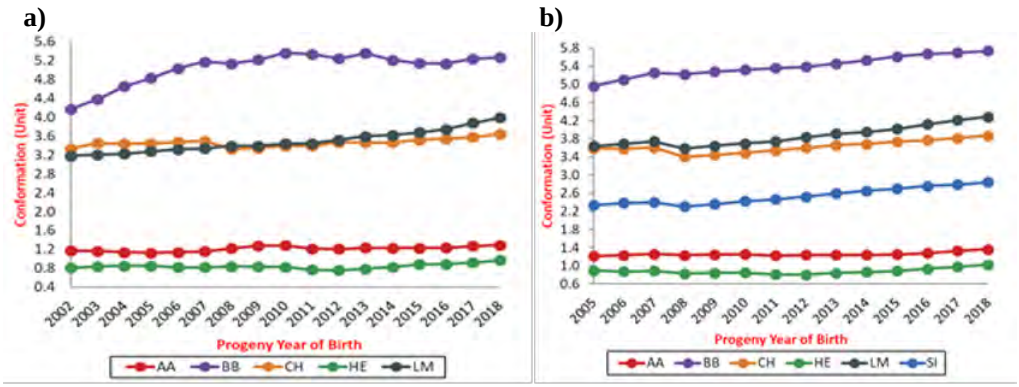

Figure 2. Genetic trend of sire EBVs for carcass conformation within breed used on (a) dairy dams and (b) beef dams.

et al., 2020). Furthermore, the breed substitution observed for genetic trends in beef sires used on dairy cows is linked to a higher selection towards breeds that are renowned for their ease of calving, such as AA and HE. Interestingly, with regards to carcass conformation, the genetic gain estimated within each breed for sires used on both dairy and beef dams was similar except for traditional breeds such as the AA and HE, where a lower genetic gain was observed. The lower genetic gain in these two breeds for conformation is potentially due to the lower genetic variability for carcass conformation within AA and HE compare to LM and CH, (Kause *et al.*, 2015). In additional analysis, the genetic gain in standard deviation units within the traditional breeds, AA and HE, were still lower for carcass conformation (0.02) in comparison to continental breeds like CH and LM 0.08 and 0.09 respectively. Thus the lower genetic gain observed in these two breeds is likely due to a higher intensity of selection for other traits like calving in comparison to the selection of carcass traits in continental breeds.

The genetic gain within sire breeds used on dairy cows suggest that dairy farmers are selecting higher beef merit sires within breed. However, higher gains could potentially be achieved for carcass traits in dairy-beef animals if dairy farmers selected across breed. Furthermore, there was no breeding objective available for beef sire selection for mating on dairy cows in Ireland until 2019 (Berry *et al.,* 2019). Adoption of this breeding objective will likely lead to an improvement of genetic gain across breed for beef sires used on dairy cows. In contrast, there was no breed substitution in the genetic trends for beef sires used on beef dams. Thus, selection of sires in beef dams has been within and across breed.

Abstract

Poultry provides rural families with a low cost, highly efficient and nutritious protein. Providing access to improved chicken breeds suitable for African conditions is one of the key elements to increase the rural poultry productivity at small scale farmer level. A breeding program (BP) including performance testing under African conditions is essential to be able to improve these chicken breeds. We show that we can increase the body weight of a pureline breed housed in France by including crossbred offspring performance from Burkina Faso into the BP of SASSO. The selection differential increased from +15 to +52 considering including and selecting for the performance measured in Burkina Faso. Running an effective BP for developing the best performing breeds under African conditions does not only require collecting performance information locally but also keeping the pureline in a bio-secure environment. Through such a program it is possible to serve customers world-wide consistently.

Introduction

Poultry constitutes an important economic activity for the rural poor in many African countries. Additionally in many poor rural families, poultry provides the family with a low cost, highly efficient and nutritious protein. The local indigenous breeds can be inefficient and unproductive compared to other alternative and improved breed options. Unfortunately, the smallholder farmers in rural areas often do not have access to these improved genetics. Providing access to an improved low-input and dual-purpose chicken could be a contributing element to transforming the rural poultry production chain.

In a number of African countries investments are made for providing access to improved breeds such as the African Poultry Multiplication Initiative (APMI). The APMI model generally operates through capable local private companies to establish a parent stock and hatchery operation for the production of day-old-chicks of improved dual purpose chicken breeds for smallholder farmers. The hatching eggs from the parent stock farm and set and hatched to produce day-old-chicks. The vaccinated day-old chicks are transported to so-called 'Brooder Units' (equivalent to 'Mother Units' or 'Ambassadors') who are specialized in the brooding, feeding, and proper vaccination process for the first 30-40 days of the chicks' life. The brooder units sell these chicks to smallholder farmers for meat and egg production. Through this APMI system, local smallholder farmers get access to improved genetics and the chickens have a high chance to survive due to their good start.

In 2018 Hendrix Genetics received a grant from the Bill & Melinda Gates Foundation to further enhance the use of improved poultry genetics to provide a better living to smallholder farmers in Africa. The program named 'Sustainable Access to Poultry Parent Stock for Africa (SAPPSA)' aims to: (1) secure access to poultry parent stock; (2) grow the APMI-like initiatives within and across countries; and (3) improve the dual-purpose breeds to better meet the needs of African smallholder farmers. In SAPPSA, we built on the experience and the dual purpose breeds developed within SASSO, our specialized colored broiler breeding division.

In this conference paper, we focus on the recurrent test program which we have developed and incorporated in the breeding program for dual purpose birds to better fit the challenging conditions in rural Africa.

Breeding. As part of the SAPPSA project, we developed and implement a recurrent testing scheme to improve performance of dual purpose poultry under African conditions. The recurrent test is directed towards improving performance at the crossbred level under local circumstances, whereas selection is performed at pureline level. To improve performance of the dual-purpose birds, both growth and egg performance on crossbred chickens are measured. In this paper, we present results only on growth performance in which BW_PL reflects the body weight measured at pureline level(BW_PL). Pureline males are used to produce crossbred offspring. The crossbred offspring are measured in our recurrent test facility in Burkina Faso (BW_BF; open housing, local feed supplier and high temperatures) and at recurrent test facility in France (BW_FR; closed housing; label rouge certified feed; mild climate). The recurrent test performances have been included in the genetic evaluation of the pure line.

The data. The data collected is on the slow growing broiler line which is used to produce the commercial cross SASSO Ruby C for smallholder farmers in Sub Saharan Africa. Both pureline data of the line Ruby as crossbred data between a pureline Ruby sire and another pureline line (not always the same) are included in the genetic analyses. Table 1 shows the number of observations in the different tests. Body weight was recorded on in total 7,544 pureline animals and 11,853 crossbred animals of which 7,517 in Burkina Faso.

Important to note is that flock number 1 in France were full sibs of the flock number 2 that was tested 2 weeks later in Burkina Faso. This close genetic link enabled us to estimate the contribution of genotype-by-environment effect from a pureline-crossbred effect. The pureline data consists of 8 discrete generations of animals which were all housed at our bio-secure pedigree complex in Sabres, France.

Fixed effects fitted were sex and date of birth. Linear mixed models were used to estimate the variance components and the data was fitted in the program DMU (Madson and Jensen, 2008). Bivariate or tri-variate analyses were run for BW, where the traits were defined by being measured either in pureline or crossbred animals. In the trivariate analyses, the BW in Burkina Faso, the BW measured in France on crossbreds and purebreds were treated as separate traits. The resulting genetic correlations do reflect a combination of pureline-crossbred performance effect and/or genotype-by-environment effect. Covariances between

Table 1. Overview of the dataset with number of observations, mean and SD of the body weights for pureline and its crosses.

Line	Location	N sires tested[1]	Sex[2]	n	Mean BW	SD BW
Ruby PL	Pureline facility, France		F	4,002	977	224
			M	3,542	1,069	231
Flock 1: Ruby XB	France	81	F	2,130	996	102
			M	2,206	1,078	110
Flock 2: Ruby XB	Burkina Faso	73	F	1,471	630	82
			M	1,362	691	93
Flock 3: Ruby XB	Burkina Faso	31	F	1,680	637	111
			M	1,757	749	123
Flock 4: Ruby XB	Burkina Faso	27	F	642	533	77
			M	605	571	76

[1] Sires with >20 offspring tested.

[2] F = females; M = males.

residual effects in the pureline and crossbred dataset were set to zero, as animals did not have observations in different environments.

To mimic the breeding program, we compared the expected selection gain from selection of sires sires based on EBV calculated on three distinct sources for BW: BW_PL, BW_BF and BW_FR. For each scenario, we selected 30 sires, which reflects the number of sires selected to produce the next generation of purebred animals.

Results & discussion

The h^2 estimated for BW_PL, BW_BF and BW_FR were 0.43, 0.39 and 0.63 respectively (with a standard error of 0.02, 0.03 and 0.09). The genetic correlation based on the bivariate model between pureline and crossbred was 0.45 (se ±0.10) for both data from France and Burkina Faso. The genetic correlations from the trivariate analyses was 0.39 (±0.11) between BW_PL and BW_BF, 0.67 (±0.11) between BW_PL and BW_FR and 0.63 (±0.09) between BW_FR and BW_BF showing clearly a significant pureline – crossbred interaction and genotype-by-environment interaction.

In Figure 1 the realized genetic trend of the three BW traits is shown. The selection has included the RT data from Burkina Faso into the index since generation G005 which resulted in higher genetic progress for the RT_BF and RT_FR traits in G006. Previous generations have solely been selected on BW measured on pureline birds. From generation G005 onwards, 70 sires have been tested in the two recurrent test environments (preselection step to select the best 70 sires based on an index including BW but also other traits). In total 30 sires were selected to renew the generation.

Table 2 shows the differences in selection differential between the three selection scenarios. For each scenario, the breeding goal is to improve BW under challenging conditions in Africa (BW_BF). This tables shows, that by using RT data from Burkina Faso and selecting on EBV for BW_BF, we could more than double the selection differential for the sires (+52 compared to +15) compared to using purebred information. This clearly illustrates the opportunities for making more genetic progress for the environment where the customers are growing the broilers.

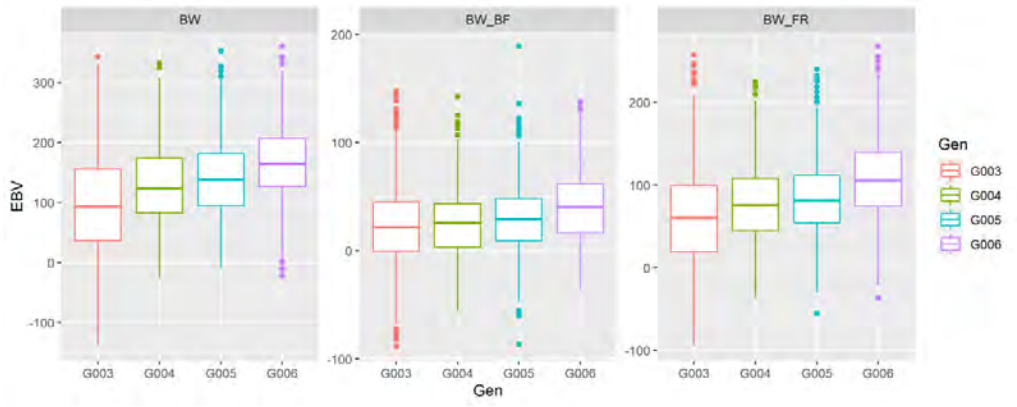

Figure 1. Overview of the genetic trend for the last 4 pureline generations for BW_PL measured on pureline animals, BW_BF measured in Burkina Faso and BW_FR measured in France.

Table 2. The realized selection differential for BW_BF (g/d) for three scenarios which differed in selection criteria.

Selection criteria	Mean all 70 sires	Mean for top 30 sires	Selection differential
EBV BW_PL	28	43	+15
EBV BW_FR	28	52	+24
EBV BW_BF	28	80	+52

Conclusions

Meeting the needs of smallholder farmers in Africa does not only involve developing improved genetics but also ensuring access to the improved genetics. We have learned that the APMI model is a very effective way to provide smallholder farmers access to improved genetics produced by local parent stock farms. By setting-up an international distribution network, we have secured access for our parent stock customers in Africa to high quality material developed in France. To further improve the genetics, we have developed and implemented a recurrent test. The recurrent test enables us to improve the breeding program of dual-purpose breeds by capitalizing on information collected under the challenging conditions in Africa. The results show that both pureline – crossbred correlation and genotype-by-environment interactions exist. This demonstrates the benefit of including performance information collected locally. Running an effective breeding program for developing the best performing breeds under African conditions does not only require collecting performance information locally but also securing the pureline by keeping it in a bio secure environment. Through such a program it is possible to serve customers across the world consistently.

431. Genomic selection in the US: where it has been and where it is going?

K.J. Retallick[1*], D. Lu[1], A. Garcia[1] and S.P. Miller[1,2]

[1]Angus Genetics Inc., 3201 Frederick Ave., Saint Joseph, MO 64506, USA; [2]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; kretallick@angus.org

Abstract

Genomic selection (GS) has gained extensive ground in the past decade. The American Angus Association has led the way for incorporation of GS in the US beef industry. Since 2009, GS has been employed for Angus breeders to make selection decisions. Several updates to increase the accuracy of GS has occurred over the years. The most notable being the shift from multistep approaches to single-step genomic BLUP methods to predict genetic differences among individuals. Now after nearly a decade, GS has started to tout its impacts across the industry. Over one million American Angus animals have been genotyped and now enter Angus's genetic evaluation each week. Increased predictive ability and improved rates of genetic progress have supported the growth of this technology across the industry. Selection candidates can now be selected and purchased with more confidence.

Introduction

The American Angus Association (AAA) is the largest beef breed association in the world with over 300,000 annual registrations. The demand for Angus genetics has been one of the strongest in the United States (US). Undoubtedly, some of this success has been driven by the genetic improvement programs that have been offered via AAA. In 1957, AAA launched the Angus Herd Improvement Records program to facilitate the necessary data capture for genetic improvement. The first estimated breeding values on American Angus cattle were published in the Group 1 Report-*Sire Evaluation Report* in 1974. Since that time, significant changes to genetic evaluations have taken place.

Genomic selection (GS) may be one of the most notable changes. Making its debut in late 2009, GS has been making headlines ever since most recently being that of the millionth animal being added to Angus's genomic database in July 2021. While this milestone was certainly celebrated, the success of genomic testing has come about through a series of improvements. This paper's objective is to provide a status overview of GS in American Angus cattle and perspective on how GS has affected producer decisions and the opportunities that lie ahead.

Materials & methods

To illustrate the trend in genetic testing over time, trends were acquired from the AAA. To depict the genetic progress made prior to and presently with the use of GS, genetic trends and variances were acquired. Genetic trend was standardized using each trait's genetic standard deviation. Standard units across traits were determined by regressing average expected progeny differences (EPD) by year from 2001-2009 (prior) and 2010-2021 (present).

Results

Looking back. Companies including Zoetis Animal Health (formerly Pfizer) and Neogen (formerly Igenity owned by Merial Animal Health) took the early initiative to bring GS to the industry. Molecular value predictions described genetic variation captured by markers alleles. These created confusion by placing multiple predictions on the same animals. It was not until AAA made the step towards incorporating GS

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_431, © K.J. Retallick *et al.* 2022

inside genetic evaluation models that widespread adoption took place. The first Angus genomic-enhanced EPD were introduced late 2009, a first for the US beef industry. At the same time, AAA moved to the industry's first weekly genetic evaluation, which was a major change from the previous bi-annual schedule. Enabling breeders to utilize genomic information as quickly as possible was a necessity to increase relevancy of genomic testing, a weekly genetic evaluation supported that initiative.

The first models to augment Angus EPD with genomic information was with a multistep evaluation described by Kachman (2008) and was employed for routine evaluation until 2017. Genomic information was included into genetic evaluations by computing molecular breeding values then fitting these values into genetic models through a correlated trait approach. The challenge to this method was the reliance on training populations, the need for animals in the training population to also be included in prediction pipelines, and the systematic calibration of marker effects as more information was added from the population.

The impact of these effects led AAA to work towards methods that allowed for real time inclusion of genomic information. Several groups had been researching ways to utilize marker information to fit a genomic relationship matrix transitioning genetic evaluations to using SNP genotypes to estimate genomic relationships rather than molecular breeding values (Misztal *et al.*, 2020).

Single-step genomic BLUP (ssGBLUP) had the potential to greatly simplify Angus's genetic evaluation. The method did not rely on deregressed proofs and properly weighted information from genotyped sires and dams. This avoided double counting issues which previously riddled Angus's evaluation as well as properly accounting for preselection bias of genomically tested parents (Legarra *et al.*, 2014). The method aimed to combine pedigree and genomic relationships into a combined genomic relationship matrix (GRM). However, the method relied on the inversion of the GRM and the computational cost of this direct inversion limited its usefulness in large routine evaluations (Aguilar *et al.*, 2011). Then in 2014, Misztal *et al.* presented the algorithm of proven and young (APY). By using approximate inversions of genomic relationships based on the recursions of a fraction of the total population, ssGBLUP was able to be effectively implemented for routine evaluation.

Current evaluation. On July 7, 2017, AAA deployed an updated evaluation. Employing single-step methodology was monumental for Angus and the entire US beef industry. Genetic trends and predictive ability of EPD were analysed using methods employed in 2009 compared to ssGBLUP models. The new ssGBLUP model on average increased the ability to predict future progeny performance for growth traits to 36% compared to previous models at 24%. Genetic trends from ssGBLUP models more closely mimicked genetic trends from traditional models supporting previous multistep trends were overestimated (Lourenco, 2018). At that time, ~300,000 genotypes had been submitted on cattle entering the genetic evaluation. Currently >1.09 million animals have genotypes. Figure 1 outlines the trend in genotype collection since inclusion into the genetic evaluation.

This growing number of genotypes creates alternate challenges. In 2017, a group of high accuracy animals were utilized as core animals for APY (Lourenco, 2018). Overtime this group became less representative of the genotyped population as discussed by Garcia *et al.* (personal communication) in a paper submitted to this congress. Slower convergence and increased run times resulted, making it cumbersome to execute a

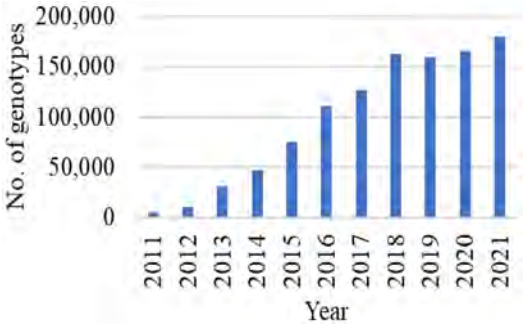

Figure 1. Trend in genotype collection on animals available for Angus's weekly genetic evaluation.

weekly genetic evaluation. The American Angus Association took the step in Summer 2021 to update this core group leading to decreased run times and subtle genetic prediction movements.

Breeders are realizing the promise of genomic testing. The impact of GS can be analysed through standardized genetic progress. Figure 2 illustrates standardized genetic progress prior (2001-2009) to and presently (2010-2021) influenced by genomics for EPD traits with high economic relevance in the US beef industry. Genetic progress for growth and carcass traits have accelerated in favorable directions with the inclusion of genomics with the exception of maternal milk and marbling. The downward trend in backfat is favorable as it would have positive outcomes for carcass yield. The pattern in maternal milk could be explained by breeder selection pressure working to hold a female's maintenance energy requirement to an optimal level. Marbling EPD has not accelerate with genomics. This could be explained by several high genetic bulls for marbling being culled from the Angus population due to lethal genetic defects in 2008.

In addition to accelerated progress, increased EPD accuracy allows users of Angus genetics to purchase bulls with less risk. This risk can be assessed in terms of the number of progeny equivalents added to an individual when genotyped. In Angus, genotyping a non-parent animal is equivalent to an animal producing, on average, 20 progenies, depending on the trait (American Angus Association, 2018). This

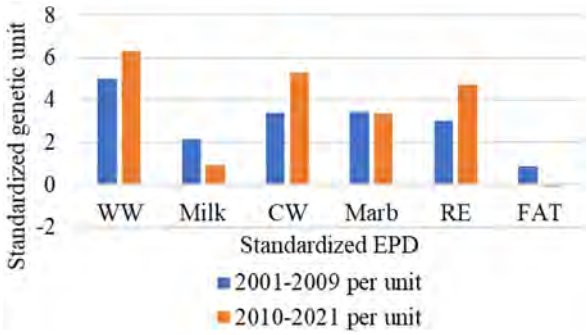

Figure 2. Standardized genetic progress made prior (2001-2009) to and presently (2010-2021) influenced by genomics for EPD traits with high economic relevance in the US beef industry including weaning weight (WW), maternal milk (Milk), carcass weight (CW), marbling score (Marb), ribeye area (RE) and backfat (BF).

accuracy increase is approximately equivalent to the amount of progeny information a sire could manifest with his first calf crop. This increased accuracy has driven the demand for genomic-tested Angus bulls.

Discussion

The future of GS is bright. Over one-half of yearly Angus registrations are now being genotyped. Price reductions have made widespread testing affordable. Sophisticated methodology has improved prediction accuracy and reliability of genetic predictions increasing trust by the user of Angus genetics. Genetic progress has amplified creating favourable marketing conditions for seedstock producers. Based on the number of genotypes submissions, many 'performance orientated' breeders have made genomic testing a standard operating procedure. The demand of genomic-tested bulls has been strong with bull stud companies and bull buyers not only rewarding breeders who test but demanding it.

One area GS has not found a firm foothold is in the US commercial cattle sector. Tests are available to the commercial cattle industry; however, the return on investment has yet to be large enough to pique widespread interest. Unique programs to provide genetic descriptions on groups of calves entering the feeding phase have opened the door to marketing opportunities with genetic predictors. These efforts have allowed for a window of transparency to GS to another sector in the beef supply chain. If the fed cattle industry can utilize GS to better manage their feed yards, increasing production efficiency, commercial cattlemen may be rewarded for providing that information. Continued education on the value of GS along with integrating GS in ways that are accessible, cost effective, and useful to make management decisions will continue to increase awareness and uptake of GS in the future.

432. Efficient genetic progress for quantitative traits through genomic selection

S. Tsuruta*, D.A.L. Lourenco and I. Misztal

University of Georgia, 425 River Rd, Athens, GA 30602, USA; shogo@uga.edu

Abstract

The objective of this study was to investigate the genetic progress through genomic selection for a quantitative trait over generations, assuming different numbers of QTL and genotyped animals. Simulations were conducted for populations with an effective size of 40 with 20 overlapping generations and phenotypes for a trait with a heritability of 0.5. Genotypes simulated for the last 10 generations comprised 30K SNPs across 30 autosomes including 30 to 3,000 QTL from 200 to 30,000 genotyped animals. Genetic trends were compared when selection was based exclusively on either genomic predictions or traditional genetic predictions. When the population size was small, the genetic gain by genomic selection was smaller than that by genetic selection. The genetic progress through genomic selection was more efficient when the population size was large enough to cover the genomic information in genotypes, especially with more QTL, implying that the trait behaved as polygenic.

Introduction

Genomic selection has been conducted over the past decade to accelerate genetic improvement in various species as genotyping costs dramatically decline. However, field data are often insufficient to quantify the long-term effect of genomic selection for different genetic architectures. Simulations with genotypes can be used to investigate accuracy and bias in genomic predictions (Lourenco, *et al.*, 2017). Additionally, simulations can help identify in which scenarios genomic selection would maximize the genetic progress in breeding population. Genetic trends based on genomic predictions via single-step genomic (ssG)BLUP (Aguilar *et al.*, 2010) and genetic predictions via traditional pedigree-based (A)BLUP start diverging when genomic selection becomes effective (Abdollahi-Arpanahi *et al.*, 2021). This is because ABLUP is biased under genomic selection as this method does not account for genomic information. However, depending on the number of genotyped individuals, how much the selection process relies on genomic information, and the trait architecture, genetic trends based on ABLUP and ssGBLUP may be more or less divergent. The objectives of this study were to understand the nature of genomic selection for quantitative traits and to investigate more efficient genetic progress over generations by assuming various numbers of QTL and genotyped animals.

Materials & methods

For populations with an effective size of 40, 20 overlapping generations with phenotypes for 400, 2,000, 20,000, and 60,000 animals were generated for a trait with a heritability of 0.5 and an additive genetic variance of 50. Genotypes simulated for the last 10 generations comprised 30K SNPs across 30 autosomes including 30, 300, and 3,000 QTL (i.e. 1 to 100 QTL per chromosome) for 200, 1000, 10,000, and 30,000 genotyped animals. In this simulation, it is assumed that QTL explained all the genetic variation for the trait (i.e. no extra polygenic effects). Selection was conducted by mating the top 10% males and 50% females of evaluated animals for 20 generations. We estimated and compared genetic trends when selection was based exclusively on either genomic predictions (ssGBLUP), genetic predictions (ABLUP), or animal predictions without considering relationships among animals (IBLUP). The QMSim software (Sargolzaei and Schenkel, 2009) was used for simulations, running the BLUF90 program (Misztal *et al.*, 2014) inside the QMSim to calculate the predictions and to select animals in each generation over 20 generations. Using all

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_432, © S. Tsuruta *et al.* 2022

phenotypes, genotypes, and pedigrees for all generations, genetic trends were estimated and standardized by the additive genetic standard deviation.

Results

Population size. The genetic gain by genomic selection via ssGBLUP increased as the number of genotyped animals expanded from 200 to 30,000 in the populations with 3,000 QTL (Table 1 and Figure 1a). The realized accuracy calculated by the genetic gain per generation significantly increased as the number of animals increased (Table 1 and Figure 1b), indicating that additional genomic information contributed to the accuracy more than pedigree information in a larger population as shown in the average diagonal of $(G^{-1} - A_{22}^{-1})$ in Table 1.

Number of QTL. Figure 2 shows genetic trend (a) and realized accuracy (b) via ssGBLUP from 30 to 3,000 QTL and via ABLUP and IBLUP in a population including 30,000 genotyped animals. With fewer QTL, the genetic gain by the genomic selection was smaller than that by the traditional genetic selection via ABLUP (Table 1 and Figure 2a). As the number of QTL increased, the genetic gain became larger. However, the gentic trend was lower when the number of QTL was smaller (e.g. 30 QTL = 1 QTL/chromosome) regardless of the population size. The accuracy in ssGBLUP was also lower when the number of QTL was smaller, compared with the accuracy in ABLUP. When the number of genotyped animals was large (i.e. 10,000 and 30,000), the realized accuracies in ssGBLUP were higher than those in ABLUP, but the genetic gains for ssGBLUP were smaller when the number of QTL was 300. As shown in Figure 2a, this contradiction was due to the slow genetic progress. When the number of QTL was smaller (i.e. 30), the genetic progress slowed down more. As predicted, this tendency was more pronounced when the population was smaller than 10,000 (result not shown here).

Table 1. Genetic gains estimated for difference scenarios in the simulation.

No. genotyped animals	No. QTL	Genetic gain / generation	ssGBLUP[1] / ABLUP[2]	Realized accuracy	Diagonal $(G^{-1} - A_{22}^{-1})$
200	ABLUP	0.13	-	0.119	-
	30	0.07	0.57	0.106	0.27
	300	0.20	1.57	0.146	0.31
	3,000	0.18	1.37	0.164	0.33
1000	ABLUP	0.29	-	0.235	-
	30	0.09	0.30	0.181	0.78
	300	0.33	1.15	0.272	0.77
	3,000	0.35	1.21	0.283	0.73

[1] Single-step genomic BLUP.

[2] Pedigree-based BLUP.

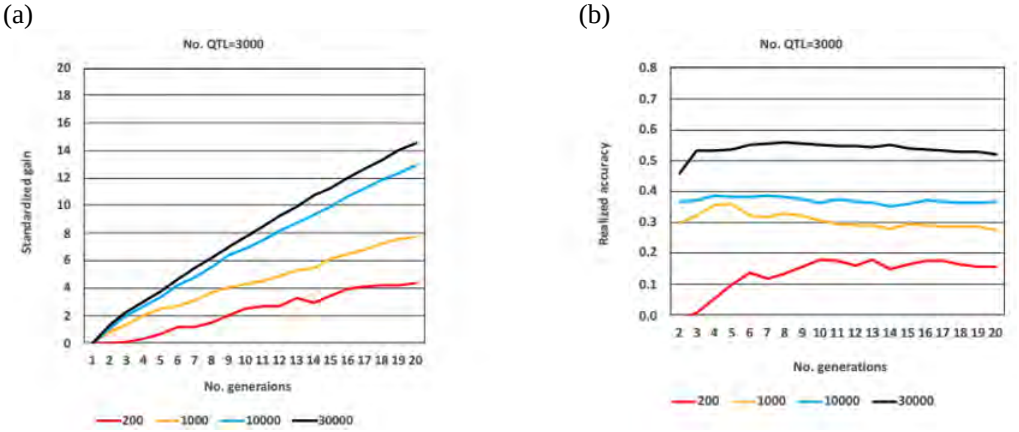

Figure 1. Genetic trend (a) and realized accuracy (b) for numbers of genotyped animals from 200 to 30,000 with 3,000 QTL.

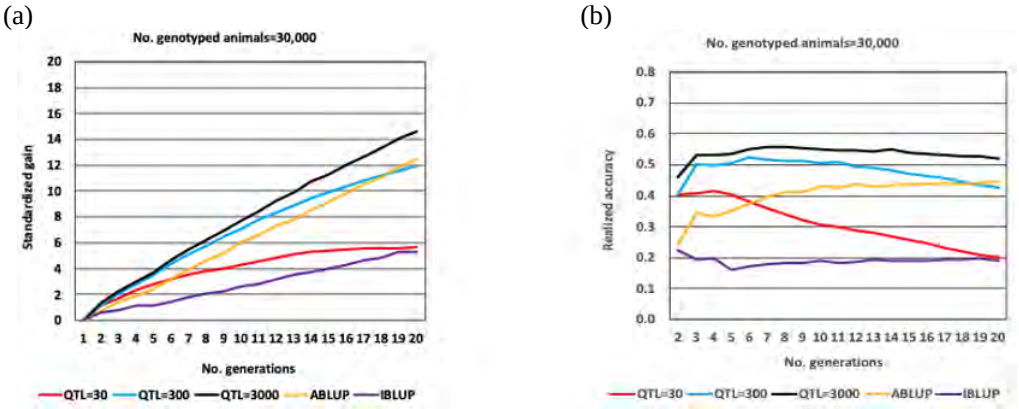

Figure 2. Genetic trend (a) and realized accuracy (b) via ssGBLUP with numbers of QTL from 30 to 3,000 and 30,000 genotyped animals, ABLUP, and IBLUP.

The number of eigenvalues that can explain 95, 98, or 99% in the genomic relationship matrix (G) can be used as a proxy for the number of independent chromosome segments segregating in the population (Pocrnic *et al.*, 2016). Figure 3 shows that for example, in a population of 30,000 genotyped animals with 30K SNPs, 15,000 genotyped animals is required to explain 98% of the variance in G. In a population with the effective population size of 40, when the number of genotyped animals is large enough (>30,000 genotyped animals), the maximum number of independent chromosome segments can be 20,000. Compared with this maximum number, when the population is small (10,000 or fewer genotyped animals), 30K SNPs can explain only less than half of the genomic variation in G. This could be one reason why higher accuracy and larger genetic gain were not achieved in a small population.

Figure 4 indicates that the additive genetic variance (V(g)) estimated with a small number of genotyped animals is largely overestimated, especially when the number of QTL is larger (i.e. the trait is more polygenic). This overestimation of variance components could result in inaccurate genomic predictions in practice.

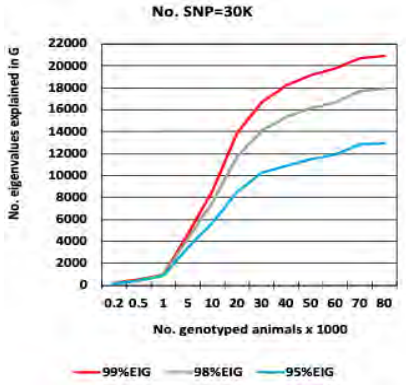

Figure 3. Numbers of eigenvalues explaining 95, 98, and 99% of the variance in the genomic relationship matrix.

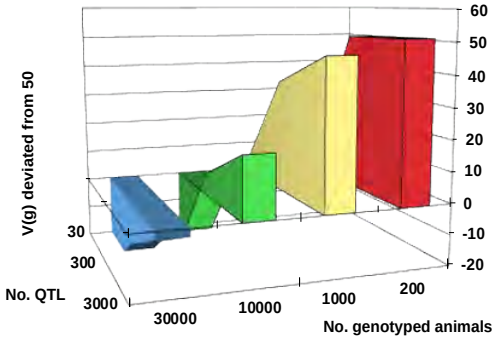

Figure 4. Additive genetic variance (V(g)) estimated with different numbers of QTL and genotyped animals as a deviation from the true V(g) = 50.

Discussion

Genetic trends based on ABLUP and ssGBLUP may diverge depending on the number of genotyped individuals, how much the selection process relies on genomic information, and the trait architecture. Suboptimal gains can be observed if the number of genotyped animals is fewer than that of independent chromosome segments segregating in the population. Therefore, small genotyped populations reap less benefits from genomics. Maximizing the rate of genetic gain under genomic selection would require a large number of genotyped animals that explain sufficient genomic variation, especially for a polygenic trait under directional selection. A trait with fewer QTL or causative SNP (less polygenic) tends toward fixation more rapidly, resulting in low genetic trend. Genetic trend for species with small genomes likely reaches the plateau quickly and then deteriorates due to inbreeding. It is also expected that genomic selection for lowly heritable traits is more effective when the trait is more polygenic and a large genotyped population is available. A long-term genomic selection study on genetic trends with field data should be conducted with caution.

Breeding programs

433. Strategies to support phenotyping for genomic selection R&D and implementation in beef and sheep industries

R.G. Banks

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, Armidale, NSW, 2350 Australia; rbanks@une.edu.au

Absract

Phenotypic recording is central to all genetic improvement. In the pre-genomics era, such recording tended to be focussed on selection candidates, particularly in beef cattle and sheep. In the genomics era, recording and selection can be completely uncoupled. This in turn makes explicit the importance of the key decisions: what to breed for, which leads to what to record, which leads to how to invest in recording (what traits, when recorded, how many records per trait, and which individuals). In single integrated organisations these decisions are relatively straightforward, but in multi-owner or –stakeholder situations, new approaches and levels of investment planning and coordination will be required for optimal sustained genetic progress. Approaches for such planning and coordination have been used (e.g. simulation modelling) are under development (for business aspects of the problem), but organisations and industries will need new models and levels of management for success.

Introduction

A basic algorithm for genetic improvement has been described (Harris and Newman, 1994) and its successful implementation widely documented (e.g. Hill, 2010). The algorithm can be summarised as: (1) definition of the breeding objective; (2) recording appropriate traits; and (3) prediction of genetic merit, leading to iv) selection and mating. When carefully applied, rates of improvement in productivity of 3 to 5% are feasible and simultaneous improvement in productivity and product quality attributes can be achieved (MLA, 2021). Appropriate data collection, or phenotyping is critical.

Since the 1980s, the prediction step in most animal species has been via pedigree-BLUP procedures, enabling use of data that is often variable in terms of what traits are recorded – with recording predominantly for traits that are relatively easily recorded on-farm. This is particularly the case for extensive industries such as beef cattle and sheep, which in most countries are characterised by low levels of organisation or coordination in the sense of not having defined nucleus populations or systematic collection of off-farm data.

More recently, genomic selection (Goddard *et al.*, 2009) has become more widely used, with a key feature being the ability to estimate genetic merit in a population for which a genomic reference population exists. The value of the reference population in terms of accuracy of prediction of genetic merit is broadly understood and underpins an essential feature and opportunity of genomic selection, i.e. the decoupling of phenotype recording from selection. Under pedigree-BLUP, most recording has been conducted by individuals (or enterprises) who then make selection and subsequent marketing decisions on the recorded animals. Under genomic selection, provided a suitable reference population exists, breeding enterprises can operate effectively without conducting any recording themselves. Another way of thinking about this is that it implies scope for explicit investment decisions on what to record, and how much to invest in recording, recognising that accuracy generally increases with level of investment, but with declining marginal return on investment (Goddard *et al.*, 2009). This paper considers some implications of this feature and opportunity, with particular focus on the beef and sheep industries of Australia.

Implementation of genomic selection for beef and sheep in Australia

The beef and sheep industries in Australia (and elsewhere, to varying degrees) are characterised in genetic terms by wide variation in: enterprise size in the breeding sector (MLA, 2019a); phenotype recording effort (e.g. Johnston, 2007); selection effort (expressed as i/L, selection intensity relative to generation length); and the role and effectiveness of breed associations. Within this context, there have been solid achievements, including development of reference populations through co-investment models; introduction of single-step genomic evaluation; expansion of traits under evaluation; and accelerating growth of genotyping for genomic prediction (MLA, 2021). This early phase implementation provides a basis for confidence in the technology and for continued and potentially increased investment. How best to invest is the challenge.

Challenges to investment in genomic selection

The starting point for considering investment for genetic improvement, at any level of organization, should be to define the breeding objective. Under genomic selection, this need not be constrained either by what is currently recorded or what is currently paid for by product markets or value chains. In this sense, genomic selection shifts genetic improvement towards being a design enterprise and, thus, managers of improvement programs should think broadly about both current and future attributes of their product (e.g. social license traits, see Miller and Retallick, *these proceedings*). Decision-making on breeding objectives needs to take account of all stakeholders in current value chains, including consumers, and to carefully assess what might seems likely to become important in the medium-term. If traits are prioritised that are not currently important, how to fund the data collection and how to report genetic merit for recorded traits in ways that do not distort current enterprise finances, become important challenges.

