Abstract

Tenebrio molitor is now a promising species for insect farming to produce high protein products with low environmental impact. However, the molecular diversity and the genetic structure in available *T. molitor* populations are understudied. We analysed the genomic structure of 18 populations from 12 countries using Illumina pool-seq data. More than 5 million SNPs were selected to compute allele frequencies, then multivariate and pairwise-F_{ST} analyses were used to estimate their relative genetic distances. The results showed two very distant populations, one wild population sampled in Serbia and one from Germany, both presenting very distinct genomic structure. The populations from USA, Spain and Holland presented moderate genomic differentiation and 13 populations were closely-related. This pool-seq analysis highlighted a lack of molecular diversity between most of the sampled populations and will allow the identification of loci under selection. Current phenotyping and genotyping efforts will help guiding future breeding programs.

Introduction

By 2050, the global population will reach approximately nine billion people, increasing the demand for animal protein by 76% (Alexandratos and Bruinsma, 2012). This future demand starts to question the sustainability of our conventional production systems. Nowadays, insect production is considered as a serious alternative for food and feed production for many reasons. Essentially for the nutritional composition of edible insects (Nowak *et al.*, 2016) and for the low environmental impact of its production compared to other conventional livestock production systems (van Huis, 2013).

The yellow mealworm beetle *Tenebrio molitor* has been described as a good candidate for animal and even human nutrition (Cortes Ortiz *et al.*, 2016). Thus, genomic efforts and industrial scale production of *T. molitor* progressed during the last decade (Eleftheriou *et al.*, 2021). Despite promising results on *T. molitor* production, several aspects concerning the *T. molitor* biology remain challenging to sustain its production (Morales-Ramos *et al.*, 2019). The need to have access to the molecular and phenotypic diversity of *T. molitor* is a first step before further genetic improvement. Indeed, industrial farming of *T. molitor* will require monitoring the molecular diversity in order to better anticipate inbreeding depression that may cause decrease of biomass production. Here, we used Illumina pool-seq on 18 *T. molitor* populations and sequenced 720 individuals to identify their molecular diversity and genomic structure.

Materials & methods

Biological material. A total of 18 populations were provided by academic institutions and private companies. University of Burgundy (Dijon, France) provided three populations, one called *Dijon*, one called *Serbia* that corresponds to a wild population sampled in a disaffected mill in Serbia and one called

R.F. Veerkamp and Y. de Haas (eds)

Holland that corresponds to a population initially provided by a private Dutch company. University of Thessaly (Volos, Greece) provided seven populations, two populations from Italy called *Italy_1* and *Italy_2*, one population from Greece called *Greece*, one population from Spain called *Spain*, one population from Germany called *Germany*, one population from the United States of America called *USA* and one population from Turkey called *Turkey*. Mystik Farms (Cap Santé, Québec, Canada) provided one population called *Canada*. Papek s.r.o. (Jaroměřice nad Rokytnou, Czech Republic) provided one population called *Czech*. Two populations called *Pro_+* and *Pro_-* were provided by Pronutrix (Harelbeke, Belgium). One population called *Belgium* was provided by Nusect (Deerlijk, Belgium). The Ynsect company (Evry, France) provided one population called *AAF_Dole*. The Kinsect company (France) provided one population called *Kynsect_HOL*. The Star Food company (Barneveld, Netherlands) provided one population called *Starfood_HOL*.

Pool-seq sequencing. *Tenebrio molitor* larvae were first ground individually using ZR BashingBead Lysis Tubes (2 mm) (ZymoResearch, CA, USA) and subsequently DNA extraction was performed using the Quick-DNA 96 Plus Kit (ZymoResearch). The extracted DNA was normalized and 40 individuals from the same population were pooled equimolarly. For each pool, DNA libraries were prepared using the NEBNext® Ultra II DNA Library prep kit for Illumina (New England Biolabs, MA, USA) and sequenced on an Illumina NovaSeq6000 instrument (Illumina, San Diego, CA, USA) using 150 base-length read chemistry in paired-end mode to reach around 20x of depth of coverage by individual.

Population genomic analysis. Raw reads were cleaned and aligned against the *T. molitor* reference genome using *bwa mem* (Li and Durbin, 2009). Reads duplicates were removed and SNPs were called using samtools/bcftools. For each SNP, the alternative allele frequency was calculated, to get rid of sequencing errors, only SNPs with a minimum frequency of 5% in at least one population were kept. The relatedness between populations was first observed by principal component analysis (PCA) using the allele frequencies as input data. Then, the genomic distance between each population was estimated by computing the pairwise-F_{ST}, first we computed the F_{ST} for each allele as follow: $FST = var(p) / (mean(p) \times (1 - mean(p)))$, where p is a vector of alternative allele frequencies of two populations. Second, we used the median F_{ST} over all alleles to compute the final pairwise-F_{ST}.

Results & discussion

We obtained more than 3 million SNPs from each pool of individuals. The PCA analysis based on the allele frequencies of 5,285,733 SNPs showed that the two first PCA axes (explaining only 36% of the total variance) are strongly linked to *Serbia* and *Germany* populations while the other 16 populations are clustered into one single group located close to the origins of the axes (Figure 1.A). This suggests that *Serbia* and *Germany* have very different genomic structures while the 16 other populations may have closer genomic structures.

The pairwise- F_{ST} analysis showed that *Serbia* presented F_{ST} values ranging from 0.09 to 0.34 with the other populations, the larger value corresponding to the F_{ST} with *Germany* (Figure 1.B). *Germany* presented F_{ST} values ranging from 0.25 to 0.34. *Kynsect_HOL*, *USA* and *Spain* pairwise- F_{ST} values between 0.03 and 0.12. The last 13 populations presented low genomic differentiation between them with F_{ST} value ranging from 0 to 0.06. The F_{ST} analysis confirmed the PCA results by highlighting *Serbia* and *Germany* as two populations with high genomic differentiation compared to the 16 other populations but also validates the presence of different genomic structures between these two populations. But the F_{ST}-based analysis showed that a moderate differentiation occurred in *Spain*, *USA* and *Kynsect_HOL* and a low differentiation between the 13 other populations whose eight were sampled from private breeders. The recent interest in mealworm production by private companies may have led them to supply recently on the same or closely-related suppliers explaining possibly the observed low differentiation between their populations. On the other hand, evolutionary forces such as genetic drift and/or selection may also have occurred in the five more differentiated populations especially for *Serbia* that was sampled in a disaffected mill.

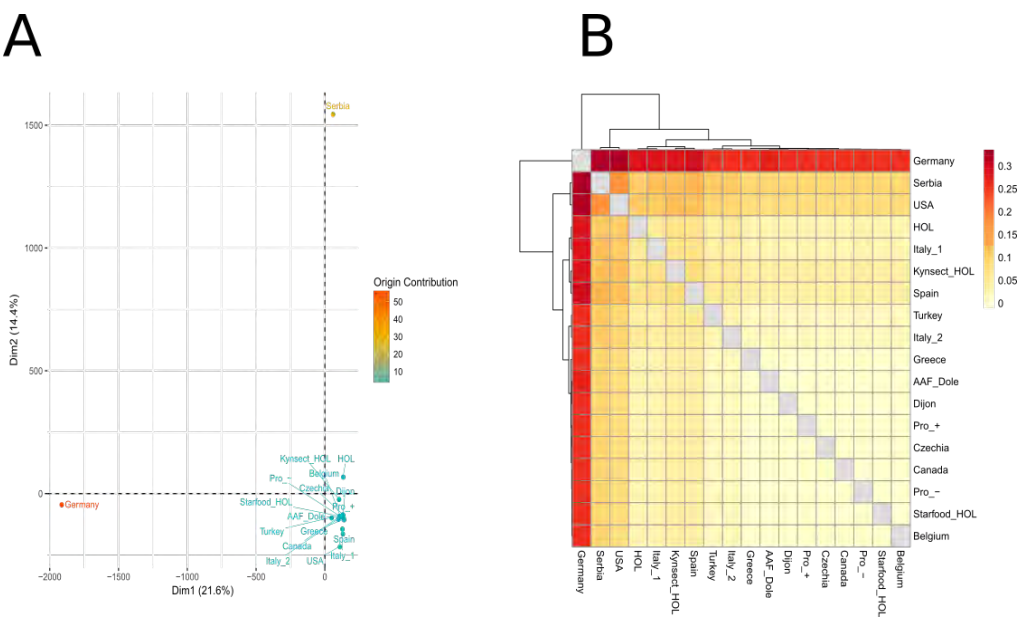

Figure 1. Genomic structure in 18 *T. molitor* populations. (A) PCA based on allele frequencies. (B) Pairwise-F_{ST} distance matrix.

Conclusions

From the pool-seq analysis presented in this study, we identified two populations having strong differentiation compared to the other 16 populations. We may consider that our results highlighted that the majority of the sampled populations presents a low molecular diversity between them. Current phenotyping of complex traits such as growth rate, fertility and immunity in available populations as well as their genotyping will help the selection of the populations having the most interesting performances for industrial production and will guide future breeding programs. Finally, to better understand molecular evolution of *T. molitor*, further analysis will be performed from the data generated in this study to identify genes under natural selection and the corresponding biological processes.

Abstract

Although honeybees are the most important managed pollinators, their demographic history is not fully clear. Here we inferred whole-genome succinct tree sequences with *tsinfer* software to determine the honeybee population parameters and demographic history. We used a dataset of 691 whole-genome sequenced drones out of which 240 had subspecies info and 451 were hybrids. Our results confirmed that the A lineage subspecies are the least differentiated from the rest of subspecies and the most diverse. We also showed that the C lineage experienced a bottleneck followed by a large expansion related to their commercial use. Future work will use the inferred tree sequence to estimate the effective population size of the ancestral population and date the ancestral nodes and split events.

Introduction

Although honeybees are the most important managed pollinators, their demographic history remains undetermined. Previous studies agree that the genus *Apis* originated from Asia, but the origin of *Apis mellifera* is still debated with possible origins being Asia (Wallberg *et al.*, 2014), the Middle East (Cridland *et al.*, 2017), or Africa (Whitfield *et al.*, 2014). Studies agree that *A. mellifera* split from *A. cerana* around 6 million years ago (Chen *et al.*, 2018). In contrast, the estimated split time of the subspecies ranges from between 35 and 20ky ago (Wallberg *et al.*, 2014; Chen *et al.*, 2016) to around 1 million years ago (cited in Whitfield *et al.*, 2006). These differences are partially due to each study analysing different sets of subspecies. The aim of this study was to use drone whole-genome sequences to infer succinct tree sequences and shed light on demographic history of the honeybee.

Materials & methods

Inference of the ancestral alleles. We used Cactus (Armstrong *et al.*, 2020) to align the reference genomes of *Apis mellifera* (Amel_HAv3.1, GCF_003254395.2), *Apis cerana* (ACSNU-2.0, GCF_001442555.1), *Apis dorsata* (Apis dorsata 1.3, GCF_000469605.1), and *Apis florea* (Aflo_1.1, GCF_000184785.3). Next, we used a custom Python script to prepare the file for ancestral inference using *est-sfs* (Keightley and Jackson, 2018). The file contained allele counts for the focal species and the outgroups for 12,449,207 out of 18,972,875 variants in the raw VCF. We ran the *est-sfs* with three outgroups and the Kimura 2-parameter model.

Data set. We used a genomic dataset of 724 drones (Parejo *et al.*, unpublished data, provided by David Wragg). The raw VCF contained 18,972,875 variants. We first removed the variants identified as heterozygous when called diploid (Wragg *et al.*, 2021). Next, we filtered the data by genotype quality (>30), depth (>5), minor allele frequency (>0.01), and missing frequency (<0.1). We removed the samples and variants with >10% missing genotypes. The final VCF included 691 samples and 2,216,964 variants on chromosomes. 62 samples were marked as *A. m. carnica* (C lineage), 10 as *A. m. ligustica* (C lineage), 93 as *A. m. mellifera* (M lineage), 10 as *A. m. caucasica* (C or O lineage), 8 as *A. m. unicolor* (A lineage), 28 as *A. m. capensis* (A lineage), 29 as *A. m. scutellata* (A lineage), and 451 samples were considered as hybrids.

Inference of the demographic history. We used the final VCF for the demographic inference. We included the ancestral allele where available, elsewhere the *A. mellifera* reference allele was considered to be ancestral. We used *tsinfer* (Kelleher *et al.*, 2019) to infer the genealogical history of the samples by chromosome. We used the tree sequences to compute principal component analysis (PCA), fixation index (Fst), Nei's nucleotide diversity, Tajima's D, and the genealogical nearest neighbour (GNN) between the samples. We combined the results from the chromosomes by weighting the output by the chromosome length.

Results

We inferred the ancestral allele for 7,781,679 sites from the raw VCF. This represented 1,201,346 sites from the final VCF file. For 80.8% of the sites, the inferred ancestral allele matched the major allele of our sample of drones, and the *A. mellifera* reference allele for 59.4% of the sites. In the PCA (Figure 1) the subspecies of a particular lineage grouped together. African A (lineage) subspecies (*A. m. scutellata, A. m. capensis*, and *A. m. unicolor)* separated most from the rest of subspecies. Inspecting PC3 revealed a further separation of African subspecies, with *A. m. unicolor* diverging from the other two African subspecies. The analysis also revealed that the hybrids from Reunion placed between the A and the C lineage.

We inspected the differentiation, diversity, and selection neutrality of the subspecies by computing the Fst, Nei's nucleotide diversity, and Tajima's D (Figure 2). First, we observed the lowest Fst, 0.05, between *A. m. carnica* and *A. m. ligustica,* and the highest Fst, 0.47, between *A. m. ligustica* and *A. m. unicolor* (Figure 2a). The Fst results suggested non-uniformity of the African subspecies. While the Fst between *A. m. scutellata and A. m. capensis* was 0.11, the Fst of the two with *A. m. unicolor* was higher, respectively 0.25 and 0.27. The results also suggested that the *A. m. unicolor* is the most differentiated from the non-African species. Next, we inspected Nei's nucleotide diversity (Figure 2b) and observed the highest values for the A lineage subspecies (>0.0015). The diversity for other subspecies was an order of magnitude lower and was lowest in the subspecies of the C lineage (<0.00062). Last, we observed the highest positive Tajima's D for the A lineage subspecies and the lowest negative Tajima's D for the C lineage subspecies (Figure 2c).

We computed the GNN for all the samples for the subspecies and hybrids from the island of Reunion (Figure 3). Without hybrid samples the subspecies grouped in concordance with the PCA and previous knowledge (Figure 3a). The subspecies of the lineages grouped together, and the O lineage grouped with the C lineage. Inclusion of hybrid samples from the island of Reunion changed the output: the hybrids grouped with the *A. m. unicolor*, and the clade was 'pulled' into the C lineage clade (Figure 3b).

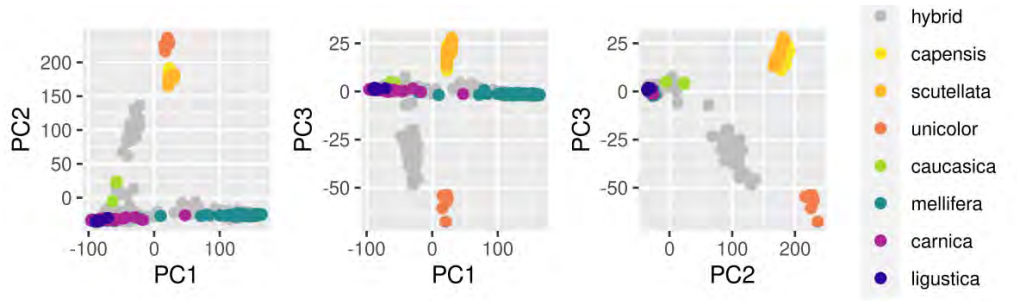

Figure 1. Principle component analysis on the tree sequences.

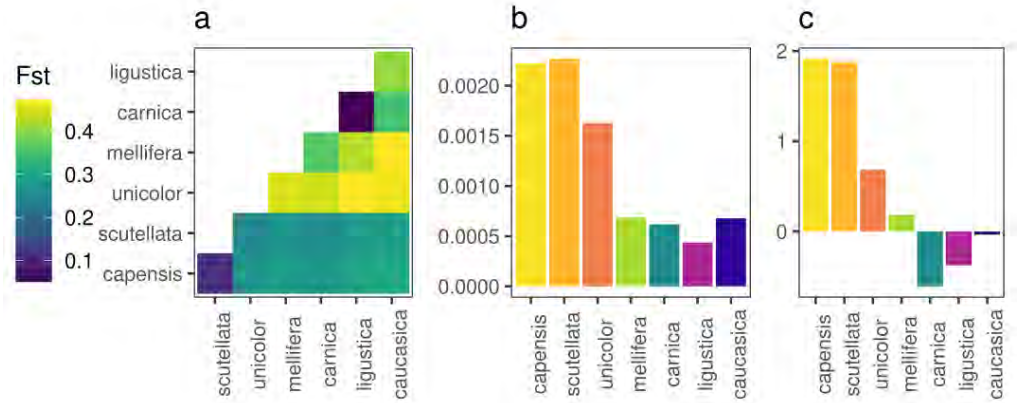

Figure 2. Fst (a), Nei's nucleotide diversity (b), and Tajima's D (c) of the subspecies.

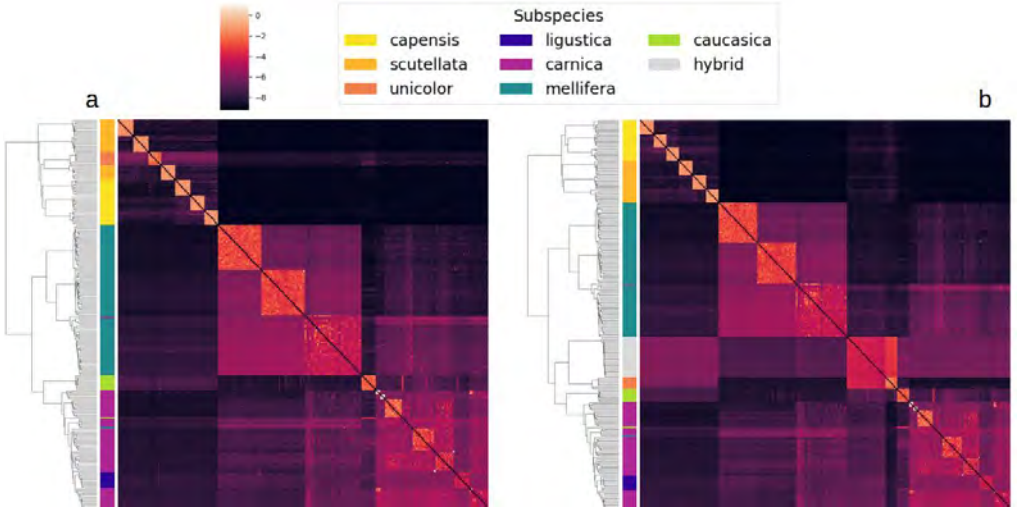

Figure 3. Genealogical nearest neighbour of (a) the subspecies samples and (b) subspecies samples and hybrid samples from the island of Reunion.

Discussion

In this study, we inferred whole-genome tree sequence to study the population parameters and demographic history of the *Apis mellifera*. Tree sequences present an efficient way to encode whole-genome information, while revealing the evolution of genomes. PCA results suggested a non-uniformity of the subspecies of the A lineage, which can be explained by the geographical location of the subspecies. While *A. m. capensis* and *A. m. scutellata* are indigenous the African mainland, *A. m. unicolor* is indigenous to Madagascar.

Our Fst pattern was in concordance with previous studies revealing that the A lineage is the least differentiated from the rest of the subspecies and that the subspecies of the M lineage are more differentiated from the C than from the A lineage (Cridland *et al.*, 2017; Dogantzis *et al.*, 2021). This supports the theory of an earlier split of the C and the M lineage and a separate colonization of Europe via two routes (Whitfield *et al.*, 2006; Cridland *et al.*, 2017). Computing the Tajima's D revealed highly negative Tajima's D for both subspecies

of the C lineage. Negative Tajima's D suggests a purifying selection or a population expansion after a bottleneck. The latter could explain the large negative Tajima's D of the *A. m. carnica* and *A. m. ligustica* since they have been widely distributed due to their commercial use. The clustering of the subspecies in the GNN structure confirmed the PCA results. When we included the hybrids from the island of Reunion, they clustered with the *A. m. unicolor*. This was expected since Reunion is geographically closest to Madagascar, the origin of *A. m. unicolor*. However, the hybrid's clade was 'pulled' into the C lineage clade. This can be explained by the fact that historically, routine imports of *A. m. carnica* and *A. m. ligustica*, have had a lasting impact on the genetic make-up of the island's honeybees – remaining long after importing of bees became prohibited (Wragg *et al.*, 2019).

The succinct tree sequence is a genealogical representation of whole-genome sequence data and are hence a powerful tool to store the data and estimate population parameters. In this paper we present only few of the metrics that can be computed from the succinct trees. Future work will include estimating the coalescent rates to determine the trajectory of effective population size of the subspecies and dating the ancestral nodes in the tree sequences to determine the time of splits between lineages and subspecies.

618. Heritability of disease resistance to chronic bee paralysis, chalkbrood and nosemosis in the honeybee (*A.m.carnica*)

A. Hoppe*, R. Bernstein, M. Du and K. Bienefeld

Institute for Bee Research Hohen Neuendorf, Friedrich-Engels-Str. 32, 16540 Hohen Neuendorf, Germany; andreas.hoppe@hu-berlin.de

Abstract

Honeybee diseases related to viruses and fungi play a major role in colony losses. Because of the ubiquity of the pathogens, breeding for genetic resistance is highly desirable as a sustained strategy. Culling affected colonies in breeding populations has apparently not sufficed to develop resistance. Arguably, targeted selection on yield and other traits overshadowed the culling effect and explicit consideration of resistance traits is necessary. Here, we present the development of additive-genetic models of disease traits on the basis of best linear unbiased prediction in the European Carnica www.beebreed.eu breeding program. Although the data is sparse and the diseases are only reported as binary information, validation shows that disease resistance is heritable and can be used for targeted selection. According to heritability estimations and predictability of phenotypic values, chronic bee paralysis is the most promising target, followed by chalkbrood, and finally nosemosis.

Introduction

Chalkbrood, caused by the fungus *Ascosphaera apis*, is a widely distributed honeybee disease and generally connected to cold and humid weather conditions (Aronstein and Murray 2010). Increased brood hygiene has been found as a partially protecting factor (Gilliam *et al.* 1983). *Nosema apis* is an important threat to professional beekeeping (Martín-Hernanández *et al.* 2018) with a clear seasonal pattern (Fries *et al.* 2010), whereas occurrence of chronic bee paralysis (CBP) follows an erratic pattern (Amiri *et al.* 2014).

In general, three conditions must come together for the occurrence of these diseases: (1) the infectious agent must be present in the apiary in a certain quantity and infectivity; (2) the environmental conditions must be unfavourable; and (3) the colony must have susceptibility to the disease. As disease control is mostly done with medication and altered management techniques, the focus lies on the former two, whereas the hereditary component of susceptibility has received only some attention for chalkbrood (Invernizzi *et al.* 2009). While resistance breeding may be the most elaborate approach, it is potentially the most lasting.

Materials & methods

Breeding system, pedigree cutting, data preparation. Studbooks of the international Carnica population maintained in www.beebreed.eu (Hoppe *et al.* 2020) were downloaded on 29th Nov 2021. Performance testers recorded the information whether the tested colony suffered from chalkbrood, nosemosis, or CBP as a binary trait. Only apiaries/test years with both ill and healthy colonies were considered as valid phenotypes. Starting from the set of valid phenotypes as seed set, the pedigree was constructed as a subset of all 229,732 colonies in an iterative process with a cycled application of the following steps: (1) add siblings if any sister is in the set; (2) if any colony on an apiary-year combination is in the set, add the remaining colonies; (3) add any colony which is both an ancestor and descendent of colonies in the set. Finally, add all ancestors of colonies in the set. In a pedigree constructed in this way, the calculated relationships between colonies with phenotypes are identical to those calculated with the full pedigree.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_618, © A. Hoppe *et al.* 2022

Using this set of relevant colonies, a pedigree was set up with the following items: (1) queen; (2) worker community; (3) pseudo sire; and (4) potential offspring queen as in (Hoppe *et al.* 2020). Then, PInCo (Bernstein 2018) was used to calculate the inverse relationship matrix of all pedigree items for direct input in BLUPF90 programs (Misztal *et al.* 2002).

The breeding model applied is a mixed-linear additive genetic model:

$$y = Xb + Z_W a_W + Z_Q a_Q + e \quad (1)$$

where Z_W, Z_Q and X are known incidence matrices, a_W are the worker and a_Q the queen effects of the pedigree items, b are the apiary effects, and e is the residual (Hoppe *et al.* 2020).

Genetic and residual variances were fitted with AIREMLF90 (Misztal *et al.* 2002). As recommended by (Du *et al.* 2022), the results were confirmed with subsequent REMLF90 applications.

To assess the quality of of the models, we applied: (1) the year validation as described in (Hoppe *et al.* 2020); (2) a 5-fold cross-validation of original vs predicted phenotypes; (3) a cross-validation of phenotypes where the apiary effect (calculated in an initial BLUP run) was removed; and (4) a cross-validation of prospective vs realized breeding values.

Results

As can be seen in Table 1, chalkbrood was by far the most frequently observed disease, while for nosemosis and CBP there were still sufficiently many cases to assess a familial accumulation.

AIREML convergence was fast and robust for CBP and chalkbrood, while for nosemosis it was slow. Different heritabilities are shown in Table 2, where he heritability of selection criterion is calculated from (Brascamp *et al.* 2019), while the accessible heritability is the honeybee-specific adaption to satisfy the breeder's equation (Hoppe *et al.* 2020). CBP showed a high heritability similar to gentleness (Hoppe *et al.* 2020), chalkbrood a medium heritability (similar to honey yield), while the heritability for nosemosis was low. The estimated queen/worker correlation for nosemosis was close to -1, presumably because the data was not sufficient to support separation of worker and queen effects (Du *et al.* 2022). The standard errors were lowest for chalkbrood, as the model was supported by the most data. For nosemosis and CBP, the standard errors were relatively high. But even the low end of the standard error range shows high heritability for CBP. Oppositely, the upper end of the standard error range for Nosema indicates still a low Heritability for Nosema.

See Table 3 for the results of the three types of cross-validation. Although the correlations between predicted and real phenotype resp. prospected and realized breeding values were not high compared to the regular breeding traits (see Hoppe *et al.* 2020), it underlines that a genetic predisposition for disease susceptibility exists.

Table 1. Data overview.

	CBP	Chalkbrood	Nosemosis
Disease cases	259	1,792	519
Apiaries with disease cases	115	783	186
Relevant non-disease cases	1,359	8,942	2,533
Colonies in pruned pedigree	4,820	15,962	6,414

Table 2. Heritabilities.

	CBP	Chalkbrood	Nosemosis
Accessible heritability	0.28 (±0.10)	0.18 (±0.03)	0.04 (±0.02)
Heritability of selection criterion	0.68 (±0.25)	0.45 (±0.08)	0.10 (±0.04)
Direct heritability	0.61 (±0.20)	0.20 (±0.05)	0.23 (±0.08)
Maternal heritability	0.51 (±0.23)	0.03 (±0.04)	0.18 (±0.07)
Correlation between worker and queen effect	-0.76 (±0.24)	-0.34 (±0.46)	-1.0 (±0.14)

Table 3. Results of 3 Types of cross-validation.

Validation	Parameter	CBP	Chalkbrood	Nosemosis
Cross-validation of phenotypes	Correlation predicted / real phenotype	0.48	0.29	0.38
Cross-validation, removed apiary effect	Correlation predicted / real phenotype	0.05	0.11	0.064
Cross-validation of breeding values	Correlation prospective / realized breeding value	0.53	0.82	0.66

See Figure 1 for the graphical representation of the results of the relation with relates prospective breeding values to next year's relative phenotypes. For CBP, the quarter of the lowest estimated breeding values stood apart while the rest was less differentiated. For chalkbrood, the separation of the worst and best breeding values was good, but not for the middle values. For nosemosis, there was a separation of the highest breeding values, however, the worst phenotypes could not well be predicted. The absolute difference in both breeding values and phenotypes were very low, underlining the fact that nosemosis appeared clearly as the most problematic trait for targeted selection.

Comparison of prospective breeding values with phenotypes. Estimated Breeding values are calculated without the phenotypes of the test year and later. The test year is iterated from 2014 to 2021 and the results are averaged. Phenotypes shown are standardized to an average apiary. The bars represent the adjusted average disease phenotype shown in the left y-axis (where 0 is ill and 1 is healthy) for the four quartiles of breeding values, whose averages are represented by the line and the y-axis to the right.

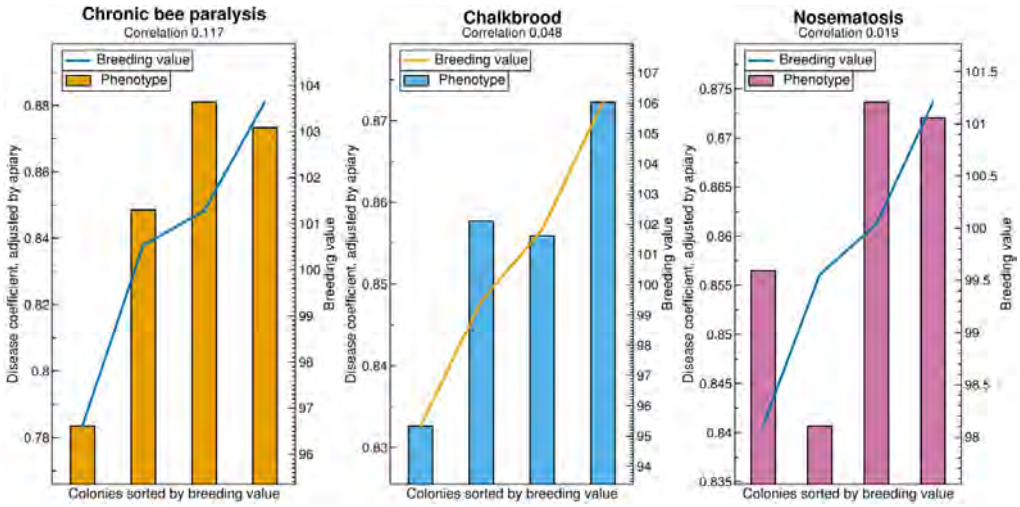

Figure 1. Year validation charts.

Discussion

As demonstrated by validations, BLUP models for disease susceptibility are a promising tool for selection for resistance. Breeding values for chalkbrood in the Carnica population (Hoppe *et al.* 2020) have been published in www.beebreed.eu for many years. Breeding progress has been slow (not shown), but chalkbrood is only a minor burden in this population. CBP has recently been a topic of intense discussion among bee breeders in Germany (Dittes *et al.* 2021) and increased awareness has led to better reporting. Here, it is shown that there is genetic variance within the Carnica population with substantial familial clustering, which suggests that CBP is a great target for resistance breeding. Compared with this, nosemosis appears to be a rather tenacious target for resistance breeding. However, this may change if awareness increases and more cases are reported.

Concerns about sustainability, feasibility and desirability of resistance breeding raised for other farm animals (Stear *et al.* 2001) must also be addressed for honeybees. The invasion of *Varroa* caused a dynamic evolutionary situation for deformed wing virus and it may also affect the sustainability of CBP resistance breeding. The feasibility of nosemosis resistance breeding is critically discussed by Villa *et al.* (2013) because, as opposed to our finding, no genetic effect was found.

619. Genetic analysis of royal jelly production and behaviour traits of honeybees

B. Basso[1,2], T. Kistler[2,3], T. Gerez[4] and F. Phocas[2,3*]

[1]INRAE, Abeilles et Environnement, 84914 Avignon, France; [2]UMT PrADE, France; [3]Université Paris-Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; [4]GPGR, Agrapole, 69364 Lyon, France; florence.phocas@inrae.fr

Abstract

To improve their honeybee population, the royal jelly producers focus their selection objectives on both production and colony behaviour traits to maintain a sustainable production. To estimate genetic parameters for all these traits, a dataset from the French royal jelly producers group including records collected from 1,347 colonies was analysed using ReML methodology applied to animal models. Heritability estimates for royal jelly production traits were moderate while estimates for colony behaviour traits (gentleness, non-swarming behaviour, spring development, non-sanitary susceptibility and feed autonomy during hollow of honey flow) ranged from low estimates (0.10±0.10 for non-swarming behaviour) to very high estimates (0.68±0.10 for feed autonomy). Unfortunately, the dataset was too small to obtain reliable estimates for the genetic correlations between production and behaviour traits.

Introduction

Royal jelly production requires highly selected strains of honeybees to be profitable for beekeepers. Therefore, French royal jelly producers belonging to the 'GPGR' group conduct a collective breeding program with data recording since 2011. This very specific production requires a full-time work for a beekeeper taking care of only about a few dozen of colonies. Therefore, information to be analysed even after ten years of data collection is based on less than 1,500 colonies with performance testing, which corresponds to a very small dataset size for any analysis in quantitative genetics. Due to its very high economic value, the main trait of interest for the beekeepers is the amount of royal jelly produced per colony. However, beekeepers have also to consider various colony behaviour traits in order to maintain sustainable production conditions. First of all, the colonies being visited often, it is important that the bees are not too aggressive. The non-swarming tendency and the absence of susceptibility to disease are all the more important traits than royal jelly production relies on small size apiaries for which any colony loss has major economic impact. In addition, feed self-sufficiency becomes a major issue for colony survival and productivity in the context of climate change, the lack of floral resources being increasingly felt even during the production season. Beyond the risk of colony loss, the overall dynamics of the colonies will be lower and the production penalized for colonies with little feed autonomy. For all these reasons, it is important to develop a multicriteria breeding program considering jointly production and behaviour traits. The aim of the study was therefore to estimate genetic parameters for the main traits of interest for royal jelly producers to better orient the breeding program.

Materials & methods

Honeybee population. The French Royal Jelly Producers Group 'GPGR' is carrying out a breeding program at the national scale to select improved honeybees for their very specific production. Although data collection started in 2011, only records from years 2013 to 2021 were kept for the analysis because data have only been homogeneously recorded since 2013. Our dataset included records for 1,347 queens of which 808 were open mated and 539 were mated by artificial insemination and were potential breeding queens (BQs). Each year, a new generation of queens was produced from a pool of 9 BQs on average born the previous year. Those breeding queens came from 6 bee breeders that have been working together since

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_619, © B. Basso *et al.* 2022

2011. Each year, 8 to 18 different beekeepers have been involved in performance testing of an average of 12 BQs' daughters to select the drone-producing queens (DPQs) of the next generation. Generation interval is therefore 2 years on the sire path.

Performance testing. Queen performance test starts after the first colony wintering, when all workers are daughters of the tested queen (Büchler *et al.*, 2013). Beekeepers initiate royal jelly production for the tested queens as early as possible in the season, generally between April and May, depending on the year and the area. To do so, each hive has a queenless part in which queen cells with young larvae (stage L1) are introduced. Then, every 3 days, beekeepers harvest the royal jelly produced and introduce new queen cells with young larvae. For each colony, amount of royal jelly is recorded for the first two harvests in the season (respectively named P1 and P2) and the mean production (PROD=(P1+P2)/2) is also analysed.

Regarding behaviour traits, gentleness (GENT), non-swarming tendency (SWAR) and spring colony development (DEVE) are assess according to the COLOSS BEEBOOK recommendations (Büchler *et al.*, 2013) with a visual score ranging from 1 (worst score) to 4 (best score). In order to assess overall disease resistance (SANI) and feed autonomy (AUTO) during hollows of honey flow in the production season, beekeepers evaluate their colonies with scores ranging also from 1 to 4 almost every three days at harvest time. SANI and AUTO were analysed considering information collected the days with the worst average scores within apiary.

Genetic parameters estimation. BLUP animal genetic models were used to fit the data using BLUPf90 and its AIREMLF90 program was used to estimate genetic parameters based on the inverse of a relationship matrix derived from an R program based on Brascamp and Bijma (2014, 2019) methodology and software. To build this matrix, we assumed that each queen was mated to 8 drones bred either by a single DPQ for artificially inseminated queens or by 100 unrelated DPQs for open mated queens. Genetic parameters were initially estimated with a model considering both direct (Worker effect) and maternal (Queen effect) random genetic effects in the model describing any phenotype y_{ijk} for colony k along with the fixed effect of the comtemporary group CG_{ij} constituted by the combined environmental effects of apiary i and year j:

$y_{ijk} = \mu + CG_{ij} + Worker_k + Queen_k + e_{ijk}$, with μ the overall average and e_{ijk} the residual effect.

For all the behaviour traits, the ReML algorithm did not converge and, therefore, a simple model was used only accounting for the contemporary group fixed effect and a single random genetic effect as a colony effect combining both worker and queen effects (Du *et al.*, 2022):

$y_{ijk} = \mu + CG_{ij} + Colony_k + \varepsilon_{ijk}$, with μ the overall average and ε_{ijk} the residual effect.

For production traits (P1, P2 and PROD), heritability estimates were obtained for both the direct genetic effect (h^2_d) and the maternal genetic effect (h^2_m), as well as the genetic correlation between the two effects (r_{dm}). The simple colony effect model produced a unique estimate of heritability for a synthetic colony trait (h^2c). Genetic correlations between production and behaviour traits were calculated under this simple model.

Results

Performance statistics. Most of the queens have recorded data on all traits (Table 1). AUTO is the exception because its evaluation started in 2017 and only 733 records have been used in the analysis. During the production period considered, the average royal jelly produced was 32.9 g per harvest day and colony (Table 1).

Table 1. Performance statistics for production at first (P1), second (P2) harvests, and in average (PROD) and scores for gentleness (GENT), swarming (SWAR), sanitary status (SANI), colony development (DEVE) and feed autonomy (AUTO).

Trait	All tested queens			Open mated queens			Artificially inseminated queens		
	n	Mean	SD	n	Mean	SD	n	Mean	SD
Production traits (g)									
P1	1,293	31.0	16.2	772	27.8	15.2	521	35.7	16.4
P2	1,298	34.9	18.0	775	30.8	16.9	523	41.0	18.0
PROD	1,293	32.9	15.9	772	29.3	14.8	521	38.3	15.9
Behaviour traits (score ranging from 1 to 4)									
GENT	1,114	2.97	0.64	639	2.94	0.68	475	3.00	0.58
SWAR	1,018	3.51	0.71	593	3.45	0.80	425	3.59	0.56
SANI	1,269	3.21	0.70	755	3.09	0.68	514	3.93	0.70
DEVE	961	2.98	0.88	602	3.00	0.87	359	2.95	0.89
AUTO	733	2.03	0.94	396	2.10	0.97	337	3.11	0.51

Genetic parameters. Table 2.a shows that moderate to strong estimates of direct heritability were derived for all the production traits while estimates of maternal heritability were low and not significantly different from zero. In addition, strong negative genetic correlations between direct and maternal effects were estimated, but with extreme standard error values (ranging from 0.7 to 1.9). With a colony effect model, heritability for any production trait was moderate. The genetic correlation between P1 and P2 was strong (0.66) and their genetic correlations with PROD was not significantly different from 1 (Table 2.b).

Heritability for behaviour traits ranged from low estimates for SWAR to very high estimates for GENT and AUTO (Table 3). Apart from SWAR, all values were significantly different from zero. At the only exception of the negative estimates of the genetic correlations between DEVE and productions traits, correlations between all other colony behaviour traits and production traits could not be considered as reliable (strong difference between L1 and L2 estimates) and/or significantly different from zero.

Table 2. Genetic parameters across production traits.

a. Worker-Queen model				b. Colony model

[1] na = ReML did not converge for this parameter.

Discussion

Royal jelly production showed a relatively high heritability at the colony or direct worker genetic effect level, which confirms earlier results (Phocas *et al.*, 2017) on the same historical population and the possibility of improving production performance. Estimates of heritability for behaviour traits were less consistent across analyses since Phocas *et al.* (2017) estimated quite different values for GENT (0.40), SWAR (0.40) and SANI (0.10), but considering a different genetic model than the colony one. Nevertheless, apart from swarming tendency, our results are therefore encouraging to integrate behaviour traits in the breeding program. However, correlations between production and behaviour traits were clearly not reliable. Phocas *et al.* (2017) found a significant negative genetic correlation (-0.71±0.14) between PROD and SANI, while this correlation appeared now to be null or even positive depending on the production trait considered.

Last but not the least, it is important to notice that the estimates of genetic correlation between direct and maternal effects were strongly negative. The huge standard errors of these estimates give evidence that the structure and size of our dataset was clearly insufficient to disentangle worker and queen genetic effects in the colony performance. While it imposes caution on the true value of direct-maternal genetic correlation, it is however interesting to notice that our estimates are close to estimates derived for larger datasets on other bee populations and traits (Brascamp *et al.*, 2018). Our results confirm the ones based on simulated data from Kistler *et al.* (2022) and the importance of very large datasets to get reliable estimates of genetic parameters. Therefore, we are facing many uncertainties for implementing robust breeding programs for small honeybee populations.

Abstract

Despite their impact on food production both in economic terms and regarding the sustainability of production, the majority of honeybee queens are currently not selected based on estimated breeding values. Although methods for the genetic evaluation of honeybees have been suggested and are in use in smaller populations across the area of endemism of the Western Honeybee (*Apis mellifera*), they have yet to penetrate into the commercial populations across e.g. the Americas and Oceania. Here we present estimates for heritabilities for three traits, honey yield, gentleness and brood in early spring, on the basis of records obtained from commercial beekeeping operations. In comparing results using an Animal and Dam Model, heritabilities for the Animal Model (0.14 for honey yield, 0.79 for gentleness and 0.004 for brood in early spring) were more closely aligned with heritabilities for these traits found in current literature.

Introduction

At the moment, the widely cultivated Western Honeybee (*Apis mellifera*) does not undergo the same rigorous genetic improvement process as other livestock species. This lack of targeted breeding exists despite the honeybee being one of the biggest contributors to the economic success and sustainability of agricultural production worldwide due to its role as the only insect pollinator which can be managed and provided to producers at a sufficient scale to satisfy pollination needs (Khalifa *et al.*, 2021). Efforts to bring honeybee breeding into the world of modern animal breeding are often driven by lone operators such as universities or government institutions, and have resulted in the development of methods for the genetic evaluation of honeybee queens (Bienefeld, Ehrhardt and Reinhardt, 2007; Brascamp and Bijma, 2014). However, these methods cannot be readily applied to commercial honeybee populations which form the backbone of large pollination-dependent production systems, even though these would benefit most from the application of genetic evaluations and are a likely target market for the provision of queen genetic evaluation as a service. One issue around the genetic evaluation of honeybee queens used as breeder queens in commercial beekeeping operations is the lack of performance records for these queens, which are usually the offspring of selected mothers, but who are managed in a way that makes the evaluation of their own performance impossible. Simultaneously, their progeny, queens that could be evaluated under field conditions, usually lack paternal pedigree and cannot be readily selected to be transferred back into the queen production part of the operation. Although both parties involved in this, the breeder queen and her queen daughters, are female, these circumstances create a situation comparable to the genetic evaluation of bulls for milk traits in their daughters. This suggests that genetic evaluation using a Dam Model could be preferable over the Animal Model previously suggested for honeybees, irrespective of whether queen and worker effects are being considered within the model.

Materials & methods

Pedigree data. The pedigree data consisted of 2,966 individuals where only maternal pedigree was available. There were 339 dams and 185 dams of dams represented in the pedigree, with the number of dam generations ranging from 1 to 17.

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_620, © G.E.L. Petersen *et al.* 2022

Performance data. Performance data from 2004 to 2021 was obtained from a specialised queen breeding operation in the South Island of New Zealand, although records were not complete for all traits due to changes in recording strategies over the years (Table 1). Through working with two commercial beekeeping operations, protocols for the performance evaluation of queen progeny in the field were developed and performance information was collected in one operation with a honey production focus and one operation with a pollination focus. Recorded traits were honey yield (kg honey produced per season per colony), brood present in early spring (at the first visit after the winter break), bees present in early spring (recorded at the same time as the brood record) and mean gentleness over the season (scored by beekeepers at each visit on a scale from 1 (aggressive) to 5 (gentle)). Gentleness was on average recorded two times per season in the commercial populations and 3.5 times per season in the queen breeding population.

Calculation of heritabilities and estimated Breeding Values (eBVs). Heritabilities were calculated and eBVs estimated using standalone ASReml (Gilmour *et al.*, 2015). A Dam and Animal model were fit with identical fixed effects, apiary and year×region. Since some individual queens had repeated records over two years, both models were run as a single record model with the later record removed and as a repeated records model. Animal model heritability was additive genetic variance divided by the sum of the additive and residual variance components or V_A / V_A + V_R. Dam model heritability was four times the additive genetic variance divided by the sum of the additive and residual variance components or $4V_A$ / V_A + V_R. The Potential maternal effects were not partitioned out in the Animal model, as this resulted in similar estimates with increased standard errors (data not shown).

Table 1. Honeybee performance records collected from 2004 to 2021.

	Queen Breeder				Commercial operations (2)

[1] Prior to 2012, honey yield had mainly been estimated using a proxy trait.

Results

Results could only be obtained for 3 out of the four recorded traits. For the trait 'bees present in early spring', all models converged, but found no genetic effect on variation. For the 3 traits honey yield, gentleness and brood in early spring, heritabilities were found to be consistent across the single record and repeated records models for the Animal Model and Dam Model, respectively. However, for both gentleness and brood in early spring, the heritability calculated with the Animal Model and Dam Model differed, with gentleness showing the biggest discrepancy between models (0.79 using the Animal Model vs 0.05 using the Dam Model; Table 2).

Discussion

The purpose of this work was to investigate the impact of the choice of model in the calculation of genetic parameters and genetic evaluation of honeybee queens. Given that honeybee pedigrees often cover only the maternal line and in our dataset, there was more data available at a dam level, it was hoped that a dam model would provide more stable heritability estimates. Heritabilities (and standard errors) were consistent between single-record and repeated record models but differed depending on the choice of Animal Model or Dam Model. The heritability for honey yield (Animal Model) of around 0.14 is consistent with previously published estimates of heritability for the queen effect on honey production (Bienefeld and Pirchner, 1990), while the heritability of gentleness (Animal Model) of 0.79 is higher than previously published estimates of around 0.16 to 0.41 (Bienefeld and Pirchner, 1990; Brascamp *et al.*, 2016). It is important to note that the assessment of gentleness was done by beekeepers during routine work and although calmness / docility was assessed at the same time, it is possible that these two traits were not separated sufficiently in these assessments. The very low heritability for brood in early spring (Animal Model) and fact that bees in early spring was found to not have a genetic contribution to variation indicates that the variability in the measurement time in spring due to weather, climatic conditions and varying beekeeper management strategies might create too much external variation to allow for a sensible analysis. This can potentially be addressed by including existing records on interventions (e.g. winter feeding) or the month or calendar week of assessment as fixed effects. Although the dataset used for the present analysis is currently still being expanded and data collection protocols are being refined, which is expected to lead to a better basis for the calculation of more reliable estimates of heritability and more accurate EBVs, one big issue in the genetic evaluation of honeybee queens remains. Due to their highly polyandrous mating habits which see one honeybee queen mated to up to 20 drones (Page Jr. and Metcalf, 1982) and mating 'on the wing' and out of the human sphere of influence, honeybee pedigree can only be observed and recorded in a one-sided, maternal-only pedigree in the absence of instrumental insemination or controlled mating in mating stations managed by breeding associations (Büchler *et al.*, 2013). Both methods are restricted in their availability and too expensive to find application in 'smallholder'-type beekeepers in developing countries and commercial beekeeping operations. However, commercial beekeepers own and manage a significant proportion of the honeybee population in developed countries, especially those with a mature beekeeping industry such as New Zealand or Canada (New Zealand Ministry for Primary Industries, 2021). As a result, absence of pedigree or dam-only pedigree is the norm for most honeybees worldwide. This is the case for

Table 2. Heritability and standard error for honey yield, gentleness and brood in early spring.

	Animal model		Dam model	
Year	Single record	Repeated records	Single record	Repeated records
Honey yield	0.14 (±0.11)	0.13 (±0.11)	0.05 (±0.07)	0.05 (±0.08)
Gentleness	0.79 (±0.07)	0.79 (±0.07)	0.05 (±0.04)	0.04 (±0.04)
Brood early	0.004 (±0.05)	0.03 (±0.05)	0.18 (±0.11)	0.29 (±0.12)

all the commercial queen records in the present dataset, with only a very small number of queens in the commercial dataset linked to the queens in the queen breeder dataset via pedigree, despite regular transfer of breeder queens from the breeding population into both commercial operations. A set of around 400 queens from both the commercial populations and the breeding population has been sampled for Whole-Genome Sequencing, the data from which is still being processed. The resulting genomic relationship matrix will be used to investigate the possibility of genomic selection using commercial 'production' queen performance records to select breeding stock both in the commercial and breeding populations. While the possibility of using genomic selection in honeybees has been suggested with the use of modelling studies (Bernstein *et al.*, 2021), the potential for reaching large commercial operations running comparatively genetically homogenous populations is currently poorly understood and to our knowledge, this will be the first attempt to improve selection decisions in bigger populations with the use of genomics.

Abstract

The honeybee *Apis mellifera*, major pollinator worldwide, is facing multiple threats to survival with the infestation by *Varroa destructor* being a major concern. Resistance to such infestation is a crucial mechanism for the maintenance of the honeybee population. However, to date, genetic components explaining this resistance are poorly known making selection for resistant honeybees a challenge. In this study we perform a genome wide association study on about 300 *A.m. mellifera* colonies for one trait measuring varroa resistance, the recapping of varroa infested brood cells. On about 300 *A.m. mellifera* colonies we identified multiple chromosome regions showing significant effects for this polygenic trait. We reported a heritability of 0.57 (±0.21). Recapping of varroa infested brood cells could be a trait of interest for the selection of resistant honeybees.

Introduction

The honeybee, *Apis mellifera*, is the main domestic pollinator worldwide. Despite its critical value for pollination services, production of honey, royal jelly and pollen, it is currently facing considerable challenges due to land anthropication (loss of flower resources and suitable habitats, pesticide use), climate change and the spread of biological threats. The ectoparasite *Varroa destructor* is one of these threats, as it is the principal cause of honeybee colony mortality in the Western world (Le Conte *et al.* 2010). For about a decade, resistance to varroa has become a key trait of interest for beekeepers. Colonies naturally resistant to varroa infestation have been identified by natural selection when untreated colonies were left to die or survive in isolated environments (Mondet *et al.* 2020). However, the genetic mechanisms to explain the variation in varroa infestation resistance observed across honeybee colonies is poorly known. Only a few genetic markers of interest have been identified in small honeybee populations (Mondet *et al.* 2020). Moreover, it is difficult to define a relevant measure to score resistance to a parasite and estimate its genetic parameters. Multiple traits have been described, for example mite none reproduction (MNR), varroa sensitive hygiene (VSH), hygienic behaviour, recapping, and very variable genetic parameters were estimated (Guichard *et al.* 2020). Identifying genetic markers linked to resistance to varroa infestation is key to understanding the genetics behind this resistance and in the long run, to perform genomic selection for this trait. In this study, about 300 French colonies of the *A.m. mellifera* genetic background, endemic to Western Europe, were sampled for genetic material and traits expected to be linked to resistance to varroa infestation and we present results from recapping of varroa infested brood cells by adult bees. A pool of workers from each colony was sequenced, providing sequencing depth and allele counts giving allele frequencies within the colony rather than traditional genotype information. In the context of eusocial insects, a method was developed to reconstruct queen genotype from such pool data (Eynard *et al.* 2021). We applied this method to reconstruct honeybee queen genotypes for each of the colonies which were

used in a Genome Wide Association Studies (GWAS) for the trait of interest. Its heritability was estimated and markers and genome regions with significant effects were identified. These results contribute to the knowledge on honeybee resistance to varroa infestation and will be valuable for future implementation of genomic selection.

Materials & methods

Genetic material and sequencing. A total of 306 honeybee colonies, with a major *A.m. mellifera* genetic background, coming from beekeepers in France were sampled within the framework of the FranceAgriMer, Investissement d'Avenir BeeStrong project. Each genetic sample consisted of about 500 honeybee workers. An initial DNA extraction, using tailor made protocols, was performed. Thereafter, pool sequencing was done in order to obtain 30X raw sequencing depth. These reads were aligned on the honeybee reference genome Amel HAV3.1 (Wallberg *et al.* 2019), using BWA-MEM (Li 2013). Pool sequences were analysed using Samtools mpileup (Li *et al.* 2009) and Popoolation2 (Kofler *et al.* 2011) on 6,914,704 single nucleotide polymorphisms identified in Wragg *et al.* (2021). Markers were filtered for minor allele frequency above 0.01 and missing rate below 5% for further analysis.

Queen genotype reconstruction. Honeybee queen genotypes for all markers and each colony were reconstructed from sequencing depth and allele counts data using the method of Eynard *et al.* (2021). In short, the method is based on the likelihood of the queen genotype that can be written as:

$$x_l^c | d_l^c, f_l^c, g_l^c \sim Binomial(\frac{f_l^c + g_l^c}{2}, d_l^c) \quad (1)$$

where g_l^c is the unknown honeybee queen genotype, f_l^c is the unknown reference allele frequency in the males founder of the colony and d_l^c and x_l^c the sequencing depth and allele counts obtained from pool sequencing experiments for locus l and colony c. Assuming all colonies come from an homogeneous population, Equation 1 can be expressed as a function of a common allele frequency f_l which can be estimated by maximum likelihood and used to compute posterior probabilities of the queen genotype.

Measure of resistance to varroa infestation. One way for honeybee colonies to control *Varroa* infestation is by recapping infested brood cells as this behaviour breaks the reproductive cycle of the mite. Recapping status was thus proposed as a measure of varroa resistance (Büchler *et al.* 2017) and therefore the proportion of recapped brood cells that are infested by varroa was used as a resistance trait in this study.

Genome wide association study. We performed a GWAS using a multivariate linear model as proposed in GEMMA (Zhou and Stephens 2012). The relationship matrix between colonies was estimated on allele frequencies for 2,387,893 markers from the pool sequencing experiment, taking SNP linkage disequilibrium into account using LDAK Speed *et al.* (2012). The association of the reconstructed queen genotypes with the phenotype was tested for 2,694,182 markers. Markers' *P*-values were obtained by GEMMA and q-values and s-values were estimated using the R package 'ashr' (Stephens 2017). SNPs with a s-value less than 0.1 were considered significant.

Results

The proportion of phenotypic variance explained (pve) by the markers, a proxy for heritability, for recapping of varroa infested brood cells was 0.57 (95% confidence interval [0.16, 0.98]). The GWAS inflation factor was 1, indicating an accurate correction for population stratification (Figure 1).

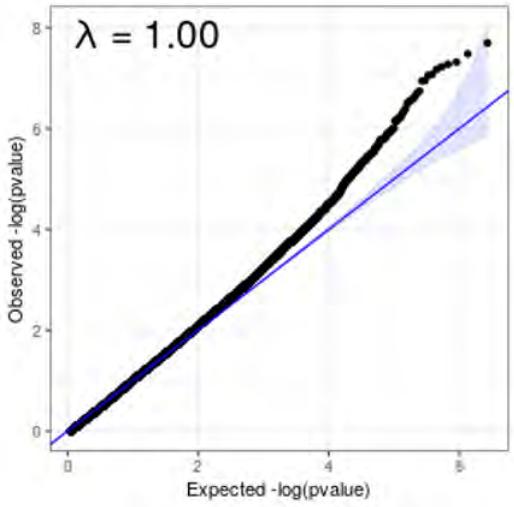

Figure 1. Quantile-quantile (QQ) plot of observed versus expected *P*-values for the GWAS with inflation factor, lambda.

We identified 18 chromosome regions significantly supported by at least one marker for both standard *P*-values and after adaptive shrinkage (Figure 2). These regions were found on 13 of the 16 chromosomes.

Discussion

Resistance to varroa infestation in honeybees is a complex trait to measure and thus far there is no consensus way to accurately measure it. One way to infer varroa resistance in a honeybee colony is to estimate the ratio of varroa infested brood cells that have been recapped. This is under the assumption that recapping of an infested brood cell by worker bees will cause a disturbance in the *Varroa destructor* reproductive cycle within the sealed brood cells and thus reducing its pressure on the colony by impairing its development (Oddie *et al.* 2018, Oddie *et al.* 2021). This trait relies highly on the initial infestation status, meaning that a colony with a low infestation rate will have a less accurate estimate of recapping than a

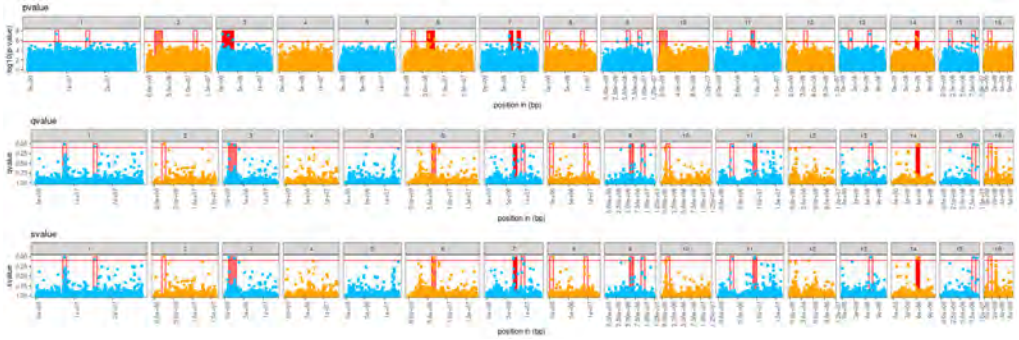

Figure 2. Manhattan plot of the GWAS results for -log10(*P*-value), q-value and s-value, estimated by adaptive shrinkage, along each of the chromosomes. Regions containing significant markers are highlighted in red, brightness of red being linked to the number of significant markers in the region. The red line marks the significance threshold.

highly infested colony, as the ratio will be based on a smaller number of observed brood cells. This causes a high variability between measures that need to be accounted for, which is done in our case by using an Empirical Bayes transformation giving weights to the phenotypes that are proportional to their estimated accuracy. Additionally, a logit transformation was needed to linearise the measured ratio and allow the use of this trait for GWAS. In our study, we identified 18 chromosome regions that appear to have a significant effect on the trait. Most chromosomes carry a region of interest meaning that the recapping of infested brood cells is a highly polygenic trait. Our results contrast with other studies in which a small number of significant markers have been observed (Guichard *et al.* 2021). We could estimate the heritability, as the phenotypic variability explained by our markers, for the trait to be 0.57 (±0.42). Although still imprecise, this estimate of heritability shows the potential there is to use this trait in a breeding program. It would now be interesting to identify genes underlying regions that appear to have a significant effect on the recapping of varroa infested brood cells in order to unravel the biological mechanisms explaining this behaviour in worker honeybees.

622. New approach to identify Mendelian inconsistencies between SNP and pedigree information in the honey bee

R. Bernstein*, M. Du, A. Hoppe and K. Bienefeld

Institute for Bee Research Hohen Neuendorf, Friedrich-Engels-Str. 32, 16540 Hohen Neuendorf, Germany; richard.bernstein@hu-berlin.de

Abstract

In preparation of genomic selection, the genomic data is compared to pedigree information, and samples causing Mendelian inconsistencies are removed. Traditionally, opposing homozygotes and coefficients of inbreeding and relationships were used for this purpose. Here, we adapted these methods to the peculiar mating biology in honey bees. We developed a rule system for the removal of Mendelian inconsistencies in honey bees based on the empirical distributions of opposing homozygotes and coefficients of inbreeding and relationship in real and simulated data. To initiate genomic selection in the honey bee, 2,970 phenotyped queens were recently genotyped for about 100,000 markers. The samples of 207 and 135 queens were removed by the checks for opposing homozygotes and abnormalities in the relationship matrices, respectively. We suggest, that our approach should be used to prepare data for genomic selection in the honey bee.

Introduction

Genomic selection is a standard practice in many agricultural species, but not in honey bees, and methods require careful adaptation to the peculiarities of this species. Honey bees are haplodiploid, i.e. the female queens and workers are diploid and the male drones are haploid. A colony consists of several thousand workers which perform all non-reproductive tasks, and a fertilized queen which produces workers, queens, and drones. Virgin queens undertake nuptial flights to mate with several drones. To ensure lasting breeding success, the genetic quality of the drones must be controlled (Plate *et al.* 2019). Therefore, mating stations are used, where only drones of specialized drone producing queens (DPQs) are present. For unrelated DPQs, daughters of the same dam queen (full-sibs) can descend from the same drone (super-sisters), different drones but the same DPQ, or different DPQs, resulting in genetic relationships of 0.75, 0.5, and 0.25, respectively, a weighted average of which (0.32) is assumed in pedigree-based analyses. However, the DPQs on a mating station are typically full-sibs, leading to slightly closer relationships among their offspring. Recently, a marker array for 100,000 SNPs has been developed and used to genotype 2970 phenotyped queens to initiate genomic selection in the honey bee (Jones *et al.* 2020) with promising validation results for genomic breeding values (Bernstein *et al.*, submitted). Here, we focus on the quality control (QC) comparing the genotypes to the pedigree. In diploid species, the most common method to spot Mendelian inconsistencies checks for opposing homozygotes (OHs; Hayes 2011), because it is very rare that the detected genotypes of parent and offspring are homozygous for different alleles at the same locus. For the same purpose, comparisons of the pedigree-based to the genomic relationship matrix can be applied, which can also be applied to check siblings for Mendelian inconsistencies (Calus *et al.* 2011).

Materials & methods

Data. From the 2,970 genotyped queens in (Jones *et al.* 2020), 312 queens were removed since less than 90% of all loci were called in their samples. SNPs were removed, when the SNP was called in less than 90% of all samples, had a minor allele frequency (MAF) below 0.01, or showed significant deviations from Hardy-Weinberg-equilibrium after Bonferroni-correction (P-value$<0.05\times10^{-5}$). 63,240 SNPs remained in the data set.

Quality control based on opposing homozygotes. The number of OHs was calculated for all pairs of genotyped queens. Pedigree data maintained at www.beebreed.eu (Hoppe *et al.* 2020) was downloaded on 14th Feb 2021. For pairs of dam and daughter, full-sibs, and unrelated queens, the empirical distributions of the number of OHs were considered. The appropriate threshold for QC should be higher than the frequent numbers of OHs in dam-daughter-pairs, but lower than the frequent numbers of OHs in pairs of unrelated queens, and be in between two peaks for pairs of full-sibs. In our data set, a threshold of 50 OHs satisfies these conditions (see the results section). Mendelian inconsistencies and confirmations between the pedigree and the genomic data were counted in the following way: Two samples of the same queen were counted as an inconsistency, when the number of OHs was above 50. A pair of dam and daughter counted as a confirmation when the number of OHs was below 50, otherwise as an inconsistency. Full-sibs were excluded from this test (see Figure 1 C). Other sample pairs counted as inconsistencies when the number of OHs was below 50. For each sample an inconsistency score was calculated by subtracting four times the number of confirmations from the number of inconsistencies. The sample of highest score was removed, and the scores were re-evaluated. The procedure was iterated until no sample with a positive score was left. The factor four is based on the heuristic that a dam should not be removed unless 80% of her genotyped offspring had a conflicting genotype (Calus *et al.* 2011).

Quality control based on relationship matrices. After the QC based on OHs, further steps of QC followed. The pedigree-based relationship matrix A_{22} between genotyped queens was calculated using the software PInCo (Bernstein *et al.* 2018). The genomic relationship matrix G was calculated according to Method 1 in (VanRaden 2008) using preGSf90 (Misztal *et al.* 2002). To develop a rule system for the matrix-based consistency check, matrices A_{22} and G were calculated for a simulated population of 10,000 genotyped queens, distributed over 10 years, and selected for a trait of moderate heritability (Bernstein *et al.* 2021). Based on comparisons of the simulated genomic and pedigree relationships, combinations of relationship values were defined to constitute inconsistencies or confirmations. The values of A_{22} and G for two samples i and j, denoted by a_{ij} and g_{ij}, respectively, counted as an inconsistency, if:

$$(a_{ij}<0.25 \;\&\; g_{ij}>0.5) \text{ or } (a_{ij}>0.25 \;\&\; g_{ij}<0.0625) \text{ or } (a_{ij}\geq 0.5 \;\&\; g_{ij}<0.125) \text{ or } |g_{ij}- a_{ij}|>0.5, \quad (1)$$

and as a confirmation, if:

$$a_{ij}>0.25 \;\&\; g_{ij}>0.25 \;\&\; |g_{ij}-a_{ij}|<0.5 \quad (2)$$

In a QC step for high coefficients of inbreeding, queens with diagonal entries in G>1.5 were removed. Subsequently, a score based on inconsistencies and confirmations was used in an iterative procedure as described in the subsection on the QC for OHs.

Results

Based on the empirical distribution of the number of OHs (Figure 1), the threshold of 50 was chosen, as 64% of parent-daughter-pairs, 10% of the pairs of full-sibs, and 0.1% of the pairs of unrelated queens showed 50 or less OHs, respectively. 207 queens were removed due to the QC based on OHs.

The samples were further controlled based on the empirical distributions of A_{22} and G (Figure 2). The simulated data set indicated that no QC is possible in the area ($A_{22}<0.25$ & $G<0.5$). This is due to the possibly high discrepancy between genomic and pedigree-based relationships in full-sibs, which is inherited by offspring. E.g. queens with pedigree-based relationships of 0.32 showed genomic relationships between 0.17 and 0.83. The empirical distribution of A_{22} and G in the real data were even further spread out. Possible causes include that the SNP array includes a large number of SNPs with MAF below 0.05, and diverging

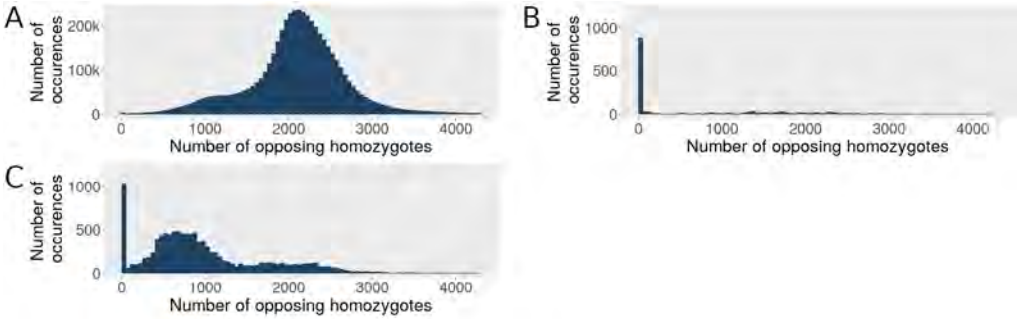

Figure 1. The number of OHs was calculated for all pairs of genotyped queens (A), dam and daughter (B), and full-sibs (C). 14,856 occurrences in (A) and 6 occurrences in (C) are not shown, as the corresponding numbers of OHs exceeded 4,300. The width of each bar covers 50 numbers of OHs.

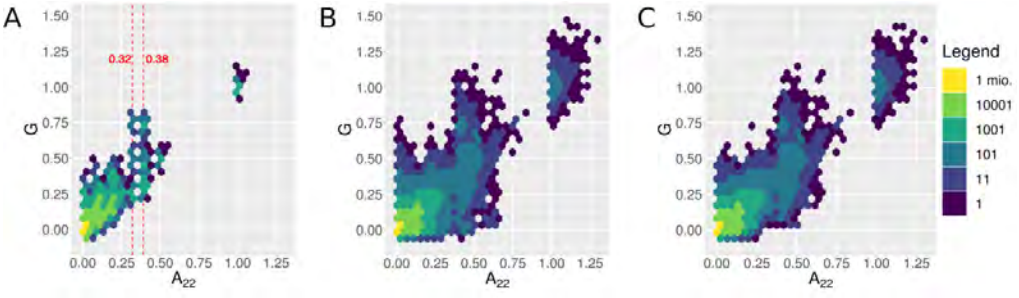

Figure 2. Comparison of the distributions of the pedigree-based and genomic relationship matrices A_{22} and G, respectively. (A) shows the matrices in a simulated data set, (B) shows the matrices after samples with high coefficients of inbreeding were removed and (C) shows the matrices after the QC was finished. Since the complete matrices are shown, coefficients of inbreeding are shown at $A_{22} \geq 1.0$. In (A), the red lines mark full-sibs sired by unrelated DPQs, and DPQs which are non-inbred full-sibs, respectively. At $A_{22}=0.32$, peaks are visible for super-sisters (G=0.75), daughters of the same DPQ (G=0.5), and of different DPQs (G=0.25). The full-sibs in (B) and (C) are visible at $A_{22} \geq 0.38$, as the corresponding DPQs were full-sibs and their offspring in some cases inbred.

breeding lines or regions. Equation 1 targets the areas ($A_{22}<0.25$ & $G>0.5$), ($A_{22}>0.25$ & $G<0.0625$), and ($A_{22} \geq 0.5$ & $G<0.125$) for QC, because they were unoccupied in the simulations, and genotyping errors are likely to show in areas were the values of A_{22} and G strongly diverge. The number of occurrences in these areas was reduced by 87% by the QC based on relationship matrices.

Nine and 135 queens were removed by the QC step for high coefficients of inbreeding, and the following iterative procedure based on a score, respectively. The quality controlled, final data set contained 2,307 queens. A stricter control is possible, but also more likely to remove correct genotypes.

As expected, the QC based on the comparison of A_{22} and G increased their similarity (Table 1). However, the simulated matrices showed considerably lower spreads of the coefficients of inbreeding and relationship. The low correlation of the coefficients of inbreeding in the simulated matrices compared to the matrices in the real data set is due to the absence of high coefficients of inbreeding in the simulated data. Based on the maximum absolute difference between A_{22} and G, the condition $|G-A_{22}|>0.5$ was included in Equation 1 to mark Mendelian inconsistency.

Table 1. Quantitative comparison of the pedigree-based and genomic relationship matrices A_{22} and G, respectively.

Version of A_{22} and G[1]	(A)	(B)	(C)
Correlation of inbreeding coefficients in A_{22} and G	0.11	0.32	0.33
Correlation of coefficients of relationship in A_{22} and G	0.63	0.49	0.51
Maximum absolute difference $\lvert A_{22} - G \rvert$	0.51	0.74	0.67

[1] (A) = Simulated matrices, (B) = matrices after correction for high inbreeding coefficients, (C) = final matrices.

Discussion

In honey bees, super-sisters have similar numbers of OHs like pairs of parent and offspring. Therefore, OHs can be used to refute parentship, but not for parentage assignment, which is possible in diploid species, if monozygotic twins can be excluded (Hayes 2011). We employed a boundary of 0.5 on the absolute difference between genomic and pedigree-based relationship, and identified three areas where Mendelian inconsistencies are likely to occur. A strict boundary of 0.2 on the absolute difference between genomic and pedigree-based relationship was employed in a real data set (Calus *et al.* 2011). Such a narrow boundary is inappropriate for honey bees, as the discrepancy between pedigree-based and genomic relationships of full-sibs must be considered in honey bees. In real data sets, unsafe mating stations can exacerbate the difference between genomic and pedigree-based values. Therefore, genomic coefficients of inbreeding are considerably more reliable than pedigree-based inbreeding coefficients for honey bees. Thus, the discrepancy between the values of A_{22} and G could be an advantage for genomic selection in the honey bee. Unknown paternity reduces the accuracy of pedigree-based selection, but is countered when genomic data is available (Bernstein *et al.* 2021).

Abstract

Honeybee pedigree cannot be readily recorded based on the observation of mating, since this is hindered by their reproductive behaviours, including mating in flight and extreme polyandry. Due to these circumstances, genotyping of queens with partial pedigree with the maternal line only or entirely unknown pedigree could be a valuable tool to link queens observed under field conditions back to breeding stock. However, queen management in beekeeping operations often leads to the grand-daughters of breeder queens being placed in the field, which requires pedigree reconstruction beyond dam or sire assignment. Here we investigate parental contribution to 64 queens produced in a closed mating scheme across five generations. Differences in the resulting relationships between paternal sisters as well as the relationships of sets of paternal sisters to their dam suggest variation in the paternal contribution, possibly due to the effects of the purging of deleterious haplotypes in the haploid male drone.

Introduction

Honeybees (*Apis mellifera*) differ from other livestock species in their reproduction dynamics, which impacts their patterns of inheritance. Not only do these eusocial insects display reproductive division of labour, wherein reproduction is limited to one female per colony (the queen), but also haplodiploidy, where female workers and queens are diploid and male drones are haploid. As a result, supersisters, who share both parents, are related by 0.75, while full sisters, who share a mother and whose sires come from the same source, are related by 0.5. Colony genetic diversity is maintained by extreme polyandry practised by the queen, which results in groups of full sisters coexisting with each other.

To estimate breeding values in honeybees using mixed model methodology, the relationships between individual queens need to be defined, either via recorded pedigree, which comes with its own challenges, or genotyping. Honeybee-specific methods have been defined for the efficient estimation of breeding values and inbreeding coefficients (Brascamp and Bijma, 2014, Bernstein *et al.*, 2018) based on pedigree. However, although cost-effective options for the genotyping of honeybees are available (Petersen *et al.*, 2020), the resulting relationship matrices cannot easily be transcribed into pedigree due to the skew in (sister) relationships (unpublished). This becomes particularly challenging when there is no pedigree information available for queens involved in field tests, which is often the case in commercial beekeeping operations.

In order to attempt definition of (deep) pedigree from genomic relationships, the scale of Mendelian sampling (i.e. the meiotic contribution to the genotype of a particular queen from each parent) needs to be understood. Here we present an experiment based on managed mating of honeybee queens through Artificial Insemination (AI) over five generations to investigate the contribution of the great-grand-dam to the last generation.

Materials & methods

Honeybee queens and drones. In cooperation with a commercial beekeeping business, maternal lineages were established based on Progenitor Queens, designated generation G0, in the summer of 2018

R.F. Veerkamp and Y. de Haas (eds)

in Dunedin, New Zealand. Individual queen progeny from each Progenitor Queen were inseminated with semen from sets of drone brothers to guarantee sufficient genetic diversity within each colony to maintain colonies capable of rearing drones for the next generation (as opposed to single-drone insemination). Different drone producing queens were used for each generation (Table 1). While the original design saw all generations reared in a single beekeeping season, due to some unforeseen issues around drone rearing and weather limitations, G1 and G2 were produced and inseminated in the season 2019/20, while the rearing and insemination of G3 and G4 queens had to be delayed into the spring of 2020. All mating within the experiment was performed via AI, with drone source queens carefully selected and subsequently harvested to be sequenced. Drones were confined within the hive to guarantee their genetic origin. All queen dams were harvested at the end of their generation for genotyping (Table 1). In addition to queens, all drones used for AI were also collected to enable the determination of individual drone sires at a later date.

DNA extraction, library preparation and sequencing. DNA was extracted from individual honeybee heads. Heads were homogenised at room temperature using four 3.2 mm stainless steel ball bearings and 500µl of 1xPBS solution for two passages of 30-45s each at 20Hz. The homogenised tissue solution was then centrifuged at 4,000rpm for 10 minutes and about 150 mg of the pellet transferred to 96 deep well plate for lysis treatment. Lysis and DNA extraction were performed using the Zymo Quick-DNA Magbead Plus Kit (Zymo Research, Irvine, USA) on an ep*Motion*® 5075 (Eppendorf, Cologne, Germany). 200 ng of genomic DNA from each sample was used for library preparation using NEBNext Ultra II FS DNA kit (New England Biolabs (NEB), Ipswich, USA) at ⅓ volume with NEBNext Unique Dual Index Primer Pairs (NEB). The libraries were subsequently generated according to their respective protocols and sequenced on either a HiSeq X or NovaSeq 6000 platform (Illumina, San Diego, USA) to generate 2×200 bp paired-end libraries with ~15× read depth.

DNA quality analysis and processing. Sequence quality was checked by FastQC v0.11.8 (Andrews, 2015). Adaptors and low-quality sequences were trimmed using AdapterRemoval v2.3.2 (Schubert *et al.*, 2016). Trimmed reads were mapped using BWA-mem2 v2.2 (Li and Durbin, 2009). Mapped reads were sorted and duplicates marked using SAMtools v1.14 (Li *et al.*, 2009) and variants called using GATK4 (Van der Auwera and O'Connor, 2020). Variants for all queens in each line were combined using GLnexus v1.4.1 (Yun *et al.*, 2020) and Genetic Relationship Matrices (GRMs) were built using PLINK v1.90b6.21 (Purcell *et al.*, 2007).

Analysis of queen relationships. The relationships within each honeybee queen line were assessed by building GRMs that were based on genetic variants identified after mapping whole-genome sequencing reads to the reference genome (ENA Assembly: GCA_003314205.1). Distances between related queens were expressed as allele counts and in doing so the relative inheritance between mother / daughter queens was inferred.

Table 1. Honeybee queens collected throughout the crossing experiment.

	Queen dams	Drone sources	
Generation	No of dams per generation	No of drone sources per generation	Total queens genotyped
G0	5	0	5
G1	5	5	10
G2	6	4	10
G3	15	4	19
G4	18	3	20
Total	49	15	64

Results

Three of the five maternal lines in the dataset are represented in Figure 1 with lines P and W showing identical pedigree structure. Examination of differences in allele counts between G0–G1 across all lines showed varying levels of inheritance. However, with each generation there was a consistent trend of increasing distance from the Progenitor Queen (Figure 1A, 1B, 1D).

Comparison of identical pedigree structures between lines P an W showed that paternal sisters with the same grand-dam may be more closely related (Figure 1A) maternal sisters and that paternal sisters may be more related to their dam (Figure 1B) than maternal sisters, suggesting differences in meiotic contribution between the male and female line. With each generation, differences in genetic relatedness to the maternal line were observed in line R (Figure 1E), showing the importance in identifying specific genomic regions that may play a role in differences in genetic contribution.

Discussion and outlook

The goal of the work presented here was to gain a better understanding of Mendelian sampling in honeybees, with the intention of building a steppingstone to the development of a method to reconstruct deep pedigree based on genomic relationships in honeybees. The contribution of the paternal / sire line has

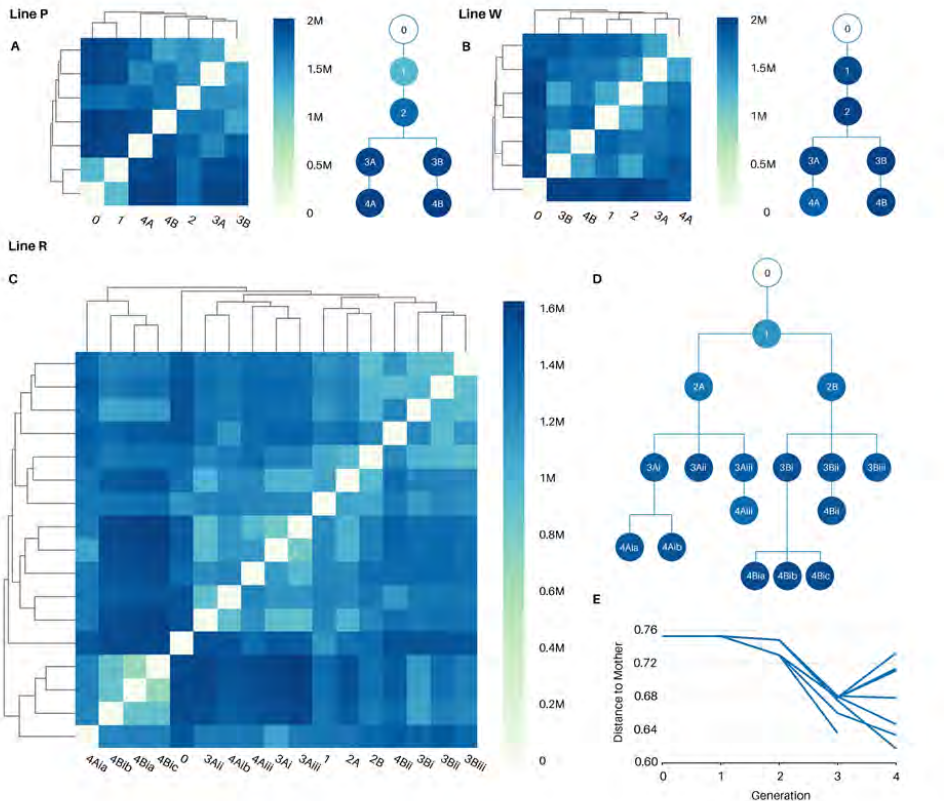

Figure 1. Relationships within honeybee lines across generations G0 to G4. (A) Heatmap and pedigree structure of line P. (B) Heatmap and pedigree structure of line W. (C) Heatmap of the distance matrix for all direct descendants of line R. (D) Pedigree for queens in line R, with each node coloured according to the relatedness of the individual to the Progenitor Queen (G0). (C) Relatedness of queens to their predecessor across Generations G0 to G4.

been assessed in isolation with a combination of long-read sequencing and deep variant calling, and the paternal contribution to inherited variation can now be removed.

Analyses are still ongoing, and by assigning individual drone sires to each queen in generations G1 to G4 and removing the paternal portion of the SNP variation in each queen, patterns of maternal contribution can now be analysed over the 4 generations where drone sires are known. With this information, not only should it be possible to assign genetic relationships derived from the inheritance of haplotypes, but also to gain a deeper understanding of the impact of meiosis and recombination on inheritance.

Purifying selection, the purging of deleterious alleles in the haploid male lineage, could compromise the resolution of meiotic contribution due to skewed inheritance of haplotypes from dam and sire, since not all haplotypes present in a drone source can be expected to be passed down in the paternal line, potentially unilaterally masking paternal contribution. The ongoing analysis of DNA sequence of individual drones from each drone source used in AI will shed light on this.

624. SIMplyBee: stochastic simulator of honeybee populations and breeding programmes

L. Strachan[1*], J. Bubnič[2], J. Obšteter[2] and G. Gorjanc[1]

[1]The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush, Midlothian, EH259RG, United Kingdom; [2]Agricultural Institute of Slovenia, Hacquetova ulica 17, 1000 Ljubljana, Slovenia; l.k.strachan-1@sms.ed.ac.uk

Abstract

In recent years there has been increased interest in the simulation of honeybee breeding programmes, due to their biological and commercial importance. However, existing simulators do not provide all the functionality to replicate honeybee specificities. We developed an R package, SIMplyBee, which extends the popular AlphaSimR simulator with haplo-diploidy, polyandry, complementary sex determination, caste system, and colony quantitative genetics. We developed two classes representing operational units, Colony and Colonies, and a SimParamBee class holding global honeybee simulation parameters. Next, we assigned four levels of functions; Auxiliary, Population, Colony and Colonies to allow the simulation of both individual and colony events such as swarms or supersedures. To demonstrate the package, we simulated a yearly cycle of an isolated apiary and inspected variability at the *csd* locus. SIMplyBee represents the first flexible and holistic simulator of honeybee genomes, biology, reproduction, colony events, and quantitative values at individual and colony levels.

Introduction

The Western honeybee *(Apis mellifera)* is the most important managed pollinator contributing to food security through pollination and hive products. However, in recent decades both native and managed populations have experienced severe over-winter colony losses. These colony losses are due to numerous factors, such as habitat change, disease, pesticides and parasites (Moritz *et al.*, 2010). Due to the related economic damage, there has been an increased interest in honeybee breeding. Breeding programmes aim to improve production and behaviour, reduce labour and colony losses, and manage genetic diversity. However, certain aspects of the honeybee reproductive biology constrain creation of effective breeding programmes.

The honeybee belongs to the insect order Hymenoptera that is characterised by haplo-diploid inheritance with diploid females and haploid males (Goulet *et al.*, 1993). Drones develop from unfertilized eggs and inherit only a copy of the recombined mother's genome. The sole role of drones is to transmit the inherited genome through mating, effectively making them a flying generator of identical gametes (Winston, 1987). Another specificity of the honeybee is the complementary sex determination (*csd*) locus. Fertilised eggs that are heterozygotes for the *csd* locus develop into diploid females, while homozygotes develop into non-viable diploid drones. High rates of inbreeding hence lead to empty brood cells, also called spotty brood pattern (Hasselman *et al.*, 2008). Honeybees are one of the more extreme examples of random mating within the animal kingdom (Laidlaw Jr and Page Jr, 1984). The queen is polyandric and mates on average with about 17 drones during her mating flights. To control the mating, modern breeding programmes often utilise a close population mating structure, artificial insemination, or isolated mating stations.

The increased interest in honeybees has spurred research in quantitative genetics and the breeding of honeybees. The latter is intrinsically supported with stochastic computer simulations that are commonly used to evaluate quantitative genetic models, statistical methods, and breeding strategies (e.g. Bienefeld *et al.*, 2007). Due to biological and reproductive specificities of the honeybee, most of the existing simulators

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_624, © L. Strachan *et al.* 2022

cannot simulate honeybee populations and breeding programmes in entirety. The existing honeybee simulators handle either the colony quantitative genetic values (Du *et al.*, 2021a, 2021b; Plate *et al.*, 2019a) or the dynamics within the colony or hive (Becher *et al.*, 2014). The aim of this paper is to present the SIMplyBee R package, which is a honeybee extension of the popular AlphaSimR stochastic simulator of breeding programmes (Faux *et al.*, 2016). The package simulates the honeybee genomes, biology, reproduction, colony events, and quantitative values at individual and colony level.

Implementation

We extended AlphaSimR with functions addressing the biological peculiarities of honeybees: haplo-diploid system, polyandry, complementary sex determination, colony events, and quantitative values at individual and colony level. To this end we have developed three R classes; one holding global simulation parameters, SimParamBee, and two classes representing operational units: Colony and Colonies. We then assigned four levels of functions; Auxiliary, Population, Colony and Colonies, to allow the simulation of both individual and colony events, therefore permitting the user a greater amount of flexibility.

Classes. SimParamBee is a class holding global simulation parameters. It inherits information from the AlphaSimR SimParam class, such as the number of chromosomes, segregating sites, causal sites, simulated traits, variance components, etc. Additionally, it holds default colony size as values or functions, information on the *csd* locus, and mapping of individual queen, virgin queens, workers, or drone genetic or phenotypic values to colony phenotype values. Colony class represents a honeybee colony and contains 14 slots. The slots hold identification and location, castes (the queen, virgin queens, workers, and drones), information about past events of the colony (split, swarm, supersedure, collapse, and production), and phenotypic values of the colony. The queen slot in addition stores fathers, which are the drones the queen mated with. Colonies class combines multiple Colony objects into one to simplify simulating a whole breeding programme.

Functions. Level0 functions are Auxiliary functions that provides different parameters about populations like number of individuals, information about genome or *csd* related information. Level1 returns AlphaSimR Pop objects. These functions create individuals (virgin queens, workers, or drones), extract or pull individuals of a certain caste from the colony, cross a virgin queen with selected drones, create drone congregation area with the drones from selected colonies and pull drones groups from it, etc. Level2 returns Colony objects. These functions create a new colony, cross a colony, add, replace or remove individuals of a caste to the colony, requeen or build up a colony to full size, to simulate events in colony life (collapse, swarm, supersedure, split), to reset colony events, set location and phenotype, etc. Level3 returns Colonies objects. Functionalities of Level3 mirrors the Level2 but they work on Colonies instead of Colony.

Example. We simulated a founder population of 1000 individuals with 16 chromosomes, 1000 segregating sites per chromosomes, and 128 *csd* alleles. Next, we simulated 10 years of an isolated managed apiary with 20 or 40 colonies with 20,000 workers and 4,000 drones per colony. In the first year, we created mated-queen colonies from the founder population. Within each year, we simulated three periods resembling spring, summer, and winter. In period 1, we build up the colonies to their full size, split all the colonies with a queen of age 1 and requeened the splits, swarmed 5%, superseded 5% of the colonies with the queen of age one or two, mated the virgin colonies to available drones, and collapsed 10% of the colonies with a queen of age one or two. In period 2, we swarmed 1% and superseded 5% of the colonies, mated all the virgin colonies to available drones, and collapsed 10% of the colonies with a queen of age one or two. During period 3, we collapse 25% of colonies with a new queen (queens of that year), 30% of colonies with a queen of age 1, and all the colonies with a queen of age two. At the end of the season, we removed the splits (resembling a sell) to keep a constant number of colonies in the apiary. At the end of each year, we inspected the average number of *csd* alleles in the colony and the apiary.

Results

We created a stochastic simulator of honeybee populations and breeding programmes and ran an example session to simulate the yearly cycle of a managed apiary. We annually inspected the average number of distinct *csd* alleles per apiary and per colony (Figure 1). An isolated apiary with 20 colonies did not sample all the available 128 *csd* alleles from the start (average 119), and lost approximately half of the *csd* alleles in 10 years of isolated mating (average 57.8 in year 10). An isolated apiary with 40 colonies sampled nearly all *csd* alleles from the start (average 127) and lost a third of the alleles by year 10 (average 88.1). The dynamics within an individual colony was different. In year 1, each colony sampled on average 27.4 *csd* alleles in both scenarios. This number increased to 34.2 in year 5 with 20 colonies and 38.7 in year 6 with 40 colonies. This was followed by a step decline in the average number of 19.8 and 23.8 *csd* alleles per colony respectively with 20 and 40 colonies.

Discussion

We have developed a flexible and holistic simulator of honeybee populations and breeding programs that accounts for the biological specificities of honeybees. We provide the simulator as an R package named SIMplyBee. SIMplyBee builds upon the work of the popular AlphaSimR simulator (Gaynor *et al.*, 2021). We have used this framework to allow for the simulation of individual bees with individual genomes and quantitative values, but combining them into castes of objects of the Colony class. Here we demonstrated the functionality of SIMplyBee by modelling the yearly cycle of an isolated managed apiary. The whole script was only 306 lines long (including comments and loops) and ran 10 years in about 90.4 minutes with 20 and 163.7 minutes with 40 colonies per replicate. This shows that SIMplyBee can simulate whole breeding programmes with ease.

Future work will aim to improve the simulation of colony phenotypes, opposed to individual honeybee phenotypes. SIMplyBee already allows for the simulation of individual genetic and phenotypic values as well as their mapping to colony phenotypes. However, to map these onto the colony phenotype, the user must specify a custom function. We want to provide sensible defaults for such functions to account for the queen and worker effects and associated quantitative genetic parameters. We are also working on improving simulation of the founder genomes based on the honeybee demographic history. Currently, additive genetic relationships between colonies and caste members are not dealt with but needs to be modelled with additional external tools based on either the pedigree or genomic data obtained from the simulator. SIMplyBee is currently under active development and will be released as open source to the community.

625. Assessment of uncertainty in direct and maternal genetic parameters estimates for honeybee colony phenotypes

T. Kistler[1,2*], E.W. Brascamp[3], B. Basso[4,2], P. Bijma[2] and F. Phocas[1,2]

[1]Université Paris-Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; [2]UMT PrADE, France; [3]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [4]INRAE, UR 406 Abeille et Environnement, 84914 Avignon, France; tristan.kistler@inrae.fr

Abstract

Genetic parameters in honeybees are commonly estimated using REML methodologies applied to animal models with maternal effects. These methodologies were adapted to the species' peculiarities, including: phenotypes measured on colonies, haplo-diploïdy and polyandrous mating. However, estimations' reliability is hindered by the small size of the breeding nuclei commonly used. We assessed the uncertainty of variance component estimates in small simulated honeybee populations by evaluating the impact of the breeding nucleus size, the mating strategy and the direct-maternal genetic correlation. The convergence of estimations was strongly hindered when considering a small breeding nucleus with less controlled mating and negatively correlated genetic values. Furthermore, biases could be observed in this scenario. Individual estimates deviated strongly from the real values in about 40% of the populations. When considering real breeding populations, these results highlight the caution to be taken with estimates from small populations with complex pedigree structures.

Introduction

Most of economically important traits in honeybees are not recorded on an individual scale, but at the scale of the colony. A colony consists of a single diploid queen and thousands of sterile female workers that descended from the queen and from 10 to 20 haploid drones that have mated with the queen. The performance of a colony is affected by the joint genetic effects of all workers (called worker or direct effect) and of the queen (called queen or maternal effect). Polyandry and haplo-diploid sex determination are biological specificities that require an appropriate relation matrix for honeybee genetic evaluation. Efficient methodologies based on BLUP and REML applied to animal models are widely used to estimate breeding values in farm animals and have been adapted for honeybees (Bienefeld *et al.*, 2007; Brascamp and Bijma, 2014).

The phenotypic variance of colony performance can be partitioned into an environmental variance, an additive direct genetic variance, a maternal genetic variance and a potential covariance. A reliable estimation of these genetic variances as well as of the covariance between direct and maternal effects requires to get data and pedigree records in a large population constituted from genetically well-connected apiaries. Unfortunately, most of honeybee breeding programs are applied to small nucleus populations, usually ten to a few tens of breeding queens. This is different from livestock species for which seedstock includes hundreds or thousands of animals. Therefore, the main aim of our study was to assess the uncertainty in estimates of genetic parameters for polygenic traits measured in small simulated honeybee populations. In addition, we studied the impact of two mating designs on these estimates. In the first design, the drones fertilizing a virgin queen came from a single drone-producing queen (DPQ) that can be considered as a 'single diploid sire' (SS) of the workers. In the second design, the drones came from a group of sister DPQs, and this group of DPQs can be treated as a 'dummy diploid sire', referred to as a pseudo-sire (PS).

Materials & methods

Population structure and stochastic simulations. Performance and breeding values of honeybee populations were simulated at the scale of individual queens, drones and worker groups. In the base population, queens' breeding values were drawn from a normal distribution $N(0, \Sigma^2_{BV})$ with Σ^2_{BV} the genetic variance-covariance matrix with both direct and maternal variances equal to 10 and a covariance assumed either to be 0 or -5. The base drones' breeding values were drawn from $N(0, \frac{1}{2}\Sigma^2_{BV})$. The only identified fixed effect was a year effect drawn from $N(0, 20)$ and residual effects on the performances were drawn from $N(0, 30)$.

Ten generations of within-line (one new breeding queen per maternal sister group) phenotypic selection were run, starting from non-inbred and unrelated breeding queens (either 12 or 24 BQs for a small and larger nucleus size scenario) and unrelated drones in the base population. Two-third of the same pool of maternal lines were selected each year to form DPQ families. Eight DPQs were then randomly chosen per selected family.

Two mating strategies were used: either sister DPQs formed a PS, jointly producing the drones mating a single potential dam queen with a random participation of each sister to the drone pool, or only one SS was randomly chosen to produce all the drones mating a single potential dam queen (controlled mating). All DPQs were mated to drones coming from a wild population (open-mating) with the same expected breeding values than those of the base population. Each queen (BQ or DPQ) was mated to 8 drones. Each year, wintering mortality was modelled by randomly eliminating 25% of all queens. Phenotypes were obtained after wintering, within the first year of birth and before reproduction of the dams. Both potential BQs and DPQs had phenotypes. Generation interval was 1.5 years (1 year on the maternal path and 2 years on the paternal path). Each BQ produced 24 potential BQs and 20 potential DPQs. Further details including genetic inheritance modelling can be found in Kistler *et al.* (2021). Each simulation scenario was repeated 100 times to assess the sampling standard deviations and the uncertainty of the estimates of genetic parameters.

Genetic evaluation model and estimation of genetic parameters. The vector of phenotypes y was described using a linear animal model accounting for maternal genetic effects: $y = Xb + Z_d a_d + Z_m a_m + e$, where b is the vector of fixed year effects with a corresponding incidence matrix X, a_d the vector of direct effects with incidence matrix Z_d, a_m the vector of maternal effects with incidence matrix Z_m, and e the vector of residual effects. Pedigree and performances of all simulated colonies were used for a single REML evaluation after 10 years of queen phenotypic selection. The total number of colony records was either 4,176 or 8,352, with 132 or 264 dam families for small or larger breeding nuclei, respectively.

BLUPf90 (Misztal *et al.*, 2002) with its AIREMLF90 program was used to estimate genetic parameters based on the inverse of a relationship matrix, following Brascamp and Bijma (2014, 2019). In this, it accounts for the DPQs being either a pseudo-sire, a single sire or a wild set of bees (open mating).

Results

Table 1 presents the 8 study scenarios. Around 90% of all estimations converged. However, PS mating hindered convergence, as well as a small nucleus size and a negative direct-maternal correlation (r_{dm}) to a lesser extent. Thus, only 2/3 of the 100 simulations lead to converged estimates of variance components in scenario PS12$^-$.

Among converged cases, scenario PS12$^-$ had a significantly biased σ^2_d estimate (P-value<5% using a t-test). Other scenarios showed tendencies to over- (or under-) estimate one or several (co)variances but without clear statistical significance.

Even among scenarios with mean estimations centred on the true values, individual estimates varied strongly around the real (simulated) values, with the nucleus size having the greatest impact (Table 1). Smaller nucleus scenarios had (co)-variances estimates deviating strongly in 10 to 20% more repetitions than bigger nucleus scenarios.

Strongly deviating estimates occurred more often for the direct variance (in 45% of all repetitions) than for the maternal (37%) or for their covariance (32%). To a lesser extent, PS mating compared to SS mating also increased the number of strongly deviating estimates, mostly for the maternal variance and the direct-maternal covariance.

For the large nucleus size scenarios with PS mating, Figure 1 shows the relation between direct and maternal variance deviations, coloured by the deviation of the direct-maternal covariance (strong negative deviations in lavender and strong positive ones in red). In both scenarios, a clear structure appears: when

[1] Proportion of estimated variances deviating by more than 20% of the true values.

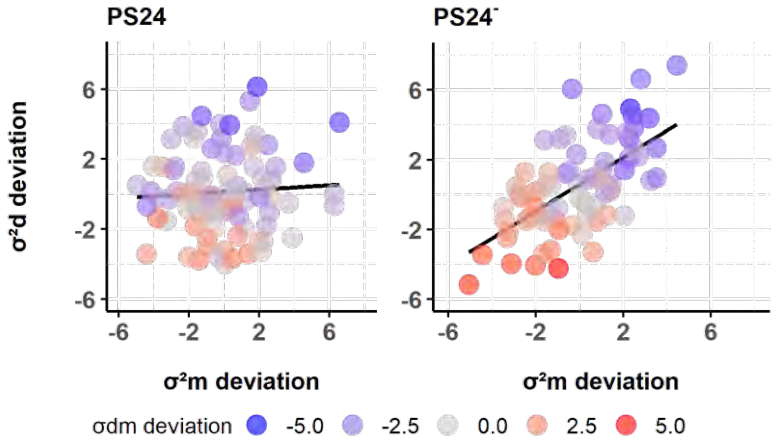

Figure 1. Estimated genetic parameters' deviations from true (simulated) values for two scenarios with a null (PS24) or negative (PS24$^-$) direct-maternal genetic correlation.

both direct and maternal variances were underestimated, the covariance was overestimated, and *vice-versa* for overestimated variances. In addition, in particular for the negative correlation scenario, when the direct variance was under- (over-) estimated, the maternal variance tended to be under- (over-) estimated as well.

Discussion

Very unreliable estimates of variance components were observed for scenarios combining a small size of the breeding nucleus, PS mating and a negative direct-maternal genetic correlation. In PS mating, true relationships between DPQs and descendants are unknown and have to be probabilistically accounted for, making estimates less precise. Additionally, direct and maternal effects are more difficult to disentangle when they are correlated, which can be seen in Figure 1. A last explanation that may explain some bias in the estimates of variance components lies in the different hypotheses considered for the contributions of various DPQs and drones to any queen's offspring in the simulation of the population and in the derivation of the relationship matrix. In our simulations, these contributions were balanced while they were drawn from a Poisson distribution in Brascamp and Bijma (2014)' relationship matrix.

Beyond the biased estimates in one scenario, the number of estimates deviating strongly from their true values was always very high. Using real datasets with very small populations sizes, Guichard *et al.* (2020) and Basso *et al.* (2022) could not estimate jointly direct and maternal effects for various honeybee traits. While 24 breeding queens in a nucleus population is currently considered as a decent size in honeybee breeding, it remains a small population for genetic parameters' estimation purposes, even with 10 years of records. Furthermore, we simulated a simplistic situation in which the whole population was composed of a unique apiary only submitted to a year effect. In real life, Clément *et al.* (2001) showed that low genetic connectedness between herds (apiaries) would induce severe biases in the estimated genetic parameters. A strategy to avoid these issues in genetic evaluation for small honeybee populations could be to use estimates of genetic parameters based on large datasets, such as in Hoppe *et al.* (2020), and to assume that they are very similar in the small population of interest.

626. Very local genotype by environment interaction in Austrian honey bees

E.W. Brascamp[1*], M. Rubinigg[2,3], R.F. Veerkamp[1] and P. Bijma[1]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Biene Österreich, Georg-Coch Platz 3/11a, 1010 Vienna, Austria; [3]CARE, Appalachian State University, ASU, Box 32049, Boone, NC 28608, USA; pim.brascamp@wur.nl

Abstract

We investigated genotype by environment interactions (G×E) in the breeding programme of the Austrian Carnica population administered by Biene Österreich by the estimation of genetic correlations (r_G) at three levels: between geographical regions, between colonies that were bred at home or elsewhere, and between individual test locations. Traits included were honey yield, gentleness, calmness and swarming behaviour. Results suggest that honey bees are very prone to G×E, not only between regions and bred at home v. elsewhere, but also at the level of individual test locations. Despite this abundance of G×E we conclude that breeding programmes covering larger areas are justified, and will result in selection for general adaptability.

Introduction

Between 2009 and 2012 a Europe-wide experiment was carried out to study genotype by environment interaction (G×E) in honey bees (Costa *et al.*, 2012). It was triggered by the phenomenon of colony losses (Neumann and Carreck, 2010), partly associated with Varroa infestation, and the experiment intended to clarify whether G×E played a role in vitality and performance of colonies. To evaluate G×E, queens that were fertilized at their location of origin were distributed across locations in Europa and introduced in host nuclei. An overview of the published results was given by Meixner *et al.* (2014). G×E was found for vitality, performance and behavioural traits, and for vitality colonies performed best at their local environment. This lead to the notion of local adaptation, a long-term adaptation to the local environment by selection. Presently the notion of local adaptation is dominant in thinking about honey-bee genetic improvement and conservation of local breeds.

Despite the evidence of G×E there are breeding programmes that cover larger geographical areas, like the whole of Germany and Austria and a few other countries in the case of Beebreed (Hoppe *et al.*, 2020), Austria in the case of Biene Österreich (Brascamp *et al.*, 2016) and Switzerland (Guichard *et al.*, 2020).

Here we investigate G×E in the breeding programme of the Austrian Carnica population administered by Biene Österreich by the estimation of genetic correlations (r_G) at three levels: between geographical regions, between colonies that were bred at home or elsewhere, and between individual test locations. We briefly discuss the consequences of our findings for breeding-programme design.

Materials & methods

The data contained 16,924 records on honey yield, gentleness, calmness and swarming behaviour, collected in the breeding programme of Biene Österreich from performance testing year 1998 to 2020. Honey yield was weighed, and the other traits were scored on a scale of 1-4. Full pedigrees were available. For details, see Brascamp *et al.* (2016) with data until 2014.

Austria recognizes eight 'landwirtschaftliche Hauptproduktionsgebiete' (main agricultural production areas, MPA). The MPA in which colonies were tested, were known for all records. MPA8 differs from

MPA1-7 in an agro-ecological sense, and shows a far higher honey yield. For this reason, we considered two geographical regions, MPA1-7 v. MPA8.

We also distinguished between colonies bred at home v. bred elsewhere. For all records, both the breeder of the queen heading a colony and the tester of the colony were known. When the breeder differed from the tester, the colony was said to be bred elsewhere. In case of colonies tested elsewhere, the identities of queens were blinded to ensure objective measurements, but testers could distinguish own colonies from colonies bred elsewhere. Table 1 summarizes the data.

Methods. We studied G×E by estimating the genetic correlation (r_G) between the traits expressed in one environment v. the other. In honey bees, the consensus statistical model includes two random genetic effects, a worker effect and a queen effect (Bienefeld and Pirchner, 1990). However, after splitting the data into groups for different environments, this model did not converge. We, therefore, included only a worker effect. The numerator relationships matrix was based upon a pedigree file including groups of workers, dams, and groups of drone-producing queens (sires), following Brascamp and Bijma (2014). All models included a fixed effect for year×tester×apiary (called *test location*), and also for bred at home v. elsewhere except when analysis was limited to bred at home. Data were analysed using ASReml (Gogel *et al.* 2015).

To evaluate G×E due to the MPA, we estimated r_G between MPA1-7 and MPA8, either using all records or only the records of colonies bred at home (9,038 for MPA1-7 and 2,703 for MPA8). To evaluate G×E due to bred at home v. elsewhere, we estimated r_G between the trait expressed in colonies tested in MPA1-7, bred at home (9,038) v. elsewhere (4,724).

To evaluate G×E at the level of individual test locations, we defined two hypothetical traits ('between test locations' scenario). We randomly selected half of all test locations present in our data, and allocated all records of these test locations to the first trait. All records of the remaining test locations were allocated to the second trait. When a tester had different test locations within a year, care was taken that these were evenly distributed over the two traits. Consequently, the genetic correlation between the two hypothetical traits originates solely from covariances between test locations, whereas information for genetic variances originates also from covariances between records belonging to the same test location. Hence, an $r_G<1$ indicates G×E between test locations.

To validate our analysis, we tested whether G×E fully disappeared (i.e. $r_G\approx1$) when there was no systematic difference between the environments for the two hypothetical traits. For this purpose, we randomly selected half of all records from each test location, and allocated these records to the first trait. The remaining records

Table 1. Numbers of colonies (N), means and standard deviations (between brackets) for colonies tested and bred in different regions (MPA1-7 v. 8).

Tested	Bred	Home/elsewhere	n	Honey	Gentleness	Calmness	Swarming
1-7	1-7	Home	9,038	39.1 (24.9)	3.67 (0.49)	3.65 (0.48)	3.66 (0.72)
1-7	1-7	elsewhere	4,724	34.5 (21.7)	3.54 (0.61)	3.54 (0.59)	3.53 (0.89)
1-7	8	elsewhere	174	39.2 (28.3)	3.62 (0.52)	3.61 (0.52)	3.46 (0.93)
8	8	Home	2,703	85.0 (38.3)	3.64 (0.46)	3.61 (0.46)	3.52 (0.85)
8	8	elsewhere	102	75.1 (28.5)	3.66 (0.50)	3.65 (0.54)	3.35 (0.85)
8	1-7	elsewhere	183	36.4 (20.0)	3.59 (0.49)	3.61 (0.50)	3.39 (0.93)

of each test location were then allocated to the second trait. Hence, each test location was split into two, including an equal division of full sib colonies within a test location ('within test locations' scenario). In this analysis, both the information for the genetic correlation and the information for the genetic variances originate from between and within test-location covariances. Hence, this analysis should yield $r_G \approx 1$, which served as a check for spurious G×E.

Results

Table 2 shows results for r_G. Even though the dataset is of considerable size, standard errors on estimated r_G were large. The estimated r_G for honey yield between MPA1-7 and MPA8 was low to moderate, but not significantly different from one. The large standard errors on these estimates indicate a lack of statistical power, and our results should not be interpreted as evidence of absence of G×E. The estimated r_G for honey yield between colonies bred at home and bred elsewhere was small (0.36±0.14), and significantly different from one, indicating clear G×E. When entire test locations were randomly divided over two hypothetical traits, then the estimated r_G between these two traits was significantly different from 1 for all four traits. Thus there was clear G×E at the level of individual test locations. In contrast, when records within test locations were randomly divided over to the two traits, all estimates of r_G were virtually unity, as expected. Hence, we did not find indications of spurious G×E in our analysis.

Discussion

Because G×E might be caused by the skewed distribution of the four traits, we looked at Box-Cox transformed data (Box and Cox, 1964) in the analysis in the full dataset of MPA1-7 v. MPA8. The transformed variables equalled $(y^{\lambda}-1)/\lambda$ where y is the observed value. For honey yield λ was 0.3 and for the other three traits it equalled 2. Results were similar to those in Table 2 and for that reason we didn't transform the data for final analyses.

The standard errors for the estimates of r_G were much lower in case test locations were divided randomly over two traits as compared to the dataset with the actual trait groups (Table 2). This was probably caused by the tighter genetic relationships between colonies assigned to both traits as compared to the actual groups.

Results suggested that honey bees are very prone to G×E. Even when dividing test locations arbitrary over two traits, there was considerable G×E between these traits. This result contrasts with results generally found in farm animals, where r_G is often high.

Genetic correlations between different regions found here were in line with Hoppe (2021, personal communication) who observed a broad range of genetic correlations between regions in the dataset of Beebreed (*re* Hoppe, 2020, for description of the data) using statistical models similar to ours. In our

Table 2. Genetic correlations with SE (between brackets) between regions, between bred home vs elsewhere tested in MPA1-7, between test locations, and within test locations.

Data used	Honey	Gentleness	Calmness	Swarming
MPA1-7 v. MPA8	0.55 (0.32)	-0.31 (0.64)	0.64 (0.28)	-0.51 (0.58)[1]
MPA1-7 v. MPA8, home bred	0.28 (0.61)	0.88 (0.39)[1]	0.84 (0.56)[1]	-0.95 (0.69)
Home v. elsewhere in MPA1-7	0.36 (0.14)	0.68 (0.17)	0.89 (0.28)	0.92 (0.70)[1]
Between test locations	0.63 (0.07)	0.85 (0.07)	0.75 (0.08)	0.41 (0.16)
Within test locations	0.99 (0.01)	0.99 (0.02)	0.99 (0.02)	0.96 (0.06)

[1] This analysis did not result in stable estimates for the additive genetic (co)variance components.

analysis this G×E wasn't statistically significant in terms of r_G, but given the significant G×E when dividing test locations arbitrary over two traits, the null-hypothesis of r_G=1 is not realistic, and therefore we consider the G×E between regions as real. This type of G×E may arise because different sets of alleles or allele frequencies may be optimal for different regions and may be expected to remain so over longer periods. On the other hand, for the contrast bred at home *v.* elsewhere one might think of short term effects, perhaps of an epigenetic nature. Yagound *et al.* (2020) demonstrated in honey bees that methylation patterns in paternal germ cells, through drones, were present in worker offspring. In our case it would involve the maternal pathway, as workers in colonies bred at home and elsewhere often share the same sire. The queens heading the colonies of course differed. If G×E for tested at home *v.* elsewhere is a short-term effect indeed, it may diminish over generations. This might have implications for experiments in which different genetic stocks are being tested at home and elsewhere, as in the Europe-wide experiment. Based on our findings, one should consider to evaluate stocks for successive generations, such that in later generations all are tested at home.

For farm-animal scenarios Mulder and Bijma (2006) addressed the question which level of r_G would justify to set up different breeding programmes for different countries or regions, or at least to work with different sets of estimated breeding values. Considering the high degree of G×E in honey bees it seems tempting to set up local or region-specific breeding programmes, suggesting splitting a breeding programme into very many small ones. However, the resulting small scale for each programme would obviously hamper genetic progress and increase rates of inbreeding. Furthermore the estimates of heritability of Brascamp *et al.* (2018), who used largely overlapping Biene-Österreich data and ignored G×E, suggest that genetic improvement across environments is realistic for the population as a whole. Hoppe *et al.* (2020) demonstrated considerable genetic improvement in Beebreed as well, where breeding value estimation ignores G×E.

We conclude that G×E is abudant in Austrian honey bees, but that this provides no basis to split breeding programmes into smaller ones, and that the solution lies in selection for general adaptability.

Bovine beef

627. Genetic prediction for growth traits in beef cattle using selected variants from imputed low-pass sequence data

C.A. Russell[1*], L.A. Kuehn[2], W.M. Snelling[2] and M.L. Spangler[1]

[1]Department of Animal Science, University of Nebraska, Lincoln, NE 68583, USA; [2]USDA, ARS, Roman L. Hruska U.S. Meat Animal Research Center, Clay Center, NE 68933, USA; crussell17@huskers.unl.edu

Abstract

A beef cattle population (n=2,343) was used to assess the impact of variants identified from imputed low-pass sequence on the genetic prediction of birth weight (BWT) and post weaning gain (PWG). Variants (n=1,145,892) were selected based on functional impact and were partitioned into low, modifier, moderate, and high based on predicted functional consequences. Each subset was used to construct a genomic relationship matrix (GRM) in univariate animal models. When all variants were included in a single GRM, heritability estimates for BWT and PWG were 0.41±0.05 and 0.37±0.05, respectively. Heritability estimates for BWT when the GRM was comprised of only low, modifier, moderate, or high variants were 0.36±0.05, 0.39±0.05, 0.33±0.05, and 0.10±0.03, respectively. Similar estimates for PWG were 0.33±0.05, 0.34±0.05, 0.32±0.05, and 0.10±0.03, respectively. Results suggest that despite predicted functional consequences, the high variants accounted for only ~24-27% of the genetic variance. The USDA is an equal opportunity employer and provider.

Introduction

Although advances have been made in recent years relative to the incorporation of genomic data into routine genetic evaluations of beef cattle and corresponding increases in predictive accuracy, hope remains that the inclusion of causal variants into prediction models will lead to further gains in accuracy. Such efforts require the use of whole-genome sequencing (WGS), and despite decreases in cost, wide-spread deep sequencing of seedstock cattle is cost prohibitive. The use of low-pass sequencing at much shallower depths (e.g. 0.5×) is a much more attractive alternative, when coupled with imputation, to garner genotypes of potentially causal variants on large numbers of individuals. Such an approach also represents a means of making marker subsets actually used in genetic evaluations more flexible and dynamic.

Large effect variants for complex traits such as birth weight in beef cattle are known to exist and are predictive in populations external to where they were identified (Snelling *et al.*, 2017). However, the general benefits of including putative causal variants in genetic predictions or the use of WGS for prediction more generally has had mixed results in the literature (e.g. Heidaritabar *et al.*, 2016; Veerkamp *et al.*, 2016; Warburton *et al.*, 2020). Several challenges exist relative to the use of WGS for genetic prediction, including the inability to accurately estimate the effect of all WGS SNP using currently available phenotypic datasets to allow for accurate pre-selection of variants. Additionally, currently available high-density panels may sufficiently capture enough genetic variation through LD with causal variants to limit gains from using WGS (e.g. Frischknecht *et al.*, 2018). However, evidence in the literature supports the concept of pre-selected WGS variants to improve prediction accuracy in multi-breed populations (e.g. Raymond *et al.*, 2018). Consequently, the objective of the current study was to investigate the benefit of fitting variants based on predicted functional impact in prediction models for birth weight (BWT) and post weaning gain (PWG) in a multi-breed beef cattle population using a genomic best linear unbiased prediction framework.

Materials & methods

Data. A composite beef cattle population (n=2,343) with sequence variant genotypes imputed from low-pass (~0.5×) WGS and recorded BWT and PWG was used. Animals were part of the U.S. Meat Animal

Research Center (USMARC) Germplasm Evaluation (GPE) project. The low-coverage sequence was submitted to the Gencove pipeline for imputation with loimpute (Loimpute-Public, 2020) to a haplotype reference panel constructed from WGS of 946 cattle (598 available from NCBI Sequence Read Archive; 348 GPE sires) (Snelling *et al.*, 2020). Functional impact of the imputed variants was assessed with snpEff using the Ensembl annotation of the ARS-UCD1.2 assembly of the bovine genome (Aken *et al.*, 2016; Cingolani *et al.*, 2012; Rosen *et al.*, 2020). Genotypes for interesting variants were extracted from the imputed calls of each individual with low-pass sequence. Interesting variants included variants in exons of protein-coding genes, which may affect gene function, and variants in untranslated regions (UTR) and non-coding RNA, which may impact gene regulation. Low-pass calls were required to have a genotype probability greater than 0.95, then a 0.95 call rate filter by animal and variant was applied to the set of interesting variants. In total, a set of 1,145,892 interesting variants was identified for further analysis. Interesting variants were then partitioned into four distinct classes based on level of likely impact: Low (440,684 variants across 21,700 genes), Modifier (372,024 variants across 18,174 genes), Moderate (318,063 variants across 20,908 genes) and High (15,121 variants across 9,326 genes).

Statistical analysis. All analyses were conducted using the ASREML 4.1 software package (Gilmour *et al.*, 2015). Five GRMs were constructed, one including all variants and one for each of the four classes. Genetic parameters were obtained from univariate animal models in a GBLUP framework by fitting fixed effects of sex, contemporary group (concatenation of year, season of birth, and age of dam) and linear covariates of heterosis and breed fractions. Random effects included the additive genetic effect associated with each GRM and a residual. Models analyzed included fitting a single random effect associated with the GRM comprised of either Low, Modifier, Moderate, or High impact variants, models that included multiple random effects each associated with a different GRM (e.g. Low and Modifier, Moderate and High, all four subsets), and a model that included all variants in a single GRM (Full).

Results

Estimates of variance components and heritability for BWT and PWG are reported in Tables 1 and 2, respectively. Differences in heritability estimates were negligible with the exception of models that omitted Low and Modifier variants. Estimates from models that included a GRM based on Moderate or High impact variants, as well as the model that fitted both of these GRM, resulted in lower heritability estimates.

Discussion

Estimates of heritability from models fitting the Full GRM were 0.41±0.05 and 0.37±0.05 for BWT and PWG, respectively, both in the range of estimates previously reported for these traits in beef cattle (Koots *et al.*, 1994). As expected, the models with four additive genetic effects corresponding to the four GRM based on predicted functional impact provided a very similar estimate of heritability. Interestingly, only fitting the GRM comprised of low variants resulted in a negligible decrease in the additive variance compared to the Full GRM. Perhaps more interesting are results from fitting only the GRM comprised of high impact variants. These loss-of-function variants are predicted to substantially alter protein-coding genes and yet only accounted for ~24% of the additive genetic variation in BWT and ~27% in PWG in this population. Approximately 38% of annotated genes are affected by high impact variants, and the low amount of phenotypic variation explained by high impact variants could indicate that genes with similar function may compensate for genes affected by high impact alleles (El-Brolosy and Stainier, 2017). Similarly, Veerkamp *et al.* (2016) reported a marginal gain in the proportion of genetic variation explained when fitting a GRM based on full sequence data as compared to a GRM based on a common SNP array for traits in Holstein cattle despite identifying 42 variants that explained ~23% of the genetic variance when they were fitted alone. More recently, Warburton *et al.* (2020) reported results from a beef cattle population comparing the use of a single GRM with pre-selected WGS variants added to panel SNP and a multiple GRM model whereby panel SNP comprised one GRM and WGS variants comprised a second GRM. The multiple GRM model produced greater accuracy than the single GRM model in their study.

If reduced subsets of variants were to be selected for model inclusion, selecting from the High subset would be reasonable. However, additional information (i.e. pedigree or more global SNP representation) would be needed to fully capture additive genetic variation. The use of low-pass sequencing may allow for more robust molecular breeding values without increasing genotyping cost (Snelling *et al.*, 2020), and future research including different classifications for partitioning variants into GRM and expanding the current research across different traits complexes is needed.

628. *Bos indicus* genome percentage effects gene expression profile and differentially expressed genes in Brahman cattle whole blood

E.M. Ross[1*], L.T. Nguyen[1], B.N. Engle[1], A.J. Chamberlain[2], E. Kho[1] and B.J. Hayes[1]

[1]Centre for Animal Science, Queensland Alliance for Agriculture and Food Innovation, The University of Queensland, St. Lucia, QLD 4067, Australia; [2]Centre for AgriBiosciences, Agriculture Victoria, Bundoora, VIC 3083, Australia; e.ross@uq.edu.au

Abstract

RNA sequencing was used to quantify the gene expression in whole blood from 372 Brahman cattle. The percentage of the genome that was of *Bos indicus* origin (BI%) was calculated from genotype array data. BI% was associated with differential gene expression of 1,337 genes and could be significantly predicted from the gene expression matrix (prediction accuracy = 0.443). The effect of including BI% as a covariate in a differential gene expression model was then tested. Differentially expressed genes associated with weeks pregnant were identified with and without BI% in the model. 12% more genes were identified as differentially expressed when BI% was included in the model. This suggests that BI% should be included as a covariate in gene expression analysis of Brahman cattle, even when those traits are not phenotypically associated with BI%.

Introduction

RNA sequencing (RNAseq) is a sequencing method that is commonly used to perform differential gene analysis, where genes associated with phenotypic traits are identified. As sequencing costs decrease, the number of biological replicates that are used in differential gene expression studies is increasing. With this increase in biological replication more subtle phenotypic traits can be explored. The importance of appropriate co-variates for the correct identification of these traits is poorly understood.

B. indicus cattle are the result of a separate domestication event to *B. taurus* cattle. Modern Brahman cattle are a breed which was developed through the integration of both *B. indicus* and *B. taurus* breeds. This has resulted in modern Brahman cattle having a variable percentage of *B. indicus* content in their genomes, estimated on average around 9% (Koufariotis *et al.* 2018).

Here we tested the hypothesis that inclusion of *B. indicus* genome content in differential gene expression analysis of weeks pregnant would change the differentially expressed genes identified.

Materials & methods

Animals and phenotypes. Animal use in this study was approved under animal ethics number QAAFI/270/17. Animals were manually palpated by a trained veterinarian. Weeks pregnant were estimated by the veterinarian, with 0 being non-pregnant.

***Bos indicus* genome proportion.** A measure of *B. indicus* content expressed as a percentage (BI%) was calculated as an approximation of the proportion of each animals' genome that was of *B. indicus* origin, as opposed to *B. taurus* origin. BI% was calculated using the 35K SNP array by comparing each animal to a large purebred *B. indicus* dataset (Hayes *et al.*, 2019). Using a GBLUP model, phenotypes were assigned as 1 for *B. indicus* and 0 if not and the effect of each SNP was back-solved (Yang *et al.*, 2011). Prediction equations for *B. indicus* purebred then directly estimated BI% (Hayes *et al.*, 2019).

RNA sequencing. Transcript levels were quantified in whole blood from 372 Brahman (*B. indicus*) cows and heifers collected in remote Queensland (Australia) using Qiagen RNAprotect Animal Blood Tubes and sequenced on an Illumina NovaSeq on a 2×100 bp run. RNA-seq reads were trimmed using QUADtrim v2.0.2 (Robinson and Ross 2019). Trimmed adapters, strings of Gs (an artifact of 2 dye Illumina chemistry) and bases with Q-score <20 from the start and end of reads and then filtered out reads with >5 poor quality bases (Q-score <20) and/or length <50bp. Only read pairs where both reads passed the trimming were used in the analysis.

To avoid mapping bias, the ARS-UCD1.2 (Rosen *et al.* 2020) *B. taurus* genome assembly merged with the Btau5 Y chromosome was masked at all known variant sites with an allele not present at that position. Sequencing reads were aligned to the genome with STAR v2.5.3 (Dobin *et al.* 2013) using the two-pass method. The abundance of each annotated gene was quantified using Subread v1.5.1 featureCounts (Liao *et al.* 2014) with the Ensembl_annotation v97 ARS-UCD1.2 and Btau5.0.1 Y GTF files which were merged to ensure gene identifiers on the Y chromosome were annotated correctly. Subsequent analysis was performed in R v4.1.0.

Statistics. To perform differential gene expression analysis edgeR (Robinson *et al.* 2010) was used with the glmQLFit method. Benjamini-Hochberg correction was used to control for multiple testing. Two separate models were fit to the gene expression matrix, one with BI% (model A), and one without BI% (model B). Both models also included RNA sequencing batch number (binary), blood sampling date (binary), lactation status (binary wet vs dry), whether the animal was a cow or heifer (binary), and weeks pregnant (integer).

The pseudo gene counts per million from edgeR (which includes correction for library size) were log transformed and divided by the mean log counts per million for each gene. A relationship matrix was then calculated using the *A.mat* function of the rrBLUP package (Endelman 2011). The resulting expression relationship matrix was used in BLUP model. 5-fold random cross validation was used to calculate the accuracy of the prediction.

Results

Gene expression of 372 Brahman cows and heifers was measured using RNA-seq of whole blood. Structure was visible in the relationship matrix that was generated from the expression profiles (Figure 1A), suggesting that certain animals had more similar expression profiles than others. The prediction ability of these similarities was then tested on two traits, BI% (Figure 1B) and weeks pregnant (Figure 1C). Weeks pregnant was not significantly associated with BI% ($P>0.05$). The accuracy of *B. indicus* content predicted from the expression profiles was r=0.443 ($P<0.001$); while prediction of weeks pregnant was not significant ($P>0.05$).

A differentially expressed gene analysis of 12,912 genes was then performed. BI% was associated with 1,337 total differentially expressed genes, the top three most significant genes that were annotated were D-dopachrome tautomerase (DDT), torsin family 1 member B (TOR1B), and agouti signalling protein (ASIP). Weeks pregnant was associated with 190 (model A) and 170 (model B) differentially expressed genes when BI% was included and excluded as a co-variate respectively. The two models from weeks pregnant had 163 genes in common. While the ranking according to most significant *P*-value was similar for the most significant genes in both models, genes with less significant *P*-values shows substantial re-ranking (Figure 1D). The three most significant genes for weeks pregnant were osteoglycin (OGN), mitogen-activated protein kinase 8 interacting protein 1 (MAPK8IP1), and solute carrier family 45 member 3 (SLC45A3).

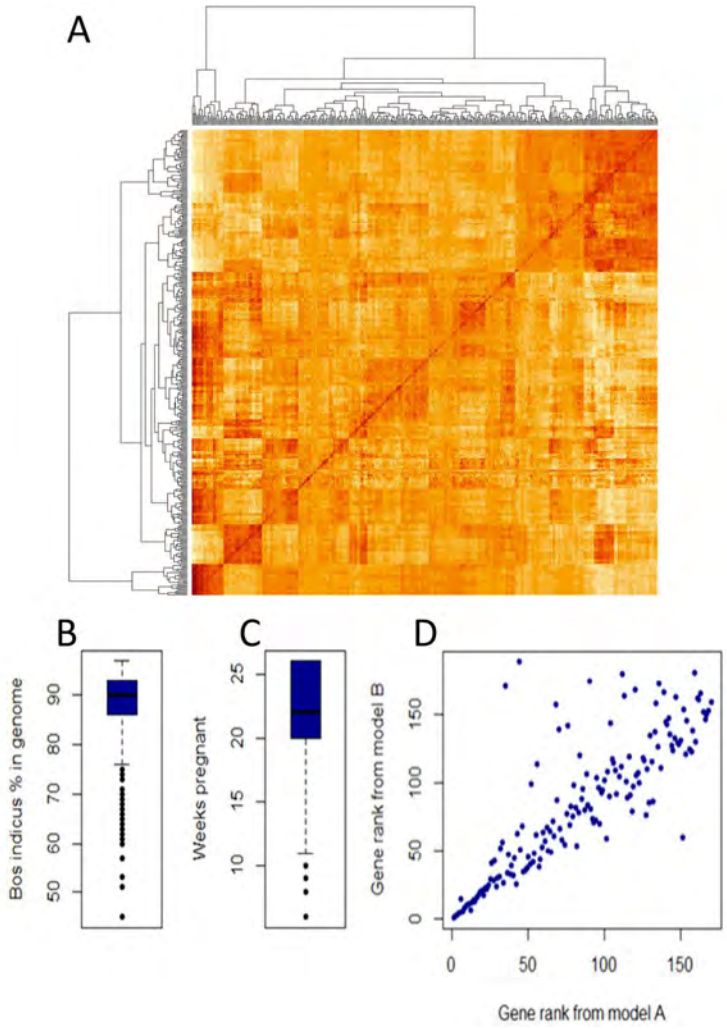

Figure 1. (A) Expression relationship matrix based on whole blood gene expression profiles of 372 Brahman females. (B) Distribution of *B. indicus* genome percentage in the animals used in the RNA-seq study. (C) Distribution of weeks pregnant in the pregnant females used in the RNA-seq study. (D) Order of significance (most significant = 1, least significant = 163) of the differentially expressed genes from both 'weeks pregnant' models: model A includes BI% as a covariate; model B does not include BI% as a covariate.

Discussion

Brahman cattle are considered to be genomically indicine cattle, however the distribution of the amount of *B. indicus* content in the genomes of the animals that were used for this study, which were all registered Brahman from Queensland Australia, was highly variable.

Here we found that BI% had a large effect on blood gene expression, to the extent that BI% could be predicted from the gene expression profile. Given the large effect of BI% on gene expression we tested its effect on our ability to identify genes that were associated with weeks pregnant. Inclusion of BI% in the model resulted in a 12% increase in the number of differentially expressed genes for weeks pregnant, which

while not dramatic, does suggest that inclusion of BI% in gene expression models, even for traits which are not phenotypically correlated with BI%, is beneficial.

Additionally, this is the first report of a BLUP based prediction being used with a gene expression relationship matrix. BLUP models have been extensively used for genomic predictions (Meuwissen *et al.* 2001), and have also been used for metagenomic predictions (Ross *et al.* 2013) and epigenetic predictions (Hayes *et al.* 2021). This finding emphasizes the flexibility of relationship matrix based predictions and could be useful in the identification of biomarkers for traits that involve gene expression variation in many genes.

Abstract

Several mutations in the myostatin gene have been identified that explain the increased muscling in cattle, one of which is an 11-base pair deletion in the gene, known as nt821 mutation. As several studies have indicated a significant effect of this mutation on traits related to carcass and meat quality, this study aimed to evaluate the effect of one copy of nt821 mutation on ultrasound carcass traits in Senepol cattle. Records from 2,044 purebred Senepol cattle from commercial performance tests in Brazil were used. Phenotypes and expected progeny difference (EPD) for ribeye area, backfat thickness, and intramuscular fat percentage were analyzed. The effect of one copy of nt821 mutation was significant ($P<0.05$) for all traits, both for phenotypes and EPD. Heterozygous animals presented a larger area for *Longissimus dorsi*, while their carcasses were leaner with less subcutaneous and intramuscular fat compared to the ones with no copy of the mutation.

Introduction

The myostatin gene was identified in cattle as responsible for double musculature or muscle hypertrophy in 1997 (McPherron and Lee, 1997). Several distinct mutations have been identified that explain the increased muscling in cattle, one of which is an 11-base pair deletion in the third exon of the gene that results in the production of a truncated inactive protein (Casas *et al.*, 2004). This mutation, known as nt821, has been associated with muscle hypertrophy in several breeds (eg. Dunner *et al.*, 1997; Globet *et al.*, 1998).

Since 2018, genetic tests for the nt821 mutation have been carried out in the Senepol breed in Brazil, allowing the identification of heterozygous animals carrying a copy of the mutant variant. There are several studies in the literature for different beef cattle breeds that indicate a significant effect of the nt821 mutation on traits related to carcass and meat quality (e.g. Casas *et al.*, 2004; Allais *et al.*, 2010). Therefore, as the Senepol breed is a bovine genetic resource used for the efficient production of high-quality meat under tropical conditions, it is important to understand how the nt821 mutation affects traits linked to carcass and meat quality to support better selection decisions by breeders. Thus, this study aimed to evaluate the effect of one copy of nt821 mutation in the myostatin gene on ultrasound carcass traits in Senepol cattle.

Materials & methods

Records from 2,044 purebred Senepol individuals (*Bos taurus taurus*) were used. The data were obtained from a compilation of commercial performance tests coordinated by Embrapa Geneplus Program in Brazil, between 2011 and 2020. The animals finished the tests with an average weight of 437±63 kg and age of 574±65 days. The animals had *ad libitum* access to diet and water.

The studied traits were recorded at the end of the tests on live animals by trained technicians. The carcass traits collected by ultrasonography in the region between the 12th and 13th ribs in the *Longissimus dorsi* muscle were: ribeye area (REA – cm^2), backfat thickness (BF – mm) and percentage of intramuscular fat

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_629, © G.R.O. Menezes *et al.* 2022

(IMF – %). All animals had valid phenotypes for three traits. In addition to phenotypic data, expected progeny difference (EPD) for all individuals and traits were used. The EPDs for ribeye area (REAg – cm^2), backfat thickness (BFg – mm), and percentage of intramuscular fat (IMFg – %) were obtained from the 2021's Brazilian Senepol Genomic Evaluation conducted by Embrapa Geneplus Program and Brazilian Senepol Breeders Association (Geneplus Senepol, 2021). The single-step GBLUP methodology (Aguilar *et al.*, 2010) has been adopted for evaluating Senepol cattle in Brazil since 2019.

All animals were genotyped using GGP Bovine 50k from NEOGEN®, which allowed better prediction of breeding values as well as to assess the number of copies of the mutation known as nt821 in the myostatin gene (McPherron and Lee, 1997). Table 1 shows the distribution of the animals in this study according to sex and genotype for nt821 mutation.

Data were analyzed by a fixed-model ANOVA with the GLM procedure (SAS, SAS onDemand for Academics, Cary, NC). For phenotypes, fixed effects of contemporary group (CG) and genotype for nt821 mutation were included in a statistical model for all variables, as well as the age of the animal at the end of the test as a linear covariate. For EPDs, a similar model was adopted, except for not including the fixed effect of CG. The CGs were defined as birth year/season, sex, test edition, and farm of origin of the animal. The Tukey's test was used to compare the means for all variables, considering 0.05 as the significance level.

Results

In Table 2, the least square means for REA, BF and IMF are presented for animals with one or no copy of nt821 mutation in the myostatin gene. The effect of one copy of nt821 mutation was significant for all variables ($P<0.05$). Heterozygous animals presented a larger area for *Longissimus dorsi*, while their carcasses were leaner with less subcutaneous and intramuscular fat.

In Table 3, the least square means for REAg, BFg and IMFg are presented for animals with one or no copy of nt821 mutation in the myostatin gene. The effect of one copy of nt821 mutation was significant for all variables ($P<0.05$). Heterozygous animals presented greater genetic merits for producing more muscular and leaner carcasses.

Table 1. Description of studied animals according to sex and genotype for n821 mutation.

Genotype[1]	Sex		Total
	Male	Female	
mh+	92	224	316
++	494	1,234	1,728
Total	586	1,458	2,044

[1] mh+ = One copy of nt821 mutation; ++ = No copy of nt821 mutation.

Table 2. Effects of one copy of nt821 mutation on phenotypes for ultrasound carcass traits in Senepol cattle.

	Genotype[2]		*P*-value
Variables[1]	mh+	++	
REA (cm^2)	73.05±0.49	69.20±0.25	<0.0001
BF (mm)	5.02±0.09	5.45±0.05	<0.0001
IMF (%)	2.42±0.05	2.70±0.03	<0.0001

[1] REA = phenotype for ribeye area; BF = phenotype for backfat thickness; IMF = phenotype for intramuscular fat.
[2] mh+ = One copy of nt821 mutation; ++ = No copy of nt821 mutation.

Table 3. Effects of one copy of nt821 mutation on expected progeny differences (EPD) for ultrasound carcass traits in Senepol cattle.

	Genotype[2]		*P*-value
Variables[1]	mh+	++	
REAg (cm^2)	0.7473±0.0789	-0.1809±0.0337	<0.0001
BFg (mm)	-0.0689±0.0224	0.0921±0.0096	<0.0001
IMFg (%)	-0.0293±0.0072	0.0072±0.0030	<0.0001

[1] REAg = EPD for ribeye area; BFg = EPD for backfat thickness; IMFg = EPD for intramuscular fat.

[2] mh+ = One copy of nt821 mutation; ++ = No copy of nt821 mutation.

The effect of one copy of nt821 mutation was significant ($P<0.05$) on ultrasound carcass traits regardless of their types: phenotypes or EPDs (Table 2 and 3).

Discussion

Heterozygous animals for the nt821 mutation showed greater REA (Tables 2 and 3), which has been related to higher commercial cuts yield and carcass weight (e.g. Silva *et al.*, 2012). Casas *et al.* (2004) and Allais *et al.* (2010) found similar results to this study with crossbred cattle and French beef breeds, respectively. In Brazil, in the Senepol breed, homozygous individuals for the nt821 mutation are discarded from breeding, according to the recommendation of the Brazilian Senepol Breeders Association. However, heterozygotes are accepted, which may represent an opportunity to improve production systems with a focus on increasing meat productivity, as half of their progenies will be carriers of the nt821 mutation.

Regarding fat deposition in the carcass, the effects of a copy of the nt821 mutation are antagonistic to those found for REA. The results show that heterozygotes have leaner carcass with poorer carcass finishing and intramuscular fat (Table 2 and 3). Similar to REA, studies carried out by Casas *et al.* (2004) and Allais *et al.* (2010) corroborate our findings. To meet markets that want lean meat, the use of animals carrying the nt821 mutation may be desirable. In Brazil, however, the predominant demand is for carcasses with adequate fat cover, which protects against rapid cooling and consequently prevents cold-shortening that decreases meat tenderness. Additionally, there is a tendency to prioritize cuts with an adequate level of marbling, which has a direct impact on the juiciness and flavor of the meat.

The Senepol breed is a taurine genetic resource option for the efficient production of high-quality meat under tropical conditions. In Brazil, it has been used especially in crossbreeding programs with zebu breeds with the aim of improving productivity and, above all, meat quality. Therefore, the results found are important to support breeders in decision-making processes regarding the role of Senepol genetics in beef production. Additionally, there are reports of the negative effects of muscle hypertrophy on survival and reproductive traits (Fiems, 2012), which were not investigated here, that should not be overlooked.

Abstract

Temperament in cattle is defined as the behavioural response of animals to human handling. Its expression is influenced by environmental and genetic factors. TBX20 is a candidate gene associated with bovine temperament. The objective was to determine the genetic variability of TBX20-191081 in three cattle beef breeds and evaluate its effect on temperament traits. The allelic frequencies confirmed both alleles segregation in the studied breeds and a significant allelic substitution effect for the G allele was observed, which decreases exit velocity (EV) and temperament score (TS). Thus, its association with docility of beef cattle is evident and genotyping for the marker early in life (e.g. neonates) may allow more flexibility in breeding and selection strategies.

Introduction

Cattle farming is one of the most developed and practiced livestock activities in Mexico. More than 50% of the national land is used to raise around 32 million head of cattle (SIAP, 2020). Temperament is a complex and economically relevant trait; it reflects the well-being of the animal and has been found to be related to productivity traits and job safety (Burdick *et al.*, 2010); it is closely related to gene expression at different levels (Cooke *et al.*, 2014). Few studies have explored characteristics of cattle temperament at the genomic level, mainly due to its biological complexity, difficulties in the management of animals, and statistical analyses. However, as a result of applying different approaches such as the scanning of complete genomes and the use of candidate gene strategy, now it is known that regulation of temperament involves multiple genes with divergent functions. Using genome wide association analyses, we identified candidate genes with the potential to significantly affect temperament in Brahman cattle (Paredes-Sánchez *et al.*, 2019). Among these genes, the marker TBX20-191081 (rs43398069) located within an intron of the T-box transcription factor gene was significantly associated with exit velocity, pen score and temperament score, methods commonly used to precisely score cattle temperament (Paredes-Sánchez *et al.*, 2019). This study aimed to estimate the genetic effect and allele frequencies of the genetic marker in three different beef cattle breeds: Angus, Brangus and Charolais.

Materials & methods

Hair samples and temperament records of 89 yearling bulls in a central performance test (35 Angus and 27 Brangus and 27 Charolais cows were included. The data and samples were collected by Garza-Brenner (2017) in the facilities of the Unión Ganadera Regional de Chihuahua (UGRCH), Chihuahua, México and in particular herds located at Nuevo León, Mexico, and kept in the Centro de Biotecnología Genómica-Instituto Politécnico Nacional (CBG-IPN), Reynosa, Tamaulipas, México.

Three methods were used to evaluate the animals temperament: (1) pen score (PS), which is a non-restrictive technique, in which the cattle are segregated into small groups (three to five animals) in a pen

(Burdick *et al.*, 2010) to score their reaction when approached by an evaluator; (2) exit velocity (EV), considered as an objective quantitative measure, because it is calculated by an electronic device (Schmidt *et al.*, 2014), defined as the time required for an animal to cross 6 feet (1.83 m) of distance when released from the handling press; and (3) temperament score (TS), that classifies animals into calm and temperamental combining data from PS and EV (King *et al.*, 2006; Burdick *et al.*, 2010; Schmidt *et al.*, 2014).

Genotyping. DNA isolation from hair follicles was achieved using the Genelute Mammalian Genomic DNA kit (Cat. G1N350, Sigma-Aldrich Co. LLC, St. Louis, Missouri, USA). PCR was used to obtain a 298 pb product including the TBX20-191081 marker. Allelic discrimination was achieved using the Nextera XT protocol and sequencing in the MiniSeq system (Illumina, Inc., San Diego, California, USA). The sequences obtained were subjected to bioinformatics analysis for genotype-assignation to each sample. The allele frequencies were calculated with the GENEPOP online program version 4.0.

Effect of 191081-TBX20 marker. A mixed model was fitted, considering the fixed effects of genotype (AA, GA, GG), sex of the animal (male, female) and breed (Angus, Brangus and Charolais). Since animals were from several herds, this effect was considered as a random. The least squares mean for breed, sex, and genotype were estimated for each variable and compared with the least significant difference test. Additionally, the allelic substitution effect of the markers was estimated, considering the genotype as a linear covariate. Analyses were run using the software SAS on Demand for Academics (SAS Institute Inc., Cary NC, USA).

Results

Compared with A allele, a lower frequency of the G allele, previously reported as the favourable allele for docility, was found in the three tested breeds (Table 1).

A significant effect of breed was observed, in a pooled analysis across breeds. No significant differences were found among genotype means for each behavioural trait (Table 2). However, the allelic substitution effect showed significance for EV and TS, with a negative value for the G allele (Table 2).

Table 1. Allele and genotype frequencies for the TBX20-19108 marker in the studied sample (n=89).

Breed	Genotype			Alleles	
	AA	AG	GG	A	G
Angus	0.48	0.40	0.11	0.68	0.31
Brangus	0.25	0.51	0.22	0.51	0.48
Charolais	0.40	0.29	0.29	0.55	0.44

Table 2. Least square means ± standard error and allelic substitution effect (*a*) of genotypes of 191081 locus of the TBX20 gene effects on temperament traits.[1]

Trait	AA	AG	GG	*a*
	(35)	(36)	(18)	
EV	1.73±0.15	1.91±0.15	2.14±0.18	-0.20±0.09**
PS	1.80±0.10	1.90±0.11	1.98±0.12	-0.09±0.05*
TS	1.77±0.13	1.91±0.13	2.06±0.15	-0.15±0.07**

[1] EV = exit velocity; PS = pen score; TS = temperament score. Sample size between brackets. * = $P<0.10$, ** = $P<0.05$.

Discussion

The T-box transcription factor gene (TBX20) has been studied in human and non-human species and proposed as candidate gene associated with Heart Rate (HR) (quantification of the number of times the heart beats in a given time interval, usually a minute, while the unstressed body is at rest). In cattle, some evidence has shown that temperament and HR are correlated. Curley *et al.* (2008) found that cortisol concentration in temperamental Brahman heifers was greater than in calmer animals, assessed using exit velocity. Sutherland *et al.* (2012) reported that High Responder cows had higher basal HR and cortisol concentrations compared with Low Responder cows, which may hint at the relationship between exit velocity-TBX20- and heart rate.

Here, we demonstrated in a small sample, that allelic frequencies distribution of intronic TBX20-19108 between beef breeds are similar to those found in Brahman cattle (Paredes-Sánchez *et al.,* 2019) and also that an effect of allelic substitution is observed for EV and TS temperament traits.

Once confirmed in a large cattle sample, the results of this research may be important not only for basic research but also for the application of genomic tools for the improvement of beef cattle in the medium term, given that temperament is an economically relevant trait for beef cattle production. Identification of markers that allow detection of temperamental animals early in life (e.g. neonates) will allow the producer more flexibility in their breeding and selection strategies.

631. Innovative phenotyping strategies exploiting immune response to heat stress conditions

P. Lemal*, M. Schroyen and N. Gengler

Gembloux Agro-Bio Tech, University of Liège, Passage des Déportés 2, 5030 Gembloux, Belgium; pauline.lemal@uliege.be

Abstract

Evaluating the heat stress status of an animal is a challenge. Indeed, currently, the heat stress status is determined on the basis of a significative change of a response variable known to be correlated with a temperature-humidity related variable. These response variables are, most often, milk yield or similar traits. However, it is known that heat stress has a negative effect on the immune system, but this information is still very little used in the context of heat stress phenotyping. Indeed, only a few studies highlight immune genes involved in heat stress. In addition, these studies provide very little information on the molecular mechanisms that link these genes to the observed phenotype. Immune response based deep-phenotyping strategy would provide a more comprehensive understanding of heat stress and could also serve as a basis for identifying heat stress indicators through genomics.

Introduction

Currently, phenotypes used for genetic improvement remain often defined in a very straightforward fashion, e.g. to improve production traits, these traits are recorded. Recently, interest for breeding of resilient and healthy livestock has strongly increased. Indeed, the idea has emerged that by selecting animals based on immune traits, it would be possible to reduce the occurrence of diseases and thus also increase profitability of the farm (Mallard *et al.*, 2015; Thompson-Crispi *et al.*, 2014). In addition, it is shown that, generally, healthier animals show better growth and better reproductive abilities (Mallard *et al.*, 2015). However, in this condition direct phenotyping quickly reaches its limits as disease traits are manifestations of the reaction of the animal to underlying mostly unknown solicitations. Moreover, direct recording of this data is notoriously unreliable and biased as only recognized positive cases are recorded and the quantity of false-negative cases is expected to be high.

Recently, some studies have developed technologies allowing to predict cell mediated response and humoral immune response of an animal. Even if this type of studies is still rather rare, the heritability for the immune response was estimated to be between 0.25 and 0.35 which was clearly higher than traditional disease traits and at a level where important responses to selection can be expected (Mallard *et al.*, 2015; Thompson-Crispi *et al.*, 2012). However, these technologies can hardly be used to determine the immune status of an animal in real time.

Heat stress is known to have a negative effect on the immune system (Bagath *et al.*, 2019; Dahl *et al.*, 2020). However, this knowledge is not currently used as an indicator of heat stress. The most used approach is to relate a response variable, often milk yield or similar traits, to a temperature-humidity related variable. The status of heat stress is then associated with a significant change in this response variable, i.e. decrease for production related traits, or an increase for traits like somatic cell count. The temperature at which this decrease, or increase, begins, and its slope vary from animal to animal. In current implementations, reaction norm models are used with, in general, a heat stress threshold set and only the slope being assessed for each animal. The already implemented genomic breeding value estimation for thermotolerance is based on this type of phenotypes (Nguyen *et al.*, 2017).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_631, © P. Lemal *et al.* 2022

Only a few studies highlight the genes and pathways that could be involved in thermotolerance (Garner *et al.*, 2020; Halli *et al.*, 2021; Otto *et al.*, 2019; Sigdel *et al.*, 2019; Srikanth *et al.*, 2017). And, even if these studies provide a lot of information, few of those are looking at the molecular mechanisms which lead to the observed phenotype, and therefore could serve as basis for the definition of indicators (i.e. biomarkers) of heat stress. For this reason, the objective of the present paper was to extend the work of Otto *et al.* (2019) toward innovative potential deep-phenotyping strategies exploiting immune response in the context of heat stress.

Innovative deep phenotyping strategies for biomarkers of heat stress

From heat stress to cortisol secretion. In the event of heat stress, the paraventricular nucleus of the hypothalamus will produce the corticotropin-releasing hormone (CRH) (Mishra, 2021). This hormone will bind to the CRH receptors expressed on the surface of the anterior pituitary cells, which triggers exocytosis of the adrenocorticotrophic hormone (ACTH) stored in secretory vesicles (Rehfeld and Bundgaard, 2010). ACTH enters the adrenal gland through the bloodstream and stimulates cortisol synthesis (Feher, 2012). Once released into the bloodstream, cortisol is able to passively cross the plasma membrane of target cells. Its receptor, the glucocorticoid receptor (GR) is located in the cytoplasm where it is sequestered by several proteins including HSP90. The binding of cortisol to the GR causes its dissociation from this protein complex and its translocation to the nucleus. The GR can then bind to the glucocorticoid response element (GRE) regions of the promoter of the target genes. The GR-cortisol complex is also able to modulate the function of other transcription factors by interacting directly with them (Nicolaides *et al.*, 2020).

From cortisol secretion to greater occurrence of diseases. Among the target cells of cortisol are immune cells including macrophages. These phagocytic cells exhibit a wide variety of phenotypes *in vivo*. This panel of phenotypes has two extremes, M1 and M2. The former is associated with the initiation of inflammation and the eradication of pathogens and the latter with the inhibition of inflammation and the prevention of damages (Maciuszek *et al.*, 2020). The polarization of macrophages in M1 is initiated, among other, by lipopolysaccharide (LPS) of bacterial origin. This is because LPS binds to the CD14 receptor expressed on the surface of macrophages. The complex formed then interacts with Toll like receptor 4 (TLR4) to trigger a signaling cascade dependent on p50/p65 nuclear factor kappa B (NFκB). This leads to the activation of gene transcription encoding proteins involved in the antimicrobial activity of macrophages such as the inducible nitric oxide synthase (iNOS) as well as pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α) (Tugal *et al.*, 2013).

However, after binding to its receptor, cortisol is capable of sequestering the p65 subunit of NFκB and inducing the expression of IκB, an inactivator of NFκB (Feher, 2012; Nicolaides *et al.*, 2020). Moreover, the glucocorticoid-induced leucine zipper (GILZ) whose expression is controlled by the glucocorticoid receptor, is also capable of inhibiting NFκB (Cannarile *et al.*, 2019). In this way, heat stress appears to prevent M1 polarization and thus promote M2 polarization which is associated with reduced antimicrobial activity.

In addition, NFκB was also shown to be involved in the activation of T and B lymphocytes (Haselager *et al.,* 2020; Krawczyk and Penninger, 2014). The type of cytokines produced by dendritic cells are also modulated by the activation of NFκB (Walsh and Mills, 2013). All these data suggest that heat stress through, among others, the production of cortisol and inactivation of NFκB, may lead to a weaker immune response against pathogens by reducing the ability of immune cells to react to infection.

From heat stress to pro-inflammatory response. However, cortisol levels vary greatly with the time of exposure to heat stress (Mishra, 2021). Chronic heat stress is even associated with increased inflammation, possibly as a result of decreased cortisol levels in affected animals (Most and Yates, 2021). The increased inflammation in the absence of cortisol could be due to cell death induced by increased body temperature as well as the overexpression of heat shock proteins (HSPs). Indeed, in cells such as macrophages which express TLR4 and CD14, HSPs have been shown to be able to generate a pro-inflammatory response like other molecules released during cell damage. In this way, this pro-inflammatory response is possible via the activation of NFκB (Asea and Kaur, 2017).

From pro-inflammatory response to greater occurrence of diseases. It has been shown that with greater inflammation the symptoms of a disease can also be greater (Hunter, 2012). In this way, if the heat stress induces an increase in inflammation, it would not lead to an increase in the occurrences of infectious disease but could cause more severe symptoms which would cause more animals to pass from subclinical to clinical level.

From deep phenotyping to identification of heat stress markers. On this basis, it is expected that NFκB activity and therefore the expression of its target genes will be different between stressed and unstressed animals. This difference could then be exploited as a marker of heat stress.

From biomarkers identification to genetic progress for heat stress resilience. Translating heat stress markers into genetic progress requires several conditions. First, deep phenotypes must be acquired in sufficient quantities and on relevant animals to serve as a basis for heat stress indicators. Indeed, it is necessary to confirm the heat stress status of the animals to find reliable markers of heat stress based on these animals. Based on Otto *et al.* (2019), these markers could be target genes of NFκB. Of course, as already mentioned, significant differences must be obtained between the groups formed for the markers tested. Ideally, these markers should also be validated to determine whether they are capable, on their own, of discriminating between stressed and non-stressed individuals and be considered as biomarkers (Ou *et al.*, 2021). In the case of selection purpose, once biomarkers obtained, it is still required to link variations of these indicators to genetic variation. Moreover, this genetic variation has to be additive, therefore heritable and can be improved by selection. Many strategies are possible to implement biomarkers for selection. These can be very traditional approaches where immune response-based biomarkers are added in multi-trait settings. Indeed, these precise biomarkers not available in large quantities could be added with less precise traits but available in larger quantities. Moreover, very innovative approaches using novel methods as machine learning and these biomarkers as input could be used to generate predictions of heat stress resilience.

Conclusions

We followed the direction shown by Otto *et al.* (2019), who have identified among others, that NFκB as a transcription factor is associated with heat stress. Extending on this study, we showed how it is possible to go further and directly link NFκB to heat stress and to the higher occurrence of infectious diseases which results from it. This is far from the only opportunity to perform deep innovative phenotyping exploiting immune response to heat stress conditions. Indeed, the information given above is, of course, far from exhaustive, but it does allow to link genomic studies to molecular mechanisms, and therefore also to potential molecular phenotypes (i.e. biomarkers) associated with heat stress. Linking studies in this systematic way should allow a better understanding of the mechanisms involved at the systemic level but also facilitate the identification of biomarkers. Heritable variation of these identified biomarkers could subsequently be used in animal breeding to generate genetic progress for heat stress resilience.

Abstract

Genetic interactions between SNPs can lead to phenotypic changes. Herein, we used the WISH-R method to test for epistasis in residual feed intake (RFI) and residual methane emission (RME) of Nelore cattle. The genomic interaction modules identified four and ten significant SNP-SNP modules for RME and RFI traits, respectively. The region's annotation identified genes that could be impacted by SNPs modules correlated to the traits. The over-representation analysis showed that the SNPs correlated to the RME trait were close to genes involved with the ion transport, glutamate receptor signalling pathway, RAC1 GTPase cycle, and ERBB2 signalling. Regarding the RFI trait, the over-representation analysis showed genes involved in the Ca-dependent events and regulation of cation transmembrane transport. Knowing these SNP–SNP interactions could improve understanding of the genetic and physiological mechanisms contributing to feed efficiency and methane emission.

Introduction

The beef cattle industry is a fundamental and growing part of the Brazilian economy. Feed efficiency is directly associated with increased meat production and can provide information useful to reduce environmental impact, such as methane emission. Different approaches were carried out to identify genetic variants and genes associated with different traits of interest in Nelore cattle (de Lima *et al.*, 2020; de Oliveira *et al.*, 2014, 2018). However, studies exploring the epistatic effects over these traits are generally scarce. Genetic interactions between SNPs occur when the phenotypic effect given to a mutation is affected by other modifications in the genome (Papp and Pál, 2011) and are key to understanding how genes relate functionally. This study aimed to identify SNP-SNP interactions using the WISH-R method (Carmelo *et al.*, 2018) to test for epistasis in residual feed intake and methane emission traits of Nelore cattle.

Materials & methods

Animals and phenotypic data. The Nelore population used in the current work has been previously described by Andrade *et al.* (personal communications). The experimental population consisted of 52 animals born in 2014 and submitted to two diets. The animals were then sent for slaughter at 23-24 months of age, following the Humane Slaughter of Cattle guidelines, and were approved by the EMBRAPA Livestock Science Ethics Committee on Animal Experimentation, São Carlos, São Paulo (Protocol No. 09/2016). Residual feed intake (RFI, kg/d) and residual methane emission (RME) traits were measured as described elsewhere. In summary, the RFI was computed as described by Koch *et al.* (1963), and RME was obtained as described by Donoghue *et al.* (2016).

Reducing genotype data dimensionality. DNA extractions were performed with TRIZOL, and all animals were genotyped using the GGP *Bos indicus* 50k beadchip. Samples were filtered according to the minimum call rate (95%) and minimum allele frequency (95%). Sexual and monomorphic SNPs were also excluded from the dataset. A total of 43,439 SNPs were available for further analysis. Genome-wide association analysis was performed to reduce genotype data dimensionality using PLINK software (Purcell *et al.*, 2007) based on the *assoc* function. Phenotypic data were corrected for diet and contemporary groups (i.e. diet, weight group, slaughter date). SNPs with $P<0.1$ were selected from each association and used to carry out the epistatic interaction calculation individually for each trait.

Epistatic networks and trait association analyses. The epistatic interactions for RFI and RME in Nelore cattle were calculated using the WISH-R package (Carmelo *et al.*, 2018), considering the default parameters. The epistatic signed weighted networks were constructed for each trait, and genomic interaction modules were created based on the WGCNA pipeline (Langfelder and Horvath, 2008). Significant modules with positive and negative correlations for each trait were selected for downstream analysis. The SNPs' genomic location annotation was performed based on the ARS-UCD1.2 bovine genome coordinates. Functional Annotation and biological interpretation were performed using the ClueGo plugin for Cytoscape (Bindea *et al.*, 2009).

Results

SNP-SNP network analysis. From the 43,439 SNPs markers kept after QC, a total of 3,885 and 4,481 SNPs were associated ($P<0.1$) with RME and RFI traits, respectively. These SNPs were then used as input for the genome-wide epistatic analysis for each trait separately. The genomic interaction modules based on the WISH-R approach identified four and ten significant SNP-SNP modules ($P\leq0.05$ and $r>|0.7|$) for RME and RFI traits, respectively (Figure 1). In this case, the modules can be defined as clusters of highly correlated SNPs. Considering the RME trait, half of the modules showed positive and half negative correlation with the RME. For the RFI trait, six modules showed a negative correlation, while four were positively correlated. No SNP module was associated with both analyzed phenotypes.

Annotation of SNP modules and gene enrichment. For the RME trait, 52% of the hub-SNPs identified from the significantly correlated modules were harbored in intron regions, followed by 36% in intergenic regions. Regarding hub-SNPs associated with the RFI trait, 51% were in intronic variants, followed by 37% in intergenic regions. Additionally, for both traits, about 10% of the hub-SNPs were located in regulatory regions, i.e. upstream or downstream regions. The annotation of hub-SNP regions retrieved 415 and 466 genes that could be impacted by hub-SNPs of positive and negative modules correlated to RME trait, respectively. Over-representation analyses showed that the hub-SNPs of modules negatively correlated to the RME trait were involved in the *neuronal system development*, *ion transport*, and *glutamate receptor signaling pathway,* while the hub-SNPs of the positive modules were involved in the *RAC1 GTPase cycle*, *ERBB2 Activates PTK6 Signaling* and *PI3K events in ERBB2 signaling*. Regarding the RFI trait, a total of 609 and 702 genes may be impacted by hub-SNPs of positive and negative modules correlated to the trait, respectively. Over-representation analyses showed that the hub-SNPs of the negative modules were involved in the *Calmodulin induced events* and *Ca-dependent events*. Likewise, the hub-SNPs of the positive modules correlated to the RFI trait were involved in pathways related to the *regulation of cation transmembrane transport*.

Discussion

The livestock sector demands an increase in profitability and a reduction in environmental impacts through an improvement on feed efficiency and a decrease in methane emission traits (Sakamoto *et al.*, 2021). Various genetic and environmental factors can influence both traits, and this genetic variability indicates

that genomic selection is possible (de Oliveira *et al.*, 2014; Donoghue *et al.*, 2016). In this study, we used genome-wide SNPs to unravel the genetic contribution of the epistatic effects onto the RFI and RME variation in Nelore cattle. We found several modules associated with the analysed traits and identified genes and pathways possibly involved in phenotype determination from the network analysis. The *RAC1 GTPase cycle* and pathways involved in the *ERBB2 signaling* were over-represented in the RME positive correlated modules. Both pathways are involved in various cellular processes, including cytoskeleton organization, transcription, and cell proliferation (Bosco *et al.*, 2009, Appert-Collin *et al.*, 2015). Based on the over-representation pathway analysis, RME negatively correlated modules were involved with ion transport. Through the ion's concentration and pH regulation, the host physiology can exert a selective pressure on the gut microbiota (Engevik and Engevik, 2021). Another top pathway is involved in *glutamate receptor signaling*. Previous studies showed that the glutamatergic signaling along the microbiota-gut-brain axis may modulate the gut microbiota (Baj *et al.*, 2019). The relationship between the abundance of microorganisms and methane emission has already been reported (Bowen *et al.*, 2020; Ghanbari Maman *et al.*, 2020).

Regarding the RFI phenotype, our findings indicate that observed gene networks are primarily related to metabolic processes underlying *Ca-dependent events* and *regulation of cation transmembrane transport*. Previous studies showed the impact of ion metabolism as calcium in feed efficiency trait (de Oliveira *et al.*, 2014; Marchesi *et al.*, 2021; Shi *et al.*, 2020). Further studies will be performed with the genes and the hub-SNPs found here. The knowledge of these SNP–SNP interactions may improve our understanding of the genetic and physiological mechanisms that contribute to feed efficiency and methane emission.

633. Host-genomically influenced ruminal microbial genes are temporally stable during the finishing phase in beef cattle

J. Lima[1*], M. Martínez-Álvaro[1], J. Mattock[2], M.D. Auffret[1], C.A. Duthie[1], M.A. Cleveland[3], R.J. Dewhurst[1], M. Watson[2] and R. Roehe[1*]

Abstract

The temporal stability of rumen microbiome composition is very important for microbiome-driven breeding of host performance traits because it helps to identify the number of samples needed over time and best timepoints to obtain highly informative samples. Therefore, we investigated the temporal stability of the abundances of host-genomically influenced microbial genes throughout the finishing phase in beef cattle, and their associations with estimated breeding values (EBVs) of host traits such as feed conversion efficiency and methane emissions. Our results indicate that rumen microbiome profiles generated from different timepoints throughout the finishing phase are remarkably stable, with pairwise correlations of 0.74 or higher, and that their associations with EBVs of host traits were stable and strong throughout. Based on these results, we concluded that microbiome profiles at any sampling timepoint are representative of the finishing phase and can be used to predict EBVs of performance traits at similar accuracy.

Introduction

Ruminants are unique in their ability to feed on diets rich in human-indigestible materials due to the symbiotic relationship with their rumen microbiota comprised of bacteria, protozoa, and fungi that ferment complex polysaccharides into volatile fatty acids, vitamins, and microbial proteins, the main energy and nutrient sources for the host animal. During this process, methanogenic archaea use excess hydrogen leading to methane (CH_4) emissions. Previous studies demonstrated the close association between rumen microbial genes (MG) and host traits – for example, Roehe *et al.* (2016) identified 20 and 49 rumen MG that explained 81 and 86% of the variation in CH_4 emissions and feed conversion ratio (FCR), respectively, and Lima *et al.* (2019) found that sets of fewer than 20 rumen MG explained more than 60% of the variation in traits including average daily weight gain (ADG), daily feed intake (DFI), and FCR. Host-genomically influenced microbial genes (hMG) have been proposed as potential selection criteria of beef cattle in breeding programs (Martínez-Álvaro *et al.*, 2021a, 2021b). Overall, rumen MG have been suggested as accurate predictors of host performance traits at phenotypic and genomic levels.

Studies on the association between the rumen microbiome (microbiota and their genes) and host traits in beef cattle often rely on microbiome data generated from sampling at slaughter. However, whether MG abundances generated from slaughter samples are representative of rumen microbiome profiles at earlier stages of the host animal life is still unclear.

Therefore, in this study, we aimed at assessing the temporal stability of hMG, and of the associations of hMG with host performance traits, including FCR, ADG, DFI, residual feed intake (RFI), and CH_4 yield (g/kg daily dry matter intake) throughout the finishing phase of beef cattle.

Materials & methods

The experimental trial included 84 steers from breeds Charolais and Luing, fed diets with forage:concentrate ratios of 520:480 (FOR), or 84:916 g/kg dry matter basis (CON). Twenty steers (6 from each breed fed CON, and 4 fed FOR) had their rumen digesta sampled at 6 timepoints throughout the finishing phase: at 418±32 days (d) old (T1), at the start (average of 460±32 d old, T2), mid (average of 492±32 d old, T3), and end (average 520±32 d old, T4) of the performance test period, on the day the animal left the respiration chamber (T5), and at slaughter (T6). During the 56-d testing period, DFI was obtained as dry matter intake (DMI, kg/day), ADG was obtained by fitting a linear regression of body weight (measured weekly before fresh feed was offered) on test day. FCR was calculated as DMI divided by ADG. Each steer spent 3d in respiration chambers (RC) from which the final 48h were used to estimate daily CH_4 emissions, which were divided by average DMI measured within the RC, resulting in CH_4 yield. Estimated breeding values (EBV) of traits were calculated based on FCR, ADG, DFI, RFI, and CH4 records from a larger set of 359 animals (which included our 84 steers), using univariate GBLUP models corrected for systematic effects (diet, breed, and trial) using the same assumptions as in Martínez-Álvaro *et al.* (2021c).

Estimating abundances of microbial genes. Microbial DNA extracted from ruminal samples was sequenced in Illumina HiSeq and PE150 systems by Edinburgh Genomics (Edinburgh, UK). Whole metagenome sequencing reads were assembled using MEGAHIT (Li *et al.*, 2015), proteins predicted with Prodigal (Hyatt *et al.*, 2010) and identified using KofamScan (Aramaki *et al.*, 2020) and the Kyoto Encyclopedia of Genes and Genomes database (Kanehisa and Goto, 2000). MG absent from at least one animal, or with relative abundance ≤0.001% were removed from the dataset. Due to the compositionality of microbiome data, abundances were additive logratio transformed (alrMG), using the reference MG K00858, based on the criteria proposed by Greenacre, *et al.* (2021). A total of 443 MG had previously been shown to be heritable (Martínez-Álvaro *et al.*, 2021b), and therefore were used in the further analyses.

Statistical analyses. We explored the temporal stability of the alrMG within each animal by calculating the pairwise Pearson correlation (*r*) between timepoints. To assess the temporal stability of the alrMG over all the animals, we calculated Pearson correlations between the alrMG (adjusted for fixed effects breed and diet) from different timepoints. Additionally, alrMG from each timepoint (adjusted for fixed effects) were used in partial least squares models (PLS) to predict EBVs computed from GBLUP, to evaluate the stability of the associations between hMG and EBVs of host performance traits. All analyses and plots were produced in R version R-4.1.1, using packages mixOmics (Rohart *et al.*, 2017), and tidyverse (Wickham *et al.*, 2019).

Results

The within-animal correlations revealed that alrMGs generated throughout the finishing phase were mainly stable. For example, for T1-T6, correlations varied between r=0.56 (Figure 1, blue font), and r=0.90 (Figure 1, orange font). The correlations between alrMG (adjusted for fixed effects) were strong throughout the finishing phase, varying from r=0.74 (between T1 and T2) and r=0.87 (between T3 and T4) (Table 1). Host-genomically influenced alrMGs generated from each timepoint strongly predict EBVs of the traits, for example, between 63.83 and 77.92% of the variability in FCRebv was explained by alrMGs generated from sampling the rumen at T3 and T1, respectively. Additionally, 70.25±3.43% of the variability of ADGebv was explained by hMG generated throughout the finishing phase, with the lowest variance being 66.84%, explained by alrMGs generated from T2 (Table 2). Overall, the results indicate that alrMGs generated from all timepoints explained more than 56% of the variability of the EBVs of performance traits.

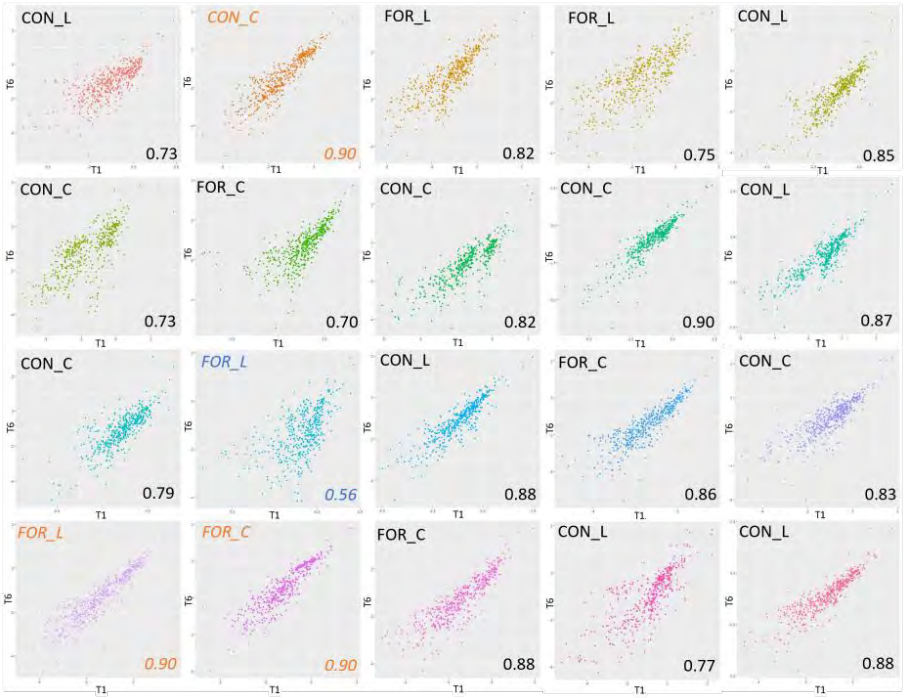

Figure 1. Temporal stability of the abundances of host-genomically influenced microbial genes. Biplots show the additive logratio abundances of microbial genes generated from sampling at timepoints T1 (x axis) and T6 (y axis) for each of the 20 animals fed concentrate (CON) or forage (FOR), of breeds Charolais (C) or Luing (L). Pearson correlations presented in the bottom-right corner of each plot.

Table 1. Pairwise Pearson correlations between abundances of host-genomically influenced microbial genes generated from samples collected at 6 different timepoints (T1 to T6) throughout the finishing phase of beef cattle.

[1] ebv = estimated breeding values; FCR = feed conversion ratio; ADG = average daily weight gain; DFI = daily feed intake; RFI = residual feed intake; CH_4 = methane emissions yield (g/kg dry matter intake).

Discussion

Our results indicate that hMG abundances generated from sampling throughout the seven-month long finishing phase are remarkably constant, suggesting that microbiome profiles of beef cattle are substantially stable. This result agrees with Snelling *et al.* (2019), which used microbiota data generated from 16S rRNA gene sequencing, and suggested that in the absence of major perturbations such as a change in diet rumen microbiome profiles are temporally stable. We showed that the associations between hMG abundances and EBVs of host performance traits are strong and stable, with hMG abundances generated from different timepoints explaining more than 56% of the variability of EBVs. In agreement, using microbiome profiles from slaughter samples, Lima *et al.* (2019) identified sets of rumen MG whose relative abundances explained more than 63% of the phenotypic variation of FCR, ADG, RFI, and DFI. Our results are highly relevant for the current research on the rumen microbiome, particularly for microbiome-driven breeding because they suggest that one rumen microbiome sample per animal at any time during the finishing phase of cattle is sufficient to predict EBVs of performance traits at similar accuracy.

Abstract

We herein describe a novel phenotype related to meat quality in Belgian blue cattle breed, named 'tough and dry meat syndrome'. A genome-wide association study pinpointed a single significantly associated locus on chromosome 25, encompassing the *ATP2A1* gene coding for the SERCA1 protein. A previous reverse genetic screen identified a breed-private missense mutation *(R143W)* in this gene. It segregates at high frequency (0.15) without deviation from expected genotypic proportions and was proven to be causative for this syndrome. The prevalence of the condition is estimated at 12.5% and its severity correlates with *W143* allelic dosage. The mutation is partially dominant with a penetrance of 43 and 100% in *R/W* and *W/W* animals respectively. Retrospective examination of *W143* frequency revealed a clear linear upward trend, likely due to the fact that the *W143* variant has a positive effect on muscle mass. Direct selection against the mutation is underway.

Introduction

Belgian blue cattle (BBC) breed is known for its exceptional double-muscling phenotype due to the fixation of a loss-of-function mutation in the *myostatin* gene (Grobet *et al.*, 1997). It is directly associated with a lower collagen content in muscle resulting in a superior meat tenderness much appreciated by consumers. But, since several years, meat cutters reported the occasional observation of meat cuts that were described as 'tough and dry'. Most of the affected muscles were located in high-value cuts in the hindquarter: silverside (m. *glutaeobiceps*), topside (m. *semimembranosus*) and top rump (m. *quadriceps femoris*). In the worst cases the eye-muscle (m. *longissimus dorsi*), the underblade (m. *subscapularis*) and the shoulder tender (m. *teres major*) were also impacted. Here we report the identification of a mutation in the *ATP2A1* gene associated with a major negative effect on meat quality.

Materials & methods

Carcass phenotyping. Meat quality phenotypes were classified into six discrete categories (C) of increasing severity (0, 1, 1.5, 2, 2.5 and 3). Carcasses without any macroscopic meat defect are classified as C0. Upon cutting of the carcasses, all affected animals (C > 0) exhibited exudate at the surface of the *m. semimembranosus*, and a 'tough and dry' feeling of the *m. adductor femoris* and inner parts of the *m. glutaeobiceps* and *m. semimembranosus* (C1 and 1.5), as well as of the *m. quadriceps femoris, m. semitendinosus, m. longissimus dorsi, m. subscapularis* and *m. teres major* for the most severe cases (C2 to 3).

Genome-wide association studies (GWAS). For the association studies, DNA samples were genotyped on custom LD12K (1st cohort) or MD50K (2nd cohort) EuroGenomics SNP arrays (Illumina, Inc) as described in Charlier *et al.*, 2016. After QC, 11,088 and 47,473 autosomal SNPs were kept in the 1st and 2nd cohorts, respectively. GWAS between SNP or haplotypes and meat quality (0 = normal; 1 = 'tough and dry') were performed using GLASCOW (Zhang *et al.*, 2012). The genomic relationship matrix was estimated either based on SNP similarity or on haplotype similarity as described in Zhang *et al.* (2012). For this, haplotypes were reconstructed with Beagle 4.1 (Browning and Browning, 2007) and then grouped at each

marker position into 10 clusters of ancestral haplotypes (hidden states; HS) based on their similarity with the model described in Druet and Georges (2010) using HiddenPHASE.

Results

Using genotypes from 38 affected meat pieces (cases) and from 1,058 unrelated breed-age-matched animals as controls, we obtained a single genome-wide significant signal on chr25 with the two models (single SNP and 10 HS) (Figure 1A and 1B). The most significant variant was a missense variant *(R143W)* in the *ATP2A1* gene encoding the SERCA1 protein (P=3.6×10^{-21}). The maximum 10 HS signal (P=6.2×10^{-23}) overlapped this variant, and was due to the enrichment in cases of a single haplotype that was in near perfect linkage disequilibrium (r^2≥0.91) with the *ATP2A1 R143W* variant (Figure 1C). The SERCA1 protein is a Ca^{2+} ATPase that is embedded in the membrane of the sarcoplasmic reticulum of muscle fibers, pumping Ca^{2+} ions from the sarcoplasm back into the reticulum thereby controlling muscle relaxation (eg. Wuytack *et al.*, 2002). Loss-of-function mutations in *ATP2A1* cause autosomal recessive Brody myopathy in humans (e.g. Brody, 1969; Odermatt *et al.*, 1996), congenital muscular dystonia I in BBC (Charlier *et al.*, 2008), and perinatal lethality in *ATP2A1* knock-out mice (Pan *et al.*, 2003). Since, missense *ATP2A1* variants have been associated with recessive pseudo-myotonia of variable severity in at least four other beef cattle breeds (OMIA 001464-9913). The *R143W* mutation is located in *ATP2A1* coding exon 5 and affects a highly conserved residue in the first cytoplasmic loop of SERCA1 (Figure 1 D-F). *R143W* is only reported in BBC. It had a frequency of 15% in the GWAS control population, yet of 55% in the 38 affected samples (P=9.5×10^{-23}). Based on these initial findings, we performed a systematic survey for 'tough and dry' meat cuts in Belgian slaughter-plants. We first examined 496 carcasses of adult Belgian Blue cows, 62 (12.5%) were considered to be affected to various extend. A striking feature was the systematic increased loss of fluid from the carcass (referred to as 'drip') during the cooling process. Upon cutting of the non-C0 carcasses, they exhibited exudate at the surface of the respective affected muscles (see M&M). Samples of the m. *glutaeobiceps* were collected from 26 affected (5 C1; 9 C1.5; 9 C2; 3 C2.5) and 21 non-affected C0 animals and analysed for standard meat quality traits. Briefly, non-C0 samples had altered colour (darker) and colour stability, texture (higher hardness, gumminess, chewiness, and shear force), and moisture content (reduced EZ-drip, thawing and cooking loss; increased dry matter content) compared to C0 controls. We genotyped 116 case (non-C0) samples as well as 127 unaffected (C0) controls. A case-versus-control GWAS confirmed the chr25 association, maximizing at the *ATP2A1 R143W* position with individual SNP (P=1.7×10^{-36}) and the HS10 (P=4.8×10^{-54}) models. The frequency of the *W143* allele was 8.2% in the 'hyper' C0 controls, while it was 55.1% in non-C0 cases. We further tested (within cases) whether there was an association between *R143W* genotype and severity of the condition by regressing dry meat score (C1 to 3) on dosage of the *W* allele (1 or 2). The average score of *R/W* cases was 1.46 while it was 1.88 for *W/W* cases (P=0.0005). We retrospectively examined the change in frequency of the *W143* variant in the general BBC population over time (>65,000 animals from 2014 to 2020).

It showed a clear linear upward trend from 14.5% in 2014 to 17.5% in 2020. To understand what may cause this trend, we studied the effect of the *W143* variant on 22 phenotypes that are systematically recorded in BBC as described in Gualdrón Duarte *et al.* (2020). Significant (Bonferroni-corrected) positive effects were observed for five traits pertaining to muscular development of the front and hindquarters (data not shown).

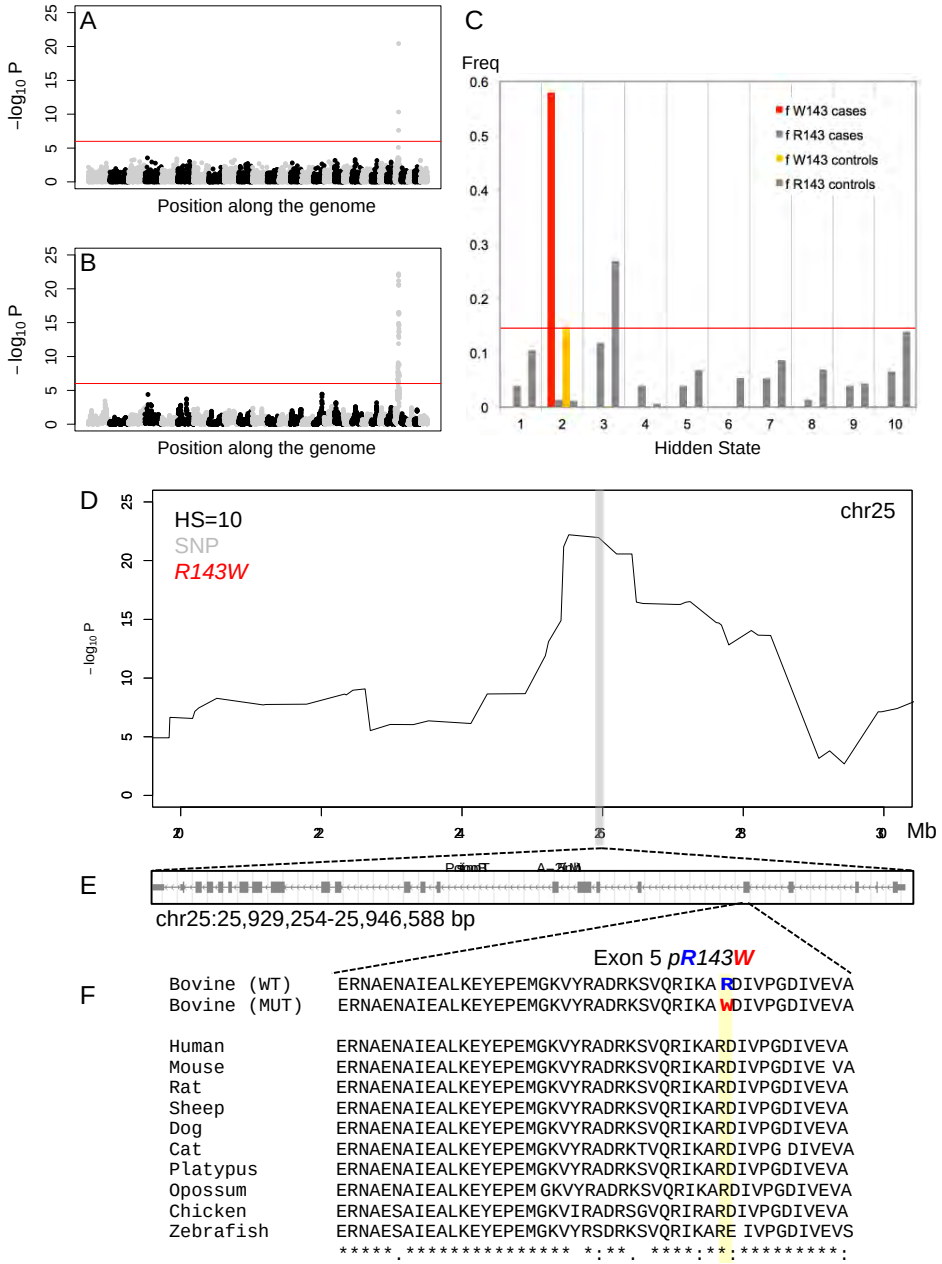

Figure 1. Mapping and fine-mapping of the 'tough and dry meat' phenotype. Manhattan plots show the respective significance of a single SNP model (A) and a ten hidden-states (HS) model (B); the horizontal red line indicates the significance threshold; alternating colors (black and grey) mark the limits between each of the 29 autosomes. (C) Frequency of the 10 HS in the 38 cases and the 1,058 controls at peak position; within each HS, frequency is given for haplotypes carrying the *W143* mutation or the wild-type allele in cases and in controls; the horizontal red line indicates the *W143* freq. in the population. (D) Association signals for a single SNP model (grey dots) and a 10HS model (black line). (E) Gene model for the *ATP2A1* gene (adapted from UCSC browser). (F) *ATP2A1* exon 5 protein alignment across vertebrates highlighting the *R143W* aa change; * marks invariant aa.