The practical and financial imperative of this 'design perspective' is that it must be backed by investment in recording the appropriate traits in the reference population. Given that in highly dispersed (in the ownership sense) industries, breeders only capture a small share of total income generated from progeny of bulls or rams (typically 5 to 10% in beef and sheep in Australia), there is a risk of insufficient funds for recording at the required scale. Two broad responses seem possible: firstly, leave this to the market and hope that at least some breeders have sufficient scale to make more speculative investments; or actively invest at a breed or industry level, using whatever funds can be collected, including industry or government R&D funds and, potentially, royalties imposed on genomic testing. Under the more active strategy, two challenges remain: the need for investment in recording is ongoing, in that reference populations need to be 'topped up' with new data so that prediction accuracy is maintained (Dekkers *et al*., 2021); and secondly, some form of coordination of funding becomes essential.

Such coordination is outside the traditional domains of both R&D funding agencies and breed associations, at least in Australia, although both groups have moved in this direction in the last decade (through co-investment in designed recording projects). However, it is not clear to what extent the required permanency of the funding is appreciated. Indeed, the fact that data collection for genomic reference populations is essentially continuing or real-time R&D (with new knowledge being generated continuously) challenges existing definitions of, and funding approaches for, R&D.

The rationale for role of industry or government agencies in funding the R&D aspects of genetic improvement has been considered previously (e.g. Smith, 1981, Elsen *et al*., 1986), but no obvious long-term system or approach has been implemented anywhere, although sustained sequential R&D investment has occurred in several countries (e.g. US (USDA), France, Ireland, and Australia).

Investment questions – what to invest in, how to fund it, and how to make decisions

The challenge in the genomics era for all organisations (public or private) can be distilled to two questions: (1) what to breed for; and (2) how to fund the data collection that will enable high rates of progress towards that goal? The inherent goal is to maximise return on investment. Defining a breeding objective is in principle straightforward and tools are available to assist the process (Barwick *et al*., 2005). For multi-member organisations, or for whole industries, the challenge of obtaining 'buy-in' is real and is likely facilitated by widespread extension and consultation, particularly around traits that are currently not recognised in market prices but which are expected to enhance value in the future. This is somewhat analogous to the challenge of developing and achieving acceptance of multiple goals within a breed, which is technically straightforward but can be very difficult for such organisations (P. Parnell, *pers. comm.*)

Defining a breeding objective directly defines the data collection strategy, which should aim at maximising prediction accuracy for breeding objective traits (Van der Werf *et al.*, 2018). In broad terms, this means recording as many animals as can be afforded (as an approximation, the number to record should be proportional to the size of the commercial or production population, M. Goddard, *pers. comm*.), although an attractive feature of genomic selection is that recording can be concentrated and optimised, rather than depending on 'partial' recording of large numbers of animals across multiple enterprises across the population. Particularly if the objective includes hard-to-measure and/or social license traits, it is likely that these: (1) will not currently be recorded; (2) require expensive equipment; and (3) require consciously planned recording projects. This implies access to funds and sound management of those funds.

To a large extent, funds for such recording have to date been obtained via R&D grants and it may be that this avenue will always be available but this cannot be guaranteed, and mechanisms to collect funds from other avenues will likely be valuable. An efficient and equitable mechanism for sharing recording costs across recorders and users was outlined by Banks (2021). This approach can incorporate funding from diverse sources, such that if industry and (or) government is willing to assist with costs of hard-to-measure and (or) as yet unpriced traits.

At an industry level, investment in recording phenotypes should incorporate breed comparisons where possible, both to facilitate across-breed genomic selection and reduce individual breed recording requirements, but also to inform sire-buying markets, thereby increasing focus on objective merit and likely stimulating faster genetic progress within breeds.

The more rigorously investment thinking is applied to these challenges, the more likely specialised recording operations will become. In this, beef and sheep breeding will become more like the more intensive livestock industries, where ownership and recording is more concentrated. This will bring challenges for the roles of individual enterprises, in particular for 'seedstock breeders', and for how data access is funded. It is plausible but not necessarily optimal that recording and selection would become completely uncoupled business strategies.

Conclusions – key features of possible solutions

Optimally designed and scaled phenotyping is the fundamental issue for all genetic improvement programs into the future and holds special challenges for extensive multi-agent industries such as the beef cattle and sheep industries. Sustained genetic improvement utilising genomic selection seems certain to include the following features:

- definition of breeding objectives that draw on multiple stakeholders' perspectives;
- specialist phenotype recording operations that complement activities of individual breeders and that are optimised at the breed or industry level for scale and traits included;
- mechanisms for harvesting appropriate shares of the value created to maintain funding for optimal recording and that, accordingly, explicitly value and remunerate recording efforts;
- and sound investment management for organisations, including sustained co-investment partnerships with industry and/or government.

Genomic selection increases scope for extensive industries to design and achieve more valuable genetic improvement than hitherto possible, but this will require new models for multi-member organisations and levels of coordination. Ongoing R&D into optimal breeding program design and, in particular, into methods for coordinating investment in phenotypes, will be valuable.

434. The infrastructure for cattle data at the Swedish university of agricultural sciences, Gigacow

T. Klingström*, I. Ohlsson[1] and D.J. de Koning

Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; tomas.klingstrom@slu.se

Abstract

Research in animal breeding and precision livestock farming both require vast volumes of highly heterogeneous data, often beyond the capabilities of the universities' own research farms. To facilitate access to detailed phenotypes from a network of farms, we established the infrastructure for cattle data at the Swedish University of Agricultural Sciences (SLU Gigacow). A main achievement of SLU Gigacow has been the development and implementation of automated daily collection of records from each participating farm's herd management system to a centralized server at SLU. SLU Gigacow will monitor around 5,000 cows (including annual replacements) when it is fully operational. Although still under development, SLU Gigacow has already received much attention from various stakeholders, as well as media. In the long-term we expect SLU Gigacow to become a valuable infrastructure for discoveries, as well as a testbed for implementation of new technologies.

Introduction

While a university can do much research in their own dedicated research farms, many studies, especially those related to genetics and genomics, require much larger sample sizes and access to field data. It is very demanding and highly inefficient for individual researchers to recruit farms that are willing to contribute data for each individual research project. To address this challenge, the infrastructure for dairy cattle data at the Swedish University of Agricultural Sciences, Gigacow (SLU Gigacow), was founded in 2018. Its main purpose is to support research projects in dairy cattle genetics, precision agriculture, and other research concerning dairy farms and the environment. In a modern dairy, farm machines and sensors automatically collect data on milk composition, activity, and feeding behaviour of cows to ensure good animal health and high productivity. Genotyping of calves for estimation of genomic breeding values is now also routine procedure at many farms and genotyping with a 45K SNP-chip is available as a commercial service at a low cost. At a farm, the pedigree of each cow is known and the herd structure ensures that between 60 and several hundred animals are exposed to the same environment.

The purpose of SLU Gigacow is to establish a single data collection platform useful to researchers at SLU and elsewhere to accelerate the scientific process. Once an infrastructure has been established, large amounts of data can be collected at a low cost. The cost of establishing a data collection infrastructure with legal agreements and software solutions for automated data collection and data curation is however a major investment. The limitations of funding and a lack of dedicated infrastructure have been identified as the major bottlenecks in phenome research in non-model organisms, as projects are either narrowly focused on a single biological pathway in response to phenotypic change, while ignoring the rest of the dataset, or limited to broad sweeping conclusions about the dataset based on shallow interpretations (Burnett *et al.*, 2020). By providing a rich dataset of phenotypes and associated data, researchers can better plan the scope of projects and engage in exploratory projects with minimal overhead and startup costs. Thus, SLU Gigacow can provide the mechanism necessary to encourage junior and senior investigators to conduct focused, hypothesis-driven research framed in a genome to phenome context and to critically consider experimental design, power, and sample sizes when launching '-omics'-based experiments.

Materials & methods

Production data from farms is collected by the software Gigacow Kollector, written in Python 3 (Beaverton, USA), and automates export of data from herd management systems such as DeLaval DelPro (Tumba, Sweden) and Lely T4C (Maassluis, the Netherlands). Data in certain reports on the DeLaval DelPro can be scheduled for automatic exports and other sensor manufacturers also provide similar solutions, enabling data from the herd management system and other equipment to be automatically exported to the temporary file storage area created by Gigacow Kollector. Each day, Gigacow Kollector runs a scheduled task to upload data with Secure File Transfer Protocol (SFTP) to a file storage server located at SLU, which stores the raw files. A verification script run on the server side ensures that all expected reports are uploaded. Data from the SLU Gigacow data collection server is then imported to the Gigacow SQL Server database (DB) by means of multiple processes for extraction, transformation and loading that are maintained with SQL Server Integration Services (SSIS) (Microsoft, Redmond, USA). Researchers can download data directly from the DB via a database data connection or, to facilitate analyses, by connecting the tool of their choice, such as Excel, to a regularly preprocessed and aggregated Online Analytical Processing cube deployed with SQL Server Analysis Services (SSAS).

In addition to data collected on farms, SLU Gigacow also collects data through an agreement with Växa Sverige AB (Uppsala, Sweden), which is a service that aggregates information on subjects such as claw health, veterinary visits, and other key performance indicators related to animal health and productivity. This data is compiled quarterly in fixed length files and sent to the SLU Gigacow server using SFTP. Genome analysis of animals is performed by the service Växa Genomanalys using the 45k EuroG MD beadchip (Amsterdam, the Netherlands). Calves born in herds that participate in SLU Gigacow are genotyped as a part of the tagging process, in which a sample is collected by the farmer and submitted to the genome analysis service. Adult animals are sampled by the farmers or visiting technicians from Växa by collecting blood or hair samples from the tail. Ethics approval from the authorities is required and has been granted for collection of blood samples from adult animals but is not required for hair sample collection.

The data collection system of SLU Gigacow is under continuous development but, in its current form, presents a modular solution to quickly integrate information from many different sources (Figure 1).

Results

Data collection from dairy farms was delayed by the Covid-19 pandemic but was started by remote installations in 2021. In a steady state situation, approximately 5,000 animals on 15 farms will be monitored on an annual basis, with a budgeted annual replacement rate of 35%. So far 1300 animals have been genotyped in collaboration with Växa and the farmers. Using Växa Sverige's commercial service for genome

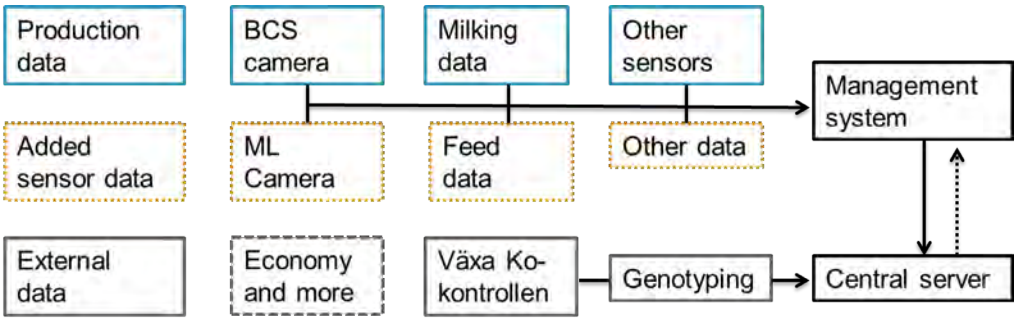

Figure 1. Data collection in Gigacow. Dotted boxes are currently under development.

analysis, the cost per genotyped calf is ~25 Euro at an exchange rate of 0.1 SEK per Euro. Genotyping of adult animals is done by arrangement and cost between 32 and 36 Euro, depending on the size of the farm, who performs the sampling, and labour required to collect animals.

A number of key performance indicators have been tracked during the establishment of SLU Gigacow (Table 1). The SLU Gigacow infrastructure was established not only to support genomics research but also to serve as an interdisciplinary infrastructure that serves all fields related to dairy farming. Education of agronomists specialising in agricultural technology was abolished in Sweden ~20 years ago and SLU is currently working to increase its focus on agricultural technology, bioinformatics, and precision farming. Establishment of SLU Gigacow has created a natural contact point at SLU for stakeholders in the industry and at other universities to bring technology developers and the farming industry closer together. SLU Gigacow has therefore been used as an example in multiple articles and conferences on smart farming and data collection. SLU Gigacow has also participated in numerous grant applications with partners at Linköping University, Uppsala University, Dalarnas University, the University of Oslo, and several nodes in the Elixir European life science infrastructure for biological information (ELIXIR). The total approval rate for grant applications supported by SLU Gigacow has so far been 42%, compared to an average funding rate of 14% for the Swedish Research Council for Sustainable Development (FORMAS) and 20% for grant applications in Natural science and technology by the Swedish Research Council (VR).

Technology development and testing is also an important topic, as the implementation of smart solutions is a key area in the digital transformation of the agricultural sector (OECD, 2019). Gigacow is developed to function as a testbed for innovation and is a member of the Nordic Testbed Network (https://nordictestbednetwork.se/gigacow-2/). Data from farms is continuously collected, facilitating both longitudinal (before and after implementation) and case-control studies, enabling users to 'test before invest'. Activities in this role include projects integrating Edge Artificial Intelligence into farming decision support systems, in collaboration with Uppsala University and a major equipment manufacturer, and assessment of market acceptance for remote sensing applications, together with a major producer of visible, near infrared, and short-wave infrared sensors. To formalise this role, SLU Gigacow also participates in the application for a European Digital Innovation Hub, in collaboration with Linköping University, the Research Institutes of Sweden, and multiple regional actors for technology and innovation.

Discussion

The major challenges during the development of SLU Gigacow have not been how to collect data but to identify what data there is to collect, what agreements are necessary with various stakeholders to collect the data, and finding a robust technical infrastructure that enables the collection of data from heterogeneous

Table 1. Key performance metrics tracked in SLU Gigacow.

data sources and present it in an accessible manner. There is fierce competition in the agricultural sector, both between equipment manufacturers and service providers, which makes protection of international property rights a key concern for these commercial companies. At the same time, partnering with the industry can yield considerable benefits of scale, as well as new research opportunities. The estimated cost of genotyping at the National Genomics Infrastructure would, despite an academic subsidy have amounted to ~52 Euro per animal, even before adding costs for sample collection and DNA extraction, which would have had to be performed in-house at SLU. There is also a strong interest, both among equipment manufacturers and service providers, to further increase the precision and scope of data collection in farming. Close collaboration between researchersm farmers and other stakeholders in primary production can thereby both yield new technology for the study of animals and insights that motivate initiation of new research.

Conclusions

Digital transformation is rapidly changing all sectors of society and many sectors face a lack of computer scientists and bioinformaticians who can process and analyse biological data (Batut *et al.*, 2018). Data collection and analysis is, therefore, an increasingly large part of the workload for many researchers (Klingström, 2017). Automation and collaboration with industry is, therefore, important to reduce the workload of researchers by making sure that data is readily available in a format that is accessible to both domain experts and technology developers who are aiming to bring technological innovations into new domains. Thus, the establishment of livestock data infrastructures can accelerate genetics research by genotyping and phenotyping animals at a scale that is not feasible outside the agricultural sector.

Acknowledgements

SLU Gigacow is financed by an infrastructure grant from SLU and acknowledges in-kind support from VÄXA Sverige. We gratefully acknowledge the Swedish farmers who participate in Gigacow without financial compensation.

435. Optimizing sampling strategies for sib test schemes in a broiler breeder program

C.A. de Hollander[1*], V.P. Breen[1], J. Henshall,[1] F.B. Lopes[1] and M.P.L. Calus[2]

[1]Cobb-Vantress Inc., 4703 US Highway 412 E, Siloam Springs, AR 72761, USA; [2]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; charlie.dehollander@cobbvantress.com

Abstract

In broiler breeding there is a known genotype by environment interaction for bodyweight measured in a bio-secure (BW_B) or in a commercial environment (BW_C), thus a sib test scheme to record and use BW_C records is beneficial. This study estimated a genetic correlation of 0.59 between BW_B and BW_C. To optimize the sib scheme, different genotype proportions (25, 50, 75%) and sampling strategies were studied. No pedigree information was available for birds in the commercial environment unless they were genotyped. Genotyping based on phenotypes, heaviest and lightest, resulted in the highest accuracy compared to random genotyping 0.88 vs 0.80 at 25%, 0.94 vs 0.89 for 50 and 0.97 vs 0.95 at 75% genotyped. No bias was observed with random sampling, however bias was detected with sampling based on phenotypes (0.58 at 25%, 0.76 at 50 and 0.91 at 75%).

Introduction

Broiler poultry breeding companies keep and select their genetic pure lines in a bio-secure environment to reduce the risk of any diseases. However, this environment differs from the environment in which commercial broilers are usually reared. Because the selection environment does not completely reflect the commercial environment, a genotype by environment interaction (G×E) is likely present. The G×E causes the expressions of different phenotypes to be affected (Kolmodin and Bijma 2004) and thereby lead to reranking of families in different environments. A genetic correlation between body weight of the same purebred broiler line in a bio-secure and in a commercial environment was reported between 0.46-0.69 (Chu *et al.* 2019; Kapell *et al.* 2012). Therefore, it would be valuable for broiler breeder companies to set up a sib scheme test design to increase the genetic gain in body weight in a commercial environment. This study explored different genotyping strategies and proportions of birds to be genotyped to optimize a broiler breeding sib scheme set up. The two following strategies were chosen: the first is Random sampling (RND), this strategy is known to result in higher accuracies and lower bias compared to genotyping strategies based on mean phenotypes or best phenotypes (Howard *et al.* 2018; Jiménez-Montero *et al.* 2012). The second strategy is sampling based on Extreme phenotypes (EXT), the heaviest and lightest birds are chosen to be genotyped. This strategy has been found to result in the highest accuracies of breeding values compared to random sampling (Boligon *et al.* 2012; Howard *et al.* 2018; Jiménez-Montero *et al.* 2012). Additionally, three different proportions of genotyped birds were studied: 25, 50 and 75% of the available birds in the commercial environment.

Materials & methods

Phenotypes and genotypes. Data was provided by the poultry breeding company Cobb-Vantress, Inc. (Siloam Springs, Arkansas, USA). The data included performance information collected on pure-line broiler chickens that were either raised in a pedigree bio secure environment (Env B) or in a commercial environment (Env C). Once a bird is placed in Env C, they cannot return to Env B and will therefore be excluded from the breeding program. Of all birds hatched in one selection round, about 30% were placed in Env C, this was found to be sufficient by Chu *et al.* 2018 considering selection intensity, inbreeding and accuracy. These birds were all either full or half sibs of the other 70% birds that were placed in Env B. Data was collected over approximately 3.5 generations. The number of body weight phenotypes and the number

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_435, © C.A. de Hollander *et al.* 2022

of genotypes are represented in Table 1. Body weight was recorded in both environments at the same age. Birds included in this study were offspring from 519 Sires and 2,368 Dams. Genotypes were collected on all birds in Env C but only on a selected amount of birds in Env B (Table 1). All chicks placed in Env B have a known pedigree and the selection candidates are genotyped.

Sampling strategies for Env C. Having all chicks in Env C genotyped, allowed to retrospectively evaluate different sampling strategies. For each strategy, to reflect a scenario in which chicks placed in Env C are hatched in a commercial hatchery, animals that were not sampled in Env C were assumed to have no pedigree, and were therefore not included in the ssGBLUP analysis. The following sampling strategies are studied: Random sampling (RND): based on the proportion, X chicks were randomly sampled. Extreme phenotypes sampling (EXT), based on the proportion, 0.5X birds were sampled based on the highest body weight and 0.5X birds were sampled based on the lowest body weight.

Statistical analysis. A multivariate pedigree based model was used to estimate variance and covariance components. The multivariate model included six traits; BW_B, BW_C, White Meat Percentage (WMPct), Leg Quarter Percentage (LegQPct), Gain and Feed Efficiency (FE). BW_B, WMPct, LegQPct and FE and Gain were only recorded in Env B. BW_C was only recorded in Env C. All traits were corrected for gender and contemporary group. Additionally, for both BW_B and BW_C a random permanent maternal environmental effect was added to the model.

$$y_{BwB + BwC} = Xb + Za + Wc + e \quad (1)$$

$$y_{Gain + RFI + BRM\% + LegQ\%} = Xb + Za + e \quad (2)$$

X, Z and W are incidence matrices; where a, c and e are vectors for direct additive genetic, environmental maternal and residual effects, respectively. These random effects were assumed to be normally distributed $a \sim N(0,A\sigma_a^2)$, $c \sim N(0,I_d\sigma_c^2)$ and $e \sim N(0,I\sigma_e^2)$, where A is the pedigree relationship matrix and I_d the dam's identity matrix and I the identity matrix for all individual birds.

The variance components were estimated with the use of AIREML procedure in the DMUAI program from DMU (Madsen and Jensen 2013). Estimated variance components were used in single-step genomic BLUP (ssGBLUP) to estimate breeding values with the use of BGF90 (Misztal *et al.* 2002). The ssGBLUP models were identical to models described above (Misztal, *et al.* 2009). For computational reasons APY method (Misztal *et al.* 2014) was used to compute the inverse of the G matrix used in ssGBLUP. Core animals included parents and all selection candidates.

Validation. Validation was done using LR method (Legarra and Reverter 2018) to evaluate the differences in GEBV accuracies and bias. Full data contained all genotypes on all birds raised in Env C, the reduced data only contained a proportion of the genotyped birds in Env C based on each strategy. The number of genotypes in Env B remained the same across all strategies. Accuracies of different scenarios were measured by the correlation of GEBVs between the full data and reduced data. Dispersion bias was evaluated by the

Table 1. The number of phenotypes and genotypes used in this study.

	Phenotypes	Genotypes
BW_B	87,381	26,867
BW_C	34,863	34,816

slope of the regression of GEBVs from the full data on the GEBVs of the reduced data for the different strategies.

Results & discussion

Accuracy. Table 2 shows the accuracy of different ratios and different strategies of genotype sampling. The EXT clearly shows an advantage over RND sampling in terms of accuracy, especially at lower sampling rates (0.88 vs 0.80 at 25%, resp.). The magnitude of the advantage disappears as sampling proportion increases (0.94 vs 0.89 at 50% and 0.97 vs 0.95 at 75% of birds genotyped resp.). This increased accuracy of EXT over RND is in accordance with multiple other studies (Boligon *et al.* 2012; Howard *et al.* 2018; Jiménez-Montero *et al.* 2012).

Bias. Table 2 shows that bias is virtually absent for RND, while considerable for EXT, especially at a lower proportion (0.58 at 25% genotyped). When the sampling proportion increases the bias decreases for EXT but is still present even at 75% (0.76 at 50% and 0.91 at 75% genotyped). It is known that with an increase in the number of genotypes there is a decrease in bias (Daetwyler *et al.* 2012) and that genotyping randomly reduces bias compared to sampling based on phenotypes or family index (Boligon *et al.* 2012; Howard *et al.* 2018; Jiménez-Montero *et al.* 2012).

Table 2. Accuracies (r) and regression slopes (β) across strategies and proportions.

Strategy	Ratio	$r_{f\text{-}r}$	SE	$\beta_{f\text{-}r}$	SE
Random	25%	0.80	0.007	0.98	0.008
Extreme phenotypes	25%	0.88	0.005	0.58	0.003
Random	50%	0.89	0.005	0.98	0.005
Extreme phenotypes	50%	0.94	0.002	0.76	0.003
Random	75%	0.95	0.002	1.01	0.004
Extreme phenotypes	75%	0.97	0.001	0.91	0.002

Conclusions

In a sib test scheme where siblings tested in a commercial environment are removed from the breeding program and the correlation between body-weight measured in two different environments is 0.59, the following genotype strategies are advised for different proportions. When the genotyping is limited to less than 75% of all animals, it is advisable to sample animals based on extreme phenotypes as this strategy results in the highest accuracy. However, caution should be taken with interpreting the breeding values as this strategy shows higher levels of bias. When the sampling ratio is 75% or higher, random sampling of animals is recommended as this reduces the bias and shows similar accuracy compared to extreme phenotyping strategy.

Abstract

Over a six-year period, indigenous beef cows (Afrikaner, Bonsmara, Nguni) were crossed with indigenous and exotic (Angus, Simmental) sires in a hot and arid area, to produce 15 breed groups. Inter-year variation among the breed groups in performance was large. This stimulated a study of plasticity of the breed direct effects and heterosis and considerable plasticity of these effects was observed. The interaction of breed direct effects on 205-day weaning weight indicated less plasticity of Afrikaner and Nguni than Angus and Simmental. The individual heterosis effects on 205-day weight did not interact with the year effects. This demonstrates low plasticity in the indigenous breeds, indicating more tolerance to variation in climate. Adequately resourced producers may provide exogenous inputs to offset environmental variation and use genotypes with high plasticity. However, subsistence farmers might choose less plastic genotypes, which can produce irrespective of the environment.

Introduction

A crossbreeding trial is currently running at the Vaalharts research station near Jan Kempdorp in the Northern Cape Province of South Africa, in which Afrikaner, Bonsmara and Nguni cows (Sanga types) are mated with Afrikaner, Bonsmara, Nguni, Angus and Simmental (exotic) bulls in all possible combinations. This creates 15 different genotypes. Large variation has been observed in the weaning weights of the different crosses between years. For example, Sanga sired calves and exotic sired calves had the same 205-day corrected weaning weight (171 kg) in the 2015/16 summer, which was very hot (average maximum summer temperature 32.2 °C) with well below average season rainfall of only 302 mm. In contrast, the 2016/17 summer was cooler (31.1 °C) and wetter (469 mm) and the weaning weights of the exotic sired calves were 27 kg heavier than the Sanga sired calves.

This phenomenon stimulated a study on plasticity of breed direct and individual heterosis effects in beef cattle under the extensive conditions where the crossbreeding is carried out. Plasticity refers to changes in an organism's behaviour or performance in response to a specific, sometimes unique environment (Price *et al.,* 2003). Plasticity is a way for an organism to cope with environmental variation and encompasses all types of environmentally induced changes. These changes may be temporary or permanent (Kelly *et al.,* 2012). In this study, plasticity is higher when the genetic effects show greater variation between years and lower when these interaction effects are smaller.

Santana *et al.* (2013) found that superior genotypes in favourable environments may not necessarily perform the best in unfavourable environments and this was specifically demonstrated for weaning weight. They concluded that there is genetic variation in the sensitivity of animals to a specific environment. This study aims to investigate the plasticity of breed direct and individual heterosis effects of the breeds used in the crossbreeding project.

Materials & methods

Study site. The Vaalharts research station is located in the centre of South Africa at 27°51' south and 24°50' East at an altitude of 1,175 meters and is in an area with sandy red soil with lime rock underneath (Laker, 2003). The veld type is mixed *Tarchonanthus* veld, Veld type No 16b, 4 (Acocks, 1988). The research station has a recommended carrying capacity of 10 ha/large stock unit. The climate at the Vaalharts research station is characterized by hot summers and cold winters with frost being a common occurrence. The highest monthly average temperature is around ±32 °C and is experienced during December and January. The average precipitation is around 450 millimetres per annum of which 88% is experienced during the summer months from October to April in the form of thunderstorms.

Breeds. The Afrikaner and Nguni breeds are indigenous to Southern Africa and classified as *Bos taurus africanus* (Meyer, 1984), also referred to as Sanga breeds. The Bonsmara is a composite breed developed from the Afrikaner × British Hereford and Shorthorn in a combination of 5/8 Afrikaner: 3/8 British (Scholtz, 2010). The Angus is a British breed and the Simmental a European breed.

Data collection. The data (birth, weaning and cow weights) was collected according to the approved standard operating procedures the National Beef Recording and Improvement Scheme in South Africa, which is accredited with the International Committee for Animal Recording (ICAR). The data resulted from mating Afrikaner (AF), Bonsmara (BN), Nguni (NG), Angus (AN) and Simmental (SM) bulls to AF, BN, and NG cows over a six-year period. In total 212, 324, 303, 179 and 234 calves were sired by AF, NG, BN, AN and SM sires, respectively. There were 182, 633 and 437 calves produced by AF, NG and BN cows, respectively. More details on the data collection and the management can be obtained from Pyoos *et al.* (2020). Breeding occurred on natural veld and all calves were raised by their dams from birth through weaning at approximately 205 days of age. Birth dates were recorded and calves were weighed within 48 hours of birth. Each year, all calves were weaned and weighed on the same day. It should be noted that calves are born in spring and weaned in the autumn of the next year.

The weather data from Vaalharts is unfortunately not complete. Thus, weather data from Hartswater, which is 25 km from Vaalharts, was thus used. The Temperature-Humidity Index (THI) was calculated as follows (Bohmanova *et al.* 2007):

$$THI = 0.81 \times T\ (\text{dry bulb}) + 0.143 \times RH + 0.0099 \times RH \times T\ (\text{dry bulb}) + 46.3$$

where: T (dry bulb) = ambient dry-bulb temperature (°C) and RH = relative humidity (%).

Daily THI values were calculated for the summer months from September to April. The length of the rainfall season was calculated from the first rains (at least 5 mm) to the last rains of the spring to autumn season. The number of heat wave days was calculated as the number of days within the rainfall season with THI values≥72.

Statistical models. The data were analysed using PROC Mixed of SAS. The linear models for birth weight and 205-day weight included effects of year, sex, age of dam, the genetic expectation for breed group as proposed by Dickerson (1969), and the interactions of year with the breed direct and maternal effects and individual heterosis. The direct effects of the Bonsmara in each year were set to zero to make the other effects estimable.

Results

The *P*-values for the interaction terms indicate the degree of plasticity, where a numerically larger *P*-value indicate less genetic variability between environments and hence less plasticity. For birth weight, the *P*-values for the interaction of breed direct effects and year indicate considerable plasticity with respect to the inter-year environment (Figure 1). For weaning weight, the *P*-values for the interaction effects of breed direct effects and year indicate the direct effects of Afrikaner and Nguni were less plastic and showed less variation among years than the direct effects of Angus and Simmental. Overall, birth weight, which is a manifestation of growth *in utero*, appeared more plastic, i.e. more sensitive to the variation among years, than 205-day weight.

Individual heterosis effects on birth weight varied considerably among years with the effects being large in 2014, 2016 and 2018, and essentially nil in the other years (Figure 2). However, the inter-year variation in heterosis effects on 205-day weight was smaller and overall not different from zero.

The rainy season THI during the study period varied between 78.5 and 81.6, whereas Bohmanova *et al.* (2007) indicated that heat stress is induced if THI≥72 in semi-arid regions. This indicates that the environment is very harsh.

The rainfall varied between 240 and 788 mm per season, the length of the rainfall season varied from 156 days to 228 days and the number of heat wave days within the rainfall season between 171 and 232 days.

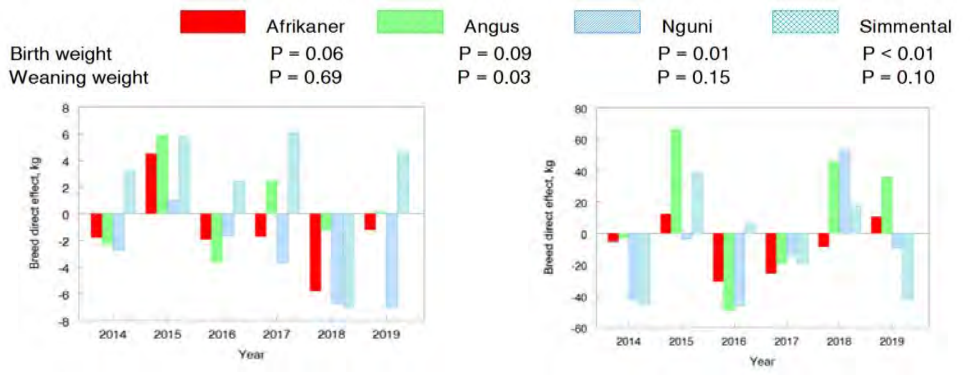

Figure 1. Interactions of the breed direct effects with year for birth (left) and 205-day (right) weights expressed as a deviation from the Bonsmara.

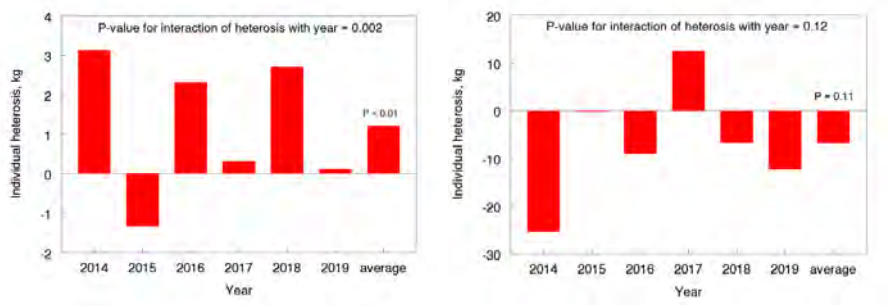

Figure 2. Interactions of the heterosis effect with year for birth (left) and 205-day (right) weights expressed as a deviation from the Bonsmara.

Discussion

It is clear that the breed direct effects for birth weight varied from year to year, and it is possibly influenced by climate. There also appears to be large interactions between breed direct effects and year for 205-day weaning weight. The Afrikaner shows the least interaction, followed by the Nguni. This demonstrates low plasticity in the indigenous breeds, indicating more tolerance to variation in climate. The exotic breeds demonstrated the more plasticity. The next step will be to use weather data such as maximum temperature, seasonal rainfall, and length of the growing season, temperature-humidity index and number of heat waves per season, to see whether it can be linked to the plasticity expressed between different genotypes.

Producing beef cattle can simultaneously optimize the use of additive (breed differences) and non-additive (heterosis) effects (Akanno *et al.,* 2018). However, it is impossible to change the breeding scheme on an annual basis to best account for inter-year environmental variation. Adequately resourced commercial producers may choose to provide exogenous inputs to offset this environmental variation, for example through the purchase of feedstuffs in drought years. They may therefore choose to use breed resources with high average genetic potential for production without regard to their plasticity. However, some commercial producers and probably all subsistence producers might choose a less plastic set of breed resources that can be dependent upon to produce even under less favourable environmental circumstances.

437. Polled Accelerator – a unique application of genomic technologies to address a beef breeding challenge

D.J. Johnston[1*], M.H. Ferdosi[1], J. Cook[1] and D.B. Savage[2]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]The North Australian Pastoral Company, GPO Box 319, 4000 Brisbane, Australia; djohnsto@une.edu.au

Abstract

Genetic improvement requires selection for all traits in the breeding objective and increasingly this includes consideration of traits associated with animal welfare and social licence. A unique program called the 'Polled Accelerator' was developed for a large beef cattle population to rapidly increase the frequency of polledness. The program was constructed using a unique combination of existing and emerging genomic technologies and methods including DNA tests for polled/horn and Pompe's disease, DNA sire assignment, genomic breed composition, imputation and single-step genomic evaluation. Phenotypically polled young males were harvested from the commercial tier and through the program, high genetic merit polled animals were eligible for promotion to the multiplier and nucleus tiers of the breeding program. The application of multiple genomic technologies will allow the rapid introgression of polledness into this population without compromising the composite breed composition, breeding program structure, future genetic progress or genetic diversity.

Introduction

Surgical removal of horns from beef cattle (called dehorning) is becoming an animal welfare and management issue, and is associated with increased calf losses. Dehorning of calves improves safety of both cattle and people during handing and reduces the risk of bruising to cattle. Pain mitigation strategies are available, however there is a permanent alternative to dehorning through genetic selection, though the speed at which it can be achieved may be slow for breeds with low gene frequency for the polled allele. This is the challenge facing the breeding program of The North Australian Pastoral Company (NAPCO) that developed its own composite breed in an extensive northern Australian production environment. The breeding program is closed and relies on retained heterosis, especially for adaptation and reproduction traits. NAPCO is a vertically integrated operation, retaining ownership and management from breeding to slaughter, including a short phase in the company's feedlot prior to slaughter. The foundation breeds were horned and therefore the opportunity to change from within the nucleus tier would be very slow and there is a risk of increased inbreeding, loss of genetic diversity, change of breed composition and slower genetic progress. Selection occurs based on a defined breeding objective, however there is increasing demand to make the composite genetically polled. The Polled Accelerator (PA) program is addressing this breeding challenge through the use of new and emerging genomic tools to enable the rapid increase in polled allele frequency, without compromising the original composite breed makeup, existing genetic merit, future progress or diversity while maintaining manageable levels of inbreeding.

Materials & methods

The cattle used were a composite beef population developed at Alexandria Station, a 1.6M ha property on the Barkly Tableland region of the Northern Territory in northern Australia. The Alexandria Composite (AC) development commenced in 1982 with the crossing of the foundation breeds of Shorthorn to Brahman, and was followed by crossing those progeny with Charbray and Belmont Red (Kowald 2019). The composite was closed in 1990 and has been *inter se* mated since for 5-6 generations in the nucleus tier, resulting in a theoretical stabilised composition of 3/8 Brahman, ¼ Shorthorn, ¼ Belmont Red, 1/8 Charolais.

Breeding structure. A classical pyramid breeding design was implemented, with a nucleus (approx. 1,200 cows), a bull multiplier (BM) tier (approx. 2,500 cows) and a commercial tier comprising of approximately 50,000 cows. The initial composite development program and subsequently all 3 tiers of the breeding program have been run in the same location.

Performance recording and genetic evaluation. Intensive recording and genotyping occurs in the nucleus tier with approximately 1000 calves born per year. Recording includes: date of birth, birth weight, weaning weight, 400d and 600d weights, flight time, cow weight, carcase scanning, feedlot performance test, scrotal circumference and days to calving, and recently feed intake and abattoir carcase traits. Data is analysed through AC BREEDPLAN evaluation with genetic parameters and adjustment factors estimated from their own data. The evaluation is full multiple-trait, and recently transitioned to a single-step evaluation (Johnston et al. 2018) using a genomic relationship matrix (GRM) with 10,131 genotyped individuals from the nucleus tier.

Sourcing polled commercial bulls and heifers. During annual branding muster of the commercial herd, structurally sound and phenotypically polled males and females were retrieved, (males remained entire) and DNA samples taken. A total of 1,036 males (termed AC_PA animals) and 1,604 females (termed polled AC_BM breeders) were initially retained in the first two years of the program.

DNA testing. Genotyping AC nucleus animals has been occurring for more than a decade using a range of commercially available SNP chips. AC_PA and recent nucleus cohorts were genotyped and tested for polled/horn (PP, PH, HH) and Pompe's disease. All SNP genotypes were processed through the BREEDPLAN genomic pipeline (Connors et al. 2017) and all genotypes are imputed to a common density using an AC reference with 800K genotypes.

Genomic breed composition. SNP frequencies for AC were used to genomically define breed composition using the procedure described by Borner (2017). Principal component analyses were undertaken to compare the AC to the foundation breeds (viz: Brahman, Shorthorn, Belmont Red and Charolais) and the AC_PA individuals.

Single-step evaluation and selection of AC PA males. AC_PA genotypes were processed through the genomic pipeline and those that could be matched, passed SNP QC, and were >80% related to the AC genomic reference, and which were PP or PH, were included in AC BREEDPLAN single-step evaluation through their inclusion in the GRM (n=421). This generated the full suite of EBVs and AC specific BreedObject selection index ($EBV) for the AC_PA subsets of PP and PH animals, which could be selected based on direct comparisons with all 2018 born nucleus animals (NU18).

Transition of the BM tier from horned to polled. The retained young females (polled AC_BM breeders) were selected as the foundation of a new BM herd. While the contribution of these females to increasing the rate of genetic progress will be limited, their role in introducing polled alleles to the breeding program is valuable. Over a period of 6 years, the existing BM females (which are predominantly horned) will be superseded by polled AC_BM breeders. Only polled sires are selected for mating to the polled AC_BM females and these are sourced from the nucleus tier and AC_PA cohort.

Results

Genomic breed composition of AC is presented in Figure 1a and show AC is a distinct population with the first principal component differentiating on the basis of Brahman versus Charolais and Shorthorn. AC_PA

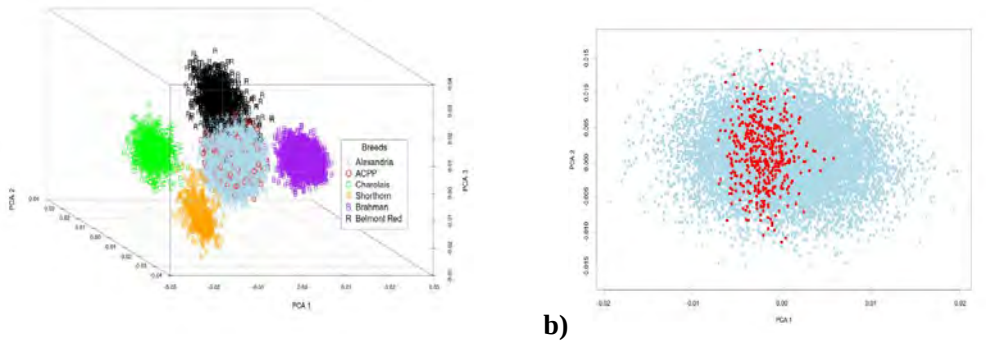

Figure 1. Principal Component analyses (a) AC and foundation breeds and (b) AC (blue) and AC_PA (red)

individuals ranged in genomic breed composition from 40-93% with 69% greater than 80% threshold and are shown in Figure 1b.

Of the 421 AC_PA eligible for inclusion in the GRM, a total of 117 were PP and 304 were PH. The frequency of polled in the NU18 was 11% with only 5 PP bulls in total. Summary statistics for $EBV (Table 1) and key EBVs and accuracies (Table 2) show the EBVs for the two groups of AC_PA (i.e. PP and PH) were similar but lower than NU18, clearly showing the commercial tier animals were genetically inferior. Long term genetic trend of 0.9 kg 600d/yr suggesting the AC_PA animals were genetically about 16 years (or 3 generations) behind the nucleus tier. However, there is considerable spread in AC_PA with a total of 16 and 28 bulls with average or above $EBV and 600d EBV, respectively.

Discussion

The PA program has identified commercial males that could be promoted to the nucleus tier to increase frequency of polled in the AC. The lower average genetic merit and differences in foundation breed percentage highlighted the risk to the program of simply promoting a polled commercial animal to the nucleus. The use of elite AC_PA will still give up some selection differential compared to using top nucleus (horned) bulls but that would likely change if polled was included in $EBV with a high economic value. Also, the AC_PA have lower individual accuracies but this risk could be minimised by using a syndicate of AC_PA selected bulls. AC_PA could be used directly in the nucleus tier (especially PP) but could also be used in the polled BM to increase the number of PP bulls introduced to the commercial tier, resulting in an immediate reduction in horn phenotype (polled being dominant) even though the commercial cow herd would remain predominantly horned in immediate future generations.

Table 1. Summary statistics for self-replacing Index ($EBV) for the 3 groups.

Group[1]	N	Mean	Std	Min.	Max.
PP	117	16.6	8.2	-6.6	40.6

[1] BW=birth weight; 600d=600 day weight; DC=days to calving; SC=scrotal circumference.

[2] PP=AC_PA homozygous polled; PH=AC_PA heterozygous polled; NU18=Nucleus 2018 born animals.

The PA program highlights the potential risk of simply introducing outside genetics; it could result in a change to the breed composition with no guarantee of improving genetic merit. Depending on the breed of outside genetics chosen, there could also be consequences for progeny adaptation as well as the logistical challenge of sourcing sufficient numbers for such a large herd. There is an opportunity to use mate allocation algorithms to optimise the use of AC_PA animals and to manage potential inbreeding. Gene flow analyses could be used to model the increased polled allele frequencies and to explore where the use of AC_PA animals would have the greatest benefits. EBV accuracies of future AC_PA animals could be increased by expanding the reference population for key traits. Multiple genomic technologies have been exploited in NAPCO's Polled Accelerator program to address a challenge in the breeding program where a non-genomic solution would be slow and introduce additional compromises. Opportunities exist to use more genomic technologies to further increase progress towards a polled population whilst maintaining the benefits and genetic progress for this composite breed.

Acknowledgements

Authors acknowledge the contribution of NAPCO and AGBU staff for their intellectual and operational contributions. Acknowledged is the MLA funding for AGBU's R&D of single-step BREEDPLAN and ABRI for access to NAPCO databases and extracts. Special thanks to Christian Girard for running the evaluations.

Abstract

Design and optimization of modern breeding programs requires methods and software to predict response to multiple-trait and multiple-stage breeding programs based on estimated breeding values and genomic predictions. Here, we introduce and describe the ShinySelAction software for these purposes. ShinySelAction is based on the widely used software SelAction for breeding programs with discrete generations but with a more exact implementation of multiple-stage selection programs and a more direct implementation of information from genomic predictions. This software can be used by breeders to reliably compare alternative breeding programs and for investment decisions for breeding programs that include genomic information.

Introduction

In the past decades, theory to predict selection response for quantitative traits in pedigree-based multiple-trait livestock breeding programs has been well developed, validated, and implemented, for example in the software SelAction (Rutten *et al.*, 2002). SelAction uses to deterministic recursive equations that were developed based on standard quantitative genetic and selection index theory and pseudo best linear unbiased prediction (BLUP) methodology, to model changes of trait means and variance-covariance structures as a result of selection. It's aim is to predict equilibrium responses to multiple trait selection on estimated breeding values (EBV) that are obtained under the infinitesimal genetic model with consideration of the Bulmer effect but ignoring the effect of inbreeding on genetic (co-)variances. Nowadays, breeding programs are enhanced by genomic EBV (GEBV) based on genomic prediction, which provide more accurate EBV of animals at a younger age and can improve the effectiveness of breeding programs. Schrooten *et al.* (2005) and Dekkers (2007) showed how the GEBV for a trait can be incorporated in standard selection index programs such as SelAction by specifying an additional trait with heritability (close to) one and a genetic correlation with the original phenotype-based trait equal to the accuracy of the GEBV. Genetic and phenotypic correlations of the GEBV with other phenotype-based traits and with the GEBV of other traits were derived by Dekkers (2007). These approaches require estimates of the accuracy of GEBV as inputs, which have been derived by several. Recently, Dekkers *et al.* (2021) derived accuracies of GEBV by formulating the GEBV as an index of the standard pedigree-based EBV and a conceptual EBV based on genomic-deviated-from-pedigree relationships (DEBV). Combined with already available methods to model the accuracy of pedigree-based EBV (PEBV), this allows genomic information to be incorporated following Dekkers (2007) but using the accuracy of DEBV rather than of GEBV. Against this background, the purpose of this paper is to present and describe a computer program called ShinySelAction that extends the SelAction software to incorporate genomic information. In addition, a more exact derivation of predictions for multiple-stage selection programs is implemented.

Materials & methods

Available program code for the discrete generations option of SelAction from Rutten *et al.* (2002) was translated into Python. The user interface was implemented in Shiny from R Studio (https://shiny.rstudio.com/).

Implementation of the Bulmer effect for multiple-stage selection breeding programs was updated. In SelAction, Bulmer equilibrium parameters were derived by iterating on information available in the final stage of selection, in order to avoid multi-variate normal integrals. Because the final stage has the highest accuracy, this leads to overestimation of the reductions in genetic (co-)variances and accuracies. In ShinySelAction, exact derivations of reductions in (co-)variances of and among the index used at each stage and of true and estimated breeding values at each stage are implemented based on the moment generation function of the n-dimensional truncated multi-normal distribution, following Tallis (1961).

Genomic information is incorporated as in Dekkers (2007) by specifying genomic predictions as correlated traits with heritability (close to) one. However, following Dekkers *et al.* (2021) genomic information was incorporated based on the accuracy of DEBV, rather than that of GEBV. In the following, parameters that are required for DEBV will first be described, followed by formulation of the genetic and phenotypic correlations among DEBV for multiple traits and their correlations with the phenotype-based traits.

DEBV parameters. In ShinySelAction, parameters for genomic information that must be provided include, for each trait, the accuracy of the DEBV in selection candidates (r_{D}) and the proportion of genetic variance captured by the markers (q^2). Both parameters depend on the effective number of chromosome segments, M_e, which is a population parameter that can be derived based on empirical accuracies of GEBV and of PEBV for an available reference data set for the population, as described by Dekkers *et al.* (2021) and implemented below. The required empirical accuracies of GEBV (r_{G_r}) and PEBV (r_{A_r}) in the reference can be estimated based on available phenotypic and genotype data by leave-one-out cross-validation, following Cheng *et al.* (2021). Based on these accuracies, an estimate of M_e for the population can then be derived in the following iterative manner (Dekkers *et al.* 2021, Appendix 1):

1. Compute the accuracy of DEBV in the reference population as: $r_{D_r} = \sqrt{\frac{r_{G_r}^2 - r_{A_r}^2}{1 + r_{A_r}^2(r_{G_r}^2 - 2)}}$.
2. Set the proportion of genetic variance captured by markers for DEBV equal to 1: $q^2 = 1$.
3. Compute θ_{D_r} in the reference population as: $\theta_{D_r} = \frac{r_{D_r}^2(1 - r_{D_r}^2 q^2 h^2)}{q^2 - r_{D_r}^2}$, where h^2 is heritability.
4. Compute M_e in the reference population as: $M_e = Nq^2h^2/\theta_{D_r}$, where N is the size of the reference population.
5. Update q^2 as: $q^2 = M/(M + M_e)$, where M is the number of genotyped markers.
6. Return to step 3 until stable values for q^2 and M_e are obtained.

Accuracies of GEBV and PEBV in the reference population (r_{G_r} and r_{A_r}) for use in step 1 of the above procedure to estimate M_e can be obtained based on data (phenotypes and genotypes) from a population that is under selection and for any trait (or as the average across traits) because M_e is a population parameter that is little affected by selection and heritability of the trait, as shown by Dekkers *et al.* (2021). If a suitable reference population is not available to estimate M_e, predictions of M_e by, e.g. Goddard (2009) or others can be used.

Based on the resulting population estimates of q^2 and M_e, the accuracy of DEBV in an unselected reference population, i.e. ignoring the Bulmer effect, for a trait with base population heritability h^2 and reference size N can then be derived as follows, which is based on the correction of Bijma and Dekkers (2021) (Equation 3b) to Dekkers *et al.* (2021):

$$r_{D_r} = \sqrt{\left[1 + \theta_{D_r} - \sqrt{\left(1 + \theta_{D_r}\right)^2 - 4h^2q^2\theta_{D_r}}\right]/2h^2} \text{ with } \theta_{D_r} = Nq^2h^2/M_e$$

The accuracy of DEBV of selection candidates (=target population), r_D, depends on the accuracy of DEBV in the reference population, r_{D_r}, as derived above, and the loss of accuracy, p_{rt}, from the reference population to the target population due to recombination in each effective chromosome segment, and can be computed following Dekkers *et al.* (2021) as:

$$r_D = r_{D_r} p_{rt} = r_{D_r}(1 - 2L/M_e)^{(l_p + l_m)}$$

where L is the genome size in Morgans and l_p and l_m are the number of generations between the selection candidates and their closest paternal and maternal, respectively, ancestors in the reference population (= 1 if selection candidates are progeny of individuals in the reference population). Accuracy r_D is what is required to be entered into ShinySelAction for each trait with genomic information.

Adding genomic traits. Given the accuracy of the DEBV of selection candidates for each trait i, r_{Di}, and the proportion of genetic variance explained by markers for trait i, q_i^2 (typically assumed the same for each trait), genomic information is incorporated into ShinySelAction by adding the DEBV as genetic traits with heritability equal to 0.999. Following Dekkers (2007), the expanded genetic correlation matrix can then be derived as follows for a 3-trait example:

	BV_1	BV_2	BV_3	$DEBV_1$	$DEBV_2$	$DEBV_3$
BV_1	1	r_{g12}	r_{g13}	r_{D1}	$r_{g12} r_{D2}$	$r_{g13} r_{D3}$
BV_2	r_{g12}	1	r_{g23}	$r_{g12} r_{D1}$	r_{D2}	$r_{g23} r_{D3}$
BV_3	r_{g13}	r_{g23}	1	$r_{g13} r_{D1}$	$r_{g23} r_{D2}$	r_{D3}
$DEBV_1$	Symmetric			1	$r_{g12} r_{D1} r_{D2} / q_1 q_2$	$r_{g13} r_{D1} r_{D3} / q_1 q_3$
$DEBV_2$				$r_{g12} r_{D2} r_{D1} / q_2 q_1$	1	$r_{g23} r_{D2} r_{D3} / q_2 q_3$
$DEBV_3$				$r_{g13} r_{D3} r_{D1} / q_3 q_1$	$r_{g23} r_{D3} r_{D2} / q_3 q_2$	1

which can be computed using the following direct product (∘) of matrices:

$\begin{matrix} 1 & r_{g12} & r_{g13} \\ r_{g12} & 1 & r_{g23} \\ r_{g13} & r_{g23} & 1 \end{matrix}$	$\begin{bmatrix} 1 & r_{g12} & r_{g13} \\ r_{g12} & 1 & r_{g23} \\ r_{g13} & r_{g23} & 1 \end{bmatrix} \circ \begin{bmatrix} r_{D1} & r_{D2} & r_{D3} \\ r_{D1} & r_{D2} & r_{D3} \\ r_{D1} & r_{D2} & r_{D3} \end{bmatrix}$
	$\begin{bmatrix} 1 & r_{g12} & r_{g13} \\ r_{g12} & 1 & r_{g23} \\ r_{g13} & r_{g23} & 1 \end{bmatrix} \circ \begin{bmatrix} 1 & r_{D2}/q_2 & r_{D3}/q_3 \\ r_{D1}/q_1 & 1 & r_{D3}/q_3 \\ r_{D1}/q_1 & r_{D2}/q_2 & 1 \end{bmatrix}' \circ \begin{bmatrix} 1 & r_{D2}/q_2 & r_{D3}/q_3 \\ r_{D1}/q_1 & 1 & r_{D3}/q_3 \\ r_{D1}/q_1 & r_{D2}/q_2 & 1 \end{bmatrix}$

Similarly, the block of phenotypic correlations between BV and DEBV (upper-right block) can be computed as:

$$\begin{bmatrix} 1 & r_{g12} & r_{g13} \\ r_{g12} & 1 & r_{g23} \\ r_{g13} & r_{g23} & 1 \end{bmatrix} \circ \begin{bmatrix} r_{D1} & r_{D2} & r_{D3} \\ r_{D1} & r_{D2} & r_{D3} \\ r_{D1} & r_{D2} & r_{D3} \end{bmatrix} \circ \begin{bmatrix} h_1 & h_1 & h_1 \\ h_2 & h_2 & h_2 \\ h_3 & h_3 & h_3 \end{bmatrix}$$

Note that phenotypic correlations among DEBV are the same as their genetic correlations.

Results & discussion

The approach described enables prediction of response to selection in multi-trait breeding programs with genomic prediction. This is essential for the design and optimization of most modern livestock breeding programs. The multi-variate normal infinitesimal genetic model is assumed but changes in genetic (co-) variances among traits as a result of the Bulmer effect are considered. The effects of inbreeding on genetic

(co-)variances are, however, ignored, such that an equilibrium is reached in terms of genetic parameters and response to selection, following Rutten *et al.* (2002). This equilibrium response is a crucial outcome for comparison and optimization of breeding programs, along with the rate of inbreeding that the breeding program generates. The approach is based on the methodology implemented in the SelAction software of Rutten *et al.* (2002) but with a more exact implementation of the Bulmer effect for multiple-stage selection.

The developed approach implements information from genomic predictions by considering them to be correlated phenotypes for genetic traits that are also assumed to follow the infinitesimal genetic model but with heritability equal to one, following Schrooten *et al.* (2005) and Dekkers (2007). Key input parameters for incorporating genomic predictions are their accuracy and the proportion of genetic variance explained by the markers. Both depend on M_e as a key population parameter, which can be derived as described by Dekkers *et al.* (2021) and summarized in this paper. The approach was validated using simulation in Dekkers *et al.* (2021).

In the proposed approach, the accuracy of DEBV is derived based on a pre-determined reference population size. This does not take into account that, in an ongoing breeding program, the reference population size increases over generations. Assuming a constant size of the reference population may, however, be realistic because there is evidence that data from older generations do not contribute much information to current GEBV and may even reduce their accuracy (Weng *et al.* 2016, Howard *et al.* 2018, Hidalgo *et al.* 2021).

Future developments include allowing for groups of selection candidates with different amounts of information, beyond male versus female selection candidates. This will allow the modelling of breeding programs where not all selection candidates are genotyped or not all selection candidates are phenotyped for all traits.

Abstract

Crossbreeding is the most common breeding system for pigs and poultry, but not for dairy cattle. When selecting purebred lines for crossbred performance, it becomes possible to take advantage of both breed complementarity and heterosis. In this paper, we present a new structure of dairy cattle breeding with the aim to improve crossbred performance in production cows. The structure of the dairy sector can be organised like a pyramid with nucleus herds, multiplier herds, and production herds. Genetic improvement of purebreds takes place in the nucleus. Surplus females from the breeding nucleus are transferred to the multiplier level, where they are used as dams of crossbred animals for production herds. In addition, we hypothesise that joint breeding planning and formulation of breeding goals for each parental breed are necessary in order to optimise crossbred performance.

Introduction

Crossbreeding is the most common breeding system for pigs and poultry. During the last decades, crossbreeding has also increasingly been used in dairy cattle (Clasen, 2021), primarily because of better profitability of crossbred cows due to heterosis for important production and functional traits (Sørensen *et al.*, 2008). Until now, crossbreeding systems in dairy cattle, such as two- or three breed rotational crossbreeding or terminal crossbreeding have only been managed at herd level. To our knowledge, no breeding organisation selects their purebred lines specifically for crossbred performance (CP) and no crossbreeding programs are coordinated at sector level. When purebred lines are specialised to be used in crossbreeding programs, it becomes possible to take advantage of both breed complementarity and heterosis to improve performance of crossbred production animals. Breed complementarity means that the traits of the two breeds complement each other. Breed complementarity may be especially large when traits are unfavourably correlated, such as between milk yield and resistance to mastitis or milk yield and reproduction traits. The use of specialised sire and dam lines as typically used in pig and poultry breeding (Smith, 1964), could previously not be applied for dairy cattle to the same extent because nearly all female offspring were used as replacements due to the low reproduction rate of cattle. Today, the use of sexed semen and multiple ovulation embryo transfer allow for a change of dairy cattle breeding into a multi-layer structure similar to what is found in poultry and pig breeding. Currently, the organisation of dairy cattle breeding is primarily carried out with the purpose of improving the genetic level of purebred populations. Therefore, AI bulls used in crossbred herds can only be selected among AI bulls that are already selected for use in purebred herds. A change in the structure of dairy cattle production at herd and sector level will make it possible to exploit crossbreeding in a better and more efficient way.

In this paper, we present an idea for a new structure of dairy cattle breeding, with the aim to improve CP in production cows. We argue that a multilayer structure as typically seen in pigs and poultry can improve the competitiveness of the dairy sector by utilising the full potential of crossbreeding between dairy breeds.

A new dairy breeding structure

The structure of the dairy sector can be organized like the pyramidal structure in pig breeding with nucleus herds, multiplier herds, and production herds (Figure 1).

At the top of the pyramid are the nucleus herds where genetic improvement of the pure breeds takes place. The population sizes of the nucleus herds need to fulfil the requirements for genetic gain given an acceptable level of inbreeding. The breeding scheme in the nucleus herds rely on intensive use of ovum pick-up on young heifers that are selected based on genomic breeding values to increase selection intensity and decrease generation interval. Surplus females from the nucleus herds are transferred to the multiplier herds, where they are used as dams for production of F1 animals. The multiplier herds must be able to deliver enough F1 females to meet the demands from production herds. The demand for F1 females can be reached through intense use of embryo flushing of purebred donors with sexed semen from another dairy breed to produce F1 embryos. Recipients for the embryos will be F1 heifers, which are reared within the multiplier herds. The F1 heifers calve in the multiplier herds and are hereafter sold to the production herds as soon as possible. An alternative is to produce F1 embryos in the nucleus herds, while the recipients remain in the multiplier herds. In that case, management tasks will be more specialized at each level. In either case, the production herds will consist of F1 females and will not be producing their own replacement animals. Instead, all F1 production cows, except if they need to be contracted by the multiplier herds as recipients, are inseminated with beef semen from a terminal beef sire line suited for production of beef on dairy calves (Hjortø, personal communication). Taking this approach, dairy producers in the production herds can fully focus on milk production.

Such a terminal crossbreeding program can be extended by a third breed. The advantage of a three-breed crossbreeding program is to be able to combine the strength of more breeds for specific production systems.

Breeding goals. We hypothesise that joint breeding planning and setting of breeding goals for each pure breed are necessary in order to ensure that genetic levels, heterosis and complementary effects in the crossbred production animals are at the highest possible level. This will lead to higher CP relative to the present situation, where each parental breed is managed independently of the other breeds focusing on purebred performance. Even without assuming non-additive gene action for individual traits, a number of traits combined multiplicatively makes up the total economic merit of an individual. The consequence is that

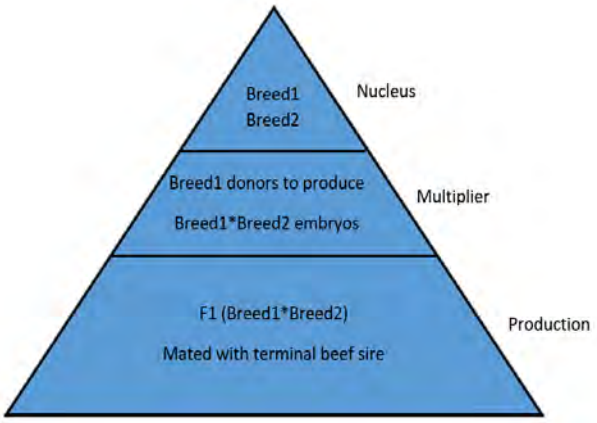

Figure 1. Structure in a terminal F1 dairy crossbreeding program with two breeds.

there is an additional crossbred superiority for total economic merit on top of the heterosis. This additional superiority is larger if the individual traits are highly different in the involved breeds. The economic value of this crossbred superiority should be quantified for the whole sector using decision support tools such as SimHerd Crossbred (Østergaard et al., 2018). In addition, economic weights to be used in breeding goals of the parental breeds need to be derived to obtain the crossbred superiority. Setting diverse breeding goals across the breeds which complement each other will increase the overall genetic diversity and sustainability of the dairy cattle populations globally, on top of creating more profitable production animals.

Breeding value estimation. In the new structure for dairy cattle breeding, the aim is to improve the performance of crossbred cows. This performance depends both on genetic merit of the traits for the parental pure breeds but also on heterosis on a given trait. Therefore, selection for CP involves both improving purebred performance and heterosis. In pig breeding, records from crossbred animals in production herds are often lacking and selection is based on performance of purebreds. On the contrary to pigs, most countries routinely register the performance of the majority of dairy cows, providing the opportunity to select purebreds directly for CP. However, Esfandyari *et al.* (2017) demonstrated that selection for CP is only favourable for a few generations. Therefore, combined selection for CP and purebred performance is expected to result in a better performance of crossbred animals in the long term compared to selection for CP only. Statistical models that utilise phenotypic information in crossbred animals to estimate both genetic merit in the purebreds and crossbreds with high accuracy are essential. In the new structure, it is assumed that the selection of purebreds is based on genomic information and crossbred animals providing phenotypes are also genomically tested.

Discussion

In this paper, we presented a new structure of dairy cattle breeding with the aim to improve CP in production cows. The large advantage with the presented structure is that dairy producers will be able to take the benefits of crossbreeding to an increased level, as parental breeds are selected with the aim of improving crossbred performance. Furthermore, producers will be able to fully focus on milk production since breeding is carried out in the nucleus herds, rearing of heifers in the multiplier herds, and fattening of the beef×dairy offspring by meat producers. The presented structure can however only succeed in a cooperative organisation where the parental breeds are managed together and follow the breeding goals set to optimize crossbred performance. These breeding goals may not be the most optimal in case each of the pure breeds are used for commercial production. That is why the number of animals in the nucleus need to be minimized given the constraint on acceptable genetic gain. Whether or not such a breeding program will be economically feasible will depend on the number of production cows in the crossbreeding program, and on the extra economic gain that can be obtained by using breeding material from pure breeds selected for crossbred performance instead of breeding material from pure breeds selected for purebred performance. The program will be economically feasible if the cost of running such crossbreeding programs will be lower than the extra gain obtained in the production herds due to increased heterosis and improved complementarity from having lines suited for crossbreeding. It needs to be investigated how much extra heterosis is necessary to justify the costs of the breeding scheme, proposed in this paper. In addition we need to estimate how large the crossbred production population needs to be to be able to pay for the extra cost given different levels of increased heterosis and breed complementarity to be achieved. Another advantage of the presented program is increased breed and genetic variation, which may be of value for the future. All these questions are to be answered in the Danish project DairyCross supported by the green development and demonstration programme (GUDP) from the Danish ministry of food, agriculture and fisheries DairyCross project supported by the green development and demonstration programme (GUDP) from the Danish ministry of food, agriculture and fisheries (J. nr. 34009-18-1365). https://qgg.au.dk/projekter/projektdeltagelse/dairycross-krydsning-optimering-paa-tvaers-af-malkeracer/

Abstract

As the number of discovered loci carrying undesirable alleles continues to increase, culling carrier animals is not an option. Thus, we used a method that derives a genetic value for each genotype at a given locus. Using stochastic simulations, we assessed various strategies for a goat breeding program that combined two selection criteria used in a preselection step and four mating strategies between sires and dams to produce candidates for artificial insemination. Even without a strategy dedicated to reduce undesirable allele frequency, lethal alleles were purged and their frequencies slowly decreased whereas the average frequency of non-lethal alleles remained constant. Using, in a preselection step, an index including the genetic values for loci likely to carry an undesirable allele, was an efficient alternative to reduce the frequencies of non-lethal alleles and gave higher decrease for lethal alleles frequencies. After selection, the ability to control the frequencies of undesired alleles was similar across mating strategies. However, some mating strategies, based on optimizing an objective function including at least genetic values and increased inbreeding, enable to reduce undesired alleles at no or small cost for both genetic gain and increase in inbreeding.

Introduction

In sheep and goat selected populations, the number of discovered loci carrying undesirable alleles is growing, both including lethal (e.g. Ben-Braiek *et al.*, 2021) and non-lethal (e.g. Martin *et al.*, 2016) alleles. The control of known undesired alleles can be operated at a preselection step by culling carrier animals. This method becomes difficult to adopt due to the increase in the number of undesired alleles to be included. A selection criterion that incorporates both the estimated genetic values for selected traits and a set of genetic values associated to genotypes at these specific loci can be applied (Boichard *et al.*, 2016). The undesirable effects can also be controlled by optimizing mating strategies to avoid producing homozygous carriers as in Cole (2015). In French goat breeding programs, only a few matings are optimized at the individual level, i.e. those to produce male candidates for artificial insemination (AI).

Focusing on a breeding program for goats, we performed stochastic simulations to assess the annual genetic gain, the increase in inbreeding and the control of undesired alleles (known and unknown i.e. genotyped and not genotyped) according to various designs combining a preselection step and strategies to select and optimize matings that produce male candidates for AI. Two cases have been separately considered: lethal and non-lethal alleles.

Materials & methods

Using a stochastic model, we mimicked the Saanen goat breeding program of the French Breeding Society Capgenes, where around 70, 000 females divided in 196 flocks are recorded each year for a maternal trait.

To set up a reference population for genomic selection we first applied a classical design based on the progeny testing of AI sires over 10 years. The next fifteen years, we applied eight different genomic breeding program designs (2 types of selection index × 4 mating systems). The male candidates, elite dams and elite AI sires were selected based on: (1) on GEBV; or (2) an index *ISp* that combines GEBV and genetic values at five specific loci potentially carrying undesired alleles (*R*).

CC BY

DOI: 10.3920/978-90-8686-940-4_440, © J. Raoul *et al.* 2022

For an individual i, $ISp_i = \alpha GEBV_i + \sum_{r=1}^{R} \hat{\beta}_{rg_i}$ where α denotes the relative emphasis put on both the selection trait and allele management, and $\hat{\beta}_{rg_i}$ the genetic value associated to the locus r given the genotype g of the individual i.

As proposed by Boichard *et al.* (2016), $\hat{\beta}_{rg}$ is $2f^2c_r$, $-f(1-2f)c_r$ and $-2f(1-f)c_r$ for $g = ++$, $g = m+$ and $g = mm$, respectively. Where f denotes the frequency of the deleterious allele m, and c_r the cost associated to the genotype mm. These genetic values assume that m is recessive.

Then, we considered 4 mating systems between elite dams and sires that produce male candidates for AI:

1. Elite dams and sires were randomly mated (RAND)
2. Elite dams and sires were mated according GEBV (assortative mating) but matings between animals with a common grandparent were excluded. (AM)
3. Matings were designed based on an objective function OFP_{ij} including the GEBV of a dam i and an elite sire j and and their kinship coefficient F_{ij} (from Pryce *et al.*, 2012): $OFP_{ij} = 0.5(GEBV_i + GEBV_j) - \lambda F_{ij}$, where λ is a penalty coefficient (arbitrarily set to 0.1) and F_{ij} is the pedigree-based inbreeding coefficient of the offspring resulted from mating dam i and elite sire j.
4. Matings were designed based on the previous objective function plus the probability that a mating between a dam i and elite sire j produces an homozygous carrier $g = mm$ for the locus r (from Cole *et al.*, 2014): $OFC_{ij} = OFP_{ij} - \sum_{r=1}^{R} P(g = mm)_{ij,r} \times c_r$.

In a first approach all c_r were arbitrarily set to 1 for all loci r (genetic values and *OFP*).

In (3) and (4), a score based on the objective function was computed for all potential matings between elite AI sires and female candidates for AI (around 80% of adult females). Then 1,050 matings were sequentially selected based on the best score and under constraints (one female is mated with only one male and a maximum of 3,000 females per male are inseminated along his reproductive life).

In addition, to assure the replacement of females, 46% of the breeding females were selected on (G)EBV and mated to an AI sire. Other females and females that did not conceive with AI (fertility after AI was set to 60%) were mated to a natural mating sire. Natural mating sires were all self-replaced within flocks and born from AI sire. The number of progenies per dam depended on the mode of reproduction and parity. Some dams were randomly culled after each reproductive cycle and the maximum parity was five. Around 30% of dams were replaced per year by females that were preferentially chosen among newborn progeny from AI matings. No selection step was considered for newborn females before they were mated.

We simulated individuals and their genome based on a real goat 50 K SNPs chip, as in Raoul *et al.* (2017). In addition, we simulated 5×2=10 loci (5 known and 5 unknown) with a starting frequency respectively equal to 1, 4, 7, 10 and 13%. These loci are independent (no linkage disequilibrium) from the rest of the genome (i.e. 50 K SNPs). Within simulations, undesirable alleles are all lethal (homozygous carriers were stillborn) or all non-lethal (no effect on fitness). In both cases, they did not have any effect on the main selected maternal trait (h^2=0.3, rep=0.5). The model included: (1) the establishment of the founder population; (2) the simulation of 1000 QTL picked from the 50K SNPs and their effect drawn from a Gamma distribution; (3) the simulation of phenotypes and genotypes based on the 50K SNP panels (SNPs selected as QTL were excluded from genotypes); (4) and the estimation of both breeding values and pedigree inbreeding respectively. The last estimations were performed with single step GBLUP using the Blupf90 software developed by Misztal *et al.* (1999) and inbupgf90 software developed by Aguilar *et al.* (2008).

The annual genetic gain ΔG and annual increase in inbreeding ΔF were estimated as the regression slope of the average true breeding value and inbreeding coefficients of first parity females on time for years 10 to 25,

respectively. As well the annual decrease in frequency for known (i.e. genotyped) Δf_k and unknown (i.e. not genotyped) Δf_u loci were estimated from years 10 to 25 and averaged across known and unknown loci separately. The means and standard deviations presented are based on 30 replicates.

Results

Figure 1 gives the annual genetic gain ΔG, increase in inbreeding ΔF and changes in the frequencies of known Δf_k and unknown Δf_u alleles according to 8 breeding strategies. In Figure 1a (lethal alleles) we observed that the selection based on *ISp* gave faster decrease in known undesired alleles frequencies than GEBV only, regardless of the mating design. The frequencies of unknown lethal alleles decreased in all breeding strategies without significant differences on average across breeding strategies. The frequencies tended to converge below 6% at time 10 and below 5% at time 25 for GEBV based strategies (results not shown). For *ISp* based strategies, the trend is the same until time 10 but the frequencies of genotyped lethal alleles tended to converge below 2% at time 25 (results not shown). No significant difference across strategies was observed for the frequencies of ungenotyped alleles. For non-lethal alleles we observed on Figure 1b that ungenotyped alleles are subject to genetic drift and their frequency remains, on average across loci, constant over time. For genotyped alleles, decrease in frequency is significantly higher for *Isp* than GEBV strategies regardless of the mating optimization. The decrease in frequency of the undesired allele at specific loci is poorly influenced by the mating system. We observed a slightly better result for OFP

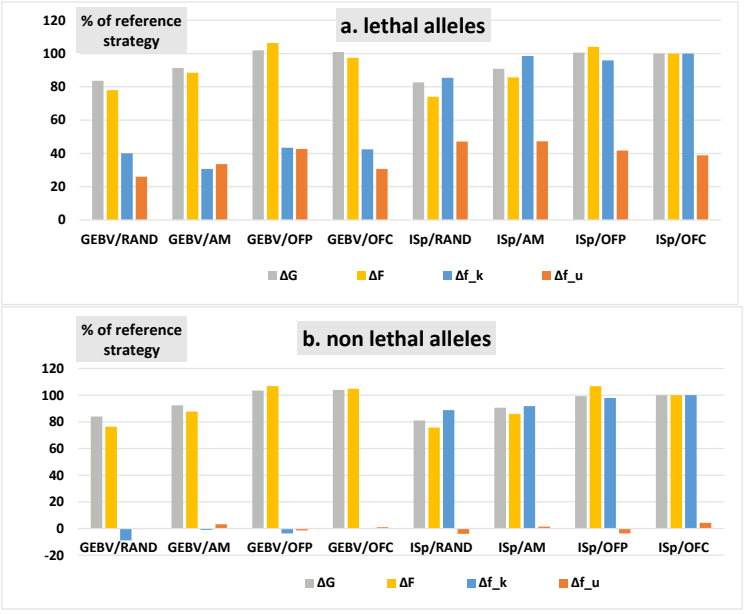

Figure 1. Annual genetic gain (ΔG), increased in inbreeding (ΔF) and changes in the frequencies of known (Δf_k) and unknown (Δf_u) alleles according to the selection criteria × mating design (30 replicates) for lethal (a) and non-lethal (b) alleles. ΔG, ΔF and both Δf_k and Δf_u are respectively expressed as the % of ΔG, ΔF and Δf_k obtained for the reference strategy = ISp/OFC. a. Reference strategy: ΔG=0.180 σa, ΔF=0.33% per generation, Δf_k = -0.15% per year. b. Reference strategy: ΔG=0.179 σa, ΔF=0.32% per generation, Δf_k = -0.38% per year. Selection criteria: GEBV or *ISp* (index combining GEBV and genetic values at five specific loci potentially carrying undesired alleles). Mating designs: RAND (random mating), AM (assortative mating), OFP (objective function including GEBV and penalty to F), OFC (OFP + penalty to probabilities to produce homozygous carriers at five specific loci potentially carrying undesired alleles).

and OFC compared to RAND and AM for non-lethal alleles (significant) and even smaller differences for lethal alleles (non-significant). Avoiding the production of homozygous individuals at specific loci had no or a small effect on the control of the allele frequencies. However, the optimization of matings had significant consequences on the genetic gains and the increase in inbreeding. OFP and OFC gave higher ΔG (but also higher ΔF) than RAND and AM. A better adjustment of λ (penalty coefficient applied to ΔF in OFP and OFC strategies) would be necessary to fairly compare ΔG across strategies.