Discussion

We herein provide very strong evidence that a likely hypomorphic *ATP2A1* missense variant (*R143W*) is the cause of a newly discovered 'tough and dry meat' phenotype in BBC. Assuming that the prevalence of the condition is 12.5% in the BBC population and given the genotypic proportions observed in cases and controls, we estimate that the penetrance of the anomaly is 43% in heterozygotes and 100% in homozygotes, which at present account for 30 and 3%, respectively. We can estimate the depreciation of the non-C0 carcasses at roughly 20% by assuming that the affected cuts can only be valorized as minced meat. Further work is still needed to determine which factors affect the penetrance of the *W143* mutation. We have since confirmed that the defect is present as well in young bulls with a similar prevalence (data not shown). The frequency of the *W143* mutation appears to have been steadily increasing in the BBC population. We showed that this is likely due to the fact that the *W143* allele has a positive effect on muscle mass. It thus represents another example of the increase in frequency of a variant with a major deleterious effect because of its perceived positive impact on muscle mass – the phenotype that remains the primary selection goal in BBC. Knowing the causative mutation, will allow for effective counter selection against the *W143*. However, as heterozygotes may have a high probability to be affected (>40%), avoiding matings between carrier animals would not be sufficient to control the condition. Animals carrying the *W143* mutation should be identified by direct genotyping and progressively eliminated from the breeding stock.

635. Mitochondrial DNA copy number as a potential genetic indicator of growth and carcass traits in beef cattle

L.P. Sanglard[1*], L.A. Kuehn[2], W.M. Snelling[2], and M.L. Spangler[1]

[1]Department of Animal Science, University of Nebraska, Lincoln, NE, 68583, USA; [2]USDA, ARS, Roman L Hruska U.S. Meat Animal Research Center, Clay Center, NE, 68933, USA; lpereirasanglard2@unl.edu

Abstract

Mitochondrial DNA copy number (mtDNA CN) was investigated as a potential indicator of growth and carcass traits in a beef cattle population. Blood or leucocyte samples were subjected to low-pass whole-genome sequencing resulting in nuclear DNA (nuDNA) and mtDNA reads for 2,371 animals. Mitochondrial DNA CN was estimated as the ratio of mtDNA to nuDNA coverages. Growth and carcass traits were available for up 60,989 individuals. Genetic parameters were estimated from a bivariate animal model based on pedigree. Estimate of heritability of mtDNA CN was 0.11±0.07. Genetic correlation estimates of mtDNA CN were -0.30±0.16 with birth weight, -0.31±0.16 with age-adjusted weaning weight, -0.15±0.14 with post-weaning gain, -0.11±0.13 with slaughter weight, -0.14±0.13 with carcass weight, -0.07±0.14 with carcass backfat, 0.14±0.14 with carcass marbling, and -0.06±0.14 with carcass ribeye area. Thus, mtDNA CN is heritable and lowly correlated with growth and carcass traits. The USDA is an equal opportunity employer and provider.

Introduction

Mitochondrial DNA copy number (mtDNA CN), defined as the ratio of mitochondrial DNA (mtDNA) to nuclear DNA (nuDNA) coverages, could be a potential genetic indicator for economically important traits in beef cattle. Decreasing cost of low-pass whole-genome sequencing (LPS) makes this approach an attractive alternative to obtain mtDNA and nuDNA; hence mtDNA CN is relatively easy to obtain (Ding *et al.*, 2015). Mitochondrial DNA CN correlates with the size and number of mitochondria, which are critical determinants of mitochondrial function (Knez *et al.*, 2016). Mitochondrial DNA CN has been shown to be moderate to highly heritable (h^2~0.31 to 0.65) and associated with traits of interest in humans, such as semen quality (Tian *et al.*, 2014; Workalemahu *et al.*, 2017). However, studies are lacking in the literature for livestock species such as beef cattle. Therefore, the objectives of this work were to estimate genetic parameters for mtDNA CN and its genetic correlation with growth and carcass traits in a composite beef population comprising the Germplasm Evaluation (GPE) program from the U.S. Meat Animal Research Center (USMARC).

Materials & methods

Samples of blood (n=1,205) and leucocyte (n=766) were obtained from the USMARC GPE program and sent to GeneSeek (Neogen company, Lincoln, Nebraska) for DNA extraction and LPS. Reads were aligned to bosTau9 (ARS-UCD1.2) reference genome using bwa men v. 0.7 (Li, 2013). Mapped reads were split into mtDNA and nuDNA to estimate coverages (samtools v. 1.9). Mitochondrial DNA CN was calculated as the ratio of mtDNA to nuDNA coverages. Quality control included the removal of unmapped reads and reads with a quality score <20. Joint variant calling for mtDNA was performed in GATK v. 4 (Poplin *et al.*, 2017). SNP calls were then filtered as recommended by the software provider. Samples with <900,000 nuDNA reads were removed. Mitochondrial DNA CN was natural log-transformed for further analyses such that the distribution approached normality and the impact of potential outliers was decreased. Carcass and growth traits available included birth weight (BWT; n=60,989), age-adjusted weaning weight (AWWT; n=56,122), post-weaning gain (PWG; n=50,968), slaughter weight (SLWT, n=25,067); carcass weight (CWT; n=23,953); carcass backfat (FAT; n=23,586); carcass marbling (MRB; n=23,196), and carcass ribeye

area (REA; n=23,828). Pedigree information was available for up to 28 generations. Breed heterozygosity was calculated as one minus the sum of the products of breed fractions obtained from pedigree of the sire and dam. A more detailed description of the breeds included in the GPE project have been previously reported (Schiermiester *et al.*, 2015; Ahlberg *et al.*, 2016; Zimmermann *et al.*, 2019).

Genetic parameters were obtained from a bivariate animal model by fitting fixed effects of sex, heterosis, breed composition, contemporary group (confounded with tissue type), age at sample collection (mtDNA CN), age of slaughter (SLWT, CWT, FAT, MRB, and REA), maternal heterosis (BW and AWWT), maternal breed compositions (BW and AWWT), and age of dam (BW and AWWT). Random effects included the additive genetic effect for all models and maternal genetic and maternal permanent environment effects for BW and AWWT. Maternal effects (genetic, heterosis, and breed composition) were also investigated for mtDNA; however, they were removed from the model given that the maternal h^2 was ~0 and the effects of maternal heterosis and breed compositions were not significant.

Results

Distribution of natural log ratio mtDNA CN by sex, age of tissue collection, direct heterosis, and maternal heterosis can be seen in Figure 1. Blood samples had lower mtDNA CN than leucocyte samples ($P \leq 0.001$). Linear and quadratic effects of age were significant ($P \leq 0.02$). The effect of heterosis was not significant ($P \geq 0.47$).

Estimates of h^2 of mtDNA CN and genetic correlation can be seen in Table 1. Estimates of h^2 for mtDNA CN was 0.11 (0.07). Estimates of genetic correlation of mtDNA CN ranged from -0.31 (0.16) with AWWT to 0.14 (0.14) with MRB.

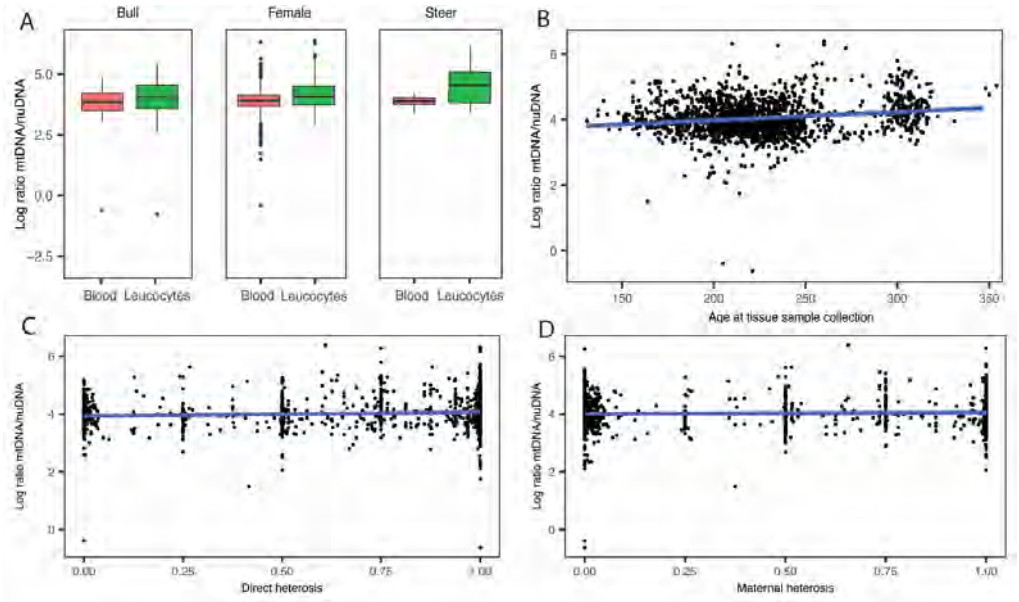

Figure 1. Distribution of natural log ratio mitochondrial DNA copy number by sex (A), age of collection (B), direct heterosis (C), and maternal heterosis (D).

Table 1. Estimates of heritability and correlation of growth and carcass traits with mitochondrial DNA copy number (mtDNA CN).

Trait[1]	Heritability	Maternal heritability	Genetic correlation	Phenotypic correlation[2]
BWT	0.44 (0.02)	0.07 (0.009)	-0.30 (0.16)	-0.06 (0.03)
AWWT	0.21 (0.01)	0.11 (0.01)	-0.31 (0.16)	-0.05 (0.03)
PWG	0.38 (0.01)	-	-0.15 (0.14)	0.009 (0.03)
SLWT	0.57 (0.02)	-	-0.11 (0.13)	-
CWT	0.56 (0.02)	-	-0.14 (0.13)	-
FAT	0.51 (0.02)	-	-0.07 (0.14)	-
MRB	0.62 (0.02)	-	0.14 (0.14)	-
REA	0.49 (0.02)	-	-0.06 (0.14)	-

[1] Birth weight, BWT; age-adjusted weaning weight, AWWT; post-weaning gain, PWG; slaughter weight, SLWT; carcass weight, CWT; carcass backfat, FAT; carcass marbling, MRB; carcass ribeye area, REA.

[2] Residual covariance was set to zero for carcass traits given no individual had both traits recorded.

Discussion

Interest in the use of whole-genome sequence data has increased, in part due to lower-cost options enabled by LPS and the possibility of including functional variants in genomic evaluations. A collateral advantage of this technology is the extraction of mtDNA and, consequently, estimation of mtDNA CN. Previous studies have shown that mtDNA CN in humans is highly heritable and associated with traits semen quality and obesity (Tian *et al.*, 2014; Ding *et al.*, 2015). Therefore, mtDNA CN could be a potential indicator trait to improve the rate of genetic gain for traits of interest in livestock. In the current study, we estimated h^2 and genetic correlations of mtDNA with growth and carcass traits in beef cattle.

Estimates of h^2 obtained in this study were lower (~0.11) than previous reports in the literature for human populations (~0.40). The differences observed could be attributed to differences in the tissue utilized to extract mtDNA, the technique to obtain mtDNA CN (PCR vs whole-genome sequencing), species (human vs cattle), the ability to quantify and fit various systematic effects in human populations, among others.

The genetic correlation estimates of mtDNA CN with growth and carcass traits were low although larger in magnitude for earlier growth traits (i.e. BWT and AWWT). The difference in sign of the correlation estimates between mtDNA CN and early growth traits vs MRB is consistent with the negative correlation between BWT and AWWT with MRB (Cundiff *et al.*, 1971; Arnold *et al.*, 1991). These results indicate that selection to decrease mtDNA CN would increase BWT and AWWT. Similarly, Reverter *et al.* (2017) reported a negative correlation between breast muscle mtDNA CN with muscle (-0.27) and carcass yield (-0.26) in broilers. Lower mitochondrial content relates to lower costs with the production and maintenance of mitochondria. Therefore, mitochondrial DNA content could be associated with metabolism efficiency (Hudson *et al.*, 2008; Hudson, 2009).

Estimates reported herein suggest that mtDNA CN is under additive genetic control of the nuclear genome in beef cattle. Mitochondrial DNA CN can be relatively easy to be obtained as a by-pass product of LPS and has the potential to be used as a genetic indicator in beef cattle. Additional research is warranted to investigate its relationship with more sparsely collected phenotypes of economic interest.

Abstract

Consumer satisfaction influences purchasing habits and ultimately the premiums consumers are willing to pay for beef. There are four criteria currently used to describe consumer satisfaction: tenderness, juiciness, flavour and overall liking. While previous studies have focused on the traits associated with consumer satisfaction such as marbling and shear force, few have analysed consumer traits directly. The aim of this study was to determine if genomic regions affecting consumer satisfaction could be discovered using a genome-wide association study. Phenotypic data including consumer sensory scores were collected for 1,924 animals from a breed diverse population of cattle genotyped for a minimum of 50k single nucleotide polymorphisms. A single region linked to the CAST gene on chromosome 7 (BTA7) was associated with tenderness. The CAST gene is responsible for muscle proteolysis after slaughter and has been well documented as impacting on the mechanical tenderness measurement of Warner-Bratzler shear force.

Introduction

Consumer satisfaction is a key trait in beef cattle breeding programs as consumers express a willingness to pay premiums for guaranteed quality and consistency (Shackelford *et al.*, 2001). Currently, predicting consumer satisfaction relies on objective carcass measurements (such as marbling, shear force and muscle pH) as databases for consumer satisfaction traits (tenderness, juiciness, flavour and overall liking) are too small and expensive to analyse alone. Recent global collaborations have allowed datasets to expand, therefore making consumer satisfaction traits more feasible to analyse. This also presents the opportunity to identify regions of the cattle genome linked directly to consumer derived sensory traits as genomic information can aid the prediction accuracy for objective carcass measurements (Pimentel and König, 2012; Mehrban *et al.*, 2017; Bedhane *et al.*, 2022). This study aims to identify genomic regions linked to consumer derived eating quality traits along with their associated variance components and respective heritabilities in a multi breed population of cattle.

Materials & methods

Animals. The data used in this study included 1,924 records sourced from various research projects conducted from 1997 to 2019. Cattle were sourced from 77 cohorts with a recorded breed profile consisting of five temperate beef breeds, five tropical beef breeds, two dairy breeds, crossbreds of the aforementioned breeds and some cattle having breed not identified in the data. This study included steers (n=1,481), heifers (n=403) and bulls (n=40). The data was recorded from ten commercial abattoirs in five states across Australia, with all animals graded for carcass characteristics such as pH, rib fat depth, fat colour, eye muscle area, meat colour, marbling, carcass weight and ossification by accredited graders. All consumer sensory data for tenderness, juiciness, flavour and overall liking was collected as described by Watson *et al.* (2008b) for cuts *longissimus lumborum* (STR045; n=1,591) and *longissimus thoracis* (CUB045; n=333) cooked using the grill method (Watson *et al.*, 2008). All samples were consumed by 10 untrained consumers and scored on a 0-100 point scale for each of the sensory variables. To remove extreme values, the two highest and two lowest values were removed. The remaining six values were then averaged for a 'clipped' sensory score. Animals with recorded age had their phenotypes pre-corrected by applying the effect of age observed in a linear model to the deviation from the mean age.

Genomic data structure, quality control and GWAS analysis. Animals were genotyped across 5 different single nucleotide polymorphism (SNP) chips (BovineSNP50 Genotyping Beadchip v1, BovineSNP50 Genotyping Beadchip v2, GGP Bovine 50K, GGP Bovine 100K and a 50k TropBeef chip). Plink v1.9 was utilised for the QC of genotypes, where SNPs with a missing rate of >0.1, a minor allele frequency (MAF) of <0.01 and those departing from the Hardy-Weinberg equilibrium at P<1E-08 were removed. The ARS-UCD 1.2 (Rosen *et al.*, 2020) map was used to merge genotypes by retaining only the markers with known genotypes on at least 60% of all individuals. This resulted in 54,728 SNPs across 29 bovine autosomes for the 1,924 cattle with phenotypic records. A GWAS was carried out using GCTA 1.93.3 *(Yang et al.*, 2011) for each consumer derived trait (tenderness, juiciness, flavour and overall liking) separately. The genomic relationship matrix (GRM) was constructed for a larger dataset of 2,567 animals through GCTA before being utilised in the GWAS. A Principal Component analysis (PCA) was carried out based on the GRM to assign individuals to breed groups in further analysis. A single SNP regression model was used to identify SNPs which were associated to the desired phenotypes using the Mixed Linear Model-based Analysis (MLMA) in GCTA software. The fixed effects in the model were cut and cohort (slaughter group), and the first three principal components of the GRM were included as covariates. The model in matrix format is stated below:

$$y = Xb + Wq + Zu + e \quad (1)$$

where y is the vector of phenotype, b is the vector of fixed effects, q is the vector of allele substitution effects, u is a vector for additive genetic effects and it was assumed to be distributed as $u|\sigma^2_g \sim N(0, G\sigma^2_g)$, where, G is the GRM as described above, X and Z are the corresponding design matrices that relates the observations to the fixed effects (b) and the random effects (u), respectively. W is the matrix of genotype codes (0,1,2) for each SNP and e is the vector of residual effects. Significance threshold was determined using the Bonferroni correction and set at $9.13e^{-07}$. Variance components and heritability were also estimated in the MLMA using GREML.

Results

The principle component analysis confirmed a large amount of background population structure in the dataset. It confirmed that the crossbred and unknown animals were likely a cross between breeds known in the population. Figure 1 illustrates the separation of the *Bos Indicus*, *Bos Taurus* beef and *Bos Taurus* dairy animals. It demonstrates the diverse population in which we attempted to find SNP associations for the four traits observed and confirmed the need to adjust for background population effects in the GWAS analysis. The phenotypic means, minimum, maximum, additive, residual variances and heritabilities (with their standard errors; SE) of the four meat quality traits are represented in Table 1. There was more phenotypic variation in consumer scores recorded for tenderness (177.7) than for flavour (106.7). Tenderness also had the highest (0.2±0.05) heritability across the four traits with juiciness having the lowest (0.13±0.05) heritability.

Table 1. Descriptive statistics, variance components and heritability of sensory traits examined with standard error (SE).

Trait	Mean	Min	Max	$V_G \pm SE$	$V_E \pm SE$	$h^2 \pm SE$
Tenderness	59.1	11.52	95.49	34.2±9.80	140.5±9.1	0.2±0.05
Juiciness	58.5	19.4	93	19.1±7.79	123.4±7.54	0.13±0.05
Flavour	60.2	21.96	92	17.1±5.55	89.6±5.55	0.16±0.05
Overall liking	59.3	12.23	96	24.2±7.40	106.3±6.86	0.19±0.05

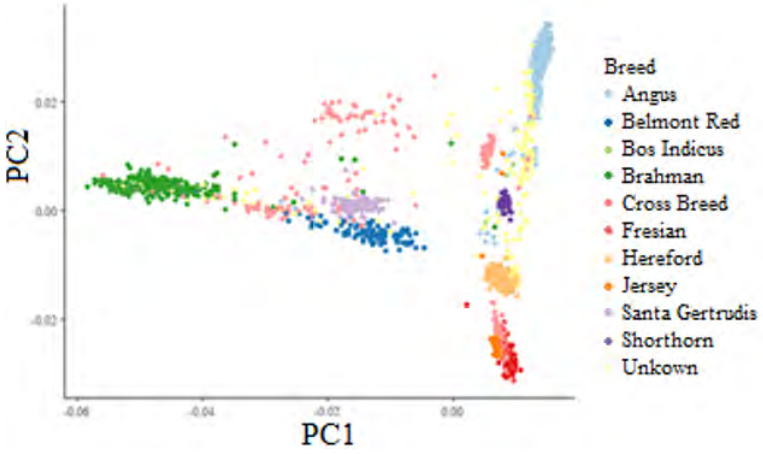

Figure 1. Plot of first two principal components depicting the genetic structure and relatedness of the population. High content *Bos Indicus* cattle stretched to the left with composite breeds between *Bos Taurus* cattle on the right.

Tenderness and overall liking were the only two traits to have observable peaks above the threshold of 5-$\log_{10}$, however only tenderness had SNPs (rs137601357 and rs109677393) on BTA7 surpassing the Bonferroni threshold (Figure 2). With rs137601357 having an effect of -3.3 tenderness units. This same region had the highest significance for other traits, however, neither juiciness or flavour passed the significance threshold. A downstream analysis of the position of the two SNP was undertaken and the two SNP were closely located to the CAST gene on BTA7.

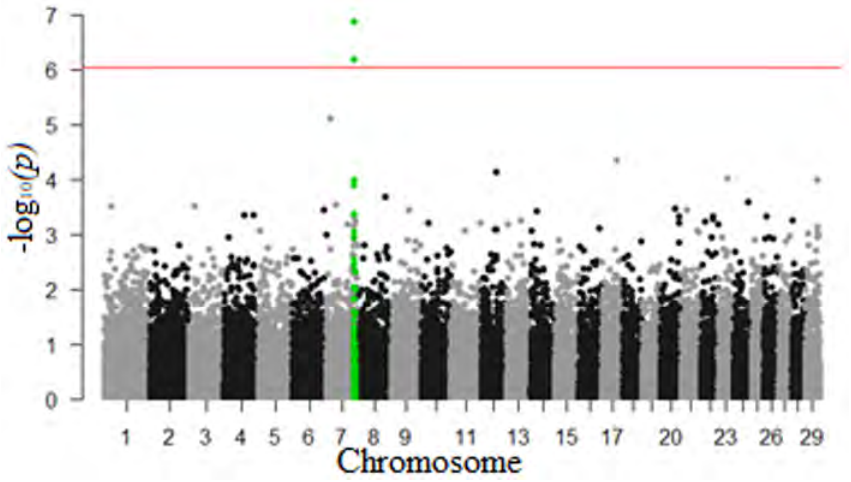

Figure 2. Manhattan plot of association between common SNPs in the population and tenderness. The genomic position is represented on the x axis and -$\log_{10}$(p) on the y axis. The red line indicates P=9.13e^{-07} to represent the Bonferroni threshold.

Discussion

This study found a low to moderate heritability for the traits included, these heritabilities are within the range of those observed by Johnston *et al.* (2003), who estimated heritability for the same traits in tropical and temperate breeds separately. Tenderness was the only trait to pass the more stringent threshold of the Bonferroni correction, both rs137601357 and rs109677393 have previously been linked to the CAST gene (on BTA7) which regulates calpastatin production which is known to influence proteolysis after slaughter and, therefore affect tenderness (Mateescu *et al.*, 2017; Abo-Ismail *et al.*, 2018). A unique feature of the current study is that it utilised a very unstructured and semi commercial dataset, achieving similar results to previous studies with more structured datasets. Future research could observe if the separation of the dataset between tropical and temperate breeds of cattle as noted in Johnston *et al.* (2003) would impact on observable peaks for consumer satisfaction traits. Alternatively the dataset could be divided based on the date of collection to observe if peaks have moved over the 23 year period of collection as important quantitative trait loci are known to move or even disappear over generations (Meuwissen *et al.*, 2016). The challenges experienced in this dataset have highlighted the importance of improved uniformity in data collection for future analysis.

This preliminary study has identified a region of the cattle genome which has been previously identified and linked to tenderness. This is supportive of the theory that muscle proteolysis due to variation in calpastatin production influenced by the CAST gene is significant for tenderness when judged by consumers. Further research is required to ascertain if this same region is evident in other populations of cattle. The next stage of this research is to incorporate a wider data set from overseas to examine if the same results are replicated on a larger scale.

637. A genome-wide scan for signatures of selection in Hanwoo and Angus cattle using whole-genome sequence data

H.J. Kim, S. de las Heras-Saldana, S. Clark and J.H.J. van der Werf*

School of Environmental & Rural Science, University of New England, Armidale, NSW, 2351, Australia; jvanderw@une.edu.au

Abstract

Signature of selection in livestock is a method used to identify genomic regions and candidate genes related to economic traits when phenotypic information is unknown. This study used 406 beef cattle (203 Hanwoo and 203 Angus) with a whole-genome sequence to find selection signatures. As a result, we identified 298 significant genomic regions within Hanwoo, including the candidate genes such as *LPL* related to the lipid metabolism and 33 genomic regions within Angus with *HK1* and *ACTC1* genes linked with glucose metabolism and muscle formation. From the between populations results, 36 significant genomic regions were detected, including the *CCKBR* gene associated with the feed efficiency. This study can assist in understanding the history of these breeds and identifying the genomic regions under selection for breeding programs in beef cattle.

Introduction

A signature of selection refers to genomic regions selected under natural or artificial selection (Qanbari and Simianer, 2014). The process of selection signature provides opportunities to find target selected genomic regions and genes related to economic traits, and understand the history of populations (Qanbari and Simianer, 2014). Many methods have been proposed for detecting signatures of selection. A common method is the extended haplotype homozygosity (EHH) method, which assesses the probabilities that two randomly chosen chromosomes carry a core haplotype homozygous for a region from the core SNP to a distant locus (Sabeti *et al.*, 2002). The use of haplotypes for signatures of selection studies has shown a higher potential to detect selection than other methods (Ma *et al.*, 2015). When searching for selection signatures, it is also important to select breeds with divergent attributes such as high meat yield in Angus and good meat quality in Hanwoo. It is then hypothesised that such breeds have been subjected to different breeding objectives and environments (Taye *et al.*, 2018). This study aimed to identify the signature of positive selection in Hanwoo and Angus cattle using whole-genome sequence data.

Materials & methods

A total of 406 animals with whole-genome sequence data, including 203 Hanwoo and 203 Angus, were used in this study. A quality control assessment of the genotypes in PLINK v.1.9 was applied to remove the SNPs with a genotype call rate of less than 95%, less than 1% minor allele frequency, and a *P*-value for Hardy Weinberg equilibrium <0.00001. After the quality control step, we extracted the SNPs that overlapped between both data sets resulting in the use of 7,868,872 SNPs from *Bos Taurus* autosome (BTA). All individuals were phased using Eagle v.2.4 to infer haplotypes in each population. The extended haplotype homozygosity (EHH) method was used with the R packages '*rehh*'. In addition, the integrated haplotype score (iHS) for within a population (Voight *et al.*, 2006) and the Rsb statistic (Tang *et al.*, 2007) for between populations assessment were used. The values of iHS and Rsb were standardized using a mean of 0 and a standard deviation of 1 for allele frequency at the core SNP and transferred from each value to the *P*-value using the Gaussian cumulative distribution function. The significance threshold for each analysis was used for iHS ($-\log_{10}$*P*-value (0.0001)>4) and for Rsb ($-\log_{10}$*P*-value(0.05)>5.48). The significant genomic regions were defined within 1 Mb of significant SNPs, and extended until there were no significant SNPs. We used the Ensembl database with the ARS-UCD1.2 bovine reference genome

to identify the candidate genes in significant genomic regions. These genes were compared with those previously identified in the Cattle QTL database (https://www.animalgenome.org/cgi-bin/QTLdb/BT/search).

Results

We constructed Manhattan plots with the *P*-value of iHS scores for each population and Rsb between populations (Figure 1). As a result, 298 significant genomic regions ($-\log_{10}$(*P*-value)>4) were detected for Hanwoo, but only thirty-three regions were identified in Angus. The most significant value of iHS was located on BTA6 (iHS=6.95) in Hanwoo and BTA10 (iHS=4.87). For the signature of selection results of the between population analysis using Rsb, 36 significant regions were detected and the most significant value of Rsb was -6.55 on BTA12.

Nine candidate genes surrounding the top 5 significant regions within the Hanwoo population were detected on BTA8 and BTA16. For Angus, there were 50 candidate genes detected in the top 5 significant regions on BTAs 6, 10, 20, 28 and 29. From the between population results, 32 candidate genes were identified in the top 5 significant genomic regions. Interestingly, the region on BTA28 was significant and shared between populations (Rsb) and the iHS results in Angus (Table 1).

Discussion

The EHH values were used to detect signatures of selection in each population. iHS, the EHH method for within population analysis, compares the ancestral allele and derived allele, while Rsb compares between populations. The iHS method found 298 and 33 significant genomic regions for Hanwoo and Angus, respectively. Genes related to the immune system and intramuscular fat were previously reported in Hanwoo (Lim *et al.*, 2016) on BTAs 2, 3, 9, 10, 11, 12, 22 and 26. But genes involved in body size, body structure and meat quality were identified for Angus on BTAs 2, 3, 4, 14, 15 and 16 (Paim *et al.*, 2020). Some significant genomic regions that overlapped with previous studies were on BTA2 and BTA11 in Hanwoo and on BTA14 in Angus.

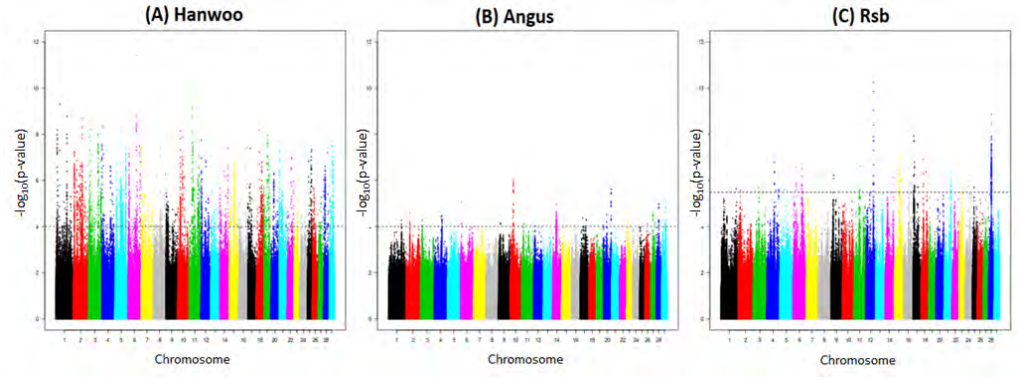

Figure 1. The Manhattan plot of $-\log_{10}$(*P*-value) of (A) iHS in Hanwoo, (B) iHS in Angus, and (C) Rsb between Hanwoo and Angus.

Table 1. The top 5 significant genomic regions and associated genes.[1]

Method	Population	Chr	Regions (Mb)	n SNP	Genes
iHS	Hanwoo	6	75.2-76.2	18	-

[1] Chr = chromosome; Mb = mega bases; n SNP = The number of SNPs in the region.

The results of iHS in Hanwoo were stronger than Angus. We assumed that Hanwoo might have had less selection pressure than Angus because the effective population size of Angus decreased faster than Hanwoo in this study. iHS is a more powerful method to detect intermediate selection sweeps than complete selection signatures. A population with weak selection pressure can have a higher number of intermediate allele frequencies than a population with strong selection pressure due to relatively taking more time for complete sweeps under a weak selection pressure population (Lopez *et al.*, 2019). This might be the reason why more significant regions were found with iHS in Hanwoo. In contrast with iHS, Rsb has the power to detect complete selective sweeps (Tang *et al.*, 2007). Most significant genomic regions from Rsb were related to Angus since this breed shows more evidence of strong selection. The nine candidate genes located close to the top 5 significant regions for the within population (iHS) assessment in Hanwoo were *LPL* and *ZBTB41*, which have been associated with the intramuscular fat in Qunchaun cattle (Oh *et al.*, 2013), and residual feed intake in Holstein (Zhou *et al.*, 2018), respectively. For Angus, the *HK1* and *ACTC1* genes were linked to glucose metabolism (Ebara *et al.*, 2013) and muscle formation (Qanbari *et al.*, 2011). These results confirm that Hanwoo has been mainly selected for meat quality traits (lipid metabolism), while Angus has been selected for growth and meat yield. For Rsb, 32 candidate genes were detected from which the *LRBA* gene was associated with the kinase A related to the immune effector of molecules (Mapholi *et al.*, 2016), and the *CCKBR* gene was associated with feed efficiency in cattle (Abo-Ismail *et al.*, 2013). These results can be helpful to confirm the evidence of selection and pre-selecting these SNPs could help to increase the genomic prediction accuracy (Ye *et al.*, 2020) for economically important traits in beef cattle breeding programs.

Abstract

Heat stress is a principal factor limiting production of animal protein in subtropical and tropical regions, and its impact is expected to increase dramatically. Development of effective strategies to improve the ability to cope with heat stress is imperative to enhance productivity of the livestock industry and secure global food supplies. However, selection focused on production and ignoring adaptability results in beef animals with higher metabolic heat production and increased sensitivity to heat stress. The heritabilities estimated in this study in an Angus-Brahman multibreed population demonstrate genetic variation, which supports the hypothesis that selection for improved thermal tolerance is possible. Moreover, the estimated genetic correlations are favorable and indicate the opportunity to develop genomic tools for simultaneous improvement of tolerance to heat stress as well as production.

Introduction

In tropical and subtropical regions where more than half of the world cattle are maintained, climatic stress is a major limiting factor of production efficiency. This stress is expected to increase due to predicted changes in climate. Beef cattle when exposed to environmental high temperature and humidity, exhibit significant declines in feed intake, growth, fertility and welfare. Selection to increase productivity disregarding the genotype × environment interaction is likely to increase susceptibility to climatic stress. This makes the quest for heat-tolerant cattle with increased efficiency of production and reproduction increasingly important. Beef producers in tropical and sub-tropical environments are incorporating a certain proportion of 'indicus' genes in their herds but, without knowledge of genes associated with thermotolerance, this also brings along negative aspects of indicus cattle. Research is needed to uncover the phenotypic and genetic relationships underlying this thermotolerance-production complex and subsequently identify the functional variants for thermotolerance without an antagonistic pleiotropy on production and reproduction. This will allow the incorporation of the G×E interaction in genomic selection programs for improvement of economically important traits in a predicted hotter world.

Animals vary in their ability to dissipate heat and, therefore, in their ability to cope with heat stress, and this variability has a genetic component. The goal of this research is to describe novel traits which can be used to characterize genetic pathways for thermotolerance which are independent or positively associated with production performance.

Materials & methods

Animal population. The University of Florida Institutional Care and Use Committee approved the research protocol (Approval no. 201203578). The population consisted of 330 heifers from the University of Florida multibreed herd (Elzo and Wakeman, 1998; Elzo *et al.*, 2016, 2017) over 2 years in 2017 and 2018. For mating purposes, animals in the multibreed herd are assigned to 6 breed groups based on breed composition: 100% Angus = 100 to 80% Angus; 75% Angus = 79 to 60% Angus; Brangus = 62.5% Angus; 50% Angus = 59 to 40% Angus; 25% Angus = 39 to 20% Angus; and 100% Brahman = 19 to 0% Angus.

Heifers were managed similarly across both years. DNA was extracted from blood samples from all animals and genotyped with the Bovine GGP F250 array (Illumina Inc., San Diego, CA, United States).

Skin biopsies. Skin samples were taken during summer (July 17, 2017 and August 7, 2018) between 07:00 and 11:00 h. Skin samples were collected from the back, 4 inches down from spine and halfway along horizontal axis. The skin was cleaned and disinfected with 70% ethanol and chlorhexidine (Clorhexidine 2%; VetOne, Boise, ID). A skin biopsy sample was collected using a 0.6 cm diameter punch biopsy instrument (Biopsy Punch, Miltex Inc., PA) and fixed in 10% formalin for approximately 24 h. Samples were dehydrated in 70% ethanol and infiltrated in liquid paraffin and stored until sectioned and stained at the UF Molecular Pathology Core. Sections were cut on a microtome with a thickness of 7 um, and sections were placed on slides, then stained with Harros-Eosin Hematoxylin. All histological sections were analyzed from digitized images obtained from a Nikon T3000 inverted phase microscope equipped image capture equipment (DMZ1200F with NIS Image Elements software). Images were obtained with the microscope in 40 X, and analyzed with ImageJ software. Sweat gland area (mm^2) and sweat gland depth as the distance from the top of the sweat glands to the skin surface (mm) were determined from a constant 4.6 mm^2 cropped image area.

Hair samples. Hair samples were collected from the shoulder, 4 inches down from spine and halfway along horizontal axis of each animal, as described in Hamblen *et al.* (2018). Hair samples were measured for length using ImageJ software. Five long and 5 short hairs from each individual were measured to evaluate the length of the topcoat and undercoat, respectively. The averages of the 5 short and long hairs were used in the statistical analysis.

Body temperature. Core body temperature was measured as vaginal temperature at 15-min intervals for 5 d using an iButton data logger (Dikmen *et al.*, 2014) inserted into a blank CIDR device and then into the vagina of each animal. Each iButton was calibrated before the study started and pre-programmed to record body temperature at 15-min intervals on a 24-h cycle. Ambient environmental conditions were monitored using HOBO data loggers which continuously record temperature, humidity dew-point temperature with HOBO-U23 data logger (Onset Computer Corp., Bourne, MA), and black globe temperature by using HOBO-U22 data logger. The temperature humidity index (THI) was calculated as in (1):

$$THI = (1.8 \times T + 32) - [(0.55 - 0.0055 \times RH) \times (1.8 \times T - 26)] \quad (1)$$

where T = air temperature (°C) and RH = relative humidity (%). This equation has been shown to be a good indicator of heat stress (Dikmen and Hansen, 2009). Only body temperatures from the 3 continuous days when cattle were on pasture undisturbed were analyzed, as described in Sarlo Davila *et al.* (2019). Based on the thresholds defined by the livestock weather hazard guide and the THI level encountered during our experiment, THI conditions between 84 and 86 were considered high THI. Body temperatures at high THI for each individual were calculated by averaging all measurements collected during the time that the THI windows occurred. This was accomplished for each heifer by averaging the body temperature from all 15-minute windows when the heifer was exposed to a high THI interval.

Carcass traits. A certified technician recorded ultrasound images from yearling calves using an Aloka 500 ultrasound system (Hitachi Aloka Medical, Ltd., Wallingford, Connecticut, USA). Analysis of the ultrasonic images with UICS Scanning Software by Walter and Associates, LLC (Ames, 106 Iowa, USA) yielded yearling ultrasound backfat (UFAT, cm) and yearling ultrasound percent intramuscular fat (UPIMF, %) phenotypes.

Statistical analyses. Average information restricted maximum likelihood (AIREML) variance components, heritabilities, additive genetic correlations, and phenotypic correlations were estimated using single-trait and pairwise two-trait animal linear mixed models. The statistical model for both analyses included the direct additive genetic and residual as random effects, breed group (based on genomic breed composition) and group of data collection as class effect, except for short hair length and skin biopsy records, where group was not significant, and age at measurement as a covariate. The pedigree file consisted of 2,327 individuals, 715 sires and 1,286 dams. All analyses were performed using the airemlf90 package from BLUPF90 software (Misztal *et al.*, 2002).

Results

Heritability estimates for skin histology characteristics, hair characteristics, body temperature under high THI conditions, and ultrasound carcass traits are provided in Table 1. A high heritability of 0.69 was estimated for the sweat gland area while the sweat gland depth had a low heritability estimate of 0.09. Heritability was estimated to be 0.33 for short hair length (undercoat) and 0.16 for long hair length (top coat). Heritability for coat score has been estimated to be 0.6, (Turner and Schleger, 1960) and McEwan Jenkinson *et al.* (1975) estimated the heritability of hair follicle measurements to range from 0.15 to 0.76. The heritability for body temperature under high THI conditions was estimated to be 0.13 which is similar the heritability estimated reported for rectal temperature in a Brahman × Angus crossbred population (0.19; Riley *et al.*, 2012) and dairy cattle (0.17; Dikmen at al., 2012). Both studies utilized cattle located in Florida. High heritability estimates were obtained for backfat (0.76) and intramuscular fat (0.37) ultrasound measures.

Two-trait AIREML estimates of direct additive genetic and phenotypic correlations between skin histology characteristics, hair characteristics, body temperature under high THI conditions, and ultrasound carcass traits are presented in Table 2. Sweat gland area had a negative genetic correlation with sweat gland depth (-0.49), short and long hair length (-0.45 and -0.28, respectively), and body temperature under high THI conditions (-0.65). These negative correlations suggest a similarity in the genetic control underlying these traits which would allow for selection of animals with large sweat glands, short hair (both topcoat and under coat), and able to maintain a lower body temperature under high THI conditions. More importantly, although weak, the genetic correlations between sweat gland area and the two production traits (backfat and intramuscular fat) were favorable (0.22 and 0.20, respectively). Similarly, there was a medium negative genetic correlation between the body temperature under high THI and the two ultrasound carcass traits, suggesting animals able to maintain a lower body temperature would be more productive.

Table 1. Additive genetic variance (σ^2_a), residual variance (σ^2_e), and heritability (h^2) estimates for skin histology characteristics (sweat gland area and depth), hair characteristics (short and long hair length), core body temperature under high THI conditions, and ultrasound carcass traits (backfat thickness and intramuscular fat) with approximate sampling errors (in parentheses).

Trait[1]	σ^2_a	σ^2_e	h^2
Sweat gland area (mm^2)	2.03 (0.62)	0.89 (0.49)	0.69 (0.18)
Sweat gland depth (mm)	0.002 (0.004)	0.02 (0.004)	0.09 (0.15)
Short hair length (mm)	1.95 (1.07)	3.97 (0.99)	0.33 (0.18)
Long hair length (mm)	3.21 (3.39)	16.82 (3.42)	0.16 (0.17)
Temperature at high THI (°C)	0.02 (0.02)	0.10 (0.018)	0.13 (0.15)
UFAT (cm)	0.001 (0.0003)	0.0003 (0.0002)	0.76 (0.19)
UPIMF (%)	0.22 (0.12)	0.38495 (0.11)	0.37 (0.19)

[1] UFAT = ultrasound backfat (cm); UPIMF = ultrasound intramuscular fat (%).

Table 2. Two-trait AIREML estimates of phenotypic (above diagonal) and direct additive genetic (below diagonal) correlations between skin histology properties, hair characteristics, and carcass traits.

Trait[1]	SWGA	SWGD	SHL	LHL	THighTHI	UFAT	UPIMF
SWGA	0.69	-0.18	-0.22	0.02	-0.23	-0.05	-0.13
SWGD	-0.49	0.09	0.32	0.26	0.12	0.08	0.22
SHL	-0.45	0.27	0.33	0.75	0.23	0.07	0.17
LHL	-0.28	0.02	1.00	0.16	0.23	0.04	0.11
THighTHI	-0.65	-0.61	-0.28	-0.45	0.13	-0.17	0.04
UFAT	0.22	-0.57	-0.34	-0.60	-0.38	0.76	0.23
UPIMF	0.20	0.49	0.08	0.09	-0.33	0.42	0.37

[1] SWGA = sweat gland area (mm^2); SWGD = sweat gland depth (mm); SHL = short hair length (mm); LHL = long hair length (mm); THighTHI = temperature at high THI (°C); UFAT = ultrasound backfat (cm); UPIMF = ultrasound intramuscular fat (%).

Discussion

The values of heritability estimated in this study indicate a large, exploitable genetic variance which can be used in selection programs to improve heat tolerance in cattle. Novel traits describing the thermotolerance phenotype such as sweat gland area, short hair length and body temperature under high THI had medium to high heritabilities. More importantly, the genetic correlations estimated in this population are encouraging, indicating favorable relationships between the thermotolerance phenotypes and the production traits. This would suggest that genetic programs to improve resilience to environmental stress could be successful and opportunities exist for simultaneous improvement of production related traits.

Abstract

Bos taurus and *Bos indicus* are the two main types of domestic cattle bred worldwide. Due to their genetic distance to a common ancestor and history of natural and human-oriented selection, they evolved different beneficial characteristics relating to animal production. It is known, in crossbred animals, that the ancestral composition affects several production traits. We defined the ancestral origin of SNP alleles and associated it with two production traits (hip height and body weight) in bulls and cows of tropical composite cattle. Four genomic regions with ancestry-related effects were identified at previously described quantitative trait loci, adding information on their origin. The methodology applied here warrants further investigation using other cattle populations and traits. A better understanding of ancestry effects on production traits opens opportunities for guided selection to accumulate favourable alleles in crossbred cattle.

Introduction

Most beef cattle production systems are based on *Bos taurus*, *Bos indicus*, or their crosses. These two ancestral cattle types (taurine and zebu or indicine) have a long history of separation, different domestication events, and distance to a common ancestral population over 280,000 years ago (Achilli *et al.* 2008, Murray *et al.* 2010). The local environmental adaptation plays a major role in the cattle type distribution worldwide, being the taurine cattle more prevalent in temperate environments, while zebu cattle are primarily bred in the (sub)tropics.

Local adaptation is highly beneficial from an animal production viewpoint. Nonetheless, it often carries productivity trade-offs. For instance, zebu cattle tend to become sexually mature later than taurine cattle. However, they are also more resistant to external parasites. Crossbreeding between these two types of cattle is used to combine the positive attributes of each ancestral type into a single animal that often outperforms their pure-bred counterparts. The proportion of taurus vs indicus ancestry in crossbred cattle has long been known to affect production traits (Porto-Neto *et al.* 2014). However, the precise location of genomic regions driving these effects needs further exploration. This article aims to map genomic regions with variable ancestry patterns and their impact on production traits.

Materials & methods

Animals and traits. The Cooperative Research Centre for Beef Genetic Technologies established the population used in this experiment to explore the genetic links between adaptation and profitability in northern Australia (Barwick *et al.* 2009). We used males and female tropical composite cattle and two trait observations, hip height (HH) and body weight (WT), measured at a mature age (cows) or post-yearling (bulls) (Table 1).

SNP genotypes. The cattle were genotyped using either the Bovine SNP50 v1, v2 or BovineHD (Illumina Inc, San Diego). Animals genotyped using the lower density arrays had their genotypes imputed to HD using an industry reference on 1,220 animals; then up to whole-genome sequence (~22.6 million SNP) using a reference set from 1000 Bull Genome Project run6 (Bouwman *et al.* 2018), 472 animals of 18 breeds.

DOI: 10.3920/978-90-8686-940-4_639, © L.R. Porto-Neto *et al.* 2022

Table 1. Summary statistics for hip height (HH, cm) and body weight (WT, kg) in cows (adult) and bulls (post-yearling).

Trait	n	Mean	Standard deviation	Min	Max
HHcow	1,034	137.30	4.68	119.30	154.69
HHbull	1,126	125.20	5.29	103.00	139.00
WTcow	1,037	523.49	55.58	282.40	737.12
WTbull	1,450	325.74	43.76	174.00	550.00

For both imputation rounds, the genotypes were first phased using Eagle (Loh *et al.* 2016), then imputed using Minimac3 (Das *et al.* 2016).

Ancestry calling of SNP alleles and genome-wide association. The haplotype-based software ChromoPaint (Lawson *et al.* 2012) was used to estimate, for each SNP in each animal, the likelihood of those alleles having *Bos taurus* or *Bos indicus* ancestry. Similarly, to the SNP imputation procedure, ChromoPaint uses a reference population to define ancestry. Here we used an extract from the 1000 Bull Genome Project run6 (Bouwman *et al.* 2018) as reference (taurine n=203 of six breeds, and zebu n=101 of three breeds). Then, the likelihood of being taurine that varies from 0 to 1 was recoded to a binary format using hard thresholds. If the likelihood was >0.75 the allele was called taurine (or 'A'), if <0.25 zebu (or 'B'), and between 0.25 and 0.75 undefined (or '0'). Only SNP with both alleles defined were considered for the genome-wide association analyses. The bi-allelic form of ancestry was used in a mixed linear model using GCTA (Yang *et al.* 2011). The mixed models included the genomic relationship matrix based on ~50K SNP genotypes (BovineSNP50), and the population and trait specific fixed and covariate effects.

Results & discussion

The considerable genetic distance between taurine and zebu cattle allowed ChromoPaint (Lawson *et al.* 2012) to define the allele ancestry of most SNP sites. On average per animal, ancestry was defined for 92% (SD=8%) of SNP. Ancestral definition was not constant along the genome, with some alleles having its ancestry definition on as low as 9% of the animals. Some genomic regions had poor ancestral definition such as parts of BTA5 and BTA15 (data not shown). These lowly differentiated regions might represent genomic regions that are less differentiated between taurine and zebu cattle either by a common selection or simply due to no selective pressure.

After recoding the likelihood of ancestry for each allele into the binary form (*taurus* vs *indicus*), and removing those undefined sites, we run genome-wide associations for each of the four traits. Inspecting the results, two chromosome regions were highly significant for most traits, a region on BTA5 and BTA14 (Figure 1).

Applying the significance threshold of $P<1.0E-7$ to the association analyses, four ancestry-related quantitative trait loci could be defined, with some regions encompassing many SNP (Table 2). If the significance threshold is relaxed, the three regions on BTA5 would be merged into one that previously has been associated with several production traits (Bolormaa *et al.* 2011, Porto-Neto *et al.* 2014, Aguiar *et al.* 2018). Our analyses also confirmed reported results showing the relevance of a region on BTA14. This region had been associated with human and bovine stature (Pryce *et al.* 2011, Bouwman *et al.* 2018) and linked to a taurine-derived allele effect on traits (Fortes *et al.* 2013), among several other associations to production traits. However, the exact gene that was suggested before (*PLAG1*) is close but outside the critical region on our analyses.

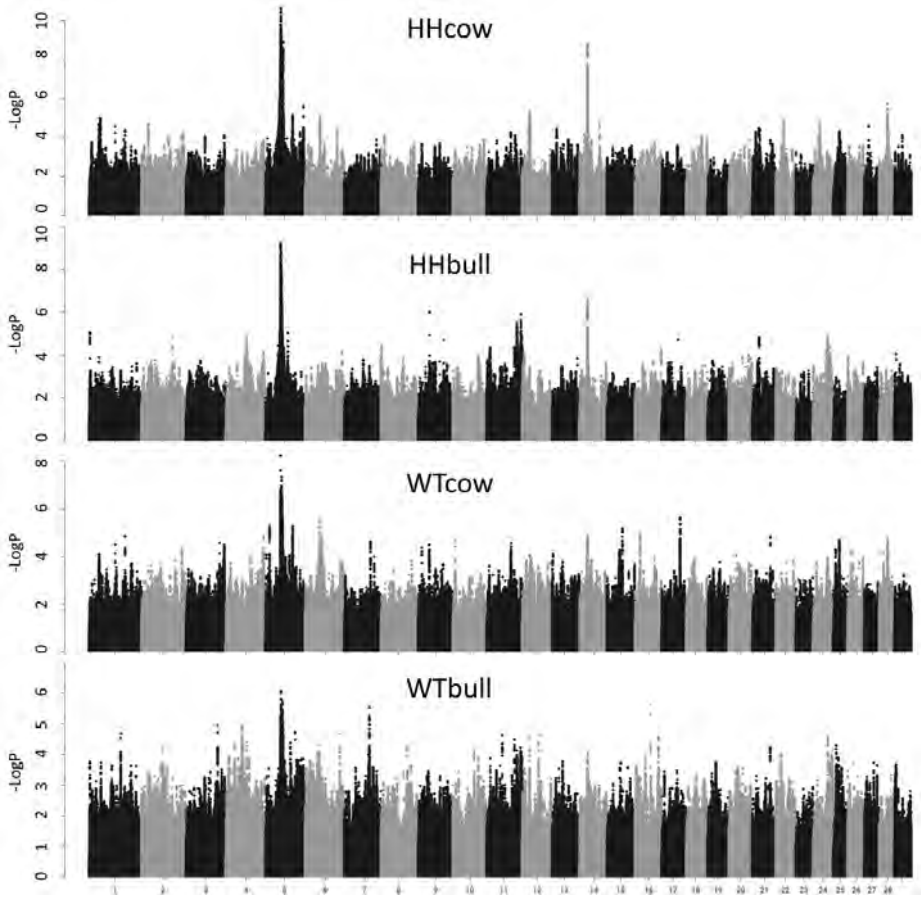

Figure 1. Manhattan plot of genome-wide association of ancestry on hip height (HH) and Weight (WT) of cows and bulls. Autosomes are in alternate colours from 1, on the left, to 29.

Table 2. Summary of the genomic regions' ancestry associated to production traits.

BTA	Main peak			N SNP <1.0E-7	Transcript type (number)	Trait[1]
	Start (Mbp)	End (Mbp)	Lowest *P*-value			
5	46.222	46.339	6.20E-10	1,902	protein coding (1)	HHbull
5	47.289	47.362	2.40E-11	4,741	0	HHcow
5	49.285	49.285	4.80E-08	14	protein coding (1)	WTcow
14	24.899	24.995	1.60E-09	272	protein coding (3), snoRNA (1), snRNA (1)	HHcow

[1] Hip height and body weight in bulls and cows.

It is worth noting that some alleles related to differential ancestry have been selected in composite cattle populations. Bolormaa *et al.* (2011) observed the accumulation of genomic segments carrying the favourable alleles in tropical composite cattle. A similar observation was done in Brahman cattle for the region on BTA14 linked to stature and BTA1 at the polled locus (Koufariotis *et al.* 2018).

The methodology applied here confirmed the relevance of considering the ancestral origin of alleles in association analyses. Further investigation could include other cattle populations and more production traits, under natural and human-guided selection. Further, it will be informative to discern the direction of each effect, to determine the ancestral origin conferring the desirable production trait. A better understanding of the effects of ancestry on production traits could assist in breeding crossbred cattle that accumulate favourable alleles, improving the sustainability of animal production systems.

Abstract

The objective of this study was to develop a novel editing criteria for anomaly detection of beef cow and calf live-weight data. Methods included generation of within-herd regression estimates and partial correlations between cow and calf live-weight records; five sources of live-weight data (i.e. professionally-recorded, owned-scales, borrowed-scales, scales hired from a depot, other) were investigated. Results suggest anomaly detection should use both within-herd regression and partial correlation estimates jointly. A contingency table was formed with herds grouped into five classes according to their herd-level regression and partial correlation estimates between cow and calf live-weight. The distribution of herds within each level of the table was the same irrespective of the source of the live-weight data, suggesting that data source did not impact the data quality. This editing criteria developed can nonetheless be used to quality control data at an individual herd-level.

Introduction

Animal live-weight contributes substantially to profitability in beef herds and is a key determinant of the overall efficiency of the beef sector (McHugh *et al.*, 2012). Calf live-weight provides an indication how soon an animal will reach slaughter, while the live-weight of the cow can directly affect its feed intake and maintenance requirements and, by extension, the herd stocking rate. Live-weight of the beef calf, cow or a combination of both has been studied extensively with both phenotypes used frequently in beef genetic evaluations globally. Live-weight can be recorded through various media such as through livestock marts (McHugh *et al.*, 2010), recorded by professionals or by producers themselves or even inferred from carcass data. Irrespective of the source of the data, errors will exist and these can impact downstream analyses. Detection of outliers or anomalies in farmer-recorded data can, for example, improve the predictability and accuracy of genetic evaluations (McHugh *et al.*, 2017; Ribeiro *et al.*, 2021). The objective of the present study was to develop a novel editing criteria for anomaly detection of beef cow and calf live-weight data. Results from this study will contribute to the formation of a specific editing criteria for live-weight data in national genetic evaluations.

Materials & methods

Data. A total of 754,118 live-weight records from 371,212 beef cows and 382,906 beef calves collected from 17,008 herds in the year 2019 were available. The live-weight data for both calf and cow were recorded on the same day; several options existed to record the live-weight data and these were categorised into five data sources (Table 1). Beef calves in this study were defined as singleton-born, aged between 50 and 365 days and weighing between 70 and 700 kg. Only beef dams from parities 1 to 15 and weighing between 300 and 1,200 kg were retained. Dam parities were subsequently categorised as 1, 2, 3, 4 or ≥5.

Table 1. Description of sources of live-weight data and number (N) of records in each.

Type	Description	n
Professional	Professionally trained individuals record weights for producers on-farm	17,740
Owned Scales	Producers that own their own scales	94,573
Borrowed Scales	Producers that borrow scales	76,246
Depot Scales	Producers that rent scales	87,493
Other	Data recorded without a defined weighing method	67,167

Only herds that recorded at least 5 calf-cow pairs of live-weight records, recorded on the same day were retained; this resulted in the removal of 4,304 herds. In all instances, professionally recorded live-weight data were assumed to represent the gold standard. Live-weight records more than ±3 standard deviations (SD) from the mean of the professionally recorded weights were initially discarded; 1,759 total calf-dam pairs were removed. Following all edits, 327,354 cow-calf weight pairs remained.

Anomaly detection. A series of strategies were used to detect live-weight anomalies. Firstly, to ensure the greatest possible quantity of data was retained, a mixed regression model was fitted to the professionally recorded live-weight data only:

$$Y = \mu + Age + Age\times Parity + Month + Sex + Sex\times Age + Sex\times DamWt + Parity\times DamWt + SirePTA + SirePTA\times sex + DamWt\ (Herd) + e \quad (1)$$

where Y is calf live-weight, μ is the population mean, Age is calf age at weighing in days, Parity is the parity of the dam, Month is calendar month of weighing, Sex is calf sex, DamWt is the covariate of dam live-weight, SirePTA is the covariate of the PTA of the calf's sire for carcass weight, DamWt is the random term for DamWt by Herd of weighing and e is the residual term. From the resultant random regression herd estimates, only herds with a random regression coefficient within ±3 standard deviations (SD) of the mean random regression estimates of the professionally recorded live-weight data were retained; this resulted in the removal of four herds.

Following the removal of the four outlier herds, the mixed regression model as described in Equation 1 was reran, but without the random terms of dam weight and herd. The fixed effect solutions from the mixed model were then subtracted from the calf live-weight data in the entire dataset.

A similar approach was taken to derive an adjusted dam live-weight, in that the mixed model which was fitted to the professionally recorded live-weight data only:

$$Y = \mu + Days + Days\times Parity + Month + Sex + Sex\times Days + Parity + e \quad (2)$$

where Y is dam live-weight, μ is the population mean, Days is days since calving, Parity is dam parity, Month is calendar month of weighing, Sex is calf sex and e is the residual term.

For the newly derived adjusted calf live-weight trait, a random regression mixed model was fitted to generate a random regression estimate per herd using the model:

$$Y = \mu + DamWt\ (Herd) + e \quad (3)$$

where Y is the adjusted live-weight, μ is the population mean, DamWt(Herd) is the linear random regression on dam weight by herd and e is the residual term.

In a second set of analyses, two generalised linear models were used with (a) the newly derived adjusted calf live-weight as the dependent variable, with no fixed effects included and (b) the newly derived adjusted dam live-weight as the dependent variable, with no fixed effects included to determine the residuals. The within herd partial correlations were then estimated between the residuals of the adjusted calf live-weight and the residuals of the adjusted dam live-weight. From the estimated herd-level random regression estimates and partial correlations between the adjusted calf and dam live-weight, a contingency table was constructed whereby herds were categorised into five distinct classes for the random regression estimates and five classes for the partial correlations (Table 2). The five classes were determined based on the distance of each herd from the standard deviation of the professional recorded data for both the regression and partial correlation estimates separately.

Results

Across all sources of live-weight data, the average age and weight of calves was 174 days and 258 kg (SD=74 kg), respectively; the average calf weight of the professionally recorded data was 253 kg. Across the five live-weight sources, the average herd-level random regression estimates for calf live-weight regressed on dam live-weight ranged from 0.009 to 0.035 (Figure 1a). The average partial correlation estimated per herd between the calf and dam live-weight residuals ranged from 0.130 to 0.324 across the five live-weight source (Figure 1b).

From the contingency table (Table 2), 10.21% of herds ranked in the very low and very high class for both the herd-level random regression and partial correlation estimates between calf and dam live-weight residuals; 3.51% herds ranked within the average class for each. Across both the herd-level random regression and partial correlation estimates, the proportion of herds within each of the five live-weight sources that ranked within very low or very high classes varied from 0.56% (professionals) to 3.04% (other).

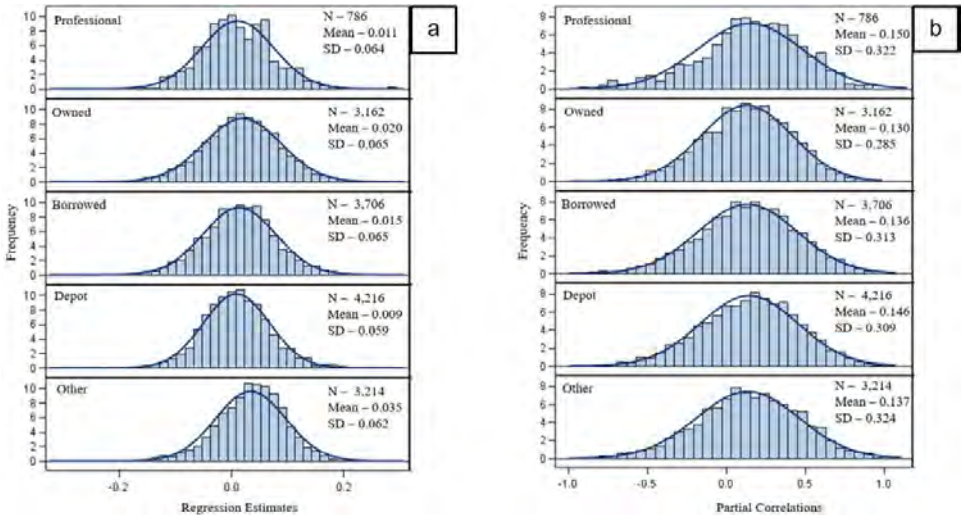

Figure 1. Frequency distribution of herd-level (a) random regression estimates of calf live-weight regressed on dam live-weight and (b) partial correlations between calf and dam live-weight residuals for each of the five data sources.

Table 2. Contingency table representing the percentage of herds within each of the five categories (very low, low, average, high and very high) for both the random regression estimates and partial correlations between calf and dam live-weight residual per herd.

		Partial correlation				
		Very low	Low	Average	High	Very high
Regression estimates	Very low	1.29	1.62	2.35	3.08	4.02
	Low	1.60	1.95	2.92	3.98	5.69
	Average	1.84	2.72	3.51	4.98	6.93
	High	2.07	3.08	4.47	5.76	8.16
	Very high	2.61	3.98	5.52	6.95	8.92

Discussion

Ensuring the integrity of the growing quantity of data being generated from multiple sources is a growing challenge. This is important not only for management purposes, but also for use in genetic evaluations. Approaches of anomaly detection in large datasets are therefore required. Although Ribeiro *et al.* (2021) investigated methods of anomaly detection using simulated data, no such analysis has been investigated using cattle live-weight on a nationally recorded dataset. Regression estimates and partial correlations between calf and dam live-weight were used to detect atypical data or indeed herds with atypical data. The contingency table revealed that only 21% of herds ranked within the same category using the partial correlations and random regression estimates, both calculated per herd for calf live-weight regressed on dam live-weight. This implies that anomaly detection using calf and dam live-weight data will vary depending on whether herd-level random regressions or partial correlations between calf and dam live-weight residuals are used separately or jointly. These results are not unexpected given that the regression estimate can be derived once the correlation and standard deviations are known for both traits (Bewick *et al.*, 2003). Regardless of the source of live-weight data, the percentage of herds that ranked below or above average in the contingency table (Table 2) (i.e. relative to the professional scored herds) was 28 and 51%, respectively. However, based on the contingency table a similar number of herds irrespective of live-weight source ranked across classes; this indicates that the sources of live-weight did not determine the quality of the data recorded by each herd. The use of this novel editing criteria has the potential to highlight herds that are providing poor data. Better data recording can be enhanced through herd-level inspections, providing higher data quality for national genetic evaluations.

Abstract

Improving sexual precocity can reduce unproductive lifetime and thus may increase farm profitability. The objective of this study was to estimate the genetic variability of sexual precocity and its relationship with pre and post-weaning performance traits. A total of 633 purebred Charolais heifers was used in this study. Sexual precocity was defined as month class from 1 (first oestrus at 14 months) to 8 (at 21 months or later). Genetic parameters were estimated using WOMBAT software. Sexual precocity was moderately heritable (0.20±0.09). Genetically, sexual precocity was positively correlated with birth weight (0.29±0.21) and average daily gain at 14 months (0.41±0.26) and negatively with backfat thickness (-0.27±0.26). Environmentally, all traits were negatively correlated with sexual precocity. Combining genetic selection of sexual precocity with good environmental conditions for raising animals seems to be the solution for reducing early unproductive lifetime of females.

Introduction

Reducing the duration of unproductive life in beef cattle could lead to an increase farm profitability. A key component of this unproductive duration in early life is the sexual precocity: early puberty enables early first mating. On one hand, age at puberty is influenced by environmental conditions, such as diet at juvenile stage (Cardoso *et al.*, 2014). On the other hand, genetic variability of age at puberty exists among French Charolais heifers (Mialon *et al.*, 1999b; Phocas and Sapa, 2004). To understand the genetic determinism of sexual precocity, an experiment was conducted with purebred Charolais heifers to estimate genetic relationship with several pre and post-weaning performance traits.

Materials & methods

Animal management and phenotypes. Between 2011 and 2015, 633 purebred Charolais heifers were born and raised in two experimental farms of the French National Institute for Agriculture, Food and Environment (INRAE): 305 animals at Bourges-La Sapinière farm (https://doi.org/10.15454/1.5483259352597417E12) and 328 animals at Le Pin-au-Haras farm (https://doi.org/10.15454/1.5483257052131956E12). Two seasons of birth were defined: winter (October to January) and spring (February to May). All females were weighted at birth (BW), double weighted at the weaning (WW) and every months during the experiment. Two average daily gains were calculated with regression of weights over time with R software (version 3.5.0): a pre-weaning one between BW and WW (ADGW) and a post-weaning one between WW and 14 months of age (ADG14). The last calculation was used to establish the weight at 14 months (W14) for everyone, the animals being not always weighted at the exact same age.

At 14 months of age, metric body measurements were performed on all females such as wither height (WH), trochanter width (TW) and body length (BL). At the same time, backfat thickness (BF) was assessed by ultrasound measurements at the fourth lumbar and body condition score (BCS) was assessed from palpation by trained technicians on a 5-point scale, from 0 (leanest animals) to 5 (fattest animals) (Agabriel *et al.*, 1986). Blood samples were collected at every 10 days from weaning to 20 months of age, and blood progesterone concentration was determined by radioimmunoassay (Terqui and Thimonier, 1974) to assess

puberty. That trait was defined as month puberty class (PC) from 1 (first oestrus at 14 months) to 8 (first oestrus at 21 months or later).

Statistical analysis. Genetic parameters were estimated using the restricted estimation of maximum likelihood (REML) method with WOMBAT software (Meyer, 2007). The model included a contemporary group, combination of farm, year and season of birth (18 groups), being born twin or singleton and age of dam at birth (classes of 3, 4, 5, 6, 7 and 8 years and older) as fixed effect for all traits, age at the weaning as covariate for WW, age at the last weight for W14, age at the mensuration as covariate for WH, TW and BL and random effect of dam (432 animals) for BW, WW and ADGW. Phenotypic correlations were calculated with R software (version 3.5.0) with corrected phenotypes using the same fixed effects and covariates as the genetic model.

Results

Mean PC was 4.5 (±2.1), however a large effect of season could be observed (Figure 1). Figure 1 presents the evolution of number of females that reached puberty at a given age regarding the season of birth. Females born in spring season were in oestrus earlier than heifers born in winter season (3.8±2.0 vs 5.5±1.7 months). As a consequence, most of the spring-born heifers were in oestrus at 17 months, while that age corresponds to the mean age at puberty of the winter-born heifers.

Descriptive statistics and heritability for all traits and phenotypic and genetic correlations with PC are presented in Table 1. The highest heritability estimated was for BW (0.51±0.12) and the lowest was for BL (0.13±0.08). Heritability of PC was intermediate (0.27±0.10). It should be noted that all traits were negatively environmentally correlated with PC. Phenotypically, all traits were also negatively correlated with PC, except BW which was independent. Genetically, low correlations were estimated except positive correlations with ADG14 (0.41±0.26) and BW (0.29±0.21) and a negative correlation with BF (-0.27±0.26).

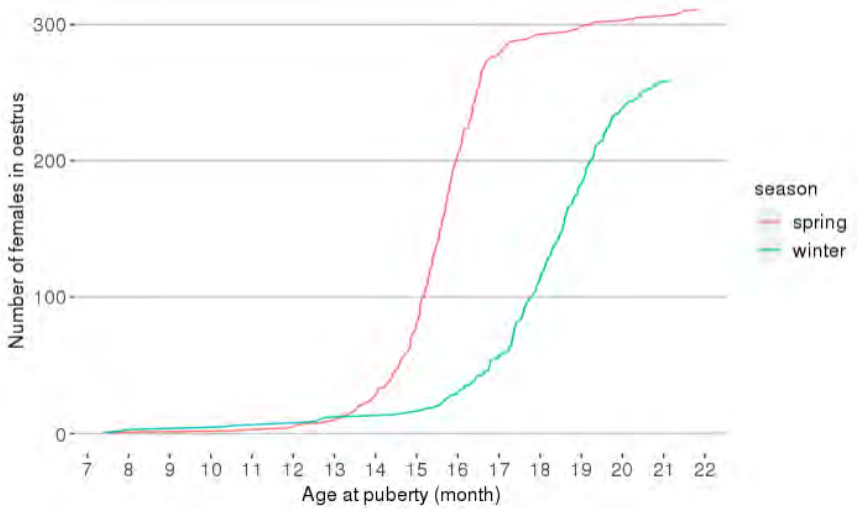

Figure 1. Number of heifers that reach puberty according to the age and the season of birth.

Table 1. Mean, standard deviation and heritability (± SE[1]) of traits and phenotypic, genetic (± SE) and environmental (± SE) correlations with month puberty class.

Trait[2]	Number	Mean	Std	h^2	r_p[3]	r_g	r_e
PC	617	4.5	2.1	0.27±0.10	-	-	-

Discussion

The average age at puberty found in this study was higher than values previously reported in the literature in the same breed. For example, 56% of Charolais heifers had a positive progesterone test at 15 months in the study of Mialon *et al.* (1999a) and 60% were observed in oestrus at 15 months in the study of Phocas et Sapa (2004). This difference may be due to the existence of two birth seasons in this experiment which had an impact on the onset of puberty: heifers born in spring were in oestrus earlier. All animals were kept indoor in winter and started grazing in March. Therefore, environmental conditions were better in spring and thus, females began to be in oestrus at this moment. Heifers born in winter were older when the environmental conditions became favourable. In the study of Mialon *et al.* (1999a), all heifers were born from mid-January to mid-April, and their results were similar to our heifers born in spring. Moreover, Cardoso *et al.* (2014) tested effect of different diet treatments on sexual precocity and highlighted that a critical window existed between 4 and 6.5 months of age. In our study, spring-born heifers were raised outdoor between birth and weaning. This practice would therefore improve the sexual precocity of heifers by optimizing the development of animals before weaning.

These results influenced the estimation of genetic parameters: for environmental correlations, all traits were indeed negatively correlated with PC. If the environment is favourable for heifers, they will have better growth and thus will be in oestrus earlier. Despite this strong effect of environmental conditions, some genetic variability was highlighted in this study, with a moderate heritability estimated for PC. Interestingly, this trait was unfavourably genetically correlated with ADG14, meaning that animals genetically driven to have higher growth between weaning and 14 months of age were also driven to an older puberty. Same trend was observed by Johnston *et al.* (2009) with an unfavourable genetic relationship between dry-season growth rate and age at corpus luteum in Brahman breed. However in the study of Mialon *et al.* (1999b), they found favourable genetic correlation between age at puberty and ADG between weaning and 12 months of -0.39 (±0.18). Sexual precocity was negatively correlated with BF, therefore heifers with higher backfat in 4th lumbar were in oestrus earlier. However, no genetic relationship was found with BCS in our study. Johnston *et al.* (2009) also highlighted negative relationship between fat trait and age at corpus luteum.

This study highlighted that sexual precocity was influenced by both environmental conditions and genetics. A genetic selection for sexual precocity combined with favourable environmental conditions can help decreasing age at puberty and therefore contribute to reduce unproductive life of females.

642. Estimation of variance components for female longevity in Australian Angus cattle using random regression models

H. Aliloo* and S. Clark

School of Environmental and Rural Science, University of New England, Armidale, NSW 2350, Australia; haliloo@une.edu.au

Abstract

Cow longevity is an economically important trait for beef cattle breeding. In this study, random regression models were used to estimate genetic parameters for female longevity in Australian Angus cattle. Longevity was defined using 10 binary records (0 for 'not in the breeding herd' and 1 for 'active in the breeding herd') between age 2 to 11. A Bayesian random regression model was fitted separately to 5 different groups of disposal reasons supplied by breeders. The heritability estimates were generally low with peaks ranging from 0.03 to 0.12. The highest and lowest heritability estimates were obtained for performance and fertility datasets, respectively. Genetic correlations were high between ages 3 to 5 and age 6 for all groups except for the structural problems group in which age 3 showed a low genetic correlation. This illustrates that selection for longevity could be undertaken early in cow's life.

Introduction

Cow longevity is a complex, economically important trait for beef cattle breeding programs. It directly relates to lifetime productivity and farm profitability by decreasing the ratio of rearing costs to production profit per animal. Improving cow longevity leads to improved animal welfare and a more sustainable beef production. Improving cow longevity also impacts the breeding program by reducing the number of replacement heifers required, for a constant herd size, which provides more opportunities for voluntarily culling based on animal performance.

Different definitions of longevity have been used in livestock breeding programs. In cattle, the most common measurements are lifetime (e.g. length of productive life) and stayability traits. Survival analysis using a proportional hazard model (PHM) is a popular method used for genetic evaluation of lifetime traits (Ducrocq *et al.*, 1998). Veerkamp *et al.* (2001) showed the equivalence between a PHM and a random regression model (RRM) when applied to binary representation of survival data (i.e. stayability). RRM were further compared to PHM by other studies where some found advantageous features of RRM (Jamrozik *et al.*, 2008) and suggested them as the method of choice for the genetic analysis of longevity traits.

The objective of this study was to apply RRMs for estimation of variance components and genetic parameters for female longevity in Australian Angus cattle population and to inform an optimal age for selection for cow longevity.

Materials & methods

Data. Raw culling and calving information of 1,438,363 cows were extracted from the Angus Australia database. For data cleaning, animals with missing date of birth, missing date of disposal or without a specific disposal reason were removed. Cows born before 2000, and those with an age at disposal of less than 19 months or greater than 20 years were excluded. The progeny records with a missing date of birth, sire and dam or those bred via an embryo transfer program were removed. Only calving records from cows with an age at first calving between 19-30 months were kept. A maximum of 2 missing calvings was permitted between two reported calving events and between the last reported calving and culling for each cow. This resulted in a total of 249,711 real calving events reported for 69,316 cows with known disposal

R.F. Veerkamp and Y. de Haas (eds)

reasons. Individual disposal reasons were categorized into 4 groups based on disposal codes supplied by breeders. This included disposal because of fertility, structural problems, animal performance and natural death (Table 1). All disposal codes were also combined into a single longevity analysis. Longevity was defined as stayability to consecutive ages. Animals present in the herd after first calving were coded as 1 at age *t* if the animal avoided disposal from age *t-1* to age *t* and as 0 if the animal was disposed from the breeding herd before age *t*. Initial investigation showed almost no variation in data after age 11. Therefore, for each animal 10 binary records were assigned from age 2 to 11 years.

Statistical model. A single-trait random regression model was fitted to estimate variance components using a Bayesian Gibbs sampler from gibbs3f90 software (Misztal *et al.*, 2018):

$$y=Xb+Hh+Za+Wp+e \quad (1)$$

where y is the vector of phenotypes, b is the vector of estimates for fixed class effect of embryo transfer and fixed regression coefficients for year-season of cow birth, h, a and p are random regression coefficients for herd of calving within year-season of cow birth, animal additive genetic and permanent environment deviations, respectively, and e is the vector of random residuals. Initial analyses were undertaken to determine the appropriate number of Legendre polynomials to use in the model. The same order of 4 Legendre polynomials was then used for fixed and all random regression terms. Random residual variance was assumed to be heterogeneous (i.e. 10 classes 1 each for each age). A total of 150,000 rounds with a burn-in of 50,000 and a thinning of 10 were used for the MCMC chain. The variance components, genetic correlations, breeding values and heritabilites were calculated using the appropriate formulations (Oliveira *et al.*, 2020).

Results

The number of animals in each disposal group are included in Table 1. The largest number of animals with known disposal reasons (~52%) were removed from the breeding herd because of fertility problems with natural death (~35%) being the second largest group. Only around 6% of cows were disposed because of voluntarily culling i.e. performance.

The estimates of additive genetic variance and heritabilites are shown in Figure 1. For all groups of disposal reasons additive genetic variance was small resulting in low heritability estimates across all ages. The highest additive genetic variance was found at age 4 for fertility, structure and performance datasets while for natural death and all reasons, the highest additive genetic variance was found at age 5 and 7, respectively. Between all groups of disposal reasons, the group with voluntarily culling reasons (i.e. performance) resulted in the highest heritability estimate while the heritability for the fertility dataset was the lowest. The heritability estimates for all disposal reasons were similar to those from natural death. High heritability values were estimated at extreme ages for animals culled due to structural problems. This was because of low amounts of phenotypic variation at extreme ages.

Table 1. The number of cows within each culling reason group.

Culling group	Number of cows
Fertility	36,442
Natural death	24,497
Performance	3,847
Structural problems	4,530
All reasons	69,316

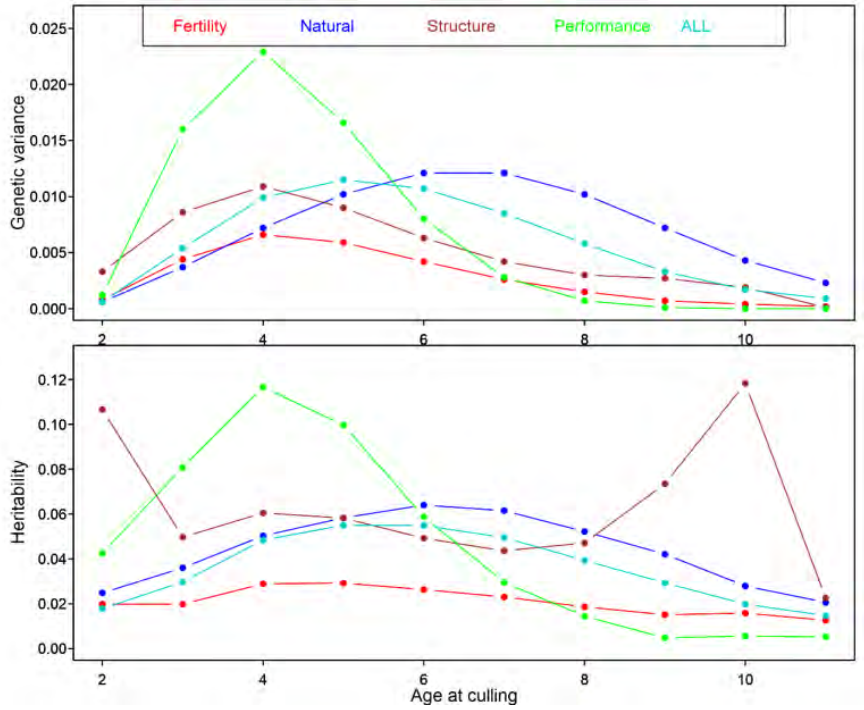

Figure 1. The estimated additive genetic variance (top) and heritabilites (bottom) for fertility (red), natural death (blue), structural problems (brown), performance (green) and all reasons (pink) disposal groups.

The genetic correlations between ages 3 to 5 and age 6 for all groups of disposal reasons are given in Table 2. As expected, for all groups of disposal reasons higher genetic correlations were observed between age 6 and more adjacent ages. Genetic correlations were lower in group of structural problems and higher in groups of performance and all reasons.

Discussion

Improving longevity can increase profitability by decreasing the involuntarily culling and therefore enabling more voluntarily culling. It is, therefore, very important to provide more specific reasons for culling animals to be able to distinguish between voluntarily and involuntarily culling. In the current study, the largest number of cows were culled due to fertility. This agreed with previous studies investigating the specific reasons of culling cows in beef cattle populations (e.g. Oliviera *et al.*, 2020).

Table 2. The genetic correlations between ages 3 to 5 and age 6.

Culling group	Age at culling		
	3	4	5
Fertility	0.8050	0.9062	0.9734
Natural death	0.7302	0.8909	0.9778
Performance	0.9019	0.9422	0.9788
Structural problems	0.5665	0.7953	0.9409
All reasons	0.8728	0.9442	0.9863

The size of estimated additive genetic variance was largest from the performance dataset and lowest from fertility. This resulted in highest and lowest heritability estimates from performance and fertility disposal groups, respectively. This may indicate that longevity from performance and fertility disposal groups can be deemed as a proxy for the actual performance and fertility traits, respectively. The estimated heritabilities from the current study are lower than those reported by Oliviera *et al.* (2020) but agree with previous studies on longevity traits in cattle (e.g. van Pelt *et al.*, 2015; Heise *et al.*, 2018).

Similar to Oliviera *et al.* (2020), we also found considerable variation in heritability from different groups of disposal reasons. This suggest that the expected genetic progress is likely to be higher from selection based on disposal reasons with higher heritability and combining all groups of disposal reasons will likely weaken the genetic progress for longevity because of a lower overall heritability. Nevertheless, the magnitude of heritability from all groups of disposal reasons imply that direct selection for longevity could improve the longevity in Australian Angus cattle. Higher number of observations are needed for all groups of culling reasons to accurately estimate variance components especially at extreme ages.

Random regression models enable the inclusion of repeated measurements of longevity at different ages to be used for estimation of genetic variance and correlations. This leads to a better use of all available information as records at adjacent ages are highly genetically correlated, resulting in an increase in stability and accuracy of EBVs compared to when only records from a single age is used. Therefore, if the aim is to select for longevity at the traditional age of 6, the inclusion of records before and after this age can help in predication of longevity at age 6. Given the high genetic correlation between age 6 and earlier ages of 3-5, selection can be done at an earlier age to maximize the genetic gain for longevity by choosing an age with the highest heritability and by shortening the generation interval.

This study showed that female longevity has a low heritability in Australian Angus cattle population and that the estimates of heritability obtained from different culling reason groups differ from each other. The peak of heritability for different groups aligned with ages where there was a balance between disposed and active animals resulting in largest variation across all ages. High genetic correlation between ages at close vicinity provides the opportunity to select at an earlier age even if target age is a later age. This lined up with ages with heritability peaks can maximize the genetic gain from selection for longevity in Australian Angus cattle.

Acknowledgements

We thank Angus Australia for providing data and funding for this study. We acknowledge Andrew Byrne, Peter Parnell and Julius van der Werf for their valuable feedbacks.

643. Eye muscle area and lean muscle area are genetically different traits in high marbling Wagyu carcasses

R.A. McEwin[1*], M.L. Hebart[1], R. Tearle[1], J. Grose[2] and W.S. Pitchford[1]

Abstract

The relationship between marbling (fat) and muscle (protein plus some fat) is generally antagonistic in beef cattle. Both traits are key components of breeding objectives with marbling determining meat quality aspects while muscle, particularly loin eye muscle area (EMA), has implications for yield especially of high value cuts. However, this antagonistic relationship does not appear to hold true in highly marbled carcasses, with high levels of marbling (intramuscular fat, IMF) pushing muscle fibre bundles apart and increasing EMA. The genetic correlation between IMF and EMA, measured using Meat Image Japan camera technology, was 0.23. Lean muscle area, calculated as EMA/(1-IMF), had a genetic correlation of -0.48 with IMF, which is more aligned to expectation from lower marbling breeds. In conclusion, caution is advised when including EMA breeding values in the breeding objectives of highly marbled animals as it is a function of IMF in addition to muscling.

Introduction

Wagyu, particularly Japanese Black Wagyu, are a breed of cattle originating from Japan that are famed for their high propensity to produce highly marbled beef. Marbling, is defined as the accumulation of adipocytes within muscle fibre bundles resulting in visible white flecks of fat when a cross section of the muscle is taken (Harper and Pethick 2004). This trait has become a strong focus in many beef breeding programs due to its association with meat eating quality through tenderness, juiciness and flavour (Thompson 2004). This is particularly important for high value cuts, such as those obtained from the *longissimus dorsi* muscle, more commonly known as the loin or eye muscle. The size of the eye muscle measured as cross-sectional area (EMA) and amount of intramuscular fat (IMF) are large profit drivers in Wagyu cattle.

Generally, accumulation of muscle and accumulation of fat are antagonistic traits, that is animals with more muscle generally have less fat due to energy partitioning. While this is particularly true when comparing muscle versus subcutaneous fat, marbling is a late maturing trait with genetic correlations against EMA usually negative and/or close to zero (Gregory *et al.* 1995, Torres-Vázquez *et al.* 2018). Distinctly different to this is the genetic correlation between EMA and marbling score reported in Wagyu which is moderate and positive (0.43, Oyama 2011).

The aim of this paper is to demonstrate that EMA is describing both marbling and muscle in highly marbled cattle and discuss implications for breeding programs, providing alternate measures.

Materials & methods

Genotype data. Genotype information on a subset of 1,091 Full-Blood Wagyu individuals with carcass information was utilised for this study. These animals were genotyped with the 30K GGP-LD (NeoGen Australasia: GeneSeek Genomic Profiler Low-Density) SNP chip. Animals were not excluded on sample call rate, however, SNPs were excluded if they possessed ≥5% missing data (95% call rate) and/or a minor allele frequency (MAF) less than 0.05. 20,955 of 29,547 SNPs were retained for the analysis. Homozygous

DOI: 10.3920/978-90-8686-940-4_643, © R.A. McEwin *et al.* 2022

genotypes were coded as -1 and 1, with heterozygous genotypes as 0. After genotype cleaning, a genomic relationship matrix (GRM) was constructed as per VanRaden's first method (VanRaden 2008);

$$\boldsymbol{G} = \frac{\boldsymbol{zz'}}{2\sum_{i=1}^{n} p_i(1-p_i)} \quad (1)$$

where Z denotes a centred matrix of allele effects with a mean of zero, p_i is the frequency of the second (minor) allele at locus i and division by $\mathbf{2}\sum p_i(1-p_i)$ scales the G matrix to be similar in magnitude (diagonal elements average 1) to the numerator relationship matrix constructed from pedigree (VanRaden 2008).

Phenotype data. A subset of phenotype data on 1,079 individuals was provided. The traits under investigation were hot standard carcass weight (HSCW, kg) and Meat Image Japan (MIJ) camera image traits; image eye muscle area (EMA, cm^2) and image intramuscular fat (IMF, %), measured at the 5^{th}-6^{th} ribbing site (Kuchida *et al.* 2006). A fourth trait, image lean muscle area (LMA, cm^2) was estimated from the camera data as:

$$\text{LMA} = ((100 - \text{IMF}) / 100) \times \text{EMA} \quad (2)$$

Model development and statistical analysis. Datum was first analysed as a series of univariate models with a general linear mixed model using ASReml-R 4.0 (Butler *et al.* 2017) such that;

$$\boldsymbol{y} = \boldsymbol{Xb} + \boldsymbol{Zu} + \boldsymbol{e} \quad (3)$$

where, b is the vector of fixed effects, u is the vector of random effects (with X and Z their respective design matrices) and e is the vector of residuals. All traits included fixed effects of dam age (Maiden; <2 year of age, Mature; 3-9 years or Old; >10 years), heterozygosity (calculated as the proportion of heterozygous genotypes, 0.36±0.02) and birth group based on a predefined age slice that grouped animals born within the same year and calving period. A birth date co-variate was also fitted nested within management group. Management groups were defined as the combination of weaning group (200 days), slaughter group and slaughter date of which there were 23 levels. EMA, LMA and IMF were not adjusted for HSCW in the models.

Having identified the appropriate models from the univariate analysis, a bi-variate analysis between all traits was conducted incorporating the univariate models. Let $\boldsymbol{y} = (\boldsymbol{y_1'}, \boldsymbol{y_2'})'$, be the combined vector of data between two traits. The mixed model for the bivariate analysis is given by:

$$\boldsymbol{y} = \boldsymbol{X^*b} + \boldsymbol{Z^*u} + \boldsymbol{e} \quad (4)$$

Table 1. Summary statistics and number of records in the subset provided for the four traits under investigation.

Trait	Units	Mean	Min	Max	SD[1]
HSCW	kg	437.8	302.0	618.5	46.8
EMA	cm^2	45.4	25.0	82.2	7.8
LMA	cm^2	32.1	17.4	65.2	6.1
IMF	%	29.1	13.5	60.3	6.6

[1] SD refers to standard deviation.

Where $\boldsymbol{b} = (\boldsymbol{b_1'}, \boldsymbol{b_2'})'$ is the $2m \times 1$ vector of fixed effects with $\boldsymbol{X^*} = \boldsymbol{I_2} \otimes \boldsymbol{X}$ the associated design matrix; $\boldsymbol{u} = (\boldsymbol{u_1'}, \boldsymbol{u_2'})'$ is the $2n \times 1$ vector of random effects with $\boldsymbol{Z^*} = \boldsymbol{I_2} \otimes \boldsymbol{Z}$ the associated design matrix and $\boldsymbol{e} = (\boldsymbol{e_1'}, \boldsymbol{e_2'})'$ the vector of residual variance ordered as for the data vector. The variance assumptions for the random effects are:

$$var(\boldsymbol{u}) = var\begin{pmatrix}\boldsymbol{u_1}\\ \boldsymbol{u_2}\end{pmatrix} = \begin{bmatrix}\sigma_1^2 & \\ \sigma_{12} & \sigma_2^2\end{bmatrix} \otimes \boldsymbol{G} \quad (5)$$

where σ_1^2 is the genetic variance at trait 1, σ_2^2 is the genetic variance at trait 2 and σ_{12} is the genetic covariance between the two traits. Univariate and bi-variate models were fitted for all traits utilising a genomic relationship matrix and heritabilities, genetic and phenotypic correlations were calculated.

Results

All traits were highly heritable (Table 2). The heritability of eye muscle area was similar to lean muscle area (0.38 vs 0.43).

The genomic phenotypic and genetic correlations were determined between all four traits (Table 3). HSCW was moderately and positively correlated with traits describing muscling, EMA and LMA respectively. However, correlations between HSCW and IMF were very low and close to zero. IMF presented differing correlations against the two muscling traits, namely the genetic correlation with EMA is lowly to moderately positive (0.23) while the genetic correlation to LMA is strongly negative (-0.48). The phenotypic correlations among these traits were similar to the genetic correlations.

Discussion

The key finding is the genetic correlation between EMA and IMF which is moderately positive (0.23, Table 3). This agrees with Oyama (2011), whom presented an unweighted mean genetic correlation of 0.43, averaged across 6 studies, and McEwin (2016) who reported a genetic correlation of 0.24 in a different data set from that herein. McEwin (2016) demonstrated that this positive correlation was explained by excessive intramuscular fat depots pushing muscle fibre bundles apart, thereby increasing EMA. This hypothesis was tested by creating a new trait which estimates LMA using a similar method to that used herein. The

Table 2. Variance components and heritabilities (with standard errors; se) of traits from univariate analysis.

Trait	σ_A^2	σ_P^2	h^2	se
HSCW	32.9	1,928	0.56	0.05
EMA	20.7	54.9	0.38	0.06
IMF	5.21	40.1	0.68	0.05
LMA	13.2	30.8	0.43	0.06

Table 3. Phenotypic (r_p above diagonal) and genetic (r_g below diagonal) correlations between traits[1]

	HSCW	EMA	LMA	IMF
HSCW		0.32	0.26	0.10
EMA	0.33		0.85	0.19
LMA	0.30	0.75		-0.39
IMF	0.02	0.23	-0.48	

[1] Standard errors range 0.01-0.04 for r_p and 0.05-0.10 for r_g.

MIJ data herein is expected to provide a more accurate description of IMF %. McEwin (2016) reported the genetic correlation between marble score and LMA as -0.37, in agreement with -0.48 reported herein for camera data. This relationship is substantially more severe than the genetic correlations reported close to zero in other breeds (Gregory *et al.* 1995, Torres-Vázquez *et al.* 2018), highlighting a potential biological preference to partition energy towards marbling over muscle in Wagyu.

The genetic and phenotypic correlations between LMA and EMA are high (0.75, Table 3), indicating IMF was removed with some accuracy and lean muscle area was truly estimated. The current breeding objective is a function of muscle weight and quality determined by IMF. It is possible that modelling the components separately may more accurately describe genetic variation in this trait of such high value. Selection index theory will be utilized to investigate this further.

Abstract

Female fertility is essential in any beef breeding program but is often treated with low priority in genetic evaluations due to low heritability, long generation intervals and difficulty of measurement. Days to calving is a female fertility trait that is both easy to measure and can be measured early in life i.e. first joining as a yearling. Utilising early in life fertility measure allows for selection at an earlier age thus it will lead to greater genetic change and improvement in the breeding objective of lifetime weaning rate. This paper reported that treating early in life measures as a different trait increased heritability estimates and variance components of days to calving, increasing accuracy. The genetic correlation between early in life measures and mature measures was high (0.81), thus selection on early in life days to calving will improve lifetime traits.

Introduction

Female fertility is the most important profit driver in beef production systems but is often ignored in genetic evaluations. This is due to female fertility traits having a low heritability, coupled with difficulty to measure, few correlated traits and longer generation intervals (Johnston *et al.* 2013). Fertility is particularly important in tropical environments however little to no genetic progress has been made. A potential solution is using early in life female fertility traits, early in life being measured in the first few years of life. This potential solution allows for genetic improvement on female fertility.

Days to calving is the number of days from the start of joining (day the bull goes in) to subsequent calving (Meyer *et al.* 1990). This trait is a function of both anoestrus and gestation length. Days to calving is a trait that can be measured multiple times over a cows lifetime, typically days to calving is evaluated as a repeated measure trait (Graser *et al.* 2005). Days to calving is a female fertility trait that uses yearling joining and subsequent joinings that measures both attainment of puberty and pregnancy rate which can produce a better selection criterion as it is cheaper and easier to measure than using multiple ovarian scans to determine age at puberty.

The present paper evaluates the effects of treating the first joining independent to mature joinings through genetic correlation, heritability estimates and variance components to allow for more genetic gain. A unique feature is that yearling joinings are rare in tropically adapted cattle so the first joining is a year earlier than typical Northern beef systems (first joined at two years).

Materials & methods

Data. Phenotype and genotype data used was provided by Popplewell Composites; a bull breeding program with a focus on breeding composite bulls adapted for Northern Australia. The breeding objective of Popplewell Composites is utilisation of retained heterosis, increasing fertility, reducing age of puberty and good growth that are well adapted for tropical environments such as Northern Australia.

CC BY

DOI: 10.3920/978-90-8686-940-4_644, © M.L. Facy *et al.* 2022

Approximately 2,600 composite cattle were genotyped across the breeding program, this was conducted over multiple years which resulted in different SNP chips being used. The SNP chips used were Illumina, GGPLD V3 30K, Illumina GGPLD V4 30K and Weatherbys Scientific Versa50K. There were 10,830 common SNPs across all SNP chips. The common SNPs were imputed to GGPLD30K (27,755 SNPs) using FImpute 2.2 (Sargolzaei *et al.* 2011) for all genotypes. Genotype data was then filtered to exclude SNPs with <1% minor allele frequency and duplicate animals. The genomic relationship matrix (GRM) was constructed from a total of 2,609 animals and 27,638 SNPs.

Phenotype data was used to calculate days to calving which is defined as the time from the day the bull goes in with the cow to the day the cow gives birth. The data included bull in date, bull out date, pregnancy test results (fetal age) and calf date of birth. Cattle in this dataset were first joined at 12-15 months old. There was a total of 649 joining one days to calving records (J1_DC) and a total of 1,593 mature (second joining onwards) days to calving records (JM_DC) with 903 unique animals. For cows that did not conceive a calf were given a corrected value. The corrected value was defined as the maximum days to calving value within each joining group plus 32 days (1.5 × 21-day oestrus cycles). The assumption is that the cows would have conceived in the next 1.5 cycles, on average, if given the opportunity. This penalty was deemed by the breeder as more appropriate than the commonly used 21 days due to some influence of indicus in the genetic makeup of the composite.

Genomic model. A linear mixed model to estimate breeding values can be written as:

$$y = X\beta + Zu + e \quad (1)$$

where y is the vector of phenotypic values for days to calving; β represents fixed effects with design matrix X; the fixed effects included in all models are contemporary group, joining number, lactation and heterozygosity fraction; Z is the design matrix for animal additive effects u; and e is the vector of residuals.

The genomic relationship matrix was constructed following VanRaden's method 1 (VanRaden 2008).

Statistical model. A linear mixed model was fit for joining one days to calving (J1_DC) with variance components and breeding values estimated. The fixed effects for J1_DC were contemporary group (which included birth group and all lifetime management groups), dam age, heterozygosity fraction covariate. Birth group was defined by year of birth and birth time: A for early in the season (1st of June to 4th of September), B for mid-season (5th of September to 30th of November) and C for late in the season (anything from 1st of December onwards. Two repeatability linear mixed models were run for days to calving: one with all joinings included (DTC) and another with all mature joinings (JM_DC; where J1_DC was excluded). The fixed effects for JM_DC was joining number, lactation status, heterozygosity fraction covariate, days postpartum (DPP) covariate nested within contemporary group. The fixed effects for DTC was joining number, DTC management group, lactation status, heterozygosity fraction covariate and DPP covariate nested within contemporary group. DPP was calculated as the number of days from last calf date of birth to next bull in date. Animal tag was fit alongside the genomic relationship matrix as a random term to account for multiple records on the same animal, thus estimating the permanent environmental variance. All models were run using ASReml-R 4.0 (Butler *et al*., 2017). A genetic correlation was estimated between J1_DC and JM_DC.

Results

Table 1 lists variance components and heritability estimates for all models. The heritability estimates for J1_DC was 0.20 with a heterozygosity coefficient of -1.90 days/%. The heritability estimates for J1_DC (0.20) was higher than DTC and JM_DC which were 0.13 and 0.14 respectively. J1_DC had the smallest heterozygosity coefficient with JM_DC having the largest heterozygosity coefficient of -2.55d/%. The residual variance was lower for JM_DC than DTC and J1_DC. The repeatability of DTC was 0.09 which was higher than JM_DC (0.03). The genetic correlation between J1_DC and JM_DC was high (0.81±0.21).

Discussion

The current study reported DTC to have a heritability of 0.13. Meyer *et al.* (1990) reported days to calving heritability in a zebu cross to be 0.086 which is lower then what was reported in the current study. However, Johnston *et al.* (1996) reported a heritability of 0.12 in an Angus herd, similar to the estimate in this study. Olasege *et al.* (2021) estimated a higher heritability for days to calving for the first five joinings, with a heritability of 0.31 for tropical composites. JM_DC had a similar heritability estimate to DTC of 0.14. There is variation in heritability estimates across different populations for days to calving.

J1_DC had a heritability of 0.20 which is high for a fertility trait. Johnston *et al.* 2013 have previously reported a heritability of joining one days to calving to be 0.22 in Brahmans and 0.13 in tropical composites. Johnston *et al.* (2013) cattle were first mated at two-year-old whereas herein they were mated as yearlings. The Brahman estimates are similar to the current study estimate of J1_DC however the tropical composites are more similar to DTC. This is due to the difference of age at first mating between Brahman and tropical composite since tropical composite mature at an early age and joining one days to calving should be measured around age of puberty.

The heritability of days to calving was lower when all joinings were included compared to the other two models (JM_DC and J1_DC). This demonstrates that when joining one is removed and treated as a different trait, more genetic variance can be accounted for thus more genetic gain can be made. This increase allows for greater genetic gain and accuracy.

Days to calving for yearling (J1_DC) and mature (JM_DC) joinings were highly correlated which suggests they could be treated as the same trait. Johnston *et al.* (2013) also reported a high genetic correlation between J1_DC and lifetime fertility traits (0.75). However, given that there was more than double the genetic variation in J1_DC than combined traits and that yearling joining success is a trait of major focus for the breeding program, it is worth reporting J1_DC and JM_DC GEBVs separately. Using early in life joining allows selection on cows after first joining, increasing selection intensity and genetic gain. Johnston *et al.* (2013) also concluded that selecting cattle based on early lifetime days to calving will improve lifetime fertility.

Table 1. Summary of variance components (standard error in parentheses), heritability, repeatability and heterozygosity coefficient (Het) estimate for days to calving models.[1]

Models	Additive variance[a]	Permanent env variance[a]	Residual variance[a]	Heritability	Repeatability	Het coefficient[b]
DTC	124 (43)	82 (43)	811 (38)	0.13 (0.04)	0.09 (0.05)	-2.45
JM_DC	115 (39)	26 (42)	741 (42)	0.14 (0.04)	0.03 (0.05)	-2.55
J1_DC	257 (122)	-	1,049 (110)	0.20 (0.09)	-	-1.90

[1] DTC = days to calving; JM_DC = mature days to calving, J1_DC = joining one days to calving; [a] days^2; [b]days/%.

Abstract

The objective of the present study was to quantify the maternal variance contributing to carcass traits. The dataset compromised of a random sample of 50,000 beef animals. Direct and maternal variances were estimated for each of the carcass traits using a linear mixed animal model. The direct genetic standard deviation for carcass weight, carcass conformation, carcass fat score and age at slaughter was 21 kg, 0.77 units, 0.99 units and 42 d, respectively; direct heritability estimates ranged from 0.42 to 0.52. Maternal variance was significantly different from zero for carcass weight and age at slaughter; maternal heritability estimates were 0.03 for age at slaughter and 0.04 for carcass weight. There was a strong negative correlation between direct and maternal effects for age at slaughter (-0.89) and carcass weight (-0.61). This study clearly shows the potential to improve maternal traits in beef cows to improve carcass performance of their progenies.

Introduction

Animals for beef production originate from suckler-based system, where cows rear calves for beef (Hocquette and Chatellier, 2011) and surplus animals from dairy systems. In suckler-based systems, weight gain of progeny in early life is influenced by the milk availability from the dam. Twomey *et al.* 2020 documented that early life differences in milk availability can influence carcass performance, where beef dams originating from dairy herds produced heavier and younger cattle at slaughter compared to beef dams originating from dairy herds, assuming the same progeny had the same genetic merit for growth traits. The present study will be the first, to our knowledge, to quantify the maternal variance contributing to carcass traits in beef cattle. The objective of this study was to estimate the direct and maternal genetic variance, for carcass weight, carcass conformation, carcass fat score and age at slaughter.

Materials & methods

Carcass records for 5,362,210 animals were obtained from the Irish Cattle Breeding Federation database 2016 to 2020, inclusive; ancestry and breed composition was also available. Carcass weight (kg), conformation score (5-score as per European Council regulations 1208/81 and 2930/81), fat score (score as per European Council regulations 1208/81 and 2930/81) and age of animal at slaughter were available. Carcass weight was measured, on average, 1 h after slaughter following the removal of the head, legs, thoracic and abdominal organs, and internal fats and hide. As described by Pabiou *et al.* (2011), carcass conformation and fat scores were graded using video image analysis and were graded under the European Union beef carcass classification system (EUROP). The resulting EUROP classification grades were transformed into a 1 to 15 scale as outlined in Englishby *et al.* (2016). Age at slaughter in days was also available for all animals.

Data edits. Dam parity was categorized as 1, 2, 3, 4, 5+; parities >10 were not considered further. Only steers and nulliparous females (i.e. heifers) slaughtered between 14 and 36 months of age and young bulls slaughtered between 12 and 24 months of age were retained. Carcass records were discarded from animals that resided in more than 3 herds during their lifetime, and/or were present in the herd they were slaughtered from for <100 days prior to slaughter. Animals with an unknown sire or dam were not considered further. Only animals originating from a beef herd and beef dam were retained. Beef herds were defined as herds

DOI: 10.3920/978-90-8686-940-4_645, © A.J. Twomey and T. Pabiou 2022

where the average dairy (Holstein-Friesian, Jersey, Norwegian Red, Ayshire, Mountbellard, and Brown Swiss) breed percentage of the cows, calving between the years 2015 and 2020, was ≤55%.

Animals were allocated to a contemporary group for subsequent use in the statistical model. All contemporary groups were formed using algorithm described by Berry and Evans (2014). The algorithm is based on grouping animals together, within herd that have dates in close proximity. Contemporary group of slaughter was defined as animals grouped based on date of slaughter, herd prior to slaughter and gender (i.e. heifer, steer, young bull). Contemporary group of entry in to the herd was defined as animals grouped based on gender, age when purchased into the same herd (from which they would be eventually slaughtered from) and the date they entered that herd. Prior to the estimation of variance components a random sample of contemporary groups was chosen, to result in a dataset with approximately 50,000 records per trait. Only contemporary groups with ≥10 animals and >1 sire represented were retained.

Statistical analysis. Variance components were estimated for carcass weight, conformation, fat score and age at slaughter using univariate animal linear mixed models in ASReml (Gilmour *et al.*, 2009). The fitted model was

$$y = X\beta + Za + Wm + Tme + e$$

where y is the vector of the trait of interest (carcass weight, conformation, fat score and age at slaughter); β is the vector of fixed effects; a is the vector of direct additive genetic effects of the animal; m is the vector of direct additive genetic effects of the animal's dam; me is a vector of permanent environmental effects of the animal's dam; e is the vector of residual effects; X is the incidence matrix for fixed effects; Z is the incidence matrix relating to the random direct additive genetic effects; W is the incidence matrix relating to the random maternal additive genetic effects; and T is the incidence matrix relating to the random maternal permanent environmental effect. The covariance structure for the random effects included in the model were assumed to be as follows:

$$\text{var}\begin{bmatrix} a \\ m \\ me \\ e \end{bmatrix} = \begin{bmatrix} A\sigma_a^2 & A\sigma_{am} & 0 & 0 \\ A\sigma_{am} & A\sigma_m^2 & 0 & 0 \\ 0 & 0 & I\sigma_{me}^2 & 0 \\ 0 & 0 & 0 & I\sigma_e^2 \end{bmatrix}$$

where A is the numerator relationship matrix; I are identity matrices with their order equal to the number of observations; σ_a^2 is the additive genetic variance; σ_m^2 is the maternal genetic variance, σ_{am} is the direct-maternal genetic covariance, σ_{me}^2 is the maternal environmental variance and σ_e^2 is the residual variance. The fixed effects included in the model for all dependent variables were a general heterosis coefficient (0.0%, >0.0 to <0.1%, ≥0.1 to <0.2%, …, ≥0.9 to <100.0%, 100.0%), a general recombination loss coefficient (0.00%, >0.00 to <0.05%, ≥0.05 to <0.10%, …, ≥0.45 to <0.50%, 0.50%, >0.50%) and dam parity. When the dependent variable was carcass weight, conformation or fat, age in months and contemporary group of slaughter were also included as fixed effects. Only when the dependent variable was age at slaughter, the fixed effects for carcass fat score and contemporary group of entry in to the herd were included in the model. The pedigree of each animal was traced back to the founder population, which was allocated to 11 genetic groups on the basis of breed.

Results

The direct genetic standard deviation for age at slaughter, carcass weight, conformation and fat score was 42 d, 21 kg, 0.77 units, and 0.99 units, respectively (Table 1). The direct heritability estimates ranged from 0.42 and 0.53. The maternal heritability estimate for age at slaughter and carcass weight was significant;

Table 1. Mean performance, genetic standard deviation for direct (σ_D), genetic standard deviation for maternal effects (σ_M), standard deviation for maternal permanent environmental effects (σ_{PE}), phenotypic standard deviation (σ_P), direct heritability estimates (h^2_D; SE in parentheses), maternal heritability estimates (h^2_m; SE in parentheses), and genetic correlation between direct and maternal effects (corr; SE in parentheses) for each carcass trait.

Trait	mean	σ_D	σ_M	σ_{PE}	σ_P	h^2_D	h^2_m	corr
Age at slaughter (days)	733	42	10	18	58	0.53 (0.024)	0.03 (0.012)	-0.89 (0.110)
Carcass weight (kg)	388	21	7	0	32	0.43 (0.022)	0.04 (0.014)	-0.61 (0.085)
Conformation (1-15)	9.36	0.77	0.06	0.00	1.18	0.43 (0.024)	0.00 (0.009)	-0.34 (0.517)
Fat score (1-5)	8.08	0.99	0.23	0.24	1.53	0.42 (0.024)	0.02 (0.013)	-0.24 (0.153)

maternal heritability for age at slaughter was 3% and for carcass weight was 4%. Maternal variance was not significant for both conformation and fat score. The genetic correlation between the direct age at slaughter and maternal age at slaughter was -0.89 (SE=0.110). For carcass weight the genetic correlation between the direct and the maternal effect was -0.61 (SE=0.085).

Discussion

In Irish suckler beef systems, calves are predominantly weaned at 5 to 9 months of age (Lorenz *et al.*, 2011). It is well documented that there is a significant maternal variance for weaning weight in beef cattle, with heritability estimates ranging from 0.20 to 0.67 (Cantet *et al.*, 1988; Weik *et al.*, 2021). In addition, Twomey *et al.*, 2020 did document a significant difference between carcass performance from progeny of beef X beef cows compare beef X dairy cows (known to have a higher milk yield) when direct genetic effects for growth were the same. Nevertheless, breeding evaluations for carcass traits in beef cattle currently do not consider the maternal variance. Thus, the objective of this study was to estimate the direct and maternal genetic variance for carcass traits.

The smaller contribution of maternal variance to carcass weight compare to weaning weight is somewhat expected as there is, on average, 15 to 19 months between weaning and slaughter in the present study and other environmental factors would have diluted the contribution of maternal variance (e.g. compensatory growth). The low maternal heritability estimates in the present study for carcass weight in cattle was similar to other species. The maternal heritability in carcass weight for Mukota pigs was 0.04 (Chimonyo *et al.*, 2007), for Brazilian commercial broilers it ranged from 0.04 to 0.10 (Grosso *et al.*, 2010) and for Swedish sheep it ranged from 0.08 to 0.12 (Näsholm 2004). Although heritability estimates are low, similar to fertility traits (Berry and Evans, 2014), there was considerable maternal genetic variability observed for age at slaughter and carcass weight which suggests that there is large potential to genetically improve dams maternal characteristics to subsequently improve their progeny carcass performance. The lack of maternal variance observed in the present study for carcass conformation and carcass fat score suggest that milk yield of the dam has no influence on muscle and fat deposition for slaughter later in life. This is likely due to the majority of growth in muscle and fat occurring later in life and closer to the time of slaughter (Wegner *et al.* 2000).

The strong negative association between direct and maternal effects reported in the present study is similar to growth traits in a large number of species, sheep (Fitzmaurice *et al.*, 2020), broilers (Grosso *et al.*, 2010) and cattle (Weik *et al.* 2021). Genetic correlations between most terminal and cow traits tend to be antagonistic (Phocas, 2009; Berry and Evans, 2014). The negative correlation observed in the present study between direct and maternal effects for carcass weight was similar to what is reported for weaning

weight, where correlations between direct and maternal effects for weaning weight range from -0.52 to -0.79 (Weik *et al.*, 2021; Cantet *et al.*, 1988). Although there is a moderate to strong genetic correlation between maternal and terminal traits, the combination of both direct and maternal traits for carcass weight and age at slaughter in a selection index can potentially achieve genetic gain in both simultaneously.

Abstract

A tropical beef composite population was studied to investigate the effects of biological type, heterosis and recombination on weaning weight, one of the most important and complex traits for the beef industry. Biological types used to group the breed composition were N (*Bos indicus* breeds), A (*Bos taurus* adapted to tropics), B (*Bos taurus* of British origin) and C (*Bos taurus* of Continental origin). The pedigree and breed composition files had 943,334 observations, while the weaning weight file had information from 230,567 animals. Biological types differed in direct and maternal genetic effects. The A group had the poorest performance in both direct and maternal effects, while the C group excelled in direct effects and the B group was better in maternal effects. The N group was intermediate for both genetic effects. The direct and maternal heterosis were both positive and important, but recombination effects acted in the opposite direction.

Introduction

The Montana Composite beef population is a project that started, in Brazil, in 1994, with the objective of producing beef bulls that should be used in natural mating, producing calves with high level of heterosis to be raised under tropical conditions. The founders were purebred Nellore cows and their crosses, and the genetics from founding sires were semen bulls from several *Bos taurus* breeds adapted to these conditions, or from British or Continental origin. Since the early stages, this population has been under full control, with pedigree and breed composition information recorded for each animal, as well as phenotypic data. In recent years, genomic data based on SNP arrays has been obtained in a broad representation of Montana cattle, being recently introduced in the genetic evaluation of the population.

The analyses of data obtained in composite populations represents a challenge, particularly when several breed groups are included. Indeed, with this data structure, the fixed part of the mixed model analyses should include, in addition to the common fixed factors (contemporary group, sex, age of dam, etc.), also the fixed effects of biological type for direct and maternal genetic effects, as well as the direct and maternal heterosis, as appropriate for the trait under consideration. However, the important effects of recombination, as proposed by Dickerson (1969), also studied by VanRaden and Sanders (2003), and, more recently by Berry *et al.* (2021) should also be considered, but were seldom studied.

The objective of this work was to investigate how weaning weight in Montana beef cattle is affected by biological type of cattle, and by direct and maternal heterosis for that trait. In addition, we wanted to assess the magnitude of maternal and individual recombination effects in a trait of economic relevance such as weaning weight, using a large data set obtained in a composite beef population.

Materials & methods

Description of population, pedigree and breed composition control. Since the beginning of the project, all founders and animals with records had pedigree and breed composition controlled. The pedigree and breed composition data sets for this analysis included 943,334 animals, with 230,567 weaning weights recorded, by 1,386 sires and 110,291 dams and belonging to 1,497 contemporary groups.

As many breeds were involved, the breed composition of each animal was expressed as biological type, as suggested by Gregory *et al.* (1985), Cundiff and Gregory (1999) from the Germplasm Project of USDA-MARC types. The groups were: N, grouping the *Bos indicus* breeds; A, for *Bos taurus* adapted for tropical conditions; B, for *Bos taurus* of British origin; and C for *Bos taurus* of continental origin. The description of the population and genetic analysis were presented in Ferraz, Eler and Golden (1999a, b). The major breed of biological type N was Nellore; in type A many breeds were included, with Bonsmara and Senepol being the most important; in group B, Red Angus and, more recently, Aberdeen Angus; in group C, Simmental was the major breed. The program was controlled by the Brazilian Ministry of Agriculture, under a program named CEIP, Special Certificate of Identification and Production, where animals can be certified and sold as breeders only if they belong to the best 30%, under a selection criterion specified by the program. To be considered a Montana Composite, the animal must have the biological type as described in Table 1.

Genetic analysis. The genetic analyses were performed with AIREML from the BLUPF90 family of programs (Misztal *et al.* 2002, 2014). The variance of contrasts among biological types was obtained from MTDFREML, which estimates standard errors of prediction of estimable functions, reported in the MTDF67 output file (Boldman *et al.*, 1995). Those analysis included in the model the fixed effect of contemporary groups (including farm, year, season, sex) and, as covariates, age of dam (linear and quadratic), age at weaning, the effects of N, A, B and C direct and maternal genetic effects, as well as the direct and maternal heterosis and recombination effects for weaning weight. In addition, the model included the random direct and maternal animal genetic effects and the permanent environment of the dams.

Significance of effects and their contrasts. The statistical significance of contrasts among biological types, and of the estimates of direct and maternal heterosis and recombination effects was tested by the ratio of the estimate relative to its standard error, assuming a t-distribution with very large degrees of freedom.

Results

Descriptive statistics. For the 230,567 weaning weight records analysed, the mean was 199.42±38.54 kg, ranging from 84.0 to 315.0 kg, with a coefficient of variation of 19.32%, with an average age at weaning of 217.18±26.93 days. The average age of dam was 67.01±35.46 months.

Biological types and their constraints, direct and recombination effects. The estimates of the direct and maternal effects for biological types N, A, B and C, and their contrasts, as well as direct and maternal

Table 1. Breed composition, grouped in biological types of Montana seedstock.

Biological type	Minimum	Maximum
Number of biological types	3	No limit
N	0	6/16
A	2/16	14/16
N + A	4/16	16/16
B	0	12/16
C	0	12/16
N + C	0	12/16

heterosis and recombination effects, expressed in kg and in percentage of the global mean weaning weight are reported in Table 2.

Discussion

The various biological types differed in their direct and maternal genetic effects for weaning weight, which is a trait of high economic relevance for the beef industry. However, more important than the biological effects, their contrasts presented very interesting results, with a significant advantage in direct genetic effects of the *Bos indicus* cattle (type N), over the *Bos taurus* adapted to tropical condition (A) and a small, but not statistically significant advantage over *Bos taurus* of British origin (B) and even a disadvantage when compared to animals of Continental origin (C). The contribution to weaning weight performance was negative for the taurine breeds adapted to the tropics, and Continental breeds had a better contribution in direct genetic effects than any other biological type.

As related to maternal genetic effects, the N group was better than A, similar to C but not as good as B. Group A had important negative effects when compared with the British and Continental groups and those European breeds did not differ significantly from each other.

Table 2. Estimates of biological type effects and their differences and direct and maternal heterosis and recombination effects on weaning weight of the Tropical Montana beef cattle population.[1]

Effect	Estimate, kg	Percentage of mean weaning weight
Biological types[2]		
N	-25.29	-12.68
A	-29.94	-29.94
B	-25.72	-12.89
C	-17.28	-8.67
Maternal N	65.53	32.86
Maternal A	56.85	28.50
Maternal B	68.35	34.28
Maternal C	66.42	33.31
N-A	4.65***	2.33
N-B	0.43 NS	0.22
N-C	-8.00***	-4.01
A-B	-4.22***	-2.12
A-C	-12.66***	-6,35
B-C	-8.44***	-4.23
Maternal N – Maternal A	8.68***	4.35
Maternal N – Maternal B	-2.82**	-1.42
Maternal N – Maternal C	-0.90 NS	-0.45
Maternal A – Maternal B	-11.50***	-5.76
Maternal A – Maternal C	-9.58***	-4.81
Maternal B – Maternal C	1.92 NS	0.96
Direct Heterosis	13.03***	6.53
Maternal Heterosis	9.44***	4.73
Direct Recombination	-10.11***	-5.07
Maternal Recombination	-5.91***-	-2.96

[1] Statistical significance levels: * = $P \leq 0.05$; ** = $P \leq 0.01$; *** = $P \leq 0.001$; NS = $P \geq 0.05$.

[2] Biological type effect: N = *Bos indicus*; A = *Bos taurus* adapted for tropical environments; B = *Bos taurus* from British origin; C = *Bos taurus* from Continental origin.

Overall, the A group had the poorest performance in both direct and maternal effects for weaning weight while the C group excelled in direct effects and the B group was better in maternal effects. The N group performed intermediately for both direct and maternal genetic effects.

Although the effects of direct and maternal heterosis for weaning weight were not of a very large magnitude, they were very important nevertheless. As expected, the direct and maternal recombination effects acted in the opposite direction to heterosis, possibly cancelling part of the positive effects of crossbreeding in the performance of calves at weaning. These results suggest that heterosis and recombination effects must be included in the analysis of composite populations, in addition to direct and maternal breed or biological type effects. Ignoring direct and maternal heterosis and recombination effects can have an impact in the rank of select seedstock when genetic merit is used as selection criteria.

Abstract

Montana is a composite cattle breed developed in Brazil in the 1990's, established with the goal of performing well in tropical climates. The Montana breed was developed with a contribution to its gene pool of nearly 52% from *indicus* cattle (N), 25% from British breeds (B), 13% from adapted *taurus* breeds (A) and 10% from continental breeds (C). Nearly 64% of the maximum heterozygosity has been retained in Montana cattle. Our results indicate that important differences in calving interval exist between the biological groups contributing to the formation of Montana cattle, with the lowest calving interval associated with the contribution of the B group, followed by N. The maximum estimated heterosis for calving interval in this population is about 12 days, corresponding to 3% of the mean. The effect of recombination was expressed as a 'recombination gain', revealing the possible existence of negative epistatic combinations retained in purebred animals.

Introduction

Crossbreeding is a well-established strategy in animal breeding, with the goals of capitalizing on heterosis and taking advantage of breed differences in various production and adaptation traits (Dickerson 1969, Dickerson, 1973). In tropical regions, crosses with B. *indicus* are very common, given their ability to adjust to the climate-associated challenges prevailing in those regions (Ferraz and Felicio, 2010). Among the different crossbreeding strategies possible in livestock species, the development of composite breeds is one approach that is particularly appealing, because it is essentially managed as a purebred system while enabling the combination of the additive genetic effects of various breeds, though maintaining some of the benefits of heterosis (Koch *et al.*, 1985). Nevertheless, in composite breeds the parents used are crossbred, and any favourable epistatic combinations that were maintained in purebred animals tend to be broken, with a consequence known as 'recombination loss' (Dickerson, 1969, Kinghorn, 1980). The consequences of recombination may, to some extent, offset the benefits arising from heterosis in these crosses (Brotherstone and Hill, 1994); however, it is also possible that recombination may result in a gain rather than a loss if, for example, epistatic interactions resulted in the maintenance of genetic combinations in purebred animals with a negative net effect on some trait(s). The Montana is a breed of cattle which was developed in Brazil in the 1990's, with the goal of combining various breed sources in one composite type of cattle, with the ability to perform well in tropical climates (Ferraz *et al.*, 1999).

The objective of this work was to investigate how calving interval in Montana beef cattle is affected by the genetic contributions of different biological types of cattle, and by heterosis and recombination effects, with the goal of assessing in retrospect the best way to combine the available breed resources.

Materials & methods

In this study, we have analysed the data set comprising pedigree and performance records for the Montana breed since it was established in 1994.

Animals. The Montana composite breed was established from four biological groups of cattle, as follows: N group, including *Bos indicus* breeds (mostly Nellore cattle); A group, including *Bos taurus* adapted to tropical conditions (Bonsmara and Senepol); B group, including *Bos taurus* of British origin (mostly Aberdeen Angus and Red Angus); C group, including *Bos taurus* of continental origin (mostly Simmental). Throughout the development of the Montana composite, those breeds were combined in different proportions, with the goal of maintaining a predominant contribution of the N group, as it is expected to have better adaptation to tropical climates. Over time, animals were selected, mostly for growth and reproductive efficiency.

Pedigrees were recorded, such that the expected contribution of each biological group to a given animal could be computed from the genetic composition of its parents, in a recursive procedure. The level of heterosis and recombination effects expected for each animal were estimated from the genetic composition of each individual and its parents, according to the model of Dickerson (1969), and computed with the modification proposed by VanRaden (2003).

Assuming that α_i^s and α_i^d are, respectively, the proportional contribution of the ith breed to the sire and dam of the jth individual, the expected heterosis in that individual is calculated as:

$$Het_j = 1 - \sum_{i=1}^{n} (\alpha_i^s \, \alpha_i^d)$$

and the expected recombination effects can be computed as:

$$Rec_j = 1 - \sum_{i=1}^{n} \frac{1}{2} \left[(\alpha_i^s)^2 + (\alpha_i^d)^{\,2} \right]$$

Data and statistical analyses. Calving intervals were calculated for all the cows in the data set, and validated if they were between 280 and 499 days. After this validation, a total of 213,038 intervals by 79,750 cows with a mean calving interval of 413.5±113.5 days were included in a mixed model analysis. The model included the fixed effects of contemporary group (418 groups), age of cow (quadratic covariate with a mean of 68.8±35.5 months), the linear effect of the contribution by each of the four biological type groups and the linear effect of the expected heterosis and recombination component for the individual. The random effects in the mixed model were the breeding value of the animal and the permanent environmental effect of the cow, using a genetic relationship matrix with 181,407 animals.

Data were analysed and variance components estimated using the BLUPF90 package and the AIREML procedure (Misztal *et al.*, 2014). After convergence, the estimated variance components were used in analyses with MTDFREML (Boldman *et al.*, 1993), to estimate the significance of differences between the solutions for biological group effects, by specifying the appropriate estimable functions to test various contrasts among biological group solutions.

Results & discussion

The calculated contributions of each of the four biological groups to the population analysed and the mean level of heterosis (relative to F1) and of recombination effects are in Table 1.

Table 1. Estimated contribution (mean % ± standard deviation) of different biological groups to the Montana population analysed and proportional heterosis and recombination effect achieved.

Contribution to current population[1]	
N	52.2±28.2
A	12.6±21.2
B	25.0±24.7
C	10.2±16.9
Heterosis	0.637±0.384
Recombination effect	0.212±0.233

[1] N = *indicus* breeds; A = *taurus* adapted breeds; B = British breeds; C = Continental breeds.

These results indicate that approximately one-half of the genetic pool of Montana cattle is contributed by the N group, one quarter by the B group, and nearly one quarter is shared between the A and C groups, in similar proportions. The level of realized heterosis was quite high, achieving nearly 64% of the maximum heterosis observed in F1 individuals. On the other hand, the amount of recombination loss achieved is over 20%, which represents the expected loss of the possible epistatic superiority present in purebreds.

Differences between biological groups for calving interval were large (Table 2), and the estimates indicate that B is the group with the shortest calving interval (i.e. best reproductive efficiency), followed by N, which was better than the A and B groups. The A group resulted in the longest calving interval.

The estimated heterosis for calving interval (Table 3) indicates that full heterozygosity, such as that observed in F1 females, is expected to result in a reduction of about 12 days in calving interval, which corresponds to about 3% of the global mean. The recombination effect had a negative value associated, i.e. it reveals the possible existence of a negative epistatic combination retained in purebred animals, which would be broken and result in a 'recombination gain' when crossbred parents are used.

Even though the impact on calving interval of both heterosis and recombination effects appears to be small in Montana cattle, these are nevertheless significant and larger than those reported for dairy cattle (Wall *et al.*, 2005). Further studies should be conducted to investigate the levels of heterosis and recombination effects realized when specific combinations of biological groups are considered in the statistical model.

Table 2. Estimated difference between biological types for calving interval.[1]

	N-A	**N-B**	**N-C**	**A-B**	**A-C**	**B-C**
Estimate (days)[2]	-19.47***	10.31***	-6.79*	29.77***	12.67***	-17.10***
Standard error	2.67	2.60	3.05	2.56	2.97	2.23

[1] Biological types: N = *indicus* breeds; A = *taurus* adapted breeds; B = British breeds; C = Continental breeds.

[2] Statistical significance: * = $P \leq 0.05$; ** = $P \leq 0.01$; *** = $P \leq 0.001$.

Table 3. Estimated effects of heterosis and recombination on calving interval in Montana cattle.

Parameter	**Estimate (days)**	**Standard error**	**% of mean**
Heterosis	-12.37***	1.33	3.0
Recombination effect	-4.48***	1.77	1.1

In conclusion, important differences in calving interval ability were detected between the biological groups contributing to the formation of Montana cattle, with advantage for the British group, followed by *indicus*. Heterosis for calving interval was small but significant, and a recombination gain was observed, possibly reflecting the existence of negative epistatic combinations in purebred animals.

Abstract

The prediction ability for growth and maternal traits using different low-density customized SNP arrays selected by informativeness and distribution of markers across the genome employing single-step genomic BLUP (ssGBLUP) was performed. The SNPs arrays were customized based on different length size windows per chromosome to select proportions of 10.0, 5.0, 2.5, 1.25 and 0.625% of markers from the 427k panel. The SNPs arrays were customized with densities of 40k, 20k, 10k, 5k and 2k, respectively. Two criteria were used to select the SNPs within a chromosome window: (1) highly informative SNPs; and (2) evenly distributed SNPs. The linear regression method (LR) was used to evaluate the prediction ability, inflation and bias of GEBV. The prediction ability was higher as the array density increased and it was similar with customized arrays higher than 10k SNPs. The genomic selection with low-density customized arrays could be feasible and cost-effective in Nellore cattle.

Introduction

To predict the GEBV for complex traits, the highest the number of markers, the increased is the chance to pick-up more markers in LD with a quantitative trait locus (QTL), improving the prediction ability of the markers. However, the use of denser marker arrays does not guarantee better predictions since the additive genetic variance is captured by a limited number of markers (Lourenco *et al.*, 2020). In a simulated study, Pocrnic *et al.* (2016) demonstrated that the number of markers required to explain the variation of the genomic matrix increased as a function of the Ne and concluded that the optimal dimension of the genomic matrix should include markers explaining 95 to 98% of the additive genetic variation to obtain reliable predictions with a less computational cost. The customization of low-density SNPs arrays has been a topic of interest to reduce the genotyping costs as well as the computational requirements for the genomic evaluations. It is well understood that *Bos taurus indicus* breeds need a different subset of informative SNPs than *Bos taurus taurus* breeds to adequately perform genomic selection in such breeds (Nayee *et al.*, 2018). The Illumina BovineHD BeadChip opened opportunities to develop customized or *in silico* SNPs arrays for *Bos taurus indicus* beef cattle breeds to be applied on genomic evaluations. Therefore, the knowledge of the population structure and the use of low-density SNP arrays that prioritize informative markers is an interesting strategy to obtain reliable and unbiased GEBV predictions with a lower cost and higher computational optimization (Wongpom *et al.*, 2019). The minor allele frequency (MAF) is an important informative propriety of the population's background to predict the GEBV (Zhu *et al.*, 2017), and the estimation of the genomic matrix allows the inclusion of more markers with high MAF (VanRaden, 2008). The objective of this study was to evaluate the prediction ability for growth and maternal-related traits using SNPs arrays with different marker densities based on SNP informativeness employing the ssGBLUP methodology in a Nellore beef cattle population.

Materials & methods

Phenotypic and genotypic records from the Nellore Brazil breeding program coordinated by the National Association of Breeders and Researchers (ANCP, Ribeirão Preto-SP, Brazil) were used. A total of 1,195,831 records for adjusted weight at 210 days were used. Weight records were measured between 1974 and 2018. The phenotypic and genomic data of the population was divided into partial and complete datasets using information of animals born from 1974 to 2008 and 1974 to 2018, respectively. A total of 945 representative sires of the main Nellore lineages were genotyped with the Illumina BovineHD BeadChip (Illumina Inc., San Diego, CA, USA). Quality control was performed on PreGSf90 program (Aguilar *et al.*, 2014). After quality control, 427,495 markers (427k) and 914 animal samples were available for analyses. The descriptive statistic for adjusted weight at 210 days is presented in Table 1. The SNPs arrays were customized based on different length size windows per chromosome to select proportions of 10.0, 5.0, 2.5, 1.25 and 0.625% of markers from the 427k panel. As a result, the SNPs arrays were customized with densities of 40k, 20k, 10k, 5k and 2k, respectively. Two criteria were used to select the SNPs within a chromosome window: (1) highly informative SNPs (H-I); and (2) evenly distributed SNPs (E-D). For the first criteria, markers with MAF close to 0.5 were selected by chromosome for each customized marker density. To select evenly distributed SNPs, the average distance between adjacent SNPs by chromosome for each customized marker density was considered. A total of 11 scenarios were evaluated considering the customized SNP arrays (427K, 40K_H-I, 40K_E-D, 20K_H-D, 20K_E-D, 10K_H-I, 10K_E-D, 5K_H-I, 5K_E-D, 2K_H-I, and 2K_E-D). The contemporary group (CG) were composed by farm, sex, year and season of birth, and management group at weaning (n=36,196). Records within ±3.5 standard deviations range from the CG mean, and CG with at least ten animals were considered in the analysis. The ssGBLUP was implemented to obtain the genomic predictions (Aguilar *et al.*, 2010). The model included the fixed effects of CG, calving dam age and the animal age at weaning as covariable (linear effect). The random effects of direct genetic additive, maternal genetic and maternal permanent environmental were also included in the model. The prediction ability, inflation, and bias of the genomic prediction for each scenario was evaluated with the Linear Regression (LR) method (Legarra and Reverter, 2018). The genotyped animals born after 2008 were selected for the validation dataset (n=267) and those before 2008 for the training dataset (n=647). The correlation (r) between the GEBVs obtained with the complete dataset and 427k array (GEBVc_427k) with the GEBVs predicted with the partial dataset (GEBVp) for each scenario (GEBVp_427k, GEBVp_40k, GEBVp_20k, GEBVp_10k, GEBVp_5k, GEBVp_2k) was calculated. The inflation was evaluated through the regression of GEBVc_427k on GEBVp for each scenario considering only the animals of the validation dataset. The bias was measured as the difference of the average GEBVp with the average GEBV of complete dataset.

Table 1. Number of records and descriptive statistics for the complete and partial dataset for adjusted weight at 210 days.

Dataset	Genotypes	Offspring	Total records	Mean±SD
Partial[1]	647	84,510	523,935	181.49±31.14
Complete[2]	914	266,546	1,195,831	189.10±31.10

Results

The prediction ability or correlation (r), inflation (b1) and bias (d) between the GEBVc_427k and the GEBV obtained with customized SNP densities in the validation subset (partial dataset) is shown in Table 2.

Discussion

The prediction ability improved as the marker density increased. The prediction ability was similar and moderate to high for marker density arrays higher than 10k. Comparing the criteria to select SNPs (H-I or E-D), similar prediction abilities were obtained for marker densities higher than 2k arrays. For 2k arrays, higher prediction abilities for W210 were observed for E-D markers. The inflation (b) of the predictions increased as the marker density decreased. The higher inflation (b) was observed for marker densities arrays of 2k and 5k, while the 10k, 20k, and 40k displayed similar and less inflated predictions. Minor differences between H-I and E-D criteria were detected when considering marker densities arrays below 5k. As the SNP density decays, the low heritability trait (0.12), such as the maternal effect for adjusted weight at 210 days, displayed the highest inflation (b), and the inflation was maximum at the lowest SNP density arrays. The bias (d) tends to decrease as the SNP densities array decrease, and there were no major differences among the criteria applied to select such SNPs. Despite there was a trend in decreasing the bias (d) as the SNP density array decreased, the dispersion or variance of the predictions increased, elucidated by the standard deviation. For all customized SNP arrays, the bias was higher for direct effects than did for the maternal. The results obtained in this study shown that moderate to low density in silico arrays, prioritizing

[1] H-I= selected markers with high informativeness; E-D= markers evenly distributed.

informative markers, were capable to estimate genomic relationship coefficients allowing the estimation of reliable genomic predictions for growth and maternal related traits in Nelore cattle. The results revealed that genomic selection with low-density customized arrays could be feasible and cost-effective in Nellore beef cattle. Therefore, there is an important margin to reduce high or moderate to low-density SNPs arrays without compromising the predictive capacity of the genomic information using the ssGBLUP method. This fact opens the opportunity for indicine beef cattle breeding programs develop *in silico* SNPs markers arrays for GEBVs predictions, minimizing the number of SNPs to be imputed. At least 10,000 informative SNPs obtained from the Illumina BovineHD BeadChip SNPs are necessary to adequately predict the GEBVs for growth and maternal related traits of young candidates with the ssGBLUP method.

649. Applying single step genomic evaluation and integrating local with foreign EBVs to increase calving performance

S. Naderi*, T. Pabiou and R.D. Evans

The Irish Cattle Breeding Federation, Highfield House, Newcestown Road, Bandon, Cork, Ireland; snaderi@icbf.com

Abstract

The objective of this study was to validate single step genomic breeding values (ssGEBV) for direct calving difficulty compared with non-genomic breeding values (EBV) and integrated (ssG)EBV. Calving difficulty genetic evaluation are undertaken for dairy heifers (DH), dairy cows (DC), beef heifers (BH) and beef cows (BC) calving scores with birth weight and birth size included as predictor traits. Single step GTBLUP approach was applied for a 6-trait calving difficulty evaluation on 1.77 million genotyped animals. To incorporate the international EBVs into domestic evaluation a joint evaluation was run where deregressed EBVs (DRP) were used as extra records weighted by their associated effective record contributions (ERC). The correlation between (G)EBV from well proven sires and their adjusted phenotypes was considered as the accuracy. Including genomic information and applying ssGTBLUP improved the accuracy for all six traits. In addition, blending the international EBVs into the domestic evaluation further improved the accuracy.

Introduction

The current routine GEBV estimation for Irish dairy and beef calving performance traits are based on a two-step approach, in which a reference population is first built to estimate the SNP marker effects, which are then used to calculate GEBVs for young animals. Incorporating the genomic information into traditional animal models used in national evaluations and applying a single-step genomic evaluations (ssGBLUP) could reduce potential biases in the GEBV estimation by simultaneously combining genomic, pedigree and all local phenotypic information. ssGBLUP has not been broadly implemented in large-scale national dairy or beef cattle evaluations due to large computational cost. Mäntysaari *et al.* (2017) developed an efficient computational approach for ssGBLUP called ssGTBLUP which requires less computation than ssGBLUP in iteratively solving by a preconditioned conjugate gradient (PCG) method. Moreover, integrating foreign information (i.e. MACE) into the national evaluation is advantageous but poses further challenges. Implementing a joint evaluation with national phenotypes in a single evaluation would enable the propagation of foreign information into domestic animals' evaluations even if they did not participate in the international evaluation itself. Therefore, the objective of this study was to explore and validate a ssGTBLUP approach comparing it with a traditional evaluation but also exploring the benefit of integrating foreign EBVs into the Irish genetic evaluation for calving performance traits.

Materials & methods

Calving difficulty in Ireland is assessed on a scale from 1 (i.e. no assistance) to 4 (i.e. with veterinary assistance). Four different calving traits are defined: dairy heifers (DH), dairy cows (DC), beef heifers (BH) and beef cows (BC) were defined. Birth weight (BW; kg) and birth size (BSIZE; 1 to 5 scale) are included in the multi-trait genetic evaluation as predictor traits. The number of records as well as some statistics for each trait is in Table 1. The total number of animals in the pedigree was 25,957,178 while the number of genotyped animals in the evaluation was 1,775,185.

Table 1. Number of records and the statistics for six different traits of dairy heifers (DH), dairy cows (DC), beef heifers (BH), beef cows (BC), birth weight (BW; kg) and birth size (BSIZE).[1]

Traits	Mean	SD	Min	Max	No.[2]
DH	1.31	0.60	1.00	4.00	1,894,408
DC	1.21	0.51	1.00	4.00	6,347,887
BH	1.40	0.71	1.00	4.00	924,801
BC	1.26	0.57	1.00	4.00	5,889,128
BSIZE	3.16	0.68	1.00	5.00	1,932,005
BW	41.47	7.91	20.00	115.00	199,759

[1] Max = maximum; Min = minimum; SD = standard deviation.

[2] Number of phenotypic records (No.) for each trait.

Traditional breeding values (EBVs) as well as genomic breeding values (GEBVs) were estimated for each of the six traits using the following multiple linear mixed model:

$$y_i = \mathrm{Xb} + Z_a u_a + Z_m u_m + Z_{mpe} u_{mpe} + \mathrm{e}$$

where y_i is a vector of phenotypes record for all animals with records and for trait i (i =1: 6), X is the incidence matrix for fixed effects, b is the vector of fixed effects consisting of breed proportions and specific heterosis effects, birth year, sex of calf and age of dam, Z_a, Z_{am} and Z_{mpe} are the incidence matrices relating the random effects u_a for direct additive genetic, u_m for maternal genetic and u_{mpe} for maternal environmental effects to observations in y; and e is a vector of random residuals. For the traditional genetic evaluation, it was assumed that $\boldsymbol{u_{a(m)}} \sim N\left(0,\ \boldsymbol{A}\sigma^2_{ua(m)}\right)$ where $\sigma^2_{ua(m)}$ are the direct(maternal) additive genetic variances and A is pedigree relationship matrix, and $\boldsymbol{u_{mpe}} \sim N\left(0,\ \boldsymbol{I}\sigma^2_{umpe}\right)$ where σ^2_{umpe} are the maternal environmental variance For the estimation of GEBV, an efficient computational approach presented by Mäntysaari *et al.* (2017) called ssGTBLUP was used where the genomic relationship matrix was constructed based on the following equation:

$$\mathrm{G_C} = \mathrm{G_0} + \mathrm{C}$$

where $\mathrm{C} = w\mathrm{A}_{gg}$, w is the residual polygenic proportion, A_{gg} is the pedigree relationship matrix among the genotyped animals and $\mathrm{G_0}$ is the genomic relationship matrix constructed based on VanRaden (2008) method 1. The matrices and vectors which are describing the linear equations system as well as efficient computation method with low memory cost for solving the equations in ssGTBLUP is outlined in detail by Mäntysaari *et al.* 2020.

To integrate direct Interbull EBVs and reliabilities into the Irish dairy evaluation as well as direct and maternal Interbeef EBVs and reliabilities, direct and maternal DRP were included into the model as extra traits weighted with their corresponding ERC. The ERC for both direct and maternal EBVs were computed using the reversed Harris *et al.* (1988) algorithm based on the reliability, pedigree and the traits' heritability. Direct and maternal EBVs were deregressed into direct and maternal DRP using the methods proposed by Jairath *et al.* (1998). The direct ERC and DRP for Interbull information and ERC and DRP for direct and maternal effects using Interbeef information were computed independently. Details on avoiding double-counting of Irish and foreign information and calculating adjusted ERCs and DRPs as well as the modelling are described by Vandenplas *et al.* (2014) and Pabiou *et al.* (2018). For all the computations, the MiX99 software (MiX99 development team, 2020) was used.

Validation. To assess the model prediction accuracy a group of 'well' proven sires with at least 100 progeny in the domestic evaluation were identified for each trait. The progeny records of these sires were masked in all evaluations. The correlation between the (G)EBVs of those proven sires with their daughter yield deviation (DYD) reflected the prediction performance. DYDs were calculated based on the average yield deviation from progenies of each sire including all phenotypic records (full data set). The correlation between (G)EBV from validation animals (progeny of the proven sires) and their phenotypes which were corrected for all nongenetic effects was considered as prediction accuracy at animal level. The validation of the integrated (G)EBV was performed by comparing integrated (G)EBV with non-integrated (G)EBV for the corresponding evaluations. The slopes of the regressions of DYD on (G)EBV of the validation sires was computed to measure bias of the evaluations.

Results & discussion

Validation results from four different models at sire level as well as number of validation sires for each trait are presented in Table 2. The results demonstrate that including genomic information and applying the single step genomic approach improved the prediction accuracy for all six different traits. For instance, the prediction accuracy for DH increased from 0.40 to 0.59 by incorporating the genomic information into the model.

The greatest improvement in accuracy was for BW where the traditional approach with only pedigree information had a correlation of only 0.27 which improved to 0.49 when the ssGBLUP approach was applied. Across all traits, the slope of DYD on (G)EBV of validation sires where the expectation of the slope was 0.5, improved with the inclusion of genomic information into the model indicating ssGBLUP could reduce potential biases.

The integration of Interbull and Interbeef information into the domestic evaluation also improved prediction accuracy at both the EBV or GEBV level and across all six different traits; however, the gain in prediction performance was not huge and in context of bias reduction only small improvement was observed. Small number of sires in the validation set which had a foreign sire with a MACE or an Interbeef proof could explain this modest improvement (i.e. only 256 sires for DC). Prediction performance at the animal level

Table 2. Correlations and slope for direct (G)EBV of validation sires with(out) foreign EBVs for six different traits of dairy heifers (DH), dairy cows (DC), beef heifers (BH), beef cows (BC), birth weight (BW; kg) and birth size (BSIZE).

Trait	No. of sires	Statistic	EBV	EBV inc. foreign EBVs	GEBV	GEBV inc. foreign EBVs
DH	1,143	Cor.	0.4	0.43	0.59	0.63
		Slope	0.14	0.15	0.45	0.47
DC	5,194	Cor.	0.44	0.47	0.60	0.62
		Slope	0.26	0.28	0.57	0.59
BH	343	Cor.	0.59	0.62	0.63	0.66
		Slope	0.28	0.27	0.41	0.42
BC	9,289	Cor.	0.37	0.38	0.43	0.44
		Slope	0.20	0.19	0.48	0.47
BSIZE	2,235	Cor.	0.28	0.29	0.47	0.50
		Slope	0.11	0.10	0.38	0.38
BW	363	Cor.	0.27	0.25	0.49	0.52
		Slope	0.08	0.11	0.29	0.30

followed the same pattern as observed at sire level with the inclusion of genomic information or foreign information improving the accuracy (Table 3). The gain in prediction accuracies was more pronounced for incorporating the genomic information rather than integrating foreign EBVs into the model.

Table 3. Correlations for direct (G)EBV of validation animals with(out) foreign EBVs for six different traits of dairy heifers (DH), dairy cows (DC), beef heifers (BH), beef cows (BC), birth weight (BW; kg) and birth size (BSIZE).

Trait	EBV	EBV inc. foreign EBVs	GEBV	GEBV inc. foreign EBVs
DH	0.17	0.18	0.2	0.22
DC	0.14	0.16	0.17	0.18
BH	0.15	0.16	0.17	0.19
BC	0.13	0.14	0.2	0.21
BSIZE	0.12	0.12	0.2	0.2
BW	0.18	0.18	0.26	0.27

Conclusions

The result from present study is encouraging in that the single step genomic approach and using foreign breeding values in the Irish domestic genetic evaluation improved prediction performance and reduced the bias in the evaluations. However, before implementing, the validation results should be compared with the current routine two-step approach.

Abstract

Fertility and temperament are important drivers of productivity in the beef industry of northern Australia. The purpose of this study was to determine the heritability of temperament and fertility traits and to estimate the genetic correlation between these traits using a gBLUP analysis. Fertility phenotypes, Post-partum anoestrus interval (PPAI) and age at puberty (AGECL, Tscore) were recorded in Brahman (n=936), Tropical composite (n=1,097) and Smart Futures Heifers (n=3,696). Flighttime records totalled 4,645. The genotype data was imputed from 35k to 800k SNP. Heritability was 0.56(0.08), 0.37(0.08), 0.44(0.11), 0.24(0.08), 0.19(0.03) and 0.33(0.03) for AGECL(Brahman), AGECL (Tropical composite), PPAI (Brahman), PPAI (Tropical composite), Tscore (Smart Futures Heifers) and Flighttime respectively. Genetic correlation was -0.01(0.10), -0.06(0.11), -0.03(0.07) and 0.32(0.09) between AGECL and Flighttime, PPAI and Flighttime, Tscore and Flighttime and PPAI and AGECL respectively. The result suggests that selecting for improved temperament would not improve fertility.

Introduction

Fertility of beef breeding females, measured by pregnancy, weaning rates and age at puberty is poor in northern Australia. Whilst environment is a significant contributing factor, the heritability of fertility traits indicates that substantial gains could be made in fertility through targeted selection. Fertility traits are, however, time-consuming, expensive and in some cases, completely unfeasible to measure in the extensive environments of northern Australia. Temperament is also heritable and is comparatively simple to measure. A potential, beneficial genetic correlation between temperament and fertility would allow for fertility to be improved through measurement of temperament only. The first objective of this project was to verify the heritability of individual temperament and fertility traits. The second and primary objective was to probe a potential genetic correlation between temperament and fertility.

Materials &methods

Animal data. The data utilised in the project stems from research undertaken by the Cooperative Research Centre for Cattle and Beef Quality (CRC) as part of the Northern Australian breeding project (Johnston *et al.*, 2009). The animals were located on seven commercial beef operations located across Northern Australia – four for BRAH and three for TROPCOMP, as well as data from the 'Belmont' research station in Central Queensland (Johnston *et al.*, 2009). Data from the SmartFutures (SF) project was also included (Burns *et al.* 2013).

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_650, © J.P. Copley *et al.* 2022

Age at first *Corpus Luteum* (AGECL) was used to measure age at puberty. AGECL measurements in BRAH and TROPCOMP cohorts were obtained through multiple ovarian ultrasound scans of heifers conducted at 4-6 week intervals, commencing when heifers reach ~200 kg at 10-12 months (Johnston *et al.*, 2009). Length of Post-partum anoestrus interval (PPAI) measured the period of non-cyclicity following calving. Records in the BRAH and TROPCOMP cohorts were obtained similarly to AGECL, scanning commenced post-calving and continually every four weeks up until weaning (Johnston *et al.*, 2009). Tscore was an analogous measure to AGECL taken from a single ovarian ultrasound scan conducted at ~600 days of age using the procedures outlined by Corbet *et al.* (2017) in the SF cohort. Temperament was measured by Flighttime, using the standard practice outlined by Fordyce *et al.* (1988).

Statistical analysis. The statistical model fitted to the AGECL data set (separately for TROPCOMP and BRAH) was:

$$y=X\beta+Zu+e$$

Where; y = vector of phenotypes X= design matrix allocating phenotypes to fixed effects, β = vector of fixed effects, including age as a covariate, contemporary group, and percentage *Bos indicus*, Z= design matrix allocation records to animal effects, u = vector of (random effect) additive breeding values, one for each animal, distributed Normal $(0,G\sigma_u^2)$, e = vector of residual errors, distributed $N(0,\sigma_e^2)$. The G matrix is the genomic relationship matrix among the animals, calculated from the SNP data, following the formulas of VanRaden *et al.* (2008). GCTA was the software used to calculate the G matrix and to estimate the variance components, σ_u^2 and σ_e^2 (Yang *et al.* 2010). The heritability of the traits were calculated as $h^2 = \sigma_u^2 /(\sigma_u^2+ \sigma_e^2)$.

Results

The heritability of individual temperament and fertility traits are presented in Table 1.

Genetic correlations amongst fertility and temperament traits are given in Table 2.

Table 1. Heritability of fertility and temperament traits from the G-REML analysis. Standard errors are given in brackets.

Trait	n	Range	Std	h^2
AGECL (BRAH)	922	423-1,169	138.53	0.56 (0.08)
AGECL (TROPCOMP)	999	344-945	120.40	0.37 (0.08)
PPAI (BRAH)	582	17-484	108.44	0.44 (0.11)
PPAI (TROPCOMP)	822	19-473	109.89	0.24 (0.08)
Tscore	3,696	0-5	1.29	0.19 (0.03)
Flighttime	4,645	39-528.8	54.90	0.33 (0.03)

Table 2. Genetic correlations among fertility and temperament traits from G-REML analysis. Standard errors are given in brackets.

Trait	AGECL	PPAI	Tscore	Flighttime
AGECL	-	0.58 (0.10)	-	-0.01 (0.10)
PPAI	0.58 (0.10)	-	-	-0.06 (0.11)
Tscore	-	-	-	-0.03 (0.07)
Flighttime	-0.01 (0.10)	-0.06 (0.11)	-0.03 (0.07)	-

Discussion

The heritability estimates of AGECL across the BRAH and TROPCOMP datasets indicated that the trait was moderately to highly heritable. This confirmed that direct selection for AGECL is possible. The results aligned closely to those derived by Johnston *et al.* (2009) for the same trait (0.57) and Vargas *et al.* (1998) (0.45). The heritability in TROPCOMP was lower than the estimate by Johnston *et al.* (2009) (0.52). The minor divergence between these results was potentially due to differences in the fixed effect modelling in the respective datasets. The Tscore measurement used for the SF dataset was a related, but less precise measure of age at puberty compared with AGECL. It interpreted the development of the uterine tract of heifers from a single measurement taken at 600 days. The obtained result for Tscore aligned closely with estimates made by Corbet *et al.* (2017) (0.18-0.32). Tscore, while a less precise measurement of puberty, is potentially a viable alternative to the multiple scannings required for AGECL, allowing puberty traits to be recorded in larger herds from more extensive, commercial businesses. This approach has been utilised in studies such as Hayes *et al.* (2019).

The estimated heritability of PPAI in both the BRAH and TROPCOMP datasets suggested PPAI was moderately to highly heritable. The results compared favourably to estimates by Johnston *et al.* (2013) who found heritability of PPAI to be 0.52(0.14), 0.20(0.12), 0.24(0.14) for *Bos indicus* females aged three, four and five years respectively. PPAI was found to be sufficiently heritable as to warrant direct selection in targeted breeding programs. In productive beef herds where breeding females should ideally produce one calf every twelve months, reducing PPAI is vital to improving reproductive success (Shatz *et al.*, 2011).

Flighttime was estimated to be moderately heritable. Numerous other results by Burrow *et al.* (2001), Burrow *et al.* (1988) and Burrow and Corbet (2000), all using pedigree rather than genomic data in their estimates, found the heritability of Flighttime to be 0.40, 0.26, 0.35 and 0.48 respectively. Estimates by Valente *et al.* (2015) and Valente *et al.* (2017) found the heritability to be lower, 0.27(0.07) and 0.22(0.02). The estimate obtained by this study emphasises Flighttime is a low to moderately heritable trait suggesting that selection would be possible. Selection for any trait relies on the collection of precise data using repeatable and objective methods. Temperament has been subjectively measured using metrics such as 'crush score' and 'temperament score', however, using the objective measure of Flighttime avoids issues stemming from human error and unconscious bias (Curley *et al.*, 2006). The potential for selection of improved temperament would be welcomed in Northern Australia, where temperament impacts directly on productivity (Fordyce *et al.*, 1988).

Estimated genetic correlation between PPAI and AGECL was positive and high, 0.58(0.10), suggesting the possibility of indirect selection. The previous results indicated that both these traits are highly heritable on an individual basis. The estimated correlation between PPAI and AGECL for TROPCOMP, closely matched results obtained by Johnston *et al.* (2014) who found correlation to be 0.72(0.07) and 0.31(0.18) for Tropical composite and Brahman females respectively. This result suggests females with earlier puberty tend to have shorter PPAI and are thus more likely to reconceive and calve again within the ideal 12-month cycle. Puberty, either AGECL or Tscore, can be measured earlier in an animals life, this combined with the favourable genetic correlation means that reduced PPAI can be reliably selected for without waiting for the animals to conceive and subsequently calve.

The second objective was to investigate if superior temperament, expressed as longer Flighttime in female beef cattle, can be used as a proxy trait to select indirectly for fertility. The estimated genetic correlation between Flighttime, and all fertility traits was effectively zero. This result of low, negative correlations between temperament and fertility traits was similarly observed by Valente *et al.* (2015) who found the correlation between Flighttime and early puberty in males and early pregnancy in females to be -0.09(0.09)

and -0.07(0.08). Burrow *et al.* (2001) found no genetic correlation between Flighttime and fertility traits including pregnancy status and early puberty. Cooke *et al.* (2011) and Burrow *et al.* (1988) found a positive relationship, between temperament and success rate of artificial breeding programs, however this was evaluated to be caused by easier management of quieter cattle rather than these cattle being inherently more fertile. A significant genetic correlation would have allowed direct selection for temperament traits to lead to indirect selection for fertility traits. Temperament and fertility appear to be independent traits. To improve fertility, temperament cannot be used as indicator trait, rather fertility must be measured and selected for directly.

651. Genomic prediction with non-additive genetic effects for carcass weight and beef marbling in Japanese Black cattle

K. Inoue[1*], M. Nishio[2], Y. Inoue[3], M. Takeda[1] and H. Hirooka[4]

[1]National Livestock Breeding Centre, Nishigo, 961-8511 Fukushima, Japan; [2]NARO Institute of Livestock and Grassland Science, Tsukuba, 305-0901 Ibaraki, Japan; [3]Tottori prefectural Livestock Research Centre, Kotoura, 689-2503 Tottori, Japan; [4]Kyoto University, Sakyo, 606-8502, Kyoto, Japan; k1inoue@nlbc.go.jp

Abstract

In total, 1,908 genotyped Japanese Black cattle were used to infer non-additive genetic effects for carcass weight and beef marbling score (BMS) and to validate accuracy of the genomic predictions for the traits. Genomic models including dominance, imprinting, or both effects were used in this analysis. Ratios of the dominance and imprinting variance to the phenotypic variance for the traits were small and ranged from 0.08 to 0.10 and from 0.05 to 0.06, respectively. In addition, any genomic models including non-additive genetic effects did not improve accuracy of the genomic predictions. In contrast to the previous pedigree-based studies which showed large imprinting variances and effects for BMS, small imprinting variances and variance ratios for BMS were found in this study using genomic information. To find out the differences between pedigree and genomic based studies, further studies are required.

Introduction

Non-additive genetic effects, such as dominance and genomic imprinting effects are important as well as an additive genetic effect in animal breeding systems because they could lead to bias in genetic parameters and breeding values. Neugebauer *et al.* (2010) and Tier and Meyer (2012) reported imprinting effects for carcass traits using pedigree-based imprinting models in beef cattle. In addition, large relative imprinting variances for beef marbling score (BMS) were found in different Japanese Black cattle populations (Inoue *et al.*, 2020, 2021; Okamoto *et al.*, 2019). In recent years, the genotypic coding and construction of a genomic relationship matrix for an imprinting effect using single nucleotide polymorphism (SNP) data from animal-parents trios were developed by Nishio and Satoh (2015) in the context of genomic prediction. Using their methods, some studies have been reported dominance and imprinting effects and predictive ability of the models (e.g. Guo *et al.*, 2016). However, there are no reports on the effects of using SNP information in Japanese Black cattle. The objectives of this study were to infer dominance and imprinting effects for carcass weight (CW) and BMS and to validate predictive ability of the genomic models for these traits in Japanese Black cattle.

Materials & methods

Data. The data used in this study were obtained from the carcass records (i.e. Animal Care and Use Committee approval was not necessary) of 1,908 Japanese Black steers and heifers fattened in Japan. The carcass records included CW and BMS, which is scored from 1 (poor) to 12 (abundant). BMS was evaluated between the sixth and seventh rib in accordance with the Japan Meat Grading Association (1988). Those 1,908 animals with records and their parents were genotyped using the GeneSeek GGP LD v4 SNP chip (Neogen GeneSeek Operations, NE, USA). The call rate of these animals was over 0.95. The SNP genotype data were imputed to the Illumina BovineSNP50 v2 BeadChip (Illumina, CA, USA) and then were phased by using Beagle ver. 4.0 (Browning and Browning, 2007) with pedigree information to distinguish the parental origin of the alleles. Finally, 34,481 SNPs on the 29 cattle autosomes were used.

Statistical models. The following four statistical models were fitted to phenotypic values. The full model including an additive genetic effect in addition to dominance and imprinting effects (model 1) can be written as follows:

$$y = X\beta + Z_a a + Z_d d + Z_i i + e \quad (1)$$

where y is a vector of the observed traits CW and BMS; β is a vector of fixed effects, including the sex of animals (two levels; steer and heifer), slaughter year (13 levels; 2006 to 2018), slaughter month (12 levels), carcass market (five levels), linear and quadratic covariates for age at slaughter (average 28.6 months); a, d and i are vectors of additive genetic, dominance and imprinting effects, respectively, and distributed as $\mathbf{a} \sim N(0, \mathbf{G_a}\sigma_a^2)$, $\mathbf{d} \sim N(0, \mathbf{G_d}\sigma_d^2)$ and $\mathbf{i} \sim N(0, \mathbf{G_i}\sigma_i^2)$, respectively; e is a vector of random residual effects as $\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2)$; and X, Z_a, Z_d and Z_i are known incidence matrices. G_a, G_d and G_i are the additive genomic, dominance genomic and imprinting genomic relationship matrices, respectively; I is an identity matrix; σ_a^2 is the additive genetic variance; σ_d^2 and σ_i^2 are variances due to the dominance and imprinting effects, respectively; and σ_e^2 is the residual variance. All other covariances between random effects were assumed to be zero. The genomic relationship matrices G_a, G_d and G_i were calculated according to VanRaden (2008), Nishio and Satoh (2014) and Nishio and Satoh (2015), respectively, as follows:

$$\mathbf{G_a} = \frac{\mathbf{M_a M_a'}}{\sum_{j=1}^{m} 2q_j(1-q_j)},$$

$$\mathbf{G_d} = \frac{\mathbf{M_d M_d'}}{\sum_{j=1}^{m} \{2q_j(1-q_j)\}^2},$$

$$\mathbf{G_i} = \frac{\mathbf{M_i M_i'}}{\sum_{j=1}^{m} 2q_j(1-q_j)},$$

where M_a, M_d and M_i are $n \times m$ matrices (n is the number of genotyped individuals and m is the number of SNPs). Considering two alleles A_1 and A_2 with frequencies $1 - q_j$ and q_j, respectively, in the population, the elements of M_a, M_d and M_i for the i^{th} individual at the j^{th} SNP were calculated as follows (Nishio and Satoh, 2015):

$$\mathbf{M_a}_{ij} = \begin{cases} 2q_j & A_1A_1 \\ 2q_j - 1 & A_1A_2 (A_2A_1), \\ 2q_j - 2 & A_2A_2 \end{cases}$$

$$\mathbf{M_d}_{ij} = \begin{cases} -2q_j^2 & A_1A_1 \\ 2q_j(1-q_j) & A_1A_2 (A_2A_1), \\ -2(1-q_j)^2 & A_2A_2 \end{cases}$$

$$\mathbf{M_i}_{ij} = \begin{cases} 0 & A_1A_1 \\ 1 & A_1A_2 \\ -1 & A_2A_1 \\ 0 & A_2A_2 \end{cases},$$

The three reduced models, which excluded either imprinting (model 2) or dominance (model 3), or both (model 4), from the full model were as follows:

$$y = X\beta + Z_a a + Z_d d + e \quad (2)$$

$$y = X\beta + Z_a a + Z_i i + e \quad (3)$$

$$y = X\beta + Z_a a + e \quad (4)$$

The RKHS function in BGLR statistical package (Pérez and de los Campos, 2014) was used for obtaining posterior distributions of variance components. For each analysis, a single Markov chain with 15,000 samples was generated, with the initial 5,000 samples discarded as burn-in. Finally, variance components were determined based on the remaining 10,000 samples.

Cross-validation of genomic predictions. Predictive ability of the models was examined by 10-fold cross-validation. The animals with phenotypes were randomly split into 10 folds. Accuracy of the predictions was evaluated based on Pearson's correlation coefficient between the phenotypic values (y) and predicted phenotypic values ($\hat{y}$) which were the sum of the estimated fixed effects and predicted genetic effects.

Results

Posterior means of the variance components and ratios of variance for carcass traits are shown in Table 1. Additive genetic variances (σ_a^2) and ratios of σ_a^2 to the phenotypic variance (h_a^2) for CW in models including non-additive effects (model 1, 2 and 3) were slightly smaller than those in model including only an additive effect (model 4). Similarly, for BMS, σ_a^2 and h_a^2 in model 1 and 3 were slightly smaller than those in model 2 and 4. The ratios of dominance variance to the phenotypic variance (h_d^2) for CW and BMS were ranged from 0.08 to 0.10. The ratios of imprinting variance to the phenotypic variance (h_i^2) for CW and BMS were 0.06 and 0.05, respectively.

Correlations between phenotype and predicted phenotype for different models of analysis are shown in Table 2. The correlations for CW and BMS in models including non-additive effects (model 1, 2 and 3) were slightly higher than those in model including only an additive effect (model 4), in particular, the correlations in models including dominance effects (model 1 and 2) were highest among them but the differences were all small and negligible.

Discussion

In studies using pedigree-based imprinting models, Neugebauer *et al.* (2010) reported a significant imprinting effect for paternal gametes on fat score in German Simmental. Tier and Meyer (2012) reported paternal and maternal gametic effects for intramuscular fat percentage in Australian Angus. In Japanese Black cattle, large imprinting variances for BMS were inferred in different populations (Inoue *et al.*, 2020, 2021; Okamoto *et al.*, 2019). In contrast to the previous pedigree-based studies, small imprinting variances and h_i^2 for BMS were inferred by using genomic relationship matrices in the present study. In addition, any genomic models including non-additive genetic effects did not improve the accuracy of the genomic predictions. Some previous studies also reported that non-additive genetic variances and effects were small and models including non-additive genetic effects did not improve predictive ability, probably due to overfitting of the models with more parameters (Hu *et al.*, 2016).Garcia-Baccino *et al.* (2020) reported h_d^2 of 0.01 for growth traits and no improvement of predictive ability on the models including non-additive genetic effects in American Angus. In Danish Duroc pigs, h_d^2 for dairy gain and backfat thickness were ranged from 0.040 to 0.049 and h_i^2 for the traits were ranged from 0.013 to 0.019 (Guo *et al.*, 2016). As described above, there were large differences between the imprinting effects for BMS from pedigree-based imprinting models and from genomic information. Therefore, further studies are required to find out the differences between pedigree and genomic based studies.

652. Reaction norm models contribute to the investigation of environmental sensitivity for weaning weight in Nellore cattle

I. Carvalho Filho[1*], D.A. da Silva[1], C.S. Teixeira[1], T.L. Silva[1], L.G. Albuquerque[1,2] and R. Carvalheiro[1,2]

[1]São Paulo State University (UNESP), School of Agricultural and Veterinarian Sciences, Jaboticabal, Brazil; [2]National Council for Scientific and Technological Development (CNPq), Brasília, Brazil; ivancf08@gmail.com

Abstract

Reaction norm models (RNM) can be used to assess environmental sensitivity of animals for traits affected by genotype by environment interaction. Three RNM were tested for weaning weight (WW) in Nellore cattle. Phenotypic data from 772,855 animals were obtained from the Aliança Nelore dataset. The best model, according to the AIC criteria, was a spline linear-linear heteroscedastic RNM. Results suggest existence of a non-linear component in the reaction norm of WW and that the slope of the first and second segments are highly and negatively correlated. For animals selected in the low environment gradient (EG), the EBV average decreased in the medium and high EG. Trajectories along the EG when animals were selected in the medium and high gradients were similar. To reduce animal sensitivity to environmental variation, the selection could be based on genetic performance and environmental sensitivity, which can lead to a better genetic response for all EG.

Introduction

In genotype by environment interaction (G×E) studies, reaction norm models (RNM) can be used for the prediction of genetic values as a function of environmental conditions (Knap and Su, 2008). For traits that require additional random effects, such as maternal genetic and maternal permanent environment effects, the RNM can become highly parameterized and difficult to apply in practice. A possible solution is to fit a RNM only for the direct genetic effect and model the other effects for an average environment (Carvalho Filho *et al.*, 2021).

Finding the best model that fits the data is of utmost importance to promote more accurate genetic evaluations prediction. Thus, the objective was to compare different RNM for weaning weight in Nellore cattle considering goodness of fitting measures.

Materials & methods

Phenotypic data for weaning weight (WW) were obtained from the Aliança Nelore dataset. After the criteria used of keeping only animals with known parents, contemporary groups (CG) with at least 20 animals and WW between 100 and 280 kg, 772,855 animals from 15,448 CG were considered for the analysis. The CG was comprised by animals born in the same herd, year and season, of the same sex and raised in the same management group from birth to weaning. The CG effects estimated previously using a regular mixed model (without modelling G×E) were standardized to have mean and variance equal to 0 and 1, respectively, and were used in RNM as environmental gradients (EG). Genetic sensitivity to environmental variation was assessed by fitting three different RNM.

The first (RNM_homo) assumed residual variance homogeneity and is described by the equation:

$$y_{ijk} = \mathbf{X}_j\boldsymbol{\beta} + \emptyset\widehat{EG}_i + b_{0_j} + b_{1_j}\widehat{EG}_i + m_j + mpe_k + e_{ijk} \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_652, © I. Carvalho Filho *et al.* 2022

where: y_{ijk} is the phenotypic data of animal j in a given environment i, β is the vector of fixed effects and covariates; X_j is the incidence matrix related to β; ϕ is the overall linear fixed regression coefficient of y_{ijk} in $\widehat{EG}_i$; $\widehat{EG}_i$ is the standardized EG solution of environment i, estimated previously; b_{0_j} is the random direct additive genetic effect or the intercept of animal j for an average EG, b_{1_j} is the coefficient of random regression or slope of the animal j in the environment represented by $\widehat{EG}_i$; m_j is the maternal genetic effect, mpe_k is the maternal permanent environmental effect and e_{ijk} the residual effects. The following assumptions were assumed for RNM_homo:

$[b_{0_j}, b_{1_j}] \sim N(0, \mathbf{A} \otimes \begin{bmatrix} \sigma^2_{b_0} & \sigma_{b_0 b_1} \\ \sigma_{b_0 b_1} & \sigma^2_{b_1} \end{bmatrix})$, $m_j \sim N(0, \mathbf{A}\sigma^2_m)$, $mpe_k \sim N(0, \mathbf{I_d}\sigma^2_{mpe})$ and $e_{ij} \sim N(0, \mathbf{I_n}\sigma^2_e)$, where:

A is the relationship matrix based on pedigree information (⊗ is the Kronecker product); $\sigma^2_{b_0}$, $\sigma^2_{b_1}$ and $\sigma_{b_0 b_1}$ are the variances of the intercept, the slope and their covariance, respectively; σ^2_m is the variance of the maternal genetic effect, σ^2_{mpe} is the variance of the maternal; I_d is an identity matrix of order equal to the number of dams, I_d is an identity matrix of order equal to the number of animals with phenotypic records and σ^2_e is the residual variance.

The second model (RNM_hete) differed in relation to RNM_homo by assuming that the residual variance is heterogeneous across EG, using a linear regression on $\widehat{EG}_i$, with the intercept and slope coefficients being modeled using the log-residual function (Foulley and Quaas, 1995). The third model (RNM_l-l) also assumed heteroscedasticity, and used a linear-linear spline function to model the genetic merit of animals across the EG, using the same knot in the average EG (knot = 0) for all animals, according to the following equation:

$$y_{ijk} = \mathbf{X_j}\boldsymbol{\beta} + \emptyset_1 \widehat{EG}_i + \emptyset_1^* \widehat{EG}_i^* + b_{0_j} + b_{1_j} \widehat{EG}_i + b_{1_j}^* \widehat{EG}_i^* + m_j + mpe_k + e_{ijk} \quad (2)$$

where: $\emptyset_1^*$ is the difference of the regression coefficient between the first and the second segments of the linear-linear spline function of y_{ij} on $\widehat{EG}_i^*$, where $\widehat{EG}_i^*$ is equal to zero if $\widehat{EG}_i$ is less than or equal to zero, if $\widehat{EG}_i$ is greater than zero, $\widehat{EG}_i^*$ is equal to $\widehat{EG}_i$; $b_{1_j}^*$ is the difference between the first and the second segments of the linear–linear spline function of the random additive genetic effect of animal j on $\widehat{EG}_i^*$ expressed as a deviation from $\emptyset_1^*$; the other terms were as previously described.

(Co)variance component estimates for all models were obtained by restricted maximum likelihood using the AIREMLF90 software (Misztal *et al.*, 2002). The different models were compared based on the Akaike information criterion (AIC).

In all, 508 sires remained after the filter of having at least fifty offspring and among these at least ten offspring in the low EG (-3 to -1) and ten in the high EG (1 to 3). Ten sires (Top10) with the highest EBV in each environmental gradient (low, medium and high) were selected to have their reaction norm described along the environmental gradient. Additionally, forty sires with the highest EBV in the medium environmental gradient were selected. Of these, the ten most robust sires (top10 robust), i.e. with the slope closer to zero, will be shown.

Results

Based on the AIC criterion, both heteroskedastic models outperformed the homoscedastic model, and RNM_l-1 presented the best fit, suggesting the existence of a non-linear component in the trajectory of the WW reaction norm in Nellore cattle (Table 1).

Table 1. Estimates of variance (diagonals), covariance (upper triangular; in italic) and correlation (lower triangular; in bold) among coefficients of reaction norm models (RNM) for the additive genetic effect of weaning weight in Nellore cattle, with respective maternal (mat), maternal permanent environment (mpe) and residual variance estimates, and Akaike information criterion (AIC).

[4] Number of estimated parameters.

Figure 1 illustrates the expected consequence of different selection strategies, showing the reaction norms and the average of the ten best sires EBV for different EG. It is possible to observe the different trajectories along the EG according to the environment in which the animal is selected.

When observing the reaction norms trajectory for the 10 best selected sires in the low EG (Figure 1A), there is a decrease in EBV average and greater dispersion in the medium and high EG. Trajectories along the EG when animals were selected in the medium and high gradients are similar (Figure 1B and 1C). In the robust Top10, the EBV varies little along the EG (Figure 1D).

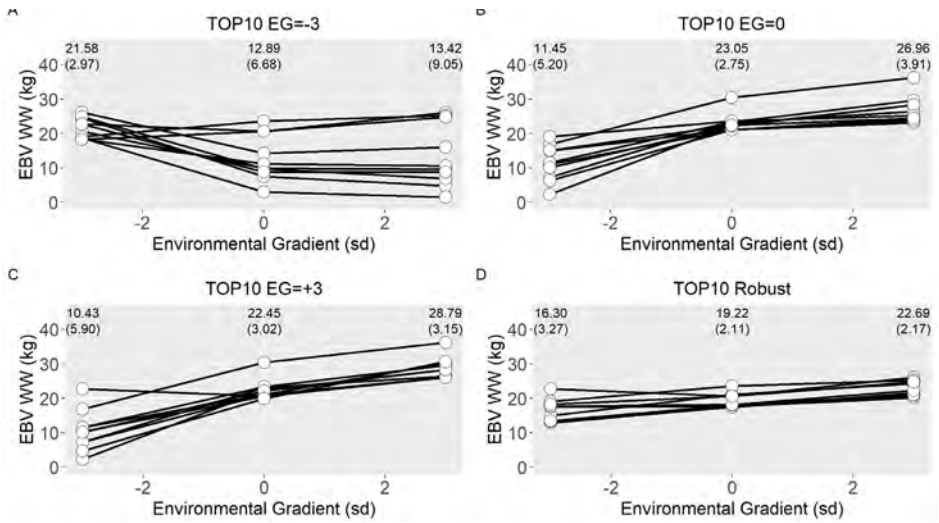

Figure 1. Estimated breeding value (EBV) reaction norms for weaning weight (WW) of Nellore cattle sires classified as top 10 for low (A), medium (B) and high environmental gradient (C), and top 10 robust (D), i.e. with slopes closer to zero that are among the best forty sires in the medium EG, considering the reaction norm model (RNM) fitted with a spline linear–linear function and assuming heteroscedasticity (RNM_l-l). The numbers above the reaction norms trajectories represent the mean and in parentheses, the standard deviation.

Discussion

RNM_homo and RNM_hete showed moderate to high correlation between intercept and slope, unlike Ribeiro *et al.* (2015), who found a high correlation between intercept and slope for weaning weight in Nellore cattle. However, this moderate correlation suggests that animals are reclassified in different environments and that it is possible to carry out joint selection in order to increase performance and reduce sensitivity (Santana *et al.*, 2013; Su *et al.*, 2006). The correlation estimates between the coefficients presented by RNM_l-1 suggest that this association is moderate only for the first segment. For the second segment, the correlation between intercept and slope was low and negative, showing that there may be different patterns of animals environmental sensitivity according to the EG level.

In Figure 1A, among the top ten sires for low EG, there is a reduction in the mean EBV value in the medium and high gradients, indicating that the selection response would be lower for these environments if the selection was based on animals with higher EBV for low EG. On the other hand, if the selection was based on superior animals for medium and high EG, the expected response in these environments would be higher for these EG, at the expense of worse expected responses for low EG (Figures 1B and 1C, respectively), when compared to the top ten sire averages for low EG.

Robust sires, i.e. sires that are less sensitivity to environmental variation, are shown in Figure 1D. These sires are among the top 40 sires in medium EG and in the top 50 sires in extreme EG (low and high). The selection of these robust animals could lead to an increase in performance and a decrease in environmental sensitivity.

Therefore, we concluded that reaction norm models can help in the selection of animals with high weaning weight and less sensitivity to environmental variation.

Abstract

Inheritance transmission modes of five carcass traits (carcass weight, rib eye area, rib thickness, subcutaneous fat thickness and marbling score) of Japanese Black cattle were investigated using pedigree-based breeding values and genomic breeding values based on genotypic information from triplet sources of sires, dams and offspring. The phenotypic and genotypic information of 1,908 feedlot animals and genotypic information of their parents were used in this study. The inheritance transmission modes (genetic contributions of sires and dams) were quantitatively represented by path coefficients of sires and dams estimated breeding values on offspring breeding values. A large difference of genetic contribution between sires and dams was found for marbling score (0.490 for sires and 0.681 for dams) when pedigree-based breeding values were used, indicating the maternally expressed genomic imprinting. In contrast, there was no such difference between genetic contributions (0.546 for sires and 0.568 for dams) when genomic breeding values were used.

Introduction

Japanese Black cattle (a breed of Wagyu) has been utilized for draft before 1950's but became a beef breed since 1960's. A genetic evaluation program for carcass traits of the breed have started in 1980's using BLUP method (Sasaki, 2001). In recent years, genomic selection programs using GBLUP have been implemented for carcass traits of the breed (Onogi *et al.* 2014) and the new breeding program has become a standard procedure in genetic evaluation for Japanese Black cattle. The genetic evaluation programs in livestock are generally based on the assumption that the genetic contribution of parents is equal between sires and dams. Recently, however, Okamoto *et al.* (2019) first found the existence of maternally expressed genomic imprinting for marbling score of the breed using sire-MGS model based on the theory by Blunk *et al.* (2017). Subsequently, Inoue *et al.* (2020,2021) also reported the maternally expressed genomic imprinting for the marbling score using sire-dam gametic relationship matrix and sire-MGS model for different Japanese Black populations. As the next step, such findings should be assessed using genomic information. In this study, 'trio' genotyped data which consist of genotypes from sire-dam-offspring triplets were used for the purpose. The objective of this study was to investigate the inheritance transmission modes on carcass traits in Japanese Black cattle using pedigree-based breeding values and genomic breeding values estimated from the trio genotyped data.

Materials & methods

Data. The phenotypic data set in this study were obtained from the carcass records of 1,908 Japanese Black feedlot steers and heifers with 8,312 pedigree ancestors reared in National Breeding Centre and Tottori Prefecture, Japan. The carcass traits were carcass weight, rib eye area, rib thickness, subcutaneous fat thickness and marbling score (scores 1-12, with 12 as the most abundant). The carcass traits were evaluated between the sixth and seventh rib in accordance with the Japan Meat Grading Association (JMGA, 1988). The feedlot animals and their sires and dams were genotyped using the GeneSeek GGP LD v4 SNP chip (Neogen GeneSeek Operations, NE, USA). The SNP markers on autosomes were pruned with call rate (>0.95), minor allele frequency (>0.01) and Hardy-Weinberg equilibrium ($<10^{-4}$). The SNP genotype data

DOI: 10.3920/978-90-8686-940-4_653, © H. Hirooka *et al.* 2022

were imputed to the Illumina BovineSNP50 v2 BeadChip (Illumina, CA, USA) and then were phased by using Beagle ver. 4.0 (Browning and Browning, 2007) with pedigree information to distinguish the parental origin of the alleles. Finally, 34,481 SNPs on the 29 cattle autosomes were used in this study. The genotypic data were characterized as 'trio' data consisting of genotypes from sire-dam-offspring triplets.

Statistical models. The pedigree-based breeding values and genomic breeding values were estimated by BLUP and GBLUP methods, respectively, using BLUPF90 package (Misztal 2015). In this study, the GBLUP method without pedigree information instead of single step GBLUP method (Misztal *et al.*, 2009) was used to make clear the differences of utility of pedigree information and genomic information in estimating breeding values and inferring genetic transmission modes of sires and dams. The fixed effects were the sex of animals, slaughter year, slaughter month and linear and quadratic covariates for age of slaughter. The differences between pedigree-based and genomic breeding values were evaluated with Pearson's correlation coefficient.