Discussion

These preliminary results show that including a genetic value at specific loci is an efficient alternative to reduce their frequencies in a goat breeding scheme especially for non-lethal alleles. The genetic architecture simulated in this study, based on an independent segregation of specific loci and other markers as well as the use of a penalization on a pedigree based ΔF, do not enable to assess the apparent contradiction between a general maximization of the SNP heterozygosity and the fixing of favourable alleles at the level of specific loci and QTLs. To go further it is necessary to simulate specific loci which are in linkage disequilibrium with markers and QTLs, use a penalization on a genomic based ΔF and analyse the sensitivity of the result to the value of both λ and c_r.

441. Prediction of gametic variance and its use in bovine breeding programs

C. Hozé[1,2*], A. Baur[1,2], S. Fritz[1,2] and D. Boichard[2]

Abstract

With genomic selection, gametic variance has been of increasing interest for breeding top animals. Two gametic variance estimates based on SNP effects estimated in 2018, were obtained deterministically and by simulating progeny. They were compared with each other, with the variance of the genomic breeding values of real progeny in fall 2020, and with the variability of the phenotypes of the female offspring. As expected, both predictors of gametic variances were similar, provided that the number of simulated progeny is large enough (500). The correlation between those predictors and gametic variances observed on real progeny was rather high, although limited by the number of offspring available. The correlation between the gametic variance of the sires and the phenotypic variance ranged from 0.14 to 0.85 (mean=0.33) according to the heritability of the trait. Gametic variance is useful to select parents of future bulls, but its potential to control phenotypic variability is more limited.

Introduction

Since its implementation in France in 2009, genomic selection has had a tremendous development, all bulls are genomically evaluated and more and more females are genotyped annually. Young bulls are selected on the basis of their genomic values among a large number of male progeny of bull sires and bull dams. Under the polygenic model, gametic variances of each parent or, equivalently, the Mendelian sampling (MS) variance of the progeny depend only on inbreeding F_s and F_d of the parents [$Var(MS) = 0.5\ \sigma_g^2\ (1 - 0.5\ F_s - 0.5F_d)$] and is constant without inbreeding. In genomic selection, not only the MS term of the progeny can be predicted but also the gametic variance of each parent, provided that SNP effects and genotype phases of the parents are known. According to the large investments necessary to select the very best young bulls (matings, genotyping, embryo production and transfer), it is essential to maximize the probability to generate and find them. This probability depends not only on the genetic merit of the parents but also on their gametic variance. As already shown in the literature, gametic variance is of major importance when breeding top animals (Bijma *et al.*, 2020; Segelke *et al.*, 2014). However, in spite of its increasing interest, little investigation was done on its practical prediction and use. In this study, we (1) compared two approaches to predict the gametic variance of the genotyped parents; (2) investigated the impact of gametic variance in the selection success of candidates; (3) compared the predicted gametic variances with the variance of genomic breeding values of real genotyped progeny, and (4) with the phenotypic variability of the daughters. In this validation procedure, SNP effects were estimated in French Holstein population with the information available in June 2018 and genomic breeding values and phenotypes of progeny were those available in fall 2021.

Materials & methods

Population studied. We used genotypes and breeding values for 426 widely used bulls in Holstein breeds born between 1991 and 2016. Bulls were selected to have more than 200 daughters with morphology phenotypes, 1000 daughters with lactation phenotypes and 500 genotyped progeny. Genotypes of sires were obtained with different Illumina chip platforms with at least 50K SNPs, and imputed and phased with Fimpute3 software (Sargolzaei *et al.*, 2014).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_440, © C. Hozé *et al.* 2022

SNP effects were obtained from the French national genomic evaluation (Boichard *et al.*, 2012) computed in June 2018. These effects were used as input for simulation software and gametic variability prediction. Five production and 10 morphological traits were studied.

Simulation procedure and prediction of gametic variance. Two different approaches were used to predict the gametic variance of each bull. The first one was based on simulation (Segelke *et al.*, 2014). For each bull mated to one simulated fully homozygous dam, 500 progeny were simulated. For each progeny, segregations were randomly sampled and recombinations were simulated assuming 1cM corresponds to 1 Mbase. Progeny direct genomic value was obtained by combining the SNP effects with its genotypes. The MS variance was estimated by the variance of the DGV (direct genomic value) of the 500 progeny. Because SNP effects are estimated with an accuracy lower than 1, the MS variance was underestimated.

The second approach is the one described by Santos *et al.* (2019). The gametic variance (V_{theo}) of each sire was predicted from the contrasts within loci with the following formula:

$$V_{theo} = 0.25 \left[\Sigma_i \alpha_i^2 + 2 \Sigma_i \Sigma_{j>i} \alpha_i \alpha_j (1 - 2r_{ij})\right] \quad (1)$$

where: α_i is the signed contrast between effects of the paternal and maternal alleles for marker i, and r_{ij} is the recombination rate between markers i and j. Recombination rate was assumed equal to 0.5 across chromosomes.

DGV and yield deviations (YD) obtained from the French National evaluation run computed in November 2021 were used to validate gametic variance predictions on real data. YD were performances of the female offspring adjusted for fixed effects of the evaluation model and dam genetic merit. For each sire, we computed the variance (V_{obs}) of DGV of progeny genotyped after 2018. The phenotypic variance (V_{yd}) was obtained by computing YD variance. Due to the increase in reference population size and change in French evaluation model (especially change in imputation results due to switch from UMD3 to ARS-UCD1 assembly), markers and haplotypes effects might differ between June 2018 and November 2021, allowing us to test the robustness of our predictors.

Results

Comparison of gametic variance predictions. The predicted and simulation based gametic variances were very similar, with the same mean, very close standard deviations, and correlations in the [0.82-0.94] interval. A larger number of simulated progeny would probably have led to higher correlations. Therefore in practice, the deterministic approach is preferable because it is more accurate and faster to compute. But simulations can be a more flexible tool especially to study covariations between traits or more complex genetic determinisms with dominance or epistasis.

The same indicators computed with 2021 SNP estimates were consistent with those of 2018, showing a good conservation of SNP effect: the correlations between V_{theo} in 2018 and 2021 ranged from 0.87 to 0.99 according to traits. Correlations are presented on Table 1.

Heterogeneity of gametic variance between bulls. Gametic variances observed on real progeny DGVs (V_{obs}) varied widely between sires and ranged from simple to triple for most traits. This is much more than expected under the polygenic model. Figure 1 shows the distribution of V_{obs} for fat content (left) and stature (right). Differences were particularly large for fat content due to the effect of DGAT1 major gene, and lower but still important for stature with most values ranging from 0.3 to 0.9. This large variability of gametic variance observed across animals highlights its interest when breeding top animals. Assuming

[1] Theoretical gametic variance computed either in November 2021 (Vtheo_Nov21), Simulated gametic variance computed either in November 2021 (Vsim_Nov21) or June 2018 (Vsim_June18), Observed gametic variance computed in November 2021 on DGV (Vobs_Nov21) or on YD (Vyd_Nov21).

these predictions are accurate and reflect true gametic variance (this depends on the accuracy of SNP effects), very good predictions of extreme deciles can be obtained, as well as the probability to obtain an elite progeny above a given threshold. For instance, for milk yield, the prediction of the 90th percentile was: P90% = 0.999 Genomic Pedigree Index + 1.29 σ_{MS} (R^2=0.99), with σ_{MS} the MS standard deviation for a given couple of parents.

Validation of predicted gametic variance. Depending on the traits, the correlations between predicted variance V_{theo} in 2018 and observed variance V_{obs} in 2021 ranged from 0.47 to 0.92 and reached 0.62 on average. Figure 2 presents these results for fat content and stature. These moderate values probably reflect both the limited number of progeny and the variability due to dams.

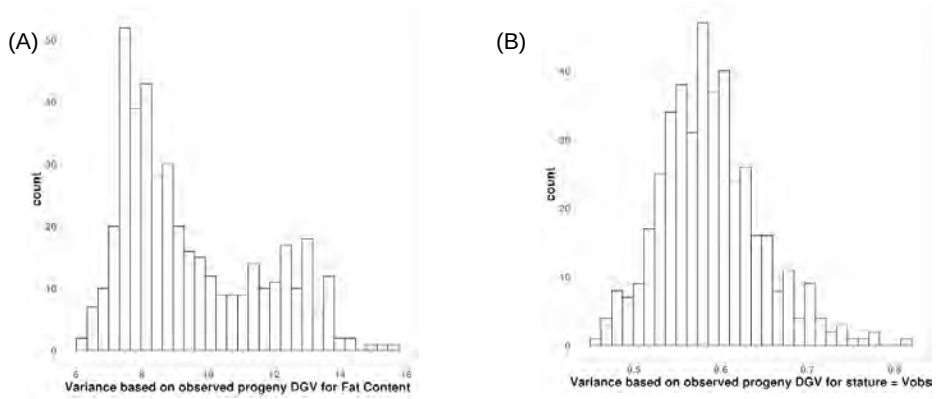

Figure 1. Distribution of progeny DGV variances (V_{obs}) for fat content (A) and stature (B).

The correlation between V_{theo} and the within bull variance of phenotypes was quite low with an average of 0.25 across traits. On the youngest animal (58 bulls born after 2015), correlations were a bit higher with an average of 0.33. Except for a high correlation for fat content (0.85), correlations were moderate for heritable traits (0.44 for protein yield or 0.38 for body depth) and as low as 0.14 for low heritability traits such as rear udder height. All correlations are presented on Table 1.

Discussion

This study in Holstein cattle breed investigates the opportunity to predict progeny variability from genotypes and SNP effects. We observed large variation in progeny variability among bulls supporting the growing interest for an indicator of gametic variability, especially in the choice of bull sires and dams to maximize the probability to conceive top ranking bulls. Validation on real data showed that the proposed theoretical indicator performed quite well to predict the genetic variability of progeny but was not accurate enough to predict the phenotypic performance variability, highly dependent on environmental factors. Computation of the theoretical predictor with Equation 1 is fast, meaning that it can be obtained routinely and used to select animals for the breeding scheme. In this perspective, development of specific selection criteria such as those developed by Bijma *et al.* (2020) is expected on a routine basis. In spite of its cost of computation, the estimation of gametic variance by simulation of progeny may also be interesting especially in complex situations, mainly in case of non-additive determinism.

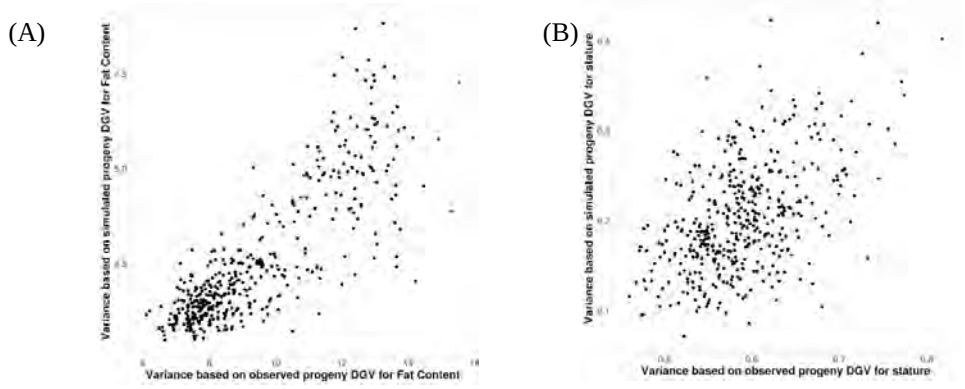

Figure 2. Relationship between DGV within sire variances for simulated and observed progeny, for fat content (A) and stature (B).

Abstract

Optimal contribution selection (OCS) is a selection method that optimises genetic gain and diversity simultaneously. It has been implemented in French dairy goat breeding programmes since 2006. When genomic evaluation was applied in 2018, genomic OCS replaced pedigree OCS, accounting for genomic coancestries and differences of GEBV accuracies between progeny tested sires and untested sires. The genomic OCS efficiency was assessed based on the actual matings scheduled in 2021. Compared to candidates, selected sires had a higher genetic level despite a lower coancestry. Contribution of untested sires was only 30-35%. The future offspring showed a high genetic level and a genomic inbreeding from 3.0 to 3.6%. The survey of the AI bucks born between 2000 and 2022 confirmed the long-term efficiency of OCS: the annual genetic gain was about 0.17 genetic standard deviation on the total merit index whereas the annual rate of inbreeding only ranged between 0.05 and 0.07%.

Introduction

The implementation of genomic selection in many species generates additional genetic gain but raises questions about its impact on genetic diversity. For a large international breed like the Holstein breed, many studies (Doekes *et al.*, 2018; Forutan *et al.*, 2018; Doublet *et al.*, 2019) showed that genetic diversity was dramatically reduced once genomic selection was introduced. OCS is a powerful method (Meuwissen, 1997) maximising genetic gain at restricted rate of inbreeding. Colleau *et al.* (2004) developed an alternative method where the coancestry rate was minimized at fixed genetic gain. In France, two main dairy goat breeds are raised: the Alpine and the Saanen breeds. A total of 600 breeders and 175,000 females is involved in both breeding schemes. Since 2018, genomic selection has been implemented with two main changes: breeding values (GEBV) have been estimated with single step GBLUP (Legarra *et al.*, 2009; Carillier *et al.*, 2014) and 5 month-old AI bucks have been eligible for selection based on their GEBV. Their GEBV accuracy is not high enough to stop progeny testing, unlike dairy cattle. The management of genetic diversity has always been a major concern for the goat breeding schemes. In 2006, pedigree OCS (Colleau *et al.*, 2004) was introduced for producing young AI bucks, born from elite sires and dams. From the start of genomic evaluation in 2018, GOCS has been implemented, accounting not only for genomic coancestries, but also for GEBV accuracies. It was due to the very lower accuracy of not yet progeny-tested sires (NT) compared to progeny tested sires (PT). The goal of this paper was first to present the principles and results of the GOCS actually implemented in the two French dairy goats in 2021. The evolution of the genetic gain and the genetic diversity of AI bucks born between 2000 and 2020 was also analysed, in order to evaluate the long-term impact of OCS.

Materials & methods

Animals involved. GOCS is applied once a year for both breeds, in order to produce the new generation of young AI bucks. The result is a list of matings between elite sires and dams. To perform the optimisation, the breeding organisation provided different datasets and information. The list of candidates dealt with ungenotyped dams (871 Alpine / 822 Saanen) and genotyped elite sires (151 Alpine/ 76 Saanen). Because GOCS should produce minimal coancestry within the pool of males likely to perform AI in the future, the

four last cohorts of young bucks (4C) born form OCS the four last years, were also considered (415 Alpine / 302 Saanen). GEBVs for the total merit index (ICC) and 16 other GEBVs were included, in reference with minimum thresholds in order to compute the number of defects for each mating. Genomic data corresponded to 2,901 Alpine and 1,980 Saanen 54K Illumina genotypes for the 46,707 SNP used in the official genomic evaluation. The overall pedigree included 41,557 Alpine and 34,678 Saanen animals.

The survey of AI bucks included 959 AI progeny-tested bucks in Alpine breed and 694 in Saanen breed, born between 2000 and 2020. For cohorts 2021 and 2022, progeny testing was not completed so that their statistics were those of the corresponding mating cohorts (about 700-750 per breed and per year). Trends in genetic gain, inbreeding and coancestry were analysed. Genetic gain was measured for ICC, expressed in σA. GEBV came from the French official genetic evaluation, performed in June 2021.

Genomic coancestry and optimisation methods. Genomic coancestries between pairs of genotyped individuals were computed according to Van Raden's method (2008). Otherwise, they were estimated by the method described by Colleau *et al.* (2017). Finally, SNP genomic coancestries and inbreeding were expressed in a converted scale, established once for all in 2018, based on data not influenced by genomic selection, as proposed by the same authors.

The optimal contributions of candidates and the corresponding mating design were computed based on the simulated annealing Monte-Carlo method (Metropolis *et al.* 1953, Kirkpatrick *et al.,* 1983). Constraints were accounted for by a constrained simulated annealing (CSA), according to the method proposed by Colleau *et al.* (2009), Chapuis *et al.* (2016). For computing optimal contributions, the corresponding CSA considered two major nuisances: the average coancestry coefficient (in a rolling window including 4C and future progeny) and the average inaccuracy (1-CD) of sires. These nuisances were expressed on a 0-1 scale from the minimum to the maximum values. Extreme values were given by dedicated CSA procedures, of course accounting for the constraint imposed for the average ICC of future progeny. Afterwards, scaled nuisances were minimized, while constrained to be equal, because considered of equal importance by the breeding organisation. The mating design basically minimized a linear function involving inbreeding coefficient and number of defects, standardized in reference to the whole variability of possible matings. A special sampling procedure was introduced to avoid extreme percentages of NT sires in the farms holding the selected dams and, thus, to increase acceptability by breeders.

Results

GOCS selected 60 sires (40% of candidates) in the Alpine breed and 37 sires (48%) in Saanen breed. Among them, about 60% were NT sires but their contribution to matings were only 39% in Alpine breed and 34% in Saanen breed. Each PT sire contributed to 19 matings, on average, in the Alpine breed and 33 in the Saanen breed, whereas NT sires contributed to 8 and 10 matings, respectively. The difference of contribution between PT and NT sires was explained by the gap of GEBV accuracy: NT sires had a much lower CD than PT sires (0.56 vs 0.90 on average). In contrast, candidate NT sires showed a genetic superiority over candidate PT sires of 1.12 ICC units (0.36 σA) in the Alpine breed and 0.70 ICC units (0.22) in the Saanen breed. Globally, GOCS selected sires (PT+NT) with a selection differential of 0.29 ICC unit (0.09 σA) in Alpine breed and 0.70 (0.22) in Saanen breed. In comparison with candidates, the average coancestry of selected sires with 4C was decreased by 15% in the Alpine breed and 9% in the Saanen breed. Table 1 shows the results for the 760 matings in the Alpine breed and 700 in the Saanen breeds. The mean ICC was fixed by the breeding organisation. The average genomic coancestry of offspring with 4C was 4.70% in the Alpine breed and 5.35% in the Saanen breed. The average genomic inbreeding reached 2.96% in the Alpine breed and 3.58% in the Saanen breed. Compared to all possible matings between selected sires and dams (before mating optimisation), the average inbreeding was reduced of 40% in the Alpine breed and 35% in

Table 1. Genetic gain, genetic diversity and number of defects of offspring.[1]

Breed	Alpine	Saanen
ICC	7.00 (0.65 / 5.57-9.93)	6.90 (0.58 / 5.58-9.04)
Inbreeding (%)	2.96 (0.57 / 1.16-4.51)	3.58 (0.63 / 1.90-5.57)
Coancestry[2] (%)	4.70	5.35
# defects	0.19 (0.43 / 0-3)	0.09 (0.31 / 0-2)

[1] Mean (standard deviation / min-max.

[2] Average genomic coancestry coefficient between offspring and 4C.

the Saanen breed. The average number of defects was very low, ranging between 0 and 3 depending on the mating. Consequently, offspring had balanced GEBV profile for all the traits.

The annual rate of inbreeding for AI bucks born between 2000 and 2022 (Figure 1) was 0.07% in the Alpine breed and 0.05% in the Saanen breed. It corresponded to an increase of 0.26% per generation in the Alpine breed and 0.21% in the Saanen breed. Before the implementation of OCS (2000-2006) the rate of inbreeding reached 0.30%/year in the Alpine breed and 0.22%/year in the Saanen breed, whereas after the implementation of POCS (2007-2018) it decreased to 0.14%/year and 0.17%/year, respectively. When focusing on the GOCS period (2019-2022), we observed that the rate of inbreeding dramatically decreased: -0.08%/year in Alpine and 0.07%/year in Saanen. The trend in annual coancestry rate was the same, decreasing from 0.01 to -0.19% in the Alpine breed and from 0.01 to -0.06% in the Saanen breed, between POCS and GOCS. The annual genetic gain on ICC was 0.165 σA in the Alpine breed and 0.169 σA in the Saanen breed during the 2000-2022 period. No major difference was observed before or after POCS. But, under the GOCS period, the preliminary results showed that the annual genetic gain substantially increased by 30% (Alpine) to 46% (Saanen).

Discussion

The implementation of genomic evaluation in dairy goat breeding programmes led to modifying OCS. Accounting for genome-based coancestries was necessary, as demonstrated by Sonesson *et al.* (2012). Otherwise, the inbreeding rate would have been underestimated. Including NT sires had contradictory

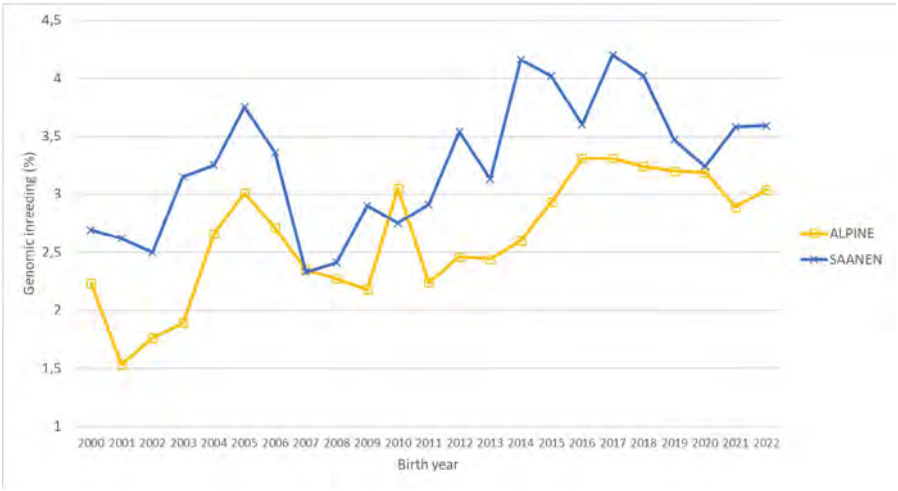

Figure 1. Genomic inbreeding trend for AI bucks between 2000 and 2022.

effects because the value of their genetic superiority for the breeding scheme was tempered by a low at-birth-GEBV accuracy. Currently, goat breeders have not been yet ready to use a high percentage of NT sires. But, the breeding organisation plans in the near future to use 60% of NT sires, still under the current GEBV accuracy, in order to reduce the generation interval. This could generate more genetic gain without decreasing genetic diversity, thanks to GOCS.

Our first results illustrated the efficiency of GOCS that combined moderate inbreeding and balanced GEBV profile of offspring, customized allocation for each NT sire while respecting desired genetic gain. Consequently, the rate of inbreeding for AI bucks remained reasonable, and much lower than in dairy cattle (Doekes *et al.*, 2018; Forutan *et al.*, 2018; Doublet *et al.*, 2019).

443. Partition in long-term contributions of the genetic trend of Basco-Béarnaise dairy sheep

S. Antonios[1*], A. Legarra[1], J.M. Astruc[2], S.T. Rodríguez-Ramilo[1] and Z.G. Vitezica[1]

[1]GenPhySE, INRAE, INPT, ENVT, 31326 Castanet Tolosan, France; [2]Institut de l'Elevage, 149 rue de Bercy, 75595 Paris, France; simona.antonios@inrae.fr

Abstract

The objective of this work was to study long-term contributions to genetic gain in Basco-Béarnaise dairy sheep breed. From estimated breeding values, contributions from males and females and from five categories were analysed. The AlphaPart R package was used to partition the genetic gain into ancestral Mendelian samplings by sex and by category. The categories were defined as: (1) best males after the progeny testing; (2) males discarded after progeny testing; (3) natural mating males; (4) dams of males; and (5) dams of females. The results showed that the selection scheme works by capturing at each generation the originality (Mendelian samplings) of the animals, and that females contribute largely to the final genetic gain by their originality (or genetic variability).

Introduction

The breeding value of an individual can be expressed as the average of its parental breeding values plus a Mendelian sampling deviation. This last term (the Mendelian sampling) captures the 'originality' of the individual with respect to their parents. In this way, the breeding value of an individual can be decomposed as a sum of Mendelian samplings of all its ancestors.

Analysing long-term contributions of individual Mendelian samplings to the successive generations of the breed allows to understand the different gene flow among, and contributions of, groups and categories of animals (Woolliams *et al.*, 1999; García-Cortés *et al.*, 2008). A retrospective analysis of these long-term contributions in the selection process allows to know the dynamic of the contributions, the ultimate sources of 'originalities' and to predict the future evolution of inbreeding.

The objective of this work was to study long-term contributions to characterize the sources of genetic progress in Basco-Béarnaise (BB) dairy sheep.

Materials & methods

In matrix notation, the vector of breeding values (a) can be written as a linear combination of Mendelian sampling terms and their ancestors as $a = Tw$, where T describes flow of genes through pedigree (Woolliams *et al.*, 1999) and w is the vector of Mendelian samplings. This equation also holds for unbiased predictors as BLUP, $\hat{a} = T\hat{w}$ (García-Cortés *et al.*, 2008), thus Mendelian samplings can be estimated as $\hat{w} = T^{-1}\hat{a}$, where $\hat{a}$ contains the Estimated Breeding Values (EBV).

Our study considered the BB breeding scheme until 2016, time at which genomic selection was introduced. Based on the 2021 official national genetic evaluation (single step GBLUP, Genomic Best Linear Unbiased Prediction), EBVs for milk yield of 138,572 animals born between 1985 and 2016 (136,234 females and 2,338 males) and their pedigree were used in the analyses.

We decomposed the total genetic gain into contributions from males and females, or into contributions from categories defined by the selection pathways. In the BB selection scheme, there are females (recorded for milk yield), Artificial Insemination (AI) males, and Natural Mating (NM) males. Males (AI or MN) are

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_443, © S. Antonios *et al.* 2022

always sons of AI males, while females can be progeny of AI or MN males. AI males produce ~70% of the females, with the remaining ~30% coming from NM males. AI males were selected (until 2016) by progeny testing. Accordingly, we defined 5 categories of animals: (1) AI males (AI_males), the best males kept after progeny testing; (2) discarded AI males (discarded_AI_males), the males discarded after progeny testing; (3) NM males (NM_males); (4) dams of males (DM), elite females chosen to generate AI males; (5) dams of females (DF), who were not chosen as elite females and are considered to be less good than DM.

From EBVs and the pedigree of the breed that shows the flow of genes, the Mendelian samplings terms were computed. The AlphaPart R package (Obsteter *et al.*, 2021) was used to partition the genetic gain into Mendelian sampling trends by sex and by the categories defined above. All results are based on data obtained before the implementation of genomic selection; since then, partitioning probably differs.

Results

Between 1985 and 2016, the total genetic progress was 3.1 l/year, adding up to more that 100 liters. Decomposition of genetic trends into contributions from males versus females allowed the monitoring of their contribution.

Figure 1 shows the decomposition of genetic trend into contributions from Mendelian sampling terms of males and females. The slope indicates that Mendelian sampling terms of dams contribute highly to response, for instance, through their selected sons. The contribution on average was 79 and 21% for females and males, respectively.

Figure 2 presents the average Mendelian samplings gained (selected for) by year. The two categories of dams (DF and DM) and AI males show a progress between 1 and 2 liters per year. The average Mendelian sampling varies between -1 and 1 liter for discarded AI males, and it is around zero for NM males. The discarded AI males are not 'good enough' after progeny testing, and they stop contributing their genes. As for NM males, after initial selection based on Parent Average, NM males are not further selected, and so their Mendelian sampling are unselected for upcoming generations. There is some erratic behaviour of average Mendelian samplings in the last years, particularly for AI males. This happens, first, because accurate estimates of Mendelian Samplings occur several years after the animal has been selected (as sire or dam), when the animal has a large number of progeny or even grand-progeny; and second, because the long-term contributions stabilize only after some generations.

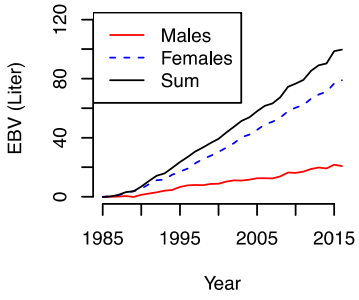

Figure 1. Partitioning the genetic gain into contributions from males and females.

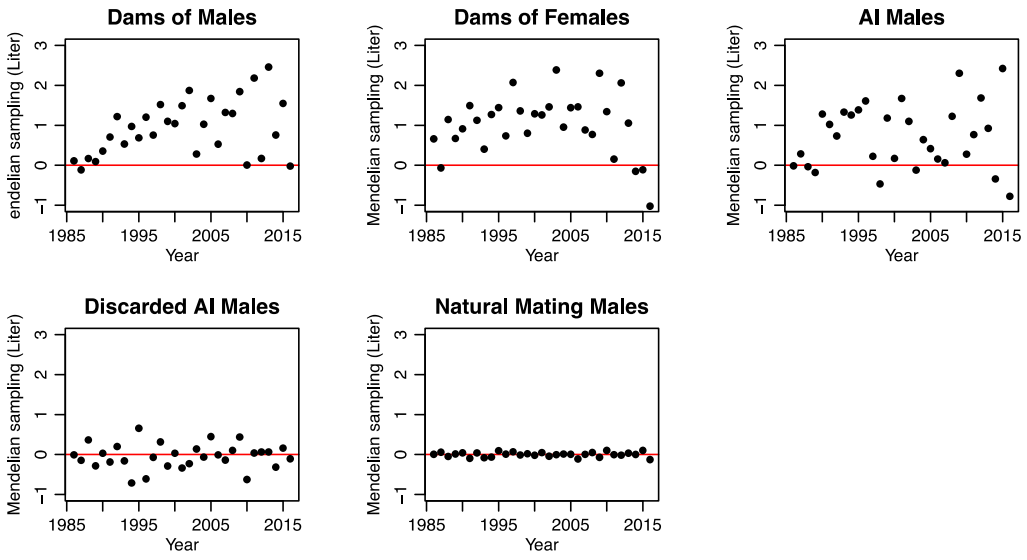

Figure 2. Average Mendelian sampling for each year.

Discussion

To improve a population, we need certain animals to be better than their parents. For this, the originality of the animals with respect to their parents, i.e. the Mendelian sampling, has to be captured. The latter is estimated from different sources of information: (1) own phenotype (milk yield for females, collected in in the selection scheme); (2) phenotypes of the progeny of males (progeny test, i.e. in the AI rams in this scheme); (3) by genomic evaluation (not studied in this work as genomic selection was not yet implemented in 2016). Although the precision in capturing Mendelian sampling is higher in males (by progeny testing), the final genetic progress is largely given by the originality (or genetic variability) of the females, even if their prediction (by own phenotype) is less accurate and their progeny number is smaller. Even if a female has few offspring, a selected female can be the mother or grandmother of an AI male, and consequently have a large number of offspring. Moreover, since the number of eligible females is very high, the selection intensity to be a 'dam of a male' can be very high.

Therefore, fine partitioning in Mendelian sampling trends demonstrates that females are the main reservoir of genetic variability for selection. Still, AI males are crucially important because they allow the spread of best genetics in the population.

Abstract

Sheep litter size is an important economical and reproduction trait. Tunisian Barbarine sheep 'W-INRAT' provide carrier FecX^{Bar} animals, referring to a mutation in the *BMP15* gene. This mutation causes increased ovulation rate in heterozygous ewes. The aim of this work was to introgress the FecX^{Bar} mutation in two conventional multipliers flocks through the development of a marker-assisted selection scheme. The dissemination of the mutation was conducted by artificial insemination of total 350 conventional ewes during two successive years (2019-2020) by four prolific 'W-INRAT' rams (FecX^{Bar}/Y). The F1 offspring were genotyped for FecX^{Bar} mutation by allele-specific PCR. For both years, female lambs (n=92) were heterozygous. They were selected and kept as future prolific breeders. Their mattings with conventional rams will serve to increase prolificacy and produce prolific males. This study shows the importance of genotyping at an early age for the selection and management of mattings for an efficient dissemination of the prolificacy mutation.

Introduction

Reproductive ability has important impacts on the profitability of sheep farming (Abdoli *et al.,* 2016). Reproduction traits such as ovulation rate and litter size are genetically affected by causative mutations in major genes called fecundity (Fec) genes (Davis, 2004). Tunisian Barbarine sheep are a fat-tailed breed found in all production systems and are distinguished by adaptations to environmental conditions (Ben Salem *et al.,* 2011). Barbarine sheep is well known for providing a major source of meat in Tunisia with an acceptable reproductive performance; a high fertility rate (85.2%) but a modest prolificacy mean value of 106.9% with a productivity that does not exceed 0.8 lamb/ewe/year (Atti *et al.,* 2004; Brahmi *et al.,* 2016). The reproduction of Barbarine ewes is, as in most sheep breeds, seasonal and photoperiodically controlled. However, like most breeds from the Mediterranean area, the effect of photoperiod on the seasonality of reproduction is limited, that makes traditional spring (April-May) a mating season (i.e. out of season) (Atti *et al.,* 2004). Furthermore, considering the reproductive ability of the Barbarine, genetic strategies have currently focused on reproduction traits to improve the income of sheep farmers. Thus, a prolificacy-based selection program was implemented since 1979 by the Tunisian National Institute for Agronomic Research (INRAT) in the experimental Oueslatia station Kairouan by screening prolific ewes. The selection process yielded the prolific 'W-INRAT' strain with litter size (LS) of 1.6 and a fertility rate ranging between 82 and 91% (Bedhiaf *et al.,* 2016). Therefore, a novel mutation 'FecX^{Bar}' in the Bone morphogenetic protein 15 (*BMP15*) gene associated with prolificacy was reported for the 'W-INRAT' strain with an additive effect on LS in heterozygous ewes (Lassoued *et al.,* 2017). The FecX^{Bar} mutation is a composite polymorphism associating a single nucleotide substitution (c.301G > T), a 3 bp deletion (c.302_304delCTA) and a C insertion (c.310insC) in the ovine BMP15 cDNA leading to a frame shift at protein position 101. Thus, heterozygous ewes had an increased both ovulation rate (OR) by 0.7 ova and LS by 0.3 lambs (P=0.08)

DOI: 10.3920/978-90-8686-940-4_444, © E. Arari *et al.* 2022

but homozygous females carrying $FecX^{Bar}$ exhibited streaky ovaries with a blockade at the primary stage of folliculogenesis. Moreover, inclusion of genetic information of the *BMP15* gene associated with reproductive ability could efficiently enhance the selection response. This is why the 'W' strain selected from INRAT could strengthen the national selection nucleus by providing animals of high genetic potential for multiplier flocks (Bedhiaf *et al.,* 2016). The aim of the present work was to increase prolificacy by creating prolific carrier females to produce carrier males to disseminate the mutation.

Materials & methods

Farm and animal management. The present study was carried out for 2 years (2019 and 2020) in two Black-headed Barbarine sheep farms in the north and north-east of Tunisia (OEP and OTD). The experiment was conducted during the spring (April-May) using a total of 334 and 394 ewes respectively in 2019 and 2020 aged between 2 to 4 years old, with a body condition score of 2.5-3.0. All animals were kept in the same management system. The main source of feed was pasture supplemented with 0.5 to 1 kg hay and 200-300 g concentrate feeds per head per day during the breeding period. In addition, four prolific rams were selected from 'W-INRAT' strain from Ousslatia farm, to use them in FecXBar diffusion.

Selection of animals and marker-assisted scheme. A marker-assisted scheme (MAS) was developed to disseminate the FecXBar mutation from the nucleus (prolific W-INRAT strain) to multipliers flocks in order to increase prolificacy in conventional Barbarine flocks. The FecXBar allele diffusion plan aimed to provide carrier females and to avoid the production of homozygous sterile females. An initial step was established by selecting four carrier rams from 'W-INRAT' strain to inseminate two conventional ewes' flocks from two public farms (OTD and OEP) to obtain heterozygous females among the F1 progeny. The second level consists to inseminate those heterozygous selected females with conventional rams to increase the number of effective carriers at F2 progeny. Diffusion of prolificacy mutation will be realized by male carriers from F2 at commercial farms by adopting this MAS (Figure 1).

Sample collection and allele-specific PCR (AS-PCR) Jugular vein blood samples (5 ml per animal) were obtained from F1 offspring (n=143 in 2019 and n=151 in 2020) during the two years. Genomic DNA was isolated from frozen blood samples using the standard phenol–chloroform–isoamyl alcohol extraction method. The quality, purity and concentration of isolated genomic DNA were evaluated using standard techniques (Sambrook and Russell, 2001). Two independent AS PCRs were used to amplify a fragment of 445 (or 440) bp from *BMP15* exon 1 for each individual, using the same forward primer (F) and one of the two allele specific reverse primers, (R+) for the $FecX^{+}$ wild-type allele and (R-) for the $FecX^{Bar}$ mutated allele. The PCR products were examined on a 1% agarose gel after 35 cycles of amplification (94, 62, 72 °C/30s). Heterozygous females' lams tested positive for both PCRs, but male lambs tested positive for only the wild allele.