In this study, the inheritance transmission modes (i.e. genetic contributions of sires and dams to their sons and daughters) were quantitatively represented based on path coefficients (Wright 1934, 1960). The model considered was:

$$EBV_o = b_s \times EBV_s + b_d \times EBV_d + \phi_o \quad (1)$$

where EBV_o, EBV_s, EBV_d are estimated breeding values for feedlot animals (offspring), sire and dam, respectively, estimated from pedigree or genomic information and b_s and b_d are the partial regression of offspring on sire and dam, respectively. As noted by Cantet and Vitezica (2014), the error term ϕ_o represents the deviation from the mid parental estimated breeding values and originates in random Mendelian sampling of the grand-parental gametes present in the parents' segregation.

The path coefficient (standardized regression coefficients) for sires (β_s) and dams (β_d) were calculated as:

$$\beta_s = b_s \times \sigma_s / \sigma_o \quad (2)$$

$$\beta_d = b_d \times \sigma_d / \sigma_o \quad (3)$$

where σ_o, σ_s and σ_d are the standard deviation of pedigree-based or genomic breeding values for feedlot animals, sire and dams, respectively. The path coefficients represent the direct effects of sires or dams on the breeding values of the offspring animals.

Results & discussion

The estimated breeding values from pedigree and genomic information of sires, dams and offspring are shown in Table 1. The higher breeding values of offspring over average of sires and dams for all traits except subcutaneous fat thickness may result from genetic improvement in one generation toward desirable direction for the carcass traits by breeding programs in Japan. Furthermore, it should be noticed that the breeding values of carcass weight of dams were lager that those of sires derived from both procedures, indicating higher genetic improvement of carcass weight for dams (female side) than sires (male side). In Japan, carcass traits have been evaluated for dams as well as sires using breeding values estimated from pedigree-based BLUP method, although dams did not have phenotypic records for carcass traits. Historically, selection for sires have been more emphasized for marbling score than other carcass traits through progeny testing programs.

Table 1. Means of genomic and pedigree estimated breeding values for carcass traits.

	Genomic breeding value			Pedigree-based breeding value		
	Sire	Dam	Offspring	Sire	Dam	Offspring
No. animals	234	1,509	1,908	234	1,509	1,908
Carcass weight (kg)	-8.396	1.692	0.022	-0.716	5.369	6.134
Rib eye area (cm^2)	-1.149	-1.459	-0.007	2.112	1.786	3.338
Rib thickness (cm)	-0.105	-0.020	0.000	0.151	0.196	0.240
Subcutaneous fat thickness (cm)	0.004	0.039	0.000	0.043	0.068	0.036
Marbling score	-0.283	-0.513	0.002	1.259	1.084	1.587

The correlation between pedigree-based breeding values and genomic breeding values can compare performance of genomic prediction with pedigree-based prediction. The correlations between pedigree-based and genomic breeding values (Table 2) were largest (0.895 to 0.927) for offspring with phenotypic records, followed by sires (0.893 to 0.911) and dams (0.771 to 0.839). The result indicates that ranking of dams based on pedigree-based breeding values differed from those on genomic breeding values. In general, it is suggested that genomic breeding values of dams were much more reliable than pedigree-based ones especially when dams were genotyped. On the other hand, it should be noted that genomic prediction did not more reliable and advantageous for sires than pedigree-based prediction, when sires have many progeny and the breeding values were estimated with high reliabilities.

The path coefficients from sires and dams to offspring for the carcass traits are given in Table 3. From theoretical point of view, as an offspring receive half of the genetic materials from each parent, genetic contribution of each parent should be equal according to Mendelian law of segregation. In fact, the genetic contributions of sires and dams were almost equal for all traits except marbling score. However, for pedigree-based breeding values, the different genetic contributions between sires and dams were found for marbling score (0.490 for sires and 0.681or dams). This result may indicate evidence of existence of maternally expressed genomic imprinting for marbling score of Japanese Black cattle and is well in agreement with previous studies (Okamoto *et al.*, 2019; Inoue *et al.*, 2020, 2021). In pedigree-based analysis, the consistent results were obtained for marbling score of Japanese Black cattle regardless of different populations in Shimane Prefecture (Okamoto *et al.,* 2019), Yamagata Prefecture (Inoue *et al.*, 2020) and Tottori Prefecture (Inoue *et al.*, 2021). In contrast, however, there was no difference of genetic contributions for marbling scores when using genomic estimated breeding values in the present study.

Table 2. Correlations of genomic and pedigree-based estimated breeding values for sires, dams and progenies.

	Sire	Dam	Offspring
Carcass weight (kg)	0.911	0.789	0.927
Rib eye area (cm^2)	0.844	0.777	0.924
Rib thickness (cm)	0.877	0.794	0.895
Subcutaneous fat thickness (cm)	0.897	0.771	0.913
Marbling score	0.893	0.839	0.924

Table 3. Path coefficients (standardized regression coefficients) from sire or dam to offspring for carcass traits.

	Genomic breeding value		Pedigree-based breeding value	
	Sire	Dam	Sire	Dam
Carcass weight (kg)	0.567	0.549	0.674	0.645
Rib eye area (cm^2)	0.571	0.532	0.598	0.618
Rib thickness (cm)	0.607	0.565	0.616	0.650
Subcutaneous fat thickness (cm)	0.616	0.529	0.644	0.633
Marbling score	0.546	0.568	0.490	0.681

The 'missing' genomic imprinting effects in using genomic breeding values may be caused by the two possibilities: (1) the spurious effects resulted from ambiguous genetic transmission modes assumed in pedigree-based analysis; and (2) rigid assumption of additive effects of each SNP in genomic analysis. In our companion paper, Inoue *et al.* (this proceeding) also reported small and negligible imprinting variance for marbling score of Japanese Black cattle in genomic analysis in spite of the fact that large imprinting variance were inferred in pedigree-based analysis. Further research would be required to explain the results.

654. Genetic parameters for fatty acid traits of beef in Australian Angus

C.J. Duff[1,2*], A.M. Samaraweera[1], P. McGilchrist[2] and S.A. Clark[2]

[1]Angus Australia, 86 Glen Innes Road, Armidale, New South Wales, Australia; [2]School of Environmental and Rural Science, University of New England, Armidale, New South Wales, Australia; christian@angusaustralia.com.au

Abstract

Preliminary genetic and phenotypic parameters were estimated for fatty acid traits in feedlot finished Australian Angus cattle. This included the relationships between saturated fatty acids (SAT), monounsaturated fatty acids (MONO) and polyunsaturated fatty acids (PUFA), with carcase weight (CWT), carcase rump fat (CP8) and carcase intramuscular fat (CIMF). All fatty acid traits showed phenotypic variation, with a considerable portion attributed to genetics as shown by heritabilities for SAT, MONO and PUFA of 0.64±0.11, 0.67±0.12 and 0.25±0.09 respectively. SAT had moderate negative genetic correlation with CWT, CP8 and CIMF (-0.30±0.16, -0.21±0.17 and -0.38±0.14 respectively), while MONO and PUFA have moderate positive genetic correlation with CWT, CP8 and CIMF ranging from 0.14±0.17 to 0.46±0.22. The results show that the proportion of MONO and PUFA can be increased, and SAT decreased, in intramuscular fat through selection. Importantly, this can be achieved without being detrimental to carcase weight, carcase rump fat or total intramuscular fat.

Introduction

Beef delivers a valuable source of nutrition to the consumer by providing macronutrients such as fat and protein, vitamins such as B12 and minerals such as iron and zinc. However, there is often a focus in society on the role of fat in the diet, particularly from red meat sources like beef. Fat from beef cattle has two main forms – saturated and unsaturated fats. It is well understood that any increase in saturated fats in the diet is associated with detrimental effects on consumer health such as chronic heart disease. Conversely, some unsaturated fatty acids (e.g. Linoleic and Linolenic acid) are essential in the diet and have potential positive effects on the aetiology of chronic disorders (National Health and Medical Research Council, 2006).

To understand the potential role of selection on fatty acid composition in beef cattle, several previous studies have generated genetic parameters for fatty acid traits (Malau-Aduli *et al.*, 2000; Inoue *et al.*, 2011; Saatchi *et al.*, 2013; Kelly *et al.*, 2012). However, few studies have examined the relationship between meat fatty acid composition traits to eating quality traits such as intramuscular fat (IMF) and quantity traits such as carcase weight, particularly within Australian Angus cattle.

Therefore, the purpose of this study was to estimate preliminary phenotypic and genetic parameters for fatty acid traits that are prevalent in beef products, and to determine their relationship with carcase weight (CWT), carcase rump fat (CP8) and intramuscular fat (CIMF) in Australian Angus cattle.

Materials & methods

All phenotypes, associated fixed effects and pedigree data used in this study were generated from the Angus Sire Benchmarking Program (ASBP) as described by Parnell *et al.* (2019). The animals involved (n=927) were born in the 2015, 2018 and 2019, and consisted of straight-bred steers (n=810) or heifers (n=117) that are progeny of Angus sires (n=129) and Angus dams (n=847) from seven co-operator herds located in New South Wales, Australia. Of the dams included in this study, the majority had a single progeny represented, while 71 had two progeny. Nine animals with phenotypes did not have a dam recorded.

All animals undertook an initial feedlot phase of approximately 100 days at the University of New England Tullimba Feedlot, Kingstown, NSW, Australia. From feedlot entry, all animals were fed a conditioning ration for approximately 21 days, following which they had *ad libitum* access to a ration composed of 74.8% tempered barley, 4.6% cotton hulls, 6% cottonseed, 5% mill run, 4.6% chopped hay and 5% liquid mineral supplement. This ration being a common formulation used in Australian feedlots with Angus cattle. Following the Tullimba Feedlot feeding phase, around half the animals (n=440) were slaughtered, based on herd of origin, to reflect the Australian mid-fed feeding program. The remaining animals (n=487) were relocated to Rangers Valley Feedlot, Rangers Valley, NSW for a second phase (i.e. further 170 days on feed) to reflect the Australian long-fed feeding program. Here they were fed a similar ration as in phase one, under a normal, controlled commercial feeding program. The mean age at slaughter was 651.3 (SD 66.0) days for all animals, with the long-fed animals being older than the mid-fed animals at 700.7 (SD 39.1) days and 596.7 (SD 42.5) days respectively.

At the end of the feeding periods all animals were slaughtered and their carcases weighed on a hot standard carcase basis and rump fat measured at the p8 site. The following day meat samples (50 grams) were collected on chilled carcases from the *longissimus thoracis* muscle at the carcase grading site, in this case between the 12th and 13th rib. The samples were assessed for IMF using near infrared spectrophotometry (NIR), described by Perry *et al.* (2001) and seven fatty acid composition traits using the gas chromatography-mass spectrometry (GC-MS) method. The fatty acid composition traits included C14:0 (Myristic Acid), C16:0 (Palmitic Acid), C16:1 (Palmitoleic Acid), C18:0 (Stearic Acid), C18:1 (Oleic Acid), C18:2 (Linoleic Acid) and C18:3 (Linolenic Acid). Three fatty acid groups were formed by combining the saturated fats (SAT = C14:0, C16:0 and C18:0), the monounsaturated fats (MONO = C16:1, C18:1) and the polyunsaturated fats (PUFA = C18:2 and C18:3). All fatty acid traits were measured on a grams per 100 grams of dry beef product basis, which were converted to a proportion of total fatty acids on a wet beef product basis for this study.

ASReml software (Gilmour *et al.*, 2021) was used to fit the animal model to each trait to estimate parameters based on univariate and bivariate mixed model analysis using three generations of pedigree. Fixed effects fitted in all models included the contemporary group and dam age. Age at slaughter was fitted for CWT, while CWT was fitted as a co-variate for CIMF, CP8 and the fatty acid traits. The contemporary group included herd, year of birth, sex, birth type (twin vs single), breeder-defined management group and slaughter date. Feeding period in the feed lot was allocated based on herd of origin therefore accounted for in the contemporary group formation. Heritabilities, as well as phenotypic and genetic correlations, were calculated from the resulting variance components.

Results

The characteristics of the traits included in this study, their heritability estimates and phenotypic variances are listed in Table 1, with the genetic and phenotypic correlations given in Table 2. The results, particularly genetic correlations, should be considered preliminary due to the large standard errors. The mean proportion of the individual fatty acid composition traits ranged from 0.22% (Linolenic acid) to 39.2% (Palmitic acid). SAT accounted for the highest proportion (mean of 58.9%) of total fatty acids, ranging from 48.9 to 67.8%. MONO was the next most prevalent (mean of 37.3%), ranging from 27.7 to 47.1%. PUFA had the lowest concentration (mean of 3.8%), ranging from 1.1 to 8.4%.

Table 1. Descriptive statistics, heritability (h^2 with standard error in parenthesis) and phenotypic variance (σ^2_p) for carcase weight, rump fat, intramuscular fat and fatty acid traits.

Trait[1]	n	Mean	Min	Max	SD	CV %	h^2	σ^2_p

Table 2. Genetic (above diagonal) and phenotypic (below diagonal) correlations for carcase weight, carcase rump fat, intramuscular fat and fatty acid groups (standard error in parenthesis).

Trait	CWT	CP8	CIMF	SAT	MONO	PUFA
CWT	-	0.51 (0.15)	0.02 (0.16)	-0.30 (0.16)	0.32 (0.16)	0.27 (0.22)
CP8	0.26 (0.04)	-	0.04 (0.16)	-0.21 (0.17)	0.14 (0.17)	0.46 (0.22)
CIMF	0.10 (0.05)	0.02 (0.04)	-	-0.38 (0.14)	0.41 (0.14)	0.17 (0.20)
SAT	-0.05 (0.05)	0.01 (0.04)	-0.08 (0.04)	-	-0.96 (0.17)	-0.67 (0.15)
MONO	-0.01 (0.05)	-0.02 (0.04)	0.10 (0.04)	-0.90 (0.01)	-	0.44 (0.22)
PUFA	0.16 (0.04)	0.05 (0.04)	-0.02 (0.04)	-0.49 (0.03)	0.09 (0.04)	-

All traits showed phenotypic variation, with a considerable portion attributed to genetics. The heritabilities for SAT, MONO and PUFA were 0.64, 0.67 and 0.25 respectively, while the heritabilities for the individual fatty acid traits ranged from 0.27 (Oleic acid) to 0.62 (Stearic acid). The genetic correlations between the fatty acid composition traits to the production traits show contrasting results. SAT has moderate negative genetic correlation with CWT, CP8 and CIMF (-0.30, -0.21 and -0.38 respectively), while MONO and PUFA have moderate positive genetic correlation with CWT, CP8 and CIMF (ranging from 0.14 to 0.46). The genetic correlations between the fatty acid composition traits followed expectations, with strong negative genetic correlations between SAT to MONO and PUFA at -0.96 and -0.67 respectively. The present study also showed a moderate positive genetic correlation between MONO and PUFA of 0.44.

Discussion

The preliminary genetic parameters from this study indicates that selection can be applied in Australian Angus beef cattle breeding programs, with a feedlot finishing component, to change the proportion of SAT to healthier unsaturated fatty acids (MONO and PUFA) within the fatty acid profile of IMF.

Like previous studies (Malau-Aduli *et al.*, 2000; Inoue *et al.*, 2011; Saatchi *et al.*, 2013; Kelly *et al.*, 2012), a portion of the phenotypic variation observed in fatty acid traits can be attributed to genetics. However, the heritability estimates across the fatty acid traits were generally higher from this study (0.25 to 0.67) compared to those reported by Kelly *et al.* (2012), Malau-Aduli *et al.* (2000) and Saatchi *et al.* (2013) which ranged from 0.05 to 0.54, 0.05 to 0.27 and 0.06 to 0.55 respectively. In contrast, they were lower than those reported by Inoue *et al.* (2011) which ranged from 0.34 to 0.86. The differences observed across studies probably being a function of variation in dataset size and structure (764 to 2,110 animals), production systems (length of feeding or ration composition) and breed composition (Angus, Wagyu or multibreed).

The results from the present study also show that the proportion of MONO and PUFA can be increased in IMF through selection, without being detrimental to CWT, CP8 or CIMF. Conversely, the results also indicate that selection for heavier CWT, more CIMF or more CP8 will indirectly increase the proportions of MONO and PUFA, and beneficially reduce the proportion of SAT. These findings are consistent with Kelly *et al.* (2012) who found a negative genetic correlation between carcase rump fat (P8) to the saturated fatty acids (ranging from -0.19 to -0.46) and a positive genetic correlation to the monounsaturated fatty acids (ranging from 0.25 to 0.56). Malau-Aduli *et al.* (2000) also found similar results for marbling (which is highly related to IMF), with a moderate negative genetic correlation to saturated fatty acids (-0.42) and moderate positive genetic correlation to monounsaturated fatty acids (0.45).

To further develop breeding program advice on selection for fatty acid composition in beef, research is required to understand their genetic relationships to a range of selection traits including calving ease, live weight, fertility, temperament, feed efficiency, immune competence and carcase traits, including consumer eating preference traits such as tenderness, juiciness and flavour. Through the ASBP and industry collaborations more fatty acid phenotypes are being collected to confirm the results of this study and reduce the associated uncertainty as indicated by the large standard errors for the estimated genetic parameters.

Acknowledgements

The authors thank Meat and Livestock Australia (MLA) for providing co-funding support for the ASBP (PSH.0528 and P.PSH.1172). Tyson Burey and Xuemei Han from the University of New England are also gratefully acknowledged for the provision of fatty acid composition data.

Abstract

Beef cattle international evaluations, led by Interbeef, combine data from different countries to compute international estimated breeding values (EBV_{INT}) which are expressed on the same country scale as national ones, allowing participating countries to compare national and foreign sires. These two EBV might be in disagreement due to differences in the information used in national and international evaluations. This can be overcome by integrating the EBV_{INT} into the national evaluations to obtain a 'blended' EBV. Here we tested and validated a general procedure to integrate publishable sires EBV_{INT} at the national level. Using evaluations for Limousin weaning weight and the integration for Italy as a case study, we show that the integration procedure accurately blends international information at the national level while avoiding double-counting of national information which are used as input to compute EBV_{INT} in Interbeef evaluations. This procedure can also be used with other traits and breeds.

Introduction

International evaluations allow comparing estimated breeding values (EBV) of foreign elite animals with national animals by computing international EBV (EBV_{INT}) and associated reliabilities (REL_{INT}). EBV_{INT} usually would have higher reliabilities than national EBV (EBV_{NAT}) as international evaluations take into account data from relatives recorded in other countries (Bonifazi *et al.*, 2020b). In beef cattle international evaluations as performed by Interbeef, each participating country receives a list of EBV_{INT} and REL_{INT} for: (1) all animals in the national pedigree; and (2) so-called 'publishable sires', i.e. sires that meet Interbeef publication rules, as described in Bonifazi *et al.* (2021). Thus, an individual could have two EBV at the national level: EBV_{NAT} and EBV_{INT}, which can differ due to differences in information between national and international evaluations (e.g. national evaluations are usually multi-trait and in some cases multi-breed while international evaluations are trait-specific and performed within-breed). To overcome this issue, the EBV_{INT} and its associated measure of precision (e.g. REL_{INT}) can be integrated into the national evaluations (Vandenplas and Gengler, 2015), resulting in a single 'blended' EBV that includes and propagates international information to all animals in the national evaluation. However, double-counting of national information needs to be removed from the EBV_{INT} as Interbeef uses national phenotypes as input for international evaluations. Thus, the objectives of this study were to test and validate the accuracy of a general procedure to integrate publishable sires' EBV_{INT} at the national level using Limousin weaning weight and Italy (ITA) as a case study for national evaluations.

Materials & methods

Data and software. A total of 441,691 Limousin males and females individual age-adjusted weaning weights (AWW) were available. AWW were recorded in eight different countries for a total of six populations: Denmark, Finland and Sweden (modelled as one population), Czech Republic, Ireland,

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_655, © R. Bonifazi *et al.* 2022

Germany, Switzerland, and Italy. A total of 7,506 AWW (of which 2,304 from ITA) were recorded from animals born between January and May 2019. The international pedigree included 683,317 animals. All analyses were performed using MiXBLUP (ten Napel *et al.*, 2020): the convergence criterion was 'CD≤10^{-5}, and reliabilities were computed using the Tier and Meyer (2004) algorithm.

International and national evaluations. The direct and maternal EBV_{INT} and REL_{INT} were estimated using the Interbeef model which is equivalent to a multi-trait animal model with maternal effects where each population national model was fitted as a different correlated trait (see Bonifazi *et al.* (2020a) for a complete description). Direct and maternal genetic effects were modelled using an across-populations genetic (co)variance matrix following the Interbeef procedure as described in Bonifazi *et al.* (2021). Random environmental, maternal permanent environmental, and residual effects were modelled using block-diagonal variance matrices. Both genetic and environmental variances were the same as those used in the national genetic evaluations of participating countries. The direct and maternal EBV_{NAT} and REL_{NAT} for ITA were obtained by running a single-trait evaluation using only ITA submitted phenotypes and the same national model as the one used for the international evaluations.

Integration. After EBV_{INT} and EBV_{NAT} and their associated REL (i.e. REL_{INT} and REL_{NAT}) on a 0 to 1 scale were obtained following the aforementioned models, publishable sires' international information was integrated into national evaluations in four steps as follows.

Step 1. For each publishable sire *i*, direct and maternal effective record contributions (ERC) associated with REL_{NAT} and REL_{INT} (ERC_{NAT} and ERC_{INT}, respectively) were computed as: $ERC_i = \lambda \cdot REL_i/(1-REL_i)$, where $\lambda = \sigma^2_{residual} / \sigma^2_{genetic}$ with $\sigma^2_{genetic}$ being either the direct or maternal genetic variance.

Step 2. For each publishable sire *i*, direct and maternal de-regressed proofs for both national and international EBV (DRP_{NAT} and DRP_{INT}, respectively) were computed following Garrick *et al.* (2009): $DRP_i = PA_i + (EBV_i - PA_i)/ REL_{i\,(o+p)}$, where PA_i is the parent average EBV of the individual computed as $(EBV_{sire} + EBV_{dam})/2$, and $REL_{i\,(o+p)}$ is the reliability due to the individual own performance (o) and its progeny (p) computed as $dERC_i / (dERC_i + \lambda)$. The de-regressed ERC for the individual *i*, $dERC_i$, is computed as $ERC_i - ERC_{PA}$, with ERC_{PA} being the ERC calculated from parent average reliability defined as $(REL_{sire} + REL_{dam})/4$. If the $dERC_i$ was ≤0, both the $dERC_i$ and its associated DRP_i were set to 0.

Step 3. For each publishable sire *i*, to avoid double-counting of national information, the direct and maternal adjusted DRP (DRP*) and its associated weight (dERC*) adjusted for national data were computed based on Vandenplas *et al.* (2014): $DRP^*_i = ((dERC_{INTi} \cdot DRP_{INTi}) - (dERC_{NATi} \cdot DRP_{NATi}))/ dERC^*_i$, where $dERC^*_i = dERC_{INTi} - dERC_{NATi}$. If $dERC^*_i$ was ≤0 or if the gain in reliability (defined as the difference between REL_{INT} and REL_{NAT}) was smaller than 0.01, both the $dERC^*_i$ and its associated DRP^*_i were set to 0.

Step 4. The direct and maternal blended EBV were computed with a national evaluation using national phenotypes and publishable sires' direct and maternal DRP* as pseudo-phenotypes. The dERC* were used as weights for the DRP*. The maternal DRP* were associated with the maternal effect of the animal itself and not of its dam. The direct and maternal DRP* were modelled as additional phenotypes for the same trait and fitted using one general mean for each DRP*.

Scenarios and validation. We applied the above procedure for ITA where national and international data differ due to differences in publication calendars. We integrated EBV_{INT} from an international evaluation in January 2019 into a national evaluation in May 2019. All analyses used the complete international pedigree. Hereafter, we will refer to ITA phenotypes as 'national', and to phenotypes from other countries

as 'foreign'. First, the two following evaluations were performed and their outputs were used as inputs for the integration procedure:

- INT_{JAN}. An international evaluation using both national and foreign phenotypes of animals born up to January 2019. Publishable sires to be integrated are selected from this evaluation.
- NAT_{JAN}. A national evaluation using only national phenotypes of animals born up to January 2019. EBV and REL from this evaluation are used during the integration procedure to avoid double-counting of national information.

Then, three scenarios were implemented and validated:

- NAT_{MAY}. A national evaluation using only national phenotypes of animals born up to May 2019. This scenario is used for comparison with $BLEND_{MAY}$ and GOLD to illustrate the benefits of the integration procedure over a national evaluation without any integration.
- $BLEND_{MAY}$. A blended national evaluation using national phenotypes of animals born up to May 2019 with the integration of publishable sires' information from INT_{JAN}.
- GOLD. As $BLEND_{MAY}$ but integrating information of publishable sires from an international evaluation using only foreign phenotypes of animals born up to January 2019. This international evaluation avoids double-counting of national information when integrating publishable sires' information in GOLD, providing a 'gold standard' for comparison with $BLEND_{MAY}$.

We validated the integration procedure by comparing publishable sires' EBV obtained with either NAT_{MAY}, $BLEND_{MAY}$, or GOLD with their EBV from a reference scenario (REF) that is an international evaluation using national phenotypes of animals born up to May 2019 and foreign phenotypes of animals born up to January 2019. Scenario REF uses the same sources of information as in $BLEND_{MAY}$ and GOLD, but without approximating foreign information by DRP* and dERC*. Therefore, the more accurate the integration procedure, the closer the EBV are to those of REF. As validation metrics, we computed the Pearson correlations (ρ) between EBV, and the slopes (b_1) of the regression of REF EBV on the EBV of the validated scenarios. Publishable sires were divided into three groups: (A) domestic publishable sires with ≥15 recorded offspring in ITA; (B) domestic publishable sires with <15 recorded offspring in ITA; and (C) foreign publishable sires with no recorded offspring in ITA.

Results

The number of publishable sires in groups A, B and C was 1,382, 94 and 3,470 for direct EBV, and 491, 51, and 1,165 for maternal EBV, respectively. The mean dERC* of all publishable sires and the number of dERC*>0 were similar between $BLEND_{MAY}$ and GOLD (Table 1). As expected, for direct EBV, group A of publishable sires had a smaller amount of international information to be integrated (mean dERC* equal to 0.5 for $BLEND_{MAY}$) compared to sires in groups B and C (mean dERC* equal to 5.2 and 2.5, respectively, for $BLEND_{MAY}$) (Table 1). For all groups, direct EBV ρ and b_1 improved in both $BLEND_{MAY}$ (0.98 and 1.02, respectively, on average across groups) and GOLD (0.98 and 1.06 on average) compared to NAT_{MAY} (0.60 and 0.77 on average) (Table 1). For maternal EBV, $BLEND_{MAY}$ and GOLD resulted in similar ρ and b_1 as NAT_{MAY} for all groups except for foreign sires (Table 1). For foreign sires, $BLEND_{MAY}$ and GOLD had ρ closer to 1 but worse b_1 compared to NAT_{MAY}. Overall, $BLEND_{MAY}$ gave similar ρ and similar or slightly worse b_1 than GOLD: on average across groups and effects, ρ and b_1 were 0.93 and 0.88 for $BLEND_{MAY}$, and 0.93 and 0.94 for GOLD.

Table 1. Validation results for direct and maternal EBV of publishable sires.[1] All scenarios are validated against EBV from scenario REF.[2]

Sire group	Scenario[2]	Direct EBV				Maternal EBV			
		ρ	b_1	Mean dERC*	n. dERC* >0	ρ	b_1	Mean dERC*	n. dERC* >0
A (Domestic ≥15 off)	NAT_{MAY}	0.95	0.96	-	-	0.99	1.01	-	-
	$BLEND_{MAY}$	0.99	0.96	0.5	97	0.98	0.96	0.1	52
	GOLD	0.99	1.01	0.3	121	0.98	1.02	0.1	70
B (Domestic <15 off)	NAT_{MAY}	0.63	0.66	-	-	0.86	0.80	-	-
	$BLEND_{MAY}$	0.97	0.96	5.2	94	0.84	0.72	0.7	51
	GOLD	0.97	1.03	4.0	94	0.86	0.87	0.7	51
C (Foreign)	NAT_{MAY}	0.24	0.69	-	-	0.51	0.98	-	-
	$BLEND_{MAY}$	0.97	1.13	2.5	3,469	0.83	0.57	0.5	1,127
	GOLD	0.97	1.14	2.4	3,470	0.81	0.58	0.4	1,165

[1] ρ = Pearson correlation; b_1 = slope; dERC* = adjusted de-regressed ERC; n. = number; off = recorded offspring in ITA.

[2] REF = reference international evaluation; NAT_{MAY} = national evaluation without integration; $BLEND_{MAY}$ = blended evaluation with integration of publishable sire's information; GOLD = as $BLEND_{MAY}$ but integrating publishable sire's information computed without national data.

Discussion

Our results show that a blended evaluation is especially beneficial for sires in groups B and C which have only a few or no recorded offspring at the national level. Also, double-counting of national information during blending was properly removed as shown by the good agreement of $BLEND_{MAY}$ and GOLD. Scenario GOLD completely avoids double-counting of national information but would require Interbeef to run and distribute for each population EBV and REL from an international evaluation from which national phenotypes are removed. Instead, $BLEND_{MAY}$ can be directly applied by countries, assuming that the publishable sires' parental EBV_{INT} and REL_{INT} are known and that national information submitted for the international evaluation (here NAT_{JAN}) are available. Overall, maternal EBV showed lower ρ and b_1 compared to direct EBV, which could be due to the lower gains in REL associated with maternal EBV compared to direct EBV. The outlined integration procedure enables the integration of publishable sires' EBV_{INT} at the national level in a single blended EBV. Results show that the integration procedure yields accurate results for both direct and maternal EBV.

[1]Purdue University, 270 S Russell Street, West Lafayette, IN 4790,7 USA; [2]Angus Genetics Inc., 3201 Frederick Avenue, Saint Joseph, MO 64506, USA; [3]Lactanet, N1G 2W1, Guelph, Canada; [4]AGBU, The University of New England, 2351, Armidale, Australia; [5]Angus Australia, 86 Glen Innes Road, NSW 2350, Armidale, Australia; alvarena@purdue.edu; britol@purdue.edu

Abstract

The main goal of this study was to investigate the feasibility of an across-country genomic evaluation for claw-set and foot angle scores in North American and Australian Angus populations, by analysing within and across-country genotype-by-environment interactions (G×E). In total, 123,322 and 1.13M animals had phenotype and genotype information. Reaction norm models fitting environmental gradients based on the effects of management group and bivariate animal models were used to evaluate genetic correlation within- and across-countries, respectively. Similar heritability estimates were obtained for both North American and Australian populations (0.22-0.25), and moderate-to-high genetic correlations between foot scores (claw-set: 0.73; foot angle: 0.51) were observed between countries. On average, high genetic correlations (>0.90) were observed among pairs of environmental gradients within countries. However, moderate correlations were observed among contrasting environmental gradients (e.g. 0.50), indicating moderate G×E. In general, gains in both theoretical and prediction accuracy of genomic estimated breeding values from a joint- versus within-country genomic evaluation were observed.

Introduction

Animal soundness has been ranked within the top five traits to be selected in a breeding program based on a survey taken by American and Australian Angus stakeholders (Santos *et al.*, 2019; Bell *el al.,* 2019). Furthermore, structural problems affecting foot angle (FA) and claw set (CS) are important culling reasons, representing around 6% of animals culled from North American Angus farms (Oliveira *et al.*, 2020). Foot problems have a direct impact on animal longevity, welfare, and the profitability of the production system. Low-to-moderate heritability estimates and clinical trials highlight the influence of environmental conditions on the phenotypic expression of foot scores (Wang *et al.*, 2017; Giess *et al.*, 2021). With the globalization of germplasm, genotype-by-environment interactions (G×E; Lynch and Walsh, 1998) can be a concern. With significant G×E, cattle ranking highly in one environment may not be the best in a different environment resulting in losses of revenue and jeopardizing genetic improvement.

The overarching goal of this study was to characterize the genetic sensitivity of foot scores within and among the United States of America (USA) and Australian (AU) Angus populations to allow an optimal across-country genomic evaluation. More specifically, the main objectives were to: (1) estimate the genetic correlation between countries for two foot score traits (i.e. FA and CS); (2) evaluate G×E within-country based on the Best Linear Unbiased Estimates (BLUE) of management group effect as the environmental gradient; and (3) assess the predictive ability of genomic prediction of breeding values based on single- and across-country training populations. This study comprises the largest beef cattle dataset for foot score collected in a wide range of climatic conditions and production systems.

Materials & methods

Data. American Angus Association (Saint Joseph, USA) and Angus Australia (Armidale, Australia) provided the datasets used in this study. The scores for CS and FA, respectively were recorded on a scale

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_656, © A.B. Alvarenga *et al.* 2022

from one (i.e. spread or steep) to nine (i.e. scissor or weak), in which five is the optimal score (www.angus.org/performance/Documents/footscorebrochure.pdf). Measurements of foot scores are collected annually from yearling through older ages. The information on the worst foot at specific ages was considered as the phenotypic record of each animal. The incidence of one through four scores were very low, therefore, only scores from five to nine were included in the analyses. The quality control applied included removing records with unknown management group, management groups with fewer than three records, or groups without phenotypic variation. Finally, 123,322 (50,621 USA and 72,701 AU) CS records from 109,055 (46,864 USA and 62,191 AU) animals and 120,730 (48,442 USA and 72,288 AU) FA records from 106,333 (44,485 USA and 61,848 AU) animals remained for further analyses. The USA and AU animals were born from 2002 to 2020 and from 1993 to 2020, respectively. The animals had from one to six repeated records. In total, 1.13 million animals (996K USA and 132K AU), which were genotyped and/or imputed to a 54K marker density panel, were available for this study, including 36,786 USA and 23,023 AU animals with both phenotypic and genomic information.

Population stratification. Principal components were estimated based on the genomic relationship matrix to investigate the genomic similarities of the Angus populations. The linkage disequilibrium for each population and consistency of gametic phase among populations were also investigated. Both SNP1101 and ADMIXTURE (Alexander and Lange, 2011) were utilized for the analysis of population structure.

Statistical models. A repeatability animal model was used, which included management group and age in days (linear covariate) as fixed effects; and animal, permanent environment, and residual as random effects. The results from threshold and linear models were highly correlated (results not shown), therefore, a linear model was used in all analyses.

Genetic parameter estimation. A single-trait animal model was used to estimate the heritability for each trait (CS and FA) per country (USA and AU). A two-trait animal model was used to calculate the genetic correlation between countries for each trait separately. To evaluate the genetic correlation within countries, two scenarios were evaluated: (1) randomization of farms into two groups to be considered as different traits, and (2) a reaction norm approach, in which the effect of each management group was used as the environmental gradient. A two-trait model was used for scenario 1. For the reaction norm analyses, a similar approach as proposed by Carvalheiro *et al.* (2019) was employed. Accurate estimation of management group effect (environmental gradient) is crucial for these analyses. Therefore, additional quality control on the data was performed requiring a minimum of 20 animals per management group. The first step was to estimate the management group effects (i.e. BLUE), which were then rounded to one decimal digit, and standardized to have mean equals to zero and variance equals to one. Then, the reaction norm was defined as:

$$y_{ij} = x_j'\beta + b\hat{\theta}_i + n_{0_u} + n_{1_u}\hat{\theta}_i + n_{0_{pe}} + n_{1_{pe}}\hat{\theta}_i + e_i \quad (1)$$

Where y_{ij} is the phenotypic observation on the animal j in the environmental gradient i; β is the vector of fixed effects, and x_j' is its corresponding incidence vector; $\hat{\theta}_i$ is i environmental gradient (i.e. management groups' BLUE-standardized), and b is the overall fixed regression coefficient of y_{ij} on $\hat{\theta}_i$; n_{0_u} and n_{1_u} are the reaction norm intercept and slope of animal j regressed on $\hat{\theta}_i$ for the additive genetic random effect, while $n_{0_{pe}}$ and $n_{1_{pe}}$ refer to the permanent environment random effect; and e_i is a homogeneous residual. For all genetic parameters' estimation, a pedigree-based relationship matrix was implemented, in which four generations were traced back from the animals with phenotypic records (1.9M animals). The (co) variance components were estimated using thrgibbsf90 and airemlf90 software (Misztal *et al.*, 2014a) for the reaction norm step and remaining analyses, respectively.

Forward genomic prediction. We used a single-step GBLUP two-trait model (CS and FA) and implemented the Algorithm for Proven and Young with 22k core animals (Misztal *et al.*, 2014b) to estimate the Genomic Estimated Breeding Values (GEBV). Animals born in 2020 (4,755 animals) and 2019-2020 (4,366 animals) were considered as the validation group in the USA and AU datasets, respectively. Different scenarios were evaluated alternating the training population such as (1) USA as training and validation; (2) AU as training and validation; (3) joint genomic evaluation of USA and AU (as training and validation). The predictive performance of the scenarios was evaluated using the Legarra and Reverter (2018) method.

Results & discussion

Population structure. The USA and AU Angus populations are highly linked at the genomic level based on principal components, admixture, and consistency of gametic phase (correlation equal to 0.84 for a distance of markers up to 5.0 Mb). Similar patterns were observed among Angus populations raised in Canada and Brazil (Cardoso *et al.,* 2020).

Genetic parameters estimation. Heritability estimates are similar among countries and foot score measurement, being moderately heritable [0.22 (0.01) and 0.25 (0.01) for CS, and 0.23 (0.01) and 0.24 (0.01) for FA using USA and AU animals, respectively; values are mean (SE)]. Even with exchange of germplasm and the populations being similar based on genomic information, moderate genetic correlations were observed between countries [0.73 (0.08) for CS; 0.51 (0.12) for FA]. Some hypotheses justifying these lower correlations are: (1) differences in the trait recording (i.e. cattlemen record foot score in the USA while a certified technician is responsible for the recording in AU); (2) differences in age at recording (i.e. ~60% of USA recording happens at yearling while ~77% of recordings in AU is equally distributed up to 2 years of age); (3) subpopulation stratification or G×E due to management system that could be even observed within country; and (4) across-country G×E.

To investigate the potential source of the moderate genetic correlation between countries, farms within a country were randomly assigned to two different groups and each group treated as a different trait, similar how USA and AU were treated as different traits. Moderate-to-high genetic correlations (from 0.66 to 0.85) were observed within country by randomization of herds to separate traits. Further investigation of within-country G×E based on reaction norms considering BLUE of management groups as the environmental gradient was performed. The management groups represent sex and the location of the farm, which could potentially reflect the production environment. Figure 1 represents the heatmap of genetic correlations among all environmental gradients. High averages of genetic correlation were observed in all scenarios (from 0.91 to 0.99). However, the correlation among extreme environments varied from 0.50 to 0.94. This suggests that among extreme environmental gradients within countries, lower genetic correlations could be observed, indicating G×E.

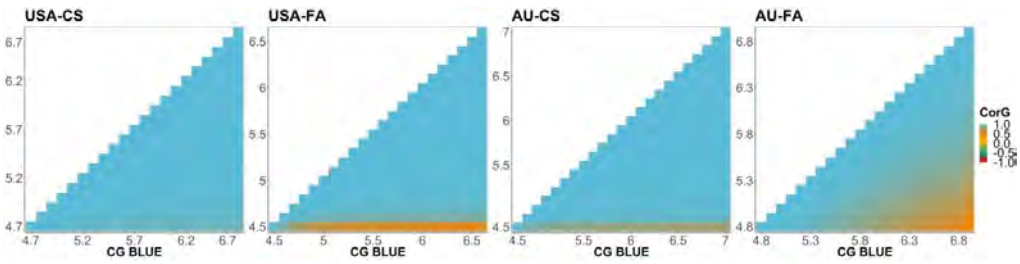

Figure 1. Estimates of genetic correlations across environmental gradients.

Forward genomic predictions. An improvement in predictive accuracy was observed while performing a joint genomic evaluation for the USA (from 0.59 to 0.60 for CS; 0.56 to 0.58 for FA). In the AU data, in which a larger training population was available, no gain in predictive accuracy was observed while adding the USA dataset into the evaluation. However, a reduction in dispersion (from 0.94 to 0.98 for FA) was observed. Small improvements in the predictive ability could be because the data is already large enough to accurately estimate GEBVs. Even though small or no improvements were observed in the overall predictive ability combining USA and AU datasets, a joint genetic evaluation is of great interest in terms of the exchange of genetic material. Furthermore, the joint genetic evaluation allows improvement in the accuracy of individual estimated breeding values compared to a within-country evaluation. Individual accuracy increased by up to 38% while performing a joint genetic evaluation.

657. Single-step GBLUP evaluation for categorical traits for beef cattle

A. Nazari-Ghadikolaei[1*], S. Eriksson[1] and W.F. Fikse[2]

[1]Swedish University of Agricultural Sciences, P.O. Box 7023, 75007 Uppsala, Sweden; [2]Växa, P.O. Box 288, 75105 Uppsala, Sweden; anahit.nazari@slu.se

Abstract

In order to study the performance of single-step genomic prediction for a categorical trait such as calving difficulty in beef cattle, data was simulated and single-step genomic breeding values (GEBV) and pedigree-based breeding values (PEBV) were estimated. Different number of trait categories with and without normal score transformation, and including different information sources, were studied. For a trait with a heritability of 0.30 and four categories, the increase in accuracy using GEBV compared with PEBV was 28.6% with, and 27.9% without normal score transformation, respectively. Moreover, in a scenario without phenotypes for males, the accuracy of GEBV was 26.6% higher than for PEBV for a binary trait with a heritability of 0.05. All results indicated that single-step genomic evaluation of categorical traits is beneficial to use in beef cattle breeding programs.

Introduction

Striking improvement of accuracies by using genomic breeding values (GEBV) has been seen in dairy cattle (Hayes *et al.*, 2009). GEBV accuracies are generally lower for beef cattle, due to smaller reference populations, fewer tested progeny and limited use of artificial insemination (Meuwissen *et al.*, 2016). Single-step genomic prediction (ssGBLUP) has been applied successfully for e.g. Angus in the U.S. (Lourenco *et al.*, 2015). The ssGBLUP that allows adding genomic, phenotype and pedigree information at the same time is well suited for beef populations (Legarra *et al.,* 2014), and was shown to improve breeding value accuracies for growth traits in simulated and real data (Lourenco *et al.*, 2013; 2015). Pedigree-based genetic evaluation of categorical traits is often done using linear models, and breeding values tend to have satisfactory properties despite ignoring the categorical nature of the observations (Meijering and Gianola, 1985). However, for single-step GBLUP evaluation experiences with categorical traits are scarcer.

In this study, we simulated a population mimicking the structure of the most common beef breeds in Sweden to compare breeding value accuracies using pedigree-based BLUP (PBLUP) and ssGBLUP in different scenarios. We studied traits with two or four categories, similar to calving ease, with and without normal score transformation and with different information sources.

Materials & methods

Simulated population. The QMsim software (Sargolzaei *et al.*, 2009) was used to create a population with genomic information, a single quantitative trait with a heritability of 0.30, and phenotypic variance of 1. True breeding values (TBVs) were calculated as the sum of polygenic and QTL effects, both effects explaining 10 and 20% of the phenotypic variation. For the genome, 750 QTL and 40K SNP were simulated across 29 autosomal chromosomes. Marker mutation rate was assumed to be zero, and neither missing marker genotypes nor marker genotyping errors were considered. In order to create LD, a historical population was created consisting of 1000 individuals in generation zero and kept constant in number for 1,020 generations. In generation 1,020, the population was decreased to 100 males and 100 females. From the last generation of the historical population, the population BeefA consisting of 100 males and 100 females was created using the option random union gamete mating system, allowing females to mate with more than one male per generation, and five offspring per dam were simulated. At this stage, the population was expanded with a factor five for each of five generations. Furthermore, population BeefB was simulated

from the last generation of BeefA, using 200 males and 3,300 females, followed by random mating system and sire and dam replacement rate of 0.30 and 0.20, respectively. The simulation was continued for 25 generations with one offspring per dam. Finally, the genotypes and phenotypes of 86,000 individuals in population BeefB were available for further analyses.

Phenotypes. We generated an additional phenotype with a low heritability (LH) of 0.05 by adding random variation to the simulated quantitative trait. Binary traits were created with thresholds at: (1) the 0.75 quantile ($C2_{constant}$); and (2) quantile 0.70 in males and 0.75 in females in generation zero and with a slight decrease of 0.002 in each generation ($C2_{changed}$). The latter was made to mimic better calving ease for female calves that tend to be smaller compared to male calves and to mimic an environmental improvement in calving ease over time. In addition, binary traits with four categories were created with thresholds at and 0.94, 0.97, and 0.99 ($C4_{constant}$). Normal score (NS) transformation was done to reduce extreme phenotypes and generate traits closer to a normally distributed trait (Table 1).

Breeding value estimation. Different approaches for estimating breeding values were conducted using the BLUPF90 family programs (Aguilar *et al.*, 2018). Pedigree-based breeding values (PEBV) and GEBV were estimated using blupf90 for the different traits. All traits were analysed using linear models (LM), and binary traits were also analysed using threshold models (TM) in Thrgibbs1f90 with 100,000 iterations, and the first 2,000 as burn-in; results of the Gibbs sampling were summarized using postgibbsf90.

Table 1. Scenarios, traits, models, heritability (h^2) and data for breeding value estimation.

Scenario	Trait and Model type[1]	h^2†	Generations with phenotype data		Generations with genotype data

† h^2 on the underlying scale for categorical observations.

Scenarios studied. We created several different scenarios with respect to data included in the genetic/genomic evaluation (Table 1). In all cases, we removed phenotypes for animals in the last two generations (24 and 25). In Scenario A, we used all genotype information (approximate 40K SNPs) from the last seven generations; more generations could not be considered due to program limitations. In Scenario B, we include phenotypes of females only and used genotypes in two different settings: (1) for males in the last seven generations and for females in the last two generations; (2) for females in the last seven generations and for males in the last two generations. Accuracies for PEBV and GEBV were estimated as the correlation with TBV. Five replicates were made for each simulation, and average accuracies of these were used.

Results

Using ssGBLUP instead of PBLUP in scenario A, improved accuracies with 22.4 to 29.6% for animals in the last two generations and without progeny (Table 2). Overall, the increase in accuracy was higher for the last generation (gen. 25) compared to the previous generation (gen. 24). In Scenario A, the largest improvement of accuracy by using ssGBLUP instead of PBLUP was for the trait C4 with heritability 0.30, followed by the corresponding normal score transformed trait C4NS, for individuals with no progeny in the last two generations. The accuracy improvement from using ssGBLUP instead of PBLUP for Scenario B, was generally higher when the animals with phenotypes (females) were genotyped (22.6–28.2%), than when males without phenotypes, were genotyped (14.2-20.5%). Relatively small effects of the normal score transformation were seen in scenario A (Table 2).

Discussion

The increase in accuracy from using ssGBLUP compared to PBLUP was higher for the trait C4, than for the binary C2 and C2NS traits, probably due to the lower initial accuracy for C4 (using PBLUP). For the low heritability traits (LH), all accuracies were as expected lower compared to the corresponding traits with higher heritability. More records for predicting accurate GEBV are needed for traits with lower heritability, such as calving ease, compared to traits with higher heritability (Hayes *et al.*, 2009). However, the use of genomic information improved the accuracies for binary (C2) traits in this study. This shows that adding genomic information and using ssGBLUP is beneficial also for categorical traits with lower heritability, such as calving, fertility and health traits. When phenotypes only for females were included, using genotypes for females resulted in higher accuracies (Scenario B (b)) compared to using genotypes of males (Scenario B (a)).

To conclude, genomic selection has opened a window for estimating more accurate breeding values also for categorical traits in beef cattle, especially for traits such as calving ease with low heritability. Although the response to selection for such a trait is not as fast as for other traits with higher heritability, having an appropriate phenotype recording along with adding genotype data could improve accuracy of selection. Moreover, genotyping of animals with poorly defined phenotypes like for categorical traits appeared better than having disparate phenotyped and genotyped populations. The current simulated results showed that using ssGBLUP could improve accuracies within different scenarios in simulated Swedish beef cattle population.

Table 2. Accuracies and accuracy improvements when using ssGBLUP instead of PBLUP for animals in generations 24 and 25 without phenotypes and progeny.

Scenario[1]	Trait type[2]	Accuracy

Abstract

Traits related to muscle and fat deposition are economically relevant for beef cattle finishing but may also influence reproductive performance in mature beef cows. The aim of this study was to examine the genetic relationships of mature cow body condition scores (BCS) with fat and muscle traits in finishing cattle. Genetic correlations among BCS at different seasonal time points were high, with the lowest estimate of 0.84 between BCS at weaning and BCS prior to calving. Generally, muscle and fat traits in both mature cows and finishing cattle were lowly genetically correlated but similarly so across all measured time points. There is scope to identify animals with favourable genotypes for both maternal and finishing fat and muscle traits. Improving genetic merit for muscling or fat content in finishing cattle may be achieved without greatly impacting on body energy reserves in mature cows.

Introduction

Body energy reserves are key components determining the reproductive performance of beef cows in the breeding herd (Osoro and Wright 1992). The optimum condition of cows may differ throughout the production cycle and for varying production systems. Cow body condition scoring is a tool to subjectively assess stored energy reserves in cows, made up of fat and muscle (Hickson *et al.* 2017). Currently, in New Zealand breeding values are commonly available for ultrasound (US) or carcass fat and muscle traits in finishing cattle but not for body condition score (BCS) in mature cows. Some breeders are selecting carcass fat traits with the objective of maintaining BCS in cows. Although extensive research exists on the genetic relationships among economically relevant traits in beef cattle, there is only limited information on the relationship of subjective measures of body condition in cows with objectively measured muscling and fat traits in slaughtered cattle (De Lacerda *et al.* 2019). Weik *et al.* (2022) showed that genetic correlations were low between cow BCS and finishing traits in New Zealand beef cattle, assuming that BCS measured at different time points was genetically the same trait. The aim of this study was to determine whether distinct genetic relationships exist for cow BCS at different seasonal time points, considered as separate traits, with muscle and fat traits in finishing beef cattle.

Materials & methods

Dataset. All manipulations were approved by the AgResearch Animal Ethics Committee. Data originated from an ongoing beef progeny test by Beef + Lamb NZ Genetics conducted on commercial New Zealand hill country farms since 2014 (Weik *et al.* 2021). Measures on several performance and production traits were recorded for the original population of Angus or Hereford cows and their crossbred progeny. This study used data on traits related to muscling and fat composition measured on cows in the breeding herd (Angus, Hereford or Stabilizer sired) and males and females as part of the finishing operation (Angus, Hereford, Simmental, Stabilizer or Charolais sired).

Traits. Body condition score was obtained through visual assessment of body energy reserves of mature cows from three years of age on a 1 to 10 scale (1= emaciated, 10 = obese; Hickson *et al.* (2017)) for a

R.F. Veerkamp and Y. de Haas (eds)

total of 4,590 cows. Scoring was conducted by a trained scorer or by the farmer under regular supervision and training. Measures were taken at three seasonal time points: prior to mating, at weaning and prior to calving. Scanning of the US traits eye-muscle area (UEMA) and rib fat depth (URF) was conducted on live animals between 475 and 616 days of age by a Breedplan-accredited technician on 1,900 steers and 2,049 heifers. The traits carcass eye-muscle area (CEMA) and carcass rib fat depth (CRF) were recorded between 541 and 1,029 days of age by trained graders using the Meat Australia chiller assessment system (AUS-MEAT 2018) on the day following slaughter of 1,615 steers and 354 heifers.

Data editing. A contemporary group (CG) was assigned to each animal and trait. For BCS, CG comprised herd, recording date and management group at the time of measurement. For US and carcass traits, CG also included the sex of the animal and management groups leading up to the US scan or slaughter date, respectively. Phenotypes were removed from the dataset when only one individual was recorded in a CG or when all animals within a CG had equal phenotypes.

Cow BCS was pre-adjusted to five years of age by fitting a fixed effects model with cow age in years (cows≥12 years of ages in a single class) and CG as class effects in the model. Finishing traits were pre-adjusted to either a constant live weight of 432 kg for US traits or a constant carcass weight of 310 kg for traits measured at slaughter (representing the mean weight at US scanning or slaughter, respectively) to compare muscularity and fatness rather than absolute size. Adjustments on an individual animal basis were obtained using the four-step procedure presented by Reverter *et al.* (2000) and fitting either live weight at US scanning or carcass weight as linear and quadratic covariates as well as CG as a factor in that model. Following pre-adjustments, observations above or below three standard deviations (SD) from the CG mean were removed. All traits were tested for heterogeneity of variances. Traits with a significant regression ($P<0.05$) of the CG SD on the CG mean were scaled to homogenize the variances (Pickering *et al.* 2012, Weik *et al.* 2022).

Statistical analysis. Data cleaning and pre-adjustments of the phenotypes were done using R version 3.6.0. Genetic parameters were estimated using restricted maximum likelihood in ASREML 4.1 (Gilmour *et al.* 2015). Variance components were obtained for BCS and US traits using univariate animal models. For carcass traits bivariate models were used by including live weight at US scanning as a correlated trait to account for any selection prior to slaughter due to drafting of animals in weight-dependent slaughter management groups following US scanning. Genetic and phenotypic correlations were estimated from bivariate animal models, or trivariate models when a carcass trait together with live weight at US scanning was included.

A CG class effect, and covariates for breed percentage and heterosis (0 = purebred; 1 = first-cross) were fitted as fixed effects for all traits, and an age of dam class effect was included for US traits only. A random animal and residual error term were fitted for each trait. Additionally, a random permanent environmental effect was fitted for each BCS trait to account for correlated residuals on repeated measures from the same animal. Variance structures for the random effects were assumed as follows: $var(a)=A\sigma_a^2$, $var(pe)=I\sigma_{pe}^2$ and $var(e)=I\sigma_\varepsilon^2$. The numerator relationship matrix A comprised a total of 14,240 animals including 424 sires and 4,473 dams.

Results

Among seasonal BCS traits, the phenotypic mean was lowest prior to calving but the associated SD were similar and small across seasons (Table 1). Variance components for BCS traits were in a similar range across seasons for the additive genetic (0.13-0.17) and the residual (0.33-0.37) variances, however, the permanent environmental variance was slightly higher at weaning than at other seasons, and this is

Table 1. Means (±standard deviations), variance components (σ_a^2=direct additive genetic, σ_{pe}^2=permanent environmental, σ_ε^2=residual), heritabilities (h^2±standard errors) and repeatabilities (t±standard errors) in New Zealand beef cattle.[1]

Trait	Mean	σ_a^2	σ_{pe}^2	σ_ε^2	h^2	t
BCS mating	7.25 (0.91)	0.15	0.04	0.37	0.27 (0.04)	0.34 (0.01)
BCS weaning	6.93 (0.91)	0.17	0.10	0.36	0.27 (0.04)	0.43 (0.01)
BCS calving	6.46 (0.93)	0.13	0.05	0.33	0.26 (0.06)	0.35 (0.01)
UEMA[2]	63.24 (5.03)	5.84		10.26	0.36 (0.05)	
URF[2]	3.53 (0.98)	0.53		0.45	0.54 (0.05)	
CEMA[2]	74.58 (6.75)	13.91		18.79	0.43 (0.11)	
CRF[2]	5.35 (2.59)	2.01		5.18	0.28 (0.07)	

[1] BCS = mature cow body condition score; UEMA = eye-muscle area (ultrasound); URF = rib fat depth (ultrasound); CEMA = eye-muscle area (carcass); CRF = rib fat depth (carcass).

[2] Finishing cattle; parameters first published by Weik *et al.* (2022).

reflected in the higher repeatability. Heritabilities for BCS traits were the same across seasons (0.26-0.27). Heritabilities of finishing fat and muscle traits were higher overall compared to BCS at any season. At US scanning, heritability was higher for URF compared to UEMA whereas CEMA was more heritable than CRF at slaughter.

Genetic correlations among BCS traits were high across all seasons, ranging from 0.84 to 0.99 (Table 2). The lowest estimate was observed between BCS at weaning and BCS before calving.

Genetic correlations were generally low among BCS at all seasonal time points with finishing traits (Table 3), but moderate correlations were obtained for BCS prior to calving with either UEMA (0.31) or URF (0.32). Genetic correlations of finishing traits with BCS tended to be highest at calving and lowest at weaning with the exception of CEMA. Across all time points BCS traits were slightly higher genetically correlated with fat traits compared to muscling.

Table 2. Genetic (±standard errors; below diagonal) and phenotypic (±standard errors; above diagonal) correlations for body condition scores (BCS) at different seasons in mature New Zealand beef cows.

	BCS mating	BCS weaning	BCS calving
BCS mating		0.65 (0.01)	0.47 (0.01)
BCS weaning	0.95 (0.03)		0.54 (0.01)
BCS calving	0.99 (0.06)	0.84 (0.09)	

Table 3. Genetic (r_g) and phenotypic (r_p) correlations (±standard errors) among BCS in mature New Zealand beef cows and muscle and fat traits in finishing cattle.[1,]

	UEMA		URF		CEMA[2]	CRF[2]
	r_g	r_p	r_g	r_p	r_g	r_g
BCS mating	0.18 (0.07)	0.06 (0.04)	0.27 (0.06)	0.10 (0.04)	-0.07 (0.11)	0.08 (0.12)
BCS weaning	0.14 (0.08)	-0.01 (0.04)	0.16 (0.06)	0.08 (0.04)	-0.05 (0.12)	-0.06 (0.12)
BCS calving	0.31 (0.09)	0.14 (0.05)	0.32 (0.08)	0.21 (0.05)	0.03 (0.12)	0.17 (0.13)

[1] BCS = mature cow body condition score; UEMA = eye-muscle area (ultrasound); URF = rib fat depth (ultrasound); CEMA = eye-muscle area (carcass); CRF = rib fat depth (carcass).

[2] No r_p identifiable between traits not expressed within the same animal (carcass and mature cow BCS traits).

Discussion

Heritabilities for BCS were similar across seasons but overall higher compared to results presented by Arango *et al.* (2002). Arango *et al.* (2002) reported slightly higher permanent environmental variation at weaning compared to measures taken prior to mating and calving, which aligns with results found in the current study. Results indicate potential to improve BCS through direct selection at any season, but genetic progress may be slow due to low phenotypic variation. A selection response is likely to be stronger for muscling and fat traits in finishing animals compared to BCS traits in cows due to higher heritabilities (Wolcott *et al.* 2013).

In agreement with Arango *et al.* (2002) and Wolcott *et al.* (2013), cow BCS traits were highly genetically correlated across seasons. Thus, animals with a higher genetic merit for BCS at any season are likely to also exhibit greater body energy reserves at other seasons in the annual production cycle. The lower genetic correlation between BCS at weaning and BCS prior to calving compared to BCS at mating may be attributable to the physiological status of the cows during lactation or pregnancy which is likely to impact on fat deposition (Arango *et al.* 2002).

Generally, genetic associations of fat and muscle traits in finishing cattle with mature cow BCS traits were low and similar across time points such that treating seasonal BCS measures as different traits may not be required. The BCS before calving, however, tended to be slightly higher genetically correlated to all finishing traits compared to BCS at other seasons and this may also be induced by physiological differences during late pregnancy. Direct selection on carcass traits with the objective of increasing cow BCS throughout the annual cycle is likely to be inefficient. Ultrasound rib fat and UEMA offered the best options for selecting on finishing traits to generate a correlated response in cow BCS and results were similar to those presented by De Lacerda *et al.* (2019). However, genetic progress in maternal and finishing fat and muscle traits is likely to be more efficient when animals are measured for both trait groups.

659. Decision support tools to support a more sustainable beef-on-dairy industry

S.C. Ring[1*], R.D. Evans[1], J. McCarthy[1], A. Cromie[1], and D.P. Berry[2]

[1]Irish Cattle Breeding Federation, Highfield House, Shinagh, Bandon, Co. Cork, P72 X050, Ireland; [2]Animal & Grassland Research and Innovation Centre, Teagasc, Moorepark, Fermoy, Co.Cork, Ireland; sring@icbf.com

Abstract

The global agri-industry is challenged with improving sector sustainability. Cattle production systems are not exempt, especially as dairy cow genetic merit becomes more specialized for dairy production, often to the determinant of beef value. Using national measures of genetic merit, the Irish industry has developed and deployed three interdependent strategies to complement the sustainable productivity and profitability of the dairy and beef sectors. The first tool, the Dairy Beef Index (DBI), was developed to identify genetically elite beef bulls for mating to dairy females with the goal of simultaneously improving calving performance and beef merit. Adoption of the DBI will be incentivized through: (1) sire mating advice to aid in mating decisions; and (2) a *Commercial Beef Value* per animal to aid beef producers in valuing cattle.

Introduction

Dairy cow reproductive performance in Ireland has progressively improved reducing the requirement for replacement dairy females and, in turn, create an opportunity to increase surplus calf value. Consequently, the frequency of mating beef sires with dairy females has increased 10% in the previous five years, a trend expected to continue. Beef sire selection by dairy producers has traditionally focussed on breed, easy expected calving, and short expected gestation length. The antagonistic genetic correlation between calving performance and beef merit will contribute to a progressive deterioration in beef merit of the beef sires available. Therefore, decision support tools are required to: (1) identify suitable beef sires for mating with dairy females that possess both desirable calving and beef attributes; (2) recommend optimum matings of beef bulls with dairy females taking cognisance of genetic and phenotypic characteristics of the female; and (3) value surplus cattle destined for slaughter. These three tools must be inter-dependent in that suitable beef bulls must be available from which to suggest the recommended matings and the value of the resulting progeny must, on average, reflect the expected value at the time of mating. Combined, these decision support tools will help to improve the profitability and sustainability of the intrinsically linked dairy and beef systems. The objective here is to provide an overview of these decision support tools which can be relatively easily extended to other jurisdictions.

Materials & methods

Measures of genetic merit for calving, beef, and docility performance traits (Evans, 2007, 2008, 2009, 2020) from the national multibreed genetic evaluations were available to construct each of decision support tools.

Dairy beef index. The DBI was derived to rank beef bulls for mating to dairy females (Berry *et al.*, 2019) as:

$$DBI = direct\ dystocia + direct\ gestation + mortality + feed\ intake + carcass\ weight + carcass\ conformation + carcass\ fat + desirable\ carcass\ specification + docility + polledness$$

where each trait was a function of the sire's predicted transmitting ability (PTA) multiplied by the economic value and cumulative discounted genetic expression (Berry *et al.*, 2019). The economic value applied to direct dystocia was non-linear (Berry *et al.*, 2019) whereby bulls with a higher dystocia PTA were penalised more severely.

DOI: 10.3920/978-90-8686-940-4_659, © S.C. Ring *et al.* 2022

Mating advice. The mating advice decision support tool ranks matings between each member of a team of beef bulls (selected by the dairy producer) to each dairy female in a herd where easier calving bulls are more favoured towards females more prone to calving difficulty while also considering the carcass merit of the bull to correct the deficiencies in carcass merit of the female (e.g. very light, poor conformation). Each sire × female mating receives an index based on the expected profit of the resulting progeny as:

$$INDEX = CALVING + (1\text{-}Pred_{MORT_BIRTH}) \times POLLED + (1\text{-}Pred_{MORT_FINISH}) \times BEEF$$

where $Pred_{MORT_BIRTH}$ is the predicted calf mortality at birth based on the phenotypic mean of the base population plus the sum of the PTA for perinatal morality of both parents, $Pred_{MORT_FINISH}$ is simply $Pred_{MORT_BIRTH}$ + 0.03 where the 0.03 is the mean mortality from birth until slaughter and POLLED is the economic value of whether or not the beef bull is polled. The CALVING and BEEF components of the index are described as:

$$CALVING = Pred_{dystocia} \times COST_{dystocia} + Pred_{gestation} \times COST_{gestation}$$

$$BEEF = Pred_{CARCASS} \times PRICE_{CARCASS} + Pred_{docility} \times EW_{docility} + Pred_{feed\ intake} \times EW_{feed\ intake} + breed_bonus$$

The prediction of dystocia ($Pred_{dystocia}$) considers the direct PTA of the parents for dystocia plus twice the female's maternal PTA for dystocia all estimated from the national genetic evaluations. Non-linearity in the economic impact of calving difficulty is accounted for. Prediction of gestation length ($Pred_{gestation}$) is simply the sum of the parental direct PTAs. The prediction of carcass and carcass price per kg is a function of the expected EBV of the progeny for carcass weight, conformation and fat score individually but also includes a penalty if the resulting carcass does not adhere to abattoir carcass specifications for carcass weight and conformation. Predictions for docility and feed intake are based on the sum of the parental PTAs; a breed bonus was applied to Angus and Hereford bulls.

Commercial beef value. The Commercial Beef Value (CBV) values cattle for slaughter (Dunne *et al.*, 2021) as:

$$CBV = carcass\ weight + carcass\ conformation + carcass\ fat + docility + feed\ intake$$

where each trait was a function of the animal's estimated breeding value multiplied by the economic value and cumulative discounted genetic expression; non-genetic effects are likely to be added to the CBV in later versions.

Results & discussion

Growing consumer awareness of farming practices has strengthened the need to re-examine the inter-dependency between the dairy and beef sectors. Assuming 20-25% of calves born in the dairy herd are required as replacements, approximately 75-80% of calves are destined for slaughter; of the latter in Ireland, many are purchased <6 weeks old, weaned, and finished typically at 22-24 months of age by beef producers. Because dairy farmers are often not directly impacted by the sale value of the animal at slaughter, this can lead to a lack of consideration and appreciation of the importance of beef bull selection. In addition, the purchaser of the resulting calf <6 weeks of age cannot have any great knowledge of the carcass potential of the animal at such a young age. The decision support tools outlined here should incentivise stakeholders to work in unison towards the same common goal, a sustainably profitable dairy beef system. All data flowing into these tools originate from the one source, the ICBF database. The ICBF database maintains and utilises data from an array of sources including farmers, abattoirs, marts, etc.; all data used in these decision

support tools are updated bi-monthly as additional phenotypes become available; decision support tools are also updated.

The DBI rewards bulls that produce a live calf with minimal calving assistance following a short gestation; docile, polled progeny that attain an acceptable carcass weight and both a desirable carcass conformation and fat grade are also favoured. The ability of this index to deliver phenotypically has been validated (Berry and Ring, 2020). The mean DBI for some beef breeds are provided in Figure 1. The Dairy Beef Index is comparable across beef breeds since the genetic evaluations used to develop the index are based on a multibreed population where all beef breeds are included in the same genetic evaluation. The DBI has highlighted the desirability of some breeds which would not traditionally have been used in dairy herds (e.g. Aubrac, Saler).

Although dairy producers remain cautious on selecting beef bulls that are acceptable on calving performance, the beef merit of beef bulls used in dairy herds has improved since the inception of the DBI, and this has also translated to a favourable change in CBV trends; trends in DBI and CBV pre and post the DBI launch are in Figure 2. Future versions of the DBI are likely to consider meat eating quality, animal health, age at slaughter and direct measures of methane.

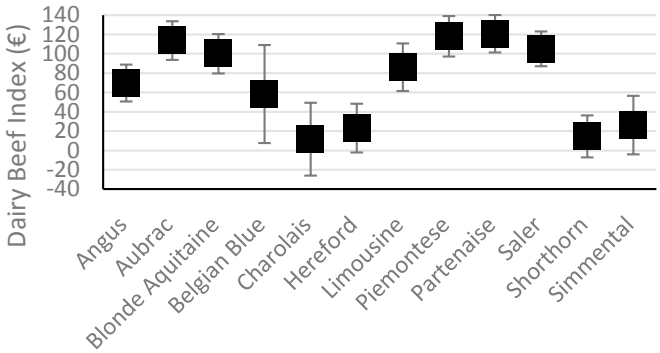

Figure 1. Mean and SD (at each side of SE bar) Dairy Beef Index value for the main beef breeds used in Ireland.

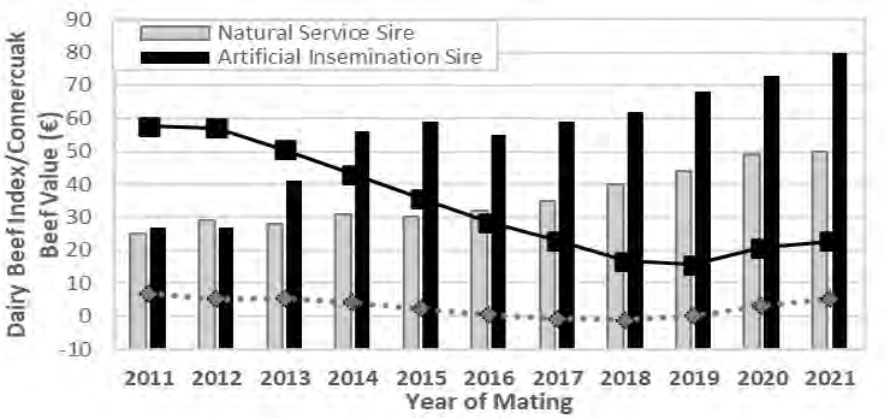

Figure 2. Trend in Dairy Beef Index (columns) and Commercial Beef Value (markers) for natural service sires and artificial insemination sires pre and post the availability of the Dairy Beef Index in 2019.

The framework of the sire mating advice algorithm is built on that of the DBI thus exploiting the gains in beef seedstock producing cattle of increasing DBI. Dairy producers must first select a team of beef bulls with a separate team selected for heifers and cows; the maximum usage per bulls is inputted. Future versions will recommend a bull team and usage. Using the sire advice, an older cow with good direct and maternal genetic merit for dystocia may be allocated the more difficult of the bulls in the team in the pursuit of achieving a better calf value through improved carcass credentials. The producer decides which females are to be served to dairy bulls, beef bulls, and which females are to be culled (and not bred) based on the COW index (Kelleher *et al.*, 2015); it is common practice in Irish dairy herds to use dairy semen for the first 6 weeks of the 15-week breeding season after which beef bulls are used. The sire mating advice program mates each bull in the team to each female; the three sub-herds are treated separately so that the intended proportional representative use of bulls should be close to the eventual usage in: (1) heifers; (2) cows that the farmer has indicated should be served with a beef bull; and (3) all other cows which are not destined to be culled. An index value for each candidate bull × female combination is generated within a sub-population; then linear programming is used to maximise the expected index value of the resulting progeny within the constraints of the desired proportional representation of each bull. A check is also included to avoid some predefined matings like those which might result in very difficult calvings; this is at the discretion of the user. Some 8,000 dairy herds (out of a total of 17,000 nationally) already use sire mating advice to rank dairy bulls for use on dairy females; the user interface for the beef-on-dairy mating system is close to a mirror representation of the dairy-on-dairy sire advice. The output to the farmer is a user-friendly report which identifies the female and the three highest ranked bulls on the index. Users can save the results for their own use as well as onto their AI technicians handheld, enabling the immediate identification of preferred bull by technicians on the day of service.

Potential purchases need a reliable method of identifying profitable progeny from the beef-on-dairy matings. Assuming no/minimal market failure, this should logically facilitate higher market demand for the seller thus encouraging the dairy producer to use more elite beef bulls and closing the loop. The Commercial Beef Value was developed to support decisions on how much to pay for a calf destined for prime beef production. Dunne *et al.* (2021) validated that knowledge of the breed and Commercial Beef Value of the animal was a better indication of than knowledge of the animal breed alone. Each of these decision support tools should have a substantial impact on the future sustainability of both dairy and beef sectors alike; methods applied in the present study can be replicated in other jurisdictions to improve the profitability of beef progeny originating from the dairy herd.

Bovine dairy – genetic evaluation methods

660. Breed and heterosis effects for fatty acid composition of milk from dairy cows milked once- and twice-a-day

I. Sanjayaranj[1*], N. López-Villalobos[1], H.T. Blair[1], P.W.M. Janssen[2], S.E. Holroyd[3] and A.K.H. MacGibbon[3]

[1]Animal Science, School of Agriculture and Environment, Massey University, Private Bag 11 222, Palmerston North 4442, New Zealand; [2]School of Food and Advanced Technology, Massey University, Private Bag 11 222, Palmerston North 4442, New Zealand; [3]Fonterra Research and Development Centre, Palmerston North 4442, New Zealand; i.sanjayaranj@massey.ac.nz

Abstract

The objective of this study was to estimate the effects of breed and heterosis on the gross composition and fatty acid composition of milk from cows milked once-a-day (OAD) and twice-a-day (TAD). Milk samples were taken from 39 Holstein-Friesian (F), 27 Jersey (J) and 34 F×J crossbred cows from a OAD milking herd, and 104 F and 83 F×J crossbred cows from a TAD milking herd. Holstein-Friesian cows were superior for the production traits compared to J cows in both milking frequencies. Jersey cows milked OAD produced significantly higher percentage of fat and a higher proportion of C18:0 fatty acid. The heterosis effects for the production traits were positive and significant in cows milked OAD. The heterosis effects for fatty acids were not significant in both milking frequencies. The butter produced from F milk would likely be softer than of that of J milk, mainly from F cows milked OAD. These results can be used to assist with selecting breeds and animals that are suitable for either OAD or TAD milking and this can allow closer alignment with milk processing needs.

Introduction

The New Zealand dairy industry is pasture-based, with most of the cows calving in spring. Twice-a-day (TAD) milking during the whole lactation is practiced in about 55% of the herds and once-a-day (OAD) during the whole lactation in about 10% of herds, with the remainder using a mixture of TAD and OAD (Edwards, 2018). Once-a-day milking has been adopted by several farmers due to its benefits of reducing the cost of labour, feed and management and creating alternative employment opportunities (Edwards, 2018). Milk composition, especially milk fat and fatty acids (FAs), affects the processability of milk into products such as cheese and butter (MacGibbon, 1996; Auldist *et al.* 2004). The variation in milk composition and fatty acid composition is caused by several factors, including genetics, breed, feed, season, stage of lactation and age of cows. Heterosis is defined as the superiority of the first crossbred cows compared to the average performance of the parents. Heterosis is considered as an important factor which affects the economically important traits. There are no studies reporting the effect of milking frequency on the fatty acid composition of cows under grazing conditions. The objective of this study is to estimate the effects of breed and heterosis on gross composition and fatty acid composition of cows milked OAD and TAD.

Materials & methods

The experiment was carried out at Massey University dairy farms from July 2020 to March 2021. Massey University No. 1 Dairy farm is a low-input system with cows milked OAD and cows grazing on ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*) pasture with limited supplements. Massey University No. 4 Dairy farm is managed as a high-input system with cows milked TAD and cows grazing on rye grass and white clover pasture with a higher proportion of supplements.

Sampling and determination of milk composition and fatty acids. Morning milk samples were collected from 39 Holstein-Friesian (F), 27 Jersey (J) and 34 F×J crossbred cows from a OAD milking

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_660, © I. Sanjayaranj *et al.* 2022

herd. Morning and evening milk samples were collected separately from 104 F and 83 F×J crossbred cows from a TAD milking herd. Milk samples were collected from first and second parity cows on both farms. The analysis of milk composition was carried out within two days of sampling. Gross milk composition and FA composition were determined using a Milkoscan FT1 (Foss Analytical, Hillerød, Denmark) for individual samples. Prediction equations for FAs were developed in the FTIR calibrator software (Foss Analytical) using a data set with mid infrared spectral data and gas chromatography reference values. The The coefficient of determination values of the prediction equations for all the FAs were greater than 0.8. Composition of morning and evening milk samples was analysed separately, and an average weighted by volume was calculated for daily yield to get the final values for daily yield and composition.

Statistical analysis. Data were analysed using the MIXED procedure of the SAS package version 9.4 (SAS Institute Inc., Cary, NC, USA). The model included the fixed effects of milking frequency, lactation number, stage of lactation, proportion of F and F×J heterosis within milking frequency, and deviation from median calving date with linear and quadratic effect, and the random effect of cow and residual error.

Results

The proportion of saturated fatty acids was lower ($P<0.05$), and the proportion of unsaturated fatty acids was higher in cows milked OAD compared to cows milked TAD (Table 1). The proportions of short-chain fatty acids (SCFA) and long-chain fatty acids (LCFA) were significantly lower, and the proportion of medium-chain fatty acids (MCFA) was significantly higher in cows milked OAD. Breed effects for daily milk yields of milk, protein and lactose, percentages of fat and protein and proportions of SFA, C18:0 and omega6 in cows milked OAD were significantly different ($P<0.05$) from zero (Table 2). Breed effects for the proportions of C18:0 and LCFA were significantly different from zero in cows milked TAD. The breed effects for the percentages of fat and the proportions of SFA and C18:0 were negative in cows milked OAD and TAD. Friesian cows produced milk with an average 1.08% less SFA than J cows milked OAD. The breed effects for the percentage of protein and proportions of C16:0 and LCFA were significantly different between miking frequencies. The heterosis effects for the daily yield of milk, fat, protein and lactose of cows milked OAD were positive and significantly different from cows milked TAD.

Discussion

Holstein-Friesian cows had greater yields of milk, protein, and lactose than J cows, but J cows produced milk with higher concentration of fat in both milking frequencies as previously reported in New Zealand (Lambeye *et al.* 2015). The F×J heterosis effects for milk, fat and protein yield were greater in OAD than TAD milking, suggesting that heterosis effects are expressed differently according to the environment. The breed effect for the proportion of C18:0 was negative and significantly different from zero in both milking frequencies.

Friesian cows produced milk with a lower proportion of C18:0 compared to J cows which suggests that the butter produced from F milk is likely to be softer than the butter from the J milk. This is in agreement with MacGibbon (1996), who reported that the SFC_{10} (solid fat content at 10 °C) was positively correlated with the proportions of high melting point long-chain saturated fatty acids in the milk and negatively correlated with the proportion of C18:1n_9. Similarly, the F cows milked OAD would produce softer butter than F cows milked TAD. For bulk milk, cows milked OAD produce harder butter than cows milked TAD due to the higher proportions of MCFA (MacGibbon, 1996). However, the seasons of the year also have significant effect on the hardness of the butter as Auldist *et al.* (1998) reported that the butter produced during the spring was softer than the butter produced in summer due to lower proportions of long-chain saturated fatty acids. This suggests that F cows milked OAD will produce softer butter in spring.

LCFA	296	65.5±0.19	543	67.37±0.12	<0.0001

[1] LCFA = long chain fatty acids (sum of C16:0, C18:0 and C18:1n_9 and Omega6); MCFA = medium chain fatty acids (sum of C10:0, C12:0 and C14:0); PUFA = polyunsaturated fatty acid; SCFA = short chain fatty acids (sum of C4:0, C6:0 and C8:0); SFA = saturated fatty acids; UFA = unsaturated fatty acid.

The findings of this study reveal that the *de novo* synthesised FAs, the SCFA and MCFA were significantly affected only by milking frequency but not by the breed. The breed effects for percentages of fat and protein of cows milked OAD would be more important in the processability of milk than the fatty acid composition. These results suggest further studies should be undertaken to study the effects of milking frequency, with the prospect that better decisions could be made when selecting breeds that are suitable for either OAD or TAD milking frequency according to the processability of milk.

661. Long term effect of growth in rearing phase on reproduction and production trait in Murrah buffalo

P. Joshi[1*], A. Verma[1], G.R. Gowane[1], R. Alex[1], I.D. Gupta[1] and D. Worku[2]

Abstract

The purpose of the study was to determine the effect of average daily gain (ADG) on reproductive and milk production traits of Murrah buffalo. For this purpose, animals were divided into 3 groups based on ADG during different growth phase *viz* low, medium and high, respectively. Murrah heifers in the high ADG group (9-18month of age) reached age at first calving (AFC) 96 days earlier than those in low and medium ADG group ($P<0.05$). A significant increase of 206 kg of milk was found in the animals of higher ADG group ($P<0.01$).

Introduction

Dairy farmers face a complex dilemma in minimizing costs associated with rearing heifers while ensuring the lifetime economic productivity. Decisions about heifer management are influenced by underlying biological aspects of growth, thereby influencing future profitability of the herd (Mourits *et al.*,1999). Simplest approach to reduce costs is to shorten the non-productive period of dairy heifers, which can be accomplished by breeding the heifers early. It is already understood that puberty in heifers occurs when females achieve approximately 45 to 55% of their mature body weight (BW) (Freetly *et al.*, 2011). This goal requires a rapid growth rate during pre-pubertal and post pubertal phase.

Effect of growth during rearing phase on future performance of beef cattle has been studied by many researchers. However, there is no comprehensive study that has investigated the association between growth rate during rearing in Murrah buffalo with their productive and reproductive performance later in life. Therefore, the aim of this work was to evaluate the effect of average daily gain (ADG) before and after puberty on first lactation production and reproduction traits in Murrah heifers.

Materials & methods

The dataset used in this study consisted of growth, first lactation and reproduction records of Murrah buffaloes maintained at ICAR-National Dairy Research Institute, Karnal during 1974 to 2019. Body weights were measured at monthly intervals starting from time of birth up to 24 month of age. Average daily gain (ADG) was calculated using the difference in body weight (BW) between 2 consecutive months during the period analysed. ADG was calculated for different growth phases like birth to 3 month of age, birth to 6 month of age (up to birth to 24 month of age), 3 month to 6 month, 3 month to 9 month (up to 3 to 24 month of age) up to 18-24 month of age. Animals with missing birth date, body weight and calving date were pruned. Milk yield data of first parity were recorded and reproductive parameters like age at first calving (AFC), first service period (SP) and calving interval (CI) were generated.

Statistical analysis. The explanatory variable i.e. ADG of the heifers was divided into 3 (low, medium, high) classes for each growth trait in particular growth phase and the effect of each ADG class was studied on dependent variable (Table 1). The MIXED linear model, corrected for other significant effects, was applied to determine the effect of the heifer rearing period on production and reproduction during subsequent lactation. The Bonferroni method was used for means comparison.

$$Y_{ijklm} = \mu + A_i + Sj + BV_k + ADG_l + b(AFC_{ijkl}) + e_{ijklm}$$

where, Y_{ijklm} = the responding variable as mentioned in Table 1 below; μ = the overall mean; A_i = effect of the i^{th} year of calving; S_j = the effect of j^{th} season of calving (j= spring, summer, autumn or winter); BV_k = the effect of k^{th} estimated sire breeding value for respective trait; ADG_l = the effect of l^{th} ADG class on trait; $b(AFC_{ijkl} - AFC)$ = regression coefficient of age at first calving in days (exclude a scenario, when AFC is a responding variable); e_{ijklm} =the random error.

Results

ADG during different growth phase. During early rearing phase, highest ADG of 0.51 kg/day and 0.52 kg/day was found during the period from birth to 12 month and birth to 24 month of age. After 3 months of age, mean ADG was between 0.49 to 0.65 kg/day. Growth of nearly 0.52 kg/day was seen in 6 month to 12 month of age. Higher ADG of 0.60 kg/day was seen during the phase 9 to 12 month of age. After 1 year of growth period, mean ADG was 0.48 kg/day.

ADG and subsequent AFC performance. A significant difference of days (P<0.05) between the highest and the lowest ADG group in evaluated time period was observed in relation to the AFC(Figure 1). Studying ADG association revealed that the highest ADG was associated with the earliest AFC. A reduction of 67 days in AFC was achieved in the high ADG group of heifers as compared to low ADG group during the growth phase of birth to 18 months. The earlier AFC by 73 and 66 days was achieved with the highest ADG group 9-18 month and 12 to 18 month of age, respectively.

ADG and subsequent total lactation milk yield, 305day milk yield and lactation length. Higher ADG during various growth period was associated with increase in the TLMY. Significant increase (P<0.01) of 207 and 255 kg milk in TLMY was found in heifers of the high ADG group birth to 12 month and 12 month to 24 month of age, respectively. Significant increase (P<0.01) of 466 kg in TLMY was found in the 3 month to 24 month high ADG group. Similar trend was observed in the 305d milk yield. Increase of 26 days(P<0.05) in LL of heifer was observed in higher ADG group of 3 month to 24 month age.

ADG and subsequent service period and calving interval. The groups with increased service period were observed to have higher ADG during the evaluation period starting since birth. Similar results of ADG effects were observed between other evaluated periods. Significant increase of 38 days in Service period (P<0.05) was observed in higher ADG group of 9 month to 12 month of age. The results for calving interval revealed that elongated CI was associated with higher ADG group during entire rearing phase except 3 month to 6 and 9 month of age where CI was less in high ADG group.

Table 1. Evaluated parameters in heifer and first lactation (dependent variable).[1]

Trait	Mean ± S.E.
Age at first service	975.45±4.93 (1,354)
Age at first calving	1,354.55±5.00 (1,946)
Total lactation milk yield (TLMY)	1,987.42±16.80 (1,655)
305d milk yield	1,841.37±14.36 (1,655)
Lactation length	314.84±2.00 (1,655)
Service period	163.47±2.81 (1,179
Calving interval	475.12±2.84 (1,249)

Figure 1. Effect of ADG during different time period on dependent traits.

Discussion

In this study, faster growth led to earlier AFC, which was related to early maturity of these animals. Likewise, Lopez *et al.* (2018) and Atashi (2021) also reported that heifers with a rapid daily gain calved at a younger age than those which shows delayed growth. This association can be explained by assuming that those animals with higher pre pubertal and post pubertal growth rate reach the weight required for a successful pregnancy at a younger rate. Our results showed positive effect of ADG on milk yield of first lactation. A few studies have also documented similar findings where greater pre-weaning -ADG)- had a positive effect on the future production (Moallem *et al.* 2010; Soberon *et al.* 2012; Soberon and Van Amburgh, 2013),

mainly due to higher growth rate during early life. On the contrary, Ettema and Santos (2004) and Daniels (2010) reported negative effect of high ADG during the heifer rearing period on milk production in first lactation due to the reduction of parenchyma growth in the mammary gland.

Conclusions

Overall results suggested that better ADG during early life has significant beneficial effect on future reproduction and production performance.

662. Integrating parent-of-origin effects in random regression models for milk traits

R.E. Jahnel*, I. Blunk and N. Reinsch

Research Institute for Farm Animal Biology (FBN), Institute of Genetics and Biometry, Wilhelm-Stahl Allee 2, 18196 Dummerstorf, Germany; jahnel@fbn-dummerstorf.de

Abstract

The importance of parent-of-origin effects (POEs) for the genetic variability of quantitative traits is frequently addressed by current research in farm animals, humans and laboratory animals and may have implications for animal breeding. An epigenetically induced non-equivalence of identical alleles when inherited either from sire or dam is assumed as the underlying mechanism. In order to restrict the number of necessary (co-)variance components in random regression models to a minimum we suggest that POEs are considered for lower-order terms of Legendre-polynomials only. Using 256,089 milk samples from 31,345 German Holstein cows we attributed shares between 5.9 and 12.6% of the total additive genetic variance to POEs (yield and composition traits; protein percentage: not significant). Consequences for selection and genetic evaluation remain to be investigated in follow-up studies.

Introduction

The potential action of parent-of-origin effects (POEs, including genomic imprinting) can be investigated by (generalised) gametic models (Schaeffer *et al.* 1989; Reinsch *et al.*, 2021), where each individual with a phenotype is represented through four gametic effects: two with paternal and two with maternal expression patterns. Such models can account for both full and partial imprinting (Neugebauer *et al.*, 2010 a,b; Meyer and Tier, 2012). The non-equivalence of paternal and maternal inheritance at these loci is summarised in a single parameter called the imprinting variance, which can be interpreted as the variance of the difference of gametic effects under both parental expression patterns (Neugebauer *et al.*, 2010a,b; Blunk *et al.*, 2017a,b). Including POEs into random regression models (RRM; Jamrozik and Schaeffer, 1997) increases the number of genetic (co-)variance parameters drastically. Even with only 2nd order Legendre-polynomials, as many as 21 parameters need to be estimated in a POE-RRM, compared to six parameters under the assumption of a RRM without POEs (Mendelian inheritance). Therefore, we assume POEs only for the lower order parts of the Legendre-polynomials, i.e. at least the intercept, and neglect POEs for all the higher-order terms. We demonstrate and discuss our new POE-RRM by analysing milk traits measured in 31,345 Holstein cows from Mecklenburg-West Pomerania, Germany.

Materials & methods

Cow data. Data for milk yield (MY), fat yield (FY) and -percentage (FP), and protein yield (PY) and percentage (PP) from first lactation dairy cows in Mecklenburg-West Pomerania were collected between 2008 and 2019 and were provided by the German Evaluation Centre (VIT, Verden/Germany). Cows with known parents and grandparents of German Holsteins were kept. The calving age of these cows was between 20 and 40 months. Samples taken between 5 and 330 days in milk (DIM) were taken into account for cows with ≥3 records or one record ≤DIM 80 or two records ≤DIM 100. Cows were either milked by an automated milking system or in a traditional milking parlour. This resulted in 31,345 cows with 256,089 milk samples and 125,041 individuals in the pedigree.

POE-RRM. The model was implemented in Echidna MMS (Gilmour, 2021) and can be written as:

$$\boldsymbol{y}_{irjd} = \boldsymbol{HTD}_i + \sum_{k=0}^{3} \boldsymbol{\phi}_{tk} \boldsymbol{\beta}_{kr} + \boldsymbol{u}^{s}_{j1} + \boldsymbol{u}^{d}_{j2} + \sum_{k=1}^{2} \boldsymbol{\phi}_{tk} \boldsymbol{u}_{kj1} + \sum_{k=1}^{2} \boldsymbol{\phi}_{tk} \boldsymbol{u}_{kj2} + \sum_{k=0}^{3} \boldsymbol{\phi}_{tk} \boldsymbol{pe}_{jk} + \boldsymbol{e}_{irjd} \quad (1)$$

where y_{irjd} is the test day yield of the d^{th} test day of cow j, HTD_i is the fixed effect of the i^{th} herd-test-day x milking frequency, ϕ_{tk} are coefficients of Legendre-polynomials of order two or three at DIM (t); β_{kr} represents the k^{th} regression coefficient of the fixed lactation curve of the fixed effect r representing calving age-year-season of cow j; $\boldsymbol{u}^s_{j1}$ ($\boldsymbol{u}^d_{j2}$) is the paternal (maternal) gametic effects of cow j as sire (as dam), superscripts s and d indicate paternal and maternal expression patterns of the imprinted random intercept effect; u_{kj1} and u_{kj2} are the un-imprinted linear and quadratic random regression coefficients for paternal (1) and maternal (2) gametes of cow j assuming mendelian inheritance; pe_{jk} is the k^{th} random regression coefficient of cow j for permanent environment effects and e_{irjd} is the residual. It was assumed, that the covariance structure of the random genetic effects is:

$$\text{var}\begin{bmatrix}\boldsymbol{u}^s\\ \boldsymbol{u}^d\\ \boldsymbol{u}_1\\ \boldsymbol{u}_2\end{bmatrix} = \left[\begin{array}{cc|cc} \sigma^2_{\boldsymbol{s}} & \sigma_{\boldsymbol{sd}} & \sigma_{\boldsymbol{s},\boldsymbol{u}1} & \sigma_{\boldsymbol{s},\boldsymbol{u}2} \\ \sigma_{\boldsymbol{sd}} & \sigma^2_{\boldsymbol{d}} & \sigma_{\boldsymbol{d},\boldsymbol{u}1} & \sigma_{\boldsymbol{d},\boldsymbol{u}2} \\ \hline \sigma_{\boldsymbol{s},\boldsymbol{u}1} & \sigma_{\boldsymbol{d},\boldsymbol{u}1} & \sigma^2_{\boldsymbol{u}1} & \sigma_{\boldsymbol{u}1,\boldsymbol{u}2} \\ \sigma_{\boldsymbol{s},\boldsymbol{u}2} & \sigma_{\boldsymbol{d},\boldsymbol{u}2} & \sigma_{\boldsymbol{u}1,\boldsymbol{u}2} & \sigma^2_{\boldsymbol{u}2} \end{array}\right] = \begin{bmatrix}\boldsymbol{V}_{1,1} & \boldsymbol{V}_{1,2}\\ \boldsymbol{V}'_{1,2} & \boldsymbol{V}_{2,2}\end{bmatrix} = \boldsymbol{V} \tag{2}$$

where $V_{1,1}$ and $V_{2,2}$ represent gametic (co-)variance components for imprinted (here: the intercept) and non-imprinted (linear and quadratic) components of the Legendre-polynomials, respectively, and $V_{1,2}$ comprises all covariances between the two kinds of gametic effects. Furthermore, it is assumed that $\text{var}(\boldsymbol{u}) = \boldsymbol{V} \otimes \overline{\boldsymbol{G}}$, $\text{var}(\boldsymbol{pe}) = \boldsymbol{C} \otimes \boldsymbol{I}_{\boldsymbol{N}}$ and $\text{var}(\boldsymbol{e}) = \boldsymbol{I}_{\boldsymbol{n}}\boldsymbol{\sigma}^2_{\boldsymbol{e}}$. $\overline{\boldsymbol{G}}$ is the generalised gametic relationship matrix (Reinsch *et al.*, 2021) and $\otimes$ denotes the Kronecker product. I_N is an identity matrix of order N of the cows and n being the sample size. C is a symmetric matrix, containing variance components for permanent environmental effects, corresponding to the Legendre-polynomials (4×4 matrix). Significance of the imprinting variance (see below) was tested through a restricted maximum log-likelihood ratio test with four degrees of freedom.

Genetic Parameters over lactation. Estimates were derived using variance components for each DIM t ϵ {5, …, 330}, similar to Jahnel *et al.* (2021) using self-written programs in R (R Core Team, 2020). If the vector of Legendre-polynomials for the paternal gamete is $\phi_{s,t} = (\phi_{t,0},0,\phi_{t,1},\ldots,\phi_{t,n})$ and maternal gamete is $\phi_{d,t} = (0,\phi_{t,0},\phi_{t,1},\ldots,\phi_{t,n})$, the additive genetic variance σ^2_a was obtained at DIM t as: $\sigma^2_{a,t} = (\phi_{s,t}V\phi_{s,t}') + (\phi_{d,t}V\phi_{d,t}')$. The imprinting variance at DIM t is defined as:

$$\boldsymbol{\sigma}^2_{\boldsymbol{i},\boldsymbol{t}} = (\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}') + (\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}') - 2(\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}') \tag{3}$$

If no imprinting effect is observed $(\phi_{s,t}V\phi_{s,t}') = (\phi_{d,t}V\phi_{d,t}') = (\phi_{s,t}V\phi_{d,t}')$ and $\sigma^2_i = 0$. The relative imprinting variance can be estimated as:

$$\boldsymbol{i}^2_{\boldsymbol{t}} = \frac{(\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}') + (\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}') - 2(\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}')}{(\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{s},\boldsymbol{t}}') + (\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}\boldsymbol{V}\boldsymbol{\phi}_{\boldsymbol{d},\boldsymbol{t}}')} \tag{4}$$

Results & discussion

To account for the complex nature of traits with repeated measurements, the new POE-RRM was tested on 256,089 milk samples of German Holstein cows. Investigating POEs can lead to a large system of equations and reducing equations in RRM is crucial. For the sake of simplicity, we assumed that most of the potential POEs can be explained by an imprinted intercept, neglecting POEs for all higher polynomial terms and reducing the variance component matrix V from 21 unknown parameters to 10. In other words, a constant imprinting variance σ^2_i over time was assumed. The model, in principle, could however be expanded up to a full POE-RRM by assuming POEs for every variance component (For 2nd order Legendre-polynomials: paternal gamete vector $\phi_{s,t} = (\phi_{t,0},\phi_{t,1},\phi_{t,2},0,0,0)$ and maternal gamete vector $\phi_{sd,t} = (0,0,0,\phi_{t,0},\phi_{t,1},\phi_{t,2})$.

With the new POE-RRM we estimated a potential action of POEs on five milk production traits: MY, FY, FP, PY and PP and found significant imprinting effects in the yield traits (MY, FY, PY) and FP. The error probability for PP was slightly above the 5% significant threshold (Table 1). This was also reflected by the genetic correlations between gametic effects as sire and dam. The lowest genetic correlation between both gametes in PY is 0.8918, whereas both gametes in PP are expressed almost equally (r_g>0.99). When averaged over lactation i^2 ranged from 5 to 12% (Table 1) where σ^2_i was significant. Our model is unique in that it can account for the differences in i^2 over time. Thus, we can demonstrate highest i^2 estimates in the early lactation stage before DIM 70, peaking at DIM 60 with 14.9% for MY, at DIM 57 with 9.3% for FP and at DIM 69 with 18.7% for PY (Figure 1). Only i^2 for FY peaked at the end of the early lactation stage (<DIM 120) at DIM 115 with 9.4%. This suggests a stronger influence and importance of POEs in the expression of the traits during peak lactation. Generally, research on POEs in milk traits is still scarce, to the best of our knowledge with only three previous studies (Kaiser *et al.* (1998): significant imprinting effect in MY, Essl and Voith (2002): significant imprinting effect in PP, Jiang *et al.* (2017): imprinting in MY, FY and PY). However, none of these studies estimated POEs through a RRM approach.

Follow-up research will, of course, be needed for a confirmation of our results. Details of potential applications in breeding programs will depend on wether few imprinted loci with larger effects can be identified or if many chromosomal regions with small contributions to POEs exist. At least in the latter case our parsimonious version of a POE-RRM may also be useful for the purpose of genetic evaluation.

Abstract

The present research aimed to describe recombination rates, their patterns through autosomes, as well as the identification of high-frequency recombination sites in the genome of Mexican Holstein cattle. Recombination, like functional mutations, can be considered as the raw material of the evolution of species, since both, mutation and recombination change the configuration of paternal alleles during meiosis. Genotypes (98,619 markers) of 652 animals from 298 families (father, mother and offspring) were included in the study. Based on the ~2.4 million recombination events identified from the families studied, the recombination frequencies in pairs of single nucleotide polymorphisms (SNP) were calculated in a permutation process, obtaining an average frequency of 0.08, with a maximum frequency of 0.14 and a minimum of 0.03. Those SNP whose recombination value exceeded 2.5 standard deviations of the mean were assumed as hotspots, finding 2,230 that represent the 2% higher than the genotype studied.

Introduction

Species need an adequate amount of genetic variation to cope with environmental conditions and their changes. During recombination, parental genotypes are mixed resulting in new gene combinations, and phenotype expression. Recombination begins with a double break in the deoxyribonucleic acid (DNA) strand, the break site as a first step is degraded and later repaired. During repair, recombination events known as crosses can occur, since DNA strands of homologous chromosomes are occupied (Petes, 2001; Úbeda and Wilkins, 2011).

Estimation of recombination frequencies across genomes has evolved; In the beginning, crossover events were detected by counting phenotypes, parental and recombinant, which allowed the calculation of linkage disequilibrium (LD) and gene mapping; At present, with the advancement of technologies, such events can be identified using molecular markers and statistical methodologies, which allow the estimation of parameters for the studied populations, thus obtaining high-density maps with information on LD regions, patterns recombination frequencies and hotspots, which are small regions of genome where recombination events occur most frequently and can explain a large part of the recombination that occurs throughout the entire genome from one generation to the next.

Evidence has been found that the increase in genetic variation allows an increase in the response to selection in the short term, as well as the management and use of knowledge of meiotic recombination, increasing genetic variation between generations, would allow a response to the selection with greater intensity in the long term(Gonen *et al.*, 2017).

Knowledge of recombination rates and the presence of high-frequency recombination sites could help to understand the origin of genetic variability in a population and assist in the design of optimal selection programs for that population.

Materials & methods

Data set and genotypes. In the present study included 652 animals, in 298 families with information of father, mother and offspring. The genotype used comes from three different chips: 1) Bovine HD® Beadchip (777,962 SNP), 2) Genomic Profiler HD-V3 (139,376 SNP) and 3) GGP HDv02 (138,892 SNP). The study included only those SNPs in common in all panels, leaving a final markers number of 98,619 (for each individual).

Construction of the high-density maps. The construction of the high-density maps was carried out with the information of the frequency of the recombination events observed in the population, as well as the physical position between adjacent SNPs and the genetic distance.

Estimation of recombination rates. For this estimation was used the direct recombinant counting methodology θ (Ott, 1999; Garbe and Da, 2003), θ is a vector with the estimated frequency of recombination, which consist in divide off the observed number of recombination events found (n), by the total number of meiosis, the offspring (T) (these frequencies vary from 0 to 0.5) for each pair of markers (i), obtaining the estimated recombination frequency by Equation 1:

$$\theta_i = n_i / T_i \quad (1)$$

The methodology is an iterative process, where recombination events are estimated through a permutation analysis between a marker with its adjacent ones, obtaining the frequencies of the recombination events for θ.

Identification of the hotspots. Was carried out according to Sandor *et al.* (2012), which designate those sites where the recombination frequencies are 2.5 standard deviations greater than the mean of θ, computed in the LocusMap® package (Ma *et al.*, 2015; Shen *et al.*, 2017).

Visualization of the recombination patterns throughout the genome. The θ data was smoothed by fitting the data with a 'smooth spline' model and a relative physical position was set for each of the marker intervals, dividing the original physical position by the length of the corresponding chromosome, the information obtained was plotted and compared with the information of each chromosome using the 'ggplot2' package of the statistical software R version 4.0.5

Results

Around 2.4 million recombination events were identified in the 298 families studied, and recombination frequencies were calculated with a mean of 2.4 crosses, with a maximum value of 146 and a minimum of 47 for each pair of markers, with a mean of 58 crosses.

The position of the recombination windows was standardized by dividing the position of the first marker in the window by the size of the chromosome. Recombination rates in an average chromosome were graphed, as well as the division of the bovine karyotype into three groups (large, medium and small) with respect to the size of the chromosomes measured in bp (*Bos taurus* ARS-UCD1.2 2016), as show in Figure 1.

Based on the frequencies of crossing or recombination of the 98,619 SNPs, those SNPs were assigned as hot spots whose recombination value exceeded 2.5 standard deviations of the means of θ, finding 2,230 hot spots that represent the upper 2% of the recombination frequencies of the genotypes studied, as can be seen in Figure 2 (hotspots in red points).

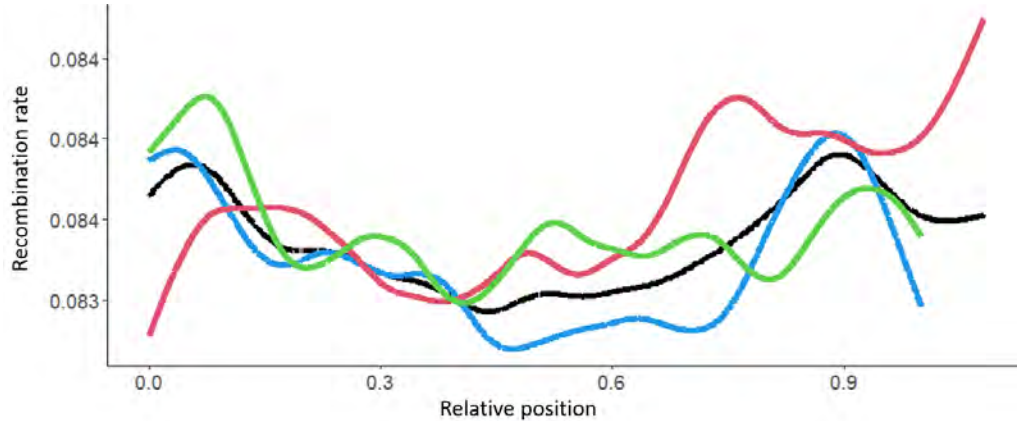

Figure 1. Recombination rate patterns in different autosomes sizes (general, large, medium and small autosomes in black, red, blue and green respectively).

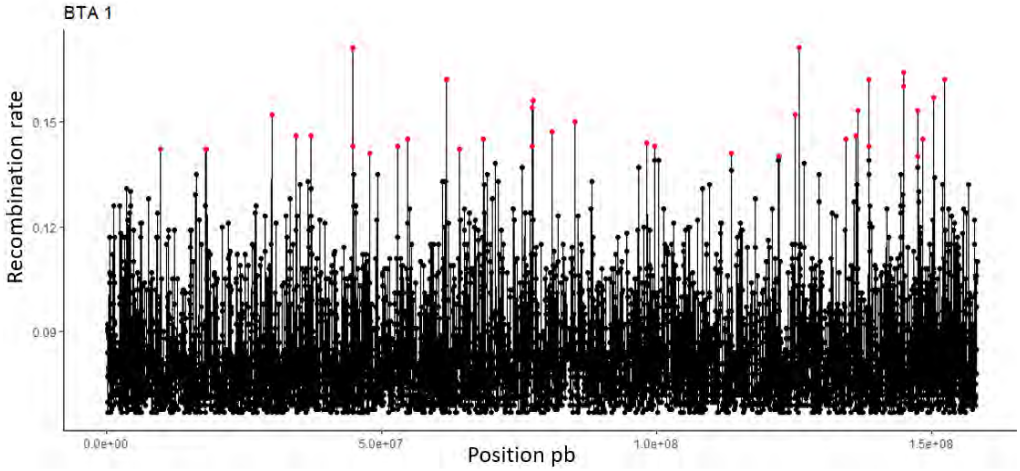

Figure 2. Hotspots (red points) in autosome 1.

Discussion

The average behaviour of the recombination frequencies through all the chromosomes can be seen in Figure 1, where the values of θ are usually higher in the telomeres of the chromosomes, showing a depression of the same in the physical center. This is similar to results presented by Li Ma *et al.* (2015) with 1.6 million recombination events and Shen *et al.* (2017) with 3.4 million, with an average of 24 recombination events per SNP window.

For the hot spots results, we also found differences from those reported by Li Ma in 2015 and Qanbari in 2020 (Qanbari and Wittenburg, 2020), and we attribute these differences to the different density of markers used. In this work we used 98K SNPs, being almost twice as many compared with the aforementioned studies, who used 50k SNP's.

664. Longevity in genetic evaluation of Holstein cows in Uruguay

N.F. Silveira*, O. Ravagnolo and I. Aguilar

Instituto Nacional de Investigación Agropecuaria (INIA), Montevideo, CP 11500, Uruguay; nferraz@inia.org.uy

Abstract

The objective of this study was to estimate variance components and to analyze the possibility of carrying out a genetic evaluation of the longevity trait in animals of the Uruguayan dairy production system of the Holstein breed. Longevity was defined as a binary trait with values of 1 and 0 whether or not the cow survived a lactation, respectively. For the analysis of the variance components, programs of the Blupf90 package were used, using the REML methodology and the Bayesian methodology. Heritability (with values between 0.03 to 0.13) was increasing according to the lactation. These results of the present study shows that even though it has a high influence of environmental factors, there is additive genetic variance available and therefore there is the possibility of inclusion of longevity in the genetic evaluation of Holstein cows in Uruguay.

Introduction

Stayability, is defined as the probability of a female to remain in production at a specific age, given that she had the opportunity to reach this age (Hudson and Van Vleck 1981). Therefore, the selection for longevity has the objective of identifying those individuals with the greatest capacity to remain productive, that is, with the greatest probability of survival due to voluntary and involuntary culling within the herd.

With the increase in the lifespan of the cow, it is possible to achieve a greater dilution of the maintenance and replacement costs of females, as demonstrated by Gabler, Tozer, and Heinrichs (2000). They showed that the highest lactation yield occurs after the third parturition, so keeping the animal in the system for a longer time will result in an increase in the dairy production of the establishment.

For the evaluation of longevity, different ways to define the trait to be included were proposed (Imbayarwo-Chikosi *et al.* 2015). The chosen form and the statistical model used depend on different factors related to the final objective of the analysis and the data available.

The objective of this study was to estimate variance components and analyze the possibility of carrying out a genetic evaluation of the longevity trait in animals of the Uruguayan dairy production system of the Holstein breed.

Materials & methods

Data. Records were available from the 'Instituto Nacional para el Control y Mejoramiento Lechero' (MU). The database was composed of milking cow's historical information, including reproduction, milk production and disposal information. Genealogical data was available from the 'Asociacion Rural del Uruguay' (ARU).

For variance components analyses, animals were required to have a known sire and dam and with the year of first calving between 1990 and 2014, giving the cow the possibility of completing at least five lactations. After editing the final dataset include records of 828,246 animals.

DOI: 10.3920/978-90-8686-940-4_664, © N.F. Silveira *et al.* 2022

Trait definition. Longevity was defined as a binary trait with values of one and zero whether or not the cow survived the lactation, respectively. Thus, analyzing the probability that the animal remains in the dairy during the first five lactations.

Statistical model. Variance components analyses were performed using programs from the BLUPF90 package (Misztal *et al.*, 2002), using the REML methodology (REMLF90 and AIREMLF90) and the Bayesian analysis methodology through Gibbs sampling (GIBBS2F90, THRGIBBS1F90 and POSTGIBBSF90). Multiple trait linear models and non-linear models were analyzed for the binary longevity traits at different lactations.

The following multi-trait model used was:

$$y = Xb + Zu + Zp + e$$

Where y is the survival observation vector (1/0), X the incidence matrix that links the observations with the fixed effects, b the fixed effects vector (contemporary group effect, composed of herd-year of first calving and age at first calving), incidence matrix Z for the animal additive genetic effect, $u = N(0,G_0 \otimes A)$ with genetic covariance matrix (G_0) and additive genetic relationship matrix (A), p = vector corresponding to the permanent environment effect and the residual effect, $e = N(0,R_0 \otimes I)$, with a residual covariance matrix (R_0).

Breeding values were estimated for the linear and non-linear models in order to establish the correlations between the predictions and to asses the re-ranking of the animals according to the methodology used.

Results & discussion

Variance component analysis. The results of the variance components performed by the linear model (REML and Bayesian methodology) and nonlinear (Bayesian) are shown in Table 1, 2 and 3, respectively. The estimates of additive genetic variance for the first five lactations are highlighted, confirming that there is genetic variability for longevity, allowing genetic improvement for the trait.

Table 1. Additive genetic variance, heritability and genetic correlations for the first five lactations – linear (REML).

Additive genetic variance / genetic correlation[1]					Heritability
0.004	0.004	0.005	0.006	0.007	0.03
0.97	**0.004**	0.005	0.007	0.008	0.03

Table 3. Additive genetic variance, heritability and correlation for the first 5 lactations – nonlinear.

Additive genetic variance / genetic correlations[1]					Heritability
0.313	0.225	0.188	0.225	0.245	0.06
0.92	**0.197**	0.153	0.198	0.220	0.06
0.88	0.89	**0.152**	0.199	0.199	0.07
0.78	0.85	0.94	**0.298**	0.282	0.08
0.77	0.85	0.86	0.88	**0.341**	0.09

[1] Upper triangle: additive genetic variance; lower triangle: genetic correlation between the first 5 lactations.

Heritability increased according to the lactation analyzed, showing that the survival of the cow at a greater number of lactations depends more on genetic components. The methodologies present similar values for heritability and high genetic correlation values between the lactations.

The estimated values for heritability by the different models were similar to previous studies that showed values between 0.03 and 0.25 (Essl and Voith 2002; Jamrozik, Fatehi, and Schaeffer 2008; Sewalem *et al.* 2005).

The correlations obtained in the present study were similar with the previous studies for dairy cattle from Germany and Canada, (Heise *et al.* 2016 and Sewalem *et al.* 2007, respectively), finding a high correlation between the different lactations.

The high correlation between traits will allow prediction of longevity at later ages from analysis carried out using the first lactations.

Correlations of the breeding values. The breeding values for the linear and non-linear model were estimated using BLUPF90 and THR1GIBBSF90 respectively, using the estimated variance components. Reliabilities were calculated using prediction error variance from the inverse of the mixed model (linear model) and from the posterior standard deviation of breeding values (non-linear models).

The correlation between the breeding values obtained through the linear model and the non-linear model for the first five lactations were greater than 0.98, which will not cause re-ranking of animals from the alternative genetic evaluation models. The correlation of the reliabilities between linear and non-linear models were greater than 0.99. No difference was found between the use of statistical analysis by direct analysis (blup) and analysis by Gibbs sampling (Bayesian).

Considering the computational cost and the greater complexity of performing a non-linear model and considering the correlation between the different models, the linear model can be used to estimate genetic values.

These results of the present study shows that even though it has a high influence of environmental factors, there is additive genetic variance available and therefore there is the possibility of inclusion of longevity in the genetic evaluation of Holstein cows in Uruguay.

Abstract

The objective of this study is to establish a model suitable for the Dairy Herd Improvement (DHI) records under tropical/subtropical climate in Taiwan. There are 62,068 lactation records of 28,722 cows obtained from Taiwan the DHI program during 2009~2019. A model with the physical situation of lactation (*PSL*) as a fixed effect which accounts for abnormal physiology and subclinical mastitis is compared to a model without that effect. The heritability of milk yield and somatic cell score are decreased and the number of sires with the accuracy of estimated breeding values greater than 75% would also change in the model with *PSL* as a fixed effect. Moreover, AIC and BIC in the model with *PSL* are lower than the model without *PSL*, which indicates the former model is more appropriate for this DHI dataset.

Introduction

Taiwan is located in the area under tropical/subtropical marine climate with high temperature and humidity. Such climate has a great impact on milk production, milk quality, reproduction and health of dairy cows. Mastitis is the most common disease in dairy cows with great impact on milk production and profit of dairy farm. There were 14.7% of cows with clinical mastitis in Taiwan (Chen *et al.*, 2013). Besides, there are approximately 10% of lactation records of cows with subclinical mastitis according to Taiwan DHI program. A metabolic disease, ketosis, is mainly caused by systemic dysfunction resulted from carbohydrate and volatile fatty acid metabolism disorders in the body. The incidence of clinical ketosis accounts for 18% of postpartum illnesses in Taiwan, which mainly occurs between 2-7 weeks postpartum (Chen *et al.*, 2008). Because considerable proportion of dairy cows in Taiwan may have abnormal physiology of lactation, it should be considered in the model of genetic evaluation for the DHI data in Taiwan. The objective of this study is to establish a model suitable for the DHI records under tropical/subtropical climate.

Materials & methods

Data. The milk production data and pedigree during 2009~2019 were collected from the Taiwan DHI program. Those records having: sire ID in blank or not identifiable; phenotypic and tested values collected less than 106 in the first lactation and 136 days in the later lactations were eliminated. Thus, 62,068 lactation records of 28,722 cows with 2,356 sires and 39,965 animals in the pedigree were obtained. Production traits include milk yield (MY), milk fat percentage (MF%), milk fat yield (MFY), milk protein percentage (MP%) and milk protein yield (MPY) are standardized to 305d-2X yield. Somatic cell count is transformed to somatic cell score (SCS) to achieve normality of this trait and homogeneity of its variance (Ali and Shook, 1980).

Statistical analysis. Based on the above data and pedigree of lactating cows, the following multiple-trait animal models were used to estimate the variance and covariance components as well as heritability and correlation. The first model is shown as following:

$$y_{ijlm} = \mu + HYS_i + L_j + pe_l + a_{ijlm} + e_{ijlm} \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_665, © Y.H. Lan *et al.* 2022

where, y_{ijlm} is the record for each trait of the cow; μ is the overall population mean; HYS_i is the fixed effect of i^{th} herd-year-season; L_j is the fixed effect of j^{th} lactation; pe_l is the random permanent environmental effect; a_{ijlm} is the random additive genetic effect; and e_{ijlm} is the random residual effect.

In addition to the effects in the model (1), an extra fixed effect, PSL_k, is included for physical situation of lactation k, where k=1 represents the cows might have subclinical mastitis (average lactation SCS>4.585 or somatic cell counts $>3\times10^5$), k=2 represents the cows might have abnormal physiology (305d-2X milk yield <5,713 kg), k=3 represents the cows might have subclinical mastitis and abnormal physiology simultaneously, and k=4 represents the cows were in normal physiological situation. The second model is shown as following:

$$y_{ijklm} = \mu + HYS_i + L_j + PSL_k + pe_l + a_{ijklm} + e_{ijklm} \quad (2)$$

The number of lactation records for PSL_k with k=1~4 were 6,249 (10.0%), 4,948 (8.0%), 1,261 (2.0%) and 49,610 (80.0%), respectively. The statistical analyses were conducted using ASReml software 4.1 (Gilmour *et al.*, 2009).

Results

The estimates of heritability, genetic correlations and phenotypic correlations for different traits using model (1) are shown in Table 1. The heritability estimated for MY, MF%, MFY, MP% and MPY are 0.249, 0.588, 0.284, 0.504 and 0.275, respectively. These estimates are similar to those obtained from DHI data analysis in different countries (Cassell, 2009; Roman *et al.*, 2000; Suzuki and Van Vleck, 1994). However, the heritability of SCS estimated by the model (1), 0.274, is higher than the usual estimates, but few studies had similar estimates to those from the model (1) (Roman *et al.*, 2000; Sabedot *et al.*, 2018). The estimates of genetic correlation among different traits are similar to those from several studies except for those negative ones between SCS and production traits (Rincón *et al.*, 2015; Sabedot *et al.*, 2018).

However, when a physical situation of lactation (PSL_k) was used as a fixed effect in the model (2), estimates of heritability for SCS, MY and MPY were significantly decreased 46.7, 12.0 and 9.5%, respectively (Table 2). It may due to the fixed effect which accounts for the abnormal lactation physiology and subclinical mastitis in Taiwan dairy herds. Those estimates of genetic correlation between SCS and production traits changed from 26.5% (SCS and MFY) to 227.8% (SCS and MP%). The estimate of genetic correlation between SCS and MY is closed to zero, which is similar to some studies (Kheirabadi and Razmkabir, 2016; Rincón *et al.*, 2015).

Table 1. Estimates with standard errors of heritability (on diagonal), genetic correlations (above the diagonal) and phenotypic correlations (below the diagonal) using model (1) from multiple-trait model analyses.[1]

	MY	MF%	MFY	MP%	MPY	SCS
MY	0.249±0.008	-0.372±0.017	0.550±0.015	-0.268±0.018	0.849±0.006	-0.181±0.023
MF%	-0.288±0.005	0.588±0.007		0.632±0.009		-0.116±0.018
MFY	0.782±0.002		0.284±0.008		0.726±0.010	-0.264±0.022
MP%	-0.342±0.005	0.507±0.004		0.504±0.008		-0.036±0.019
MPY	0.931±0.001		0.827±0.002		0.275±0.008	-0.198±0.023
SCS	-0.214±0.005	0.005±0.006	-0.203±0.005	0.104±0.005	-0.187±0.005	0.274±0.008

[1] MY = milk yield; MF% = milk fat percentage; MFY = milk fat yield; MP% = milk protein percentage; MPY = milk protein yield; SCS = somatic cell score.

Table 2. Estimates with standard errors of heritability (on diagonal), genetic correlations (above the diagonal) and phenotypic correlations (below the diagonal) using model (2) from multiple-trait model analyses.[1]

	MY	MF%	MFY	MP%	MPY	SCS
MY	0.219±0.008	-0.366±0.018	0.378±0.020	-0.270±0.019	0.759±0.009	-0.026±0.032
MF%	-0.253±0.005	0.590±0.007		0.625±0.009		-0.191±0.023
MFY	0.708±0.003		0.291±0.008		0.633±0.013	-0.194±0.028
MP%	-0.281±0.005	0.495±0.004		0.526±0.008		-0.118±0.024
MPY	0.902±0.001		0.771±0.002		0.249±0.008	-0.091±0.030
SCS	-0.134±0.005	-0.014±0.005	-0.128±0.005	0.053±0.005	-0.114±0.005	0.146±0.007

[1] MY = milk yield; MF% = milk fat percentage; MFY = milk fat yield; MP% = milk protein percentage; MPY = milk protein yield; SCS = somatic cell score.

Discussion

An additional fixed effect of PSL_k in the model (2) would reduce the accuracy of estimated breeding value (EBV) in some traits. The number of sires with accuracy of EBV greater than 75% decreased in MY, MF%, MPY and SCS, with 7.37, 0.33, 5.34 and 37.06%, respectively (Table 3). The degree of decrease in accuracy of EBV would be in accordance with the decrease of heritability.

The percentage of changes in the rank of those sire EBV with accuracy greater than 75% are 49.5, 43.1 and 80.1% for MY, MPY and SCS, respectively (Figure 1). For analyzing data in the tropics/subtropics climate, it is necessary to reconsider the effects in the model, otherwise the accuracy of EBV for sires might be overestimated.

The Akaike Information Criteria (AIC) and Bayesian Information Criteria (BIC) of MY in the model (1) are 920,993.11 and 921,020.05, while those in the model (2) are 900,280.55 and 900,307.49. The AIC and BIC of SCS in the model (1) are 96,309.85 and 96,336.80, while those in the model (2) are 60,845.68 and 60,872.62. It shows that the AIC and BIC in Model (2) are all smaller than those in the model (1). The decreases of AIC and BIC for both MY and SCS show that the model (2) might be a more appropriate model for this DHI dataset.

Conclusions

The model (2) with the fixed effect, PSL_k, accounts for abnormal physiology and subclinical mastitis in dairy cows, has a lower AIC and BIC than the model (1) without the fixed effect, which indicates the model (2) is better in the analysis. The heritability of MY and SCS are decreased largely than other traits, and the number of sires with accuracy of EBV greater than 75% also reduced. To analyze DHI data in tropical/subtropical climate, we need to be more careful in the effects accounting for physical situation of lactation in the model, otherwise, it might lead to some bias in estimation of genetic parameters and breeding values.

Table 3. Number of sires with the accuracy of estimated breeding values greater than 75% for different traits in the two models.[1]

	MY	**MF%**	**MFY**	**MP%**	**MPY**	**SCS**
Model (1)	543	906	609	858	580	564
Model (2)	503	903	627	864	549	355
Change	-7.37%	-0.33%	2.96%	0.70%	-5.34%	-37.06%

Abstract

This study aims to identify the most appropriate random regression test-day model (RRTDM) for the South African Jersey dairy breed, using Legendre Polynomials (LP) to model the lactation curve. The data comprised of production test-day records for milk yield (MY), fat yield (FY) and protein yield (PY) from 33,852 multiparous cows. Genetic parameters were estimated using single trait RRTDM using AIREML90. The fixed effects fitted were Herd × Test-day × Birth Year of the Cow × Calving year × Parity × Number of Milkings (HTDBCPNM), production system (PROD) (TMR, pasture or both), age at first calving (AFC) and inter-calving period (ICP), and fixed regressions on age class-season-district. Random effects were direct additive, permanent environmental and residual effects. The estimated heritabilities for MY, FY and PY were 0.254, 0.182 and 0.170, respectively. The genetic correlations between total milk production and persistency were low (0.06 to 0.24). Overall, the heritability estimates of all the traits analysed were low to moderate.

Introduction

The accurate estimation of genetic parameters and (co)variance components associated with RRTDM is important for the estimation of accurate breeding values (Danell, 1982). The genetic parameter estimates obtained are largely dependent on the regression functions used to model the lactation curve, as well as the covariance structure for additive, permanent environmental, and residual effects (Bignardi *et al.*, 2011). The most common functions used to model the lactation curve include the ones proposed by Ali and Schaeffer (1987), Wilmink (1987), splines (White *et al.*, 1999), and orthogonal polynomials (Kirkpatrick *et al.*, 1990). Parametric functions such as those of Ali and Schaeffer (1987) and Wilmink (1987) have mostly been abandoned because the estimated covariance matrices show high correlations between random regression coefficients which can hinder the estimation process (Schaeffer, 2004). Therefore, orthogonal polynomials such as the Legendre Polynomials (LP) introduced by Kirkpatrick are more commonly used since their parameters tend to be less correlated than the aforementioned functions (Guo *et al.*, 2002), and they provide estimates of covariance matrices that are more robust over different datasets (Schaeffer, 2004). This study makes use of LP to estimate lactation curves, based on additional benefits outlined by Pool (2000).

In South Africa, dairy cattle breeding values are estimated for production traits based on a fixed regression test-day model (Mostert, 2007). Dzomba *et al.* (2010), outlines how the current South African model is criticised for assuming a standard lactation curve for cows in similar contemporary groups, homogenous additive genetic variances across lactations, and for its inability to account for persistency. The adoption of a RRTDM would overcome these limitations and has other advantages such as improved accuracy of breeding value estimates, extra possibility to decrease generation interval, and consequently improved genetic response to selection. This study aims to identify the most appropriate RRTDM for the South African Jersey dairy breed, using Legendre Polynomials to model the lactation curve.

Materials & methods

Data ranging from 1988 to 2017 were obtained from the South African Jersey Association. A total of 429,940; 420,691 and 420,691 test-day records were analysed for MY, FY, and PY respectively. The data analysed was from 33,852 multiparous cows, of 1,558 sires, in 51 herds located across South Africa. Age at calving ranged between 15-36, 26-53, and 38-67 months for first, second, and third parity respectively (Interbull, 2015). Test-day yields from 5 to 305 days of lactation were considered. Lactations included at least five test-day records per cow. Contemporary groups were defined as a concatenation of Herd × Test-day × Birth Year of the Cow × Calving year × Parity × Number of Milkings (HTDBCPNM), with a total number of 12,033 groups containing at least 10 individuals and 2 sires per group. Only animals containing information on production system (i.e. pasture, total-mixed ration, or a combination of these systems) were included. Test-day yields for milk, fat, and protein were adjusted according to the ICAR guidelines (2017).

Analyses were performed using single trait RRTDM, including the direct additive, permanent environmental, and residual effects. The fixed effects included in the model were contemporary group (as defined above), PROD, AFC, and ICP, and age average lactation curve modelled with fifth-order LP within age class × season × district classes where age classes were assigned per lactation according to Mostert (2007). The chosen statistical model is as follows:

$$y_{tijklmn} = \mathrm{HTDBCPNM}_i + \mathrm{PROD}_j + \mathrm{AFC}_k + \mathrm{ICP}_l + \sum_{r=1}^{5} ASD_{mn0}\, x_n + \sum_{r=1}^{5} a_{mn} x_n + \sum_{r=1}^{5} pe_{mn} x_n + e_{tijklmn} \quad (1)$$

where $y_{tijklmn}$ is the t^{th} test day record (milk yield, fat and protein contents) of the m^{th} cow in i^{th} contemporary group (HTDBCPNM) effect, j^{th} production system and k^{th} age at first calving, l^{th} inter-calving period; ASD_{mn0} is the n^{th} fixed regression coefficient of the o^{th} class of cows age class-season-district; a_{mn} and pe_{mn} are regression coefficients n^{th} for additive genetic and permanent environmental effects on m^{th} cow respectively; x_n is the n^{th} Legendre Polynomial for the t^{th} day; $e_{tijklmn}$ random residual effect associated with $y_{tijklmn}$.

For each trait, a single trait RRTDM was run using Average Information Restricted Maximum Likelihood methodology with the AIREMLF90 program (Misztal *et al.*, 2002). Numerous models with varying fixed effects were tested, and AIC values and variance components were compared for each model.

Results

The first coefficient of LP can be related to the total yield in each lactation and the second regression coefficient can be viewed as a persistency measure. The first two coefficients tend to account for most of the genetic variation (Strabel and Jamrozik, 2006). The first two coefficients accounted for approximately 94% of the genetic variation for MY, whereas for FY and PY the first four coefficients accounted for approximately 90% of the genetic variation, only results of the first two coefficients shown in Table 1.

Discussion

Assessment of AIC values showed that Model 1 produced the lowest values, and thus best fit the data for all traits (results not shown). The first random regression coefficient (intercept) of orthogonal polynomials describes the total yield in lactation, thus the heritability of this coefficient is equal to the heritability of 305-day lactation yield. The second random regression coefficient (linear) can be viewed as a persistency measure (Strabel and Jamrozik, 2006). The largest genetic variances were associated with the intercept and linear coefficients, while all other variances (not shown) were close to zero for all traits. The genetic correlation for MY and persistency was low and positive (0.1669), however not as low as the genetic correlation between total FY and persistency of fat production (0.0678). The genetic correlation between PY and persistency of protein production, although still lowly correlated (0.2410), appeared to have the strongest genetic relationship between the first two random regression coefficients.

Table 1. Genetic variances of the random coefficients (diagonal, bold face), correlations (upper diagonal), covariances (lower diagonal), phenotypic variances (σ_p), residual error variances (σ_r) and direct ratios.

Direct additive effect					
	Random regression coefficients		σ_P	σ_r	h^2
Trait	**0**	**1**			
Milk yield	5.4297	0.1669	21.4090	6.1314	0.2536
	0.4757	1.4957			0.0699
Fat yield	0.0167	0.0678	0.0920	0.0300	0.1816
	0.0008	0.0073			0.0792
Protein yield	0.0163	0.2410	0.0960	0.0100	0.1700
	0.0034	0.0123			0.1286
Permanent environmental effect					
	Random regression coefficients		σ_P	σ_r	**Ratio**
Trait	**0**	**1**			
Milk yield	7.1516	0.0444	21.4090	6.1314	0.3341
	0.0825	0.4829			0.0226
Fat yield	0.0117	0.0660	0.0920	0.0300	0.1272
	0.0005	0.0047			0.0511
Protein yield	0.0102	0.2398	0.0960	0.0100	0.1072
	0.0021	0.0075			0.0785

The variances obtained in this study were different to those obtained by Interbull (2015) for the South African Jersey population, likely do due to differences in the model, as well as the data used. Despite this, the heritabilities for the direct additive effects appeared to be similar to those obtained in this study; 0.23, 0.14 and 0.20 for MY, FY and PY respectively. The Interbull variance ratios for permanent environmental effects also appeared to be similar, ranging between 0.27-0.31, 0.13-0.18 and 0.24-0.26 for MY, FY and PY respectively. Heritabilities of 0.18 and 0.11, and variance ratios of 0.44 and 0.88 for the first two random regression coefficients for total milk production were obtained by Strabel and Jamrozik (2006). The same study also found a genetic correlation between the intercept and linear coefficients of first lactation milk production to be 0.06. Other studies have obtained heritabilities of 0.23-0.25 for milk yield (Li *et al.*, 2020). Variance ratios obtained by a fixed regression model used on South African Jersey data were 0.39, 0.21 and 0.34 for additive genetic effects of milk, fat and protein respectively, and 0.23,0.16 and 0.20 for permanent environmental effects of milk, fat and protein yields respectively. The current South African test-day model is a fixed regression model, and therefore does not have a comparative genetic measure for persistency of production traits (Dzomba *et al.*, 2010).

667. ROH describes the small holder dairy systems with Holstein cattle in Mexico

A. García-Ruiz[1*], J.G. Cortés-Hernández[2] and F.J. Ruiz-López[1]

[1]National Institute for Forestry, Agriculture and Livestock Research (INIFAP), Km 1 carretera Ajuchitlán – Querétaro, Qro. CP 76280, México; [2]National Autonomous University of Mexico (UNAM) Av. Universidad #3000, Colonia, C.U., Coyoacán, 04510 México City, México; garcia.adriana@inifap.gob.mx

Abstract

The objective of this study was to identify traits that have been incorporated into the selection processes in Holstein cows of the small holder production system (SHS) through the presence of Runs of Homozygosity (ROH) in the genome. The study included 214 animals genotyped with the GeneSeek GGP 50K® chip. Minimum ROH length and size were established (500 kb and 25 SNP), allowing 5 missing genotypes and one heterozygous. The most frequent ROHs were identified and annotations and genes identified in other populations were obtained. 10,798 ROH were detected with an average, minimum and maximum length of 4.79, 0.43 and 91.90 Mb, respectively. In the region where the most frequent ROH were found in the population (≥20 animals), QTL and genes have been reported that are related to milk production and composition, fertility parameters, susceptibility to diseases, body conformation, feed efficiency and some characteristics of the carcass composition.

Introduction

Signatures of selection are regions of the genome that have been conserved for generations in populations due to natural or artificial selection and are related to functionally important traits. Their detection helps to identify candidate genes that have been favored in selection processes to which populations have been exposed naturally or induced, and to identify beneficial mutations.

Among the methods to identify signatures of selection, those that are formed by the reduction of genetic variation stand out, such as, for example, runs of homozygosity (ROH), which are contiguous regions of homozygous genotypes that occur within an individual when two haplotypes share a common ancestor, those formed in recent generations being shorter.

The formation of ROH in the genome is influenced, among other factors, by the degree of intensity of selection in the populations, which in turn is determined by the availability of replacements and the adoption of technological and reproductive tools, such as artificial insemination (AI) and embryo transfer (ET). In dairy cattle, the intensity of selection is very high and the selection of genetic material is restricted to a limited number of families, a factor that contributes to the formation of ROH.

In Mexico, more than 30% of the national milk production was produced in the small holder system (SHS), which includes approximately 78% of dairy farms. Holstein cattle predominates in the small holder farms, although Brown Swiss animals can be found, as well as their crosses (Sainz-Sánchez *et al.*, 2016). Currently there is no reliable information on production records per animal in the SHS and on rare occasions it is possible to collect genealogical information, which makes it very difficult to carry out genetic evaluations of the animals found in this system. The genetic improvement of these animals has been carried out by the selection made by the farmer within his herd or by the genetic material introduced as AI semen, but there is no evidence of matings directed with a specific selection purpose, or which traits have been a priority at the time of selection. Genomic tools could be used to identify possible selection signatures that would allow identification of the priorities in the SHS.

Materials & methods

Genotypes and quality control. Genotypes of 214 Holstein cows from four SHS herds located in the region of Tepatitlán Jalisco, Mexico were used. Animals were genotyped with the GeneSeek GGP 50K® chip, which contains 43,285 single nucleotide polymorphism markers (SNP). Genotypes were filtered by genomic quality control which consisted of excluding animals with a call rate <0.90; exclude SNP with minor allele frequency (MAF) <0.02, or a call rate <0.95, or with a Hardy-Weinberg *P*-value<0.0001.

Identification of signatures of selection. Signatures of selection were detected by the presence of runs of homozygosity (ROH) in the genome. ROH runs that had a minimum length of 500 kb and a minimum number of 25 SNP were included. In addition, 1 heterozygous SNP and 5 missing genotypes were allowed per run. With those parameters, the risk on including short ROH was avoided (Purfield *et al.*, 2012). ROH analysis was performed with the bioinformatics platform SNP & Variation Suite v7.6.8 Win64 (Golden Helix, Bozeman, MT, USA).

Frequent ROH were classified as those that were present in 20 animals or more of the population and, according to their physical position in the genome, annotations in the genome that showed their association with genes were searched. In order to find genomic information that could help identify possible traits that have been selected in the population of the SHS in Mexico, QTLs or traits of economic interest found in the Animal QTLdb Release 43 database were examined (Zhi-Liang *et al.*, 2019).

Results

In the population studied, 10,798 ROH were detected with an average length of 4.79 Mb, finding a maximum length of 91.90 Mb and a minimum of 0.43 Mb. 70.65% of the ROH were unique in the population; that is to say, they were found in a single animal; while 29.35% (3,169) were found in more than one animal, some with the same length (identical) (10.42%) and others with variable lengths (18.93%), coinciding only in the final position.

The amount of ROH was lower compared to that reported in animals which come from the specialized production system in Mexico, indicating a lower intensity of selection. For example, in Holstein cattle from the intensive production system in Mexico, a total of 88,529 ROH were found, although the population size was larger (4,432 animals), the average length was greater than 8.95 Mb and a proportion of the genome covered of 179.57 Mb (Cortés-Hernández *et al.*, 2021). In other studies, in Holstein cattle from the specialized system in USA, an average of 299.6 Mb of the covered genome by ROH was reported (Forutan *et al.*, 2018).

The most frequent ROH in the population (≥20 animals) were found on chromosomes 1, 2, 10, 13 and 15, in regions where QTL and genes related to milk production and composition have been reported, as have traits related to fertility, susceptibility to diseases, body conformation, feeding efficiency and some carcass composition traits (Animal QTLdb Release 43; Zhi-Liang *et al.*, 2019; Chen *et al.*, 2020). To search for ROH annotations with variable length, the shortest ROH with respect to the final position was taken as a reference (Table 1).

Discussion

The results show that although the lengths of the ROH in this population (~4.8 Mb) suggest a crossbreeding of related animals of approximately ~16 generations (Ferenčaković *et al.*, 2013), the conserved regions could indicate that genetic selection in this population has been aimed at improving milk yield, its composition, fertility and health in this population. In some cases, associations with carcass traits were observed, findings that could suggest possible crosses with other breeds.

Studies in other specialized Holstein populations, have reported around 82.3±9.83 ROH per animal in USA Holstein cattle (Forutan *et al.*, 2018) and 81.7±9.7 runs per animal in Italian Holstein cattle (Marras *et al.*, 2014). These large differences may be due to the high degree of selection in the populations of specialized production systems in USA and Italy, as well as the availability of genetic material from highly selected stallions compared to small holder production system that was analyzed in where the selection objectives are not so focused.

Genomic regions (ROH) that have been maintained as a result of the selection process of the population of the family system were found. These conserved regions were found in positions within the genome where the annotations are numerous and include associations of SNP-like markers, QTL, genes, and signatures of selection; all of which are mostly related to traits of economic interest in the dairy industry, such as milk yield and composition, fertility parameters, susceptibility to diseases, body conformation, feed efficiency and some characteristics of the composition of the carcass.

These results indicate that the above-mentioned traits have been modified by the selection processes of the genetic material in the SHS population.

Abstract

National dairy evaluations use mostly multistep methods, where a nongenomic BLUP evaluation is followed by extraction of pseudo-phenotypes, genomic analyses, and merging nongenomic and genomic evaluations. With genomic preselection and many females genotyped, pseudo-phenotypes are biased, and it is hard to accommodate female genotypes fully. Such problems were successfully solved in other species by ssGBLUP, but large biases and expensive computing were experienced in dairy. This paper documents several improvements that made ssGBLUP feasible for national dairy evaluations. The pedigree relationships account for inbreeding. The formulas for unknown parent groups involve relationships for genotyped animals, and the number of groups is small. Pedigrees and phenotypes are truncated. Large data is accommodated by the APY algorithm. Multibreed evaluation is possible with judicious choice of APY core animals. In tests with the US national data and up to 3.5 M genotypes, analyses by ssGBLUP showed minimal bias and superior stability of GEBV.

Introduction

Dairy genomic evaluations at the national level use mostly multistep methods (VanRaden *et al.*, 2009), where a nongenomic BLUP evaluation is followed by extraction of pseudo-phenotypes for genotyped animals, genomic evaluation for genotyped animals, and an index to merge genomic and nongenomic values. Accurate creation of the index is difficult, and many countries use an approximate index, e.g. assuming 20% of polygenic and 80% of genomic component.

Over time as animals were genomically selected, BLUP became biased by pre-selection (Patry and Ducrocq, 2011; Masuda *et al.*, 2018). Subsequently, pseudo-phenotypes are biased and require ad-hoc corrections. Accommodating genotypes of females without double counting is difficult, potentially creating problems as now most genotyped animals are females. One alternative to the multistep method is ssGBLUP (Aguilar *et al.*, 2010; Misztal *et al.*, 2020) that is used in almost all species except dairy. It automatically accounts for genomic preselection, avoids calculating pseudo-phenotypes, and accommodates male and female genotypes without double counting. In dairy, ssGBLUP was applied as early as 2010 by Aguilar *et al.* (2010) and more recently by Masuda *et al.* (2018) and Bradford *et al.* (2019); however, the evaluations were biased in all the cases. Another problem was a relatively large computing time due to slow iteration. Recently, two studies looked at an evaluation using Holsteins only (Cesarani *et al.*, 2021) and multibreed using 5 breeds (Cesarani *et al.*, 2022), and evaluations were nearly unbiased in both cases. An additional study compared evaluations in the last study with the official CDCB evaluations (Mota *et al.*, 2022). That study found that the reliability of ssGBLUP was up to 0.07 higher, and stability was up by 0.12 higher. Subsequently, the current implementation of ssGBLUP seems beneficial for the routine evaluation in dairy cattle. The purpose of this paper is to describe steps that made ssGBLUP unbiased, accurate, and computationally efficient.

Materials & methods

Data. Recently, several ssGBLUP evaluations for milk, fat, and protein were run with the CDCB data, only for Holsteins (Cesarani *et al.*, 2021) or for five dairy breeds altogether that included Holstein, Jersey, Ayrshire, Brown Swiss, and Guernsey animals (Cesarani *et al.*, 2022). Genotyped animals used in the analyses ranged from 800k to 3.9 million. The developments and improvements required to make ssGBLUP a suitable method for dairy evaluations are described below.

Compatibility between pedigree and genomic relationships. To avoid biases, pedigree and genomic relationships need to be compatible. Standard scaling is by a linear transformation of the genomic relationship matrix (G) for equal mean with the pedigree relationship matrix (A) (Vitezica *et al.*, 2011). While A is affected by the completeness of pedigree, G is not. Therefore, an important part of scaling is accounting for inbreeding in the pedigree relationships. If pedigrees are missing, the inbreeding of animals with missing parents is calculated as 0, so accounting for nonzero inbreeding of missing parents (VanRaden, 1992) could provide additional compatibility.

Unknown parent groups (UPG). Under selection, the merit of missing parents over time needs to be accounted for. Early studies in ssGBLUP accounted for UPG only in A, resulting in slow convergence and biases. Later studies found that a reasonable option is also considering UPG for pedigree relationships for genotyped animals (A_{22}). Many BLUP evaluations use 100s of UPG. With UPG in A_{22}, there is not enough information to account for many groups, and considerably reducing the number of groups was a good option to reduce bias.

Interaction among pedigree, data truncation, and UPG. In general, the additive information decays fast with subsequent generations, and old data can be discarded without losses in accuracy for new animals but with gains in computing time. Including more than 2 generations of data with additional 2 generations of pedigree did not improve the accuracy for young animals and sometimes even lowered it (Lourenco *et al.*, 2014; Cesarani *et al.*, 2021). The broiler industry uses at most 3 generations of data despite many more available. Potential reasons for lower accuracy with older data are changing definitions of traits, model adjustments, and poor convergence for the solutions for young animals. Additionally, age adjustments vary over time as cows are indirectly selected for early calving. Truncation of old pedigrees eliminates the effect of missing pedigrees prior to truncation and reduces the number of needed UPG. If the number of generations is small, accounting for inbreeding is less or not critical.

Metafounders (MF) in ssGBLUP. MF are generalizations of UPG with scaling and inbreeding plus covariances accommodated (Legarra *et al.*, 2015). In regular scaling, G is scaled for compatibility with A_{22}. With MF, G is created with 0.5 gene frequencies, and pedigree relationships are adjusted for compatibility with G. Variance and covariances across MF potentially account for inbreeding of unknown parents and relationships among unknown parents. While MF did very well in simulations, problems with parameter estimation are still under investigation in real populations.

Large number of genotypes. The dairy populations accumulated a large number of genotypes, and many algorithms exist that can support that number in single-step methods (Misztal, 2018). All of them exploit the fact that the rank of genomic computations (based on SNP or G) is limited by the number of SNP (usually 60k) and by the small dimensionality of G in populations with small effective population size. This dimensionality is about 15k in dairy cattle (i.e. 15k core animals). With the APY algorithm (Misztal, 2016), which relies on the limited dimensionality of G, calculations have linear computing and storage costs past the number of core animals. An advantage of APY is the low cost and easy application of UPG. A disadvantage is some fluctuations of GEBV with the choice of core animals, which can be handled by

keeping the core constant. An important part of the evaluation is pruning genotypes. While the number of genotyped animals may be very high, those without progeny or phenotypes can be eliminated from ssGBLUP evaluations, reducing computing costs. Predictions for omitted animals by indirect predictions can be as accurate with large data sets as when they are included in the model (Tsuruta *et al.*, 2021). Another factor influencing computations is the blending of G, used to avoid the singularity of G. Blending with A_{22} was costly; however, computing coefficients separately for core and noncore animals is highly efficient. Blending with 0.01I is also efficient without affecting accuracy.

Other issues. Many other issues are remaining in the dairy ssGBLUP evaluations that are not discussed here but have been addressed elsewhere. They include using external information from Interbull (Guarini *et al.*, 2019), exploiting putative QTN (Misztal *et al.*, 2020), using purebred and crossbred information combined (Misztal *et al.*, 2022), and approximating accuracies of GEBV (Bermann *et al.*, 2022).

Results

Holsteins (Cesarani et al., 2021). Phenotypes were truncated for cows recorded before 1980, 1990, or 2000, and pedigrees were truncated to 2 or 3 generations beyond phenotyped cows. Two UPG formulations were used, the QP transformation for A (UPG1) or A and A_{22} (UPG2). With forward prediction, reliabilities were calculated for bulls and predictivity for cows. Only genotypes for contributing animals were used (about 800k). With UPG2, reliabilities and accuracies were the same with all truncations. Inflation was minimal as the b_1 parameter was close to 1.0. With simple UPG, reliabilities were smaller and varied with truncation.

Five breed analyses (Cesarani et al., 2022). Holstein, Jersey, Ayrshire, Brown Swiss, and Guernsey data were analyzed separately and altogether in a model with UPG2, truncation of phenotypes recorded before 2000, and 3 generations beyond phenotypes. The total number of genotyped animals was 3.9 million. When the multibreed evaluation used 15k randomly selected core animals in the APY algorithm, the reliabilities were lower for the smaller breeds than in the single-breed analyses. When core animals were selected to include 5k animals of each smaller breed and 15k of each Holstein and Jersey, the reliabilities were close to those from single breeds, and they were higher for Jerseys. One explanation is that the Jersey population included Holsteins in the past. In all cases except for the smallest breeds, the inflation was low (i.e. b_1 close to 1.0).

Official comparisons. Evaluations for Holstein bulls from the previous analyses were compared with official multistep evaluations (MS) by CDCB (Mota *et al.*, 2022); the latter were computed using different weights for SNP in a nonlinear approach, whereas ssGBLUP assumed equal weights for SNP. For milk, R^2 based on DYD for raw MS was 0.07 lower than for ssGBLUP. After age adjustments, this difference reduced to 0.01. Stability of evaluations was calculated by correlations of GEBV derived with 2017 and 2021 data. The stability for MS was 0.86 (0.89 with correction for age). The stability for ssGBLUP was 0.90 (0.92 after age correction). Regression coefficients were close to 1.0 for both ssGBLUP and MS predictions.

Discussion

The results for reliability and stability indicate a dilemma on how to judge an evaluation system. If DYD is derived from BLUP, it is biased even for bulls with many daughters. Also, GEBV by unadjusted MS are biased. Subsequently, it is not clear whether adjustments for age compensate GEBV, DYD, or both. In terms of stability, ssGBLUP was ahead of MS. After many developments as described, ssGBLUP is finally ready for implementation at the national level. This method provides evaluations that are possibly more accurate than the current one, does not require adjustments, and is simpler to run. Further improvements of accuracy can be expected with the inclusion of external Interbull data and possibly weighing SNP differently.

Abstract

This work aimed to develop single-step multibreed genomic predictions for US dairy population. About 45M yield phenotypes recorded between 2000 and 2020 in purebred Ayrshire, Brown Swiss, Guernsey, Holstein, and Jersey animals were analyzed. Genotypes at 79,294 SNPs were available for 3.9M animals. A 3-traits model with milk, fat, and protein yields was applied to four different scenarios: each breed separately; all five breeds together; Aushire, Brown Swiss, and Guernsey together; Holstein and Jersey together. For each scenario, BLUP and single-step genomic BLUP were carried out and were validated using the correlation between adjusted phenotypes (for cows) or daughter yield deviations (for bulls) and (genomic) breeding values. As expected, all ssGBLUP scenarios led to higher values compared to BLUP. The ssGBLUP multibreed evaluation for US dairy population is feasible, but model fine-tuning is needed to achieve good validation results.

Introduction

In 2007, a multibreed genetic evaluation was implemented for US dairy cattle, and it was extended to a multistep genomic evaluation in 2009 (VanRaden *et al.*, 2007; 2009). Currently, US dairy cattle are evaluated with a two-step method: a multibreed BLUP model followed by SNP effects estimation and direct genomic values computation within each breed. Single-step genomic BLUP (ssGBLUP) has been adopted in lieu of the multistep method for genetic evaluations in several farm animal species over the years. ssGBLUP has been applied with satisfactory results in almost all livestock species (e.g. Macedo *et al.*, 2020; Pimentel *et al.*, 2021). Genomic models have been tested also in a multibreed context (e.g. Winkelman *et al.*, 2015; Khansefid *et al.*, 2020). The aim of this work was to develop ssGBLUP multibreed genomic predictions for US dairy cattle. In particular, we used the algorithm for proven and young (APY) to compute the inverse of the genomic relationship matrix.

Materials & methods

Data. Official data used in the multibreed genomic evaluations for US dairy cattle breeds were provided by the Council on Dairy Cattle Breeding (CDCB, Bowie, MD). Only purebred Ayrshire (AY), Brown Swiss (BS), Guernsey (GU), Holstein (HO), and Jersey (JE) animals were considered. Phenotypes for milk (MY), fat (FY), and protein (PY) yields recorded from 2000 to 2020 were considered. The 305-d yields (about 45M recorded on 19.4M cows) for the first 5 lactations included projected records for the final lactation and for lactations not yet completed by June 2020. About 3.9M animals were genotyped at various densities and imputed to 79,294 selected SNPs within each breed. Only purebred animals were included in the evaluation.

Analysis. Two evaluation methods were considered: (1) traditional BLUP, with unknown parent groups (UPG); (2) ssGBLUP, with QP transformation of unknown parent groups applied to A and A_{22}, implemented as in Tsuruta *et al.* (2019) and Cesarani *et al.* (2021). UPG were defined based on breed, sex, and year of birth for a total of 8 UPG for each breed. The two methods were carried out for: (1) each breed

separately (SINGLE); (2) the 5 breeds together (5_BREEDS); (3) AY, BS, and GU (AY_BS_GU); (4) HO and JE together (HO_JE). The APY algorithm was applied with 15k core animals in SINGLE (for HO and JE), 30k for AY_BS_GU and HO_JE, and 45k core animals for 5_BREEDS. A 3-trait repeatability animal model was applied with herd-management, age-parity, inbreeding coefficient and heterosis covariates, and UPG as fixed effects and herd-sire combination, animal, and permanent environment as random effects. For the multibreed models, all effects were made breed-specific by adding the breed code to each level of the effects.

Validation. Each scenario was run two times: FULL, with all phenotypes; REDUCED, removing the phenotypes of cows born in the last 4 years (2015-2018). Validation of each model was assessed by the correlation between adjusted phenotypes in FULL and (genomic) estimated breeding values ((G)EBV) in REDUCED for cows (predictive ability), and by the correlation of daughter yield deviation (DYD) in FULL on the (G)EBV in REDUCED for bulls. Validation cows were genotyped females born in 2015-2018 with no records in REDUCED, whereas validation bulls had at least 10 (AY, BS, GU), or 50 (HO, JE) daughters in FULL and no daughters in REDUCED.

Results

Correlations between raw EBV from BLUP estimated in all the different models were 1.00 for all breeds and traits, whereas correlations between raw GEBV estimated in ssGBLUP SINGLE and ssGBLUP 5_BREEDS ranged from 0.95 (MY for AY and BS) to 1.00 (HO and JE). Moreover, we also computed the slope of the regression of (G)EBV in 5-BREEDS on (G)EBV in SINGLE for each breed: slopes for BLUP were always 1, confirming that in practice each breed was independently evaluated, as breeds were not connected by the pedigree. Acceptable slope values were also found for ssGBLUP as values ranged from 0.93 (MY and PY for BS) to 1.02 (MY for AY). Table 1 shows the validation results for both cows and bulls. As expected, ssGBLUP SINGLE gave better results compared to BLUP for all considered breeds and traits. Within ssGBLUP, higher values were observed for 5_BREEDS compared to SINGLE for all breeds, expect for BS bulls, for which a slight decrease was observed in the multibreed scenario. Results in AY_BS_GU and HO_JE were similar to SINGLE. However, results for AY, and GU are strongly affected by the very low number of bulls.

Table 2 reports the slope of DYD or adjusted phenotypes on (G)EBV for bulls and cows, respectively. Results were similar to those in Table 1, where ssGBLUP SINGLE led to better results, on average (i.e. values closer to 1) compared to BLUP. All regression coefficients estimated for HO and JE were within 15% of the unit, considered acceptable values (Tsuruta *et al.*, 2011). In this case, results for AY and GU were also affected by the limited number of validation animals.

Regarding computing time, about 7 hours were needed to solve the MME with ssGBLUP in HO SINGLE (3.4M genotypes); this time increased by a factor of 9 for the 5_BREEDS scenario.

Discussion

The use of genomic information is expected to increase the reliability of breeding value prediction in livestock. ssGBLUP gives higher validation accuracies in several livestock, but applications of this method in large-scale dairy evaluations have been limited. Recently, Cesarani *et al.* (2021) showed the superior performance of ssGBLUP compared to BLUP in US Holsteins. The present study gave insights into using this genomic model in a multibreed context. As expected, using genomic information within each breed improves validation statistics for both bulls and cows. Results for Holsteins were similar in all scenarios involving this breed because of the greatest number of genotypes and records. This study demonstrates that large-scale multibreed genomic evaluations are feasible, as we obtained results in the multibreed scenarios

that were at least similar to the ones in single-breed evaluations. Fine-tuning of models and a better representation of each considered breed in the core animals are needed to avoid reducing the reliability of smaller breeds when evaluated together with numerically dominant breeds. This is the first step towards the multi breed evaluation, in which crossbreed and external information will be considered.

670. Integrating MACE breeding values into multiple-trait single step random regression test day evaluations of Aussie Reds

V. Boerner[1,2*], T. Nguyen[3] and G. Nieuwhof[3]

[1]GHPC Consulting and Services PTY. LTD., Armidale 2351, Australia; [2]Centre for Quantitative Genetics and Genomics, Aarhus University, Denmark; [3]DataGene, AgriBio, 5 Ring Road, Bundoora VIC 3083, Australia; vinzent.boerner@gmx.de

Abstract

Interbull's multiple across country evaluation provides national breeding organisations with breeding values for internationally used bulls which must be integrated into the domestic evaluation. For that purpose several methods have been proposed which either model Interbull breeding values as prior information in a Bayesian approach, or as additional pseudo data points. Single step random regression models add complexity to the integration because of the dimensionality discrepancy between the number of Interbull breeding values and the number of modelled genetic effects. This paper presents the results from integrating 16,063 Interbull breeding values into the domestic single step random regression test day model for milk, fat and protein yield for Australian red dairy cattle breeds. Results suggest that the integration was successful with regard to alignment of Interbull breeding values with their domestic equivalent as well as with regard to the individual and population-wide increase in reliabilities.

Introduction

National breeding programs can only benefit from Interbull's multiple across country evaluation if the breeding values reported by Interbull are integrated into the national evaluation system. This is even more relevant for single step genetic evaluation as the number of breeding values affected by the integration is expected to increase. External breeding values can be integrated as prior information in a Bayesian approach (Vandenplas *et al.* 2014) which requires manipulation of the mixed model equation system's right-hand side and a special co-variance matrix between animals, or as additional pseudo data (Pitkänen *et al.* 2020) which requires derivation of one or several additional data points and manipulation of the residual co-variances matrix. The integration for production traits like milk, fat and protein yield is complicated due dimensionality discrepancies between the Interbull model and the domestic multiple-trait random regression test day models. In this paper we present results from the integration of Interbull breeding values for milk fat and protein yield into the domestic single step random regression test day model genetic evaluation for Australian Red Dairy breeds.

Materials & methods

The data set for genetic evaluation of production traits of Australian red dairy breeds consisted of test day observation on litre milk, kilogram fat and kilogram protein in the first three lactations with a total of 10,000,614 observations across all nine traits. The pedigree consisted of 73 phantom parents and 975,532 individuals of which 8,191 were genotyped on various platforms. Genotypes underwent internal quality control and imputation procedures and after being imputed to a common set of about 73,000 markers were used to construct a genomic relationship matrix. The total number of bulls to be integrated was 16,063 where 466 bulls had Australian information provided to Interbull (*A*bulls), and 15,597 bulls may have Australian information but it was not provided to Interbull or did not have Australian information at all (*B*bulls). Breeding values of *A*bulls for integration were identified by a positive difference between the Interbull reliability and the local reliability of at least 0.01. If the difference was only achieved for a subset of an *A*bulls's breeding values, e.g. for milk yield, but not for fat and protein yield, only the subset was integrated. All breeding values of *B*bulls were integrated regardless of the Interbull reliabilities. The genetic evaluation

model into which the Interbull breeding values were integrated modelled phenotypic observations as linear functions of fixed herd-year, season, age and lactation curve effects, where the latter used Legendre polynomials of order 1 to 4, of correlated direct random genetic effects using Legendre polynomials of order 0 to 2, of of correlated direct random permanent environment effects of the animal using Legendre polynomials of order 0 to 2, and correlated random residuals. Vectors of direct genetic effects ~$N(0,\Gamma\otimes\Sigma_a)$ and vectors of permanent environmental effets ~$N(0,I\otimes\Sigma_q)$, where Σ_q is co-variance matrix of the permanent environmental effects of dimension 27×27 and Σ_a is the genetic co-variance matrix of dimension 27×27, and $vec(\Gamma) = [\Theta, Q\Theta, \Theta Q', QQ\Theta' + H]$ where Θ is a diagonal matrix with elements equal to 0.62, Q is the pedigree derived genetic group regression matrix, and H is the single step relationship matrix (Christensen and Lund 2010) constructed using a polygenic weight of 0.2. Interbull breeding values were modeled as additional data points with the data point specific residual variance as the single tuning parameter. For aligning within animal dimensions Interbull breeding values u_{MACE} and reliabilities r_{MACE}, and sent breeding values u_{SENT} and reliabilities r_{SENT} were mapped from $\Re_3$ to $\Re_9$ using a block-diagonal matrix K of dimension 9×3 containing 3×1 column blocks of ones. Further Σ_a was mapped from $\Re_{27}$ to $\Re_9$ using a 9×27 block diagonal matrix $L = t\otimes I_9$ with $t = [1'f_0(d), 1'f_1(d), 1'f_2(d))$ where I_9 is an identity matrix of dimensions 9×9, t is a vector of length 3, d is a vector containing a consecutive sequence from 6 to 305, f_i is a vector-valued function applying the Legendre polynomial order i to the argument, and 1 is a vector of ones. Therefore $u_{:,m} = Ku_{:}$ and $r_{:,m} = Kr_{:}$, where ':' was either $_{MACE}$ or $_{SENT}$ and $\Sigma_{a,m} = LS_aL'$. In case only a subset of breeding values within animal met the integration requirement the above dimension were adjusted accordingly. Within animal a vector of prediction error variances was calculated by $p_{:} = diag(\Sigma_{a,m})(1 - r_{:,m})$, where $diag(\ )$ denotes a vector of diagonal elements of a squared matrix. The system for deriving a diagonal matrix $D_{:}$ of inverse residual variances across traits within animal was $diag\left(\left(D_{:} + (\Sigma_{a,m})^{-1}\right)^{-1}\right) \equiv diag(p_{:})$ where $D_{:}$ was be obtained directly only if the system's dimension is 1. Otherwise $D_{:}$ was established iteratively using a procedure similar to (Vandenplas 2012). Within animal vectors of pseudo-phenotypes $y^x_{:}$ were calculated for *A*bulls as $D_r = D_{MACE} - D_{SENT}$ and $y^x = D_r^{-1}\left(\left(D_{MACE} + (\Sigma_{a,m})^{-1}\right)u_{MACE,m} - \left(D_{SENT} + (\Sigma_{a,m})^{-1}\right)u_{SENT,m}\right)$ and for *B*bulls as $y^x = D_{MACE}^{-1}\left(D_{MACE} + (\Sigma_{a,m})^{-1}\right)u_{MACE,m}$.

A maximum of nine pseudo-phenotypes y^x of animal i were added to the evaluation.

The genetic evaluation model was solved and reliabilities were deterministically calculated using MiX99 and Apax, respectively(Lidauer *et al.* 2017).

Results

Generally, results for all three traits were very similar. Therefore, only results for milk yield are summarised in Figure 1. Correlations between Interbull breeding values and domestic evaluation breeding values increased from about 0.05, 0.05 and 0.04 pre-integration to 0.99, 0.98 and 0.99 post-integration for milk, fat and protein yield respectively. The regression intercept changed from 392, 12.4 and 11.3 to 261, 14.3 and 7.11, and the regression slope from 0.05, 0.06 and 0.06 to 1.01, 1.01 and 1.01 for milk fat and protein yield, respectively. Results were similar for the reliabilities, but correlations and regression parameters are weaker and, due to the nature of reliabilities, do not provide the same goodness-of-fit information as for the breeding values. However, post-integration reliabilities of all bulls were at least as high as the Interbull reliabilities. For *A*bulls, the post-integration reliabilities aligned very well with the Interbull reliabilities. Further, for *B*bulls breeding values with a pre-integration reliability of zero the procedure returned a post-integration reliability similar to the Interbull reliability. For the entire evaluation population, but excluding the integrated bulls, about 40% of the reliabilities of all three traits were not affected by the integration, and only 5% of the reliabilities increased by more than 0.1. Contrarily, every single breeding value changed as a result of the integration with 27, 29, and 29% of the breeding values for milk, fat and protein yield, respectively, having changed by more than 10%.

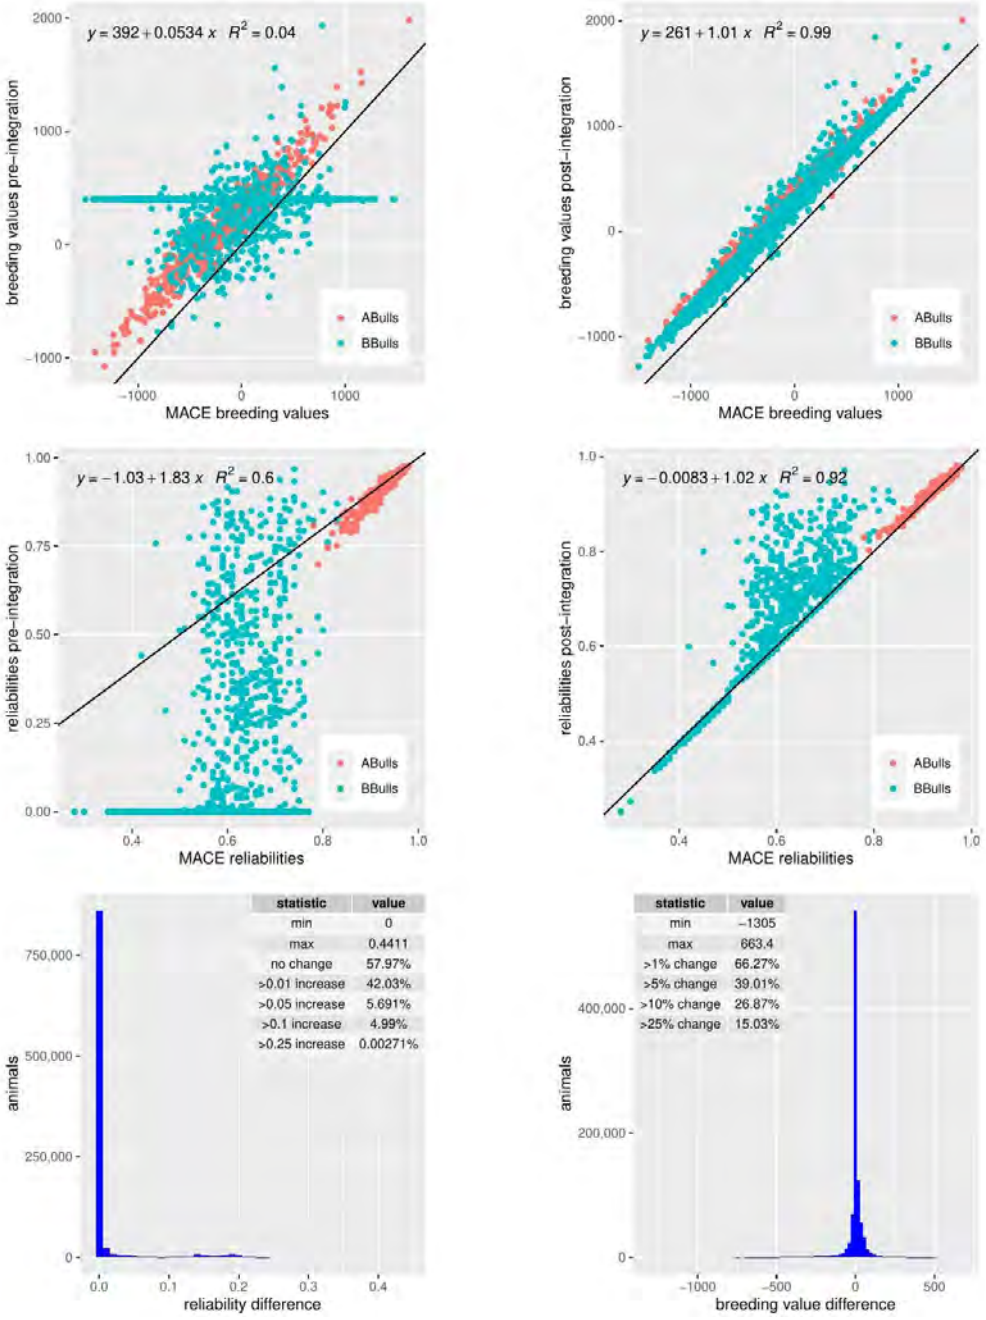

Figure 1. Single Step H-BLUP breeding values (first row) and reliabilities (second row) for litremilk per 305 day lactation pre-integration (left) and post-integration (right) for bulls with (Abulls) and without (Bbulls) Australian information in the Interbull evaluation, respectively. Histograms of the integration impact on breeding values and reliabilities of the entire evaluation population (third row).

Discussion

Results shown here align very well with the expectations and therefore the integration of Interbull breeding values into the domestic single step random regression test day evaluation is regarded as successful. The current integration approach ignores the relationships between integrated bulls when deriving individual specific residual variances. Empirically, ignoring the relationships between integration animals does not pose a problem if the reliabilites are high and integration candidates are not closely related. Accounting for relationships poses a computational problem (Vandenplas *et al.*, 2014). For the approach presented here the procedure for deriving D_i required up to tens of thousand of inversions. Extending the approach to system of $\Sigma_a \otimes \Gamma_{:,:}^{-1}$ will certainly affect inversion time and most likely also the required number of iterations, and will also require block extractions from a complex Γ matrix. An intermediate approach is to approximate some matrix $K = C_{a_i,a_i} - C_{a_i,-a_i}\left(C_{-a_i,-a_i}\right)^{-1} C_{-a_i,a_i}$, where C is the mixed model coefficient matrix and a_i is a vector indexing the block in C related to animal i. Subsequently K is used instead of Σ_a in $diag((D_{:} + K)^{-1}) \equiv diag(p_{:})$ (Pitkänen, personal communication). However, it might be computationally prohibitive to apply such procedure to a single step system.

Abstract

We compared the effects of using three genomic relationship matrices and a pedigree based relationship matrix for optimum contribution selection (OCS) with a constraint on number of sires selected, on genetic gain, kinship and additive genetic variance. This was done by simulating a genomically selected small dairy cattle population. The cattle population underwent genomic selection for 11 generations. In total, 6,000 females and 2,500 males were genotyped per generation. We compared a pedigree-based matrix as well as VanRaden's method 1 to construct genomic relationship matrices using either allele frequencies of the base population, of the current generation, or allele frequencies among all genotyped animals. The pedigree-based OCS resulted in higher kinship and more loss of genetic variance than using genomic OCS based on base population frequencies. Thus, genomic OCS with genomic relationship matrices using base population frequencies are preferable compared with pedigree-based OCS.

Introduction

Genomic selection has increased genetic gain in dairy cattle in recent years, but in some cases at the cost of higher inbreeding rates (Makanjuola *et al.* 2020). Small local breeds that are not genomically selected have become increasingly less competitive to the transboundary breeds. However, simulations have shown that small dairy cattle populations can also benefit from genomic selection (Thomasen *et al.* 2014; Obšteter *et al.* 2019), but research is lacking on ways to balance genetic gain and inbreeding in small populations. To achieve genetic gains through selective breeding in future generations, genetic diversity must be preserved. Inbreeding has to be managed to avoid inbreeding depression. This is not least the case in small populations. Optimum contribution selection (OCS; Meuwissen 1997) maximizes genetic gain while restraining inbreeding. OCS has been implemented using pedigree relationships (POCS), but genomic OCS (GOCS) can be an alternative by using a genomic relationship matrix (GRM). A common way to form GRMs is VanRaden's method one (VanRaden 2008). This method scales the cross-product of centered genotype scores by $\Sigma 2p(1\text{-}p)$, where p is the marker allele frequency. The choice of reference allele frequencies to use is an important parameter to consider when constructing GRMs. VanRaden (2008) recommended the use of base population frequencies. Berg *et al.* (subm.) found important differences in results depending on the type of reference used for GOCS. The aim of this study was to compare four scenarios, three different allele frequencies to construct GRMs and the pedigree based relationship matrix, on genetic gain, kinship and additive genetic variance in a small dairy cattle population undergoing genomic selection.

Materials & methods

The simulations were modelled to mimic the breeding program of the Icelandic Cattle population (Sigurdsson and Jonmundsson 2011). QMSim (Sargolzaei and Schenkel 2009) was used for simulating a base population. The R package Modular Breeding Program Simulator (MoBPS; Pook *et al.* 2020) was used for breeding program simulations. We used GMATRIX (Su and Madsen 2012) to construct GRMs. EVA (Berg *et al.* 2006) was used to optimize genetic contributions of selection candidates. DMU (Madsen and Jensen 2013) was used to estimate breeding values.

Historical population. We simulated a genome of 29 chromosomes each with 2,000 evenly spaced loci. The mutation rate was 2.5×10^{-5} per locus per generation. For each replicate of scenarios, a new historical population was simulated. The population size was 1000 individuals for 2,000 generations and increased over 200 generations to 12,000. Genotype data were converted into Plink *ped* format (Purcell *et al.* 2007) and read into MoBPS. We randomly sampled 2,000 segregating loci to be quantitative trait loci (QTL), which were not used for construction of GRM. We assigned effects to the QTL by drawing from a gamma distribution with shape 0.4 and scale parameter 1.66. We discarded very low frequency marker loci so that the genotyping markers reflected the allele frequency distribution of commercial SNP chips. The number of polymorphic genotyping marker loci were around 39,000 at the start of the genomic selection, with some variation across replicates. We simulated a sex-based trait with a constant heritability of 0.4. We used three replicates for each scenario.

Breeding program structure and breeding value prediction. We simulated four discrete generations of pedigree-based best linear unbiased prediction (PBLUP) selection before genomic selection started. We then simulated three generations of genomic prediction using single-step genomic BLUP (ssGBLUP), and subsequently eight generations of GBLUP. Each generation contained 6,000 males and 6,000 females. Each cow had exactly two calves. In each generation of genomic selection, 2,500 male and 6,000 female selection candidates were selected for genotyping based on their parent average and their genomic breeding values (GEBVs) were estimated. Selection was according to optimum contribution selection, only on the sire side, with additional constraints described below. Dams of selection candidates had phenotypes at the stage of selection. The model for genetic evaluation included the additive genetic animal effect, an intercept and a residual: y = Xb + Za + e, where y was a vector of animal phenotypes, b was a vector of fixed effects, a was a vector of (genomic) estimated breeding values where a followed $N(0, A\sigma_g^2)$, $N(0, H\sigma_g^2)$ and $N(0, G\sigma_g^2)$ for PBLUP, ssGBLUP and GBLUP, where A was the numerator relationship matrix, H was a combined pedigree and genomic relationship matrix (Christensen and Lund 2010) and G was a GRM computed using VanRaden's method one. X and Z were design matrices and e was a vector of random residuals following $N(0, I\sigma_e^2)$. We used the true values of variance components.

Optimum contribution selection. To constrain the number of sires selected, we constructed a 'pseudo-female' out of all female selection candidates. The pseudo-female had a relationship with itself that was equal to the mean relationship among female selection candidates, and a relationship with each bull that was equal to the mean relationship of all female candidates to that bull. The pseudo-female was assigned 30 matings, and each bull was allowed one mating. The 30 selected bulls were then randomly mated to females and used equally. The genetic contributions were optimized to achieve the same target rate of inbreeding, while maximizing genetic gain, and selecting a fixed number of bulls, and using them equally. Genetic contributions *c* were optimized in each generation to maximize the genetic level in the offspring generation, *G*: G=c'â where â was a vector of GEBVs, subject to the constraint: c'Rc=C where R was a relationship matrix, and the target rate of average coancestry was set to 0.005, and the constraint that the sum contributions of males and females each equaled ½ (Meuwissen 1997; Woolliams *et al.* 2015).

We used the first method of VanRaden (2008) to compute GRMs: $G = ZZ^T/(2\Sigma p_j(1-p_j))$, where Z = M – P where M is the genotypic matrix for genotyped animals for which rows are genotypes with values 2 and 0 for the two homozygotes, and 1 for heterozygotes; P is a matrix where all elements in the j^{th} column are $2p_j$, where p_j is the frequency of the allele at locus *j* that was counted in M. We used three estimates of p_j: *Base* used the allele frequencies in the base population, *Recent* used genotyped animals in the current generation, and *All* used all genotyped animals to estimate p_j. Additionally, we used a pedigree-based relationship matrix (*Pedigree*). Thus the study composed of four scenarios of OCS: *All*, *Base*, *Recent* and *Pedigree*.

Statistical analysis. We computed the mean true breeding value and estimated mean identical-by-descent (IBD) based genomic kinship for the selection candidates in each generation. Kinship 'represents the value of chromosome segments of two different individuals to be IBD at a random position when randomly drawing one of the two haplotypes of each individual' (T. Pook, pers. comm.). We used the following linear model for generations six to 16:

$$y = Replicate + Scenario + Scenario \times Generation + error \quad (1)$$

where y was breeding value, kinship or additive genetic variance. We used the standard errors of the linear regression coefficients for significance testing. The interaction term of scenario and generation gave a regression coefficient nested within scenario.

Results

Figure 1 shows the average results of the simulation from generation 1 to 16. Genetic gain was 0.827, 0.846, 0.818 and 0.835 genetic standard deviations; kinship rate was 0.81, 0.84, 0.73 and 0.98%; and loss of additive genetic variance was -3.0, -3.0, -2.9 and -3.6% per generation, for *All*, *Recent*, *Base* and *Pedigree*, respectively, according to the linear model. Pedigree-based OCS resulted in significantly higher rate of increase in kinship than GOCS ($P<0.01$), and *Base* resulted in significantly lower kinship increase than *Recent* and *Pedigree* ($P<0.05$). *Pedigree* resulted in significantly more loss of genetic diversity than genomic OCS ($P<0.05$). The difference in genetic gain among scenarios was not statistically significant.

Discussion

The results suggest that genomic OCS can outperform pedigree-based OCS, contrary to the conclusion of Henryon *et al.* (2019), but agreeing with the recommendation of Sonesson *et al.* (2012). Henryon *et al.* (2019) assessed inbreeding rate at a set of IBD loci not used for prediction, while we assessed true kinship using recombination points and founder chromosome segments. The faster build-up of kinship, and more rapid loss of genetic diversity observed with POCS, suggests that genomic OCS is preferable to pedigree-based OCS under the conditions in this simulation. Our results agree with results of Berg *et al.* (*subm.*).

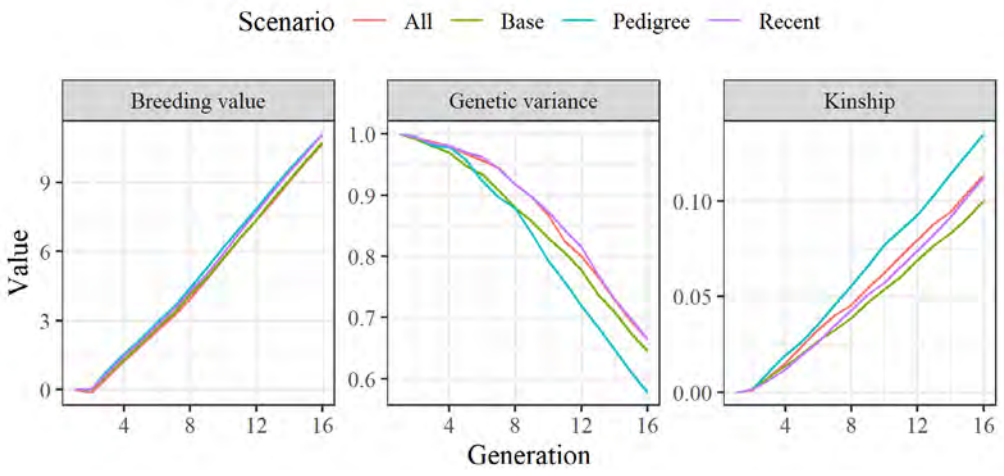

Figure 1. Mean breeding value, additive genetic variance and kinship. Genomic selection started in generation six. Breeding value is in units of additive genetic standard deviation, genetic variance is the proportion of variance in the base population and kinship is based on genomic identity-by-descent.

They found that distant reference frequencies for GOCS resulted in less build-up of kinship than using recent frequencies. We simulated a population with number of markers and animals resembling a feasible breeding scheme for the Icelandic dairy cattle population. This included simulating a breeding scheme that used a fixed number of bulls and equal use of these bulls. While this is a deviation from the theory of optimum contribution selection, we believe that this resembles a practical and cost-effective way for genomic breeding of a small dairy cattle population, since number of AI bulls is a limiting factor in a small closed population. Our results suggest that in such settings, GOCS should be conducted, using old animals to compute reference allele frequencies for the GRM.

672. The rising popularity of embryo transfer in U.S. dairy cattle and implications for national fertility evaluations

A.M. Miles*, J.L. Hutchison and P.M. VanRaden

Animal Genomics and Improvement Laboratory, Agricultural Research Service, United States Department of Agriculture, Beltsville, MD 20705-2350, USA; asha.miles@usda.gov

Abstract

This research was motivated by the exponential increase in embryo transfer (ET) use with >5 times as many ET calves born in the U.S. in 2021 compared to just 5 years earlier. A survey of the national database revealed that only 1% of ET calves correspond to ET breeding events, 2% are incorrectly reported as artificial insemination, and 97% have no associated breeding event. Herdyears reporting >10% of calves born by ET but less than half of the expected number of ET breeding events were removed, and sire conception rate recalculated with this new dataset. Subsequent analysis showed that censoring herdyears with inconsistent ET reporting has little effect, except in the case of elite young bulls popular for ET use. Improved ET reporting will be critical for providing accurate fertility evaluations, especially as the popularity of these advanced reproductive technologies continues to rise.

Introduction

Commercial embryo transfer (ET) began in the 1970s and today has become common practice in herds desiring to increase their rate of genetic progress (Hasler 2014; Moore and Hasler 2017). Part of the attraction of ET can be explained by substantially reduced generation intervals among habitual ET users. For example, consider a top genetic merit heifer whose embryos were collected starting at 7 months old (Table 1). The maternal line continued this rapid turnover resulting in a remarkable 7 generations in 10 years (average generation interval 16.7 months). Embryos purchased in high enough volumes could cost as little as $125 per embryo, putting ET at a comparable price level to artificial insemination (AI) services (Trans Ova, personal communication). As transfer technologies become more affordable, ET use has grown exponentially with 11% of U.S. dairy calves born in 2021 attributable to ET (Figure 1). However, the trend in ET breeding event reporting (red line) does not parallel the ET calf birth rate (blue line) and this lack of congruence can interfere both with national evaluations and on-farm management of fertility. This discrepancy could be explained by a number of things, including embryo donation or implantation not being reported at all or ET being incorrectly reported as AI. Some of these errors can be eventually corrected when breed associations provide pedigree records, but they arrive 9 months too late as unofficial fertility evaluations are provided to U.S. producers on a weekly basis. Previously, the USA imposed edits for ET donors and reported recipients in our evaluations, and only 3 Interbull-participating countries account for ET by excluding ET records (Interbull Centre, 2021). Completely censoring ET-associated records is not necessarily the desired approach, as these represent the most elite animals and herds, and unreported ET could also bias fertility trait evaluations in the population. In this paper we propose an edit to account for incorrect ET reporting and explore its impact on sire conception rate (SCR), as an example.

Table 1. Maternal line and genotyped embryo of dam HOCAN13913420.

	Maternal generation

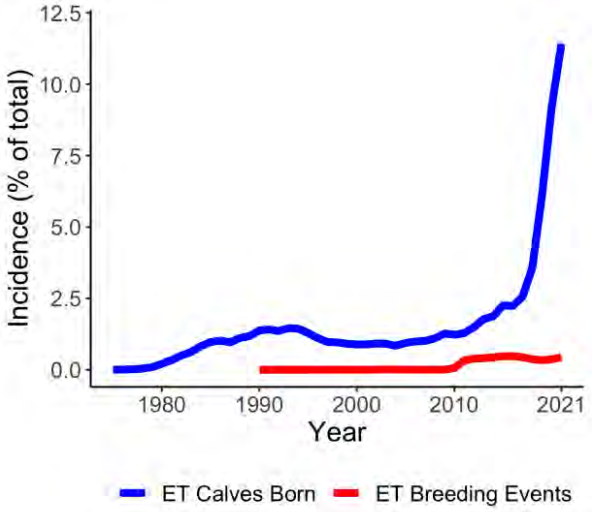

Figure 1. ET use in the USA.

Materials & methods

Data were extracted from the National Cooperator Database maintained by the Council on Dairy Cattle Breeding in December 2021, representing the most current information available on ET use in the USA. Reported mating types were matched with recorded birth types to assess ET reporting error rates. A new dataset was created by removing herdyears that reported >10% of calves born by ET but less than half of the expected ET breeding events given the number of ET calves born. This edit maximizes data preservation while removing the records most likely to introduce confounding bias. All summaries were performed in SAS version 9.4 (SAS Institute, Cary NC, USA) and data visualization performed with R version 4.1.1 (R Foundation for Statistical Computing, Vienna, Austria). This new dataset was used to compute SCR with the same methodology used for the official evaluations. SCR is computed with an all-breed animal model, including Ayrshire, Brown Swiss, Guernsey, Holstein, Jersey, and Milking Shorthorn, and using only the most recent 4 years of data (Council on Dairy Cattle Breeding, 2021). Pearson correlation coefficients between the new and old values were calculated, and the differences in SCR (SCR_{DIFF}) were computed for each bull by subtracting the official values from the new values generated with the proposed edit.

Results

For calves born by ET, breeding events reported 9 months earlier revealed only 1% of recipients correctly reported as ET, 2% incorrectly reported as AI, and 97% with no breeding event reported at all. The ET edit resulted in the removal of 252 herdyears for SCR, accounting for a 1.2% reduction in the total number of records included in the calculations. The number of publishable bulls was reduced for all breeds except Milking Shorthorn, which do not appear to be utilizing ET and only have one publishable bull (Table 2). The median SCR_{DIFF} is close to zero for all breeds and the biggest changes were observed in Holstein bulls (range of -1.9 to 1.3). A wider spread in SCR_{DIFF} is observed among bulls more frequently used for ET (Figure 2A), though SCR_{DIFF} converges on zero as more matings are reported (Figure 2B). ET usage is not strongly correlated with total number of matings, as many of the highest merit young bulls with comparatively few matings are now being used almost exclusively for ET (Figure 2C).

Table 2. Summary statistics of the impact of ET edits on sire conception rate.

		SCR_{DIFF}[2]				
	Publishable bulls[1]	Minimum	Median	IQR[3]	Maximum	Correlation[4]
Ayrshire	6 (7)	-0.3	-0.1	0.4	0.3	0.98*
Brown Swiss	44 (48)	-0.9	-0.1	0.3	0.6	0.99*
Guernsey	14 (17)	-0.6	0.1	0.6	0.6	0.96*
Holstein	1,379 (1,454)	-1.9	0.0	0.2	1.3	0.99*
Jersey	132 (141)	-1.4	-0.1	0.3	0.9	0.99*
Milking Shorthorn	1 (1)	0.0	0.0	0.0	0.0	--

[1] Publishable bulls with ET edit (publishable bulls without edit).

[2] Difference in SCR, computed as new values – old values.

[3] Interquartile range.

[4] Correlation between the new and old values. *$P<0.0001$.

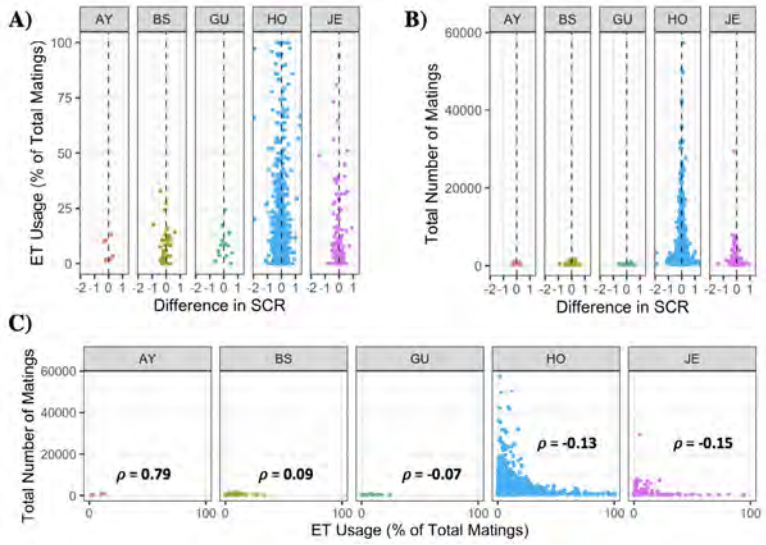

Figure 2. By-breed differences in SCR plotted against (A) percent of matings related to ET for each bull, (B) total number of matings for each bull, and (C) the correlation of total number of matings and popularity of each bull for ET. AY (Ayrshire), BS (Brown Swiss), GU (Guernsey), HO (Holstein), JE (Jersey), ρ = Pearson correlation coefficient.

Discussion

The new SCR computed from data filtered for ET was consistently highly correlated to the official values as shown in Table 2. The small effect of this edit can also be appreciated by examining the SCR_{DIFF} for individual bulls. The wider range of SCR_{DIFF} values among popular ET bulls was expected given that records were censored on the basis of ET usage. By plotting SCR_{DIFF} against the total number of reported matings for each bull, we see that as more records are added SCR_{DIFF} converges on zero, suggesting that the true effect of ET on SCR for proven bulls is nearly zero. This trend is most obvious in Holstein and Jersey, due to the larger amount of data available. It is notable that even for non-zeros, the difference is small (1-2 percentage points) and will have overall little effect. However, most breeds indicate a negative correlation

between the total number of matings and the amount that bull is used for ET, suggesting that popular, proven bulls are not being prioritized for ET over young bulls. This explains anecdotal reports of young bulls whose SCR estimates may change a lot as more records are added or edited out, especially if their daughters are nearly all born by ET. Similar edits for unreported ET had larger effects on heifer conception rate than cow conception rate or SCR and might be needed for other fertility-related traits such as daughter pregnancy rate, gestation length, and early first calving. Acquiring high-quality ET records (comprising details like multiple ovulation ET versus *in vitro* fertilization, fresh versus frozen, embryo grade and stage, recipient synchrony, follicle stimulating hormone protocol, numbers of degenerate embryos, etc.) can help partition genetic effects among fertility, conception rate, and pregnancy rate. The Beef Improvement Federation recently approved guidelines for using ET records and necessary considerations in evaluation models, such as accounting for the effects of both the donor (e.g. calf genetics) and recipient (e.g. birth weight) dams. These principles could also be adopted by the dairy industry with the establishment of new data pipelines. Currently, unstandardized ET reporting is having minimal effect, but that is not a guarantee if the ET calf birth rate continues to rise without a parallel increase in accurate ET breeding event reporting.

Conclusions

The rapid increase of ET is likely to continue as advanced reproductive technologies become more affordable. An investigation of SCR shows that censoring herdyears without consistent ET reporting has overall negligible effect, except for young bulls. Even though the SCR correlations are high with small effects, the biggest changes are observed in elite new bulls which have a huge influence on the breeding program. There is an urgent need to improve ET reporting to facilitate the delivery of accurate fertility evaluations.

673. Simulating technical, economic and environmental performance of a dairy herd under selection in future climate conditions

J.G. Burns[1,2*], V. Eory[1], R. Mrode[1,3], G. Simm[2] and E. Wall[1]

[1]Scotland's Rural College (SRUC), Edinburgh, Scotland, EH9 3JG, United Kingdom; [2]The Global Academy of Agriculture and Food Security, University of Edinburgh, Roslin, Scotland, EH25 9RG, United Kingdom; [3]International Livestock Research Institute, Kenya, Box 30709-01001 Nairobi, Kenya; jay.burns@sruc.ac.uk

Abstract

Climate change will have direct effects on performance of livestock. Simulations that mimic livestock systems risk misrepresenting performance if these effects are not accounted for. Here, the technical, economic and environmental performance of a Scottish dairy herd under genetic selection (for 7-correlated traits) was investigated using an original simulation model. There were two scenarios: in the control scenario, the technical performance of individuals was not affected by daily weather; in the treatment scenario, technical performance was dynamic to daily weather conditions. Herds were simulated for 20-years. By the final year of the simulation, for herds in the treatment scenario relative to the control scenario, annual gains in gross margin were reduced by 2.1% and gains in greenhouse gas emissions intensity were reduced by 1.7%. Failure to account for weather effects in models that simulate herds into the future will likely cause over-estimation of technical, economic and environmental performance, even in temperate regions such as southwest Scotland.

Introduction

It is likely that global temperatures will continue to rise. This, together with increasing magnitude and frequency of extreme weather events, will present major challenges to livestock production in the coming years (IPCC, 2021). The production of ruminant livestock, such as dairy cows, is under particular pressure given that some negative externalities of the system (e.g. greenhouse gas – GHG – emissions, which not only include enteric emissions but also emissions from manure management and managed soils – for details, see Gavrilova *et al.*, 2019) will exacerbate existing environmental challenges. In the face of such challenges, dairy production must remain efficient, which means the system and its components must be resilient (Friggens *et al.*, 2017). This resilience may be improved with artificial selection (e.g. Poppe *et al.*, 2020), however, the value of resilience at the animal-level is not well established, and is likely to be proportionate to the degree of challenge expected for a given system. Against this back-drop, we present the application of an individual-based model (IBM) under different scenarios of future climate, where the objective is to demonstrate the value of herds if individuals are resilient – or not – to variable daily weather conditions.

Methods

Using an original, daily time-step, IBM, we mimic the daily biological performance and management of a herd of individuals, where individuals are represented according to a set of underlying genetic characteristics, covering production and functional traits. As in real life, individuals differ in their genetic ability, and, over time, the genetics of the herd improves, driven by breeding dams to genetically improved sires and subsequent selection of genetically superior replacements. This, together with stochastic functions in the model, generates variability in the performance of individuals, resulting in realistic variation in the performance of the herd. The performance of individuals can also be dynamic to key weather variables, based on scenarios of future climate change. In terms of model outputs, individual performance data were collected daily and used to calculate raw technical performance, economic outcomes and GHG emissions at the herd level.

The model was parameterised to be representative of a specialist dairy herd in southwest Scotland. Therefore, the simulated herd consisted of approximately 200 lactating cows; they were housed for 6 months per year (October – March, inclusive), and housed part of the day for the remainder, as is common in the United Kingdom (March *et al.*, 2014). The herd was simulated for 20-years into the future (2021-2040).

The daily performance of herd-members was affected by 7-traits of economic importance, these were: milk yield, fat yield and protein yield (production), dry matter intake (maintenance), probability of mastitis infection (health), number of inseminations to conception (fertility), and days of life (longevity). The daily phenotypic performance of each individual across these traits was a function of their genetic ability and environmental factors (including daily weather). According to these phenotypic functions, each day individuals would yield a given quantity and quality of milk, would consume a given quantity of dry matter, may succumb to mastitis infection, may conceive, and/or may be culled, respectively. Main interactions of productivity, reproduction and health occurring during the productive lifetime were integrated. However, the simulation was not an optimisation model, therefore, herd management rules remained static between climate scenarios and across time. In addition to this, we assume no adoption of climate mitigation technologies or practices by the farmer.

In one scenario of the simulation (herein, the treatment scenario), the explicit weather-dependence of daily phenotypes enabled prediction of the degree and extent of weather effects on herd performance. Here, weather affected daily yields, feed intake, and rates of mastitis, conception and mortality. This allowed us to capture the cumulative impact of seasonal and long-term weather variations on herd performance. As well as simulation runs that accounted for climate change in this way, the simulation was also run with static weather variables that did not reflect climate change, which acted as a baseline where animals were resilient and therefore unperturbed by variable weather (herein, the control scenario). Weather variables came from UK Climate Projections 2018 (UKCP18), downscaled for the target area.

The technical output and production characteristics of the herd were used to calculate economic and environmental performance. Gross margin was calculated as income (e.g. from milk sales) minus variable costs (e.g. pregnancy testing). For the environmental performance, we calculated enteric and manure methane, and direct, volatilised and leached nitrous oxide from manure; these emissions were calculated according to the IPCC 2019 refinement to the IPCC 2006 national GHG inventory (Gavrilova *et al.*, 2019). We did not directly calculate emissions from spreading manure on managed soils, as we assumed these emissions are captured by feed component emissions factors (EFs). Dietary assumption and associated EFs were provided by consultants at SRUC as representative for the modelled system. Emissions intensity is reported as total emissions of the lactating herd per unit of energy-corrected milk (kg CO_2-eq/kg ECM). Total emissions of the herd were calculated as kg CO_2-eq, using the IPCC AR5 GWP100 conversion. ECM accounts for yield, fat and protein content of milk (Sjaunja *et al.*, 1990).

Results

Results show that estimates of technical, economic and environmental performance were significantly different between simulation runs for control and treatment scenarios (statistical model outputs not shown). Accounting for the effects of climate change on the technical performance of individuals led to unfavourable changes in several key herd parameters: for example, an overall decrease in productive lifespan and increased incidence of mastitis (see Figures 1a-c). In addition, we found similarly unfavourable results for age at first calving, calving index, conception rate and ECM.

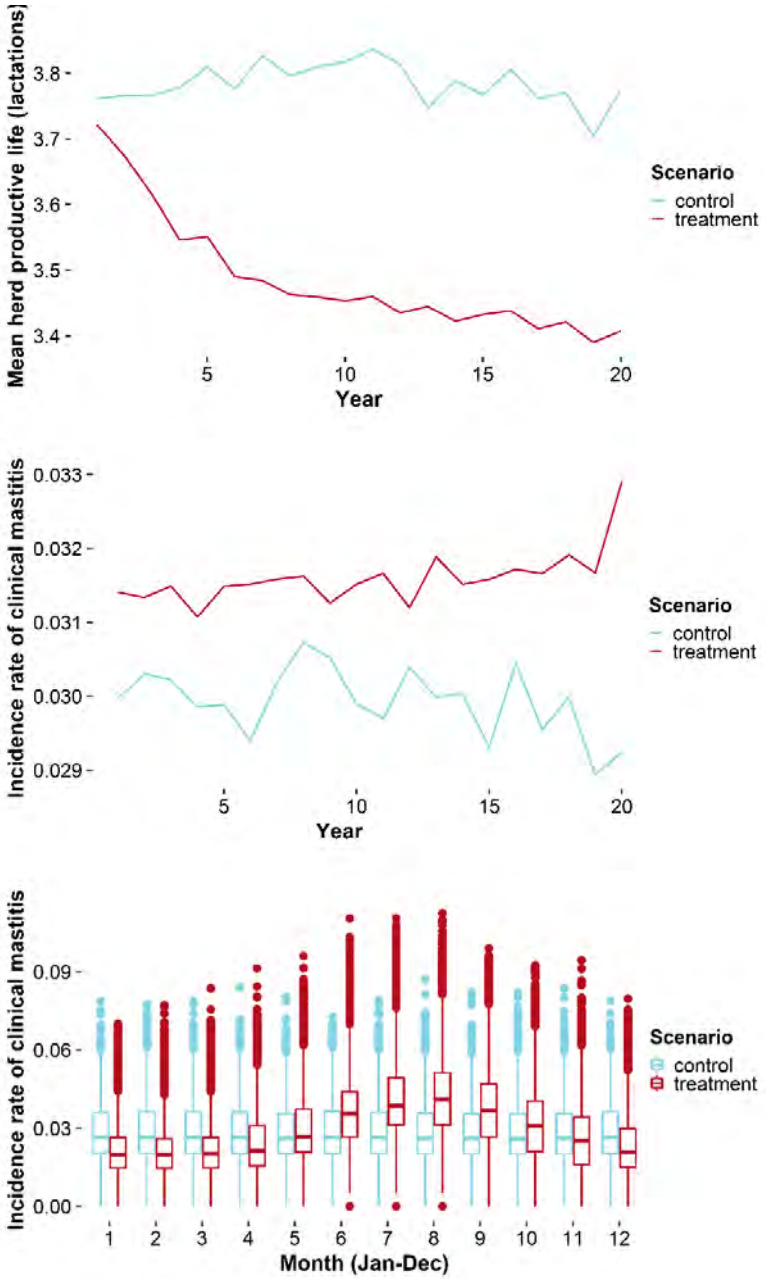

Figure 1 Plots to demonstrate the impacts of key weather variables on (a) productive lifespan across years, (b) incidence rate of clinical mastitis across years, and (c) incidence rate of clinical mastitis within years. Treatment scenario refers to simulation runs that account for climate change, and control scenario refers to simulations run with static weather variables. Please carefully note the y-axis scales when interpreting these plots.

Accordingly, relative to the control scenario, where individuals were robust to variation in daily weather conditions, gains in gross margin were reduced by 2.1%, and gains in GHG emissions intensity were reduced by 1.7% in the treatment scenario. With 900 herds in the Scottish dairy system, this reduction in gross margin could amount to £15m for the industry – and the difference in emissions intensity could lead to an extra 25,000 tonnes CO_2-eq– resulting from less efficient production over the next 20-years, even in the temperate climate of southwest Scotland.

Discussion

Without cattle who are resilience to the impacts of projected weather over the coming decades, we can expect negative impacts on the technical, economic and environmental performance of dairy herds, even in temperate regions. Resilience to these direct effects may be introduced through selection for traits that promote individuals who are able to maintain production in the face of environmental perturbations by, for example, accounting for genetic-by-environment interactions in breeding decisions. Animals who are resilient will not only be more profitable but also produce better quality milk in greater quantities at a lower emissions intensity. As research into breeding for resilient animals continues (e.g. www.GenTORE.eu), a critical question is what value should be placed on these novel traits. Towards this question, the current paper is an important contribution.

However, also important are the methodological implications, which suggest that failing to account for the effects of climate at the animal-level in such models will cause the misrepresentation of key performance indicators, especially as this type of model becomes increasingly popular and simulated scenarios can run for many years into the future. Therefore, if researchers aim to mimic the biological performance of a herd, it is increasingly difficult to overlook relationships between climate and herd functioning, even in temperate regions.

Conclusions

This paper presents the results of a novel approach to estimating the value of resilience at the animal-level in a way that can be tailored to specific regions within production systems. We report substantial differences in individual and herd performance between production scenarios.

Abstract

Lameness in dairy cattle is primarily caused by foot lesions including sole haemorrhage (SH) and sole ulcers (SU). This study investigated the genetic architecture of SH and SU in different lactation stages based on accurate phenotyping, genetic parameter estimation, genome-wide association (GWA) and functional enrichment analyses. Foot lesion records were collected from 2,353 Holstein cows on four herds at four time-points: prior to calving, immediately after calving, early lactation, and late lactation stages. Heritability estimates were 0.11-0.20 for SH and 0.05-0.13 for SU across stages, and genetic correlations between stages were high for both traits. Candidate genes associated with SH and SU link to immune functions such as complement activation and inflammation, nervous system and muscle functions. To conclude, SH and SU are under genetic control and foot health can be improved with selective breeding.

Introduction

Lameness in dairy cattle is primarily caused by foot lesions including sole haemorrhage (SH) and sole ulcers (SU) as two common claw horn lesions (CHL). Recent studies have shown genetic variation in resistance to foot lesions (Heringstad *et al.*, 2018). A few genome-wide association (GWA) analyses have shown a complex genetic background for foot health (e.g. Swalve *et al.*, 2014; Sánchez-Molano *et al.*, 2019; Butty *et al.*, 2021; Lai *et al.*, 2021), but results generally differ between studies. Most previous studies utilized foot-trimming data that may be subject to variability between recorders and populations and may miss some mild lesion cases.

In the present study we closely monitored cohorts of cows across lactation and collected detailed foot lesion records. The objectives were to: (1) estimate genetic parameters of CHL in different lactation stages; and (2) characterise the genomic architecture of CHL.

Materials & methods

Animals and data recording. A total of 2,353 Holstein cows from four herds in the United Kingdom were included. The studied cows calved between April and September 2019. Individual animals were assessed for SH and SU at four time points: prior to calving (pre-calving stage, mean=55.3 days before calving), immediately after calving (calving stage, mean=5.4 days in milk), at peak yield time (early lactation stage, mean=83.9 days in milk), and in mid-late lactation (late lactation stage, mean=199.6 days in milk).

Foot lesions were recorded by qualified veterinary surgeons using case definitions in the ICAR claw health atlas (Egger-Danner *et al.*, 2020). Over 90% of foot lesion identification and recording was performed by a single researcher. All four feet were examined for each lesion, which were scored as 0 (no lesion), 1 (mild lesion), 2 (moderate lesion) and 3 (severe lesion). The pedigree spanning seven generations was available for all phenotyped animals.

Phenotypes. The phenotype of each lesion severity was calculated as the average score across all assessed feet. The phenotype was calculated for each studied time-point, so each animal had repeated records across lactation stages.

Genotypes. Genotypes were available for 2,250 of the studied animals. The genotypes had been imputed to 80K SNPs within the national dairy cattle genomic evaluation. Chromosome locations of the 80K SNP panel were based on ARS-UCD 1.2. Genotype quality control kept SNP and animal call rates higher than 90%, SNPs with minor allele frequency higher than 0.05, and animals with no parent-progeny Mendelian conflicts.

Genetic parameter estimation. Variance components and heritability for SH and SU were estimated for each lactation stage using the airemlf90 software (Misztal, 2013). Multivariate analyses were conducted to estimate correlations between stages. The model used was:

$$y = Xb + Za + e \quad (1)$$

where y is the phenotype; b is the fixed effect for parity and herd-year-season of recording; age effect was not included because variance explained by age effect has been explained by its correlated effect of parity; a is additive genetic effect with var(a) ~ $N(0, H\sigma_a^2)$, where σ_a^2 is the additive genetic variance and H is the relationship matrix incorporating pedigree and genomic information (Legarra *et al.*, 2009); e is random residual with var(e) ~ $N(0, I\sigma_e^2)$; and X and Z are incidence matrices for b and a, respectively.

Subsequently, repeated records of individuals across lactation were combined and analysed with an animal repeatability model. The model was as model (1) with the addition of a fixed effect for lactation stage and a random permanent environmental effect. Single-step GBLUP animal GEBVs were estimated by the animal repeatability model and blupf90 software (Misztal, 2013).

Genome-wide association analyses. Animal GEBVs were back-solved to obtain SNP effects for each trait, using the postGSf90 software (Wang *et al.*, 2012). In addition, sliding genomic windows with a size of 0.65 Mb were constructed to calculate the proportion of genetic variance explained by each genomic window. The window size of 0.65 Mb was determined based on the average distance in the genome where linkage disequilibrium between markers halved. The proportion of genetic variance explained by sliding windows was calculated with the method described by Wang *et al.* (2014) with postGSf90 software.

Candidate genes located close to the large-effect variants within 0.2 Mb upstream and downstream or within the candidate regions were examined with functional enrichment analyses using the DAVID bioinformatic resource.

Results & discussion

Incidence rates of SH and SU. The incidence rate of SH in the study population (83.0%) was higher than that of SU (13.9%) over the whole lactation. The higher prevalence of SH than SU can be partly explained by the fact that SU cases may be developed from severe SH cases. The incidence rates of SH and SU were at the highest at early lactation stage (57.5% for SH, and 6.1% for SU). Our findings infer a higher risk of SH and SU in early lactation with high yield. Unfavourable genetic correlations between foot lesions and milk yield were reported previously (Koenig *et al.*, 2005).

Genetic parameters for CHL. The heritability estimates ranged from 0.11 to 0.20 for SH, and 0.05 to 0.13 for SU across stages, with no significant differences between stages (Table 1). Although the phenotypic correlations between stages were generally lower than 0.50 for both traits, their genetic correlations were

much higher, especially for SU (Table 1). The high genetic correlations suggest that CHL may have similar genetic background across lactation.

Single-marker GWA results. Significant SNPs were identified on BTA1 for SH, and on BTA8 and BTA5 for SU (Table 2). Genes located closest to these SNPs were *PGM5, TAC3, and BACE2*. The *PGM5* gene was associated with human lower-limb muscle injury (Aguilar *et al.*, 2015). The *TAC3* gene links to nervous system function, smooth muscle contraction, and leukocyte gene expression after burn injury or trauma-haemorrhage in mice (Topaloglu *et al.*, 2009). The *BACE2* gene is related to bovine muscle formation (Lee *et al.*, 2012).

Genomic windows associated with CHL. For SH, highest proportions of genetic variance were explained by genomic regions on BTA20, BTA22 and BTA3 (Table 3). The region on BTA3 was associated with digital dermatitis (Sánchez-Molano *et al.*, 2019). Genes within the region of BTA3 (*C8B, C8A*) link to complement activation. Genes within the regions on BTA20 and BTA22 link to immune functions including inflammation regulation (*OTULIN, OTULINL*), leukocyte migration (*TRIO),* and T cells cytokine production (*BHLHE40*).

Respective regions for SU were found on BTA18 and BTA14 (Table 3). The *CHD9* gene within the region on BTA18 is involved in osteogenesis. Genes within the regions on BTA14 link to neutral system function (*KCNQ3*) and inhibition of cell growth and proliferation (*KHDRBS3*).

Gene enrichment. Enrichment of the above-mentioned genes link to Gene Ontology terms of DNA transcription regulation (*OTULIN, BHLHE40*), KEGG pathways of complement and coagulation cascades (*C8A, C8B*), cholinergic synapse (*ITPR1, KCNQ3*), and Reactome pathway of regulation of complement cascade (*C8A, C8B*).

Table 1. Heritability estimates (diagonal, in bold) for sole haemorrhage (SH) and sole ulcer (SU) at pre-calving stage, calving stage, early and late lactation stages, and genetic correlations (upper-diagonal) and phenotypic correlations (below diagonal) between stages; standard errors of estimates are in brackets.

Trait		Pre-calving	Calving	Early	Late
	Pre-calving	**0.11** (0.03)	0.98 (0.02)	0.78 (0.05)	0.80 (0.04)
SH	Calving	0.35 (0.02)	**0.14** (0.03)	0.74 (0.05)	0.72 (0.07)
	Early	0.27 (0.02)	0.21 (0.02)	**0.20** (0.04)	0.98 (0.02)
	Late	0.25 (0.02)	0.16 (0.02)	0.36 (0.02)	**0.13** (0.04)
	Pre-calving	**0.13** (0.04)	0.97 (0.01)	0.96 (0.01)	0.96 (0.02)
SU	Calving	0.38 (0.02)	**0.07** (0.03)	0.92 (0.03)	0.97 (0.01)
	Early	0.29 (0.02)	0.21 (0.02)	**0.05** (0.02)	0.96 (0.01)
	Late	0.37 (0.02)	0.39 (0.02)	0.44 (0.02)	**0.08** (0.04)

Table 2. Significant markers for sole haemorrhage (SH) and sole ulcer (SU) in single-marker GWA analyses with respective chromosome (BTA) and position (Pos), minor allele frequency (MAF), *P*-value, closest gene, and distance to the gene.

Lesion	BTA	Pos	MAF	*P*-value	Gene	Distance (bp)
SU	8	44,652,431	0.08	6.76E-06	*PGM5*	39,594
	8	44,735,178	0.08	8.21E-06	*PGM5*	122,341
	5	56,420,099	0.06	1.37E-05	*TAC3*	2,087
SH	1	141,365,527	0.21	2.22E-05	*BACE2*	16,070

Table 3. Genomic regions that explain the highest proportions of genetic variance (Var%) for sole haemorrhage (SH) and sole ulcer (SU), including chromosome (BTA) and positions (Pos_start, Pos_end) and genes located within.

Trait	BTA	Pos_start	Pos_end	Var%	Genes
SH	20	58,161,594	58,795,440	0.78	*ANKH, OTULIN, OTULINL, TRIO*
	22	21,284,764	21,911,533	0.63	*BHLHE40, ITPR1, SUMF1*
	3	88,750,416	89,386,272	0.50	*C8B, C8A*
SU	14	8,954,477	9,597,429	0.93	*KCNQ3, EFR3A*
	18	21,454,669	22,081,129	0.69	*CHD9, RBL2, AKTIP, FTO*
	14	5,922,777	6,526,644	0.53	*KHDRBS3*

Conclusions

SH and SU are under genetic control and animal resistance to CHL may be improved with selective breeding. The CHL may have highly similar genetic background in different lactation stages with high genetic correlations. As polygenic traits, SH and SU were associated with immune functions such as complement activation and inflammation, nervous system and muscle functions, DNA transcription regulation, and cell growth and proliferation.

Abstract

In order to evaluate the mammary gland transcriptome response to an early lactation intramammary challenge with viable clinical mastitis pathogen isolates, 24 and 12 German Holstein cows in their early first lactation were challenged with *Staphylococcus aureus* or *Escherichia coli*, respectively. RNA from challenged and control mammary gland tissue was isolated and after depletion of milk and whey protein gene transcripts subjected to RNA sequencing using the Illumina HiSeq 2500 system. A differential expression analysis of the transcriptome of challenged and control mammary gland samples within animal was conducted. An Ingenuity Pathway Analysis (IPA) was performed using the detected differentially expressed genes (DEGs). Both pathogen challenges showed an overlap regarding inactivation of pathways related to energy and lipid metabolism and activating and deactivating effects on immune response pathways.

Introduction

The infection and inflammation of the mammary gland is one of the most frequent and costly diseases in dairy cows (Halasa *et al.* 2007), which can seriously damage the health of affected animals, if left untreated. The course of the disease is crucially influenced by the pathogen species. Mastitis can be caused by gram-positive and gram-negative bacteria. Of particular interest are *Staphylococcus aureus*, mostly inducing chronic and subclinical mastitis, and *Escherichia coli*, predominantly inducing an acute and clinical mastitis. While most previous studies investigated mid-lactation cows of different lactations and used inactivated pathogens or bacterial endotoxins, we focussed on the early first lactation period and challenged the cows with a viable pathogen. In a comprehensive multi-tissue project, a holistic approach was used in order to gain deeper insights into the underlying biological networks affected by an intramammary challenge via monitoring the local (mammary gland), intermediate (blood) and peripheral (liver) response. The aim of this part of the study was to characterize the local (mammary gland) response to an intramammary challenge with *S. aureus* or *E. coli* in primiparous German Holstein cows.

Materials & methods

Animals and study design. For this study, thirty-six healthy German Holstein heifers shortly before first calving were selected. At approximately 36 days after parturition, 24 of these animals were challenged intramammarily with *S. aureus* in both hind quarters of the mammary gland. Twelve animals were challenged with *E. coli* in one hind quarter of the mammary gland. In both groups, one udder quarter of each animal was infused with sterile sodium chloride solution (NaCl) as a control. This challenge scheme had already been established and successfully applied in previous studies (Jensen *et al.* 2013, Petzl *et al.* 2012). Animals were sacrificed 96 hours or 24 hours after challenging with *S. aureus* or *E. coli*, respectively. At these time points, peaks of inflammation of the mammary gland had been observed in previous mid-

lactation challenge experiments (Petzl *et al.* 2008, Petzl *et al.* 2012). Mammary gland parenchymal tissue samples of all udder quarters were collected during necropsy of the animals, immediately frozen in liquid nitrogen and stored at -80 °C. All ethical evaluations were performed as required by the German Animal Care Law and associated legislative regulations.

Transcriptome analysis. The effect of the intramammary challenge on global gene expression was monitored by comparative transcriptome analysis of challenged and NaCl-infused udder quarters. Therefore, total RNA was extracted as described earlier (Weikard *et al.* 2012). Prior to library preparation, highly abundant milk and whey protein gene transcripts were depleted using a previously established protocol (Brodhagen *et al.* 2019). Stranded indexed libraries were prepared using a TruSeq RNA Library Preparation Kit (Illumina) including polyA-selection. After quality control using a Bioanalyzer 2100 (Agilent), RNA libraries were subjected to paired-end sequencing on the Illumina HiSeq 2500 system.

Bioinformatic analysis. For data processing and analysis, SAMtools (Li *et al.* 2009) as well as Linux and R-based scripts were used. After quality trimming, processed reads were aligned to the bovine reference genome ARS-UCD1.2 with Ensembl 95 reference annotation using Hisat2 v2.1.0 (Pertea *et al.* 2016). Additionally, a guided transcript assembly was performed using StringTie v1.3.5 (Pertea *et al.* 2016) to allow the assembly of reads for unannotated transcripts. Differential expression analysis based on count matrices established via featureCounts v.1.6.2 (Subread package) (Liao *et al.* 2014) was performed using DESeq2 v1.18.1 (Love *et al.* 2014). The identified differentially expressed genes (DEGs) were submitted to IPA (Qiagen) using a threshold for significance of $P_{adj}<0.05$.

Results

Using the milk protein transcript depletion method, a total of 14,546 gene transcripts annotated in the Ensembl database could be detected. In both pathogen groups, clearly different expression patterns were found between the challenged and control udder quarters.

***E. coli* challenge.** The mammary transcriptome analysis revealed a total of 6,727 differentially expressed genes between challenged and control udder quarter (3,453 genes higher and 3,274 genes lower expressed). Among genes with highest expression differences (>8 log fold change) in response to pathogen challenge were acute-phase protein (*SAA2*, *HP*, *DEFB10*) and chemokine genes (*CCL20*, *CXCL2*). As the expression of 46% of all annotated genes was modulated by *E. coli* challenge, we only included DEGs with a $P_{adj}<0.01$ in IPA to highlight the most severely affected pathways. IPA revealed 317 significantly enriched canonical pathways in the mammary transcriptome in response to intramammary *E. coli* challenge. The pathways with the lowest activation score relate to lipid metabolism, whereas the most significantly activated pathways affect the immune system (Table 1). In addition, *SOCS1* and *IL10RA,* known to be repressors of the immune response, were identified as inactivating upstream regulators.

***S. aureus* challenge.** After intramammary challenge with *S. aureus,* 4,637 genes were differentially expressed (2,529 higher, 2,108 lower expressed). Similar to the *E. coli* challenge, genes of the acute-phase response (*SAA3*, *CFB*) as well as chemokine genes and genes encoding their receptors (*CXCL8*, *CXCR1*) were upregulated. Using IPA, we obtained 293 significantly enriched canonical pathways after the *S. aureus* challenge. Analogous to the *E. coli* challenge, pathways related to energy metabolism showed inactivation, whereas a variety of immune response pathways were activated (Table 2). Micro-RNAs and *SOCS1* were identified as inactivating upstream regulators.

Table 1. Five canonical pathways with the highest and lowest activation score (*Escherichia coli* challenge).

Ingenuity canonical pathways	-log(*P*-value)	z-score
PPAR signaling	6.87E+00	-6.091
White adipose tissue browning pathway	1.42E+00	-4.352
LXR/RXR activation	4.25E+00	-3.772
PPARα/RXRα activation	1.04E+01	-3.474
Dopamine-DARPP32 feedback in cAMP signaling	2.23E+00	-3.395
IL-6 signaling	8.47E+00	5.485
Neuroinflammation signaling pathway	9.49E+00	5.438
Systemic lupus erythematosus in B cell signaling pathway	1.29E+01	5.274
Hepatic fibrosis signaling pathway	1.19E+01	5.225
TREM1 signaling	5.73E+00	5.209

Table 2. Five canonical pathways with the highest and lowest activation score (*Staphylococcus aureus* challenge).

Ingenuity canonical pathways	-log(*P*-value)	z-score
PPAR signaling	6.58E+00	-4.768
Sumoylation pathway	1.68E+00	-2.828
Inhibition of angiogenesis by TSP1	2.24E+00	-2.111
Dopamine-DARPP32 feedback in cAMP signaling	1.89E+00	-2.082
LXR/RXR Activation	1.01E+01	-1.897
Dendritic cell maturation	1.05E+01	5.842
Neuroinflammation signaling pathway	1.21E+01	5.511
TREM1 signaling	6.71E+00	5.209
Production of nitric oxide and reactive oxygen species in macrophages	9.35E+00	4.662
IL-6 signaling	9.49E+00	4.423

Discussion

The exceptionally strong response to an intramammary challenge with *E. coli* and *S. aureus* is consistent with the substantial systemic response of the heifers observed in the periphery at transcriptional level, as described in the liver transcriptome of these animals in response to both pathogens (Heimes *et al.*, 2020). In spite of substantial differences in the clinical outcome of the challenge (Rohmeier *et al.*, 2020), both local pathogen challenge responses of the mammary gland share several similar affected pathways, e.g. inactivation of the PPAR signaling and LXR/RXR Activation pathways, indicating an impaired lipid metabolism. In addition, selected activating and deactivating effects on the innate immune response were affected by both pathogens, though their modulation was stronger in response to *E. coli*.

Compared to previous studies (Petzl *et al.* 2008, Petzl *et al.* 2018), the number of DEGs in our approach is higher than in previous studies. This might be due to the early lactation stage, in which cows encounter a negative energy balance (Meyerholz *et al.* 2019) and are particularly vulnerable to infectious diseases. The advantages of our study design are a significantly higher number of animals studied and the tailored transcriptome analysis (depletion of milk and whey protein gene transcripts), which may also contribute to revealing previously undetected transcriptomic responses due to an increased sensitivity of the transcriptomic analysis. The intramammary gland challenge experiments with two divergent mastitis pathogens showed that both pathogens have activating and deactivating local effects on the expression of genes involved in the innate immune response directly in the mammary tissue. However, *E. coli* challenge caused a more pronounced modulation of the gene expression.

Abstract

Hereford bulls are being used in dairy farming systems to sire calves that can be finished as beef cattle, bred to cows that would not otherwise be used for replacement cows. Their characteristically white faces offer simple markers for parentage, however we observed that some dairy × Hereford crossbred calves have splotchy faces. We conducted a genome-wide association analysis for face colour in 128 Hereford-cross calves using genotype data from the GMK50kv1 chip and found that the adulteration of the white face trait is caused by an epistatic interaction between mutations at the *KIT* and *MITF* loci. We found that the one copy of the G allele at rs209784468 was sufficient to rescue pigmentation in the face in Hereford-cross calves. These results present a novel gene × gene interaction and suggest that the white face trait is not technically dominant.

Introduction

Public demand for higher animal welfare standards is rising across the globe, and in particular, there have been rising concerns about bobby calves (Coleman 2020). Bobby calves are surplus calves that are not required by farmers to replace cows in their current herd and are slaughtered when they are less than 30 days old. Coat colour and patterning traits can be utilised to reduce the number of bobby calves produced annually by serving as an inexpensive, easily identifiable marker of beef parentage. Cows in the herd that will not be bred for replacement cows can be mated to a beef bull so that the progeny will grow and perform like a beef animal, thus giving an advantage over 'pure' dairy calves. For this reason, calves that are born from dairy dams and beef sires receive a higher premium when sold if they have visible markers that can prove beef parentage (Coleman 2020). Hereford bulls are often used for this purpose due to their characteristically white face, however some dairy × Hereford calves have splotchy faces. The splotchy face trait is undesirable to farmers, and reduces the value of these calves.

The aim of our study was to investigate the genetic architecture of the splotchy face trait in New Zealand Hereford crossbred cattle.

Materials & methods

Study population and genotype data. Tissue samples were obtained from ear tissue biopsies from 21 Angus × Hereford calves, and 107 Holstein-Friesian × Jersey × Hereford calves with either white, or splotchy faces. These calves were born on commercial farms in the Waikato region, New Zealand. DNA extraction was conducted at GeneMark (Hamilton, New Zealand), using the Qiagen BioSprint kit, and genotyping was carried out using the GeneMark 50kv1 (GMK50kv1) single nucleotide polymorphism (SNP) chip (manufactured by Illumina). All procedures involving animals were approved by the AgResearch Animal Ethics Committee (15174).

Phenotypes, population structure adjustments, and association analyses. Face colour (i.e. white or splotchy; Figure 1) was reported by farmers or scored from photographs taken by farmers. A 'leave one chromosome out' approach was used to construct 29 genomic relationship matrices (GRM), where each

Figure 1. Image of a splotchy-faced calf (left) and a white-faced calf (right).

GRM lacked one autosome to avoid double fitting when testing the effect of candidate variants from that autosome. The GRM were calculated using variants from the GMK50kv1 platform used to genotype these cattle (n=21,159 variants), where variants had been filtered based on minor allele frequency (those with a minor allele frequency <0.02 were removed), deviation from Hardy Weinberg equilibrium (those with a $P<0.15$ were removed), missing genotype rates (those with a genotyping rate <0.01 were removed), and high linkage disequilibrium (LD) with another marker on the panel (those with pairwise $R^2>0.9$ were removed). The GCTA software (v1.93.2beta) (Yang *et al.* 2011) was then used to perform a mixed linear model-based association analysis (MLMA) using the GMK50kv1 resolution genotype data. For significance testing, we used a *P*-value of 5×10^{-8} as the significance threshold to account for multiple hypothesis testing.

Results

A strong association signal was detected on chromosome 22, with the top variant mapping to Chr22 g.31651404T>C, with a *P*-value of 2.41×10^{-20} (Figure 2). This variant mapped to intron 2 of the skin-expressed isoform of *MITF* (Koufariotis *et al.* 2015; Zerbino *et al.* 2018), a transcription factor that is involved in pigment cell (i.e. melanocyte) survival, maintenance, and differentiation (D'Mello *et al.* 2016). The third top associated variant (Chr22 g.31651379A>G; rs209784468) was near-equivalently associated ($P=5.97\times10^{-20}$), and was previously identified to be a candidate causal mutation in white spotting in Holstein-Friesian, Jersey, and crossbred cattle (Jivanji *et al.* 2019). When the rs209784468 SNP was fitted as a fixed effect in the association model, all significance at the chromosome 22 locus was removed, suggesting that the signal was likely representative of a single biallelic effect (smallest residual genome-wide $P=0.00088$ for Chr22 g.50885680C>G).

Candidate causative regulatory variant at the MITF locus. The rs209784468 variant maps to a region immediately upstream of the annotated *MITF* transcription start site (Zerbino *et al.* 2018), and intron 2 of the skin-expressed *MITF* gene isoform (Jivanji *et al.* 2019; Koufariotis *et al.* 2015; Zerbino *et al.* 2018). The variant appears to be highly conserved, mapping to a constrained element identified from 32-way amniote vertebrate alignments, and having a site-wise genome evolutionary rate profiling (GERP) score of 1.21 (Zerbino *et al.* 2018). The putative mutation appeared to operate in a Mendelian fashion, where nearly all calves carrying the 'G' allele manifested splotchy faces, and nearly all pure white-faced animals were homozygous for the 'A' variant (Figure 3). None of the Hereford crossed calves in our population were homozygous for the rs209784468 G allele.

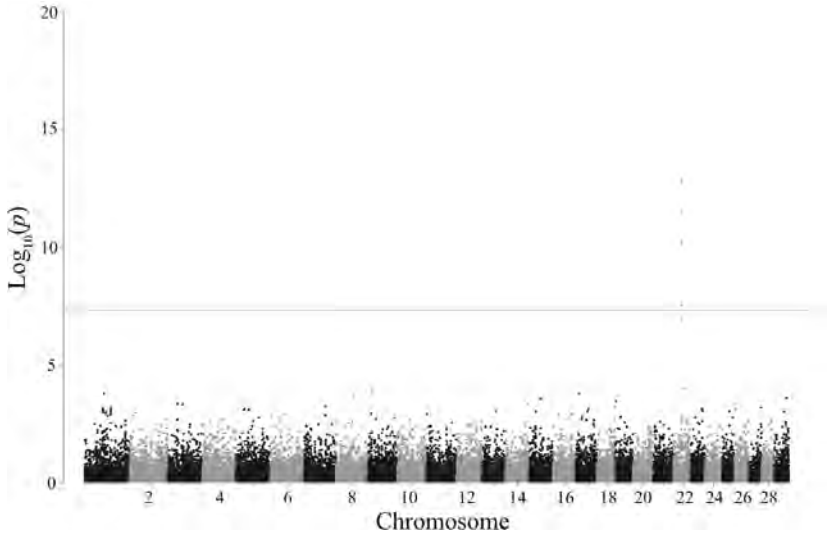

Figure 2. Manhattan plot based on the GWAS result for the splotchy-face trait. A single association signal is observed on chromosome 22, with the top variant mapping to Chr22 g.31651404T>C, $P=2.41\times10^{-20}$. The red line indicates the genome-wide significance threshold $P=5\times10^{-8}$.

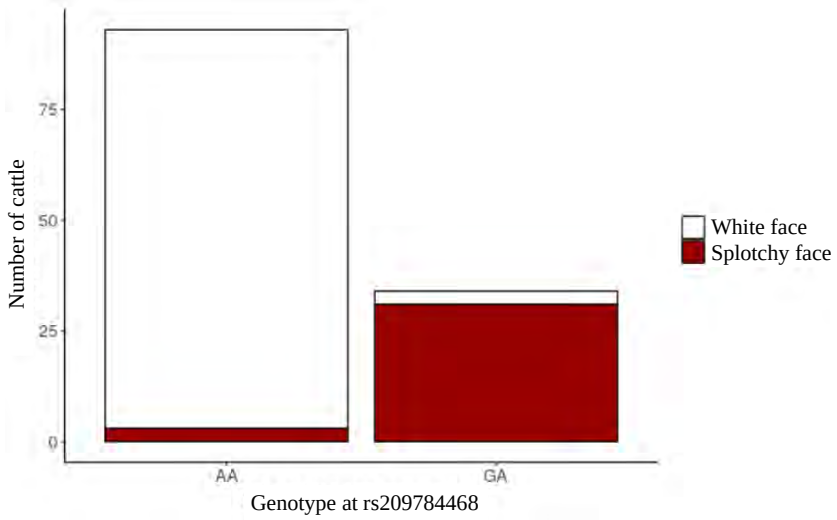

Figure 3. The number of cattle with white faces (white) or splotchy faces (red) plotted by their genotype at candidate causal mutation rs209784468 (Chr22 g.31651379A>G).

Discussion

We present a novel epistatic interaction between variants at the *KIT* and *MITF* loci that cause a splotchy-face phenotype in calves with Hereford parentage. The G allele at the *MITF* rs209784468 site appears to rescue pigmentation, presumably through interaction with the serial duplication upstream of *KIT* proposed to be causal for the white face trait characteristic of Hereford cattle (Whitacre 2014).

The Hereford white-face mutation has long been believed to be a dominant effect mutation, caused by a serial duplication upstream of the *KIT* gene. Inheritance of one copy of this mutation appears sufficient to cause the white-face trait (Whitacre 2014). This mutation is proposed to modulate *KIT* expression and result in a complete lack of pigmentation in the face. However, when Hereford cattle are crossed with some typically solid-coloured cattle (e.g. Angus or Jersey), or crosses thereof, their calves sometimes have a broken white-face, or 'splotchy' face. Inheritance of one copy of the rs209784468 G allele, mapping to intron 2 of the skin-expressed *MITF* gene isoform, appears to be sufficient to cause the splotchy-face trait in Hereford cross calves. The rs209784468 G allele has also been implicated in reduced white-spotting of the coat in Holstein-Friesian, Jersey, and crosses thereof (Jivanji *et al.* 2019). We hypothesise that the rs209784468 G allele has a positive effect on *MITF* expression and/or function, enabling survival, differentiation, and/or migration of functional melanocytes that are otherwise impacted by the white-face *KIT* mutation, and perhaps other white-spotting mutations. Our observation that inheritance of one copy of the rs209784468 G allele appears to be sufficient to cause a splotchy face also suggests that the Hereford white face trait is not technically dominant. Although we did not have any individuals in our study that had two copies of the rs209784468 G allele, future studies could aim to investigate how face colour may change if calves had different combinations of genotypes across the *KIT* and *MITF* loci.

The results presented here provide valuable insight into pigment biology and epistasis. Knowledge of how face colour is modulated could also enable breeders to produce dairy × Hereford claves with pure white faces for beef rearing, thus enhancing animal welfare by minimising the number of calves that need to go on the bobby truck per season.

677. Searching for genes involved in heat stress response in lactating cows through transcriptomics

C. Diaz[1], M. Ramón[2], C. Gonzalez-Verdejo[1] and M.J. Carabaño[1*]

[1]INIA-CSIC, P.O. Box 28040 Madrid, Spain; [2]Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla-La Mancha (IRIAF), Av. del Vino s/n, 13300 Valdepeñas, Spain; mjc@inia.es

Abstract

Understanding the genetic mechanisms that regulate the response of animals to heat stress (HS) events is of interest when developing selection strategies towards more thermotolerant animals. In this study, we have addressed, in dairy cattle, the study of genes that are differentially expressed (DE) under heat stress compared to a comfort situation. A total of 407 genes DE between heat stress and comfort conditions were found, many of them being upregulated (230) under HS conditions. The study of the biological processes to which these genes are associated has shown processes associated with response to external aggressors, immune response or cellular repair.

Introduction

Heat stress (HS) is one of the most significant sources of distress for animals and of economic loss for famers. In this aspect, dairy cattle farming is one of the livestock sectors most severely affected by HS, since highly productive cows are under a high metabolic burden. Unveiling the genetic basis of heat stress response should help in understanding the complex cellular, metabolic and physiological mechanisms triggered by HS and in providing farmers with tools for selection of heat tolerant animals. However, although a number of studies have dealt with the goal of finding genes and/or genetic markers, only a few genes, such as the heat shock protein (HSP) and heat shock factor (HSF) genes (see, e.g. review by Collier *et al.*, 2008) and the slick hair gene (Dikmen *et al.*, 2014) are widely accepted as associated with HS response and HS tolerance, respectively. Genome-wide information both from DNA or RNA sequencing is expected to provide useful and complementary results when searching for the genetic basis of complex traits. In this study RNA-seq was used to investigate the genetic background of HS response in lactating Holstein cows.

Materials & methods

This study was carried out under a Project License from the INIA Scientific Ethic Committee. Animal manipulations were performed according to the Spanish Policy for Animal Protection RD 53/2013, which meets the European Union Directive 86/609 on the protection of animals used in experimentation. The INIA Scientific Ethic Committee, which is named IACUC, specifically approved this study.

Data and experimental design. Nineteen multiparous lactating cows were blood sampled twice in HS (on July1 and July 7) and once in Comfort (October 10). Cows were all from the same farm and had the same management all along the experiment. All cows were multiparous and started the experiment on the first third of their lactation. Cows participating in the study did not have common parents in order to allow for a wider genetic variability. On each blood collection date, respiration rate (rpm) and rectal temperature (°C) were measured individually. Milk yields from the official milk recording of the farm were also available. Weather data (daily maximum, average and minimum temperature) from one week before the beginning of the study until the last sampling were provided by the National Meteorological Agency (AEMET).

RNA extraction and samples preparation. RNA was isolated from blood samples using RiboPure™ -Blood Kit protocol. After, performing RNA quality controls, contamination removal was carried out in 56

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_677, © C. Diaz *et al.* 2022

samples with Agilent RNA 6000 Nano Kit (Agilent Technologies, Germany) and RQ1 RNase-Free DNase (Promega Corporation, USA). RNA-seq libraries were constructed with the SMARTer® Stranded Total RNA-Seq Kit for High-input strand specific total RNAseq for Mammalian samples (Takara Bio USA, Inc.) according to the manufacturer's instructions, which is compatible with input ranges from 100 ng to 1 µg of total RNA. Sequencing of stranded mRNA was performed in a NovaSeq 6000 SP Illumina platform to obtain 50bp long paired-end reads.

Statistical analyses. Quality control of the raw and trimmed paired-end reads were performed with FastQC v.0.11.7 (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/). Trimming was carried out with Trimmomatic v.0.38 (Bolger *et al.* 2014) to remove low quality reads and adaptors. Trimmed reads were mapped to the Bovine reference genome (Bos taurus ARS-UCD1.104) with BWA (Li and Durbin, 2009) and mapped transcripts were assembled individually with Stringtie v.1.3.3b (Pertea *et al.* 2015). Differential abundance (DA) analysis was carried out using DESeq2 (Love *et al.*, 2013). Genes were considered to be DA when the significance level (adjusted *P*-value for multiple comparisons) was lower than 0.05, after the Benjamini-Hochberg correction and the absolute value of the Log2FoldChange was higher or equal to 2. Annotation of the DE genes between the two climate conditions was retrieved with BiomaRt (https://www.ensembl.org/biomart). Functional Enrrichment Analysis and Gene annotation for Biological process was performed via PANTHER (Mi *et al.*, 2020) based on Biological Proceses (BP) and pathway analysis.

Results

Average daily milk yield and fat and protein contents of cows were 51.5 kg; 3.34%; 3.07% (sd=11.1; 0.7; 0.3). Daily maximum/average/minimum temperatures on the three collection dates were 35.2/26.1/17.0 °C, 34.9/28.8/22.8 and 18.3/13.0/7.6 °C. Figure 1 represents the distribution of rectal temperature and respiration rates physiological measures of cows for the HS and comfort samplings, showing clear differences between periods for both variables. Basal levels of both variables as well as the dispersion changed from Comfort to HS. Some cows showed only small changes between periods, pointing at a wide variability in physiological response to heat stress across animals.

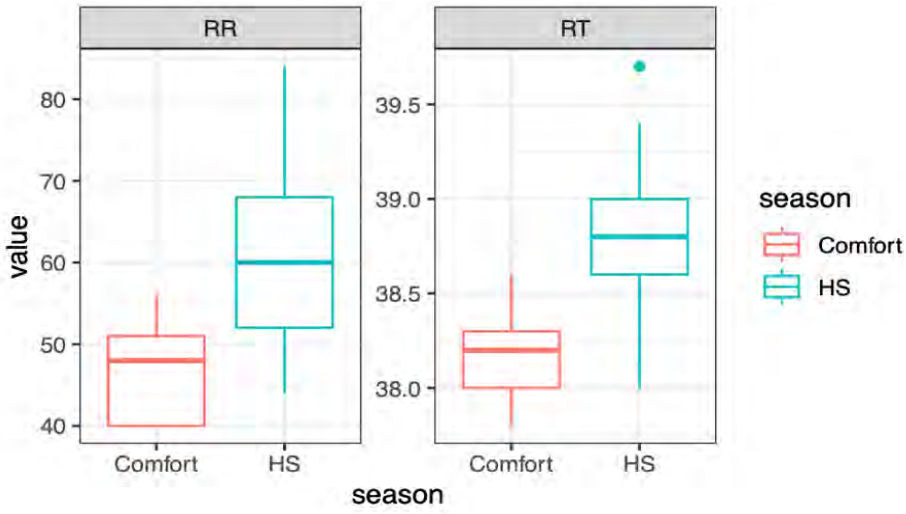

Figure 1. Differences on respiration rate (RR, rpm) and rectal temperature (RT, °C) between heat stress and comfort conditions.

A total of 407 genes DE between heat stress and comfort conditions in blood samples of dairy cows were found. From those DE genes, 230 genes were upregulated under HS conditions and 177 were downregulated. Among all DE genes, we identified 80 Non-coding RNAs in several forms (Small nucleolar RNAs (3), ribosomal RNAs (9), spliceosomal RNAs (43), Y-RNAs (3), 7SK_RNA (7), Metazoa_SRC signal recognition particles (7) and miRNAs (8) that were mostly (70 out of 80) upregulated under HS conditions. Those elements are of potential great interest due to their regulatory role in the mammalian response to heat shocks (Place and Noonan, 2014). Moreover, some miRNAs are being proposed as biomarkers of HS (Liu *et al*., 2020). For this first analysis, those non-coding elements were excluded for the Functional Enrichment Analysis and Gene Annotation. Thus, a total list of 327 genes were used, 160 and 167 genes upregulated and downregulated in HS, respectively.

For the analysis of the main Biological Process (BP) represented in gene ontologies (GO) only 308 genes were uniquely mapped. Figure 2 presents the main BP that were found as well as the number of genes classified into each of them. According to the GO, DE genes were classified in 18 different BPs. The BPs more represented by PANTHER GO-Slim classification involved cellular process (GO:0009987) that included cellular stress, biological regulation (GO:0065007), metabolic process (GO:0008152, immune-system process (GO:0002376), response to stimulus (GO:0050896), signaling (GO:0023052). We also searched BP significantly associated with the gene lists based on their FDR (P<0.05) using as a reference list GOdatabase (http://geneontology.org). Most of the biological process are conserved between lists but some other appealing groups appear such as Nervous system process, sensory receptors as well as regulation groups (Figure. 2).

Discussion

Livestock production systems, and in particular dairy cattle are facing the impact of climate change. Breeding for thermotolerant animals is a strategy that will help to the dairy sector to cope with this challenge. In order to establish a selection strategy, it is of great interest to understand the physiological mechanisms underlying HS since so far selection criteria are based on slopes relating production traits with THI (Carabaño *et al.*, 2020). With this purpose, we have performed a first analysis of the changes in the transcriptome profiles of dairy cows between comfort and HS conditions. In this analysis, we have not

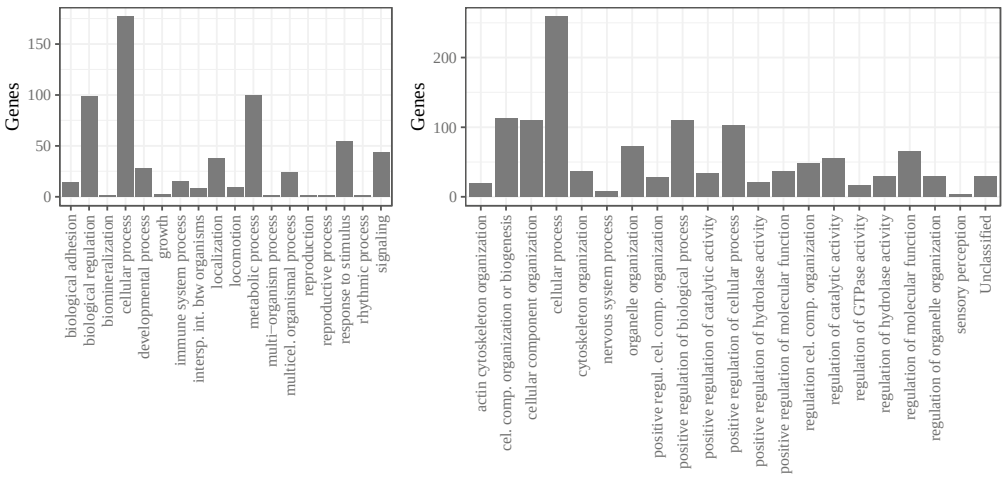

Figure 2. GO classification of genes into different biological processes based on GO-Slim (PANTHER; left) the GO database (right).

distinguished between short and long exposure to HS or what is to say acute versus chronic HS provided that thermal loads, RR and RT were similar between sampling dates under HS. The results showed how under heat stress conditions some genes involved in important biological processes such as response to external aggressors, immune response or cellular repair were up-regulated providing thermotolerant animals with an advantage in responding to the effects of heat stress. Biological processes identified were very general and involved interleukins, cytokines or chaperones among others, clearly associated in the response to stress events, and specifically, to heat stress.

Abstract

The incidence of stillbirth has increased in the past decades, negatively affecting the welfare and the economic profitability of dairy herds. Recently, high confidence copy number variants regions were found to be associated with stillbirth traits in Canadian Holstein cattle. Concomitantly, genomic regions showing transmission distortion associated with reproductive defects were identified in an independent study performed in the same population. The functional profile of the overlapped regions between those studies was investigated. Four genes (ENSBTAG00000047181, ENSBTAG00000023309, ENSBTAG00000046041, and *PIK3CD*) were shared between the three enriched pathways ('Antifolate resistance', 'ABC transporters' and 'cAMP signalling') hinting at abnormal uterine inflammation in late pregnancy, which could affect the viability of the placenta and/or foetus. With further studies validating these findings, breeding against stillbirth could potentially be improved by using CNV information.

Introduction

Stillbirth (SB) is defined by calf death after 260 days of gestation until 48 hours after parturition (Berglund *et al.*, 2003). The number of SB cases is a cause of significant economic and welfare losses for the dairy industry (Fonseca *et al.*, 2022). Causes of stillbirth are not well documented and are rarely assessed. For instance, about 50% of the stillborn calves can be attributed to dystocia or malformations, but more than 30% of the recorded stillbirths cannot be explained (Berglund *et al.*, 2003). A better understanding of the genetic background of this trait can help to explain some of the unknown causes of SB recorded on farms and decrease its incidence through genetic selection. Multiple approaches can be used to investigate and understand the biological mechanisms underlying SB. Recently, high-confidence copy number variants (CNV) regions were found to be associated with SB in Canadian Holstein cattle (Oliveira *et al.*, 2021). These CNV regions were found to overlap with genomic regions of a study investigating the mating success linked to the gametic compatibility of mated pairs (Martin *et al.*, 2021). This overlap suggests that CNV may be responsible for mechanisms of transmission ratio distortions (TRD) affecting stillbirth. Therefore, the functional profile of the overlapped regions was investigated in this study.

Materials & methods

Previously identified CNV and TRD regions. The CNV regions previously found associated with SB in Oliveira *et al.* (2021) were used for this study. In summary, the association analyses were performed using four alternate deregressed breeding values (heifers, cows, and bulls when mated to either heifers or cows) and high confidence CNV regions identified in 5,211 animals genotyped using a 95K SNP panel. The TRD regions were identified in an independent study performed using the same population (i.e. Canadian Holstein cattle; Martin *et al.*, 2021). Regions associated with gametic incompatibility were identified using a TRD model, which measures deviations from the Mendelian inheritance, i.e. one allele is preferentially transmitted to the next generation. An interaction effect related to the offspring genotype, called genotypic interaction, was added to the classic TRD model containing direct TRD effects (Id-Lahoucine *et al.*, 2019),

to scan the genome for TRD signals potentially associated with gametic incompatibility, using different sizes of haplotypes. A set of 283,817 parent-offspring trios genotyped using 50K SNP genotypes was used in this analysis, and a total of 474 TRD regions were identified as potentially displaying gametic incompatibility.

Functional profile of the overlapped regions. Only overlapping CNV and TRD genomic regions were used for further functional analysis. The positional genes and quantitative trait loci (QTL) located in the overlapped regions were identified using the GALLO package (v1.3; Fonseca *et al.*, 2020) implemented in R (v4.1.1; R Core Team, 2019). Thereafter, a functional analysis was performed on the retrieved gene list using the AmiGO 2 software (v2.5.17; Carbon *et al.*, 2009). Additionally, a protein-protein interaction network was created using the String database (v11.0; Szklarczyk *et al.*, 2019), which was based on functional and physical protein associations. Furthermore, an over-representation analysis (ORA) was performed to determine if any Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways or Gene Ontology (GO) terms were more abundantly present in the investigated gene network compared to what would be expected from a random gene sample.

Results

Out of the 11 unique CNV regions identified by Oliveira *et al.* (2021) for the four SB trait EBVs, ten overlapped with at least one TRD region (Table 1). Interestingly, all TRD regions that overlapped with significant deletions (DEL) showed a strong genotypic interaction effect and moderate direct effect, indicating a strongly skewed allelic transmission. Only one CNV region containing duplication (DUP) was found to overlap with TRD regions. For the single DUP CNV region, the corresponding TRD region had a close-to-zero magnitude for both genotypic interaction and direct effects, showing a haplotype transmission close to the expected Mendelian proportions. A total of 67 positional genes were found, including 56 genes with NCBI annotation. A total of 572 unique QTL were identified, from which 9% were linked to reproduction. There were 44 QTL associated with calving ease and one with SB. The functional analysis of the whole gene list resulted in one enriched GO-Molecular Function term: 'ATPase-coupled transmembrane transporter activity' (*P*-value=0.02). There were four significant KEGG pathways (Table 2) but no enriched GO

terms. The same four proteins coded by three genes (ENSBTAG00000047181, ENSBTAG00000023309, ENSBTAG00000046041), were shared between the four pathways, with the addition of *PIK3CD* for the cAMP signalling pathway.

Discussion

Both ATP-binding cassette (ABC) transporters and cAMP signalling pathways are essential to many cellular processes. ABC transporters family is one of the largest protein families that is conserved across vertebrates (Dean and Annilo, 2005), and cAMP is one of the most common and universal second messengers, internalizing external signals to the cell (Serezani *et al.*, 2008). Interestingly, there are several examples of recent duplications and deletions in the evolution of ABC transporters (Dean and Annilo, 2005). Remarkably, nine out of eleven CNV regions associated with SB were deletions. The sole overlapping DUP CNV region was associated with a low TRD magnitude, whereas the DEL CNV regions were associated with strong transmission distortion. DEL CNV could be linked to a loss of function or a decreased level of gene expression that would increase reproductive defects and potentially cause SB. The common four proteins shared between the four KEGG pathways were part of the ABC subfamily C member 4, also called multidrug resistance-associated protein, which are yet to be annotated in the *Bos taurus* genome but thoroughly studied in other mammals. The ABC transporters can be linked to a form of antifolate resistance as antifolate efflux transporters (Assaraf, 2007). Antifolates are the natural down regulators of DNA replication, controlling the proliferative activity of cells (Chabner *et al.*, 2006). In early pregnancy, the supplementation of folate reduces the chance of stillbirth (Imdad *et al.*, 2011), whereas excessive antifolates can induce abortion by blocking normal embryo development (Chabner *et al.*, 2006). The overexpression of ABC transporters could provoke an increased antifolate efflux, a known mechanism of antifolate resistance (Assaraf, 2007). The three genes, coding for parts of the ABC transporters, were positioned in the DUP CNV region, which could lead to an overexpression and induce resistance.

Fatal preterm birth can be associated with intrauterine inflammation, which affects gene expression in the placenta. Pathways including *PIK3CD* are altered in placenta exposed to pathogens markers (Lien *et al.*, 2020). Together, these results hinted at two potential hypotheses: (1) animals carrying the CNV could have a lower tolerance to infection leading to stillbirth; or (2) overly exported antifolates could trigger unexpected inflammation. For both, pathogen protection and parturition process, inflammation is essential but needs to be strictly controlled to avoid adverse effects on the foetus and/or the mother (Christiaens *et al.*, 2008). Any abnormal late intrauterine inflammation would be strongly selected against, shaping the genetic structure of the population. The four candidate genes (ENSBTAG00000047181, ENSBTAG00000023309,

ENSBTAG00000046041, and *PIK3CD)* identified in this study seem to play an important role in stillbirth in Holstein cattle. Breeding to reduce the frequency of stillbirth could likely be improved by using CNV information, however, further studies are required to validate our findings.

679. Mating allocations in Nordic Red Dairy Cattle using genomic information

C. Bengtsson[1,2*], H. Stålhammar[1], J.R. Thomasen[1], S. Eriksson[2], W.F. Fikse[3] and E. Strandberg[2]

[1]VikingGenetics Sweden AB, 53294 Skara, Sweden; [2]Dept. of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 75007 Uppsala, Sweden; [3]Växa Sverige, Box 288, 75105 Uppsala, Sweden; chben@vikinggenetics.com

Abstract

In this study, we compared mating allocations in Nordic Red Dairy Cattle using genomic or pedigree information. We used linear programming to optimise different economic scores within each herd, considering genetic level, semen cost, the economic impact of recessive genetic defects, and genetic relationships. We found high correlations (≥0.83) between the pedigree and genomic relationship measures. The mating results showed that it was possible to reduce the different genetic relationships between parents with minimal effect on genetic level. Including the cost of known recessive genetic defects eliminated expression of genetic defects. It was possible to reduce genomic relationships between parents with pedigree information, but it was best done with genomic measures. Linear programming maximised the economic score for all herds studied within seconds, which means that it is suitable for implementation in mating software to be used by advisors and farmers.

Introduction

Mating programs are an important support tool for livestock breeders, helping them to identify the best parental matings to maximise genetic level and avoid mating between closely related individuals, preventing excessive inbreeding (Carthy *et al.*, 2019; Bérodier *et al.*, 2021). New genetic insights at single nucleotide level can be used in mating programs. Single nucleotide polymorphism (SNP) markers can give information about major genes and genetic defects. Minimising the probability of obtaining offspring homozygous for a lethal recessive genetic defect is of economic importance for farmers (Pryce *et al.*, 2012). SNP markers also offer the possibility to reduce genomic relationships between parents when optimising mating plans. Various methods have been proposed for calculation of genomic relationships, including SNP-by-SNP relationships as described by e.g. VanRaden (2008). Further, there are methods using shared genomic segments, as described by e.g. Cara *et al.* (2013), which aim to reduce the number of runs of homozygosity in the offspring.

The objective of this study was to investigate the ability of different mating scenarios to maximise expected genetic level in the next generation, limiting parent relationship and the probability of expression of genetic defects. We investigated all scenarios at herd level using real data. We used linear programming to optimise economic scores within each herd, considering genetic level, semen cost, the economic impact of recessive genetic defects, and five different measures of relationships (two pedigree-based and three genomic-based).

Materials & methods

Animals. Breeding values, pedigree data, SNP data, and data on the carrier status of genetic defects were obtained from the Nordic Cattle Genetic Evaluation. Genotype information for a total of six genetic defects were available. We selected 9,841 genotyped Red Dairy Cattle (RDC) females born in Denmark, Finland, or Sweden in 2019 to simulate matings. All females included belonged to herds with 20 or more genotyped females. The females were potentially mated to 50 genotyped RDC bulls from the Nordic breeding cooperative VikingGenetics.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_679, © C. Bengtsson *et al.* 2022

Relationship measures. We used two different pedigree relationship coefficients. The first relationship coefficient traced the pedigree three generations back from the parents of the potential mating (a_{3Gen}). The second pedigree relationship coefficient was based on all available pedigree information (a_{AllGen}). We used three different genomic relationship coefficients, one SNP-by-SNP genomic relationship coefficient (g_{SNP}) according to VanRaden (2008). The two segment-based genomic relationship coefficients were based on different minimum lengths of segments: 1 centimorgan (cM) (g_{SEG1}) and 4 cM (g_{SEG4}).

Economic score. For each potential mating between female i and bull j, we calculated an economic score similarly to Bérodier *et al.* (2021) and Pryce *et al.* (2012):

$$Score_{ij} = \left(\frac{NTM_i + NTM_j}{2} + \lambda F_{ij}\right) \times \text{prob}\,(♀) - \sum_{r=1}^{n_r} p(aa)_r \times v_r - \text{semen cost}$$

where NTM_i and NTM_j are the value of Nordic Total Merit units in Euros (€) for female *i* and bull *j*, λ is the economic consequence of an 1% increase in inbreeding similarly to Cole (2015), F_{ij} is the pedigree or genomic based co-ancestry (Relationship/2), prob(♀) is the probability of producing a female conceptus, n_r is the number of recessive genetic defects considered, $p(aa)_r$ is the probability of expression of a genetic defect *r*, v_r is the economic cost associated with the recessive genetic defect *r* similarly to Cole (2015) and Bérodier *et al.* (2021), and semen cost is the average amount (€) spent on semen for a pregnancy. In addition, an economic score based on only NTM and semen cost was calculated (MaxNTM). Mate allocation was programmed in R version 3.6.3 (R Core Team, 2020). Linear programming optimisation was performed with the 'Lp_solve' package in R (Berkelaar *et al.*, 2020). The objective of linear programming was to maximise the average economic score in the herd with a maximum of 5% of females per bull and herd. The mating R script was provided by Bérodier *et al.* (2021).

Results

The correlations between the genetic relationship coefficients were at least 0.83 or higher (Table 1). The mean value of the relationship coefficients between all possible combinations of females and males (Random) ranged from 0.009 to 0.188 (Table 2). The strongest correlation was between a_{AllGen} and a_{3Gen} (r=0.99), and the second strongest was between g_{SEG1} and g_{SEG4} (r=0.98). The strongest correlation between pedigree and genomic relationships was between a_{AllGen} and g_{SEG4} (r=0.88) (Table 1). The coefficients of regression of a_{3Gen} and g_{SNP} on a_{AllGen} were close to 1, and the coefficients of regression of g_{SEG1} and g_{SEG4} on a_{AllGen} were both 0.94.

It was possible to maximise economic score with limited impact on the average NTM level (Table 2). Including the cost of the known recessive genetic defects when optimising mating strategies eliminated the risk of loss from a genetic defect, regardless of which genetic relationship was used. When just maximising

Table 1. Correlations between the different relationship coefficients for all possible combinations of 9,841 females and 50 bulls.[1]

Relationship	a_{AllGen}	g_{SNP}	g_{SEG1}	g_{SEG4}
a_{3Gen}	0.99	0.88	0.83	0.87
a_{AllGen}		0.88	0.85	0.88
g_{SNP}			0.9	0.93
g_{SEG1}				0.98

[1] a_{3Gen} = pedigree relationships using three generations of ancestors; a_{AllGen} = pedigree relationships using all available pedigree information; g_{SNP} = genomic relationship calculated according to VanRaden (2008); g_{SEG1} (g_{SEG4}) = genomic segment-based relationship according to de Cara *et al.* (2013) with a minimum segment length of 1 (4) centimorgan.

Table 2. Comparison of outcomes of planned matings of 9,841 females for 7 mating scenarios in Nordic Red Dairy Cattle using various comparison criteria[1].

Comparison criterion[1]	Random	5% females/bull scenarios[2]					
		Max NTM	3Gen	AllGen	GSNP	GSEG1	GSEG4
NTM	19.5	20.8	20.8	20.8	20.8	20.7	20.8
a_{3Gen}	0.028	0.033	0.007	0.009	0.014	0.014	0.014
a_{AllGen}	0.066	0.070	0.046	0.043	0.050	0.050	0.050
g_{SNP}	0.009	0.014	-0.012	-0.016	-0.038	-0.034	-0.033
g_{SEG1}	0.188	0.191	0.167	0.163	0.148	0.143	0.146
g_{SEG4}	0.115	0.119	0.094	0.091	0.078	0.075	0.074
Expression of genetic defects (%)	0.4	0.4	0	0	0	0	0

[1] Average Nordic total merit (NTM) level, average five different genetic relationships between parents, the probability of expression of genetic defects.

[2] Maximum percent of females per bull and herd set to 5%. Random: All possible combinations of 9,841 females and 50 bulls. MaxNTM: mates were selected based on maximising an economic score including NTM, sexed semen, and semen cost.

[3] Gen, AllGen, GSNP, GSEG1, GSEG4: mates were selected based on maximising an economic score including NTM, sexed semen, semen cost, a penalty for genetic defects and a pedigree relationship include three generations (a_{3Gen}) or all available ancestors (a_{AllGen}), or a genomic relationship calculated according to VanRaden (2008) (g_{SNP}), according to Cara *et al.* (2013) with a minimum genomic segment length of 1 centimorgan (g_{SEG1}) or 4 centimorgan (g_{SEG4}).

NTM minus semen cost (MaxNTM), the NTM level improved compared with Random, but it resulted in higher average genetic relationship coefficients than Random and did not reduce the probability of loss from a genetic defect. Including a genomic relationship in the economic score also kept the other genomic relationship averages at a low level. For example, with the constraint of 5% females per bull and herd, including g_{SNP} in the objective function (scenario GSNP) resulted in a g_{SEG1} of 0.148, compared with 0.143 with GSEG1 (Table 2). Using the pedigree relationships also reduced the genomic relationships compared with Random and MaxNTM, but not as much as using genomic relationships in the objective function.

Discussion

The results show that it is possible to reduce genetic relationships between RDC parents in herds with minimal effect on the genetic level. Including the cost of known recessive genetic defects when optimising mating strategies eliminated expression of known genetic defects, regardless of the genetic relationship used.

The strong correlation estimated between pedigree and genomic relationships confirms that dairy pedigrees are well documented in the Nordic countries. The correlations between the pedigree relationship and genomic relationship estimates were high: ≥0.83 for a_{3Gen} and ≥0.85 for a_{AllGen} (Table 1). Carthy *et al.* (2019) reported a correlation of 0.57 between pedigree relationships and genomic relationship, which is lower than in other studies (0.67-0.88) (VanRaden *et al.*, 2011; Pryce *et al.*, 2012). Pryce *et al.* (2012) concluded that pedigree depth plays a major role for the strength of correlation between pedigree relationships and genomic relationships. They found that when the number of generations of recorded ancestry was 2, 4, 6, and 8, the correlations were 0.67, 0.73, 0.84, and 0.87, respectively (Pryce *et al.*, 2012).

In general, genomic relationships were better at reducing pedigree relationships than pedigree relationships were at reducing genomic relationships. Furthermore, using GSEG1 reduced g_{SEG1} compared with Random from 0.188 to 0.143, and 3Gen reduced g_{SEG1} to 0.163, i.e. the relative difference was 55%. Hence, using genomic relationships could be an overall better and safer option than using pedigree relationships in keeping all average relationships studied low.

Conclusions

We studied mating allocations in Nordic Red Dairy Cattle and found that it was possible to reduce genetic relationships between parents with minimal effect on genetic level. Including the cost of known recessive genetic defects entirely eliminated the risk of loss due to the six known genetic defects. It was possible to reduce genomic relationships between parents with pedigree measures, but it was best done with genomic measures. Linear programming maximised the economic score for all herds studied within seconds, which means that the method is suitable for implementing in mating software to be used by advisors and farmers.

Abstract

Complete blood counts (CBCs) measure abundance of immune and red blood cells. CBCs can indicate immune status of an animal and may be related to disease resistance. The current study aimed to identify genomic regions associated with CBCs in Holstein cows. A genome wide association study was performed with the BLUPF90 suite of programs using 60K Affymetrix® genotypes from 258 cows, with CBCs measured at three timepoints. Estimated heritabilities ranged from 0.09±0.07 (leucocytes) to 0.78±0.09 (mean corpuscular volume), while repeatably of measurements ranged from 0.28±0.54 (mean corpuscular hemoglobin concentration) to 0.99±0.06E-05 (red cell distribution width). A total of 4 one megabase genomic windows explained ≥1% of genetic variance and all of these appear pleiotropic for CBC traits. This is the first study to evaluate the genomic heritabilities of CBCs in Holstein cattle.

Introduction

Animal health is important to the welfare and profitability of dairy cows. For example, animal health can impact feed efficiency and milk quality (Siberski *et al.*, 2019). Identifying novel health traits that are heritable and understanding genetic variants impacting susceptibility to illness may be beneficial for future use in selection. To date, genetic evaluation of health traits has been largely based on producer recorded data that can be subjective and inconsistent across farms, resulting in lower heritabilities (König and May, 2018). Due to these challenges, selection for the improvement of disease resilience has yet to be implemented (Berghof *et al.*, 2019). Identification of easier to measure indicator trait(s) for animal health and stress events could help identify more production resilient animals.

Blood cells, such as those measured in complete blood counts (CBCs) are indicative of an animal's innate and adaptive immunity. Two studies have evaluated the genetic architecture of CBCs and their relationship to growth or disease in beef cattle (Chinchilla-Vargas *et al.*, 2020; Leach *et al.*, 2013). Chinchilla-Vargas *et al.* (2020) reported moderate to high heritabilities and a genome-wide association study (GWAS) for CBCs in beef cattle. In pigs, Mpetile *et al.* (2015) reported differences in CBCs between high and low feed efficiency groups, indicating a potential genetic relationship. Few studies have examined the genetic architecture of CBCs in Holstein cattle, while none are known to have assessed their relationship with resilience. Denholm *et al.* (2017) evaluated phenotype based heritabilities of neutrophils, monocytes, lymphocytes, and eosinophils in Holstein-Friesians, which were low to moderately heritable (0.15-0.35). Given the relationship of CBCs with health and productivity traits in several species, CBCs may be indicators for production resilience in dairy cattle. Thus, the objective of the study was to 1) estimate preliminary heritability and repeatability of CBC traits in Holstein cattle, and 2) identify genomic regions and single nucleotide polymorphisms (SNP) associated with CBCs in Holstein dairy cows.

Materials & methods

Animal husbandry. This study was approved by the Iowa State University (ISU) Institutional Animal Care and Use Committee protocol 18-174. Blood samples were collected on 313 Holstein cows from 8 contemporary groups (CG). The CGs were based on pen and cohort group within year, and consisted of 12 to 48 cows based on pen size. Cows ranged from parity one to six with data collected between 24 to 313

days in milk (DIM). Animals were housed in a free stall barn and received the ISU dairy farm standard total mixed ration. Animals were milked three times daily in CG 1-3 and twice a day in all other CGs. Animal health was monitored by ISU veterinary personnel.

Data collection. Blood samples were taken from the caudal vein in EDTA vacutainer tubes at three time points on all animals (2.5 weeks between samplings.) Blood samples were sent to the ISU Veterinary Diagnostic Laboratory where CBCs were measured using an Advia 2120i. Fifteen cellular measurements were reported (Table 1.) A total of 258 animals were genotyped with the 60k Affymetrix® Axiom® SNP chip. Genotypes were filtered to keep SNP markers with minor allele frequency ≥0.05 and samples with a genotyping call rate ≥0.90. Following filtering, 40,000 SNPs remained for use in the genomic analyses.

Statistical analyses. The distributions of CBC measures were assessed for normality with a quantile-quantile plot. The WBC, NEUT, LYMP, EOSI, BASO, and LUC were log transformed, and a Box-Cox transformation (lambda = -2) was used for RDW to obtain approximately normally distributed data. The remainder of the CBC measures did not require transformation for subsequent analyses.

Health events were classified into one of four categories: healthy, mastitis, lameness, and other events. The other category included multiple concurrent health events, respiratory issues, and injuries not included in lameness. The association of health status with CBC measures was assessed using the following model:

$$CBC_{ijkl} = Health_i + Lact_j + CG_k + DIM_l + e_{ijkl} \quad (1)$$

where CBC_{ijkl} is one of the 15 CBC measures (Table 1), $Health_i$ is the binary (yes/no) class effect of healthy vs each individual health event, $Lact_j$ and CG_k are the class effects of the j^{th} lactation (1, 2 or 3+) and k^{th} contemporary group, DIM_k is the fixed effect of the l^{th} day in milk, and e_{ijkl} is the random residual.

Table 1. Preliminary narrow sense heritability and repeatability estimates of complete blood count measures.

Measure	Abbreviation	Unit	Heritability ± SE[1]	Repeatability ± SE[1]
White blood cells[2]	WBC	K/ul	0.10±0.08	0.67±0.039
Red blood cells	RBC	M/ul	0.46±0.14	0.74±0.03
Hemoglobin	HGB	g/dl	0.19±0.13	0.65±0.038
Hematocrit	HCT	%	0.19±0.12	0.63±0.04
Mean corpuscular volume	MCV	fl	0.78±0.086	0.90±0.013
Mean corpuscular hemoglobin	MCH	Pg	0.76±0.09	0.89±0.014
MCH Concentration	MCHC	g/dl	0.18±0.069	0.28±0.054
Red cell distribution width[3]	RDW	%	0.51±0.029	0.99±0.06E-05

[1] Standard error.

[2] Log transformed.

[3] Box-Cox transformed.

Estimation of narrow sense heritability and repeatability of CBC measures was conducted with THRGIBBSF90 and POSTGIBBSF90 from the BLUPF90 family of software using 10,000 sampling iterations and a burn-in of 2,500 samples (Aguilar *et al.*, 2018). The GWAS were completed with the single-step GBLUP approach for each of the CBC measures with THRGIBBSF90 and POSTGSF90 programs (Aguilar *et al.*, 2018.) The general linear mixed model used for the association analysis was:

$$Y = Xb + Za + e \quad (2)$$

where Y is the CBC measure, X is the incidence matrix for fixed effects including CG, parity (1, 2, 3+) and DIM, Z is the incidence matrix for random effects (i.e. animal), b is the vector of regression coefficients for fixed effects, a is the vector of additive genetic effects, and e is the random error vector. The GWAS utilized 50,000 sampling iterations and a burn-in of 10,000 samples to estimate the amount of variation explained by 1 megabase (Mb) windows across all bovine autosomes. Gene annotations within significant genomic windows (i.e. quantitative trait loci, QTL) were obtained from the NCBI Gene Database (https://www.ncbi.nlm.nih.gov/gene).

Results

Analyses from model 1 identified associations of mastitis and other health events with log LYMPH count ($P<0.05$). Significant associations were also identified for other health events and monocyte count, and mastitis with log WBCs ($P<0.05$). There was a tendency towards an association of log BASO with mastitis, and other health events with MCHC ($P<0.10$).

Preliminary heritability and repeatability estimates for CBC measures are presented in Table 1. The largest heritability was obtained for MCV (0.78±0.086), while most of the heritabilities were between 0.10 and 0.30 (n=8). The majority (n=9) of repeatabilities were >0.60. The most repeatable measure was Box-Cox transformed RDW (0.99±0.06E-05), while the next most repeatable was MCV (0.90±0.013). The least repeatable CBC measure was MCHC (0.28±0.054).

Between 3-4 QTL per CBC trait explained ≥1% of the genetic variation in CBC measures (Table 2). Several pleiotropic loci were identified. Two 1 Mb genomic regions on *Bos taurus* autosomes (BTA) 1 (1 Mb) and 6 (71 Mb) explained more than 1% of variation for all CBC measures, as well as two adjacent genomic windows on BTA 4 (113 and 114 Mb). Two neighbouring 1 Mb windows on BTA 21 (20 and 21 Mb) explained more than 1% of the genetic variation for 12 of the CBC measures. The QTL on BTA 1, 4 (two adjacent windows), 6, and 21 (two adjacent windows) contained 25, 47, 22, and 62 genes, respectively. The windows on BTA 4 and 6 accounted for the largest amount of genetic variance (4.67-6.88% and 5.37-8.79%, respectively). The largest amount of variance explained by any genomic window was on BTA 6 for log WBC (8.79%.)

Discussion

The heritability of CBC measures reported in the current study are of similar magnitudes as previous studies (Chinchilla-Vargas *et al.*, 2020; Denholm *et al.*, 2017), with some (i.e. MCV and MCHC) being much larger which may be due to the small study size. Additionally, the ranking of CBC heritabilities is similar to that in beef cattle (Chinchilla-Vargas *et al.*, 2020). The findings of the current study are preliminary, but they do indicate that CBC traits are heritable and repeatable in Holstein cows.

Four genomic regions individually accounted for ≥1% of variation for nearly all CBC measures. These regions were identified on BTA 1, 4, 6 and 21. Interestingly, the region on BTA 6 contains the *HOPX* gene, which has been associated with higher platelet counts and lower white blood cells (Lin *et al.*, 2017).

Table 2. Summary of 1 Mb windows explaining ≥1.0% of variance in complete blood count measures.

Measure	Number of regions explaining ≥1.0% GV[1]	Range in % GV[1] explained
Log white blood cells	4	1.15-8.79
Red blood cells	3	1.19-7.23
Hemoglobin	3	1.50-6.80
Hematocrit	4	1.01-6.37
Mean corpuscular volume	4	1.30-6.74
Mean corpuscular hemoglobin (MCH)	4	1.28-6.73
MCH Concentration	4	1.27-6.49
Box-Cox red cell distribution width	3	1.34-5.37
Platelets	4	1.07-7.32
Log neutrophils	4	1.07-7.81
Log lymphocytes	4	1.26-8.67
Monocytes	4	1.12-8.66
Log eosinophils	4	1.13-6.93
Log basophils	4	1.18-7.81
Log leukocytes	4	1.29-7.82

[1] GV = additive genetic variance.

Within the 1 Mb window on BTA 1 are the *IFNAR1* and *INFAR2*.genes. A study of *INFAR1* knockout mice indicated that neutrophil development and functionality were altered without a functional copy of the gene (Siakaeva *et al.*, 2019).

Though the sample size of the current study is small, it demonstrates CBCs are heritable in Holsteins and provides the first estimates of heritability and possible candidate genes for some of the CBCs. Several pleotropic QTL were identified, which indicates shared genetic control. Future research with larger populations is needed to determine genetic correlations of CBC traits with production traits to identify if they are useful in selection. In addition, validation of pleotropic QTL would be interesting to determine which mutations may have shared genetic control of multiple immune cell traits. This information may be important in understanding disease and production resilience (i.e. more robustly efficient dairy cattle.)

Abstract

Intestinal atresia is a congenital defect resulting in calf mortality within a few days of birth. This study focuses on two half-sibling Jersey sires who were identified as having a high proportion of their progeny exhibiting atresia from a longitudinal study of 39 dairy herds over an 8 year period. The objective of this study was to investigate the genetic cause of intestinal atresia within this family. Phased high-density genotypes of the two half-sibling sires were used to identify if common haplotypes were inherited by all affected animals. Whether or not the paternal haplotype that was inherited by the affected animal at a given locus deviated from the expectation was tested. A total of 16 SNPs were significantly overrepresented, 14 located in one region on chromosome 14 and the remaining 2 located in one region on chromosome 26.

Introduction

Intestinal atresia is a congenital defect, found in a wide variety of species, which results in complete occlusion of the intestinal lumen, occurring in the jejunum, ileum, colon and/or anus (Ducharme *et al.*, 1988). In calves, the blockage inhibits the normal movement of gut contents resulting in failure to pass meconium and faeces, inappetence, abdominal distension, and usually results in death due to autointoxication within a few days of birth (Syed and Shanks, 1992). The inheritance of atresia in cattle is still not completely understood (Constable and Morin, 2000). As part of a larger study, active surveillance of 39 dairy herds over 8 years was used to assess the incidence of intestinal atresia in dairy herds in Ireland. Of interest, two Jersey sires had a high proportion of their progeny exhibiting intestinal atresia; further investigation revealed that these two sires shared a common sire. The objective of this study was to investigate the genetic cause of intestinal atresia within this family.

Materials & methods

Data collection. A total of 39 dairy herds, including 3 research dairy herds from Teagasc, participated in a longitudinal study over 8 years to assess factors associated with intestinal atresia in dairy herds in Ireland. As part of the study any calf that died within the first 7 days of life was transported to Teagasc Moorepark and subjected to a full post-mortem by a veterinary surgeon. Following post-mortem, a total of 197 cases of intestinal atresia were identified. Additional data on all calves born on each farm during study participation was provided by the Irish Cattle Breeding Federation (ICBF) and consisted of calf ID, date of birth, sex, dam breed, dam ID, dam parity, sire breed, sire ID and birth type (single or twin).

Identification of sire family. During data exploration, generalized linear models were used in SAS version 9.4 (SAS Institute Inc., Cary, NC, USA) to quantify the association of risk factors associated with atresia. Initial results indicated sire was a significant factor in intestinal atresia among Jersey sired calves. Further investigation, limiting records to sires that had greater than 50 progeny born in at least 5 different herds, indicated an over-representation of affected progeny for a number of sires. The two most significant sires, which are paternal half-siblings, had 2.5 and 4.1% of their progeny exhibiting intestinal atresia.

DNA extraction and genotyping. Muscle tissue (>1 g) was collected post-mortem from 28 atresia cases from the two prominent sires, submerged in RNAlater solution (Ambion), left overnight at 4 °C and stored at -20 °C. For DNA extraction approximately 100 mg of tissue was minced in 1.5 ml of digestion buffer (1 M Tris-HCL pH 8.0, 0.5 M EDTA, 10% SDS, 500 µg/ml Proteinase K) and incubated for 4 h at 55 °C with shaking. The sample was then extracted twice with an equal volume of phenol:chloroform and once with an equal volume of chloroform. The DNA was precipitated with 0.1 volumes of 3 M sodium acetate pH 5.2 and 1 volume of isopropanol, washed with 70% ethanol, air dried and resuspended in 100 µl of H_2O. DNA was cleaned using the Genomic DNA Clean and Concentrator kit (Zymo Research) and quality assessed by agarose gel electrophoresis. DNA was genotyped with the Illumina 777K BovineHD beadchip (Illumina Inc, San Diego, CA, USA). Illumina Bovine50k beadchip genotypes from 640 unaffected progeny of either sire were also provided by ICBF as healthy controls and imputed to HD using FImpute (Sargolzaei *et al.*, 2014).

Linkage analysis with Jersey family. High-density genotypes were available on the two sires along with 28 affected progeny; the genotypes were phased using FImpute (Sargolzaei *et al.*, 2014). The phased genotypes of the two sires were used to determine which paternal haplotypes were inherited. Only haplotypes where both sires inherited the same paternal allele and which were heterozygous in both sires were retained. Following edits 46,177 SNPs remained. Whether or not a paternal haplotype that was inherited by the affected progeny at a given locus deviated from the expectation of equal representation was tested. The critical t-statistic was calculated using Equation 1.

$$\frac{P-0.5}{\sqrt{\frac{P(1-P)}{n}+0.001}} \quad (1)$$

In Equation 1, P is the proportion of progeny with the paternal haplotype inherited from the grandsire and n is the number of grand-progeny. The level of significance was determined using a one-tailed t-test with n-1 degrees of freedom; the mean *P*-value of a 10-SNP sliding window was used to avoid sporadic single SNP significance.

Bioinformatics. SNPs in close proximity (1 Mb) were combined into a single QTL. Genes within 50 kb span of the start and end of the QTL were identified using Ensembl 94 on the UMD3.1 bovine genome assembly implemented in BiomaRt in R.

Results

Of the 730,540 autosomal SNPs available from the phased genotypes, 46,177 SNPs remained after confirming the same paternal haplotype was inherited by both sires as well as ensuring both sires were heterozygous. A total of 16 SNPs were significant, 14 located in one region on chromosome 14 and the remaining 2 located in one region on chromosome 26 (Table 1 and Figure 1). The first region between 14: 24,769,617 and 14: 24,939,286 contained 41 SNPs, 14 of which were part of the binomial analysis; this region contained six genes (Table 1). A total of 27 out of 28 affected animals had the same haplotype inherited for 41 of these SNPs with the remaining animal differing at 8 SNPs. The second region on chromosome 26 between 18,028,791 and 18,029,994 contained only the two SNPs that were part of the binomial analysis; in total 26 of the 28 animals had the same haplotype inherited from the paternal-grandsire. There was one gene located in this region, PIK3AP1.

Discussion

There was a total of 197 animals identified through post-mortem as part of a longitudinal study across 39 herds over 8 years as having intestinal atresia; of these, 28 affected animals originated from two paternal half-sibling Jersey sires. All animals within the study originated from dairy herds with the majority

Table 1. Significant QTLs associated with intestinal atresia in 28 affected Jersey cross Holstein animals originated from a common paternal-grandsire.

Chromosome	Start position	End position	Number of SNPs	*P*-value	Genes
14	24,769,617	24,939,286	14	1.79E-15	TMEM68, TGS1, LYN, RPS20, U1, MOS
26	17,890,705	17,891,907	2	3.04E-08	PIK3AP1

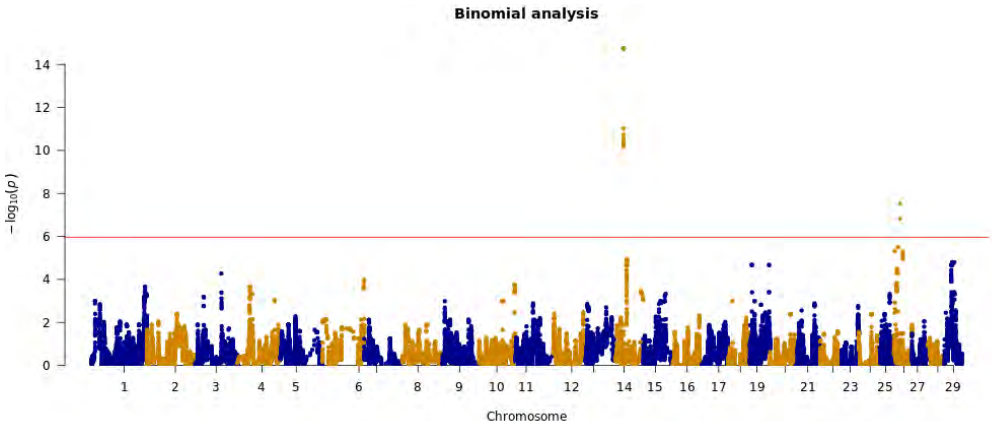

Figure 1. Binomial analysis of 28 affected Jersey cross Holstein animals originated from a common paternal-grandsire.

Holstein-Friesian or Holstein-Friesian crosses. Although Holstein-Friesian animals are reported to have a greater risk of atresia compared to other cattle breeds (Constable *et al.*, 1997), our data suggests that the genetic cause of intestinal atresia in these animals originated from the Jersey parent. The overall incidence of atresia in the current dataset was 0.35% whereas the two sires of interest in this study had an incidence among their progeny of 2.5 and 4.1%.

Unfortunately, the genotype of the paternal grandsire of the affected animals was unavailable; however, HD genotypes of both sires were available. Using both sire's genotypes, the haplotype of the paternal grandsire that was inherited by the affected animals was inferred using phased haplotypes. Due to the number of affected animals, traditional GWAS might not be able to provide strong evidence of regions associated with atresia. The alternative method used in the current study aimed to indicate any region that may require further investigation. One regions on chromosome 14 was shown to have the paternal grandsire's haplotype over-represented. In this region, all but one animal had inherited the same 169 kb region. Additionally, this region was also examined in the healthy controls; in the unaffected animals the region was also significantly over represented with 450 out of 680 animals also inheriting the same haplotype as the affected animals. None of the genes were obvious candidate genes, although mutations in these genes have been associated with multiple health and disease traits.

Conclusions

Intestinal atresia normally results in the death of the calf on-farm. Although it has been reported that bovine intestinal atresia has a genetic aetiology (Syed and Shanks, 1992) no causal mutation has been identified. In the current study we identified a sire-family that has an over-represented incidence of atresia. Although there is strong evidence of association with a region on chromosome 14, the genes within this

region have not been previously implicated in intestinal atresia. There are possible benefits to fine mapping this region in affected and unaffected animals to narrow the QTL containing any causal mutation.

Abstract

To understand the potential genomic implications of selecting for feed efficiency, 38,294 phenotypic records from 4,024 first lactation North American Holsteins for dry matter intake, energy corrected milk, metabolic body weight, and residual feed intake were used to estimate genetic parameters using single trait random regression models. The lactation was then split into two time-points (pre-and post-peak lactation) and genome-wide association studies were performed on each stage of lactation, and the random regression coefficients using imputed whole-genome sequence genotypes. A total of seven and 24 functional candidate genes were identified for pre-and post-lactation, respectively. No overlap was observed between the functional candidate genes for pre-and post-lactation. Furthermore, single nucleotide polymorphism effects associated with functional candidate genes changed in magnitude and sign throughout the lactation. These results highlight the dynamic genomic behaviour of feed efficiency and the importance of collecting data across all stages of lactation.

Introduction

With costs of production increasing, improving farm and animal efficiency is paramount to assure sustainability in the dairy industry. The physiology of lactation must also be taken into consideration when improving feed efficiency (FE). It is well known that FE is heritable and consequently, that selection for improved FE is possible (Houlahan *et al.*, 2021), causing interest surrounding the genomic background of FE to grow (Li *et al.*, 2019). Residual feed intake (RFI) is a commonly used indicator trait of FE. Generally, RFI is calculated as the residual of the fixed linear regression of dry matter intake (DMI) on an energy sink related to milk production (e.g. energy corrected milk (ECM)), and maintenance metabolic function (e.g. metabolic body weight (MBW)). Previous studies have shown that FE (RFI) and its underlying traits, such as DMI, ECM, and MBW exhibit a dynamic behaviour over the lactation (Krattenmacher *et al.*, 2019), which suggests that the candidate genes associated with FE and their effects may also change throughout the lactation. The objective of this study was to identify genomic regions and candidate genes associated with DMI, ECM, MBW, and RFI considering two stages of lactation (pre-and post-peak), and to investigate the potential differential pattern of single nucleotide polymorphism (SNP) effects over the lactation.

Materials & methods

Phenotypic data. Data was provided by the Efficient Dairy Genome Project (https://genomedairy.ualberta.ca/) and the Resilient Dairy Genome Project (http://www.resilientdairy.ca/). The data contained 31,967 (DMI), 38,294 (ECM), 26,394 (MBW), and 23,083 (RFI) phenotypic records from 4,024 first lactation North American Holstein cows in 10 research herds and one commercial farm. All cows had their first calving between January 2007 and November 2020. Data editing procedures are detailed in Houlahan

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_682, © K. Houlahan *et al.* 2022

(2021). The RFI was calculated as the residual of the fixed linear regression of DMI on ECM and MBW (body weight$^{0.75}$), where ECM was calculated following the methodology outlined in Sjaunja *et al.* (1990).

Genotypes and quality control. Imputed (Minimac3 (Das *et al.*, 2016)) whole-genome sequence (WGS) data containing 42,158,739 SNP were available for 4,702 Holstein cows. Quality control was performed, which required that variants had an R^2 value >0.90 (calculated as the observed variance over the expected variance given the observed allele frequency), minor allele frequency >0.01, and no extreme deviation from Hardy-Weinberg equilibrium ($P>10^{-8}$). A total of 9,598,535 high confidence WGS SNP remained for the GWAS analysis.

Variance components. Genetic parameters were estimated using single-trait random regression animal models. Heterogeneous residual variances across four classes (5 to 70, 71 to 140, 141 to 210, and 211 to 305 days in milk (DIM)) were fitted for all traits. A quadratic Legendre polynomial was used for all analyses, as higher-order polynomials lead to convergence problems. The general model used for all traits is described in Houlahan (2021).

GWAS. All GWAS performed in this study used deregressed genomic estimated breeding values (dGEBV) as pseudo-phenotypes for pre-peak lactation (5-60 DIM) and post-peak lactation (61-305 DIM) and were derived from the random regression coefficients. The GWAS were performed using the *mlma* option in the program GCTA (Yang *et al.*, 2011), which fits a linear mixed model, including a polygenic effect. After the GWAS, SNP for pre-and post-peak lactation were ranked based on their *P*-values and clumped according to their linkage disequilibrium pattern ($r^2>0.9$) (Prive *et al.*, 2018). To correct for the potential false positives, the threshold of significance (α) per chromosome was calculated as Chen *et al.* (2020). This resulted in SNP being considered statistically significant if the -log10 *P*-value was higher than the chromosome-wide threshold, which ranged from 4.16 to 4.66 (average ± SD: 4.40±0.14). Significant SNP were analysed in downstream analysis for potential functional candidate genes (FCG). To assess the change in SNP effects over the lactation for each trait, the significant SNP associated with FCG in pre-and post-peak lactation were used. The SNP effects for the significant SNP were calculated as the change in kilograms per two-week segment of the lactation (21 segments), using the SNP effect solutions from the random regression coefficients.

Results

A total of 30 (DMI), 24 (ECM), 30 (MBW), and 37 (RFI) significant SNP (Figure 1a) were found in pre-peak lactation. These significant SNP were associated with two (DMI), two (ECM), one (MBW), and two (RFI) FCG in pre-peak lactation. In post-peak lactation, 151 (DMI), 78 (ECM), 35 (MBW) and 64 (RFI) significant SNP (Figure 1b) were observed to be associated with six (DMI), 10 (ECM), four (MBW) and four (RFI) FCG, respectively. The FCG in pre-peak lactation were previously associated with the digestive tract (salivary and gastric secretions; Bergstrom and Xia, 2013), mammary tissue development, milk, and component synthesis (Do *et al.*, 2017), and cortisol synthesis and secretion (Soares *et al.*, 2021). In post-peak lactation, the FCG were associated with the digestive tract (smooth muscle contraction; Fiscus, 2002), oxytocin signalling (Chatterjee *et al.*, 2016), and deposition of fat (Cantalapiedra-Hijar *et al.*, 2018).

The SNP effects associated with the FCG varied across the lactation (Figure 2). The amount of variation was dependent on the trait and SNP. For instance, the effects of a SNP associated with *KCNMA1* (a FCG associated with RFI) ranged from -3.38 to 4.43 kg from early to late lactation. Additionally, a significant SNP related to *PDE2A* (a FCG associated with DMI) changed up to 4 kg (-3.36 to 0.85 kg) across the lactation. Both ECM and MBW had lesser variation across the lactation compared to RFI and DMI, with a minimum variation of 1.50 kg (*GABRA5*, FCG associated with MBW) to a maximum variation of 3.33 kg (*CLDN23*, FCG associated with MBW) throughout the lactation.

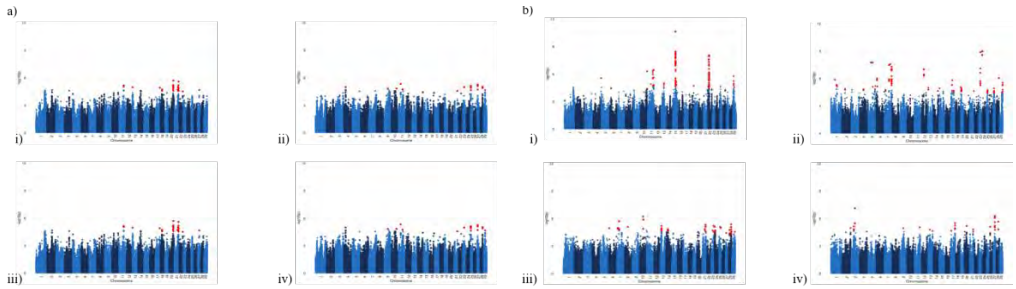

Figure 1. Manhattan plots for (a) pre-peak lactation and (b) post-peak lactation where: (1) dry matter intake (DMI); (2) energy corrected milk (ECM); (3) residual feed intake (RFI); and (4) metabolic body weight (MBW). Significant SNP are marked in red.

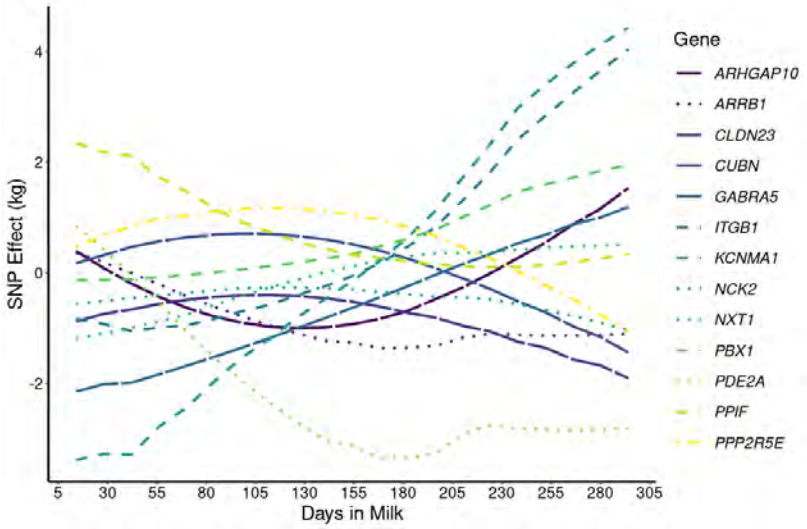

Figure 2. SNP effects over a 305-day lactation for the significant SNP associated with the functional candidate genes for dry matter intake (dotted line), energy corrected milk (large, dashed line), metabolic body weight (dot with dashed line), and residual feed intake (short, dashed line).

Discussion

Differences in the set of significant SNP and FCG between pre-and post-peak lactation suggest that the genetic architecture of FE changes over the lactation. A potential reason for the lack of overlap could be that there was a limited number of animals in this study, which limited power to detect SNP/FCG with small/moderate effects. The biological pathways associated with the FCG for all traits were different between pre-and post-peak lactation. Combined with the variability observed in the SNP effects over the lactation supports the idea that the genetic architecture of FE changes across the lactation. The changing genomic background suggests that multiple time points within the lactation should be considered for selection.

Conclusions

The different significant SNP and FCG between pre-and post-lactation, along with the dynamic SNP effects, support the idea that the genomic architecture of FE changes over the lactation. The results of this study

reinforce the complex nature of FE, which highlights the need for data collection across lactation to enable optimal selection for FE. Future studies should also consider the impact of including change in body weight or body condition score in the RFI equation.

Abstract

Holstein Friesian is by far the most reared dairy breed. An important quota of the milk production is devoted to the production of Parmigiano Reggiano cheese. Consequently, the use of specific breeding values, and specific genotypes has become an essential selective tool for breeders leading to a possible genetic differentiation of the Italian population. In this work the genetic structure of the Italian Holstein has been investigated through an ADMIXTURE analysis performed on the SNP genotypes of 286 cows split into three groups: Italian, International and Parmigiano Reggiano. In addition, a selection signature analysis through a case-control F_{ST} outlier approach was performed to identify genes of interest. Results allowed to distinguish Italian Holstein from the International population and, to a lesser extent, from the Italian Holstein reared for Parmigiano Reggiano. The selection signature identified genes of interest for several productive traits such as reproductive traits, mammal gland dimension and resistance to infections.

Introduction

The Italian Holstein herd-book was established in 1956 by the National Association of Italian Friesian Cattle Breeders (ANAFI). In Italy, Italian Holstein is the most reared breed for milk for the production of Parmigiano Reggiano PDO cheese. Consequently, the use of specific breeding values (Marusi *et al.*, 2019), and specific genotypes such as the homozygosity of the B k-casein allele (Chessa *et al.*, 2020), has become an essential tool for breeders. This could have an effect on the genetic diversity of the Holstein breed as it is known that different selection purposes within the same breed may have an effect on its population structure (Ablondi *et al.*, 2021).

Aims of this study are to explore the genetic structure of the Italian Holstein assessing its distinctiveness from the American herd, and to identify whether the Italian Holstein used to produce Parmigiano Reggiano is also distinguishable from other Italian Holsteins. Moreover, a selection signature analysis was performed through a case-control F_{ST} outlier approach in order to identify possible genomic regions harbouring loci of production interest.

Materials & methods

Source of the genotypes and quality control. Based on pedigree and herd-book information, genotypic samples were selected according to their relationship level in order to avoid close kinship among samples. Three principal groups have been generated: one including only individuals from US and Canada, a second including Italian Holstein samples not used to produce Parmigiano Reggiano and a third group including only Italian Holstein cattle used to produce Parmigiano Reggiano (hereinafter called *PA-RE-MO*). For the latter group only individuals carrying homozygosity for the k-casein locus have been selected. In order to harmonize the genotypic data, as they come from different SNPs panels, an imputation approach using the software Pedimpute was performed (Nicolazzi *et al.*, 2013). 86,841 imputed SNPs were obtained and mapped against the ARS-UCD1.2 reference genome (Rosen *et al.*, 2020). The software PLINK (Purcell *et*

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_683, © C. Persichilli *et al.* 2022

al., 2007) was then used to filter for minor allele frequency (–maf 0.05) and missing genotype call rate (–geno 0.01) obtaining a final dataset of 79,464 SNPs.

Analysis of genetic relationships and population structure. A maximum likelihood clustering approach as implemented in the software ADMIXTURE (Alexander and Lange, 2011) with K values ranging from 2 to 5 has been used to assess the presence of genetic structure. The results have been plotted and ordered following the sampling grouping using the membercoef.circos function in the R package BITE (Milanesi *et al.*, 2017). Using the membercoef.cv function from the same package, the best values of K have been assessed.

FST-outlier analysis. In order to identify possible genomic regions under selection among the three Holstein groups, a genome-wide F_{ST} analysis was performed with a case–control model, (Mastrangelo *et al.*, 2019). Thus, F_{ST} pairwise comparisons of the three groups have been performed using the software PLINK. Significant SNPs have been detected and retained using the function *--assoc fisher* and the Bonferroni corrections have been calculated using the *--adjusted* function. To control the number of false positives, significant markers were defined by applying a *P*-value threshold of 1×10^{-20} which, corrected with the Bonferroni method resulted in a nominal value of 1.258431e-25 ($-\log^{10}(p) = 24.90$).

Results

Analysis of genetic relationships and population structure. The ADMIXTURE analysis showed a most reliable repartition at value of K=3 (Figure 1). Indeed, at this genetic structuring the *Foreign* group is clearly distinguishable from all the Italian Holstein showing a predominance of the red component. On the other hand, two main groups corresponding to the *Italian* and *PA-RE-MO* groups also showed a marked genetic distinctiveness.

F_{ST}-outlier analysis. The case-control F_{ST} analyses performed among groups, highlighted several potential genomic regions that might be under strong selection. As a consequence of our sampling strategy, therefore fully expected, a major selective sweep on BTA6 (which include the k-casein coding gene), is observable in all comparisons when including the *PA-RE-MO* group. However, additional 17 highly significant SNPs (Table 1) which are located on eight chromosomes (*1, 3, 7, 11, 12, 14, 27, 28)* are plainly detected in the *Italian* vs *Foreign* groups. Those significant SNPs fall within eight different coding genes as shown in Table 1.

Discussion

The major finding of the study is that Italian Holstein cattle have a different genetic architecture when compared to foreign cattle. To a lesser extent cattle reared for the production of Parmigiano Reggiano are also differentiated. Italian Holstein used for the production of Parmigiano Reggiano retains higher genomic diversity in terms of composition while both foreign and Italian groups seem to be characterized by less

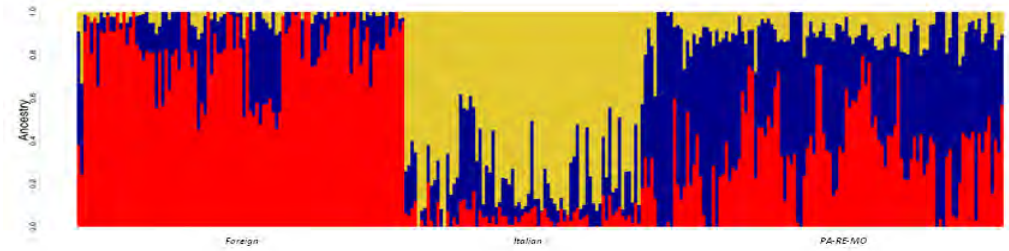

Figure 1. ADMIXTURE analysis depicted as a barplot at the most reliable number of K value (K=3).

BOVINEHD2800010243	28	37174238	0.614069	3.408E-31	*NRG3*

genetic diversity probably due to genetic drift (Senczuk *et al.*, 2020). Concerning the selection signature analysis, a strong signal was detected on chromosome 6, when comparing *PA-RE-MO* vs the other two groups. This is obviously due to the sampling criteria. On the other side, regions harbouring genes possibly responsible of the difference between Italian and Foreign population were identified. Several of these genes are also related to traits of interest in the zootechnical context: *VPS8* is involved in milk traits and reproductive traits (Taye *et al.*, 2017), *FER* has a putative role in the regulation of innate immune response (Flori *et al.*, 2009), *ST3GAL1* is related to female reproductive system in mammals (Sherblom *et al.*, 1985), *NSD3* seems to have a role in male fertility as semen quality traits (Capra *et al.*, 2019), while *NRG3* has been argued to be linked to bovine mammary gland development (Ogorevc *et al.*, 2009).

In conclusion a structure in the Holstein population reared in Italy has been identified according to the geographic origin of the individuals. Moreover, some of the loci involved in the selection for Parmigiano Reggiano production were highlighted and also loci putatively involved in the differentiation of the Italian population from the abroad.

684. Genome-wide association studies for maturity rate in grazing dairy cows

N. Lopez-Villalobos*, H.B.P.C. Ariyarathne and R.E. Hickson

School of Agriculture and Environment, Massey University, Private Bag 11222, 4442, Palmerston North, New Zealand; n.lopez-villalobos@massey.ac.nz

Abstract

The objectives of this study were to estimate heritability and perform genome-wide association analysis for maturity rate (MR) in dairy cows from two dairy farms under New Zealand grazing conditions. MR was defined as the ratio between total lactation yields in the first and third lactations. Estimates of heritability of MR for milk (MY), fat (FY) and protein (PY) yields were 0.26, 0.22 and 0.24. The corresponding genomic heritability estimates were 0.15, 0.11 and 0.13. Genome-wide association analysis identified 1 gene in chromosome 10, 4 genes in chromosome 16 and 5 genes in chromosome 18 associated with MR_{FY}. These genes are involved in metabolic pathways related with lipid and carbohydrate metabolism. Eight genes in chromosome 1 and 2 genes in chromosome 7 were associated with MR_{PY}. Some of these genes are involved in metabolic pathways related with protein metabolism. This study provided some insights into the genetics and genomics of MR for milk production in grazing dairy cows.

Introduction

In dairy cows, milk yield increases towards the fourth lactation, but there is a great variation between herds and between individuals. Maturity rate (MR), defined as the ratio of total lactation yield of the trait at first and third lactations, has been given little consideration in dairy cattle research. Hickman and Henderson (1965) reported heritability (h^2) for MR of milk yield (MY) maturity was only one-fourth to one-third as large as h^2 of first lactation production. Hargrove (1974) reported estimates of h^2 for rate of maturity for MY and fat yield (FY) of 0.089 and 0.100, respectively. de Jong (2014) reported that rate of maturity is considered as one of the traits of the life-time production index that predicts the bull's genetic merit for daughter life-time production in Netherlands. The objectives of this study were to estimate heritability and perform genome-wide association analysis for MR in dairy cows from two dairy farms under New Zealand grazing conditions.

Materials & methods

Animals and phenotypes. The total lactation yield records from 1,113 cows measured during the 2013 to 2020 production seasons at the Massey University Dairy 1 and Dairy 4 farms in Palmerston North, New Zealand were used for this study. The number of cows per breed and farm were 84 Holstein-Friesian (F), 91 Jersey (J) and 157 crossbreed F×J at Dairy 1, and 316 F, 6 J and 453 F×J crossbred at Dairy 4. Dairy 1 is managed as a once-a-day (OAD) milking system with cows predominantly grazed on fresh ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*) at a low stocking rate (2.1 cows/ha). Dairy 4 is managed as a twice a day (TAD) milking throughout the season, with higher stocking rate (2.8 cows/ha) grazing on ryegrass/white clover. Cows in Dairy 4 receive high levels of supplementary feed throughout the year. MR values for MY, FY and protein yield (PY) were estimated for each cow.

Genotypes and quality control. From the 1,113 cows with phenotypes, a subset of 947 cows had genotypes. The cows were genotyped using Bovine Illumina 50K SNP-chips. Quality control was carried out using SNP & Variation Suite (SVS 8.8) and loci with a call rate ≤80% or minor allele frequency ≤0.05, and animals with a call rate ≤80% were excluded from the data set. A total of 43,425 SNPs were available for association analysis after quality control.

Estimation of variance components and heritability. Estimates of prior values for animal additive genetic (σ^2_a) and residual (σ^2_e) variances were obtained by fitting a Bayesian linear mixed model in the JWAS package (Cheng *et al.*, 2018). The model included fixed effects of contemporary group defined as year of lactation started, milking frequency, breed group (F, J, or F×J), regression of deviation of cows from median caving date of the farm as a covariate and random effects of animal additive genetic and residual. A prior value for the genomic marker variance (σ^2_m) was estimated following the method proposed by Fernando and Garrick (2013). The variance explained by SNPs was estimated using a single-step Bayes C linear mixed model in the JWAS package using the estimated prior values for σ^2_a, σ^2_s, and σ^2_e. Genomic heritability (m^2) was estimated as the ratio between the posterior mean of variances of the genomic breeding value (σ^2_m) for each iteration across all cows and the phenotypic variance (σ^2_p) of the trait and h^2 was estimated as ratio between the sum of σ^2_m and additional polygenic variance ($\sigma^2_g = \sigma^2_a - \sigma^2_m$) and the σ^2_p. The chain included 50,000 Markov chain Monte Carlo (MCMC) iterations and marker effects from every 50th iteration were used to estimate genomic breeding values. Individual marker effects were estimated with a probability of 0.997 that any SNP would have a zero effect.

Genome-wide association analysis. The estimated prior values for σ^2_a, σ^2_m, and σ^2_e were used in this analysis. The marker effects were collectively used to predict the genomic breeding values of cows in non-overlapping 1-Mb windows based on their physical map order. The window genomic breeding values were computed by multiplying the number of minor alleles for each marker within each 1-Mb window by their corresponding posterior means of marker effects in that MCMC iteration. The proportion of genetic variance explained (PVE) by each window in any particular iteration was obtained by dividing the variance of the breeding values for that specific window by the variance of genomic breeding value for the whole genome in that iteration. There were 2,676 unique SNP windows across the whole genome. The expected proportion of variance explained by each 1-Mb window was 3.74×10^{-2}% (1/2,676 SNPs) The 1-Mb windows that explained 0.37% (10× expected PVE) of genetic variance were considered to reach genome-wide significance level. Estimated associations were represented in Manhattan plots where PVE by each 1-Mb window was plotted against genomic locations of the windows using the qqman package (Turner, 2014). The gene oncology tool (Ashburner *et al.*, 2000) integrated in Ensembl 2020 (Yates *et al.*, 2019) was used to report the functional classification of the identified genes.

Results

Means and standard errors of MR_{MY}, MR_{FY}, and MR_{PY} were 0.71 (±0.01), 0.74 (±0.01) and 0.72 (±0.01) in OAD milking, and 0.82 (±0.03), 0.81 (±0.03) and 0.82 (±0.03) in TAD milking. Estimates of variance components and heritability for MR_{MY}, MR_{FY}, and MR_{PY} are presented in Table 1. Genome-wide association graphs for maturity rate of the different traits are presented in Figure 1. No significant 1-Mb SNP windows were detected for MR_{MY} (Figure 1a). Three 1-Mb SNP windows from chromosomes 10, 16 and 18 were significantly (PVE≥0.37%) associated with MR_{FY} (Figure 1b). The proportion of genetic variance explained by the most significant 1-Mb window was 0.43% and the windows that were significantly associated with MR_{FY} at the genome-wide threshold collectively explained 1.26% of the total genetic variance. Two 1-Mb SNP windows from chromosomes 1 and 7 were significantly (PVE≥0.37%) associated with MR_{PY} (Figure 1c). The proportion of genetic variance explained by the most significant 1-Mb window was 0.44% and the windows that were significantly associated with MR_{PY} at the genome-wide threshold collectively explained 0.83% of the total genetic variance. Genome-wide association analysis identified 1 gene in chromosome 10 (SRP19), 4 genes in chromosome 16 (HLX, DUSP10, DEGS1, CNIH3), and 5 genes in chromosome 18 (N4BP1, CNEP1R1, NKD1, NOD2 and NREP) associated with MR_{FY}; and 8 genes in chromosome 1 (FOXL2, PIK3CB, ARMC8, A4GNT, DZIP1L, CLDN18, NCK1 and STAG1) and 2 genes in chromosome 7 (PPIP5K2 and C7H5orf30) associated with MR_{PY}.

Table 1. Estimates of variance components[1] for maturity rate of milk (MR_{MY}), fat (MR_{FY}) and protein (MR_{PY}) yields in grazing dairy cows at Massey University Dairy 1 and Dairy 4.

Trait	σ^2_g	σ^2_m	σ^2_e	σ^2_p	m^2	h^2
MR_{MY}	0.008	0.010	0.051	0.069	0.15	0.26
MR_{FY}	0.008	0.008	0.058	0.074	0.11	0.22
MR_{PY}	0.008	0.009	0.053	0.070	0.13	0.24

[1] σ^2_g = additional polygenic variance, σ^2_m = additive genetic variance explained by the markers, σ^2_e = residual variance, σ^2_p = phenotypic variance ($\sigma^2_g + \sigma^2_m + \sigma^2_e$), m^2 = genomic heritability calculated as σ^2_m/σ^2_p, h^2 = heritability calculated as $h^2 = (\sigma^2_g + \sigma^2_m)/\sigma^2_p$.

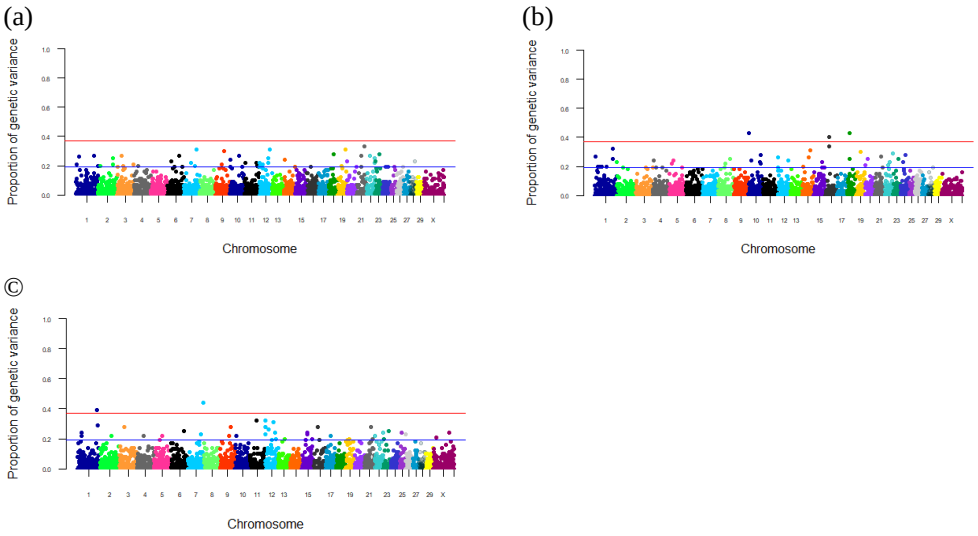

Figure 1. Manhattan plots showing genome-wide association for maturity rate of (a) milk, (b) fat and (c) protein yields. The red line shows the genome-wide significant level (PVE = 0.37%), and the blue line shows the suggestive association significant level (PVE = 0.19%).

Discussion

Cows in the OAD milking herd had lower MR than cows in TAD milking herd. This indicate that OAD milking is affecting the expression of milk production in the first lactation. The estimates of h^2 for MR of the three traits were greater than the 0.10 reported by Hickman and Henderson (1955) and Hargrove (1974) in USA Holstein dairy cows of the 1950's and 1960's. The candidate genes associated with MR_{FY} have previously been associated with fat deposition (N4BP1 gene, Martins *et al.*, 2020) and marbling score (NREP gene, Fonseca *et al.*, 2020) in Nellore cattle) and body weight and weaning weight (SRP19 gene, Grigoletto *et al.*, 2019) in Montana Tropical beef cattle. The CNEP1R1 and DEGS1 genes are associated with triglyceride biosynthesis (GO:0010867) and fat metabolism (GO:0006629), respectively. The HLX (GO:0030154) and DUSP10 (GO:0090335) genes have functions on cell differentiation whereas the former gene is also related to liver development (GO:0001889). Liver secretes bile which enables the metabolism of fat. Gene NKD1 is known to be related with FY (Cai *et al.*, 2018) while NOD2 (Wang *et al.*, 2015) and CNIH3 (Cai *et al.*, 2018) are associated with MY. Similarly, some of the candidate genes associated with MR_{PY} have been annotated in functions related to glycoprotein biosynthetic process (A4GNT, NCK1, FOXL2, STAG1 genes, GO:0009101, GO:0006417, GO:0000122, GO:0045944, respectively), protein catabolism (ARMC8,

GO:0043161) and transport of proteins (DZIP1L, CLDN18, C7H5orf30 genes, GO:0032880, GO:1900181, GO:0015031, respectively). The PPIP5K2 (GO:0016310) and PIK3CB (GO:0006468) are important genes in phosphorylation of synthesized proteins. The maturity rate is an important trait to acquire an insight into the life-time productivity of cows therefore it is important to understand the genetic and genomic control of this trait. Further studies based on a larger dataset would be beneficial to confirm these results.

Abstract

High-density SNP arrays are available and routinely used for genetic improvement of livestock populations. At the same time, mitogenome SNPs have rarely been used. In this study, we empirically evaluated 331 mitogenome SNPs included in the GGP Bovine 100K SNP array developed in collaboration with NEOGEN Genomics (Lincoln, NE, USA). Here we present a pipeline for the potential use of mitogenome SNPs with some examples: (1) classification of haplogroups with emphasis on rare ones (I, P, Q, R and T5); (2) pedigree verification; (3) pedigree and haplotype imputation; (4) deleterious mutation detection; (5) mitogenomic and nuclear diversity; and (6) standard mitogenome classification and phylogenetics. In summary, 317 mitogenome SNPs have been successfully validated and contribute as additional information to autosomal markers in population genomic analyses. We believe that our study will help to promote the use of mitogenome information in cattle breeding and biodiversity management.

Introduction

Mitochondria play a central role in cellular energy production. These organelles contain their own maternally inherited mitogenome, which in most vertebrates including mammalian livestock encodes 37 genes and has a non-coding region that has been widely used in studies of genetic diversity and evolution. While high-density SNP arrays are available and routinely used for genetic improvement of livestock populations, mitogenome SNPs have rarely been used. Therefore, this study aims to increase the use of mitogenome information in animal breeding by selecting and verifying 331 mitochondrial SNPs for the new NEOGEN GGP Bovine 100K SNP Chip and developing a pipeline for practical analysis.

Materials & methods

Reference dataset. The idea to include SNP mitogenomes in the new GGP100K SNP chip arose from a meta-analysis of sequence variability of the bovine mitogenome (Cubric-Curik *et al.*, 2021), which in the meantime, since publication, already includes a newly expanded set of 1068 sequences and over 150 breeds.

SNP selection. The discriminatory set of mitogenome SNPs was selected based on the pairwise FST values (equal to 1) between all haplogroups among them (I, P, Q, R, T1, T2, T3, T5) (Cubric-Curik *et al.*, 2021). F_{ST} values were calculated using DnaSP v6 software (Rozas *et al.*, 2017) and Arlequin v3.5 (Exoffier *et al.*, 2015), while SNP primers 150 bp in length were prepared for the GGP Bovine 100K SNP chip. Core SNP selection included 100 SNPs: (1) 70 SNPs for haplogroup classification; (2) 20 SNPs for more detailed haplogroup classification within the T3 haplogroup, as this is the most common one in commercial cattle breeds; and (3) 10 SNPs for LHON (leber hereditary optic neuropathy) disease. Additional SNP selection included 231 SNPs: (1) 199 SNPs for haplogroup classification; and (2) 32 SNPs for MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) disease.

SNP array. From the study by Cubric-Curik *et al.* (2021), 129 samples (breeds: Austrian n=9, Greek n=5, Croatian n=4, Slovenian n=1) previously sequenced using NGS technology and an additional 135 new samples (breeds: Greek n=5, Croatian n=4, Austrian n=1) were selected for genotyping.

Results & discussion

Validation. 129 samples (sequenced, genotyped) were for 'full' validation, while the new 135 samples (genotyped) were for 'blind' functionality of mitogenome SNPs. 317 of 331 SNPs passed the sequence and genotype validation comparison. This is confirmed by the haplogroup classification of the new samples, which can be seen as grey-coloured haplotypes within the known haplogroups in the median-joining (MJ) network constructed with PopART (Leigh and Bryant) (Figure 1). It is important to note that all haplogroups except 'I' were successfully validated because we had no samples of that haplogroup. Due to the simplicity of the MJ network representation, SNP positions with gaps in ancient DNA (aDNA) samples were not considered in the construction of the haplotypes. It is worth noting that all aDNA samples were in or close to the core of the haplogroups.

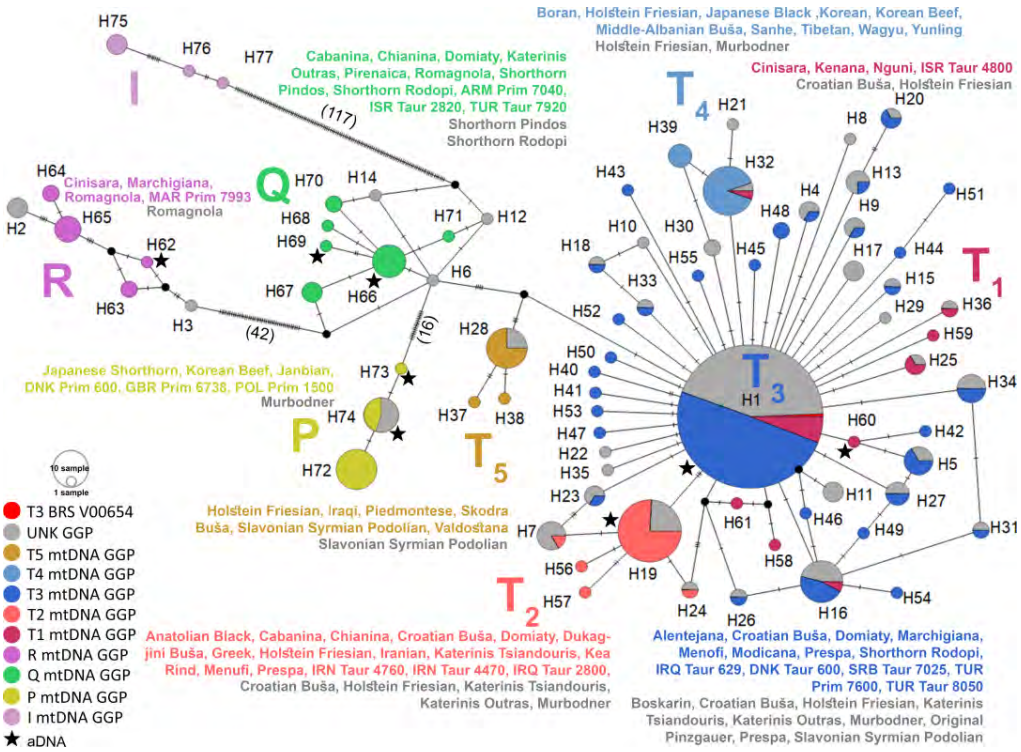

Figure 1. The Median-Joining network for the 181 mitogenome SNPs shows the phylogenetic positions of 77 haplotypes found in 383 samples of *Bos taurus*, *Bos primigenius*, and *Bos indicus* (129 samples sequenced and genotyped; 135 samples genotyped; additional 119 samples from the Cubric-Curik *et al.* (2021) study for better classification). For aDNA samples the number within the name indicates the year before present.

Mitogenome utilisation pipeline. Here we present a pipeline of potential use of mitogenome SNPs (Figure 2.)

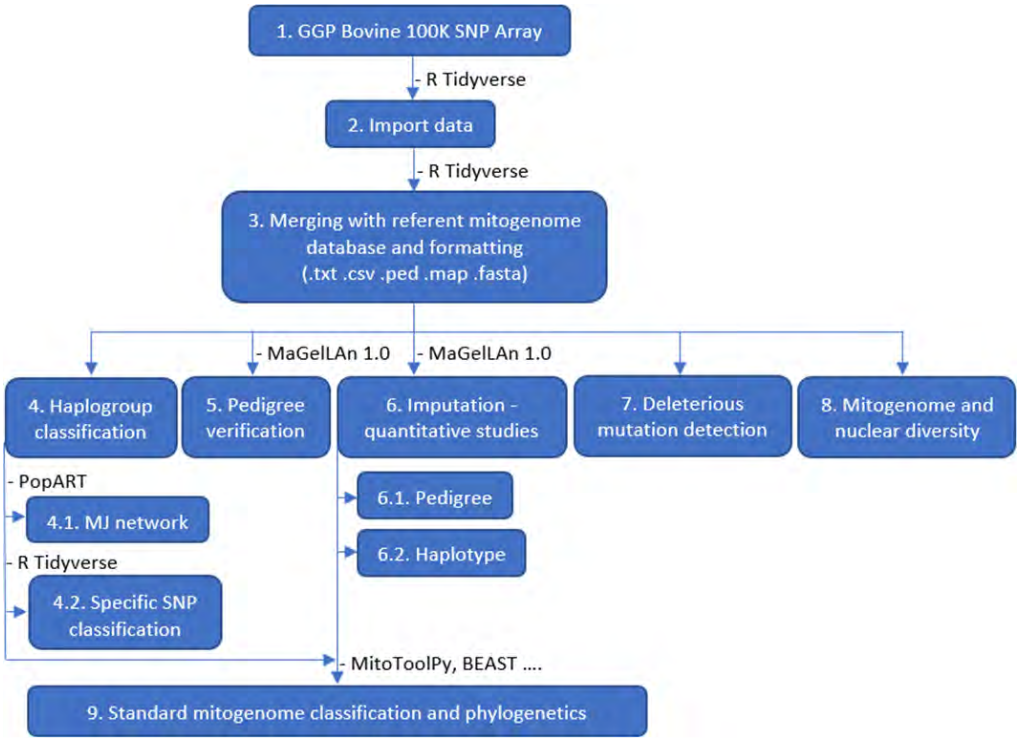

Figure 2. Utilization pipeline steps.

Step 1: Receipt of final report raw data of genotyped samples from NEOGEN Genomics.
Step 2: Import and visualise data with Rstudio (R Core Team, 2019; RStudio Team, 2020).
Step 3: Process the data using the tidyverse package collection (Wickham *et al.*, 2019), merge with the mitogenome reference database, and format according to the type of analysis.
Step 4: (1) Possible classification of haplogroups as shown in Figure 1. (2) specific SNP classification using the tidyverse package collection (Wickham *et al.*, 2019).
Step 5: Verification of complex pedigree errors using mitogenome haplotypes (maternally inherited), which has been well validated on a long and complex Lipizzaner horse pedigree using the computational approach of MaGelLAn 1.0 software (Čačić *et al.*, 2014; Ristov *et al.*, 2016).
Step 6: (1) Since the mitogenome is maternally inherited, MaGelLAn 1.0 makes it possible to quickly identify maternal lineages and assign the corresponding mitogenome sequences to all individuals in the pedigree, so that the phenotypic information can be used as input to any standard software for quantitative genetic (association) analyses (Ristov *et al.*, 2016). Such examples of estimating proportions of phenotypic variances of different traits explained by mitogenome variation can be found in rabbits (Nguyen *et al.*, 2018) and Holstein cattle (Brajkovic *et al.*, 2018). (2) Possible imputation of SNPs to construct the whole mitogenome consensus sequence considering SNPs that were not genotyped. For more information on mitogenome imputation in humans, see Ishiya *et al.* (2019) and McInerney *et al.* (2021).

Step 7: Ability to identify mitochondrial genetic disorders associated with LHON and MELAS disease by screening 42 potentially deleterious mtDNA mutations in cattle. While mitochondrial diseases are well documented in humans, to prove the concept, the first deleterious mutation, T10432C (T10663C in humans) in the ND4L subunit, was found in the Slovenian breed Cika with exophthalmos of the right eye (Novosel *et al.*, 2019), with aetiology and pathogenesis confirmed based on the tissue examined (unpublished data).
Step 8: Various diversity analyses can be performed using autosomal SNP array data. Here, we propose mitogenome-level analysis to enrich for maternal diversity. For example, the F_{ST} value between breeds can be calculated and potentially used to detect upgrading of breeds.
Step 9: Based on the imputed sequences, we can proceed with standard mitogenome classification and phylogenetic analysis, for example, using BEAST and Mitotoolpy.

In summary, 317 mitogenome SNPs have been successfully validated in the new GGP100K SNP chip and contribute as additional information to autosomal markers in population genomic analyses. We believe that our study will help to promote the use of mitogenome information in cattle breeding and biodiversity management.

686. Genomewide transcriptome profiling of milk derived primary bovine mammary epithelial cells after pathogen challenge

T. Iso-Touru[1*], D. Fischer[1], M. Kyläniemi[1,2], J. Tabell[1], A. Virta[1] and J. Vilkki[1]

[1]Natural Resources Institute Finland (Luke), Myllytie 1, 31600 Jokioinen, Finland; [2]current address: Turku Bioscience Centre, University of Turku and Åbo Akademi University, Turku, Finland; terhi.iso-touru@luke.fi

Abstract

A method was developed to collect and cultivate primary bovine mammary epithelial cells (pbMECs) from milk samples of healthy lactating cows. Cell cultures from ten Nordic Red cows were used in a pathogen challenge study with two common pathogens, *Escherichia coli* and *Staphylococcus aureus*. Transcriptome-wide changes in gene expression were monitored at four time points after challenge. We present here preliminary results from two cows, showing that pathogen specific differences in gene expression can be detected in the pbMECs, reflecting differences in the immune responses triggered by each pathogen.

Introduction

Mastitis, inflammation of the mammary gland, is the main cause of early weaning in humans, a major animal welfare concern and the costliest disease in dairy cattle. Mastitis can be expressed as mild sub-clinical, acute clinical or chronic inflammation of the mammary gland; caused by various bacteria, which may activate the mammary immune system in different ways, thereby influencing the severity and outcome of the disease (Taponen *et al.* 2017). Understanding of the molecular mechanisms that activate and regulate this response would be central to the development of effective prevention, prophylactics and treatments.

Previous studies show that the pathogen specific immune response of the mammary epithelial cells (MEC), but not of professional immune cells (e.g. macrophages) correlates best with the pathogen specific immune response of the udder (Petzl *et al.* 2018). For studying MEC function, usually tissue samples obtained by biopsies from live or slaughtered animals are used. We developed an ethical noninvasive method suitable for analysing many animals that would be available for follow-up studies. Therefore, we studied the possibility to extract and cultivate primary bovine mammary epithelial cells (pbMEC) from milk samples.

Our aim is to study the innate immune response by genomewide transcriptome profiling in pbMECs to two common mastitis pathogens known to induce different types of mastitis. The pathogens used include the Gram-negative *Escherichia coli* usually causing a strong acute inflammation and the Gram-positive *Staphylococcus aureus* causing a milder, often sub-clinical inflammation. In this paper we describe preliminary results from a subset of the full experiment, providing evidence that pbMECs extracted from milk samples can be used to identify differentially expressed genes.

Materials & methods

Primary cell culture establishment. Milk samples from two healthy lactating cows (Nordic Red Cattle) were collected by standard milking methodology to sterile collection bottles. A protocol modified from Danowski *et al.* (2012) and Hillreiner *et al.* (2017) was used to extract pbMECs. The epithelial character of the cells was confirmed by immunocytochemistry.

Pathogen challenges with *Escherichia coli* and *Staphylococcus aureus*. Cells (~1×10^5 cells/well, Greiner bio-one, collagen I coated, 392-0029) were challenged *in vitro* with two common heat inactivated mastitis pathogens, *E. coli* and *S. aureus* strains extracted from Nordic Red cows having mastitis (S. Taponen, personal communication) using 10 as multiplicity of infection (MOI). Cells were harvested before and at four different time points (3h, 6h, 12h and 24h) post challenge.

DOI: 10.3920/978-90-8686-940-4_686, © T. Iso-Touru *et al.* 2022

RNA-Seq. Total RNA was extracted from the harvested cells using Rneasy Plus Micro kit (Qiagen) following manufacturer's protocol. RNA quantity and quality were measured with BioAnalyzer, and 50 ng of total RNA was used for ribosomal RNA depletion using RiboCop V1.3 (Lexogen). Ribosomal depletion allows detection of functionally relevant coding as well as non-coding transcripts through removal of ribosomal RNAs (Choe *et al.* 2021).

CORALL Total RNA-Seq Library Prep Kit (Lexogen) was used for library generation. The quality of pooled libraries was first checked on an Illumina iSeq100 platform at the Natural Resources Institute Finland and paired-end sequencing of three biological/technical replicates per timepoints and treatments was performed on an Illumina NovaSeq platform at the Finnish Functional Genomics Centre.

All samples from above-described challenge plan were sequenced with three technical replicates resulting in total 78 samples. An in-house Snakemake RNA-Seq pipeline following common RNA-Seq practices was applied for quality checks (FastQC, multiQC), trimming (fastp), alignment (STAR) and quantification (featureCounts). The pipeline, including additional features, is available at https://www.github.com/fischuu/Pipeline-RNA-seq.

Differentially expressed genes. The data was aligned against the ARS-UCD1.2 bovine reference genome and the quantification was done with reference to the Ensembl annotation 100. Technical replicates were combined by summing the corresponding read counts per gene. Following this practice, a data matrix with raw count data for 27,607 genes and 26 samples was generated and then split pathogen-wise, using the same control samples resulting in two matrices with 18 samples, each with 10 control and 8 pathogen related samples. Next, genes were filtered based on the sample read counts and only those genes were kept that had at least for eight samples 0.5 counts per million (cpm). This way, 11,891 genes were kept for *E. coli* and 11,674 for *S. aureus*. The differential gene expression (DE) analysis was performed with edgeR, using TMM normalized counts and only DE genes with a fold-change of 1.15 (*E. coli*) respective 1.1 (*S. aureus*) were kept.

Results

Primary cell culture. We were able to extract, cultivate and cryo-preserve pbMECs derived from freshly milked milk. Cells were successfully used in pathogen challenges. The pbMECs extracted from milk samples were shown to have epithelial characters by immunocytochemistry (Figure 1).

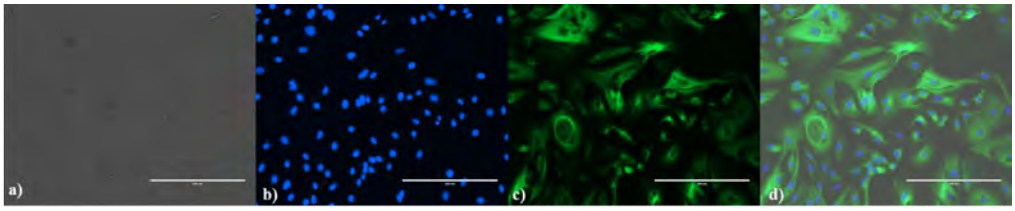

Figure 1. The (a) pbMECs under a light microscope, (b) cells stained with DAPI staining of pbMECs under fluorescence microscopy (c) cytokeratin staining using Monoclonal Anti-Cytokeratin, pan-FITC antibody (Sigma, F3418) d) merged image of light microscope, DAPI and cytokeratin staining images. The bars in the figures are 200 µm.

RNA-Seq analyses. The sequencing depth was between 41 and 87 mio 2×100 bp reads (mean: 62.8) per sample, after quality trimming and filtering the mean dropped only to 62.0, and the R1 (R2) read length to 86 bp (96 bp), indicating high-quality input data.

Prior to the DE analysis basic MDS plots of the raw data (data not shown) indicated a better separation between cases and controls for *E. coli* compared to *S. aureus*. Without fold-change filtering, 2,301 (1,849) downregulated and 2,332 (1,568) upregulated genes were detected after *E. coli* (*S. aureus*) challenge. However, after applying the fold-change filter 1,124 (868) up- and 1,219 (757) downregulated genes remained for *E. coli* (*S. aureus*).

For the top-30 differentially expressed genes, we applied a hierarchical clustering and visualised the results in Figure 2. The heatmaps show clear sample separations, as expected control samples are in a different branch compared to samples exposed to *E. coli*/*S. aureus*.

The specific top-30 up- or down-regulated DE genes differ between the two pathogens (Figure 2). The GO and KEGG analyses (data not shown) of the DE genes after each pathogen challenge show both same affected immune response related pathways (such as cytokine-cytokine receptor interaction, systemic lupus erythematosus) as well as specific affected pathways (such as oxidative phosphorylation and regulation of actin cytoskeleton for *E. coli* and ribosome, protein export and ECM-receptor interaction for *S. aureus*).

Discussion

We show here that pbMECs extracted from milk can be cultured and used for pathogen challenge experiments. The transcriptomic results indicate that we can detect pathogen specific changes in relevant pathways related to immune response, partly similar to those reported before by microarray-based analyses (Günther *et al.* 2017). The results including the full set of animals and timepoints will be published later.

Abstract

A negative genetic correlation between milk yield and fertility is now well-documented, however, the underlying biological causes are still uncertain. Our objective was to examine this problem from a genomic perspective by first using archetypal clustering to identify and group variants with similar patterns of effects across traits, and then by using pathway analysis to identify the biological processes underpinning variants with similar effects. Nine groups with distinct effects on production, fertility and conformation traits were identified. Cluster one had strong effects on fat, protein, and milk yields in contrasting directions with weak effects on fertility, and was characterized by genes affecting insulin, energy metabolism, and metabolic rate. Cluster three had strong effects on fertility but weak effects on production, characterized by genes associated with cell-cell adhesion and embryonic development. Initial results suggest that clusters are consistent with prior knowledge about the associated genes but may also suggest new areas for further research.

Introduction

Dairy cow fertility has declined significantly in dairy populations worldwide over the last 50 years. It has been well-established that there is a negative genetic correlation between milk production and fertility, and most dairy breeding programs now correct for this using genetic evaluations for this trait. However, although numerous hypotheses have been proposed, the exact physiological mechanisms linking the two traits are still unclear (Berry *et al.*, 2016). The correlation is also incomplete, indicating that some genetic variants affect milk production but have little effect on fertility and vice versa.

Our study aims to explore the physiological mechanisms linking milk production and fertility, using genes identified from a multi-trait genome wide association analysis (GWAS). We applied a combination of established and novel statistical methods to data collected from a large multi-breed population of Australian dairy cattle. Our pipeline proceeds from: (1) the identification of genomic variants in a multi-trait GWAS; to (2) the clustering of variants according to their pattern of effects on multiple traits of interest; and then (3) identification of genes through which these variants act; and (4) the prioritization of physiological mechanisms common to the genes within each cluster.

Materials & methods

Data preparation. Genotype and phenotype data for a total of 5,123 bulls and 29,081 cows from DataGene, Australia were used for this study. This data included a mix of Holstein-Friesians (4,061 bulls/22,899 cows) and Jerseys (1,062 bulls/6,174 cows).

Genotypes included a total of 46,771 sequence variants, which were selected from a total of 17,669,372 imputed variants selected by Xiang *et al.* (2021). These variants were selected based on evidence that they affect phenotype and that they are functional, as represented by their FAETH score. 247 additional variants were also included, as they were previously found to be informative for milk fat and protein percentage (Van Den Berg *et al.*, 2019).

DOI: 10.3920/978-90-8686-940-4_687, © E. Ooi *et al.* 2022

Phenotype data included trait deviations and daughter trait deviations for cows and bulls, calculated using a model that corrects for fixed effects including herd, season, and year. Twelve traits were selected which are thought to have effects on production and/or fertility. These were protein yield, fat yield, protein percentage, fat percentage, milk yield, fertility, direct survival, stature, angularity, bone quality, udder texture and body condition score.

Single-trait GWAS. Each trait was analyzed one at a time in each sex with linear mixed models using GCTA (Yang *et al.*, 2011), with results combined using a weighted meta-analysis.

To remove variants in high LD, the snp_clumping function within R package was used. This function is analogous to the –clump function implemented in PLINK 1.9 but has been adapted for memory-efficient usage within the R environment. For our study, as we were most interested in the relationship between milk production and fertility traits, we used fertility t-values as our ranking statistic. This reduced the starting set of 46,771 variants to 15,220 variants.

Archetype-based clustering. We then clustered the sequence variants according to their pattern of effects on the 12 traits of interest. This was done by first ranking the variants in descending order according to the magnitude of their effect, where magnitude = sum of ^{t2} values across the 12 traits and t = t-value for the significance of each variant. The largest magnitude variant was declared the archetypal variant for cluster 1. Proceeding down the list, a new archetypal variant and thus cluster was declared whenever a variant had <0.8 cosine similarity with all previously declared archetypal variants. Using this method, we identified nine archetypal sequence variants with unique patterns of effects on the traits of interest. The remaining 15,211 variants were then assigned to the archetype with which they had the highest measure of cosine similarity, forming nine clusters. The direction of effects was then standardized across variants within a cluster.

Identification of genes. The identification of genes took account of the distance between the variant and the gene and whether or not the variant was an eQTL for that gene. We sampled one of the 10 closest genes within 500 kb either side of each variant, using a probability distribution that prioritized genes close to the variant, or multiplied the probability by 8.18 if the variant had been classified as an eQTL for that gene in expression studies (Chamberlain *et al.*, unpublished data), as they have been found to explain approximately 8.18 times the genetic variance compared to intergenic variants (Xiang *et al.*, 2019). The list of genes was then analyzed by g:Profiler, using GO:BP and KEGG as sources, and corrected for multiple testing with the g:SCS method. This was repeated 100 times for each cluster.

The top 10 GO:BP and KEGG terms for each iteration within a cluster were then aggregated by summing the inverse of the enrichment *P*-values obtained for each appearance of a biological term. A gene-weighted score was similarly calculated, with the added step of adjusting for annotation inequality using linear regression to determine the effect of the number of terms annotated for each gene.

Results

The pattern of effects for nine clusters of interest are shown in Figure 1. Solid blocks of color represent consistent effects in the same direction, with blue and red representing negative and positive effects respectively. For example, only clusters three and four have consistently negative effects on calving interval (representing better fertility).

For this brief paper, we chose to focus on clusters one and three as they have contrasting patterns of effects. Cluster one shows antagonistic effects on fat yield (blue), protein and milk yield (red), and weak effects

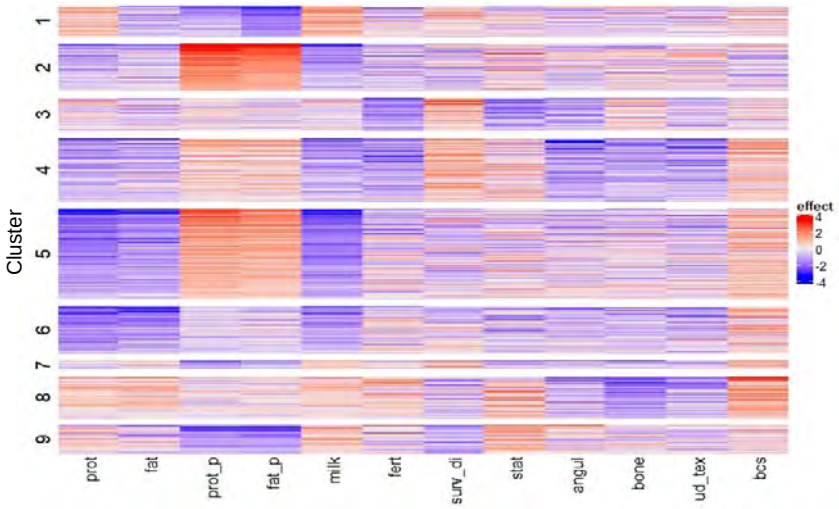

Figure 1. Heatmap showing the pattern of effects of 12,080 variants, sorted into 9 clusters across 12 traits of interest. Each horizontal line represents the effects of a single variant, with red representing positive effects and blue representing negative effects. As fertility is predominantly measured through calving interval, red represents poorer fertility.

on fertility, while cluster three shows strong effects on fertility (blue) but weak effects on production. The top genes identified for each cluster and degree of evidence for their involvement in common biological processes are shown in Figure 2.

Discussion

The archetypal variant for cluster one was associated with DGAT1, a gene which is primarily known to dairy scientists as responsible for lipid biosynthesis. However, our analysis shows that the dominant results demonstrated broader physiological mechanisms than fat synthesis, including lipid and glucose metabolism, obesity and insulin resistance/sensitivity, and differentiation of adipocytes. This is consistent with medical studies, which have focused on DGAT1 inhibition as a novel treatment for obesity and type 2 diabetes (Tsuda *et al.*, 2014). Our results suggest that this aspect of DGAT1 may be underexplored in dairy cattle.

Glucose tolerance tests in dairy cattle, have shown some evidence for adipose-specific insulin resistance (increased lipolysis) and mammary-specific insulin sensitivity (increased use of glucose as an energy substrate) in the form of phosphorylated Akt (Zachut *et al.*, 2013; Ma *et al.*, 2019). Tissue-specific insulin resistance may help to explain the high milk yields and poor body conditions which are often characteristic of the modern high-producing dairy cow. Interestingly, although our results support the hypothesis that high-yielding cattle have differences in energy partitioning, the cluster exhibits weak effects on fertility.

Cluster three, in contrast, exhibits strong effects on fertility and weak effects on production. The archetypal variant for cluster three was associated with ZNF613. Unlike DGAT1, ZNF613 is poorly studied, with little idea as to its function, although it has been implicated in dairy cattle gestation length, fertility, and conformation traits and is highly expressed in the developing embryo, placenta, and brain. However, our result may be helpful in suggesting areas of study for this gene, with the top five cluster three genes linked via their involvement in cell-cell adhesion. This area is less well-studied than diabetes and insulin, but the process may influence fertility through a variety of potential pathways, including GnRH migration in embryonic development and/or Wnt/β-catenin signal regulation.

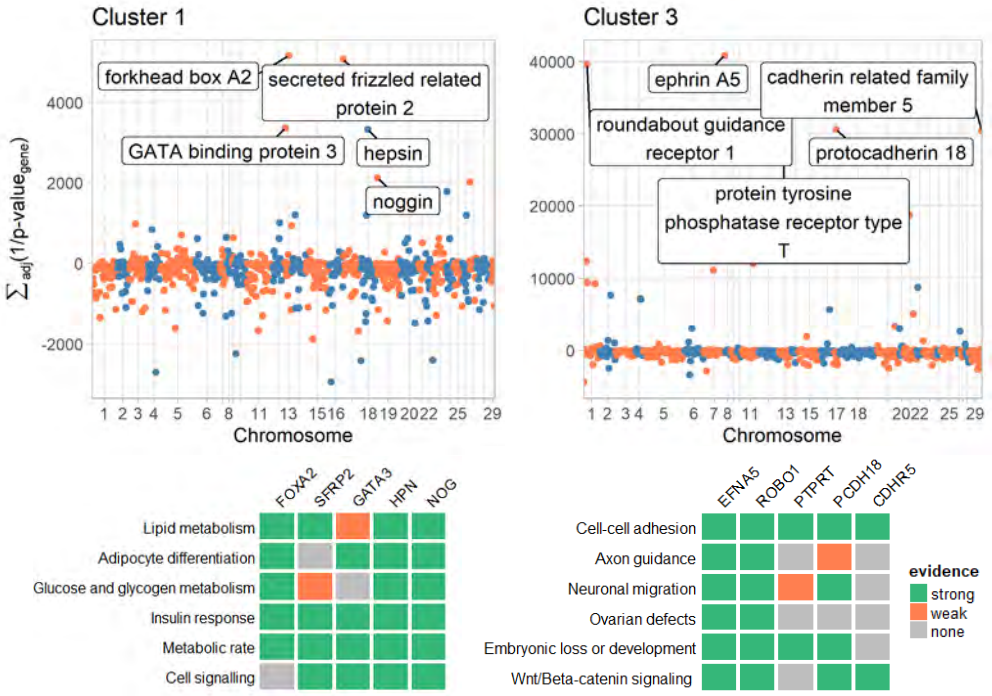

Figure 2. Top: The top five genes for cluster one were FOXA2, SFRP2, GATA3, HPN and NOG, while the top five genes for cluster three were EPHA5, ROBO1, PTPRT, PCDH18 and CDHR5. Bottom: Biological processes associated with clusters one and three. Green cells are supported by experimental evidence, orange have weak or incomplete evidence, grey have no supporting evidence.

Bovine dairy – phenotype is king

688. Candidate genomic regions for forage dry matter intake in Swedish dairy cows using single-step genome-wide association

G.M. Tarekegn[1,3*], J. Karlsson[2], C. Kronqvist[2], K. Holtenius[2], S. Andonov[1], B. Berglund[1] and E. Strandberg[1]

[1]Swedish University of Agricultural Sciences, Department of Animal Breeding and Genetics, Uppsala, Sweden; [2]Swedish University of Agricultural Sciences, Department of Animal Nutrition and Management, Uppsala, Sweden; [3]Animal Breeding and Genomics, Scotland's Rural College, Roslin Institute Building, Easter Bush, Edinburgh EH125 9RG, United Kingdom; yafetgetinet@gmail.com

Abstract

The study was conducted to identify genomic regions associated with forage dry matter intake (DMI_{For}) in Swedish Red (SR) and Holstein (SH) cows using single-step genome-wide association methods. Phenotypic data were from 1,177 lactations of 356 SR and 219 SH cows, of which 255 were genotyped. A mixed linear animal model was fitted. The gene annotation revealed 84 variants associated with DMI_{For}, 76 of which were found for parity2+ in SH. The genomic variants were annotated and generated 33 candidate genes associated with DMI_{For} only in SH. The candidate genes that include MAPK10, SOX6, TCF7L2, CREB5, INPP4A, ATP13A3, SND1 and IRS1 were detected associated with DMI_{For}. The study revealed 10 QTL regions in 9 chromosomes. Our findings offer new insights into the genetic basis of DMI_{For} and provide a guide to breeding cows producing milk on forage.

Introduction

Productivity of dairy cows has increased due to enhanced health care, continuous selection and application of various breeding techniques and improved feeding strategies (Arefaine and Bertilsson, 2015). High-yielding cows are often fed high proportions of cereal grain and pulses that could be consumed directly by humans (FAO, 2014). Replacing these feeds with forage not suitable for human consumption would increase net food production and high-quality forage has the potential to sustain high milk production (Karlsson *et al.*, 2020). However, before introducing this system, we should be able to breed cows that can meet their nutritional requirements for high milk production on diets high in forage and low in concentrates. To do this, we need better knowledge about the genetic background of forage dry matter intake (DMI_{For}) though most studies on feed intake have been focused on total DMI. In this study, we implemented a single-step genome-wide association study (ssGWAS) approach to investigate candidate genomic regions associated with DMI_{For} in Swedish Red and Holstein dairy cows.

Materials & methods

Animals, forage intake and data editing. In total 1,177 lactations of 575 cows (748 lactations of 356 SR and 429 lactations of 219 SH cows) kept at Swedish Livestock Research Centre, Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, were used in the study. Observations were recorded between August 2013 and October 2018. The housing management and milking practices, the diet and feeding practices were described in previous studies (Karlsson *et al.*, 2020). Individual daily forage intake was recorded automatically and dry matter content was determined to calculate DMI_{For}. For the final analysis, the weekly average of daily observations of feed intake were used. The average DMI_{For} was 13.2 (SD 3.8) and 14.5 (4.3) for SR and SH, respectively.

Genotyping and quality control. A total of 255 cows (150 SR and 105 SH) were genotyped with low density panel (6,910 markers), and imputed to medium density (50K) by the Nordic Cattle Genetic Evaluation (NAV). A call rate of >95% was applied at both animal and SNP level, and MAF>5% was used as

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_688, © G.M. Tarekegn *et al.* 2022

the first quality control (QC) criterion for imputed data. After the QC assessment, the imputed data (50K) were reduced to 42,431 SNP markers. These markers were further reduced to 39,326 SNPs after checking for Mendelian conflicts and monomorphic and missing markers using blupf90 (Misztal *et al.*, 2002) in preparation for ssGWAS.

Variance components and ssGWAS. Variance components were estimated using the remlf90 package (Misztal *et al.*, 2002) separately for each breed, using a mixed linear animal model with season, parity (parity 1 and parity 2+), calving year and lactation week as fixed effects, and animal and permanent environmental effects as random effects, where the *H* matrix, combining pedigree and genomic relationships (Aguilar *et al.*, 2010) was used for the animal effect, resulting in genomic breeding values (GEBVs) for all animals. To obtain SNP effects, they were back-solved from the GEBVs as implemented by the program postGSf90 (version 1.46) following the procedure described in Wang *et al.* (2012). The SNP effects were evaluated using the SNP *P*-value method as suggested in Aguilar *et al.* (2019) applying the 20 adjacent SNPs as windows. postGSf90 software was employed to generate Manhattan plots. A more liberal threshold (i.e. 10^{-4}) was applied to test significant association of the variants (Teyssèdre *et al.* 2012).

Functional enrichment analysis of candidate regions and detection of QTL. The gene annotation was performed using the bovine genome assembly (ARS-UCD 1.2) as a reference genome embedded in Ensembl Genome Browser to identify candidate genes. To classify the genes according to their biological pathways using protein-protein interaction (PPI) networks and GO terms encoded by the candidate genes, the STRING Genomics 11.0 was employed to the annotated candidate genes. At least two SNPs found in the annotated genes in the 10 Mb window in a chromosome were used to define the QTL regions.

Results

A total of 7 and 77 differentiated markers were found associated with DMI_{For} in SR and SH, respectively, and most (76) were found in parity 2+ for SH (Figure 1). Only 5 and 2 markers were found for parity 1 and parity 2+, respectively for SR. The gene annotation analysis revealed 33 candidate genes, 5 of them were uncharacterized genes, that were generated from the 84 variants. The functional enrichment analysis in STRING demonstrated 30 KEGG pathways.

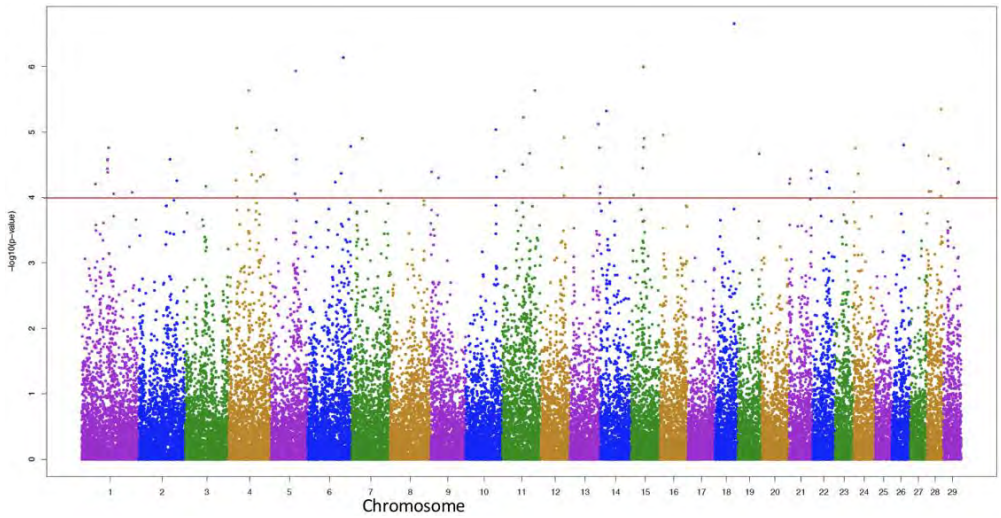

Figure 1. Manhattan plot generated for forage dry matter intake in parity 2+ in SH cows.

Detection of quantitative trait loci (QTL) regions. The identified candidate genes (18 genes, 3 of them are uncharacterized) were found embedded in 10 QTL regions in 9 BTAs, all in SH and in parity 2+. BTA4 had 2 QTL regions that contained 4 genes (AQAH, CREB5, AGMO, ENSBTAG00000051137). However, we detected only one QTL region per chromosome in the 8 BTAs. These include MAPK10 and CFAP299 in BTA6, INPP4A in BTA11, ENSBTAT00000050045 and ENSBTAG00000047383 in BTA12, KCNC1 and SOX6 in BTA15, WDR20 and MOK in BTA21, FHIT and CACNA1D in BTA22, GRID1 in BTA28, and MRPL49 and TCIRG1 in BTA29.

Discussion

In the current study, we identified variant associated with DMI_{For} in SR and SH, but the candidate genes obtained were detected only for SH indicating the breed difference on DMI_{For}. Those different genes detected were reported to be involved in various roles in metabolism, adipogenic conversion, lipogenesis, etc. For instance, the INPP4A gene associated with DMI_{For} for parity 1 and 2+ was reported associated to metabolism in cattle populations (Edea *et al.*, 2014). The CREB5 gene was reported associated to lipid and carbohydrate metabolism (Caldas, 2013). Over-expression of its family member, CREBL2, promotes adipogenesis and accelerates lipogenesis accompanied with increased GLUT (glucose transporter) 1 and GLUT4 via interaction with CREB (Ma *et al.*, 2011). The CREBL2 knockdown restrains adipogenic conversion and lipogenesis, whereas depletion of CREB could completely block the effects of overexpressed CREBL2 (Ma *et al.*, 2011). The SDN1 gene, detected in the present study, was reported in association with residual feed intake (RFI) in parity 2 in Holstein cows (Hardie *et al.*, 2017), whereas, the IRSI gene regulates milk fat metabolism and has roles in insulin activation, mediates and regulates carbohydrate and lipid metabolism (Yan *et al.*, 2019). According to Jiao *et al.* (2020), RS1 stimulated the level of Triglycerides (TAG) and increased the accumulation of lipid droplets in cow mammary epithelial cells (CMECs). The expression level of the IRS1 gene varies across lactation stages, it was highly expressed during the peak period of lactation, and was highly expressed in mammary tissue in dairy cows (Jiao *et al.*, 2020). The TCF7L2 gene was associated with fiber intake, is linked to pancreatic GLP-1 sensitivity (Loder *et al.*, 2008). The SOX6 gene has a role in carbohydrate metabolism pathway (Killeen *et al.*, 2014). It is a novel regulator of adipogenesis and modulate the transcriptional activity of carboxypeptidase M (CPM) to lower contents of C6:0 and C12:0, and increase contents of C18:1cis-9, C20:0 and total index as reported in Chinese Holstein cows, and is promising candidate gene for milk fatty acid (Shi *et al.*, 2020). Epidermal growth factor hydrolyzed by CPM enzyme (Skidgel *et al.*, 1996) involves in MAPK pathway to regulate fat metabolism (Taguchi *et al.*, 2018).

Overall, in the present study, we identified a range of genomic regions associated with DMI_{For}, but only in SH. We found only one gene, INPP4A, that showed pleiotropic effect, controlling DMI_{For} for parity 1 and parity 2+. Potential candidate genes to be further studied in SR and Holstein cows are CREB5, INPP4A, ATP13A3, SND1, TCF7L2, IRSI, SOX6 and MAPK10. Our findings offer new insights into the genetic basis of a previously little studied trait, DMI_{For}, and this new information may provide a guide to breeding strategies to forage efficient cows, however, validation of the SNPs effect with larger material could provide further evidence of the association of the candidate genes and their influence on the phenotypes.

689. Stillbirth, dystocia and weaning rates in Australian dairy calves

M.M. Axford[1,2,3*], J.E. Pryce[1,2], M. Khansefid[1] and M Haile-Mariam[1]

Abstract

In a study spanning twenty years of calving records of Australian dairy cattle, stillbirths were observed in 7% of calvings, dystocia in 9% of calvings and 97% of heifers born alive survived to at least weaning age. Breed differences in stillbirth and weaning rate provide evidence that there may be a role for stillbirth and heifer livability EBVs to improve these metrics in Australia and complement the existing Calving Ease EBV for Holsteins. This study found that some Jersey animals experience dystocia which suggests a Calving Ease EBV for Jerseys may be helpful to reduce painful calving experiences and improve calf and cow survival and animal welfare.

Introduction

Successful calving and calf rearing systems deliver healthy cows to the milking herd, herd replacements as well as opportunities to increase income from livestock trading through generating surplus stock. Calves that are selected as herd replacements influence the rate of genetic gain and productive efficiency of the herd in subsequent generations. One way of defining successful calving and calf management is that cows deliver live calves in the absence of dystocia and calves survive to at least weaning age. This definition highlights three important metrics: stillbirths, dystocia and weaning rate. Stillborn calves are classically defined as calves that have died within 48h of birth (Cole *et al.*, 2007), but in practice, the time period is less defined due to recording practices. Dystocia is defined by Lombard *et al.* (2007) as delayed or difficult parturition. Weaning rate is the proportion of calves, excluding stillbirths, that survive at least to weaning. The aim of this paper was to quantify stillbirths, dystocia and weaning rate in Australian dairy calves born between 2000 and 2021.

Materials & methods

Calving records and termination dates are routinely collected from farmers that herd-record and were obtained from DataGene. Calvings recorded between January 2000 and April 2021 were matched with identities and termination dates of the resulting calves. Calving records include calf fate, calving ease, calf size, dam breed. Calf records include calf breed, date of birth, termination date. The presence of dystocia refers to calvings that were not recorded as 'ok', 'normal' or 'none'. 'Weaned' was calculated as a binary trait based on birth and termination dates. In Australia, weaning usually occurs by 12 weeks (Dairy Australia, 2020) so a threshold of 84 days (12 weeks) was selected. Calves with a termination date after 84 days were estimated to have survived to at least weaning. Calves were grouped according to the herd and year of birth to assess the weaning performance of herd/year groups. Data was summarised using RStudio (RStudio Team, 2021).

Results

In a dataset of more than 1.7M calvings, 7% of calves are reported as stillborn, with higher percentages reported in calves from Jersey dams (Table 1). Stillbirths have remained relatively constant in Holstein and Jersey females between 2016 and 2021. In males, stillbirth rates have risen 2 and 6% in Holstein and Jersey respectively, between 2006-2010 and 2016-2021.

Table 1. Reported rates of stillbirth, dystocia and calf size in Australian dairy calves, 2000-2021 (n=1,738,300 calves).

Dam's breed	Sex	n calves	% stillborn	% dystocia	% big/huge	% small/ tiny	% stillborn calves with dystocia
Holstein	Female	836,400	5.1	7.5	5.5	8.1	34.1
	Male	696,779	5.0	12.9	11.8	7.7	39.6
Jersey	Female	107,690	6.9	2.7	2.8	7.5	19.8
	Male	97,831	9.7	3.6	3.9	7.3	18.8
All	All	1,738,300	6.6	9.1	7.8	7.9	34.6

Dystocia is reported in 9% of calvings (Table 1). Dystocia is more frequent in Holstein calvings compared to Jerseys. The highest level of dystocia occurs in calvings producing a male calf from a Holstein dam.

The next analysis shifts perspective from the cow's experience during calving to the calf's success to weaning. This subset of data contains only females that were born alive, given an identity at birth and had a recorded termination date which leads to a smaller dataset. The percentage of females that were weaned (i.e. survived to at least 84d in n=304,774 animals) averaged 97.4%. Jerseys were considerably lower than other breeds (94.5%), all other breeds were greater than the mean, with Red breed crosses being the highest and averaging 97.9% weaned, but this was only 0.3% more than Holsteins (97.6%).

Calves were grouped by herd and year with 5217 Holstein and 438 Jersey groups analysed (n=282,967 animals). Overall, Holstein herd/year groups had a weaning rate of 97.7% with a SD of 4.7, about 3% greater than Jersey groups (94.3%, SD 10.4). The percentage of Holstein and Jersey herds that achieved the 97% weaning target each year is plotted in Figure 1. Seventy-eight percent of Holstein groups achieved the target, 16% more groups than Jerseys. The most recent decade has generally poorer weaning rates than the previous across both breeds.

Discussion

Stillbirths are negatively impacting calf management on Australian dairy farms. The stillbirth rate of 7% is higher than 5.6% of Neupane *et al.* (2021) in US dairy cattle and 5.7% of Cuttance *et al.* (2017) in a group of New Zealand pastured based herds. The Holstein stillbirth rate (5%) is similar to 5.8% in reported by

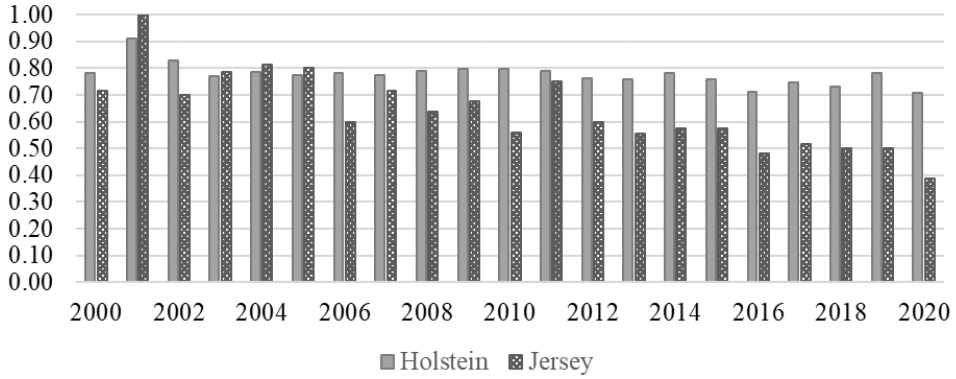

Figure 1. Proportion of Holstein and Jersey herd/year groups that achieve a target of 97% weaned 2000-2020 (n=282,967 calves, 5,655 herd/years).

Morek-kopec *et al.* (2021) Polish Holsteins. The higher stillbirth rate in Jerseys is consistent with results from Pryce *et al.* (2006). Differences in trait definition, time periods and breed proportions between studies could influence the small differences that are observed. Developing Stillbirth EBVs in Australia, such as those available in the USA (Cole *et al.*, 2007), will provide an opportunity to reduce the incidence of stillborn calves. In addition, strategies to reduce inbreeding could also contribute to lower stillbirths (Hinrichs and Thaller, 2011), especially at a time when inbreeding rates are increasing (Scott *et al.*, 2021).

Murray and Leslie (2013) suggest that dystocia is a highly painful experience for cow and calf and is known to contribute to poorer outcomes for both. The published rates of dystocia vary significantly depending on country, time-period, trait definition as well as animal factors such as parity and breed. At 9%, the level of dystocia reported in this study was higher than the USA estimate of 4.1% (USDA, 2018) and 1% in an early Australian study (McClintock *et al.*, 2003) but lower than an Irish estimate of 31% calving assistance (Mee *et al.*, 2011).

Stillborn calves are at greater risk of experiencing dystocia. More than one third of stillborn calves are dystocal, compared to just 5% of live Holstein heifer calves. Similarly, Haile-Mariam and Pryce (2018) observed a higher prevalence of stillborn calves amongst extremes i.e. tiny/small and big/huge Australian calves.

On average the weaning rate was more than 97% which is the target set for acceptable calf management by Dairy Australia's Rearing Health Calves resources (2020). Accounting for different time periods, the calf mortality to 12 weeks of 2.6% presented in this study is similar to the 4% to 18 months (Neupane *et al.*, 2021) in the USA. In a pasture-based New Zealand study which is more similar to Australian systems, post-natal mortality to 13 weeks was 4.1% (Cuttance *et al.*, 2017), slightly higher than this study.

There were some interesting breed differences in weaning rates. Compared to Jerseys, all other reported breed groups had a higher percentage of weaned calves. Norberg (2013) and Neupane *et al.* (2021) also reported higher losses in Jerseys compared to Holsteins in Denmark and USA respectively. Breed differences are also observed when weaning rate is assessed in herd/year groups. While the average weaning rate is more than the 97% target, there are herds and years that don't meet this target. About 16% more Holstein herd/year groups reach the target compared to Jerseys. While differences between breeds will provoke discussion, it is the within-breed variation that has the potential to be more useful to support farmers in making practice change that improves weaning rate through breeding. Genetic evaluations for heifer livability or survival have been released in the US (Neupane *et al.*, 2021) as well as other countries and are likely to improve weaning rates over time. This study shows that there is data on weaning rate that can be used for further study to estimate genetic variation and genetic evaluation of heifer livability in Australia.

Breed variation for stillbirth and weaning rate provide evidence that there may be a role for stillbirth and heifer livability EBVs, in Australia, to complement the existing Calving Ease EBV for Holsteins. This study found that some Jersey animals experience dystocia which suggests a Calving Ease EBV for Jerseys may be helpful to reduce painful calving experiences.

Cork, Ireland; maeve.williams@teagasc.ie

Abstract

Linear type traits were originally scored as a means of predicting functionality manifesting itself as greater cow longevity. Existing studies relating linear type traits to dairy cow longevity were generally restricted to relatively young cows, since dairy cows tended to be culled for infertility prior to reaching maturity. Improved reproductive performance, however, is contributing to an aging cow population. How linear type traits associate with survival in dairy cows should therefore be reassessed in light of this aging population. The objective of the present study was to use random regression models to quantify the genetic correlations between linear type traits and survival to the next parity, using survival data up to tenth parity. The genetic correlations between most of the linear type traits and survival were relatively consistent across parities; the exceptions being rear udder height, teat length, and udder depth, where the genetic correlations strengthened with advancing parity.

Introduction

Cow longevity has been a focus of dairy cow research since the 1950s (Rendel and Robertson, 1950) with some measure of longevity now included in most dairy cow breeding objectives (Cole and VanRaden, 2018; De Vries, 2020). Improved dairy cow longevity is associated with greater profitability, *via* a reduced requirement for replacement heifers, along with greater average herd yield, complemented with a greater opportunity for voluntary culling (van Pelt *et al.*, 2015). Nonetheless, selection for dairy cow longevity remains difficult, as a cow's true longevity is not known until she is actually culled (van Pelt *et al.*, 2015). Therefore, identifying early predictors of both phenotypic and genetic (merit for) survival are of potential importance. Although with the advent of genomic selection, having early indicators of longevity may become less critical in the future, as genotyped animals could receive accurate estimated breeding values for longevity at birth. Previous studies have genetically correlated linear type traits with measures of dairy cow longevity (Brotherstone *et al.*, 1998; Cruickshank *et al.*, 2002; Kern *et al.*, 2015), but these studies were generally limited to cows culled early on in their productive life. Nevertheless, linear type traits have frequently been included in multi-trait genetic evaluations to indirectly select for the genetic merit of dairy cow longevity (Miglior *et al.*, 2017). Despite this, no study to date has examined whether linear type traits are good (genetic) predictors of longevity in older cows. Therefore, the objective of the present study was to estimate the genetic correlations between linear type traits and survival from one parity to the next and, in doing so, evaluate if those genetic correlations change with advancing parity.