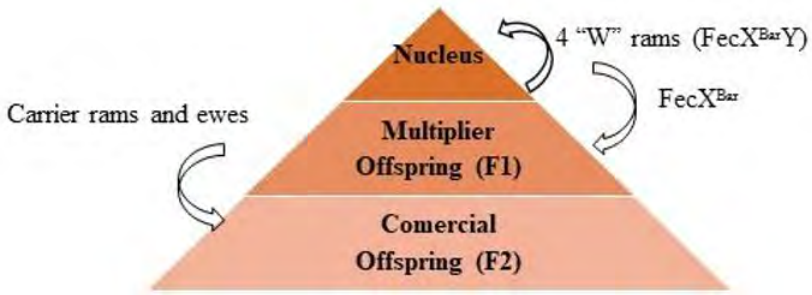

Figure 1. Breeding strategy for Barbarine carrier FecXBar sheep/ Barbarine breeding program.

Table 1. Oligonucleotide primers designed to amplify specific loci of BMP15 gene.

Gene	Region	Oligonucleotide sequence	Product size (bp)	Annealing temperature (°C)
BMP15	Exon 1	F: 5'-TTCCTTGCCCTATCCTTTGTG-3' R+: 5'-GAGGCCTTGCTACACTAGCC-3' R+: 5'-TGAGAGGCCTTGGCTACACA-3'	445	60

Results

As shown in Figure 2, the genotyping results gave two electrophoretic profiles; wild individuals (FR+) and heterozygous individuals (FR+/FR-) (Figure 2). In this context, during the two years, all female lambs produced by artificial insemination (n=92) were heterozygous ($FecX^{Bar+}$). They were selected as future breeders serving to both increase litter size and produce prolific males at F2 progeny. These males (F2) will be used to disseminate the prolificacy mutation at a national level in order to improve commercial flocks' prolificacy.

Discussion

F1 offspring (n=143 in 2019 and n=151 in 2020) during two years resulting from the artificial insemination of 350 ewes by four rams carrying the FecXBar mutation were screened for $FecX^{Bar}$ mutation by AS PCR. Knowledge that these mutations are present in Barbarine sheep breeds is helping in designing and developing breeding strategy that maximize the benefits by increased prolificacy in this breed and their crosses. Artificial insemination programme has been used to successfully introgress the fecundity genes into other breeds in several countries, and these artificial breeding technologies have been particularly useful where only small numbers of progeny tested individuals have been available (Davis, 2004). All offspring female were heterozygous. The findings of the present study are in line with those of Lahoz (2011) who demonstrated that identification $FecX^{R}$ mutation is a reliable tool to identify carrier ewes for an efficient management of the breeding program. In Barbarine ewes, the increase in OR is mainly due to an increase in double ovulations, making the use of the $FecX^{Bar}$ polymorphism suitable for application in commercial farms (Lassoued *et al.*,2017). Selection of heterozygous F1 females as a first step presents an advantage to increase litter size and produce prolific males. These recent results lead to manage the breeding program and follow breeding scheme (MAS) to control of prolificacy rate.

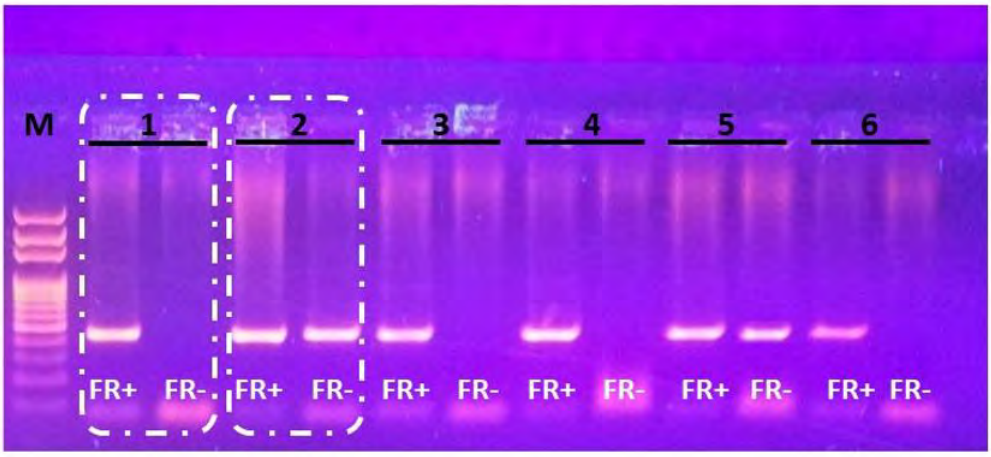

Figure 2. Allele-specific PCR amplification at $FecX^{Bar}$ and $FecX^{+}$ in *BMP15* gene. M: 450 bp ladder DNA marker. FR+ = wild type allele, FR- = mutant allele. Sample 2 and 5: mutant type. Sample 1,3,4 and 6: Wild type genotype.

Abstract

ADAM software is a stochastic simulation tool intended to model a variety of selective breeding schemes for animals and plants. ADAM can be used to generate genetic data to test statistical tools and the implemented algorithms can evaluate breeding schemes by tracing genetic change under different selective breeding scenarios. In practice, crossbreeding has been used extensively in beef cattle, pig, and poultry production systems, and the use of crossbreeding is increasing in dairy cattle breeding system due to changes in the dairy market. The aim of this paper was to present a new crossbreeding feature of the ADAM software. The software was updated to include multiple purebred populations and crossbred populations in animals with different genetic backgrounds considering both additive and dominance effects. Our simulated results showed that, by using the new features in ADAM, breeding organizations can optimize their design of crossbreeding schemes and, thereby, optimize profitability.

Introduction

The well-known effect of increased performance of crossbreds compared to purebreds has long been used systematically in livestock species such as pig and poultry (Therkildsen *et al.* 2021; Chen *et al.* 2021; Han *et al.* 2020). In dairy cattle, farmers have started to use crossbreeding to utilize the increased performance of crossbreds due to heterosis (Clasen *et al.* 2017). However, tools for the use of crossbreeding are lacking; including tools to predict genetic merit of crossbreds, tools to manage breeding of several breeds simultaneously, and decision tools for farmers to optimally use crossbreeding in a herd.

One of the major decisions to make when managing crossbreeding is which breeding scheme is optimal. Therefore, efficient computational tools that allow stochastic simulation of a variety of breeding schemes are of high importance. Among the existing software (Faux *et al.* 2016; Pook *et al.* 2020) ADAM is a well-established tool intended to model a variety of selective breeding schemes for animals and plants (Pedersen *et al.* 2009; Liu *et al.* 2019). The software simulates populations and traces genetic changes in these populations under different scenarios. ADAM accounts for different population structures and genetic models. It can be used to test different phenotyping/genotyping strategies, estimate breeding values, evaluate different selection and mating strategies and generate genetic data to test statistical tools. It is a compiled software written in FORTRAN.

The purpose of this paper is to present the novel features of the ADAM software dedicated to simulation of multiple populations of (possibly) different genetic backgrounds including dominance genetic effects, demonstrated in dairy cattle crossbreeding scheme. The implemented features naturally extend the existing ADAM functionality (Figure 1) to the case of multiple interacting populations and allow efficient evaluation of crossbreeding effects at genetic and phenotypic levels.

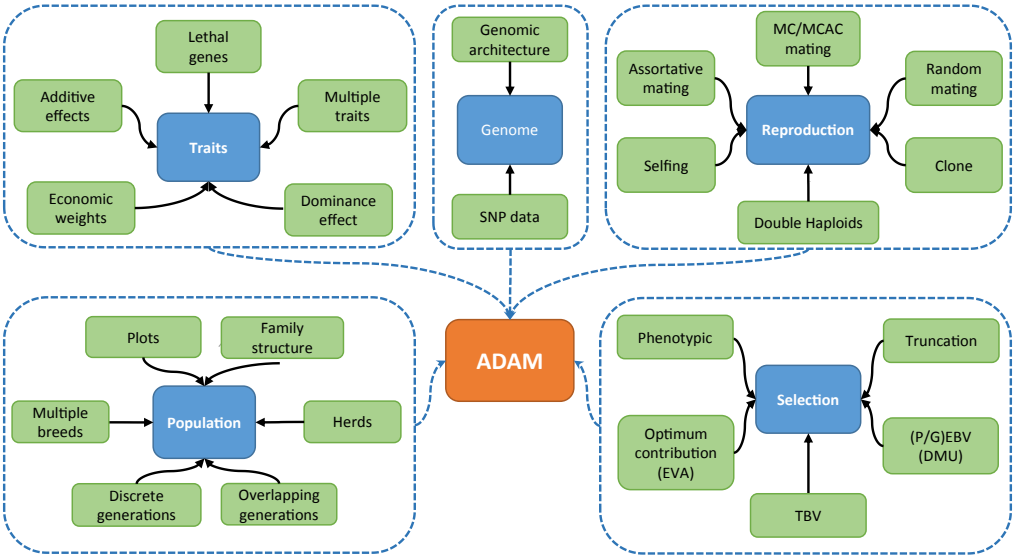

Figure 1. General overview of the ADAM software functionality. MC is minimum co-ancestry; MCAC is mating animals by minimizing the covariance between ancestral contributions; TBV is true breeding values.

Materials & methods

Multiple interacting populations. The model of interacting populations, considered in the context of crossbreed selection, is represented here in terms of evolutionary operators following the approach from Paixão *et al.* (2015). Given a finite population $P(t) = (G^n, \varphi, S_{(\iota,\lambda)})$ of size n at time t characterized by a finite collection $G^n = \{g_i\}$ of genotypes, where $g_i, i = \overline{1,n}$, genotype-phenotype mapping φ, finite collection $S_{(\iota,\lambda)} = \{s_j\}$ of selection candidates $s_j, j = \overline{1,m}$, where i are animals selected for mating and λ are their offspring. Evolution of population P (breeding) in general form:

$$P(t+1) = S_{(\iota,\lambda)}(P(t) \cup (V \circ S_{(\iota,\lambda)})P(t)) \tag{1}$$

where $P(t+1) = (G^l(t+1), \varphi, S_{(\iota,\lambda)})$ is a finite population of size l at time $t+1$; $V: G^n \to G^l$ is a variation operator (mutation, recombination, etc.); $\cup, \circ$ are union and composition operations respectively.

Let a, b, c denote two pure breeds (a,b) and one crossbred (c) populations. Then, the model of interacting populations (crossbreeding):

$$\begin{cases} P_a(t+1) = S_{(\iota\in a,\lambda\in a)}\left(P_a(t) \cup \left(V \circ S_{(\iota\in a,\lambda\in a)}\right)P_a(t)\right), \\ P_b(t+1) = S_{(\iota\in b,\lambda\in b)}\left(P_b(t) \cup \left(V \circ S_{(\iota\in b,\lambda\in b)}\right)P_b(t)\right), \\ P_c(t+1) = S_{(\iota\in c,\lambda\in c)}\left(P_c(t) \cup \left(V \circ S_{(\iota\in c,\lambda\in c)}\right)\{P_a(t), P_b(t)\}\right), \\ P_a(0) = n_{a0}, \\ P_b(0) = n_{b0}, \\ P_c(0) = 0, \end{cases} \tag{2}$$

where n_{a0}, n_{b0}, n_{c0} are sizes of populations a, b and c at the time $t = 0$ respectively.

Dominance. The following sampling was implemented in ADAM to allow a contribution of dominance effects to the total genotypic value (Wellmann and Bennewitz 2011):

$$\delta = \mu + k \cdot \sqrt{\sigma^2} \tag{3}$$

$$d = \delta \cdot |a| \tag{4}$$

where, δ is a dominance degree, $\delta \sim N(\mu, \sigma^2)$; μ is a mean of δ with a default value of 0.193; σ^2 is a variance of δ with a default value of 0.312 (Bennewitz *et al.* 2017); $k \sim N(0,1)$ is a random number; d is a dominance contribution to a genetic value at each locus; a is an additive contribution to a genetic value at each locus.

Data and simulation studies. In order to demonstrate the effect of the novel features implemented in the software, we performed a simple case study simulating a dairy cattle crossbreeding scheme. ADAM can either generate founder haplotypes with user-defined settings for historical populations or read existing haplotypes and genetic architecture into the program. The haplotypes were randomly sampled from the genotype data as used in Thomasen *et al.* (2020) to resemble the Danish dairy cattle populations. A total of 40,000 SNP markers and 1000 QTL were randomly distributed in the genome. A trait with heritability of 0.5, additive genetic variance of 1.00 and dominance variance of 0.25 were considered.

Simulated breeding scheme. A conventional progeny-testing scheme was performed in three purebred populations (population 1-3) in generation 1-10. In each generation and each population, 200 young bulls were progeny-tested and 20 proven bulls (5- to 6-year-old) were truncation-selected for breeding. In addition, 3,000 cows (1- to 5-year-old) were selected out of 10,000 cows for breeding. All progeny-tested bulls were genotyped and included in the sire reference population. In generation 11 to 13, all males and females were genotyped, and a three-way rotational crossbreeding scheme was performed. In each generation, 10 purebred males were mated to 1000 crossbred females, and the crossbred animals are considered to be in a crossbred population (population 4). The breeding scheme simulation was replicated 5 times. The average additive and dominance effects in the population were evaluated for purebred animals in generation 0-10 in population 1 (representing a purebred population) and for crossbred animals in generation 11 to 13 in population 4.

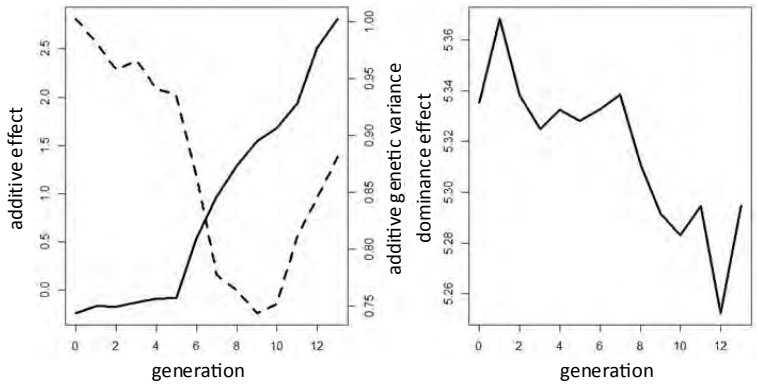

Figure 2. Additive effect (full line), additive genetic variance (broken line) and dominance effect across 13 generations of the simulated breeding schemes.

Results & discussion

The simulation results for the selected breeding scheme are depicted in Figure 2, where the trends of average additive and dominance effects across generations are shown for generation 0-10 in population 1 population and generation 11-13 in population 4. The rate of genetic gain rapidly improved due to crossbreeding in generation 11-13 (0.44 in genetic standard deviation unit per generation) compared to generation 1-10 (0.24 per generation). The dominance effect decreased during generation 1-10 due to selection within purebred populations and increased in generation 11 as the level of heterozygosity increased due to crossbreeding. The dominance effect possibly fluctuated across generations due to a small number of replicates. The introduction of crossbreeding in generation 11-13 increased the additive genetic variance from 0.74 to 0.88 (Figure 2).

This work represents the novel advanced features of ADAM software. By using a simple test case we showed that the software can simulate multiple interacting populations within one breeding scheme while accounting for dominance effects. With the new functionalities, ADAM can simulate a broad range of research-based as well as commercial-based breeding and crossbreeding schemes of variable complexity. By using ADAM, breeding organizations have the opportunity to optimize their breeding strategies and use of resources and, thereby, optimize profitability.

446. A tool for comprehensive implementation of simple and complex breeding programs

B.P. Kinghorn[1*], A.J. Kinghorn and J.L. Baller[2]

[1]University of New England, Armidale NSW 2351, Australia; [2]ABS Global, Inc., 1525 River Rd., DeForest, WI 53532, USA; bkinghor@une.edu.au

Abstract

This paper gives a brief overview of the tool MateSel, which is used for implementation of breeding programs across many animal and plant species. Progress in algorithms underlying MateSel is briefly described. An example of the Multiple EndUses feature in an industry dataset is used to help illustrate flexibility to control outcomes.

Introduction

There are many issues to handle when running a breeding program. After EBV generation, there has to be consideration of e.g. constraints on numbers of matings per individual, progeny inbreeding, targeted outcomes for specific traits, and migration of stock between groups. Attention should also be paid to Optimal Contribution Selection (OCS) to manage diversity.

Practitioners can spend a lot of time attempting to make balanced decisions across such diverse issues. This paper describes the tool MateSel, which addresses these issues and many more in a single framework, leading to discovery of compromises and opportunities, and production of a mating list to be adopted. Once established in a breeding operation, this tool gives high levels of control and performance. It can also save considerable human time and effort.

MateSel is comprehensively described by Kinghorn and Kinghorn (2022), and also in a series of short videos at https://matesel.com/Website/Support. This paper focuses on a single example that gives a new illustration, using the Multiple EndUses feature. An EndUse is a targeted application for progeny out of a group of matings. Examples are matings to produce bulls for Terminal use versus Maternal use, or for production of progeny targeted at use in the Nucleus versus use in a Multiplier. An EndUse index is the selection index that is used as a criterion to evaluate stock for that EndUse.

Materials & methods

A note on method underlying MateSel. Being used across animal and plant breeding programs, MateSel handles a wide range of biological, logistical and practical constraints. All these issues have to be well accommodated, as the mating list results are used directly in operations. This has led to increasing functionality as new applications arise, but at the time of writing, we know of no outstanding issues that cannot be accommodated. There are parameters for four categories of decision-making that are optimised for the prevailing objective function: (1) selection (matings allocated per candidate); (2) distribution of matings across Male Group × Female Group; (3) allocation of mates to make matings; (4) allocation of matings to different EndUses.

As global optimality is targeted, these parameters are optimised simultaneously in a one-step approach. Optimising selection decisions, then optimising mate allocation given these selection decisions, would be a two-step approach. Some scenarios are very challenging for optimisation, for example large problems with many group mating permission restrictions and multiple thresholds on inbreeding/trait/marker outcomes. This has led to ongoing improvement in method compared to that of Kinghorn (2011), with a mix of

stochastic and deterministic optimisation strategies coordinated in a manner that maintains the one-step approach.

Example using the multiple EndUses feature. We use an example in cattle, with thanks to ABS Global for providing the data and scenario. This ABS job relates to a subset of the breeding program, in which specialised selection for two different indices is required from a single pool of candidates. We will refer to these as EndUse 2 and EndUse 3. Just for illustration, we will later add EndUse 1, to target a fictitious breeding nucleus, with its selection criterion being the scaled average of the EndUse 2 and 3 indices.

One hundred matings are to be generated from 154 female candidates. Seventy matings are required for EndUse 2, and 30 matings for EndUse 3. The Control settings are to give equal emphasis to EndUses 2 and 3 and to practice truncation selection – no OCS required in this subset of the ABS breeding program.

Results

The top row in Figure 1 shows EndUse 2/3 index scatterplots. The left graph shows the females selected for EndUse 2 (orange) and EndUse 3 (blue), and 54 culled females (grey). The corresponding graph for males would be less informative, because males are generally used in multiple matings, and the same male can be used for matings that target different EndUses. However, the combination of male and female selections together with mate allocations is in the right-hand graph, which shows the EndUse 2/3 index scatterplot of progeny mean indices.

The top row results might not please the practitioner: Looking at the bottom-left square box of culled females (grey dots), those near the top-right have been culled, whereas those just outside the top-left and bottom-right corners have been selected, despite the fact that they are very poor for one index, and just marginally across-the-line for the other index. This is rectified in the next row of results by adding some positive emphasis on each of the two indices using MateSel's Trait Management feature (see Kinghorn and Kinghorn, 2022), without altering settings for the Multiple EndUse feature. This can be done on-the-fly, editing the relevant weightings to change the overall objective function *during* the analysis, to find weightings that give satisfactory results. These results may indeed be of higher long-term utility, as Mendelian segregation and environmental deviations can change the ultimate fate of resulting progeny.

In the top row of Figure 1, the equal emphasis given to EndUses 2 and 3 can be seen in the 45-degree line separating the blue and orange dots. In the bottom row, the weighting on Enduse 3 has been doubled, resulting in a lowering of that division between the blue and orange dots, with EndUse 3 benefitting somewhat at the expense of EndUse 2. This contributes to a better result for EndUse 3 in predicted progeny merit.

For Figure 2, 40 matings for EndUse 1 have been added, using black dots. The relative weightings for EndUses 1, 2 and 3 were 1, ½, ½ respectively, ensuring in this case that EndUse 1 (breeding nucleus) had priority over EndUses 2 and 3. The fact that the EndUse 1 index is the average of the EndUse 2 and 3 indices is seen in the truncation slope for the black dots to the top-right in the graph of female selections for truncation selection (Target Degrees (TD)=0, where TD=90 is fully for minimum coancestry selection, Kinghorn and Kinghorn (2022)).

But of course, we should pay attention to genetic diversity in a breeding nucleus. The bottom row in Figure 2 shows that under equal emphasis on parental coancestry (TD = (0+90)/2= 45), the nucleus drops selection of some higher-index females in order to select some lower coancestry females. This impact is usually higher for male selection, due to greater opportunity to vary contributions, seen in the lower response in the nucleus under OCS at TD=45 in the right-hand graph, to maintain more diversity. Dropping some high

index contributions to EndUse 1 gives opportunity for improved response for the other two EndUses, for which genetic diversity is not required.

Discussion

The right-hand graphs in Figure 1 and 2 show greater separation between EndUses than the left-hand graphs. This is due to assortative mate allocation across the multiple EndUses involved, as well as the effects of sire selection. Driving this separation gives better future opportunities, for example for satisfying the diverse needs of different seedstock buyers, or for planned splitting of a breeding line in multiple directions. This can effectively remove a generation of lag, as described here: https://www.youtube.com/watch?v=mAl0YsoFVgM

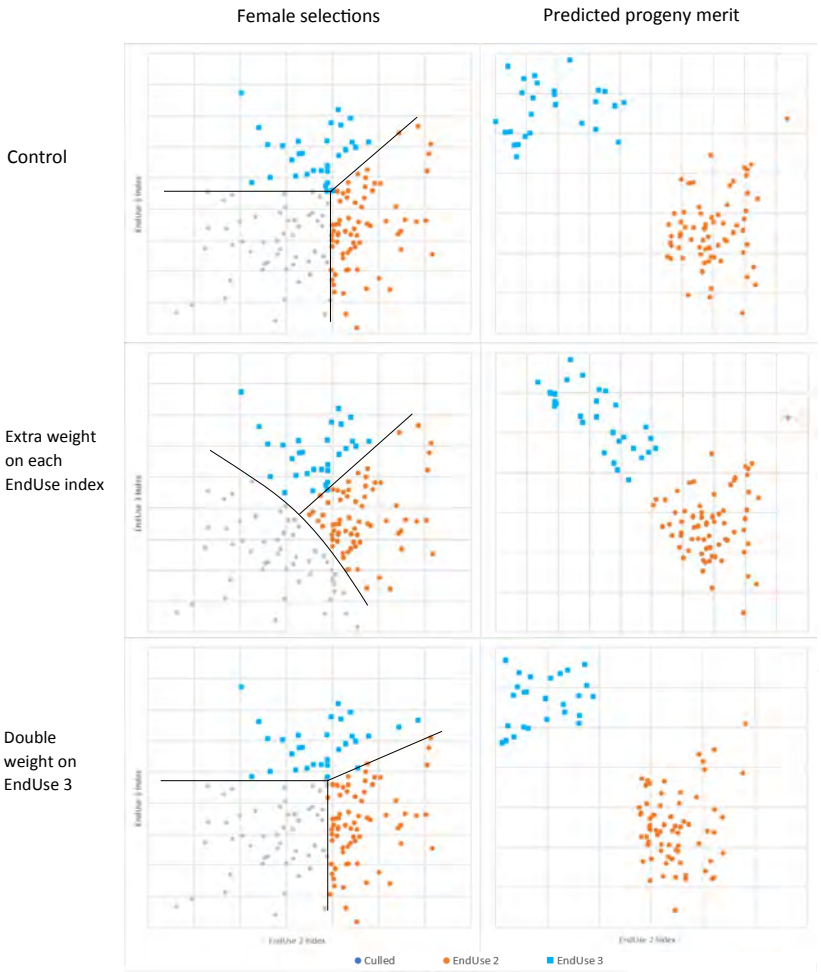

Figure 1. Scatterplots of EndUse 3 index on EndUse 2 index. Color of points shows the fate of each female (left column) and the predicted merit of each mating (right column). Black lines are for visual guidance. See text for more detail.

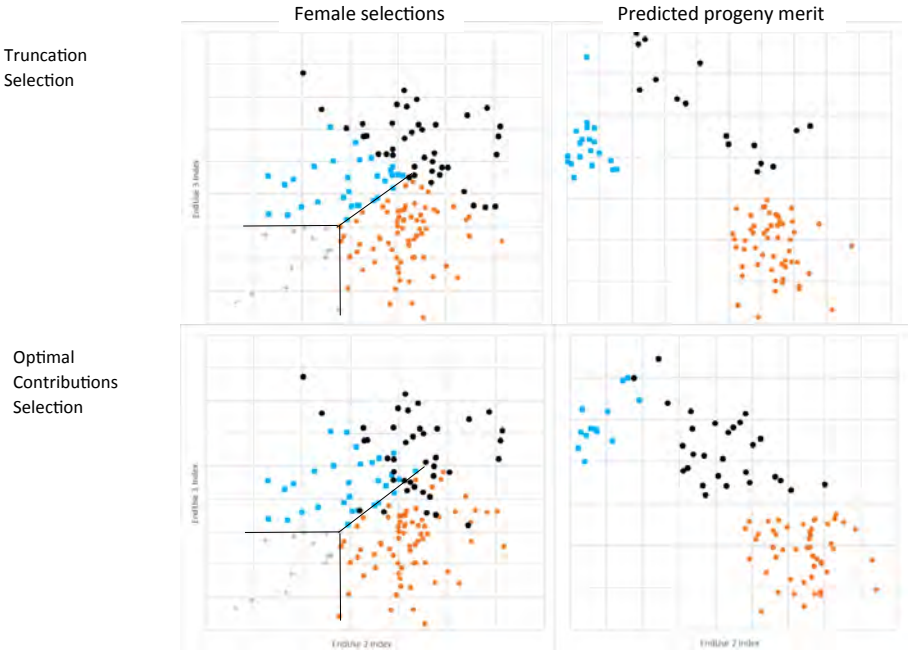

Figure 2. As for Figure 1, but with 40 EndUse 1 (nucleus population) matings added in black, leaving 40 fewer culled females (light grey). See text for more detail.

This session of WCGALP is on Methods and Tools. Most work in this area relates ultimately to genetic evaluation of individuals. MateSel takes off from that point to help fill the gap between EBVs and the implementation of a breeding program. This tool continues to evolve, with updates released every few months over the last several years. The example given illustrates just one specific feature, and is far from a comprehensive overview of the software. For that please see Kinghorn and Kinghorn (2022).

Abstract

Modern breeding programs are highly complex with various interdependent parameters and determining the optimal breeding scheme is practically impossible. Therefore, it is a common practice to reduce the optimization problem to a set of scenarios that in turn are deeply analyzed in detail. We are proposing a framework to optimize breeding programs beyond just a comparison of scenarios. We first define the design space of all possible breeding programs and approximated their outcome regarding an objective function using stochastic simulation and local smoothing. Next, the space is reduced to the most promising areas of the design space using various optimization techniques. This process is repeated iteratively until an optimal scheme is obtained. We applied our method to a dairy cattle program with an objective function that includes both genetic gain and genetic diversity conservation under a budget constraint. This study provides more detailed insights into potential approaches of designing and optimizing breeding programs by finding the optimum allocation of resources based on each objective's overall impact on mid-and long-term breeding goals.

Introduction

When it comes to addressing global challenges caused by the annual growth rate of the human population and the rapidly changing climate, the breeding sector is required to increase production capacities. Modern breeding systems are highly complex with various decisions that need to be taken, such as parent selection, mating decisions, and managing the rate of inbreeding (Martin-Collado *et al.* 2018; Simianer *et al.* 2021). In addition, the efficient allocation of resources in breeding programs involves competing objectives where the achievement of one objective oftentimes comes at the expense of another. Thus, there is a strong demand of breeders to optimize their breeding schemes and predict the performance of different breeding scenarios before conducting experiments in real-life settings. Optimization is further complicated by breeding actions or changes in parameters of the breeding scheme being highly interdependent of each other. Choosing the number of animals to use in each breeding cycle for mating and selection is one of the first and most important decisions made by a breeder, where breeders seek to maximize the expected gain in target traits by repeated selection rounds while controlling inbreeding and staying within a given budget. To find optimum test resource allocation in breeding programs, simulation techniques can be used to examine all possible resource allocation combinations individually. However, this approach becomes computationally expensive or even prohibitive with the increasing complexity of the breeding program to optimize and resources to allocate. That is why optimization algorithms are vital when the breeding programs are subject to multistage selection with many parameters, where the initial population of breeding units is evaluated in the first stage and only a fraction of the superior candidates are selected in the subsequent stage(s) as parents. Our study aims to determine the best resource utilization or near-optimal resource combination under the existing scenarios based on simulation-based optimization methods and different primary breeding objectives.

Materials & methods

In the following, we will propose a general pipeline for the optimization of breeding programs and will provide an exemplary breeding scenario of a simplified classical dairy cattle breeding scheme (Figure 1).

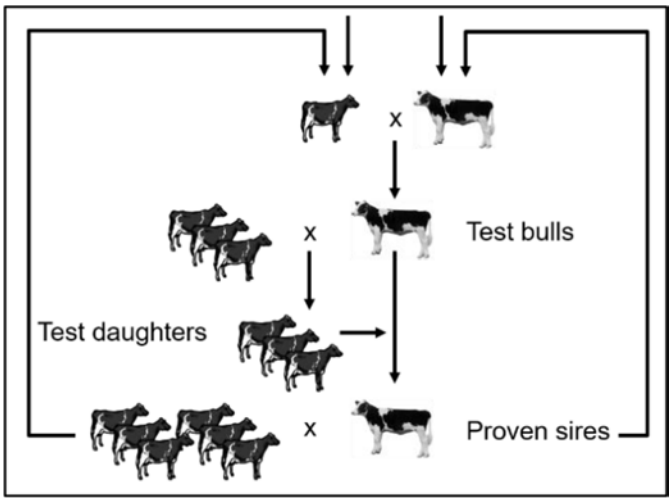

Figure 1. A dairy cattle breeding strategy.

As bulls cannot be phenotyped for performance traits, pre-selected candidates need to be mated to cows to produce test daughters, and test bulls are then selected based on their offspring performance. The selection of bulls is assumed to be based on genomic breeding value estimation, while cows were selected via pedigree breeding value estimation. The last three cow generations were considered for selection with phenotypic information being available for the two older generations. To detect the optimal number of test daughters and bulls for mating and selection in each cycle, the present study attempted to improve their characteristics over 10 generations. 5 burn-in cycles were performed to have a realistic initial population structure. A single trait was simulated with a heritability of 0.3, 1000 purely additive QTLs, a mean genomic value of 100, and a genomic standard deviation of 10. The interested reader is referred to https://github.com/tpook92/MoBPS/ for the exact simulation script of the simulation. Firstly, we have to quantify the search space of all potential breeding schemes and the parameters we are considering for the optimization. In the dairy cattle breeding scheme, the optimization problem can be defined by three main components: the number of test daughters x_1, test bulls x_2, and selected proven sires x_3. When assuming a yearly budget of 10 million euros and housing cost of 3,000 € per bull and 4,000 € per cow and setting reasonable boundaries based on stable capacities, this leads to the following set of constraints:

$$4000x_1 + 3000x_2 - 10000000 \leq 0,\ x_1, x_2, x_3 \geq 0,\ 100 \leq x_2 \leq 700,\ 3 \leq x_3 \leq 30$$

Next, we need to specify our objective function m, which we define as a composite between the genetic gain and inbreeding depending on our set of parameters. This could for example be:

$$m(x_1, x_2, x_3) = f(x_1, x_2, x_3) - 50 * g(x_1, x_2, x_3)$$

with f being the resulting genetic gain and g being the inbreeding rate after 15 years of breeding. As f and g are on a different scale, we additionally performed scaling by a more or less arbitrarily chosen value of 50 for the rate of inbreeding in the composite function. Higher values would put a higher weight on breeding for genetic diversity, while lower values would put more focus on the genetic gain, and depending on the decision-maker, a proposed weighting will of course differ (which in turn also leads to a different optimal breeding program). The next step of our pipeline is the optimization process itself to maximize the objective function within the limits of our constraints. As m cannot be derived directly, we need to approximate it.

For this, we propose to perform stochastic simulation of the breeding scheme using the R package MoBPS (Pook *et al.* 2020). Next, m is approximated using a kernel regression method, a weighted average with values closer to the value of the interest being weighted stronger (Nadaraya 1964; Watson 1964):

$$\hat{m}(x_1, x_2, x_3) = \frac{\sum Y_i * K_h(\frac{x_1 - x_{i,1}}{h_1}, \frac{x_2 - x_{i,2}}{h_2}, \frac{x_3 - x_{i,3}}{h_3})}{\sum K_h(x_1 - x_{i,1}, x_2 - x_{i,2}, x_3 - x_{i,3})}$$

with K being the used Kernel function and h_i being the bandwidth to control which simulations are considered with what weight in the smoothing procedure. Y_i represents an outcome of stochastic simulations with the input parameters ($x_{i,1}$, $x_{i,2}$, $x_{i,3}$). Note that Y_i is a random variable with expected value $m(x_1, x_2, x_3)$ and unknown variance. Subsequently, optimization techniques like gradient descent, simulated annealing, and genetic algorithms are used to obtain potential maxima for $\hat{m}$. Finally, more simulations in the areas of interest can be performed, which in turn allows for a reduction of the bandwidth and a better approximation of m. This step can be iteratively repeated until obtained maxima stabilizes.

Results

In the first step, 60,000 simulations at arbitrary positions in the search space were performed. As our search space in this particular example was 'only' three-dimensional, the initial bandwidth was chosen based on visual inspection as (h_1 = 30, h_2 = 30, h_3 = 1). As inbreeding rates showed a much smaller variance than the obtained genetic gains, bandwidth for inbreeding was divided by 3. The result of simulations in contour maps shows that genetic gain is maximized with the highest function value of 12.56 when applying strong selection and generating a high number of test daughters per test bull (x_1 = 2,418, x_2 = 109, x_3 = 3) (Figure 2a), where inbreeding in such cases is also high (Figure 2b), leading to a not ideal performance in the composite function.

Results are in-line with current breeding theory, where the optimum response to selection can be obtained by maximizing genetic gain with high selection intensity, where a low number of test bulls are beneficial with resulting higher accuracy of the breeding value estimation (due to the higher number of test daughters per bull). On the contrary, a higher number of proven sires and lower selection intensity results in a decreased response to selection and inbreeding rates, where the minima for g was obtained at (2,423, 102, 30) with the best function value of 0.025 (Figure 2b). In the optimization phase for the composite function m, all optimization methods suggested the best function value around 107.86 and the local optimum at (2,371, 172, 14), (2,353, 189, 12), and (2,332, 224, 16) (Figure 2c and 3a). In the second iteration, a further 50,000 simulations were performed with the search space being reduced based on the result of the first optimization to $120 \leq x_2 \leq 260$, $10 \leq x_3 \leq 20$. As this leads to about 10 times as many simulations in the target area, the bandwidth for the second cycle was halved (h_1 = 15, h_2 = 15, h_3 = 0.5) with the best solution 107.89 from optimization suggesting (2,368,

175, 13) as the optimum (Figure 3b). After the third cycle with 12,000 simulations and a further reduced state space ($150 \leq x_2 \leq 200$, $10 \leq x_3 \leq 15$) with bandwidth again halved, the optimization suggests (2,365, 179, 13) indicating stabilization of the optima with the best value of 107.91 (Figure 3c).

Discussion

Optimum allocation of resources has been addressed in breeding mostly focusing on whether the selection decisions should be made upon genotypic or phenotypic information (Henryon *et al.* 2014). Yet, these concessions remain underexploited and little attention had been devoted to the potential benefits of resource optimization in animal breeding. Simulation studies have become increasingly important by enabling breeders to make informed decisions on suitable breeding strategies. Although there is no practical way to exhaustively examine all possible combinations of test parameter values in a complex breeding program, our proposed pipeline is based on a combination of a multivariate optimization approach and systematic zooming in into promising regions of the design space by forming iterative guesses in the proximity of the initial solutions. With gradient descent, multiple optima can be obtained depending on the starting value of the optimizer. Our results provide a promising perspective for test resource optimization by integrating nonparametric approaches that yield the best tradeoff between changes in inbreeding and rates of genetic gain in breeding programs subject to multistage selection. Future research directions include finding the optimal selection of the bandwidth of the kernel using automated techniques and finding a robust optimization framework for problems with a large number of parameters.

448. Predicting the outcome of a selection scheme in maternal traits

A.V. Mäki-Tanila* and J. Pietarinen

University of Helsinki, P.O. Box 28, 00014 Helsinki, Finland; asko.maki-tanila@helsinki.fi

Abstract

The rate of selection response in maternal traits is predicted with a BLUP approximation allowing an assessment for a wide range of genetic parameters and data recording schemes. The method exploited Willham model separating the direct and maternal effect in the analysis. It is accommodating the changes in genetic (co)variances due to selection. The focus is on uniparous species yielding a simple situation and on the benefits of augmenting the sib information with cousin information under commonly found antagonistic correlation between the effects. There is indication that the cousin information brings qualitative benefits to the approximation.