Materials & methods

Survival trait. Calving and pedigree information was available for 1,959,423 Irish Holstein-Friesian dairy cows calving in 40,437 herds. All cows were born between 1999 and 2008, inclusive, and calved for the first time in, or before, 2010. Only records from herds where <50% of the cows were registered with the breed society were retained; all calving records from the herdbook-registered cows in these herds were discarded, as were cows without a known sire. Records where first parity cows calved younger than 600 days of age were removed. The median age at calving was calculated for each parity, and cows calving more than 180

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_690, © M. Williams *et al.* 2022

days from the parity median was discarded. The entire records of an individual cow were discarded if any calving event (prior to culling) was set to missing after previous edits. Survival was defined for each parity (1st to 9th parity) based on whether or not a cow calved in the next lactation.

Linear type trait edits. Linear type traits data from 21 linear type traits from 203,136 primiparous Holstein-Friesian cows were available. Classification of cows was performed by a single professional classifier for a given herd, on a given date. Differences between classifiers were accounted for as described by Brotherstone (1994). Contemporary group for the linear type traits was defined as herd-date of inspection, and contemporary groups with <10 cows were discarded.

Subset selection for statistical analyses. Only survival records of cows with at least one linear classified paternal half-sib were retained. The retained survival records were assigned to contemporary groups based on proximity in calving dates within herd. A maximum duration of 60 days between calving events in the same contemporary group was allowed, and only contemporary groups with ≥10 records were retained. All survival data from herds where at least one cow had a linear type trait phenotype were retained. Survival information from an additional 852 herds were randomly selected. Similarly, all linear type trait information from herds where at least one cow had a survival phenotype were retained. Linear type trait data of cows in the linear type contemporary groups where at least one sire also had progeny with survival records were retained; all additionally retained linear scores, however, had to have been undertaken in or before 2010. After all edits, survival records were available for 52,447 Holstein-Friesian cows, with 152,894 lactations of information (1st to 9th parity). Linear type trait records were available from 52,122 Holstein-Friesian cows, of which 1,394 also had a phenotype for survival in the data for analysis.

Statistical analyses. The (co)variance components of survival were quantified using random regression animal models in ASReml (Gilmour *et al.*, 2009):

$$Surv_{ijklmno} = CG_j + Het_k + Rec_l + AGE_m + \sum_{n=1}^{3} b_n\, Parity^n + a_i * \sum_{o=1}^{3} b_o Parity^o + e_{ijklmno} \quad (1)$$

where $Surv_{ijklmno}$ was the survival observation; CG_j was the fixed effect of contemporary group j; Het_k was the fixed effect for heterosis class k (k=0 to 11); Rec_l was the fixed effect for recombination loss class l (l =0 to 6); Age_m was the fixed effect for age class relative to the parity median m (m=1 to 5); $\sum_{n=1}^{3} b_n\, Parity^n$ was the fixed effect nth order Legendre polynomial regression on parity number; $a_i * \sum_{o=1}^{3} b_o\, Parity^o$ was the random Legendre polynomial regression on parity number for animal$_i$ and $e_{ijklmno}$ was the residual term. No significant permanent environmental variance across lactation existed. Residual variances were estimated separately for each parity with no covariance assumed among parities. A series of bivariate animal random regression models were then used to estimate the covariances between survival at each parity and each linear type trait. The fixed and random effects included in the models were those used in the univariate analyses of survival and those used to estimate variance components of linear type traits described by Berry *et al.* (2004). The genetic (co)variances and genetic correlations between longevity in each parity, and each linear type trait, were estimated from the matrix of Legendre polynomial regression coefficients and the animal additive genetic covariance matrix estimated from the random regression models.

Results

A fixed cubic polynomial regression and a linear random regression were chosen as the most parsimonious orders for modelling longevity. Heritability estimates for survival per parity ranged from 0.02 (SE=0.004; 1st parity) to 0.05 (SE=0.01; 9th parity). Pairwise genetic correlations between survival among different parities varied from 0.42 (1st and 9th parity) to 1.00 (8th to 9th parity). The strength of the genetic correlations between survival in the different parities were inversely related to the interval between the compared

parities. Heritability estimates ranged from 0.22 to 0.39 for the body-related type traits, from 0.02 to 0.36 for the udder-related type traits, and from 0.08 to 0.26 for the feet and leg-related type traits.

The genetic correlations between survival and the individual linear type traits varied across parities for nine of the 21 linear type traits examined, but only three of the linear type traits became more strongly correlated with survival as cows aged; these three traits were rear udder height, teat length, and udder depth (Figure 1). With each successive parity post first-calving, shorter teats, a greater distance between the vulva and the udder (i.e. lower rear udder height scores), and a shallower udder depth, became increasingly more strongly genetically correlated with survival (Figure 1). While the genetic correlations between survival and locomotion were strongest in young parities, with each successive parity, after fourth parity, good locomotion scores became progressively more strongly associated with survival (Figure 1).

Discussion

The fact that the genetic correlations between survival and some linear type traits vary with age, suggest that different factors govern survival as the dairy cow ages; this was particularly true for some udder characteristics. In addition to the changes in genetic correlations between survival and individual linear type traits across ages, the range in the genetic correlations between survival in different parities further substantiates the hypothesis that survival may not be the same trait across the entire lifespan of a dairy cow. Previous studies have reported a large range in genetic correlations between individual linear type traits and different measures of longevity/survival in dairy cows; for example, the genetic correlations between longevity/survival traits and udder depth ranged from -0.07 for British Holstein-Friesian cows (Brotherstone *et al.*, 1998) to 0.31 for Brazilian Holstein cows (Kern *et al.*, 2015). The range in previously reported genetic correlations between longevity/survival and other individual linear type traits were similarly large (Brotherstone *et al.*, 1998; Cruickshank *et al.*, 2002; Kern *et al.*, 2015), potentially reflecting differences in scoring systems between countries/breed organisations, and the different definitions of survival/longevity.

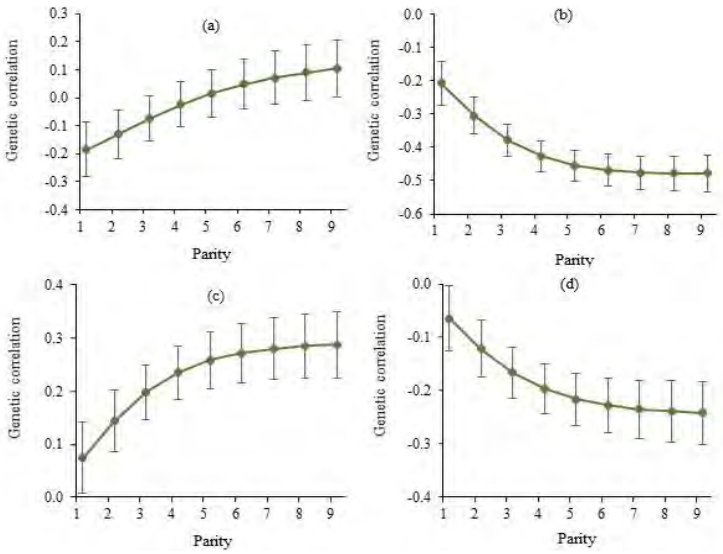

Figure 1. Genetic correlations between survival and (a) locomotion, (b) rear udder height, (c) udder depth, and (d) teat length in each parity. Standard error bars represent above and below the genetic correlation. Locomotion is scored from lame (1) to excellent (9); rear udder height is scored from low (1) to high (9); udder depth is scored from below hocks (1) to above hocks (9) and teat length is scored from short (1) to long (9).

Nonetheless, many of the genetic correlations reported in the present study were similar to those previously reported in other dairy cow populations, even though many of these studies were limited to younger cows.

As expected, better locomotion scores and shallower udders with shorter teats were favourably associated with survival, especially in older parities. Given linear type traits are frequently scored in first parity (Berry *et al.*, 2004), and are genetically correlated with survival in older parities, they may be suitable early predictors of survival. Additionally, the direction of the genetic correlations between survival and rear udder height, teat length, and udder depth did not change between parities; hence, selection for survival in older parities using these linear type traits should not hinder survival in younger parities.

Abstract

The objective of this study was to estimate genetic and phenotypic correlations and heritabilities for milk composition and fertility traits in cows milked either once-a-day (OAD) or twice-a-day (TAD) across 21 spring-calving dairy herds in New Zealand. Fertility traits evaluated were submission in the first 3 weeks of mating (SR21), the interval from the start of mating to conception (SMCO), in-calf in the first 3 weeks of mating (PR21), and conception to the first service (PRFS). Heritability estimates of fertility traits were low and varied from 0.02 to 0.07 across the population. Phenotypic correlations between milk production and fertility traits were close to zero and most of the genetic correlations were antagonistic in both milking systems. Protein to fat ratio had positive genetic correlations with SR21, PR21 and PRFS in both milking frequencies. Estimates of genetic correlations of P:F ratio with PR21 and PRFS were relatively greater in OAD than TAD indicating that cows milked OAD had a higher P:F ratio and were more likely to get in-calf early in the breeding season than cows milked TAD.

Introduction

Genetic parameters of milk production and fertility traits have been estimated in seasonal dairy-producing systems (Grosshans *et al.*, 1997, Berry *et al.*, 2013). The main conclusion from cited studies is that genetic correlations between milk production and fertility traits are antagonistic. Since the late 1990s, some farmers have adopted OAD milking for the entire lactation in New Zealand (Davis *et al.* 1999), and for the production season of 2015-16, about 9% of the tested herds were milked OAD for the whole lactation (Edwards, 2018). Hemming *et al.* (2018) reported herds milked OAD for the entire lactation had better reproductive performance than those milked TAD. Genetic correlations between milk production and fertility traits have not been reported for the OAD population. Therefore, this study aimed to estimate genetic and phenotypic correlations between milk composition and fertility traits of cows milked OAD in New Zealand.

Materials & methods

Data. Herd test milk yields, calving, mating, and pregnancy diagnosis information of spring-calved dairy cows in production season 2017-18 were extracted from the animal database of Livestock Improvement Corporation (LIC). Selected herds had at least 50 cows per herd, herd tested four or more times per lactation and at least 80% of cows in a herd had early, aged pregnancy testing information to allow conception dates to be calculated. Herds were classified as OAD or TAD for entire lactation if more than 90% of the tested cows had the same milking frequency at each herd test-day and all the herd tests were classified as the same milking regimen. After the OAD herds had been identified, the geographically closest TAD milking herd was selected within 20 km from OAD using GPS visualizer (Schneider, 2012). The final dataset contained 4,629 milking cows from 10 OAD (2,008 cows) and 11 TAD (2,621 cows) milking herds with Holstein Friesian 816 (F), Jersey 1566 (J), and 2247 their crossbred (F×J).

Production traits. Milk production data included milk yield (MY), fat percentage (FP), protein percentage (PP), and lactose percentage (LP). Protein to fat (P:F) and protein to lactose (P:L) was calculated as the ratio between protein and fat percentages and protein and lactose percentages, respectively. Only animals with lactation lengths from 150-305 days were analysed.

Fertility traits. Four fertility traits were defined: submission for artificial insemination in the first 3 weeks of mating (SR21), interval from the start of mating to conception (SMCO), in-calf in the first 3 weeks of mating (PR21), and conception to the first service (PRFS). Pregnancy testing results where the foetal age was estimated and where cows were tested between 35-122 days (inclusive) from conception were used. Conception dates were calculated as the date of pregnancy diagnosis minus the estimated foetal age for cows with a pregnancy status of 'pregnant'. Non-pregnant cows (11.8%) were retained to estimate genetic parameters and penalized conception dates were calculated by adding 105 days (a 12-week mating period plus 21 days) to the herd start of mating date. The mating start date of each herd was sourced from the LIC database. The variables SR21, PR21 and PRFS were coded as 1 if the cow was mated or conceived in the first 3 weeks of mating, or conceived to the first service, and 0 otherwise. Cows in their first four parities were considered separately and cows in parity five and above were amalgamated into one group.

Statistical analysis. Heritability and genetic and phenotypic correlations were estimated using ASReml 4.1 (Gilmour *et al.*, 2015). A single-trait animal model was used for the estimation of heritability for each trait and bivariate animal models were used separately to estimate the genetic and phenotypic correlations. Models included the fixed effects of herd, parity, proportion of F, heterosis, and linear and quadratic effects of deviation of calving date from the herd median calving date and the random effect of animal.

Results

Cows milked TAD produced greater MY and higher LP than those cows milked in OAD (Table 1), but had poorer fertility outcomes. Fat and protein percentages were higher in cows milked OAD (Table 1). Compared with cows milked TAD, a higher proportion of cows milked OAD were mated (>2.5%) and conceived (>9.9%) within 3 weeks of the mating season and were pregnant (>7.4%) to their first AB.

Heritability of production and fertility traits varied from 0.22 to 0.72 and 0.02 to 0.05 in OAD, from 0.13 to 0.67 and 0.02 to 0.07 in TAD respectively (Table 2). In both milking systems, the genetic correlations of MY with FP, PP, and P:L were moderate and negative. Milk yield was moderately positively correlated with P:F in TAD. In both milking systems there were strong negative genetic and phenotypic correlations between FP and P:F, while correlations of FP with PP and P:L were positive and moderate to strong. Genetic and phenotypic correlations between PP and P:L were strongly positive but LP and P:L were moderately negatively correlated in both OAD and TAD herds.

Table 1. Summary statistics for milk production and fertility performance of cows milked once daily (OAD) and twice daily (TAD).

Traits[1]	OAD		TAD	
	Mean	SD	Mean	SD
MY (kg)	2,696.6	686.5	4,437.7	1,112.0
FP (%)	5.6	0.9	5.0	0.8
PP (%)	4.1	0.3	3.9	0.3
LP (%)	4.9	0.2	5.0	0.2
SMCO (days)	21.1	17.8	24.6	19.4
SR21 (%)	85.6	35.2	83.1	37.5
PR21 (%)	58.6	49.3	48.7	50.0
PRFS (%)	68.3	46.5	60.9	48.8

[1] MY = milk yield; FP = fat percentage; PP = protein percentage; LP = lactose percentage; SMCO = start of mating to conception; SR21 = proportion of cows that presented for mating within 21 days of the start of mating; PR21 = proportion of cows that conceived within 21 days of the start of mating; PRFS = proportion of cows that conceived to their first service.

[1] Genetic correlations are shown below the diagonal, phenotypic above, and heritabilities along in the diagonal. Standard errors for all phenotypic and genetic correlations were ≤0.03 and ≤0.53 in both milking frequencies respectively.

[1] MY = milk yield; FP = fat percentage; PP = protein percentage; LP = lactose percentage; P:F = protein to fat ratio; P:L = protein to lactose ratio; SMCO = start of mating to conception (days); SR21 = proportion of cows that presented for mating within 21 days of the start of mating; PR21 = proportion of cows that conceived within 21 days of the start of mating; PRFS = proportion of cows that conceived to their first service.

In general, phenotypic correlations between milk production and fertility traits were low and close to zero for both milking frequencies. Most genetic correlations between milk production and fertility traits were negative and low to moderate. Genetic correlations of MY with PR21 and PRFS were moderate and negative in TAD, which was relatively greater compared to OAD. In OAD milking, FP was moderate and negatively correlated with SR21, PR21 and PRFS. In both milking frequencies, genetic correlations of PP, P:F and P:L with PR21 and PRFS were positive and low to moderate whereas PP, P:F and P:L were moderate negatively correlated with SMCO. Genetic correlations with P:F and SR21 were positive in OAD and TAD, but relatively greater in TAD. Genetic correlations of LP with SMCO were positive and moderate in OAD, but close to zero in TAD. Genetic correlations of LP with PR21 and PRFS were positive and moderate in TAD, but this was moderately negatively correlated in OAD.

Discussion

Heritability estimates and phenotypic and genetic correlations between milk yield and compositional traits in cows milked OAD and TAD for this study were consistent with Lembeye *et al.* (2016) in New Zealand. Estimated heritabilities for fertility traits were low and similar to previous findings (Grosshans *et al.*, 1997; Berry *et al.*, 2013). The low heritability of fertility traits are a consequence of small genetic variation and relatively large residual variation of cows in both milking frequencies. Our results indicate that increases in

MY were associated with a decrease in submission and in-calf and lengthening SMCO. This antagonistic genetic relationship between production and fertility of cows implies that selecting only for cows with higher milk production leads to a genetic decline in cow fertility. For this reason, New Zealand and most other national genetic evaluation systems now include fertility in their selection indices.

Our findings show that cows with a higher PP, P:F and P:L ratio, are more likely to get pregnant early in the breeding season and to conceive to their first service in both milking populations. A positive genetic association of PP with fertility has been reported by Morton *et al.* (2018), highlighting better fertility in cows with higher milk PP. Though the genetic correlations of PP with PR21 and PRFS are higher in TAD compared to OAD milking, genetic correlations of P:F and P:L with fertility are comparatively greater in OAD than TAD milking cows. This indicates that herds milked OAD have better fertility and a higher milk solids percentage, so each kilogram of milk provides a greater return to the farmer. The reason for the negative genetic correlation between FP and fertility outcomes with OAD milking in this study has not yet been identified. Davis *et al.* (1999) reported that LP decreased in OAD milking cows due to changes in mammary permeability which enhanced efflux of lactose through mammary tight junctions. The negative association between LP and fertility in cows milked OAD should be further investigated. The findings of this study indicate that there is potential to increase the fertility performance of dairy cattle by identifying the causes of the association between milk protein concentration and fertility of cows.

Abstract

Dairy cattle routinely face a variety of different stressors such as intense heatwave events that can lead to more frequent bacterial infections. In the present study, Holstein heifers (n=20) were allocated to different treatment groups receiving saline, 100, 200 or 400 ng/kg of bacterial lipopolysaccharide (LPS) administered intramuscularly, and serum was collected to profile changes in circulatory stress biomarkers. All LPS-challenged animals demonstrated distinct cortisol responses as compared to the saline controls 2 hr post-LPS challenge. Cytokines TNFα and IL-10, were found to be induced between 2 and 4 hr. Finally, regulatory miR-1246, miR-223, miR-29 and miR-31 were also significantly induced by LPS challenge. The present study demonstrates that the bovine stress response to LPS is dynamic, and variability in the response warrants further investigation to better understand the genetic contribution to stress resilience.

Introduction

Dairy cattle routinely face a variety of different stressors; for instance, cattle are being subjected to intense heatwave events as a result of climate change and subsequently to more frequent bacterial infections (Lacetera, 2019). Higher bacterial load leads to reduced milk production and reproductive ability, thereby contributing to economic losses to dairy producers (Abdelhay Kaoud, 2019). To combat this, farmers have become reliant on antimicrobials that have contributed to the development of antimicrobial resistant pathogens, which are now a global health threat (Robinson *et al.*, 2016). It is imperative to have a thorough understanding of the bovine stress response triggered by bacterial stressors, like bacterial lipopolysaccharide (LPS), to identify genetic and epigenetic factors that regulate these physiological responses so that enhanced stress resilience of animals can be pursued through selective breeding. The aim of this study was to optimize an immune stress challenge using LPS and identify biomarkers that may be used to stress phenotype dairy cattle.

Materials & methods

Twenty Holstein heifers (7.4±1.9 months of age) were used to determine an intramuscular dose of LPS sufficient for eliciting a systemic stress response. Animals were randomly divided into four different treatment groups (n=5/treatment); each receiving 1 ml of either 100, 200 or 400 ng/kg of *E. coli* LPS (O111: B4, Sigma-Aldrich), or equal volume of sterile phosphate-buffered saline (control) injected into the trapezius muscle. Blood was collected hourly for 8 hr and again at 24 hr. Measured serum parameters included total cortisol (IMMULITE/ IMMULITE 1000 Cortisol chemiluminescent enzyme immunoassay, Siemens Medical Solutions Diagnostics, Los Angeles, CA, USA) and cytokine (MILLIPLEX® MAP Custom 13-Plex Bovine Magnetic Bead Panel, EMD Millipore Corp., Burlington, MA, USA) concentrations. Serum miRNA was extracted (Qiagen miRNeasy® Serum/Plasma Advanced Kit, Hilden, Germany) and analysed by PCR using a StepOne Plus (ABI) qPCR machine. The qPCR reaction was subjected to denaturation at 95 °C for 10 min, 40 PCR cycles of 95 °C for 15 sec, then 58 °C for 1 min of primer annealing and amplification. Primer sequences were derived from Sharma *et al.* (2020). The statistical analyses were performed using repeated measures ANOVA using PROC GLIMMIX procedures available in SAS (SAS/STAT®, SAS Institute Inc, NC, USA).

Results

Dynamic changes in serum cortisol concentration occurred in response to LPS challenge (Figure 1). At 2 hr, serum cortisol increased significantly across all treatment groups, and remained significantly induced until 4 hr in the 200 and 400 ng/kg LPS treatments compared to the control (P<0.01).

Dynamic changes in IL-10 and TNF-α also occurred following LPS challenge. IL-10 was most significantly induced in heifers 2 hr post challenge with 400 ng/kg of LPS (P<0.0001) as compared to the saline control group (P<0.0001) and returned towards basal levels by 4 hr (Figure 2A). TNFα was most significantly induced at 2 hr for animals challenged with 200 and 400 ng/kg of LPS (P<0.01) as compared to the saline control animals (Figure 3A).

LPS-induced changes in serum miRNA are shown in Table 1. Of the six miRNA analysed, miR-223, miR-31, miR-29b and miR-1246 were found to be significantly expressed during the study period as compared to their baseline values (P<0.05).

Discussion

Activation of the innate immune system by LPS is triggered primarily by TLR4, which results in a signalling cascade that triggers the release of pro- and anti-inflammatory mediators, and activation of the HPA axis leading to the release of cortisol (Burdick Sanchez). As expected, cortisol was significantly induced in all of the treatment groups in this study with concentrations peaking between 2 and 4 hr. These findings are

[1] * indicates $P<0.05$, ** indicates $P<0.01$, *** indicates $P<0.001$, Fixed effects = interaction of LPS dose (ng/kg): hr post LPS challenge.

consistent with the findings of Boam *et al.* (2019), who assessed the effect of Holstein genotype on innate immunity and metabolism when heifers were challenged intravenously with 500 ng/kg of LPS; they report a peak cortisol response of approximately 220 nmol/l 3 hr following the *iv* LPS challenge. Our study was capable of eliciting a comparable cortisol response when heifers were challenged intramuscularly with 200 and 400 ng/kg of LPS, with averages 183 and 184 nmol/l, respectively. It has been demonstrated using sheep that the cortisol response to bacterial LPS is moderately heritable ($h^2 \cong 0.13$), and 16 single nucleotide polymorphisms (SNPs) on 13 different chromosomal regions have been implicated in the ovine stress response (Pant *et al.*, 2010). Future studies should aim to assess the heritability of the cortisol response in dairy cattle.

In the present study, LPS also induced a cytokine response as noted in the significant increase in serum TNF-α and IL-10. TNF-α has a diverse range of functions; it elicits inflammation, the acute-phase response, and triggers programmed cell death as a means of resisting microbial infections (Idriss and Naismith, 2000). In a beef steer calf study, researchers demonstrated a peak in TNF-α production 1 hr after intravenous administration of 250 ng/kg of LPS, which remained significantly induced until 2 hr (Burdick Sanchez *et al.*, 2020) these findings are in agreement with our study. IL-10 is a potent anti-inflammatory cytokine that is known to protect against LPS lethality by suppressing the production of inflammatory cytokines. In mice, IL-10 exhibited a biphasic response to intravenous LPS challenge, with an early peak at 1.5 hr and decrease to baseline at 6 hr (Barsig *et al.*, 1995). These authors found the IL-10 response was synchronous with the TNF-α response, and we also observed this. Peak IL-10 and TNF-α expression also coincided with peak cortisol concentrations.

MiRNAs play a key role in immune cell differentiation and modulation in response to pathogenic infections. Specifically, Hsieh *et al.* (2012) demonstrated a significant increase of 15 miRNAs in murine whole blood 2 hr following intraperitoneal LPS challenge that persisted for at least 6 hr. Despite their potential to be used as stress biomarkers, there is limited literature supporting the expression of bovine circulatory miRNA. Bovine miR-223 demonstrated the most prominent response to LPS as it was strongly upregulated by 100 and 400 ng/kg of LPS. MiR-223 helps to induce the proliferation and differentiation of neutrophils and is a proposed diagnostic biomarker of human sepsis (Liu *et al.*, 2020). MiR-29b has been reported to upregulate production of the inflammatory chemokine CXCL8 (IL-8) and may contribute to intestinal fibrosis by up-regulating fibroblast collagen production in Crohn's patients (Nijhuis *et al.*, 2017). Since LPS is known to target the lungs in ruminants (Warner *et al.*, 1988) the role of miR-29b in lung fibrosis in response to

bacterial and viral challenges could be more thoroughly investigated. LPS doses 100 and 200 ng/kg also upregulated bovine miR-31, which is in contrast to our previous ovine study (Naylor *et al.*, 2020). MiR-31 plays a role in maintaining homeostasis by acting as a negative regulator of the FOXP3 gene, which is a master regulator for the expansion of T regulatory (Treg) cells (Magni *et al.*, 2014). The upregulation of miR-31 in the present study implicates a potential reduction of Treg cell activity. Finally, animals challenged with 200 ng/kg of LPS demonstrated significant upregulation of miR-1246 and these findings are consistent in heat-stressed Holstein cows (Zheng *et al.*, 2014). The present study shows the sensitivity of cortisol, inflammatory cytokines and miRNA to low-dose intramuscular LPS challenge and indicates their potential to be used as biomarkers of bovine stress in response to a bacterial challenge.

693. Estimation of genetic correlations between predicted energy balance and milk fatty acids of Holsteins in Japan

A. Nishiura[1*], O. Sasaki[1], M. Aihara[2], Y. Saito[1], R. Tatebayashi[1] and H. Takeda[1]

[1]Institute of Livestock and Grassland Science, National Agriculture and Food Research Organization, 2 Ikenodai Tsukuba, 3050901, Ibaraki, Japan; [2]Livestock Improvement Association of Japan, 11-17 Fuyuki Koto, 1350041, Tokyo, Japan; akinishi@affrc.go.jp

Abstract

It is important to optimize the energy balance of dairy cows in lactation to prevent any deterioration of health or fertility. We estimated the genetic correlations between predicted energy balance (PEB) and milk β-hydroxybutyrate (BHB) and three types of milk fatty acid (FA) composition (*de novo* FA on a milk basis (DNM), *de novo* FA on a fat basis (DNF) and preformed FA on a fat basis (PRF)) from Holsteins using datasets for test-day milk records. PEB was calculated using multiple regression equations. The genetic parameters of PEB, BHB, DNM, DNF and PRF were estimated using a random regression model. Genetic correlations in the early stage of lactation were estimated to be negative for PEB-BHB and PEB-PRF, and positive for PEB-DNF. Sufficient data was acquired to reveal the relationship between each milk components and energy balance, suggesting PEB to have potential for use as an index for improving energy balance.

Introduction

Increases in milk yields over the last few decades have resulted in postpartum energy deficits (Hüttman *et al.*, 2009). The energy balance (EB) of dairy cows tends to be negative, especially in early lactation, because energy intake via feed cannot match the energy demands of milk production (de Vries *et al.*, 1999). A negative energy balance causes a deterioration in fertility, metabolic disorders such as ketosis, and mastitis (Goff and Horst 1997; Collard *et al.*, 2000; Ingvartsen *et al.*, 2003). It is important to improve EB, but EB is difficult to measure, making it a challenge to obtain enough data to carry out a genetic evaluation (Coffey *et al.*, 2001). This prompted us to formulate an equation to predict EB from readily-acquired records of milk yield and its components. Records of milk β-hydroxybutyrate (BHB) and milk fatty acid (FA) composition are increasingly obtainable from routine herd tests in Japan. BHB and milk FA composition are thought to be related to energy status (Koeck *et al.*, 2014, Stoop *et al.*, 2009). It is necessary to elucidate the relationship between predicted EB (PEB) and BHB and milk FA composition. Our objective was to investigate the relationships between PEB and BHB and milk FA composition using herd test data.

Materials & methods

Data. The datasets we used consisted of test-day milk records for the first three lactations of Holstein cows in two regions: Hokkaido and the rest of Japan. The records were collected by the Livestock Improvement Association of Japan. All the cows had records of milk β-hydroxybutyrate (BHB), three types of milk FA composition (*de novo* FA (C4 to C14) composition on a milk basis (DNM), *de novo* FA composition on a fat basis (DNF) and preformed FA (≥C18) composition on a fat basis (PRF)). Milk components were predicted using mid-infrared spectrometry and BHB was $\log_e(x+1)$ transformed. All the lactation records of the cows covered days in milk (DIM) 6-305. All the cows were aged 18-50 months, 30-67 months and 42-84 months at the time of calving for their first, second and third lactation respectively. There were more than three cows for each herd test day and number of milking times class and more than four records for each lactation. The pedigree data used for the analysis were traceable back through three generations of cows that had records. There were 1,100,399 records from 175,154 cows in Hokkaido and 1,553,475 records from 142,887 cows in the rest of Japan.

Prediction of energy balance. EB was predicted using Equation 1:

$$\begin{aligned}PEB = {} & 401.015 - 1.640sDIM + 7.925sDIM^2 + 27.302sDIM^3 - 30.097sDIM^4 - 34.243FPR - \\ & 5.566MY + 0.178MY^2 - 0.002MY^3 + 4.853P - 130.278L^2 + 45.568L^3 - 4.430L^4 + 3.932dMY \\ & - 2.690dMY^2 - 0.778dMY^3\end{aligned} \quad (1)$$

where DIM is days in milk, sDIM is standardized DIM ((2×(DIM-6))/(305-6)-1), FPR is fat-to-protein ratio, MY is milk yield, P is protein %, L is lactose %, and dMY is the current MY minus the previous MY value.

Estimation of genetic parameters. Genetic parameters were estimated using a random regression model, Equation 2:

$$y_{hijk} = HTDT_h + \sum_{m=0}^{5} CM_{im} x_m(t) + \sum_{m=0}^{5} PCA_{jm} x_m(t) + \sum_{m=0}^{3} a_{km} x_m(t) + \sum_{m=0}^{3} pe_{km} x_m(t) + e_{hijk} \quad (2)$$

where y_{hijk} is the value of a trait (BHB, DNM, DNF, PRF, EB); $HTDT_h$ is the fixed effect of the h^{th} herd test day and number of milking times; CM_{im} is the fixed regression coefficient of the i^{th} calving month corresponding to the m^{th}-order polynomial; PCA_{jm} is the fixed regression coefficient of the j^{th} parity calving age (in months), corresponding to the m^{th}-order polynomial; $x_m(t)$ is the Legendre polynomial of order m (m=0-4) and Wilmink's exponential function (exp(–0.05t); m=5) for t DIM; a_{km} is the m^{th}-order additive genetic random regression coefficient of the k^{th} animal; pe_{km} is the m^{th}-order permanent environmental random regression coefficient of the k^{th} animal; and e_{hijk} is the random residual effect. The Gibbs2f90 program (Misztal *et al.*, 2002) was used to estimate variance-covariance components. A single chain of 100,000 samples was generated, and 50,000 samples after a burn-in period of 50,000 cycles were used to estimate posterior means for the model parameters.

Results

Daily average values of BHB, DNM, DNF and PRF fluctuated widely in the early stages of lactation but stabilized in the mid to late stages (Figure 1). There were few differences among parities and regions except for BHB. A different pattern was shown in the early stages of lactation of BHB average changes for different parities and regions.

The heritability estimates of BHB were mostly stable at 0.1-0.2 throughout lactation (Figure 2). The heritability estimates of DNM were around 0.2 soon after parturition and rose to around 0.5 in the mid to late stages of lactation, similar to milk fat %. The heritability estimates of DNF were 0.1-0.3 and heritability estimates of PRF were 0.2-0.3 throughout lactation.

The genetic correlation between PEB and BHB was estimated to be -0.2 to -0.3 soon after parturition, decreasing in the mid to late stages of lactation (Figure 2). The genetic correlation between PEB and DNM was estimated to be -0.1 to -0.3 and remained negative throughout lactation. The genetic correlation between PEB and DNF was estimated to be about 0.4 soon after parturition and became negative in the late stage of lactation. In contrast, the genetic correlations between PEB and PRF were estimated to be about –0.25 soon after parturition but became positive in the mid to late stages of lactation. For both DNF and PRF, there was little difference between Hokkaido and the rest of Japan.

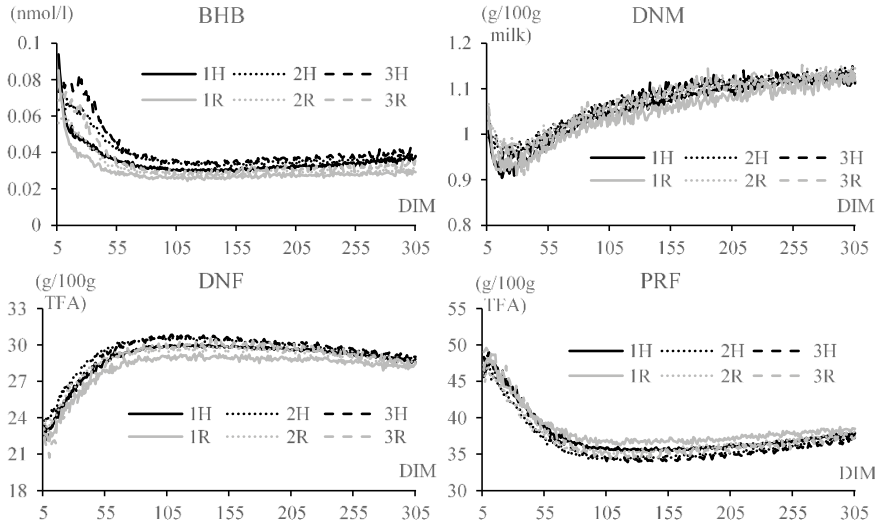

Figure 1. Changes in average BHB, DNM, DNF and PRF across days in milk (DIM) (1: 1st parity, 2: 2nd parity, 3: 3rd parity, H: Hokkaido, R: Rest of Japan, TFA: total fatty acids).

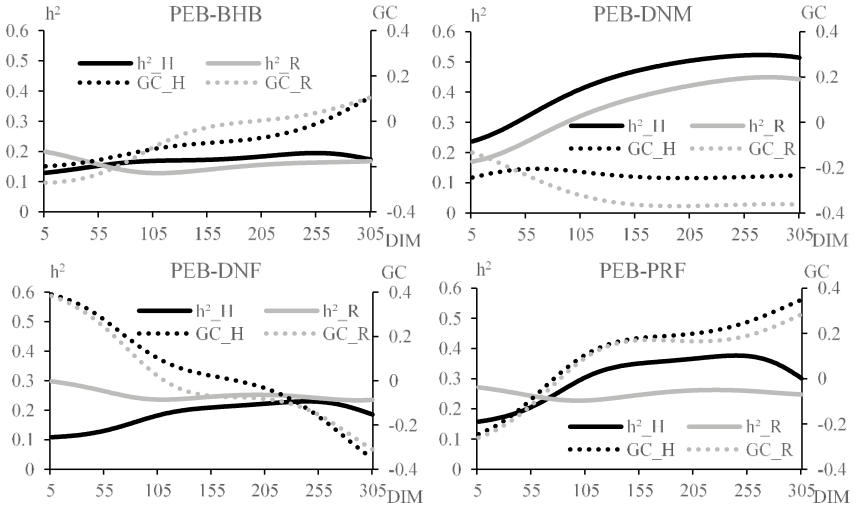

Figure 2. Changes in heritabilities (h^2) for BHB, DNM, DNF and PRF and genetic correlations (GC) between PEB and BHB, DNM, DNF and PRF across days in milk (DIM) (H: Hokkaido, R: rest of Japan).

Discussion

The heritability estimates for BHB were similar to those of Koeck *et al.* (2014) and Jamrozik *et al.* (2016) and can therefore be considered reliable. The genetic correlations of PEB and BHB were estimated to be negative in the early stages of lactation, consistent with the phenotypic relationship. However, the magnitude of these values were smaller than those of the genetic correlations between FPR and BHB (0.49: Koeck *et al.*, 2014). This may be because that FPR is a trait based on milk fat and protein, and genetic correlations between BHB and fat or protein were very high (Klein *et al.*, 2020), whereas EB is a trait estimated using

a more wide-ranging equation. The heritability estimates for *de novo* fatty acids were higher for DNM than for DNF: this was in good agreement with previous reports suggesting milk fat content to be a highly heritable trait (Bastin *et al.*, 2011). Some reports have indicated that shorter chain fatty acids tend to have higher heritability (Bastin *et al.*, 2011; Fleming *et al.*, 2018), but this was not seen in our results. The estimated heritability of PRF was in good agreement with that reported in previous studies (Stoop *et al.*, 2008; Mele *et al.*, 2008), so it appears that the heritability of DNF is slightly lower. This may be due to the multiple types and quantities of fatty acids present. For example, saturated fatty acids had a higher heritability than unsaturated fatty acids (Bastin *et al.*, 2011; Fleming *et al.*, 2018). A detailed analysis of fatty acid composition is needed to clarify this.

The genetic correlations between PEB and DNF and PRF appeared to be in good agreement with the phenotypic relationship in the early stages of lactation. The reason for the slight deviation from the phenotypic relationship between PEB and DNF and PRF in the late stages of lactation may be due to different mechanisms of energy metabolism and origin of milk components in the early and late stages of lactation.

In conclusion, PEB was estimated to have a desirable genetic correlation with BHB and fatty acid composition in the early stage of lactation. It therefore has potential for use as an index for improving the energy balance of Holsteins.

694. Associations between milk protein polymorphisms and milk production in Holstein-Friesian cows

D.N. Kelly[1*], F.L. Dunne[1], R.D. Evans[2] and D.P. Berry[1]

[1]Teagasc, Moorepark, P61 C996, Cork, Ireland; [2]Irish Cattle Breeding Federation, Bandon, P72 X050, Cork, Ireland; david.kelly@teagasc.ie

Abstract

Milk protein variants for beta casein (β-CN), kappa casein (κ-CN), and beta lactoglobulin (β-LG) affect different properties in milk influencing milk product manufacturing. The impact of selection on such variants on milk production in Irish Holstein-Friesian cows is, however, unknown. Mixed models were used to determine the associations between milk production and milk protein genotypes for β-CN, κ-CN, and β-LG in 13,095 lactation records from 5,431 cows. Presence of the β-CN A_1A_3 and A_2A_3 genotypes were associated with a greater milk yield, while the β-CN II and A_2A_3 genotypes were associated with a greater protein yield and concentration. The β-LG AA and BB genotypes were associated with a lower and higher fat concentration, respectively, relative to the AB genotype. The κ-CN AE and β-LG BB genotypes were both associated with a lower protein yield and a lower protein concentration.

Introduction

The impact of the major milk proteins namely beta casein (β-CN), kappa casein (κ-CN), and beta lactoglobulin (β-LG) on bovine milk composition and cheese making properties has been extensively studied (Gai *et al.*, 2021). For example, the presence of the β-CN B and A_1 variants or the κ-CN B variant is favourable for rennet coagulation (Gai *et al.*, 2021). Each genetic polymorphism for these milk proteins are mainly governed by a single base pair change on chromosome six for β-CN and for κ-CN and on chromosome 11 for β-LG; thus direct selection (or editing) for a specific milk variant could be relatively easily achieved. Nonetheless, before selection (or editing) for a specific milk protein variant takes place, the effect of the milk variants on other economically important traits must first be established. To that end, the impact of such variants on milk production in Irish dairy cows is unknown. Therefore, the objective of the present study was to quantify the association between milk genetic variants for three major milk proteins and milk production traits in a population of Irish Holstein-Friesian cows.

Materials & methods

Genotype data. Genotype data were available on animals genotyped with the custom International Beef and Dairy (IDB) v3 chip (Mullen *et al.*, 2013). Animals with a genotype call rate <95% were removed as well as single nucleotide polymorphisms (SNP) that were not called in at least 50% of the population. Genotypes were phased and imputed using FImpute (Sargolzaei *et al.*, 2014) in order to obtain parental haplotypes for the milk variants of β-CN, κ-CN, and β-LG. Only the milk protein variant data for β-CN, κ-CN, and β-LG for 9,069 dairy cows with a known sire and dam, of ≥87.5% Holstein-Friesian, and born from 2000 onwards were available.

Performance data. Only cows that calved for the first time between 540 and 1,240 d of age were retained (Ring *et al.*, 2021). Lactation records for milk yield, protein yield, fat yield, protein concentration, and fat concentration all adjusted to a 305-d mature equivalent were available for 33,257 lactations from 8,508 genotyped cows across 976 herds. Lactation records were removed if any milk trait deviated greater than three standard deviations from the parity mean. Lactation records following calvings that resulted in multiple births were excluded as were records where a calving event occurred <545 d or >545 d of age from the parity median. Contemporary groups were defined as per the Irish national dairy cow genetic

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_694, © D.N. Kelly *et al.* 2022

evaluations using an algorithm described in detail by Berry *et al.* (2013). Cows that calved within 10 days of each other in the same herd were initially clustered together. Contemporary groups with <10 records were clustered together if the interval between the first and last calving event per contemporary group did not exceed 100 days. Lactation records from contemporary groups with <15 records were removed from all analyses. Subsequently, 13,095 lactation records from 5,431 cows across 748 contemporary groups remained for analysis.

Statistical analyses. Associations between each milk variant genotype and performance were determined using a series of univariate animal models in DMU (Madsen and Jensen, 2008) as follows:

$$y = \text{parity}\times\text{age} + cg + \beta\text{-CN} + \kappa\text{-CN} + \beta\text{-LG} + cow_{pe} + cow_{a} + e \quad (1)$$

where y = milk yield (kg), fat yield (kg), protein yield (kg), fat concentration (%) or protein concentration (%); parity×age = fixed effect of the interaction between cow parity (1, 2, 3, 4, 5+) and age at calving (in months) relative to the parity median; cg = fixed effect of the contemporary group; β-CN = the fixed effect of β-CN genotypes; κ-CN = the fixed effect of κ-CN genotypes; β-LG = the fixed effect of β-LG genotypes; cow_{pe} = the random permanent environmental effect of the cow; cow_{a} = the random additive genetic effect; e = random residual effect. The pedigree of each cow was traced back at least four generations and contained 27,905 animals. The significance of the fixed effects for the milk protein genotypes were determined using likelihood ratio tests.

Results

The mean (± SD) milk yield, fat yield, protein yield, fat concentration, and protein concentration was 7,220.24 kg (±1,485.96 kg), 302.36 kg (±64.71 kg), 254.87 kg (±49.19 kg), 4.22% (±0.53%), and 3.55% (±0.25%), respectively. The β-CN genotypes of A_1A_2, A_2A_2, A_2I, and A_1A_1 were the most common in the sample population with genotype frequencies of 30.2, 23.2, 13.2 and 10.1%, respectively. The most common κ-CN genotypes were AB, AA, and BB with genotype frequencies of 45.5, 33.1, and 14.5% respectively. Similarly, the genotype frequencies of β-LG AB, AA, and BB were 49.9, 23.8 and 26.2%, respectively.

The estimated effects of the β-CN, κ-CN, and β-LG genotypes on the milk performance traits are in Table 1. A_2A_3 cows produced 623.83 kg (i.e. 8.55%) more than A_1A_2 cows. Cows with the β-LG BB genotype produced 64.67 kg (i.e. 0.89%) less milk than AB cows. Less milk was associated with the κ-CN BB genotype relative to the AA genotype. All of the β-CN FI, κ-CN BB, and β-LG AA genotypes were associated with a less fat yield compared to the respective reference genotypes. A_2A_3 cows produced milk with a 5.38% lower fat concentration than their A_1A_2 genotype contemporaries. β-LG AA cows had a 0.62% lower fat concentration, and BB cows had 0.72% higher fat concentration, than AB cows. κ-CN was not associated with fat concentration.

The β-CN genotypes A_2A_3, II, and A_2I had respective protein yields 8.02, 3.22 and 1.66% higher than the A_1A_2 genotype. Similarly, compared to the A_1A_2 genotype, the β-CN genotypes BF, II, A_1I, A_2I, and A_1A_1 were associated with a 2.47, 2.02, 1.07, 0.99 and 0.60% higher protein concentration, respectively. In contrast, the κ-CN AE and β-LG BB genotypes were both associated with a less protein yield and a lower protein concentration than their respective reference genotypes of κ-CN AB and β-LG AB.

Discussion

Modern large-scale genotyping programs use SNP-chips that also contain probes to call major genetic variants. These data are being relayed back to the producer who, in turn, are rightly questioning the value of such data and the impact of selection on individual variants. Evidence is clear that some of the casein

[1] Solutions were relative to the genotypes of A_1A_2 for beta casein, AB for kappa casein, and AB for beta lactoglobulin.

variants are favourable for cheese manufacturing, including rennet and acid coagulation properties (Gai *et al.*, 2021). This could prompt milk processors to actively promote the use of dairy sires carrying those alleles or the creation of herds with favourable allele combinations aligned to the product portfolio of the processor. Prior to embarking on such an aggressive strategy, the impact on other performance traits should firstly be quantified prompting this study.

The A_2-type β-CN variants include A_2, A_3, and I and allele combinations of these variants (i.e. A_2A_3, A_2I, II) generally had more favourable relationships with protein yield and concentration than the A_1-type variants; these A_2-type variants are also associated with higher casein yields (Gai *et al.*, 2021). Milk with A_2-type β-CN variants, however, is not always desirable for cheese manufacturing due to poor rennet coagulation but may be more suitable for yoghurt products (Gai *et al.*, 2021). The greater protein concentration associated with the κ-CN BB genotype, compared to the AA and AB genotypes, is advantageous as a desirable shorter

rennet coagulation time and higher cheese yield is associated with this genotype (Gai *et al.*, 2021). On the other hand, there must be cognisance of the trade-off between the higher protein content but lower milk and fat yield associated with the κ-CN BB genotype; the genotype frequency of κ-CN BB genotype is actually higher within the sample population used in the present study compared to other Holstein/Friesian populations (Gustavsson *et al.*, 2014; Comin *et al.*, 2008). The present study demonstrates that variation exists in the milk production of Holstein-Friesian cows of different milk variant genotypes. Producers or processors that wish commence selection (or editing) for individual variants or allele combinations should remain mindful of the potentially adverse, as well as favourable, impacts of such an approach on economically important milk production traits.

Abstract

The aim of this study was to estimate heritabilities and breeding values for milk flow (MF), dead milk time (DT) and milking time (MT) using the records of 3,069 primiparous Holstein cows collected by an automatic milking system. Estimated heritabilities using the three-trait animal model was 0.37 for MF, 0.22 for DT and 0.29 for MT. Genetic correlations among the traits ranged from 0.76 to 0.88 on an absolute scale. While the genetic trends of MF and MT were slightly positive, a negative trend was observed for DT. The results of this study suggest that genetic improvement of these milking traits is feasible. The breeding value of milking traits was correlated with the somatic cell score, udder traits and milking speed. These traits can be used as indicators for indirect selection of milking traits.

Introduction

The automatic milking system (AMS) is an effective tool to reduce labour cost and increase milk production; thus, the number of dairy herds using AMS has dramatically increased in Japan. AMS can also collect detailed milking information for milking cows (Aerts *et al.* 2021). Santos *et al.* (2018) suggested that compared to conventional milking systems, AMS data could provide a more accurate estimation of genetic parameters for milk production and milking traits. In addition, AMS offers the ability to assess traits where genetic evaluation has not been implemented. Therefore, further analysis of these data may help improve the efficiency of milking cows (Wethal and Heringstad 2019).

To increase the efficiency of AMS operation, cows with faster milk flow and milking time are preferable. In this study, we aimed to estimate genetic parameters and breeding values for milk flow (MF), dead milk time (DT) and milking time (MT) in Japanese Holstein cows. In addition, genetic relationships between milking traits and milk production, type traits, milking speed which is scored subjectively on a 5-point scale and Nippon total profit index were investigated.

Materials & methods

Data. We used the records of primiparous Holstein cows, which were collected by the Livestock Improvement Association of Japan and Hokkaido Dairy Milk Recording and Testing Association, from 2007 to 2021 at 249 dairy herds with Lely AMS. The following were excluded: (1) individuals moved to the other herd between 5 and 305 days in milk; (2) milking records with extreme intervals from last milking (i.e. <1 hour or >24 hours); and (3) cows with unknown parents. A total of 967,531 AMS records consisting of 3,069 animals were available for genetic analysis.

Three milking traits were considered in this study: MF (kg/min), which is the average milk flow rate during milking; DT (sec), which is the time gap between cluster attachment and start of milking; and MT (min), which is the time difference between milking start and cluster removal time. Traits were averaged for every milking. Descriptive statistics for the milking traits are presented in Table 1. The averages of the traits were 2.7 kg/min for MS, 17.4 sec for DT and 3.3 min for MT.

Table 1. Means, standard deviations (SD), minimum, and maximum values for milking traits.

Trait	N	Mean	SD	Minimum	Maximum
Milk flow (kg/min)	967,531	2.7	0.90	0.2	9.0
Dead milk time (sec)	967,531	17.4	8.46	2.0	60.0
Milking time (min)	967,531	3.3	1.28	1.0	10.2

Model. The three-trait animal model was used for genetic analysis of milking traits. We considered the same effects in the model, as shown in the following equation:

$$y_{ijklmn} = HYS_i + CA_j + CM_k + SOL_l + u_m + pe_m + e_{ijklmn}$$

where y_{ijklmn} is the observation; HYS_i is the fixed effect of the i-th herd-year-season (1,542 levels); CA_j is the fixed effect of the j-th calving age (14 levels); CM_k is the fixed effect of the k-th calving month (12 levels); SOL_l is the fixed effect of the l-th stage of lactation (10 levels); u_m and pe_m are random effects for the m-th cow for additive genetic and permanent environmental effects, respectively; and e_{ijklmn} is the random residual associated with each record. The season at HYS_i was grouped into four categories of March to May, June to August, September to November and December to February. We used 13,950 pedigree animals that were traced back up to three generations from cows with records.

Genetic parameters and breeding values were estimated using the AIREMLF90 and BLUPF90 programs, respectively (Misztal *et al.*, 2002). To investigate genetic relationships with other traits, Pearson correlations between breeding values of the milking traits and milk production, type traits, milking speed, and Nippon total profit index were calculated. The breeding values of their traits except milking traits, were obtained from the national genetic evaluation in August 2021 by the National Livestock Breeding Centre (Fukushima, Japan).

Results

Estimates of heritabilities for milking traits and their genetic and phenotypic correlations are presented in Table 2. The heritabilities ranged from 0.22 to 0.37. While strong genetic correlations were estimated on an absolute scale with a range of 0.76 to 0.88, the phenotype correlations were moderate.

The genetic trends of milking traits for cows with records and domestic sires (n=347) with at least one daughter are shown in Figure 1. Genetic bases were based on cows born in 2015. While slight positive trends were observed for MF and MT, DT showed a slightly negative trend.

Pearson correlations between the breeding values of milking and other traits are presented in Table 3. In the cows, all milking traits were significantly correlated with the protein yield, somatic cell score, mammary system, front teat length, milking speed and Nippon total profit index. On the other hand, in domestic sires, significant correlations with the somatic cell score, udder depth and milking speed were found.

Discussion

Heritabilities of milking traits was moderate, and the values for MF and MT were similar to those in previous reports, which ranged from 0.25 to 0.55 for MF and 0.19 to 0.42 for MT (Aerts *et al.*, 2021; Carlstrom *et al.*, 2013; Carlstrom *et al.*, 2014; Dechow *et al.*, 2020; Santos *et al.*, 2018). To the best of our knowledge, no study has reported the heritability of DT. The results of this study suggest that the improvement of these traits can be achieve through genetic selection.

There were strong genetic correlations among milking traits, as previously reported by Dechow *et al.* (2020) and Santos *et al.* (2018). We observed negative genetic correlations between MF and the other milking traits, MT and DT. This suggests that genetic improvement for faster MF can lead to a shorter DT and MT. Since the records of milking traits were collected only from dairy herds with AMS, indirect selection by traits that which have been routinely evaluated in national genetic evaluation can be one way to improve milking traits. Therefore, the somatic cell score, udder traits and milking speed, which were genetically related to milking traits in this study, are expected to be valuable indicators of genetic improvement.

The results of the genetic trend for MF and DT indicated that milk flow and the time from teat cup attachment to milking improve annually. A slight positive trend of MT may be caused by genetic improvement in milk production.

Abstract

The present research aimed to describe the genetic parameters and correlations among fertility traits of Holstein cattle from Mexico and their changes over time. The reproductive parameters (RP) included were: calving interval to first service, number of inseminations per conception, days open, calving interval, and age at first calving. The study included female records provided by the Mexican Holstein association (2006-2019). Variance components for the mentioned RP were estimated using restricted maximum likelihood and an animal model using the BLUPF90 software. Heritability estimates ranged from 4 to 9%, and repeatability estimates between 8 and 9%, similar to previously reported for fertility traits. The phenotypic and genetic correlations showed positive values among almost all RP. Estimates of additive genetic variance in the analyzed sample showed changes over time for the fertility characteristics of Mexican Holsteins probably due to the implementation of genomic selection in the origin populations of imported germplasm.

Introduction

Fertility is one of the factors of utmost importance in productivity, because its decrease can be the cause of economic losses. Genetic fertility studies are important to support the future profitability of production systems and reduce waste generated by poor fertility. Genetic parameters (heritability and repeatability) are specific to the populations or subpopulations evaluated and can vary through the years, so their estimation is justified in the Holstein population of Mexico. Considering that the fertility characteristics have been improved in Holstein cattle in the United States and that Mexico has imported germplasm from the US, it is possible that the latter shows changes over time in these traits even though no direct selection has been applied for these traits. The objectives of this study were to describe the parameters, correlations and genetic trends of reproductive traits in Holstein cattle from Mexico.

Materials & methods

Reproductive data and parameters analyzed. This study included 415,859 reproductive records of Holstein cows (*Bos taurus taurus*) from January 2006 to December 2019, information provided by the Mexican Holstein association. The reproductive parameters calculated were: calving to first insemination (CFI), number of services per conception (NSC), days open (DO), calving interval (CI) and age at first calving (AFC).

Variance components. Variance components were estimated with an animal model, using restricted maximum likelihood (Patterson and Thompson, 1971), and running the BLUF90 program (Misztal *et al.*, 2014). The general model used was:

$$y = Xb + Zu + e \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_696, © C. Durán-Alvarez *et al.* 2022

where y = vector of the records of: CFI, NSC, DO, CI or AFC; b = vector of fixed effects (herd-year-station (hys), production level (np), calving number (nop), calving age (ep) and herd-year-season of birth for AFC (hysn)); u = vector of random effects (effect of the animal and permanent environment when applicable); X and Z = incidence matrices that relate the observations to the fixed or random effects, respectively; e = vector of the effects of the error or residuals.

Genetic parameters and correlations. Heritability, repeatability and genetic correlations were obtained from the estimates of the variance components. The standard deviation of the estimated parameters was approximated from their expectations using the REMLF90 program (Misztal, 2002).

Analysis by periods. Considering the exchange of germplasm between the United States and Mexico, as well as the changes in the values of the genetic parameters of the former, the data was grouped into three periods (P1: 2006-2009, P2: 2010-13 and P3: 2014-2017).

Results

Genetic parameters and correlations. The heritability of the reproductive parameters ranged from 4 to 9%, while the repeatability estimates were around 8% (Table 1).

The estimated phenotypic and genetic correlations are shown in Table 2.

Table 1. Number of records and individuals with phenotypic information included in the study, as well as descriptive statistics and genetic parameters.[1]

NSC-CI	139,901	5.93	0.78*	0.88 (0.02)
NSC-AFC	84,675	0.05	0.01*	0.22 (0.08)
DO-CI	137,158	224.60	0.98*	0.99 (0.002)
DO-AFC	80,467	0.82	0.06*	0.09 (0.08)
CI-AFC	62,999	1.04	0.07*	0.12 (0.11)

[1] CFI = interval to first service in days; NSC = number of services per conception; DO = days open; CI = calving interval in days; AFC = age at first delivery in months; * $P<0.001$, in parentheses the standard deviation.

Analysis by periods, additive genetic variance. The results can be divided into two groups of comparisons, group I: period 1 and 2, and group II: period 2 and 3 (Table 3). The additive genetic variances for group I were similar for all traits except for AFC which showed a significant decrease. In group II there was an increase in CFI, a decrease in NSC, DO and CI while the AFC was similar.

Genetic values. Figure 1a and 1b show how, in general, average BV was similar between P1 and P2, decreasing in P3.

Table 3. Additive genetic variance for five reproductive parameters in three time periods (P1: 2006-2009, P2: 2010-13 y P3 2014-2017).[1]

RP	Period	$\sigma^2_a \pm$ SD
CFI	P1:06-09	12.48±2.2
	P2:10-13	11.17±2.0
	P3:14-17	19.88±3.0
NSC	P1:06-09	0.15±0.02
	P2:10-13	0.16±0.02
	P3:14-17	0.10±0.02
DO	P1:06-09	229.8±35.32
	P2:10-13	214.6±33.87
	P3:14-17	194.8±25.66
CI	P1:06-09	478±51.1
	P2:10-13	466.7±52.5
	P3:14-17	266.8±53.9
AFC	P1:06-09	1.23±0.12
	P2:10-13	0.19±0.04
	P3:14-17	0.15±0.03

[1] CFI = interval to first service in days; NSC = number of services per conception; DO = days open; CI = calving interval in days; AFC = age at first delivery in months; σ^2_a = additive genetic variation; SD = standard deviation.

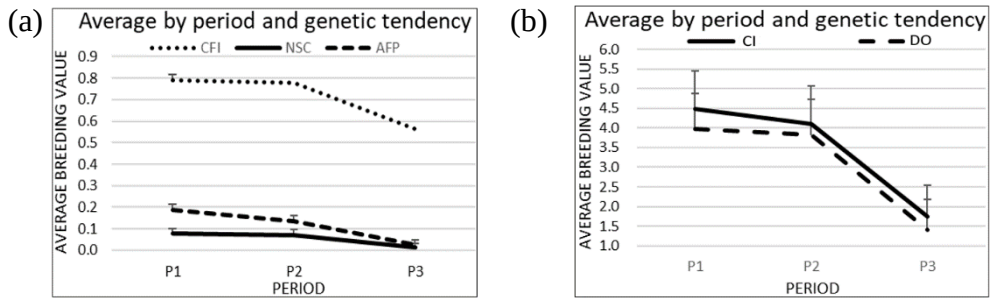

Figure 1. Trends of the average genetic values for CFI, NSC, AFP (a) and CI, DO (b) for the Holstein population of Mexico in three time periods.

Discussion

Phenotypic averages of the five reproductive parameters were similar to those previously reported in other dairy cattle populations (Weigel and Rekaya 2000; Ríos-Ultrera *et al.*, 2010). The variations could be due to the fact that there is no consensus on the biologically acceptable limits of the measurements of these characteristics, which generates possible biases to the estimates and, on the other hand, the fertility characteristics vary between individuals largely due to the environment (Ghiashi *et al.*, 2011).

The heritability and repeatability estimates were found within previously reported limits (González-Recio and Alenda 2005). The estimated values in the Holstein population of Mexico are low, less than 10%, so that in addition to genetics, the environment and management issues as a source of variation have an important effect (Weigel and Rekaya, 2000). Making genetic improvement of reproductive traits will allow permanent benefits in the populations, unlike improvements in management (environments), which offer benefits temporarily.

The phenotypic and genetic correlations showed positive values between the reproductive parameters (Table 2), similar to those reported (González-Recio and Alenda, 2005, Ríos-Ultrera *et al.*, 2010) The high genetic correlation between DO-CI of 0.99, as reported by González-Recio and Alenda (2005) and by Ghiashi *et al.* (2011), suggests that these two traits, are almost equivalent.

When comparing additive genetic variance changes across time, in P1 vs P2 we observe a decrease for age at first calving, possibly due to the selection. In the second period (P2 vs P3), there was an increase in CFI, which tells us about genetic diversity and the greater the genetic diversity, the greater the opportunity for the response to selection (Oldenbroek, 2017); while decreases were observed for NSC, DO and CI. Average genetic values were similar in the first two periods but showed a decrease for four of the five reproductive parameters (CFI, DO, CI and AFC) from P2 to P3, this reduction in genetic values being desirable. These changes in fertility traits could be attributed to the incorporation of genomic information in the selection processes in the United States as of 2009, as shown by Wiggans *et al.* (2017), and García-Ruiz *et al.* (2016), because of the use of germplasm imported mainly from the United States. For the NSC, no changes were observed in the genetic values.

Our result suggest that it would be convenient to select only for one parameter, since it could be considered that its effects are controlled by the same genetic regions (i.e. they are the same trait).The estimates of additive genetic variances and genetic values in different periods showed the existence of changes over time in our population, possibly derived from the influence of the use of germplasm from imported bulls from countries where genomic selection has been implemented.

Abstract

This is a preliminary study on estimating genetic parameters for dry matter intake (DMI), BW and residual feed intake (RFI) using 3D cameras in 4,069 cows from three dairy breeds. Weekly records of DMI and BW were recorded during 2019-2021 for 1,643 Holstein, 1,211 Jersey and 1,215 Red Dairy Cattle (RDC) cows at Danish commercial farms. Estimated heritabilities for DMI ranged from 0.23 to 0.34, whereas for BW ranged from 0.38 to 0.49. Estimated heritabilities for RFI were 0.19 for Holstein, 0.15 for Jersey and 0.16 for RDC. Genetic correlations between DMI and BW were moderate positive (0.23-0.57), whereas, the genetic correlations between RFI and DMI were highly positive (0.76-0.98) and between RFI and BW were low positive (0.28) to close to zero. With these results we conclude that feed efficiency (RFI) calculated using DMI and BW measured by 3D cameras (and ECM) is heritable for the three dairy breeds.

Introduction

In the last decade, several countries have included feed efficiency in their breeding goal (Veerkamp *et al.* 2014; Pryce *et al.* 2015, Holstein USA, 2021). The Saved feed index in the Nordic Total Merit Index (NTM; NAV, 2020) now includes the breeding value for metabolic efficiency and maintenance (Lidauer *et al.*, 2019). Residual feed intake (RFI) has been proposed as proxy trait for feed efficiency in several species including cattle, pig and poultry (Martin *et al.* 2021). RFI is usually calculated as the partial regression of dry matter intake on energy sinks (energy-corrected milk; ECM, metabolic body weight; MBW, and BW change; Tempelman *et al.* 2015). As dry matter intake (DMI) and BW records are required to calculate RFI, new technologies are being developed to increase the number of individual records in an easier and more efficient way. In the last years, a 3D camera's technology to measure feed intake and body weight (BW) on individual cows at large scale has been developed. Using artificial intelligence and 3D cameras, the Cattle Feed InTake System (CFIT, Viking Genetics, 2020; Lassen *et al.* 2018) is an alternative tool to record individual feed intake and BW compared to scale based systems. The CFIT 3D cameras, located in barns, can identify individual cows and by using artificial intelligence algorithms, record individual DMI and BW for the entire herd. The squared correlation between traditional feed bins and 3D cameras is 0.9 (Lassen *et al.* manuscript submitted to WCGALP 2022). However, as with every new phenotype, the traits (DMI and BW) need to be quantified genetically. In this study, we estimated the genetic parameters including genetic correlations between DMI, BW (obtained by 3D cameras) and RFI from 4,069 Danish Holstein, Jersey and RDC commercial cows.

Materials & methods

Data description. The data included weekly records of DMI and BW from 4,069 Danish cows. Only data from 1st to 6th parity from the first 330 days in milk was utilized. The cows were recorded for DMI and BW using 3D cameras technology on 12 (4 per breed) commercial farms in Denmark during 2019-2021. The cows were fed with a total mixed ration diet that mainly consisted of maize silage, grass silage and concentrates. The cameras were located above the feeding area floor, and the cows were recorded when eating. An algorithm based on artificial intelligence identify the cows and translate their 3D images into phenotypes (DMI and BW). Lassen *et al.* (2018) have presented a description of the 3D cameras

methodology to measure feed intake. Body weight is also predicted using 3D images of the back of the cow, from these images, contours of the back were obtained. Using a PLS method, a prediction model was developed based on scale measures of the cows. Posteriorly DMI and BW weekly averages were calculated. Residual feed intake (RFI; Tempelman *et al.*, 2015) was the residual of the partial regression of DMI on metabolic BW (MBW), energy corrected milk (ECM) and body weight change (ΔBW). The model used to calculate RFI is the one used to calculate the breeding values for RFI by the Nordic Cattle Genetic Evaluation (NAV; Stephansen *et al.* 2021). Milk yield and content were available through the national milk recording system. Metabolic BW (MBW) was defined as $BW^{0.75}$. Body weight change (ΔBW) is described as change in kg per day. As the recording cameras were installed at different times at the different farms, there is a great variation in the number of records available per animal. These records are also at different times of the lactation. For this reason, a repeatability model was not considered at this time. Instead, averages per animal per lactation for DMI, BW and RFI were calculated. Given that only quarter of the animals have more than one lactation, only one lactation per animal was considered.

Statistical analyses. A univariate animal model was performed to estimate the variance and covariance components using DMU software (Madsen and Jensen 2014) for each trait. To estimate the genetic correlations, pairwise bivariate models between the three traits were fitted.

The general model used to estimate the variance components for DMI, BW, and RFI was:

$$y = Xb + Z_1a + e \quad (1)$$

Where y is the vector of phenotypes (DMI, BW, RFI); b represent the vector of fixed effects (herd-year; parity and age of cow); X is the incidence matrix relating observations with fixed effects; a is the vector of direct additive genetic effects; Z_1 is the incidence matrix relating observations with random genetic effects; and e is the vector of residual effects. Distributions of the random effects are $var(a) = A\sigma^2a$ where A is the pedigree relationship matrix, and $var(e) = I\sigma^2e$, where I is an identity matrix of an order equal to the number of observations and σ^2e is the residual variance. The pedigree for Holstein included 8,349 cows, whereas, for Jersey 5,405 cows and for RDC 7,963 cows.

Results

Descriptive statistics for DMI, BW, and RFI in Danish Holstein, Jersey and RDC cows are presented in Table 1. DM content was assumed to be 40%. The mean DMI was 27.9 kg/d in Holstein, 22.1 kg/d in Jersey and 27.6 kg/d in RDC. While, the mean BW was 680.6 kg for Holstein, 454.4 for Jersey and 658.2 for RDC. Genetic variances, heritabilities, genetic correlations, and phenotypic correlations of DMI, BW, ECM and RFI in Danish Holstein cows are shown in Table 2. Estimated heritabilities for DMI were 0.34, 0.23 and 0.30, for Holstein, Jersey and RDC. Whereas, for BW were 0.42, 0.38 and 0.49; and for RFI were 0.19, 0.15 and 0.16 for Holstein, Jersey and RDC respectively. Genetic correlations between DMI and BW ranged from 0.23 to 0.57 for the three breeds. RFI and BW showed low correlations (0.06 to 0.26) with large standard errors. Additionally, genetic correlations between DMI and RFI were highly positive for the three breeds (0.76 to 0.98).

Discussion

The average DMI for Holstein were slightly higher than previously reported (19.5 kg/d and 607 kg) for Danish Holstein cows by Difford *et al.* (2020). Additionally, Li *et al.* (2018) reported lower DMI and BW averages for the three breeds in primiparous Nordic cows measured within 32 weeks of lactation (Holstein= 19.4 kg/d and 601.2 kg; Jersey= 15.8 kg/d and 433.0 kg; RDC=18.5 kg/d and 575.1 kg, respectively).

Table 1. Descriptive statistics for dry matter intake (DMI), body weight (BW), energy corrected milk (ECM), residual feed intake (RFI) in Danish Holstein, Jersey and Red Danish (RDC) cows with number of animals in parenthesis.

	Holstein (n=1,643)				Jersey (n=1,211)				RDC (n=1,215)			
Trait	Mean	SD	Min	Max	Mean	SD[1]	Min	Max	Mean	SD	Min	Max
DMI	27.9	4.0	17.9	39.8	22.1	3.5	12.3	33.9	27.6	3.4	14.1	36.3
BW	680.6	76.3	449.9	907.3	454.4	40.6	351.3	568.2	658.2	76.0	428.0	889.2
RFI	0.0	1.2	-4.4	4.8	-0.1	2.0	-6.5	6.5	0.0	1.4	-5.3	4.8

Table 2. Genetic and phenotypic variances, heritabilities (diagonal), genetic correlations (lower diagonal) and phenotypic correlations (upper diagonal) of dry matter intake (DMI, g/d), body weight (BW, kg), residual feed intake (RFI, g/d) in Danish Holstein, Jersey and Red Danish (RDC) cows with standard errors in parenthesis.

Breed	Trait	σ^2_a	σ^2_e	DMI	BW	RFI
Holstein	DMI	1.6	3.0	**0.34 (0.06)**	0.49 (0.01)	0.72 (0.01)
	BW	1,352.7	1,857.8	0.57 (0.09)	**0.42 (0.06)**	0.07 (0.01)
	RFI	0.3	1.2	0.76 (0.07)	0.12 (0.15)	**0.19 (0.05)**
Jersey	DMI	1.8	5.9	**0.23 (0.07)**	0.24(0.02)	0.84 (0.01)
	BW	304.6	488.5	0.23 (0.17)	**0.38 (0.07)**	0.24 (0.02)
	RFI	0.6	3.5	0.98 (0.02)	0.06 (0.15)	**0.15 (0.05)**
RDC	DMI	1.8	4.1	**0.30 (0.07)**	0.42 (0.03)	0.67 (0.02)
	BW	1,732.4	1,782.1	0.50 (0.12)	**0.49 (0.07)**	0.06 (0.03)
	RFI	0.3	1.6	0.80 (0.09)	0.26 (0.18)	**0.16 (0.06)**

Genetic parameters and correlations. Estimated heritabilities for DMI (Table 2) using 3D cameras were within the range (depending on the lactation week) reported by Li *et al.* (2016, 2018) for the 3 breeds (0.30-0.55 for Holstein; 0.17-0.0.52 for Jersey; and 0.20-0.48 for RDC) in primiparous Nordic cows. Likewise, estimated heritabilities for BW were within the range reported by Li *et al.* (2018) for the 3 breeds, ranging from 0.49 to 0.63 in Holsteins, and from 0.46 to 0.61 in Jersey cows, whereas in RDC was from 0.32 to 0.53. Additionally, NAV (2021) reported heritabilities between 0.51 and 0.53 for second and third lactation Holsteins and Jersey cows. Furthermore, Difford *et al.* (2020) reported higher heritabilities for DMI (0.43), BW (0.52) and RFI (0.21) for Danish Holstein cows measured with conventional methods. Finally, heritabilities for RFI reported by Li *et al.* (2017) were similar (0.10-0.23) than the reported in this study (0.19) for Holstein. Moderate to high genetic correlations were estimated between DMI and BW, these values were within the range of values previously reported (0.3-0.7) for Danish Holstein and RDC cows across lactation stages with traditional methods (Li *et al.* 2018). Furthermore, Manzanilla-Pech *et al.* (2017) reported lower genetic correlations (0.43) between DMI and BW in Dutch Holstein cows. Genetic and phenotypic correlations between RFI and DMI were large and positive as expected given that RFI is the residual of DMI after been corrected by energy sinks. Thus, genetic and phenotypic correlations between RFI and BW were between low positive and close to zero (with large standard errors) as expected, as RFI has been corrected by BW. This study has showed that 3D phenotypes (DMI and BW) are heritable and their heritability is comparable to the heritabilities reported with conventional measuring methods. Furthermore, feed efficiency (RFI) calculated using DMI and BW measured by 3D cameras is also heritable. The results of this study are promising, endorsing a new technique of recording feed intake and body weight that has be implemented in commercial farms. We conclude that feed intake, efficiency and body weight measured by 3D cameras are heritable traits, endorsing a new technology of recording feed intake

and weight that has be implemented in commercial farms allowing to measure feed intake in a larger and efficient way.

698. Insemination values to support mating decisions under dairy heifer calf herd size constraints

A. De Vries[1*], N. Bliznyuk[1], P. Sharma[1], Y. Han[1] and P. Pinedo[2]

[1]University of Florida, P.O. Box 110910, Gainesville, FL 32611, USA; [2]Colorado State University, 307 University Ave, Fort Collins, CO 80523, USA; devries@ufl.edu

Abstract

Dairy producers have many factors to consider regarding insemination of dairy cattle, including semen type (sexed, conventional), semen breed (dairy, beef), price, and probability of conception based on sire and dam factors. Usually, the decisions are constrained by the need to produce a certain number of dairy heifer calves. To aid decision making, we calculated insemination values for each potential sire mated to every non-pregnant cow based on dynamic programming. We also calculated the probability of a live heifer calf born for each possible mating. Herd profitability is maximized by choosing per cow the sire with the greatest insemination value, subject to generating a target number of dairy heifer calves per batch of inseminations. We used a mixed integer linear program to make individual mating decisions. An illustration with 50 open cows showed opportunity cost from $3 to $10 per mating if matings are based on calf values instead of insemination values.

Introduction

Dairy producers have many options when it comes to mating their heifers and cows. In the last decade, the options have expanded to the availability of sexed dairy and beef semen from multiple sires. Combined with much better reproductive performance on dairy farms, dairy producers now also need to plan for the right size of the heifer inventory to replace cows to be culled and herd expansions.

The ability to accurately predict the probability that an insemination results in a pregnancy and subsequent calving is also increasing due to activity sensors, information contained in past health events, and genetic merit of reproduction traits. The mating decision further depends on the expected genetic merit of the calf, the level of inbreeding, and the price of semen. The best decision could be to delay insemination, do-not-breed, or replace the cow. Collectively, these many factors call for better guided mating decisions with the goal to increase profitability while meeting herd constraints such as a required number of dairy heifer calves.

Research conducted decades ago on optimization of replacement and insemination decisions (Van Arendonk, 1988; Mourits *et al.*, 1999) provides direction for the further development of insemination values to support mating decisions. The objective of our project is to develop and deploy insemination values for individual mating pairs subject to producing a target number of dairy heifer calves. If successful, this outcome is an important step towards solving a practical problem on many US dairy farms.

Materials & methods

Dynamic programming models. Economically optimal mating decisions result in the highest profit subject to constraints. Conceptually, this involves a comparison of future cash flows resulting from each decision and making the decision that results in the greatest net present value (NPV) of future cash flows. Cash flows can be optimized by also taking optimal decisions in the future, for example, by calculating when to optimally stop inseminating cows that have failed to get pregnant. Such decisions that span several points in time often break apart recursively. Dynamic programming (DP) is a mathematical optimization

CC BY

DOI: 10.3920/978-90-8686-940-4_698, © A. De Vries *et al.* 2022

method that can be used to simplify a decision by breaking it into simpler sub-problems in a recursive manner. See De Vries (2006a) and Nielsen and Kristensen (2015) for an overview in livestock.

For this project, we developed two related DP models: a herd DP model and an individual cow DP model. We developed a new herd DP model that used value-iteration to optimize replacement and insemination decisions for cows. The DP model had weekly steps, 10 lactations, 140 weeks in milk, 3 oestrus cycle states, 40 weeks of pregnancy, and 3 types of sires for matings (sexed dairy, conventional beef, conventional dairy), and 9 levels of economy-corrected milk. A bio-economic module included biological functions such as lactation curves for milk, fat and protein, dry matter intake, body weight, and probabilities of involuntary culling, oestrus detection, and conception. Prices were added and weekly revenues and costs were calculated per state. Transition probabilities between states were calculated based on biological functions and model decisions, for example when the cow was culled and replaced with a calving heifer. Starting from arbitrary starting conditions, the DP model ran until convergence was reached and steady-state results were obtained. Convergence criterion was the weekly change in NPV of the cash flow from a calving heifer. This change equals the expected weekly profit of the herd in steady state conditions.

Although this herd DP model contains optimal mating decisions for the states in the model that represent cows eligible for mating, these decisions were not used further. Instead, the model then was run for another 100 weeks while the NPV of cash flows of the first week in milk for each lactation and level of economy-corrected milk were saved. This 3-dimentional matrix of NPV of cash flows (100 weeks × 10 lactations × 9 levels of economy-corrected milk) was stored for use by the individual cow DP model, as follows.

Although herd DP models may contain millions of states, in practice some cows may not be well represented. Even in large herds, cows are unique and vary in many attributes relevant for future cash flow predictions, such as expected milk production, health risks, fertility, genetic merits of many traits, body weight, dry matter intake, etc.

The accuracy of cash flow predictions of individual cows can be improved by separating calculations for the current lactation from those for future lactations (De Vries, 2006b). The idea is to model the biological performance in the remainder of the current lactation for individual cows as accurately as possible and apply DP to only the current lactation for mating and replacement decisions. The NPV of cash flows after the cow calves again, or if she is replaced before calving again, are read from the stored 3-dimentional matrix using the most appropriate lactation number, economy corrected milk levels, and weeks into the future. This individual cow DP model is run separately for every cow in the herd for which mating decisions need to be made. This solution allows for every cow to have her own lactation curves, probabilities of conception and abortion, body weight, dry matter intake, health risks, genetic merit, etc. in the current lactation. It also allows for accurate valuing of the calf that follows from a mating.

Insemination values. An insemination value is the NPV of the cash flow following an insemination, minus the NPV of the cash flow when the decision is to delay the insemination (Mourits *et al.*, 1999). The decision to delay implies that the cow may be inseminated at a future insemination opportunity, for example in the next oestrus cycle, or be replaced with a calving heifer, as determined by the individual cow DP model. The decision to inseminate includes the cost of semen, the probabilities of conception, abortion and involuntary culling, and the probability a dairy heifer calf will be born whose value depends on the genetic merit of the dam and service sire.

An insemination value is calculated for every sire considered for a cow's mating. Sire attributes include semen price, relative probability of conception and abortion, genetic merit, and sex and breed of the calf. The DP models make the mating decision that results in the highest cash flow, which is equivalent to the decision associated with the highest insemination value. However, for actual decision support for cows that need a mating decision today, all insemination values are presented to the decision maker. In addition, the probability that a mating results in the birth of a live dairy heifer calf is also calculated.

Mixed integer linear program. Herd profitability is in theory maximized when the mating with the highest insemination value is chosen for each cow. However, this policy may result in more or fewer dairy heifer calves than are needed. The problem now is one of maximizing the sum of insemination values in a batch of cows, subject to the required number of dairy heifer calves. A simple mixed integer linear program solves this problem.

Illustration. We obtained cow records from a herd of 1,007 cows. Using default prices, we first ran the herd DP model and stored the 3-dimentional matrix of NPV of future cash flows. Next, we calculated 3 insemination values and three probabilities of a live dairy heifer calf for every non-pregnant cow, considering sexed, conventional, and beef semen. We also calculated the value of the calf for each mating pair. Finally, we determined optimal mating decisions for a batch of 50 cows eligible for insemination, subject to bounds on the number of dairy heifer calves.

Figure 1 shows the 150 insemination values for the 50 cows. The values ranged from -$34 to +$96. Unbound by the number of dairy heifer calves, the profit maximizing mating decisions resulted in a sum of insemination values of $2,430, equivalent to $48.50 per cow. This policy resulted in 4.57 expected dairy heifer calves. Table 1 shows the average insemination values if the policy is bound by a minimum and maximum number of dairy heifer calves. Bounds on the number of dairy heifer calves reduce the average insemination values. The opportunity cost shows the loss per mating if mating decisions were based on the highest calf values instead of the highest insemination values.

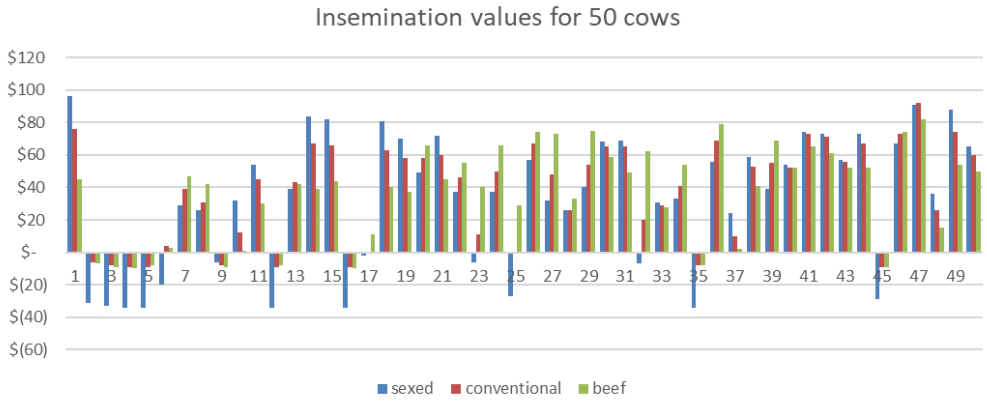

Figure 1. Insemination values for 50 cows. Each cow has 3 insemination values reflecting mating options with sexed dairy, conventional dairy, and conventional beef semen.

Table 1. Average insemination values, calf values and opportunity cost for matings of 50 cows bound by a window of the number of dairy heifer calves.

Mating	# dairy heifer calves			Inseminations (50 cows)				Average	Opportunity
criterion	min	max	actual	#sexed	#convent	#beef	#delay	ins. value[1] ($)	cost/insem. ($)
Ins. value	0	50	4.571	21	3	17	9	48.60	-

[1] Insemination value.

Discussion

The framework of insemination values combined with a mixed integer linear program offers a solution to the problem of determining optimal mating decisions given multiple sire choices and requirements on the number of dairy heifer calves. The application is fast and can in principle be applied on dairy farms. Many extensions and improvements are possible. For example, the probability of conception may be better predicted from the strength of the oestrus display (Cerri *et al.*, 2021) and health events (Pinedo *et al.*, 2020). A DP model for replacement and insemination decisions for heifers will be added soon.

Abstract

The impact of heat stress on dairy production traits was investigated and genomic predictions for heat tolerance in US Holsteins and Jerseys were developed. Data included 12.8 and 2.1 million test-day records for milk, fat, and protein yield (kg) for the first five parities of 923,311 Holstein and 153,714 Jersey cows in 27 US states. Genotypes were available for 76,481 and 46,046 Holsteins and Jerseys, respectively. Production was affected by heat stress when the temperature-humidity index (THI) exceeded 69 for Holsteins and 72 for Jerseys. The additive genetic component of heat tolerance for production traits was estimated using a random regression repeatability model on a function of THI. Negative correlations between general and heat tolerance additive effects were observed for Holsteins (Jerseys): -0.38 (-0.37) milk, -0.51 (-0.49) fat, and -0.43 (-0.52) protein. Estimates for the heat tolerance additive genetic values were obtained with single-step GBLUP, potentially identifying heat-tolerant dairy cattle.

Introduction

High temperatures and relative humidity have negative impacts on production (Fuquay, 1981) and reproduction (Hansen and Aréchiga, 1999) of dairy cattle thus affecting overall economic return (Kadzere *et al.*, 2002; St-Pierre *et al.*, 2003). Cattle experience heat from both environmental factors including radiation, conduction, and convection as well as through metabolic processes such as exercise, growth, lactation, gestation, and feeding (Fuquay, 1981). Excess environmental heat unable to be managed through thermoregulation can result in heat stress. The stress can be mediated by provisions of cooling technologies such as sprinkler systems, fans, and shade. Additionally, developing a genetic evaluation for heat tolerance of dairy cattle will allow producers to select animals whose production is least affected by environmental heat stress. Different approaches have been previously explored with test-day yields in US Holsteins (Ravagnolo *et al.*, 2000; Bohmanova *et al.*, 2005, Aguilar *et al.*, 2009), non-return rate in US Holsteins (Ravagnolo *et al.*, 2002) and test-day yields in Australian Holsteins and Jerseys (Nguyen *et al.*, 2016). The objectives of this study were to investigate the impact of heat stress on test-day yields and develop single-step genomic predictions to identify heat tolerant US Holsteins and Jerseys.

Materials & methods

Test-day data. Select Sires, Inc. (SSI; Plain City, OH, USA) supplied 12.8 and 2.1 million test-day records from the first five parities containing milk, fat, and protein yield (kg) for 923,311 Holstein and 153,714 Jersey cows. Each cow was required to have at least 5 test-day records per lactation. Test-day records were obtained from 331 herds in 27 different US states from 2015 to 2021. Genotypes from different density arrays were available for 76,481 and 46,046 Holstein and Jersey animals, respectively. Genotypes were imputed to approximately 50k SNP density using FImpute3 software (Sargolzaei *et al.*, 2014).

Weather data. Weather data was obtained from Automated Surface Observing System (ASOS) stations at airports closest to each herd. Iowa State University's Iowa Environmental Mesonet (IEM) provides this data and can be accessed using R package 'riem' (Salmon, 2016). Geographical coordinates for each herd were obtained using R package 'ggmap' (Kahle and Wickham, 2013) and the distances between each herd

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_699, © T.M. McWhorter *et al.* 2022

and each airport were calculated using the Haversine formula in R package 'geosphere' (Hijmans, 2019). The Haversine formula determines the distance between two geographical coordinates on Earth using an average radius of 6,371 km. This measure was used to determine the airport with the minimum distance to each herd. Daily mean temperature and daily mean relative humidity for the 4-days prior to and the day of test (Nguyen *et al.*, 2016) were obtained for each airport and the daily temperature-humidity index (THI; NOAA, 1976) were calculated as proposed by Ravagnolo *et al.* (2000) as:

$$THI = (1.8 \times t + 32) - (0.55 - 0.0055 \times rh) \times (1.8 \times t - 26) \quad (1)$$

where t is the mean air temperature in degrees Celsius at approximately 2 meters, and rh is the mean relative humidity as a percentage. A final THI for each herd and test-day was calculated as the average THI over the 5 days.

Threshold. Statistical analyses were conducted separately based on the breed of the cow providing the test-day records. To determine the THI threshold where heat stress affects production traits, the least square estimates (LSE) of production were obtained from a repeatability multi-trait animal model as:

$$y_{hijklmno} = HTD_{ih} + (DIM \times s)_{jh} + lact_{kh} + state_{lh} + THI_{mh} + age_{nh} + a_{oh} + pe_{oh} + e_{hijklmno} \quad (2)$$

where $y_{hijklmno}$ is the yield of milk, fat, and protein in kg for trait h, categorical fixed effects included herd test-day i (HTD_{ih}), days-in-milk class by calving season class j $(DIM \times s)_{jh}$, lactation k ($lact_{kh}$), state l ($state_{lh}$), 5-day average THI of test-day m (THI_{mh}), and age of calving class n (age_{nh}). Random effects included general additive genetic effect for animal o (a_{oh}), general permanent environmental effect (pe_{oh}) for animal o, and residual ($e_{hijklmno}$). The LSE of production were regressed on THI. The discovered thresholds ($THI_{threshold}$) for each breed were used in a function, f(THI), and implemented in a random regression repeatability model to identify animals with superior genetic merit for heat tolerance:

$$f(THI) = maximum(0, THI_{TD} - THI_{threshold}) \quad (3)$$

where THI_{TD} is the calculated average THI of a given test-day.

Random regression. The multi-trait random regression repeatability model used for variance component estimation and genetic evaluation of test-day milk, fat, and protein yield (y) was:

$$y_{hijklno} = HTD_{ih} + (DIM \times s)_{jh} + lact_{kh} + state_{lh} + age_{nh} + a_{oh} + \alpha_{oh}[f(THI)] + pe_{oh} + \pi_{oh}[f(THI)] + e_{hijklno} \quad (4)$$

that included the additive genetic random regression effect of heat tolerance for animal o (α_{oh}) and the permanent environmental random regression effect of heat tolerance for animal o (π_{oh}). Additive and permanent environmental variances were assumed only to change with heat stress. Variance components were calculated using GIBBS2F90 and estimates for heat tolerance additive genetic values were calculated using BLUP90IOD2OMP1 as implemented in the BLUPF90 family of programs (Misztal *et al.*, 2014). The Algorithm for Proven and Young (APY; Misztal, 2016) was implemented with 11,000 Jersey and 15,000 Holstein core explaining >99% of variation.

Results

The average distance between herds and matched airports was 20 (12 SD) km with a minimum of 2 and maximum distance of 75 km. The 331 US herds averaged 44,913 (65,892 SD) test-day records but ranged from contributing 3 to 459,326 records. A substantial decrease in milk, fat, and protein yield for Holsteins

occurred after a THI of 69, whereas for Jerseys this value was 72. Approximately 14.6% Holstein and 9.9% Jersey test-day records were recorded at THI above the respective thresholds and therefore under heat stress. The maximum THI observed was 82. Heritability for general genetic merit of Holsteins was 20.8% for milk, 15.7% for fat, and 17% for protein, whereas Jerseys was found to be 20.0, 10.5 and 13%, in the same order. The heritability for production at each heat stress level is presented in Figure 1. A negative correlation between general and heat tolerance additive effects was observed for Holsteins (Jerseys): -0.38 (-0.37) milk, -0.51 (-0.49) fat, and -0.43 (-0.52) protein for all THI. Statistics of heat tolerance additive genetic values for milk, fat, and protein yield are in Table 1; these are the random regression coefficients and represent the expected change in yield (kg) from average change for each unit above THI threshold.

Discussion

Production yields decreased due to heat stress at different THI thresholds for each breed. It would be beneficial to have a greater number of test-days for cows experiencing heat stress. Heritability at each THI was greater than previously found in Ravagnolo *et al.* (2000) where first-parity Holstein milk yield was 16% at 72 THI and increased to 21% at 85 THI and little to no increase in fat and protein. In this study, a greater increase in heritability was observed from 20% at 70 THI to 35% at 82 THI when all five lactations were included. Heritability of protein increased from 16 to 31% from THI 70 to 82; thus, selection for heat tolerance for production traits is possible. Small increases in heritability at extreme THI could be due to artifacts of the random regression model and a need for more records under heat stress. The negative correlations between general and heat tolerance additive effects for production traits indicate an antagonistic relationship. High-producing cows are expected to have a lower heat tolerance. However, the

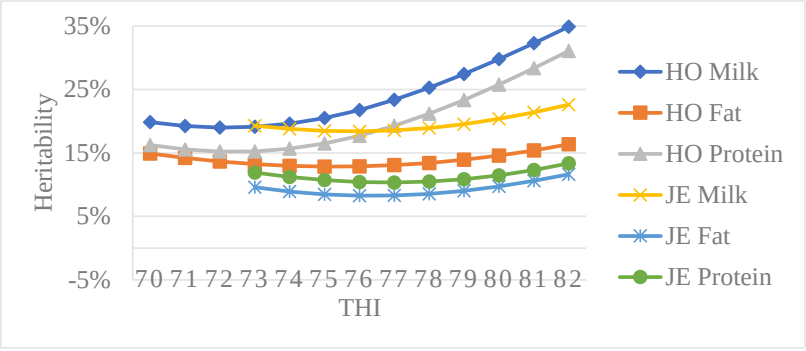

Figure 1. Heritability for production under heat stress for Holsteins (HO) and Jerseys (JE).

Table 1. Heat tolerance additive genetic values[1] for milk, fat, and protein yield for 1,189,386 Holstein and 240,813 Jersey animals.

Breed	Trait	Mean	Min	Max	SD
Holstein	Milk	0.033	-1.132	1.384	0.169
	Fat	0.001	-0.028	0.034	0.005
	Protein	0.001	-0.030	0.041	0.005
Jersey	Milk	-0.009	-0.516	0.475	0.086
	Fat	-0.001	-0.023	0.023	0.004
	Protein	0.000	-0.016	0.017	0.003

[1] Interpreted as the expected change in yield (kg) from average change for each unit above THI threshold.

low to moderate correlations and increasing heritability for heat tolerance over THI show potential to improve both production traits and heat tolerance simultaneously using a selection index. Estimates of heat tolerance additive genetic values for milk, fat, and protein yield were obtained with single-step GBLUP, potentially allowing the identification of heat-tolerant Holsteins and Jerseys. A validation on the genetic predictions will be explored. Production for first lactation cows has been observed to be least affected by heat stress. Further analysis of models containing first lactation only, and later lactations (lactations 2-5) will be explored.

Abstract

Bovine tuberculosis (bTB) is a zoonotic disease primarily affecting cattle and leading to important economic losses. Eradication programmes in various countries focus on surveillance, movement restrictions and culling, with some considering also selective breeding. These breeding strategies focus on reducing animal susceptibility to the disease and thus, the potential of reducing disease transmission by selecting also animals with low infectivity remains unknown. The first step in assessing this potential is to detect underlying genetic variation in infectivity. In the present study, the number of secondary cases attributed to a given index case in a breakdown was used as an infectivity phenotype, and a range of linear and generalised linear mixed sire models were used to estimate its genetic variance and heritability. Substantial genetic variance was detected for this trait, suggesting that infectivity can be reduced via selective breeding, hence contributing to more efficient eradication strategies.

Introduction

Bovine tuberculosis (bTB) is a chronic disease caused by *Mycobacterium bovis*, a Gram-positive bacterium of the *Mycobacteriaceae* family. Although mainly found in cattle, it also affects many other mammals, including humans (Michel *et al.* 2010; Payeur 2014). In the UK, bTB is one of the major causes of economic losses in cattle industry, due to the costs of the testing programme and the compensation payments to farmers when animals are culled (Abernethy *et al.* 2013).

Given the costs associated with this disease, several programmes across different countries were set up to eradicate rather than to control bTB. These are mainly based on intensive test and culling regimes, and stringent biosecurity measures to limit the spread of the disease. Although in many cases these strategies reported successful results, in others, such as the UK, the disease has proven difficult to eradicate with these measures alone (Allen *et al.* 2018). Given this, the TB Advantage genetic index was introduced as a complementary strategy in the UK in 2016 (Banos *et al.* 2017). This index indicates the degree of resistance to bTB that a bull is expected to pass on to his offspring and thus, allowing to reduce bTB susceptibility via genetic selection.

There is evidence for the presence of bTB super-spreaders, i.e. highly infectious animals responsible for transmitting the disease to many herd-members (O'Hare *et al.* 2014). Hence, a promising additional strategy to eradicate the disease may also be to consider infectivity as part of the selection index, allowing for the reduction of the propensity of infected animals to transmit the infection. Previous studies have demonstrated that including infectivity in the selection index could drastically accelerate reduction in risk and prevalence of disease (Tsairidou *et al.* 2018), however the genetic basis of bTB infectivity is still unknown. Therefore, the purpose of this preliminary study was to assess the existence of underlying genetic variation for infectivity using real data from UK bTB breakdowns.

Materials & methods

Breakdown data. Repeated bTB skin test records collected in 60-day intervals, from all animals in a herd, for 32,745 breakdowns, were available for the period between 1995 to 2017. From these data, only closed breakdowns were considered, and the first animal with a positive test result (reactor) or slaughtered after an inconclusive test (inconclusive reactor) was identified as a potential index case. An index case is defined as the first infected animal in a herd that transmits infection to its herd members. In this study, breakdowns with more than one index cases (reactors detected on the same first test date) were discarded. After quality control, the total number of breakdowns retained for analysis was 4,598, with each breakdown corresponding to one given index case.

Index cases with high infectivity would be expected to generate, on average, more secondary cases than index cases with low infectivity. Hence, for each breakdown, the response variable (numR) was calculated as the total number of secondary cases (non-index case reactors or slaughtered due to inconclusive test results) identified in a given period since the start of the breakdown (either 120 or 365 days). Based on previous estimates of the disease stage durations (O'Hare *et al.* 2021), the chosen periods were assumed to be sufficiently long for secondary cases to be detectable and sufficiently short to minimise bTB cases resulting from transmission between secondary cases.

Pedigree data. A full pedigree consisting of 910,170 records was available. From this data, two shorter pedigrees corresponding to the 4,598 index cases described above were extracted, comprising the last seven generations (58,753 records). These index cases corresponded to 2,544 different sires, of which 80.7% (2,054) were sires of at least two index cases.

Data analysis. The above data was analysed with sire models to estimate the genetic effect of the index cases on the total number of secondary cases per breakdown (numR) identified in either the first 120 or 365 days after the breakdown start date. A sire would be associated to index cases in different breakdowns, thus expected to account for potential across-herd genetic variation in susceptibility of the infected animals. Different distributions of the response variable were examined, thus estimating genetic variances and heritabilities in the latent scale.

Initial exploratory analyses were performed only for the 365 days period using ASReml (Gilmour *et al.* 2015), without including any fixed effects. However, given the skewed distribution of the number of secondary cases and the high proportion of breakdowns with zero secondary cases, the response variable was transformed to log(numR+1), which was assumed to be normally distributed.

A further analysis was performed through a generalised linear mixed model accounting for an over-dispersed Poisson distribution (de Villemereuil *et al.* 2016) of the response variable using ASReml (Gilmour *et al.* 2015). In this case, the response variable was transformed to numR+1, and the following covariates and fixed effects were included in the analysis: index case age in months at test, maximum herd size during breakdown, risk code (type of risk area), season at onset of breakdown and breakdown duration (in days).

One potential issue of using Poisson distributions (even if accounting for over-dispersion) is the fact that they account poorly for zero inflation. Therefore, additional distributions for the response variable were considered in the generalised linear mixed models.

A negative binomial distribution was firstly assumed, with the number of successes (φ) being 1 and, therefore, effectively resembling a geometric distribution. This analysis was done in ASReml, with the

response variable being transformed to numR+1, given the logarithmic link function and using all the previously described fixed effects and covariates.

An additional two-step model was also applied to the data, following the rationale of a Hurdle model (Mullahy 1986). In this analysis, after accounting for the above fixed effects and covariates, the data was assumed to follow a mixture of a Binomial and Poisson distributions. The response variable (numR) was firstly analysed in ASReml as a binary variable (presence or absence of secondary cases) and the probability of non-zero values (breakdowns with numR≥1) was analysed following an over-dispersed Poisson model in ASReml.

A final model was tested using Markov Chain Monte Carlo techniques via the MCMCglmm package in R (Hadfield 2010). In this model, the response variable (numR) was assumed to follow a zero-inflated Poisson distribution (ZIP), and all previous fixed effects and covariates were included. The model was run for 200,000 iterations, plus 10,000 burn-in, with a thinning interval of 100. The prior assumed independent residual and random effect variances for the count and binary terms.

Results

The distribution of the number of secondary cases per breakdown in the first 365 days (Figure 1) was skewed, presenting an excess of zeros, and with a mean of 2.23 and variance of 34.37. About 0.8% of the breakdowns presented more than 30 secondary cases during this interval, with the maximum being one breakdown with 108 secondary cases.

Results for the estimates of genetic variance and heritabilities on the latent scale are presented in Table 1 for each of the two intervals considered. Heritability and genetic variances for the binomial part of the two-step models were not estimable.

Discussion

Under the assumption of a normal distribution for the transformed response variable, none of the analyses resulted in a significant genetic variance estimate. This was clearly due to the lack of normality in the response variable and the high frequency of zero secondary cases. Similarly, the use of generalised linear mixed models assuming over-dispersed Poisson distributions resulted in significant but overestimated heritabilities, likely due to the lack of concordance of these distributions with the observed in the data.

Both the negative binomial or the zero-inflated Poisson distribution models derived significant and relatively reliable heritability estimates; these estimates are in line with those observed for resistance to bTB in previous studies (Banos *et al.* 2017) as well as with those expected for other fitness-related traits (Gibson and Dechow 2018).

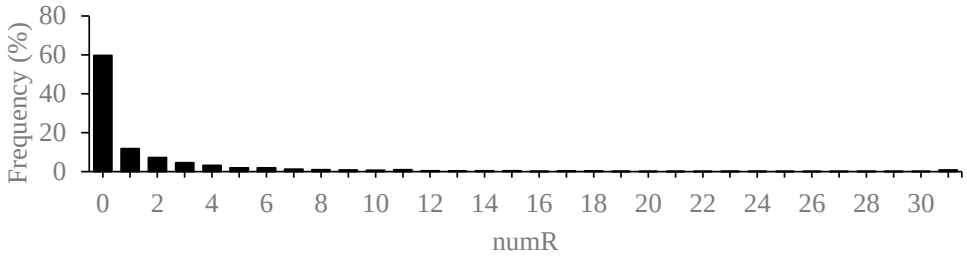

Figure 1. Distribution of the average count of secondary cases per sire.

Table 1. Heritabilities (h^2) and genetic variances (σ_a^2) in the latent scale for the different models and periods.

Distrib.[1]	Response variable	365 days		120 days	
		σ_a^2	h^2	σ_a^2	h^2
Normal	log(numR+1)	0.004±0.017	0.006±0.021	-	-
OP	log(numR+1)	1.657±0.107	0.599±0.038	1.169±0.085	0.674±0.047
NB	log(numR+1)	0.094±0.048	0.144±0.072	0.151±0.060	0.214±0.083
TS-P	numR≥1	1.582±0.154	0.408±0.044	1.475±0.161	0.591±0.068
ZIP	numR	0.157±0.004	0.066±0.002	0.188±0.004	0.086±0.002

[1] Studied distributions were: Normal, Over-dispersed Poisson (OP), Negative Binomial (NB), Poisson part of the two-step model (TS-P) and Zero-inflated Poisson (ZIP).

These results showed consistently higher heritabilities for secondary cases in the first 120 days than for the first 365 days. This was probably the consequence of the effects of the increased strength of the genetic component (the smaller the timeframe, the more likely that the infection of secondary case was transmitted by the index case) and the lower total phenotypic variance.

This study presents a simple approach to estimate the genetic component and heritability of bTB infectivity, resulting in low but substantial significant heritabilities for the studied trait. However, further research is required to validate these results. Given the length of the different disease stages reported in recent studies (O'Hare *et al.* 2021), a more accurate definition of secondary cases attributed to the index case is needed. Furthermore, additional models must be tested and used to take advantage of the data available from breakdowns with more than one index cases and to incorporate transmission from all infected cows.

701. Dairy female fertility traits in seasonal and non-seasonal herds in Ireland

K. Stachowicz[1*], P.R. Amer[1], M.M. Kelleher[2], S.C. Ring[2] and R.D. Evans[2]

[1]AbacusBio Limited, P.O. Box 5585, Dunedin 9058, New Zealand; [2]The Irish Cattle Breeding Federation, Highfield House, Bandon, Co. Cork, Ireland; kstachowicz@abacusbio.co.nz

Abstract

In Ireland, the genetic trait representing dairy female fertility, namely calving interval, has high emphasis in the selection index (EBI), but recent validation testing has raised concerns about its predictive effectiveness deteriorating in recent years (Ring *et al.*, 2021). The goal of this work was to evaluate a wide range of possible fertility trait definitions in order to find ones that best fit seasonal and non-seasonal herds in Ireland. Phenotypes for over 40 traits were evaluated. Heritabilities were estimated as well as genetic correlations for the same traits between seasonal and non-seasonal systems. Based on these results a sample of the most promising traits were selected and genetic correlations were estimated between those traits within and between calving systems. Finally, recommendations were made for prototype genetic evaluation systems to be tested and validated against the current genetic evaluation system.

Introduction

In Ireland, the proportion of herds that operate a seasonal calving pattern has been systematically increasing in the last 20 years from around 50% in the early 2000s to over 70% in 2021. Seasonal calving reflects a high proportion of calvings occurring within the first four months from the beginning of the calving season. Despite this fact the genetic evaluation system for fertility and survival traits continues to be the one developed when less compact calving patterns were prevalent. Fertility and survival traits are evaluated jointly in a multiple trait animal model which includes 23 traits (Berry *et al.*, 2013). The main fertility trait is calving interval (CINT), with calving to first service, number of services (NS) and age at first calving (AFC) as predictor traits. The use of CINT is consistent with the fertility trait definition used in many countries with predominantly all year-round calving systems. It is also a trait widely accepted by the scientific community as providing an accurate reflection of genetic merit for fertility. However, CINT is not the optimal selection criterion for fertility in seasonal systems, as the goal in seasonal herds is not to reduce the CINT, but rather to maintain a compact calving pattern. For example, early calvers which are likely the more fertile cows often have longer CINTs compared to their later calving contemporaries because they are withheld from mating, to avoid them calving too early in the next calving season.

The objective of this work was to investigate a wide range of possible fertility traits definitions to find ones that best fit seasonal and non-seasonal herds in Ireland. Phenotypes for over 40 traits were created and assessed for differences between seasonal and non-seasonal herds. Heritabilities were estimated as well as genetic correlations for the same traits between seasonal and non-seasonal systems. Based on these results a sample of the most promising traits were selected and genetic correlations were estimated between those traits within and between calving systems. Finally, recommendations were made for prototype genetic evaluations systems to be tested and validated against the current genetic evaluation system.

Materials & methods

Phenotypic data were obtained from the Irish Cattle Breeding Federation database (www.icbf.com). The criteria used to differentiate seasonal from non-seasonal herds has been previously described by Stachowicz *et al.* (2018). Data was filtered at the individual cow level to include only dairy animals with both parents known, and only cows which did not move herd in their lifetime. Data was filtered at the herd level to

ensure reasonable size, consistent seasonal or non-seasonal data across the 2010 to 2018 seasons, and herds that record matings systematically.

Definitions of fertility and survival trait phenotypes are presented in Table 1. Traits more suited for non-seasonal calving system were derived based on mating and calving dates, and intervals between them. Traits more suited to seasonal calving were derived based on intervals between mating or calving dates and planned start of mating (PSM) or calving (PSC) dates for the contemporary group. Definitions of PSM and PSC were as described by Stachowicz *et al.* (2018). Using PSM and PSC dates as the reference points for seasonal fertility traits accounts for the involuntary withholding period. CINT preadjusted for involuntary withholding period (CINT*) was introduced, which is the standard CINT trait after pre-adjustment for the time between the first calving within the herd-season and PSM date (i.e. the withholding period). In addition to cow survival as in the current evaluation (Berry *et al.*, 2013) three heifer survival traits were tested.

Variance components were estimated using animal models in ASReml (Gilmour *et al.*, 2015) Fixed effects and covariates included in the models were: herd-year for seasonal herds and herd-year-calving season (2 seasons per year) for non-seasonal herds; month of birth for heifer traits, month of calving for cow traits; linear and quadratic effects of age at previous calving; mating type for mating traits; breed as a categorical fixed effect with 4 levels: Friesian, Holstein, Cross between Friesian and Holstein and Other Dairy; breed specific heterosis; recombination loss. Cow traits were modelled using repeated records up to 6 parities.

Results & discussion

Heritabilities and genetic correlations estimated for and between all the traits are presented in Table 1. Inflated heritabilities were found for birth to mating and birth to calving survival traits in non-seasonal herds, possibly due to farmers being less likely to keep heifers from lower index sires through to mating. The binary trait, of whether or not the heifer calved following a recorded mating showed reasonable and consistent heritability across herd types and should be pursued further. However, the estimate of the genetic correlation for this trait between seasonal and non-seasonal herds is low. Age at first service and AFC had lower heritabilities in seasonal herds. Heifer traits based on reference to mating or calving planned start dates were more promising in seasonal herds (TCCH, PR21H, PM21H and CSDH) with h^2 ranging as expected from 0.02 to 0.03. CINT had almost zero heritability in seasonal herds, which confirms that it is not a trait suitable for seasonal calving systems. CINT* (adjusted for withholding period) recovers some heritability in seasonal herds and might be a viable alternative to CINT whereby a single trait is evaluated, with pre-adjustment in herds defined as seasonal, and no adjustment in herds defined as non-seasonal. Pregnant to first mating, Pregnant to any mating, and the interval traits have low h^2 across both herd types. Calving to first mating (and CINT) is an exception in non-seasonal herds. The conception-based traits look comparable to calving based traits in heritability. They have the advantage of being independent from gestation length, and potential to get data into a genetic evaluation earlier in the season. Three/six week in calf rate could be a good early predictor of fertility, as NS, which is currently used is censored for cows still available to be mated, whereas not getting in-calf on the first or second service is the key economic driver. The continuous timing of conception trait (TCC) has higher h^2 than binary pregnancy rates, but binary traits are more practical to use as they avoid censoring.

Based on these results the traits that are included in Table 2 were chosen for further analysis. Genetic correlations between chosen traits within and between seasonal and non-seasonal herds are presented in Table 2. The genetic correlation between CINT in non-seasonal herds and CINT* (adjusted for voluntary withholding period) in seasonal herds was 0.99. The genetic correlation between 6-week in calf rate for cows (pregnant in 1st 21 days from 1st herd-year mating) in non-seasonal herds with 6-week in calf rate

	FSTC42C									0.44

for cows (pregnant in 1st 21 days from PSM) in seasonal herds was also found to be very high (0.92). This indicates that both CINT and 6-week in calf rate, although defined differently in the two herd types, could be evaluated as one trait in a genetic evaluation system. A similar recommendation of combining traits across systems was made for survival despite the lower genetic correlation between seasonal and non-seasonal herds of 0.66. It is anticipated that further enhancement of contemporary group definitions for survival in both herd types as well as heterogenous residual variances could improve this correlation. Heifer survival from mating to calving, if included in a genetic evaluation, would need to be a separate trait for seasonal and non-seasonal herds due to the low genetic correlation and differences in variances. Additionally, AFC in non-seasonal herds and calving season day (CSDH) for heifers in seasonal herds were recommended for consideration when building a new genetic evaluation. AFC is currently utilised as an early predictor of fertility. CSDH would be a novel trait for Ireland but was recently introduced into fertility evaluation in New Zealand seasonal system (Stachowicz *et al.*, 2021).

Abstract

Age at first calving (AFC) is around a 2-years non-productive period (on average in Holstein cows) which plays a relevant role in the cost of rearing replacements in dairy herds. In the present study we aimed at evaluating the heritability of AFC and estimating breeding value of the trait in the Italian Holstein population. A linear animal model was used and heritability was 0.03 (Posterior Standard Deviation of 0.005). Further analyses will be performed to obtain a genomic evaluation of AFC and to evaluate the economic importance of this trait.

Introduction

Age at first calving (AFC) is the period from birth to first calving that a female calf needs to reach puberty and to reproduce for the first time. The AFC plays a relevant role in the cost of rearing replacements in dairy herds. Boulton *et al.* (2017), considering an average AFC of 25.8 months, estimated that the mean cost of rearing increased by £2.87 for each additional day of AFC. An earlier AFC allows animals to generate income earlier and the effects of AFC on production traits in dairy cattle have been estimated (Hutchison *et al.*, 2017). Hence, the aim of this study is to evaluate the genetic aspects of AFC (heritability, genetic trend and correlation among estimated breeding values) in Italian Holstein population.

Materials & methods

Data editing. Data stored in the national database at ANAFIBJ including AFC of 4,510,986 Holsteins born from 1993 and with first calving from January 1996 to 2020 were used. AFC was limited from 18 to 36 months and gestation length was restricted to 240 to 305 d. Furthermore, only animals with both parents in the pedigree were selected. In order to have an effective comparison between contemporaries for herd-year-season of birth (HYS), groups with less than 4 observations were removed. Cows' pedigree was traced back to at least 4 generations. Table 1 reports the description of the dataset.

Table 1. Dataset description.

Item	N	Parameter	Mean	SD
Animals	4,510,986	Mean AFC 1996[2], months	28.14	2.94
Herds	21,080	Mean AFC 2020[3], months	26.09	3.07
HYS[1] groups	428,650	Animals/HYS	10.52	

[1] HYS = Herd/Year/Season of birth class.

[2] Mean age at first calving of cows that calved in 1996.

[3] Mean age at first calving of cows that calved in 2020.

CC BY

DOI: 10.3920/978-90-8686-940-4_702, © V. Ferrari *et al.* 2022

Statistical model. In order to evaluate sources of variation of AFC, a forward stepwise approach based on Akaike Information Criterion was used. Fixed effects were selected using the general linear model procedure of R version 4.0.3. The linear animal model used to evaluate AFC was:

$$AFC_{ijkl} = HYS_i + GL_j + A_k + e_l \quad (1)$$

where, HYS_i is the herd-year-season of birth class, with season defined according to 4 classes (1 = Nov-Dec-Jan; 2 = Feb-Mar-Apr; 3 = May-Jun-Jul; 4 = Aug-Sep-Oct), GL_j is the gestation length in classes (240 to 260, 261 to 280, 281 to 290 and 291 to 305 days), A_k is the random additive genetic effect, and e_l is the random residual error.

Genetic parameters estimation. Variance components estimation was carried out with the Gibbs sampler THRGIBBS1F90 (Misztal *et al.*, 2002; Misztal, 2008) on the entire final dataset, with 160,000 iterations, a burn-in of 10,000 and a thinning rate of 10. The post-Gibbs analysis was carried out using the software POSTGIBBSF90 (Misztal *et al.*, 2002) using the last 150,000 samples. From the total final dataset, 3 randomized sampling were created selecting heifers from herds with at least 200 observations. The heritability (h^2) was calculated as:

$$h^2 = \frac{\sigma_a^2}{\sigma_a^2+\sigma_e^2}$$

where σ_a^2 is the additive genetic variance, and σ_e^2 is the residual variance.

Breeding values estimation (EBV). For pedigree analyses Relax2 program version 1.65 was used. Animals' EBVs were estimated with the linear animal model described above with MiX99 software (Lidauer *et al.*, 2019) and standardized to mean 100 and standard deviation 5, where high values mean animal with lower AFC within the population.

Results & discussion

From 1996 to 2020, the phenotypic mean of AFC decreased by 2.05 months, probably due to the increased selection for milk yield and for better management made by farmers resulting in earlier AFC in recent years (Figure 1). Indeed, this is observable when comparing the frequency of average AFC in 1996 and 2020; in 1996 the greater percentage of animals calved at 27 months, whereas it decreased at 24 months in 2020

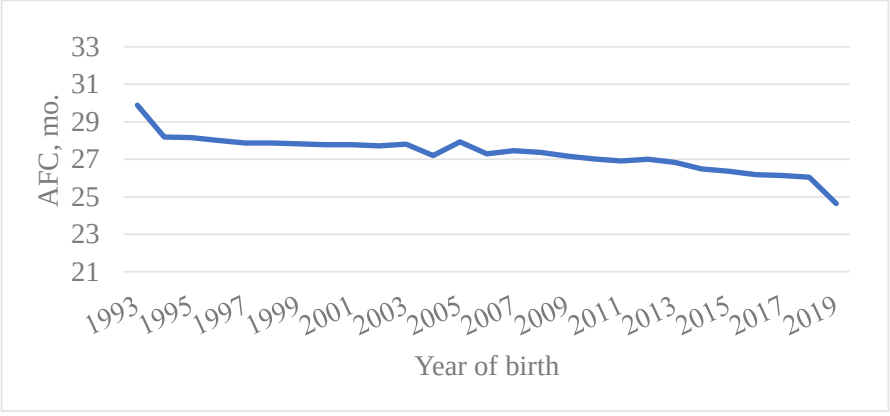

Figure 1. AFC trend by year of birth.

(Table 2). These results are in accordance with findings of Hutchison *et al.* (2017) who reported a decrease of AFC by 2.4 months for Holstein from 1997 to 2015.

The R^2 of the selected model was 47%. The analysis of the fixed effects revealed that 45.6% of the total variance was explained by HYS, whereas GL explained only 1.3% of the total variance.

Results of genetic parameters estimation are reported in Table 3. Heritability of AFC ranged from 0.03 to 0.04, showing low values. Low heritability values were also found by VanRaden and Klaaskate (1993), by Hutchison *et al.* (2019), and Heise *et al.* (2018) in Holstein cattle (0.02, 0.027, and 0.10, respectively), whereas Brzáková *et al.* (2020) found different results of heritability (from 0.18 to 0.23 in Aberdeen Angus and Charolais, respectively). Differences can be due to differences in genetic variation between breeds or due to management choices applied within breeds population.

Figure 2 depicts the genetic trend of AFC by year of birth. The tendency line displays a positive trend across years resulting in higher value in more recently bulls. The strong positive tendence across years is due to the increased selection for milk yield. This can be observed in Figure 3 also, where correlations of AFC with other traits are presented. The positive relationship of AFC with both production and fertility traits is displayed in Figure 3; only body condition score presents a negative correlation with AFC.

Table 2. Frequency of age at first calving (AFC) by month.

AFC, months	1996	2020
18-20	0.10	1.09
21	0.30	3.02
22	1.04	8.05
23	3.49	14.30
24	7.53	15.19
25	12.24	14.39
26	13.86	11.19
27	14.35	9.07
28	12.12	6.61
29	9.87	5.02
30	7.35	3.57
31	5.74	2.80
32	4.16	2.00
33-35	7.86	3.72

Table 3. Results of genetic parameters estimation.[1]

	h^2	PSD	Burn-in
Sample 1	0.04	0.005	10,000
Sample 2	0.03	0.004	10,000
Sample 3	0.03	0.005	10,000
μ	0.03	0.005	

[1] h^2 = heritability; PSD = posterior standard deviation.

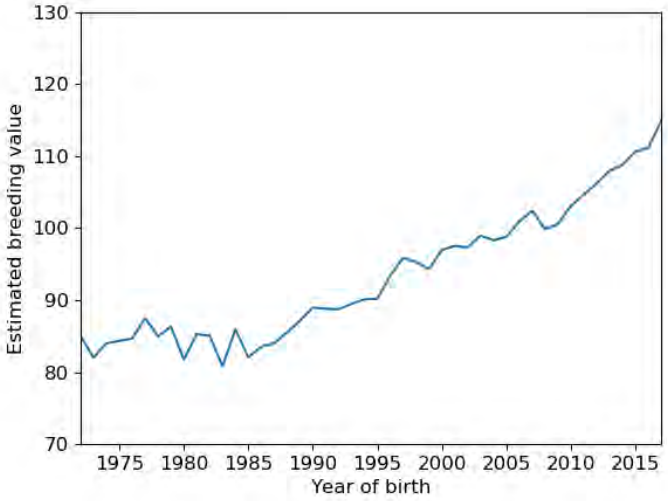

Figure 2. Genetic trend of AFC by year of birth.

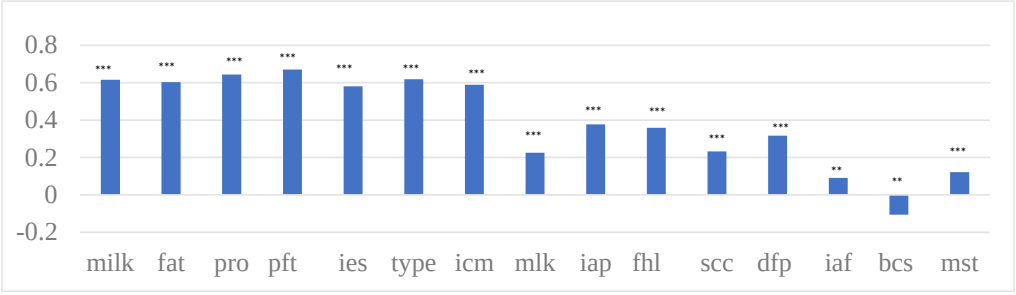

Figure 3. Correlation of indexes with AFC – Milk: Milk yield; fat: fat yield (kg); pro: protein yield (kg); pft: productivity, functionality and type index; ies: economic and functional index; type: type index; icm: udder composite index; mlk: milkability; iap: feet and legs composite index; fhl: functional longevity; scc: somatic cell score; dfp: calving ease; iaf: female fertility; bcs: body condition score; mst: udder healt index (*P<0.05, **P<0.01, and ***P<0.001).

Conclusions

Based on the results, the estimated heritability confirms the possibility for AFC genetic selection. Positive correlation of AFC with both productive and fertility traits reveals that selecting for an earlier AFC can improve herd profitability. Further studies will be conducted to evaluate its optimum value and to define the economic importance of this trait and to investigate the possibility to include AFC in the others selection index for Holstein.

703. Genetic and genomic approaches to ewe's artificial insemination success in the Spanish Assaf and Manchega sheep breeds

M. Serrano[1], M.A. Jiménez[1], M. Ramón[2*] and O. González-Recio[1]

[1]Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria CSIC-INIA, Ctra. de la Coruña km 7.5, 28040 Madrid, Spain; [2]Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla-La Mancha (IRIAF), Avda. del Vino s/n, 13300 Valdepeñas, Spain; m.ramon.fernandez@gmail.com

Abstract

Artificial insemination (AI) is an essential tool in genetic programs of dairy livestock. In sheep AI has low success rates for several reasons, among which, the anatomy of the reproductive tract of the sheep, the non-detection of the oestrous cycle and the use of fresh semen, can be highlighted. In this work classical genetic and genomic approaches to the evaluation of this trait in the Spanish Assaf and Manchega breeds have been performed. Several threshold models have been tested considering the male and female contribution in different ways. Heritability estimates for AI success ranged from 0.07 to 0.10 for Assaf and from 0.01 to 0.05 for Manchega. The inclusion of genetic markers in the evaluation model yields more accurate breeding values predictions, but highly inflated. Results pointed out the possibility to exert some selective pressure over this trait to improve AI results.

Introduction

In the current dairy sheep sector, reproductive rates achieved by artificial insemination (AI) are one of the major concerns, due to the importance of this tool for the efficiency of the breeding programs. AI allows the progeny testing of rams, herds' connection, and an efficient dissemination of genetic improvement. Fertility, defined as the ability to produce offspring, is due to effects contributed by the male and the female, most likely in a non-purely additive fashion. The phenotype observed for the fertility of a mating, is a binary trait (0/1) and a continuous underlying variable is assumed under a threshold model assumption (Gianola, 1982). Two models can be fitted to the binary results of AI, considering the female and the male components, the additive and the product threshold models (David *et al.*, 2011). Both models yield low heritability estimates for the female component (0.10) and very low for the male one, (0.01) in the additive model, and (0.10) in the product model (David *et al.* 2011). Modern genomic tools, as medium and high SNPs platforms, can help through the incorporation of genotypic information to the classical genetic models, recovering a proportion of the genetic component responsible of fertility variation and achieving more accurate estimates of the animals' genetic values. In this work, we studied the AI fertility in the Assaf Spanish and the Manchega sheep breeds, by fitting different threshold animal models. Traditional genetic and genomic approaches, including 11,269 and 4,874 genotyped animals for the Assaf and Manchega, respectively, with the Affimetrix 50K platform, were compared in terms of genetic parameters estimates and accuracy of breeding values predictions.

Materials & methods

Data. Assaf breed data consisted of 203,621 AI records provided by the Spanish Assaf breeders association (ASSAFE) between 1998 and 2021 and 11,269 genotyped animals. Manchega breed data consisted of 168,154 AI records provided by the Manchega breeders association (AGRAMA) recorded between 2006 and 2017, and 4,874 genotyped animals (Table 1).

Methods. A threshold model was used to estimate variance components and genetic parameters, as well as to predict breeding values for fertility using a binary trait 0/1 as an indicator of the absence/presence of an ewe AI outcome. Some genetic models were fitted according to how the ram effect was considered,

No. ewes genotyped (with data)	4,144 (2,016)	1,591 (615)
No. rams genotyped (with data)	7,125 (559)	3,378 (184)

that is, if the ram was included as a fixed or a random permanent effect and the inclusion of repeated measures of the ewes as a random effect. All models were implemented either in a genetic or a genomic approach. For the Assaf breed, the comparison group herd-AI date (2,857 levels), the ewe age and the ram age (8 levels in both cases) were included as fixed effects in the model. For the Manchega breed, fixed effects considered were herd-AI date (2,474 levels), number of parity-age interaction (16 levels), age of the ram (9 levels), days from lambing to AI service (5 levels) and level of milk production of the ewe at the service (10 levels). Technicians making inseminations were not included in the model since each of them inseminates always the same herds and therefore effects are confounded. Model 1 included the ram as a fixed effect and the additive effect of the ewe; Model 2 fitted the ram as a random permanent effect and the additive effect of the ewe; Model 3 included the ram and ewe permanent effects in addition to the additive effect of the ewe; Model 4 included both permanent and additive effects for rams and ewes. Genetic groups were included defined on a basis of a generation interval of 3 years. The animal additive genetic and the residual were assumed to be randomly distributed. Genomic information file consisted of 11,269 animals genotyped for 42,479 SNPs in the Assaf breed, and of 4,874 animals genotyped for 38,433 SNPs in the Manchega breed, after a quality control on animal call_rate (≥90%), SNPs call-rate (≥90%) and Minimum allele frequency (MAF≥3%). The software used for both the genetic and genomic approaches was the THRGIBBSF90 (BLUPF90 family programs. University of Georgia. http://nce.ads.uga.edu/software/). Gibbs sampling consisted of a single chain of 100,000 iterations, with a burning period of 10,000 samples and saving samples every 10 iterations, leaving a total of 9,000 samples for final inferences. Models were compared based on DIC (deviance information criterion) values, and genetic and genomic predictions, based on heritability and accuracy estimates.

Results

Table 2 and 3 shows DIC values and variance components estimates obtained in each of the breeds and genetic models fitted under both, the classic genetic and genomic approaches. For the Assaf breed, models comparison revealed under both, genetic and genomic approaches, that Model 3, which includes the ram and ewe environmental permanent effects and the additive effect of the ewe, had the best performance in terms of DIC values (the lower the better). For the Manchega sheep, model 1 with the ram as a fixed effect and the permanent and additive effects of the ewe resulted in a better fitting. In general, variances estimates and heritabilities were of lower magnitude for the Manchega sheep. Additive variances estimates were very similar for all models, and something higher under the genomic approach with respect to the classic genetic

[1] 1 Fixed ram; 3 Permanent ram; 4 Permanent plus additive ram and ewe.

[2] DIC deviance information criterion; σ^2a_{ewe} (sd) additive variance of the ewe and its standard deviation; σ^2p_{ewe} (sd) permanent variance of the ewe and its standard deviation; σ^2a_{ram} (sd) additive variance of the ram and its standard deviation; σ^2p_{ram} (sd) permanent variance of the ram and its standard deviation; σ^2e (sd) residual variance and its standard deviation; h^2s heritability on the underlying scale; h^2r heritability under the observed scale.

one. Rams permanent environmental variance estimates were very low, about 10 times less than that of ewes. For the Assaf breed, heritability on the underlying scale ranged from 0.10 to 0.17, being slightly higher those estimated under the genomic approach. Under the observed scale, heritability estimates ranged from 0.06 to 0.10. Estimates were lower for the Manchega breed, ranging between 0.01 (male trait) to 0.08 (female trait) in the underlying scale and between 0.01 (male trait) and 0.05 (female trait) when back-transforming to the observable scale.

In the Assaf breed and considering results from the best model (Model 3), lower DIC, correlations among the estimated breeding values for AI fertility under the genetic (EBV) and genomic (GEBV) approaches was 0.93 for all evaluated animals and 0.80 for the genotyped ones. Average accuracies of fertility EBVs under Model 3, was 0.37. For the genomic evaluation with Model 3, average accuracies of GEBVs were 0.44 and 0.56, for all animals and genotyped animals, respectively. For Manchega, Model 1 showed the best goodness of fit. For this model, correlations between EBV and GEBV were 0.99 for all animals, and 0.89 for

the genotyped ones. Average accuracies were 0.40 for model 3 not including genotypes, 0.41 when genomic information was included and 0.45 for the genotyped animals. In this breed, when the additive effect of the ram was included (model 4), correlations between EBV and GEBV were 0.99 for all animals and 0.82 for the animals with genomic information. Average accuracies were 0.37 for model 4 with no genotypes, 0.38 when including genomic information and 0.51 for the animals genotyped.

Discussion

Improving artificial insemination efficiency is critical to dairy genetic programs. Most of this improvement will come through innovations in reproductive techniques, however, genetic selection is also possible despite the low heritability of the trait. Precisely due to the low genetic determinism of AI fertility, genomic information could contribute to improve the accuracy in the choice of future breeders. A single-step approach that uses the combined relationships, allows for a simple evaluation that takes all available phenotypic, pedigree, and genomic information (Chen *et al.*, 2011). In this work a heritability of 7 to 10% has been estimated for the AI success in Assaf and of 5% for Manchega breeds. Despite the fact that no direct selection pressure has been exerted on this trait, a positive trend of breeding values over the last decade has been observed in both breeds. Even though only a few animals with phenotypic data have genotype information, the genomic approach provides higher accuracy of breeding values.

Abstract

The objective of this study was to investigate the impact of sire on variation in methane (CH_4) production and dry matter intake (DMI). Methane emissions were measured on 60 Suffolk and Texel ewe lambs from 20 sires using respiration chambers (RC) and portable accumulation chambers (PAC). Daily DMI was measured on lambs fed an *ad libitum* grass pellet diet. The mean CH_4 output was 13.65±2.63 g/day (PAC Pre-RC), 28.07±4.96 g/day (RC) and 13.53±3.83 g/day (PAC Post-RC). Methane production differed by sire ($P<0.05$) and varied from 20.70 to 40.25 g/day in the RC. A strong correlation (0.68) was observed between CH_4 output measured in PAC Pre-RC and RC. Dry matter intake differed by sire ($P<0.05$). Methane production did not differ by breed ($P>0.05$), however, DMI differed by breed ($P<0.05$), with greater intakes associated with Suffolk (2.14 kg DM/day) compared to Texel lambs (2.01 kg DM/day).

Introduction

Respiration chambers are considered the 'gold standard' method of measuring CH_4 emissions in ruminants (Robinson *et al.*, 2014). To date RC have been used to quantify an animals CH_4 output, compare emissions on different diets (Zhao *et al.*, 2017) and to validate new CH_4 measurement techniques (Jonker *et al.*, 2018). In recent years there has been a movement away from using the RC due to the expense involved in construction and maintenance, and also the restriction on the number of animals that can be measured at any one time (Jonker *et al.*, 2018). One such alternative technique for measuring CH_4 emissions are the PAC, a short-term spot sampling method, which measures the accumulation of gas over a 50-minute period (Jonker *et al.*, 2018). This method allows for a high throughput of animals over a short period of time (O' Connor *et al.*, 2021), thereby providing CH_4 emission values on grazing sheep (Jonker *et al.*, 2018). Sire variation in CH_4 emissions measured using the RC and subsequent DMI has been estimated previously (Robinson *et al.*, 2014). However to date the simultaneous measurement of CH_4 and DMI from Irish sheep is relatively unknown. Feed intake has been shown to be the main driver of CH_4 production (Oddy *et al.*, 2019). Dry matter intake is easily measured during the RC period (Jonker *et al.*, 2018; Zhao *et al.*, 2017) while fewer studies have attempted to measure DMI around PAC measurements due to the challenges with feeding protocols prior to measurement (Hegarty, 2013). Therefore, the objectives of this study were to investigate the effect of sire on the variation in: (1) CH_4 emissions measured using both RC and PAC, and (2) DMI.

Materials & methods

Methane and DMI measurements were taken on a total of 60 nulliparous purebred Suffolk (30) and Texel (30) ewe lambs (c. 6 to 7 months of age) from October to December 2019. Each lamb was assigned to one of ten groups; each group consisted of six ewe lambs. These 60 ewe lambs represented the progeny from 20 sires (11 Suffolk and 9 Texel), with the number of ewe lambs per sire ranging from 1 to 6, and the number of CH_4 production and DMI records per sire ranging from 6 to 36.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_704, © E. O'Connor *et al.* 2022

Dry matter intake. At the commencement of the experiment each group, consisting of six ewe lambs balanced for weight and breed, were housed in individual pens for 20 days. Following a 5 day diet adaption period, all animals had *ad libitum* access to a grass pellet (91.31% dry matter) diet. Individual DMI was measured from days 6 to 14 in individual pens, days 15 to 17 in the RC and days 18 to 20 in individual pens. Daily DMI of each animal was determined based on the quantity of feed offered and refused on a daily basis.

Methane measurements. Portable accumulation chamber measurements as described by Jonker *et al.* (2018) were taken on days 13 and 14, the two days prior to entry to the RC (hereon referred to as PAC Pre-RC) and on days 18 and 19, two days after the RC (hereon referred to as PAC Post-RC). One hour prior to CH_4 measurement, animals were removed from feed in their individual pens and were weighed. On day 18, immediately after a 72 hour RC measurement animals were returned to the individual pens and offered *ad libitum* access to feed for 2 hours before being removed from feed for a minimum of 1 hour and a CH_4 measurement was taken using the PAC. Methane (ppm), oxygen (%) and carbon dioxide (%) measurements were obtained using individual chambers over a 50 minute measurement period at three specific time points (0, 25 and 50 minutes) using the RKI Eagle 2 monitor (Weatherall Equipment and Instruments Ltd, UK).

Open-circuit respiration chamber measurements, as described by Zhao *et al.* (2017), were carried out over a 72 hour period from day 15 to 17. Within each group, consisting of six animals, individual lambs were assigned randomly to one of six chambers, with the first 24 hour period used as an acclimatisation period and 2×24 hour test periods thereafter. Animals had *ad libitum* access to the grass pellet diet throughout the 72 hour period.

Statistical analysis. To investigate the effect of sire on CH_4 (g/day, CH_4 per kg live-weight and CH_4 yield) and DMI (kg DM/day), linear mixed models in PROC MIXED (SAS, Inst. Inc., Cary, NC.) were used with animal live-weight, measurement group (n=1 to 10), sire (n=20), age of dam, birth and rearing type of the lamb (single, twin, triplet or quadruplet) included as fixed effects. In all models animal was included as a repeated effect. When the dependent variable was CH_4 production, DMI, chamber number, chamber number of measurement and measurement period (PAC Pre-RC, RC, PAC Post-RC) were also included as fixed effects. Biological interactions of interest were also investigated. In a secondary analysis sire was substituted with breed (Suffolk or Texel) to determine the effect of breed on CH_4 production and DMI. To quantify the relationship between gaseous measurements undertaken in the PAC and RC, the correlations between both CH_4 output (g/day) measured in PAC and RC were calculated.

Results

The mean CH_4 output measured during each period was 13.65±2.63 g/day (PAC Pre-RC), 28.07±4.96 g/day (RC) and 13.53±3.83 g/day (PAC Post-RC). Methane production differed by both sire and measurement period (i.e. PAC Pre-RC, RC and PAC Post-RC; $P<0.001$). Although a significant interaction between sire and measurement period was observed for CH_4 ($P<0.05$), further investigation showed that this was due to the re-scaling rather than the re-ranking of sires across measurement periods. Sire 1 (Texel) ranked as the highest emitter for CH_4 output measured in both the PAC and RC, with two other sires remaining in the top six CH_4 emitters across both measurement techniques. Two of the lowest emitting sires remained in the bottom six when measured in both the PAC and RC. The coefficient of variation for CH_4 production across sires ranged from 4.40 to 9.04%. Moderate to strong correlations (0.51 and 0.68) were estimated between CH_4 output measured in PAC, either Pre or Post-RC, and RC. The correlation between the two PAC measurements Pre- and Post-RC was 0.56. The ranking of sire for CH_4 output measured using the RC is shown in Figure 1 and ranged from 20.70 to 40.25 g/day. Methane output did not differ by breed ($P>0.05$).

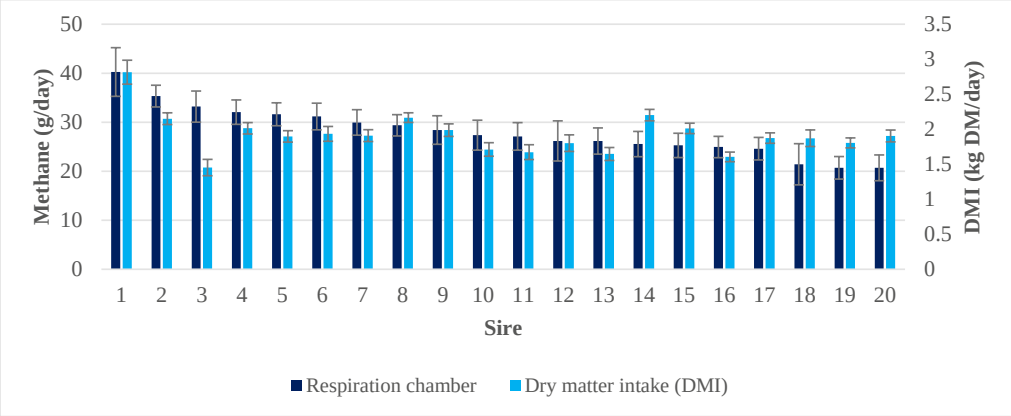

Figure 1. Ranking of sires from highest to lowest for methane output (g/day) measured in the respiration chamber and their respective dry matter intake (kg DM/day).

When methane emissions were expressed as CH_4 per kg live-weight, emissions were found to differ by sire ($P<0.05$). Strong to moderate correlations ranging from 0.62 to 0.76 were observed between CH_4 per kg live-weight measured during the three measurement periods (i.e. PAC Pre- and Post-RC, and RC). Methane per kg live-weight ranged from 0.14 to 0.63 g CH_4/kg live-weight when measured in either PAC measurement period with values ranging from 0.36 to 0.88 g CH_4/kg live-weight when measured in the RC.

The average DMI measured for all animals was 1.92 kg DM/day and ranged from 1.45 to 2.81 kg DM/day. Sire had a significant effect on DMI ($P<0.05$). The DMI of each sire is shown in Figure 1. The same sire (Sire 1) had the highest DMI along with CH_4 output (g/day) across the measurement period. Dry matter intake differed by sire breed ($P<0.05$), with Suffolk ewe lambs having a greater DMI (2.14 kg DM/day) compared to Texel ewe lambs (2.01 kg DM/day). Suffolk lambs also had a higher DMI per kg metabolic live-weight (0.12 kg DMI/kg metabolic live-weight) compared to Texel lambs (0.11 kg DMI/kg metabolic live-weight; $P<0.05$) Methane yield differed by sire ($P<0.05$) and ranged from 10.62 to 18.58 g/kg DMI when measured in the RC, while a smaller range of methane yield was observed during both PAC measurement periods (range 6.41 to 11.77 g/kg DMI). The correlations between CH_4 yield across the three measurement periods ranged from 0.40 to 0.50.

Discussion

Variation across sire is common among a plethora of traits such as lamb birth weight (Speijers *et al.*, 2010), however, the ability to identify sires with low CH_4 emissions is paramount in order to identify and breed sheep for reduced CH_4 emissions. Similar to results observed by Robinson *et al.* (2014) using RC data, sire was found to have a significant effect on CH_4 production (g/day) irrespective of the measurement technique used. As there was a 14.81 g/day of CH_4 difference between the top and bottom emitting sires this suggests there is ample variation between sires to be able to select for reduced CH_4 production. The large variation between sires was observed in the current study irrespective of how CH_4 was expressed (i.e. CH_4 production (g/day) or expressed in terms of live-weight or DMI), which suggests that variation in CH_4 between sires could not be solely accounted for due to live-weight or DMI differences. Dry matter intake differed by sire in the current study, which is in agreement with Robinson *et al.* (2014) and Oddy *et al.* (2019). A 1.36 kg DM/day difference was seen between the top and bottom sire, highlighting the large variation between sires for DMI. The phenotypic correlations estimated between the measurement techniques investigated in

the present study (i.e. PAC or RC) were similar to the genetic correlation (0.67) calculated by Jonker *et al.* (2018) between the same measurement techniques; this aids the validation of the PAC for more widespread use in larger genetic studies. The lack of differences between the two breeds investigated in the present study for CH_4 production was not unexpected, as both Texel and Suffolk are terminal breeds with relatively similar live-weights, however, interestingly DMI did differ by breed. Results from this study highlight large sire variation in both CH_4 production and DMI, indicating that selecting sires with low CH_4 emissions, while taking cognisance of DMI will aid in breeding sheep with lower environmental footprints.

Abstract

Prepubertal nutrition has been proposed as an important factor for feed efficiency and milk production in later life. Moreover, nutritional restrictions during prepubertal mammary gland development may influence the milk production potential. This study aims to evaluate the potential impact of a nutritional challenge during the allometric growth of the mammary gland on the milk transcriptome of dairy ewes with different feed efficiency phenotypes. The differential expression analyses identified 29 genes whose expression was significantly different for feed efficiency and relevant regarding the nutritional challenge. Eight differentially expressed genes were clustered under the biological process 'cell adhesion'. Molecules involved in cell adhesion are crucial in the proper development and function of the mammary gland. In conclusion, the main genes impacted by the nutritional challenge and showing a different expression pattern related to feed efficiency could be involved in the development of the proper architecture of the mammary gland parenchyma.

Introduction

In the last years, selecting animals for feed efficiency (FE) has become a major research objective in the livestock industry. Feed provision accounts for around 60-70% of costs in dairy sheep farming. Moreover, breeding high feed efficient sheep reduces carbon fingerprint, thus, decreasing farming environmental impact. The residual feed intake (RFI) is one of the most used indexes to measure feed efficiency. In order to elucidate the genetic determinism of this complex trait in livestock, several RNA-Seq approaches have been applied in different tissues such as the liver, muscle, rumen, and duodenum to identify polymorphism and genes associated with FE (Brito *et al.*, 2020). However, till now, RNA-Seq has not been applied to the milk somatic cell (MSC) transcriptome in relation to this trait.

Early live nutrition has been proposed as an important factor for feed efficiency and milk production in later life. It has been demonstrated that a restricted diet, compared to an *ad libitum* one during the prepubertal stage, improves the ewes' feed conversion potential (Villeneuve *et al.*, 2010). Moreover, several studies in heifers, goats, and sheep have focused on elucidating the impact of nutrition during this period on the mammary gland parenchyma, showing that a high plane of nutrition reduces mammary gland development while nutrient restriction improves its development (Bowden *et al.*, 1995; Capuco *et al.*, 1995; Villeneuve *et al.*, 2010).

In dairy sheep, postnatal mammary gland development implies a succession of allometric and isometric growth to accomplish a full development by the onset of lactation. Although most mammary gland growth is related to pregnancy, duct network ramifies during the prepubertal allometric growth, which may influence the milk production potential (Anderson, 1975).

This study aims to evaluate the potential impact of a nutritional challenge during the allometric growth of the mammary gland on the MSC transcriptome of dairy ewes with different feed efficiency.

Materials & methods

Experimental design. An experimental population of 40 new-born female lambs of the Assaf breed was constituted. Once these animals passed the veterinary control and got adapted to the experimental facilities, they were separated into Control group (C, n=20) and Nutritional Challenge group (NC, n=20). The NC lasted approximately two months, between 3.5 and 5.5 months of age of the animals. In this period, the NC group received a 42% protein restriction diet compared with the C group. Ewes were mated at around ten months of age.

Management at feed efficiency sampling period. After lambing, the sheep were housed in individual tie stalls and fed *ad libitum* a total mixed ration formulated from alfalfa hay (particle size>4 cm) and concentrate (50:50). Feed intake was individual and daily measured over four weeks (week 6^{th}-9^{th} of lactation) by weighting the diet dry matter (DM) offered and refused by each animal. At the morning and evening milkings (08:30 and 18:30 h), total milk produced by each animal was also collected and weighed individually and daily to calculate the milk yield. The body weight (BW) of each sheep was recorded at the beginning and the end of the 4-week sampling period.

Estimation of feed efficiency. RFI was calculated as the residuals of the following regression model using the GLM procedure of the SAS software package (version 9.4; SAS Institute Inc., Cary, NC, USA):

$$DMI = \mu + a \times ECM + b \times MBW + c \times \Delta BW + RFI \quad (1)$$

Where, DMI represents the mean DM intake over the period (kg/day); μ is the intercept; ECM is the mean energy-corrected milk (kg/day); MBW is the mean metabolic body weight (BW0.75; kg); ΔBW is body weight change over the period adjusted for mean body weight (ΔBW × BW); RFI is the residuals; and a, b, and c are the regression coefficients. All variables included in the model were statistically significant.

Sampling, RNA extraction and sequencing. Milk samples were collected on week 7^{th}-9^{th} of lactation. RNA was extracted following the protocol by Suarez-Vega *et al.* (2016). From the 40 ewes with records for milk production and individual feed intake, 24 animals were selected for mammary gland transcriptome analysis by RNA-seq (12 NC vs 12 C). For the analysis of the present study, we choose the most extreme animals for the RFI value: 6 HighFE (3 NC, 3C), with an average RFI of -0.17 (SD=0.05), and 5 LowFE (3 NC, 2C), with an average RFI of 0.16 (SD=0.06). The RNA-Seq was conducted at NOVOGENE in Cambridge (UK). cDNA libraries were sequenced to a minimum depth of 30 million paired-end reads on a Novaseq 6000 (Illumina), generating stranded paired-end reads of 150 bp.

RNA-Seq data analyses. The alignment against the reference genome (Oar_rambouillet_v2.0) was carried out using the STAR software (Dobin *et al.*, 2013), and the transcript quantification step was performed with the RSEM software (Li and Dewey, 2011). Differential expression analyses between the groups or conditions were performed with the DESeq2 package (Love *et al.*, 2014). The model for DESeq2 was fitted assuming an interaction between the nutritional challenge and the RFI:

$$Y = \text{nutritional challenge} + RFI + \text{nutritional challenge:RFI} \quad (2)$$

Differentially expressed genes (DEGs) were considered at a false discovery rate (FDR)<0.05. Functional enrichment analyses of DEGs were performed with ToppGene (Chen *et al.*, 2009) and terms were considered significantly enriched when there were more than two genes clustered in Gene Ontology (GO) term and FDR<0.05.

Results

After massive parallel RNA sequencing, an average of 34 million paired-end reads were obtained for each animal. On average, 95% of the reads aligned to unique locations of the Oar_rambouillet_v2.0 reference genome.

When compared between HighFE and LowFE groups, 213 DEGs were found for the control group, and 86 DEGs were found for the NC group; from these two subsets, 12 DEGs were found in common in both analyses (Figure 1a). When comparing C vs NC groups, 37 and three DEGs genes were found for the HighFE and LowFE ewes, respectively. Among the DEGs identified between C vs NC, 17 genes were also DEGs between the feed efficiency comparisons (Figure 1a). The functional enrichment analysis used the 29 genes identified as differentially expressed by at least two comparisons. For the GO database, we found 5 terms enriched for the GO: Molecular function category, 2 terms for the GO: Biological Process, and 1 term for the GO: Cellular component categories. The top enriched term in each category was 'calcium ion binding', 'cell adhesion', and 'cell surface', respectively.

Discussion

This study represents the first evaluation of the transcriptomic changes in the mammary gland of dairy ewes with extreme feed efficiency phenotypes. It is remarkable that a different response in the MSCs transcriptome is observed between HighFE and LowFE animals when subjected to a nutritional challenge. Fewer differences in gene expression were observed for the RNA-Seq data in the NC group, suggesting that changes in the milk transcriptome for FE phenotype in the C group are more relevant than for NC animals.

Regarding the enriched GO terms identified, the 'calcium-binding' function has also been found enriched in previous studies on feed efficiency in pigs (Xu *et al.*, 2018), which supports that this function plays an important role in feed efficiency.

Eight DEGs were involved in the GO:biological process term 'cell adhesion'. Cell adhesion is important for the mammary gland as it is required for the survival and differentiation of luminal cells during lactation. In this sense, Eph- and ephrin-signalling pathways play a role in the morphogenic processes of various tissues (Andres and Ziemiecki, 2003). In our study, the expression of the *EPHA4* gene, included in the last cited pathway, was downregulated in the HighFE C group while it was higher expressed in both HighFE and LowFE NC ewes (Figure 1b). Several molecules from the ephrin-Eph system have been shown to be involved in branching morphogenesis and the establishment of the mammary gland functional structure (Kaenel *et al.*, 2014). Moreover, genes from this family have been shown to act as positive factors for the increase and

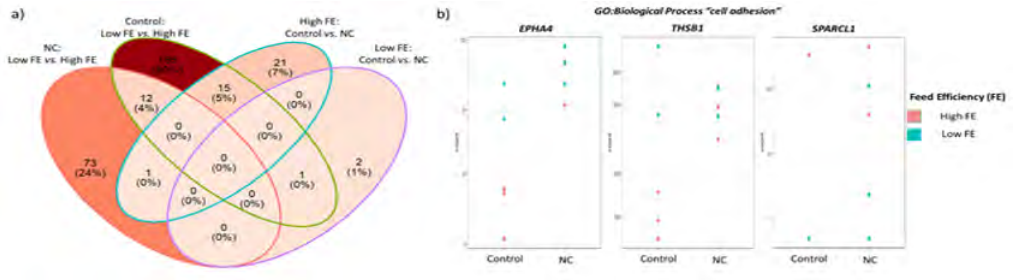

Figure 1. Differentially expressed genes between the conditions evaluated: Feed Efficiency (FE) and Nutritional Challenge (NC). (a) Venn Diagram integrating the results from the differential expression analyses performed. (b) Expression of three genes clustered under the GO: Biological Process 'cell adhesion'.

maintenance of the epithelial cells in the mammary gland (Kang *et al.*, 2018). Other genes included under the 'cell adhesion' GO term, such as *SPARCL* or *THBS1*, were previously identified as important genes in relation to feed efficiency in livestock (Tizioto *et al.*, 2016; de Lima *et al.*, 2020), highlighting their relevancy for this complex trait.

Taking into consideration our results, it can be hypothesised that the main genes affected by the nutritional challenge and showing a different expression pattern between the HighFE and LowFE groups could be involved in the proper development and function of the mammary gland parenchyma.

Abstract

Katahdin sheep are a composite hair breed reared for meat production and known for parasite resistance traits. The aim of this study was to calculate observed heterozygosity (Het_O), inbreeding coefficients and effective population size (Ne) in a study population representing 23 U.S. flocks (n=4,884 sheep) with 50K genotype data. In the U.S. Katahdin, mean Het_O was 0.37 and mean inbreeding coefficient (Fhat2) was 0.01. Inbreeding coefficient estimates were statistically different (Kruskal-Wallis $P<2.2e-16$) between flocks. The Ne of the study population examined was n=172 at 13 generations ago, with average linkage disequilibrium r^2 of 0.04 for the generation. Maintaining genetic diversity relies upon maximizing Ne and minimizing inbreeding within a population. The current study found that mean inbreeding of Katahdin sheep was lower than published for other sheep breeds, mean Het_O was greater and Ne was intermediate to estimates for other breeds.

Introduction

Genetic diversity is important for the preservation of livestock species. Inbreeding can result in increased homozygosity, reduction of genetic diversity and the accumulation of detrimental alleles (Vostry *et al.*, 2018). Negative outcomes related to increased homozygosity can also occur through inbreeding depression, which can affect economically important traits such as birth weight, weaning weight, average daily gain and litter size (Gholizadeh and Ghafouri-Kesbi, 2016; Selvaggi *et al.*, 2010). The Katahdin breed of sheep was developed in the later half of the twentieth century (Wildeus 1997) and has since grown to become economically important to the United States sheep industry (Thorne *et al.*, 2021). The aim of this study was to characterize observed heterozygosity (Het_O), inbreeding and effective population (Ne) size in a large population of 4,884 Katahdin sheep with 50K genotype data.

Materials & methods

Twenty-three U.S. Katahdin flocks enrolled with the National Sheep Improvement Program (NSIP) participated in the current study. Sheep producers collected blood cards and DNA samples were extracted and genotyped with the Neogen GGP Ovine 50K genotype array. All autosomal markers were filtered by the following exclusionary parameters: sample call rate <0.90, marker call rate <0.90, marker minor allele frequency <0.01. Sex chromosome markers were not included in analyses. In total, 37,856 markers were used for principal component analysis (PCA) and effective population (Ne) size estimation. Data for heterozygosity and inbreeding analyses were pruned to remove markers in high linkage-disequilibrium (LD) using the --indep-pairwise function in plinkv1.9 with the parameters window size of 50 kb, variant count moving five markers per window and r^2 threshold of 0.8. Following LD-pruning, 34,772 autosomal

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_706, © G.M. Becker *et al.* 2022

markers were used in inbreeding and mean heterozygosity analyses. Observed heterozygosity, inbreeding and PCA analyses were conducted using plink v1.9 with the functions --het, --ibc and –pca, respectively (Chang *et al.*, 2015). Ne analysis using LD-based methods were conducted with SNeP1.11 with default parameters (Barbato *et al.*, 2015). R version 4.1.1 was used for data visualization with packages 'ggpubr' and 'ggplot2' (Kassambara 2020; Wickham 2016). Statistical significance of (Fhat2 ~ Flock) was evaluated with the Kruskal-Wallis test. The r package 'rcompanion' was used to calculate 95% confidence intervals for inbreeding coefficients (Mangiafico 2020).

Results

The structure of the study population was investigated by PCA (Figure 1). The flocks in this study were located across the five geographical regions of the U.S.: the East Coast (EC), Gulf Coast (GC), Midwest (MW) and the West Coast/Rocky Mountain (WR) regions. There was greater diversity of sheep from the GC region in comparison to sheep from other regions.

The mean heterozygosity observed (Het_O) in the study population was 37%. This was found to be higher than mean Het_O for previously reported breeds (Table 1). The range in mean Het_O by flock was 0.36 to 0.39 with a standard deviation of 0.01. The range in Het_O for individual sheep of all flocks was 0.25 to 0.45 with a standard deviation of 0.02.

Population and flock inbreeding coefficients were calculated using Fhat2, which is calculated (observed homozygous – expected) / (1 – expected) (Rovelli *et al.*, 2021). Individual sheep inbreeding coefficients for all flocks ranged from -0.42 to 0.34 with a standard deviation of 0.07, and the mean inbreeding coefficients by flock ranged from -0.1 to 0.07 with a standard deviation 0.04 (Figure 2). Inbreeding coefficients differed significantly across flocks (Kruskal-Wallis $P<2.2e-16$). The mean inbreeding coefficient over the entire study population was 0.01 and all inbreeding coefficient mean calculations were supported by 95% confidence intervals.

Fhat2 inbreeding coefficients have been previously estimated in other sheep breeds (Davenport *et al.*, 2020; Rochus *et al.*, 2020). The mean inbreeding coefficient calculated for this study population was smaller than

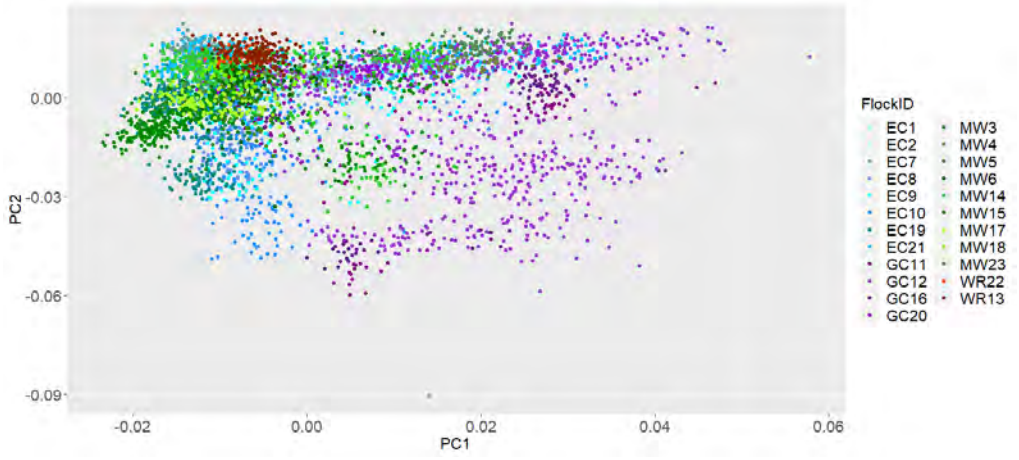

Figure 1. Principal component analysis (PCA) for U.S. Katahdin sheep. Animals are color-coded by region (East Coast in blue shades, n=2,167; Gulf Coast in purple shades, n=1,088; Midwest in green shades, n=1,414; West Coast/Rocky Mountain in orange shades, n=215) and labelled by flock from 1 to 23, with a total of 4,884 sheep.

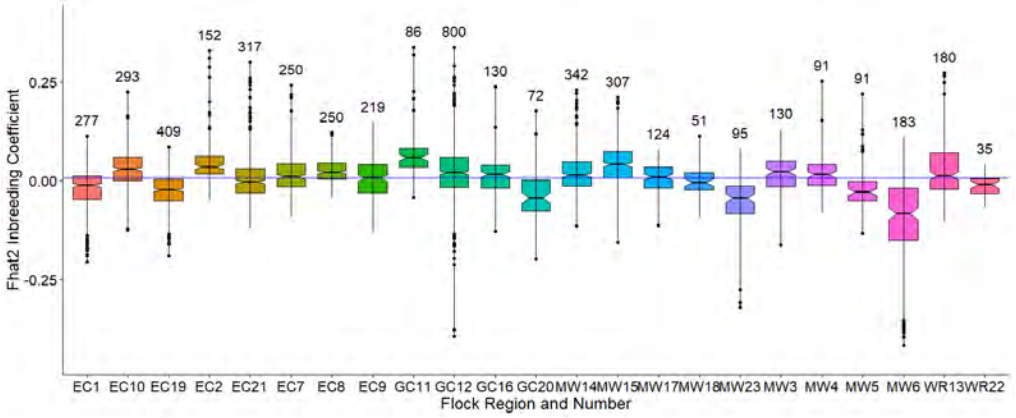

Figure 2. Fhat2 inbreeding coefficients by Katahdin flock. Overall population mean is given by the blue line and individual flock size (n) are given above each boxplot.

mean estimates published for other breed populations (Table 1). Inbreeding coefficients may be difficult to directly compare across studies due to differences in sample structure and size.

For this population, historic Ne was estimated to be 901 (as of 234 generations ago) while the most recent Ne estimate was 172 (as of 13 generations ago). The average LD per bin decreased from r^2 of 0.12 (standard deviation 0.16) at 234 generations ago to r^2 of 0.04 (standard deviation 0.06) at 13 generations ago.

Discussion

This study encompasses nearly 5,000 sheep from 23 Katahdin flocks located across the United States. Some of the sheep in this study exhibited inbreeding coefficients of 6.25% or greater, indicating cousin mating (Li *et al.*, 2011); however, the mean inbreeding coefficient was smaller than estimates for other breeds and the mean observed heterozygosity was higher. Previous estimations of Ne for other breeds range from 25 to 1,317 (Kijas *et al.*, 2012; Pasandideh *et al.*, 2020). Two of the founding breeds of the Katahdin, the Wiltshire and Suffolk, have previously reported Ne estimates of 100 and 300/569 (Irish/Australian Suffolk), respectively (Kijas *et al.*, 2012). In the current study, 4,884 Katahdin sheep were evaluated and found to have an estimated Ne that falls intermediate of other breed reports. These statistics have allowed for characterization of genetic diversity within a robust sample population of U.S. Katahdin sheep.

Table 1. Inbreeding coefficient and observed heterozygosity compared to other published estimates.[1]

Abstract

This study aimed to decipher the genetic diversity and structure of different dairy goat populations kept at KALRO-research station Naivasha to facilitate national genetic improvement program. We used 49,773 genome-wide SNP data to quantify levels of and patterns of genetic diversity among 243 individuals from five goat populations: Toggenburg (n=69), Alpine (n=54), Saneen (n=24), Toggenburg Kenya Dual Purpose goat (TKDPG) (n=4), Kenya Dual Purpose Goat (KDPG)(n=11) and crosses (n=81). Inbreeding coefficient, observed and expected heterozygosity ranged from-0.01-0.07, 0.56-0.60 and 0.57 respectively. Principal component analysis clustered the populations into three distinct clusters namely; cluster one-Saanen, Alpine and their crosses, cluster two-Toggenburg, Alpine, TKDPG and their crosses, and cluster three-KDPG, Toggenburg, TKDPG, Alpine and their crosses. Genetically admixed genotypes were identified in each cluster, indicating intermixing within the populations. High number of ROH proofed there is some level of homozygosity in the goat genotypes in Kenya. Results provided understandings into genomic variations and relationships which is vital in furthering genetic improvement and conservation of goat kept at Kenya Agricultural and Livestock Research Organization (KALRO) research station and Kenya as a whole.

Introduction

Goats are an integral part of the whole farming system with multiple biological (meat, milk, manure and skin) and non-biological (asset, security, and socio-cultural) functions (Ajmone-marsan *et al.*, 2014). Recent studies have also shown that goat farming could be one of the alternative agricultural practices due to the diminishing land sizes in the medium to high potential areas as a result of human population pressure and climate change-related challenges. These challenges are a trigger for alternative farming practices such as intensive dairy goat production which offers more multi-functionality, flexibility and adaptability to varied production conditions (Scarpa *et al.*, 2003). In Kenya, dairy goats were introduced through community-based breed improvement programs by various NGOs. Common dairy goat breeds include Saanen, Toggenburg and Alpines, and their crosses. Crossbreeding between the exotic breeds (Saanen, Toggenburg, Alpine and Anglo-Nubian) and local goat (Galla and Small East African) populations has resulted in different dairy goat genotypes kept by farmers (Peacock *et al.*, 2011). Since introduction of different goat genotypes, farmers have been practicing unsystematic crossing due to lack of breeding programs to guide in genetic improvement of dairy goats in the country (Kosgey and Okeyo, 2007). Currently, admixtures of exotic and local goats reared as dairy goats are present in different parts of the country under different production systems. The genetic diversity and relationships of these genotypes remain undocumented. It is therefore important to decipher their genetic diversity and relationships of dairy goat breeds in Kenya for conservation strategy as well as to further genetic improvement.

Materials & methods

Sample collection. A total of 243 blood samples were collected from goat population maintained on-station at the Dairy Research Institute of the Kenya Agricultural and Livestock Organization (KALRO) in

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_707, © C.M. Kamidi *et al.* 2022

Naivasha. The breeds sampled included Toggenburg (n=69), Saneen (n=24), Alpine (n=54), KDPG (n=11), TKDPG (n=4) and crosses (n=81). Blood samples were collected via jugular venipuncture from each animal into EDTA vacutainer tubes. The collected blood samples were kept in iceboxes until refrigeration at 4 °C before DNA extraction. The study was conducted in strict accordance with the recommendations for the Institute of Primate Research (IPR) ethical guidelines on animal care and the use of laboratory animals (ISERC/03/2020).

DNA extraction and genotyping. Genomic DNA was extracted from the whole blood using the DNeasy Blood and tissue kit 149 (Qiagen®, Hilden, Germany). Genomic DNA was quantified using Nanodrop Spectrophotometer 150 (Nanodrop ND-1000) and genotyped using the GoatSNP50 Bead Chip (Illumina, Inc. San Diego, 151 CA 92122 USA) developed by the International Goat Genome Consortium (IGGC).

Data analysis. Genetic diversity indices; inbreeding coefficient, observed and expected heterozygosity were calculated within genotypes using PLINK (Purcell *et al.*, 2007). Minor allele frequency (MAF) was determined for each goat genotype using PLINK. The MAF were categorized into 0.0- 0.1, 0.1-0.2, 0.2-0.3 and 0.4-0.5. Population structuring and genetic relatedness were estimated by principal components analysis (PCA) in TASSEL and visualized in R-package ggplot2 (Zheng *et al.*, 2012).

Results

Breed genetic diversity. Inbreeding coefficient and observed heterozygosity (Ho) ranged from -0.01 to 0.07 and 0.56 to 0.60 respectively (Table 1). A negative F value was recorded in the KDPG breed indicating heterozygote excess contrary to the deficit (positive F-values) in other goats. Mean Ho were generally close to the expected heterozygosity (He) than He levels were 0.43.

Population genetic structure. Principal component analysis (PCA) was used to investigate the genetic relationships among the dairy goat genotypes. The PCA showed three distinct clusters (Figure 1) with the principal components one (PC1) and two (PC2) accounting equally (50%) to the genetic variation. The three PCA clusters are; cluster 1 (Saanen, Alpine and their crosses), cluster 2 (Toggenburg, Alpine, TKDPG and their crosses, and cluster 3 (KDPG, Toggenburg, TKDPG, Alpine and their crosses).

Discussion

Our study revealed some levels of diversity within the 243 goat genotypes. Toggenburg Kenya Dual Purpose Goat (TKDPG) genotype was the most inbred genotype with an inbreeding coefficient of 0.07. KDPG as non-inbred (-0.01). The studied goat genotypes reserved high levels of genomic diversity as shown by mean Ho and He above 0.39 and 0.42, respectively (Table 1). While these heterozygozities are high, they are in the close range to those described in other goats (Onzima *et al.*, 2018).

Table 1. Inbreeding coefficient, observed and expected heterozygosities for different goat genotypes.

Genotype	Inbreeding coefficient (F)	Observed heterozygosity (Ho)	Expected heterozygosity (He)
Alpine	0.0377	0.411	0.427
KDPG	-0.0165	0.434	0.427
Saanen	0.0292	0.415	0.427
TKDPG	0.0799	0.393	0.427
Toggenburg	0.0298	0.414	0.427
Crosses	0.0406	0.410	0.427

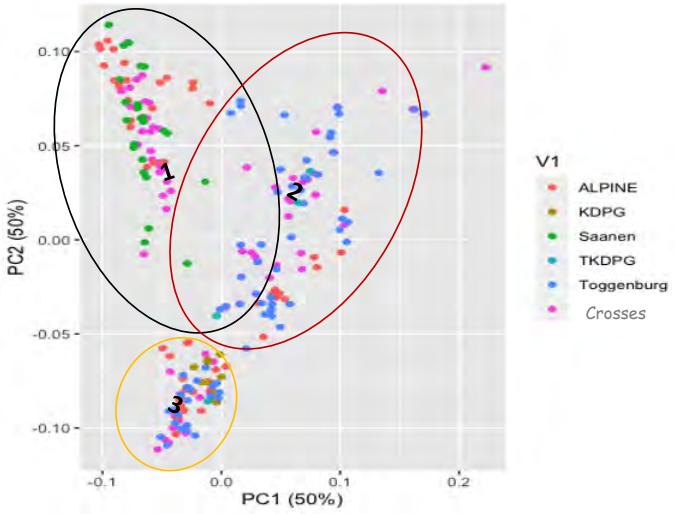

Figure 1. PCA plots for the first principal components (PC1) and second principal component (PC2) and their respective variations.

Principal component of population structure confirmed distinctiveness among the goat genotypes (Saanen, KDPG, Crosses, Toggenburg, TKDPG and Alpine) in Kenya. PCA showed 3 distinct clusters (Figure 1) corresponding to their relatedness between populations. Principal component analysis clustered the populations into three distinct clusters namely; cluster one-Saanen, Alpine and their crosses, cluster two-Toggenburg, Alpine, TKDPG and their crosses, and cluster three-KDPG, Toggenburg, TKDPG, Alpine and their crosses. This clustering revealed that admixture has occurred and genetic links exist between the genotypes due to crossbreeding. Genomic analysis of goat genotypes revealed three distinct genetic pools, and these genetic relationships is essential for selection and breeding in the ongoing breeding program at KALRO, Naivasha.

Trikoupi 36, 45332 Ioannina, Greece; acom@aua.gr

Abstract

Aim of the present study was to explore the genetic relationships of 18 sheep breeds originating from Greece (n=9), Albania (n=4), North Macedonia (n=2), Turkey (n=1), Romania (n=1), and Cyprus (n=1). To this end, admixture, population structure and phylogenetic analyses were performed. Results of admixture analysis showed the fat-tailed sheep (Chios, Sakiz, and Cyprus fat tailed) to be genetically differentiated from the rest breeds. Both admixture and population structure analyses revealed Katsika (Greece) and Karakachanska (North Macedonia) sheep to be clearly distinct from the rest sheep breeds. Phylogenetic analysis distinguished the Greek sheep breeds from Albanian (Shkodrane, Ruda, Lara and Recka), North Macedonian (Ovchepolean and Karakachanska), and the Romanian Tsigaia sheep. Current findings disclose the genetic relationships between the studied sheep breeds and are relevant in terms of priorities in conservation actions for rare indigenous sheep breeds.

Introduction

Interrogation of 50k genetic loci from 74 world sheep breeds revealed high levels of admixture during the development of modern sheep breeds, as well as a major migration route along an axis running from South-West Asia to the Mediterranean region, and then via central Europe to Britain and the Nordic regions (Kijas *et al.* 2012). The Balkan region has served as a hub along this migration route, with sheep populations exhibiting significant genetic overlap and distinctness from breeds in neighbouring regions (Ciani *et al.* 2020). Nevertheless, due to the limited number of breeds used, the genetic relationships among southern Balkan sheep populations remain elusive. Driven from the scarcity of relevant reports, the current study aimed to provide an insight into this part of the world's sheep breeds map.

Materials & methods

Data and quality. control Seven Greek sheep populations (Lesvos, Lemnos, Skyros, Oreino, Katsika, Agrinio and Peloponnesus) were sampled and genotyped using the Illumina SNP 50k array. Application of typical quality control criteria at the marker level (call rate>0.95, MAF>0.05, autosomal markers) resulted in a total number of 42,234 SNPs available. Quality control was also performed at the sample level and samples with a call rate<0.95 and an identity by descent degree of recent shared ancestry ($\hat{\pi}$) threshold of 0.1875 (halfway between third- and second-degree relatives) were removed. We also mined repository genotypic data on two more Greek sheep breeds (Kymi and Chios) and nine neighbouring sheep breeds from Albania (Shkodrane, Ruda, Lara and Recka), North Macedonia (Ovchepolean and Karakachanska), Turkey (Sakiz), Romania (Tsigaia) and Cyprus (Fat-tailed) made available by Ciani *et al.* (2020). A total number of 223 genotypes and 19,816 SNPs on 18 sheep breeds (see Figure 1 for details) were finally remained for further genetic analyses.

Genetic analyses. Admixture analysis was first conducted, with the *ADMIXTURE* software, assuming K (ancestral populations) in the range from 2 to 7 and a five-fold CV procedure to determine the optimal

R.F. Veerkamp and Y. de Haas (eds)
CC BY

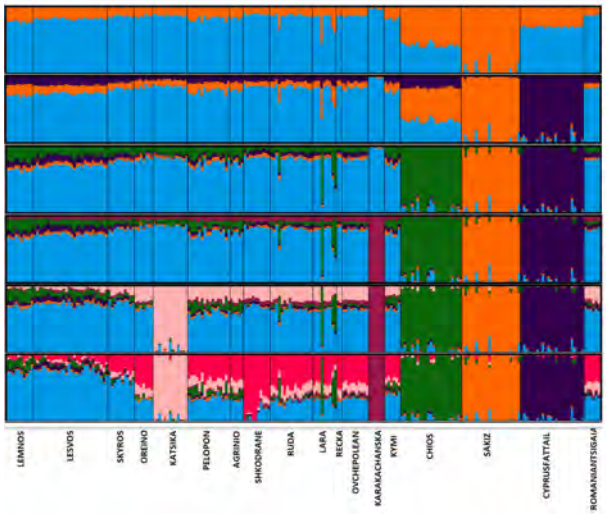
DOI: 10.3920/978-90-8686-940-4_708, © A. Kominakis *et al.* 2022

K-value presenting the lowest CV error. Admixture results were graphically visualized using Distruct from *CLUMPAK*. Population structure was then assessed via the IPCAPS (Chaichoompu *et al.* 2019) R package. *IPCAPS* assigns individuals to subpopulations and infers the total number of subpopulations present via utilizing an unsupervised clustering algorithm and an iterative process with multiple splits. Finally, pairwise Reynolds' genetic distances between breeds were calculated using the stamppNeisD' function in the *StAMPP R* package and were graphically visualized using NeighborNet graphs constructed in *SplitsTree5*.

Results

Results from admixture analysis (for K=2 to K=7) are shown in Figure 1. With the number of clusters (K) set at 2, only one distinct cluster was generated with animals of the Sakiz breed (orange color). This cluster was persistent from K=2 to K=7. At K=3, the Cyprus fat-tailed sheep (dark blue color) first emerged and remained as distinct group from K=3 to K=7. At the optimal step (K=4), another cluster was generated with the Chios breed genotypes (green color). Finally, the Karakachanska sheep (purple color) and the Katsika sheep (light pink color) were revealed as distinct genetic clusters at higher K values (K=5 and K=6, respectively).

Clustering analysis by IPCAPS resulted in a total of 13 groups (Figure 2). Here, the Karakachanska and Katsika breeds formed distinct clusters (1 and 8, respectively). Furthermore, the Cyprus fat tail genotypes were distributed across 3 clusters (2-4) not overlapping with any other breed and this was also the case for the Sakiz sheep (clusters 5-7). Furthermore, genotypes from east Aegean islands (Lemnos, Lesvos) along with those from Skyros and Kymi clustered together with Agrinio, Oreino and some Peloponnesus genotypes (cluster_11), whereas cluster_12 included genotypes from Lara, Oreino, Ovchepolean, Peloponnesus, Tsigaia, and Ruda sheep. Finally, cluster_13 consisted of the Chios genotypes and one Lara genotype (Figure 2).



Breed/population	Country	n
Agrinio	Greece	5
Chios	Greece	23
Fat tailed	Cyprus	24
Karakachanska	North Macedonia	6
Katsika	Greece	13
Kymi	Greece	6
Lara	Albania	9
Lemnos	Greece	10
Lesvos	Greece	28
Oreino	Greece	7
Ovchepolean	North Macedonia	10
Peloponnesus	Greece	16
Recka	Albania	2
Ruda	Albania	16
Sakiz	Turkey	22
Shkodrane	Albania	10
Skyros	Greece	10
Tsigaia	Romania	6

Figure 1. Ancestry proportions (left) and number of samples (right) of 18 Greek and neighbouring sheep breeds. The x-axis represents individuals grouped according to breed. Each colour represents a population and each individual is represented by a vertical line partitioned into colored segments whose lengths represent the admixture proportions from K=2-7 ancestral populations.

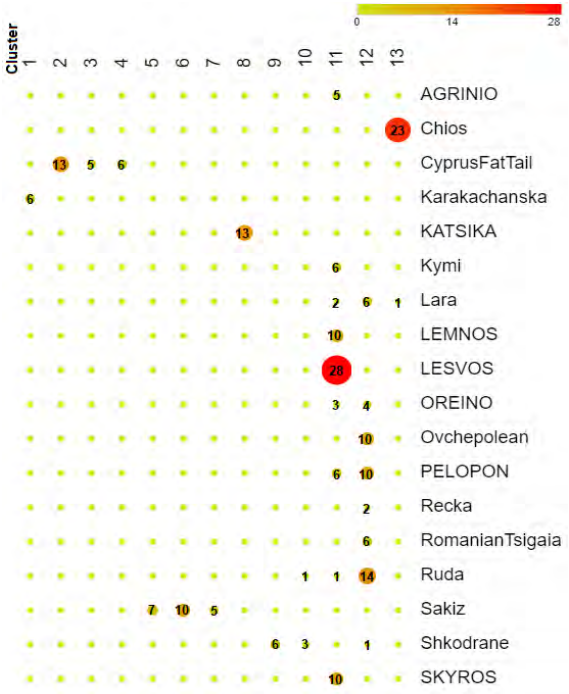


Figure 2. Distribution of sample genotypes across the inferred clusters obtained by IPCAPS (numbers indicate the number of animals per breed assigned to clusters).

Phylogenetic network (Figure 3) revealed two distinct geographically corresponding branches: one with the Karakachanska, Shkodrane, Ruda, Ovchepolean, Recka and Tsigaia breeds (west-north) and the other (east) with the rest of the breeds. One sub-branch emerged at the base of the latter branch, consisting of Greek sheep from Peloponnesus, Epirus (Katsika and Oreino), Kymi and Agrinio. Finally, a major east

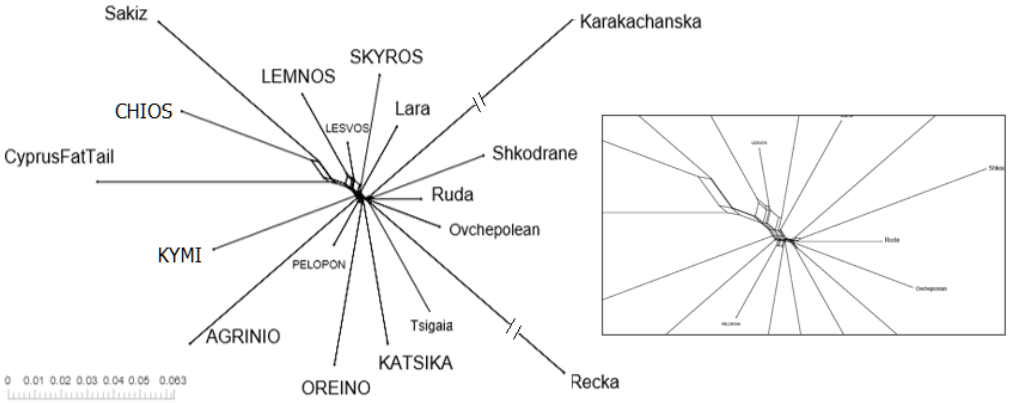

Figure 3. Phylogenetic network based on the estimated pairwise Reynolds' genetic distances between 18 Greek and neighboring sheep herds. Long terminal distances reflect small samples. Breed names in capital letters are of Greek origin.

sub-branch emerged, consisting of one group of Aegean islands populations (Skyros, Lesvos, and Lemnos) along with the Lara breed (Albania) and another outgroup formed by the fat-tailed breeds (Sakiz, Chios, and Cyprus fat tail). For the Greek breeds, an east-west genetic cline was noticed.

Discussion

In the present study, we attempted to resolve the population structure and phylogenetic relationships between nine Greek and nine neighbouring sheep populations. Our results exhibited a genetic differentiation of the Albanian and North Macedonian sheep from their Greek counterparts, and this was obvious even for geographically neighbouring breeds, such as those from Epirus (Greece) (Katsika and Oreino) and Albania. Our results also confirmed previous findings, as they showed: (1) a geography-related genetic differentiation for sheep from Albania and Greece (Pariset *et al.* 2011); (2) an east-west genetic cline for the Greek breeds (Ciani *et al.* 2020, Kominakis *et al.* 2021); and (3) close genetic relationships between the Albanian sheep breeds (Shkodrance, Recka and Ruda) (Hoda *et al.* 2011). Finally, since some of the sheep breeds evaluated here are endangered (e.g. Agrinio, Oreino, Katsika, Shkodrane, Lara, Karakachanska), the current findings could be used to design and prioritize future conservation efforts.

709. Genetic determinism of quality of lamb leather in Lacaune dairy sheep breed

H. Larroque[1], E. Dugas[1], F. Woloszyn[1], F. Plisson-Petit[1], J. Gayraud[2], J.-C. Duchêne[3], J. Frayssignes[4], A. Gille[4], S. Brenot[5], D. Allain[1] and L. Drouilhet[1*]

Abstract

Lacaune lamb skins are well known for their high quality and their use in the leather industry and luxury ready-to-wear clothing. In France, for several decades, the quality of this leather has deteriorated, mainly due to two skin defects: pinhole and straw-like bushiness. To explore the genetic determinism of these defects, around 1,400 Lacaune lambs, from 72 rams, were phenotyped for the 2 skin defects and 4 wool traits. The pinhole defect showed a high heritability (0.59±0.07) and was highly genetically correlated to the wool predicted core bulk (r_g=0.54±0.08). The straw-like bushiness defect had a lower heritability (0.25±0.06), and was correlated to the mean fiber diameter (r_g=0.41±0.15). A genome wide association study revealed for the pinhole defect one major signal on chromosome 3 close to a cluster of keratin genes, known to play an important role in skin development.

Introduction

Lamb skins are generally considered to be a by-product of sheep production and genetic studies of traits directly related to sheep skin are infrequent in the literature. The Lacaune sheep milk breed is bred in south of France, in the Roquefort cheese production area. Lacaune lamb skins are well known for their high quality and their use in the leather industry and luxury ready-to-wear clothing. Therefore, historically, a large majority of French tanneries was located in the same geographical region. However, for several decades, a degradation of this leather quality was observed, mainly due to the presence of two skin defects: pinhole and straw-like bushiness. Pinhole consists of small holes in the grain surface of the dewooled pelt, which decreases the leather quality. The straw-like bushiness defect is defined as perforations due to the presence of forage debris planted in the thickness of the dermis. In the present study, we explored the genetic determinism for these two main skin defects and their possible relationship with wool traits.

Materials & methods

Animals and phenotypes. Around 1,400 Lacaune lambs (from 72 rams) were born around February 2020 and 2021 (in 16 different farms) and identified at birth with electronic ear tags. At around 35 days-old lambs were brought together in a unique fattening farm. Around 60 days-old, a blood and a wool samples of each animal were collected (they were carried out in the fattening herd within the framework of the usual practices of breeding by authorized persons from OVI-test AI organization). After an average fattening period of 79 days, animals were slaughtered and their skins were sent to the ALRIC tannery to proceed to the tanning. Each skin was identified in order to be assigned to one lamb. The two defects were scored at the end of the tanning procedure: skin pinhole score (from 0=absent to 4=abundant corresponding to several heavily marked regions), and straw-like bushiness score (from 0=absent to 2=abundant). Wool samples were analysed by Optical Fibre Diameter Analyser (OFDA) for determining mean fibre diameter (MFD, µ), coefficient of variation of fibre diameter (CVD, %) and mean fibre curvature (MFC, °/mm). Predicted core bulk (PCB), expressed in cm3/g, represents the occupied volume by 1 gram of wool under a pressure of 10^{-3}

N (Sumner *et al.*, 2005). At the end, 1379 lambs were phenotyped for wool traits, 1,166 for leather defects, and 1,158 for both (Table 1).

SNP genotypes. DNA of a subset of 1,248 animals was extracted from blood sample and genotyped using the Illumina OvineSNP50 BeadChip. Genomic analyses were performed using 1,248 phenotyped and genotyped lambs, plus their 72 rams' genotypes (available from a previous project). SNP quality was checked (i.e. SNP call rates >95%, minor allele frequency >5%, inconsistent for Hardy-Weinberg disequilibrium). Finally, 38,439 autosomal SNPs were retained and 14 lambs failed QC and were removed.

Statistical analysis. Variance-covariance components were estimated with the airemlf90 software (Misztal *et al.*, 2002) using pedigree information (8,575 animals over 6 generations) combined with SNPs information. Heritabilities were estimated with linear single trait animal models, and genetic correlations with linear bivariate animal models. For leather defects, the models included environmental fixed effects of birth herd (16 levels), year×housing condition during the fattening period (3 levels), litter size (2 levels: 1, 2 or more), duration of fattening period (as co-variable, 79±15.71 d) and a random additive genetic animal effect. For wool traits, the models were the same excepting for duration of fattening period replaced by the age at sampling (61±12.07 d). Genome wide association analysis (GWAS) was performed using GEMMA software (Zhou and Stephens, 2012) using phenotypes adjusted for environmental effects defined above with the procedure GLM of SAS software, the threshold of significance was at the genome level (probability of 0.05 divided by the number of SNP used).

Results

Phenotypes characteristics of leather and wool traits are presented in Table 1. The mean of the pinhole score was 1.47, and 25% of skins did not express the defect whereas the percentages of skins classified of 1 to 4 were of 28, 27, 17 and 4% respectively. For Straw-like bushiness, the mean was 0.86, and 45% of skins showing no defect, whereas 27% presented this defect with a low density (score 1) and 28% with a high density (score 2). Straw-like bushiness presented a moderate estimated heritability of 0.25, whereas the other traits had a high estimated heritability ranging from 0.48 for MFD to 0.61 for MFC (Table 1).

Phenotypic and genetic correlations estimated between each leather defect and wool traits are shown in Figure 1. The two leather defects showed low to moderate phenotypic correlations with wool traits and reach 0.33 and 0.17 with PCB (for pinhole and straw-like bushiness defects respectively). Although the two defects were genetically highly correlated (0.66±0.11), their correlations with wool traits were somewhat different. Pinhole defect presented a strong positive genetic correlation with MFC (0.38±0.09) and PCB (0.54±0.08). Lambs with high MFC or high PCB wool had genetically a skin with more pinhole defects. Straw-like bushiness defect showed a moderate positive genetic correlation with PCB (0.31±0.14) and a higher genetic correlation with MFD (0.41±0.15). The two defects were related to PCB.

Table 1. Summary of phenotypes used for estimation of genetic parameters and heritability estimations.

	Records	Mean	Std	Heritability	SE[1]
Pinhole	1,166	1.47	1.14	0.59	0.07
Straw-like bushiness	1,166	0.86	0.84	0.25	0.06
MFD	1,379	19.31	2.02	0.48	0.07
CVD	1,379	25.75	5.85	0.51	0.06
MFC	1,379	93.45	10.38	0.61	0.06
PCB	1,379	28.02	1.43	0.57	0.06

[1] Approximated standard error of heritability.

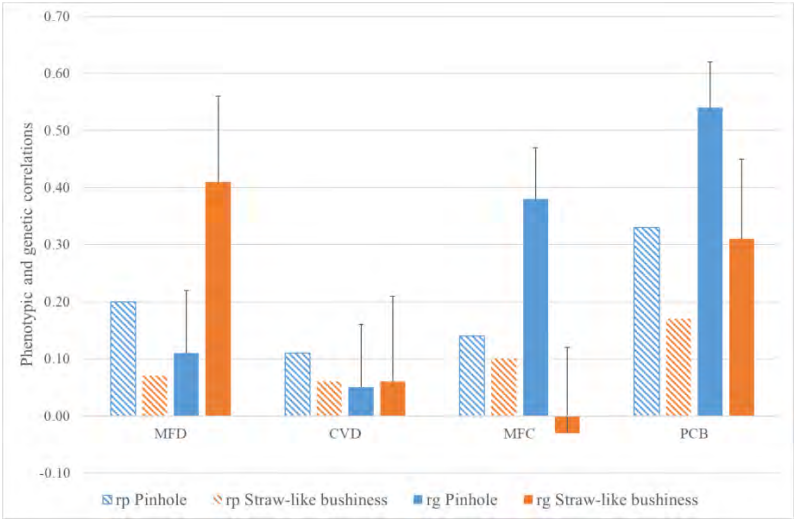

Figure 1. Phenotypic and genetic correlations between leather defects and wool traits (rp: phenotypic correlation, rg: genetic correlation, vertical line: approximated standard error).

Genome wide association studies were performed on 1,147 animals for the pinhole defect and the straw-like bushiness defect. A significant signal was detected at the genome-wide threshold for the pinhole defect, localized on OAR3 (Figure 2).

We identified the most significant SNP at a position of 146.2 Mb on the ovine reference genome (Oar_rambouillet_v1.0). Considering the significant region at the chromosome-wide threshold, it encompasses 4 Mb and the cluster of Keratin genes localised between 143-144 Mb. In contrast, no significant signal was found for the straw-like bushiness defect.

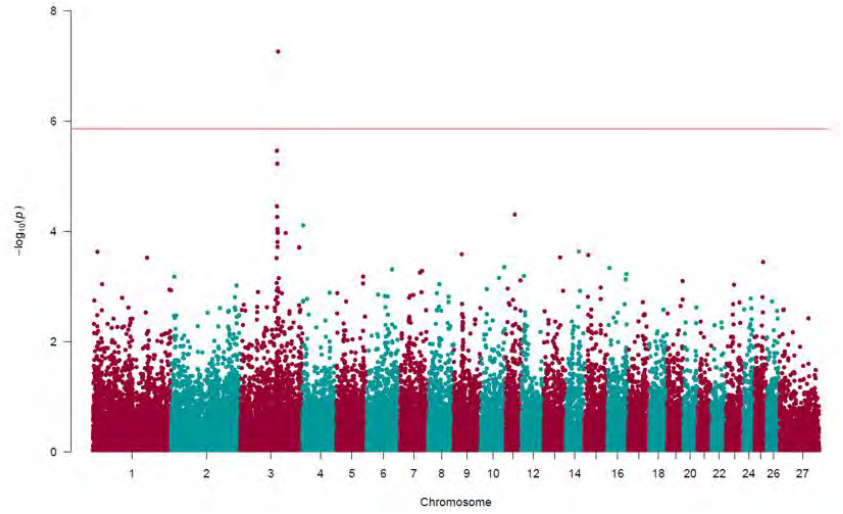

Figure 2. Manhattan plot for GWAS of pinhole defect. This plot is based on −log 10 (*P*-value) from GWAS against chromosome position, each colour represents different chromosome. Red line indicates genome-wide significant threshold.

Discussion

A defect similar to the pinhole defect was studied in New-Zealand and Australia. We found an estimation of pinhole heritability of 0.59, which was close to the estimation of 0.6 found by Campbell *et al.* (1997) on fewer animals. We have found a high genetic correlation (0.54) between pinhole defect and PCB, a higher level of wool PCB being related to a higher presence of pinhole defect. This can be related to previous studies carried out in New-Zealand, where a phenotypic positive relationship was found between the presence of the pinhole defect and PCB (Scobie *et al.*, 1997; Cooper, 2002). In these previous studies, high PCB was related to a more pronounced curvature of fibers. These authors proposed that when removing the fleece, fibers that have a high curvature remove part of the collagen matrix at the same time, affecting the skin (Scobie *et al.*, 1997).

No data on genetic parameters for the straw-like bushiness defect are available in literature. Its heritability estimation was 0.25, suggesting a large influence of the environment on this skin defect. Length of the fattening period (highly correlated with age at slaughter) seemed to influence the presence of this defect. Indeed, lambs with a longer fattening period had more straw-like bushiness defects, which could be linked to a longer exposition of their skin to the plant debris.

Our genetic study led to the identification of a region nearby the cluster of Keratin genes localized on OAR3. Keratin genes is a family of structural fibrous proteins also known as scleroproteins. It is the key structural material making up scales, hair, nails, feathers, horns, claws, hooves, and the outer layer of skin among vertebrates. Keratin also protects epithelial cells from damage or stress. Sequencing of finely chosen animals is currently on-going to identify one or several candidate mutations in our region of interest.

For pinhole defect, its high heritability, its strong genetic correlation with a wool trait measurable on live animals and the detection of a QTL affecting it, indicate that a genetic selection could be considered in order to decrease its frequency in Lacaune breed. However, additional studies must be conducted in order to better understand its genetic determinism and to evaluate its relationship with traits currently selected in this dairy sheep breed.

Abstract

Sheep farming plays an important role in the rural economy and about 250 million sheep are reared for dairy purpose worldwide. The whole amount of sheep milk is used for cheese making and the presence of non-coagulating milk affects negatively economics of dairy industry. Beside the effects exerted by the environmental factors, additive genetic individual differences in coagulation exist and allow genetic improvement. The aim of this work was to study differences between coagulating and non-coagulating milk samples, to estimate h^2 and conducting a genomic association study on milk coagulation phenotypes. A total of 8.7% samples did not coagulate within 30 min and a difference in milk composition between normal and non-coagulating samples was observed. Genetic analysis allows both to estimate h^2 for the coagulation event of 0.23 (0.04) and to suggest 45 genes involved in mammary gland metabolism and udder health status.

Introduction

Sheep farming plays an important role in the rural economy, in particular for Mediterranean area, Asian, and developing countries. About 250 million of dairy purpose sheep farmed worldwide produce about 10 million t of ovine milk (Pulina *et al.*, 2018), which is nearly all processed into cheese. Thus, the ability of milk to coagulate properly is crucial. Milk coagulation is assessed by individual laboratory rennet coagulation time (RCT) and curd firmness (A_{30}) (i.e. the time between the addition of rennet to milk and the beginning of the clot formation and the curd consistence, respectively). The combination of low RCT and high A_{30} are usually associated with higher cheese yield (De Marchi *et al.*, 2008). However, a variable proportion of individual milk samples of different species did not coagulate within this time range. The latter aspect is strongly associated with milk composition (e.g. protein, lactose, pH, and somatic cells) (Bittante *et al.*, 2012). In small ruminants, beside the effects exerted by different environment and management, individual differences exist due to the additive animal variability (Puledda *et al.*, 2017). Thus, the coagulation ability could be improved though breeding schemes. Moreover, genome-wide analysis (GWA) of non-coagulating milk allowed to map QTL in cattle (Duchemin *et al.*, 2016) but a few reports are available in dairy ewes (Marina *et al.*, 2021). The aim of this work was to study differences between coagulating and non-coagulating milk samples, to estimate the variance components and heritability and to find regions associated with this trait.

Materials & methods

Data. Individual milk samples of 1,018 ewes from 47 flocks located in Sardinia (Italy) were analyzed. Data came from a project aimed to investigate milk coagulation properties (MCP) in Sarda dairy sheep (Manca *et al.*, 2016; Puledda *et al.*, 2017). RCT was determined by Formagraph instrument (Foss Electric A/S, Hillerød, Denmark) for all samples, that were divided in two classes: (1) COAG, samples coagulating within 30 minutes; (2) NON-COAG, samples that did not coagulate in this time range. Milk composition traits (fat, protein, lactose, SCS, chloride and urea) were recorded for all samples to compare the two groups.

Moreover, 769 ewes were genotyped with Infinium Ovine SNP50 v1 BeadChip (Illumina Inc., San Diego, CA). After quality control, 44,619 SNPs on 27 OAR chromosomes remained for GWA study.

Heritability estimation. The following threshold animal model was fitted to estimate variance components and heritability (h^2)

$$y = Xb + Z_1f + Z_2a + e \quad (1)$$

where: y is the vector of coagulation binary trait; b is the vector of fixed effects including the month of lambing (4 levels), days in milk in classes of 30d (5 levels) and parity (3 levels); f is the vector of the random effect of flock-test days of sampling combination (69 levels) ~$N(0, I\sigma^2_{ftd})$; a is the vector of the random additive genetic effects ~$N(0, A\sigma^2_a)$ where A is the numerator relationship (5,031 animals) and e is the vector of random residuals ~$N(0, I\sigma^2_e)$ The σ^2_{ftd} σ^2_a σ^2_e are the flock-test day, additive genetic and residual variances. The X, Z_1 and Z_2 are the incidence matrices relating records to effects. Variance components and heritability were estimated using thrgibbs1f90 software (Misztal *et al.*, 2014), which implements a Gibbs sampling method. The following parameters were used: 50,000 samples were generated, with the first initial 5,000 rounds discarded as burn-in, and all were saved. The heritability was estimated as intra-herd h^2. The value on the liability scale, which is a function of h^2 and incidence of coagulation classes, was transformed on the observed scale.

GWA study and gene discovery. The model (1) was modified under the ssGBLUP framework to accommodate H^{-1} matrix in place of A^{-1} and later used for GWA study according to Cesarani *et al.* (2021). Briefly, the GEBV were back-solved into SNP effects and the additive genetic variance explained by each SNP was computed. The SNP exceeding the 99.9th percentile were retained as suggestive of trait association. Using genome browser (https://genome.ucsc.edu/) genes included in the neighbour of suggestive SNP were retrieved, and a gene-by-gene literature review was performed in order to assess previously association with MCP and milk traits.

Results

A total of 89 milk samples (8.7% of the total) did not coagulate within 30 min from the rennet addition. Average RCT for the COAG group was 15.13±6.5 minutes. Samples of the NON-COAG group showed larger values for protein (5.72 vs 5.38%, P<0.001), chloride (194.5 vs 141 mg/100 ml, P<0.001), and SCS (7.50 vs 4.37, P<0.001), whereas they exhibited lower values for lactose (4.44 vs 4.85%, P<0.001) and urea (33.2 vs 38.4 mg/dl, P<0.001). The heritability of the coagulation ability was moderate (0.23±0.04).

As far as GWA is concerned, a total of 458 SNP overcome the threshold defining 40 QTL regions over 18 chromosomes (autosome and sexual); OAR12, 13, 15, 16, 17, 18, 19, 24 and 25 did not show any associated SNP with failure in coagulation phenotype. The distribution of suggestive SNPs and the proportion of additive genetic variance are presented in Figure 1.

Among the genomic regions identified by tag SNPs, nearby 17 of them, 260 genes were retrieved, but only 45 (Table 1) were involved in cellular function associated to dairy traits in ruminant species (i.e. milk coagulation, milk production and composition, udder health, heat stress resistance).

Discussion

Literature reports quite high percentage of non-coagulating milk samples, both in cows and sheep. In Swedish Red cattle breed, about 18% of milk samples did not coagulate within 30-40 minutes (Gustavsson *et al.*, 2014); lower percentages were reported for Holstein (9.7%; Cecchinato *et al.,* 2011) and Brown Swiss

[1] OAR *Ovis aries* chromosomes.

(3.5%; Cecchinato *et al.*, 2011). For sheep milk, about 10% of samples were found to be NON-COAG in studies involving Sarda sheep milk (Manca *et al.*, 2016).

A higher proportion (17.7-19.4%) of NON-COAG samples was reported by Caballeros-Villalbos *et al.* (2017) and Garzón *et al.* (2021) in Manchega sheep breed. In our study, the main differences between the two investigated groups of milk samples seem to be associated with health indicator or involving permeability of mammary gland epithelium, which facilitates the exchanges of molecules from bloodstream to the alveolus of the mammary gland. As far as the heritability was concerned, we did not find reports on coagulation trait as binary trait in sheep. In dairy cattle, threshold model applied on binary outcome rather than linear model on RCT (with the exclusion NON-COAG) halved the h^2 estimates (Cecchinato and

Carnier, 2011). In our case, the h^2 estimate was in agreement with previous report on RCT excluding the NON-COAG samples in different sheep breed (Puledda *et al.*, 2017; Sanchez Mayor *et al.* 2019).

The gene discovery on GWA results allow us to prioritize a set of genes previously associated to milk or cheese related traits in dairy ruminants, such as those affecting somatic cell count (*CHKA*, *TCIRG1*, *PPIL3*), mastitis (*ALKBH6, SPCS3, LRRC41*), either overexpressed in mammary gland in different lactation stage (*CMPK1*) or in different milk ability group (*ZCCHC17*) and involved in lactose synthesis (*SLC35A2*) (Bonnefont *et al.* 2011; Dhorne-Pollet *et al.*, 2012; Ghahramani *et al.*, 2021; Michailidou *et al.*, 2021; Sadovnikova *et al.*, 2021). Many other retrieved genes have been previously associated to milk fat and/or composition in sheep milk. In conclusion, the genes of interest are mostly linked to mammary gland metabolism, udder health status and milk compound known to affect the ability of milk to coagulate. These findings are consistent in explaining the differences in the milk composition observed between COAG and NON-COAG individual milks.

Abstract

The development of an international genomic evaluation may represent an interesting opportunity for small ruminant populations, especially to increase the size of their reference population. In this perspective, 4 countries have decided to evaluate the feasibility of an international caprine genomic evaluation of the Alpine breed. For this purpose, variance-covariance components analysis was performed in order to estimate heritabilities and across countries genomic correlations for 3 traits, milk yield, fat content and rear udder attachment. The heritabilities were accurately estimated and coherent with previous estimations. The genomic correlations were high for rear udder attachment ranging from 0.76 (0.037) to 0.92 (0.004) and for fat content with correlation of 0.78 (0.013). However, they were only estimable in one case for milk yield with a moderate value of 0.45 (0.095). The results for the first 2 traits are encouraging but the results for milk yield need to be further investigated.

Introduction

International genomic evaluations may represent an interesting opportunity for small ruminant populations to pool their efforts to access genomic selection or to expand their reference population (Brøndum *et al.*, 2011), especially for traits that are difficult or costly to measure. In goats, 4 countries, Canada (CAN), France (FRA), Italy (ITA) and Switzerland (CHE) have decided to evaluate the feasibility of an international caprine genomic evaluation in Alpine breed, within the H2020 Smarter project. For that, they shared their phenotypes, pedigrees and genotypes. A preliminary study evaluated their genetic exchanges, as well as the genomic distance between their populations (Teissier *et al.*, 2022). The results of the PCA and Admixture analyses demonstrated that European populations, in particular French and Italian, are very close, while the Canadian populations are further apart. Italy is the country that imports the most animals from France, which may explain the genetic proximity between these two populations. In contrast, the Canadian and European populations are more genetically distant. This might be explained by the little exchange of animals and the geographical distance that separates Canada and the European countries. To develop an international genomic evaluation a prerequisite is that the genetic correlations across countries for common traits under selection are high. The objective of our study was therefore to estimate in Alpine breed the variance components and genetic correlations between the four countries for common traits. We present here the results for 3 traits representative of situations encountered according to the type of trait, the number of countries involved and the level of heritability: milk yield (MYI), milk fat content (FCO), and rear udder attachment (RUA).

Materials & methods

Phenotypes and pedigrees. The phenotypes considered are those currently used by each country for its genetic evaluations. MYI is phenotyped by the four countries, RUA by Canada Italy and France, and FCO is only common to Italy and France. Table 1 present all records shared by each country and used in these analyses. Given the large amount of phenotypes recorded in France and Italy for milk production,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_711, © M. Teissier *et al.* 2022

we limited the phenotypes for animals born from 2000 to 2010 in France and born from 2002 to 2015 in Italy. For Canada and Switzerland, all MYI phenotypes shared were used. For udder type trait (RUA), all phenotypes from the four countries were used. Even so, France had the highest number of phenotypes, followed by Italy, Switzerland and Canada (Table 1).

The RUA trait is recorded in the three concerned countries according to a scale from 1 to 9. For FCO, France expresses it in g/kg of milk and Italy in dg/kg of milk. MYI in kg is not similar across the 4 countries. Indeed, France calculates MYI for a reference lactation duration of 250 days, Canada for a 305-day lactation, Switzerland evaluates MYI from 1 to 100 DIM and from 101 to 200 DIM so the two quantities were summed up, and Italy uses a multiplicative pre-adjustment for parity, age and number of kids.

In total for MYI analysis, 807,534, 71,276, 25,497 and 8,007 animals were kept in the French, Italian, Canada and Swiss pedigree file respectively. For FCO, 806,877 French and 63,617 Italian animals were in the pedigree file. And for RUA, it contained less animals (474,963 French, 29,721 Italian and 9,434 Canadian animals respectively) (Table 1). The pedigree consists of 91% females and these animals were born between 1936 and 2020 for milk production traits and between 1960 to 2020 RUA.

Genotypes. The four countries also shared their genotypes on the Goat SNP50 BeadChip (Illumina Inc., San Diego, CA, USA). SNP quality was checked with PLINK 1.9 software (Purcell *et al.*, 2007) within breed and country and then by merging the genotypes of the 4 countries (i.e. SNP call rates >90%, minor allele frequency >1%, inconsistent for Hardy-Weinberg disequilibrium, genotypes call rate >90%). Finally, 50,578 SNPs and 6,102 animals were retained, with around 50% of the genotypes coming from France (Table 1).

Statistical analysis. Variance-covariance components were computed via Gibbs sampling, with the gibbs1f90 software (Misztal *et al.*, 2002), using pedigree information combined with SNPs information. For each trait, a multi-trait animal model was used where each country was considered as a different trait and for which the model was the one used in routine national genetic or genomic evaluation. For milk yield traits, random animal and permanent environment effect were added in addition of national fixed effect. For France, fixed effects were herd×year×parity, age_at_kidding×parity×year×area, month_kidding×parity×year×area, length_of_dry_period×parity×year×area; for Italy herd-year-season of calving; for Switzerland lactation, year×season, herd (random); and for Canada herd, lactation and birth. For RUA, models contained one random genetic animal effect and fixed effects: herd×year×parity, age at scoring×year,

lactation stage at scoring×year (France); DIM×parity, classifier, herd-season of classification, age(linear + quadratic) (Italy); herd×year×classifier(random), breed, parity, age, DIM (Canada). Covariances across country was estimated only between countries for animal effect. For each trait, heritability estimates obtain in 2-by-2 multi-country model were averaged. Genomic correlations were computed with the countries involved for each trait. However, for MYI it was not possible to estimate correlations across the 4 countries. Only, correlation between France and Italy has proven to be sufficiently accurate.

Results

Phenotypes characteristics are presented in Table 1. For RUA, the mean score is close between Canada and Italy and a little weaker in France in Alpine breed. For FCO, despite the difference of unit, we can observe that the means for the two countries (France, Italy) are close but a little higher in France. For MYI, due to the differences in calculation between countries mentioned above, the means of this phenotype are very different between countries. Italy and Switzerland have lower lactation MYI levels than the other two countries: 524.02 and 565.74 kg respectively in the Alpine breed (Table 1).

All estimates of heritabilities had small to moderate standard error. Averages of estimates with 2-by-2 multi-country models are presented in Table 1. For each country, these estimates are relatively close to the ones used in the national genetic evaluations. MYI had low (0.11 in Switzerland) to moderate (0.32 in Canada) heritabilities. FCO had high a heritability in France (0.50 in ALP) and a moderate one in Italy (0.23). RUA shown comparable estimated heritabilities in Canada and Italy (0.25 and 0.19, respectively) and almost twice as high in France (0.38). Highest differences were observed for Canada between official h^2 (0.08) and estimated h^2 (0.25).

Genomic correlations between countries in the Alpine breed are presented in Table 2. For MYI, only estimates between France and Italy are presented. For RUA, correlations were high ranging from 0.76 between France and Italy to 0.92 between France and Canada. For FCO, the correlation between France and Italy was also high (0.78). Whereas for MYI, the correlation between France and Italy of 0.45 was only moderate.

Discussion

In our study heritabilities estimates were relatively accurate and consistent with the within-countries estimations (Official h^2, Table 1) (Carillier *et al*., 2013; Massender *et al*., 2022). However, the estimations of genomic correlations showed different patterns according to traits. Our results shown that for RUA, despite a low level of genetic connection between the Canadian and European populations and very unbalanced data amounts, the correlations across the 3 countries are high. The definition of the phenotype for this trait seems close between countries. The lower correlations for FCO than for RUA between France and Italy could be due to little difference in calculation of this phenotype. The most surprising result was the

Table 2. Across countries genomic correlations (and SE) in Alpine breed.

Trait[1]	Country	Italy	Canada
MYI	France	0.45 (0.095)	
FCO	France	0.78 (0.013)	
RUA	France	0.76 (0.037)	0.92 (0.004)
	Italy		0.78 (0.002)

failure to accurately estimate genomic correlations for the most prevalent trait (common to all 4 countries) MYI. For this trait, convergence was not reach when using data from Canada and Switzerland. It can be supposed that the estimation of covariances for this trait is the victim of a combination of circumstances: a weak genetic connection except between France and Italy, a very unbalanced amount of phenotypes (more than 80% from France), different calculations of the phenotypes together with different heritabilities and analysis models. Only correlation between France and Italy could be estimated but is relatively low.

These analyses were performed in Saanen breed too and similar results regarding heritabilities as well as genetic correlations have been found on the same traits (results not shown). In the same manner, difficulties in estimating genetic correlations for MYI across countries were encountered in this breed.

The strong genomic correlations estimated for RUA and FCO across countries, especially between France and Italy, are promising for future international genomic evaluations in goats. However, given the importance of MYI in breeding objectives, work will have to be done to better understand the difficulty to calculate the across countries correlations for this trait.

712. Wool colour traits in Gotland sheep and association with a deletion in ASIP

A.M. Johansson

Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; anna.johansson@slu.se

Abstract

In Gotland sheep several different traits including wool colour traits are recorded in most breeding rams. Here, the distributions of three wool colour traits are described and an association analysis is performed with a five base pair deletion (D_5) in the gene A*SIP*. Phenotypes were available for 96 rams of which 43 also had a D_5 genotype. There was a significant association between presence of D_5 and the trait 'cleanness of colour'. This investigation also confirmed earlier indications of that all Gotland sheep seem to have multiple copies of *ASIP*.

Introduction

Gotland sheep is a Swedish sheep breed famous for their grey curly and shiny wool. Gotland sheep can be of different shades of grey and some have the same grey colour all over the fleece whereas others have different grey shades in different parts or even some white strings in the grey fleece. The history of the breeding and the traits are described in (Näsholm 2005). The heritability for the nuance of fleece colour have been estimated to 0.48 (Näsholm 2005). The undesired phenotype of white strings in the grey fleece is called 'pepper and salt' and has been observed to increase but have a low heritability (Näsholm 2009).

Adalsteinson (1978) suggested an allele at the *agouti* locus together with modifiers to explain the variation in grey colour in Gotland sheep. The *agouti* locus has later been identified as the gene *ASIP*. In a previous study of Gotland sheep and some other Swedish breeds it was shown that the nine base pair deletion (D_9) of the gene *ASIP* was present in all investigated Gotland sheep and in most grey sheep of other Swedish breeds (Rochus *et al*., 2019). Another deletion of five base pairs (D_5) of *ASIP* have been shown to be associated with black colour in homozygotes for D_5 (Norris and Whan 2008, Rochus *et al.* 2019). Norris and Whan (2008) also identified a duplication of *ASIP* as the dominant white allele at the *agouti* locus. In the study of Rochus *et al.* (2019) it was shown that Gotland sheep most likely have multiple copies of *ASIP* since they all were heterozygous for most of the polymorphic sites. The only site with more than one genotype in *ASIP* in Gotland sheep was regarding D_5, where some sheep were heterozygous for the deletion and the non-deleted allele (D_5N_5) and some were homozygous for the non-deleted allele (N_5N_5). In the study by Rochus *et al.* (2019) different grey shades were not considered but all grey sheep were grouped into the same phenotype. In this study I use a more detailed description of the phenotype and investigate the association of the D_5 mutation with three colour traits in Gotland sheep.

Materials & methods

Records from 96 rams of Gotland sheep from the Gotland sheep association were used and nasal swab samples were taken using Performagene™ from DNA Genotek, Canada. The data were derived from the routine ram examination that is usually done for potential breeding rams of this breed. Most of the rams (64) were young rams born in 2020, but 32 of them were older rams (born 2015-2019). The rams were from 10 different farms. There were three colour phenotypes: (1) colour (categories: white, extra light grey, light grey, grey, dark grey, black grey); (2) cleanness of the colour (categories: medium, clean, blue); and (3) the undesired trait 'pepper and salt' with white strings in the grey fleeces (categories: no, some, yes, a lot). The distributions of the three colour phenotypes in the 96 rams are shown in Table 1.

Table 1. Distribution of colour phenotypes in the 96 rams.

Main colour		Cleanness of colour		Pepper and salt	
Colour	**Number**	**Cleanness**	**Number**	**Presence**	**Number**
white	1	medium	82	no	46
extra light grey	1	clean	13	some	33
light grey	13	blue	1	yes	15
grey	60			a lot	2
dark grey	17				
black grey	4				

DNA extraction and Sanger sequencing was done by a research technician at Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences. DNA was extracted from the nasal swabs according to the instructions from the manufacturer. The first part of the gene *ASIP*, including the sites for the nine base pair deletion (D_9) and the five base pair deletion (D_5), was sequenced with the same primer pair and the same conditions as in Rochus *et al.* (2019). The DNA quality from the nasal swabs was not good enough for getting high quality sequences in all samples. Good enough sequences in the region encompassing the D_5 mutation were obtained from 45 samples and for D_9 from 56 samples. The D_5 allele is easiest to detect in Gotland sheep in the reverse sequence due to the proceeding heterozygosity for the D_9 allele in all Gotland sheep in the forward sequence. For the D_5 allele it is the sequence AGGAA that is deleted in the forward sequence and thus it is the sequence TTCCT that is deleted in the reverse sequence. The non-deleted alleles for the sites of D_9 and D_5 are denoted N_9 and N_5, respectively.

The sequences were examined with the software 4peaks (from Nucleobytes, the Netherlands). The Fisher's exact test for testing of association between D_5 genotype and the three colour phenotypes was done in R (R Core Team 2021). For the Fisher's exact test, phenotype groups with small numbers were combined with one or two other groups, i.e. for the main colour dark grey plus black grey were in one group and the lighter colours in one group, for the pepper and salt phenotype 'no' was in one group and the phenotypes with some degree of pepper and salt was in the other group, for cleanness of colour the medium was in one group and clean and blue was combined into the other group (see footnotes in Table 2). In this way was there was 2×2 contingency tables for Fisher's exact test for all three tests.

Results

In agreement with the results from Rochus *et al.* (2019) the D_9 mutation was observed in heterozygous form in all samples where that region was possible to analyse (56 samples). This supports that there is a duplication of *ASIP* in Gotland sheep. The D_5 mutation was more difficult to accurately determine the

Table 2. Distribution of colour phenotypes among the 43 samples with good *ASIP* sequence in the D_5 region and phenotype.

Main colour			Cleanness of colour			Pepper and salt		
Colour	D_5N_5	N_5N_5	**Cleanness**	D_5N_5	N_5N_5	**presence**	D_5N_5	N_5N_5
light grey[1]	1	2	medium	14	21	no	12	10
grey[1]	17	14	clean[1]	6	1	some[1]	6	9

black grey[1]	1	2				a lot[1]	0	1

[1] Combined in Fisher's exact test.

genotype, since the peaks from the haplotype with D_5 were always lower than the haplotype without a deletion (see an example in Figure 1). Thus, in some samples it was difficult to distinguish a possible D_5 haplotype from background noise. The presence or absence of D_5 was clearly determined in 45 samples but two of these had some unclarities in the linking of IDs to phenotypes. Only the 43 samples that both had been successfully genotyped for D_5 and had undoubtful phenotypes were used for association analysis with the colour phenotypes. Out of these 43 sheep 21 were D_5N_5 and 22 were N_5N_5. The phenotype distribution among these two groups can be seen in Table 2. The Fisher's exact test showed that the distribution of the phenotype cleanness was significantly different (P=0.021) between the sheep with D_5 and those without D_5. For the other two phenotypes there were no significant differences. The six rams with phenotype 'clean' and genotype D_5N_5 are born in four different farms (3 of them from one farm) and all six are thus not closely related. The ram with phenotype 'clean' and genotype N_5N_5 is born in the same farm as three with phenotype 'clean' and genotype D_5N_5.

Discussion

The nasal swabs are less likely to give good enough DNA quality than blood samples or tissue samples, but the advantages are that it is a non-invasive testing method that can be done by the owner and that samples can be stored in room temperature which facilitates the sampling.

The significant association of presence of D_5 with cleanness of colour is interesting and genotyping of this mutation could be useful for breeding where the colour phenotypes are important. The number of sheep in this study with the phenotype clean is however low and confirmation of the results from a larger number of sheep would be necessary before using the genotype data in breeding. In this study, data on relatedness between the rams is not available, but the rams with phenotype 'clean' and genotype D_5N_5 comes from four different herds and is thus not closely related. The lower peaks from the haplotype harbouring the D_5 mutation in combination with the indications of a duplication of *ASIP* in all Gotland sheep is interpreted as a presence of the D_5 allele in a single copy and the N_5 allele on multiple copies of *ASIP* in the sheep heterozygous D_5N_5. Quantification of the different alleles of *ASIP* in Gotland sheep would be valuable in future research projects and can hopefully give further insights into the background of different colour traits. Also, investigation of other colour genes would be interesting.

Figure 1. A screenshot from the software 4peaks showing the region with the D_5 allele in *ASIP* in one of the Gotland sheep with the D_5N_5 genotype where it was clearly visible. The highlighted region is the region that is deleted in in D_5 haplotype (TTCCT here in reverse, AGGAA in forward). The deletion is detected by the occurrence of double peaks after the deletion. The lower peaks of the haplotype harbouring D_5 was observed in all Gotland sheep with the D_5 allele.

The category blue in the cleanness of colour phenotype is a desired trait and it would be of importance to investigate the genetic background to this trait, but in this data there was unfortunately only one ram with this phenotype. A larger number of samples with this phenotype would be necessary for further research.

713. Breeding initiatives around reduction of methane emissions in meat sheep – an international review

N.R. Lambe

Scotland's Rural College, Hill and Mountain Research Centre, Crianlarich, West Perthshire, FK20 8RU, Scotland, United Kingdom; nicola.lambe@sruc.ac.uk

Abstract

This review considers breeding initiatives around reduction of methane emissions in meat sheep. It discusses genetic strategies that are being tested, considers research results to date, and summarises the current state of implementation across different countries for the potential to reduce methane emissions from sheep production systems through breeding.

Introduction

Globally, ~1.2 billion sheep produce 6.87 million tonnes of methane (i.e. 186.9 million tonnes of CO_2 equivalent) per annum due to enteric fermentation (FAOSTAT, 2019). A long-term strategy for cumulative reductions in greenhouse gas (GHG) emissions is to breed more efficient animals with lower methane emissions, which fits the Organisation for Economic Co-operation and Development's approach for mitigating GHG emissions (Macleod *et al.*, 2015), as selective breeding is permanent, cumulative and highly cost-effective.

Various genetic solutions have been proposed to mitigate methane emissions from sheep production systems. As more productive animals have lower environmental impact per unit of product (Macleod *et al.*, 2015), wider use of existing breeding goals, designed to reduce waste and increase meat yield per animal, may go a long way towards reducing GHG emissions. Another long-term genetic strategy is to breed more feed-efficient animals. Residual feed intake (RFI) gives a measure of feed efficiency independent of growth and body size, and selection for RFI should produce more biologically and economically efficient animals that consume less feed for the same output, reducing methane production per day or per unit of dry matter intake. Alternatively, livestock can be bred directly for reduced methane, by measuring or predicting emissions under relevant conditions (Robinson *et al.*, 2020). As methane measurement technology is expensive relative to the value of sheep, proven, low-cost predictors are needed, benchmarked against methane measurements. Proxy measures related to rumen morphology and function have been investigated. Understanding their relationships with methane emissions, and their genetic control may be key to identifying more practical ways to accurately predict individual methane emissions.

The aim of this paper is to review breeding initiatives around reduction of methane emissions in meat sheep – genetic strategies being tested, research results to date, and the current state of implementation across different countries to reduce methane through breeding.

Materials & methods

Several studies have modelled the effects of current genetic selection goals on GHG emissions over time and the impact of different traits on GHG emissions (e.g. Nakielny and Roden, 2011; Wall *et al.*, 2010). The impacts of changing index weightings and/or including feed efficiency and methane measures in indices, with different economic values, have been modelled (Cottle and Conington, 2012a,b; Wall *et al.*, 2010). Other studies have used biological or life cycle analysis models to predict methane emissions based on data from sheep of high or low genetic merit for a production index (Bohan, 2021; Lambe *et al.*, 2014).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_713, © N.R. Lambe 2022

Internationally, sheep breeding research is at different stages in developing resource populations to generate data on feed intake and methane emissions. Although feed intake measurement has been more widely studied in cattle, various methods and proxy measures are now under investigation in sheep. Animal-mounted sensors and biological markers for predicting feed intake at pasture have been tested by several research groups. However, for large scale recording of feed intake for breeding programmes, automated feed intake recording equipment, suitable for recording individual animal intakes from groups of sheep in indoor or outdoor pens, is closest to wide-scale implementation.

Methods for direct measurement of methane include respiration chambers (considered to be the gold standard) and shorter-term techniques, such as portable accumulation chambers (PAC), extraction hoods (e.g. GreenFeed), sniffers, or laser detectors (Jonker *et al.*, 2020). The sulphur hexafluoride (SF6) method allows methane measurements from grazing animals (Johnson *et al.*, 1994), but is unsuitable for large-scale use. Proxies relating to rumen function or methanogenesis pathways include: rumen morphology measured by computed tomography (CT) or post-mortem (Goopy *et al.*, 2014); characterisation or genotyping of rumen microbial communities (Rowe *et al.*, 2019); and analysis of rumen metabolites (Jonker *et al.*, 2019).

Results

Current UK breeding goals are predicted (Wall *et al.*, 2010) to reduce GHG emissions per breeding female or kg product for upland and lowland sheep systems, but to *increase* GHG emissions for hill sheep, largely due to an emphasis on maternal traits. Using selection indices for Welsh sheep, Nakielny and Roden (2011) predicted small annual methane reductions for hill and lowland sheep, assuming no ewe weight change. Concurring research in Ireland found that high genetic merit (5-star) ewes produced less methane compared to low genetic merit (1-star) ewes (Bohan, 2021). Changing index weightings (Lambe *et al.*, 2014; Wall *et al.*, 2010), or including methane emissions and/or feed intake as breeding objectives and selection criteria could further reduce emissions (Cottle and Conington, 2012a,b).

Understanding of the genetic control of feed efficiency and methane emission traits in sheep is increasing rapidly, laying the foundations for breeding strategies to reduce methane emissions. Low to moderate heritabilities are estimated for feed intake, RFI, feed efficiency and feeding behaviour traits, across sheep studies where environmental and experimental conditions vary (Pulina *et al.*, 2013). High genetic correlations imply that selection to decrease feed intake or RFI will decrease methane and carbon dioxide (Paganoni *et al.*, 2017; Robinson *et al.*, 2020). Additionally, selecting lambs post-weaning to decrease feed intake and methane would also decrease these traits in adult sheep (Paganoni *et al.*, 2017) and promising repeatabilities have been found for methane production across ages and physiological states (Oddy *et al.*, 2019). An earlier review suggested that methane emissions measured in respiration chambers are moderately repeatable across diets and feeding levels, and that shorter-term methane measurement techniques show promise for use in genetic evaluations under optimal protocols (Pickering *et al.* 2015; Jonker *et al.* 2020). Heritabilities for methane production are low to moderate (h^2 0.11-0.29) when measured by respiration chambers or PAC (Jonker *et al.*, 2018; Paganoni *et al.*, 2017; Robinson *et al.*, 2020). Genetic parameters have also been estimated for methane proxy traits. In Texel sheep, rumen volume measured during routine CT scanning was moderately heritable (h^2 0.45; Lambe *et al.*, 2022), although genetic correlations with methane emissions are not yet available. Rumen microbial profiles are heritable and correlated with methane emissions and feed intake (Rowe *et al.*, 2019). Volatile fatty acid concentrations are also moderately heritable and repeatable, with moderate genetic correlations to methane yield, but depend on the diet (Jonker *et al.*, 2019).

Discussion

Selection indices designed to reduce methane emissions. Although studies suggest potential to reduce methane emissions further by changing current index weightings, or including breeding goals of feed intake and/or methane emissions, such indices are not yet being widely used in commercial sheep breeding. However, with increasing research knowledge, alongside potential financial incentives to reduce methane emissions expected in many countries, this may be closer to realisation. Implementation of carbon credits (or penalties), and their value, could influence selection pressure to reduce methane emissions (Black *et al.*, 2021).

Selection for improved feed efficiency. Advances in electronic animal identification and recording of feed consumption by computer-controlled machinery present opportunities to measure individual feed intake during performance trials. Best methodologies to measure feed efficiency in sheep flocks in different systems are under investigation and selection for feed efficiency has proven successful in research flocks (e.g. Tortereau *et al.*, 2020), resulting in breeding stock selected for RFI becoming available in some countries and breeds.

Selection for reduced methane emissions. Viable proxy traits for methane prediction are emerging. Rumen sampling to predict methane emissions from the microbiome, when coupled with high-throughput, rumen profiling (Hess *et al.*, 2020), could provide a quick and accurate method to determine genetic merit in breeding programmes. If CT-measured rumen volumes prove to accurately predict methane at the genetic level, then mechanisms are in place in some countries (e.g. UK, NZ) to incorporate them into breeding programmes with other CT traits. Direct PAC measurements of methane are a promising route to large-scale measurement of emissions across sheep production systems and are in use within research flocks (e.g. Australia, NZ, Uruguay, Ireland, Norway), often with strong genetic links to national breeding programmes. In some cases (e.g. NZ, Ireland, Norway), PACs are measuring methane from industry flocks participating in these breeding programmes. The next steps are to develop environmental selection indices, including methane emissions.

Work underway to address knowledge gaps. Numerous national and international projects have been funded to progress understanding and implementation of strategies to reduce GHG emissions from livestock, including sheep. The Global Research Alliance on Agricultural Greenhouse Gases (GRA) oversees projects to improve international research in this area, including the production of good practice guidelines for more consistent measurement methodology (Jonker *et al.*, 2020). Another pertinent example is the 'GrassToGas' project (Strategies to mitigate GHG emissions from pasture-based sheep systems; ERA-NET), with seven partner countries combining expertise to address knowledge gaps, considering various technologies, protocols and approaches to breed sheep for reduced GHG emissions.

Future potential. Although some lower-cost, shorter-term methods show potential for widespread estimation of methane emissions from individual sheep, most methods still require expensive equipment, or laboratory processes, and intensive animal handling. The most feasible breeding strategy is likely to be through genomic selection (Black *et al.*, 2021). Datasets of genotypes and phenotypes are developing in several countries, with some already of sufficient size to estimate genomic breeding values for methane emissions. International collaboration, to standardise protocols and methodology and combine data and resources, can fast-track genetic and genomic strategies to mitigate methane emissions from sheep production systems. A trans-national approach is necessary to address this global issue.

Abstract

Quantifying methane (CH_4) output from ruminant animal production systems is crucial in the development of mitigation strategies. This study aimed to develop an understanding of CH_4 output across life stage and the effects of key performance indicators on CH_4 output in a multi breed sheep population. A total of 7,027 CH_4 records from 2,404 animals collected from four flocks between 2019 and 2021 were available. Factors associated with CH_4 output were determined using linear mixed models. Highest CH_4 output was associated with ewes, with lambs being the lowest (P<0.001). When measuring CH_4 using portable accumulation chambers the atmospheric pressure, relative humidity and time since feed removal must all be recorded (P<0.001). Singleton reared litters had lower CH_4 output than multiple rearing litters when measured in both the ewe and the lamb (P<0.001). Results highlight the impact of multiple environmental and animal factors on CH_4 output in sheep systems.

Introduction

There is intensifying pressure on the global agricultural community to reduce greenhouse gas emissions from animal agriculture. Worldwide agricultural methane (CH_4) emissions account for over 38% of total CH_4 emissions (FAO, 2020). As it is one of the primary outputs of digestion in ruminant animals, there is a major focus on identifying more efficient animals with lower lifetime levels of CH_4 output per unit of production. Quantifying CH_4 output of individual ruminant animals is labour and resource intensive, particularly when using the gold standard CH_4 output measurement method, respiration chambers. Subsequently, alternative apparatus have been developed allowing for data of CH_4 output to be collected for large cohorts of animals in a resource efficient manner. Scientific evidence shows that there is a possibility to breed animals for lower methane emissions (Rowe *et al.*, 2019). However in order to incorporate this trait into a national breeding programme investigation must firstly be carried out into the variation surrounding the trait and the factors affecting it. Understanding the impact of phenotypic factors associated with correlated traits and primary traits of interest enables appropriate adjustments within genetic evaluation models. While striving for lower methane emitting animals is merited, the importance of maintaining production levels and overall farm gate efficiency and profitability cannot be forgotten. Therefore, the objective of the present study was to determine the phenotypic factors affecting methane output in sheep systems.

Materials & methods

Phenotypic data collection. Methane measurements were obtained using portable accumulation chambers (PAC) as described by Jonker *et al.* (2018). Briefly, animals were removed from feed a minimum of 1 hour prior to entering the PAC for a 50 minute period. Methane, oxygen (O_2) and carbon dioxide (CO_2) levels were recorded at three separate intervals; 0 minute (animal entry), 25 minute and 50 minute post entry to the PAC. A total of 7,027 methane measurements were collected from 2,404 animals across four flocks between the years 2019 and 2021, inclusive. Animals were classified as lambs (<12 months; n=2,151 records), nulliparous hoggets (12 to 24 months; n=763 records) and ewes (primiparous or greater; 24 to 174 months; n=3,892 records) which were further classified as lactating or dry (non-pregnant and non-

lactating). The exact time of each measurement, the time since feed was removed, ambient temperature, atmospheric pressure and relative humidity were recorded for each PAC measurement run. Live-weight was recorded on all animals on the day of measurement. Data was also available on date of birth, age, breed composition, stage of production (referred to hereafter as life-stage) and diet type for all animals. A contemporary group of the date of measurement, flock and PAC run the animal was measured in was fitted to the data. For all ewes the lambing date, parity, age at first lambing, number of lambs born and number of lambs reared, combined litter weight at birth, 40d, weaning and ewe body condition score (BCS) were also available. For all lambs data on the sex, birth, pre-weaning and weaning weight, litter size at birth and rearing litter size and daily live-weight gain between each time point were available. Ewe parity was categorised as 1, 2, 3, 4, or ≥5. Age of the dam was categorised as lambing either: (1) between 8 and 18 months of age; or (2) between ≥18 and 28 months of age. Number of lambs born (litter size at birth) was the total number of lambs (dead and alive) per lambing event; only litter sizes between one and four were retained for final analysis. Number of lambs reared (rearing litter size) was defined as the number of lambs reared in the litter (including the lamb itself); only rearing sizes between one and three were retained. Following all edits there were a total of 6,771 records from 2,392 animals, including 2,140 individual lamb records and 3,868 individual ewe records.

Statistical data analysis. All PAC and live-weight data were checked for normality using PROC UNIVARIATE (SAS Inst. Inc., Cary, NC, USA); records with data outside three standard deviations from the mean were removed for the final analysis. Factors associated with animal production performance and methane output were estimated separately using linear mixed models in PROC HPMIXED; contemporary group (date-flock-PAC run) was included as the random effect in all models. Potential fixed effects considered in the models included: life-stage, time of measurement, time off feed prior to measurement, ambient temperature, atmospheric pressure, relative humidity, age and live-weight on the day of measurement and breed. For ewe analysis parity, age at first lambing, number of lambs born, number of lambs reared, BCS and combined litter weight were included while for lambs sex, birth, pre-weaning and weaning weight, birth and rearing litter size were included. For all dependent variables and all analysis, a multiple regression model was also built using stepwise forward – backward regression; the significance threshold for entry and exit of variables into/from the model was set at 5%.

Results

The average live-weight of lambs, hoggets and ewes was 43.7, 66.1 and 74.5 kg, respectively, with lactating ewes weighing on average 3 kg heavier than non-lactating ewes. Methane output increased with stage of production whereby lambs ranked the lowest for CH_4 output, 12.62 g CH_4/day while lactating ewes ranked highest, 27.12 g CH_4/day (P<0.001). The phenotypic standard deviation in CH_4 output of lambs, hoggets and ewes was 6.14, 6.26 and 7.48 g, representing 49, 45 and 35% of the mean methane output, respectively. Factors associated with CH_4 output included animal life stage, diet type, breed, time from feed removal, atmospheric pressure, relative humidity, PAC chamber number, age and live-weight (P<0.001). Overall animal life-stage and diet type accounted for 35% of the variation in methane output. Regardless of life-stage the time from feed removal affected methane output as shown in Figure 1.

The main breed proportion of the animal affected CH_4 output, with Charollais and Texel animals having higher CH_4 output in comparison to Belclare and Suffolk animals (P<0.01). Across the full dataset for every 1 kg increase in live-weight CH_4 output increased by 0.12 g/day, however for lambs a 1 kg increase in live-weight resulted in a CH_4 output 0.26 g/day higher (P<0.001). In addition, ewe CH_4 output increased up to a BCS of 3 after which it declined (P<0.001). Animals consuming perennial ryegrass or a combination of perennial ryegrass plus chicory ranked higher for CH_4 output when compared to those grazing a combination of perennial ryegrass plus clover (red or white; P<0. 001). Animals measured indoors on a

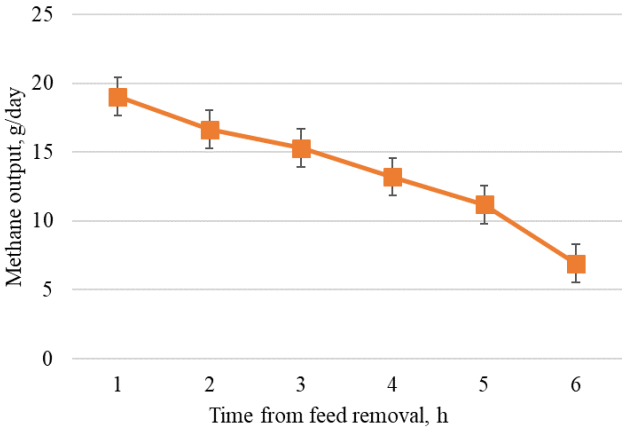

Figure 1. The effect of time from feed removal on methane output as measure in the PAC.

diet of perennial ryegrass silage ranked lower for CH_4 output than animals grazing outdoors ($P<0.001$). For both lambs and ewes rearing litter size affected CH_4 output. When ewes were rearing multiple lambs (>1 lamb per litter) CH_4 output was on average 6.7% higher and similarly when lambs were reared as multiples their CH_4 output was 8.6% higher than those reared as singletons. Parity 1 ewes ranked higher for CH_4 output which declined as parity increased, whereby parity 4 and 5 ewes ranked lowest ($P<0.001$).

Discussion

One of the main challenges for ruminant scientists is developing mitigation strategies for methane output without comprising animal production. Understanding the effect of various phenotypic and environmental factors on methane output in sheep production systems is therefore crucial to facilitating the development of mitigation strategies and comprehending relationships with measures of animal efficiency. Results from this study signify that a plethora of key performance indicators in conjunction with environmental conditions impact methane output when measured in small ruminants using PAC. Methane is produced in the rumen whereby methanogenic bacteria convert excess hydrogen to methane as a metabolic end product of digestion. Multiple factors have previously been shown to impact methane production including the type of carbohydrate in the diet, feed intake and feed passage rate (McAllister *et al.*, 1996). Recording the time of feeding relative to when the methane output of animals was measured is important as the rate of digestion declines over time as seen in the results of this study. However, further work from our research group has shown the ranking of animals for methane output remains unaffected by the length of time since feeding (O'Connor *et al.*, 2021). There was an effect of diet type whereby animals consuming feeds with higher organic matter digestibility had lower methane output. Due to the large population of animals measured in the current study, it was impractical to measure individual feed intake. Previous research has shown that dry matter intake increases in line with animal age and stage of production. Therefore, the increase in methane output across each of the life-stages investigated was expected and aligns with Jonker *et al.* (2018) who reported methane output from lambs and ewes measured using the PAC. As BCS increased CH_4 output declined, while this merits further biological investigation, it aligns with results previously reported in sheep (Reintke *et al.*, 2020) and dairy (Zetouni *et al.*, 2018) whereby negative genetic correlations were identified between BCS and CH_4 production. The relationships between CH_4 and other, more widely recorded, production traits outlined in this study will deepen the understanding of their interaction which is required prior to inclusion in genetic evaluations.

Abstract

Mitigation strategies are required to reduce methane emissions without impacting animal productivity; genetic improvement is one potential strategy. The objective of this study was to estimate genetic variance components for methane emissions in an Irish sheep population using a spot-sampling technique. Spot-sampling methane measures using portable accumulation chambers were available from 1,213 animals in 4 flocks. Variance components were estimated using an animal linear mixed model. Mean methane (CH_4) emissions of the ewes was 19.29 (SD=7.50) g CH_4/day, with a coefficient of genetic variation of 9.67%. The direct heritability and animal repeatability were 0.25±0.12 and 0.39±0.05, respectively. The direct heritability estimate for methane emissions expressed in daily g CH_4/LW was 0.13±0.07. The mean estimated breeding value of methane emission per breed varied from -0.13 (Belclare breed) to 0.14 (Suffolk breed) g CH_4/day.

Introduction

Global agriculture sector accounts for an estimated 38.62% of the potent greenhouse gas methane (FAO, 2020), with mounting international pressure to identify mitigation strategies. Reducing ruminant livestock populations is one drastic option which could impact food security. Nutritional strategies using complementary feeds have also been proposed. Breeding programs, by comparison, have a long, well-proven history in tackling grand challenges. However, successful breeding programs are conditional on the availability of phenotypes from which to undertake genetic evaluations. The development of spot-sampling, portable, high-throughput measurement techniques for sheep (Jonker *et al.*, 2018) has enabled the collection of vast quantities of methane phenotypes. Previous studies have clearly demonstrated genetic variability in methane emissions from sheep (Robinson *et al.*, 2014; Jonker *et al.*, 2018), but estimates of the genetic variation in methane emissions from the Irish national sheep population at pasture are lacking. The objective of this study was to estimate genetic variance components for spot-sampling measures of methane emissions in a multi-breed population. Results from this study will be useful in determining the suitability of methane for inclusion in sheep breeding programs.

Materials & methods

Data. A total of 4,007 spot measure methane records from 2,075 animals collected from 4 flocks between the years 2019 to 2021, inclusive were available. Methane records were collected using the portable accumulation chambers (PAC) as described by Jonker *et al.* (2018). Briefly animals were removed from feed one hour prior to measurement and the live weight of each animal was recorded; animals were then placed in 1 of 12 chambers and methane was measured at the point of entry and immediately prior to removal from the chamber (approximately 50 minutes after entry). A range of PAC-specific measurements such as duration of each individual animal measurement, the time since last available feed, ambient temperature, atmospheric pressure and relative humidity were available. Only records from females who had at least one recorded lambing event were considered in the present study; furthermore, only data from ewes weighing

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_715, © N. McHugh *et al.* 2022

between 45 and 120 kg were retained. Methane or carbon dioxide (CO_2) records that were ±3 SD from the mean were removed (n=45 records removed).

Data were also available on date of lambing, ewe parity, breed composition, and the ancestry of each ewe. Ewe parity was categorised as 1, 2, 3, 4, or ≥5. Age of the dam at first lambing was categorised as lambing either: (1) between 8 and 18 month of age; or (2) between ≥18 and 28 month of age. Birth type (single to quadruplets) and rearing size (single to triplets) of each ewe for the same production year as methane measurement was also available. Only ewes with a known sire and dam were retained for analysis. Each ewe was allocated to a contemporary group of flock-date of measurement-measurement lot (i.e. group of 12 animals measured at the same time). Following all edits, 2,114 methane measurements on 1,213 individual ewes remained. Methane emissions were expressed both on a total daily emissions (i.e. g CH_4/day) but also relative to live weight (i.e. daily g CH_4/LW).

Data analysis. Genetic and residual components were estimated in ASReml (Gilmour *et al.*, 2015). Fixed effects included in the model were contemporary group (flock-date-run), ewe parity, ewe age at first lambing, the breed proportion of the most common breeds (Belclare, Charollais, Suffolk and Texel), and the heterosis and recombination loss coefficient of the ewe. Approximately 15% of the methane data was recorded on lactating ewes, therefore days since lambing and number of lambs born and reared by the ewe within the same production year were also included as fixed effects. A direct ewe additive genetic effect and a ewe permanent environmental effect were included as random effects; 42% of ewes had >1 record. With genotypes available on 54% of ewes, relationships among animals was accounted for using a H matrix which combines the genomic and pedigree-relationship matrix.

Due to large temporal variation in grass quality between paddocks or farms and time off feed (Jonker *et al.*, 2018), standardisation of methane emissions was undertaken to account for the heterogeneity of residual variances across time. Before the estimation of variance components for methane emissions, residuals from a fixed effects model with methane emissions as the dependent variable and the aforementioned fixed effects included in the model (excluding contemporary groups) were standardised to the mean residual SD within the contemporary group of flock-date-run. Standardised residuals were added back to the respective fixed effects solutions for each animal to generate a standardised methane emission trait. Variance components of the standardised methane emissions are reported in the present study.

Results

The mean methane emissions of the ewes was 19.29 (SD=7.50) g CH_4/day and varied from 18.61 g CH_4/day for ewes during the dry period to 26.75 g CH_4/day for lactating ewes. When expressed on a per live weight basis, the mean methane emissions was 0.26 (SD=0.10) daily g CH_4/LW. The genetic SD for the two methane emissions traits were 1.87 g CH_4/day and 0.02 daily g CH_4/LW. The coefficient of genetic variation for methane emissions expressed as total daily emissions was 9.67%. The direct heritability estimate for methane emissions ranged from 0.13±0.07 (expressed in daily g CH_4/LW) to 0.25±0.12 (expressed in g CH_4/day). The animal repeatability was 0.39±0.05 (expressed in g CH_4/day) and 0.49±0.03 (expressed in daily g CH_4/LW).

The mean carbon dioxide produced per ewe was 1,255 (SD=484) g CO_2/day. The genetic SD and coefficient of variation was 142 g CO_2/day and 11.29%, respectively. The heritability for carbon dioxide was 0.14±0.11 while the animal repeatability was 0.60±0.04. The phenotypic and genetic correlation between the methane emissions and carbon dioxide (both expressed as g/day) was 0.24±0.05 and 0.41±0.10, respectively.

The distribution of methane emission (g CH_4/day) estimated breeding values (EBVs) for animals of the four main breeds is in Figure 1. The mean methane emissions EBV for the Belclare (n=399), Charollais (n=77), Texel (n=723), Suffolk (n=723) breeds was -0.13, 0.18, -0.03 and 0.14 CH_4/day, respectively.

Discussion

Animal genetic improvement can play a pivotal role in the mitigation strategy to reduce greenhouse gases from the ruminant livestock sector. Parameters estimated in this study will be useful in firstly generating genetic evaluations (i.e. the lambda in the mixed model equations), secondly determining the optimal phenotypic strategy for a breeding program (i.e. number of phenotypes per family versus number of families phenotyped) and thirdly populating models to determine the possible rate of genetic gain and mitigation potential (i.e. selection index theory).

The moderate heritabilities estimated for methane emissions in sheep in the present study (0.13 to 0.29) corroborate previous estimates from the southern hemisphere using both PAC and respiration chambers (Robinson *et al.*, 2014; Jonker *et al.*, 2018). Assuming a heritability of 0.13, 29 phenotyped progeny per sire would be required to achieve an accuracy of selection of 0.70 using traditional pedigree-based genetic evaluations. The high animal repeatability (0.39) for ewes in the present study, coupled with the strong correlation (0.85 to 0.99) calculated by Jonker *et al.* (2018) between methane emissions in lambs and ewes suggests that methane remains genetically similar across an animal's lifetime.

Dry matter intake (DMI) was not available in the current study but has been shown to explain 76% of the variation in methane production between animals (Swainson *et al.*, 2018). In cattle a strong correlation has been estimated between methane yield (i.e. CH_4 per unit of DMI) and methane emissions expressed as CH_4 per unit of live weight, indicating the suitability of methane emissions expressed as daily g CH_4/LW as a proxy for methane yield where DMI data are not available, especially in growing animals. Nonetheless, the impact of selecting animals for lower methane emissions on DMI warrants further investigation in an Irish grass based context, to ensure that indirect selection for lower DMI does not negatively impact individual

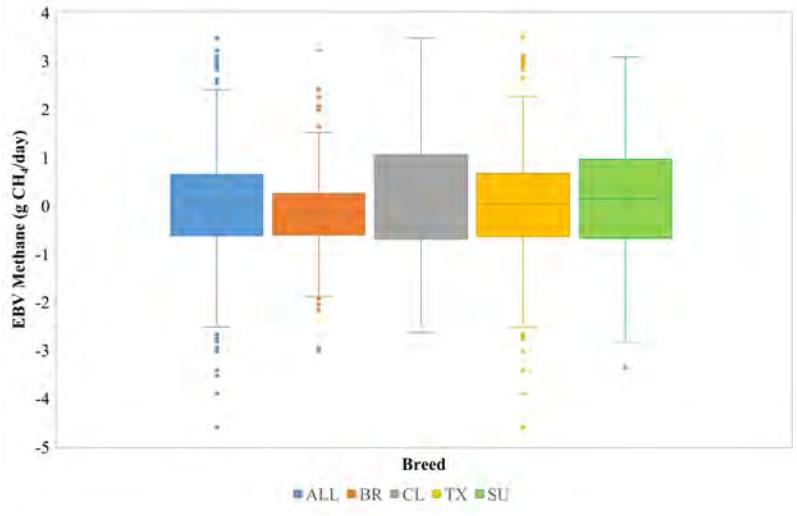

Figure 1. Box and whisker plot of estimated breeding values (EBVs) for methane emissions (g CH_4/day) for all animals (ALL), and the Belclare (BR), Charollais (CL), Texel (TX) and Suffolk (SU) breeds.

animal performance, such as growth rate, which could actually contribute to greater total flock emissions per unit of output.

Data used in the present study were generated on commercial crossbred ewes, but the future phenotyping strategies should also consider the phenotyping of seedstock young rams for methane emissions thereby ensuring that breeding values of high accuracy are generated on the parents of the next generation. Using a repeatability of 0.39, the accuracy of selection for an individual ram with 1, 2, or 3 measures is 0.36, 0.43 and 0.47, respectively.

With the advent of spot-sampling techniques such as PACs, methane emissions can now be routinely generated on large numbers of sheep. This coupled with the existence of ample genetic variation for methane emissions, facilitates their inclusion in Irish sheep breeding objectives to aid in the reduction of the carbon footprint for the Irish sheep industry.

Abstract

Genetic selection using multi-trait breeding objectives can be used to improve flock productivity, profitability, and greenhouse gas (GHG) emissions intensities (kg CO_2-eq /kg of product), however validation is required. Phenotypic data from commercially farmed animals divergent in genetic merit for maternal traits were inputted into a bio-economic model to compare two contrasting flocks, ranked as either High (top 20%) or Low (bottom 20%) on the Irish replacement sheep breeding objective. The two flocks were then simulated using life cycle assessment (LCA) to estimate GHG emissions. The flock of High genetic merit ewes sold 3.29 kg more lamb carcass per ewe and €18/ewe higher net profit than the flock of Low genetic merit. Although total flock GHG emissions were higher for the High genetic merit flock, GHG emissions intensities were 22.1 and 23.7 kg CO_2-eq /kg lamb carcass sold for the High and Low genetic merit flocks, respectively.

Introduction

Improvements in flock productivity and profitability can be achieved through genetic selection using multi-trait breeding objectives. Ireland's sheep breeding objectives have not yet been validated for effects on flock productivity and profitability. Validation will confirm the sheep industry is breeding suitable animals and ensure farmer confidence in the breeding objectives. Previous studies have validated herd level improvements in production and profit for commercial Irish dairy farms with cows ranked higher on the Irish economic breeding index (Ramsbottom *et al.*, 2012). Previous modelling studies of pastoral sheep and dairy production systems have predicted reductions in GHG emissions intensity (GHG emissions / kg of product) of up to 10% through improvements in genetic merit without compromising profitability (Harrison *et al.*, 2014; Jones *et al.*, 2014). To date no study has yet modelled the potential economic and environmental benefits of improved sheep genetic merit using data from a national database of commercial farms. The objectives of this study, therefore, were to model production data differences from sheep divergent in genetic merit and to quantify their impact on farm profit and GHG emissions.

Materials & methods

Two flocks were modelled in the current study: a *High* and *Low* maternal genetic merit flock. The *High* genetic merit flock consisted of ewes ranked in the top 20% of the Irish Replacement breeding objective, and a proportion were bred with rams ranked in the top 20% of the Replacement breeding objective to produce replacement ewe lambs of *High* genetic merit. The remaining ewes were bred with terminal rams ranked in the top 20% of the Terminal breeding objective to produce lambs destined for slaughter. The *Low* genetic merit flock consisted of ewes ranked in the bottom 20% of the Replacement breeding objective, with a proportion of ewes bred with replacement rams ranked in the bottom 20% of the Replacement breeding objective and a proportion of ewes bred with rams ranked in the bottom 20% of the Terminal breeding objective. Both modelled flocks consisted of 168 ewes stocked at 7.91 ewes/ha, lambing annually in spring, grazing on pasture the majority of the year, and housed over winter until 48 hours post-lambing. Ewes were mated for the first time at 19 months of age to lamb at two years old and both flocks had a flock replacement

rate of 22%. Production values assumed for animals divergent in genetic merit in this study were derived from the Irish national sheep production database, using data from 4,200 animals born between 2018 and 2020 in commercial flocks in the Irish Central Progeny Test scheme (McHugh *et al.*, 2022). Traits investigated in the study included lambing (birth weights, lambing difficulty and survival), lamb growth rates (weight pre and at weaning, as well as, days to slaughter) and ewe traits (ewe litter size, barren rates and mature weight).

An established bio-economic model of an Irish lowland sheep flock, the Teagasc Lamb Production Model (Bohan *et al.*, 2016), was utilised to predict the production and profit of the *High* and *Low* genetic merit flocks. Key model inputs included animal production data, market prices and wool sales, variable and fixed costs, stocking rate, and fertiliser use. Key model outputs included stock inventories, total income and expenses, farm gross margin, and net profit expressed on a whole farm, per ha, per ewe, or per kg of carcass sold basis. Net profit was estimated as gross margin (total income less variable costs) less fixed costs and overdraft loan interest costs. Farm income was generated from sheep and wool sales, with average market prices from 2017 to 2020 utilised, with variable and fixed costs were informed by market values from the same period and from sources described in Bohan *et al.* (2016). Lambs were sold after reaching the target 20 kg carcass weight. After 1 October all lambs remaining on-farm were offered concentrate supplementation. A monthly feed budget was estimated, with feed surpluses conserved as silage and feed deficits requiring diet supplementation with silage and/or concentrates (Bohan *et al.*, 2016). Life cycle assessment (LCA) was conducted in accordance with the International Organisation for Standardization 14040 and 14044 standards to calculate greenhouse gas emissions generated by the two flocks. A cradle-to-farm gate system boundary was adopted, encompassing emissions up to the point in which the animals leaves the farm. Environmental impact embodied in capital goods (i.e. farm machinery and infrastructure) and medicines were not included in the LCA. For prediction of emission intensity, economic allocation was used to disaggregate the total environmental impact between co-products based on their economic value at farm level. Greenhouse gas emissions were scaled to per kg carcass weight and per hectare. A full description of the LCA model used can be found in O'Brien *et al.* (2016).

Results

Ewes in the *High* genetic merit flock had a higher scanning rate and their lambs had a higher survival rate, resulting in a higher weaning rate (1.70; lambs weaned per ewe joined) than the *Low* genetic merit flock (1.54; Table 1). With higher weaning and post-weaning weights, the *High* genetic merit flock sold more lambs before 1 October (from an all-pasture diet) with an average age of slaughter of 190 days, 13 days sooner than lambs in the *Low* genetic merit flock. The *High* genetic merit flock also sold 28 more lambs than the *Low* genetic merit flock, equating to 3.29 kg more lamb carcass per ewe. Lamb income was € 27,693 for the *High* genetic merit flock, € 3,083 higher than for the *Low* genetic merit flock. Total farm costs were similar for the two modelled flocks, and net profit was € 45/ewe for the *High* genetic merit flock, € 18/ewe higher than for the *Low* genetic merit flock. Total GHG emissions per hectare were 5,750 and 5,470 kg CO_2-eq for the High and Low genetic merit flocks, respectively. However, the GHG emissions intensity for the High genetic merit flock was 22.1 kg CO_2-eq/kg of lamb carcass sold, 6.7% lower than for the Low genetic merit flock.

Discussion

Through use of both replacement and terminal animals of *High* genetic merit, the *High* flock was effectively exploiting the potential production benefits of selecting for higher genetic merit on both of the Irish national breeding objectives. The current analysis has shown that the higher level of productivity at a trait level for animals of superior genetic merit validated by McHugh *et al.* (2022) resulted in higher production and profit at a flock level for the modelled *High* genetic merit flock compared to the *Low* genetic merit

Table 1. Production, profit, and greenhouse gas emissions of modelled flocks ranked *High* (top 20%) and *Low* (bottom 20%) of the Irish Replacement breeding objective.

	Flock	*High* genetic merit	*Low* genetic merit
Production	Ewes bred with terminal sires (%)	61	57
	Scanning rate (%)	1.87	1.70
	Lamb survival to weaning (%)	93.48	92.87
	Weaning rate (%)[1]	170	154
	Lamb weaning weight (kg)	31.52	30.65
	Lamb post-weaning weight (kg)[2]	39.24	38.29
	Days to slaughter (days)	190	203
	Lambs sold (head)	248	220
	Carcass sold per ewe joined (kg/head)	30.43	27.14
	Lambs drafted before 1 October (%)	66	57
Profitability	Lamb income (€)	27,693	24,613
	Total income (€)	30,045	26,962
	Total variable costs (€)	16,370	16,264
	Gross margin (€)	13,675	0,699
	Total fixed costs (€)	5,040	5,039
	Total farm costs (€)	21,410	21,303
	Debt servicing (€)	1,104	1,101
	Net profit (€)	7,585	4,607
	Net profit per ewe (€/ewe)	45	27
GHG emissions	Emission intensity (kg CO_2-eq/ha)	5,750	5,470
	Emissions intensity (kg CO_2-eq/kg carcass)	22.1	23.7

[1] Lambs weaned per ewe joined.

[2] Lamb weight at 120 days of age.

flock. The difference in weaning rate between the two modelled flocks appeared to be a main driver of the greater production and profitability of the *High* genetic merit flock, with more lambs weaned and sold than the *Low* genetic merit flock. Traits related to lambing and weaning rate are heavily weighted in the replacement breeding index, thus differences in lamb production for flocks with higher ranking on the index were expected.

In a secondary analysis, both flocks were modelled with *Average* terminal sires, i.e. rams ranked in the top 40 to 60% of the Terminal breeding index, so that the effects of choosing replacement vs terminal rams of *High* genetic merit could be explored. The results suggested increasing the ewe genetic merit into the next strata (quintile) ranking on the replacement breeding index to increase farm net profit by € 4/ewe. For example, a farm with a flock of *Average* genetic merit, ranked in the top 40 to 60% of the replacement index, might increase net profit by € 4/ewe through increasing flock genetic merit into the top 60 to 80% of the replacement index. Conversely, increasing terminal sire genetic merit into the next strata (quintile) ranking on the Terminal breeding index was predicted to increase farm net profit by € 1/ewe.

Without published data on differences in the feed efficiency and GHG emissions of animals divergent in genetic merit, the higher production of the modelled *High* genetic merit flock was assumed to increase flock feed intake and enteric methane emissions, GHG emissions were higher at a flock level for the *High* genetic merit flock. However, the higher weaning rate (lamb production) and lower age of lamb sale (reduced feed intake per lamb sold) contributed towards the lower emissions intensity of the *High* genetic merit flock, i.e.

the increase in production of the *High* genetic merit flock compared with the *Low* genetic merit flock was proportionally greater than the increase in GHG emissions.

Overall, the study results validated the greater productivity and profitability of flocks of higher genetic merit according to their ranking on the Irish breeding indices. Key maternal traits which did not differ between both the High and Low genetic merit flocks in the present analyses, but would be beneficial for the profitability and environmental impact of sheep production systems, were ewe longevity (determining flock replacement rate), barren rate and dam live weight. These traits should be considered in future adjustments to the Replacement breeding objective. When selecting animals of *High* genetic merit according to the national Irish replacement and terminal breeding objectives, net profit per ewe was predicted to be 67% higher and GHG emissions intensity 6.7% lower than the modelled flock with *Low* genetic merit animals. The results suggest Irish sheep producers can make substantial profit gains through selection according to the national breeding indices while also reducing their environmental impact, and farmers should consider genetic merit when purchasing their rams, particularly replacement rams.

Abstract

Feed costs constitute a substantial portion of livestock production costs; therefore, improving feed efficiency (FE) is a major research topic nowadays. However, obtaining individual FE records in commercial populations requires specialized infrastructure. This research aimed to study the association between milk fatty acids (MFA) and FE in Assaf dairy sheep to determine potential MFA biomarkers for FE. Individual feed conversion ratio (FCR) of 39 ewes were estimated. Spearman correlation, regression, and orthogonal partial least squares were then used to analyze the relationship between FE and a profile of 101 MFA. We identified 33 MFA significantly associated with the FCR. These MFAs achieved a predictive performance of 0.82 for the FCR, and were successfully used to identify the most and least feed efficient animals. Thus, we propose a list of potential biomarkers to validate as an easy-to-measure phenotype for FE trait in a larger population.

Introduction

Nowadays, livestock feed efficiency (FE) is a major research topic, and it constitutes a desirable target for animal breeding. Selecting feed-efficient animals would reduce feed usage and farming costs while maintaining animal performance (Ellison *et al.* 2017). However, individual FE measurement in commercial populations is costly, time-consuming, and requires specialized infrastructure. In this sense, obtaining molecular biomarkers correlated to FE could be useful for the genetic improvement of the trait. Previous research in our group has suggested that more efficient ewes tend to have higher milk concentrations of de novo fatty acids and lower proportions of cis-9 18:1 and C20 to 22n-6 polyunsaturated fatty acids than less efficient ewes (Toral *et al.* 2021). The study presented herein uses an independent population of Assaf sheep and three analytical approaches (Spearman correlation, regression, and orthogonal partial least squares analyses) to identify potential biomarkers for FE in milk and validate those proposed in the previous study.

Materials & methods

Feed efficiency indicators. To estimate the individual FE of 39 Spanish Assaf ewes housed in individual tie stalls, we monitored the dry matter intake (DMI) by weighing the feed offered and refused by each animal over four weeks. Moreover, the milk yield and milk composition data were used to calculate the energy-corrected milk (ECM) parameter according to INRA (2018). The feed conversion ratio (FCR) was calculated as the relationship between the average DMI and ECM.

Milk composition. Lipids in 1 ml of milk sampled from the 39 Assaf ewes were extracted and converted to fatty acid methyl esters by base-catalyzed transesterification (Shingfield *et al.* 2003). The fatty acid methyl esters profile was determined following the procedure detailed by Hervás *et al.* (2021).

Centered-log ratio. The constant sum of the 101 milk fatty acids (MFAs) examined in this study suggests compositional data (Gloor *et al.* 2016). Therefore, MFA measurements were transformed via centered log-ratio (CLR) for correcting sparse compositionality (Aitchison, 1982).

Association analyses. To assess whether MFA composition discriminates animals in high and low FCR, three quantitative analyses were applied. In the first analysis, we estimated the Spearman correlation and regression coefficient for each MFA analysed with the FCR parameter to characterise the association level of the CLR-transformed MFA measurements ith the FCR. Secondly, we carried out an orthogonal partial least squares (OPLS) analysis on the CLR-transformed MFA data and an orthogonal partial least squares discriminant analysis (OPLS-DA) considering only the ten extreme animals (most and least efficient) ranked using the FCR index. These last analyses (OPLS and OPLS-DA) aimed to identify those MFAs useful in predicting the FCR parameter and were performed using the R package ROPLS (Thévenot *et al.* 2015).

Results

Basic statistics. The MFA phenotypes were normally distributed. The average of the CLR-transformed MFA values was close to zero, and the minimum standard deviation corresponded to the *'iso 17:0'* MFA (0.07) and the maximum to the *'trans-11 cis-15 18:2'* MFA (1.06). The distribution of the values was not affected by the CLR transformation, as expected. Furthermore, the FCR parameter was on average 1.36 with a standard deviation of 0.26.

Association analysis. Firstly, the Spearman correlation analyses between the MFA matrix and FCR revealed a total of 50 significant correlations (P-value<0.05) ranging from 0.32 to 0.70 (absolute values). Furthermore, the regression analysis revealed 38 significant associations (P-value <0.05) between the MFAs and the FCR parameters studied. The R^2 Adjusted values identified ranged from 0.08 to 0.31. Table 1 depicts the 36 common MFAs associated with the FCR parameter identified through both the Spearman correlation and the regression analyses.

Orthogonal partial least squares analysis (OPLS). MFAs achieved a predictive performance of 0.82 for the FCR index. A total of 40 MFAs achieved variable importance in the projection (VIP) score higher than one (P<0.05) (Figure 1A). Out of the 40 MFAs highlighted by the OPLS analysis, 33 matched the 36 MFAs highlighted by Spearman correlation and regression analysis (Table 1). The OPLS-DA revealed a predictive performance of 0.90 for the FCR index. As can be appreciated in Figure 1B, the results of the OPLS-DA confirmed the ability of the values of the 101 MFAs considered in this study to distinguish between the most efficient and least efficient group of animals in terms of FCR.

Discussion

The concordances in the results obtained by the three independent analyses (Spearman correlation, regression, and OPLS analyses) performed in this study emphasise the importance of this list of MFA as potential biomarkers for the FCR index. Moreover, we also identified 17 out of 33 MFA previously described as associated with FE in dairy sheep by Toral *et al.* (2021) (Table 1). Ten long-chain MFAs out of the 33 MFAs highlighted in this study showed negative correlations with FCR, suggesting that selecting for higher FE would reduce their concentration in the milk. The negative correlation between cis-9 18:1 and FE was also previously estimated by Toral *et al.* (2021), which influences the physical properties of milk fat by increasing its melting point (Chilliard *et al.* 2000). Particularly, the FCR index showed a positive and negative correlation with the lauric acid (C12:0) and conjugated linoleic acid (CLA), respectively. Both fatty acids have been extensively studied in relation to human health (Markiewicz-kęszycka *et al.* 2013; Djordjevic *et al.* 2019). The results from OPLS analyses indicate that the MFA profile can be used to predict the FCR, which could potentially reduce the costs associated with its measurement and enhance its implementation in breeding programs. In addition, the discriminant analysis (OPLS-DA) revealed that the MFA profile could be used to classify the most and least FE animals. The robust associations revealed in this study between certain MFAs and the FCR suggest that selecting the most efficient animals in terms of milk production might impact the MFA profile of dairy sheep. Regarding the importance of the milk

Abstract

Genomic selection (GS) started in French dairy sheep in 2015, first in the Lacaune breed, then in the Pyrenean breeds, and finally in the Corsican breed. This was favoured by a strong genetic organisation and enabled thanks to an intensive phase of research and development to undertake all the prerequisites: constitution of reference populations, implementation of a pipeline for genotype editing and of a genomic evaluation, design of a GS scheme suitable to each breed. This paper first presents an overview on how GS was organised in dairy sheep in France and in which way the breeding scheme differs from the conventional program based on progeny tested. Second, the results of 6 years of GS in the Lacaune breed and 4 years in the Pyrenean breeds are studied in terms of genetic gain, both through the evolution of the breeding values over time and through the analysis, year after year, of the different pathways of selection.

Introduction

Selection programs are implemented in French dairy sheep in 5 breeds: the Lacaune breed (LAC), the Pyrenean breeds (Manech Tête Rousse – MTR; Manech Tête Noire – MTN; Basco-Béarnaise – BB), the Corse breed (COR). The programs are designed on a pyramidal organisation of the population with selection flocks limited to 15 to 25% of the total ewes, targeting at generating the genetic gain and producing the rams for the whole population. Before genomic era, conventional breeding schemes were based on progeny-test of artificial insemination (AI) rams. The AI rate in the selection flocks ranges from 45% (COR) to 85% (LAC). The number of yearly progeny-tested rams varied from 20 rams in COR breed to 450 in LAC breed. Accordingly, the annual genetic gain (AGG) obtained was estimated between 0.09 (COR) to 0.22 (LAC) genetic standard deviation. Consequently, the reference populations are constituted by progeny-tested rams with a depth getting back to the early 2000's. After half a decade of R&D programs aiming at genotyping the rams, building pipelines for genotype handling and genomic prediction, assessing the feasibility and the cost-benefit of genomic selection (GS) in dairy sheep situation, the LAC breed decided in 2015 to shift to GS (replace the progeny-test process by using the genomically pre-selected rams). The Pyrenean breeds followed in 2020 and the COR breed in 2020. Initiation and conception of French dairy sheep GS was the last undertaking and accomplishment before retirement of Francis Barillet, who spent his successful whole career in dairy sheep genetics. We dedicate this paper to him.

Materials & methods

Genomic predictions. Genomic evaluation has been implemented since 2015 with the shift to GS of the LAC breed. We compute a single-step GBLUP from the package BLUPf90 (Misztal *et al.* 2002, Aguilar *et al.* 2010 and 2011), using all performances, pedigree and genotyped rams. The predictions were validated, showing a significant gain of precision compared to the pedigree predictions (Baloche *et al.*, 2014). In 2021, the reference populations vary across breeds (Table 1), from 326 rams in the COR breed up to 6,397 in the LAC breed.

Genomic breeding schemes. GS schemes were designed following different simulations aiming at optimising the genetic gain and the cost of the program (Buisson *et al.*, 2014, 2018). The key points are the use of fresh semen in sheep and the seasonality of the mating period (the majority of the AI are concentrated

Table 1. Importance of genomic breeding schemes in French dairy sheep in 2021.

Breed	First year of GS	Females in selection	# new AI rams/ year	# adult AI rams	# sires of sires	# rams genotyped/ year	Reference population[1]
LAC	2015	192,928	297	674	75	2,974	6,397
BB	2017	28,061	60	110	26	240	880
MTN	2017	10,547	28	68	22	102	585
MTR	2017	84,286	174	302	49	714	2,842
COR	2020	18,863	21	28	14	374	326

[1] Rams genotyped with daughters.

in 2-3 months). This leads to the presence in the AI centre of a great number of rams. The young rams are genotyped at 3-months old and a strong pre-selection on genomic prediction is applied (with a selection intensity equivalent to an elimination rate of 75% in the LAC breed). At 8 months (LAC breed) or 1.5 year (other breeds), the rams are used in AI for the first time in the selection flocks with the goal to maintain the reference population. Very few of them are considered as potential sire of breeding rams because, as young rams, they have a too low semen production to be mated to enough dams of rams. There is no longer lay-off, and at 1.5 year-old (LAC breed) or 2.5 year-old (other breeds), the rams are fully used as sire of males and females, both in the selection flocks and in dissemination towards the base population. When daughters are included in the predictions (2.5 or 3.5 year-old depending on the breeds), a second selection occurs, lower than in conventional progeny-test programs, with a 20% elimination. The rams are then used based on prediction with daughters, during 1 to 3 years. The dairy sheep breeding schemes are therefore hybrid, with a part of the rams with genomic prediction without daughters performances (genomic rams), and a part of rams with daughters performances. In 2021, in the selection flocks, the rate of AI from genomic rams varies from 62% (LAC) to 88% (MTN).

Breeding goal. The breeding goals differ across the breeds. As the COR breed selects for milk yield only, the other breeds select for a total merit index (TMI), named ISOL, including fat and protein yield, fat and protein content, somatic cell score (SCS), udder morphology. The respective part of production traits (yield, content) and functional traits (SCS, udder) in the TMI is 50/50 in the LAC breed, 56/44 in the MTR breed, 59/41 in the BB breed, 91/9 in the MTN breed. Within the functional trait, SCS and udder account for the same part. ISOL is expressed in equivalent liters, like milk yield, since the breeders got used to its dimension and scale.

Estimation of genetic gain through evolution of EBVs. Genetic gain over a given period may be estimated by the slope of a plot of the average TMI (or the elementary traits) into the birth years. The method is used both for males and females. We estimated the slope for a 15-year period before GS and for the period since GS has started. This comparison could actually be done only in the LAC breed, for which GS started in 2015, allowing to get a reliable genetic gain across a 5-year period.

Estimation of expected genetic gain through the pathways of selection. The selection pathways methodology permits a vision of the effort of selection each year. Thus we studied how the replacement males and females of a given birth year (e.g. 2021) are generated from their sires and dams. We calculated the AGG in all 4 selection paths (MM, MF, FM and FF for males to males, males to females, females to males, and females to females, respectively), as follows (Rendel and Robertson, 1950; Lindhe, 1968):

$$AGG = \frac{\Delta GMM + \Delta GMF + \Delta GFM + \Delta GFF}{LMM + LMF + LFM + LFF}$$

where ΔG is the estimated genetic superiority of the selected animals over their contemporaries born in the same year, L is the average age of the selected animals when their offspring were born, and AGG is the annual genetic gain. ΔG was calculated by multiplying the selection differential by the root square of the reliabilities. We verified that the standard deviation of ISOL (expressed in milk yield scale) was very similar to the genetic standard deviation of milk yield. The sires of rams (MM) and dams of rams (FM) are respectively the sires and dams of the genotyped rams. The candidate males are the progeny tested rams (for birth year within the conventional selection period) or the genotyped rams (for birth year within the GS period. The selection differentials are calculated within each birth year of sire and dam, then averaged across year, weighted by the part of the replacement animals produced by each sire's and dam's birth year. The unknown sires and dams are not considered. All the rams have known dams and sires. The percentage of ewes born from unknown dam is 0.7, 3.7, 4.6, 1.9, 19.2, respectively in LAC, BB, MTN, MTR and COR breeds. The percentage of ewes born from unknown sire is 4.1, 29.9, 30.7, 19.7, 62.7, respectively in LAC, BB, MTN, MTR and COR breeds.

Results & discussion

The evolution of TMI over the time in the LAC breed (Figure 1) shows a clear inflexion after 2015, with the implementation of GS. Between 2000 and 2014, the estimated yearly AGG (expressed in equivalent litres) is 5.74 (0.19 σ_g) and 5.23 (0.17 σ_g) in rams and ewes. After 2015, the AGG is 9.19 (0.31 σ_g) and 7.96 (0.27 σ_g) in rams and ewes. The extra genetic gain due to GS is 60% in rams and 52% in ewes. Such an inflexion is not yet clear in the other breeds since the GS is more recent. Moreover the shift in selection criteria at the same time of GS in the Pyrenean breeds, makes a reliable analysis on a long period difficult.

The AGG observed using the methodology of the selection pathways are presented in Table 2. When comparing the AGG calculated in 2021 vs the AGG calculated as an average of the years 2011-2015, we can derive the increase in AGG in the LAC and Pyrenean breeds. This increase is 57% in the LAC breed and ranges from 16 to 29% in the Pyrenean breeds. This difference may be attributed to how long the GS has been implemented (6 years in LAC vs 3 years in the Pyrenean breeds).

The results obtained with both methods are similar in the LAC breeds (0.35 σ_g with the pathways method; 0.27-0.31 with the TMI evolution method). The slight differences comes from the fact that the slope in the TMI evolution reflects a mean increase over 6 years. Yet the effort of selection since 2015 has increased steadily, as the rams used were more and more generated by a process of genomic pre-selection before use in AI.

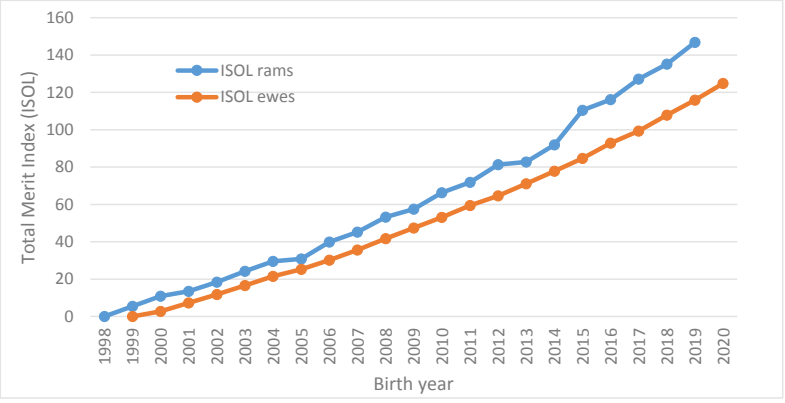

Figure 1. Evolution of rams and ewes TMI over the birth years in the Lacaune breed.

Table 2. Genetic trends (in genetic standard deviation or σ_g) obtained through the selection pathways in the French dairy sheep breeds in genomic situation and comparison with classical program.

Breed	Sum of progress in litres	Sum of generation interval in years	σ_g of milk yield (litres)	Genetic trend 2011-2015 in σ_g	Genetic trend 2021 in σ_g	Extra genetic gain genomic vs classical program
Lacaune	4.13	11.93	30	0.22	0.35	+57%
BB	2.07	13.66	26	0.13	0.15	+16%
MTN	1.74	14.92	25	0.09	0.12	+29%
MTR	2.15	13.24	28	0.13	0.16	+25%
Corse	2.23	19.91	15	0.11	0.11	

Conclusions

Extra genetic gain permitted by GS in the LAC breed appears to be above the predictions obtained in the simulations (Buisson *et al.*, 2014), thanks to a strong selection intensity of the young rams. Close attention is paid by the breeding programs to manage the inbreeding, which is made easier by the high number of rams used quite evenly. The highest genetic gain in GS is intended to be used for including new resilience (functional longevity, resistance to parasites) and efficiency (proxies of feed efficiency) traits in the next years. These good results obtained from GS and the motivating perspectives towards more balanced breeding goals are strong drivers to reinforce the genetic organisation that has existed for decades in French dairy sheep.

Abstract

Genomic information is used in genetic evaluation to improve prediction accuracy in most livestock species. Such is less so in sheep, particularly in the U.S. In this study, the impact of implementing single-step genomic BLUP as compared to pedigree BLUP for weight and faecal egg count traits was evaluated in U.S. Katahdin sheep. Two methods of cross validation were utilised to compare the predictive ability and bias of estimated breeding values of these methods. Genomic information improved predictive ability for both traits, and reduced bias in the evaluation of faecal egg counts. Accuracies of estimated breeding values improved appreciably in genotyped animals. The benefit from including genomic information based on cross validation was minimal but is expected to improve as the reference population grows. Single-step genomic BLUP procedures developed will be used to update those applied in the routine genetic evaluation offered through the U.S. National Sheep Improvement Program.

Introduction

Many global genetic evaluation systems now utilise genomic information routinely. To date, this has not been possible for the National Sheep Improvement Program (NSIP) evaluation system, which provides genetic evaluation services to the U.S. sheep industry (Notter, 1998). Through a U.S. Department of Agriculture grant, and in collaboration with NSIP Katahdin breeders, a large number of genotypes and phenotypes were collected on key traits. Katahdin are an increasingly popular hair sheep breed in the U.S., recognized for tolerance to parasite resistance and twinning. These data provided a foundation to test and implement genomically assisted genetic evaluation. As a result of this research and development, and as a first for the U.S. sheep industry, NSIP recently implemented single step genomic BLUP (SS-GBLUP) (Legarra *et al*., 2014) within their genetic evaluation for Katahdin sheep. SS-GBLUP has been implemented and is successfully running in Australian evaluations since 2016 (Brown *et al.,* 2018), each using the same evaluation platform (OVIS; Brown *et al.,* 2007*)*. The aim of this study was to use cross validation methods with forward prediction to compare pedigree based BLUP (PBLUP) with SS-GBLUP in the Katahdin evaluation for weaning weight (wwt), post-weaning weight (pwt), weaning faecal egg count (wfec), and post-weaning faecal egg count (pfec).

Materials & methods

Data for this paper was based on the June 2021 Katahdin NSIP genetic evaluation. The analysis has close to 100,000 sheep and is multi-trait with 12 traits across age stages including body weights, carcase scans, faecal egg counts and reproductive traits. Approximately 5,000 animals have been genotyped using the GeneSeek Genomic Profiler Ovine 50k array (Neogen Corp., Lincoln, NE, USA) with most genotyped animals being born within the last 5 years.

Forward cross validation was undertaken using both PBLUP and SS-GBLUP procedures. These were full multi-trait analyses. The SS-GBLUP evaluation used the equations of Aguilar *et al.* (2010). A lambda value

of 0.5 was used (McMillan and Swan, 2017), which placed equal emphasis on the pedigree and genomic relationships for animals when both recorded.

Phenotypic data were pre-corrected for standard fixed effects such as age of dam, birth-rearing type, and age of measurement; a fixed effect for contemporary group was included directly. Phenotypes for animals born after 2018 were removed from the data and the BLUP analyses used to estimate breeding values (EBV) from this partial dataset. In Table 1, phenotypic data for wwt, pwt, wfec and pfec are shown. Accuracy of prediction was assessed by examining the ability for EBV to predict phenotypes pre-corrected using the OVIS evaluation procedures (Brown *et al.*, 2007). The expectation of these regressions is a slope of 1.0. The accuracy of prediction was also calculated using the correlation of adjusted phenotypes with EBV and dividing by the square root of the heritability. As an additional method of validation, accuracy and bias metrics were calculated using the LR method (Legarra and Reverter, 2018) as the correlation and regression slopes between the EBV from the full analysis and the partial analysis for the animals in the validation group with phenotypes (Legarra *et al.,* 2008). The EBV accuracy was estimated for each model using OVIS and compared as a further test of the improvements in predictive ability from each model.

Results

Changes in phenotypic predictive ability and bias are shown in Table 2. For all traits the SS-GBLUP approach increased predictive ability based on the variance explained by the model and accuracy of prediction. The improvements ranged from 2% for wwt up to 10% for pfec across both metrics. For the weight traits, there was a tendency for genomic information to overestimate the phenotypic differences compared to PBLUP. Although, the fec traits showed less bias with the SS-GBLUP model, the phenotypes still were under-predicted.

Result for the EBV regression are shown in Table 3. Based on the correlation of EBV, over all for animals in the validation set, the predictive ability slightly increased for all traits with the incorporation of genomic information. For animals with a genotype, the improvement was more substantial and ranged from 2-3% across all traits.

The bias was either not significantly different or improved when comparing SS-GBLUP to PBLUP. In genotyped animals the bias was closer to the expectation of 1 across traits with SS-GBLUP. The trait showing the largest bias under SS-GBLUP evaluation for genotyped animals was wfec although the bias was much improved compared to PBLUP evaluation.

Table 1. Summary of pre-2018 (training) and post-2018 (validation) datasets.

Trait[1]	Pre-2018			Post-2018		
	Records	Mean	Std	Records	Mean	Std
wwt	57,791	20.52	3.99	14,038	20.52	4.22
pwt	44,525	31.50	4.82	12,254	31.70	5.08
wfec	6,910	9.41	5.96	3,522	8.89	5.53
pfec	9,779	8.78	5.63	4,058	9.63	5.37

PBLUP	pwt	0.97±0.06	0.38	0.57
PBLUP	wfec	0.57±0.08	0.27	0.28
PBLUP	pfec	0.58±0.07	0.24	0.13
SS-GBLUP	wwt	1.20±0.07	0.41	0.70
SS-GBLUP	pwt	1.12±0.06	0.44	0.63
SS-GBLUP	wfec	0.63±0.08	0.33	0.35
SS-GBLUP	pfec	0.70±0.07	0.34	0.19

[1] PBLUP = pedigree BLUP; SS-GBLUP = single-step genomic BLUP.

[2] Traits defined as in Table 1.

Table 3. Results from LR method for regression of full EBV with part EBV.

Analysis[1]	Trait[2]	All animals			Genotyped animals		
		Records	Slope (s.e.)	Corr	Records	Slope (s.e.)	Corr
PBLUP	wwt	13,768	1.00±0.01	0.77	2,076	0.94±0.02	0.79
PBLUP	pwt	11,784	0.92±0.01	0.71	2,529	0.95±0.02	0.76
PBLUP	wfec	3,394	0.84±0.02	0.62	1,691	0.85±0.03	0.60
PBLUP	pfec	3,906	0.88±0.02	0.65	1,761	0.97±0.02	0.68
SS-GBLUP	wwt	13,768	0.98±0.01	0.77	2,076	1.00±0.02	0.81
SS-GBLUP	pwt	11,784	0.93±0.01	0.72	2,529	1.04±0.02	0.79
SS-GBLUP	wfec	3,394	0.87±0.02	0.65	1,691	0.90±0.03	0.64
SS-GBLUP	pfec	3,906	0.94±0.02	0.67	1,761	1.02±0.02	0.71

[1] PBLUP = pedigree BLUP; SS-GBLUP = single-step genomic BLUP.

[2] Traits defined as in Table 1.

The comparison of EBV accuracy from each model is shown in Figure 1. Clear improvements in EBV accuracy are seen for genotyped animals from the SS-GBLUP model compared to PBLUP. Such was particularly the case where the accuracies based on PBLUP were low.

Discussion

Accuracy of prediction of phenotypes was significantly improved with the use of SS-GBLUP for all traits. The benefit was more obvious for fec traits. This is likely a function of the difference in heritabilities, and the number of phenotypes available on fec as compared to weight traits on the validation animals as weights are more commonly recorded. Thus, the weight traits had a larger amount of data supporting them compared to fec, and therefore a higher starting accuracy. The benefit from genomic information therefore becomes smaller. These differences were more obvious for genotyped animals.

The prediction of phenotypes from EBV were more biased for weight traits when comparing SS-GBLUP and PBLUP. In contrast, the predictions of phenotypes for fec traits were much less under predicted with genomic information. The benefit of the SS-GBLUP model can also be observed by comparing the improvement in estimated EBV accuracy from this model over PBLUP. This benefit is greater for animals with lower PBLUP accuracy.

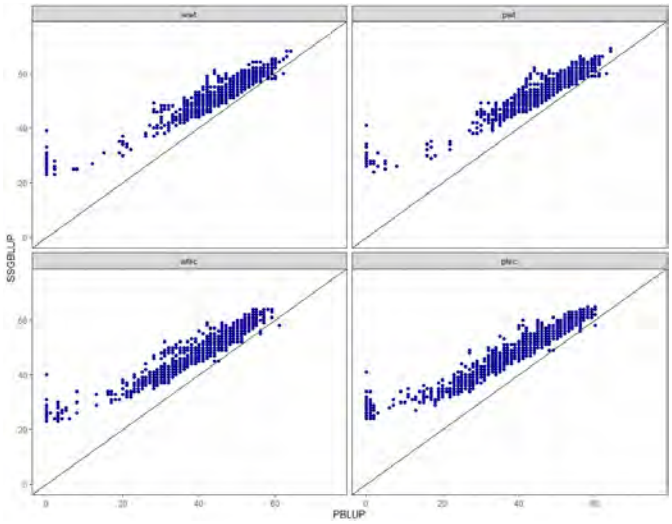

Figure 1. Comparison of EBV accuracy for genotyped animals from pedigree BLUP (PBLUP) and single-step genomic BLUP (SS-GBLUP) models for each trait.

In most cases, though, a small improvement in accuracy of prediction was observed. The benefit from including genomic information based on cross validation is minimal currently but is expected to improve as the size of the reference population grows. The new genetic evaluation procedures and models developed are now being used in the routine genetic evaluation of U.S. Katahdin sheep through NSIP. They will be the foundation for applying SS-GBLUP to other U.S. breeds once sufficient genomic information becomes available.

720. Partitioning of genetic trends by flock and gender in Istrian sheep breed

M. Spehar[1*], J. Ramljak[2], V. Poslon[2] and A. Kasap[2]

[1]Croatian Agency for Agriculture and Food, Svetošimunska 25, 10000 Zagreb, Croatia; [2]University of Zagreb Faculty of Agriculture, Svetošimunska 25, 10000 Zagreb, Croatia; marija.spehar@hapih.hr

Abstract

Istrian sheep is Croatian native breed traditionally selected for milk yield, but the success of past selection efforts has never been studied. Genetic trends play an important role in this regard, and their decomposition is effective in identifying the main contributors to trait related genetic change. The objective of this study was to estimate recent genetic trends (2014-2018) obtained under framework of single step genomic BLUP (test-day animal model) and to partition them by gender and flock. The overall genetic trend was positive, but negligible and inconsistent. Males contributed slightly more to the overall genetic trend than females, while the partitioning by flock was inconclusive. The results implicate absence of systematic selection in the recent period and impose a need to conduct selection based on the estimated breeding values. The ongoing transition to single step genomic BLUP in this population will provide sufficiently accurate breeding values to provide faster and consistent selection gain.

Introduction

Istrian sheep is Croatian native multi-purpose breed (milk-meat). The milk recording in this population started in early 2000 following ICAR guidelines, while the BLUP genetic evaluation for dairy traits has been carried out for about a decade. Recently, genotyping of a large part of the population with 50K SNP chip has been conducted. The aim is to upgrade the existing genetic evaluation system to genomic selection in order to increase the accuracy of estimated breeding values (EBVs) (Duchemin *et al.*, 2012; Legarra *et al.*, 2014). There are many uncertainties about success of historical selection work in this population since up to date there has not been a systematic analysis of genetic trends. Monitoring of selection success (genetic trends) can be simply obtained by averaging EBVs per birth year (Blair and Pollak, 1984) or by regressing BVs on birth year. Following the idea of Garcia-Cortes *et al.* (2008), these trends can be partitioned into contributions by the predefined different 'paths' (country, gender, flock, line, etc.). This can provide additional information on the main contributors to selection gain. The method has already been used to assess the contribution of different countries in Brown Swiss cattle (Gorjanc *et al.*, 2011), Croatian Simmental cattle (Špehar *et al.*, 2011), and two pig breeds in Croatia (Škorput *et al.*, 2015). To our knowledge, there are no reports of using this methodology in sheep. In order to analyse the success of previous selection work in the Istrian sheep, we estimated genetic trend for daily milk yield and decomposed it by flock and gender.

Materials & methods

Data. Phenotypic records for daily milk yield (DMY) and pedigree were provided by the Ministry of Agriculture. Phenotypic records were collected following the ICAR guidelines (ICAR, 2018). Before the final inferential statistical analysis, the original data set was 'pruned' leaving a total of 37,703 records obtained from 5,071 ewes. The pedigree file was created using all available relationships to phenotyped ewes and included a total of 7,208 animals. A total of 719 animals were genotyped using the Illumina OvineSNP50K BeadChip® (52,152). Genotyped animals and SNPs were included in the analysis after quality control parameters for call rate per animal, call rate per SNP, and MAF set to 0.9, 0.9, and 0.05, respectively. A total of 26 animals and 5,150 did not pass the above quality control. Monomorphic markers (n=898) and markers with unknown genome position or located on the sex chromosome (n=1,176) were also removed. The final number of genotyped animals and markers was 693 and 45,349, respectively.

Genetic evaluation. The BLUPF90 family of programs (Misztal *et al.*, 2018) was used in genetic evaluation of the reference population. RENUMF90 was used to renumber data sets and prepare parameter files for estimation of variance components (AIREMLF90) and estimation of BVs (BLUPF90). Covariance components were estimated using the AI REML algorithm within single trait repeatability test–day model. The model included the following fixed class effects: parity, litter size, season of lambing, and flock. Days in milk (DIM) and age at lambing were fitted as covariates. DIM was modelled using the Ali–Schaeffer lactation curve (Ali and Schaeffer, 1987) nested within parity and litter size for DMY. Age at lambing was modelled as linear regression nested within parity. The random part of the model included flock–test–day, permanent environmental effect within lactations, direct additive genetic effect (modelled by combining pedigree and genomic relationships), and residual. The same model was used to predict BVs. The matrix notation of the model was:

$$y = Xb + W_c c + W_p p + W_a a + e \quad (1)$$

where: y is a vector of the phenotypic observations for DMY, X is an incidence matrix for the fixed effects; W_c, W_p and W_a are incidence matrices for the flock-test-day, permanent environmental, and additive genetic effects, respectively; b is a vector of unknown fixed effects; c, p and a are vectors of unknown random effects; e is a vector of residuals. Pedigree additive relationship was combined with genomic information following the theory of ssGBLUP (Aguilar *et al.*, 2010). The inverse of numerator relationship matrix A^{-1} in the mixed model equation was replaced by matrix H^{-1} as follows:

$$H^{-1} = A^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & G^{-1} - A_{22}^{-1} \end{bmatrix} \quad (2)$$

Partitioning of genetic trends. Genetic trends obtained as the average BV by year of birth were estimated for animals born from 2014 to 2018. The BV of an individual can be partitioned as $a_i = 1/2a_s + 1/2a_d + w_i$ where a_i is the BV of the individual, a_s and a_d are BVs of sire and dam, and w_i is the Mendelian sampling term. These partitions of BVs can be allocated into group-specific contributions to the change in genetic mean (Garcia-Cortes *et al.*, 2008). The â was partitioned by the gender and flock using the package AlphaPart 0.8.1. (Obšteter *et al.*, 2021) in R (R Core Team, 2020) following the method proposed by Garcia-Cortes *et al.* (2008) as follows:

$$\hat{a} = \boldsymbol{TP_1T^{-1}}\hat{a} + \boldsymbol{TP_2T^{-1}}\hat{a} + \cdots + \boldsymbol{TP_kT^{-1}}\hat{a} \quad (3)$$

where matrix T traces the flow of genes from one generation to the other, i.e. it describes the expected genetic contribution of genes identical by descent between each individual and all its ancestors, while P_i matrix is the 'path' matrix for the i^{th} origin that selects a partition of animals' BV attributed to selection work performed by the i^{th} origin.

Results

Regression of BVs on birth year revealed a negligible positive (0.005 kg per year) overall genetic trend over the period studied. However, the gain was inconsistent throughout the period with significant decreases in 2016 for both genders and in 2018 for ewes (Figure 1a). Decomposition of genetic trend by gender revealed that rams had greater contribution in selection gain than ewes throughout the period, especially in the last examined year where discrepancy was the most pronounced. When BVs were regressed on birth year within gender, the estimated slopes for rams and ewes were 0.007 and 0.005 kg, respectively. Because of the high oscillations in estimated BVs between adjacent years, these regressions were estimated with a relatively high standard errors and were statistically insignificant (P>0.05). However, due to the similar number of animals throughout the years, these regressions are still to some extent informative in general

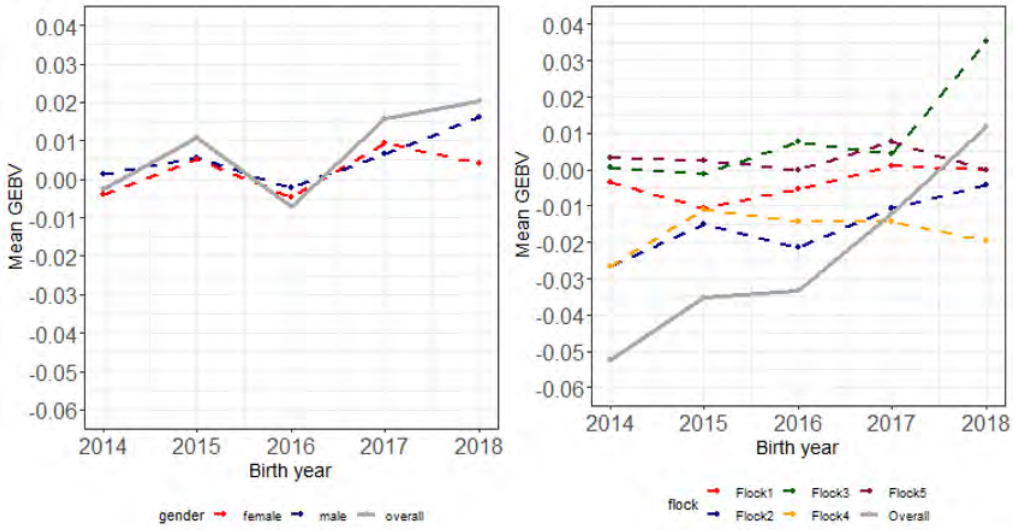

Figure 1. (A) Decomposition of overall genetic trends by gender and (B) flock for DMY.

description of genetic trends. The Figure 1b. shows decomposition of genetic trend by flock for the most informative and most reliable part of this population (flocks with >50 animals). The estimated annual rate for this subpopulation was 0.01435 kg with inconclusive contribution of the flocks' genetics to the overall selection gain.

Discussion

Analysis of genetic trends is important to monitor the success of past breeding activities and to carefully plan future breeding actions. The main intention of this study was to examine recent genetic trends in the Istrian sheep with special attention to determining the main contributors to the genetic trend. We used all the available phenotypic, pedigree, and genomic information to estimate genetic trends. The obtained results suggest that selection had a negligible positive overall trend, but oscillations in average BVs between years suggest that selection was not systematically conducted. The BVs used in this analysis were post-hoc obtained (after selection had been done), so it is ungrateful to derive firm conclusions on this issue. By not having the same information on genetic merits of the animals (potential disproportion of current and past BVs), as well as information which breeders selected based on EBVs, we can only hypothesise that selection on many of the examined flocks was 'happening by chance' rather than following the estimated BVs. In addition, partition of genetic trend by gender indicates that breeders in this population paid more attention to the selection of rams. There are many indications that rams are selected (based on different criteria among the breeders), while ewes are often 'recruited' by chance (often the ones not slaughtered for meat). According to the national breeding programme (Mioč *et al.*, 2011), animals should be selected based on the BVs, but since this is not obligatory, it is obviously sporadically applied. Decomposition of genetic trend by flock was inconclusive because none of the flocks studied had positive trend throughout the study period. Inconsistent genetic trends among flocks can be partially explained by differences in breeders selection criteria, but also as a consequence of limited genetic connectedness between the flocks. It is well known that many sheep populations, including this one, suffer from poor connectedness which leads to inability of the BLUP procedure to disentangle average genetic level from flock effects. Implementation of genomic information in genetic evaluation can alleviate this issue to some extent (Yu *et al.*, 2017) and therefore the results obtained probably nicely reflect true genetic trends in this population. A great precaution is needed

in ranking the flocks according to their estimated genetic merit, thus the obtained results should serve the best on within-flock level. The initial steps towards genomic selection in this population have been taken and continuous genotyping should additionally enlarge the reference population, likely leading to even more accurate predictions. To conclude, the results obtained indicate a very slow and inconsistent genetic gain for DMY and additional efforts need to be made to make it faster and more consistent. Breeders should be more decidedly advised to select replacements based on the estimated BVs. High accuracy of genomic BVs should serve as a strong argument in this regard. The connection between advisors and breeders should be more firm to adopt and carry out the proposed selection methods in order to bring this breed much closer to the world-famous dairy sheep breeds.

Funding

This research has been fully supported by the Croatian Science Foundation under the project Genomic characterization, preservation, and optimum contribution selection of Croatian dairy sheep (OPTI-SHEEP), grant number IP-2019-04-3559.

721. Comparison of GEBV accuracies predicted using the pedigree matrix of female and male potential reference populations

A. Carta*, M.G. Usai, S. Casu and S. Salaris

Agris Sardegna, Genetics and Biotecnology, Località Bonassai, 07100 Sassari, Italy; acarta@agrisricerca.it

Abstract

We propose a procedure to predict the accuracies of GEBV of selection candidate rams which uses the pedigree matrix to estimate the amount of information on relatives in a female (4,486 ewes) and a male (3,074 Herd Book sires) potential reference populations. Two predictive functions were obtained fitting the estimates of the amount of information on relatives to the GEBV accuracies of a sample of genotyped males. The two functions provide good predictions (R^2: 0.94 and 0.73). The predictive functions were applied to 677 ungenotyped selection candidate rams. The predicted accuracies for the male reference population show higher average (0.55 vs 0.46) and higher variability (sd: 0.044 vs 0.020). We showed that the traditional approach for genomic selection in Sarda breed is less effective than in dairy cattle and other dairy sheep breeds and that the female nucleus provides accurate GEBV for a portion of well genetically connected selection candidates.

Introduction

Over the past decade, genomic selection has become the reference approach for the genetic improvement of dairy livestock (Wiggans *et al.*, 2017). In dairy cattle, relative high accuracies of GEBV of young bulls are due to the consistency of male reference populations that include progeny tested bulls with large numbers of daughters. Moreover, GEBV of selection candidates can be calculated for several productive and functional traits that have been recorded on a large number of genotyped animals or their progeny. Although there are some exceptions (Baloche *et al.*, 2014), in dairy sheep the situation is generally worse (Carta *et al.*, 2009). First, the artificial insemination (AI) is less efficient and not widely used which makes the male reference populations less powerful compared to dairy cattle. Second, the overall consistency of genetic evaluations is negatively affected by the relative high costs of performance recording which led to very simplified recording schemes. Third, the range of traits for which GEBV may be calculated is limited by the lack of records for genotyped animals or their progeny for most functional and health traits. In these conditions, the applications of genomic selection may take advantage of experimental female nuclei which can integrate the information content of male reference populations for traits routinely recorded in the Herd Book (HB) and serve as reference populations for traits costly to record on a large scale (Pryce *et al.*, 2018). The potential contribution of experimental female nuclei depends on the number of animals bred, the depth of historical records and the strength of the genetic links with the HB population. For the Sarda breed, a female nucleus, consisting of ewes generated by HB rams, has been pedigree recorded, genotyped and phenotyped for most functional, health and production traits for twenty years. However, the design of a breeding program with genomic selection that includes a female nucleus as reference population requires to appreciate its effectiveness by predicting the accuracy of GEBV (Dekker *et al.*, 2021). In this study, we propose a procedure to predict the expected accuracies of GEBV of selection candidate rams which uses the pedigree matrix to estimate the amount of information on relatives in the reference populations. The final aim was to compare the potential effectiveness as reference population for genomic selection of the Sarda female nucleus and a hypothetical population of HB sires before starting their genotyping.

Materials & methods

The female nucleus proposed as reference population (FRP) was created in 2000 for a QTL detection experiment. It consists of approximately 800 milking ewes with a replacement rate of about 25% generated

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_721, © A. Carta *et al.* 2022

by mating adult ewes with rams coming from the HB of the Sarda breed. Ewes of FRP are raised in an experimental farm that has a typical Sardinian dairy sheep farming system. Ewes are routinely recorded with intense scheme for milk yield and 14,999 lactation records from 4,486 ewes born from 1999 to 2019 were available. All the ewes, 272 male ancestors and further 1,311 HB rams were genotyped with the Illumina Inc. OvineSNP50 Beadchip. SNP editing was performed on the 26 OAR autosomes using call rate and MAF thresholds of 95 and 1% respectively. After quality control, 43,390 SNP were retained.

First, GEBV of 1,561 genotyped HB rams were predicted using the FRP records with the model $y = \mu + Xb + Zg + Wp + e$; where y is the vector of the lactation records; μ is the overall mean; b is the vector of fixed effects; g is the vector of GEBV; p is the vector of random permanent environmental effects; e is the vector of random residuals and X, Z and W are incidence matrices. Vectors p, g and e were assumed distributed as $p \sim N(0, I\sigma_p^2)$, $g \sim N(0, G\sigma_g^2)$ and $e \sim N(0, I\sigma_e^2)$, where G is a genomic relationship matrix including FRP ewes and HB rams (Van Raden, 2008) and σ_p^2, σ_g^2 and σ_e^2 are the corresponding variances.

An alternative GEBV prediction was performed by using as reference population 995 genotyped rams with at least two milk-recorded daughters in HB and using their DYD calculated basing on 173,147 lactations from 70,981 ewes (on average 71 daughters per sire with a maximum of 929). DYD were weighted by $\{1 - [SE_i^2/(\sigma_s^2)]\}^{1/2}$; where SE and σ^2_s are the approximated standard errors and the sire variance estimated by a model including the ram as random effect. Then, GEBV of the 566 genotyped rams with no daughters in HB were predicted with the model $y = \mu+Zg+e$; where y is the vector of DYD and μ, e and Z are as above and g is the vector of GEBV distributed as $\sim N(0, G\sigma_g^2)$ where G is a genomic relationships matrix including the 1,561 genotyped HB rams.

Both the analyses were carried out using the airemlf90 software (Misztal *et al.*, 2002). For both the models the expected GEBV accuracies (r_{GEBV}) were calculated as $\{1 - [SE_i^2 / (G_{ii}\times\sigma_g^2)]\}^{1/2}$ where SE is the standard error, G_{ii} is the diagonal element of the G matrix and σ_g^2 is the model-specific genetic variance. The amount of information on relatives (IR) of a selection candidate on the two reference populations was estimated using the pedigree relationships matrix A including all the available pedigree records in HB of the 6,047 individuals (4,486 ewes and 1,561 rams) as $IR_{i=}[(a_{ir}'A_{rr}^{-1} a_{ir})/ a_{ii}]^{1/2}$, where A_{rr} are the sub-matrices including the relationships between the animals of FRP or the 995 sires of daughters in HB, a_{ir} are the vectors of relationships between the selection candidate i and FRP or the 995 sires of daughters in HB, a_{ii} is the diagonal element of the relationships matrix corresponding to the selection candidate i. Then, for each reference population a specific function of IR fitting to r_{GEBV} was identified. The next step was to compare the expected accuracies predicted by the two functions (Pr_{GEBV}) of the 677 ungenotyped selection candidates that will start breeding in the next reproduction season. Finally, a hypothetical reference population of males (MRP) was formed by all the sires born from 2010 to 2019 with at least two recorded daughters in HB. Finally, 3,074 rams were included in MRP. The potential impact of the two genomic selection approaches was discussed focusing on the distributions of the 677 Pr_{GEBV} obtained by the specific predictive functions in both FRP and MRP.

Results

Figure 1 shows the pattern of r_{GEBV} with IR for the 1,561 validation rams evaluated using FRP as reference population. The values of r_{GEBV} ranged from 0.28 to 0.94 (0.53 on average). The values of IR ranged from 0.00 to 0.99 (0.43 on average). The large variability of r_{GEBV} and IR is related to the different origins of the genotyped rams. Indeed, 272 out of them are ancestors of the FRP ewes and showed the highest r_{GEBV}. On the other hand, most of the other selection candidates recently genotyped come from flocks not genetically linked with FRP due to the scarce aptitude of farmers to use external rams or participate to the AI programs.

Figure 2 shows the pattern of r_{GEBV} with IR for the 556 validation rams evaluated using the 995 sires of daughters in HB as reference population. The values of r_{GEBV} ranged from 0.25 to 0.76 (0.49 on average). The values of IR ranged from 0.19 to 0.83 (0.56 on average). Polynomial functions of IR were fitted to r_{GEBV} for FRP and the male reference data set. Both the functions provide good predictions of r_{GEBV} with R^2 of 0.94 and 0.73 respectively. The lower fitting ability of the function applied to the 556 rams may be due to the high percentage of false pedigree records in HB where the ascertainment of paternity through DNA is not routinely realized. Nevertheless, the predictive function accomplished the aim of comparing the distributions of Pr_{GEBV} of the HB selection candidates rather than predicting accurately the single r_{GEBV}.

In Figure 3 the distributions of IR for the 677 selection candidates are reported for both FRP and MRP. As expected, IR was on average higher in MRP than FRP (0.66 vs 0.31) but with lower variability (sd: 0.054 vs 0.064). Indeed, most selection candidates have male ancestors in MRP whereas, at present, only those coming from the AI center or from flocks that have continuously participated to the AI programs have relatives in FRP. Figure 4 shows the distributions of Pr_{GEBV} of the 677 selection candidates for both FRP and MRP. The values for MRP showed a higher average (0.55 vs 0.46) and higher variability (sd: 0.044 vs 0.020).

Discussion

Our results confirm that IR in potential reference populations can be used to predict GEBV accuracies and to compare different scenarios of breeding programs with genomic selection. It has to be noted that the predictive functions applied in this study are population-specific and should be re-estimated in different populations. Although we hypothesized 10 years of routine genotyping of the HB male

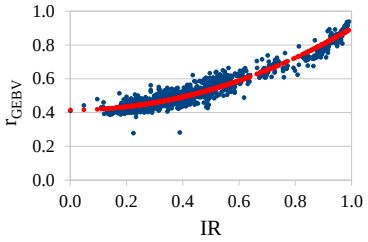

Figure 1. Relationship between expected accuracies (r_{GEBV}) and amount of information on relatives (IR) in FRP. In red the pattern of the predictive function.

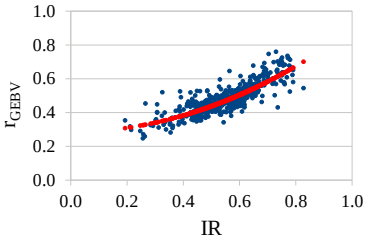

Figure 2. Relationship between expected accuracies (r_{GEBV}) and amount of information on relatives (IR) in 995 sires of daughters in HB as reference population. In red the pattern of the predictive function.

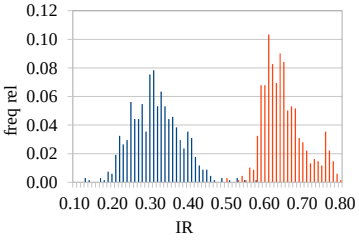

Figure 3. Distribution of amount of information on relatives (IR) of the first service rams candidates estimated from FRP (in blue) and MRP (in red) reference population.

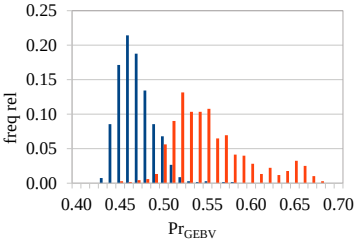

Figure 4. Distribution of expected accuracies (Pr_{GEBV}) predicted from the amount of information on relatives of the first service rams candidates in FRP (in blue) and MRP (in red) reference population.

population, the average Pr_{GEBV} obtained for MRP is not particularly promising for the application of a traditional genomic selection approach based on genotyping the HB rams. The average Pr_{GEBV} obtained for FRP shows that the current genetic structure of FRP can realize sufficient accuracies of GEBV only for few selection candidates well connected with the nucleus. However, it should be considered that the effects of pedigree errors in HB and the higher accuracies of performance records in FRP were not considered in our study. From a practical point of view, we showed that the traditional approach for genomic selection in Sarda breed is less effective than in dairy cattle and other dairy sheep breeds with more structured selection schemes. For traits routinely measured in HB, FRP may be useful to start genomic selection while planning and realizing the genotyping of HB rams. Successively, it could integrate the information content of the male reference population along with the progressive piling up of genotypings of the HB rams. In this perspective, the availability of single-step Genomic BLUP methodology is fundamental to develop models able to jointly exploit information from male and female reference populations (Lourenco *et al.*, 2020). For traits too costly to measure in the HB, FRP can currently provide accurate GEBV at least for the breeding rams well genetically connected. However, the number of breeding rams with sufficiently accurate GEBV can be increased by using the predictions of the expected accuracies to set up the size of the nucleus and the flow of animals between HB and FRP.

722. Quantification of the effect of incomplete reproduction data on the accuracy of selection

W.J. Olivier

Grootfontein Agricultural Development Institute, Private Bag X529, Middelburg (EC), 5900, South Africa; willemo@dalrrd.gov.za

Abstract

The aim of this study was to quantify the effect of incomplete reproduction data on the accuracy of estimated breeding values. The trait included in the analysis was total weight of lamb weaned per lambing opportunity (TWW). The complete dataset for reproduction traits of the Grootfontein Merino Stud was used in this study and subsets of the data were created by excluding or including the reproduction records of ewes. This was done to simulate different levels of data completeness. It is clear from the results that the omission of mating and lambing data will result in an increase of the mean of TWW, as well as a decrease in the variation available for selection. It is therefore of the utmost importance that all relevant mating, lambing and weaning data must be recorded for the evaluation of reproduction traits and the improvement of flock productivity.

Introduction

It is a well-established fact that incomplete phenotypic or pedigree data will reduce the accuracy of BLUP models (Henderson, 1973), which will subsequently lead to bias in the estimated breeding values (EBV; Stock and Distl, 2010). Using these EBV in selection programs will have a negative impact on the genetic gain of the population which will subsequently result in the decrease of the profitability of the enterprise, making all the effort and time worthless (Id-Lahoucine and Casellas, 2017).

Reproduction is the most important trait for small stock enterprises in South Africa to be considered during the selection of replacement rams and ewes. Accurate selection for reproduction is challenging because of the low heritability of these traits, as well as the fact that it is a sex limited trait that is expressed after selection was performed (Olivier *et al.*, 1998). On top of this, genetic progress could even further be hampered by incomplete and inaccurate reproduction data.

The lack of measurements for production traits are seen as a missing value in the estimation of EBV and will probably not have a big influence on the EBV of related animals (Olivier, 2018). However, for reproduction traits, it is important to note that a ewe that did not lambed or wean a lamb should not be regarded as missing data and be excluded from the analysis. The completeness of reproduction data can be defined as all data with regard to ewes that weaned a lamb, ewes that lambed that did not wean a lamb and ewes that were mated but did not lambed. Omittance of the mating and lambing information can therefore be a major constraint to the usefulness of reproduction data. The aim of this study was therefore to quantify the effect of incomplete reproduction data on the accuracy of estimated breeding values.

Materials & methods

Data collected on the Grootfontein Merino stud (GMS) from 1968 to 2017 were used for this analysis. A detailed description of the management and selection of the stud was done by Nemutandani (2017).

The trait included in the analysis was total weight of lamb weaned per lambing opportunity (TWW). The complete dataset for reproduction traits of the GMS was used in this study, which included data from all the ewes that were born since 1968 in the stud. Subsets of the data were created by excluding or including

DOI: 10.3920/978-90-8686-940-4_722, © W.J. Olivier 2022

the reproduction records of ewes. This was done to simulate different levels of data completeness. The first subset (TR – all mating, lambing and weaning data) included data from all the ewes that were mated, lambed or did not lamb and weaned or did not weaned a lamb/s for each lambing opportunity. The second subset (TL – lambing and weaning data) included the data of the ewes that weaned at least one lamb of the litter, as well as the data of ewes that lambed but did not wean a lamb for each lambing opportunity. The third subset (TW – only weaning data) include only the data of the ewes that weaned at least one lamb of a litter of each lambing opportunity.

The Proc MEANS-procedure of SAS (SAS, 2016) was used to obtain the descriptive statistics of the datasets. The estimation of the genetic parameters for TWW of the three subsets, as well as the EBVs was done with ASReml 4.0 program (Gilmour *et al.*, 2014) by fitting a repeatability model. In order to quantify the effect of data completeness, the Spearman rank correlation under the PROC CORR-procedure of SAS (SAS, 2016) was used to estimate the correlations between the ranks of these EBVs for TWW of all three subsets.

Furthermore, lists were compiled of the Top 10% and Top 20% of the animals having the highest EBVs for TWW, estimated in the different data subsets. These lists were compiled for all animals in the pedigree file. The number and percentage of animals common to the different top lists were evaluated among the subsets.

Results

The description of the data for the different subsets is summarised in Table 1. It is clear that there was a clear increase in the number of lambs born (NLB) and weaned (NLW) and total weight of lamb weaned (TWW) with a decrease in completeness of the data. The increases in the means of NLB, NLW and TWW are clearly linked to the exclusion of information of ewes that did not lamb or wean a lamb. An important part in the success of selection for reproduction is the available variation in these traits. It is evident from Table 1 that there is a substantial decrease in the coefficient of variation (CV) of the traits as the completeness of the data decreases.

The heritabilities of the TWW were low and ranged from 0.03±0.01 to 0.06±0.01 and increased with an increase in the completeness of the data. These values are in correspondence with values summarised in the

Table 1. Data description of different data subsets (TR – All mating, lambing and weaning data; TL – Lambing and weaning data; TW – Weaning data) used for this analysis.

Reproduction data	Traits	Number of records	Mean	CV[1] (%)
Subset 1 – TR include: all mating, lambing and weaning data	Lambing opportunities	3,866	3.34	48.09
	Number of lambs born	3,866	1.2	45.27
	Number of lambs weaned	3,866	0.92	58.03
	Total weight of lambed weaned	3,866	24.52	58.09
Subset 2 – TL include: all lambing and weaning data	Lambing opportunities	3,565	2.93	49.91
	Number of lambs born	3,565	1.55	25.43
	Number of lambs weaned	3,565	1.18	42.45
	Total weight of lambed weaned	3,565	31.28	41.83
Subset 3 – TW include: all weaning data	Lambing opportunities	3,340	2.72	51.27
	Number of lambs born	-	-	-
	Number of lambs weaned	3,340	1.39	26.53
	Total weight of lambed weaned	3,340	36.97	25.35

[1] Coefficient of variation.

literature (Olivier, 2014). The estimates for c^2_{pe} were very low and ranged from 0.02±0.01 to 0.04±0.01 and are at the lower end of the range of 0.00 to 0.13 summarised by Olivier (2014).

The average and range of repeatability model EBV and accuracies of the EBVs for total weight of lamb weaned (TWW) for the respective subsets are summarised in Table 2. It is evident from Table 2 that the top end of the EBVs decreased with 2.15 kg as the variation in TWW decreased because of the unavailability of mating and lambing data. However, the lower boundary of the TWW EBVs increased substantially with 4.73 kg as the available variation decreased.

These changes in the upper and lower boundaries resulted in a decrease in the EBV range between TR and TL of 24%, between TR and TW of 59% and between TL and TW of 28%. These changes suggest that EBVs of the better reproductive ewes will be effected negatively. However, the biggest concern is the fact that the EBVs of the ewes with poorer reproduction will increase. It is also evident that there were a decrease of in the mean accuracies between the TWW EBVs of TR and TL of 8% and between TR and TW of 15%.

The Spearman rank correlations between TR and TL was 0.84, between TR and TW 0.63 and TL and TW 0.75. According to these values it is evident that the unavailability of mating and lambing data will result in a major re-ranking of the ewes, especially when only weaning data is included.

The number and proportion of common animals in the Top 10% and Top 20% lists when all animals in the pedigree were included are presented in Table 3 for TWW EBV estimated for TR, TL and TW. The highest percentage common animals in Table 3 were in the Top 20% lists between TR and TL, as well as between TL and TW, with just more than 70% common animals. The lowest percentage of common animals in both the Top 10% and Top 20% lists were 54.26 and 57.24% between TR and TW respectively, which could be expected due to difference in the level of completeness of the data.

Table 2. The average of repeatability model estimated breeding values (EBVs; Min-Max) and accuracies of the EBVs (Accuracy; Min-Max) for total weight of lamb weaned for the respective subsets.[1]

Traits	EBV	Accuracies
TR (Total reproduction)	0.54 (-8.92 to 9.53)	51.79 (23.33-67.23)
TL (Lambing data)	0.42 (-5.80 to 9.06)	47.96 (0.18-65.48)
TW (Weaning data)	0.23 (-4.19 to 7.38)	45.19 (0.13-64.14)

[1] TR = all mating, lambing and weaning data; TL = lambing and weaning data; TW = weaning data.

Table 3. The number and proportion of common animals in the Top 20% and Top 10% lists for total weight of lamb weaned (TWW) for the three subsets.[1]

Subsets	Top 10% list (n=387)		Top 20% list (n=774)	
	Number	%	Number	%
TR vs TL	259	66.93	556	71.83
TR vs TW	210	54.26	443	57.24
TL vs TW	256	66.15	549	70.93

[1] TR = all mating, lambing and weaning data; TL = lambing and weaning data; TW = weaning data.

Discussion

It is evident from the results of this study that the completeness and accuracy in the collection of reproduction data will have a substantial impact on the improvement in total weight of lamb weaned per generation through selection. It is clear from the results that the omission of mating and lambing data will result in an increase of the mean of TWW, as well as a decrease in the variation available for selection. This decrease in the phenotypic variation was also reflected in the decrease of h^2_a, as well as the decrease in the EBV ranges. It is therefore of the utmost importance that all relevant mating, lambing and weaning data must be recorded for the evaluation of reproduction traits and the improvement of flock productivity.

Abstract

Random Regression is increasingly popular as a method to model longitudinal traits, such as growth, in animal populations. However, these models perform optimally when some specific criteria are met such as the availability of sufficient records at the beginning and end of the age distribution to avoid 'edge' effects. Also, the performance of these models with sparse data is not well known. This research investigates the use of random regression models with data for Scottish Blackface (SBF) and mixed breed sheep, where data is rather sparse. Polynomial regressions and Splines presented a good fit at the phenotypic level. Estimates of heritabilities and genetic correlations for SBF varied from medium to high. This study will help expand the functions used to model growth in sheep and allow for more flexible phenotype recording strategies.

Introduction

Breeding animals for desirable traits is a practice as old as domestication. One of current animal breeding's top priorities is creating sustainable and efficient food supply for the growing human population. Thus, animal breeding uses genetic analysis to identify and breed animals that have the genetic potential to grow quickly. Accurately modelling growth curves is an important way to understand how quickly and efficiently animals grow. With the advent of modern statistical genetics, genetic models can be used to precisely identify animals with superior genetic effects and then select those animals for breeding. Over several generations of breeding this benefit can be disseminated population wide (Hermesch *et al.*, 2003, Kirkpatrick and Heckman 1989). There are several ways to model growth and select for superior genetic potential. The random regression model has been used to accurately represent the entire dynamic process of growth across an animal's life. The basic structure of the random regression model remains generally constant across various applications (Schaeffer 2004).

The structure is: $Y_{ijkn:t} = F_i + g(t)_j + r(a,x,m1)_k + r(pe,x,m2)_k + e_{ijkn:t}$ where Y is the n^{th} observation of the k^{th} animal at time t belonging to the i^{th} fixed factors and the j^{th} group. *Fi* is a fixed effect. The next variable, $g(t)$ j is a function that accounts for the phenotypic trajectory of the average observations across all animals belonging to the j^{th} group. The next term $r(a,x,m1)k$ is the notation adopted for the random regression function. The next variable is another regression coefficient for the permanent environmental effect for the k^{th} animal. Lastly e is the random residual effect (Schaeffer 2004).

Random regression models represent growth as a function rather than a finite set of measurements, which allows it to account for variability in the rate of growth and variability in environmental effects throughout an individual's life. However, random regression models can be difficult to fit to real world data which may be unbalanced or sparse. Firstly, it cannot accommodate non-linear functions to represent the data. Although generally traits such as growth curves can be modelled with a linear function, a specific dataset can have variable rates of change or be highly correlated. It is difficult to validate the assumption that the data would necessarily follow a linear relationship. The second key issue is the number of records required for the model to converge. Random regression models are often used on lactation data in dairy cattle where

test day records follow a well-defined pattern compared to growth data; especially in sheep where data may be sparse. Thus, this research examines the application of random regression models when the data is sparse, highly correlated, or there are large gaps in age between weight recordings for an individual animal.

Materials & methods

The project was conducted with two datasets. The first was provided by the Agriculture and Horticulture Development Board. It consisted of mixed breed animals included in the RamCompare (RC) project which sought to identify the genetic merit of key sires currently used in UK sheep breeding. The dataset consisted of approximately 74,124 individuals with a total of 174,815 weight records. This dataset included three possible weight recordings with an accompanying age for each individual sheep. The second dataset was records from an SRUC SBF research flock and included 23,256. The datasets were also split into two versions. The first version of the dataset included weight records across the entire age distribution while the second included weight records that were taken from 1 to 200 days of age. The first version of the RC data included 174,815 records and the second version included 120,897 records. The first version of the SBF data included 23,256 records and the second version included 18,595 records. Three generation pedigrees were used.

Phenotypic curves. Initially, several curves were fitted at the phenotypic level to determine how several functions fit the data before including the genetic component. The datasets were analyzed with polynomial regression models of several orders (1 to 6) with weight fitted as a function of age using excel. Also spline functions were fitted in R using the 'stats' package and the 'rm. smooth' function in R studio. These methods were applied to the cut version of the dataset and the full version of the dataset when the latter was possible. The quantity and size of the full datasets were, at times, impossible to use when they exceeded the computation capacities of excel or R studio.

Genetic analysis. A random regression model consisting of the fixed effects: birth year, sex, genetic line, birth rearing rank, dam's age, grazing code, a fixed regression on age, month of recording, a combination of year month and day of recording, season of recording, and a combination of year and season of weight recording. A random animal effect with Legendre polynomial (LP) of order 1 and a permanent environmental (PE) effect were fitted to the full data set for SBF using ASREML (Gilmour *et al*., 2006). A random regression model including the fixed effects: breed, flock id, sex, birth type, and a fixed regression on age. A random animal effect with Legendre polynomial of order 1 and a PE effect were fitted for the cut data set for RC data using ASREML. Heritabilities and genetic correlations among several weights at different ages were generated from the analysis. It was observed that correlation between the intercept and slope for the LP parameters was close to the parameter boundary at 0.99 and this yielded genetic parameters that were not biologically reasonable. Therefore this correlation was fixed at three different levels and the correlation with the most biologically reasonable genetic parameters was chosen. These correlations were 0.2, 0.5 and 0.7 for SBF and 0.1, 0.5 and 0.9 for RC.

Results

Phenotypic curves. A summary of the results for the various phenotypic curves fitted is presented in Table 1. The polynomial regression had R squared values above 0.80 for both the RC and SBF datasets. The R squared values for the SBF were slightly higher indicating a slightly better goodness of fit. Spline functions were selected based on R squared values with the best for RC containing 80 knots and the best for the SBF containing 100 knots. The Gompertz functions for both datasets converged and resulted in equations for both models. Results are in Table 1.

Table 1. Phenotypic model summary values.

	Polynomial regression R^2 values	Spline	Gompertz:
RamCompare	Order 2: 0.826	R^2: 0.615	Residual standard error:
	Order 3: 0.835	$P<0.001$	5.344 on 15,053 df
	Order 4: 0.837		
	Order 5: 0.837		Equation: $Y=43.12e^{-1.73*0.98\wedge t}$
	Order 6: 0.838		
Scottish Blackface	Order 2: 0.870	R^2: 0.942	Residual standard error:
	Order 3: 0.872	$P<0.001$	3.561 on 23,253 df
	Order 4: 0.877		
	Order 5: 0.877		Equation: $Y=45.52^{e(2.19*0.98\wedge t)}$
	Order 6: 0.879		

Genetic analysis. The model with fixed correlation of 0.5 between both components of LP was chosen for the SBF and a corresponding value of 0.7 for the RC based on the biological plausibility of the genetic parameters obtained. The estimates of heritabilities for weight at different ages, as well as genetic and phenotypic correlations among weights at several ages are shown in Table 2 for SBF Sheep and Table 3 for RC. Heritabilities increased with age to reasonably high estimates at 376 days for SBF and 197 days for RC. In general, genetic correlations were high between close ages and much lower between ages that were further apart. Phenotypic correlations also followed an expected pattern, being higher between adjacent ages and decreasing at weights which are far apart in age.

Discussion

The curves from the phenotypic analyses, indicates the feasibility of fitting polynomial regressions of several orders. The polynomial regressions in excel increased in R squared as the order of the polynomial regression increased which is a trend that must be balanced with the increasing degrees of freedom in the model. The spline functions had reasonably high R squared values with SBF having a higher R squared value indicating a better goodness of fit. However, at the genetic level such high number of knots will not be feasible. The Gompertz models had similar resulting equations suggesting that the models for both data would be similar, which may indicate a poor goodness of fit as other curves have shown differences between the data sets. In addition, Gompertz functions may not be easy to fit in random regression setting.

The correlation between the intercept and slope of the LP being at the parameter boundary space accounted for the high heritabilities initially obtained for both breeds. However, examining this correlation at different levels helped to obtained reasonable genetic parameters. The impact of this on the rate of genetic progress will be examined. These results provide an initial basis to investigate further the impact of sparse data on the performance of random regression models. Although the birth weight heritability did not follow the general pattern of increasing over time, this is reasonable if birth weight is under different genetic control than growth at other points during a lamb's life. Further investigations on the use of covariance functions and more flexible functions such as the Spline are planned.

724. Impact of the order of polynomials in random regression model on the accuracy of genetic evaluation for weight traits

U. Paneru[1*], D.J. Brown[2], N. Moghaddar[1] and J.H.J. van der Werf[1]

[1]School of Environment and Rural Science, University of New England, 2351, Armidale, Australia; [2]AGBU, a joint venture between NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; upaneru@myune.edu.au

Abstract

Random regression is suggested as a better model for genetic evaluation for a trait with multiple measurements. A random regression model with a higher order of polynomials is often selected as a more parsimonious model based on log-likelihood and information criteria. However, limited empirical studies assessed whether higher order of polynomials corresponds to better predictive ability. This study investigated the predictive ability of random regression models with different polynomials using forward prediction in Australian maternal sheep, using 141,056 repeated weight records from 33,564 animals. Results showed a random regression model with quadratic polynomials for all random effects was the best model, producing an average accuracy estimate of 0.72 and a slope of 0.96 in regressing phenotypes on estimated breeding values. A random regression model with a quadratic polynomial is suggested as the best alternative to model multiple weight records for genetic evaluation of sheep.

Introduction

Random regression (RR) is advocated as a method of choice to estimate genetic parameters and estimated breeding values (EBVs) for a trait with multiple records because it allows variance and covariance to vary across a trajectory of time (Fischer *et al.*, 2004; Schaeffer, 2004; Van der Werf *et al.*, 1998). Further, the RR model does not limit the number of records that need to be considered per animal, removes the need for age correction, and allows the genetic merit of animals to be estimated at any point in the trajectory (Meyer, 2001). Most RR analyses tend to select an optimal order of fit in the estimation of variance components, based on higher log-likelihood, lower Akaike Information Criteria (AIC), and Bayesian Information Criteria (BIC) (Fischer *et al.*, 2004; Meyer, 2001). However, the predictive ability of EBVs was seldom assessed to investigate whether a higher order of fit also corresponds to a better prediction of progeny performance. This study aimed to examine the accuracy of genetic evaluation from various RR models using weight records of Australian sheep.

Materials & methods

Data were taken from the LAMBPLAN dataset consisting of weight records of Australian and New Zealand sheep from maternal breeds (Brown *et al.*, 2007). Weights recorded from 61 to 525 days of age were analysed for animals born between 2009 and 2019, resulting in a data set of 141,056 records from 33,564 animals. A plot of the number of records and mean weights of animals across ages are presented in Figure 1.

Fixed effects. Mean weight was modelled as fixed cubic regression of body weight on a Legendre polynomial of age in days. Contemporary group included breed, flock, management group, sex, and day of measurement and was fitted with Legendre polynomial of order 1. Additional fixed effects included birth type and rear type fitted with a Legendre polynomial of order one and two, respectively and dam age with order zero based on a partial F test (Gilmour *et al.*, 2015). The same fixed effects were fitted for all models, to allow analysis to be directly comparable.

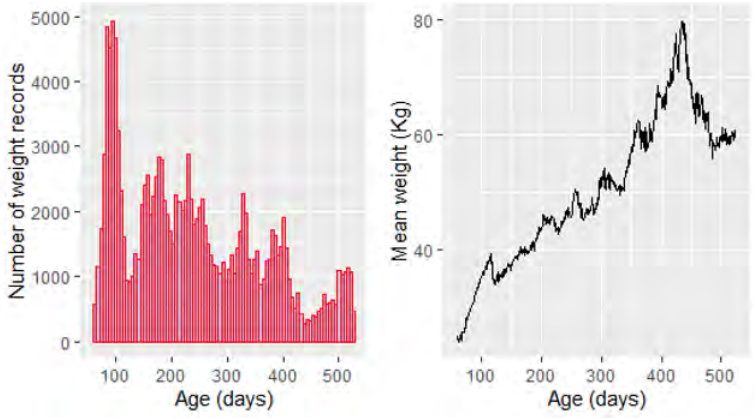

Figure 1. Histogram of number of weight records across age on the left, and mean weight of animals across age on the right.

Random effects fitted for RR. The RR models fitted random effects as Legendre Polynomials of age at recording (in days). A simple model was fitted first, with a first-order polynomial for all random effects, i.e. with effects being constant across ages. Higher-order polynomials for each random effect were added successively, and log-likelihood, lower AIC, and BIC values were compared. All analysis was done using ASReml 4.1 (Gilmour *et al.*, 2015).

The model in matrix notation is:

$$y = Xb + Z_4\alpha + Z_5\gamma + W_3\delta + W_4\rho + Z_4\eta + e$$

The structure of the expected values and covariance matrix was:

$$\mathbf{E}\begin{bmatrix} y \\ \alpha \\ \gamma \\ \delta \\ \rho \\ \eta \\ e \end{bmatrix} = \begin{bmatrix} X\beta \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}; \mathbf{V}\begin{bmatrix} \alpha \\ \gamma \\ \delta \\ \rho \\ \eta \\ e \end{bmatrix} = \begin{bmatrix} K_P \otimes A & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & K_Q \otimes I & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & K_R \otimes A & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & K_S \otimes I & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & K_T \otimes AQ & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & R \otimes I \end{bmatrix}$$

Where y is a vector of observations, β is a vector of fixed effects, α is a vector of additive genetic (breeding value) coefficients, γ is a vector of animal permanent environmental coefficients, δ is a vector of maternal genetic coefficients, ρ is a vector of maternal permanent environmental coefficients, η is a vector of genetic group coefficients, and e is a vector of random residuals. X, Z_4, Z_5, W_3, W_4, Z_4 are incidence matrices; K_P, K_Q, K_R, K_s and K_T are variance and covariance matrices between respective random regression coefficients; A is a relationship matrix, Q is breed proportion matrix, I is an identity matrix containing a number of levels for each effect and $\otimes$ is a Kronecker product, and R is a matrix of heterogeneous residual variance and covariance with eight classes from 61 to 525 days at 58 days interval.

Forward prediction. Forward cross-validation was performed to investigate the empirical predictive ability of the models and to observe how well the breeding values predict future animal's performance. The full data set was divided into two subsets: animals born from 2009 to 2016 were used as a training set, and animals born after 2016 were used as a validation set. EBVs of all animals were estimated using the training set. EBVs of the validation animals were compared to their phenotypic performance using two parameters: accuracy and slope. Performance of the validation animals was corrected for fixed effects at fixed ages for

each weight stage. The Pearson correlation coefficient between EBVs and adjusted phenotype was scaled by dividing it by the square root of the heritability to estimate the accuracy of EBVs. Slope was estimated by regression of adjusted phenotype on EBVs, with an expectation of slope one, i.e. no bias. A lower value indicates the under-dispersion of EBVs, while a higher value indicates over-dispersion.

Accuracy and slope estimates obtained from the above method are sensitive to the correction of the fixed effect phenotype. Therefore, accuracies and slopes estimates were also derived from the method of Legarra and Reverter (2018). With this method, accuracy was defined as the correlation between EBVs of the validation animals obtained from the partial set and the full set (true EBVs). Similarly, slope was estimated by regressing EBVs estimated from the full set (true EBVs) on EBVs estimated from the partial set.

Results

Log-likelihood and Aikaike's and Bayesian information criteria for all models are presented in Table 1. Under the simplest model (Model 22222); 1st order polynomial was fitted for each additive genetic, maternal genetic, maternal permanent environmental and genetic group effect, with a total of 22 parameters. Model 44334, with a total of 44 parameters, was observed as a more optimum model, assessed based on a significantly higher log-likelihood of -232121, lower AIC 464331, and lower BIC value 464763.

Accuracy and slope estimates of EBVs for a different order of fit calculated using adjusted phenotypes were presented in Table 2. Accuracy estimates from model 22222 were 0.75,0.74, 0.68, 0.64, and slope were 0.87, 0.94, 0.91, 0.90, respectively, for Wwt, Pwt, Ywt and Hwt. Accuracy increased to 0.77, 0.75, 0.69, and 0.66 for Wwt, Pwt, Ywt and Hwt using model 33333 was significant (P<0.05). Similarly, regression slope improved to 0.95, 0.93, 0.97, 0.99 and was significant improvement (P<0.05) over 22222 model. Higher-order of fit 44334 produced no improvement over the 33333 model.

The accuracy estimate observed from the Legarra-Reverter method for Model 22222 was 0.89, 0.86, 0.83 and 0.81 and slope was 0.96, 0.96, 0.96 and 0.92, respectively, for Wwt, Pwt, Ywt and Hwt (Table 3). There was no significant improvement from the higher order of fit over the 22222 and 33333 models.

Table 1. Log-likelihood and corresponding information criteria.

Model[1]	Parameters estimated	Log likelihood	AIC	BIC
22222	22	-234,831	469,706	469,922
33333	35	-233,134	466,338	466,681
44331	42	-232,133	464,351	464,764

Discussion

We observed only minor differences in accuracy between RR models with various orders of fit that differed significantly in log-likelihood, AIC, and BIC. The ability of a model to predict progeny performance was improved for a model with a quadratic fit for all random effects, which showed that high order of polynomial beyond quadratic fit is not required for accurate genetic evaluation. Many large-scale genetic evaluations could not easily implement the RR model because of higher computation requirements, and the present study showed that a reduced order of polynomial fit performs not worse compared to a higher order of fit. All animals had at least four measurements which were sufficient to model a cubic fit. Further, we validated our findings by checking how well EBVs estimated from the partial set can predict true EBVs; accuracy observed from this method was higher than regressing phenotypes on EBVs, but there was a non-significant difference between different models. Li *et al.* (2020) also observed RR with quadratic fit better in dairy cattle when validating EBVs. Therefore, the RR model with quadratic order of fit is suggested to be used in genetic evaluation for a trait with repeated measurements.

Conclusions

Random regression with quadratic order of Legendre polynomials performed better than RR models with other polynomials to model repeated weight records in Australian maternal sheep. Therefore, RR models with Legendre polynomial orders higher than three are not required to model multiple weight records in Australian sheep.

725. Estimation of linkage disequilibrium in Pag and Istrian sheep breed: towards genomic optimum contribution selection

A. Kasap[1*], J. Ramljak[1] and M. Špehar[2]

[1]University of Zagreb Faculty of Agriculture, Svetošimunska 25, 10000 Zagreb, Croatia; [2]Croatian Agency for Agriculture and Food, Svetošimunska 25, 10000 Zagreb, Croatia; akasap@agr.hr

Abstract

Knowledge of the genetic architecture of the population is important to predict the potential of genomic selection. The strength of association between genome wide single nucleotide polymorphisms (SNPs) and unknown quantitative trait loci (QTL), measured by linkage disequilibrium (LD), represents the corner stone of genomic selection. The aim of this study was to estimate LD in two Croatian native dual purpose (milk-meat) sheep breeds (Pag sheep, n=719 and Istrian sheep, n=749) using the Illumina Ovine 50K SNP chip. The main goal in these populations is to improve dairy yield traits, preferably via genomic optimum contribution selection. The estimated LD was low (r^2_{Pag}=0.04, D'_{Pag}=0.28, $r^2_{Istrian}$=0.06, $D'_{Istrian}$=0.39,) with very steep LD decay in both breeds. The results obtained are promising for conservation of these breeds, but less promising for the success of genomic selection. In order to maximize benefits of genomic information, single step genomic BLUP should be applied.

Introduction

Istrian and Pag sheep are Croatian native dairy orientated breeds with great economical, traditional and cultural importance. In order to preserve them '*in situ*', it is necessary to permanently increase their productivity. Small breeds under selection are under risk of genetic erosion, but low productivity leads them towards extinction due to non-competitiveness with highly selected breeds (FAO, 1998). Balancing between selection gain and loss of genetic variability is a challenging but feasible task, best achieved by following the principles of optimum contribution selection (OCS) (Wellmann *et al.*, 2021; Wooliams *et al.*, 2015). High-density SNP arrays have been used as an important source of information for selection (Van Raden, 2020) and conservation (Windig and Engelsma, 2010) in many livestock populations. However, benefits of genomic information in selection vary between populations, and depend heavily on population genetic parameters such as linkage disequilibrium (LD). Association between marker alleles (SNP) and causative alleles (QTL) directly affects the accuracy of genomic selection (Meuwissen *et al.*, 2001) and estimation of genetic diversity parameters (Boettcher *et al.*, 2010, Li *et al.*, 2011). Wishing to upgrade the existing selection strategy to genomic optimum contribution selection, we aimed to estimate the genome-wide levels of LD. The obtained results will serve as a base to ascertain the benefits of potentially novel selection strategy in these breeds.

Materials & methods

Samples for genotyping were collected with the permission of the Bioethical committee for protection and welfare of animals at University of Zagreb Faculty of Agriculture. Ear tissue from 719 Istrian sheep (13 flocks) and 749 Pag sheep (11 flocks) were taken with Allflex tissue sample unit applicator. Animals were originally genotyped for 52,152 SNPs, using the Illumina OvineSNP50K BeadChip. Only autosomal SNPs were included in the analysis after quality control parameters for missingness per animal, missingness per SNP, and minor allele frequency set to 0.9, 0.95, and 0.01, respectively. SNPs were also removed if they deviated from the Hardy-Weinberg equilibrium (*P*-value cut-off set to 1×10^{-6}). A total of 693 Istrian (44,743 SNPs) and 713 Pag sheep (46,685 SNPs) passed the above control. The linkage disequilibrium (LD) between pairs of SNPs was calculated with the PLINK (version 1.9) (Purcell *et al.*, 2007; Chang *et al.*, 2015) using the two most commonly used statistics r^2 and D'. Post hoc statistical analysis of genome wide LD was

conducted with dplyr (Wickham *et al.*, 2021) and ggplot (Wickham 2016) packages in R (R Core Team, 2020).

Results

The minimum and maximum chromosome-wide average LDs were: r^2_{min}=0.046, r^2_{max}=0.078, D'_{min}=0.314, D'_{max}=0.423 for Istrian; and r^2_{min}=0.027, r^2_{max}=0.049, D'_{min}=0.245, D'_{max}=0.307 for Pag sheep breed. The overall genome wide LDs were: $r^2_{Istrian}$=0.06, $D'_{Istrian}$=0.39, r^2_{Pag}=0.04, D'_{Pag}=0.28. The tabular (Table 1) and graphical representations (Figure 1) of LD change accompanied by between-marker distance revealed very similar pattern of LD decay between these populations. Graphical representation of LD decay obtained by plotting the average LD vs average between-marker distance of bins spanning 20 Kbp revealed a very steep decay of LD within first 150 Kbp, an intermediate decay from 150 to 250 Kbp, and negligible decay after 250 Kbp.

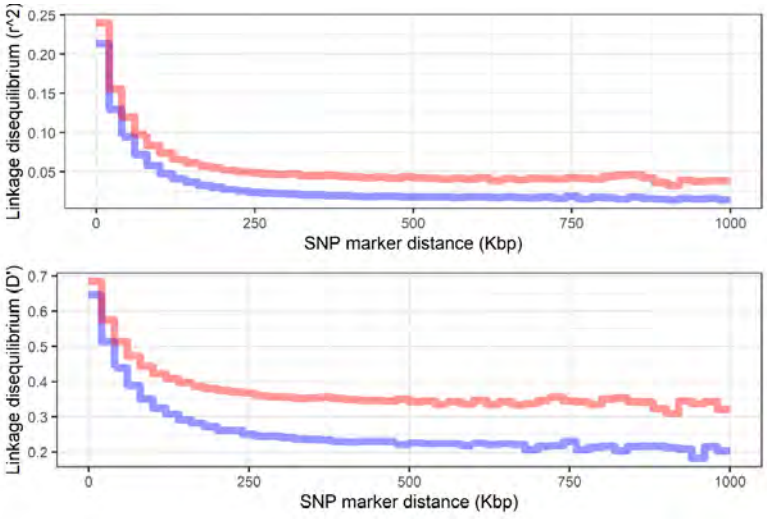

Figure 1. The linkage disequilibrium (LD) decay in Istrian (red) and Pag (blue) sheep.

Discussion

The extent of genome-wide LD and pattern of LD decay are important for GWAS studies, genomic selection, conservation genetics and many other applications. Therefore, our intention was to ascertain this parameter in Istrian and Pag sheep breeds and compare them with some other populations. In this study, we used the two most commonly used statistics, r^2 and D', to allow easy comparison of these results with some previous reports. However, in the between-study comparisons, we focused on r^2 due to its' greater robustness to allele frequency variation than D' (Ardlie *et al.*, 2002). Estimates of genome-wide LD and LD decay in both breeds were very low and steep, respectively. The estimates were very similar to those obtained for French Lacaune (Baloche *et al.*, 2014), Australian Merino, crosses Merino × Border Leicester, crosses Merino × Border Leicester × Poll Dorset (Al-Mamun *et al.*, 2015) and Chinese Merino (Liu *et al.*, 2017). The LD was considerably lower and LD decay less pronounced compared to pure Border Leicester and Poll Dorset breeds (Al-Mamun *et al.*, 2015). The results of the study by Alvarenga *et al.* (2018), conducted in Brazilian Santa Inês sheep, are also comparable to the estimates from this study, especially their reports for chromosome wide LD that were considerably lower (LD r^2_{min}=0.010, r^2_{max}=0.023, D'_{min}=0.176, D'_{max}=0.248). The low levels of LD and high rates of LD decay suggest high level of genetic variability in both breeds which is perspective from the conservation point of view, and less perspective for success of genomic selection. The required level of r^2 for genomic selection to achieve an accuracy of 0.85 should be 0.2 (Meuwissen *et al.*, 2001). The estimates of LD and LD decay have been reported in some other studies in sheep (e.g. Prieur *et al.*, 2017), but because of the different methodology and metric used in presentation of results it would be inappropriate to compare them with results from this research. The low LD in this study confirm many previous conclusions that sheep populations exhibit substantially higher genetic variability than cattle (e.g. De Roos *et al.*, 2008, Sargolzaei *et al.*, 2008). However, regardless of being less favorable than in dairy cattle, the estimated LD should be sufficient for accurate genomic selection (Goddard, 2009). To conclude LD profiles of the Istrian and Pag sheep indicate substantial genetic variability of the breeds and limited benefits of applying genomic selection in term of increased accuracy of estimated breeding values. Some objectively applicable strategies to bridge this gap in practice include genotyping with high density chips in combination with imputation techniques and implementation single step genomic approach in routine genetic evaluation system. Financial investments in novel selection strategies in these populations should be carefully examined to optimize selection under reasonable costs.

Funding

This research has been fully supported by the Croatian Science Foundation under the project Genomic characterization, preservation, and optimum contribution selection of Croatian dairy sheep (OPTI-SHEEP), grant number IP-2019-04-3559.

Abstract

The aim of this study was to investigate the genetic architecture of milk composition traits (i.e. protein and fat percentages), in first and later lactations, for the Canadian Alpine and Saanen dairy goat breeds. A total of 24 unique single nucleotide polymorphisms (SNP) were significantly associated with the traits at the genome-wise level. These SNP were located within 50 kb of 35 unique positional candidate genes on *Capra hircus* autosomes (CHI) 6 and CHI14, including the casein genes and *DGAT1*, which have been previously associated with milk composition traits in various dairy species.

Introduction

In the last decade, the Canadian dairy goat sector rapidly expanded. The province of Ontario produces most of the goat milk in Canada, with an estimated 55 million litres produced (86.8% of national production) in 2019 (Canadian Dairy Information Centre, 2021). The number of goats on Ontario dairy goat operations increased by 23.1% between 2011 and 2016, as the sector grew to meet market demand (McGonegal, 2017). Canadian dairy goat producers are paid based on milk components. However, unlike Canadian dairy cattle, goat milk production is not supply managed and prices continuously fluctuate based on supply and demand. Most Canadian goat milk is processed into cheese. Thus, milk composition contributes to both producer revenue and affects the cheese-making properties of the milk produced.

Although milk production traits in dairy goats are highly polygenic, there are several genes, such as *CSN1S1* and *DGAT1,* that have been reported to have a major influence on the composition of goat milk (Martin *et al.*, 2017). In French dairy goats, genotypes for *CSN1S1* have been reported to explain 24 to 38% of the phenotypic variation for protein percentage (PP) and 9 to 18% of the phenotypic variation for fat percentage (FP) (Carillier-Jacquin *et al.*, 2016), while *DGAT1* genotypes explained up to 46% of the phenotypic variation in FP (Martin *et al.*, 2017). Genetic testing for *CSN1S1* has been used as a selection tool in dairy goat breeding programs in several countries, including Canada, and it has also been shown that accounting for the effects of major genes may increase the accuracy of genomic predictions (Carillier-Jacquin *et al.*, 2016). However, little is known about the genetic architecture of milk composition traits in the Canadian dairy goat populations.

In this context, the objective of this study was to perform a genome-wide association study (GWAS) for milk composition traits (PP and FP) in the two main Canadian dairy goat breeds.

Materials & methods

Phenotypes and pedigree. The data used in this study were provided by the Canadian Centre for Swine Improvement (www.ccsi.ca) through the Canadian Dairy Goat Genetic Improvement Program (www.goatgenetics.ca). Phenotypes were 305-day lactation records for PP and FP recorded for does of the Alpine

and Saanen breeds. The first and later lactation (2-11) records were considered separate traits and are noted with the number 1 for first lactation records (i.e. PP1) and 2+ for later lactation records (i.e. PP2+). The final datasets included first lactation records for 6,409 Alpine and 3,434 Saanen does, whereas the later lactation datasets included 12,236 Alpine records on 5,827 does and 5,008 Saanen records on 2,632 does. Pedigree information was obtained from the Canadian Livestock Records Corporation (www.clrc.ca) and trimmed to only include ancestors of animals with phenotypes or genotypes. The pedigrees for Alpine and Saanen had 13,437 and 7,379 animals, respectively, with an average pedigree depth of 15.8-18.4 generations for animals with records. Additional description of the studied populations is presented in Massender *et al.* (2022).

Genotypes. A total of 1,707 genotypes were used in this study, of which 833 were from the Alpine breed (78 bucks, 755 does) and 874 were from the Saanen breed (97 bucks, 777 does). All animals were genotyped with the first version of the GoatSNP50 Bead Chip (Tosser-Klopp *et al.*, 2014) from Illumina Inc. (San Diego, CA, USA), which contains 53,347 single nucleotide polymorphisms (SNP). Genotype quality control was performed within breed, as described in Massender *et al.* (2022), retaining 44,598 (83.6%) and 43,598 (81.7%) SNP for further analyses for the Alpine and Saanen breeds, respectively.

GWAS. The single-step GWAS was performed using the blupf90 family of programs (Aguilar *et al.*, 2014; Aguilar *et al.*, 2019) and the models described in Massender *et al.* (2022). Briefly, the single-trait animal models included fixed effects of the trait mean, doe age (in months, 8 to 108+), as well as parity (2 to 7+) for later lactation traits, and a linear covariate of days in milk at the final milk test for the lactation. The random effects included contemporary group (herd and year of test) and animal additive genetic effect, as well as permanent environmental effect in the models for later lactation traits. The SNP were considered to be significantly associated with the trait if the $-\log_{10}$ *P*-value was greater than the genome-wise significance threshold, after a Bonferroni correction for multiple comparisons at a 5% family-wise error rate (5.95). The GALLO package (Fonseca *et al.*, 2020), available in the R software version 4.0.4 (R Core Team, 2021), was used to retrieve positional candidate genes located within 50 kb of the significant SNP using the gene annotation information for *Capra hircus* assembly ARS1 in NCBI Datasets release 102 (www.ncbi.nlm.nih.gov/assembly/GCF_001704415.1).

Results

Significant SNP. There were 24 unique SNP significantly associated with the milk composition traits at the genome-wise level. The significant SNP were located on CHI 6 for PP1 and PP2+ in both breeds, CHI6 and CHI14 for FP1 in Saanen and CHI14 for FP2+ in Saanen (Figure 1). No SNP were significantly associated with FP1 or FP2+ in Alpine.

Positional candidate genes. A total of 35 unique positional candidate genes were annotated across both breeds and lactations, of which 30 (85.7%) were protein coding. Four positional candidate genes were common in both breeds (*CSN2, TRNAC-ACA, MOB1B, DCK*), three were unique to Alpine (*CSN1S1, SLC4A4, LOC102179276*) and 28 unique to Saanen (Table 1).

Discussion

The genome-wise correction for multiple comparisons was strict, thus, only major genes were expected to be detected. Genes in the casein cluster on CHI6 were identified as positional candidate genes for PP in both breeds, which was expected as *CSN1S1* has a major effect on goat milk composition (Carillier-Jacquin *et al.*, 2016; Martin *et al.*, 2017). Significant SNP for FP were only observed for Saanen, suggesting possible differences in the genetic architecture for this trait between the two breeds, differing from results reported in other populations (Martin *et al.*, 2017). Positional candidate genes identified on CHI14 have

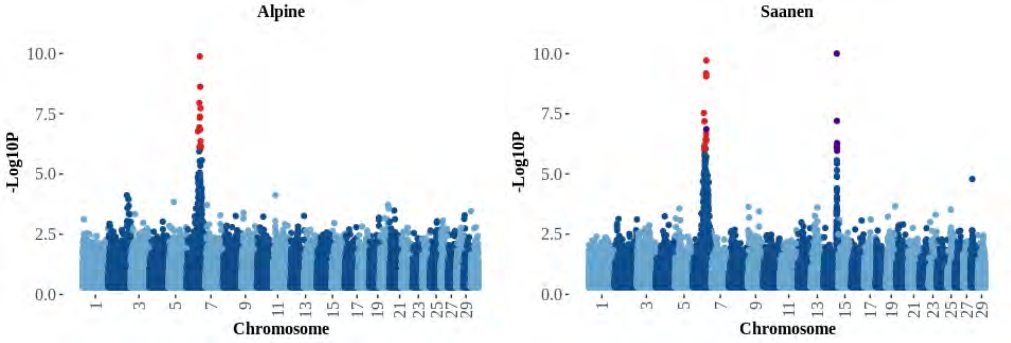

Figure 1. Manhattan plots for milk composition traits in the Alpine and Saanen breeds across first and later lactations. Genome-wise significant SNP are red for protein percentage and purple for fat percentage.

Table 1. Positional candidate genes within 50 kb of genome-wise significant SNP.

727. Evaluating performance of Suffolk, Columbia, and crossbred lambs at birth and weaning

R.M. Lewis[1*], N. Vargas Jurado[1,5], D.J. Brown[2], D.R. Notter[3] and J.B. Taylor[4]

[1]University of Nebraska – Lincoln, Lincoln, NE 68583, USA; [2]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [3]Virginia Tech, Blacksburg, VA 24060, USA; [4]USDA, ARS, Range Sheep Production Efficiency Research Unit, U.S. Sheep Experiment Station, Dubois, ID 83423, USA; [5]Current address: Natural Resources Institute Finland (Luke), 31600 Jokioinen, Finland; rlewis5@unl.edu

Abstract

Crossbreeding is an important strategy in the sheep industry. The evaluation of purebred individuals alongside crossbred progeny requires considering heterosis in the crossbreds and the potentially differing impacts of systematic environmental effects on performance. As such, the aims of this study were to: (1) compare effects of dam age and birth (or birth and rearing) type; and (2) estimate direct and maternal heterosis effects on body weights. An animal model with maternal and genetic group effects was fitted to birth and weaning weight records from Columbia, Suffolk, and crossbred lambs. Purebred and crossbred records were treated as different traits. Dam age effects differed among breeds at birth and weaning, while effects of birth (or birth and rearing) type did not. Heterosis estimates ranged from 5.2±1.2 to 12.2±4.1%. Direct and maternal heritability estimates were moderately low. The importance of accounting for heterosis and systematic effects was highlighted.

Introduction

Crossbreeding is a common practice in the sheep industry (Alvarez *et al.*, 2013; Notter and Taylor, 2019). Despite the beneficial effects of crossbreeding (Gregory and Cundiff, 1980), and the potential gain in accuracy of sire and dam evaluations due to the increase in the number of records available, crossbred performance data are not often included in routine genetic evaluation.

Due to the diversity in selection and breeding strategies among producers, variability within a given breed is often observed (Brown *et al.*, 2010). To account for this additional source of variability when combining different breeds into a single evaluation, it is important to define founder breed or line genetic group. Furthermore, retained heterosis (direct and maternal) may influence the performance of crossbred progeny (Van Raden, 1992).

When evaluating individuals from different breeds and their crossbred progeny, it is also necessary to consider potential differences in the magnitude of systematic environmental effects. As such, the aims of this study were to: (1) compare the effect of dam age and birth (or birth and rearing) type; and (2) estimate direct and maternal heterosis effects on crossbred lambs, on birth and weaning weights. In addition, variance components for direct and maternal additive effects, maternal uncorrelated environmental effects, and genetic groups effects were estimated.

Materials & methods

Data used were from various sheep genetics projects conducted at the USDA, Agricultural Research Service, Range Sheep Production Efficiency Research Unit, US Sheep Experiment Station (Idaho, USA). All husbandry practices and related animal-care procedures were reviewed and approved by the Unit's Institutional Animal Care and Use Committee.

Traits. Performance records of purebred Suffolk and Columbia lambs, and crossbred lambs produced by mating purebred and crossbred Suffolk, Columbia, and(or) Texel sires and dams, were used. A total of 4,135, 2,481, and 5,075 birth weight (BN), and 2,486, 1,049, and 3,673 weaning weight (WW) records were available for Columbia, Suffolk, and crossbred lambs, respectively. Mean (SD) BN was 5.2 (1.1), 5.4 (1.1), and 5.5 (1.2) kg. Mean (SD) WW was 40.1 (6.8), 40.7 (7.7), 39.5 (7.7) kg for Columbia, Suffolk, and crossbred lambs, respectively. Correspondingly, these lambs were, on average, 123 (11.2), 124 (11.7), and 121 (12.7) d of age at weaning.

Fixed effects, heterosis, and variance component estimation. Tri-variate models were fitted separately to BN and WW in ASREML 4.0 (Gilmour *et al.*, 2009), with records of Columbia, Suffolk, and crossbred lambs considered different traits The model fitted was:

$$y = Xb + Z_a a + Z_m m + Z_a Qg + Wc + e \quad (1)$$

where $y = [y_1, y_2, y_3]$ was the vector of phenotypic records for the trait of interest (BN or WW), $b = [b_1, b_2, b_3]$ was the vector of fixed effects, $a = [a_1, a_2, a_3]$ was the vector of direct additive effects, $m = [m_1, m_2, m_3]$ was the vector of maternal additive effects, $g = [g_1, g_2, g_3]$ was the vector of genetic group effects, $c = [c_1, c_2, c_3]$ was the vector of maternal uncorrelated environmental effects, and $e = [e_1, e_2, e_3]$ was a vector of residuals. Similarly, $X = \text{diag}(X_1, X_2, X_3)$, $Z_a = \text{diag}(X_{1a}, X_{2a}, X_{3a})$, $Z_m = \text{diag}(Z_{1m}, X_{2m}, X_{3m})$, and $W = \text{diag}(W_1, W_2, W_3)$ were the design matrices relating to fixed, direct additive, maternal additive, and maternal uncorrelated environmental effects, respectively. The diag(·) refers to a block diagonal matrix. The matrix Q contained covariates for genetic group fractions. Three genetic groups were defined for each of the Columbia and Suffolk breeds, while for crossbreds there was an additional genetic group for Texel sires for a total of 7 genetic groups. Fixed effects included dam age (1, …,7+ years) for BN and WW, birth type (1, 2, 3+) for BN, or birth and rearing type (for single-single, multiple-single, multiple-double, and multiple-multiple) for WW, the interaction between dam age and birth type (or birth and rearing type), contemporary group, and lambing day. For the crossbred trait, direct and maternal heterosis, calculated from breed composition were included as continuous covariates. Direct and maternal additive effects for purebreds and crossbreds at BN and WW were assumed to be correlated while additive effects between purebreds were assumed to be uncorrelated. Furthermore, maternal environmental, genetic group, and residual effects were assumed to be uncorrelated among breeds.

Results

Using a likelihood ratio test, the final model for BN included all effects described above, while for WW the model did not include maternal additive effects. Based on an approximate F-test ($P<0.001$) and their confidence intervals, dam age had a smaller effect on Columbia lambs as compared to Suffolk and crossbred lambs at birth and weaning (Table 1). The effect of birth type as well as birth and rearing type on the other hand, differed little among purebreds and crossbred lambs.

In crossbreds at birth, direct and maternal estimates of heterosis were 7.9 (3.9) and 5.9 (1.8) percent, respectively. Similarly at weaning, direct and maternal heterosis estimates were 12.2 (4.1) and 5.2 (1.7), respectively.

Variance estimates are provided in Table 2. At birth, direct and maternal heritability estimates were, respectively, 0.13 (0.04) and 0.31 (0.05) in Columbia, 0.29 (0.06) and 0.30 (0.06) in Suffolk and 0.18 (0.03) and 0.28 (0.04) in crossbreds. Correspondingly, at weaning direct heritability estimates were 0.26 (0.06), 0.18 (0.07), and 0.23 (0.04). At birth, the direct additive correlation between Columbia and crossbreds was 0.55 (0.34) and between Suffolk and crossbreds was 0.87 (0.21). The maternal additive correlation between

Table 1. Contrasts between levels of dam age (years), birth type (single, double, multiple) and birth and rearing type (single-single, multiple-single, multiple-double, multiple-multiple) for purebred and crossbred lambs at birth and weaning.

Trait	Effect	Breed	Contrast		
			1-2	1-3	1-4+[1]
Birth	Dam age	Columbia	0.86 (0.09)	1.23 (0.11)	1.19 (0.06)
		Suffolk	1.29 (0.10)	1.57 (0.13)	1.78 (0.10)
		Crossbred	1.51 (0.06)	1.80 (0.08)	1.90 (0.07)
	Birth type	Columbia	-1.18 (0.08)	-1.75 (0.11)	-
		Suffolk	-1.29 (0.10)	-2.02 (0.18)	-
		Crossbred	-1.20 (0.07)	-1.60 (0.33)	-
Weaning	Dam age	Columbia	7.80 (0.65)	9.48 (0.85)	9.65 (0.48)
		Suffolk	8.62 (0.92)	12.44 (1.15)	11.72 (0.90)
		Crossbred	9.06 (0.43)	11.98 (0.52)	11.93 (0.51)
	Birth-rearing type	Columbia	-3.55 (1.09)	-7.65 (0.95)	-8.36 (0.92)
		Suffolk	-4.49 (1.79)	-7.89 (1.27)	-10.62 (3.30)
		Crossbred	-2.23 (1.35)	-8.70 (0.69)	-6.96 (2.74)

[1] For dam age the contrast is the difference between age 1 and the average of ages 4 to 7+.

Table 2. Estimates of phenotypic (σ_p^2), direct and maternal additive ($\sigma_{A_D}^2$, $\sigma_{A_M}^2$), and maternal uncorrelated environmental variance (σ_c^2) for Columbia, Suffolk, and crossbred lambs at birth and weaning. Standard errors of estimates in parentheses.

Trait	Breed	σ_p^2	$\sigma_{A_D}^2$	$\sigma_{A_M}^2$	σ_c^2
Birth	Columbia	0.88 (0.03)	0.12 (0.03)	0.27 (0.05)	0.06 (0.03)
	Suffolk	1.02 (0.05)	0.29 (0.06)	0.31 (0.07)	0.01 (0.03)
	Crossbred	0.97 (0.03)	0.18 (0.04)	0.27 (0.04)	0.04 (0.02)
Weaning	Columbia	29.41 (1.06)	7.73 (1.82)	-	1.92 (0.71)
	Suffolk	32.46 (1.69)	5.94 (2.52)	-	4.34 (1.41)
	Crossbred	32.01 (0.93)	7.36 (1.42)	-	4.24 (0.67)

Columbia and crossbreds was 0.69 (0.12) and between Suffolk and crossbreds was 0.77 (0.15). At weaning, direct additive correlations between Columbia and crossbreds, and between Suffolk and crossbreds, were 0.97 (0.22) and 0.37 (0.34), respectively. The proportions of phenotypic variance explained by the maternal uncorrelated environmental variance were low for both traits.

Discussion

Anett *et al.* (2011) reported different effect sizes for dam age at birth for Scottish Blackface and crossbred hill ewes, especially for three- and four-years old ewes. In our study, differences between age categories at birth, were larger for the crossbreds and Suffolk while smaller for Columbia.

Estimates of direct and maternal heterosis were considerably larger than those reported in Brown *et al.* (2016). The discrepancy could be due to fewer observations on crossbreds in this study and different breeds considered. Also, in the current study, records from the purebreds and crossbred were considered different traits, which was not the case in Brown *et al.* (2016). Still, the estimates of heterosis highlight the

benefit of using crossbreeding in sheep. Estimates of the correlation for direct additive effects between Suffolk and crossbreds at birth, and between Columbia and crossbreds at weaning, were consistent with those of Brown and van der Werf (2015) for Dorset sheep, and their crosses. Heritability estimates were, in general consistent with the literature (Borg *et al.*, 2009; Fitzmaurice *et al.*, 2020). Due to the moderate size of maternal heritability estimates it seems feasible to enhance the influence that dams have on the performance of their progeny.

Due to the different impact of systematic effects among the breeds evaluated, and the considerable effect of direct and maternal heterosis, adjustment factors can be developed to help reduce bias when evaluating purebred and crossbred individuals.

728. Genetic selection for sensory eating quality of lamb using consumer assessments

S.Z.Y. Guy[1*], S.I. Mortimer[2], L. Pannier[3], P. McGilchrist[4], D.J. Brown[1], D. Pethick[3] and A.A. Swan[1]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]NSW Department of Primary Industries, Armidale Livestock Industries Centre, 2351, Armidale, Australia; [3]College of Science, Health, Engineering and Education, Murdoch University, 6150, Perth, Australia; [4]School of Environmental and Rural Science, University of New England, 2351, Armidale, Australia; sarita.guy@une.edu.au

Abstract

This paper reports genetic parameter estimates for correlations between consumer eating quality and carcase traits for Terminal sire sheep breeds. Four consumer sensory-assessment traits (tenderness, flavour, juiciness, liking) were collected on loin and topside cuts (n~2,700). Heritability estimates (h^2) were low to moderate for these traits ($0.12<h^2<0.33$), with the topside cut having slightly more genetic variation than the loin. Genetic correlations ($\hat{r}_g$) between sensory traits were high within cuts ($\hat{r}_g>0.94$) and across cuts ($\hat{r}_g>0.61$). There were moderate to high correlations of sensory with the objective eating quality traits (intramuscular fat and shear force) and low to moderately negative correlations with carcase lean meat yield. These estimates can be used to revise selection indexes, and potentially develop breeding values for consumer eating quality in multi-trait models with on-farm and carcase traits.

Introduction

Australian terminal sire breeders have achieved substantial genetic gains in various traits (Swan *et al.* 2017). Balanced selection for carcase yield and eating quality was further enhanced from 2017, with new genetic tools underpinned by substantial investment in genomic reference populations. Genomically enhanced breeding values are now available for carcase yield traits, as well as the objectively measured eating quality traits of intramuscular fat and shear force. Breeding programs can now balance the antagonistic relationship between yield and eating quality using modified selection indexes. These indexes are based on breeding objectives where an economic value is defined for consumer-assessed eating quality (Swan *et al.* 2015).

Genetic correlations between consumer eating quality and selection traits (carcase yield and objective measures of eating quality) are required to develop indexes. Current eating quality indexes are based on correlations estimated from consumer eating quality trials on approximately 1,500 animals from multiple breeds. The continued collection of this information has resulted in almost double the amount of both consumer and carcase data available. This paper reports updated genetic parameter estimates between consumer eating quality and carcase traits for Terminal sire sheep breeds. These estimates can be used to revise selection indexes, and potentially develop new multi-trait breeding values for consumer eating quality.

Materials & methods

Data were available for crossbred lambs from terminal sire breeds (mainly Poll Dorset, White Suffolk and Dorper) recorded in Australian sheep reference populations across multiple years and data sources; mainly the Sheep CRC Information Nucleus Flock 2009- and 2010-born (Van der Werf *et al.* 2010), and the 2017- and 2018-born lambs from the MLA Resource Flock. Lambs were processed at an average age of 266±54 days (mean ± SD), hot carcase weight of 24.2±3.9 kg and carcase fat of 4.5±2.5 mm.