Introduction

In mammal species, e.g. beef cattle, the dam has an influence (maternal effect) on early growth and other juvenile traits in progeny. According to the Willham (1963) model, the genetic variation in maternal traits is allocated to the components due to the individual's own (direct) effect (a) and the dam's (d) (indirect) maternal effect (m_d) (Bijma 2006). In mammals, these effects are mostly genetically antagonistic. In maternal traits, the genetic evaluation relies on information across generations. For multi-generation data, the BLUP methodology would automatically yield reliable estimates of breeding values (EBV). When we are launching a selection scheme in a new breed or, in particular, in a new species, e.g. reindeer (Muuttoranta *et al.* 2014), we need tools to assess the requirements for organising an optimum recording. Wray and Hill (1979) developed a method, which is approximating the BLUP procedure in predicting the short-term outcome for a selection scheme. We have developed the method for maternal traits with a comparison to simulated results (Pietarinen and Mäki-Tanila 2020). Except the case with substantial genetic antagonism, the method worked in a satisfactory manner. The objective of the present work is stemming from a suggestion by Pieter Bijma (pers. comm.) to improve the approximation by including information on collateral relatives beyond sibs, i.e. cousins. The immediate interest of our research is in planning selection schemes for reindeer, which is a uniparous species like cattle. The methodological development also stays simpler when we consider only half-sibs and their progeny.

Materials & methods

A maternally affected phenotype (p) is expressed as: $p = a + m_d + e$, where e is environmental deviation (variance σ_e^2). We use the notation σ_p^2, σ_a^2 and σ_m^2 for phenotypic variance and direct and maternal genetic variance, respectively, and σ_{am} for the covariance. We assume that the effective population size is so large that selection does not affect the (co)variances σ_{a0}^2, σ_{m0}^2 and σ_{am0} (0 referring to the base generation) due to segregation.

We construct a family index based on the selection candidate's phenotype and its half-sibs' mean $\overline{HS}$ so that its *EBV* for either effect is $b_1(p - \overline{HS}) + b_2\,\overline{HS}$ where b_j is the respective index weight. In a hierarchical mating structure, each sire (s) mates with f dams each having one offspring. Usually, maternal traits are analysed separating technically the direct and maternal effect into two traits. In constructing the index we use the compact approach of Van Vleck (1970). The selection index $I = b'x$ has the coefficient vector $b = P^{-1}\,G\,w$ with the phenotypic (co)variance matrix P and G matrix for the covariance of a and m with the information of sources in the index. The weighting of the effects in the aggregate selection goal are expressed by a vector w. The variances in generation t are according to Willham (1963):

$\sigma^2_{(p-\overline{HS})t} = \frac{f-1}{f}\left(\frac{1}{4}\sigma^2_{a(t-1)d} + \frac{1}{2}\sigma^2_{a0} + \sigma_{am(t-1)d} + \sigma^2_{m(t-1)d} + \sigma^2_e\right)$ and

$\sigma^2_{\overline{HS}(t)} = \frac{1}{4}\sigma^2_{a(t-1)s} + \frac{1}{f}\left(\frac{1}{4}\sigma^2_{a(t-1)d} + \frac{1}{2}\sigma^2_{a0} + \sigma_{am(t-1)d} + \sigma^2_{m(t-1)d} + \sigma^2_e\right)$, and P is diagonal. Using the notation $A_w = \frac{1}{4}\sigma^2_{a(t-1)d} + \frac{1}{2}\sigma^2_{a0} + \sigma_{am(t-1)d}$ and $M_w = \frac{1}{4}\sigma_{am_{(t-1)d}} + \frac{1}{2}\sigma_{am_0} + \frac{1}{2}\sigma^2_{m_d}$), we have:

$$\boldsymbol{G'_t} = \begin{pmatrix} \frac{f-1}{f}A_w & \frac{1}{4}\sigma^2_{a(t-1)s} + A_w/f \\ \frac{f-1}{f}M_w & \frac{1}{4}\sigma_{am(t-1)s} + M_w/f \end{pmatrix}$$

The columns of G are indicated by g_a and g_m. The BLUP approximation is constructed adding the selection candidate's dam's and sire's EBV of a and m and the half-sibs' dams' respective EBV-means amongst the index terms. The $p - \overline{HS}$ is correlated only with $\hat{a}$ and $\hat{m}$, i.e. $\frac{f-1}{f}\left(\frac{1}{2}\sigma^2_{\hat{a}(t-1)} + \sigma_{\hat{a}m(t-1)}\right)$ and $\frac{f-1}{f}\left(\frac{1}{2}\sigma_{\hat{a}m(t-1)} + \sigma^2_{\hat{m}(t-1)}\right)$ while $\overline{HS}$ has the covariances $\frac{1}{2}\sigma^2_{\hat{a}(t-1)} + \sigma_{\hat{a}m(t-1)}$ with both $\hat{a}_d$ and $\overline{\hat{a}_d}$ and $\frac{1}{2}\sigma_{\hat{a}m(t-1)} + \sigma^2_{\hat{m}(t-1)}$ with $\hat{m}_d$ and $\overline{\hat{m}_d}$ and $\frac{1}{2}\sigma^2_{\hat{a}(t-1)}$ and $\frac{1}{2}\sigma_{a\hat{m}(t-1)}$ with $\hat{a}_s$ and $\hat{m}_s$, respectively. In the matrix P the EBV's and their means have (co)variances within individuals and between the effects and their covariances with a and m in G are alike, respectively.

The BLUP approximation may be improved by adding phenotypic information on the sire's female half-sibs' progeny (each sired by a different male) and their parents' EBV. The progeny is a paternal half-cousin (*HC*) with respect to the selection candidate. The essential part in $\overline{HC}$ correlated via the common grandsire (GS) with p and $\overline{HS}$ and sire's EBV's, is $\frac{1}{2}a_{dHC} + m_{dHC}$. We have e.g. $cov(\overline{HS}, \overline{HC}) = \frac{1}{16}\sigma^2_{a(t-2)GS} + \frac{1}{8}\sigma_{am(t-2)GS}$ (cf. Willham 1963; Bondari 1971; Thompson 1976).

A somewhat cumbersome part in the construction is the derivation of the covariances involving *HC*'s (related) dams' EBV. This kind of machinery has been developed in predicting the rate of inbreeding (cf. Woolliams and Bijma 2000). As we have $\hat{a} = \boldsymbol{b'_a}\,\boldsymbol{x}$ where $\boldsymbol{b_a} = \boldsymbol{P^{-1}g_a}$, then for P matrix e.g. $cov(HS, \overline{\hat{a}_{dHC}}) = cov\left(\frac{1}{2}a_s, \boldsymbol{b'_a}\,\boldsymbol{x}\right) = \frac{1}{2}\boldsymbol{b'_a}\,cov(a, \boldsymbol{x})_{HS}$ where $cov(a, \boldsymbol{x})_{HS}$ or $\boldsymbol{g_{aHS}}$ differs from $\boldsymbol{g_a}$ in having the first element A_w/f. Similarly $cov(\hat{m}_s, \overline{pHC}) = cov\left(\boldsymbol{b'_m}\,\boldsymbol{x}, \frac{1}{2}a_{dHC} + m_{dHC}\right) = \frac{1}{2}\boldsymbol{b'_m}\,\boldsymbol{g_{aHS}} + \boldsymbol{b'_m}\,\boldsymbol{g_{mHS}}$ with the first element of $\boldsymbol{g_{mHS}}$ being M_w/f. Obviously there are also covariances between half-sibs' EBV's. For example, $cov\left(\hat{m}_s, \overline{\hat{a}_{dHC}}\right) = cov\left(\boldsymbol{b'_m}\,\boldsymbol{x_i}, \boldsymbol{b'_a}\,\boldsymbol{x_j}\right) = \boldsymbol{b'_m}\,cov\left(\boldsymbol{x_i}, \boldsymbol{x_j}\right)_{HS}\,\boldsymbol{b_a}$. The phenotypic covariance matrix $cov\left(\boldsymbol{x_i}, \boldsymbol{x_j}\right)_{HS}$ has the [1,1] element as A_w/f and the covariance of $p - \overline{HS}$ with $\hat{a}_d$ is now $\left(\frac{1}{2}\sigma^2_{\hat{a}(t-1)} + \sigma_{\hat{a}m(t-1)}\right)/f$ and that with $\hat{m}_d$ is $\left(\frac{1}{2}\sigma_{a\hat{m}(t-1)} + \sigma^2_{\hat{m}(t-1)}\right)/f$ whereas the covariances between half-sibs' (unrelated) dams' EBV's are all 0. The selection is possible only amongst males. The genetic (co)variances among the selected sires are affected by Bulmer (1971) effect. For example, the covariance amongst selected sires is $\sigma_{am(s)} - k\ \sigma_{aI}\,\sigma_{mI}\,/\sigma^2_I$ where $k = i(i - x)$, i is the intensity of selection and x is the truncation point on the standardized scale (cf. Villanueva *et al.* 1993).

Results & discussion

We have developed a BLUP approximation for predicting the short-term outcome from a selection on maternal traits with an allowance for changes in mating ratio. The approximation is based on a selection index of the following information sources: $p - \overline{HS}$, $\overline{HS}$, $\overline{HC}$, $\hat{a}_d$, $\hat{a}_s$, $\overline{\hat{a}_{dHS}}$, $\overline{\hat{a}_{dHC}}$, $\overline{\hat{a}_{sHC}}$, $\hat{m}_d$, $\hat{m}_s$, $\overline{\hat{m}_{dHS}}$, $\overline{\hat{m}_{dHC}}$ and $\overline{\hat{m}_{sHC}}$. The number of index terms generates a huge number of parameters and the research on the selection of indirect effects usually resorts to simulation (Khaw *et al.* 2014; Lillehammer *et al.* 2020). Analytical methods are appealing, because they potentially provide general understanding and predictions for a wide range of design factors.

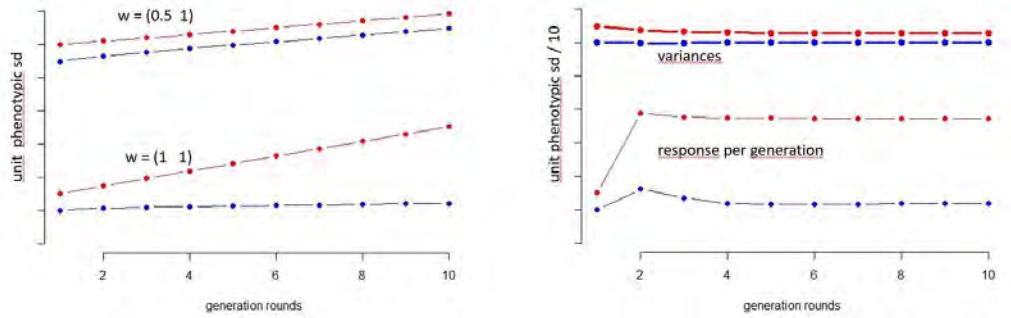

Figure 1. Left: Predicted responses in direct (red) and maternal (blue) effect (in σ_p units of the base generation) when the selection is on an aggregate index of approximated BLUP-EBV's based on selection candidate's, half-sibs' and half-cousins' phenotype and their parents' EBV for two weight combinations (vector w). Right: The changes in the variance and in the rate of progress in the direct and maternal effect across generations for equal economic weights. The heritabilities $\boldsymbol{h_a^2 = h_m^2 = 0.3}$ and r_{am} = -0.5 and the proportion selected in males is 6.7% and f = 30

The rate of progress and the changes in genetic variances behave in an expected manner and like in the previous BLUP approximations, i.e. the asymptotic response per generation and the stable variance levels are reached within few generations in both the effects (Figure 1). Using equal weights and the parameters of Figure 1, with a highly negative genetic correlation (-0.5) between the effects the asymptotic maternal response is negative (-0.017 per generation) vs positive (0.056) without vs with *HC* data while the respective direct gain is 0.254 vs 0.205. The simulation (for details, see Pietarinen and Mäki-Tanila 2020) yields an average response over 7-10th generation as 0.217 for direct and 0.055 for maternal effect. With no genetic correlation between the effects the predicted (simulated) response is 0.288 without *HC* data vs 0.304 with *HC* data (0.304) for direct and 0.152 vs 0.125 (0.163) for maternal effect. There are indicative benefits from including the cousin information in the approximation.

The BLUP approximation is very flexible and has been extended to a multi-trait context (Villanueva *et al.* 1993) and in assessing the major advantages from the use of genomic information in genetic evaluation (Dekkers 2007). These issues are of much interest also for the genetic improvement of maternal traits.

449. Inbreeding in circular and panmictic mating systems

B. Guldbrandtsen

Department of Veterinary and Animal Sciences, Grønnegårdsvej 3, 1870 Frederiksberg, Denmark;
berntguldbrandtsen@sund.ku.dk

Abstract
The performance of circular and panmictic breeding schemes are compared based on the eigenvalue effective population size. A simple coalescent approximation is used to demonstrate that for larger populations, the asymptotic behaviours of the models are identical. Consistent with previous studies circular mating schemes are found to lead to early increases in realised inbreeding. A circular mating scheme is associated with a disadvantage. However, the long-term rate of inbreeding is lower for a circular mating scheme, but only for small populations.

Introduction
Among the challenges facing small populations are loss of genetic variation and build-up of homozygosity. Loss of genetic variation leads to loss of adaptive potential, e.g. future selection response. Increasing homozygosity leads to inbreeding depression. Inbreeding depression is the general decline in performance observed in inbred individuals, for a review see, e.g. Leroy G. (2014).

An effective method frequently employed to constrain loss of genetic variation is optimal contribution selection (Meuwissen, 1997). This method has been implemented in tools such as EVA (Berg, 2006). Here, selection of breeders requires striking an optimal balance between genetic gain and the concurrent increase in coancestry in the population. However, the deployment of this kind of scheme requires complete data of high quality and it requires centralized decision-making.

Often one or both of these conditions are not satisfied. In this situation, circular mating schemes (Kimura and Crow, 1963) are used in the management of some small and endangered breeds as a tool to restrain the increase in inbreeding levels. In a circular scheme, the population is divided into a number of subpopulations. In each generation, a number of animals (typically males) are transferred from each subpopulation to the next subpopulation in the circle. The behaviour of such a scheme was previously analysed by Nomura and Yonezawa (1996). By computing the eigenvalue effective population sizes (Ewens, 1982), the performance of a circular mating scheme is compared to the performance of a panmictic mating scheme with an undivided population. In addition to deriving a coalescence approximation, I here focus on aspects relevant to whether to choose a circular mating over a panmictic scheme.

As an alternative to forward simulation, the coalescent process (Kingman, 1982) in many situations produces good approximations to the long-term behaviour of population genetic models. Such an approximation is obtained here. The results are compared to the explicit results for the eigenvalue effective population size.

Materials & methods
Eigenvalue effective population size. For inbreeding schemes, it is straightforward to set up linear systems of equations describing the probability of sampling alleles identical by descent (IBD) from animals of all possible degrees of relationship. For schemes that converge to a state where all alleles are IBD, the equations can be converted to a homogeneous system of linear equations describing the decay of outbreeding, shown in Equation 1.

$$\boldsymbol{f}' = \mathbf{M}\boldsymbol{f} \tag{1}$$

f is a vector non-IBD probabilities for pairs of alleles drawn from the same individual (f), two different individuals in the same subgroup (g_0) and two individuals from subgroups i steps apart, respectively (g_i, i=1, …, n–1), in some generation. F' is the vector of probabilities in the next generation.

For a scheme with n=5 subgroups, the equations obtained are given in Equation 2.

$$\mathbf{M}=\begin{Bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ \frac{1}{2N^*} & \frac{1}{2}-\frac{1}{N^*} & \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{1}{4} & \frac{1}{2} & \frac{1}{4} & 0 & 0 \\ 0 & 0 & \frac{1}{4} & \frac{1}{2} & \frac{1}{4} & 0 \\ 0 & 0 & 0 & \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ 0 & \frac{1}{4} & 0 & 0 & \frac{1}{4} & \frac{1}{2} \end{Bmatrix} \tag{2}$$

where $N^* = \frac{4N_mN_f}{N_m+N_f}$ with N_m and N_f being the numbers of male and female breeders in each subpopulation. Note that the first term in the second row differs from the equivalent term in Nomura and Yonezawa (1996), where the term in the present notation is given as $\frac{1}{N^*}$. The equations as stated in Equation 2 can be reduced to lower dimension by exploiting that with n subpopulations, we have that $g_i = g_{n-i}$, where g_i is the probability of sampling IBD alleles from subpopulations i steps apart.

The eigenvalue effective population size (e.g. Ewens 1982) is then derived from the leading eigenvalue of the matrix describing the development of probabilities of non-IBD for various combinations of alleles. The eigenvalue effective populations size λ_1 is obtained by solving $N_e = 1 - \frac{1}{2N_e}$.

Coalescent approximation. The coalescent process (Kingman, 1982) describes genealogy of alleles in a population. It assumes that the population is of sufficient size such that at most one coalescence event takes place in any generation. Thus, the approximations are expected to work best for large populations. The expected rate of coalescence permits the definition of a coalescent effective population size. Asymptotically, the probability that two alleles are located in the same subpopulation is $\frac{1}{n}$. The probability of coalescence for two alleles in the same subpopulation (ignoring that alleles may be in the same individual) is $\frac{1}{2N^*}$. Therefore, the asymptotic probability of coalescence is $\frac{1}{2N^*n}$. In a panmictic, population the probability of coalescence is the same, i.e. when the coalescent model is valid and the population is large enough, the rate of coalescence and, hence, the coalescent effective population size are the same.

Analysis. All numerical analyses were done in R (R Core Team, 2021). Eigenvalues were computed for specific cases of numbers of breeding males and females in each subpopulation (represented by N^*=4 or 100). The equations leading to Equation 1 were iterated to illustrate the time course of the decline in outbreeding. Results were plotted as $\log(1 - g_i)$ against generation number. The value of the leading eigenvalue was compared to the eigenvalue effective population size of a panmictic population of dioecious individuals with nN_m males and nN_f females. For such a population the eigenvalue effective population size is given by

$$N_e^p = \frac{1-\frac{1}{N'}+\sqrt{1+\frac{1}{N'^2}}}{2} \tag{2}$$

where $N' = \frac{4nN_mN_f}{N_m+N_f} = nN^*$. Whenever N' is large, $N_e^p \approx N'$.

Results

The results for iterations where each subpopulation has N^*=4 or N^*=100 are shown in Figure 1. In both situations, there is a rapid initial build-up of relationship in each subpopulation (red and blue). In a panmictic population, this happens more slowly. For the small population in the long term (more than about 40 generations), inbreeding levels in the panmictic scheme exceed those in the circular scheme. The asymptotic rate of inbreeding in the panmictic scheme is faster than in the circular scheme. In contrast, in the large population, inbreeding levels in the circular scheme always remain higher. The asymptotic rates of inbreeding are indistinguishable. After the first generations, the IBD probability in the panmictic population is indistinguishable from the IBD probability for alleles sampled from subpopulations two steps apart. In Figure 1, all probabilities increase at the same (exponential) rate, but the curves for the different statistics are displaced by a number of generations with the within-population statistics leading the between-population statistics.

Discussion

Short-term behaviour. The short-term behaviour of the circular mating scheme produces relatively high levels of realised inbreeding (as measured by f) and coancestry inside subpopulations (as measured by g_0). As previously pointed out by Nomura and Yonezawa (1996), this is caused by the restriction of choice of males in each subpopulation. Sire and maternal grand-sire of any individual will often be closely related. In a panmictic population, sire and maternal grand-sire would be drawn from a large pool of males.

In many conservation schemes the primary interest tends to be on situations with very small populations. Hence, the situation demonstrated in the left panel of Figure 1 is important. This example is extreme. In this example, the circular mating scheme is superior for a period of up to 40 generations.

Long-term behaviour. As expected from the structure of the model, asymptotically all probabilities increase at the same rate, but they are displaced by a number of generations (by 5-10 generations in Figure 1).

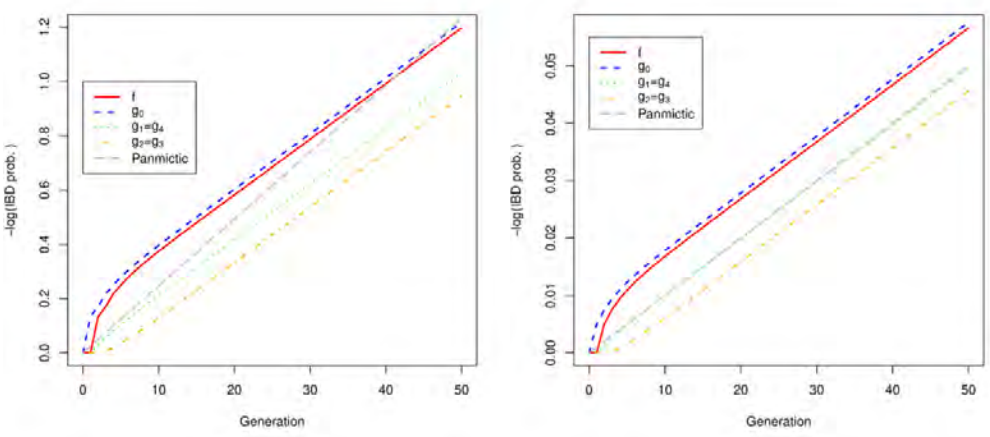

Figure 1. Time course of minus the logarithm of inbreeding levels for the first 50 generations for a circular mating scheme with N^*=4 or N^*=100 (right). f indicates the inbreeding level, whereas g_i are the IBD probabilities for alleles sampled from subpopulations i steps apart. Panmictic (dashed grey) indicates the expected increase in a panmictic population of dioecious individuals with the same number of breeders. In the right panel, panmictic line and the line for g_1 are nearly on top of each other. Note that the y-axes differ in scale.

The coalescent approximation shows that the asymptotic behaviour of the model is the same for the circular scheme and for a panmictic scheme whenever the coalescent model provides a valid description of the population. Primarily, this requires that the population should be large. This agrees with the analysis shown in the right panel of Figure 1. In this case, the behaviour of the IBD probability for alleles drawn from subpopulations two steps apart is indistinguishable from the behaviour of a panmictic population. For smaller populations the situation changes and the asymptotic rate of increase in inbreeding for circular schemes is slower than the rate observed in the panmictic population.

Choice of conservation schemes. Managing a circular mating scheme is more complex than a panmictic scheme. For populations with very small numbers of breeding animals, a circular mating scheme provides slower long-term rates of increase in inbreeding than does a panmictic scheme. However, this occurs at the expense of short-term increases in realised levels of inbreeding. Even for the very small population shown in the left panel of Figure 1, the advantage in lower long-term rate of inbreeding only manifests itself after about 40 generations. Up to that point, the realised inbreeding in a circular scheme is higher than in a panmictic scheme. The difference becomes smaller as populations get larger. In the right panel of Figure 1, it has disappeared altogether.

An additional advantage (not modelled here) of a circular scheme is that it provides some protection against (intentional or unintentional) overuse of particular animals (say, popular sires) in the breeding scheme. Disadvantages to circular schemes include susceptibility to errors. In addition, in numerically small schemes, subgroups may fail to produce males or females, which would have to be addressed by deviating from the scheme.

Abstract

Many local dairy cattle breeds are facing extinction due to a large proportion of foreign genes which have been introgressed in the past. In addition, the performance gap to popular high-yielding breeds is increasing. In this simulation study it was investigated whether a rotational crossbreeding scheme including Optimum Contribution Selection methods can promote Angler, a typical local breed, as a crossing partner for the high-yielding breed German Holstein, while regaining the genetic uniqueness of Angler. Three scenarios that differed in the constraints for Optimum Contribution Selection were evaluated. The results showed that the reduction of migrant contributions e.g. from German Holstein in Angler slowed down their genetic gain remarkably. However, the potential of preservation of the breed increased. Not restricting the amount of migrant contribution or keeping it at a constant threshold resulted in much higher response to selection and thus might be most appealing for breeders that are primarily interested in their herd's performance.

Introduction

European Red Dairy Breeds (ERDB) usually have small population sizes and thus a slower rate of genetic gain than high-yielding breeds. This caused the performance gap between ERDB and high-yielding breeds to increase, especially since genomic selection is widely used in the latter. This led to the fact that many local breeds are facing extinction from introgression of high-yielding breeds, and replacement by high-yielding breeds for economic reasons. The introgression of foreign breeds to increase the performance of local breeds was common in the past, which has caused high foreign genetic material in many local breeds, i.e. Vorderwald cattle (Hartwig *et al.*, 2014), Angler, and Red and White Dual Purpose (Schmidtmann *et al.*, 2021). To recover the original genetic background, advanced Optimum Contribution Selection (aOCS, Wellmann 2019) methods can be used for selecting dams and sires as parents of the next generation. aOCS can decrease the level of migrant contributions and recover the original parts of a breed, while achieving genetic gain and controlling the rate of inbreeding at native alleles (Wang *et al.*, 2017). Nevertheless, the genetic gain achieved by aOCS methods might not be sufficient to compete with high-yielding breeds. The low to medium performance level of local breeds and the increasing performance gap to high-yielding breeds caused many farmers to switch to high-yielding breeds. In a previous study (Stock *et al.*, 2021) we showed that to promote ERDB and to improve their competitiveness the implementation of a genomic rotational crossbreeding scheme can be advantageous. ERDB benefited due to the enlarged reference population including both ERDB and crossbred animals, and the increased performance level of crossbred animals. The aim of the present simulation study was to examine the benefit of rotational crossbreeding schemes at the example of German Angler, as a typical ERDB, and German Holstein, as a typical high-yielding breed. Several and conflicting objectives were studied, i.e. the reduction of foreign genes in Angler, the increase in inbreeding in Angler, the genetic gain of Angler for purebred and for crossbred performance and maximisation of heterosis effects in crossbred offspring.

Materials & methods

A two-way rotational crossbreeding scheme for a ERDB (Angler) and a high-yielding breed (Holstein) was simulated, using the R package xbreed (Esfandyari and Sørensen, 2017). The genotypes (Illumina

BovineSNP50 BeadChip, 50k) and pedigree data from 268 Angler cattle (Wang *et al.*, 2017) and 1,935 German Holstein (Streit *et al.*, 2013) were used as input to create the founder generations of 3,000 Angler and 6,000 Holstein animals. The first crossing was purebred Angler × purebred Holstein, followed by the rotational crossbreeding scheme, in which Angler and Holstein bulls were mated alternately to crossbred dams. Thus, purebred lines of Angler and Holstein were generated, as well. The number of animals in each population was kept constant, either 3,000 or 6,000, as well as a constant effective population size (N_e) of 100. Discrete generations were considered for both pure and crossbreeding schemes. Allocation of sires and dams was always random. Genetic gain, mean kinship, native kinship and migrant contributions in Angler and their rotational crossbred progeny with Holstein were examined in 3 different scenarios (Table 1). The simulated scenarios differed in the selection criteria of Angler. Selection of individuals to become parents was based on classical or advanced optimum contribution selection (OCS) methods. The classical OCS scenario maximized genetic gain while restricting the increase of mean kinship in the population. The advanced OCS (aOCS) scenarios additionally restricted the increase of native kinship and the increase of migrant contributions (MC) in the population. The overall optimization goal in each scenario was to maximize genetic gain, such as to maximize the breeding values. Genetic gain was measured in true genomic values (TGV), such as:

$$TGV_i = \sum_{j=1}^{1000} (a_{ij} + (2 - x'_{ij})d_{ij})x'_{ij}$$

where a_j and d_j are the true additive and dominance effects of the j^{th} QTL, and x'_{ij} = 0, 1, or 2, depending on the respective genotype.

Results & discussion

As shown in Figure 1 Angler performed best in Scenario 1, in which only the mean kinship was restricted, and worst in Scenario 3, in which the native kinship was constrained and the MC was defined to decrease 1% in each generation. This result shows that genetic gain was in conflict with the genetic uniqueness in this population. In addition, it shows the importance of Holstein contribution to the genetic gain in Angler. Crossbreds slightly outperformed Angler and Holstein in the beginning. They performed best and most stable in Scenario 1 and 2 and then converged to the TGV of Holstein as of generation 5. In Scenario 3 the genetic gain of Angler started to flatten by generation 5 and thus caused the TGV of crossbreds to drop notably. Decreasing the Holstein contribution in Angler slowed the increase of the mean kinship in the Angler population.

Thus, constraining native kinship and reducing MC (Figure 2) resulted in a higher level of genetic diversity in the Angler population, as shown by the least decrease of additive variance (Figure 3). The overall reduced genetic gain of Angler in Scenario 3 led to the largest difference between the performance of the parental breeds Angler and Holstein. The slower rate of genetic gain of Angler arises from the removal of the Holstein contributions, and from the additional constraints that were imposed. In addition, these

Table 1. Overview of simulated scenarios.

Scenario	Selection method of Angler (optimization goal)	Constraints
1	OCS (genetic gain)	Mean kinship (max. ΔF = 0.5%)
2	aOCS (genetic gain)	Native kinship (max. ΔF = 0.5%), Migrant contribution (as in founder generation)
3	aOCS (genetic gain)	Native kinship (max. ΔF = 0.5%), Migrant contribution (-1% each generation)

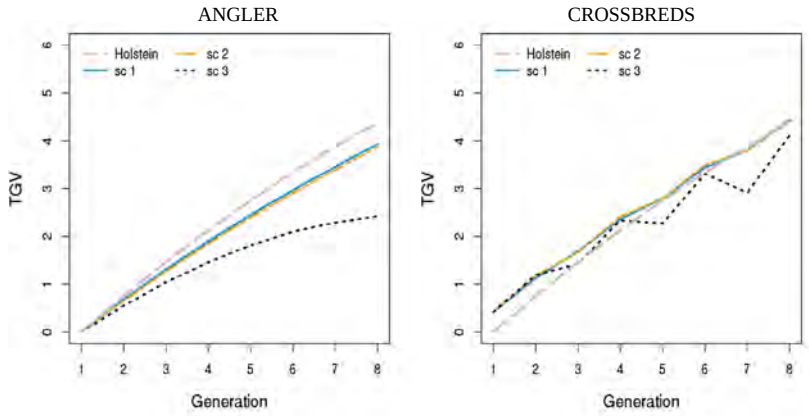

Figure 1. True genomic values (TGV) of Angler and Holstein (left), crossbred animals and Holstein (right) over the simulated time period of 8 generations of rotational crossbreeding. Sc1 = Scenario 1, sc 2 = Scenario, sc 3 = Scenario 3.

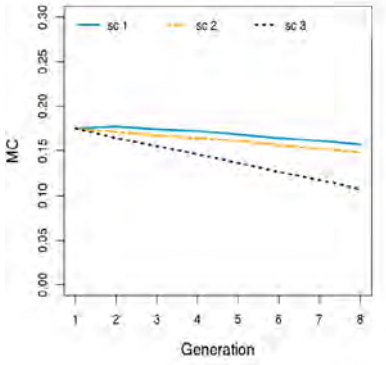

Figure 2. Amount of migrant contribution (MC) from Holstein in the Angler population over the simulated time period of 8 generations of rotational crossbreeding. sc1 = Scenario 1, sc2 = Scenario, sc3 = Scenario 3.

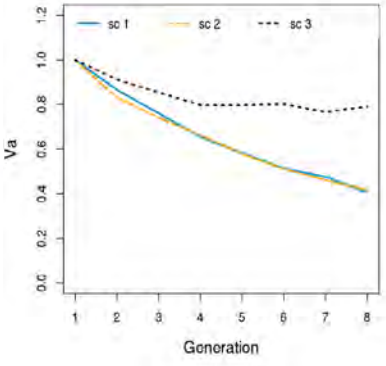

Figure 3. Additive variance (V_a) in Angler over the simulated time period of 8 generations of rotational crossbreeding. sc1 = Scenario 1, sc2 = Scenario 2, sc3 = Scenario 3.

constraints reduced availability of animals to become parents, leading to a low selection intensity and thus loss of opportunity for selection and consequent reduced rate of genetic gain in this scenario.

The difference between the genetic gain of Holstein and Angler was too large to achieve benefits from rotational crossbreeding by the exploitation of heterosis. Hence, the additional heterosis arising from making the breeds genetically more distinct did not compensate for the reduced rate of genetic gain. In addition, the large differences in the performance of crossbred animals from generation to generation can be problematic in practice, i.e. regarding the management of the herd or economic factors.

Conclusions

The results confirmed that the implementation of a genomic rotational crossbreeding scheme could be an interesting option to promote numerically small breeds like German Angler, if a suitable partner breed is available for such a scheme. If this is the case, this might increase their attractiveness, and thus might

reduce the risk of numeric extinction. The results further showed that it is in general possible to combine a genomic rotational crossbreeding scheme with the maximization of genetic gain, while simultaneously restricting the increase of inbreeding and reducing migrant contribution. The latter one turned out to be the most compromising restriction with regard to genetic gain in purebreds, and resulted in remarkable waves of genetic gain observed in the crossbred individuals. The reduction of migrant contribution with the main aim to increase heterosis-effects in crossbreds is, however, not a recommendable breeding strategy. This is because the possible gain in heterosis cannot compensate for the reduced genetic gain imposed by the additional OCS restrictions.

Abstract

Several QTL regions affecting number of teats have been detected in commercial pig lines. In this study we follow the indirect effects of index selection on different QTL regions for number of teats in two maternal lines in 40K animals with imputed 555K SNP. In total, 3 QTL regions overlap between the two populations. For a QTL on *Sus scrofa* chromosome 7 (*SSC7*), the underlying functional variation affecting number of thoracic vertebrae located in the vertnin gene has also been genotyped showing an allelic substitution effect of nearly 0.4 teats in both lines. However, allele frequencies show an opposite trend at the vertnin gene locus in the two lines. Moreover, epistatic effects between two QTL regions on *SSC7* and *SSC12* are investigated at the molecular and phenotypic level.

Introduction

Some mammals, such as mice and pigs, show variation in the number of mammary glands. In pigs, number of teats (NTE) are monitored in commercial breeding and are part of the overall selection index. The aim of this work is to identify how the selection index indirectly affects QTL regions for NTE. In a previous GWAS (van Son *et al.* 2019), we showed in different lines the segregation of the two variants at the vertnin *(VRTN)* locus which is known to cause the development of additional thoracic vertebrae and ribs. Every rib has the potential to develop an additional mammary gland and therefore also explains the effect of this QTL on NTE (Veltmaat, 2017). In addition, several other QTL regions for NTE have been reported in pigs for which the molecular basis remains unknown (Moscatelli *et al.,* 2020, Zhuang *et al.,* 2020). In this study, we identified two additional QTL in our maternal lines on *SSC10* and *SSC12.* At all three QTL, allele frequencies change over time, however, for some loci allele frequencies change in the opposite direction in the two lines. Moreover, the allelic effects of the second largest QTL located at *SSC12* differs between homozygous genotypes at the *VRTN* locus on *SSC7.* This difference can be due to distinct interactions of the *VRTN* locus with different local genetic background, i.e. epistasis (Mackay, 2014).

Materials & methods

Phenotypes, genotypes and pre-processing. We evaluated NTE in two pig populations L (Landrace) and LW (Large-White based). NTE was recorded at birth on both males and females. The L population animals were born between 2013 and 2020. The LW population animals were born between 2009 and 2020.

Two datasets from each population were used: ALL and GENOTYPED. The dataset ALL consisted of all genotyped animals and their contemporaries that had phenotypes (around 300,000 animals per line). Using ALL, the phenotypes were pre-corrected for all non-genetic effects (sex, heard-year, and litter). The non-genetic effects were estimated with a pedigree-based linear model in ASReml v3.0 (Gilmour *et al.*, 2009). The dataset GENOTYPED was a subset of ALL consisting of all animals that had both phenotypes and genotypes (39,956 L and 39,945 LW). This dataset was used to perform the GWAS. All GENOTYPED animals were genotyped on Illumina GeneSeek custom SNP chips (25K, 50K or 80K) (Lincoln, NE, USA). Genotypes of the animals were imputed within population using Fimpute v3 (Sargolzaei *et al.*, 2014) to

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_451, © C.A. Sevillano *et al.* 2022

a set of 48,075 SNPs. In addition, some boars were genotyped using the Axiom porcine 660K array from Affymetrix (Affymetrix Inc., Santa Clara, CA, United States). A second imputation was performed within population using Fimpute v3 (Sargolzaei *et al.*, 2014) from the 48,075 SNPs set to a set of 554,768 SNPs. Quality control was performed at each level of imputation as described in Van Son *et al.* (2019).

Genome-wide association analysis. A single-SNP GWAS was performed with the GENOTYPED dataset within each population using a linear animal model in GCTA software (Yang *et al.*, 2011). Only SNPs with a MAF≥0.01 were used in this step. Significant SNPs and QTL were detected using a $P<1.0\times10^{-8}$.

Results

The mean value for NTE is around 1 teat higher in the L compared to LW (16.72 vs 15.85 for GENOTYPED animals). The L line has gained 1 extra teat in the last 8 years, while the LW line has only gained 0.6 extra teat in the last 10 years (Figure 1). The heritability (h^2) was 0.39 for L and 0.34 for LW.