Carcase composition and objective eating quality traits examined were carcase eye muscle depth (mm), lean meat yield assessed from computed tomography scanning, and carcase fat (mm). The objective eating

DOI: 10.3920/978-90-8686-940-4_728, © S.Z.Y. Guy *et al.* 2022

quality traits, measured in the loin, were intramuscular fat (%) and shear force 5 days of aging (N) (collected according Pearce (2009).

Consumer eating quality traits were collected by obtaining a representative subset of animals from each project. There were 335 sires represented by an average of 8 progeny per sire. Samples were collected, prepared, cooked and tasted by consumers according to the protocol described by Pannier *et al.* (2014). Briefly, five slices were collected from the topside *(Musculus semimembranosus*) and loin (*M. longissimus lumborum*) muscles from each carcase. Samples were prepared and grilled under standardised conditions during each consumer tasting session, and randomly allocated to untrained consumers according to a 6×6 Latin square design. Consumers scored each sample for tenderness, juiciness, flavour and overall liking, scored between zero and 100 (with 100 being most preferred). The scores for each animal were averaged across the 10 consumer responses for each muscle without filtering.

The above traits were analysed in a series of bivariate models ASReml (Gilmour *et al.* 2021):

$$y = \mu + contemporary\ group + animal + genetic\ group + e \quad (1)$$

where y is the phenotype (average consumer eating quality scores per animal, or carcase composition and objective eating quality traits, preadjusted for the fixed effects of birth type, rearing type, age of dam and age at measurement); μ is the mean; *contemporary group* is a fixed effect defined as flock, management group, year of measurement, sex, and kill group sub-classes (as well as laboratory for shear force and intramuscular fat); *animal* is the random additive genetic effect based on the pedigree; *genetic group* is the random effect to account for different base animal breeds and sub-populations within breeds (not fitted for topside traits due to lack of significance); and e is the residual random effect.

Results

On average, the loin samples scored higher for eating quality compared to the topside samples, though there was generally more variation in the topside cuts (Table 1).

Table 1. Summary statistics for eating quality traits (consumer-assessed and objectively measured) and carcase composition traits.

	Trait	*n*	Mean	Min	Max	Coefficient of variation (%)
Loin (0 to 100)	Tenderness	2,707	69.3	28.2	94.0	14.7
	Flavour	2,707	67.9	40.5	91.2	12.4
	Juiciness	2,707	64.4	28.1	93.0	15.1
	Overall liking	2,707	68.6	37.8	92.0	13.1
Topside (0 to 100)	Tenderness	2,756	46.0	5.0	83.9	25.4
	Flavour	2,756	54.2	6.0	81.7	16.4
	Juiciness	2,756	49.7	7.0	84.4	21.1
	Overall liking	2,756	51.4	6.0	84.2	19.5
Intramuscular fat (%)	16,182	4.4	1.2	11.2	25.0	
Shear force (N)	16,123	32.2	10.8	110.2	37.3	
Lean meat yield (%)	1,642	57.5	46.4	68.4	6.3	
Carcase eye muscle depth (mm)	17,944	32.5	16.0	50.8	14.2	

Genetic parameter estimates are presented in Table 2. Heritability estimates were moderate for the consumer eating quality traits (0.12 to 0.19 for the loin, 0.16 to 0.33 for the topside), with the topside generally having higher estimates. Tenderness in the topside had the highest estimate (0.33±0.06), with flavour traits having the lowest estimates for both cuts. Heritability estimates were high for intramuscular fat and lean meat yield, and moderate for shear force and carcase eye muscle depth.

Figure 1 presents estimates of genetic correlation ($\hat{r}_g$). The consumer eating quality traits were highly correlated with each other within cuts (ranging from 0.95 to 1; SEs~0.03), as well as across cuts (0.62 to 0.80; Ses~0.10). There were also moderate to strong genetic correlations between consumer eating quality traits and objective eating quality traits.

Table 2. Additive genetic ($\hat{\sigma}_a^2$), phenotypic ($\hat{\sigma}_p^2$), genetic group ($\hat{\sigma}_{GG}^2$) and heritability estimates ($\hat{h}^2$)(± standard error), averaged from a series of bivariate analyses of eating quality traits (consumer-assessed and objectively-measured) and carcase traits.

	Trait	$\hat{\sigma}_a^2$	$\hat{\sigma}_p^2$	$\hat{\sigma}_{GG}^2$	$\hat{h}^2$
Loin (0 to 100)	Tenderness	20.92±4.70	89.54±2.52	13.59±8.29	0.19±0.05
	Flavour	7.68±2.74	61.81±1.73	5.90±3.80	0.12±0.04
	Juiciness	13.03±3.90	83.48±2.33	6.10±4.31	0.17±0.04
	Overall liking	9.92±3.15	69.30±1.94	7.27±4.56	0.14±0.04
Topside (0 to 100)	Tenderness	39.31±7.04	118.19±3.38	-	0.33±0.06
	Flavour	11.78±3.33	71.48±1.98	-	0.16±0.05
	Juiciness	19.58±4.65	88.70±2.49	-	0.22±0.05
	Overall liking	21.99±4.75	87.96±2.48	-	0.25±0.05
Intramuscular fat (%)	0.47±0.02	0.87±0.02	0.12±0.05	0.57±0.03	
Shear force (N)	24.58±2.07	78.97±1.13	3.65±2.02	0.28±0.02	
Lean meat yield (%)	2.83±0.59	5.96±0.23	6.48±2.85	0.47±0.09	
Carcase eye muscle depth (mm)	3.43±0.28	12.30±0.14	1.69±0.64	0.28±0.02	

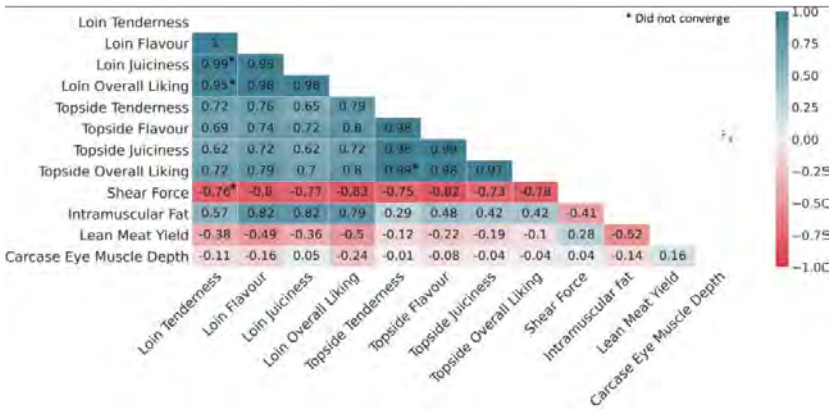

Figure 1. Genetic correlation estimates ($\hat{r}_g$) between eating quality traits (consumer-assessed and objectively-measured) and carcase composition traits (all Ses~0.10).

Shear force had strong negative (favourable) correlations with loin and topside traits (range -0.83 to -0.73). Meanwhile, intramuscular fat (sampled from the loin) had a slightly stronger positive relationship with the eating quality traits from the loin (0.57 to 0.82) compared to the topside (0.29 to 0.48).

The relationships between consumer eating quality traits and lean meat yield were moderately strong in the loin (-0.50 to -0.36), but weak to negligible in the topside (-0.22 to -0.10). Meanwhile, there were weak to no significant correlations of eating quality traits with carcase eye muscle depth (-0.24 to 0.05 for the loin; -0.08 to 0.01 for the topside).

Discussion

Consumer-assessed eating quality of lamb exhibited genetic variation, with the highest heritability estimated for tenderness in the topside cut, which reflects the multi-breed estimates reported in Mortimer *et al.* (2015). Although consumer eating quality traits of the different muscles may be genetically different traits, selection for better eating quality for one muscle will still result in an improvement in eating quality in another muscle.

Consumer eating quality traits were generally more highly correlated with shear force than intramuscular fat, particularly in the topside. However, both traits will be useful as selection criteria in breeding programs. With technological advances in objective carcase measurements, price signals are now emerging for intramuscular fat measured at processing. Therefore, future indexes may directly include intramuscular fat in the breeding objective as an economic trait.

The re-estimated genetic parameters between topside overall liking and lean meat yield align with the previous estimate reported in Swan *et al.* (2015). However, notably stronger genetic correlations were evident between topside overall liking and shear force (-0.78 vs -0.31) in the current study compared to previous estimates (Swan *et al.* 2015). This study also found a negligible relationship between topside overall liking and carcase eye muscle depth (previously estimated at -0.17). Since this study used more data, there is greater confidence in the precision of estimates of genetic correlation between these traits. However, due to changes in correlations with the updated data, it will be necessary to review indexes that include eating quality, along with predictions of response to selection. Future work will explore the development of breeding values for consumer eating quality in multi-trait models with on-farm and carcase traits.

Abstract

Size of reference population for genomic prediction can limit the increase of accuracy for small populations. Multi-country evaluation can overcome this limit but requires prerequisites such as pedigree connectedness and small genetic distances between populations. Within the SMARTER project, pedigree information and genotypes on SNP50 BeadChip of Alpine and Saanen dairy goats from Canada, France, Italy and Switzerland were shared. Pedigrees analyses have shown unilateral exchanges of animals with flows from France to other countries. Analyses of genotypes revealed a genetically closely related population between France and Italy for both Saanen and Alpine breed. On the opposite, Canadian populations showed the largest differences with European populations. There is connectedness between the different populations included in the project and the genetic distance between populations seems suitable for testing a multi-country genomic evaluation.

Introduction

Genomic prediction of breeding values are routinely performed in several livestock species (Baloche *et al.*, 2014; Boichard *et al.*, 2012; Carillier *et al.*, 2013, Massender *et al.*, 2022). However, the success of these genomic predictions depends on parameters related to the studied populations, including the level of linkage disequilibrium (LD) between single nucleotide polymorphism (SNPs), effective population size, genetic relationship between the training and target populations, pedigree connectedness and trait heritability (Lund *et al.*, 2011; VanRaden, 2020). This condition is not always met for small breeds, in particular in dairy goats. Combining data from genetically-related populations can be an efficient strategy for enlarging training populations for genomic predictions. The objective of this study was to evaluate the genetic connectedness and population structure of Alpine and Saanen dairy goats from four countries involved in the European project SMARTER (Small Ruminants Breeding for Efficiency and Resilience), including Canada, France, Italy, and Switzerland. These analyses are paramount for assessing the potential feasibility of an across-country genomic evaluation in dairy goats.

Materials & methods

Pedigrees and genotypes available. Pedigrees were recorded from 4 countries (Canada, France, Italy and Switzerland) and two goat breeds (Alpine and Saanen). A quality control was performed independently in each country to check the format of animal's identification. We checked that all animals recorded as parent where also identified as animal in the pedigree. 6,435,189 animals were registered in the total pedigree files (58% Alpine and 42% Saanen). The pedigree consists of 91% females and these animals were born between 1936 and 2020. French, Italian, Canadian and Swiss pedigree represented respectively 94.2, 3.4, 1.4 and 1.0%.

Genotypes on the Goat SNP50 BeadChip ((Illumina Inc., San Diego, CA, USA) were filtered out with PLINK 1.9 software. The quality control, performed on all genotypes, consisted of removing duplicate genotypes

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_729, © M. Teissier *et al.* 2022

based on call rate, SNPs with MAF<0.01 and call rate <0.90. Besides, animals with a call rate <0.90 were also removed. After quality control, 9,855 genotypes for a total of 50,578 SNPs were available (Table 1). France have the largest number of genotyped animals (2,968 in Alpine and 2,009 in Sannen) born between 1997 to 2019, whereas Italy started to genotype animals later (2009 to 2019) with less animals (Table 1).

Connections between pedigrees. One of the most complicated stage of the project was the standardization of animal identifiers between countries to find the pedigree connections. Imported animals may have multiple identifiers (one from the country of origin and another one in the importing country). Therefore, up to three aliases were provided by the partners in addition to the id of the animal. This identification, which required a lot of computer and manual work, was important to enable tracing the origin of the curated data but also useful for finding the connections between the different pedigrees.

Genetic structure of populations. We used several metrics to characterize the genetic structure of the four populations. Firstly, linkage disequilibrium (LD) with r^2 was estimated within-country and within-breed with PLINK 1.9 software (Purcell *et al.*, 2007). Then, the consistency of gametic phase was estimated as the correlation coefficient of the signed square roots of the LD between different country or breed. The consistency was calculated for nine categories according to the distance between SNPs: (0, 1 kb], (1, 10 kb], (10, 20 kb], (20, 40 kb], (40, 60 kb], (60, 100 kb], (100, 200 kb], (200, 500 kb], and (500, 1000 kb]. Lastly, we ran Principal Component Analysis (PCA) with PLINK 1.9 and genetic admixture analysis to investigate population structure. In order to comply with the data independence assumption for performing a PCA, the genotypes were pruned using PLINK software. A total of 31,951 SNPs was then retained for the analyses. For Admixture (Alexander *et al.*, 2009), we tested the number of clusters k values ranging from 2 to 8.

Results

Pedigree connectedness. Pedigree analysis indicates that animal flows between partner countries are rather limited. French animals were found in all pedigrees, indicating that France exported animals to all country partners of the project, but France did not import any animals from these countries. In contrast, Italian and Canadian animals were not exported to any other countries based on available recording. Italy was the only country that imported animals from France (9,037 animals) and Switzerland (1,905 animals). Only 322 (Canada) and 180 (Switzerland) French animals are shared with France (Table 2). Exports/imports are well balanced between Alpine and Saanen with 54% Alpine and 46% Saanen.

Table 1. Number of genotypes per breed and per country.

	Alpine	Saanen	Range birth year	Total
Canada	793	903	2001-2019	1,696
France	2,968	2,009	1997-2019	4,977
Italy	1,061	338	2009-2019	1,399
Switzerland	1,280	503	2000-2013	1,783
Total	9,102	3,753	1997-2019	9,855

Table 2. Summary statistics of the impact of French animals (Alpine and Saanen) in Canadian, Italian and Swiss pedigree.

	# French animals shared with France	# animals with French sire	Size pedigree
Canada	180	542	93,342
Italy	9,037	17,137	238,942
Switzerland	322	879	56,989

Consistency of gametic phase. Consistencies of gametic phase remained high between France and Italy even for long distances between SNPs (from 1 for SNP distant of (0, 1 kb] to 0.67 for SNP distant of (500, 1000 kb] in Alpine and from 0.99 for SNP distant of (0, 1 kb] to 0.60 for SNP distant of (500, 1000 kb] in Saanen. We observed lower consistency when comparing all other countries especially for long distance. For Alpine, we observed a consistency on average of 0.97 (std 0.01) for SNP distant of (0, 1 kb] to 0.0.17 (std 0.08) for SNP distant of (500, 1000 kb]. The same trend was observed for Saanen breed.

Principal component analysis. Figure 1 presents the two first components of the PCA analyses. They explained 3.2 and 2.3% of the variability respectively. The French and Italian populations largely overlap and are indistinguishable for both breeds. The Canadian Saanen population is the most differentiated and does not group with the other Saanen populations. The few individuals present between the Canadian Saanen and the European populations are in fact animals with at least one French parent. The Swiss Saanen population is also more differentiated from the other European Saanen populations than the Alpine. Indeed, for the Alpine, there is an overlap of individuals for France, Italy, and Switzerland which is not the case in Saanen with a more homogeneous cluster. We observed one of the lowest cross validation errors with k=4 for the Admixture analyses. As observed with PCA analyses, French and Italian animals have close profiles in both breeds. On the contrary, the Canadian Saanen had distinct profile compared to other groups even when comparing to Canadian Alpine.

Discussion

The first difficulties we encounter is the traceability of animals across countries. For some animals, the original ID was not retained after export, so we were not able to recover their pedigree. The importance and difficulty of exhaustive research of pedigrees has been discussed in previous studies, such as in beef cattle for Interbeef (Venot *et al.*, 2007). International genomic evaluation requires exchange between countries to be performant (VanRaden, 2020). In this case, dairy goat seems to be far from optimal with mainly exchange from France to others. Exception would be between France and Italy where connectedness is strong enough to consider an international genomic evaluation.

Our estimation of LD and consistency of gametic phase is consistent with previous studies performed in each country independently, at least for France and Canada (Brito *et al.*, 2015; Carillier *et al.*, 2013). For Italy and Switzerland, it is the first one with genomic data one in dairy goats, showing lower LD profiles than France. When comparing the consistency between Alpine and Saanen within or between each country, we observed low values. It could make a multi-breed genomic evaluation ineffective. The consistency of the gametic phases between France and Italy for both breeds is high enough to make an international genomic evaluation interesting.

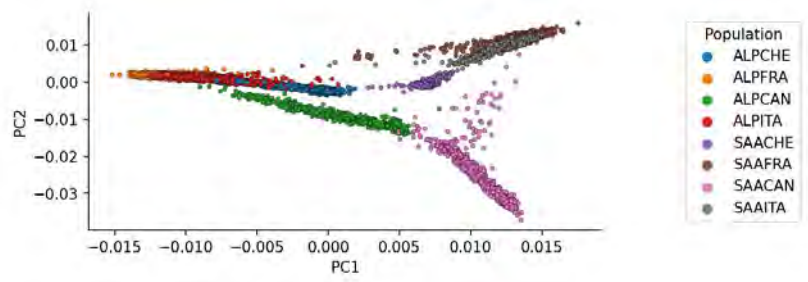

Figure 1. Principal Component Analysis (PCA) with all genotypes for each breed (ALP: Alpine, SAA: Saanen) and each country (CAN: Canada, FRA: France, ITA: Italy, CHE: Switzerland).

Genetic analyses (PCA and Admixture) revealed a distinction between Alpine and Saanen breed. This results is consistent with previous studies performed in France (Oget *et al.*, 2019) or in Canada (Brito *et al.*, 2015). No comparison was available for Italy and Switzerland but we showed that differences between Alpine and Saanen were also present. Canadian populations are quite far from European populations, especially for the Saanen. It may be an obstacle to implementation of an international evaluation. Nevertheless, French and Italian populations are both the most connected and the most genetically similar. An international genomic evaluation for these two countries seems meaningful to implement.

Funding

This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 772787 (SMARTER).

730. Value of data from ram breeding flocks as an industry reference population for Australian sheep

P. Alexandri[1*], S.F. Walkom[1], A.A. Swan[1], J.H.J. van der Werf[2] and D.J. Brown[1]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]School of Environmental and Rural Science, University of New England, Armidale, NSW 2351, Australia; palexan8@une.edu.au

Abstract

This study examined the value of using carcass data from seedstock ram breeding flocks to build upon an industry sheep reference population in Australia. Data from 995 lambs managed in 15 commercial ram breeder flocks were collected between 2017 and 2020 for carcass and meat quality measurements: hot carcass weight, tissue depth on the 12th rib (GR site), eye muscle depth, fat between the 12th and the 13th rib (C – site), intramuscular fat and shear force. Industry data were cross-validated with and without reference data from the MLA Resource Flock. Industry data did not bias the estimation of breeding values when used in combination with the reference population (MLA Resource Flock). Therefore, industry data can be used to expand an industry reference population if data collection is accurate and consistent with industry standards.

Introduction

The MLA Resource Flock (RF) is the current Australian sheep reference population and a succession of the Sheep CRC Information Nucleus Flock (Van der Werf *et al.* 2010). The flock provides a well-designed and ongoing sheep reference population and is mostly funded with national levy funds. This industry investment helps subsidise the high cost for progeny testing and measuring expensive traits such as shear force and intramuscular fat of lamb meat.

Historically most RF sites were well-resourced research stations and RF data has been used for research as well as in routine genetic evaluation to produce Australian Sheep Breeding Values (ASBVs). Large reference populations lead to increased accuracy of genomic predictions (Habier *et al.*, 2010) which can be further enhanced by collecting phenotypic and genotypic information from additional animals. As part of expanding the reference population, a series of projects were established where breeders funded data collection from their own flocks with co-investment support from industry funds. These projects allowed for more animals to be genotyped and measured for carcass and meat quality traits to help build an industry reference population with reduced investment per animal measured from industry funds. The quality of data collected on these projects, however, varied and procedures were not always fully comparable to data from the research stations used in the RF. Therefore, we investigated the value of the records collected on industry animals via the co-investment funding model as part of the reference population for sheep in Australia.

Materials & methods

Data. The seedstock data came from 995 lambs born between 2017 and 2020. The lambs came from 15 seedstock ram breeding flocks and were the progeny of 281 sires across 3 breeds (Poll Dorset, White Suffolk and Southdown). A second dataset with 4,027 RF animals was used for validation. The RF animals were born between 2015 and 2020 and were the progeny of 445 sires across the same three breeds (Poll Dorset, White Suffolk and Southdown). Carcass traits for industry and RF animals were measured after slaughter in commercial abattoirs. Weight (CWT) and tissue depth at the GR site (GRFAT, total tissue depth measured with a GR knife on the 12th rib) were measured on the hot carcass. After overnight chilling (3-4 °C), at a cut

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_730, © P. Alexandri *et al.* 2022

between the 12th and 13th ribs of each carcass, eye muscle (*M. longissimus thoracis et lumborum*, LL) depth (EMD) and fat depth at the C site (CFAT) were measured. The percentage of intramuscular fat (IMF) at the LL was determined using a near infrared procedure (NIR) as described by (Perry *et al.* 2001). Shear force (SF5) at 5 days after slaughter was measured at a section of the LL as described by Hopkins *et al.* (2010).

Statistical analyses. Estimated Breeding values (EBVs) were estimated using the LAMBPLAN genetic evaluation software OVIS (Brown *et al.* 2018). All data was pre-adjusted for birth and rear type (single, twins, triplets and quadruplets or more lambs), lamb age and age of dam. Contemporary group, defined by breed, flock, management group, sex, date of measurement and kill group, was used as a fixed effect. Hot carcass weight was included as a covariate to adjust other carcass traits to a weight constant. All models included the random effects of animal, genetic group (Swan *et al.* 2016) and sire × flock interaction. To estimate the differences in accuracy of prediction an internal cross-validation procedure was used for each data set as described by Legarra and Reverter (2018). RF data were separated into four data sets with approximately the same size as the seedstock data. RF animals were randomly assigned to groups one to four based on their sires so that half-sib families were not represented in multiple groups. All seedstock animals were assigned to group five. Numbers of records, sires and unadjusted trait means for each group are shown in Table 1.

Following analysis of the full data set, three different validation scenarios were investigated. First, EBVs were calculated for each RF validation group, using RF data from the other three groups as the training population (RF – RF analysis, performed four times – one for each group). Second, prediction of industry animals was carried out using only RF data (groups one to four) (F – seedstock analysis, replicated four times). Third, prediction of RF animals was performed using four different replicated combinations of RF (groups one to four) and industry animals (group five) (combined analysis).

For each trait, four validation metrics were calculated and averaged across replicates. Accuracy and dispersion metrics were calculated using the LR method (Legarra and Reverter 2018) as the correlation and regression slopes between the EBVs from each of the three analyses (RF – RF, RF – industry, combined) with EBVs from the full analysis. The regression slopes between EBVs are expected to have a value close to one if there is no over or under dispersion. Accuracy and dispersion were also calculated as the correlation and regressions for EBVs on phenotypes adjusted for fixed effects, with regressions performed in ASReml (Gilmour *et al.* 2015).

Table 1. Number of animals (N), sires (Sires), sires per contemporary group (Sires/CG) and unadjusted mean record values (standard deviation) for all traits and validation groups used in the validation analysis. CWT: hot carcass weight (kg), EMD: carcase eye muscle depth (cm), CFAT: fat depth at the C-site (cm), GRFAT: tissue depth at GR-site (cm), IMF: intramuscular fat (%), SF5: shear force 5 days after slaughter (N).

Group[1]	N	Sires	Sires/CG	CWT	EMD	CFAT	GRFAT	IMF	SF5
1	1,100	112	16.7	23.6 (3.8)	32.9 (4.8)	4.3 (2.4)	14.5 (6.2)	4.4 (1.0)	39.3 (12.9)
2	1,162	110	17.7	26.3 (3.7)	35.1 (4.2)	4.8 (2.6)	18.0 (5.1)	4.4 (1.0)	35.3 (10.1)
3	953	111	15.4	26.7 (3.1)	35.4 (4.2)	5.2 (2.4)	20.7 (5.8)	4.7 (1.2)	32.9 (10.3)
4	812	112	26.4	27.5 (3.5)	34.9 (4.1)	5.7 (2.9)	22.3 (6.0)	4.7 (1.1)	29.0 (8.9)
5	995	140	9.6	26.9 (5.2)	37.0 (4.5)	4.4 (2.8)	16.4 (6.7)	3.9 (1.0)	38.3 (15.0)

[1] Data for groups 1 to 4 came from RF animals, group 5 included seedstock data.

Results

Validation results followed similar patterns for two of the three different validation scenarios. For the RF – RF and combined scenarios LR EBV dispersion metrics had values close to one for CWT and CFAT and greater than one for EMD, GRFAT, IMF and SF5 (Table 2). LR EBV correlations ranged from 0.36 (EMD, combined) to 0.52 (GRFAT for RF – RF and combined, SF5 for RF – RF). Phenotypic dispersions for the same validation scenarios (RF – RF and combined) were close to one for GRFAT (0.95 and 0.94 respectively) and CFAT (0.87 for both). However, estimates greater than one were observed for EMD, IMF and SF5 for both analyses. Correlations between EBVs and phenotypes were consistent between the two analyses ranging from 0.19 (EMD) to 0.45 (CWT).

Differences were observed in the metrics when RF data was used to predict into industry animals (scenario RF – seedstock). LR EBV dispersions were closer to one for GRFAT (0.94), CWT (0.85) and CFAT (0.73) although for the last two traits the values observed were lower than the other two validation scenarios (Table 2). LR EBV accuracies were higher for all traits ranging from 0.49 (CFAT) to 0.64 (EMD). Higher phenotypic dispersions were observed for all traits ranging from 0.67 (CWT) to 1.67 (SF5). Phenotypic accuracies were similar to other validation analyses for EMD and CFAT but higher for the rest of the traits. In general, validation patterns were very similar when using RF data to predict RF progeny (RF – RF) and combined RF and seedstock data (combined) were used to validate RF phenotypes but over-dispersion was observed when RF data was used to predict industry phenotypes (RF – seedstock).

Discussion

Accuracy of genomic predictions can benefit from larger reference populations (Habier *et al.* 2010). In this study the value of expanding the Australian sheep reference population by using data from seedstock ram breeding flocks for carcass and meat quality traits was explored. Cross validation results showed that it was possible to use data from seedstock ram breeding flocks to expand the industry reference population for traits recorded using common protocols. Comparison between observed and predicted performances in a

cross-validation analysis is important to measure the efficiency of the application of the analysis to specific data sets (Legarra *et al.* 2008). Our results show that for reference and seedstock data, phenotypic and EBV dispersions can be similar when seedstock data are used in combination with a well recorded reference population (Analyses RF – RF and combined, Table 2). Using seedstock and reference data together does not introduce further bias to breeding values estimation. When reference data was used to predict seedstock phenotypes results depended upon the recorded traits. For example, EMD presents higher biases than other carcass traits both for EBV and phenotypic dispersions (Table 2) but also exhibits higher mean values in the seedstock animals compared to the reference data sets (Table 1). Moreover, data structure is different between RF and seedstock animals. The number of sires per contemporary group is typically lower for seedstock data (Table 1) and RF data also normally represents a bigger range of breeds (van der Werf *et al.* 2010). This highlights the importance of recorded data quality; the establishment of an industry reference population can benefit from accurate and consistent data recording.

In conclusion, data collected from seedstock ram breeding flocks can be used to complement managed progeny test sites to create an industry reference population. The effectiveness of commercial data depends on the trait measured (completeness of data and good representation of the flock's diversity) and the influence of fixed effects recorded on the flock. Co-investment into industry recorded carcass traits using levy funds was found to be beneficial to the growth of the reference population. However, these projects should be carried out with caution as there is a risk of reduced sire diversity, less consistent data collection, and reduced data quality if they are not managed properly.

Abstract

The selection process in Africa, both environmentally and human-driven, is expected to have led to distinctive variations on the genome between milk and meat goat breeds. We used genotypic data from the caprine 50k Illumina BeadChip to assess the genetic differentiation between nine milk-type and 12 meat-type breeds from Africa by applying a novel pairwise principal component analysis (PCA) method. Using the PCA approach, 95 comparisons contribute to the optimal dissipation on PC1 for milk-type versus meat-type breeds. We identified nine genomic regions that highly differed between milk-type and meat-type breeds in over 25% of comparisons. These SNPs are located on chromosomes 2, 3, 4, 5, 7, 12, 18, and 25. In particular, near these SNPs, candidate genes that might potentially control milk and meat production traits were located. The novel PCA approach helps the identification of genomic regions that contributed to the genomic variation of milk-type versus meat-type breeds.

Introduction

Growing human populations generate an increased demand for food, including protein-rich products from animals (Henchion *et al.* 2017). Goats can play an important role in meeting these demands (Aziz 2010). In Africa, goats are profoundly entrenched in almost every African culture, especially within communities that cannot afford large livestock (Peacock 2005). Goats offer an advantage in animal production and food security as they can produce milk and meat under harsh environmental conditions by using inexpensive food resources. Therefore, costs of goat production are relatively low (Peacock 2005; Mataveia *et al.* 2021) and milk and meat production are essential niches in most African countries to overcome poverty and malnutrition.

Research and developments to improve the relatively low level of productivity of African goats do not match their importance. As a result, many goat breeds are not sufficiently phenotypically explored. To improve the productivity, a better understanding of the animal's genomic data and its relation to phenotypes is necessary (Rexroad *et al.* 2019). Getting, genotypic data of African goat breeds is a challenge. Nevertheless, over the last decade, researchers were successful at collecting a significant amount of genotypic data.

This study aims to identify genomic regions that differentiate between milk and meat goats.

Materials & methods

Animals. Illumina Goat SNP 50K genotypes from African goat breeds were obtained from the Adaptmap project (Bertolini *et al.* 2018) collaborators, and previous own genotyping. The first step is quality control (QC) of the data: Animals where the breed designation is missing, animals that do not cluster inside their designated breed, animals classified as cross-breed animals, and animals that show high relatedness to other animals were removed from the data set. Furthermore, per breed we require a minimum of 20 animals to be genotyped after QC. This resulted in 2,044 animals belonging to 45 African breeds suitable for further

analysis. The next step was to classify each breed for its most common usage type, being primarily 'milk' or 'meat'-type goats. This was done by literature research and talking to experts on African goat breeds. In total, we reliably classify nine breeds as being milk-type breeds (Abergelle, Burundi, Guera, Gumez, Keffa, Nubian, Peulh, Saanen, and Sofia) and 12 breeds as being meat-type breeds (Ambo, Angora, Boer, Cameroon, Central Highland, Long-eared Somali, Mubenda, Nilotic, Sahel, Sebei, Small East African, Taggar). This leads to the final data set, which contained 1,098 animals belonging to 21 African goat breeds.

Genotype quality control. Since the method used here is based on PCA, no missing genotype data is allowed. We remove animals with more than 5% of SNP genotypes missing. After this step, we only kept fully genotyped markers (call rate 100%). This resulted in 1,090 animals genotyped at 21,889 markers.

Pairwise principal component analysis. To detect SNPs which have a high likelihood of being involved in meat or milk production, we adapted our principal component analysis method (Rahmatalla *et al.* 2017) into a repeated pair-wise comparison method. The method works as follows for a single comparison: Take one milk-type and one meat-type breed, perform standard PCA on the genotypes of the animals belonging to these two breeds. Find if there is a threshold in PC1 that perfectly separates the milk-type animals from the meat-type animals. If a perfect separation is found in PC1, we continue by computing the contribution of each SNP to PC1 as described previously (Rahmatalla *et al.* 2017). In short, variable correlations with PC1 were calculated by multiplying the loading factors with the principal component standard deviation. The quality of representation for variables on the factor map (cos^2) was calculated. All cos^2 values for PC1 are summed up, and the contribution of each SNP was expressed as the percentage of the total variation. After this, we estimate the significance of the SNP contribution, which is then adjusted for multiple testing using Benjamini-Hochberg correction. SNPs with an adjusted contribution <0.05 were deemed significantly contributing to the separation of the two breeds.

We exhaustively test all possible combinations of milk-type and meat-type African goat breeds, each time recording which marker is significantly contributing to PC1. We then compute for each SNP the percentage of comparisons in which it is found to differ between two breeds. Many phenotypes are different when comparing any two breeds, but only the milk/meat-type classification is consistently different in our approach. SNPs contributing to milk/meat production will be detected 'consistently', while SNPs contributing to other phenotypic differences will only be found spuriously.

Results

We performed pairwise PCA of autosomal SNPs to assess the difference between the milk type and meat type African goat breeds. In total, 95 comparisons were performed, which showed a perfect separation on PC1 that split the milk breed from the meat breed. Figure 1 illustrates the percentage of times a SNP was found to be significantly contributing to the PC1 of the pairwise PCA comparison. PCA was done using 21,889 SNPs to detect which SNPs contributed highly to PC1. After 95 comparisons we found nine SNPs that contributed highly in more than 25% of comparisons. These markers are found in chromosomes 2, 3, 4, 5, 7, 12, 18, and 25 (Table 1). Although these markers consistently differentiate between milk and meat type goat breeds we do not know the direction of the effect. The genes, *SCN1A*, *SCN9A*, *SCN7A*, *ST6GALNAC5*, *FERD3L*, *SLC41A2*, *APPL2*, *AK5*, *BCKDK*, *ITGAD*, *COX6A2*; *AHSP*, *SEPTIN14*, and *PHKG1* are located in a region ±500 kb around the identified SNPs (Table 1) and could potentially be functionally associated with the milk or/and meat traits.

Discussion

The novel approach based on pairwise PCA identified SNPs contributing consistently to PC1. These SNPs are biologically crucial in the distinction between milk and meat-type goat breeds. Both milk and meat

[3] Known quantitative trait loci.

production are complex and polygenic traits. Therefore, the distribution of the nine markers on eight chromosomes might be supporting the polygenic nature of these traits. Near to the SNP regions, different studies had QTL for conformation traits that related to meat production, such as bicoastal diameter, body length and rump length (Rahmatalla *et al.* 2018), chest width, and rump width (Luigi-Sierra *et al.* 2020) on chromosomes 2, 3, 5, 7, and 18, respectively. Recently, Talouarn *et al.* (2020) detected new signals for milk yield on chromosomes 2 and 5 in Alpine and Saanen goats, respectively, when using a multi-breed panel. Additional QTLs for milk protein yield, milk fat yield and teat number were identified in different goat breeds on chromosome 5 (Martin *et al.* 2016; Kang *et al.* 2020). Furthermore, Martin *et al.* (2016) and Luigi-Sierra *et al.* (2020) found genomic regions associated with teat number in Alpine and Saanen dairy goats on chromosome 12 and teat placement in Murciano-Granadina goats on chromosome 25. Potential candidate genes that might be associated directly or indirectly with milk or meat production traits are suggested from the PCS results of this study. Further research is required to validate the direction of the allele effect and to prioritize the positional candidate genes.

732. Linking genetic merit to phenotypes: a validation of the terminal and replacement Irish sheep breeding objectives

T. Pabiou[1*], K. McDermott[1], A. Bohan[1], L.J. Farrell[2] and N. McHugh[3]

[1]Sheep Ireland, Highfield House, Shinagh, Bandon P72 X050, Co. Cork, Ireland; [2]Teagasc, Animal and Grassland Research and Innovation Centre, Athenry, H65 R718, Co. Galway, Ireland; [3]Teagasc, Animal and Grassland Research and Innovation Centre, Moorepark, Fermoy, P61 P302, Co. Cork, Ireland; tpabiou@icbf.com

Abstract

Genomic evaluations provide producers with a tool to highlight the increase in performance achievable at farm level through genetic gain. The objective of the present study was to validate phenotypic differences for a range of economically important traits for animals divergent in Terminal and Replacement index. Validation animals were ranked into 5 strata of Terminal and Replacement index separately. Least squares regression analyses were constructed to quantify the effect of index strata on each phenotype adjusted for all fixed effects. Growth traits responded favourably to selection: +0.390 to 0.990 kg depending on the trait and index considered. Very high strata animals were drafted for slaughter 8 days earlier than the very low strata for Terminal index. Number of lambs born increased by +0.17 lamb in the Very high ewe Replacement index strata. Differences in other traits where recording may be less accurate were mostly not significantly different from zero.

Introduction

Sheep production systems are traditionally low input with low profit margins, therefore an increased focused is required identifying strategies to improve flock sustainability and profitability. Genetic indexes provide producers with a tool to aid in breeding decisions and highlight the increase in performance achievable at farm level through genetic gain. The dual sheep breeding objectives in Ireland have been defined previously (Santos *et al.*, 2015; Bohan *et al.*, 2019) and the overall breeding indexes in sheep are represented as Terminal or Replacement indexes. The objective of the present study was to validate the phenotypic differences for a range of economically important traits for animals divergent in genetic merit for the Irish national Terminal and Replacement indexes.

Materials & methods

The data used in the present study were obtained from a pre-existing database managed by Sheep Ireland.

Validation population. The validation population used in this analysis were animals born in the Central Progeny Test (CPT) flocks between 2018 and 2021. All phenotypes recorded in the validation population animals were set to missing prior to the one step genomic evaluation (MiX99 development team); their Terminal and Replacement indexes (Bohan *et al.*, 2019) were therefore computed as parent average using the economic weightings currently employed in the Irish national evaluations. Validation animals were then classified into five separate strata of equal size based on their Terminal and Replacement index values, respectively: Very high (top 20%), High (top 60 to 80%), Average (40 to 60%), Low (20 to 40%) and Very low (0 to 20%).

Validation phenotypes. Performance data from the CPT flocks across a range of animal-specific events including lambing, lamb performance, ewe performance and animal health records between October 2018 and June 2021 were extracted from the Sheep Ireland database.

Lambing performance data were available on three farmer recorded lambing traits, birth weight, lambing difficulty score and lamb survival as described by McHugh *et al.* (2016). Lamb live weights were recorded at three time points: pre-weaning, weaning and post-weaning (McGovern *et al.*, 2020) by farmers using weigh-scales. Lamb carcass data including age at slaughter, carcass conformation and carcass fat were also available on a subset of lambs slaughtered between 95 and 365 days of age (McHugh *et al.*, 2021). Ewe live-weight was defined as the weight of a female who had at least one recorded lambing event; only ewe live-weights recorded between 45 and 120 kg were retained (McHugh *et al.*, 2019). Ewe litter size was defined as the number of lambs born per litter (1 to 4 lambs per litter) for each lambing event. Barren rate was derived from the farmer recorded binary barren trait. Dag score was measured by trained technicians on a five-point scale as: 1 (no faecal soiling) to 5 (faecal soiling) and dags covering the breech area and extending down the hind legs towards the pasterns (O'Brien *et al.*, 2016). Lameness was measured by trained technicians assessing each animal individually as it walked and was recorded for each animal as a binary trait: lame or not (O'Brien *et al.*, 2016) and was treated as a separate trait for ewes and lambs.

Data analysis. The association of the Terminal and Replacement index strata and the corresponding phenotypic performance validation phenotypes was quantified separately for Terminal and Replacement indexes using a fixed effects model (Table 1) with SAS Procedure LSMEANS (SAS Institute, Cary, NC).

Results

This study will only report differences between the two most divergent startum (i.e. Very high and Very low). The average index for the Very low and Very high strata were -€0.70 and +€1.27, respectively for the Terminal index, and -€0.26 and +€2.02, respectively for the Replacement index (Table 2). For lambing traits, differences between the Very high and Very low strata were only significantly different from zero for lamb survival and the Replacement index of the ewe (+0.98%). Relative to lambs born to parents in the Very low strata, live weight traits increased by +0.390 kg to 0.990 kg for lambs in the Very high strata, depending on the traits and the index under investigation ($P<0.05$). Similar to live weight traits, the Very high strata of index showed a reduction of -8.34 and -4.85 days in age at slaughter for Terminal and Replacement, respectively relative to lambs born to parents of the Very low strata ($P<0.05$). Health traits did not differ by the index strata of either the Replacement or Terminal index ($P>0.05$). Relative to ewes in the Very low strata for Replacement index, the number of lambs born increased by +0.17 lamb for ewes of Very high strata ($P<0.05$).

Table 1. Model composition by trait types.

Trait	Fixed class effects (number/range of levels)	Fixed regression effects
Lambing traits	Ewe parity (5), contemporary group (541-628), birth type (4), sex of lamb (2), Index strata[1](5)	Breed composition[2], Index[3]
Lamb live performances	Ewe parity (5), contemporary group (190-236), birth type (4), sex of lamb (2), rearing type (3), Index strata[1](5)	Breed composition[2], Index[3]
Lamb carcass performances	Ewe parity (5), contemporary group (194), birth type (4), sex of lamb (2), rearing type (3), lamb month of birth (5), Index strata[1](5)	Breed composition[2], Index[3], carcass weight
Ewe traits	Ewe parity (5), contemporary group (76-823), age at first lambing (2), Index strata[1](5)	Breed composition[2], Index[3]
Health traits	Ewe parity (5), contemporary group (281-357), birth type (4), sex of lamb (2), Index strata[1](5)	Breed composition[2], Index[3]

[1] Terminal index strata and Replacement index strata were analysed separately.

[2] 10 breeds: Belclare, Beltex, Bluefaced Leicester, Charollais, Llyen, Suffolk, Rouge de l'Ouest, Texel, Vendeen and other.

[3] Terminal index of sire when Replacement strata was analysed; Replacement index of dam when the Terminal strata was analysed.

Table 2. Differences in phenotypes between the Very high and Very low strata for Terminal and Replacement indexes.[1]

Trait (unit)	Desired selection direction	Replacement		Terminal	
		Average phenotypes Very high strata	Phenotypic differences (Very high – Very low) strata	Average phenotypes Very high strata	Phenotypic differences (Very high – Very low) strata

Discussion

Since its inception in 2008, Sheep Ireland has promoted more profitable pedigree breeding stock for use in commercial sheep enterprises. Today Irish sheep farmers can use the Terminal and Replacement indexes as overall selection tools to increase farm profit (Bohan *et al.*, 2019). The accuracy of genetic and genomic evaluations is fundamental to realising the benefits of using index information in breeding decisions. Nonetheless, scepticism among farmers sometimes exists on the accuracy of evaluations in commercial production systems. Validation studies that report the predictability of indexes have been published in beef cattle in Ireland (e.g. McHugh *et al.*, 2014), no such study has been published on Irish sheep. Results from the present validation study show that, on average, selection for desired genetic attributes will result in favourable improvements in performances. This is particularly true for traits that show the largest differences between Very high and Very low strata: in the present validation analysis for traits that were recorded directly (live weight traits, number of lambs born) and/or with higher heritability (age at slaughter). Lower heritability traits such as lambing traits would potentially require more validation records to show pertinence. Health trait results did suffer from later recording compared to other more routinely collected traits; the recording of health traits started in the last decade only.

In conclusion, results from this study clearly show that genetic selection for improved performance will materialise in improvements in phenotypic performance. The capacity for improvement is linked to the accuracy and easiness of recording.

733. Influence of a nutritional restriction in dairy ewe lambs on the response to a later inflammatory intramammary challenge

R. Pelayo[1], H. Marina[1], A. Suarez-Vega[1], C. Esteban-Blanco[1], G. Foucras[2], J.J. Arranz[1] and B. Gutierrez-Gil[1*]

Abstract

The objective of this work was to evaluate the potential influence of a nutritional challenge performed in ewe lambs on the inflammatory response triggered against an experimental intramammary lipopolysaccharide challenge carried out at the end of the first lactation. Sixty Assaf ewes at 2 months of age were divided into a control and a nutritional challenge group, the second of which was subjected to a severe protein restriction during the prepubertal growth stage. The ewes were inseminated, and after lambing, 24 of them were subjected to an experimental inflammatory challenge of the mammary gland to induce a local inflammation. Measurements of somatic cell counts, rectal temperature and plasma concentrations of 14 cytokines were collected at different time points from the lipopolysaccharide infusion. The results showed that the effect of the nutritional challenge did not show a significant influence on the local indicator somatic cell count (SCC) traits, whereas it had a significant influence on systemic indicator traits. This research opens the way to further studies related to the potential long-time effects of the nutritional plane at early life on immune response.

Introduction

In dairy sheep, mastitis causes economic losses due to decreased milk production and cheese yield (Leitner *et al.* 2008). In dairy cattle, it has been proven that in order to moderate the mastitis related inflammatory response as well as to improve the immune status of dairy herds it is very important that the animals' nutritive needs are well balanced (Turk *et al.* 2017). Different studies in dairy cattle have shown that the plane of nutrition at the prepubertal stage, when the allometric growth of the mammary tissue starts, influences the mammary gland development and the production potential of dairy heifers (Ford and Park, 2001; Sejrsen *et al.* 1982). The majority of these studies have shown that high feeding levels of heifers during that period is detrimental to milk production as cows (Sejrsen *et al.* 2000). In sheep, Villeneuve *et al.* (2010) reported that the restricted feeding before puberty improves mammary gland development without compromising growth performance in ewe lambs. However, to our knowledge, no previous studies in dairy sheep have assessed how the nutritional plane at the time of the mammary gland development may influence the response of this organ to an inflammatory response later during the productive life of the animals. Based on this, the main objective of this work was to evaluate the potential influence that a nutritional challenge performed in ewe lambs at the prepubertal age may have on the inflammatory response triggered over time against an experimental intramammary lipopolysaccharide (LPS) inoculation carried out at the end of the first lactation.

Materials & methods

A total of 60 Assaf ewes were acquired at 2 months of age and randomly divided in two groups: a control group (C=30) and a nutritional challenge group (NC=30), the second of which was subjected to a severe protein restriction during the prepuberal stage (from 3 to 5 months of age). At 10 months of age, the ewes were inseminated, and about 5 months after lambing, 24 of the ewes (11 from the C and 13 from the NC group), were subjected to an experimental inflammatory challenge of the mammary gland through infusion

of an *E. coli* lipopolysaccharide (LPS) solution to induce a local inflammation. For all the considered ewes, rectal temperature measurements (T^{ra}) and plasma samples to measure the concentration of 14 cytokine/chemokine biomarkers were collected one day before de LPS injection (-24h) and at different time points after the LPS injection (2h, 4h, 6h, 8h, 12h, 24h, 48h, 72h and 144h). Likewise, for all the animal's measurements of the milk somatic cell count in the control udder (SCC_c) and for the SCC in the LPS-treated udder (SCC_i) were obtained at seven of the total considered time points (-24h, 0h, 6h, 24h, 48h, 72h and 144h after injection). This inflammatory challenge was approved by the Junta de Castilla y León regional government (Resolution 23/01/2020, Junta de Castilla y León).

Data processing. To consider the evolution of the different trait values across the different time points, the raw value of each measurement was transformed into a ratio trait.

Hence, for each considered systemic phenotype (T^{ra} and 14 biomarkers) and time point combinations, the -24h time point measurement of the same trait, was considered as the basal point, as indicated in the following formulae:

$$Ratio\ Trait\ 1 = [raw\ data\ Trait\ 1\ (0h/2h/4h/\ \ldots 144h)\ /\ raw\ data\ Trait\ 1\ (-24h)] \quad (1)$$

By applying the same transformation to the available measurements of the two phenotypes related to the local inflammatory response, two SCC ratio traits were also defined (r_SCC_c, r_SCC_i).

Statistical analysis. In order to analyze the relative importance of the studied traits throughout the inflammatory challenge, we performed 17 Generalized Linear Model (GzLM) analyses with the SPSS software (Statistics, 2019). The considered model included as fixed effects the 11 considered sample collection time points (-24h, 0h, 2h, 4h, 6h, 8h, 12h, 24h, 48h, 72h and 144h), and the nutritional challenge group (NC vs C). Statistical significance of the GzLM analysis was defined as $P \leq 0.05$.

Results

Phenotypic characterization. After the LPS injection, the treated half-udders of all the animals showed clinical signs of local inflammation, such as redness and pain on palpation, whereas no signs of local inflammation were observed in the control half-udder. A local response to inflammation was observed in all the animals based on a remarkable increase of the SCC in the LPS-treated udder with respect to the control udder with its maximum at the 6h time point after the inoculation. Also, a systemic response to the LPS injection was observed based on the peak of the values of some of the systemic phenotypes analysed, such as the rectal T^{ra} and some plasma biomarkers, especially IL-6, which showed the maximum concentrations between the 4h and 6h time points, with a profile very similar to those observed for the SCC and T^{ra} traits.

GLM-analysis results. The results from the GLM-analysis performed for the defined ratio traits of both groups of phenotypes, local and systemic, in relation to the different time points considered across the experiment and in relation to the early life nutritional challenge group (NC vs C) are shown in Table 1. For both r_SCC_i and r_SCC_c, the 6h and 24h time points were the only highly significant time points of the experiment. Regarding the systemic ratio traits, the r_T^{ra} trait was significant for most time points, and, r_IL-6, r_IL-8, r_IL-10, r_IL- 36RA and r_VEGF-A were the plasma biomarkers that showed the most significant values for the different time points analysed. However, this analysis did not evidence a significant effect of the nutritional challenge groups (NC vs C) on the two local traits studied (r_SCC_i and r_SCC_c) whereas significant effects of the NC group for all the systemic ratio traits considered except for r_IL-6 and r_IL-8 were identified (Table 1).

Table 1. The effect of changes in inflammatory indicators according to different time points and early life nutrition group based on the results of the Generalized linear model (GLMs) analyses.[1]

Discussion

Given the importance of the mastitis disease in dairy sheep and the increased knowledge about how the plane of nutrition at growth stages can influence phenotypes of economic interest in adult dairy animals (Villeneuve *et al.* 2010), the present study has assessed, for the first time to our knowledge, how a feeding restriction in ewe lambs may influence the response of these animals to an experimental inflammatory challenge of the mammary gland performed at their first lactation. Locally, the intramammary inoculation of LPS described in this report induced an inflammatory response within the inoculated mammary glands, characterized by a remarkable increase in SCC. A very light increase of SCC was also observed in the control udder. After 72 hours, the SCC reached its basal levels in both udders. Our results agree with those presented by Rainard *et al.* (2013) in cows, who found that the infusion of inflammatory compounds such as LPS and ovalbumin into the mammary gland induced an inflammatory response that lasted no longer than 72 h. Likewise, the systemic responses here described, based on the T^{ra} and some plasma biomarkers (especially r_IL-6, r_IL-36RA and r_IL-10), also agrees with that reported by others researchers (Bochniarz *et al.* 2017; Naylor *et al.* 2020). The results of the GLM-analysis here presented (Table 1) showed that most time points were significant for the T^{ra} trait as previously reported by Naylor *et al.* (2020) in a group of female lambs after a systemic challenge with an intravenous bolus of LPS. The increase of body temperature or fever is considered a cardinal response to infection and is thought to be driven by some proinflammatory cytokines, particularly IL-1, IL-6, and TNF-α (Naylor *et al.* 2020). In our work, the r_IL6 ratio trait was the biomarker that showed the highest relative concentration increase relative to the basal point (-24h), showing the most significant results between the 4h to 8h time points post-LPS- injection. Among the tested anti-inflammatory cytokines, the IL-10 was highly significant at 4h and 6h time points post LPS-injection and significant at the 72h time point where the levels of this protein decreased. Other studies have suggested that IL-10 is produced at a later time than the proinflammatory cytokines and regulates the course of inflammation (Bochniarz *et al.* 2017). IL-36RA, another anti-inflammatory cytokine, is known

to inhibit the effects of Interleukin-36 cytokines and thereby inhibit their proinflammatory effects (Towne *et al.* 2004). The concentration of the r_IL-36RA oscillated throughout the experiment, but only the time points 2h, 4h, and 8h were significant for this cytokine. Regarding the concentration of the VEGF-A, which is a master regulator of vascular homeostasis and angiogenesis (Pandey *et al.* 2018), it varied over the experiment, showing significant time points at 4h and 6h (P-value<0.01), but also within the 12-24h time interval (P-value<0.05). Lastly, of the chemokines studied here, r_IL-8 was the most remarkable showing a significant increase in their concentration at 24 and 48 hours after LPS injection, coinciding with the review of Kaplanski *et al.* (2003), who reported that when neutrophils or other cells are stimulated by inflammatory cytokines, IL-8 is usually produced over 24h, recruiting and activating more neutrophils locally. Regarding the results of the GLM analysis in relation to the NC/C groups effect on the local inflammation response (Table 1), our results suggest that energy restriction at the prepuberal age did not modify the local inflammatory response induced by the LPS inoculation, as the effect of animal groups (NC and C) was not significant on the SCC ratio traits. In terms of systemic response, the NC/C group effect was significant for all the systemic traits considered in this study except r_IL-6 and the chemokine r_IL-8. However, considering the results observed for the time points across the experiment, we consider that only some of the studied markers, such as IL-10, IL-36RA and the modulator VEGF-A could be of interest to further assess the potential effect of a protein restriction on the systemic response to the inflammatory challenge of the mammary gland later in life. The preliminary results reported here settle the basis to better understand how the nutritional plane at early life can influence the local and systemic inflammatory responses in dairy sheep.

734. Effects of breeding for scrapie resistance in Bavarian sheep breeding populations

J. Buitkamp* and J. Semmer

Bavarian State Research Center for Agriculture, Institute of Animal Breeding, 85586 Grub, Germany; johannes.buitkamp@lfl.bayern.de

Abstract

Scrapie is a fatal disease of small ruminants that is not transmitted to humans. The disease became the focus of research and policy when it was shown that sheep infected with BSE develop symptoms indistinguishable from scrapie, and it could not be ruled out that humans could be infected via this route. Among other measures, breeding programs were established to improve resistance to scrapie infection. These were based on selection for a single genotype (PRNP). Here we investigate the effects of the breeding program on PRNP allele frequencies and the impact of the selection for resistance in Bavarian herdbook sheep. We show that selection was successful and no severe side effects occurred.

Introduction

Scrapie is a fatal, neurodegenerative disease of sheep and goats. It has been known for nearly 300 years and is characterized by the presence of vacuole formation in neurons and abnormally shaped prion protein molecules. The nature of the infectious agent and the mechanisms leading to pathology are still not fully understood. Prusiner studied and described this entirely new pathogen species (Prusiner 1982) and introduced the term 'prions,' i.e. nucleotide-free, small proteinaceous pathogens that are highly resistant to environmental influences. Meanwhile, the family of diseases caused by prions is called transmissible spongiform encephalopathies (TSEs). TSEs include, for example, chronic wasting disease (CWD) in deer and elk and Creutzfeldt-Jakob disease in humans.

In 1987, a disease with similar pathology had been described in cattle in Great Britain (Wells *et al.* 1987). Wells *et al.* already suspected a pathogen related to that proposed for scrapie. The disease attracted considerable attention when it was found to cause a fatal TSE disease when transmitted to humans (vCJD, Hill *et al.* 1997), triggering a wave of research activity and regulatory control measures. Eventually, the disease was successfully controlled by interrupting the oral route of infection in cattle and removing the at-risk material from the carcass. However, because it could not be ruled out that some scrapie cases were caused by the BSE prion and thus posed a potential threat to human health, TSE in sheep and goats also became the focus of regulatory action. These were TSE surveillance programs and breeding for TSE resistance.

It has been recognized that there are genetic differences in susceptibility to scrapie in sheep, both between and within breeds. Later on it was shown that susceptibility was largely related to variants of the PRNP gene in sheep (Goldmann *et al.* 1994). These results allowed very efficient breeding for scrapie resistance. Therefore, in 2002, selective breeding programs in sheep were initiated in the EU in addition to other TSE control measures. Different breeding programs have been implemented depending, for example, on the endangerment status of the breed and the frequency of resistance/susceptibility PRNP alleles. In effect, these lead to sharp selection according to the genotype of one particular gene with possible side effects such as limiting the number of animals available for breeding and associated effects on performance or health traits. Here we investigated the effect of PRNP selection in Bavarian sheep. We monitored the change of allele frequencies from the year 2002 to 2008 by genotyping more than 2000 herdbook animals for the PRNP gene and investigated potential side effects.

Materials & methods

DNA Samples. EDTA-Blood samples from 2286 herdbook registered Bavarian sheep were collected in the years 2002 to 2008 in the course of routine parentage control. DNA was isolated by using the E.Z.N.A. Blood DNA Mini Kit (#12-3482-03, PEQLAB Biotechnologie GmbH, Erlangen, Germany) and stored at -20 °C. The largest number of samples (1825) was from Merinolandschaf (MLS), a smaller number of samples was from Suffolk (SUK), Schwarzköpfiges Fleischschaf (SKF), and Alpines Steinschaf (AST) with 146, 258, and 57 samples.

Genotyping. All DNA samples were genotyped using a multiplex ARMS system that allows rapid genotyping of PRNP amino acid positions 136, 154, 171 and the determination of haplotypes in the case of double heterozygote individuals (Buitkamp and Semmer 2004). ARMS primers were designed for multiplex allele specific amplification. 5' Primers for alleles 136_A and 136_V were fluorescence labeled (TET and Fam) enabling the evaluation of fragments on an ABI PRISM® 310 genetic analyser (AppliedBiosystems, Foster City, CA) and automated genotype designation using the the Genotyper® software (V. 2.5, Applied Biosystems).

Results & discussion

PRNP allele frequencies for all 2286 sheep are summarized in Table 1 for 2002-03 and from 2004 onward. The baseline frequency at the beginning of the scrapie resistance breeding program for the 'resistance allele' ARR was relatively low in MLS (0.2), while it was already very high in SUK and SKF (0.82, 0.83). This high prevalence corresponds to the results for most meat sheep breeds (Drögemüller *et al.* 2001). In the three economically relevant breeds, ARQ and ARR were the dominant alleles. The 'susceptibility allele' VRQ either did not occur or occurred with very low frequency. In the endangered sheep breed Alpine Stone Sheep (AST, listed on the Red List of the Federal Agency for Agriculture and Food (BLE) under 'conservation status', which means that an effective population size between 50 and 200 animals exists) all 5 alleles including ARH occur. Accordingly, the selection based on the PRNP genotype led to an increased frequency of the ARR allele in MLS, whereas in SUK and SKF the high frequencies were maintained. In AST there was only a moderate frequency increase for ARR, probably because the breed specific selection program is adapted to the situation for small populations.

Figure 1 shows the PRNP allele frequencies from year 2002 to 2017 for all MLS and the MLS breeding rams. The allele frequency of ARR rises from below 0.1 to above 0.6 within 2 years when the resistance breeding program starts. A slightly more moderate increase is observed in the genotypes from the whole MS population. This could be expected since the PRNP based selection program operates mainly on the rams. From the year 2004 on the allele frequencies stabilizes at 0.65 for ARR. This reflects the governmental

Table 1. *PRNP* allele frequencies summarized for the years 2002-2003 and as of 2004 for four Bavarian sheep breeds.

Breed	MLS		SUK		SKF		AST	
Year	2002-2003	2004-	2002-2003	2004-	2002-2003	2004-	2002-2003	2004-
Allele								
ARR	0.20	0.45	0.82	0.75	0.83	0.83	0.36	0.56
ARQ	0.71	0.51	0.13	0.23	0.16	0.013	0.40	0.32
ARH	0.00	0.00	0.00	0.00	0.00	0.00	0.34	0.07
AHQ	0.09	0.04	0.00	0.00	0.00	0.03	0.04	0.05
VRQ	0.00	0.00	0.06	0.01	0.01	0.01	0.08	0.00

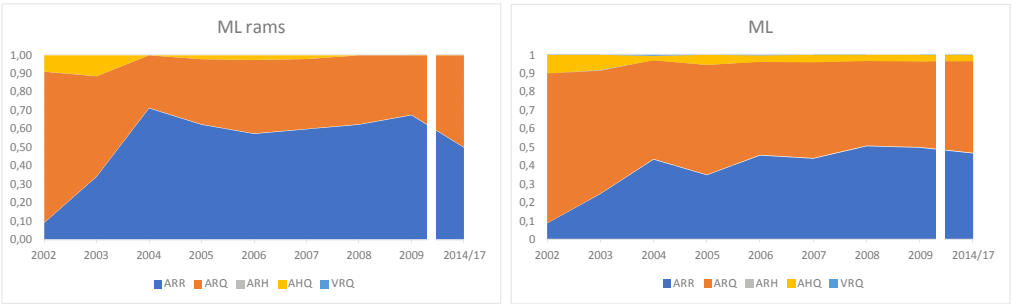

Figure 1. *PRNP* allele frequencies from all MLS sheep (bottom) and MLS breeding rams (above) in the period 2002-2017.

regulations that allow the use of rams carrying ARR/ARR or ARR/ARQ, or ARR/not VRQ respectively. These data show that the selection using a single gene genotype works highly efficient as expected.

In Germany, the numbers of BSE and scrapie cases sharply dropped with the governmental measures (ban of risk material from animal nutrition, TSE surveillance, etc.) in place and the start of breeding for scrapie resistance (Figure 2).

The side effects of the selection program are more difficult to investigate, and data are limited. By direct investigation of the allele effect no main adverse associations were found (e.g. Prokopová *et al.* 2002; Buitkamp *et al.* 2005; Vitezica *et al.* 2006; Pritchard *et al.* 2008).

In 2002 and 2003, the exclusion of MLS rams from breeding due to undesirable PRNP genotypes reduced the number of herd stock rams for selection on other traits. Therefore, it is expected that genetic progress in these years may be limited. Table 2 shows the mean values for daily gain and dressing out percentage for the test station progeny groups from the genotyped MLS rams. The values from 2002, the year with the strongest selection effect, are lower than those from all other years. This may indicate that there has been a negative effect on breeding progress. In this case, the adverse effect would be mainly due to the restriction of the selection of breeding animals, but not to undesirable effects of the ARR allele. There are few examples of sharp selection based on alleles of one gene in breeding animals. Prominent examples are selection for

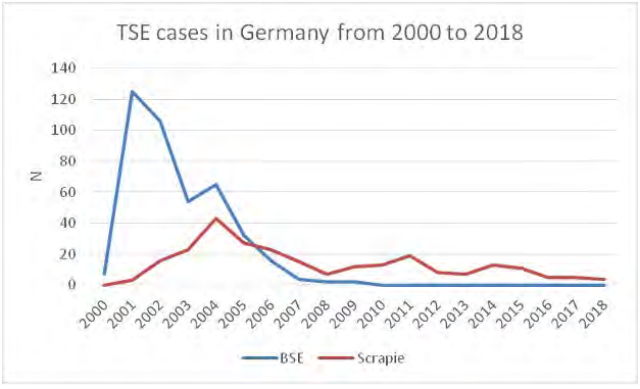

Figure 2. Number of BSE and Scrapie cases as registered by the Bundesministerium für Ernährung und Landwirtschaft ('Tierseuchenbericht').

Table 2. Means from the average values per year of the progeny groups from the progeny test station in Grub https://www.lfl.bayern.de/itz/schaf/031163/index.php

Year	Daily gain [g/d]	Dressing out %
2001	410.93	46.92

2008	451.34	47.80

MHS status in pigs or selection against Weaver in Brown Swiss, both of which led to a decrease in breeding progress in important traits.

Conclusions

The scrapie breeding program was successful and there could be a small side effect on economic traits due to the reduced number of breeding rams.

735. Options for the selective breeding for resistance to gastro-intestinal nematodes of Sarda breed sheep

S. Salaris[1*], S. Casu[1], M.G. Usai[1], A. Scala[2] and A. Carta[1]

[1]Research Unit: Genetics and biotechnology, AGRIS Sardegna, 07040 Olmedo, Italy; [2]Department of Veterinary Medicine, University of Sassari, 07100 Sassari, Italy; slsalaris@agrisricerca.it

Abstract

In this paper we summarize results of previous studies on the resistance to gastro-intestinal nematodes obtained in a nucleus of Sarda ewes in terms of heritability estimate, QTL detection, functional annotation, association analysis based on imputed sequence data and prediction of GEBV for male selection candidates of the Herd Book. Heritability of log-transformed faecal egg counts was 0.21±0.015. Ten QTL regions were defined on nine chromosomes with an LDLA approach. In the most significant QTL regions, we identified functional candidate genes that contain high or moderate impact polymorphisms. The expected accuracies of GEBV are related to the amount of relationships with the nucleus. The Sarda breeders are assessing the feasibility of a selection program for nematode resistance based on fecal egg counting and on the genotypes in the nucleus flock and of selection candidate males bred in Herd Book farms genetically connected with the experimental flock.

Introduction

Gastrointestinal nematodes (GIN) are a major health problem in grazing animals that causes important yield reductions and increased production costs due to medical treatments and higher culling rates (Mavrot *et al.*, 2015). Fecal egg count (FEC), i.e. the number of parasite eggs per gram of faeces has been largely used as proxy trait to measure resistance to GIN. In Sardinia, sheep farming systems are based on grazing natural pastures and forage crops where GIN infection is unavoidable. Thus, most farmers administrate anti-helminthics often with an empirical approach in terms of individual diagnosis, doses and frequency of treatments (Sechi *et al.*, 2010). Genetic variation between individuals and breeds has been documented (Aguerre *et al.*, 2018). However, the inclusion of GIN resistance in current breeding scheme is difficult due to the laboriousness of the FEC recording at Herd Book (HB) scale. For the Sarda breed, it is available a female nucleus in an experimental farm in which the ewes generated by HB rams, have been pedigree recorded, genotyped and repeatedly measured for FEC for twenty years. The genetic links of these animals with those of the HB make it possible to use their data to study the genetic determinism of resistance to GIN at breed level. In this paper, we summarize the results obtained in previous studies on this experimental population in terms of heritability estimate, QTL detection, functional annotation, association analysis based on imputed sequence data (Casu *et al.*, 2022) and prediction of GEBV for male selection candidates of the HB (Salaris *et al.*, 2021). Results will be discussed focusing on the feasibility of genetic improvement strategies based on genomic tools.

Materials & methods

Experimental population. The nucleus flock (FRP) was set in 1999 with the first generation of ewes consisting in 928 back-cross Lacaune × Sarda. The following generations were obtained by mating adult ewes with rams coming from the artificial insemination center of the HB. In total, 5,386 ewes from 218 rams (10 F1 and 208 Sarda) were generated until 2020. The farming system was similar to that commonly applied in Sardinia with most of the adult ewes lambing in autumn and yearlings lambing between January and March. The feeding regime was based on grazing of natural pastures and forage crops, supplemented by hay and concentrates in winter and late spring. From 2000 to 2020 individual FEC were recorded from 1 to 3 times per year on adult ewes, more frequently in September and July. After editing, 16,530 records from

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_735, © S. Salaris *et al.* 2022

4,097 adult ewes recorded on 24 separate dates were retained. FEC presented a skewed distribution and were log-transformed using lnFEC=ln(FEC+14) for genetic analyses. All ewes of the nucleus, their sires and available male ancestors (272 rams) were genotyped with the Illumina Inc. OvineSNP50 Beadchip. SNP editing was performed using call rate and MAF thresholds of 90 and 1%, respectively. After quality control, 43,390 SNP across 26 autosomes were retained for the analysis. For QTL mapping the ovine genome assembly v4.0 was used to construct the genetic map by assuming 1 Mb =1 cM.

Genetic parameter estimation and QTL mapping. lnFEC data were analysed by a repeatability animal model including the permanent environment and additive genetic random effects of ewes and using the ASReml-R 4.1 software (Butler *et al.*, 2018). Environmental fixed effects were the date of sampling, the age of the ewe (from 1 to 4 years) and the interaction between lambs born and physiological status (periparturient, lactating, non-pregnant nor lactating ewes) at the date of sampling. Genetic relationships between 4,547 animals, including the recorded ewes and their sires (194) and genotyped ancestors (78), were taken into account by calculating the genomic relationship matrix (GRM) based on 50k genotypes, following Yang *et al.* (2010). On average, the number of daughters per sire was 22±25 from 1 to 118. Pseudo-phenotypes for QTL detection were calculated as the average performance deviation (APD) of each ewe, by averaging single animal residuals and summing-up the genetic and permanent environment random predictions. QTL mapping was performed with an LDLA method as described by Usai *et al.* (2019). Only QTL segregating within gametes of Sarda origin were tested by F-test at each SNP position. The 5% genome-wide significance threshold was determined by a Bonferroni correction for the 43,390 tests, which resulted in $-\log_{10}(P\text{-value})=6$.

Analysis of sequence data. Identified QTL regions (QTLR) were imputed from whole-genome sequences of 56 target animals of the population. An association analysis and a functional annotation of imputed polymorphisms in the identified QTLR were performed to pinpoint functional variants with potential impact on candidate genes identified from ontological classification or differentially expressed in previous studies. The NCBI *Ovis aries* 4.0 reference genome and annotation (release 102) and the SnpEff software v4.3.t (Cingolani *et al.*, 2012) were used for the analyses.

Prediction of GEBV for selection candidate rams. Single step genomic BLUP (ssGBLUP) was performed using the package AIREMLf90 included in the BLUPf90 suite programs (Misztal *et al.*, 2002) using FEC and genotypes of the female nucleus including their sires and male ancestors. Genotypes of further 734 HB Sarda rams were also available. The final pedigree file included 8,565 animals. The genomic relationship matrix was created as in VanRaden (2008). GEBV were calculated for the 1,006 genotyped rams classified according to their age and level of relationship with the females of the nucleus: 272 sires or ancestors; 489 old HB rams with daughters in HB flocks; 245 young HB rams (including 27 sons of FRP) considered as selection candidates. The expected accuracy was calculated as: $r_{GEBVi}=\{1-[SE_i^2/(h_{ii}\times\sigma_g^2)]\}^{1/2}$, where SE_i is the standard error of prediction and h_{ii} is the diagonal element of the H relationship matrix for the animal i.

Results

The overall mean and standard deviation of FEC and lnFEC were 332±727 and 4.82±1.43 respectively. The heritability and repeatability estimates of lnFec were 0.21±0.015 and 0.27±0.012 respectively. In the LDLA analysis 202 SNPs encompassed the 5% genome-wide significant threshold. With the exception of OAR 1, on which only one significant location was found, many significant SNPs mapped to the same chromosome. After clustering the significant locations on the same chromosome, ten QTL regions were defined on nine chromosomes. The ratio between the ANOVA estimators of the QTL variance and the total phenotypic variance ranged from 0.0087 to 0.0176 (Table 1).

Table 1. QTL regions from LDLA analysis (Casu *et al.*, 2022).

OAR	Range (kb)[1]	Significant SNP (n)	Highest peak[1]		
			Pos (bp)	-$\log_{10}$(*P*-value)	s_{qtl}^2/s_{APD}^2
1	-	1	99988914	6.256	0.0087
2	-	1	135598790	6.078	0.0093
2	213,089-213,166	3	213135270	6.554	0.0093
4	5,252-9,837	6	5386849	7.404	0.0111
6	12,638-12,695	3	12695314	6.864	0.0099
7	88,040-88,085	2	88040710	6.762	0.0098
12	35,973-41,153	19	39430517	9.191	0.0125
15	34,024-34,081	2	34024406	7.362	0.0110
19	18,933-31,423	11	18983777	7.302	0.0104
20	16,797-36,098	154	21170858	12.861	0.0176

[1] Pos = position based on the ovine genome assembly v4.0; s_{qtl}^2/s_{APD}^2 is ratio between ANOVA estimator of QTL variance and total phenotypic variance.

The association analyses on imputed polymorphisms confirmed that the QTLs on OAR 4, 12, 19 and 20 were the most significant. None of the most significant SNPs showed a functional effect on gene transcription. However, in the most significant QTLRs, we identified genes that: contain high or moderate impact polymorphisms; have been found differentially expressed in previous studies; contribute to enrich the most represented GO process (regulation of the immune system process, defense response). Among them, the most likely candidate genes were: TNFRSF1B and SELE on OAR12, IL5RA on OAR19, IL17A, IL17F, TRIM26, TRIM38, TNFRSF21, LOC101118999, VEGFA and TNF on OAR20.

Concerning the GEBV prediction, r_{GEBV} of HB rams ranged between 0.31 and 0.95 with a mean of 0.76±0.15 for sires or ancestors of FRP; 0.49±0.06 for old HB rams and 0.50±0.08 for young HB rams. Among the selection candidates, the highest values of r_{GEBV} were obtained for 27 sons of FRP ranging from 0.62 to 0.73.

Discussion

The heritability estimate of lnFec was moderate and consistent with previous studies in adult ewes (Aguerre *et al.*, 2018; Sechi *et al.*, 2009). Five QTL regions (OAR4, 7, 12, 19, 20), identified in the LDLA analysis, overlapped with regions that were shown to be associated to traits related to GIN resistance by others (Riggio *et al.*, 2014). The combination of association analysis and functional annotation of the sequence data did not lead to identify putative causative mutations. Overall, these results show that selective breeding may be an option to limit the issues related to infestation of gastro-intestinal nematodes in sheep. On the one hand, the heritability estimate and QTL detection results confirm that both traditional progeny testing and marker-assisted selection are realistic options. However, the laboriousness of fecal egg counting on a large scale makes marker-assisted selection potentially more profitable in terms of cost-benefits. Indeed, the portion of the total phenotypic variance explained by the ten significant markers identified in our study and already available on the commercial Illumina, was about 11%. As far as the potential application of a genomic selection approach is concerned, our results show that the expected accuracies are strongly related to the amount of relationships with the nucleus. In this sense, Carta *et al.* (this congress) proposed a procedure based on pedigree information to predict the expected accuracies of the HB matings which can be used to design the flow of animals from and toward the nucleus to achieve good accuracies for most selection candidates. As a perspective, accuracies of genomic predictions may be also improved by including in the evaluation model the ten highly significant identified SNPs. In the short term, the Breeders Association is assessing the feasibility of a selection program for nematode resistance based on fecal egg counting and on the genotypes described in this study for the nucleus flock and combined with

the genotyping of selection candidate males that are bred in Herd Book farms and are genetically connected with the experimental flock.

736. Investigation of the Scrapie haplotypes in the South African Merino population

J.J. Reding* and B.E. Mostert

SA Stud Book and Animal Improvement Association, 118 Henry Street, Westdene, 9300, Bloemfontein, South Africa; jason@studbook.co.za

Abstract

Scrapie, a transmissible spongiform encephalopathy disease is described as a fatal, degenerative disease that affects the nervous system of sheep and goats and is considered an endemic disease in the European Union. Breeding programs for genetic improvement of Scrapie resistance have resulted in the identification of multiple haplotypes in the Prion protein gene that can be selected for. In this study, the occurrence and frequency of Scrapie haplotypes that are known to show varying levels of susceptibility were determined using genomic information obtained from the Illumina Ovine v2 array in 1,061 Merino sheep across five flocks in South Africa. Five haplotypes were observed in the South African Merino genotyped population and include ARQ (46.1%), ARR (31.48%), AHQ (14.47%), VRQ (6.83%) and ARH (0.61%). Of the genotyped animals, 87% have slight to high genetic resistance to Scrapie, while 13% are genetically susceptible to the disease, as they carry the VRQ haplotype.

Introduction

Scrapie is a transmissible spongiform encephalopathy (TSEs) disease, like bovine spongiform encephalopathy (BSE), i.e. a fatal, degenerative disease that affects the nervous system of sheep and goats (Acín *et al.*, 2004). Scrapie develops due to an accumulation of the Prion protein (PrP) in neuronal cells and is highly transmissible from animal to animal. This disease was first described in the UK around the 18th century. Affected animals show progressive changes in behaviour such as body tremors, stumbling and may have irritated skin which they try to scratch, resulting in excessive wool loss and/or damage to the skin.

Scrapie is considered an endemic disease in the European Union, with first incidences reported in 1878 in Iceland and has subsequently been reported all over the world in Canada, the USA, Australia, Norway, India, South Africa, Kenya, Germany, Brazil, Yemen and Sweden (Yaman and Ün, 2017) throughout the 20th century.

Breeding programs for genetic improvement of Scrapie resistance have resulted in the identification of multiple haplotypes in the PrP gene (Acín *et al.*, 2004). Studies in the Merino sheep breed have been done to identify the frequency of these haplotypes segregating in certain populations (Wiśniewska and Mroczkowski, 2010; Stepanek and Horin, 2017; Palomino *et al.*, 2019).

Haplotype assessment of animals that tested positive for classical Scrapie has indicated low occurrence rates in animals carrying the ARR haplotype (0-2.21%), while the majority of the positive animals carried the ARQ and VRQ haplotypes (13.31-43.78%; Yaman and Ün, 2017).

According to Cosseddu *et al.* (2007), the last Scrapie incidence in South Africa was reported in 1972. This is confirmed by the Animal Disease Status in South Africa Report of the Department of Agriculture, Forestry and Fisheries in 2015. In this study, the occurrence and frequency of Scrapie haplotypes that are known to show varying levels of susceptibility were determined from genomic information obtained from the South African (SA) Merino population.

DOI: 10.3920/978-90-8686-940-4_736, © J.J. Reding and B.E. Mostert 2022

Materials & methods

Blood samples from 1,106 sheep from five flocks (2 strong-wool, 1 fine-wool, 1 polled and 1 horned) of the SA Merino population were genotyped using the Ovine Illumina v2 array. During post-genotyping quality control, all genotypes with an individual call rate of less than 0.9 were excluded, leaving a total of 1,097 genotypes.

Single nucleotide polymorphisms (SNP) located in codons 136, 154 and 171 of the PrP gene known to be responsible for causing classical Scrapie were annotated using ENSEMBL. This resulted in a total of six SNPs being analysed to create the three amino acids which encode the haplotypes that have been derived for Scrapie resistance. As it required all six SNPs to be called for a successful haplotype consolidation, this excluded thirty-six animals and therefore a final population of 1,061 SA Merino sheep were available for the study. The number of genotyped animals per flock was 122 animals for Flock 1 (strong-wool), 248 animals for Flock 2 (strong-wool), 238 animals for Flock 3 (horned), 236 animals for Flock 4 (fine-wool) and 217 animals for Flock 5 (polled). Haplotype pairings were grouped under five distinct levels of resistance in accordance with the study of Palomino *et al.* (2019). This grading system ranks haplotypes with resistance level 1 (R1) being highly resistant to developing Scrapie to resistance level 5 (R5) being the haplotypes that are highly susceptible to developing Scrapie as described in Table 1.

Results & discussion

The frequencies of the five haplotypes observed in the SA Merino genotyped population are indicated in Figure 1. These include ARR (31.48%), AHQ (14.47%), VRQ (6.83%), ARH (0.61%) and ARQ (46.1%). This is in accordance with the ARQ haplotype being considered as the 'wild type'. The ARH haplotype is quite scarce (0.6%), while the highly susceptible VRQ haplotype is present in 6.8% of the genotyped animals.

Figure 2 illustrates the number of animals for the different Scrapie haplotype pairings. One hundred and seventeen of the animals (11%) carry the highly resistant haplotypes (R1), 384 (36%) animals carry the resistant haplotypes (R2), 420 animals (39.5%) carry the haplotypes that render slight resistance (R3), 50

Table 1. Grading system for classification of Scrapie resistance and susceptibility genotypes adapted from Palomino *et al.* (2019).

Level	Genotype	Outcome
1	ARR / ARR	Most resistance to Scrapie.
2	AHQ / ARR	Resistance to Scrapie. Careful selection needed in breeding.
2	ARR / ARH	
2	ARR / ARQ	
3	AHQ / AHQ	Slight resistance to Scrapie. Careful selection needed in breeding.
3	AHQ / ARQ	
3	AHQ / ARH	
3	ARQ / ARQ	
3	ARQ / ARH	
3	ARH / ARH	
4	ARR / VRQ	Susceptible to Scrapie. Should not be used for breeding.
5	AHQ / VRQ	Highly susceptible to Scrapie. Should not be used for breeding.
5	ARH / VRQ	
5	ARQ / VRQ	
5	VRQ / VRQ	

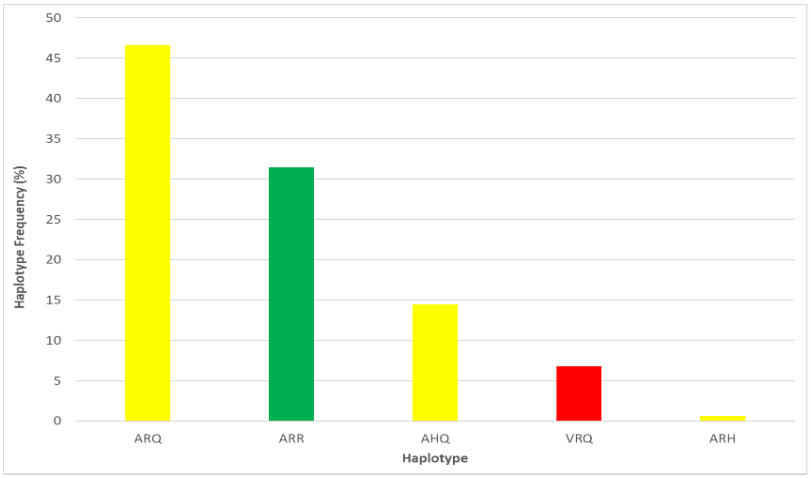

Figure 1. Frequency of the different haplotypes involved in Scrapie resistance and susceptibility of the South African Merino breed.

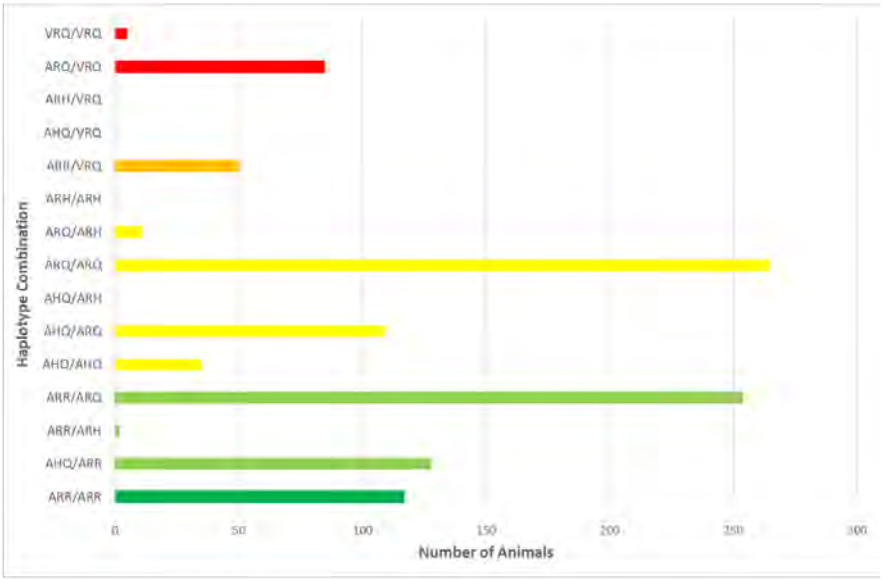

Figure 2. Number of genotyped animals with regards to the different haplotypes for Scrapie resistance and susceptibility.

animals (5%) carry the susceptible haplotypes (R4) and 90 (8.5%) carry the highly susceptible haplotypes (R5). No haplotype pairings for ARH/VRQ, AHQ/VRQ, AHQ/ARH and ARH/ARH were identified. This might be due to the small sample size of animals being genotyped at the time of the study, with representation from only five flocks in South Africa.

The distribution of the genotyped animals with regards to resistance levels over flocks are indicated in Table 2. From Table 2, all flocks have animals that are carriers of the highly susceptible haplotypes. This is an early

indication that these unwanted haplotypes are already commonly distributed across the flocks of the SA Merino population.

Looking at Figure 3 and in accordance with the grading system adapted from Palomino *et al.* (2019), 87% of the genotyped animals have slight to high genetic resistance to Scrapie, while 13% are genetically susceptible to the disease. Variation in risk of Scrapie infection is evident in the SA Merino breed, with 13% of the genotyped animals carrying haplotypes that are associated with susceptibility to high susceptibility for the disease. The exact susceptibility of the SA Merino breed still needs to be established and will only be possible once Scrapie incidences are being reported in South Africa. It is also important to consider that genetic factors other than the PrP gene might be involved in modulating animals' susceptibility to Scrapie in different populations. This might explain why Scrapie incidences in the South African population are not observed, although the highly susceptible haplotypes are present in the population. However, when Scrapie arises in a flock, the animals that are most susceptible will be those carrying the VRQ/VRQ haplotypes.

It is therefore recommended to the South African Merino breeders to consider a strategy where all stud rams are genotyped and all carriers of the VRQ haplotype are excluded from breeding. Furthermore, encouraging breeders to only use ARR/ARR rams in their flocks will increase the frequency of the highly resistant haplotype in the population. This may, however, have an adverse effect on the genetic diversity of the breed, which is also of importance.

Table 2. Distribution of genotyped animals over flocks with regards to resistance levels for Scrapie.

Level	Flock 1		Flock 2		Flock 3		Flock 4		Flock 5	
	Nr	%	Nr	%	Nr	%	Nr	%	Nr	%
Highly Resistant (R1)	28	23.0	8	3.2	53	22.3	7	3.0	21	9.7
Resistant (R2)	49	40.2	65	26.2	102	42.9	83	35.2	85	39.2
Slightly Resistant (R3)	28	23.0	95	38.3	51	21.4	141	59.7	95	43.8
Susceptible (R4)	10	8.2	25	10.1	19	8.0	1	0.4	5	2.3
Highly Susceptible (R5)	7	5.7	55	22.2	13	5.5	4	1.7	11	5.1

737. Toward a genetic evaluation for functional longevity in French dairy sheep breeds

D. Buisson[1*], J.M. Astruc[1], L. Doutre[2] and I. Palhière[2]

[1]Institut de l'Elevage, BP 42118, 31321 Castanet-Tolosan, France; [2]GenPhySE, Université de Toulouse, INRAE, ENVT, 31326 Castanet Tolosan, France; diane.buisson@idele.fr

Abstract

The increase in genetic gain due to genomic selection in French dairy sheep breeds represents an opportunity to introduce new traits in selection objectives. As breeders have selected pure local breeds in their respective production area, robustness appeared to be an important criterion to improve adaptation to breeding systems. Considering functional longevity reflects the probability of a ewe to be culled for other criteria than production level, we have chosen to study Length of Productive Life, which is the number of days between the first lambing of the ewe and its culling. The heritabilities calculated using the Survival Kit are similar to those obtained in cattle and ranged from 0.07 to 0.16. Estimated breeding values were calculated but 30 to 40 daughters uncensored are necessary to reach an accuracy of 0.7. These first results are encouraging; however, this study should be continued to integrate functional longevity in selection objectives.

Introduction

In France, genomic selection implemented since 2015 has permitted an extra genetic gain compared to classical programs (Astruc *et al*., 2022). This extra gain represents an opportunity to introduce new traits in selection objectives. To face new challenges of sustainability and improve resilience and adaptation of ewes to breeding systems mainly based on pasturing, transhumance and rangelands, breeding organisations were interested in functional longevity. Indeed, functional longevity is a synthetic trait reflecting the probability of a ewe to be culled for other criteria than production level (Ducrocq 1992). As culling in dairy sheep breeds is mainly due to production level (20-25%), mammary problems (25-30%) and reproduction problems (10-20%), integrating functional longevity into selection objectives would allow breeders to have a better control of culling (economic interest) by mitigating involuntary culling, and therefore become more efficient to manage and improve their flocks (technical interest). Among several selection criteria of functional longevity, we have chosen to study the Length of Productive Life (LPL), which is defined by the number of days between the first lambing of the ewe and its culling. It is a simple indicator which doesn't require any additional measurement. The aim of this study is to estimate genetic parameters of functional longevity in French dairy sheep breeds in order to implement a genetic evaluation in routine.

Materials & methods

Data. This study focused on four dairy sheep breeds: Lacaune (LAC), Manech Tête Noire (MTN), Manech Tête Rousse (MTR), and Basco-Bearnaise (BB). For each breed, pedigree, reproductive and flock information (insemination, lambing, animal movements, flock's size) were extracted from the French national database SIEOL. Only ewes born in selection flocks between 2010 and 2020 and with a known sire were kept for the analysis.

Censoring. Survival analysis allows to consider a proportion of ewes whose end of lifetime is unknown: these are called 'censored data'. Ewes still alive on the 31st of August of 2020 were considered as censored at that date. Records of ewes with more than 6 lactations, who quit milk recording, who are sold to other flock, or who are in flock with a size increasing or decreasing by more than 50% in one year were considered as censored. As culling or censoring dates are not always recorded, it was decided to assign a new date based

DOI: 10.3920/978-90-8686-940-4_737, © D. Buisson *et al.* 2022

on the last known event of each animal (lambing or not, milk production or not). LPL is then defined as the number of days between first calving and culling or censoring date.

Model. Taking these censored data into account requires the use of survival analyses. These analyses were carried out using the 'Survival Kit' (SK) developed by Ducrocq and Sölkner (1994) for animal populations under selection.

A Weibull model was used (Ducrocq *et al*., 2005; Terawaki *et al*., 2006):

$$h(t) = h_{0,n}(\tau) * \exp\{ \sum_m f_m(t) + hy_k(t) + s_i + 0.5\, mgs_j \} \quad (1)$$

$h_{0,n}(\tau)$ is the baseline hazard function assuming a different hazard function for nth lactation. τ denotes the number of days since the most recent lambing.

$\Sigma_m f_m(t)$ represents the sum of all fixed effects, time-dependant (t) or not, affecting the instantaneous culling risk. Considering these effects is key to focus on functional longevity rather than true longevity and correct for voluntary culling (milk production, flock strategy, etc.). The effects in the model are the age at first lambing (1, 2 or 3 years-old), the within-flock milk production (t – 11 classes), the flock size by variation in flock size interaction effect (t – 3 or 4 classes of flock size depending on the breed considered, and 3 classes of flock variation size ([-50%;-5%[, [-5%;5%],]5%;50%])), and the litter size (t – 0, 1, 2 or 3 lambs).

$hy_k(t)$ is the random log-gamma distributed flock-year effect. A single fixed parameter γ was assumed.

$s_i + 0.5\ mgs_j$ represents the additive genetic contribution of sire i and maternal grand-sire j of the ewe.

Heritabilities have been estimated using the formula of Mészáros *et al.* (2010):

$$h^2\ (sire - mgs) = \frac{4 * \sigma_s^2}{\frac{5}{4}\sigma_s^2 + \frac{1}{p} + \psi(\gamma)} \quad (2)$$

Where σ_s^2 is the sire's genetic variance, p is the percentage of uncensored data, and $\psi(\gamma)$ the variance of random effect herd×year.

Evaluation. Estimated breeding values (EBV) and coefficient of determination (CD) of all sires in our pedigree files were evaluated with the SK. EBV correlations between EBVs were also calculated to assess the relationship between LPL and the other traits under selection for all these sires. Finally, survival function of the best (top 10% – LPL+) and worse (bottom 10% – LPL-) rams, whose reliabilities were above 0.5, have been represented in order to validate our results.

Results & discussion

Data structure. Descriptive statistics for each breed are presented in Table 1. The number of ewes strongly varies according to the breed. The proportion of censored records ranges from 38.8 % in LAC to 51.1% in MTN.

Factors influencing productive life. Figure 1 shows relative risk ratios for three effects estimated in our model. Risk ratios for the different breeds are very similar for all effects. Risk ratios are higher when age at first lambing increases. Very high-risk ratios are found for the lowest milk production classes. Higher risks ratios were also observed for larger litter size. However, the risk ratio is much higher for ewes without lambs in LAC compared to the other breeds. Indeed, due to differences in sexual precocity, AI fertility, population

Table 1. Descriptive statistics of dataset.

	BB	MTN	MTR	LAC
Number of ewes	26,683	8,431	114,691	400,958
Sires in pedigree	892	399	2,851	4,595
Censored records (%)	50.7	51.1	43.3	38.8
Average LPL (days)	1,032	1,086	1,065	915

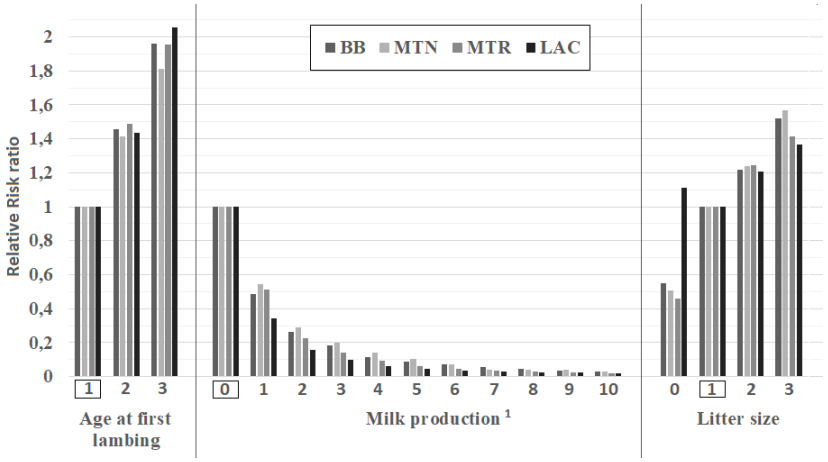

Figure 1. Relative risk ratios for three effects in the model. For each trait, these relative risk ratios are calculated in comparison to a reference level (surrounded value). Milk production: 11 classes from 0 (lower milk yield) to 10 (higher milk yield).

size and system management, culling non-pregnant ewes is more systematic in Lacaune than in Pyrenean breeds.

Genetic parameters. Table 2 shows the genetic parameters for LPL. Heritabilities range between 0.07 to 0.16 depending on the breed. These values are close to those obtained by Jenko *et al.* in 2013 in Slovenian Brown cattle (0.09-0.11) or Phocas *et al.* in 2006 (0.14-0.15) in French Charolais.

EBV. The survival curves of ewes born from the 10% sires with extreme EBV (LPL- or LPL+) are represented in Figure 2. Ewes born from LPL+ rams present a significantly higher survival rate than ewes born from LPL- rams: the survival rate at 1,400 days (almost 4 years old) is 11 to 19% superior in LPL+ compared to LPL- according to the breed. These results tend to validate EBV obtained with the SK and are encouraging

Table 2. Genetic parameters of length of productive life.

	Sire variance	Flock × year variance	Heritability	Genetic std
BB	0.0717±0.0103	0.3785	0.115	0.2867
MTN	0.0480±0.0153	0.4310	0.076	0.1918
MTR	0.0694±0.0045	0.2737	0.131	0.2776
LAC	0.0813±0.0001	0.3837	0.154	0.3252

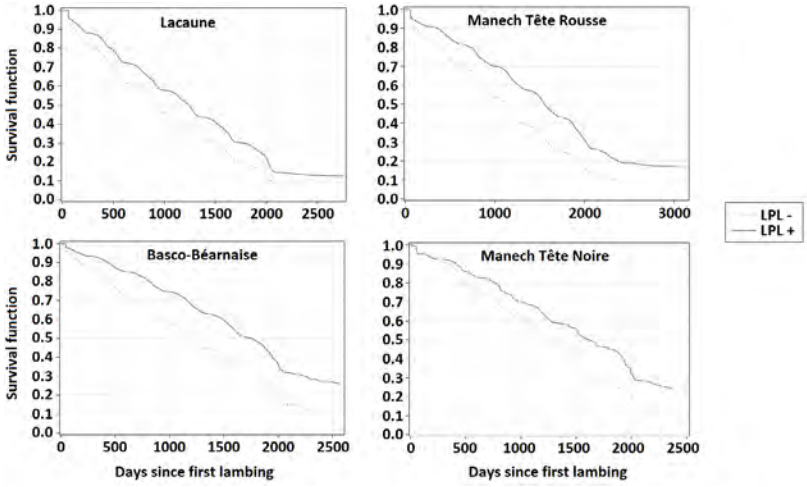

Figure 2. Survival functions of ewes born of rams with high longevity EBV (LPL+) or low longevity EBV (LPL-) in French dairy sheep breeds.

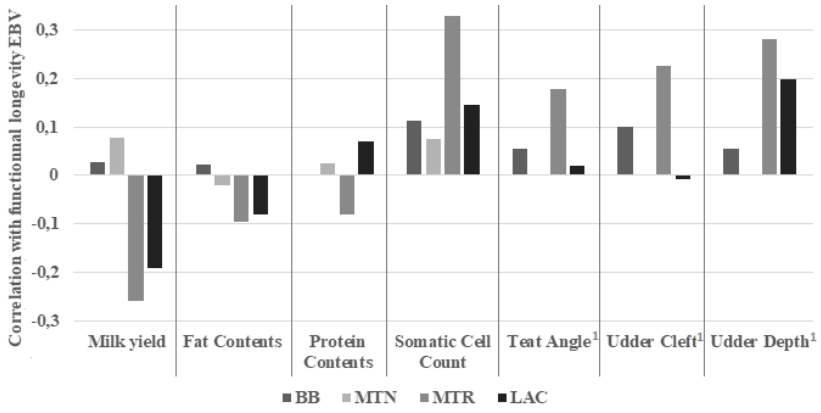

Figure 3. Correlations between longevity EBV and other traits under selection in French dairy sheep breeds. [1] No data available in MTN.

for a future genetic evaluation. However, the reliability of sires' EBV is strongly related to the number of uncensored daughters: the more uncensored daughters, the more reliable is the sire's EBV. In MTR, around 10 uncensored daughters are necessary to obtain a reliability superior or equal to 0.50, whereas only 4-5 are sufficient in LAC. In average, these accuracies can be obtained when the sire is 4 years-old in MTR and BB or 2-3 years old in LAC.

EBV correlations between LPL and other traits. Correlations between LPL and Milk Yield (MY) are negative in LAC and MTR (-25% and -19% respectively) and almost zero in BB and MTN (Figure 3). The negative correlations observed in LAC and MTR underline the antagonism between MY and LPL. Very low correlations are observed between LPL and fat and protein contents. The higher correlations are obtained with Somatic Cell Count (SCC) and udder morphology traits: improving SCC and udder morphology

would therefore improve functional longevity. However, this study should be completed by an estimation of the genetic correlations between LPL and the other traits (methodology of Tarrés *et al.,* 2006).

Conclusions

This approach about functional longevity indicates that LPL has a heritability similar to those obtained in cattle (0.07-0.16) and that it is possible to perform a genetic evaluation, even though accuracy remains low (CD<0.5) during the first years of use of rams. However, given the positive correlation between LPL and functional traits, introducing early predictors of LPL in the genetic evaluation could increase the accuracy. Further study is necessary to investigate which predictors should be used (SCC, udder morphology) to implement a multi-trait evaluation of functional longevity, as done currently in French dairy cattle (Ducrocq *et. al,* 2001).

738. Maturity, a new indicator to improve longevity of Saanen dairy goats in France

M. Arnal[1,2*], I. Palhière[2] and V. Clement[1]

[1]Instit t de l'élevage, 24 chemin de Borde Rouge 31320 Castanet Tolosan, France; [2]GenPhySE, Université de Toulouse, INRAE, INPT, ENVT, 31326 Castanet Tolosan, France; mathieu.arnal@idele.fr

Abstract

The objective of this study was to obtain a maturity EBV to improve longevity in dairy goat. Several multi-parities models were developed in this study: a multi-trait model (MULTI) that used lactational production and a test day model (TDM) that used directly test day data. They were compared to the current repeatability model routinely used in France. There were no major differences for heritabilities and EBVs. It was found that the ability to produce milk in first parity was not the same as the ability to produce milk in third lactation. The second eigenvector of the (co)variance matrix permitted to discriminate the first and the third parity and to obtain a maturity EBV. This EBV was linked positively with longevity EBV and could be used to predict longevity. The multi trait model could be used to modify the way to calculate milk yield EBV used routinely in France by putting more emphasis on third parity EBVs, which is less negatively linked to longevity than first parity EBVs.

Introduction

Longevity is declining in dairy goats in France: goats born in 1991 produced 346 days more than those born in 2011 (Palhiere *et al.*, 2018). Current selection is based on production and udder morphology traits (Clément *et al.*, 2015). Longevity evaluation is under development in France. However, the longevity EBV accuracy becomes high several years (±7 years) after the start of AI bucks' semen diffusion. The milk yield EBV is routinely obtained using a repeatability model in dairy goats in France (Clément *et al.*, 2015). However, it is possible to use a multi trait model to obtain a milk yield EBV by parity. In doing an eigenvalues decomposition to the (co)variance matrix, the first component combines the EBVs by parity to obtain a 3-parity-milk-yield EBV. The second eigenvector permits to discriminate the first and the third parity milk yield EBV. This synthetic EBV is called maturity. A high maturity EBV means that the animal had a low first parity milk yield EBV and a high third parity milk yield EBV. The objective of this paper was to compare different models to calculate this maturity EBV. In a second part, the correlation between longevity and maturity was studied.

Materials & methods

Data. Data consists in 419,550 test-days from 65,953 lactations produced by 34,322 Saanen dairy goats from 118 herds measured between 2002 and 2021. Only the first three parities were kept. The data were extracted from the goat milk yield recording scheme used for the national French genetic evaluations. 67,359 animals were in the pedigree.

Models. Several models were compared.

Lactation model (LACT). LACT was a model very close to the one used routinely for milk yield evaluation in France (Clément *et al.*, 2015). It was a repeatability model. It was developed to be a reference for milk yield EBV in this study. The phenotype used was the lactation milk yield calculated with Fleischmann method. The genetic evaluation model was:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_738, © M. Arnal *et al.* 2022

$y_{rnjlkmpi} = H_{rji} + A_{jkp} + M_{rjlp} + D_{rjmp} + a_n + p_n + e_{rnjlkmpi}$, where $y_{rnjlkmpi}$ was the lactation observation of goat n, in production year j, in parity r, belonging to kidding age class k, kidding month class l, class m of dry period length, in region p and herd i. H_{rji} is the fixed effect of herd; A_{jkp} is the fixed effect of age at kidding; M_{rjlp} was the fixed effect for the kidding period; D_{rjmp} the fixed effect of length of the dry period; a_n was the additive genetic breeding value that followed a normal distribution (mean: μ_{LACT}=0, variance= σ_{LACT}^2A) with A the additive genetic relation matrix based on pedigree information. p_n was the permanent environment value that followed a normal distribution. The genetic parameters were estimated using AIREMLF90 (Misztal *et al.*, 2002). TOT_LACT was the EBV obtained with LACT.

Test-day model (TDM). A TDM model was previously developed in Arnal *et al.* (2020). TDM was developed to obtain milk yield EBV, persistency EBV and maturity EBV using Legendre polynomial of degree 2. Here, a model using Legendre polynomial of degree 0 was used to be simpler than LEG2; persistency being not necessary in this study. The three parities were analyzed simultaneously in a multiple-parity model. The genetic and permanent environmental effects were modeled by a Legendre polynomial of order 0 for each parity: The phenotype used was directly the milk yield test day.

$$y_{rijklmdn} = HTD_{ri} + \mathrm{A}_{jk} + \mathrm{M}_{rjl} + \mathrm{D}_{rjm} + \sum_{o=1}^{6} \theta_{jrp} N_{(o,d)} + a_{rn0}\varphi_{(0,d)} + p_{rn0}\varphi_{(0,d)} + e_{rijklmdn}$$

where $y_{rijklmdn}$ was the observation of day in milk (DIM) d (7, …, 270) of goat n in production year j, in parity r, belonging to kidding age class k, kidding month class l, class m of dry period length, in region p, herd × test-date class i. HTD_{ri} is the fixed effect for the herd test-date; A_{jk} is the fixed effect for the age at kidding; M_{rjl} is the fixed effect for the kidding period; D_{rjm} is the fixed effect for length of the dry period; θ_{ko}, τ_{rlo}, π_{rmo} are fixed regression coefficients for age at kidding, the kidding month, dry period length respectively; $N_{(o,d)}$ is the o^{th} covariate at time d of a cubic natural spline function with 6 knots; a_{rn0} and p_{rn0} are respectively the random additive genetic and permanent environmental regression coefficients for the term of a Legendre polynomial of order *0*, $\varphi_{(0,d)}$ is the value of the term of the Legendre polynomial at time d and $e_{rijklmdn}$ is the residual term.

TOT_TDM which represents the milk production for the three first parities was obtained multiplying the EBVs matrix by the first eigenvector of the (co)variance matrix. MAT_TDM which represents the maturity EBV was obtained multiplying the EBVs matrix by the second eigenvector of the (co)variance matrix. The genetic parameters were estimated using WOMBAT (Meyer, 2007).

Multi-trait model (MULTI). A multi-trait model was developed to obtain milk yield EBV and maturity EBV. The phenotype used was the lactation milk yield calculated with Fleischmann method.

$y_{rnjlkmpi} = H_{rji} + A_{jkp} + M_{rjlp} + D_{rjmp} + a_{rn} + e_{rnjlkmpi}$, where $y_{rnjlkmpi}$ was the lactation observation of goat n, in production year j, in parity r, belonging to kidding age class k, kidding month class l, class m of dry period length, in region p and herd i. H_{rji} is the fixed effect of herd; A_{jkp} is the fixed effect of age at kidding; M_{rjlp} was the fixed effect for the kidding period; D_{rjmp} the fixed effect of length of the dry period; a_{rn} was the additive genetic breeding value. TOT_MULTI which represents the milk production for the three first parities was obtained multiplying the EBVs matrix by the first eigenvector of the (co)variance matrix. MAT_MULTI which represents the maturity EBV was obtained multiplying the EBVs matrix by the second eigenvector of the (co)variance matrix. The genetic parameters were estimated using AIREMLF90 (Misztal *et al.*, 2002).

Results

Heritabilities from the different models were estimated. The heritability for LACT was equal to 0.30±0.002. For MULTI, the heritabilities were equal to 0.34±0.006, 0.30±0.008 and 0.29±0.006 for first, second and

third parities respectively. For TDM, they were equal to 0.30±0.006, 0.31±0.007, and 0.32±0.008 for first, second and third parities respectively.

The genetic correlations between parities were slightly superior with MULTI than TDM for all the correlations. The highest correlation was between second and third parity (0.89±0.017 for TDM and 0.95±0.058 for MULTI). The smallest correlation was between first and third parity equal to 0.63±0.029 for TDM and 0.75±0.048 for MULTI. The correlation between first and second parity was intermediate: equal to 0.78±0.018 for TDM and 0.87±0.044 for MULTI.

The first eigenvalue representing the level of milk production for the three lactations represented the biggest part of the variance (91% for MULTI and 87.2% for TDM). The second eigenvalue represented only 8.3% for MULTI and 10.2% for TDM). Table 1 presents the first two eigen vectors for MULTI and TDM. The first eigenvector represented the production level for the first three lactations. For TDM, the value of the eigenvector for third parity (0.7) was higher than second one (0.6), higher than first parity (0.38). For MULTI, the value for second and third parity were equal to 0.6 and higher than first parity (0.52). The second eigenvector opposed the first and the third parity (-0.82 for first parity and +0.55 for third parity for TDM, and a value close to 0 for the second parity (-0.12)). For MULTI, the second eigenvector was like TDM (-0.8 for first parity, 0.1 for second parity and 0.59 for third parity).

Table 2 presents the correlations between the different EBVs and longevity EBV calculated in Palhière's study (2018) for AI bucks with at least 21 progeny (n=371). As expected, the correlation between TOT_LACT and TOT_MULTI was close to 1 (0.98). The correlation between TOT_LACT and TOT_TDM was smaller: equal to 0.89. The correlation between the two multi traits models, TOT_MULTI and TOT_TDM, was equal to 0.92. The correlation between TOT_LACT and first parity EBV were high: equal to 0.97 for TOT_MULTI and 0.95 for TDM. The correlation between TOT_LACT and third parity EBVs were smaller: equal to 0.91 for MULTI and 0.77 for TDM. The correlation between the two maturity EBVs, MAT_MULTI and MAT_TDM, was high: equal to 0.86. The correlations between TOT and MAT were close to 0 for TDM and MULTI as expected (-0.12 for MULTI and -0.02 for TDM) because they were derived from eigenvectors.

Table 1. First two eigenvectors (EV) for TDM and MULTI models.

	TDM		MULTI	
Parity	**1st EV (TOT)**	**2nd EV (MAT)**	**1st EV (TOT)**	**2nd EV (MAT)**
1st	0.38	-0.82	0.52	-0.80
2nd	0.60	-0.12	0.60	0.10
3rd	0.70	0.55	0.60	0.59

Table 2. EBVs correlations for AI bucks with at least 21 progeny (n=371).

	TOT_LACT	TOT_MULTI	MAT_MULTI	TOT_TDM	MAT_TDM
TOT_MULTI	0.98				
MAT_MULTI	-0.28	-0.12			
TOT_TDM	0.89	0.92	0.03		
MAT_TDM	-0.40	-0.27	0.86	-0.02	
LONGEVITY	-0.24	-0.18	0.37	-0.12	0.33

However, the correlation between MAT and TOT_LACT were negative (-0.28 for MULTI and -0.4 for TDM). The correlation between the longevity and milk EBVs were negative (TOT_LACT, TOT_MULTI and TOT_TDM: -0.24, -0.18, -0.12 respectively). The correlation between the first parity and the longevity was negative (-0.30 for TDM and MULTI), whereas the correlation was smaller between the third parity EBV and the longevity (-0.09 for Multi and -0.05 for TDM). The correlation between longevity EBV and MAT_MULTI was positive (0.37) close to the correlation between longevity EBV and MAT_TDM (0.33).

Discussion

The heritabilities estimated for milk yield from the different models were coherent and all around 0.3 which is the value used in the current official evaluation (Clément *et al.*, 2015). The correlation between TOT_LACT and MULTI that used same phenotypes were close to 1 and a bit smaller with TDM (significant). This difference could be due to the difference of phenotype used. The genetic correlations and consequently the eigenvectors and values were similar between TDM and MULTI model. Because MULTI and TDM gave similar EBVs and genetic parameters, MULTI, which is easier to used (less phenotypes with MULTI: several TD with TDM vs 1 lactational milk yield with MULTI), will be used to obtain maturity EBVs.

The genetic correlation between first and third parity are around 0.7 which seems to indicate that it is not totally the same trait to produce in first and third parity. The first eigenvalue is not representing 100% of the variance and the maturity that highlight the difference between first and third parity represents around 10% of the variance. This difference in genetic capacity to produce in first and third parity seems to be linked to longevity, with a smaller negative correlation with third parity than with first parity and consequently a positive correlation with maturity. This correlation strengths the utility of this new trait, the maturity, because it is linked to a trait of major interest for future breeding objectives. Indeed, longevity is a difficult trait to catch because an animal needs to have its career achieve to estimate well its EBV. Maturity could be a good predictor as SCS or udder morphology traits as showed in Palhière *et al.* (2018).

The current milk yield EBV is closer to first parity than third parity. It could be interesting to put more emphasis to third parity than first parity in the milk yield EBV. In this way, selecting for milk yield will be less damageable for longevity.

One limit of multi-traits models (MULTI and TDM) is that only the first three parities are considered whereas the LACT model used the first 10 parities which can be an advantage when maturity and difference of capacity to produce between the beginning of the career and the end of the career are studied.

Abstract

Spermatozoal cells are known to contain a wide variety of both coding and non-coding transcripts, but the physiological role of these transcripts is not fully understood. Therefore, the overall aim of this study was to characterize both coding and non-coding transcripts contained in ovine spermatozoa, and identify differences in expression patterns between three different sheep breeds (Merino, Dohne and Poll Dorset), and ejaculates that vary in quality. A variety of coding (e.g. *MVK, PAMR1, ATP2A3, KLK12,* etc.) and non-coding transcripts (e.g. XLOC_025216, XLOC_048757, XLOC_001809, XLOC_025093, etc.) were found to be differentially expressed in different sheep breeds and ejaculates of contrasting quality. Some of these transcripts have been reported to be associated with spermatozoal function or physiology in the literature. Overall, these results provide novel insights into spermatozoal transcriptomes in sheep, and also potentially indicate their functional relevance.

Introduction

Good reproductive performance is a crucial factor that influences the economics of livestock production, and successful conception is a key determinant of the reproductive performance of livestock. Consequently, artificial insemination is widely used in a variety of livestock species to maximise conception rates, while simultaneously exerting greater control over breeding, which in turn, facilitates increased genetic gain.

While the quality of semen used in artificial insemination is widely believed to influence conception outcomes during artificial breeding, poor conception outcomes can occur even when good quality semen is used (Hall 1981). This indicates that semen quality is not the sole determinant of successful conception, and additional molecular mechanisms functioning on the ram side may exist. The role of spermatozoal transcripts is interesting in this regard, as spermatozoa are known to contain thousands of transcripts, which are transferred to ova during fertilisation. It is generally understood that activation of embryonic genome is preceded by degradation of maternal transcripts post fertilisation. Therefore, the transcripts contained in spermatozoa that are transferred to the ova upon fertilization, could have an important role to play in these events.

Therefore, characterising spermatozoal transcripts, both mRNA and long non-coding RNA (lncRNAs) can be useful in increasing the likelihood of successful conception, which in turn has the potential to increase the efficiency and profitability of livestock farming.

Materials & methods

The methodology involved in semen collection, assessment, RNA isolation, library preparation, sequencing, and differential gene expression analysis to identify coding transcripts has already been published (Hodge *et al.* 2021). RNA samples extracted from spermatozoa were subjected to next-generation sequencing using the Illumina Hiseq2000 platform following manufacturer's instructions. Following sequencing, the quality of reads was assessed with FastQC v0.11.5. Poor quality bases (Phred score Q<30), adaptors, and overrepresented sequences were filtered out with trimmomatic v0.36 (Bolger *et al.* 2014).

Identification of Long non-coding RNAs (lncRNAs). Analyses to identify lncRNAs involved aligning cleaned reads to the reference genome (Ovis aries, Oar v.4) via STAR v2.7.7 (Dobin *et al.* 2013). The assemblies were merged with cuffmerge from Cufflink v2.2.1 and the GTF file produced was used in FeatureCounts function from Subread v2.0.3 software to obtain the transcript counts in each sample. A differential expression analysis was performed with DESeq2 v1.30.1 using edgeR v3.32.1 (Robinson *et al.* 2010) to filter the lowly expressed genes based on the logarithmic counts per million (lcpm) and TMM normalised gene counts (trimmed mean of M values). Ejaculate quality was used as a fixed effect in the statistical model to identify statistically significant changes in transcript abundances assessed between breeds (FDR<0.05 and logFC>1). Subsequently, a total of 9 Merino, 9 Dohne and 9 Poll Dorset rams, which passed quality control in edgeR, were included in the differential gene expression analysis. Four contrasts were performed, comparing transcript expression between breeds (Poll Dorset vs Merino, Dohne vs Merino, and Dohne vs Poll Dorset), and ejaculates of relatively high- and low-quality.

Transcripts longer or equal to 200 nt were identified as lncRNAs, and Cuffcompare v2.2.1 was used to classify transcripts. Only transcripts classified as 'u', 'o', and 'x' were retained for further analysis. Putative lncRNA candidates were then identified if their coding potential score was calculated as <0 via CNCI v2 and their coding probability was calculated as <0.5 via CPC2 v1.0.1. A miRNA database (http://rumimir.sigenae.org) on sheep was then used to remove lncRNAs that had a potential miRNA precursor (E-value 0.001) in BLAST v2.12.0. Transcripts with ORF larger than 300nt were identified using getorf function of EMBOSS (Rice *et al.* 2000) and removed. Transcript sequences were cross-matched against: (1) a protein sequence database (Pfam library) using hmmscan software; (2) the UniProt/SwissProt database; and (3) the annotated proteins for *O. aries* v4 using blastx. In all steps, any transcripts with coding potential were eliminated and remaining transcripts with an average FRKM>0.1 per breed, containing more than one exon were considered as lncRNAs, and retained for further analysis. The identified lncRNAs were used to find target genes (cis-target) within a 10 kb window of the lncRNA. Trans-target genes were identified based on a co-expression analysis using Pearson's correlation (r>±0.95 with *P*-value<0.05) between the mRNA genes and lncRNA.

Results

Differential gene expression analysis identified a number of Differentially Expressed Genes (DEGs) in each contrast that was performed. A summary of the total number of DEGs, as well as the gene symbols of the top 10 DEGs identified in each contrast, is presented in Table 1.

Analyses involving the identification of long non-coding RNAs identified a total of 1,205 lncRNAs in sheep spermatozoa, of which 150 transcripts passed the quality filtering for low expression and only 6 lncRNA were found to be differentially expressed. A summary of key differentially expressed lncRNAs along with their target genes is presented in Table 2.

Table 1. Number of differentially expressed genes in breed specific contrasts, and between ejaculates of varying quality (Hodge *et al.* 2021).

Contrast	No. of DEGs	Top DEGs
Dohne vs Merino	72	*MVK, TNS3, ALAS1, CCN1, MSRA, RRP15, PPARD, MED6, CARMIL1, FLRT2*
Dohne vs Poll Dorset	73	*PAMR1, LY6E, ARGLU1, CDO1, VARS2, TP53I11, POLK, FBXL14, MAN1A1, CHI3L1*
Merino vs Poll Dorset	570	*ATP2A3, SLC35A5, BORCS5, MSRA, KRT4, FAM210B, NKPD1, ITM2C, ANAX2, SLC2A3*
High vs Low quality	39	*KLK12, SPEM2, LYPLA1, TNNC1, LYRM4, OXCT2, SMKR1, FAM57A, SRGN*

Table 2. Differentially expressed target genes and their co-expressed lncRNAs across the comparisons of breeds sampled and ejaculate quality.

Contrast	DE lncRNA (Target Genes)
Dohne vs Poll Dorset	XLOC_048235 *(C1H1orf141, SLC38A4, XPNPEP3, NUP43, ELP4, CHRM1, PTH2R, FBXO7, ABCC9)*
	XLOC_072802 (LOC105607053, LOC105609923)
Merino vs Poll Dorset	XLOC_001101 *(CSF3R, CLEC5A, TRNAC-GCA, GRAMD1A, TREML2)*
	XLOC_001727 *(CLIC6, EX26)*
	XLOC_066444 *(FBXO7, CABS1, PPM1E, MED31)*
High vs Low quality	XLOC_023268 (LOC105611383, *SOBP)*

Discussion

There are a variety of factors on both the ram and ewe sides that influence conception outcomes in sheep, particularly when artificial breeding technologies like artificial in-semination are used. While a significant emphasis is placed on semen quality in artificial breeding programs, it is clear that other determinants influencing conception outcomes remain uncharacterized. The role of spermatozoal transcripts is of significant interest in this regard, because while spermatozoa have been shown to contain a large repertoire of transcripts which include both protein-coding mRNA and non-coding RNAs, very little is known about their influence on ejaculate quality and fertilisation.

This current study provides evidence indicating that a variety of mRNA and lncRNAs are expressed in sheep spermatozoa. A very high number of spermatozoal cells were needed for RNA extraction, because each spermatozoa conceivably carries a small amount of RNA relative to normal somatic cells. This supports the notion that spermatozoal cells are likely transcriptionally inactive for the most part.

However, in our study, we have identified several transcripts in ovine spermatozoa (e.g. *CABS1*, *CD82*, *ATP1B3*, *EFHB,* etc.), that have been previously associated with spermatogenesis, sperm morphology and ejaculate quality parameters. Therefore, it is likely that such spermatozoal transcripts play a physiological role in the development of spermatozoa, and could therefore be used as markers. Our study also identified several transcripts that were differentially expressed between spermatozoa sourced from ejaculates that varied in quality. Therefore, it is also possible that some of these transcripts can be used as markers to identify good quality semen that is likely to yield desirable conception outcomes.

Furthermore, the spermatozoal transcriptomes in different species have been found to contain thousands of transcripts, which is consistent with our findings (Selvaraju *et al.* 2017; Prakash *et al.* 2021). These transcripts are transferred from spermatozoon to the ova during fertilisation, where they could potentially play a crucial role in directing early embryonic development, thereby influencing pre-natal growth that may be correlated with economically important traits like birth weight, etc.

Overall, our findings accord with a variety of studies focused on spermatozoal transcripts in other species that also support a functional role for these transcripts. Therefore, our study offers several novel insights indicating spermatozoal transcripts could have crucial physiological roles and could potentially influence conception outcomes, and even early embryonic development. Therefore, future in depth investigations aiming to characterise the physiological role of spermatozoal transcriptomes are warranted.

Abstract

The vomeronasal organ (VNO) has long been of interest regarding the sensory control of social and sexual behaviour. In this study, high-throughput RNA sequencing was utilized to investigate transcriptional changes in the VNO between rams of Rasa Aragonesa with different sexual behaviour (active and not active). The RNA-Seq analysis generated 812,065,820 clean reads and identified six differentially expressed genes, of which *GFRA3*, *CEACAM*, and *LRIT3* were upregulated, whereas *SERPINB12, TP53INP2* and *CES4A* genes were downregulated in the active compared to the not active rams group. The Gene Set Enrichment Analysis (GSEA) of all the expressed genes in the VNO detected 128 overrepresented pathways at FDR 5%, predominantly related to biological process such as positive regulation of protein phosphorylation and cellular response to growth factor stimulus pathways. Studying these genes and the processes they control will improve our understanding of the genomic regulation of sexual behaviour in rams.

Introduction

In small ruminants, the vomeronasal organ (VNO) is morphologically constructed for the detection of pheromones, which are related to social and reproductive behavioural responses (Villamayor *et al.*, 2021). The sensory information interferes with the nervous control of gonadotropin secretion (Signoret, 1991). These chemosensory signals stimulate male sexual arousal and behaviour (Keverne, 2004). In fact, Ungerfeld *et al.* (2006) pointed out that the perception of pheromones by the VNO stimulates the sexual performance of rams, which determine a faster response to the stimulus of oestrous ewes. In addition, mountings and ejaculations increased without the need of more courtship behaviour. However, the blockage or removal of the VNO leads to a reduction of number of mounts and services in bulls (McGrath, 1981) and a depression of sexual activity in male rats (Saito and Moltz, 1986). In sheep, the ram effect is commonly used to improve the out of season reproduction. It has been observed that males with greater sexual behaviour produce a greater stimulus during seasonal anoestrous, which lead into a higher percentage of mated ewes and higher fertility. However, there is a considerable variation in sexual behaviour between rams, hypothesizing that VNO features may differ not only among species but also within the same species at mating (Villamayor *et al.*, 2021). In this study, we carried out an RNA sequencing approach to

investigate transcriptional changes in the VNO by comparing two groups of Rasa Aragonesa rams with different sexual behaviour (active and not active).

Materials & methods

Ethics statement. All experimental procedures including care of animals and euthanasia were performed in accordance with the guidelines of the European Union regulations for the use and care of animals in

research (Directive 2010/63/EU) and approved by the Animal Ethics Committee of the Research Centre (protocol number 2017/02).

Animals, tissues samples and RNA extraction. The experiment was conducted with 59 rams, submitted to individual sexual behavioural pen tests, twice for each ram. Each ram was exposed to three synchronized adult ewes for 20 minutes to observe their behaviour, and count the frequency of mounts and services. Three serial blood samples were taken one hour apart the day before, in lithium heparin tubes, to measure testosterone. In addition, individual live weight (LW) and body condition score (BCS) were assessed as well as testicular size. Two ram homogeneous groups in LW and BCS were identified after carrying out a decision tree using the package 'party' in R project, considering all the variables for the mounts and services phenotypes: active (A) (7.93±3.56, average mounts ± sd) and not active (NA; without any mount) rams. Then, six rams of each group were sacrificed. VNO tissue samples were extracted and stored at -80 °C until RNA isolation by RNeasy Lipid Tissue mini kit (QIAGEN, Madrid, Spain).

RNA-Seq data processing. Sequencing was carried out generating Illumina paired-end reads of 151 bp. Quality control of sequences was checked by FastQC. The Trimmomatic program was used to remove adaptors, low quality reads and overrepresented sequences. Then, the trimmed reads were mapped to the reference genome Oar_rambouillet 1.0 (GCA_002742125.1) using STAR v2.7.8a and gene level quantification was estimated using HTSeq. Differential expression analysis were performed with EdgeR using the threshold of CPM=0.5 in at least five samples. Multiple-testing corrections by Benjamini and Hochberg false-discovery rate (FDR 5%) controlling procedure were performed. Genes with an adjusted *P*-value≤0.05 were identified as DEGs. Enrichment Analysis were examined by GSEA. All the pipeline analysis was done using the OmicsBox platform v2.0.36 from BioBam (https://www.biobam.com/omicsbox).

Results

Active and non-active rams had similar LW and BCS, and no significant differences were found in testosterone levels or testicular size. RNA-seq data were obtained for VNO tissue samples of Rasa Aragonesa rams (n=12), ranging the number of total raw reads per sample from 60,537,894 to 83,449,630. After filtering by Trimmomatic, the total number of clean reads ranged from 41,240,636 to 78,958,466. The reads uniquely mapped by STAR to the reference genome varied from 55.4 to 84.5% among samples. These findings indicated good quality data that were suitable for subsequent analysis. After counting the reads mapped in each gene by HTseq, we next investigated the differences in gene expression data between active and not active rams by EdgeR software. As a result, 15,227 genes were expressed in the VNO. EdgeR identified six DEGs at FDR 5%. The *GFRA3*, *CEACAM* and *LRIT3* were up-regulated in the active rams whereas the *SERPINB12*, *TP53INP2* and *CES4A* were found down-regulated (Table 1). Gene set enrichment analysis included the 15,227 expressed genes. We detected 128 overrepresented pathways at FDR q-value 5%, predominantly related to biological process (BP) and molecular function (MF). The top 30 GO are shown in Figure 1.

Discussion

The principal goal of this study was to determine the possible molecular mechanisms underlying the sexual behaviour of Rasa Aragonesa rams by investigating transcriptional changes in the VNO between active and not active rams. The analysis revealed fewer DEGs, suggesting little difference in the VNO. The three up-regulated DEGs identified belong to signal term and seems to affect the sexual behaviour via network interaction with other genes. In fact, *GFRA3* correspond to the glial-cell line-derived neurotrophic factor Family Receptor Alpha 3 (GDNF), among its related pathways are RET signaling. GDNF is recognized to regulate the development of small-diameter nociceptors and may be involved in modulating

mechanosensation (Albers *et al.*, 2006). Low expression of this gene deteriorates reproductive potential via accelerated neurodegeneration (Vasiliev *et al.*, 2021). However, GFRA3 aberrant expression can increase human reproductive potential because of improvements in neural regeneration (Jankowski *et al.*, 2010). For the *CEACAM* gene, Gu *et al.* (2020) reported that CEACAM proteins disrupt transforming growth factor beta (TGFB) signaling pathway. Kim *et al.* (2013) indicated that *CEACAM* was one of the de-repressed gene families in the brain of *Peg3* heterozygous embryos and adult mice. This gene was reported to play important roles in controlling foetal growth rates and sexual behaviour in males and females. Swaney *et al.* (2008) indicated that the *Peg3* regulates sexual experience dependent preferences for oestrous odours. This is to say that mutation in *Peg3* could affect the expression of *CEACAM* gene family, which might result in a defect in reproduction or ability for mating. Similarly, *LRIT3* was reported as a modulator of Fibroblast Growth

Factor Receptor 1 (*FGFR1*) that is essential for the development of the gonadotropin-releasing hormone (GnRH) system (Tata *et al.*, 2012). Furthermore, the GSEA identified 128 overrepresented pathways, predominantly related to BP such as positive regulation of protein phosphorylation pathway, involved in the developing male and female rat brain as well as normal endocrine and behavioural processes in adulthood (Auger, 2003). Another pathway of interest was related to MF such as the protein kinase-binding pathway whose signaling pathways have been implicated in the estradiol regulation of sexual receptivity (Dewing *et al.*, 2008). These findings encourage deeper investigation towards the importance of these genes and their associated mechanisms to understand better the genomic regulation of sexual behaviour in Rasa Aragonesa rams.

Abstract

The aim of this study was to evaluate the sex-specific effects of a diet restriction in prepuberal ewes on the perirenal fat transcriptome of their offspring. For this research, we used RNA-Seq data from 11 lambs, 2 females and 3 males from control ewes, and 3 females and 3 males from ewes subjected to a nutritional challenge (NC) at the prepuberal stage. After a differential expression analysis, 116 genes showed an opposite expression pattern due to the NC between male and female lambs. These genes were functionally involved in mitochondrial activity, characteristic of brown adipose tissue. From our results, it could be inferred that the nutritional restriction at the prepuberal stage of the mothers may have an opposite effect in the transition from brown to white adipose tissue in each sex.

Introduction

Differences in fat deposition between males and females have been studied over the years in numerous species. Several factors, such as sex hormones, aging, hereditary factors and epigenetic effects, influence the fat distribution (Frank *et al.*, 2019). In sheep models, the perirenal adipose tissue (PAT) depot has been shown to be rich in brown adipocytes during the early stages of life (Henry *et al.*, 2017; Symonds *et al.*, 2015). In rodents and humans, it has been confirmed that females have more brown adipose tissue than males (Karastergiou *et al.*, 2012). In sheep, a recent study using the RNA-Seq methodology to determine differentially expressed genes (DEG) affecting fat metabolism in adipose tissue according to tail size and sex pointed out that genes regulating fat metabolism may be different for the two sexes (Fan *et al.* 2019). Besides that, also in sheep, it has been observed that maternal nutrition has a sex-dependent effect on offspring growth and carcass quality and yield (Ithurralde *et al.*, 2019). Regarding adipose tissue, both maternal under and overnutrition at the prenatal stage predisposed lambs to have visceral obesity by interfering with adipogenesis and adipose tissue functional traits (Khanal *et al.*, 2020). RNA-Seq analysis has been performed to elucidate how pre- and postnatal malnutrition can affect adipose tissue functional development in lambs (Ahmad *et al.*, 2021). However, little is known about how early life nutrition in ewes can affect the adipose tissue metabolism of lambs in a sex-dependent way. Therefore, the present study aimed to evaluate sex-specific effects of a maternal diet restriction at the prepuberal growth period on the PAT transcriptome of the lambs.

Materials & methods

Animal selection and RNA extraction. Twelve Assaf suckling lambs were selected for this study. Specifically, those animals belonged to four different groups: (1) Control (C) female (n=3), (2) Nutritional challenge (NC) female (n=3), (3) C male (n=3) and (4) NC male (n=3). Animals belonging to the NC group were descendants of dams subjected to dietary restriction during their pre-pubertal stage (from 3.5 to 5.5 months of age). After lambing, new-born lambs were kept with their mothers for the first 4 to 8 hours to suck colostrum. Then, they were fed artificially to avoid any maternal effect. Lambs were slaughtered when they reached the commercial weight established in Spain for suckling lamb meat (average live weight was 10.68±0.26 kg for females and 11.31±0.73 kg for males). All the animals were slaughtered at a local slaughterhouse, where a sample of PAT was collected from each suckling lamb. The tissue was preserved

in RNA-stabilization solution (Ambition RNAlater, Life Technologies) and stored 24h at 4 °C. After that, the solution was removed, and the samples were frozen at -80 °C until the RNA extraction. This extraction was performed using the miRNeasy Mini KIT (Qiagen) modified to its use in adipose tissue. Once the ribonucleic acid was obtained, the cDNA library construction and sequencing were conducted at Novogene in Cambridge (UK). For RNA-Seq, a Novaseq 6000 (Illumina) sequencer was used, generating stranded paired-end reads of 150 bp.

Bioinformatic pipeline. Quality control of raw sequences was performed using *Trimmomatic* (v.0.39) (Bolger *et al.*, 2014). We used *STAR* (v.2.7.6a) (Dobin *et al.*, 2013) software to map the lectures against the ovine reference genome (Oar_rambouillet_v1.0_r101). The quantification of the reads was performed by *HTSeq-counts* (v.0.6.1p1) (Anders *et al.*, 2015). *DESeq2* R package (v.1.32.0) (Love *et al.*, 2014) was used to perform the differential expression analysis (DEA) between the conditions analysed in the study. Using the normalized rlog transformed gene counts from *DESeq2,* we performed a principal component (PC) analysis to evaluate the distribution of the samples for the whole transcriptome and detect possible outliers. The model for *DESeq2* was fitted assuming an interaction between the NC and the sex:

$$y = NC + sex + NC:sex \quad (1)$$

We focused the analysis on the interaction between both conditions to establish the different responses to the treatment between the sexes. Differentially expressed genes (DEG) were considered at a false discovery rate (FDR)<0.05. Network analysis of DEG was performed using the *STRING* database (v.11.5) (Szklarczyk *et al.*, 2019) to identify protein-protein interactions (PPI). We used the 'co-expression' interaction as the source for information criteria, and interactions were considered relevant using a high confidence (0.07) score as defined by *STRING*. Gene Ontology (GO) terms from the functional enrichment analysis of the network were considered significantly enriched when the FDR<0.05.

Results

For the perirenal fat transcriptome of the 12 suckling lambs, the RNA-Seq analyses yielded an average of 32 million (32,147,225.17±1,125,254.99) paired-end reads per sample. Of those, ~87% paired-end reads per sample aligned to unique loci in the Oar_Ram_v1.0_r101 reference genome. The PC analysis helped us to identify an outlier in the C female group. After discarding this sample, the PC analysis was repeated with the remaining 11 samples. The three first PCs explained only 47% of the variance, being the 70% of the variance explained by the first six PCs. Moreover, no clustering of the samples into defined groups was observed. We detected 163 DEG when we analysed the interaction between sex and NC. Of them, 116 DEG showed an opposite expression pattern due to the NC in females and males. Thus, these genes had an augmented expression in C females compared to the NC females, while for males, they were upregulated in the NC group in comparison to the control group. In the gene network analysis, a total of 298 co-expression interactions (PPI enrichment *P*-value<1.0e-16) were identified among 94 of the 116 DEG showing an opposite expression pattern between females and males lambs from NC ewes. Functional enrichment analysis indicated that these co-expressed DEG were significantly enriched in 63 terms in the GO:Biological Process category, 16 in the GO:Molecular Function, and 38 in the GO:Cellular Component, being the top enriched GO terms for each category oxidative phosphorylation (37 genes), oxidoreductase activity (43 genes) and mitochondrion (74 genes), respectively.

Discussion

Results from our study highlight a set of genes within the PAT transcriptome whose expression patterns are opposite for male and female suckling lambs when their mothers have been challenged with a dietary restriction at the prepuberal growth stage. PPI network analysis showed that most of these genes were co-

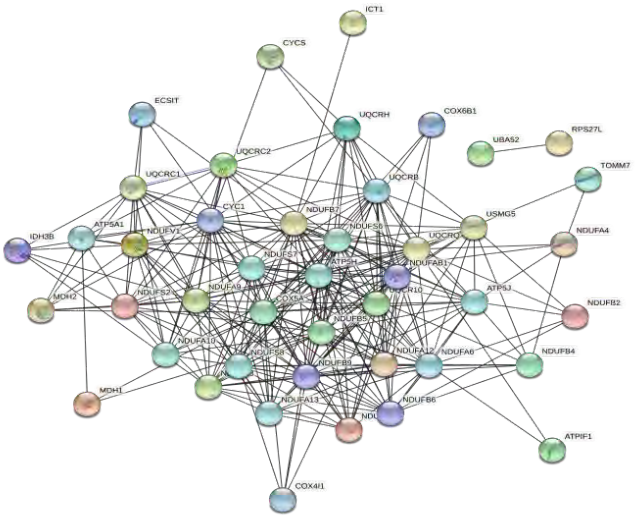

Figure 1. Protein-protein interaction network constructed with 94 co-expressed genes from the 116 DEG showing an opposite expression pattern between the male and female lambs here analyzed.

expressed and involved in functions related to mitochondrion activity (Figure 1). Brown adipose tissue (BAT) is characterized by a higher number of mitochondria compared to white adipose tissue. Mitochondrial energy expenditure in BAT is used primarily by non-shivering thermogenesis (Lee *et al.*, 2019). There is controversy about BAT deposits in suckling lambs; while some studies have observed that at 20 days of age, there is no BAT (Basse *et al.*, 2015), other studies have shown that there are BAT gene markers in lambs of the same age and older (Suárez-Vega *et al.*, 2018). One of the principal molecular markers for BAT is *UCP1* expression, whose expression in our samples was 369.5±394.63 FPKM in females and 98.06±111.03 FPKM in males. In our research, those females whose mothers were subjected to the nutritional challenge and the males whose mothers were from the control group showed a higher expression of genes that participate in oxidative phosphorylation and ATP synthesis compared with the alternative groups. In women, it has been reported that the activity and mass of BAT are greater than in men (Perkins *et al.*, 2013). Justo *et al.* (2005) detected a higher oxidative capacity in rat females. Cytochrome c oxidase (COX) is the enzyme responsible for oxygen consumption by mitochondrial oxidative phosphorylation. Our study found several COX subunits (*COX4I1*, *COX5A*, *COX8A*, *COX6B1*) upregulated in NC females and C males.

From our results, it could be inferred that a nutritional restriction in dairy ewes at the prepuberal stage has a sex-dependent effect on the transition from BAT to white adipose tissue of their offspring. While this process may be accelerated in NC male lambs, it seems to be delayed in female lambs. Other studies in rodent models and humans have showed that the influence of the maternal diet on the offspring is sex-dependent (Almeida *et al.*, 2017, Eriksson *et al.*, 2010). Overall, this is the first study in sheep showing the potential sex-dependent effects of maternal nutrition on fat deposition metabolism.

Abstract

The genomic inbreeding and heterozygosity levels were analysed in the Original and Improved Valachian sheep, and eight other breeds from open access data sets. The autosomal diversity levels were comparable between breeds. The markedly higher heterozygosity in the Improved Valachian was likely due to breed formation history, which ended ca. 40 years ago, and involved crossbreeding strategies. The heterozygosity levels in the X chromosome were clearly lower from those on the autosomes in all examined breeds. In particular, the dairy and meat Lacaune, and the Border Leicester breeds exhibited almost no heterozygosity here. In the Slovak autochthonous breeds, the heterozygosity levels were comparable to autosomes. The results of this study will be used to further improve the diversity of Valachian sheep.

Introduction

The use of single nucleotide polymorphism (SNP) markers has become common practice in sheep breeding. One of the most popular ways to utilize genomic data is to assess genomic diversity. This is especially important in small breeds, as the proper management of genetic diversity is the most important tool that keeps these breeds from the downward spiral in an extinction vortex.

The aim of our paper was to analyse the genomic diversity in two autochthonous Slovak national breeds, the Original Valachian (OVA) and Improved Valachian (IVA) sheep.

Materials & methods

Heterozygosity and inbreeding levels were computed separately on various parts of the genome to assess the diversity of OVA and IVA sheep, which are of triple production focus (milk, meat, wool). Therefore, Lacaune – milk (LMI) and East Friesian Brown (EFB) as dairy breeds, Lacaune – meat (LME) and German Texel (GTX) as meat breeds, Australian Merino (AUM) and Border Leicester (BRL) as wool breeds (Kijas *et al.* 2012) were used for comparison. Sheep outgroups, European Mouflon (*Ovis orientalis orientalis*, EMU) and Argali (*Ovis ammon*, OAM) were also used for the comparison (Ciani *et al.* 2015).

SNP data from Illumina OvineSNP50v1 chips were used for the analysis. The data set before quality control consisted of 103 LMI and 39 EFB; 78 LME and 46 GTX; 50 AUM and 48 BRL; and 24 EMU and 6 OAM individuals. The Valachian sheep were genotyped using the GeneSeek GGP Ovine 50K chip, with 96 OVA and 69 IVA animals genotyped. Due to only a partial overlap in the SNP sets, the data sets were not merged together, but the computations were done separately for each breed.

In all cases, quality control consisted of removing SNPs and animals for which more than 10% of genotypes were missing. After the quality control 46,812 SNPs remained for the open access data, and 42,595 for the Valachian data set. Only one IVA animal was removed due to missing genotype data. The genomic diversity was assessed separately on autosomal chromosomes and the X sex chromosome.

The PLINK (Chang *et al.*, 2015) software was used for general data management, quality control, and to compute heterozygosity and allele frequency based inbreeding levels on the autosomal genome using the --het option. This option was limited to autosomal genome only, so allele frequencies were computed with in-house scripts. The ROH based inbreeding was computed using the cgaTOH (Zhang *et al.*, 2013) software, considering ROH with minimal length of 1 Mb, and not allowing for any missing or heterozygous SNPs.

Results & discussion

The overall inbreeding coefficients based on the autosomal genome were widely distributed (Figure 1). The IVA population appeared to be much less inbred compared to most of the other analysed sheep, likely due to the targeted crossbreeding activities that were used to form this breed. The IVA breed was a result of the upgrade of the autochthonous OVA breed, when its overall high-altitude adaptation and disease resistance traits were augmented with increased production, using other breeds such as Texel, Hampshire Down, Lincoln Longwool, Leicester Longwool, Lacaune, and East Friesian. Such activities, carried out between 1950s and 1980s clearly resulted in a higher number of haplotypes and lower chance of even small ROH to occur. The OVA breed on the other hand, consisted of animals with numerous ROH regions, hence a very wide range of inbreeding levels.

The heterozygosity levels across the autosomes had an expected tendency, compared to inbreeding levels. The correlation coefficient between the ROH based inbreeding and heterozygosity was -0.87, between allele frequency-based inbreeding and heterozygosity -0.99. The difference between the two sets of inbreeding results was likely based on the difference in computation methodologies. Not all homozygotes were considered in ROH estimations, as part of the runs was broken by missing or heterozygous SNPs.

The expected and observed heterozygosity was 0.391 and 0.388 in OVA, and 0.425 and 0.429 in IVA breeds. The overall observed heterozygosity levels in autosomes of livestock breeds ranged on average from 0.299 in BRL to 0.429 in IVA. The heterozygosity levels were much lower in the outgroups overall, with just 0.200 in EMU and 0.106 in OAM. It is not clear, however, if the increased number of homozygotes were due to real inbreeding, or due to ascertainment bias.

The diversity of X chromosome seems to be an under researched topic based on the overall scarcity of publications, yet it was suggested as a unique tool for population-genetic studies (Schaffer, 2003). The heterozygosity levels on the X chromosome were very different from those on the autosomes, however, similarly to findings of Chen *et al.* (2018). Here, a large proportion of the sheep from open access data sets had heterozygosity level of zero, i.e. they were entirely homozygous. Also, smaller portion of OVA animals showed a very low heterozygosity level. The rest of the data showed a similar, or even higher heterozygosity on X chromosome, compared to autosomes.

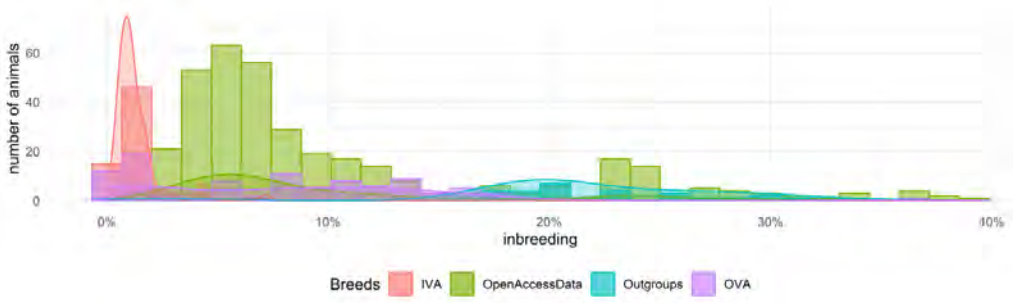

Figure 1. Genomic inbreeding coefficients based on ROH.

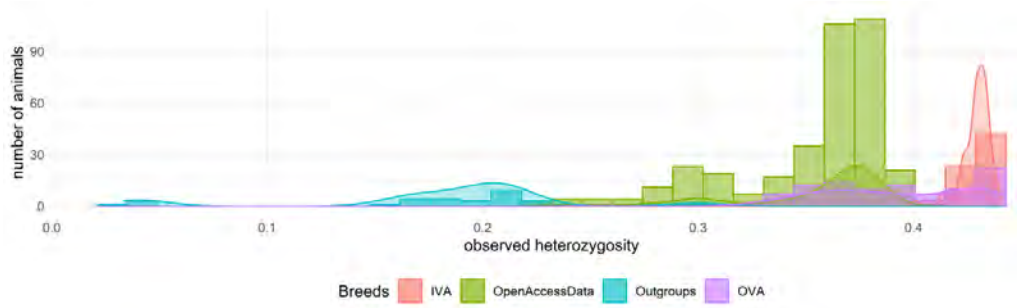

Figure 2. Observed heterozygosity levels on the autosomal chromosomes.

The reason for such difference in homozygosity levels was unclear. One possible reason could be the existence of long conserved regions on the X chromosome, as shown e.g. in pigs (Tong *et al.*, 2020), with potential candidate genes for body size. Of course, ascertainment bias in outgroups could also play a role, which would explain the low heterozygosity levels on the X chromosome of EMU and OAM (Table 1). On the other hand, even lower heterozygosity levels were found in established breeds, such as LME, LMI, and BRL. Also, the heterozygosity in other open access data was on average lower compared to autosomes in the same breed. In this respect, there was a notable variation in all breeds showed by high standard deviations, except BRL. Interestingly, both OVA and IVA had comparable average heterozygosity levels on the X chromosome and autosomes. Also here, the higher variation indicated that few animals had much lower heterozygosity levels, as also shown on Figure 3.

In conclusion, the inbreeding and heterozygosity levels in OVA population was comparable to other major sheep breeds. The higher heterozygosity levels in IVA were likely a consequence of the crossbreeding activities upon breed formation about 40 years ago, which still seem to have lasting effect in the population diversity metrics. These results will be used to further improve the diversity of the Slovak autochthonous breeds.

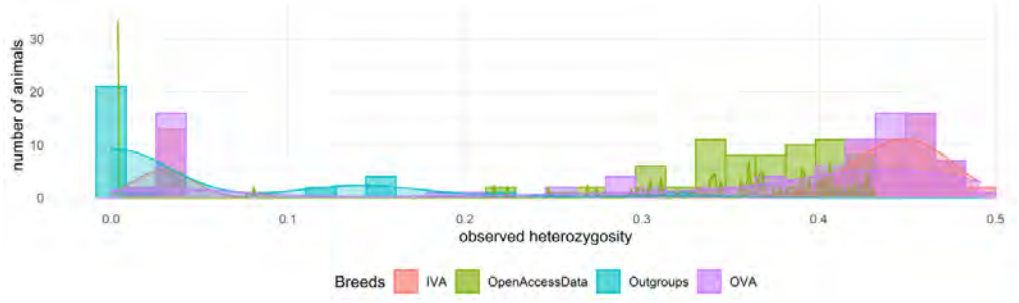

Figure 3. Observed heterozygosity levels on the X chromosomes. The y axis was truncated to improve clarity – the number of individuals with zero heterozygosity from the open access was ~300.

Abstract

Data quality influences the accuracy of estimated breeding values, and hence the accuracy of selection and genetic progress. This paper describes how a data quality score (DQS) was created to characterise the overall data quality for Australian sheep flocks. The data quality metrics investigated captured data quantity (e.g. degree of performance/pedigree recording), accuracy, structure (e.g. sire representation and linkage) and timeliness of data submission. These metrics were combined to calculate the overall DQS, with weightings dependant on breed type, variation and relationships between metrics. The DQS was well received by industry, with overwhelming support to publish the DQS after an initial producer education campaign. The DQS will help identify and highlight breeders who collect high quality data, help breeders improve their data quality, and increase information available to ram buyers. This research supports Australia's sheep industry to value phenotypes in an objective manner.

Introduction

Data is the cornerstone of genetic evaluation systems. Maximising data quality enhances accuracy of estimated breeding values and of selection decisions, which drives higher rates of genetic progress. The level and breadth of recording, and the availability and accuracy of supporting information (pedigree, fixed effects and genotypes), also impact selection accuracy and genetic progress. The genetic evaluation for the Australian sheep industry, Sheep Genetics, primarily relies on data submitted by ram breeders. While there are standards and guidelines for data submission, there is wide variation in data recording and submission across the industry.

Sheep Genetics make available 'RAMping Up Genetic Gains' (RUGG) reports, which provide breeders with feedback on their data (Stephen *et al.*, 2018). While these RUGG reports are available to breeders and have been used as an engagement tool for service providers and consultants, uptake by industry has been varied. As an incentive to seedstock breeders to improved recording, a data quality score (DQS) was developed to describe (and potentially rank) the quality of data submitted for genetic evaluation. This paper describes metrics that characterise data quality, the development of the DQS, and the response to the DQS by Australian sheep breeders.

Materials & methods

Data quality metrics. The following data quality metrics were calculated for each flock. Full Pedigree (%): the overall proportion of animals from the flock in the analyses with full pedigree. Contemporary group variation in ages (%): proportion of animals recorded that are in contemporary groups with variation in age. Variation in age within contemporary groups is expected with accurate birth date recording. Proportion of effective progeny (%): calculated as the proportion of progeny each sire has in the group, averaged across sires and all contemporary groups. Proportion of animals recorded for the weight, reproduction, wool and carcase trait groups (%). Average proportion of animals recorded that are directly linked to external flocks, by trait group (%): weight, carcase scan, reproduction and wool. Timeliness of data submission was calculated as interval between the date of recording and actual submission date (days). Calculation of the

data quality metrics that capture the above factors are provided in more detail in Guy and Brown (2021a). These metrics were calculated for 441 Terminal, 304 Merino, and 96 Maternal flocks.

The data quality score. The metrics above were combined into an overall DQS for each flock. All metrics were weighted considering breed type (Terminal, Maternal or Merino), variation and relationships within the data quality metrics and relationships between data quality metrics and metrics describing genetic gains (Guy and Brown, 2021b). Due to the different scales and variances of each data characteristic metric, they were scaled to unit variance and a mean of zero. The resulting DQS for each method was also then scaled to between 0 and 100 for ease of interpretation.

Consultation with industry. The reporting of the data quality metrics and DQS was evaluated at 6 industry events involving 96 flocks. DQS reports were generated and incorporated into the existing RUGG reports. Reports were provided for each participating flock, followed by group discussion and collection of anonymous feedback.

Results

Data quality metrics. The data quality metrics with notable variation are shown in Figure 1.

While distributions for different breed types overlapped, Merino flocks had markedly lower full pedigree recording and more variation across flocks (mean ± SD, 43.6±35.3%) compared to Maternal (89.3±18.6%) and Terminal (87.2±21.6%). There was also less variation in ages within Merino contemporary groups. Given that the majority of lambs originate from natural mating this implies less accurate recording of birth dates.

The data quality metrics relating to data structure were fairly consistent across breeds. Average effective progeny numbers were 67.5±18.2% for Merino, 64.0±20.4% for Maternal, and 57.5±21.1% for Terminal flocks. The level of linkage for weight traits was 76.0±19.7% in Merino, 68.1±13.4% in Terminal and 64.5±16.9% in Maternal flocks.

All breed types had a high proportion of animals recorded for weight traits, with Merino flocks having the lowest level of recording, and the most variability across flocks within the breed type (75.2±25.1% compared to 79.8±15.9% for Maternal and 81.4±17.2% for Terminal flocks). Maternal flocks recorded more

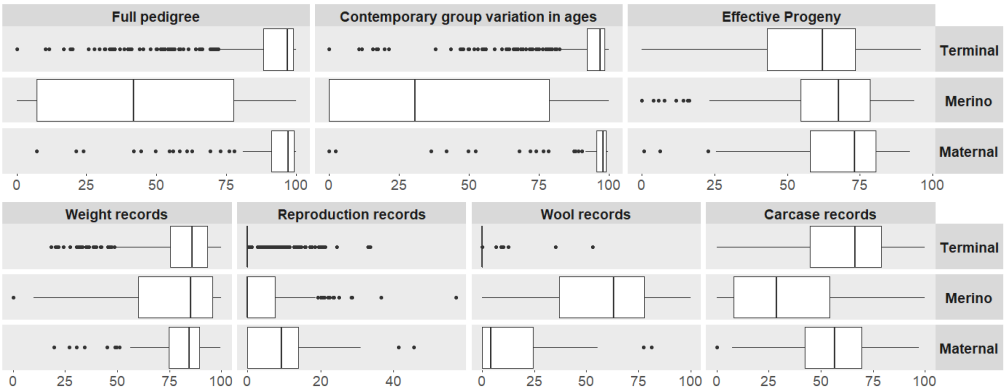

Figure 1. Distributions of data quality metrics for Terminal, Merino and Maternal flocks.

reproduction traits and had the most variation compared to other breed types (8.7±8.9%, compared to 4.2±7.6% for Merino and 1.8±4.9% for Terminal flocks). Merino flocks had a greater proportion of animals with wool traits recorded, although this varied greatly (59.3±25.9%). Terminal flocks had the highest level of carcase phenotype recording (61.4±20.1%, compared to 54.2±20.1% for Maternal and 33.2±28.4% in Merino flocks).

There was also variation in how timely data were submitted for analysis. Merino flocks took longer to submit pedigree records (average age of animals to appear in the pedigree was 376 days, compared to 240 days in Terminal and 243 days in Maternal flocks). The time taken to submit phenotypic data was similar across breeds for weight traits (submission time ranging from 92 days to 109 days post-measurement) and carcase data (range 38 days to 55 days).

The data quality score. Metrics relevant to each breed type were included in the calculation of the DQS (for example, level of recording and linkage for wool traits were not included for the DQS calculations for Terminal flocks). Specific metrics were also given higher weights to target improvements for each breed type (for example, degree of full pedigree recording was lowest for Merino flocks, so more emphasis was placed on this metric for breeders in that group).

The DQS was categorised as 'star ratings' by equally splitting the DQS range (score of 0-20: 1 star, 20-40: 2 stars, 40-60: 3 stars, 60-80: 4 stars, 80-100: 5 stars; Figure 2).

Consultation with industry. The DQS was well-received by industry. Constructive feedback was provided to further enhance the usefulness of the DQS and the reports developed to support it. The majority of anonymous survey respondents thought the DQS and star rating were useful and relevant to industry, and also a source of motivation to improve their own recording strategies (Figure 3).

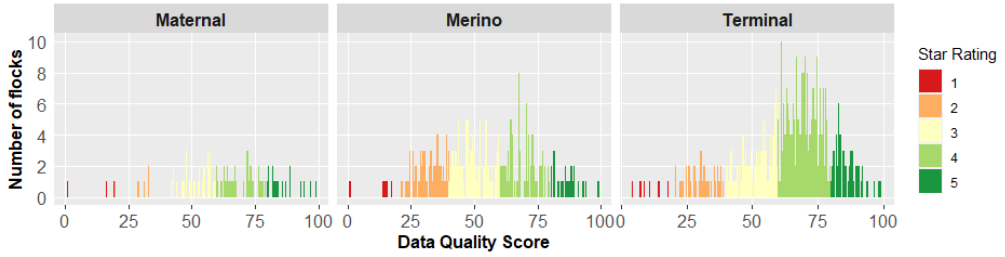

Figure 2. Distributions of data quality score for Terminal, Merino and Maternal flocks.

Figure 3. Level of agreement (green) and disgreement (red) for the usefulness of the Data Quality Score for improved recording, and relevance for industry (63 responses).

There was also overwhelming support to report the DQS to breeders, and to publish the data quality star ratings for each flock following an extension effort to help ram breeders and buyers understand the new information.

Discussion

Data quality metrics. The level of performance recording for each trait aligned with the general breeding objectives of each breed type. The high proportion of weight trait recordings across all breeds is likely to reflect the relative ease of recording compared to other traits. There was significant variation across breeds and flocks for all other trait groups, which highlights the opportunity for improvement in all breed types.

Delivering genetic progress through data quality. Data quality metrics were related to metrics describing genetic gains (average index accuracy, average index value and index trend) in Merino flocks (Guy and Brown, 2021b), as well as Maternal and Terminal flocks (unpublished). This suggests that improvement in data quality should lead to improvement in the rates of genetic progress.

Some aspects of data quality are captured in estimated breeding value (EBV) accuracies, which are reported alongside EBVs. While the accuracy of genetic merit estimation is influenced by the level of recording and management group structure (Brown *et al.* 2001; Swan and Brown, 2007), EBV accuracy is calculated using the amount and structure of information utilised (i.e. quantity), and not explicitly the precision and timeliness of information supplied to the analysis. The reporting of additional data quality metrics beyond EBV accuracy provides breeders with targeted feedback to help them improve their data recording programs.

In addition to the general reporting of these new metrics to industry, more extension and decision support tools are required to help breeders implement sensible performance recording improvements. Further work planned is to conduct cost-benefit analysis of different recording options and embed this into tools which can be used by service providers as the basis for objective breeding program advice.

Benefits to industry. The DQS will help identify and highlight breeders who collect high quality data, help breeders improve their data quality, and increase information available to ram buyers. This research supports Australia's sheep industry to value phenotypes in an objective manner, and can be further expanded to evaluating a flock's data contribution to the reference population.

Acknowledgements

The development of the data quality metrics and DQS has been a long-term project and has received significant funding from MLA and input from Sheep Genetics staff and industry ram breeders. In particular the authors would like to acknowledge the significant contributions of Caris Cornwall (nee Jones), Luke Stephen, Gabrielle Sherring and Andrew Swan.

Abstract

Estimation of breeding values (EBVs) is combined with estimation of accuracies for particular traits. These accuracies are important as they can tell the breeder how trustworthy the EBVs are. For hard to measure, low heritability traits or those measured at the end of life, EBV accuracy values tend to be low. This study aimed to examine the impact of including genotypic information in genetic evaluations to improved EBV accuracy. We analysed California mastitis test (CMT) and footrot (FR) records and over 10,000 genotypes collected on more than 30 UK Texel sheep farms. Results showed that the inclusion of genomic information based on Single Nucleotide Polymorphism (SNP) may increase the accuracy of prediction, especially for non-phenotyped animals.

Introduction

Mastitis and footrot are endemic diseases causing significant losses to the UK sheep industry (Nieuwhof and Bishop, 2007), impacting on productivity and often causing poor welfare of the animals. Phenotypes for both these traits can only be collected either late in life on lactating ewes (mastitis) and/or animals under disease challenge (footrot).

Heritabilities estimated for these or similar health traits tend to be small (McLaren *et al.*, 2018; Mucha *et al.*, 2015) meaning the obtained accuracies for EBVs remain low, if insufficient phenotypes recorded on close relatives are available. Higher accuracy means less room for bias, making the EBV more reliable, which is extremely important for the breeders. The systematic collection of these records in a cohort of animals (reference population or a network of genetically linked phenotype farms), delivers EBVs with appropriate high accuracies to help identify animals that are more resistant to disease and have higher production value. The collection of these disease or gender-specific records can be difficult and expensive. Therefore, having the phenotyped population of animals that are genetically linked to the wider population under the selection is key to the dissemination of genetically resistant livestock to disease. The development of genomic breeding values (GEBVs) by using phenotypes with corresponding genotypes to perform Best Linear Unbiased Prediction (BLUP) allows more animals to obtain more accurate breeding values for specific traits. This is especially important for young animals that not yet had a chance to be phenotyped due to their young age or to animals for which the phenotype can be collected on the opposite sex only. It is also important because some flocks may not have the capacity to accept levels of disease prevalence required for phenotyping, yet would benefit from being able to identify more resistant animals for further breeding. The aim of this study was to determine the difference in EBV accuracy values comparing genomic prediction (Single Step Genomic BLUP – ssGBLUP) with a conventional approach (BLUP).

Materials & methods

Genotypes. Texel sheep from participating flocks within the UK were genotyped between January 2015 and March 2019 using four Single Nucleotide Polymorphism (SNP) chip arrays, namely Illumina OvineHD BeadChip with 606,006 SNPs (HD), Illumina OvineSNP50 with 54,241 SNPs (50K), Illumina OvineLD BeadChip with 15,000 SNPs (LDv1) and Illumina OvineLD BeadChip with 16,560 SNPs (LDv2). Dataset contained 10,193 genotypes, which were subject to standard quality control. Firstly, genotypes that failed

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_744, © K. Kaseja *et al.* 2022

on call rate threshold were removed if the number of SNPs receiving the proper value (AA, AB, BA or BB) divided by the total number of SNPs was below 89.4%, which is the standard threshold used for the UK livestock genomic evaluations. Secondly, genotypes that were successfully assigned to registered animals in the UK National Texel (iTexel) database and had their pedigree verified were kept. After removing duplicate entries, the final dataset contained 9,391 genotypes which were subject to standard checks at the SNP level, investigating SNP call rate, minor allele frequency and Hardy-Weinberg equilibrium. This led to subsets of 45,686, 36,654, 12,427 and 10,725 SNPs for HD, 50K, LDv2 and LDv1 SNP arrays, respectively. These SNP subsets were then imputed using Findhap V3 software (VanRaden *et al.*, 2011) to 50K. For genotyped animals, five generations pedigree (n=48,244) were built using information from the iTexel database.

The imputed genotypes were used to assess the population structure of the breed using Principal Component Analysis (PCA) (Macciotta *et al.*, 2010; S Mucha *et al.*, 2015) in R software (R Core Team, 2021).

Phenotypes. Data collection was undertaken between 2015 and 2019 on 32 farms across Great Britain. Trained technicians visited farms at least once per year to score breeding females on presence of footrot on a five-point scale, where 0= no infection (healthy) and 4= severe infection (Conington *et al.*, 2008). Animals were scored between one and five times in total. Mastitis phenotypes were collected as California Mastitis Test (CMT) scores, which are highly correlated with somatic cell count causing mastitis (González-Rodríguez and Cármenes, 1996; McLaren *et al.*, 2018). In order to normalise the data, the collected scores were summed either for two halves of the udder for CMT or four feet for footrot (FRT). The sum was increased by one, to avoid sum of zero, and log transformed (McLaren *et al.*, 2018).

Variance components, heritabilities and breeding values. Genetic parameters used in this study were estimated using an animal model in ASReml (Gilmour *et al.*, 2009), with the following model: $y = Xb + Za + Wc + e$ where: y is the vector of phenotypic observations (CMT or FRT); b the vector of fixed effects, containing lambing number, litter size born, scorer, contemporary groups (month-year and farm-year) for CMT and dam age, scorer, foot vaccination status and flock for FRT; a is the vector of random animal effect; c is a vector for permanent environment (for CMT only); e is the vector of random residual effects; X, Z and W are the designed matrices for fixed (X) and random effects (Z and W).

Estimated Breeding Values were derived with BLUP (Henderson, 1949), while ssGBLUP (Legarra *et al.*, 2009; Misztal *et al.*, 2009) was used to obtain genomic EBVs, where the Genomic Relationship Matrix was constructed using VanRaden's first method (VanRaden, 2008). Calculations were undertaken in MiX99 software (Lidauer *et al.*, 2015). Breeding values, both conventional and genomic, were estimated using the same dataset including 821,692 animals from the iTexel database, containing genotyped and/or phenotyped animals with their pedigree data. In both cases, EBV accuracies were estimated with Apax99 software using a two-step method which in the first instance calculates information amount due to observations coming from defined model and secondly uses Misztal and Wiggans (1988).

Results

The breed composition of the studied population was examined by plotting first and second principal components of the genomic relationship matrix. Results, showing no major outlier groups, indicates that this population is mainly homogeneous, hence genomic analyses can be performed for all the animals included in this study. Over 35% of the variation can be explained by the first ten principal components, with 14.8 and 4.7% explained by first and second component, respectively.

Heritability estimates were 0.07 (±0.03) and 0.12 (±0.02) for CMT and FRT, respectively.

Figure 1 illustrates potential gain in accuracy for CMT and FRT for genotyped animals from ssGBLUP compared to BLUP. Animals with genotype available were divided into two groups: phenotyped and non-phenotyped; the average increase in accuracy was 0.06 and 0.08 for phenotyped and 0.21 and 0.14 for non-phenotyped animals for mastitis and footrot, respectively. Maximum accuracy gain was observed for non-phenotyped animals and was 0.52 for CMT and 0.47 for FRT. These results indicate that with a properly designed reference (genotyped and phenotyped) population, the use of genomic information is beneficial for non-phenotyped animals.

Discussion

Estimated heritabilities are in line with expectations for the health traits and other similar research (McLaren *et al.*, 2018; Mucha *et al.*, 2015; Kaseja *et al.*, 2018). The results from this study show that the estimated accuracy values increase both for CMT and FRT when genome-wide SNP genotypes were incorporated in the genetic evaluation for these health traits. This study proves that the incorporation of all available information for the prediction of genomic breeding values is highly valuable leading to more robust predictions of merit for breeding animals. It will also increase the trust in breeding values by farmers and breeders and reduce the risks associated with selection. The estimated heritabilities for disease traits were low, indicating that non-additive genetic and environmental effects are playing an important role for mastitis and footrot in sheep, although selection to reduce these diseases is valuable not least to improve animal health and welfare but also to reduce transmission and improve flock profitability and efficiency.

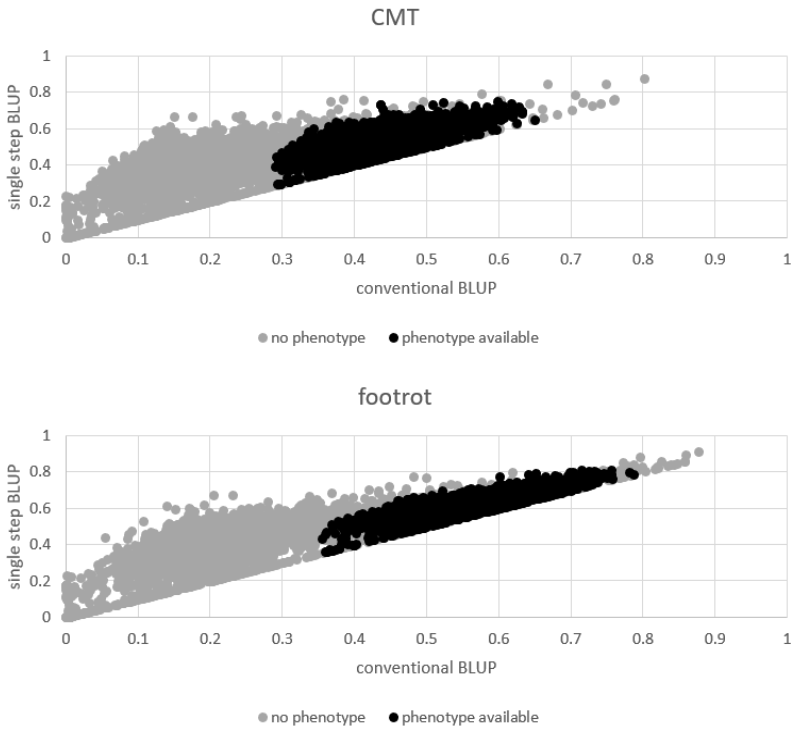

Figure 1. Accuracy values of EBVs obtained for genotyped animals for mastitis (CMT) and footrot while using conventional BLUP (horizontal axis) and single-step genomic BLUP (vertical axis).

745. Characterization of homozygous haplotype deficiency compromising fertility traits in Manech Tête Rousse dairy sheep

M. Ben Braiek[1*], C. Moreno-Romieux[1], C. Hozé[2], J-M. Astruc[3] and S. Fabre[1]

[1]GenPhySE, Université de Toulouse, INRAE, ENVT, 31326 Castanet-Tolosan, France; [2]Allice, 149 rue de Bercy, 75595 Paris, France; [3]Institut de l'Elevage, 24 chemin de Borde-Rouge, 31321 Castanet-Tolosan, France; maxime.ben-braiek@inrae.fr

Abstract

With the objective to identify deleterious recessive mutations, we have scanned the genome of 5,271 French Manech Tête Rousse (MTR) dairy sheep using 50k SNP phased genotypes and pedigree data. Five deficient homozygous haplotypes, named MTRDHH1 to MTRDHH5, were identified. These haplotypes showed a highly significant deficit of homozygous animals ranging from 84 to 100%, and a carrier frequency ranging from 7.8 to 16.6%. By comparing at-risk matings (between carriers) and safe matings, some of these haplotypes were associated with a reduced success of artificial insemination (MTRDHH2), and/or an increased stillbirth rate (MTRDHH1 and 2) suggesting the segregation of recessive variants leading to embryo and/or perinatal lethality affecting fertility. Other haplotypes are likely to be associated with lamb morphological disorders or counter-selection based on breed standard. For each haplotype, the most probable candidate genes were highlighted based on their roles in lethal phenotypes, genetic disorders, hornless or coat color.

Introduction

In livestock under selection, the small effective population size and a non-negligible inbreeding rate could increase homozygosity and thereafter lead to the emergence of genetic disorders under the control of recessive deleterious variants. When homozygous, these variants very often lead to early embryo death, or to developmental disorders that affect fetuses and subsequently young individuals altering health and welfare (Georges *et al.* 2019). Detection of homozygous haplotype deficiency using reverse genetic screen is a useful method for mapping specific haplotypes associated with deleterious recessive mutations (VanRaden *et al.* 2011). The analysis is based on high throughput genotyping data usually available in the framework of genomic selection. For the first time in sheep, we recently validated this approach in Lacaune dairy sheep by the identification of eight independent deficient homozygous haplotypes (Ben Braiek *et al.* 2021). Complementary whole genome sequence studies have led to identify the causal variant in the *CCDC65* gene within one of these haplotypes (LDHH6, OMIA 002342-9940). Homozygous lambs for the *CCDC65* mutation suffered from a lethal respiratory syndrome (Ben Braiek *et al.* 2022). The objective of the present study is to search for homozygous haplotype deficiency in the Manech Tête Rousse (MTR) dairy sheep also having a large set of genotyping data from genomic selection. This opens the opportunity to discover new deleterious recessive mutations in sheep.

Materials & methods

Animal and genotyping data. The total dataset consists of 6,845 genotyped Manech Tête Rousse animals (82% male and 18% female) born between 1993 and 2021. Genotypes were obtained in the framework of the French dairy sheep genomic selection from Ovine SNP50 BeadChip (MD; n=3,889) and SheepLD (LD; n=2,956) (Illumina Inc., San Diego, USA). Quality control for each SNP was based on: (1) a call frequency >97%; (2) a minor allele frequency >1%; and (3) the respect of the Hardy-Weinberg equilibrium ($P>10^{-5}$). Phasing and imputation (from LD to MD SNP chip) of genotypes were done using *FImpute v2.2.* After quality control, the remaining 38,523 autosomal SNPs were mapped onto the *Ovis aries* genome assembly Oar v3.1.

Detection of homozygous haplotype deficiency. The genome of 5,271 genotyped animals belonging to trios (77 offspring with both parents genotyped and 4,799 offspring with sire and maternal grandsire genotyped) was scanned by a 20 SNP sliding window as described (Ben Braiek *et al.* 2021). Consecutive 20 SNP windows with the same parameters (haplotype frequency, significant homozygous animal deficit) were clustered to define larger region called 'Manech Tête Rousse Deficient Homozygous Haplotype' (MTRDHH). For each MTRDHH, the genotypical status (homozygous non-carriers, heterozygous and homozygous carriers) was determined for all genotypes available (n=6,845).

Analysis of fertility traits. Trait records of MTR matings between 2006 and 2019 were obtained from the national database and based on ewes with a genotyped sire and genotyped rams (maternal sire and ram both having a known status at each MTRDHH; n=330,844 matings). We analyzed two fertility-associated traits, artificial insemination success (AIS) and stillbirth rate (SBR). We have considered 'at-risk' a mating between a carrier ram and a ewe from a carrier sire and the other combinations were 'safe' mating. AIS and SBR were considered to differ significantly when the fixed effect 'mating type' had a *P*-value lower than 1.0×10^{-3} after correcting for multiple testing with a level of significance at 1% following the SAS GLIMMIX procedure previously described (Ben Braiek *et al.* 2021).

Identification of candidate genes in MTRDHH regions. We extracted all annotated genes located in the MTRDHH region extended by 1 Mb from each side from the ovine genome Oar_v3.1 using CLC export annotation function (QIAGEN CLC Main Workbench 7.9). All genes related to mortality/aging phenotypes when knocked-out in mice and/or associated to mammalian genetic disorders were extracted from Mouse Genome Informatics (MGI, http://www.informatics.jax.org), Online Mendelian Inheritance in Man (OMIM, https://omim.org) and Online Mendelian Inheritance in Animal (OMIA, https://omia.org) databases.

Results

Identification of deficient homozygous haplotypes in MTR dairy sheep. Using a reverse genetic screen in MTR genotyped population, we identified 5 independent regions showing a significant deficit of homozygous animals and named MTRDHH (Table 1). Among those regions, three haplotypes (MTRDHH1, 2 and 3) showed a complete deficit of observed homozygous animal while 9 to 13 were expected. The two other haplotypes (MTRDHH4 and 5) presented a partial deficit between 84 and 91% (some homozygous animals were genotyped). The length of these haplotypes ranged from 1.8 to 4.2 Mb and carrier frequencies

Table 1. List of Manech Tête Rousse deficient homozygous haplotypes.

Haplotype	OAR	Number of markers	Position (Mb)[1]	Carrier frequency (%)[2]	Number of homozygotes			
					Exp[3]	Obs[4]	Deficit	Poisson *P*-value

[4] Observed.

ranged from 7.8 to 16.6% in the whole genotyped population. MTRDHH2 and 3 are located on the same chromosome (OAR1) but are not in linkage disequilibrium. The other haplotypes are located on different chromosomes, MTRHH1 on OAR20, MTRDHH4 on OAR10 and MTRDHH5 on OAR13. Consequently, the five MTRDHH detected are likely to host five recessive deleterious variants.

Impact of MTRDHH on the success rate of AI and on stillbirth rate. In order to identify the putative lethal effect of the MTRDHH, we studied two fertility binary traits (AIS and SBR) by comparing at-risk matings to safe matings. AIS (population mean= 60.9%) is a good proxy for embryonic loss, while SBR (population mean=7.5%) is a good proxy for perinatal lethality. As shown in Figure 1, MTRDHH1 has a significant negative impact on SBR (+7.5% in at-risk matings) and MTRDHH2 have negative effects on both AIS (-3.3%) and SBR (+4.3%). The other haplotypes showed no significant effect on the two tested traits.

Candidate genes for MTRHH regions. Among the 459 genes annotated in the five MTRDHH regions, 61 are implicated in lethal phenotype when knocked-out in mice. Among them, several are associated also with mammalian genetic disorders (Table 2). The remaining candidate genes are involved in important functions such as metabolism (*MMUT* and *SSR3*), DNA/RNA processing or transcription (*TFAP2B*, *DHX36* and *BRCA2*), or cell signaling (*PKHD1*, *SV2A*, *ECM1*, *KL* and *RXFP2*).

Discussion

In this study, we have confirmed the usefulness of reverse genetic screen to detect homozygous haplotype deficiency in sheep, even with a more reduced dataset of genotyped trios (MTR~5,000) compared to our previous work (Lacaune ~15,000, (Ben Braiek *et al.* 2021)). However, using the same parameters we identified less significant haplotypes (5 in MTR vs 11 in Lacaune) with the lower haplotype carrier frequency at 7.8% compared to 3.7% in Lacaune.

Among the five MTRDHH, three of them are totally deficient in homozygous animals leading to the hypothesis that these haplotypes host recessive lethal mutations. Accordingly, MTRDHH1 and 2 are associated with defect in fertility traits, AIS and/or SBR. This lets us think that when homozygous these haplotypes induce embryonic or fetal/neonatal lethality. To support this hypothesis, we found obvious candidate genes in these regions (*MMUT, TFAP2B, PKHB1, DHX36* and *SSR3*) all associated with

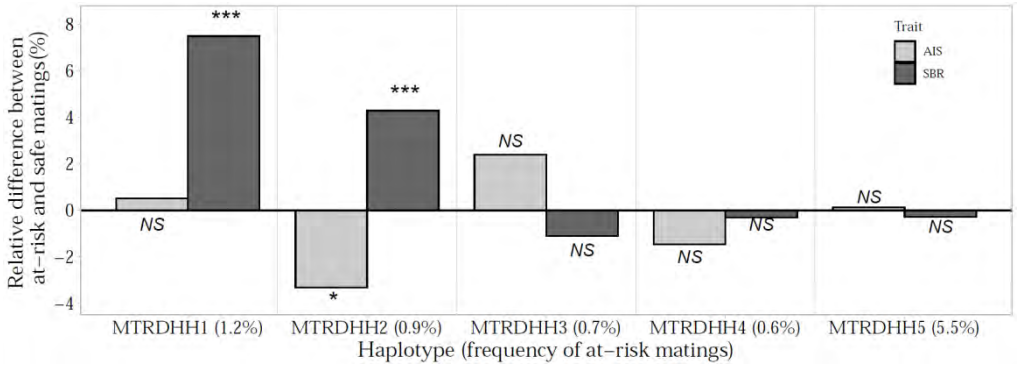

Figure 1. Effects of MTRDHH on the success rate of artificial insemination and on the stillbirth rate in at-risk matings compared to safe matings. *AIS*: artificial insemination success, *SBR*: stillbirth rate. Significant effects are indicated by the corrected *P*-value for multiple tests with a threshold set at α=1%: *$P>1\times10^{-3}$; **$P>1\times10^{-4}$; ***$P>1\times10^{-5}$. NS: not significant.

Table 2. Candidate genes located in MTRDHH regions.

Haplotype (phenotype)[1]	Gene name/Phenotype disorder in mouse and human
MTRDHH1 (Neonatal lethality)	*MMUT:* neonatal, postnatal lethality [MGI:97239]/ methylmalonic aciduria [OMIM# 609058]; *TFAP2B:* neonatal, postnatal, preweaning lethality [MGI:104672]/ patent ductus arteriosus, Char syndrome [OMIM# 601601]; *PKHD1:* perinatal, postnatal, preweaning lethality [MGI:2155808]/ polycystic kidney/ liver disease [OMIM# 606702]
MTRDHH2 (Embryo/fetus lethality)	*DHX36:* embryonic lethality [MGI:1919412]; *SSR3:* neonatal lethality [MGI:1914687]
MTRDHH3 (Juvenile lethality)	*SV2A:* premature death [MGI:1927139]; *ECM1:* preweaning lethality, premature death [MGI:103060]; skin/mucosa/viscera lipoid proteinosis [OMIM# 602201]
MTRDHH4 (Juvenile lethality, morphological disorder)	*KL:* premature death [MGI:1101771]/ tumoral calcinosis [OMIM# 604824]; *BRCA2:* postnatal, prenatal lethality, premature death [MGI:109337]/ Wilms tumor, Fanconi anemia D1 [OMIM# 600185]; *RXFP2:* Polled/Horns phenotype in sheep [OMIA 000483-9940]
MTRDHH5 (Morphological disorder)	*ASIP:* Coat color in sheep [OMIA 000201-9940]; skin/hair/eye pigmentation [OMIM#600201]

[1] Supposed deleterious phenotype in sheep.

embryonic, perinatal or neonatal lethality when altered in mouse or in human (Table 2). In contrast, MTRDHH3 showing also a complete deficit in homozygous animals was not associated with alteration of AIS or SBR. Since lambs are genotyped around three months of age, this haplotype could affect lambs after birth in the preweaning period as supposed by premature death caused by the alteration of the two candidate genes in this region (*SV2A* and *ECM1*, Table 2).

MTRDHH4 and 5 showed a partial deficit in homozygous animals and no significant effect on fertility traits. We hypothesize that these deficits are likely due to either a defect after birth in the juvenile period (alteration of *KL* or *BRCA2* genes for MTRDHH4) or counter-selection based on breed standard. Indeed, horned female and black animals are unwanted in MTR selection scheme. Interestingly, MTRDHH4 hosts the *RXFP2* gene known to be implicated in horn/polled phenotype (Wiedemar and Drögemüller 2015), and *ASIP,* known to be involved in coat color determinism, locates in MTRDHH5 (Norris and Whan 2008).

746. Genetic analysis of colostrum and passive immune transfer in divergent goat lines selected for functional longevity

M. Wicki[1,2*], C. Huau[1], T. Fassier[3] and R. Rupp[1]

[1]GenPhySE, Université de Toulouse, INRAE, Castanet Tolosan, France; [2]Institut de l'Elevage, Castanet-Tolosan, France; [3]Domaine de Bourges, INRAE, Osmoy, France; marine.wicki@inrae.fr

Abstract

The aim of this study is to find early indicators of longevity in two divergent goat lines selected for high or low functional longevity. Passive Immune Transfer (PIT) that is transfer of immunoglobulin (IgG) from mother to kid through colostrum could be one of these indicators. The first step of this project was to study the impact of PIT (n=422) on goat kid's health. Success of PIT had a positive influence on kid's health, which resulted in a decrease in the occurrence of several health problems. Then we estimated genetic parameters for colostrum quality (n=201): heritability was 0.19±0.16 for IgG concentration and 0.37±0.16 for IgG yield. PIT heritability (IgG in blood of kids) was lower: 0.04±0.07. Altogether, the study led to promising results regarding the possibility of integrating the colostrum quality traits into selection.