The GWAS results for NTE in both lines clearly show the QTL on *SSC7* which has been reported earlier to be associated with NTE (van Son *et al.* 2019). In addition, 5 other QTLs segregate on several other chromosomes in the L line, and another 4 QTLs in the LW line. Only 3 QTL regions overlap between the two populations, including the QTL on *SSC7* and the QTL regions on *SSC10* and *SSC12*. The position of the most significant SNP (top SNP) differs slightly between populations for these 3 QTL regions. On *SSC7*, the *VRTN* promoter SNP (VRTN_RS709317845) is the most significant in LW, while the SNP AX-116329721 is the top SNP in L. However, the *VRTN* promoter SNP and the AX-116329721 SNP are in high LD (r^2) (0.98 in L and 0.91 in LW). On *SSC10*, the top SNPs for each line are 124 kb apart and they show low LD in both populations (0.004 in L and 0.002 in LW). On *SSC12*, the top SNPs for each line are 96 kb apart and they are in LD in L population (0.67) but not in LW population (0.002).

In Table 1, we show the parameters for the top SNPs in the QTL regions of *SSC7* and *SSC12*, as they have the largest effect for NTE. For *SSC7,* we limited to the *VRTN* promoter SNP as it is in high LD with the other top SNP in the same region. The top SNP in *SSC12* for line L (AX-116444814) is not present in the GWAS results in LW line due to MAF lower than 0.01. The frequency of the allele C of the *VRTN* promoter SNP increasing NTE is more than four times higher in the L line compared to LW (0.75 vs 0.17) (Table 1). Figure 2 shows that the frequency has been increased over the years in L line, whereas it is dropping in the LW

[2] Relative to the allele increasing NTE.

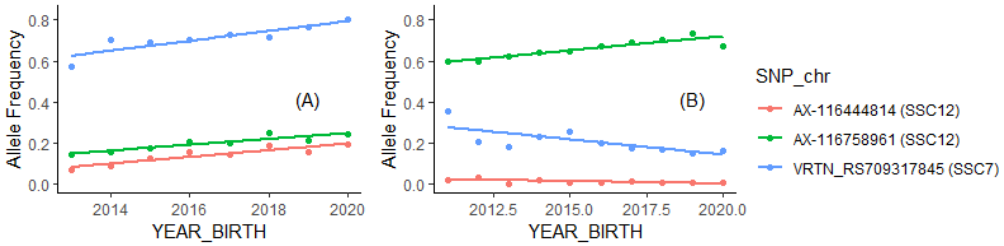

Figure 2. Allele frequency trend for three SNPs associated with number of teats. (A) Landrace population from 2013 to 2020. (B) Large White population from 2011 to 2020.

line. At the same time, the allele increasing NTE on *SSC12* is slightly increasing in both lines. The allele of the top SNP increasing NTE on *SSC12* for LW is much more frequent in LW compared to L (0.22 vs 0.70).

Table 2 shows that allele substitution effects at the *SSC12* QTL are dependent on genotype at the *VRTN* locus on SSC7 and differ between lines. In general, the size of the effect is much higher in *VRTN*-CC animals than in *VRTN*-AA animals. The top SNP in LW (AX-116758961) at the QTL on *SSC12* has a much larger effect in LW than in L but only in *VRTN*-AA animals (0.14 vs 0.06). At the same time, the top SNP in L (AX-116444814) at the QTL on *SSC12* has a lower effect in LW than in L, especially for *VRTN*-AA animals where the effect is even negative (-0.07).

Discussion

This study shows that selection acts on different QTL for NTE in the two sow lines although three QTLs overlaps across lines. However, epistatic effects seems to be playing a role between the two most significant QTL on *SSC7* and *SSC12* that overlap across the two lines. In both lines, CC animals at the *VRTN* locus have a higher genetic potential to develop additional teats than AA animals. Furthermore, the allele frequencies and their trend are the opposite in both lines. At the *VRTN* locus, the allele increasing NTE is going to fixation in L and rather low and declining in LW. At the *SSC12* QTL, the frequency of the allele increasing NTE is very high (0.70) in LW while it is only 0.20 in L. In addition, the top SNP in both lines are different and not in LD in LW. Altogether, this results in different selection pressure at the two QTL. A large proportion of the L animals carry the C allele increasing NTE whereas more than 50% of the LW animals are homozygous for the A allele. Therefore, the unknown causal mutation at the QTL on *SSC12* contributes more to the overall genetic potential and selection space for NTE in LW. Finally, the allele increasing NTE at the top SNP of the *SSC12* QTL in L is hardly present in LW and does not increase NTE in *VRTN*-AA

Table 2. Allelic effects of the largest QTL on SSC12 according to genotypes at the *VRTN* locus on *SSC7*.

Line	SNP	*VRTN*		N of animals[1]	
		CC	AA	CC	AA
L	AX-116444814	0.32	0.12	22,569	2,521
	AX-116758961	0.15	0.06		
LW	AX-116444814	0.27	-0.07	1,245	27,358
	AX-116758961	0.16	0.14		

[1] Number of animals per *VRTN* genotype.

animals. In any case, we clearly show an increased genetic potential to develop additional teats in *VRTN*-CC animals. Altogether, this example shows that rare variants are neglected by genomic selection and could get more emphasis by marker-assisted selection approaches in the breeding program. Additional analyses including data on number of vertebrae and ribs, as well as detailed sequence data, should help to pinpoint the molecular basis of this increased selection space of the *VRTN*-C allele for NTE.

452. Phylogenetic analysis of local cattle population in northern province of Sri Lanka

K.G.C.B. Wijebandara[1], M.S. Kurukulasuriya[1], P.C.G. Bandaranayake[2] and G.L.L.P. Silva[3*]

[1]Department of Animal Science, Faculty of Animal Science and Export agriculture, Uva Wellassa University of Sri Lanka, Badulla, 90000, Sri Lanka, [2]Agricultural Biotechnology Centre, Faculty of Agriculture, University of Perdeniya, 20400, Sri Lanka, [3]Department of Animal Science, Faculty of Agriculture, University of Perdeniya, 20400, Sri Lanka; pradeepas@agri.pdn.ac.lk

Abstract

The present study focused to identify phylogeny of phenotypically short, local cattle population found in Northern Province using mitochondrial Cytochrome Oxidase Sub-unit I. Two cattle populations; Mannar and Jaffna cattle from Northern Province were included in the study. The results showed that Northern local cattle have low genetic polymorphism. Phylogenetic analysis of Northern local cattle and *Bos indicus* clustered together in a separate group. The shortest evolutionary divergence reported between Mannar and Jaffna cattle identifying them in one population, distributed in two geographical destinations. Morphometric parameters of Northern local cattle showed that they are phenotypically smaller compared to other local cattle populations in Sri Lanka. However, their phylogenetic relationship with the other local cattle in Sri Lanka is yet to be identified.

Introduction

Among the cattle breeds in Sri Lanka, Lankan (*Batu Haraka)*, Thawalam and Thamankaduwa cattle breeds have been identified as the indigenous breeds (Chandrasiri, 2002). Apart from the identified breeds, a phenotypically short cattle population has been reported in Northern Province reared for milk, meat, draught and manure. A small proportion of males in this population are reared mainly for breeding and traditional gaming activities (Dias, 2019).

Due to marginal contribution to milk production and less use of them in agricultural activities, cattle in Northern Province have been subjected for genetic improvement, especially after the civil war (Szent-Ivanyi, 2017). The valuable adaptive characteristics of the native cattle breeds were neglected during the breeding activities due to the production-oriented breeding (Abayawansa, 1992). Several studies have been conducted with local (*Batu Haraka)*, Thawalam cattle and Thamankaduwa cattle populations for morphological and quantitative trait analysis (Silva *et al.*, 2010) and genetic analysis (Senavirathne and Lokugalappatti, 2020). However, the indigenous cattle population in the Northern Province of Sri Lanka are yet to be genetically characterized. Therefore, the present study was conducted to identify the phylogeny of Northern cattle population in Sri Lanka and to identify the population specific phenotypic characters.

Materials & methods

Sample collection. Sampling sites were selected according to the information gathered from the Northern Provincial Department of Animal Production and Health on availability of non-crossbred, non-descriptive, short local cattle. A total of 34 blood samples were collected from external jugular veins of 15 cattle (six males; nine females) from Mannar district (Nanattan, Manthai West Veterinary regions) and 19 cattle (seven males; 12 females) from Jaffna district (Maruthankarny Veterinary region) into EDTA tubes for DNA extraction. The selected animals were at two to three years of age. The cattle breed was confirmed using phenotypic characters and the information gathered from the farmers and the Veterinary Office regarding breeding activities. In order to ensure the genetic non relatedness, maximum of two genetically non-related animals were selected from a single farm. Phenotypic information on height at withers, rump

DOI: 10.3920/978-90-8686-940-4_452, © K.G.C.B. Wijebandara *et al.* 2022

height, heart girth, coat colour, hair coat type and presence or absence of horns of the selected animals were recorded.

Total genomic DNA were extracted from EDTA blood using the MasterPure™ DNA Purification Kit. Agarose gel electrophoresis and nanodrop spectrophotometry were used for the visualization and quantification of the extracted DNA.

Amplification of mitochondrial cytochrome oxidase sub-unit I (COI) using polymerase chain reaction (PCR) and sequencing. The complete mitochondrial COI region was amplified using the primers: (F:5'-GGTCAACAAATCATAAAGATATTGG-3';R:5'-TAAACTTCAGGGTGACCAAAAAATCA-3') and expected PCR product size is 680 bp. Polymerase Chain Reaction was carried out with 150-175 ng genomic DNA in a 25 µl reaction volume. The reaction mixture contained 14.9 µl of nuclease free water, 5.0 µl PCR Buffer 5 X, 1.5 µl 25 mM $MgCl_2$, 0.5 µl 10 µM dNTP mix, 0.5 µl each of 10 µM primer, 0.1 µl 5U/ µl Taq DNA polymerase and 2.0 µl of genomic DNA. The PCR conditions were: 1 min at 94 °C for 60 S, 51 °C for 90 S and 72 °C for 90 S and completed with final step at 72 °C for 5 min, then cooled to 10 °C. The size of amplified product was confirmed by 2% agarose gel electrophoresis and sequenced by Sanger sequencing principle using the service provided by Macrogen's sequencing service, South Korea.

Data analysis. The DNA sequences were edited and aligned using ClustalW version 2.0 programme (Larkin *et al.*, 2007) of CodonCode aligner software (Version 9.0.1; CodonCode Corporation, Centerville, MA, USA). Sequence sites representing gaps and unspecified bases were excluded from the analysis and seven COI sequences from the study population were obtained for final analysis. The reference sequences of genus '*Bos*' from several geographical locations were downloaded from NCBI database. The reference sequences include 10 *Bos taurus* breeds (NC_006853.1 *B. taurus*-Reference, DQ124411.1 *B. taurus*-Holstein, AY676857.1 *B. taurus*-Angus, AB074963.1 *B. taurus*-Japanese black, DQ124377.1 *B. taurus*-Korean native, EU177816.1 *B. taurus*-Chianina, EU177835.1 *B. taurus*-Iraqi, EU177849.1 *B. taurus*-Greek, EU177858.1 *B. taurus*-Iranian, FJ971088.1 *B. taurus*-Mongolian), seven *B. indicus* breeds (NC_005971.1 *B. indicus*-Reference, KX575711.1 *Bos indicus*–Sahiwal, AY126697.1 *B. indicus*–Nellore, MF667929.1 *B. indicus*–Vechur, MK335920.1 *B. indicus*–Trinket, MF667930.1 *B. indicus*–Kasargode, MF667931.1 *B. indicus*–Wayanad) and six ancestral and non-prominent breeds (NC_024818.1 *Bos gaurus*, NC_025563.1 *Bos mutus*, NC_013996.1_1 *Bos primigenius*, NC_012706.1 *Bos javanicus*, NC_006380.3_1 *Bos grunniens*, NC_036020.1 *Bos frontalis*).

Nucleotide polymorphism was identified by software DnaSP version 5.1 (Librado and Rozas, 2009). The phylogenetic clusters were identified by maximum likelihood method with 1000 bootstrap replications using the software MEGA X (Kumar *et al.*, 2018).

All reference samples were included into four groups; Yak, *B. taurus*, *B. indicus* and Gaur according to Felius *et al.* (2014) and Mannar and Jaffna cattle populations are considered as two populations for presenting the evolutionary divergence (mean genetic distances). The evolutionary divergence over sequence pairs between groups were estimated based on Tamura-Nei model using MEGA X software. The morphometric data of phenotypic information were subjected to basic descriptive statistical analysis using Minitab 16 software.

Results

Final analysis includes a total of seven sequences (609 bp in length) from the samples (C2, C5, C8 and C13 from Mannar cattle population and C17, C18 and C28 from Jaffna cattle population) and 13 reference sequences. The mean percentages of the four nitrogen bases were 27.7% for adenine (A), 27.2% for thymine

(T), 28.8% for cytosine (C), and 16.3% for guanine (G). A total of 58 polymorphic sites were identified and 53 of them were parsimony-informative sites while having five singleton variable sites. However, Northern cattle population had only one polymorphic site.

Phylogenetic analysis. Local cattle from Northern Sri Lanka were clustered together with *B. indicus* separating from *Bos taurus* cattle creating two monophyletic clades (Figure 1). *B. indicus* were placed in a one clade with Northern local cattle in Sri Lanka, however, they can be clearly identified as a separate group in the phylogenetic tree. Further, the evolutionary divergence over sequence pairs between groups showed, lowest mean genetic distance between Jaffna and Mannar cattle populations (0.0004) while having 0.0037 and 0.0041 mean genetic distances between Jaffna and *B. indicus* populations, and Mannar and *B. indicus* populations, respectively.

Morphological analysis. Local cattle in Northern Province are short and small animals (Table 1). According to the qualitative characters, local cattle from Northern Province were having uniform coat colours. The coat colour varied from among red, white, black, brown and grey colours, however, predominantly they were in white (38.10%) and brown (33.33%) colours. Their hair is short and straight. The shape of the body was short and stocky. Mostly animals had horn (90.43%).

Discussion

According to the evolutionary history, the local cattle found in Northern Province are inheriting from *B. indicus* cattle. Low genetic diversity and separating as a group in the *B. indicus* clade reflects that this group

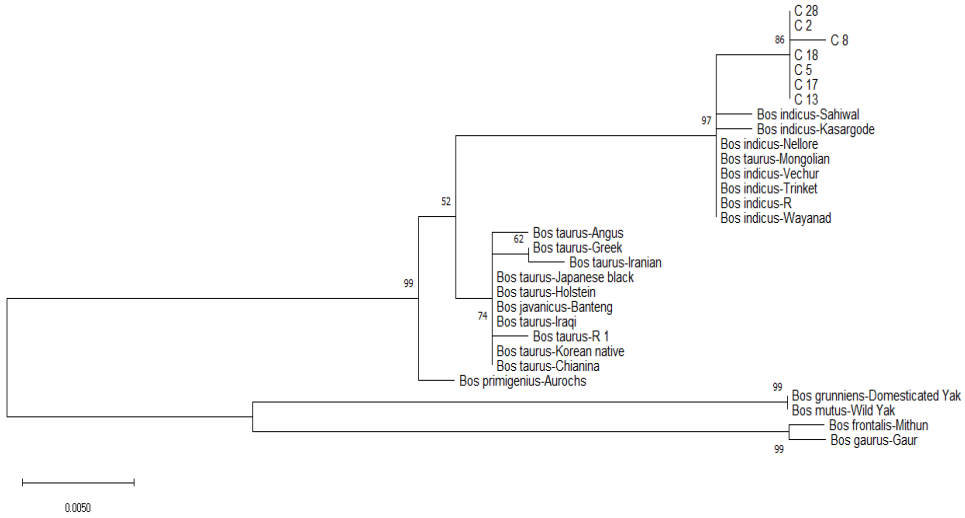

Figure 1. Maximum likelihood tree displaying the variation of cattle breeds based on phylogenetic analysis of the COI gene.

Table 1. Morphometric parameters of Northern cattle population (mean ± SD).

Gender	Height at withers	Rump height	Heart girth
Male	90.05±3.03	97.44±1.54	110.00±2.45
Female	88.14±1.52	94.49±2.17	105.20±3.44

of cattle might have developed phenocopies owing to the environmental conditions prevailing in the area in which they also have subjected to isolated breeding. These two actions might have resulted their small body conformation leading to produce distinct group of cattle unique to the area. The shortest evolutionary divergence was reported between cattle populations in Mannar and Jaffna emerging as one population, distributed in two geographical destinations. Indigenous livestock breeds are known for their hardiness, survival on little inputs and adaptability to the variable environments and disease resistance. Such breeds are therefore believed to be more economically efficient than other breeds when raised in their home tract (Ayalew *et al.,* 2003). Therefore, the Northern local cattle could have evolved over generations under low level of selections followed in traditional animal husbandry system in the area. As a result, Northern local cattle population has evolved with the adaptability to thrive in harsh native environment, showing resistance to tropical diseases and parasites and sustaining on low quality roughages and grasses. Morphometric parameters reflect that these local cattle populations in Northern Province are phenotypically small animals compared to the other local cattle populations in Sri Lanka which is in accordance with the results reported by Silva *et al.* (2010). However, their phylogenetic relationship with the other local cattle populations in Sri Lanka is yet to be identified.

453. Accounting for heterogeneity of data in implementing genomic selection models applicable to crossbred cattle in India

A. Guintard[1*], L. Bourguignon[2], G. Restoux[1] and V. Ducrocq[1]

[1]Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; [2]Institut Agro (Agrocampus Ouest), 65 rue de Saint Brieuc, 35 042 Rennes, France; ana.guintard@inrae.fr

Abstract

Indian dairy production takes place in very diverse environments. The objective of this study was to identify genotype by environment interactions in the context of establishment of a reference population for genomic selection. Data from 9,265 cows in six states were analysed. The high variability in the distribution of breed types and milk yield across India, as well as the wide range of climatic zones existing in the country are highlighted. This heterogeneity must be taken into account, defining, for example, groups of districts (administrative regions within states), rather than considering India as one homogeneous country, in order to better predict the genomic merit of individuals in their local environment.

Introduction

The dairy sector plays a major role in India, contributing 5.3% of the gross domestic product, and representing an essential source of animal protein in a country where one-third of the population is vegetarian (Belhekar and Dash, 2016). Improving productivity at the animal level is necessary to meet the demand and to ensure self-sufficiency (Chawla, 2009). Genomic selection is a way to increase the milk production in Indian smallholder farming systems (Al Kalaldeh *et al.*, 2021). To implement it, BAIF Development Research Foundation (https://baif.org.in/) has been collecting performances and genotypes for the past four years to set up a reference population. However, the heterogeneity of collected data reflects a huge diversity of production systems over India (across states, climatic zones, herd size, breeds, etc.). Thus, the aim of this study was to analyse phenotypic data from BAIF's database in order to characterise the heterogeneity of performances to account for in the establishment of a reference population for genomic selection.

Materials & methods

Data used for this study originates from the BAIF database and encompass phenotypic data recorded in the states of Andhra Pradesh, Bihar, Gujarat, Jharkhand, Maharashtra, Odisha, Punjab, Rajasthan and Uttar Pradesh between August 2016 and November 2021. Animals were crossbred cattle ranging from pure indigenous *Bos indicus* to pure exotic *Bos taurus* (Holstein or Jersey) cows. The database, contains information on daily milk yield, day in milk, lactation number, last calving date, breed type, the type of recording (by an enumerator or by the farmer himself) the farm, the CDC (Cattle Development Centre, which is a local centre providing services such as artificial insemination for eight to ten villages), the district and the state.

In order to make the dataset suitable for analysis, we filtered the data as follows: (1) Andhra Pradesh and Gujarat states were removed because data were available only on pure zebus (breeding tracks), and were not representative of the diversity of breeds in these states; (2) data from cows with fewer than four records per lactation and with a lactation lasting less than 200 days were removed; (3) data were retained only if they were recorded between eight and 340 days after calving; (4) data from cows with a coefficient of variation in daily milk yield greater than 0.8 on a given lactation or a daily milk yield greater than 25 kg were removed, being more than three times greater than the average daily milk yield (Al Kalaldeh *et al.*, 2021); (5) data from cows with a lactation rank greater than seven were deleted; and (6) for each CDC and breed, data were deleted if they were recorded on fewer than ten cows.

R.F. Veerkamp and Y. de Haas (eds)

Weather data (from worldweatheronline.com), temperature, humidity and precipitation were also considered at different levels of season which were defined as: winter (January to February), pre-monsoon (March to May), monsoon (June to September) and post-monsoon (October to December).

After data filtering and integration of weather data (not available for all the districts), 211,545 records from 9,265 cows in six states (Bihar, Jharkhand, Maharashtra, Odisha, Punjab and Uttar Pradesh), 26 districts, 75 CDC and 4,168 farms were retained for the analysis. The number of cows per herd ranged from one to 47 with an average of 2.2. Overall, 44% of the herds were composed of a single cow while 85% of the herds had three cows or less. The number of cows per CDC varied from ten to 456.

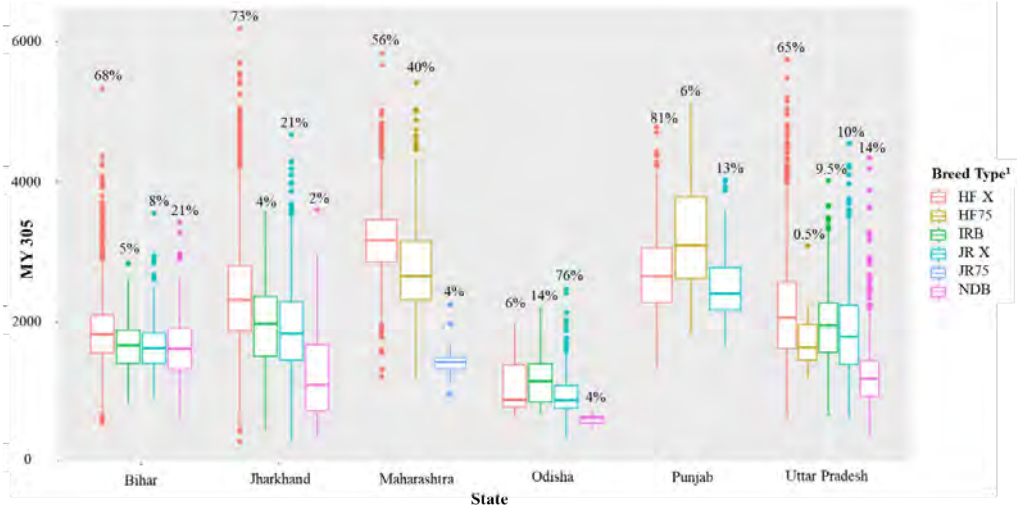
The daily milk yield was transformed into a 305-day production and corrected, using a linear mixed model including the effects of breed type, calving season, lactation rank and type of recording, all treated as fixed.

A recursive partitioning classification using decision trees allowing for clustering of individuals in homogenous sub-populations according to explanatory variables (Breiman *et al.*, 1984), was performed on corrected milk production to identify regions and subsequent characteristics with contrasted production levels.

Statistical analyses were done using RStudio (version 3.5.0) and the ggplot2 package. Recursive partitioning classification was performed using the rpart package.

Results & discussion

Breed distribution. To understand the variability of milk yield, we first looked at the distribution of uncorrected milk production according to breed types between and within states (Figure 1). The percentage of each breed between states varies a lot, ranging from places where indigenous zebus and non-descriptive



[1] HF 75: Crosses with more than 75% of Holstein origin, HF X: Crosses with less than 75% of Holstein origin, JR75: Crosses with more than 75% of Jersey origin, JR X: Crosses with less than 75% of Jersey origin, IRB: Indian Recognised Breed, NDB: Non-Descriptive Breed.

Figure 1. Milk yield production (MY 305) and percentage of each breed type within each state.

cows are an important part of the herd (Bihar, Odisha and Uttar Pradesh), to states that orientated their breeding towards high levels of exotic breeds (Maharashtra, Jharkhand).

Holstein crosses usually show the highest milk production in most of the states. However, we can identify some scaling effect (a significantly higher production in Maharashtra than in other states) and re-ranking effect (in Odisha, Holstein crosses have, on average, a lower milk yield than indigenous breeds).

Figure 1 shows a high variability in the distribution of breed types across the six states. Corrected milk yield was significantly variable among districts (ANOVA, F=170.5, df=25, $P<0.05$).

Milk production under diverse climatic conditions. The recursive portioning classification separated districts into four climatic clusters (Figure 2), with the following predicted average corrected milk productions: 2,999 kg cluster A: Ahmednagar, sd= 649.4 kg, cv=0.2), 2,750 kg (cluster B: Faizabad, Hazaribag, Khunti, Lohardaga, Pune, Ranchi, Ropar and Saharanpur, sd=767.3 kg, cv=0.3), 2,459 kg (cluster C: Ara, Bahraich, Chhapra, Gonda, Hardoi, Hoshiarpur, Kannauj and Meerut, sd=759.4 kg, cv=0.4), and 2,237 kg (cluster D: Allahabad, Bargarh, Bolangir, Buxar, Etawah, Lucknow, Sambalpur, Unnao and Varanasi, sd=701.8 kg, cv=0.4).

Maharashtra shows the highest corrected milk production, especially the district of Ahmednagar (cluster A). This district, situated in a rain shadow region, has a tough climate, with very low rainfall, even during

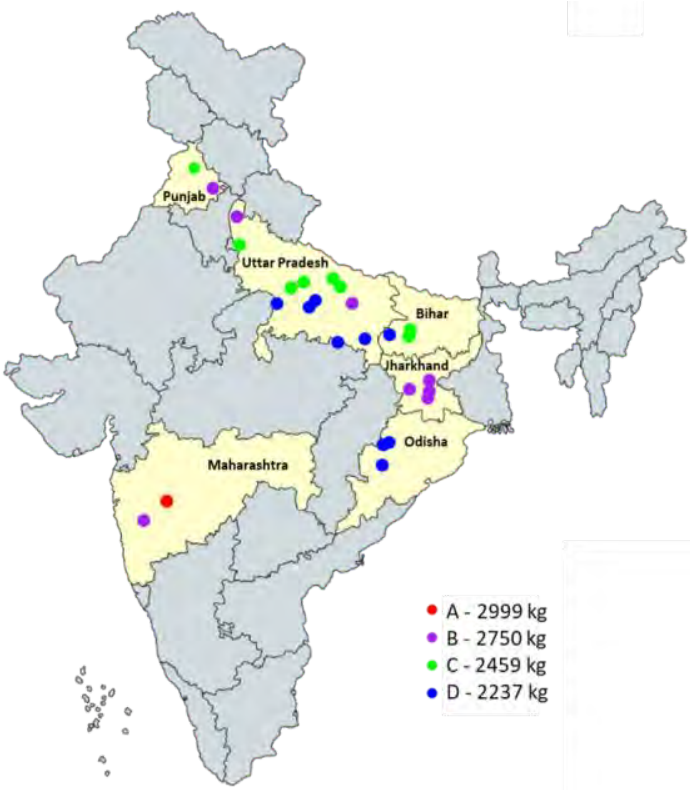


Figure 2. Map of districts partioned by corrected milk production using weather information, each dot corresponding to a homogenous climatic area.

monsoon. The higher average milk production in Maharashtra, is more likely due to a longer technical breeding support of BAIF to local farmers in this state, where BAIF influence started more than 30 years ago. The higher milk production results from years of breeding with exotic breeds, and particularly Holstein cattle. This illustrates that genotype by environment interactions do not only depend on the state, and that beyond climatic conditions, other factors greatly impact production. Particular attention should be paid to the farming system, and further analyses of agro-economic data (major crops, size of the farm, family income, economic status and feeding system of the cows) should help to identify significant determinants of milk yield in India.

Figure 2 also shows that homogeneous groups of weather are not always located within the same state. Indeed, all dots of the same cluster share similar climatic conditions, and we can see that districts of the same cluster can be found in different locations. Mountains and rivers (especially the Ganges river) play an important role in the local weather, resulting in various sub-groups of climates, influencing crops and feedstuff in the area. Considering these regional variations by classifying districts into homogenous climatic zones could help to account for the wide heterogeneity of weathers across India in a genomic evaluation.

Conclusions

India, given its size and its particular milk production, mostly ensured by small and marginal farmers, shows extreme variability in terms of production, breeds and climates, resulting in strong genotype by environment interactions. It, thus, appears crucial to account for them, along with agro-economic characteristics, when establishing a reference population in order to get an appropriate estimation of the genomic breeding value of individuals. In particular, defining a few groups of homogeneous environments across India, rather than considering it as a uniform country, could help to conduct more accurate genomic evaluation in the field.

454. Connections among local nomenclature, phenotypes and genetic characteristics of native chickens in Cambodia: a synthesis

P. Menghak* and M.G.G. Chagunda

Department of Animal Breeding and Husbandry in the Tropics and Subtropics (490h), Institute of Agricultural Sciences in the Tropics (Hans-Ruthenberg-Institute), Hohenheim University, Garbenstraße 17, 70599 Stuttgart, Germany; menghak.phem@uni-hohenheim.de

Abstract

Currently, there is little existing comprehensive information on Cambodian native chicken (CNC). Further, there is no coordinated phenotypic recording. Predominantly, CNC is known by its local names. However, information linking local names to phenotypic and genetic characteristics of CNC is sparse making phenotypic characterization of these genetic resources difficult. The current study aimed to establish the connection between the local nomenclature of CNC, with their phenotypic and genetic characteristics through a synthesis of some key literature, both published and unpublished. The synthesis involved 7 research articles, one FAO technical report, and local grey literature. Results showed that in terms of nomenclature, CNC are named based on their plumage color and other appearance characteristics such as frizzled and small-sided feathers. There was differing degrees of agreement between local names, phenotypic and genetic characteristics. It is therefore important that the native chickens be phenotypically and genetically characterized incorporating indigenous knowledge in order to initiate a platform for a designed breeding program.

Introduction

In Cambodia, livestock contribute 11.4% to national GDP (MAFF, 2021). The chicken population is approximately 50 million, of which 65% are raised in smallholder farms. The majority of native chicken breeds (98%) are in small flocks of less than fifty birds per household. The remaining 35% of chicken is imported commercial layers and broilers that are reared in intensive systems. Raising native chickens provides a source of food protein, helps farmers to generate other household income, avoids complete dependence on natural fishing, and allows women to earn extra income. The native chicken in Cambodia is also mostly used for ritual and cultural activities. This is despite that the native chicken has low productivity, raised in a poor management system with a high mortality rate due to diseases (Siek *et al.*, 2016). Among local consumers, the native chicken is preferred to the exotic breeds. In most parts of the world, local chickens have different names based on different reasons. Predominantly, the names are derived from appearance, behavior, use, region, and general human perception. However, from a local community acceptance, CNC was named based on their plumage color, feather types and a special characteristic such as frizzled feather. Information linking the local names to phenotypic and genetic characteristics of CNC is never explained. Therefore, the current study aimed to establish the connection between local nomenclature, phenotypes, and possibly genetic characteristics of CNC through a synthesis of some key literature, both published and unpublished to deliver key information for the future breeding plan.

Methods

All research findings and national and international databases, both published and unpublished on native chicken in Cambodia, were reviewed. The review synthesized all relevant information on a production system, external/phenotypic and genetic characteristics from 7 research articles, one technical report from the Food and Agricultural Organization of the United Nations (FAO), and chicken databases from a local institution report. There are external characteristics of chicken adapted from the local knowledge and language.

Results

Classification of chicken breeds. In Cambodia, chicken breeds were categorized into native/local breeds, commercial broilers and layers and crossbreds (Sun, 2018). Very few smallholder farmers used exotic breeds (2-3%) (MAFF, 2021). However, there were a few smallholder producers who had crossed their native line with the commercial lines and fighting cocks from local commercial distributors mainly Thailand, Vietnam. The native breeds were all raised mainly for both meat and egg and in general, the local term is 'Moarn Khmer or Moarn Sre' which means Khmer chicken or indigenous. There is no comprehensive information on native breeds' identities and specific region distribution, the external characteristics are non-descript types varied in plumage color, comb type, shank length and body weight. Sann and Chhum (2004) described eight breeds (ecotypes) with brief external phenotypes summarized in Table 1. In addition, there is another local nomenclature called 'Khmao' which means completely black feather, the breed also varies in body size, shank and skin color. Among all ecotypes, Sampov, Kandong, Skuoy and Kragnas accounted for 55, 10, 7, and 5% respectively, similarly to Sun (2018) mentioned that Sampov accounted for the largest population in the country. Based on the available references, native breeds were most classified by their plumage colors, feather types (frizzle, naked neck), and matured size, except for Red Jungle Fowl and fighting cock. However, the local nomenclature has utilized these external traits to differentiate the native chickens and within the country, people have accepted the names of the native chickens though some characteristics are not distinguished. Future breeding plans may need to include and conserve the local nomenclature and external traits such as plumage, skin, color, shank color.

Phenotypic characteristics of native chickens in Cambodia. In a natural-breeding population without selection, external morphologies of chicken are mixed up and complicated to identify both qualitative and quantitative traits of referenced breeds. Among the native breeds, Khmao and Skuoy were easily identified by the black and barred feathers respectively. However, some ecotypes might not be phenotypically classified as a different breed due to their non-descript characteristics such as qualitative phenotypes; colorful plumage, unidentified skin, shank, earlobe color, comb type, and quantitative phenotypes; body weight, and other growth traits, and egg production traits. Some local nomenclatures referred to feather structures (slow-growing, frizzledness, naked neck), which these phenotypes may occur in any populations

Table 1. The external characteristics of Native Chicken (adapted from Sann and Chhum, 2004).

Local name	Adjusted English name by author[1]	Characteristics adapted by author
Moarn Prey	Red Jungle fowl	Wild chicken (Gallus Gallus) with wild color feather
Sampov	Sailing ship	Large body size and its name refers to the ancient sailing ship, colorful (black, wild, silver, gold, white)
Skuoy	Adlay plant/barred feather	Large body size, sex-link barred feather/color
Kandong	No tail/less feather	Large body size, less body feather, no main tail feather, colorful (black, wild, barred, silver, gold, white)
Kragnas	Frizzle feather	Large/small body size, frizzle feather and tail, colorful (black, wild, barred, silver, gold, white)
Samley	Cotton wool	Small body size/white dwarf bantam, white feather-like cotton
Moarn Cher	Comb, small size	Dwarf local chicken/dwarf bantam, has large single comb, colorful (wild, white)
Moarn Chul	Fighting chicken	The female identity was hidden, the male is noted by the shank color (yellow, and dark green), shank and spur characteristics Colorful (Wild, black, gold, white), fighting behavior

[1] The adjusted names based on the local expert knowledge.

under natural selection for adaptation to the external environment. According to FAO (2009), body weight and shank length distribution of the native chicken were different between male and female, and agro-ecologic zones. The male chickens had heavier and taller or larger body sizes than the female, particularly the chickens in the central plain indicated the highest weight, and the smallest ones found in the coastal region but taller than the chickens in highland. The major shank color was yellow representing 50% of the total, and white and yellow skin was 50 and 35% respectively in all regions, regardless of coastal zone which had the highest yellow skin and shank color up to 60% of the total. The results illustrated differing ranges of agreement between the local names and the phenotypic characteristics of all recent ecotypes identified and accepted as breeds by the local communities. Therefore, there should be more described phenotypic traits to name the chicken breeds also they may differentiate by adapting to different agro-ecologic zones.

Genetic characteristics of native chickens in Cambodia. The Red Jungle Fowl (*Gallus gallus*) occurs over a wide geographical range in Southeast Asia. According to a complete mtDNA D-loop study by Osman and Nishibori (2014), the Red Jungle Fowls (RJFs) from Cambodia showed higher diversity than those in Laos and Myanmar. Okumura *et al.* (2006) illustrated that native chicken populations in South-East Asia are genetically similar including Thailand, Laos, Myanmar and Indonesia due to closed distance and random mating. Nishibori *et al.* (2006) conducted a genetic diversity study from 2,245 native chickens in 17 provinces in Cambodia. The genes considered for morphologic traits; plumage colors, shank colors, comb types were studied; the gene frequency of the loci of CNC except one showed a similar tendency to those of Thai native chickens, particularly those from Ratanakiri province. For dominant white plumage color (I/i locus), the frequency of the I allele was very low (0.007) than that of other Asian countries. In contrast, extend black plumage color (E/e+/e), the frequency of the E allele was higher than Asian countries (0.31), and the frequency of e+ was higher and e was lower than in Asian counties. For shank color, the gene frequency for yellow/white was slightly lower than Asian countries except for China, and females presented higher than males did. On average, this finding was similar to phenotypic frequency (50%) by FAO (2009) but quite low in a few provinces around the capital city where there are high numbers of commercial chicken farms. Cambodian native chickens could be regarded as the first to be domesticated and may share similar genetic resources to those in South-East Asian and Asian countries. Among the native population, they may be genetically different due to natural and artificial selection. Recently, Thailand conserved 4 native chicken breeds and was named them based on plumage color, utilization and main region distribution (Dorji *et al.*, 2011). These studies all suggested a further study on genetic characterization with the relevant breed name, phenotypic characteristics, breed utilization in different agro-ecological zones. Connections among local nomenclature, phenotypes and genetic characteristics of native chickens would be informative in designing breeding plans for improvement, preservation and exploiting the genetic diversity.

Table 2. Comparison of body weights and shank length in different regoins (adapted from FAO, 2009).

Sex	Costal	Central plain	Highland
Body weight (g)			
Males	1,322	1,719	1,469
Females	1,315	1,494	1,320
Shank length (cm)			
Males	9.5	9.8	8.7
Females	8.6	8.4	7.3

Conclusions

Cambodian native chicken breeds are most classified by their plumage colors, feather types (frizzle, naked neck), and matured size by the local nomenclature. Where quantitative information is available, body weight and shank length vary in different sexes and agro-ecological zones. Genetically, CNC is highly diverse. Local nomenclature utilizes external traits to differentiate the native chickens although some characteristics are not clearly distinguished. Future breeding plans may need to include and conserve the local nomenclature although robust phenotypic and genetic characterization will be required.

BAIF Development Research Foundation, Uruli Kanchan, Pune, 412202, India; kaustubh.bhave@baif.org.in

Abstract

BAIF Development Research Foundation is a large Indian NGO currently involved in establishing a female reference population (FRP) of crossbred *Bos taurus* × *Bos indicus* cows in smallholder farms in nine Indian states, with the ultimate goal to develop a genomic selection based dairy cattle genetic improvement program. Here we describe the specific challenges encountered in the data collection and its management, as well as the corrective measures adopted to resolve them.

Introduction

In developing countries like India, the majority of milk production comes from smallholder farmers maintaining mixed types of dairy animals having little or no phenotypic and pedigree information. However, limited efforts have been made to undertake genetic selection based on progeny testing for milk production traits. Furthermore, other traits related to adaptation to the local climatic conditions have not been considered either. Conventional genetic evaluation systems are logistically demanding and expensive, especially under the fragmented smallholder farms where generalized identification is lacking. Given the constraints and challenges posed by classical genetic evaluation systems as implemented in other countries, a simplified digital approach for collection of multiple-trait phenotypes is considered. Recorded animals can be genotyped in order to build up a female reference population to carry out genomic selection. Then, by applying selection with an increased level of accuracy for a sustainable selection objective under one or several specific production environments can be envisioned.

BAIF (BAIF Development Research Foundation, https://baif.org.in/) is a large NGO in India which pioneered the frozen semen technology and delivery of AI (Artificial Insemination) service at the farmers' doorstep. One of the core activities of BAIF is cattle and buffalo breed improvement. As part of the genetic improvement program, the 'Enhanced Genetics Project' (EGP) funded by the Bill and Melinda Gates Foundation (https://www.gatesfoundation.org/) is being implemented with the objective to leverage genomics tools in breed improvement. As part of this project, BAIF is developing a female reference population (FRP) of crossbred animals (and in due course, of indigenous breeds and buffaloes) in order to demonstrate the feasibility of genomic selection under the Indian context (see Ducrocq *et al.*, this congress for details). This required the development of an interactive and flexible system to collect a vast amount of information on different traits from crossbred populations spread across several Indian states.

The present paper describes the recording system implemented to build the FRP, the software and its deployment using appropriate digital devices, as well as the challenges faced and mechanisms adopted to resolve various issues during the implementation.

Materials & methods

Implementation of a data collection system and subsequent hurdles faced. The data collection system was implemented in 9 Indian states to accommodate poor to high production systems (Punjab, Uttar Pradesh, Bihar, Jharkhand, Odisha, Maharashtra, Gujarat, Rajasthan and Andhra Pradesh) with 63 data enumerators visiting the farmers' herds and updating the data in the data logger in offline mode,

synchronising the data base once in a day. The data was collected either by the enumerator on a monthly basis and by the farmer. The farmers were provided with data recording cards on which they filled up information such as milk yield on a weekly basis. The enumerator then visited the farmer and collected the data from card and entered the data into the software. To ensure correct data collection by the farmer, unannounced visits by the enumerator were conducted. The option of recording by the farmer was explored specifically to evaluate a low-cost sustainable model of data recording. This architecture is described in Figure 1.

The selection of areas for recording were made in such a way that performance recording could be done comfortably while maintaining 90% of animals from small herd size (2-4 animals of mixed breed type) and 10% from large herds. Every enumerator collected the data from 2 to 3 cattle development centres (CDC) covering 4 to 5 villages each. For every farmer, a baseline survey was carried out to record the farmer's identity and characteristics (activity, sources of income and assets). A herd management survey (herd composition, equipment, etc.) was also conducted at the time of registration of the farmers into the program.

Production performance. Individual production data of each cow and buffalo included test day milk yield using GPS enabled weighing machine and milk components such as fat%, protein%, SNF%, etc. obtained using a portable Milk Analyser. This was recorded once a month together with dry period and calving information. Information regarding calf suckling was added to the list since this is commonly practiced in indigenous cows and buffaloes.

Breeding performance. The system captures insemination details such as natural vs artificial service, pregnancy diagnosis by rectal palpation between 60-90 days. It also captures pedigree details whenever available. Breeding records are collected as and when available.

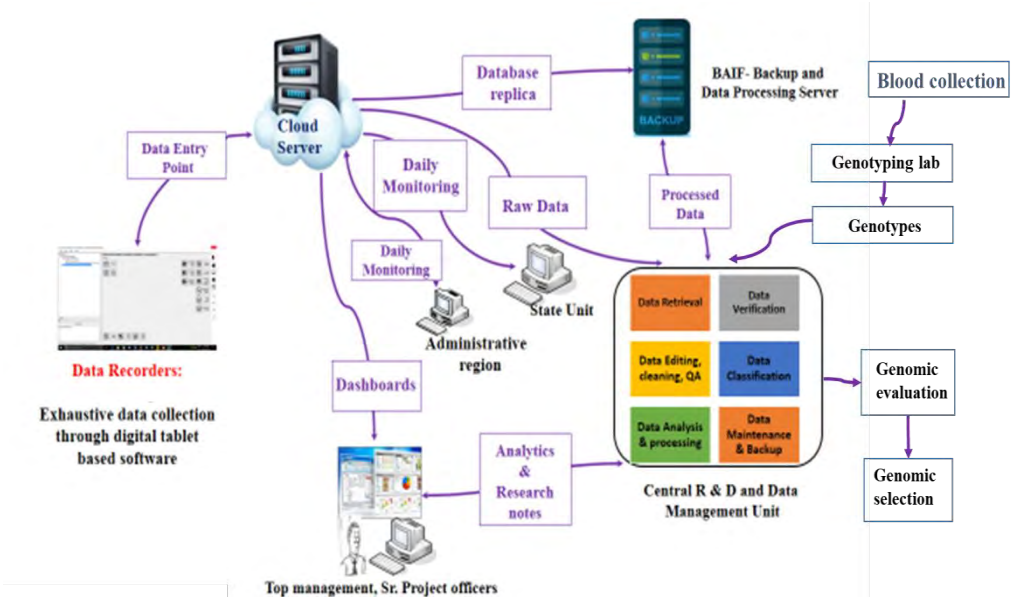

Figure 1. Overview of data collection from farms to the BAIF central research station.

Morphometric and type trait information. As exact weight measurement is not possible at farmers' level; estimated weight is calculated by measuring girth and length with a measuring tape. Morphometric information is collected once in two months. In total, 26 body type traits are also measured or recorded by a trained technician once in a lifetime of every first lactation animal usually in morning hours after milking.

Mastitis incidence. One of the aims of the project was to determine the mastitis incidence as it causes major economic loss. The occurrence of mastitis was recorded when the farmer or the enumerator observed clinical mastitis on the day of recording or during the interval since the last recording. Somatic Cell Count (SCC) information is captured using TANUCHECK SCC kits (Nithya *et al.* 2017) and measured in 5 classes of no. of cells in thousands per ml. This results in a low-cost and simple test at farmer's doorstep to know the udder health status of animals.

Results

Table 1 and 2 describe the distribution of the data collected in the country and its genetic type. Table 3 reports the information already collected at various levels.

Discussion

Data validation and checks. The hierarchical system was developed for data collection and monitoring. 10% of random data recorded by enumerator was cross-validated by a supervisor and 5% by a state coordinator paying an actual visit to the herd. The date of registration, calf birth, performance recording, artificial insemination (AI), calving, etc. were checked for consistency through the software solution. Restrictions were placed on body measurements, on feeding quantities and milk components. Bluetooth facility was used for automatic entry of milk yield into the software. Manual entry of data by enumerators was reduced wherever possible by providing drop down options.

Table 1. Characteristics of data collected between October 2016 and October 2021.

Villages	CDC	Districts[1]	Enumerators	Herds
1,390	155	42	63	13,607

[1] District: administrative region within a state.

Table 2. Breed wise animals under performance recording.

Species	Buffalo		Cow				Total animals
Breeds	Non-descript[1]	Indigenous[2]	Holstein crosses	Indige-nous[2]	Jersey crosses	Non-descript	Recorded
Total	6,836	2,292	14,415	4,134	4,676	1,824	25,049
Genotyped	-	-	6,485	2,250	1,863	517	11,115

[1] Non-Descript: animals without specific characters known to any registered breeds.

[2] Indigenous breeds: Animals with known characters and registered as a breed by NBAGR.

Table 3. Records collected between October 2016 and October 2021.

Milk yield	Milk components	Body measurement	AI records	Body type traits	Mastitis incidence
617,134	237,174	134,288	12,707	5,289	312,153

Difficulties faced and evolution of the data collection and retrieval system. Initial animal identification was difficult, as most animals did not have a tag number. Also, information on villages, cattle development centres (CDC- representing an area of 4-5 villages covered by a same AI technician), etc. was filled manually. To avoid errors, computerised unique IDs were generated for each animal, village, CDC and farmers. Another issue was the absence of uniformity in milk yield data entry. Given the vast region under recording, it was difficult to monitor whether the enumerator actually visited farmers and recorded the animal performance. We introduced GPS-enabled weighing machines with Bluetooth facility. This solved both issues regarding data monitoring as it captured geo-location as well as exact weight of morning and evening milk yield. To avoid erroneous values in milk components, enumerators were equipped with a portable milk analyser which estimated milk components and were advised to calibrate the analyser every 3 months from the local dairies. Considering the very small herd size (sometimes just one animal per herd) observed in earlier recordings, the enumerators were asked to collect data from herds with 2 or more animals in order to separate additive genetic variance from herd variance in statistical analysis.

Future prospects. Multi breed and multi trait selection program for Indian dairy cattle and buffaloes is proposed. Extra non-productive functional traits such as fertility, productive life, farmer preferred (phenotypic) traits such as animal temperament (especially valued by women farmers, panting score (to understand heat stress) will be also recorded. To streamline sample collection process from field to lab, Laboratory Information Management System (LIMS) will be introduced. To refine the genomic prediction system and increase the reference population base; a larger number of animals will be genotyped for multi trait genomic selection program to derive better prediction accuracy. It is also planned that some selected animals will be genotyped on a high density chip or on their whole genome for future studies e.g. causative SNPs for current or possibly novel traits.

Abstract

The impact and progress made in the early stages of Project Mesha's community-based goat breeding program (CBBP) are encouraging. Up-scaling and out-scaling of the CBBP, expanding on its early successes, is considered a sensible priority to reach our ultimate goal of impacting many more landless, marginal and small farm households across a larger area in India. Several factors to consider when expanding a CBBP and ensuring its sustainability stem from challenges we have observed during these early stages that are similar to those faced by other small ruminant CBBPs. Our paper highlights Project Mesha's CBBP impact, elaborates on factors such as the need for community leadership for further up-scaling and out-scaling, and discusses the opportunities that genomics can provide.

Introduction

CBBPs have the potential to genetically improve livestock in developing countries where required infrastructure for setting up national breeding schemes is unavailable (Haile *et al.*, 2020). Additionally, CBBPs engage with and incorporate the views and needs of end users considered crucial for a successful breeding program and therefore progress, while centralised government-controlled schemes seem less successful (Haile *et al.*, 2020). CBBPs generally commit to locally adapted animals, among other things to prevent erosion of these genetic resources (ICARDA, 2018; Haile *et al.*, 2020). In view of the above, the community-led program called Project Mesha that is implemented by the Aga Khan Foundation (AKF) since 2016 in Bihar, one of the poorer states of India with a large goat population (BAHS, 2019), extended its outreach with a CBBP in 2018.

Goats provide livelihood support to over 70% landless, marginal and small farm households in India. Project Mesha (meaning 'buck' in Sanskrit) aims to transform and improve the quality of life of such households in Bihar through improving the productivity and production of local Black Bengal goats owned by them and primarily reared by women. The ultimate aim of the project is to increase the income of these households and empower these women goat rearers. Project Mesha is layering goat productivity improvement interventions on the existing platform of women self-help groups, targeting goat nutrition, preventive health (vaccinations and deworming), low-cost housing and marketing as well as breeding. It also supports adoption of improved goat husbandry and management practices, with all activities being carried out by trained project staff. Preventive health care is delivered through fee-based services by pashu sakhis (meaning 'women friends of livestock'). Currently, the program is serving about 50,000 households in 240 villages in four out of 16 blocks of the Muzaffarpur district in Bihar with a cadre of 250 pashu sakhis.

A high death rate and low production of goat flocks adversely impact the livelihood potential of goat rearing. To generate genetic improvement in these traits, a CBBP has been implemented since 2018 in initially four selected villages, one in each block of the Muzaffarpur district where Project Mesha is operating. The CBBP involves tagging of Black Bengal goats (the predominant breed, being highly prolific and reared for meat production; Dey *et al.*, 2007), data recording on goat reproductive performance, weight, matings and other

measurements in the Dtreo platform (https://dtreo.io), and selecting and rotating breeding bucks among participating villages.

Project Mesha is supported by the Bill & Melinda Gates Foundation, with expert consultancy and training in breeding and genetics being provided by AbacusBio Limited and the Nimbkar Agricultural Research Institute. Our paper has a dual objective of presenting the status and impact of the CBBP implemented through Project Mesha, and elaborating on potential pathways and challenges related to up-scaling and out-scaling of a CBBP based on our learnings and experiences and those of other CBBPs reported in the literature.

CBBP status and impact

Project Mesha's CBBP is the first systematic and organized CBBP in India with operational support and daily management by AKF. Its impact has expanded since the implementation in 2018, with goat data recording currently taking place in 16 villages, and selected breeding bucks with superior performance being placed in additional villages.

Awareness among the resource-poor women goat owners on concepts related to genetic improvement and (in)breeding has increased and resulted in their empowerment as demonstrated by a recent impact study carried out by AKF surveying over 350 households participating in the CBBP. Considering inbreeding, it is typical that only free-roaming bucks are available for mating and they tend to mate most of the does in a village likely including their own progeny. By coordinating movement of selected bucks to distant villages inbreeding risks have been mitigated.

The availability and use of the Dtreo platform, AbacusBio's database system for customized animal recording, is crucial for data recording by the field team, tracking of targets and reporting on any level (e.g. individual breeding buck performance, number of doe assessments done in a village, weight trends). At present, records of 2,357 goats have been entered in the database with almost 6,500 records on weight and assessments of health, adaptive ability, previous litter size and kid survival (Table 1). Around 500 does have so far been mated with just over 30 selected breeding bucks. Data analysis to evaluate the superiority of their progeny is planned for the near future.

Table 1. Number of goats and data from Project Mesha's CBBP recorded in the Dtreo platform to date (December 2021).

Animals	**Total number with records**	**Number alive**[1]
Goats	2,357	1,783
Kids (<120 days old)	284	197
Breeding does (≥120 days old)	1,592	1,300
Bucks (≥120 days old)	481	286
Selected breeding bucks	23	23
Records	**Number**	
Kid weights	4,107	
Doe weights	925	
Doe assessments	1,232	

[1] Not representing mortality, but rather the number of animals that are still alive and therefore available for breeding, or selection in case of kids.

Recent analyses of own performance data (Nimbkar *et al.*, 2021) showed that about half of the does gave birth to twins, 26% to triplets, 20% to singles and 3% to quadruplets. Estimated average daily gain up to the age of 120 days was 57.5 g and ranged from 10 to 140 g per day, indicating substantial variation that enables the selection of superior bucks based on an index score that combines data on breeding goal traits (weight and early growth as kid traits, and size, health, twinning ability and kid survival as dam traits; identified as breeding goal in consultation with goat rearers). The production performance of the Black Bengal breed in the project area in the Muzaffarpur district has thus been characterized.

Expansion of CBBPs

Considering Project Mesha's CBBP is still in its early stages, the activities within the program and the impact and progress made so far are encouraging. Up-scaling and out-scaling of the CBBP, expanding on its early successes, is considered a sensible priority to reach our ultimate goal of impacting many more landless, marginal and small farm households in Bihar and other states of India. Factors to consider when expanding a CBBP are elaborated below.

Self-sustainability of a CBBP is key in the long term but can be difficult to realize due to various dependencies, like financial, technical and organisational support (Mueller *et al.*, 2015; based on a review of 8 CBBPs across different countries). Both Mueller *et al.* (2015) and ICARDA (2018) rightfully state that for a CBBP to be sustainable, long-term commitment by a local government or autonomous government-supported institution is essential as a CBBP typically progresses beyond the initial funding duration. Reaching the right people within such institutions and convincing them might prove to be a long-term process that requires both patience and dedication. A local knowledgeable and dedicated stakeholder (like AKF) having a good rapport with these institutions is more likely to enlist the support of such institutions.

Monitoring, evaluation and documentation of a program's impact are key to replicating and expanding a CBBP. Also, rigorous publication of its impact through various forums contributes to attracting additional funds (Mueller *et al.*, 2015). Moreover, a strong program monitoring and evaluation advises on implementation and strategy changes required to achieve the desired results. Our recent impact study identified such amendments (e.g. the need for stronger financial support for women buck keepers). A comprehensive data analysis to determine the socioeconomic impact of the CBBP and obtained genetic gain, such as that presented in Haile *et al.* (2020), is not feasible yet. Nonetheless, available data (Table 1) and findings from our recent impact study can already provide helpful trends and pointers.

Community ownership and leadership are important and inherent to any CBBP (e.g. Zoma-Traoré *et al.*, 2021), and crucial when up-scaling and out-scaling. Our recent impact study highlighted that the pashu sakhis, being local facilitators, have a big influence on the adoption and attitudes of participants towards interventions. The existing platform of women self-help groups provides the needed infrastructure to support a community-led approach to breeding buck selection, distribution and improved mating practices. This follows the work by Zoma-Traoré *et al.* (2021) who highlights the importance of a community's sense of CBBP ownership.

The Black Bengal is a goat breed spread over at least three states of India and there is demand for improved breeding bucks. Currently, some government programs source breeding bucks by purchasing entire males from trading markets with no background knowledge of their performance. There is thus an opportunity to develop breeding buck supply units/clusters for more income-generation. An example of income-generation is described by Gizaw *et al.* (2014) where there is a revolving fund for designated ram keepers in an Ethiopian CBBP. The income from selling old breeding rams is used to buy young candidates and to financially support the ram keepers. A similar scheme could be designed for Project Mesha's CBBP, as

keeping breeding bucks is empowering women goat rearers but often no surplus income is generated due to the reasonably high expenditure (e.g. buck housing and feed).

Training and upskilling are important for both CBBP maintenance and expansion, and should ideally be provided through a train-the-trainer model, with continuous development and updating of training material targeting both staff and goat rearers in their local language and in appropriate ways (for example the educational videos in the local language prepared by Project Mesha, available at https://akflearninghub.org/instructional_videos/video/agriculture-and-food-security/goat-rearing-best-practices/). Scientists and consultants play an important role in training and providing guidance to the CBBP's governing bodies on a regular basis based on updates coming from field progress reports and database statistics. Covering some basic infrastructure costs through an annual contribution from a government or autonomous governmental-supported institution targeting the social and economic empowerment of the rural poor could be a feasible solution, particularly for expanding CBBPs.

Exploiting the potential of genomics

Genomics provides significant opportunities to CBBPs through accurate measures of coancestry and pedigree reconstructions (e.g. ICARDA, 2018). Also, genomics allows for the identification of novel genomic regions and/or variants associated with breeding goal traits like growth and prolificacy (e.g. Haile *et al.*, 2020). Using these novel and known variants through either a marker-based approach or a more advanced genomic selection approach and the earlier mentioned possibility of pedigree reconstructions, allow for faster genetic improvement and better inbreeding management.

Plans are in progress to sample goats for genotyping or sequencing within Project Mesha aimed at exploiting the opportunities that genomics provides. A careful selection of goats should be made, considering both the availability of phenotypes as well as knowledge on potential coancestry. More challenging are the practicalities around sample collection, distribution and storage, as well as data repositories. Nonetheless, we would advice setting up a system to collect DNA samples from the implementation of a CBBP, or even before, so long as individual animal identification has been done.

457. Response to index selection for temperate dairy cattle breeds in tropical Sri Lanka

A.M. Samaraweera[1*], J.H.J. van der Werf[2], V. Boerner[1] and S. Hermesch[1]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]School of Environmental and Rural Science, University of New England, Armidale 2351, NSW, Australia; amamalsh@gmail.com

Abstract

This study aimed to predict selection responses for breeding objective traits based on large-scale dairy farms rearing temperate dairy breeds in Sri Lanka. Responses were predicted selecting 10% of bulls at 4 and 9 years of age assuming the availability of progeny records for the selection of older bulls. When economic weights were expressed relative to the trait genetic standard deviation, milk yield (MY, 74%) had the highest relative emphasis on selection. Favourable responses were only observed for MY and calving interval reflecting the high selection emphasis on MY to counteract with other traits. Predicted responses relative to the current mean varied from -0.67% (protein yield) to 0.40% (MY). Progeny selection increased the accuracy at the expense of higher generation interval. Predicted increase in profit due to genetic improvement was slightly higher under progeny testing compared to family selection (2,624 vs 2,506 rupees or 14.1 vs 13.5 USD per cow per year).

Introduction

Selection of dairy cattle based on estimated breeding values is currently not practiced in Sri Lanka. However, the need for development of dairy cattle breeding programmes has been highlighted. Therefore, as a precondition for establishment of a breeding programme in Sri Lanka, genetic parameters for the main traits of interest in a breeding objective for temperate dairy cattle in Sri Lanka were recently estimated, and economic values (EVs) were derived (Samaraweera 2020). Prediction of annual genetic response of traits in the breeding objective is a key criterion in evaluating the selection decisions and understanding the direction and magnitude of individual trait responses. Therefore, the objective of this study was to predict response to multi-trait selection for breeding objective traits in large-scale dairy farms in Sri Lanka.

Materials & methods

The breeding objective traits of the large-scale dairy farms rearing temperate dairy breeds were annual milk yield (MY, kg/cow/year), annual fat yield (FY, kg/cow/year), annual protein yield (PY, kg/cow/year), age at first calving (AFC, days/cow), number of services per conception (NSC, counts/cow/conception), calving interval (CI, days/cow), and number of episodes of mastitis (MS, counts/cow/lactation). Please see Samaraweera *et al.* (in press) for trait definitions and EVs.

Economic weights. The EVs were transformed into economic weights (EWs) by multiplying them by discounted genetic expression (DGE) coefficients to account for the different frequency and timing of expressions of the traits (McClintock and Cunningham 1974). Since AFC is expressed once per cow and early in the cow's lifetime, the DGE coefficient for AFC was equal to one, and EWs were expressed per cow at first calving. All other traits were expressed once per lactation. Therefore, DGE coefficients for MY, FY, PY, NSC, CI, and MS were calculated as the sum of all timings and the frequency of expressions over five lactations as follow:

$$\mathrm{DGE} = \sum_{\mathrm{Lc}=1}^{\mathrm{Lc}=5} \frac{\boldsymbol{\rho}}{(1+\mathrm{r})^{\mathrm{Lc}}} \quad (1)$$

CC BY

DOI: 10.3920/978-90-8686-940-4_457, © A.M. Samaraweera *et al.* 2022

Where ρ = a vector with each element being the proportion of cows surviving in each lactation relative to the total number of surviving cows, weighted by lactation number, r = the annual interest rate of 5%, and Lc = lactation number reflecting lactations 1 to 5. Survival rate from one lactation to the next lactation was assumed to be 90%. The EVs and calculated economic weights are given in Table 1. When expressed relative to the trait genetic standard deviation, MY (74%) had the highest relative emphasis followed by FY (11%), CI (7%), and AFC (4%) (Table 1).

Selection index. Response to selection per year was predicted for two scenarios, i.e. (1) where bulls were selected at 4 years of age based on information from their dam and paternal half sibs (scenario 1); and (2) selection at 9 years of age based on progeny test (scenario 2). The breeding programme was based on a government nucleus farm with 2,000 cows, and 10% of male calves were selected as suitable to become breeding bulls in the nucleus. Therefore, selection intensity was 1.75 in both scenarios. Higher number of dam, half-sib, and progeny records were assumed for scenario 2 than scenario 1 (2, 5, and 10 vs 1, 2, and 0). The number of half-sib and progeny information were based on the assumption of limited matings per sire in Sri Lanka. Response to selection was predicted using a multi-trait selection index programme, MTINDEX (Van der Werf 2018) which expresses selection response for each trait per standard deviation of the index. To obtain the response per year, these values were multiplied by the intensity of selection and divided by the appropriate generation interval. The genetic parameters that were used to predict response to multiple trait selection are given in Table 2.

Results

Trait accuracies were higher from progeny testing (scenario 1) compared to selection based on dam and paternal half sib information (scenario 2) (Table 3). After selection, scenario 2 had the highest response for all traits except CI and MS. Favourable (in $ terms) responses were observed only for MY and CI in both scenarios. Even though EWs were negative for FY and PY, response was positive and therefore unfavourable for FY and PY mainly due to the positive correlations between these trats with MY. The predicted increase in profit due to genetic improvement per year was slightly higher in scenario 2 than scenario 1 (2,624 vs 2,506 rupees or 14.1 vs 13.5 USD per cow per year). Predicted genetic response to selection relative to the current mean (% change, Table 3) varied from -0.67% (PY) to 0.40% (MY).

Table 1. Economic values (EV), the discounted genetic expression (DGE) coefficients, economic weights (EW), rupees per genetic standard deviation (SD), and relative emphasis (RE) of each trait.

Parameter	Traits[1]						
	MY	FY	PY	AFC	NSC	CI	MS
EV[2] (rupees[3]/cow/year)	107	-162	-15	-59	-270	-84	-8,303
DGE	2.36	2.36	2.36	1.00	2.36	2.36	2.36
EW (rupees/cow/year)	253	-382	-35	-59	-637	-198	-19,595
rupees per genetic SD	50,496	-7,341	-730	-3,122	-1,126	-4,357	-305
RE (%)	74	11	1	4	2	7	1

[1] MY = annual milk yield (kg); FY = fat yield (g); PY = protein yield (g); AFC = age at first calving (days); NSC = number of services per conception; CI = calving interval (days); ME = number of episodes of clinical mastitis.

Total[2]			2,506				2,624	

[1] Traits and units are as given in Table 1.

[2] Total: rupee value per cow per year.

Discussion

The two scenarios were compared to understand the response to selection from early selection with lower accuracy using family information versus selection based on more accurate progeny test information but with a longer generation interval. The accuracy of selection and slightly higher responses were obtained for all traits except CI and MS in scenario 2. However, the response in scenario 1 is likely overestimated since selection was based on family information, and genetic variance is reduced due to selection (Bulmer 1971). The genetic variance can be further reduced in family selection due to inbreeding. Despite the overestimated response in scenario 1, the family records can be used to achieve annual responses over a four-year period in a breeding programme until the progeny records become available.

Among the milk yield traits, the selection for FY and PY is not economically viable in both scenarios, even though, increased FY and PY in milk is favoured. Therefore, increased payment for FY and PY or reduced feed costs are recommended (Samaraweera, in press). A high relative emphasis on MY, FY, and PY (92%)

in the selection index is not beneficial for a tropical country like Sri Lanka where fertility, disease, and heat tolerance traits are equality important in the breeding objective for a more resilient dairy population. Therefore, inclusion of these functional traits in the breeding objective is recommended.

Genomic selection is advantageous in reducing the generation interval and increasing the genetic gain compared to conventional progeny testing. In Sri Lanka, genomic selection has not been evaluated so far, and a major problem for functional dairy cattle breeding programmes is the absence of reliable pedigree information. Genomic selection would benefit such systems given parentage can be traced using genetic markers. However, the cost of implementation and monetary benefits should be carefully considered before implementing genomic selection in developing countries.

In conclusion, progeny selection increased the accuracy of selection and response per year at the expense of higher generation interval. Favourable responses after selection were only predicted for MY and CI due to the very high selection emphasis on MY and its unfavourable genetic associations with other traits.

458. Challenges on construction and use of female reference populations for genomic selection under Indian smallholder systems

V. Ducrocq[1*], M. Swaminathan[2] and J.P. Gibson[3]

[1]Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; [2]BAIF Development Research Foundation, India; [3]Centre for Genetic Analysis and Applications, University of New England, Armidale, NSW 2350, Australia; vincent.ducrocq@inrae.fr

Abstract

BAIF Development Research Foundation is a large Indian NGO helping smallholder farmers, in particular through artificial insemination of their crossbred cows at their doorstep. With international support, BAIF has created for the past 5 years a large female reference population of *Bos taurus* × *Bos indicus* cows in order to enhance the genetic merit of this crossbred population through genomic selection. We review the overall context of the project and its objective, the characteristics of the reference population and the choice of the recorded traits. Efficient ways to use the results of genomic evaluations are proposed, underlying the necessary changes required, in particular in the management of the bull stud. Finally, opportunities of upscaling this initiative to other partners in India are discussed.

Introduction

The Indian subcontinent is expected to contribute to more than half of the growth in world milk production over the next ten years (OECD-FAO Agricultural Outlook 2020-2029) and it may provide more than 30% of world milk production in 2030, with 80 to 95% coming from smallholder herds of a few cows or buffaloes. In order to limit detrimental effects on the climate and environment, the increasing demand should not be met by simply increasing the number of cows but by improving the genetic merit of the existing ones. Obviously, the existing cattle populations cannot meet such a challenge: the pure 'exotic' *Bos taurus* breeds are not adapted to the local harsh environments, while indigenous animals – often *Bos indicus* cows or buffaloes – often have a very low productivity. Hopefully, this can change: in developed countries, the development of affordable genomic tools led to a doubling of yearly genetic gains at a lower cost than previously (Boichard *et al.*, 2016). It is now time to adapt these tools to countries in (sub)tropical areas: the constitution of a representative genotyped and phenotyped female population can pave the way to genomic selection of crossbred animals in order to improve production in low-input systems at a more reasonable cost than before (e.g. Ducrocq *et al.*, 2018, Mrode *et al.*, 2019).

BAIF (BAIF Development Research Foundation, https://baif.org.in/) is a large Indian NGO located at Pune, India. BAIF manages 2 large bull studs producing 16 million semen doses of Holstein-Friesian, Jersey and pure *B. indicus* breeds as well as *B. taurus* × *B. indicus* crossbred bulls and various breeds of buffaloes. BAIF has a network of several thousands of artificial insemination (AI) technicians delivering AI at the doorstep of small to marginal farmers. With the financial support of the Bill and Melinda Gates Foundation (BMFG, www.gatesfoundation.org) and scientific support from the Australian Universities of New England (UNE) and of Queensland (UQ) as well as INRAE, France, BAIF is developing a female reference population (FRP) of more than 20,000 crossbred cows in smallholder farms (average herd size: 2 cows). Details on the information collected can be found in Bhave *et al.* (this congress).

This communication reports some lessons learnt during the constitution of this FRP and the anticipated future challenges.

Materials & methods

Characteristics of the BAIF reference population. BAIF has a long experience of interaction with smallholders in various Indian states through its CDCs (Cattle Development Centers covering 8 to 10 villages, with an AI technician in charge). Recruitment of farmers for performance recording was done in selected CDCs, initially in 6 states (Bihar, Jharkhand, Maharashtra, Odisha, Punjab, and Uttar Pradesh – with the planned addition of 3 others: Andra Pradesh, Gujerat and Rajasthan).

The degree of crossing is most often unknown or very inaccurate because of absence of pedigree recording. Even *B. indicus* composition is seldom known (leading to 'non-descript animals'). However, proportion of Jersey versus Holstein-Friesian vs *B. indicus* breed composition can be determined accurately through genotyping (Figure 1), even with 500 SNP (Strucken *et al.*, 2021a). Interestingly, while close to 50% of SNP molecular genetic variation is between breeds in *B. taurus*, only about 2% of variation is between breeds in *B. indicus*, meaning that *B. indicus* breeds are very difficult to distinguish from each other using SNP data (Strucken *et al.*, 2021b). In practice, all animals in a farm are enrolled, whatever their breed composition.

The area covered by the FRP is characterized by contrasting climate and farming systems, even within most of the states considered in the project. Large variations exist between states in level of % *B. taurus*, in level of production (see Guintard *et al.*, this congress) but also for other traits (e.g. body weight. A key challenge is how to properly account for G×E sources, not only on production but also on other traits.

Choice of recorded traits. The initial focus of the project was on milk production because it is the main and most immediate source of income and it is easy to record. This is also the priority at the Indian federal level. For example, use of semen of purebred *B. taurus* bulls is currently permitted only when the dam of the bull has one recorded lactation above 9,000 kg, a level of production difficult to achieve locally without preferential treatment! Such restrictions favor imports from developed countries of semen which is completely unsuitable for Indian conditions. In fact, in the BAIF context with a continuous range of crossbreeding level, milk production could be regarded as the easiest trait to improve, simply by tuning the breed composition of the new generation in terms of % Holstein or % Jersey. To achieve this, BAIF have developed and is testing in a pilot program a cheap SNP assay with few hundred SNP to routinely determine breed composition of new animals (Stricken *et al.*, 2021a). Such strategy is often overlooked but has the advantage to leave room to stronger selection on other economically important traits. The traits which are currently recorded at BAIF (see Kaustubh *et al.*, this congress) are fat% (a major determinant of milk price in India), protein%, milk quality (somatic cell counts assessed through a simplified recording system with 5 categories), body weight (calculated based on tape measures), udder conformation, feet and legs, age

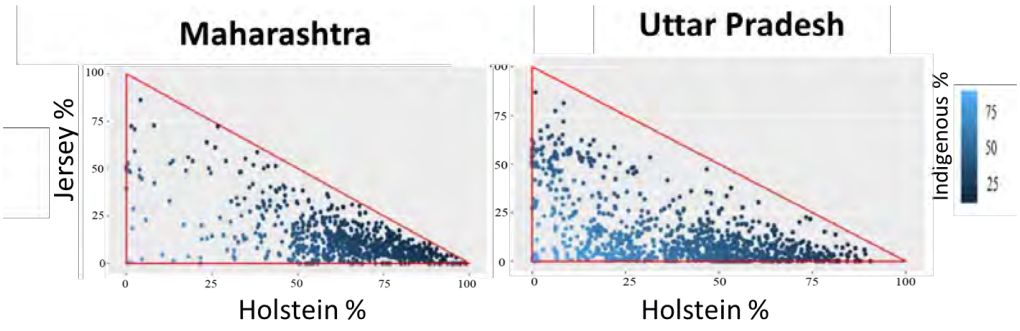

Figure 1. breed composition of the female reference population in two Indian states (here based on imputed high density genotypes).

at first calving, female fertility, etc. The range of some of these traits is much larger than what is found in developed countries (e.g. adult weights from 250 to 600 kg with huge variations between and within breed composition classes and between states). In some cases, important recorded traits are currently not usable due to unsystematic recording (e.g. mastitis incidence) but such issues can progressively be corrected. Moreover, for better acceptance in the field, other traits that are not necessarily relevant in developed countries may need to be also considered. For example, milking ease and temperament when cows are hand-milked by women should not be overlooked.

From genomic evaluation to actual selection at BAIF. Initial genomic analyses of the current FRP – so far essentially on milk production alone – illustrate the feasibility of genomic evaluations in the Indian context (e.g. Al Kalaldeh *et al.*, 2021), as long as specific features relative to smallholders are properly accounted for. As an example, among others, the joint modelling of the local environment and the breed composition in farms with on average two cows cannot be done using a usual fixed herd-year-season effect.

However, how to properly *use* the results of these evaluations to generate a genetic trend in the entire population of inseminated cows should not be neglected. The fact that BAIF has a very large and nationally significant semen production and insemination in the field is a strong point for dissemination of genetic progress. Nevertheless, to be effective requires huge strategic changes at various levels. For instance, the recruitment of a large number of young bull dams to conceive young males should be based on genomic evaluation results without excessive extra constraints (such as the regulations on minimum levels of production mentioned above). Male (but also female) progeny of these cows should be genotyped and get their own genomic evaluation as soon as possible and a drastic selection intensity should be applied to keep only the best ones. Indeed, it would be counterproductive to keep most of the genotyped animals. (There may be a tendency to assume that the animals are good simply because they were genotyped). Then, semen collection (for males) or AI (for females) should start as early as possible. Indeed, in developed countries, a large part of the increase in genetic gain due to genomic selection will be due to a drastic reduction of the generation interval and a fast turnover of bulls proposed for AI. This is a complete revolution compared with the current situation where crossbred bulls are used for a very long period.

Discussion

Upscaling genomic selection to other Indian populations. To increase and broaden the BAIF reference population, a new BMFG 5-year project started in late 2021, including three new partners (State Government breeding organisations). Extension of genomic selection to other populations of pure *B. indicus* breeds as well as buffalo breeds are also considered in a near future. Other Indian large organisations are following the same objectives (e.g. National Dairy Development Board – NDDB) and it is hoped that reference populations will be merged at some point, as happened in Europe with the Eurogenomics consortium (www.eurogenomics.com) or in North America. This will have multiple benefits: (1) an overall reduction of basic costs (under the condition that the same genotyping chip per species is used and that performance recording of the same traits are comparable); (2) a much larger shared reference population leading to more accurate genomic evaluations; (3) the possibility to eventually have a unique genomic evaluation center run by competent staff members, forming a group large enough to avoid collapse in case of departures of key players; (4) a secure connexion with a large international scientific community to help in capacity building and in issuing realistic recommendations to governmental authorities.

Interested readers can view a video overview of the whole BAIF project as presented at the FAO/IAEA international symposium on sustainable animal production and health (on-line) June 28-July 2, 2021 J.P. Gibson, O.A. Mwai, M. Swaminathan. Genetic improvement of smallholder dairy cattle for sustainable dairy systems. Traditional and genomic approaches. streaming.iaea.org/21644 (from 3:42:37 to 4:12:02)