Introduction

In goat breeding, longevity can be defined as the number of days between first kidding and reform (Palhiere *et al.*, 2018). Functional longevity corresponds to longevity corrected for production level. Among the factors influencing longevity, genetics and breeding conditions in the young animals are critical. Goat kids health status is largely based on the success of passive immune transfer (PIT) that is transfer of immunoglobulin (Ig) from mother to kid. The main consequence of a failure of PIT is the increased risk of mortality; demonstrated in cattle (Imbert, 2005) and sheep (Bekele *et al.*, 1992) mainly due to digestive disorders. In small ruminants, PIT is strongly linked to the ingestion of a quality colostrum in sufficient quantity. Thus, one of the goals of this study was to determine (and quantify) the existence of a genetic component in the observable inter-individual variability in PIT and colostrum quality. Some literature data exist in sheep (Gilbert *et al.* (1998) and cattle (Cordero-Solorzano *et al.* (2021); Conneely *et al.* (2013)). However, such genetic variability has not yet been demonstrated and estimated in goats.

Materials & methods

Animals and phenotypes. This study is based on data from two divergent lines of Alpine goat. Following the method developed by Palhière *et al.*(2018), we made a hyper-selection of dairy goats based on the genetic evaluation for functional longevity of 8,787 Alpine AI bucks. From 2017 to 2021, divergent line goats were bred, at the same conditions,in an INRAE experimental Farm (Bourges, France): 221 low longevity line (low_LGV) and 228 high longevity line (high_LGV). At birth, vigor and weight of the goat kid, litter size and time between birth (actual or estimated hour) and colostrum intake were measured. A blood sample is taken between 1 and 8 days of age in order to proceed with the assay of IgG by radial immuno diffusion (n=422) and asses PIT, which is considered successful for an IgG concentration higher than 10 g/l in the serum. From birth to 4 weeks of age, sanitary measurements are carried out every week on the kids of both sexes (n=441). Finally, at birth the colostrum of the goats was collected during the first two milkings. At this time, the weight of colostrum and the time between calving and milking recorded. Individual samples of colostrum are collected for the assay of IgG by radial immune diffusion (97 low_LGV, 92 high_LGV and 12 other lines). Milk yield, fat and protein content, and SCC were measured every three weeks in first lactation, as part of the official milk records (n=201). Lower numbers are related to fertility or colostrum collection problems.

Animals were cared and handled in accordance with the French legislation on animal experimentation and European Convention for the Protection of Vertebrates Used for Experimental and Other Scientific Purposes (European Directive 86/609) under specific authorization number APAFIS#8613-2017012012585646.

Effect of immune traits on health status. The influence of PIT (fit as a covariate) and genetic line on goat kids health status was studied using a logistic regression model. The events tested were the occurrence (binary 0/1) of several health problems during the first four weeks of goat kids life: diarrhea, nasal discharge, ocular discharge, abnormal body temperature and obstructed breathing. A hindquarters cleanliness score was also studied using the dag score (http://www.flyboss.com.au/sheep-goats/breeding-and-selection/dag-scoring-and-selection.php, X3 classes), which reflects adhesion of fecal material to the breech area. No respiratory problems occurred so we did not analyze this health indicator. In addition to fixed effect of PIT and genetic line, a fixed effect of year of birth was included in the model for dag score.

Genetic parameters estimation. The genetic parameters were estimated for two traits related to colostrum quality (n=201): IgG concentration (IgGc) and yield (IgGy); and three traits related to milk production (n=201): milk yield (MY), the ratio between fat and protein contents (FC/PC) and the lactation somatic cell score (LSCS). We also analyzed the serum IgG concentration (PIT) measured in kids (n=422).

Since the data were not repeated (only one record per animal), all variables were analyzed using the following mixed polygenic model. The model included fixed effect of the year (4 levels from 2018 to 2021) for IgGc, FC/PC, the fixed effects of lactation number (3 levels) and litter size (3 levels) for IgGy, birth year (5 levels from 2017 to 2021) for PIT, and, in addition, age at first calving (3 levels) for MY, FC/PC and LSCS. The random effects included in the model were the additive genetic effect of the animal and the residual. For all these variables, the relationship matrix A was built tracing back 5 generations. The matrix A contains between 950 and 1,474 individuals depending on the trait analyzed. Heritabilities, the different variance components, genetic and phenotypic correlations between dairy and colostrum traits were estimated by bivariate analyses while PIT was studied by univariate analysis All the analyses were done using Wombat (Meyer, 2007).

Results & discussion

Health status. The results of logistic regressions on health indicators are summarized in Table 1. For the majority of health indicators, we note a significant effect of PIT which results in a decrease in the probability of health problems with increasing IgG concentration. For the occurrence of diarrhea, the odd ratio is 0.62, i.e. an increase of 1 g/l of serum IgG decreases by 38% the probability of occurrence of diarrhea during the first 4 weeks of life of the kids. This result agrees with the study of Basoglu and Camkerten (1999) who compared a group of calves with diarrhea and a group of healthy calves. Among the latter, none of them had a PIT failure compared to 35% for the group of diarrheic calves. For ocular and nasal discharges, the odds ratios are 0.41 and 0.51, respectively.

Table 1. Results of analyses of variance (logistic regression) for health indicators.[1]

	Dag score	Diarrhea	Nasal discharge	Ocular discharge	Abnormal temperature
PIT	$<10^{e}$-5	<0.005	$<10^{e}$-6	$<10^{e}$-5	NS
Year of birth	<0.005	NS	*	*	*
Genetic line	NS	NS	NS	<0.1	NS

[1] NS: The effect is non-significant. * effect not be tested because of occurrence disparity between years of birth.

Genetic parameters. Genetic parameters for colostrum and milk production traits are summarized in Table 2. For dairy traits, the heritabilities obtained are in agreement with those found in previous studies in the alpine breed: 0.3 for milk yield (Arnal *et al.*,2019) and 0.20 for the LSCS (Rupp *et al.*, 2011). The heritability of 0.19±0.16 obtained for IgG concentration is close to that found in sheep (0.19±0.12 in Gilbert *et al.*, 1988) and not significantly different from those of cattle (0.20±0.09 in Cordero-Solorzano *et al.* (2021). To our knowledge, there is no literature on genetic parameters for IgG yield. However, Conneely *et al.* (2013) found a heritability of 0.21±0.08 for colostrum weight in cattle, which is not significantly different from our result. Furthermore, the modest positive genetic correlation between MY and IgG yield of 0.36 suggests that genetic selection for milk production applied over many years has not led to a degradation of this second trait, and has even improved it. However, MY seems to be genetically independent of the IgG colostrum concentration. The positive genetic correlation between LSCS and colostrum traits is not negligible (0.58±0.93 for IgG concentration and 0.53±0.43 for IgG yield). The large estimation errors associated with these correlations question the reliability of these results, but if they are confirmed, it will be necessary to better understand why improved colostrum quality is genetically linked to increased mastitis risk. Finally, based solely on the relatively high heritabilities of IgG concentration and IgG yield we can assume that genetic selection on these two traits would be feasible. From an operational point of view, it seems possible to develop a large scale collection system for the concentration of IgG in colostrum using the refractometer (%Brix) for example, which is easier to measure than IgG yield. However, we can partly explain our high estimation errors by the small numbers studied. Therefore, it would be important to refine this estimate of heritability with more data, using additional animals and/or lactations. Indeed, this heritability may be weaker, as found (h^2=0.10) in another study in suckling cattle (Conneely *et al.*, 2013).

Passive immune transfer. The heritability of serum IgG concentration in kids was estimated to be 0.04±0.07. This low value may be due to many factors influencing this trait that we did not capture and analyze in our study, thus increasing the residual variability. Essentially, we can underline that our study does not consider the quality of the colostrum distributed which is likely to be very variable. Despite these untested or uncontrolled factors, the heritability obtained in our study agrees with other studies. Donovan *et al.* (1986) found a heritability of 0.12±0.08 for the IgG concentration and 0.09±0.07 for the total protein content of serum in calves. Haagen *et al.* (2021) estimated the heritability of total serum protein content to be 0.06±0.01 also in cattle. Gilbert *et al.* (1988) nevertheless found a higher heritability in sheep of 0.18±0.06, perhaps due to the large number of lambs (n=964) and the control of the distribution mode (suckling) and the age at blood sampling (36h after birth). Maltecca *et al.* (2007) also found a heritability of 0.18 for this trait in sheep.

Table 2. Genetic parameters for milk production and colostrum traits in Alpine goats. Heritabilities are on the diagonal, genetic correlations in the upper right part and the phenotypic correlations in the lower left part.[1]

	IgG concentration	IgG yield	MY	FC/PC	LSCS
IgG concentration	0.19±0.16	0.73±0.39	-0.15±0.49	-0.03±0.66	0.58±0.93
IgG yield	0.29±0.07	0.37±0.16	0.36±0.31	-0.05±0.51	0.53±0.43
MY	0.01±0.08	0.27±0.08	0.46±0.21	0.42±0.45	0.11±0.6
FC/PC	-0.11±0.08	0.10±0.08	0.06±0.08	0.19±0.16	*
LSCS	-0.05±0.08	-0.07±0.08	-0.05±0.08	*	0.13±0.15

[1] An asterisk indicates software did not reach the desired convergence; results are not interpretable.

Conclusions

Our study confirmed the positive impact of PIT on the health of the kids, resulting in a decrease in the probability of occurrence of various health problems, including digestive disorders. Moreover, IgG concentration and yield in colostrum showed moderate heritabilities. However, the heritability was lower for serum IgG concentration in kids. IgG yield and milk production seem to be genetically positively correlated with each other while IgG concentration has little correlation with milk production. Therefore, it could be useful to improve this trait by selection.

747. Selection signatures in South African indigenous sheep using the HAPFLK approach

I.N. Malan[1,2], S.W.P Cloete[1] and A.H. Molotsi[1*]

[1]Department of Animal Sciences, Stellenbosch University, Matieland, Private bag X1, 7600 Stellenbosch, South Africa; [2]Ministry of Agriculture, Water and Land Reform, Directorate of Agricultural Research and Development, Private Bag 13184, Namibia; annelind@sun.ac.za

Abstract

Selection sweeps have been identified in indigenous sheep breeds using the hapFLK approach. Five indigenous fat-tailed sheep breeds, the Karakul (70), Damara (35), Pedi (30), Zulu (30) and Namaqua Afrikaner (48), one composite fat-tailed breed, the Meatmaster (20), a commercial meat breed, the Dorper (46) and one exotic sheep breed, Merino (98) were genotyped using the 50K Ovine SNP beadchip. Thirteen regions spanning 11 chromosomes were under selection across the breeds. Putative candidate genes associated with the regions under selection involved immune response (BPIFC, CLDN12, CLDN14, TRL4), ultraviolet exposure and thermoregulation (KCNJ5, FZD1, ACADSB, SCNA11), energy metabolism (MYH9) and meat production (PDEZA, UTRN). These results confirm natural selection for adaptive traits such as immunity, heat tolerance and meat production in indigenous sheep breeds.

Introduction

Indigenous sheep breeds are known for their robustness and adaptiveness, potentially superseding exotic breeds especially in semi-arid environments in Southern African regions (Molotsi *et al.* 2017). To unpack the underlying genetic mechanisms associated with the adaptiveness of indigenous sheep; diversity studies, genome-wide association studies, selection sweeps and whole genome sequencing has been implemented in various breeds across the globe (Kijas *et al.* 2009; Kijas *et al.* 2012). Selection sweeps is a method to unveil regions in the genome that has been subjected to strong selection. Candidate genes linked to heat stress (DNAJC28), spermatogenesis and pigmentation (MREG) have been observed in South African indigenous sheep breeds (Molotsi *et al.* 2018). Selection sweeps associated with adaptive traits such as coat colour (ASIP, MC1R) have also been observed by Rochus *et al.* (2018). Selection sweeps in Iranian sheep have been analysed by Manzari *et al.* (2019), identifying candidate genes putatively linked to skeletal development (HOXB13), energy metabolism (CAV1), reproduction (RARG) and immune responses (MRAP) have been identified.

There are different methods used to identify selection sweeps, some approaches use runs of homozygosity, the Bayesian approach uses Fst values, as well as HapFLK. HapFLK, quantifies the differences in frequencies of the haplotypes between the populations (Fariello *et al.* 2013). The hapFLK method allows for analysis between multiple populations and it considers the hierarchical structure of the populations involved (Fariello *et al.* 2013). Therefore, the aim of this study was to use HapFLK in an attempt to identify selection signatures in South African indigenous sheep breeds.

Materials & methods

SNP genotyping data from the 50K Ovine SNP beadchip was sourced for five indigenous fat-tailed sheep breeds, the Karakul (70), Damara (35), Pedi (30), Zulu (30) and Namaqua Afrikaner (48), one composite fat-tailed breed, the Meatmaster (20), a commercial meat breed, the Dorper (46) and one exotic sheep breed, Merino (98). Binary files (bed, bim and fam) generated in PLINK version 1.9 software (Purcell *et al.* 2007) were used to run an analysis based on the hapFLK method and using the Soay sheep breed as the outgroup. A python script was used to generate output files including Reynolds distance matrix,

population tree, kinship matrix, allele frequencies and the FLK results. To visualize plots in the R program, negative log *P*-values were used to generate a Manhattan plot (Figure 1) with the aid of the ape, phangorn, ggplot2 and qqman packages. The suggestive significant line was set at $-\log_{10}(10^{-2})$. The hapFLK values were standardized and estimates were used to generate *P*-values from a normal distribution. Candidate genes (Table 1) within 1 Mb of the SNP of interest were identified by making use of *Ovis aries* gene assemblies on the National Center of Biotechnology Information (NCBI) platform.

Results

The Manhattan plot (Figure 1) depicts thirteen regions that have been under selection, spanning a total of 11 chromosomes. HapFLK *P*-values for individual SNPs were converted to -log values for better representation of the plot.

Discussion

The putative role of those genes listed in Table 1 in ovine metabolism needs consideration in cases where annotated. MSMO1 (chromosome 17) is linked to lipid metabolic processes, particularly cholesterol synthesis (Guan *et al.* 2020). The RAB32 gene located on chromosome 8 is involved in milk fat globule synthesis (Guan *et al.* 2020). Despite these candidate genes being identified in another livestock species (goat), the genetic marker might be in a similar position on analogous chromosomes in the ovine species. Milk production in sheep is important for rearing lambs and is positively associated with increased weaning weights. Most indigenous sheep breeds are kept for meat production. Two genes playing a role in meat production have been under selection, namely PDEZA on chromosome 15 and UTRN on chromosome 8 (Xu *et al.* 2021).

The gene TRL4 on chromosome 2 is related to genes involved in adaptive immune responses unique to sheep (Ha *et al.* 2015). Several genes that are involved in thermoregulation, ultraviolet exposure, skin development and ocular protection have also been identified in this study. The gene ASCL4 on chromosome 3 is responsible for skin barrier function and development, while KCNJ5 on chromosome 1 plays a role in water balance and salt retention (Chebii *et al.* 2020). This finding concurs with recent findings that indigenous sheep breeds (Pedi and Damara) were more water efficient than exotic breeds (Mupfiga, 2022). Several genes (FZD1, ACADSB, and SCNA11 on chromosomes 4, 22, and 19) were related to thermoregulation, temperature control and thermal stress (Ababaikeri *et al.* 2020; Librado *et al.* 2015). Maintaining traits linked to thermal stress, pigmentation is vital to the survival of sheep breeds in hot and arid environments. Heat stress from exposure could compromise production. Farming with animals that can cope with natural ambient temperatures could avert this. In conclusion, this study confirms natural selection for adaptive traits such as immunity, heat tolerance and meat production in indigenous sheep breeds.

Abstract

It is well accepted that reproduction is a key profit driver in small stock production systems. The traditional approach for targeting reproductive output in many countries has been through composite trait selection, such as number of lambs weaned per ewe mated (NLW). However, there could be benefit in considering the components of NLW individually. This study reports across-flock analyses of NLW and its components, conception rate, litter size and ewe rearing ability in South African Merino resource flocks. Direct genetic effects were small, but all traits were heritable, estimates ranging between 0.02 for ewe rearing ability to 0.06 for litter size. The only noteworthy unfavourable genetic correlation was between litter size and ewe rearing ability. The traits reported here should be suitable for incorporation into commercial breeding programs of the wider industry.

Introduction

Selection for reproduction both in Australia and South Africa has in the past been based on composite traits such as the number of lambs born or weaned (NLW; Brien *et al.*, 2014). Bunter and Brown (2015) proposed using the components of NLW, such as conception rate, litter size, and rearing ability individually, since sole emphasis on composite traits could risk unpredictable outcomes as correlated responses (Bunter *et al.*, 2020). Targeting selected components could deliver more flexible selection objectives (Swan and Bunter, 2021). For example, the high requirements of ewes bearing multiples could give reason to emphasize conception rate, but not litter size in challenging production environments. In Australia, a pipeline for the evaluation of such component traits has since been developed (Bunter *et al.*, 2020) and incorporated into the national genetic evaluation of Sheep Genetics (Bunter *et al.*, 2019, 2020).

The prospects of similar developments should be evaluated for South African Merinos, but the present data structure in recorded flocks poorly supports the decomposition of NLW. A lack of mating lists restricts NLW to a 'per ewe lambed' basis and thus lacks conception rate. The sporadic recording of dead lambs in pedigrees also leads to little variation between lambs born and weaned, and thus does not appropriately reflect ewe rearing ability. However, South Africa hosts multiple Merino resource flocks maintained under well-developed recording programs by science and technology institutions (Schoeman *et al.*, 2010). Data from these flocks could serve as an example to evaluate these component traits, but studies on these flocks have thus far been restricted to within-flock analyses of only selected traits (Cloete *et al.*, 2017). The aim of this study was thus to conduct a genetic evaluation of the components of NLW from an across-flock analysis extended to four SA resource flocks.

Materials & methods

The records used in this study originated from the Elsenburg (n=6,807), Grootfontein (n=7,825), Cradock (n=8,940) and Langgewens (n=1,230) Merino resource flocks maintained across the Western and Eastern Cape provinces of South Africa (Schoeman *et al.*, 2010). Older records and pedigrees were truncated to

1986 to align with the start of the Elsenburg selection experiment. Reproduction traits were recorded as (n=24,802) repeated records on 7,173 naturally joined ewes (3.45 records per dam). This included the composite trait NLW which was decomposed into the underlying component traits, namely: conception rate (CON: 0 = did not conceive, 1 = conceived), litter size (1 to N lambs born) and ewe rearing ability (NLW/number of lambs born), where the latter two traits were censored in the case where CON = 0.

The age of the ewe (2 to 7+ years) was tested for significance ($P<0.05$) as a fixed effect, while contemporary groups in which the ewe was weaned as a lamb and also in which specific ewes lambed were fit as sparse fixed. The contemporary groups were generally defined by concatenating flock × year × season, but special cases like the selection line groups of the Elsenburg flock (Cloete *et al.*, 2004; 2017) and the Langgewens ewes mated to non-Merino sires was also accounted for by extended contemporary group definitions. Random effects considered were the direct genetic (σ^2_a) and ewe permanent environmental (σ^2_{ewe}) effects. Criteria for the retention of random effects were based on significant ($P<0.05$) differences according to the log-likelihood ratio test. All analyses commenced in ASREML V4.2 (Gilmour *et al.*, 2015). A single-trait repeatability model was used to derive the variance components of NLW, and pairwise two-trait models were used to estimate the relevant correlations of NLW with CON, LS and ERA, respectively. A three-trait analysis was used to derive the parameters and correlations among CON, LS and ERA.

Results

Ewe age was significant ($P<0.01$) in all traits considered in this study, with the best performance in ewes of intermediate (3-4 years) age. The coefficients of variation showed that component traits were less variable than NLW, but still exhibited useful variation to facilitate selection (Table 1). The addition of the σ^2_a and σ^2_{ewe} variance components to the operational model that only included systematic effects was associated with significant ($P<0.05$) increases in log-likelihood values for all traits. However, the h^2 of reproduction traits was generally low to very low (Table 1), ranging from 0.02 for ERA to 0.06 for LS. With the exception of LS, the ewe permanent environmental ratio (pe^2) was generally of larger magnitude that the corresponding h^2. Genetic correlations of NLW with the component traits were moderate to high at 0.59 to 0.70 (Table 2). This was expected given the part-whole nature underlying these relationships. Correlations among the component traits were either low to moderate or estimated with a low accuracy. Of some importance was the negative and unfavourable relationship of LS with ERA, which was negative on both the genetic and phenotypic levels.

Table 1. Summary statistics as well as variance components and ratios for number of lambs weaned (NLW), conception (CON), litter size (LS) and ewe rearing ability (ERA).

	Trait

Table 2. Genetic (above diagonal) and phenotypic (below) correlations among number of lambs weaned (NLW), conception (CON), litter size (LS) and ewe rearing ability (ERA).

	NLW	CON	LS	ERA
NLW		0.70±0.08	0.66±0.08	0.59±0.12
CON	0.59±0.004		0.16±0.13	0.25±0.22
LS	0.55±0.01	-0.05±0.01		-0.37±0.17
ERA	0.76±0.003	0.07±0.01	-0.15±0.01	

Discussion

All traits in this study were heritable and could be targeted by genetic selection, but pe^2 effects were generally of a considerably larger magnitude, with the exception of that observed for LS. Generally, similar pe^2 estimates were reported for the literature for the component traits CON (0.01-0.14) and LS (0.02-0.06) (Bunter and Brown, 2015; Bunter *et al.*, 2016, 2020; Cloete *et al.*, 2017; Walkom and Brown, 2017; Bunter and Swan, 2021) as well as ERA (0.05) (Bunter *et al.*, 2016). The low h^2 for the composite and component reproduction traits also agreed with what is generally expected from the literature for NLW (0.03-0.10) (Cloete *et al.*, 2004, 2017; Bunter and Brown, 2015; Bunter *et al.* 2016; Walkom and Brown, 2017) as well as CON (0.02-0.09) (Bunter and Brown, 2015; Walkom and Brown, 2017; Bunter *et al.*, 2020; Bunter and Swan, 2021). The h^2 of LS was slightly higher, but on the lower end of the range reported by previous studies (0.04-0.13) (Bunter and Brown, 2015; Bunter *et al.*, 2016, 2020; Cloete *et al.*, 2017; Walkom and Brown, 2017; Bunter and Swan, 2021), whereas a very low h^2 for ERA was well supported by the literature (0.01-0.08) (Bunter *et al.*, 2016, 2020; Walkom and Brown, 2017; Bunter and Swan, 2021). With a similar h^2 for NLW compared to the component traits, there should be little advantage in the use of the composite trait. In turn, targeting component traits could be beneficial, as they will more closely reflect the aetiology underlying specific reproduction outcomes. Overall, the correlations reported in Table 2 did not suggest strong or unfavourable responses from emphasis on component traits, and the low genetic correlations between CON and LS supported the premise that these traits could be targeted individually. The negative relationship between LS and ERA was expected, given the well-known higher susceptibility of multiples to adverse conditions. However, if also considering the higher h^2 of LS, it remains important to note that LS should not be targeted without additionally considering ERA (Bunter *et al.*, 2020), or lamb survival (Nel *et al.*, 2021), which is not expressed by NLW explicitly.

In conclusion, a higher resolution focus on specific characteristics will be limited by what information can be practically gathered on a large scale, but the traits reported here were all derived under relatively standard recording procedures. Thus, it should be feasible for commercial programs to accommodate the protocols followed in the resource flocks.

749. Diversity status and future breeding strategy for Tatra hound in Slovakia

R. Kasarda* and N. Moravčíková

Slovak University of Agriculture in Nitra, Tr. A. Hlinku 2, 949 76 Nitra, Slovak Republic;
radovan.kasarda@uniag.sk

Abstract

The aim of this study was to analyse the level of genetic diversity and inbreeding based on DNA using Canine SNP Bead Chip. The total number of genotyped individuals was 52. Relative low average minor allele frequency (MAF=0.25) indicates an increase of homozygotes proportion. The level of genomic inbreeding derived from homozygous excess ranged from -0.12 to 0.23 (F_{HOM}=-0.0113). Observed results showed that the inbreeding in the current generation is at the level 1.89%. Due to closed herdbook and higher probability of co-selection of relatives the future increase of the inbreeding in the Tatra hound population could be expected. Tatra Hound Breeders Club in Slovakia intends to apply family and line-breeding to manage increase in inbreeding per generationon sustainable level (bellow 1%) to prevent negative effect of inbreeding depression.

Introduction

Significant changes can be observed in Slovakia in the ownership and the structure of the farmland. Due to the current development, natural areas become more fragmented (building and construction, highway network) with low acreage, which copes with hunting areas. Due to the changes in the structure of hunting areas, there is pressure on breeds structure and dog performance.

In 2009, a group of dog breeders defined the breeding goal of Tatra Hound (TH). TH is a composite breed based on autochthonous non-pedigreed females, local Slovakian Hound (FCI standard No. 244), Bavarian Mountain Hound (FCI 217) and Standard Dachshund (FCI 148). The breeding program was established to create a new breed that will fulfil the present needs of hunting practice in Slovakia. At present, more than 1,400 individuals are registered in the herd book with fully traced pedigrees minimum up to the 4th generation of ancestors. As the number of founders is limited and the herd book closed, the mating program currently plays an important role.

In general, dogs are recognised as one of the most inbreed domestic animals, which is coming from the fact that a limited number of ancestors (often derived from common founders) and mating of close relatives to fix specific traits are relatively common (Sams and Boyko, 2019). Such mating results in the formation of long homozygous segments across DNA known as runs of homozygosity (ROH) (Gibson *et al.* 2006). Not surprisingly, ROH segments were identified even in grey wolves (Randi 2011, Gómez-Sanchez *et al.* 2018).Identification of ROH segments is essential for diversity analyses not only in the farm but also in companion animals as prevention of negative effect of inbreeding depression in small local populations under strong selection pressure (Kasarda *et al.* 2016, Kukučková *et al.* 2017, Moravčíková *et al.* 2019). Therefore, the aim of this study was to analyse the level of genetic diversity and genomic inbreeding in a small local population of the Tatra Hound breed.

Materials & methods

The total number of genotyped individuals was 52. Canine – Ilumina 230k HD Chip containing 220,853 SNPs was used for genotyping (211,256 autosomal SNPs with known position). Standard manipulation and

pruning of SNP data have been made in PLINK 1.9 (Chang *et al.* 2015). After quality control (--geno 0.1, --mind 0.1 and --maf 0.01), 162,776 SNP and 52 individuals were left for the analysis.

Diversity parameters. PLINK 1.9 (Chang *et al.* 2015) was used to calculate minor allele frequency (MAF), observed (H_o) and expected heterozygosity (H_e) and genomic inbreeding derived from the genome-wide homozygous excess (F_{HOM}). Package *detectRUNS* (Biscarini *et al.* 2015) was used to calculate genomic inbreeding derived from ROH segments distribution in the genome (F_{ROH}) under software R (R Core Team, 2021).

Screening of ROH of different lengths (0-2, 2-4, 4-8, 8-16, and >16 Mbp) was used to test the effect of the mating program in Tatra hound on the distinction between genetic information inherited from different generations of ancestors. The ROH were defined as genomic segments with a minimum 500 kb (Sams and Boyko, 2019) containing at least 46 consecutive homozygous SNP genotypes no more than 1000 kb apart. Missing or heterozygous genotypes in ROH were not allowed. In addition, each ROH had to have a minimum of one SNP per 5000 kb. Lencz *et al.* (2007) formula was used to calculate the minimum number of SNPs in the ROH. F_{ROH} was calculated by dividing the sum of the ROH length (kb) in the length class by the total length of the autosomal genome (kb) covered by the SNPs.

Genetic structure of the population. The population stratification degree was quantified by calculating Nei's genetic distances on an individual level using the R package *StAMPP* (Pembleton *et al.*, 2013) and visualised as a heatmap in program R (R Core Team, 2021).

Results

The average minor allele frequency (MAF=0.248) was low, indicating an increase of proportion of homozygotes. Similarly, the average observed H_o=0.336 and expected heterozygosity H_e=0.332 indicated a higher proportion of homozygous genotypes in the gene pool of the Tatra Hound population. The average level of genomic inbreeding F_{HOM} was -0.011, ranging from -0.118 to 0.229. The results of F_{ROH} calculated across five different length classes are summarised in Table 1. The higher the length of ROH segments, the lower F_{ROH} observed, i.e. higher historical than recent inbreeding in population. Observed results showed that the inbreeding in the current generation is at the level 1.89%. The population stratification degree is visualised as a heatmap in Figure 1. As indicated in Figure 1. the population is clustered into two main clusters (red circles) according to the breeding strategy and the fact that there are two basic coat colours (black and red) in the Tatra hound inherited from source breeds: Slovakian Hound and Standard Dachshund (black) and Bavarian Mountain Hound (red). Further clustering indicates basic family and line structure in the population.

Table 1. Summary statistics for ROH per class.

ROH class (Mbp)	No. of ROH	Distribution of ROH (%)	Mean length ROH	F_{ROH} (%)
0-2	3,503	0.642	1.064	12.09
2-4	1,027	0.188	2.808	8.84
4-8	611	0.112	5.558	6.45
8-16	255	0.047	10.519	3.97
>16	58	0.011	20.067	1.89

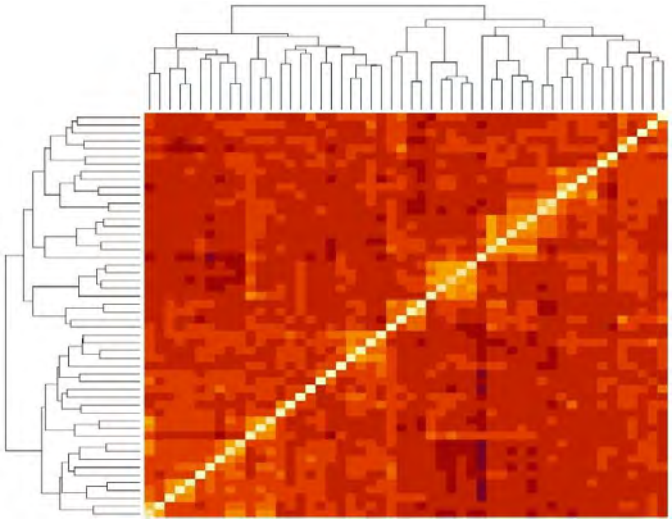

Figure 1. The Tatra hound population stratification degree (dark red = un-related; light yellow=related).

Discussion

Most dog breeds are kept for pleasure, show, sport, and hobby. However, a special place belongs to hunting dog breeding. Keeping dogs for hunting purposes is traced back to the early beginning of domestication. Today, humans better understand genetics and animal breeding and are developing new strategies using biotechnology and progressing in genetic engineering. As well documented in farm animals, progress in biotechnology and genetic engineering could speed up the selection progress. However, especially in the case of local populations, intensive selection can be accompanied by a risk of diversity damage (Curik *et al.* 2017). Therefore, this study intended to view Tatra hound population status and stratification to set up future breeding strategy better.

According to the calculated H_o and H_e the population is in equilibrium (P=0.95, χ^2-test). The negative values of F_{HOM} reflect the fact that F_{HOM} cannot distinguish IBD and IBS alleles, therefore overestimating inbreeding in population (Shi *et al.* 2020). Negative F_{HOM} values indicate less homozygous individuals in population than expected, i.e. observed heterozygosity is larger than expected heterozygosity.

The longer the ROH segments, the closer generation to the common ancestor, i.e. short ROH segments indicate the level of historical inbreeding (founders). Long segments reflect the state of inbreeding in current generations. In Tatra hound, historical and present inbreeding is generally lower than in well-established breeds with a long history like German shepherd, Belgian Shepherd or Czechoslovakian Wolfdog (Moravčíková *et al.* 2021), however higher compared to the wild ancestor of all dogs, grey wolf. Due to closed herdbook and higher probability of co-selection of relatives the future increase of the inbreeding in the Tatra hound population could be expected.

Tatra Hound Breeders Club in Slovakia intends to apply family and line-breeding to manage increase in inbreeding per generationon sustainable level (bellow 1%) to prevent negative effect of inbreeding depression. Furthermore, the Tatra hound breeders club is following regulations and recommendations of FCI to breed high performance, healthy dogs according to the highest standards and current scientific knowledge.

750. Genome-wide association study for ectopic ureter in three dog breeds

A. Stella[1*], V. Cassani[2], G. Majolino[3], P. Cozzi[1], S. Biffani[1], F. Biscarini[1] and G. Minozzi[4]

[1]Institute of Agricultural Biology and Biotechnology, Italian National Research Council – CNR, Via Edoardo Bassini 15, 20133 Milan, Italy; [2]Independent DVM, via Manara 7 Castano Primo, Italy; [3]Independent DVM, Vicolo del Forno 5, 43044 Collecchio PR, Italy; [4]Department of Veterinary Medicine DIMEVET, University of Milan, Via dell'università, 26900 Lodi, Italy; alessandra.stella@cnr.it

Abstract

The objective of the study was the identification of genomic regions associated with the occurrence of canine ectopic ureter, a congenital abnormality of the urinary system that requires surgical intervention. The study was applied to three breeds: Labrador Retriever, Golden Retriever and Newfoundland. A case: control design was used, comprising 263 animals. Numbers of cases/controls for the three breeds were Labrador Retriever (48/50), Golden Retriever (60/60) and Newfoundland (15/20). After quality control, 137,244 markers were used in the analysis. Data were analysed with a mixed model that accounted for breed and sex. After applying a Bonferroni correction, 4, 9 and 5 significant markers were observed in three regions on canine chromosomes CFA 5, 27 and 30 respectively. A preliminary GO analysis showed enrichment in processes related to regulation of signalling and system development, among others.

Introduction

Ectopic ureter (EU) is a congenital defect of the urinary system in which the ureter inserts anywhere other than the vesical trigone (Osborne *et al.*, 1995). This anatomical change can be unilateral or bilateral. The occurrence of ectopic ureter in the dog has been estimated to be 0.016% (Dean *et al.*, 1988), however, veterinarians indicate an increasing and prevalent incidence in some popular breeds. Dogs with ectopic ureters usually present urinary incontinence, male and females may present symptoms at different ages, due to difference in anatomy, and different breeds seems to exhibit a different female to male cases ratio (Hayes, 1984). It is thought to occur because of disruption in normal embryogenesis and is commonly associated with other abnormalities of the urogenital tract. Gallana *et al.* (2018) estimated the heritability of the phenotype EU (classified in three classes based on anatomical diagnosis and severity) to be very high (0.71), which may indicate involvement of one or a few major genes. The same authors applied genome-wide association analysis (GWAS) to a subsample and identified 6 loci on canine chromosomes 3, 17, 27 and 30 with 16 SNPs significantly associated with the defect. The study was performed using data from the Entlebucher breed, a small population with high inbreeding rate. This may have affected the results. The aim of our study is to investigate genome-wide association for EU in three breeds that have recorded a growing number of cases in the last decade: Labrador retriever, Golden Retriever and Newfoundland.

Materials & methods

Samples of EU cases were collected from 2017 through 2021 by veterinarians, with the informed consent of the owners (breeders, in some cases). Affected individuals were: 48 Labrador Retrievers (LAB), 60 Golden Retriever (GOL) and 15 Newfoundlands (NEW). Pedigree information was not available. Cases were matched with data from healthy unrelated individuals for each breed: 50 LAB, 60 GOL and 20 NEW yielding a total dataset of 263 individuals. Blood samples were collected in EDTA vacutainers (BD Vacutainer Systems, Plymouth, UK), refrigerated at 4 °C and then stored at -20 °C. DNA was extracted from whole blood samples using the NucleoSpinVRBlood kit (Macherey-Nagel, Duren, Germany). The Illumina CanineHD bead chip was used for genotyping the samples.

Data underwent quality control using Plink v1.9 (Chang *et al*., 2015). The final dataset was pruned for low minor allele frequency (0.05), genotyping efficiency (SNP with more than 5% missing) and failure to meet Hardy-Weinberg equilibrium (1×10^{-6}). The CanFam3.1 assembly served as the reference genome. SNP with more than 5% of data missing, or with MAF≤1% were removed. Genotyping efficiency for samples was also verified, and samples with more than 5% missing data were removed. After quality control, 137,244 markers were included in the GWAS analysis. Only autosomes were included in the GWAS. The software GEMMA v0.98 (Zhou *et al.*, 2012) was used to perform association analysis using a mixed model approach with breed and sex included in the model. Bonferroni correction was applied to estimate 0.05 significance level. ClueGO (Bindea *et al.*, 2009) was used for biological interpretation of genes underlying regions of interest.

Results

A total of 4, 9 and 5 significant markers were observed in three regions on canine chromosomes CFA 5, 27 and 30 respectively (Figure 1). Interestingly, the most significant SNP identified in our study located on chromosome 27 (position 23,004,532) overlaps closely with the region identified by Gallana *et al.* (2018) on chromosome 27 defined by 4 highly significant SNPs in positions 22,783,765 to position 23,114,194. Among the genes underlying the significant regions on chromosome 5, PDE4B and FGGY are associated with congenital organ defects, although mainly cardiac.

A preliminary GO analysis of a subset of genes (n=30) underlying the regions of interest on chromosome 5, 27 and 30 showed enrichment in biological processes related to regulation of signalling, negative regulation of biological processes, system development and regulation of cell communication.

Discussion

In the only previous case-control genome wide association study conducted on canine ectopic ureter Gallana *et al.* (2018) identified 16 significantly associated SNPs. Of these, 13 SNPs fall in the same chromosomes identified in our study, namely chromosomes 27 and 30. In detail 11 SNPs are located on chromosome 27 and 2 on chromosome 30.

Despite indicating the HOX gene cluster and the SOX5 gene as potential positional candidates on chromosome 27 and *SMAD6* and *SMAD3* on chromosome 30 Gallana *et al.* (2018) indicate that none of the genes are strong functional candidates.

However, recent gene expression and protein levels studies conducted in women affected by urinary incontinence and pelvic prolapse identified that SMAD3 gene expression levels were significantly lower in affected women compared to the control patients (P=0.008) (Akin *et al.* 2021). The reduction in the

The horizontal line denotes genome-wide significance based on Bonferroni-corrected *P*-values. (b) Q–Q plot of samples used in GWAS showing the -log10 of the expected versus the observed *P*-values.

expression levels of SMAD3 may indicate a functional importance and possible variability in its close regulatory regions should be further explored.

751. Linkage disequilibrium variability in the Czechoslovakian wolfdog genome as a result of long-term artificial selection

N. Moravčíková[1*], R. Kasarda[1], L. Vostrý[2], H. Vostrá-Vydrová[2], J. Vašek[2] and D. Čílová[2]

Abstract

The genetic makeup of any dog breed is significantly affected by mating close relatives carrying preferred phenotypic traits by breeders. Such mating simultaneously leads to changes in the linkage disequilibrium, mainly in genomic regions controlling preferred phenotypes. Following this assumption, the study aimed to analyse the variability in linkage disequilibrium (LD) in the genome of the Czechoslovakian wolfdog compared to its wild ancestor grey wolf and identify genomic regions significantly subject to artificial selection. The database included genomic information of 60 animals genotyped using the CanineHD chip. The variability in linkage disequilibrium was tested by comparing the LD level in target regions in the Czechoslovakian wolfdog and grey wolf genomes and quantified by calculating varLD score. The strongest signal of artificial selection was found on autosome 17. Inside genomic regions under selection pressure were located 59 protein-coding genes with diverse functions in the organism.

Introduction

When considering the genetic makeup of any dog breed, repeated close mating of relatives was used to fix breed-specific phenotypic traits preferred by breeders. Such a mating usually resulted in various alterations in the genome, including changes in allele frequencies (Cagan and Blass, 2016), the formation of long runs of homozygosity (Caniglia *et al.*, 2018) or changes in linkage disequilibrium (Gray *et al.*, 2009).

The Czechoslovakian wolfdog is a large dog reminiscent of a wolf. Because the Czechoslovakian wolfdog was created by crossing Carpathian grey wolf and German Shepherd dog, different patterns are manifested mainly in its behaviour than in other breeds of dogs. This breed retains the anatomical advantages of the wolf, thanks to which it can run steadily, adapt to climatic conditions and orient itself well in the field. Animals belonging to this breed are temperamental and active dogs with extremely developed senses and orientation in the field. In the current breeding program, great emphasis is placed on animals trainability. The genomic diversity of Czechoslovakian Wolfdog was analysed in several previous studies (e.g. Smetanová *et al.*, 2015; Canaglia *et al.*, 2018; Moravčíková *et al.*, 2021).

The aim of this study is to compare the level of linkage disequilibrium in genomes of Czechoslovakian wolfdog and grey wolf to find genomic regions that were subject to artificial selection and identify protein-coding genes located inside genomic regions under strong selection pressure.

Materials & methods

The genomic information of Czechoslovakian wolfdog (30 animals) and grey wolf (30 animals) was used to analyse the effect of artificial selection on the genome-wide level of linkage disequilibrium (LD) to identify those genomic regions that have been most frequently subjected to selection in the Czechoslovakian wolfdog genome. In the case of the Czechoslovakian wolfdog, nuclear DNA was genotyped by the CanineHD 230k chip in a commercial lab. The genomic information of grey wolves genotyped by the CanineHD 130k chip was retrieved from a web repository (Shannon *et al.*, 2016). The standard quality control of genotyping data was performed by Plink v1.9 (Chang *et al.*, 2015) to filter out non-autosomal SNPs, loci with unknown chromosomal positions, all animals and SNPs with a call rate lower than 90%. In addition, the minimum

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_751, © N. Moravčíková *et al.* 2022

minor allele frequency was set up to 1%. After SNP pruning, 136360 SNP markers remained and all 60 animals.

Differences in the LD level in the autosomal genome of the Czechoslovakian wolfdog and grey wolf were quantified using the VarLD program (Ong and Teo, 2010). This program compares LD in target regions in the genome between two groups and is based on the assumption that selection of specific genetic variants in the target region of one population changes the LD level in that region at the same time, while in another population not affected by the same selection pressure the level of LD remains unchanged. LD values (expressed by r_{LD}^2) calculated for windows containing 50 SNPs within each autosome were transformed into standardised varLD scores (S_i^*), based on which selection signals were identified. Genomic regions significantly affected by artificial selection were recognised as regions containing 99.9% of signals. The distribution of varLD standardised scores across the autosomal genome was visualised by R package qqman (Turner, 2018). Protein-coding genes located inside selection signals were detected by R package ensembldb (Rainer *et al.*, 2019).

Results

The analysis of LD level showed a total of 19 regions under strong selection pressure in the Czechoslovakian wolfdog genome spread across seven autosomes (Table 1). The largest region covering 6.08 Mbp (from 30,064,957 to 36,146,893 bp) was found on autosome 17, which at the same time showed the strongest signal of selection (Figure 1). On the other hand, the shortest region was identified on autosome 1 (from 24,486,423 to 24,717,376 bp). Overall, 125 protein-coding genes with diverse biological functions were identified within the detected selection signals.

[1] Canine autosome.

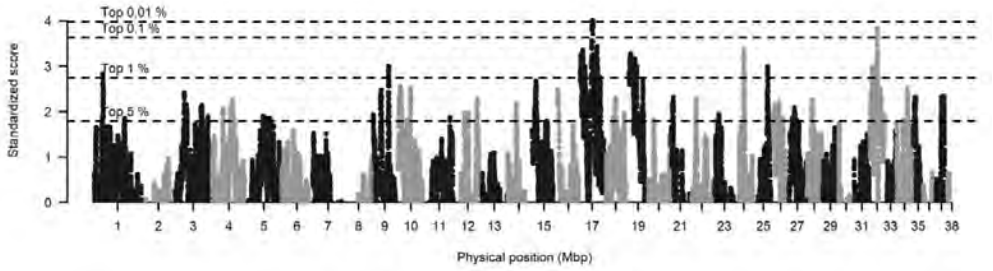

Figure 1. Distribution of varLD standardised score across autosomal genome.

Discussion

The analysis of linkage disequilibrium variability in the genome of the Czechoslovakian wolfdog confirmed that the artificial selection acted in specific genomic regions controlling different phenotypic traits, mainly coat colour, reproduction, growth, muscle and trainability.

Two genes (MC5R and ASIP) responsible for coat colour in dogs were detected within selection signals on autosomes 1 and 24. The MC5R gene was found to be related to the shedding and coat length of dogs (Hayward *et al.*, 2016) and the ASIP gene cooperates with the MC1R gene for switching between red and black pigments in dog hair (Dreger *et al.*, 2020).

Some of the genes located in regions under strong selection pressure were previously associated with reproduction in dogs, e.g. PGRMC2 (Tahir *et al.*, 2012). On the other hand, the ASIC2 located near signal on autosome 9 was found to be related to dog herding, predation, temperament and trainability traits (Shan *et al.*, 2021). On autosomes 9, 19 and were identified genes linked to muscle formation (MYO1D, MYO7B and SCD5).

On autosome 17 within selection signals, two genes causing eye diseases in dogs were found. The CYP1B1 gene was in previous studies associated with primary open-angle glaucoma in beagles (Kato *et al.*, 2009), and the NPHP1 gene was linked to retinal disease (Ahonen *et al.*, 2014). This indicates that artificial selection can affect genomic regions controlling preferred phenotypes as well as genomic regions that interact with them on a DNA level.

752. Applications of single-molecule real-time isoform sequencing (Iso-Seq) for unravelling complexity of dog transcriptomes

W. Zhang*, L. Eory, M. Salavati, E. Clark, J. Smith, A.L. Archibald and J.J. Schoenebeck*

The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush, Midlothian, EH25 9RG, United Kingdom; wengang.zhang@ed.ac.uk; jeff.schoenebeck@roslin.ed.ac.uk

Abstract

Here we present a summary of the generation of dog Single-molecule Real-time Isoform Sequencing (Iso-Seq) data, and its application for transcriptome annotation. Iso-Seq libraries from six tissues were sequenced, and read clean-up was implemented with IsoSeq V3 tools. A high retention rate in demultiplexing and refining steps, as well as a high mapping rate (90%) of Full-length non-concatemer (FLNC) reads, guaranteed enough useful information for subsequent analyses. Finally, 17,766-45,170 clustered transcripts from the six libraries were aligned to the ROS_Cfam_1.0, a male Labrador retriever dog reference genome assembly. In terms of annotation, we identified 14,059 to 26,263 transcripts and 4,985 to 10,457 genes with the sequence data in each of the libraries, with 32 to 68% unique transcripts being expressed. Coding transcripts in each tissue are expressed in a relatively stable manner, from 60-70%. This study provides an improved dog genome annotation resource and offers new insights into tissue-specific transcriptome pattern.

Introduction

Characterization of the transcriptome is crucial to understanding gene function, biological processes, and cellular states. The most popular and easily accessible sources of transcriptome information are those provided by RefSeq and Ensembl using complex annotation pipelines and multiple data sources. However, these annotations have a portion of mis-annotated genes and are far from complete (Frankish *et al.* 2015, Uszczynska-Ratajczak *et al.* 2018).

In recent years, the development of Single-molecule Real-time Isoform Sequencing (Iso-Seq) has enabled generation of transcript reads of more than 10 Kb, which allows for full length sequencing of native RNA isoforms including messenger and noncoding transcripts.

Many studies have discussed novel transcript detection with the aid of Iso-Seq (Leung 2021, Ali 2021). In short, the production of Iso-Seq data using Pacific Biosciences (PacBio) SMRT (Single-molecule real-time) technology begins with a circularised cDNA library. Library molecules contain cDNA, primer sites for polymerase, and barcodes for sequencing pooled samples. Sequencing occurs when fluorescent signals emitted during the replication of the library's cDNA molecules are imaged and coded as bases. The raw data produced by sequencing are called circular consensus sequencing (CCS) reads. Further processing from pooled experiments includes demultiplexing CCS reads according to their barcode to generate full length (FL) reads. Of note, library construction can produce concatemeric cDNA molecules; to remove these artefacts, FL reads are processed to split concatemeric reads into individual transcripts termed full length non-concatemeric reads (FLNC). Finally, FLNC reads are collapsed via clustering algorithms to provide the sequences of unique transcripts. With post-sequencing processing, the counts of CSS, FL, FLNC, and clusters should become successively smaller as artefacts and redundancy are removed. Typically, the processed isoform data is presented in fasta file format, which can be aligned to a genome assembly to assign positional context. To discriminate coding from non-coding, transcripts are typically aligned with protein databases such as UniProt (The UniProt Consortium, 2021) or their alignment processed by tools such as FEELnc, a program developed to annotate genes that encode long noncoding RNA (Wucher *et al.*, 2017).

In this study, we have employed the Iso-Seq technology to generate a full-length transcriptome from multiple tissues of dogs. We explore the characteristics of the Iso-Seq data, and show its capacity for dog transcriptome annotation in the future.

Materials & methods

Iso-Seq data generation. RNA from three dogs was pooled by tissue to maximise detection of tissue-specific transcripts. We generated SMRT cell libraries based on TeloPrime Full-Length cDNA Amplification Kit V2, which selects the methylated G capped transcripts in amplification. A total of 8 SMRT cells were sequenced corresponding to 6 types of tissues: adrenal gland, cerebellum, liver, testis, tracheal cartilage, and scapular lymph node. Both libraries construction and sequencing on the Pacific Biosciences Sequel platform were implemented at the Vienna BioCenter Core Facilities. Sequencing data was deposited under the accession PRJEB44465.

Initial Iso-seq QC and analysis. Iso-Seq raw data were processed using the IsoSeq v3 pipeline to generate transcript sequences. The reads were aligned to the ROS_Cfam_1.0 genome with minimap2 (Li 2018), and transcriptome annotation was produced by running cDNA_Cupcake collapse.

Results & discussion

Six cDNA libraries were sequenced using SMRT technology on the PacBio Sequel platform (Figure 1A) and yielded high quality clustered sequences after processing with the IsoSeq3 pipeline. The average length of circular consensus sequencing (CCS) reads in the six libraries ranged between 1,526 bp to 2,013 bp and follow an approximately normal distribution with 90% of the reads ranging from 614 bp to 3,016 bp (Figure 1B). Table 1 shows the number of reads after each IsoSeq V3 step. In the demultiplexing step, 93.8% reads were retained on average, and in the refining step, on average 96.3% reads were maintained. The mapping ability of the Full-length Non-Concatemer (FLNC) reads in the six libraries was between 87 and 94%, with lymph node library having a slightly higher proportion of unmapped reads (13.1%) and multiple mapping reads (2.3%) than the other libraries (Figure 1C. Thus, the high retention rate in IsoSeq V3 processing and the high mapping rate of the FLNC reads indicated the good quality of the Iso-Seq data generated in this study.

Among the six tissues, brain cerebellum and liver were both sequenced on two SMRT cells and therefore have the most CCS, FL, and FLNC reads. Because the final clustering step is related to gene expression abundance in tissues, the number of clustered sequences in liver dropped dramatically. Finally, the clustering step for the six libraries yielded 17.8K to 45.2K polished sequences for subsequent annotation.

Table 1. Number of reads for each tissue after each step in the IsoSeq V3 analyses.

Tissue	CCS[1]	FL[2]	FLNC[3]	Clustered sequences
Adrenal gland	451,150	426,713	413,301	23,534
Brain cerebellum	735,425	694,546	677,261	45,170
Lymph node	454,776	425,398	407,469	18,338
Liver	642,032	608,423	593,046	25,663
Tracheal cartilage	396,669	369,628	352,364	17,766
Testis	415,720	383,018	362,361	26,782

[1] Circular consensus sequencing.
[2] Full-length reads.
[3] Full-length non-concatemer reads.

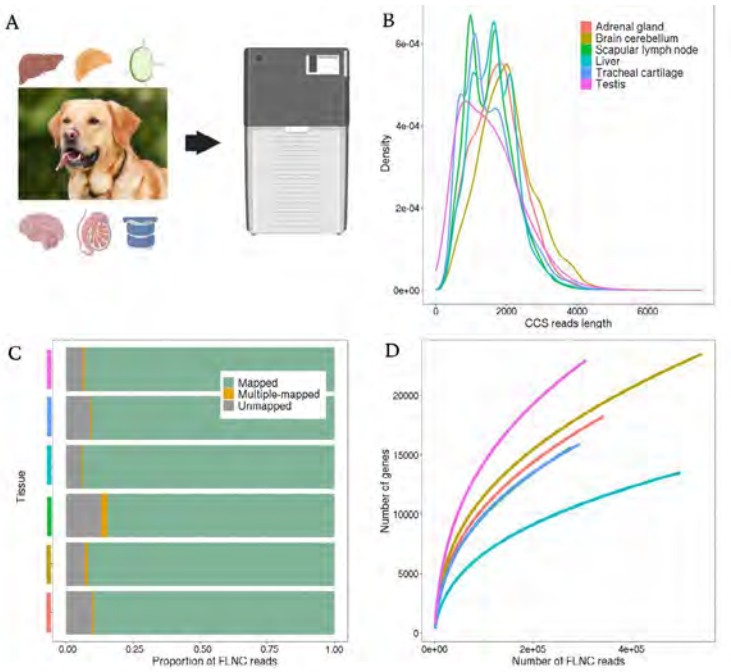

Figure 1. Overview of generation and processing of Iso-Seq data. (A) RNA from six tissues (adrenal gland, cerebellum, liver, testis, tracheal cartilage, and scapular lymph node) were sequenced on the PacBio Sequel platform. Graphic was created with BioRender.com. (B) Circular consensus sequencing (CCS) read length distribution by tissue. (C) Rarefaction curve showing gene-level does not reach saturation in the six libraries. (D) Mapping statistic of the Full-length Non-Concatemer (FLNC) reads aligned against the ROS_Cfam_1.0 genome.

Table 2 presents the number of transcripts and genes annotated in each tissue. Testis was the tissue in which the detection of expressed genes and transcripts was highest; 10,457 and 22,576, respectively. In contrast, for tracheal cartilage the expression of only 4,985 genes and 14,059 transcripts was detected. Rarefaction curve analysis at the gene level showed that sampling was still not saturated when reaching the maximum capacity of one or two SMRT cells, indicating the complexity of transcriptome (Figure 1D).

In terms of unique transcripts detected by each tissue, the proportion ranges from 32.3% (tracheal cartilage) to 68.1% (testis), with an average of 46.7%. We also predicted the coding ability of transcripts by aligning sequences against the Uniprot database and by FEELnc estimation. The transcripts, which showed coding potential in both methods, were regarded as coding transcripts. The brain cerebellum is seen to express the most coding transcripts (16,689) and tracheal cartilage has the least number (9,279). Although the brain cerebellum has nearly twice the number of coding transcripts than the least expressed tissue, the proportion of coding transcripts compared with total transcripts is relatively stable, ranging from 60 to 70%.

In summary, we have generated a high quality Iso-Seq dataset that can be used for annotation of the dog genome. In addition, knowledge of tissue-specific genes or isoforms can also provide us with a fundamental understanding of gene functions in future studies.

Table 2. Summary of Iso-Seq annotation by tissues.

Tissue	Transcripts	Genes	Unique transcripts	Coding transcripts[1]
Adrenal gland	18,541	7,632	6,938 (37.4%)	12,185 (65.7%)
Brain cerebellum	26,263	9,152	14,547 (55.3%)	16,689 (63.5%)
Lymph node	14,649	6,827	5,329 (36.4%)	9,704 (66.2%)
Liver	14,943	5,402	7,524 (50.4%)	10,500 (70.3%)
Tracheal cartilage	14,059	4,985	4,543 (32.3%)	9,279 (66.0%)
Testis	22,576	10,457	15,374 (68.1%)	13,683 (60.6%)

[1] Coding transcripts are defined as transcripts aligned with Uniprot database.

[1]University of Zagreb, Faculty of Agriculture, Svetošimunska 25, 10000 Zagreb, Croatia; [2]University of Ljubljana, Biotechnical Faculty, Jamnikarjeva 101, 1000 Ljubljana, Slovenia; mshihabi@agr.hr

Abstract

Livestock Guardian Dogs (LGDs, *Canis familiaris*) are large dogs adapted to harsh mountain environments and selected to protect grazing livestock from predators in free-ranging grazing systems. Signals of positive selection in a meta-population represented by nine LGD breeds (116 individuals) were analysed based on information from 104,618 SNP genotypes using the extreme Runs of Homozygosity islands (eROHi) and the integrated Haplotype Score (iHS) approach. We found that 28 genomic regions (11 identified using the eROHi approach and 17 using the iHS approach) had highly significant signals for positive selection. Some of the most pronounced selection signals are associated with genes such as *LRIG3*, *TRIP11*, *CNTNAP2* and *EFNA5*. The presented results will contribute to the understanding of the synergistic behavioural interaction of LGDs with humans and grazing animals, especially sheep and goats, and the mammals' adaptation to harsh mountain conditions, as well as to their breeding management.

Introduction

Livestock Guardian Dogs (LGDs, *Canis familiaris*) are large dogs specialised in protecting mostly sheep and goat flocks from large predators (wolves, bears, etc.) in free-ranging grazing systems. The phylogenetic position of LGD is described in Talenti *et al.* (2018), while a more detailed genomic characterization can be found in Janeš *et al.* (2021). They are adapted to the harsh environment in the mountains where they help people protect their flocks, usually without supervision. At the same time, the long-term artificial selection process has shaped the behaviour of LGDs toward intelligence, trustworthiness, attentiveness, and protectiveness (Yilmaz *et al.*, 2015). The oldest clear written reference to LGDs is found in Aristotle's History of Animals from around 2,360 BP and it is quite possible that the origin of LGDs dates back even to the early beginnings of domestication of sheep and goats (Linnell and Lescureux, 2015).

The main objective of this study was to improve our understanding of the mechanisms of environmental adaptation and response to artificial selection in LGDs by identifying positive selection signals. Therefore, we used the extreme Runs of Homozygosity islands (eROHi) and the integrated Haplotype Score (iHS) approaches to analyse the available high-throughput genomic data.

Materials & methods

Data and genotyping. Our analyses referred to the meta-population represented by nine LGD breeds considered as a single group, a total of 120 dogs and 23 grey wolves genotyped for 172,115 SNPs using the Illumina CanineHD BeadChip (Illumina Inc., San Diego, CA, USA). Grey wolves, Sharplanina and Tornjak dog genotypes were generated in previous study (Janes *et al.*, 2021), the remaining LGDs (Caucasian Shepherd, Fonni's Dog, Great Pyrenees, Kuvasz, Maremma Sheepdog, Mannara Dog, and Pastore della Sila) and the grey wolves (19) were taken from publicly available genotypes published in Parker *et al.* (2017), Talenti *et al.* (2018), Shannon *et al.* (2015), and Dreger *et al.* (2016). Only autosomal SNPs with known chromosomal positions were used. During quality control performed with SAS 9.4. (SAS Institute, Cary, NC) and the software PLINK v1.9 (Chang *et al.*, 2015), we removed all SNPs with a GenTrain score <0.4, with a GenCall score ≤0.8, with a call rate <90% and SNPs that deviated from Hardy-Weinberg equilibrium

DOI: 10.3920/978-90-8686-940-4_753, © M. Shihabi *et al.* 2022

with $P<10^{-7}$ as well as all individuals with a call rate <95%. All further analyses were performed with a final data set that included 104,618 SNPs and 116 dogs and 23 wolves.

Extreme runs of homozygosity islands (eROHi) and integrated haplotype score (iHS). ROHs were estimated for each individual using the SNP & Variation Suite (SVS) v8.7.0 software package (Golden Helix, Inc., Bozeman, MT, USA) according to the parameters described in Ferenčaković *et al.* (2013). For each SNP, ROH frequency was normalised to mean chromosomal frequency, while the transformed value was represented as -log10(P). Signals with -log(P)>10 were considered significant. The iHS analysis was calculated according to Voight *et al.* (2006) after chromosome-to-chromosome haplotype phasing was performed using Shapeit2 software (Delaneau *et al.*, 2014), with the ancestral allele option set up according to the SNP status observed in 23 grey wolves. iHS values were calculated for each autosomal SNP in the genome using the R package 'rehh' (Gautier and Vitalis, 2012). SNPs with -log(P) >3 were considered outliers, whereas non-overlapping 1 Mb windows (sliding for 250 kb) with >10% outliers were considered genomic regions with signals of positive selection. In the eROHi approach, signals are ordered by the highest -log(P) value within a region, whereas in the iHS approach, signals are ordered by the proportion of outliers within a window.

Results & discussion

Genome-wide visualisation of regions (eROHi) or windows (his) with significant positive selection signals is shown in Figure 1 and 2, while a more detailed description of the genes located within the 10 most significant regions/windows can be found in Table 1. Two different complementary approaches were used: his, which is more powerful in detecting soft sweeps, and eROHi, which is able to detect near and fully fixed selective sweeps.

It is more useful to look for windows of consecutive SNPs that contain numerous extreme values because selective sweeps tend to generate clusters of extreme values in the sweep region, whereas in a neutral model the extreme values are more evenly distributed (Voight *et al.*, 2006). Therefore, all individual iHS outliers have been coloured grey in Figure 2.

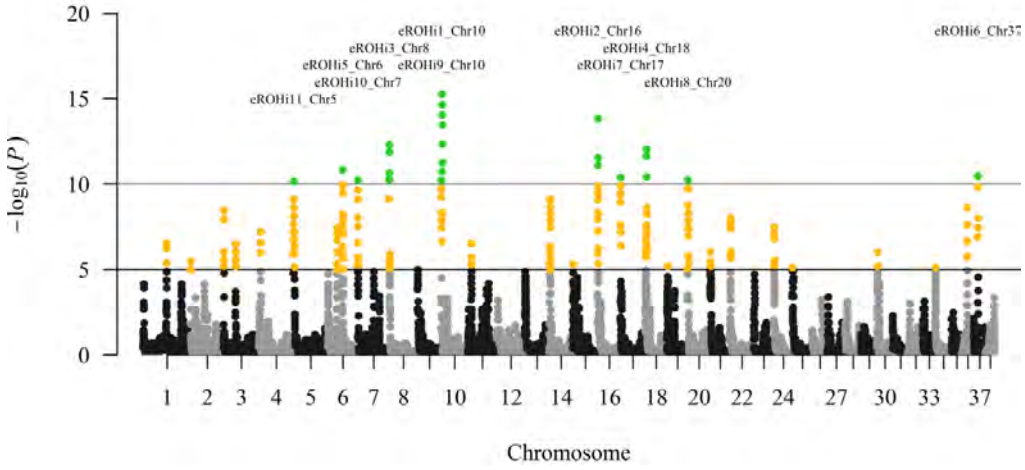

Figure 1. Genome-wide signals of positive selection analysed by eROHi approach.

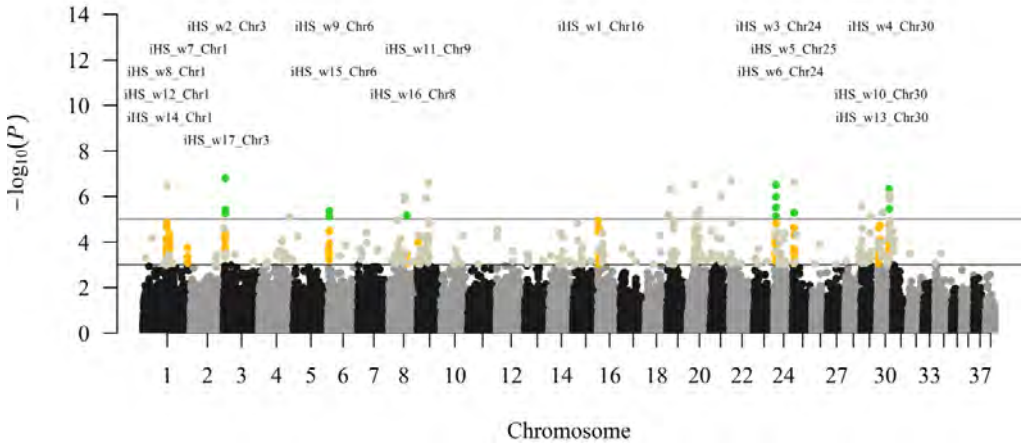

Figure 2. Genome-wide signals of positive selection analysed by iHS approach.

Table 1. Most important genes detected as positive selection signals.

Signal name	Signal region (Mb)	#SNPs[1]	Most important genes
eROHi1_Chr10	2.61-3.76	15	*LRIG3, SLC16A7*

[1] Significant SNPs in the region: (1) -log(P)>10 for eROHi; or (2) -log(P)>3 for iHS approach.

We have commented only on the most interesting genes identified as potential signals for positive selection. For example, according to the results of the eROHi approach, the region containing *LRIG3* (Leucine Rich Repeats and Immunoglobulin Like Domains 3), associated with aggression against foreign dogs in Zapata *et al.* (2020), showed the strongest signal. *LRIG3* may play a role in skull and inner ear morphogenesis during embryonic development (UniProtKB). The selection signal related to *TRIP11* (thyroid hormone receptor

interactor 11), gene associated with Golgi apparatus, encodes a protein that is interacting with thyroid hormone receptor beta, was also very strong. The strongest signals for positive selection identified by iHS point to *CNTNAP2* (Contactin Associated Protein 2) and *EFNA5* (Ephrin A5). Both are protein-coding genes associated with brain development and behaviour. In humans, *CNTNAP2* is associated with several neurodevelopmental disorders, while *EFNA5* prevents axon bundling in cocultures of cortical neurons with astrocytes, a model for late development and differentiation of the nervous system. *EFNA5* has been linked to the domestication process (Shin *et al.*, 2014). It is possible that some of the signals identified are related to adaptation to the harsh mountain environment and could be shared with wolves. However, this is an interesting topic for our future research.

The presented results will contribute to the understanding of the synergistic behavioural interaction of LGDs with humans and grazing animals, especially sheep and goats, and the mammals' adaptation to harsh mountain conditions, as well as to their breeding management. Nevertheless, further analyses are needed to provide a more complete picture of positive selection signals in LGDs.

754. Implementation of single-step GBLUP for complex behaviour traits in Labrador Retrievers used as service dogs

M.M. Riser[1*], E. Leighton[2], J. Russenberger[2], C. Moser[3] and B. Fragomeni[1,4]

[1]Department of Animal Science, University of Connecticut, 17 Manter Rd, Unit 4040, Storrs, CT 06268, USA [2]International Working Dog Registry, 4103 Hillglen Way, San Antonio, TX 78253, USA; [3]Guide Dogs New South Wales, 7-9 Albany Street, St Leonards, New South Wales, Australia [4]Institute for System Genomics, 67 North Eagleville Road, Storrs, CT 06269-3003, USA; molly.riser@uconn.edu

Abstract

The objective of this study was to evaluate the potential of genomic selection to improve behavioural traits in a population of Labrador Retrievers using the single-step GBLUP (ssGBLUP) methodology. Data consistent on phenotypes of 17 behaviour traits on approximately 5,000 individuals, their complete pedigree, and whole-genome sequence (WGS) for 463 animals. 150k SNPs were selected from WGS data. Heritabilities were low to moderate on most traits, and genomic estimated breeding values were in general more accurate than those computed with pedigrees. Gains in accuracy show that genomic selection can help the improvement of working dogs by identifying superior animals at younger ages. Gains are expected to increase as more animals are genotyped and more phenotypes are collected. The current results urge the need to continue recording behaviour traits in guide dogs and to expand the number of genotyped animals. Future steps include evaluation of multi-trait animal models and weighted ssGBLUP.

Introduction

Working dogs are highly trained in specific tasks related to their roles, including guiding people with visual impairment, servicing people with disabilities, among other services. However, not all puppies bred for pursuing their specific task will graduate from their programs due to health or behavioural issues. Genetic evaluation, like that used in ranking livestock, has been used successfully in only a small number of working dog breeding programs (Zhang *et al.*, 2009, Wilson *et al.*, 2013, Leighton *et al.*, 2019). Especially, behaviour traits pose a challenge because of the low heritability that is expected for such phenotypes in addition to difficulties regarding phenotypic coding that should be uniform across different subpopulations. The International Working Dog Registry data (IWDR; www.iwdr.org) provides an internet cloud-based database accessible from anywhere in the world for collecting and uniformly storing health and behaviour records on working dogs. The objective of the present study is to evaluate a genomic evaluation program in service dogs with single-step GBLUP using the IWDR data.

Materials & methods

Phenotypic data were collected from 4,841 Labrador Retrievers for 17 traits from IWDR behaviour checklist. A summarized description of the traits is available in Table 1. All traits were recorded with a score that varied from 1 (severe) to 5 (absent). Pedigree information included 23,593 animals starting from 1991 to 2016, with most of the data being from after 2008. Records were collected from year to year from number of different organizations, including the Guiding Eyes for the Blind (New York, USA), Guide Dogs New South Wales (New South Wales, AUS).

A total of 65,849 SNPs with minor allele frequency (MAF) less than 0.05 were removed from the data, including 22,774 monomorphic SNPs. No SNPs or animals presented call rate less than 0.9. Additionally, 43 SNPs and 8 animals were removed due to Mendelian conflicts. After quality control, a total of 137,088 SNPs were available for 457 animals.

Table 1. Description of traits and abbreviation used.

Behaviour trait	Description	Abbreviation
Anxiety in new situations	Anxious during first few visits to unfamiliar locations	AnxNewSit
Noise sensitivity	Startle, tense body language, escapes or displacement behaviours when exposed to loud noises excluding thunder	Noise
Self-modulation	It takes the dog a long time to return to a productive emotional state following exposure to an arousing or stressful stimuli	Selfmod
Handle sensitivity	Drops rear quarters when harness handle lays on back	Hsens
Fear of under footings	Fearful or apprehensive of various walking surfaces. Scored 1(severe) to 5 (absent)	UF
Body Sensitivity	Inhibited by physical contact with objects other than harness handle on back	Bsens
Activated by stress	Copes with stressful situations poorly evidenced by becoming more active with faster movements, taking treats harder, more distracted	Actstress
Inhibited by stress	Copes with stressful situations poorly evidenced passively by shutting down, avoidance and withdrawal as a response to stress	Inhibstress
Socially inappropriate with people	Exhibits poor social manners with people	SocInap
Distracted by scent	Distracted by olfactory stimuli	Sniff
Distracted by dogs	Persistent interest in and high excitability level with other dogs	Dogdist
Excited by movement	Easily distracted by non-animal movement and has trouble redirecting attention	Movexit
Excitable	Increases energy and arousal level without observed stress signals in response to stimuli	Excit
Novel objects	Fearful avoidant or suspicious of new or novel objects in the environment	NovelObj
Retreats from known person	Moves head or face away when reached for by known person	Retreats
Fear of strangers	Fearful, nervous, apprehensive of strangers	Strange
Body handling	Avoidant, anxious, or aggressive when being handled for noninvasive activities like a vet exam/grooming/nail trim	BHand

Variance components were estimated under the average information restricted maximum likelihood (AIREML) method. All the traits followed the model:

$$y_{ijkl} = sex_i + yob_j + cg_k + a_l + e_{ijkl} \quad (1)$$

Where y_{ijkl} is the behaviour phenotype for animal (a_l), of $sex_{i,}$ born in year of birth (yob_j), and with data collected in contemporary group (cg_k), and e_{ijkl} is the residual for this observation. The effects of sex, cg, and yob were considered fixed, while animal and residual were random. The contemporary group was a concatenation of the organization that carried out the animal behaviour assessment with the month and year of collection.

Once variance components were estimated, the best linear unbiased predictors (BLUP) were calculated by solving the Henderson system of equations (Henderson, 1975). Such values, calculated using pedigree to model the additive genetic effect will be hereby termed estimated breeding values (EBV). Genomic information was incorporated to calculated genomic estimated breeding values (GEBV) for all traits under a single step GBLUP (ssGBLUP) approach (Aguilar *et al.*, 2010, Christensen and Lund, 2010).

Accuracy of breeding values were assessed using a forward in time cross-validation approach. Such a method mimicked the selection of young animals. In the first step, GEBVs were calculated using the complete data. These were the benchmark and termed $GEBV_{COM}$. In the second round of analysis, 100 validation individuals were selected randomly from a list of 147 dogs that had their own phenotypes and at least ten progeny. Those animals and their progeny had their records masked, and their (G)EBV calculated with the

reduced data and termed $GEBV_{RED}$. The accuracy for (G)EBV was the average correlation of $GEBV_{COM}$ and $GEBV_{RED}$ after five replicates.

Results

Heritablities were on average 0.13 and varied from 0.02 (Retreats) to 0.37 (Hsens) (Figure 1). The accuracy was on average 0.64 for the pedigree BLUP and ranged from 0.53 (Movexit) and 0.76 (Sniff). The average accuracy for ssGBLUP was 0.70 and ranged from 0.58 (Bsens) to 0.81 (Sniff).

Discussion

Heritabilities were low to moderate for all traits, except for handle sensitivity. Such values suggest that genetic progress may be achieved for the traits in the study at a possible slow pace. Values in the present study are lower than health traits measured in a similar population (Leighton *et al.*, 2019). Schultz *et al.* (2013) estimated heritability for behaviour traits assessed through a questionnaire, and most of the heritabilities were reported to be under 0.10, which agrees with the current findings. Genomic selection should be used to overcome the low heritability limitation, as it is expected to increase the accuracy of prediction for breeding values of young animals, especially for traits that are expensive and hard to measure and traits with low heritability (VanRaden *et al.*, 2009, Harris and Johnson, 2010, Su *et al.*, 2012).

Gains in accuracy achieved by the inclusion of genomic data ranged from 0.22 (anxiety in new situations) to -0.03 (fear of strangers). Those results illustrate the potential of ssGBLUP to increase the genetic gain in a breeding program for most traits. It is obvious that the number of genotyped animals is still lower than what it should be, and gains are expected to increase as more individuals are genotyped. Additionally, the validation approach is not optimal due to only 147 animals out of 467 had at least ten progeny. This limitation likely overestimated the accuracies, as the breeding values with complete and reduced data did not change as much if more genotypes were available in the study. However, the trend of improvement encourages more effort in implementing a genomic selection program in this population.

While heritabilities were low and gains in accuracy were modest for most traits, the results suggest that a genomic selection program for behaviour in guide dogs is feasible. The quality of phenotypes and their consistency across populations allows the program to continue to expand. More animals should be genotyped so that accuracies can reach their potential, which will maximize genetic gain. The next steps for this project are to test multiple trait models and weighted ssGBLUP and evaluate their impact in accuracies

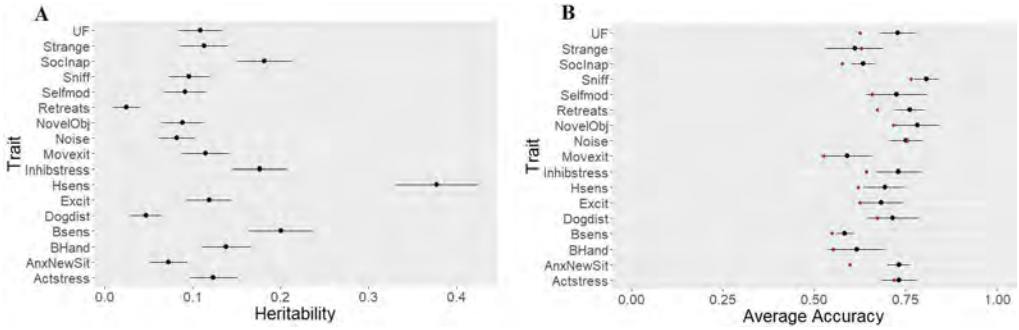

Figure 1. (A) Individual trait heritabilities. The horizontal line represents the standard error of the traits. (B) Black dots represent the average accuracy of GEBV with ssGBLUP across five replicates, and the horizontal bar is the standard deviation. The red dots represent the pedigree BLUP average accuracy.

and breeding strategies. We aim to reduce the dimensionality of the analysis by clustering traits with high correlations, which are hypothesized to be high. Additionally, we will investigate which traits are the best predictors of success of graduating from training. Finally, we intent to use this information to create an index to select animals for higher graduation likelihood.

755. Longevity and major causes of death are heritable in Irish Wolfhound

C.J.A. van Gemert[1,2], J.J. Windig[2] and P. Berg[1*]

[1]Norwegian University of Life Sciences, P.O. Box 5003, 1432 Ås, Norway; [2]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; peer.berg@nmbu.no

Abstract

Irish Wolfhound (IW) is a large dog breed developed several centuries ago with an average longevity of 7 years The genetics behind the short lifespan is poorly understood. Based on data from the Irish Wolfhound database (IWDB) on 118,095 pedigreed IW and data from the IW Longevity Study including 10,122 dogs with known longevity and 6,057 of these having a known cause of death (COD), longevity and the two most common COD were analysed. Heritability, maternal effects, and correlations were estimated accounting for sex, birthyear, country of origin and inbreeding coefficient. Both longevity (0.27) and COD (0.17-0.20) were moderately heritable. Longevity and COD showed low correlations, both genetic and residual correlations. We argue that this is likely due to short longevity being caused by early aging and COD being specific expressions of early aging. In addition, inbreeding was found to significantly reduce longevity. Implications for increasing longevity in IW are discussed.

Introduction

Dogs are popular pet animals, displaying a large variation in size, color, temperament and behaviors. Dogs are the species with the most recorded genetic defects (OMIA 2022), which is also reflected in differences in health and longevity of different breeds. Larger breeds tend to have a shorter lifespan than smaller breeds because larger breeds tend to age more quickly (Kraus *et al*., 2013). Larger breeds spend relatively more energy to reach adult size than small breeds. Thereby they would have relatively less energy left for health maintenance (Fan *et al*., 2016). Giant and large breed dogs are also at an increased risk of osteosarcoma (bone cancer), relative to smaller breeds (Breur *et al*., 2001). So size has an important influence on longevity and disease risk in dog breeds.

The Irish wolfhound is a rough-coated dog known as the largest and tallest of all coursing breeds, though not the heaviest breed. Their minimum size is defined by the American Kennel Club as 81 cm for mature males and 76 cm for mature females. They are also characterized by a median longevity lower than expected. Leading causes of death for Irish Wolfhounds are dilated cardiomyopathy and bone cancer (Urfer *et al*., 2007), which are also the most reported causes of death for dog breeds in general, besides age (Lewis *et al*., 2018).

The objective of this paper is to evaluate the potential for selecting for a longer and healthier life for the Irish Wolfhound breed, by estimating genetic variation in longevity, main causes of death and their correlation.

Materials & methods

Material. Data were obtained from the Irish wolfhound database (IWDB 2021), including an estimated 98% of all Irish wolfhounds ever registered. We used the complete and public IWDB dataset and the private Irish Wolfhound Longevity Study dataset. The pedigree used consists of 167,132 dogs, from 1859 to 2020, with 11,558 dogs having longevity records and 6,057 of these having a recorded cause of death.

There are two possible causes of bias in the longevity records. First, the older animals have a potential recording bias since recording started in 2012, and recordings back in time are likely to favor surviving and

DOI: 10.3920/978-90-8686-940-4_755, © C.J.A. van Gemert *et al.* 2022

important older dogs. Secondly, animals born in recent years do not all have longevity records yet. This is illustrated in Figure 1, with a reduced longevity in recent years, solely due to incomplete recordings. We evaluated these causes of bias by analysing different subsets of data, including years 1859-2011, 1979-2013 and 1979-2020 respectively. Results of these analyses are not included here. Further analyses presented here are based on the 1979-2013 cohort, containing 118,095 dogs in total, of which 10,122 have longevity records and 6,067 a known cause of death. There are 133 different classifications for cause of death (COD) recorded. Here we include the two most frequent categories, summarizing heart disease and cancer, recorded as 0/1. Data is summarized in Table 1.

Statistical analysis. For genetic analyses the following model was used:

$$Y_{ijklm} = Sex_i + Country_j + BY_k + \beta \times F_i + a_l + c_m + e_{ijklm}$$

Where Y is longevity or COD, Sex is male or female, Country is one of 18 countries of birth, BY is birth year, F is individual inbreeding coefficient calculated from pedigree, and a is random additive genetic effect, c is random common environmental dam effect and e is the residual.

Data were analysed using R 4.0.3 (R Core Team, 2020) and ASReml 4.1 (Gilmour *et al.*, 2015) with uni- or bi-variate models. In bivariate models the common environmental dam effect c was excluded.

Results

Irish Wolfhound is characterised by a short average lifespan of 7.25 years, see Table 1. More than half of the dogs dies from one of the two most common categories heart disease and cancer. Average lifespan is slightly shorter in dogs categorized as having died from heart disease or cancer, with an average of 6.74 and 6.86 years respectively. Longevity is however highly variable with observations ranging from 0 to 5,479 days (15 years). More specifically 18% were 5 years or younger, 57.7% were 7 years or older and 27.6% were 9 years or older. Figure 1 shows average longevity by birth year and a slight negative trend in longevity can be observed.

Heritability of longevity was estimated at 0.27 (Table 2), slightly higher than for the two main causes of death with heritabilities of 0.17 and 0.20, respectively. Thus, there is a large genetic variance in longevity, a genetic standard deviation of 482 days. Common environmental dam effects were small. Common environmental dam effects were left out of the model in bivariate analyses due to convergence problems.

The genetic correlation between cancer and longevity was positive but unfavorable, with increasing cancer resulting in increased longevity however the genetic correlation was not significantly different from zero. In contrast the genetic correlation between heart disease and longevity was favorable (-0.24) and significantly different from zero. Residual correlations between longevity and causes of death were low but unfavorable.

Table 1. Number of dogs with observations on longevity, cause of death (COD), prevalence of COD and mean longevity (days + SD) of all dogs and those diagnosed with a specific COD.

Trait	No. observations	Prevalence	Mean longevity
Longevity	10,114		2,648±925
COD Heart disease	6,057	18%	2,459±804
COD Cancer	6,057	34%	2,503±709

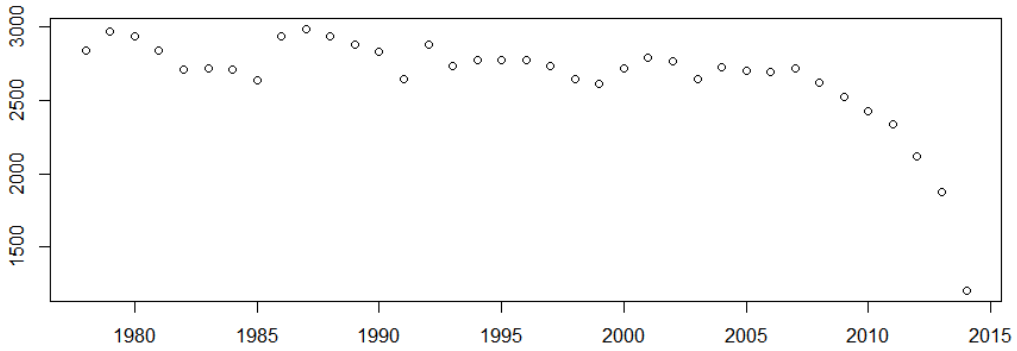

Figure 1. Mean longevity versus year of birth for Irish Wolfhound.

Table 2. Heritability, common litter effects, genetic (above diagonal) and residual (below diagonal) correlations (+ SE).

Trait	h^2	c^2	Correlations		
			Longevity	COD heart	COD cancer
Longevity	0.27±0.03	0.04±0.01		-0.24±0.09	0.10±0.09
COD heart	0.17±0.03	0.02±0.02	0.06±0.02		-[1]
COD cancer	0.20±0.03	0.02±0.02	0.01±0.02	-[1]	

[1] Not estimated.

Inbreeding significantly affected longevity. An increase of the inbreeding coefficient of 1% unit (0.01 increase) decreased longevity by 9.6 (±2.6) days, equivalent to a 0.4% reduction in longevity. Inbreeding did not significantly affect the two COD categories.

Discussion

Longevity observed in this material is in agreement with longevity observed in previous studies on Irish Wolfhound (Simpson, 2016; Urfer *et al.* 2007).

We found a significant heritability and a large genetic standard deviation of longevity of 482 days. This indicates a large potential for increasing longevity by selection. However, there are at least two challenges. First, the current relatively low longevity is likely caused by previous selection for breed characteristics and/or the severe bottlenecks that the breed has experienced during its history. Size is an important breed characteristic, but generally size is known to be negatively related to longevity across breeds and the main effect seems to be an earlier onset of aging (Kraus *et al.* 2013). Thus, a better understanding of the relationship between breed standard and health/longevity is needed. Secondly, both longevity and cause of death are observed late in life, most often after reproductive life. Thus, selection of young individuals can only be done with low accuracy, unless genetic evaluation utilizing information from relatives are implemented. Even more promising would be the implementation of genomic selection which would allow for increased accuracy on young dogs (Meuwissen *et al.* 2001). Jointly, these two challenges point to the need for early indicators of health and longevity. Promising indicators could likely be related to early indicators of aging.

Genetic and residual correlations between longevity and the two main causes of death were low and generally close to zero. This can be explained by the specific causes of death being a consequence of faster aging, but that the specific cause of death is partly caused by other loci in addition to environmental effects.

A specific and common heart disease, dilated cardiomyopathy, has been found to be affected by three loci on chromosomes 1, 21, and 37 of Irish Wolfhound (Simpson *et al*., 2016; Philipp *et al*., 2012).

We found a significant and unfavorable effect of inbreeding on the longevity of an individual. This implies that there are deleterious recessive alleles for longevity segregating in the population. Targeting these specific loci would require a large genotyping effort and would take a long time since samples for genotyping of ancestral individuals does not exist. Alternatively, the effect of inbreeding can be counteracted by the use of dogs from other breeds. However, this requires a continued gene flow from one or several other breeds to have a lasting effect on genetic diversity (Windig & Doekes, 2018).

Conclusions

Our results document a large potential for genetically increasing health and longevity in Irish Wolfhound. In the short term the most promising route seems to be identification of early indicators of aging, and in the longer term the development of a genotyped and phenotyped reference population to allow accurate genetic evaluation of younger dogs.

Abstract

The Vaika Project (https://www.vaika.org/) formed a colony of 103 retired Alaskan sled dogs (ASD) ages 8-11 years old to study the genetics of mammalian aging. The aim was to study genome variation and destabilization and link this with clinical signs of aging. Retired ASD provide a unique canine model: genetically distinct but more diverse than modern breeds. These dogs are exposed to the natural environment throughout their life and adaptable to our research colony setting. Extensive evaluation of physical performance, immune response, cognitive function, and health are used to assess the progression of aging. Illumina Canine high-density single-nucleotide polymorphism (SNP) arrays and whole-genome sequencing (WGS) data are used to identify genome variation among the dogs in the Vaika population and retrotransposons expansion in somatic cells over time. Preliminary genetic associations with arthritis were found, and retrobiome expansion with age and cancer was characterized.

Introduction

Aging is the functional decline of various physiological systems, leading to a decrease in resilience with age. Current theories of aging can be separated into two complementary groups that explain aging as either: (1) the accumulation of biological errors; or (2) a pre-determined genetic program. Regardless of the theory, genome destabilization plays a vital role in aging, and specific variants are often implicated in the clinical variation of symptoms associated with aging. Canines offer the opportunity to study aging in an organism that ages similarly to humans. They are exposed to the same environmental factors as humans, develop similar age-related diseases, have comparable medical treatments (vaccines, medications, etc.), and have an established body of knowledge on their physiology and genetics. However, privately-owned dogs introduce undesired 'noise' related to varying environmental factors and owner compliance in research protocols. Conversely, the use of purpose-bred laboratory dogs eliminates their natural exposure to environmental factors.

Aging can be viewed as a genetically programmed process that is associated with the accumulation of cells with damaged genome and dysregulated epigenome in somatic tissues that serve as a source of progressive chronic inflammation ('inflammaging') (Franceschi *et al.*, 2007). The activity of endogenous retrotransposons (i.e. SINEs, LINEs, and endogenous retroviruses collectively forming 'retrobiome') are major genome destabilizing factors that are especially active in dogs (Fleyshman *et al.*, 2021). Therefore, differences in the aging of individual dogs are influenced by inherited genetic content and are expected to be manifested by the accumulation of cells with expanded retrobiome. Both can be analysed using genomic methodologies. The Vaika Project aims to use WGS and SNP data: (1) to identify genetic variants associated with the decline of immune function, physical condition, cognitive function, and other aging parameters; and (2) evaluate genome destabilization via quantification of SINE and LINE expansion. While both aims seek to identify genome variation associated with aging parameters, they are distinct yet complementary approaches. Aim 1 identifies genomic regions highlighted by genome-wide association studies (GWAS) likely influencing phenotypic variation of aging parameters. It compares the individual dogs' genomes

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_756, © H.J. Huson *et al.* 2022

and looks for common variants within the population to aging symptoms. Aim 2 focuses more on genome variation occurring within an individual over time, specifically quantifying the accumulation of retrotransposons within an individual's cells and the association of this retrobiome expansion with aging parameters. Aim 2 will also look for common population patterns of retrobiome expansion over time regarding where the expansion occurs in the genome and to what degree it expands.

To this end, the Vaika Project created a research colony of 103 retired ASD, limiting the drawbacks and capitalizing on the benefits of privately owned and laboratory-based dogs (Fleyshman *et al.*, 2021). The ASDs have been exposed to similar environmental factors given their lifestyle and are now housed in a controlled research setting allowing for consistent diet and care with rigorous multi-disciplinary and complementary assessments of aging and resiliency in a longitudinal study. While this study of canine aging is advantageous for improving our knowledge of human aging, it may also help extend our canine companions' lifespan and quality of life.

Materials & methods

Canine colony. A cohort of 103 retired ASD ages 8-11 years old from 23 kennels spanning North America was adopted into a research colony housed at Cornell University for the remainder of their lifespan in a longitudinal study (6+ years) known as the Vaika Project. Basic health, pedigree, and performance data were collected upon admission. All dogs are maintained on the same diet (excluding medical diets) at optimal body condition, have routine medical care, and participate in outdoor exercise and enrichment programs daily. The Cornell IACUC approved the protocol (2018-0022) with Cornell's Center for Animal Resources and Education overseeing animal husbandry and veterinary care.

Genotypic and phenotypic characterization. All dogs were genotyped on the Illumina Canine HD array with 220,661 SNPs. Quality assessment and association studies were performed using Golden Helix SNP and Variation Suite v8.x (Golden Helix, Inc., Bozeman, MT, www.goldenhelix.com). DNA samples from healthy lung tissue and spontaneously developed tumours of several dogs were subjected to WGS with an average of 50x coverage. WGS libraries were prepared using the TruSeq DNA PCR-free preparation kit (Illumina, Inc.) and performed sequencing on a NovaSeq6000. A novel bioinformatics methodology, named CLARET (for classification of retroelements), has been developed to identify and quantify somatic integrations of SINE elements (in preparation) and applied to determine the degree of retrobiome expansion in individual dogs and their tumours. Phenotypic data spanning immune function, physical condition, cognitive function, and health parameters are collected annually, every nine months, or biannually. These parameters are correlated with the outcome of genetic analyses to identify potential connections between inherited genetic variants and retrobiome expansion with aging.

Here we present a preliminary GWAS for canine arthritis, meeting the objective of aim 1 by identifying common inherited genetic variants within the population associated with this aging symptom. Individual dog (n=102) computed tomography (CT) scans taken 12 months after trial initiation were used to create a categorical score for arthritis based on presence and severity. Scores were determined by a single radiography veterinarian and ranged from 0, unaffected, to 17, denoting dogs severely affected with arthritis in multiple areas of the body. In addition, we compared the number of reads for repeated elements quantified from WGS data from DNA samples. The DNA was obtained from peripheral blood of the same Labrador Retriever at 5 and 9 years of age (obtained from Cornell Biobank) and from an ASD tumour tissue (osteosarcoma) and healthy lung tissue obtained from the same dog as a control.

Statistical analyses. Genome-wide association studies (GWAS) were performed on the SNP array data using a single-locus additive mixed model incorporating a genomic relationship matrix (EMMAX) to

correct for population structure. A Bonferroni corrected *P*-value<0.05 established significance. CLARET technology enables the statistical estimation of retrobiome expansion scales in individual DNA samples. With the main effect and pair-interaction factorial design for parameters (factors) of CLARET determining the detection of new SINE repeat integrations, we compared differences in counts of collected somatic integrations between younger and older ages of dogs and between normal and tumour tissues. The Illumina read-coverage normalized whole-genome distribution for concentrations of hybrid-reads (each concentration indicates one germline integration) was approximated by combining two Beta distributions. The expectation-maximization algorithm performed an approximation in each sample.

Results

After quality control filtering using a SNP call rate <0.9, >2 alleles, and a minor allele frequency <0.03, 164,580 SNPs remained for analysis. All samples had a call rate >99%. For the GWAS on arthritis score, 75 dogs were determined arthritis-free, while 28 dogs had scores ranging from 1-17 with an average severity score of 4.5 within affected dogs (population average 1.3). The two most significant associations were on chromosomes 26 and 15, with multiple SNPs associated on chromosomes 18 and 27 (Figure 1). This included two SNPs spanning a 50 kb region on chromosome 18 within the Succinyl-CoA:Glutarate-CoA Transferase (*SUGCT*) gene.

CLARET methodology was developed and adapted to analyse germline and somatic contents of dog SINE elements. Preliminary results revealed a progressive increase in somatic cell mosaicism in acquiring new integrations of SINEs belonging to the most evolutionary recent and transcriptionally active subfamilies of C elements. A similar expansion of specific subfamilies of these SINE elements was seen in aging Labrador Retriever dogs (Figure 2A) and in the comparison of tumour cells to healthy somatic cells from ASDs (Figure 2B).

Discussion

The Vaika Project offers a multidisciplinary approach to studying aging using ASD as a canine model. The extensive phenotypic assessment of aging of this cohort of dogs provides the opportunity to identify genetic variants associated with aging symptoms. Notably, the *SUGCT* gene has been implicated in human musculoskeletal abnormalities (Nakabayashi *et al.*, 2002), making it a promising candidate gene for canine arthritis. With time, we will have multiple CT scans of the same dogs, plus physical exam and treadmill gait analysis data that may complement and add to our arthritis phenotype. Retrobiome analysis showed similar SINE subfamilies multiplying with aging and tumorigenesis. The estimated speed of this process is measured in hundreds of new integration events in somatic cells and even faster invasion of retrobiome in

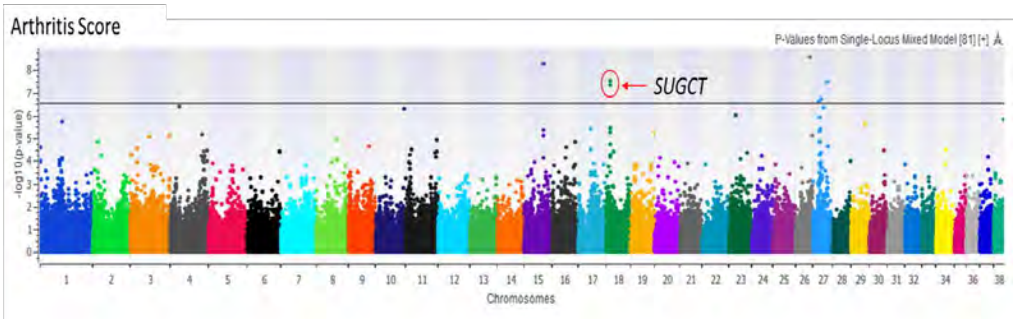

Figure 1. Manhattan plot of arthritis score genome-wide association study. Arthritis was categorically scored from 0 (unaffected) to 17 (severely affected) based upon CT scan readings of 102 dogs. Horizontal black lines represents a Bonferroni *P*-value=0.05.

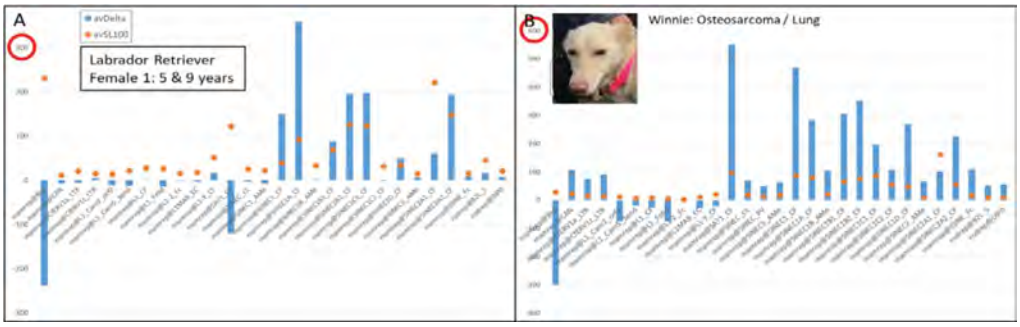

Figure 2. Subfamilies of SINE elements that underwent similar degrees of expansion in somatic cells in aging dogs. (A) Difference in copy number of SINE elements detected in peripheral blood DNA collected from the same Labrador Retriever dog at ages 5 and 9 years. (B) Difference in copy number of SINE elements detected in DNA of healthy lung tissue compared to osteosarcoma tumour of the same Alaskan sled dog. X-axis highlights SINE subfamilies; Y-axis corresponds to the difference in copy number variation.

carcinogenesis, thus, reflecting a high degree of genomic instability accompanying progression of canine tumours. As years and dogs pass, we will continue to analyse retrobiome activity in peripheral blood, and normal and tumour tissues. The Vaika Project allows us the opportunity to explore the integration of retroelements in an individual's genome over time and to identify population variation that is inherited or acquired, which affects aging.

757. Genomic diversity in selected Austrian dog populations

G. Mészáros[1*], M. Mészárosová[2] and A. Geretschläger[3]

[1]University of Natural Resources and Life Sciences, Vienna, Gregor-Mendel-Straße 33, 1180 Vienna, Austria; [2]Slovak University of Agriculture, Tr. Andreja Hlinku 2, 949 76 Nitra, Slovakia; [3]FERAGEN GmbH, Strubergasse 26, 5020 Salzburg, Austria; gabor.meszaros@boku.ac.at

Abstract

Genomic diversity was assessed in four Austrian dog populations using SNP marker data. There was considerable variation in inbreeding and heterozygosity levels within and between breeds. The correlations for these two metrics for individual dogs was r=-0.68, with considerable variation between breeds. The differences were likely caused by different considerations of IBS and IBD markers. In practice a few breeders tend to base their choice of mate pairs only on heterozygosity levels. In our paper we show this approach as counter-productive, leading to on average higher inbreeding levels in the offspring.

Introduction

Overall genetic diversity is one of the most important concerns of dog breeding organizations, and many professional breeders. With the availability of SNP marker data, consistent and standardized screening of various diversity parameters is possible (see e.g. Janeš *et al.*, 2021). The analysis of diversity based on dense genomic markers has several advantages over traditional systems, most importantly it does not rely on pedigree records, which might be missing or incomplete in some cases. Even though precise pedigree records might exist in the established traditional breeds, they might be inaccessible due to the overall secrecy surrounding especially the elite canine breeding scene.

In this work we focus on selected aspects of genetic diversity, such as heterozygosity, inbreeding levels and genomic relationships among potential mating pairs in four Austrian dog populations (Boxer, Leonberger, Rhodesian Ridgeback and Standard Poodle). The aim of our work is to explore these characteristics in the four dog populations from Austria, and highlight the relationships, or possible misconceptions related to them.

Materials & methods

Parameters of genomic diversity were assessed for 75 Boxer, 152 Leonberger, 46 Rhodesian Ridgeback and 58 Standard Poodle dogs, genotyped with Illumina CanineHD Whole-Genome Genotyping BeadChip. Within the data quality control, SNPs and individuals with more than 10% missing data and SNPs with less than 5% minor allele frequency were removed. After quality control 162,879 SNPs and 329 dogs remained for the analysis. A separate quality control was performed for the computation of genomic inbreeding coefficients, without limitation on minor allele frequency, resulting in 207,029 SNPs kept for the analysis.

The overall data management and quality control was done with PLINK 1.9 (Chang *et al.*, 2015). The genomic inbreeding was computed based on runs of homozygosity (ROH), using the cgaTOH software (Zhang *et al.*, 2013). For the purposes of this analysis the ROH segments were determined based on minimal length of 8 Mb. In order to account for non-complete genotypes in such long segments, up to two missing, but no heterozygous SNPs were allowed.

$$F_{ROH} = \frac{\sum_k ROH_k}{L} \quad (1)$$

where $\sum_k ROH_k$ is the sum of the ROH length for each segment k, and L is the length of the autosomal genome covered by SNPs.

CC BY

DOI: 10.3920/978-90-8686-940-4_757, © G. Mészáros *et al.* 2022

PLINK was used to compute heterozygosity levels for each dog, based on non-missing genotypes. Comparisons between heterozygosity levels and genomic relationships within data subsets, and all visualizations were done with R.

Results

As the first step a principal component analysis was performed (figure not shown). Here the breeds were clearly distinguished, with the first two principal components explaining about 67% of the variability between breeds. The breed clusters were well separated, with the Rhodesian Ridgeback and the Standard Poodle breeds being the closest to each other.

The inbreeding levels in the four analysed populations ranged from 0 to 31.1%. While there was certain variation in inbreeding levels in all breeds (Figure 1), the Rhodesian Ridgeback and the Standard Poodle appeared to be less inbred, while the Boxer population was shown to be the most inbred (Table 1).

The overall heterozygosity levels for each breed, compared to the entire analysed data set (Figure 2A-D) show a similar picture as the inbreeding levels. The correlation coefficient between the heterozygosity and ROH based inbreeding was r=-0.68 for the entire data set. Surprisingly, there were considerable differences between breeds, with correlation coefficients of -0.25, -0.52, -0.52 and -0.83 for the Boxer, Leonberger, Rhodesian Ridgeback and Standard Poodle breeds, respectively.

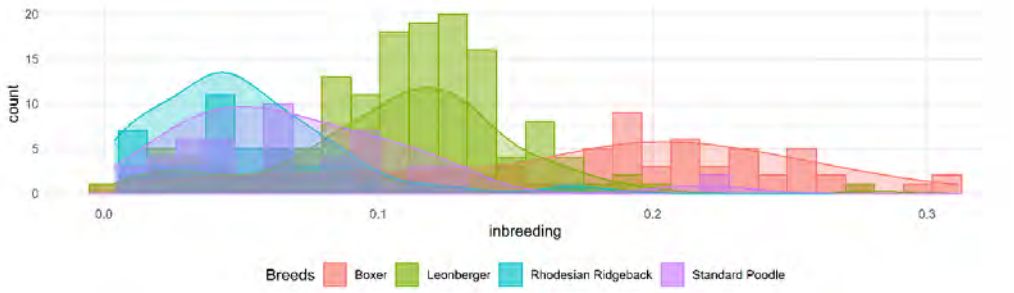

Figure 1. Distribution of inbreeding coefficients (up to 6 generations, ROH>8 Mb) in the selected populations. Bar plots show the number of dogs; the curves are the densities within the breed.

Table 1. Means and standard deviations (in brackets) for inbreeding, heterozygosity and genomic relationships[1].

	Boxer	Leonberger	Rhodesian Ridgeback	Standard Poodle
Inbreeding in all dogs	0.173 (0.0761)	0.109 (0.424)	0.049 (0.0329)	0.070 (0.0439)
Heterozygosity in all dogs	0.236 (0.0156)	0.271 (0.0124)	0.304 (0.0172)	0.316 (0.0190)
Genomic relationship in all dogs	0.229^{a} (0.0749)	0.161^{a} (0.0685)	0.092^{a} (0.0705)	0.046^{a} (0.0933)
Genomic relationship in dogs with heterozygosity > mean	0.355^{b} (0.0539)	0.269^{b} (0.0585)	0.173^{b} (0.0607)	0.092^{b} (0.1127)
Genomic relationship in dogs with heterozygosity > mean + 1sd	0.346^{b} (0.0506)	0.269^{b} (0.0635)	0.205^{b} (0.1542)	0.129^{c} (0.0771)

[1] For each column differences in alphabetic superscripts indicate significant differences.

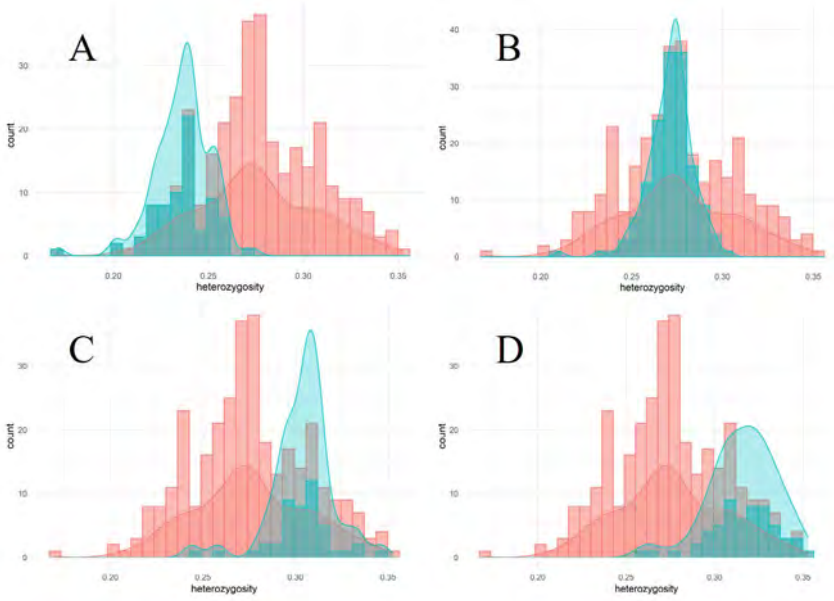

Figure 2. Heterozygosity levels in the Boxer (A), Leonberger (B), Rhodesian Ridgeback (C), and Standard Poodle (D) populations in green, compared to joint heterozygosity levels from all populations (red). Bar plots show the number of dogs; the curves are the densities within the breed.

It also came to our attention, however, in some cases, that the dog breeders use the simple heterozygosity levels in an unexpected way. Such unexpected use was, when the only criterion for selection of mating pairs was that the desired mating partner was from the more heterozygous part of the spectrum for the given population. Surprisingly, no further check on the (genomic) relatedness was performed. The hope of the breeders was that the offspring will be also highly heterozygous, as the parents. Of course, there is no guarantee for this to happen, indeed there is a real possibility for exactly the opposite outcome of more inbred offspring, with even lower heterozygosity.

In order to simulate such a scenario, we computed the average and standard deviation for heterozygosity and genomic relationship in the entire data set for all breeds (Table 1). In a follow-up we limited the data set to dogs with above average heterozygosity. We note that the genomic relationships were not recomputed between the scenarios. Also, the sex information was not considered for potential mate pairs, as the goal was a proof of principle, i.e. if the dogs with above average heterozygosity were more or less related as the average of the population.

Discussion

The inbreeding levels were computed based on the ROH methodology that considers long, continuously homozygous segments on the genome. It was assumed that the homozygosity status of SNPs along these segments with millions of nucleotides in length was not coincidental, but due to the inheritance of the same ancestral haplotypes from both the maternal and paternal side. Thus, the proportion of these ROH segments on the genome was the direct and exact measurement of inbreeding for each dog. Similarly, to other methods used to assess inbreeding levels, the number of generations of ancestors one wants to consider can be chosen using the ROH metric. The reason for considering such long segments of 8 Mb was that it corresponds to ancestry up to 6 generations in the past, similarly to the pedigree depth usually

considered by the breeders. There was a considerable variation in inbreeding levels in each breed, which was likely due to individual decisions of breeders. The differences in average inbreeding coefficients between breeds, however, were a likely consequence of breed management by breeding organizations.

The reason for the differences in heterozygosity levels (Figure 2) could be that while heterozygosity was considered on SNP-by-SNP basis, the inbreeding was measured with whole genome segments that must fulfil certain criteria (missingness and heterozygosity). Also, the overall heterozygosity, i.e. 1- homozygosity, also takes into account SNPs that are identical by state (IBS), and not just those which are IBD, and thus contribute to true inbreeding levels. As the IBS markers could be homozygous by pure coincidence, they might not properly characterize the differences between individuals. Thus, the overall heterozygosity might not be the most accurate measure of genomic diversity. Despite this slight limitation, and perhaps due to the strong correlation to overall inbreeding levels, the heterozygosity is being often used to assess diversity in practical dog breeding.

The simulation of the breeding practice of mating highly heterozygous dogs without considering their genomic relationship uncovered a flaw in this practice. Interestingly, in all breeds the genomic relationship was significantly higher in the restricted set than the population average (Table 1.), indicating that such selection of mate pairs would lead to on average higher inbreeding levels in offspring. The genomic relationship was similarly high when the populations were further restricted to the most heterozygous dogs, i.e. those with one standard deviation above the mean.

In conclusion the genetic diversity measured via genomic inbreeding and overall heterozygosity, differs considerably between breeds. It was also shown that a choice of mate pairs based purely on heterozygosity, without considering the genomic relationships was counter-productive.

758. Breed differences in the use of tools for dog breeding

M. Janes[1*], T.W. Lewis[2] J.J. Ilska[3], G. Gorjanc[1] and J.A. Woolliams[1]

[1]The Roslin Institute, Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush, Midlothian, EH25 9, RG, Scotland, United Kingdom; [2]The Guide Dogs for the Blind Association, Hillfields, Burghfield Common, Reading, Berkshire, RG7 3YG, United Kingdom; [3]The Kennel Club, Clarges Street, London W1J 8AB, United Kingdom; mateja.janes@ed.ac.uk

Abstract

Inbreeding occurs when relatives are mated together, possibly decreasing fitness. Tools to assess the potential for inbreeding in a population from selection and mating decisions could provide more robust populations. The Kennel Club (KC) tool Mate Select provides support for making informed mating decisions by offering inbreeding information spanning 222 breeds. Information on usage was assessed from 2011 to 2018 in relation to dog registrations. Breeds with up to 70 dams had an increase from 2 to 10 searches per dam registered, while breeds with 20,000 registered dams declined towards 2 searches per dam. There was significant variation between breeds of the same census size, and breeds participating in recording schemes leading to the publication of EBVs had more searches per dam (P<0.001), however this was not directly related to the availability of the EBVs.

Introduction

Inbreeding has long been used in companion animals and livestock, and has been part of the process that has led to the establishment of breeds. Inbreeding inevitably increases in restricted populations, such as dog breeds, diminishing genetic variation within the breed (Leroy *et al.*, 2011). To track genetic variation of such populations, we commonly calculate coancestry coefficients between pairs of individuals in the population, average coancestry coefficients, as well as individual inbreeding coefficients. These coefficients have been utilised in many studies to characterise inbreeding and population structure within and across dog breeds (e.g. Karjalainen *et al.*, 1997). While these coefficients are informative, it is more important to manage the rate of increase in the coefficients (ΔF) to manage genetic diversity.

The concept and definition of inbreeding were developed by Wright (1931) and it is widely recognized that lower breed census sizes and selection intensity increase ΔF (Robertson 1961). To manage ΔF, breeders use methods such as optimum contribution selection (Brisbane *et al.* 1995), which is well-established in leading animal breeding programmes (Howard *et al.*, 2017). However in dog populations this technology is more challenging due to a dispersed population and many individual breeders. This structure leads to demands for closer collaborative interactions for breeders and their breed and kennel groups that are often unmet (Fernández *et al.*, 2017). As a step towards managing inbreeding in UK dog breeds by promoting better breeding decisions KC created the Mate Select tool in collaboration with the Animal Health Trust. This provides inbreeding coefficients on individuals in the pedigree and on putative offspring of proposed matings, together with essential KC registration information. Further data comprised DNA testing for deleterious mutations, phenotypic results of health screening (such as eye tests and hip scores), and, when available, Estimated Breeding Values (EBVs) for complex traits like hip and elbow dysplasia (Lewis *et al.*, 2013). As a result, breeders may reduce propagation of lethal recessive alleles, improve complex traits, and avoid matings between close relatives. Since the impact of any tool will depend strongly on its usage, the aim of this contribution is to analyse the usage of Mate Select in UK dog breeding.

Materials & methods

Data. The information for this paper was obtained from two databases. The first database was an anonymised log of KC's Mate Select searches from May 2011 to September 2018. In this context, searches are requests for information about potential matings of two dogs. During this period, 946,632 searches were made for 213 breeds. There was also information about the user's regional location for each search. The second database was a pedigree for 10,182,582 dogs from 224 breeds. This database also included phenotypes such as coat colour, elbow and hip scores (where accessible), and sex. A total of 1,857,384 dogs were registered during the period covered by Mate Select. A unique KC dog identification number was used to link the two databases. During the study period, EBVs for dysplasia were reported, supplementing the documented phenotypes. These breeds are referred to as 'EBV-track' breeds.

Data analysis. To characterise the extent and mode of use over time, several aspects were analysed and compared. In this paper, we focus on the evaluation of disparities in the utilisation of Mate Select by breed, as well as the relationship between breed popularity and the availability of EBVs.

Searches in relation to breed. The number of searches per breed in Mate Select was compared to the breed popularity as determined by the database of pedigree registrations. The number of Mate Select searches per breed was calculated over the study period. The number of active dams was defined as those appearing in the registration of offspring across the period covered by Mate Select data. The number of dams per breed was then compared to the number of searches per breed over the same period. Breeds with less than 10 active dams in the period were excluded. The EBV-track breed subset was also considered as a breed classifier. We fitted the following mixed linear model was fitted using ASReml-R (VSN International, UK):

$$y = 1m + xb + f(x) + zc + e \quad (1)$$

where y is the base 10 logarithm of total searches for a breed; 1 is a vector of 1's, m is the population mean, x is the base 10 logarithm of the number of dams registered, b the associated regression coefficient, f(x) the smoothing spline fitted within the mixed model for x, z a binary indicator variable whether the breed had EBVs published by KC at any point in the study period, c its effect, and e is a residual vector. Since the model is on a logarithmic scale, Equation 1 can be transformed into a model for the ratio of searches to registered dams, by subtracting x from both sides. The convex hull was used to identify outlier breeds in our dataset, and is the subset of breeds that define the smallest convex polygon enclosing all the breeds in the data.

Results

The results analyse how breeders use Mate Select's 'kinship' data, which may be retrieved for any potential mating between two registered dogs. This includes information on the inbreeding coefficient of the bitch and the dog, as well as their potential offspring. In the following, a search is defined as a request for information, and a bitch is defined as a registered female with recorded offspring.

Figure 1 illustrates the association between Mate Select searches expressed as a multiple of the number of registered dams per breed and the log of the total number of registered dams for the 197 breeds with at least 10 dams registered with the KC throughout the study period. The predicted number of searches increases from 2.2 per dam for breeds with 10 dam census to 10.5 per dam for breeds with 100 dam census, then decreases to 3.5 and 2.4 respectively for 1000 and 10,000 dam censuses. The trend line in Figure 1 peaks at 11.5 searches per dam for breeds with 70 dams. For the extreme census size of the Labrador Retriever the search rate was 4.32 searches per dam. The red line shows the trend obtained from the mixed-model

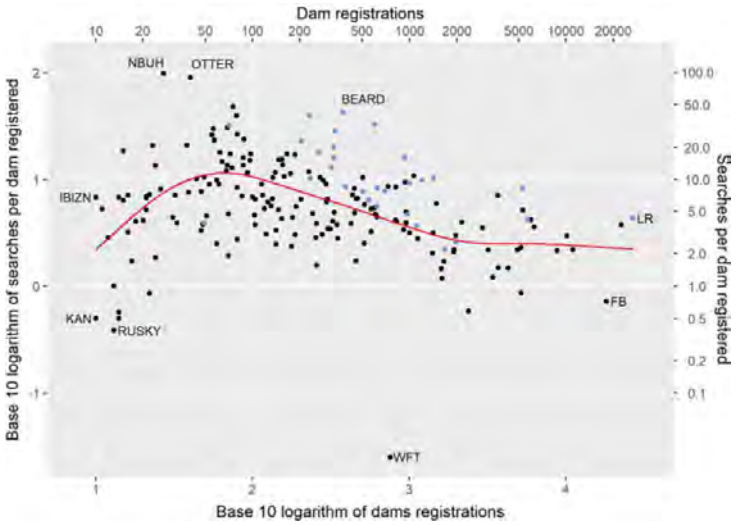

Figure 1. The relationship of frequency of searches per breed with dams registered.

Table 1. The breeds forming the convex hull of the distribution of search frequency and breed size, with the tag used to identify them in Figure 1 and the text.

Breed	Tag	Registered dams	Searches in mate select	Searches/dam	EBV-track
Otterhound	OTTER	40	3,572	89.3	No
Norwegian Buhund	NBUH	27	2,650	98.15	No
Ibizian Hound	IBIZN	10	5	0.5	No
Turkish Kangal Dog	KAN	10	5	0.5	No
Russian Toy	RUSKY	13	5	0.38	No
White Fox Terrier	WFT	757	19	0.03	No
French Bulldog	FB	18.119	13.105	0.72	No
Labrador Retriever	LR	26.723	115.451	4.32	Yes
Bearded Collie	BEARD	378	15.907	42.08	Yes

smoothing spline fitted with Equation 1. The points shown in light blue are the EBV-track breeds and these breeds have more searches per dam ($P<0.001$). The labelled breeds in Figure 1 are the 9 breeds that form the convex hull and Table 1 identifies these breeds with their labels giving further information. These breeds are on the 'edge' of the logarithmic distribution of breed size and searches per breed. For example, LR and IBIZN had a higher number of searches per dam whereas KAN, WFT and FB are extreme in having a relatively low number of searches given their census sizes, with WFT being particularly extreme having 40 times more registered dams than searches. In contrast, the NBUH had 98 times more searches than registered dams. If WFT is excluded then it is replaced in the hull by the Yorkshire Terrier.

Discussion

Inbreeding was originally used in formation of breeds, but increasingly threatens populations' genetic health. Dog breeders can use tools like KC's Mate Select to manage breeding decisions. The tool leverages data from 222 breeds with over 230,000 yearly registrations overall. Although there was large variation between breeds, Mate Select was well used by all KC recognized breeds for the given period. In principle,

more searches per dam for smaller breeds would be better for genetic management, however this was not evident for the lowest census breeds of the study. There are several reasons to doubt this expectation. First, a breed with few dams and few dogs available, restricts mating options. Second, dams may be owned by a small number of breeders, thus limiting information about accessible dams. Thirdly, it is likely the UK populations for a number of these breeds is a subset of larger (but still small) global breed populations that separately keep their own disjoint pedigree databases. Beyond the numerically smallest breeds, smaller breeds showed more searches with a peak of 70 registered dams (Figure 1) and a fall as breed populations grew larger.

However, among breeds of similar size, there is considerable variation due on breed culture or structure. The reasons for the Wire Fox Terrier's extremely low search frequency are unknown, while the high search frequency for the Norwegian Buhund coincides with the publication of a DNA test for the cerebellar ataxia that affects this breed (Jenkins *et al.*, 2020). While a multitude of DNA testing for diverse breeds have emerged in recent decades, no additional extreme search frequency coincidences have been observed. The finding concerning EBV-track breeds raised the hypothesis that providing EBVs may have prompted more searches per dam. This hypothesis was testable as EBVs for a subset were launched during the study period. Disappointingly, subsequent analysis (not shown) showed no differences in search frequency before and after the launch of EBVs, and so leaves open the question of what aspect of breed culture promotes the greater use of tools such as Mate Select.

759. Inbreeding and litter size in Dutch pedigreed dogs

J.J. Windig[1,2*], M.L. Margarita[1] and H.P. Doekes[1]

[1]ABG, Wageningen UR, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Centre for Genetic Resources the Netherlands, P.O. Box 338, 6700 AH Wageningen, the Netherlands; jack.windig@wur.nl

Abstract

Inbreeding may negatively affect fertility, especially when mating closely related individuals. We evaluated the frequency of these matings in Dutch pedigreed dogs between 1997 to 2018 and their effect on litter size in 15 breeds. The percentage of matings between half-cousins and closer has decreased since 1999. Litter size of individual matings tended to be significantly lower only for full sib and parent offspring matings. Inbreeding depression was only evident when analysed at the population level. In two breeds, a 1% increase in inbreeding of the dam resulted in an estimated reduction of litter size of 0.05 and 0.028 pups. These findings emphasize the importance for breeders and owners to avoid mating closely related dogs.

Introduction

Inbreeding is the result of mating related animals. Inbreeding can lead to the expression of genetic defects and inbreeding depression resulting in, e.g. a lower fertility (Falconer and Mackay 1996; Doekes *et al.* 2021). In many pedigreed dog breeds, inbreeding rates have been >0.5% per generation (Lewis *et al.*, 2015). To counteract the increase in inbreeding, mating between close relatives such as parent – offspring mating has been banned in breeds and kennel clubs. This does, however, not prevent inbreeding. Since pedigreed dogs form (small) closed populations high inbreeding rates may still occur and lead to inbreeding depression.

The effects of inbreeding may be (partly) compensated by natural and artificial selection. The heritability of fertility traits in dog populations tends to be low to moderate, i.e. in the range of 0.05 to 0.30 (Hare and Leighton, 2005; Leroy *et al.*, 2015). A decrease in fertility due to an increase in inbreeding may not be observed due to simultaneous selection for better fertility. Only when inbreeding rates are high, genetic drift is the main driver of allele frequency changes and selection cannot counteract the decrease in fertility over time due to inbreeding.

Pedigreed dogs provide an opportunity to investigate the effect of inbreeding on fertility. Litter sizes and relationships can be readily determined from pedigrees. Here, we used national pedigree data from the Dutch Kennel club to: (1) evaluate the frequency of close relative matings in the Netherlands from 1999 to 2018; (2) study the effect of these matings on litter size in 15 breeds; and (3) determine the amount of inbreeding depression in two of the breeds while accounting for a detailed pedigree.

Materials & methods

Data and classification of close relative matings. A data base was provided by the Dutch Kennel club. This data-base contained breed, birth date and father and mother of all registered pups of pedigreed dogs born in the Netherlands between 1997 and 2018. The following close relative matings were determined, with in brackets the corresponding relationship coefficients: parent – offspring (0.5), full sibs (0.5), half sibs (0.25), grandparent – grandchild (0.25), full uncle – niece or full aunt – nephew (0.25), half uncle – niece or half aunt – nephew (0.125), full cousins (0.125), and half cousins (0.0625). The first three could be determined only when all 4 grandparents were known, which was the case for 917,465 pups born from 1999 onwards. The other relationships could be determined if all 8 great-grandparents were known, which was the case for 103,785 pups born from 2004 onwards.

The effect of close relative matings on litter size. Close relative matings were grouped according to the relationship coefficient, resulting in 5 categories: no close relationship, 0.0625, 0.125, 0.25 and 0.5. Litters and litter sizes were determined by grouping pups with the same parents born at the same date. Only pups from the 13 most numerous breeds containing 47% of all registered dogs were analysed. This ensured that there were at least 20 animals in each relationship category, year and parity. The effects of relationship category, parity, year and interactions on litter size were determined in a 3-way ANOVA. The 13 breeds were supplemented with the Saarloos Wolfhond and Schapendoes breeds for which the breeding organisations provided detailed records over a longer period.

Inbreeding depression for litter size at population level in two breeds. The amount of maternal inbreeding depression for litter size was estimated for the databases of the Saarloos Wolfdog and Schapendoes provided by the breed clubs. These databases contained ancestry up to the start of the breeds in the 1940s. Only litters since the 1990s were used for the analysis, because before the 1990s sex ratios were skewed, suggesting that before the 1990s not all pups were registered but rather those that were later used for breeding. The following model was run with ASReml (Gilmour *et al.*, 2015):

$$LS_{ij} = u + Par_j + bF_i + A_i + Pe_i + e_{ij} \quad (1)$$

with LS_{ij} being the number of registered pups (i.e. alive at 2 months of age) for the j^{th} litter of dam i, Par_j the parity of the litter, b the coefficient of regression of LS on the inbreeding coefficient F_i of the dam i, Ai the random genetic effect of dam i, Pe_i the random permanent environmental effect of the dam i across all her litters and e_{ij} the random residual.

Results

The frequency of close relative matings decreased over the years (Table 1). Father-daughter, Mother-son, Full sib and Grandparent – grandchild matings have not occurred since 2011.

Litter size was smaller in small-sized breeds, e.g. the Chihuahua with a mean of 2.7 pups, than in large-sized breeds, e.g. the Golden Retriever with a mean of 6.6 pups (Table 2). Differences between years were significant for 11 of the 15 breeds (Table 2), but only for the Saarloos Wolfdog there appeared to be a trend, with litter size decreasing from above 6 before the 1990s to 3.5 in 2008 after which it recovered to close to 5 pups.

Differences in litter sizes over all parities were significant in all breeds except the Saarloos Wolfdog. When compared to the mean litter size within breeds, litter size was on average 6% lower for first parity litters and 8% lower for parities above 4 (Figure 1). Differences in litter size between relationship categories were

[2] Only significant interactions ($P<0.05$) are indicated.

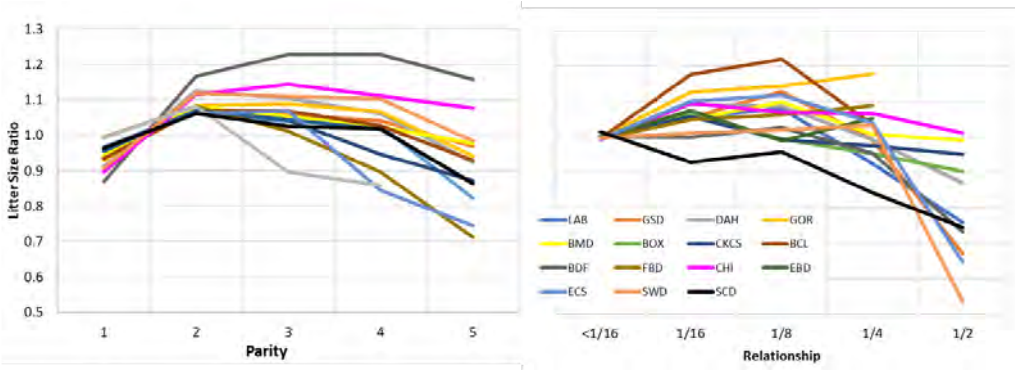

Figure 1. Litter size ratio (average within group litter size over breed average) over parity and relationship category. Breed abbreviations see Table 2.

significant for 7 of the 15 breeds. Litter size was on average 16% lower in the highest relationship category (Figure 1). Litter sizes were on average 8% higher for relationship category 0.0625 and 0.125.

Estimated heritabilities for litter size in the Saarloos Wolfdog and Schapendoes were moderate with 33 and 24% (Table 3). A 1% increase in the inbreeding coefficient of the mother resulted in an estimated reduction of litter size of 0.05 and 0.028 pups. This was equivalent to 1.16 and 0.47% of the trait mean, and 1.90 and 1.18% of the standard deviation.

Discussion

The number of matings between closely related dogs clearly decreased over the years. This is probably due to increased awareness of the detrimental effects of inbreeding and in line with observations that the rate of inbreeding in most dog breeds have gone down (e.g. Lewis *et al.* 2015). The negative effect of inbreeding on litter size in individual matings was only evident for the highest relationship category (matings between full sibs or parent offspring), and only significant for about half of the breeds. For lower relatedness categories (0.0625 to 0.125) litter size was even above the breed's average for most breeds. Various studies have previously reported (insignificant) favourable effects of inbreeding in animal populations (e.g. Doekes *et al.*, 2021). Apparently, the effect of inbreeding depression, when present, is so small that it could be masked by other factors. When the effect of maternal inbreeding was analysed at the population level it was highly significant for both breeds. Leroy *et al.* (2015) found clear inbreeding depression as well, with similar analyses as in this paper in seven breeds, and of similar size (0.007 to 0.042 per 1% F) as we found (0.028 and 0.050). One advantage of genetic analysis at the population level is that genetic effects other than inbreeding can be taken into account as well. Selective breeding, e.g. mating dogs from large litters to each other, may for example lead to relatively large litters for more inbred litters. For breeders and owners that have to select mates for their dogs, it is thus important to avoid mating closely related dogs. The effect of mating less related dogs is less obvious. Genetic management of breeds is, however, important to prevent a permanent reduction in litter size due to fixation of genetic defects with small effect due to genetic drift, i.e. an imbalance between inbreeding rate and selection/purging. The reduction in litter size as observed in the Saarloos Wolfhond may well have been the result of its high inbreeding rate over a long time.

Acknowledgements

We would like to thank the Dutch Kennel Club (RvB, Laura Roest) for providing the national database, the ALVS (Saarloos Wolfhond) and VNS (Schapendoes) for providing pedigrees, and Mila Stigter for analysing number of matings between closely related individuals.

Abstract

The present study aimed to provide insights into the genetic diversity, structure and relationships of three rare horse breeds (Pindos, Skyros and Thessaly) of Greece. To this end, we estimated measures of genetic diversity and conducted admixture and principal components analysis using equine microsatellite genotypic data on 475 animals. All populations displayed high levels of genetic variability, including the Skyrian horse that has the lowest census size and is bred in isolation. Present results confirmed the genetic differentiation of the Skyrian horse from the other two populations and the genetic proximity of the Pindos and Thessaly horses.

Introduction

In Greece, seven native horse breeds have been recognized so far: Crete, Pinias, Andravidas, Thessaly, Pindos, Zakynthos and Skyros (Zafrakas, 1991, Alifakiotis, 2000). Of these, the latter is native to the homonymous Aegean island and presents a unique phenotype with lowest withers height (in the range from 95 to 112 cm). Because of its distinct phenotype and geographic isolation, the breed has been hypothesized to be genetically distinct from mainland horse breeds (Zafrakas, 1991). This hypothesis was confirmed by Bömcke *et al.* (2011) showing the distant genetic relationship of the Skyrian horse to any other Greek and international horse or pony breed, including small sized (e.g. Exmoor, Shetland and Welsh) breeds and the Przewalski horse (feral horse). Previous reports (Bömcke *et al.*, 2011, Kominakis *et al.* 2013) have shown that the Skyrian horse displays exceptionally high levels of genetic diversity, despite its low census size (n~250). On the Thessalian plains of central Greece, the homonymous horse breed is raised mounting up to 450 animals. The famous horse of Alexander the Great, named 'Bucephalus' (meaning 'ox-head') was a Thessalian horse. It is a light riding and draft breed with withers height ranging from 135 to 145 cm. Finally, the Pindos horse is native to the Pindos mountain range spanning from West Macedonia to Thessaly and Epirus with a census population size of about 500 animals and withers height ranging from 110 to 135 cm. Like most other Greek horse breeds, this breed is also sure-footed, adaptable and hardy, being able to thrive in harsh environments. The present study aimed to provide insights into the genetic diversity, structure and relationships between and island horse breed, Skyrian, and two of the most populous breeds of the Greek mainland, Thessaly and Pindos horses.

Materials & methods

Animal sampling and data collection. The initial data set included records from a total number of n=687 animals registered with the respective Skyrian, Thessaly or Pindos horse breeding associations. Of these, a subset of n=475 records with complete information on origin, sex, place and year of birth and genotypes of microsatellite markers were used for further analysis. The total numbers of complete records per breed were n=242 (130 females, 112 males) for Skyrian, n=211 (164 females, 47 males) for Thessaly and n=22 (17 females, 5 males) for Pindos horses. Animals were genotyped using DNA extracted from hair samples

and the StockMarks™ for Horses 17-Plex Genotyping Kit (Applied Biosystems, Thermo Fischer Scientific) that included 17 short tandem repeat (STR) markers: AHT4, AHT5, ASB2, ASB17, ASB23, CA425, HMS1, HMS2, HMS3, HMS6, HMS7, HTG4, HTG6, HTG7, HTG10, LEX3 and VHL20. This STR panel included the 12 markers of the official ISAG panel recommended for parentage analysis (AHT4, AHT5, ASB2, ASB17, ASB23, HMS2, HMS3, HMS6, HMS7, HTG4, HTG10, and VHL20). The PCR amplicons were analyzed on an ABI 310 Genetic Analyzer and to extract STR allele sizes, raw data fragment analysis was carried out using the GeneMarker® software (Softgenetics®, Pennsylvania, USA).

Genetic analysis. Estimates of the number of alleles per locus (n_A) along with expected (He) and observed (Ho) heterozygosity rates were obtained with the *Arlequin* software (ver. 3.5.2.2). We tested for Hardy-Weinberg equilibrium (HWE) or disequilibrium (HWD) across all STR markers and heterozygote deficit using exact U score tests and the online version of *GenePop* ver.4.7 software. The same software was used to test for pairwise allelic and genotypic differentiation between populations using exact G tests. Fis estimates were obtained with *GENETIX* (ver. 4.05.2). Admixture analysis was conducted using the *STRUCTURE* software (ver. 2.3.4), assuming K (ancestral populations) in the range from K=1 to K=3. Each time, we run 500K for burn in and 750K for 10 rounds of MCMC at each of K=1 to K=3, and the optimum K value was assessed through the analysis of the LnP(D) distribution plots and delta K values from *Structure Harvester.* Bar plots were constructed with *CLUMPP*, to align the replicates, and *distruct*. Finally, we performed Principal Components Analysis (PCA) of genotypic data using the *GENETIX* program and plotted the first two PCs using *SAS* (ver. 4.2).

Results

Measures of genetic diversity. Heterozygosity was highest in the Pindos and lowest in the Skyrian horse populations. The highest mean number of alleles per locus (n_A) was 8.82 and the lowest 6.65 and were found in the Thessaly and Skyrian populations, respectively (Table 1).

While Pindos population was in HWE (P=0.325, U global test), the remaining two populations were in HWD (P<0.001, U global test) due to heterozygote deficit (Fis=0.019 and 0.109, respectively). Furthermore, the three populations differentiated from each other, both at the allelic and genotypic level (exact G tests, results not shown). The optimum value for ancestral populations (K) was 2 (Skyros vs Pindos and Thessaly) (Figure 1). For K=3, the Pindos (orange color) and the Skyros (blue color) populations were still presented as distinct genetic entities while individuals of the Thessaly breed either differentiated (dark blue color) or were close or shared ancestry proportions with the Pindos horse (Figure 1, K=3).

PCA showed a distinct cluster including the Skyrian horses, while Thessaly and Pindos horses overlapped (Figure 2). These results were consistent with the admixture analysis, suggesting a higher degree of differentiation of the Skyrian horse breed and a shared genetic background for Pindos and Thessaly populations.

Table 1. Means and standard deviations (in parentheses) of measures of genetic diversity in three rare horse breeds of Greece.

Breed	n_A	He	Ho	Fis (95% CI)
Pindos	7.647 (2.344)	0.784 (0.091)	0.787 (0.090)	-0.0035 (-0.0711-0.0112)
Skyros	6.648 (1.579)	0.640 (0.172)	0.630 (0.177)	0.0198 (-0.0014-0.0392)
Thessaly	8.824 (2.789)	0.767 (0.086)	0.683 (0.121)	0.1099 (0.0865-0.1281)

[1] n_A = number of alleles per locus; He = expected heterozygosity; Ho = observed heterozygosity; Fis = Fisher's fixation index.

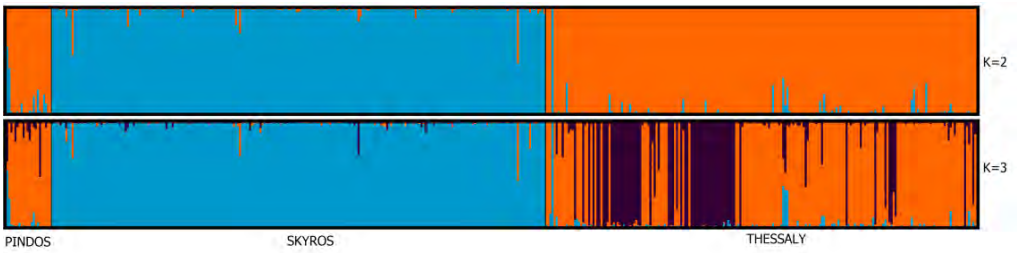

Figure 1. Ancestry proportions of three horse breeds of Greece. The x-axis represents individuals grouped according to breed. Each colour represents a population and each individual is represented by a vertical line partitioned into coloured segments, with segment lengths representing the admixture proportions from K=2 to K=3 ancestral populations.

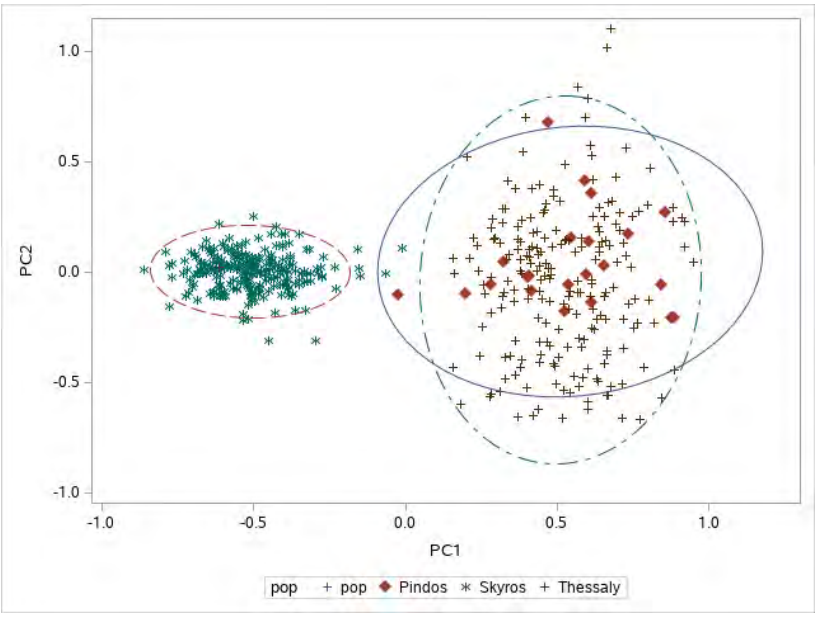

Figure 2. PCA based on genotypic data of 475 horses belonging to Skyros, Thessaly or Pindos rare breeds of Greece. PC1 and PC2 explained 5.9 and 2.62% of the variance of genotypic data, respectively.

Pairwise estimates of the genetic differentiation measure, i.e. F_{ST}, further confirmed the previous findings showing highest genetic differentiation between Skyros – Pindos (F_{ST}=0.113) and Skyros – Thessaly (F_{ST}=0.104) and genetic closeness between the Pindos and Thessaly horses (F_{ST}=0.0103).

Genetic diversity by sex and time. Estimates of genetic diversity by sex and year of birth for the Skyrian and Thessaly horses are shown in Table 2 and 3, respectively. These analyses were not performed for the Pindos horse due to limited number of available records. Interestingly, in both breeds considered contrasting estimates of the most distant time periods within breeds resulted in no statistically significant differences in either population (results not shown). In addition, there was no difference for the genetic diversity measures between males and females (results not shown).

Table 2. Means and standard deviations (underneath) of measures of genetic diversity by sex and year of birth in the Skyrian horse.

Time period	n_A	Ho	He	Sex	n_A	Ho	He
1983-2000 (n=54)	5.941	0.65	0.642	Males (n=112)	6.353	0.64	0.636
	1.749	0.19	0.178		1.498	0.193	0.176

	2.369	0.098	0.098				

[1] n_A = number of alleles per locus; He = expected heterozygosity; Ho = observed heterozygosity.

Discussion

The present study provides estimates of measures of genetic diversity for the Pindos and the Thessaly horses for the first time, while validating previous findings for the Skyrian horse. Unexpectedly, all populations displayed levels of genetic variation comparable or higher than those reported for more populous breeds (e.g. Bjørnstad *et al.*, 2000; Van de Goor *et al.*, 2011). This was especially remarkable for the Skyrian horse that has the smallest census size and is bred in isolation for decades. Estimates on observed heterozygosity and numbers of alleles per locus in the three breeds included in this study are comparable to earlier reports on the Skyrian horse (Avdi and Banos, 2008; Bömcke *et al.* 2011; Kominakis *et al.* 2013) and to figures on other international breeds (e.g. Colling and Kelly, 1996; Bjørnstad *et al.*, 2000; Van de Goor *et al.*, 2011). The results presented here further support the genetic uniqueness of the Skyrian horse when compared to the other two breeds and revealed a close genetic relationship between the Pindos and the Thessaly horses. Findings of the present study provide scientific evidence to support the continuation of the *in situ* conservation programs for these indigenous horses of Greece.

761. Genetics of new conformation traits in Italian Heavy Draught Horse foals

R. Mantovani[1*#], E. Mancin[1#], B. Tuliozi[1], G. Gomez Proto[1], G. Pigozzi[2] and C. Sartori[1]

[1]University of Padova, Department of Agronomy, Food, Natural Resources, Animals & Environment, Viale dell'Universita' 16, 35020 Legnaro (PD), Italy; [2]Italian Heavy Draught Horse Breeders' Association, Via Verona 90, 37068 Vigasio, Italy; roberto.mantovani@unipd.it; [#]these authors contributed equally

Abstract

This study aimed to estimate genetic parameters for five novel conformation traits indirectly linked to dynamic aptitude (i.e. trot) and to body condition in Italian Heavy Draught Horse. Established under the European Agricultural Fund for Rural Development, these traits are now routinely recorded on young foals. Novel traits recorded in 2,283 foals (7,895 horses in pedigree) were analysed and correlated with two traits included in the selection index. Traits showed low to medium heritability levels (from 0.084 for croup direction to 0.213 for croup length), and positive genetic correlations (from 0.073 for body condition score vs croup direction to 0.901 for neck length vs neck direction). Medium genetic correlations were found with already established traits temperament (average r_g=0.500) and fleshiness (average r_g=0.588). Results suggest the possibility to successfully include the novel traits into the selection index to improve functionality for movement (through assessed neck and croup traits) and individual well-being (considering body condition score).

Introduction

In recent years, the Italian horse breeders' associations have focused on new breeding goals under the Equinbio breeding program, financed under the European Agricultural Fund for Rural Development by the Italian Ministry of Agriculture, Food and Forestry. Among the new breeding goals, new phenotypes have been identified and recorded with the aim to exploit a possible future use in selection. Particularly, the breeders' association of the Italian Heavy Draught Horse (IHDH) has focussed on five new phenotypes mainly addressing functional aspects relating to the dynamic aptitude (mainly trot) and the body condition. Data were recorded on young foals aged between 2 and 9 months. The IHDH, originally created for both military purposes and agricultural work, was converted toward the meat production during the 1980's, but today the breed is considered suitable for both meat production and heavy draught activities, like agricultural work or use in holiday farms. Additionally, the IHDH can exert even an important role in landscape management because of its easy adaptation to low-grade pastureland (Mancin *et al.*, 2020). The aim of this study was to assess the genetic structure of the five new phenotypes recorded on IHDH foals over a period of 5 years and particularly, the genetic correlations among these new phenotypes and with two further phenotypes already under selection, i.e. the temperament and fleshiness.

Materials & methods

The five new phenotypes recorded on young foals of IHDH breed were four body measurements, the neck length (NL), the neck direction (ND), the croup length (CL), and the croup direction (CD), and the body condition score (BCS). All these traits were obtained by a linear score using a 1-5 scale and half points (i.e. 9-point scale) by skilled classifiers. Data were recorded from 2017 to 2021 on a total number of 3,664 foals. In addition, temperament (TE) and fleshiness (FL) were considered among the traits routinely collected in the IHDH breed and included in the total selection index (described in Folla *et al.*, 2019). After editing, the final dataset used for genetic parameter estimation included 2,283 single-record data for young foals, accounting for 7,895 animals in the pedigree file up to the 8th generation. A previously validated model (Folla *et al.*, 2019) included the random stud-year-classifier (SYC) as single or groups of SYC in case of single observation assembled by geographical area, type of housing, production target, vaccination of foals

and stud's mares mean body condition to identify nutritional management). Further factors accounted were the fixed effects of sex, age at evaluation (months, 9 classes), and, as surrogate of parity number, the age of the mare at foal's scoring (5 classes: <4 yrs.,…,≥14 yrs.). Univariate models were run to estimate variance components of each trait, and bivariate models allowed to estimate covariances and derive genetic correlations among traits. All analyses used AIREMLf90 (Misztal, 2008). Approximate standard errors were calculated using the Monte-Carlo technique of Houle and Meyer (2015).

Results

Descriptive statistics of traits are reported in Table 1. Averages of traits ranged from 2.81 (BCS) to 3.29 points (ND). Apart from BCS, all traits were right skewed. A low to medium heritability (h^2) was found for the five traits, ranging from h^2=0.084 (SE=0.038) for CD to h^2=0.213 (SE=0.047) for CL (Table 2). Medium to high genetic correlations (Table 3) were found across the four conformation traits for neck and croup (average r_g=0.600) with minimum for ND vs CD (r_g=0.07) and maximum for NL vs ND (r_g=0.901). Phenotypic correlations ranged from r_p=0.07 (NL vs CD) to r_p=0.717 (NL vs ND). BCS showed genetic correlations ranging from r_g=0.171 (with NL) to r_g=0.322 (with CL) with the other four novel traits, and phenotypic correlations from r_p=0.073 (with CD) to r_p=0.154 (with CL). The established traits temperament and fleshiness, already included in the selection index of the breed, showed medium correlations with the novel traits (average r_g=0.500 and 0.588, respectively; Table 4). The highest r_g estimates were found for ND vs both TE (r_g=0.586) and FL (r_g=0.601).

Discussion

Breeding for conformation involves aspects of morphology and functionality, and it is important for breeding decisions in livestock breeds. Traits may be measured or scored (in points), through a subjective evaluation based on valuating scoring or even by linear type evaluation (Koenen *et al.*, 1995). Current genetic evaluation of IHDH relies on a linear evaluation for 11 type traits scored in foals, and five of these traits are included in the total selection index (Folla *et al.*, 2019). In recent years, breeding programs financed under the European Agricultural Fund for Rural Development have led a wave of novelties in

Table 1. Descriptive statistics of the five novel linear traits considered in the study.

Trait	Descriptor range		Mean (SD)	Skewness	Kurtosis
	Min. (score 1)	Max. (score 5)			
Neck length (NL)	Short	Long	3.26 (0.48)	0.43	0.02
Neck direction (ND)	Horizontal	Vertical	3.29 (0.44)	0.66	0.19
Croup length (CL)	Short	Long	3.19 (0.38)	0.86	1.11
Croup direction (CD)	Horizontal	Sloping	3.02 (0.31)	0.55	5.04
Body condition score (BCS)	Scrawny	Fleshy	2.81 (0.56)	-1.07	2.28

Table 2. Additive genetic (σ_a^2), stud (σ_s^2), residual variance (σ_r^2), and heritability (h^2; SE in brackets) for the five novel linear traits considered in the study.

Trait	σ_a^2	σ_s^2	σ_r^2	h^2 (SE)
Neck length (NL)	0.0234	0.1139	0.0942	0.101 (0.033)

Body condition score	0.407 (0.148)	0.070 (0.026)	0.322 (0.139)	0.197 (0.024)

the phenotypic recordings for breeding in many European livestock breeds, including horses. The IHDH has been traditionally evaluated for the dual purpose of heavy draught and meat. Recently the breed has experienced a renewed attention for the original heavy draught purpose now devoted to the activity of didactic and organic farms, and to leisure pursuits such as team races (Mancin *et al.*, 2020). The novel traits for neck and croup are aimed to improve the movement ability of the horses. The neck is used for balancing while trotting, and too short or too long necks, as well as necks not in-line with the body, are less suitable to well balance the movement. Moreover, a too short and horizontally placed croup may cause problems to the movement of the limbs. However, a very sloped croup is more an aesthetic defect than in conflict with the thrust in different gaits. Linear type evaluations for croup and neck are found in many horses bred for sport activities, e.g. in Pantaneiro horse (neck length and croup length, r_g=0.46; McManus *et al.*, 2002) and in Dutch Warmblood (Koenen *et al.*, 1995). In this latter breed, patterns of genetic parameters for length and position of neck (h^2=0.21 and h^2=0.12, respectively; r_g=0.42) as well as croup length and shape (h^2=0.15 and h^2=0.28; r_g=0.40) were similar to this study. In Belgian Warmblood horses, length (h^2=0.27) and orientation (h^2=0.24) of neck, and length (h^2=0.30) and slope (h^2=0.30) of croup were also considered (Rustin *et al.*, 2009). BCS is linked to individual welfare of an animal: The trait is reflecting subcutaneous individual fat deposition and is routinely used in many livestock breeds including horses to assess body fat reserves and energy status. Development of energy balance over time can be crucial for metabolism, reproduction, and health (Coffey *et al.*, 2001). Data on evaluations of BCS in horses can be found, e.g. for Pura Raza Español horse (Sánchez-Guerrero *et al.*, 2019; h^2=0.15), Dutch Shetland Pony mares (Schurink *et al.*, 2010; h^2=0.38) and Italian Haflinger (Samoré *et al.*, 1997; h^2=0.09 for BCS). Horse literature is scarce about studies considering neck, croup, and BCS traits in parallel (e.g. Samoré *et al.*, 1997), and the genetic correlations have been studied even less. The present study can offer interesting findings about linear conformation traits related to dynamic aptitude and body status (energy supply). Positive genetic relationships have been found, but the traits have intermediate optima, so possible selection should maintain intermediate values whilst improving traditional productive traits. Temperament could also help in improving the movement aptitude, since it is scored to obtain lively individuals with favourable movement abilities (Folla *et al.*, 2019).

The high genetic correlation of temperament with new phenotypes indirectly related to dynamic attitudes could be explained considering the great attention put by classifier in the evaluation of temperament, that is in young foals strictly linked also to the observed animal movements. Fleshiness evaluates muscle masses underlying the meat production traits, and the genetic correlations indicating no antagonism with movement related conformation traits suggest the possibility to proficiently improve both meat and draught aptitude.

Abstract

The Spanish Sport Horse (CDE) is a recently developed composite breed selected mainly for show jumping performance since 2002, when the CDE studbook was officially founded. The main aim of this study was to highlight the effects of selection on this breed, regarding the breeds composition, and its repercussion in the breeding program. The CDE pedigree, with 47,884 animals (21,163 registered as CDE), was used for the analyses, including 10 breed groups corresponding to the major horse breeds present in the CDE Studbook. Two periods were considered to analyse the genetic contribution of founders for each breed group. Estimated breeding values (EBV) were available for show jumping discipline. Results showed that Other Horse Breeds group had the highest genetic contribution to CDE, followed by the Spanish Purebred. A small genetic progress was observed, as founders from most breeds showed lower EBVs than their descendants. This indicates that the genetic selection made has been effective, even though the management was not perfect.

Introduction

Recently, the equine breeding industry has become a very profitable activity, selecting not only pure horse breeds, but creating composite breeds with a focus on the horses' ability for a certain sport performance (Bartolomé *et al.,* 2011). Examples are the Irish Sport Horse, the Brazilian Sport Horse and recently, the Spanish Sport Horse (CDE). Particularly, this last breed is bred for dressage, eventing and endurance with a special focus on show jumping. The breed is managed by the Spanish Sport Horse Breeders Association (ANCADES, www.ancades.com) and its breeding program was officially approved in 2005. Previous studies on the CDE breed have shown improvements on the sport performance (Bartolomé *et al.,* 2018; Solé *et al.,* 2017), which could be a signal for certain selection in the breed. However, no studies have been conducted on CDE breeders' preferences when selecting reproducers for the next generation (EBV values for show jumping performance or breed composition) and neither on the effectiveness of the CDE Breeding Program. Therefore, the aim of this study was to highlight the effects of selection on this breed and whether it has been effective and adequate regarding the CDE main breeding objectives. This objective has been evaluated from two points of view: (1) partitioning CDE breed composition; and (2) evaluating EBV for show jumping discipline.

Materials & methods

The CDE Official Stud Book was created in 2002 and the foundational registry was closed in 2004 (Bartolomé *et al.,* 2011). The pedigree information used in this study included 47,884 animals (18,799 males and 29,085 females) with 21,163 registered as CDE horses (44.7% males and 55.3% females). According to the composite nature of this breed, different horse breeds were included in the CDE studbook via relatives of the CDE animals (55.8% of the whole pedigree). Thus, 10 breed groups were assessed corresponding to the major horse breeds present in the CDE Stud Book: Anglo-Arab Horse breed (AAH; n=1,561), Arab Horse breed (AH; n=1,835), Hanoverian breed (HANN; n=1,742), Holsteiner breed (HOLST; n=1,269), Dutch Warmblood (KWPN; n=2,120), Spanish Purebred (PRE; n=5,434), Thoroughbred (TH; n=2,924), Selle Français (SF; n=2,311), Other Horse Breeds group (OHB; n=7,525) and the Spanish Sport Horse breed group (CDE; n=21,163). The OHB group included a total of 69 breeds with less than 1000 animals each. In order

to study the evolution of these breeds over time (in terms of the proportion of individuals belonging to each breed) and their influence on CDE pedigree, two different periods were considered according to the year of birth of the animals. A first period (*P0*), including non-active animals born before 2000, was settled before the Foundational Registry of the CDE Stud Book was closed, in 2004. Consequently, no CDE animals were found in this period. Then, a second period was considered (*P1*) including active (foreign or not) animals, born from 2000 to 2021. Table 1 shows the CDE's breed composition according to the period considered.

Probability of gene origin of the CDE horse breed. In order to check the genetic representation of the founder individuals in the CDE population and in all the breed groups considered, the *genetic contribution of founders* to the descendant gene pool of the population (Lacy, 1989) was assessed for each breed group in every period considered. Following Moureaux *et al.* (1996), ancestors with both unknown parents in the available database were considered founders. These pedigree analyses were computed using the program ENDOG v.4.8 (Gutierrez and Goyache, 2005).

Genetic selection for Show Jumping discipline. Performance ability for Show Jumping was evaluated using the information from the routine genetic evaluations of CDE breeding program. The estimated breeding values (EBV) of the Show Jumping sport discipline of 12,197 horses in the CDE pedigree were available for this study (Bartolomé *et al.,* 2018). EBVs were standardized for an interval of 80-120 with a population average of 100. Genetic parameters for the Show Jumping sport discipline were estimated using a multivariate BLUP analysis carried out with the VCE software – version 6.0.2 (Groeneveld *et al.,* 2010), using the following genetic model:

$$SJ_{ijklmnopq} = b_q + Br_j + Gen_k + Ev_l + Hf_m + Cti_n + Rhi_o + pe_p + a_q + e_{ijklmnopq}$$

where $SJ_{ijklmnopq}$ was the Show Jumping score of animal q with Age i, from Breed j, of Gender k, recorded at the Event l, where Height of fences was m, Category and type of Test interaction n, Rider-horse interaction o and permanent environment p. b_q = linear covariate for the age effect of the q animal; Br_j = systematic effect of j^{th} breed (j = 1, …, 19); Gen_k = systematic effect of k^{th} gender (k = male, female, gelding); Ev_l = systematic effect of l^{th} event (l = 1, …, 1,131); Hf_m = systematic effect of m^{th} height of fences (m = 1, …, 10); Cti_n = systematic effect of n^{th} category and type of test interaction (n = 1, …, 214); Rhi_o = random effect of o^{th} rider-horse interaction (o = 1, …, 22,320); pe_p = random effect of p^{th} horse permanent environment (p = 1, …, 10,508); a_q = random effect of q^{th} animal (q = 1, …, 10,508); and $e_{ijklmnopq}$ = random residual effect.

Results

Breed groups' distribution appearing in Table 1 showed PRE and OHB as majority horse breeds in *P0*, with 4,387 and 6,357 animals born in this period, respectively. Afterwards, CDE was the majority horse breed in

Table 1. Distribution of horse breeds from the Spanish Sport Horse Official Studbook according to the period considered.[1]

	Breed groups										TOTAL
	AAH	AH	CDE	HANN	HOLST	KWPN	OHB	PRE	TH	SF	
P0	1,415	1,548	0	1,445	1,111	1,676	6,357	4,387	2,790	2,145	22,874
P1	146	287	21,163	297	158	444	1,168	1,047	134	166	25,010

[1] *AAH* is Anglo-Arab Horse, *AH* is Arab Horse, *CDE* is Spanish Sport Horse, *HANN* is Hannoverian Horse, *HOLST* is Holsteiner Horse, *KWPN* is KWPN Horse, *OHB* is Other Horse Breeds, *PRE* is Spanish Purebred, *TH* is Thoroughbred, *SF* is Selle Français, *P0* is period with animals born before 2000 and *P1* is period with animals born between 2000 and 2021.

P1. On the other hand, OHB, PRE and KWPN, breeds showed the higher representation after CDE in *P1*, with 1,168, 1,047 and 444 animals, respectively. The rest of the breeds contributed less than 300 animals.

Effect of genetic selection on the probability of gene origin of the CDE horse breed. In order to ascertain the genetic history of the CDE breed, the average genetic contribution of founders according to breed and period, was represented in Figure 1 including mean EBV for each breeds' founders and for their descendants calculated for Show Jumping discipline. Breeds were ordered according to their accumulated genetic contribution. Results showed that OHB horses had the highest genetic contribution, with almost 23% followed by PRE and TH breeds, with 14.8 and 12.6%, respectively. Whereas, AH, AAH and KWPN breeds showed the lowest, with an accumulated contribution less than 6%. On the other hand, mean EBV of founders was below the mean (EBV<100) for most breeds except for HOLST, with KWPN, SF and AAH obtaining EBVs on the mean. However, when analysing mean EBV of their descendants, most of them were over the mean, with SF, HOLST and KWPN showing EBV>101. Whereas only CDE, PRE and AH' descendants showed EBV means below 100. Furthermore, only PRE and AH founder's breeds showed higher EBVs than their descendants, indicating that breeders have not preference for PRE and AH breeds.

Discussion

The selection and mating are processes of conscious decisions for short-term achievements in intensively managed domesticated species (Medugorac *et al.*, 2011). Results from pedigree structure in the CDE population over the two periods considered, indicated that there are still some horse breeds such as the PRE and OHB that, despite their decreased influence from the founder population to the active CDE population,

Figure 1. Average genetic contribution of founders classified by breed (each column), per period (different colours within columns), with their mean estimated breeding value (EBV Founders; yellow squares) and the mean estimated breeding value of their descendants (EBV Descendants; blue triangles) for show jumping equestrian discipline, ordered according to contribution level of the founders. Where *AAH* is Anglo-Arab Horse, *AH* is Arab Horse, *CDE* is Spanish Sport Horse, *HANN* is Hannoverian Horse, *HOLST* is Holsteiner Horse, *KWPN* is KWPN Horse, *OHB* is Other Horse Breeds, *PRE* is Spanish Purebred, *TH* is Thoroughbred, *SF* is Selle Français, *P0* is period with animals born before 2000 and *P1* is period with animals born between 2000 and 2021. The red dots line indicates the mean *EBV* = 100.

they are still the largest contributing breed group. The reason for PRE retaining its position could be that it is the main national horse breed (Solé *et al.,* 2018), thus making it a very handy option for the breeders. Accordingly, the breed group OHB includes several foreign sport horse breeds, all of them with high sport standards, which have been selected for sport performance before CDE breed was created (Koenen *et al.,* 2004). And, thus, a very interesting option for CDE breeders as potential reproducers for their animals. The evolution of founder genetic contributions and the EBVs for Show Jumping, per breed group and period, showed, first, a general tendency of the breeders to follow the EBVs from the genetic evaluations of the breed published by ANCADES each year, to select the best breeding stock for their animals, thus increasing the genetic progress of the breed. And secondly, that CDE breeders have been also doing a selection against PRE and AH animals on their CDE composition. This was probably due to these horse breeds were not specialized in show jumping discipline, but in dressage (Sánchez-Guerrero *et al.,* 2014) and endurance (García-Ballesteros *et al.,* 2018), respectively, thus being not desirable breeds for Show Jumping's CDE breeders. Finally, results showed a light genetic progress, indicating that the genetic selection made is being effective, even though the management is not perfect.

763. Early selection criteria for improved longevity of jumping horses

A. Ricard[1,2*], S. Deretz[1] and B. Dumont Saint Priest[2]

[1]GABI, INRAE, AgroParisTech, Université Paris Saclay, Centre de Recherche Ile-de-France-Jouy-en-Josas-Antony, 78352 Jouy-en-Josas, France, [2]Institut Français du Cheval et de l'Equitation, Pôle développement, innovation et recherche, 61310 Exmes; France, anne.ricard@inrae.fr

Abstract

In order to find early selection criteria to improve the longevity of show jumping horses in competition, a specific protocol was constructed. Before entering competition, young horses were measured for many traits. These horses were offspring of two groups of sires selected as having the highest and lowest estimated breeding values for functional longevity in jumping competition calculated from progeny. Functional longevity was defined as the time spent in competition corrected for the level of performance. Initial results on subsamples of 346 horses for blood markers and 529 horses for surface temperature from infrared thermography are reported. Key markers of oxidative stress had significant effect on group of sires, especially superoxide dismutase. Surface temperature showed high heritability (up to 0.70) for body and contrast of body with specific locations (fetlocks, hocks, foot, eyes), but only asymmetry in right and left temperature of feet was linked to group of longevity of the sire.

Introduction

Improved longevity is beneficial for the welfare and health of the horse, as well for the satisfaction of a committed rider. To select for this objective is however difficult: heritability is low (0.08 in Ricard and Blouin, 2011) and estimated breeding values (EBV) for longevity are only obtained late in life of breeding animals, as a large number of uncensored phenotypes of relatives are required. This is further compromised as average length of jumping career is about 6 years with maximum over 20 years while horses begin competition at 4 years old. Therefore, possibilities of indirect early selection have been investigated in literature. Selection criteria in these studies were often based on traditional health status, morphological and gait measurements (Jonsson *et al.*, 2014; Seiero *et al.*, 2016; Wallin *et al.*, 2001). That is why a specific protocol was constructed in this study. Two groups of stallions were created (high and low) according to their EBVs for functional longevity in jumping competition calculated from progeny performances. Prior to start of competitive life, young horses (£4 years) descendants from these stallions were measured for different criteria: welfare, temperament, linear profiling of morphology, physiological parameters, blood biomarkers, body composition through impedance measurements (McKeen and Lindinger, 2004), gait accelerometric measurements, heart rate (during gaits and temperament tests), surface temperatures (from infrared images). Initial results on subsamples of 346 horses for blood markers and 529 horses for surface temperature are reported. The aims of the study are: (1) prediction of sire group (high longevity and lower longevity); and (2) heritability estimates for surface temperature measurements.

Materials & methods

Blood markers. A total of 91 variables were obtained from blood tests on 346 horses. Horses were mainly Selle Français (94%) aged 2 years (9%), 3 years (44%) and 4 years (47%). There were 45% females, 14% geldings and 41% stallions. A proportion of 66% descended from the group of favourable sires for longevity and 34% from the unfavourable. They were measured during 15 events (combination of location and date). Difference between the two groups of sires for longevity was equal to 0.46 genetic standard deviation, the risk ratio between the two groups was 1.2. Blood variables were divided into eight categories: liver function, kidney function, muscle function, oxidative stress, osteoarticular function, inflammation markers, blood counts and a miscellaneous section. Principal component analysis (PCA) was used to describe relationships

between variables. General linear models were used to identify environmental factors. Logistic regression was used to predict the group of sires from blood variables with stepwise selection. Quality of logistic regression was assessed by measuring area under curve (AUC).

Surface temperature. Infrared images from the Trotec IC085LV thermal imaging camera were used to measure surface temperature. For each horse, six images were taken: back, left profile, right profile, front legs, back legs, head. The software IC-IR Report allows to draw geometrical figures on the image and to extract the minimum, average and maximum temperature of a region of interest (ROI). For each image a rectangular reference area was defined to measure the temperature of the whole visible horse. Then specific morphological ROIs were defined. For each horse, the average, maximum and minimum temperatures of six reference areas and 28 ROIs were measured. Data were available for 529 horses, 3,138 images and 17,328 areas. Horses were mainly Selle Français (95%) aged 2 years (18%), 3 years (54%) and 4 years (28%). There were 48% females, 15% geldings and 37% stallions. The horses were sired by 88 sires, 343 by sires classified as favourable for longevity (65%) and 186 (35%) by sires classified as unfavourable. Difference in longevity for the two groups was the same as for the blood variables. The average number of offspring per sire was 6.0, ranging from 1 to 50. Horses were measured at 23 different combinations of location and date between 2018 and 2021 (12 to 34 horses per event). Variables were transformed to better describe the specificity of the temperatures of each horse. We defined six types of variables:

- body, overall images and per image;
- differences between body and specific areas: fetlocks, hocks, foot;
- differences between areas: fetlock to foot, hock to foot;
- differences antero-posterior for foot;
- differences right and left for fetlock, hock, back, foot and eyes;
- differences between median and lateral values for back.

A univariate animal mixed model was used with the fixed effects of age (3 levels), gender (3 levels), event (23 levels), and a random effect of the genetic value of the horse. Relationship matrix included 5,014 horses (pedigree back over 5 generations). The effect of the group of sires for functional longevity on temperature was tested. We performed a principal component analysis (PCA) of the variables corrected for the effects of age, gender and event estimated by the previous model.

Results

Blood tests. PCA confirmed the categories of blood variables according to functions with higher absolute phenotypic correlations between variables within functions. Heritabilities could not be estimated because of too low sample size, but the random effect of sire was significant for 44 variables, implying that most blood variables were probably heritable. Event effect was significant for 45% of variables, age for 25% and gender for 85%.

Blood test: logistic regression to predict sire group. The AUC of the logistic regression was 0.76, not fully satisfactory. Table 1 shows the significant variables (*P*-value£0.1). Horses descending from sires with favourable longevity had a higher level of erythrocyte superoxide dismutase (SOD in U/g Hb) as well as lower haemoglobin and bile acid levels than horses descending from sires with unfavourable longevity.

Surface temperature: environmental factors and heritability. Event effect was significant for all variables except for some left versus right asymmetry variables. Gender was rarely significant, especially when measuring asymmetry. Age was significant for almost half of the variables. Two years olds and three-years olds were cooler overall than four years olds. The temperature of the fetlocks, feet and eyes was higher relative to the body in 2- and 3-year-olds than in 4-year-olds. Youngest horses were more asymmetrical

Table 1. Blood test variables selected in logistic regression used to differentiate between the longevity group of sires: mean, standard deviation, *P*-value, estimate.

	Mean	SD	*P*-value	Estimate
Bile acids (µmol/l)	5.426	2.428	0.0130	0.24
Bilirubin (mg/l)	13.62	5.72	0.0068	-0.113
Total protein (g/l)	64.49	7.00	0.0410	-0.086
Globulin beta 1 (g/l)	9.882	3.480	0.0850	0.15
SOD (U/g Hg)	1,959	525	0.0006	-0.00148
Copper (mg/l)	0.9741	0.1807	0.0682	-2.3
Leucocyte (/mm^3)	8.754	1.946	0.0028	-0.69
Small lymphocytes (/mm^3)	3,626	948	0.0111	0.00081
Monocytes (/mm^3)	375.7	130.3	0.0582	0.0039
Haemoglobin (g/dl)	12.55	1.29	0.0030	1.104

(fetlock, back, eyes). Females had warmer feet and fetlocks relative to the body than geldings and stallions. Eyes were coolest relative to the body in stallions, followed by females and then geldings. Table 2 shows heritabilities for variables with estimates significantly different from zero for average and/or maximum temperature.

Surface temperature: PCA. The first principal component explained only 17% of the variance. Twenty-three variables were needed to explain 80% of the variance, according to the deliberate choice to avoid redundant variables by using temperature differences. The first axis discriminated between horses that had a rather cold whole body and warm eyes, hocks, fetlocks and feet relative to the body and the opposite (warm body, cold extremities and joints relative to the body). The former had accordingly greater temperature contrasts. These horses also had warm feet relative to the hocks and fetlocks. The second axis gathered the right/left asymmetry variables for fetlocks and feet. The variables calculated from the average or maximum temperatures were on the same axes and indicated the same. The third axis discriminated horses that had warmer hocks than feet, warmer fetlocks than feet and asymmetry in hock temperatures. The fourth axis highlighted the antero-posterior asymmetries of foot temperatures.

Table 2. Heritabilities (SE) of variables derived from measured surface temperatures on 6 images: back, left profile, right profile, front legs, back legs, head.

Measurement	Region of interest	Temperature	
		Average	Maximum
Reference	Overall mean	0.68 (0.19)	-
	Head – overall mean	0.31 (0.14)	-
Specific relative to Reference	Fetlocks	0.58 (0.17)	0.58 (0.16)
	Hocks	0.26 (0.15)	0.27 (0.16)
	Feet	0.64 (0.18)	0.64 (0.17)
	Eyes	0.09 (0.12)	0.70 (0.18)
Specific	Hocks relative to Fetlocks	0.25 (0.13)	0.29 (0.14)
Asymmetry antero-posterior	Feet	0.15 (0.11)	0.13 (0.10)
Asymmetry right-left	Hocks	0.22 (0.13)	0.11 (0.10)
Asymmetry median-lateral	Back polygons	0.70 (0.18)	0.00

Surface temperature: effect of longevity group of sires. Only one variable showed significant difference for EBV-based sire group for longevity (*P*-value 0.03): right and left asymmetry in posterior feet. Asymmetry was lower for the group of favourable sires.

Discussion

Results highlighted the first steps to find early selection criteria for longevity. Oxidative stress and asymmetry of feet temperature were the first interesting criteria. It is possible to relate the amount of SOD to longevity in two ways: either this antioxidant protects against the deterioration of cellular components and thus helps to maintain the cellular integrity necessary for intense exercise; or a decrease in SOD in horses with poor longevity is linked to certain diseases (muscular / respiratory) that may cause the horse to stop competing. Asymmetry in temperature may indicate inflammatory, vascular, or neurological disorder (Soroko and Howell, 2018). Even if surface temperature is highly influenced by environmental factors (Jansson *et al.*, 2021), high heritability of infrared temperatures has already been found in horses. Heritability was 0.26 (0.16) for differences in eyes temperature during effort phase and 0.52 (0.07) during recovery phase in a jumping test (Bartolome *et al.*, 2021). Heritability of eye temperature was 0.38 (0.17) before and 0.50 (0.22) just after dressage competition (Sanchez *et al.*, 2016). Eyes temperature may be related to the level of stress (Cook *et al.*, 2001). When the study protocol will be completed, and 1000 horses measured, more reliable results regarding potential early indicators for longevity can be produced.

764. Recent advances in genomics of equine health, welfare and performance

S.C.M. Mikko

Swedish University of Agricultural Sciences, Dept of Animal Breeding and Genetics, P.O. Box 7023, 750 07 Uppsala, Sweden; sofia.mikko@slu.se

Abstract

Equine research and breeding have encountered major changes due to the rapid development of molecular genetic technology. Today, there are 254 equine traits listed in Online Mendelian Inheritance in Animals (OMIA), while the *Horse*QTLdb lists 2,605 QTLs representing 64 traits. Strong selection increases the risk of inbreeding and multiplication of deleterious variants. Analysis of genomic regions under selection, and trio sequencing could complement Genome-wide Association Studies (GWAS) in the search for genetic background of traits and diseases. The increased possibilities to test for a variety of disease-causing mutations, or performance-associated QTLs, support breeders in informed breeding decisions. SNP genotyping will most likely be implemented for horse parentage analysis in the near future. This large amount of genomic data will open new possibilities to address research questions, and will make it possible to carry out marker-assisted and/or genomic selection also in horses.

Introduction

Equine research and breeding currently encounter major changes due to the rapid development of molecular genetic technology. The horse was among the first mammals to be sequenced, and the trace files, and first gene build of the EquCab2 assembly, was released in already in 2007 (Wade *et al.* 2009). This resulted in an increase of likely causal variants detected and reported to the database Online Mendelian Inheritance in Animals (OMIA) (Figure 1).

The availability of the horse genome assemblies likewise increased the number of QTLs reported to the Horse Quantitative Trait Locus Database (*Horse*QTLdb) (Figure 2; Hu *et al.* 2007, 2022). In 2018 the EquCab3.0 assembly was released providing the community with updated genomic data (Kalbfleisch *et al.* 2018), which resulting in even more variant- and QTL-associations reported.

Equine genomic research has created new possibilities to effectively identify and study genetic risk factors for hereditary diseases in order to develop new and efficient treatments. The gain in genomic understanding about complex traits has further facilitated the selection process for performance in sport horses. Breeding

organizations are obliged to monitor mutations unfavourable to animal welfare, and should be proactive in providing breeding advise promoting sound and healthy individuals. Offering a scientifically supported platform will ensure that the Animal Welfare Act and breeding advice are adapted to current and future technological developments in genomics. However, for horse breeding in practice, the new technologies present both opportunities and risks with the entire genome of a horse sequenced in an effort to detect disease-causing mutations, and at the same time reveal information about other genetic variants in this particular individual. Hence, we are facing a new era where breeders will need and demand assistance and guidance by geneticists, veterinarians and other professionals to interpret the plethora of data available so they can make informed choices in their breeding scheme. The structure of the equine breeding business mainly differs from the breeding of production animal with very few large internationally operating commercial breeding companies. Instead, the equine breeding mostly relies on smaller private companies, or single breeders gathering a quite disparate group of people with a diverse base of knowledge. To produce competitive and healthy horses, breeders therefore need reliable information based on scientific evidence.

Strong selection pressure, as in selective breeding of elite performing horses, will result in chromosomal regions with lower genetic variation, that could be referred to as 'regional inbreeding'. Identification of genetic markers or causative mutations in such regions provide new selection tools in horse breeding. By calculating breed divergence, we revealed long homozygous regions in equine chromosomes, comprising genes possibly important for performance in sport horses (Ablondi *et al.* 2019a). Further, we revealed significantly divergent selection pressure on chromosome regions comprising genes controlling cell signalling in the central nervous system in horses not bred for show jumping, compared to show jumping horses. Our analysis discovered positive selection on chromosome regions with genes involved in mobility, relaxed locomotion and sensitivity in non-show jumping horses. In show jumping horses, positive selection, to a larger extent involve regions with genes associated with mentality, postsynaptic signalling, reward system, neuromuscular control of coordination, muscle growth and -function (Ablondi *et al.* 2019b).

Important monogenic and multifactorial diseases, and traits in the horse

Strong selection increases the risk of inbreeding and multiplication of deleterious disease-causing variants, that do not only negatively affect health and welfare of individual horses, but also have negative economic consequences for breeders. Knowledge of association between traits and genotypes with major influence will therefore aid breeders to produce healthy, sustainable, and better performing horses.

Currently, OMIA lists in total 254 Equine traits, and disorders (https://omia.org/home/). The absolute majority of them are health related (82%), followed by exterior (8%), and reproduction (6%), while there are fewer growth, performance, or behaviour traits reported. A likely causal variant is known in 99 of

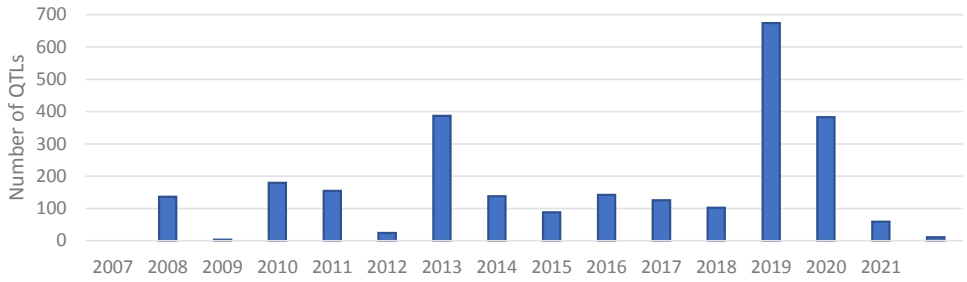

Figure 2. Number of QTL/associations published and reported in the *Horse*QTLdb per year.

these traits or disorders, where 54% of them represent coat colours, 41% are disease-causing variants, and 4% of the variants are associated with performance traits. Among the most recent studies of important monogenic diseases are Fragile Foal Syndrome (Ablondi *et al.* 2022), Dwarfism and joint laxity in Frieasian horses (Leegwater *et al.* 2016), and Ocular Squamous Cell Carcinoma (Chen *et al.* 2021).

Since 2007, 2,605 QTLs/associations representing 64 traits, have been reported to the *Horse*QTLdb (https://www.animalgenome.org/cgi-bin/QTLdb/EC/index). Also in this database, health traits are the most common (48%), followed by growth traits (24%), performance traits (17%), and exterior (6%). Reproduction and behaviour traits are the least reported in the *Horse*QTLdb. Among the most recent studies of important Equine QTLs are; Osteochondrosis (Drabbe *et al.* 2022), Height at Withers (Vosgerau *et al.* 2022), and gait and racing performance (Ricard and Duluard 2022). The difficulties in recording behaviour phenotypes probably reflect the small number of genetic associations reported in both OMIA and *Horse*QTLdb.

Inherited congenital disorders are not always reported by the breeders to the breeding association, and the frequencies of traits and disorders differ largely between breeds, why it is challenging to calculate prevalences. Breeds with an economic value may be studied more often than native and feral horse breeds kept mainly for conservation purposes. In race- and sport horses, a functional and healthy musculoskeletal system is critical for their use, while endangered breeds might instead face fertility problems due to inbreeding. Such factors will influence what specific traits and disorders will be studied, and will not always reflect the prevalence or importance of a trait. In general, health, size and performance traits are the most studied reflecting the functional use of horses.

From disease to genetic testing

To find an assumed genetic association, it is of utterly importance to obtain a detailed clinical description reflecting the correct disease classes associated with the genotypes. A GWAS could be performed using any kind of large-scale genotyping methodology; SNP arrays, 'Genotyping by Sequencing' (GBS, Elshire *et al.* 2011), or 'Skim Sequencing' (Golicz *et al.* 2015). These technologies are also useful for detection of signatures of selection, or specific haplotypes carrying disease-causing mutations. In rare diseases with few cases available, and diseases with autosomal recessive inheritance, causative variants can be detected by Whole Genome Sequencing (WGS) of family trios where candidate variants with the expected genotypes are filtered bioinformatically. In a current project we use WGS of family trios to unravel mutations causing microphthalmia where one or both eyes are underdeveloped or missing. Once a candidate variant is detected it is crucial to validate the finding in a larger sample set, and by functional studies.

Today, the increased possibilities to test for a variety of disease-causing mutations, or performance-associated QTLs, support breeders in informed breeding decisions. Such genetic tests will indeed prevent production of disease-affected foals while unaffected carriers can still be kept in the breeding pool and maintain the genetic variation of the population. Large scale genotyping, or WGS is likely to replace today's genetic tests on individual or panels of mutations. Inevitably, this technology-driven efficient mutation identification will affect the future of horse breeding.

Genomics and the breeders' perspective

Despite the continuous increase in the amount of equine genomic data, genomic selection has not yet been fully implemented in horse breeding. The main reasons are high costs, difficulties to obtain large enough reference populations, and a high effective population size or short linkage disequilibrium in many horse breeds, compared with for example cattle where genomic selection has been applied for many years. For more than 20 years, a few microsatellites have been the standard markers for parentage analysis of horses, however SNP genotyping will most likely be implemented for parentage in the near future. Such a large

amount of genomic data from a huge pool of horses comprising many breeds around the globe, will open new possibilities to address research questions, and will make it possible to implement marker-assisted and/or genomic selection also in horses.

765. Microsatellite allele imputation from SNP genotypes for parentage verification in sport horses

H. Crichan[1*], C. Engler[1], E. Goulas[1], S. Dhorne-Pollet[2], M. Addes[1] and A. Ricard[1,2]

[1]Institut Français du Cheval et de l'Equitation, Pôle développement, innovation et recherche, La jumenterie, 61310 Exmes, France; [2]GABI, INRAE, AgroParisTech, Université Paris Saclay, 78350 Jouy en Josas, France; harmony.crichan@ifce.fr

Abstract

In the major livestock species, parentage verification is done using Single Nucleotide Polymorphism (SNP) markers. ISAG is working to produce a SNP panel for parental verification in horses. There will be a transition period between microsatellites (MS) and SNPs. Without any tool for the transition, breeders will have to double genotype foals or re-genotype mares and stallions with SNPs. We wanted to produce a tool to predict MS genotypes using SNP markers that could be included on a chip with the new ISAG panel. To achieve this we built a correspondence table between MS alleles and SNP haplotypes. We validated it using kfold cross-validation. With the highest SNP density, we obtained 3.4% of incompatibilities over 2 or more MS or 96.6% of parental verification achieved over the major breeds in our study, Selle-Français (SF, 54%), French Trotters (TF, 22%), Arabs (AR, 17%), Anglo-Arabs (AA, 3%) and other saddlebreds (SE, 4%).

Introduction

Nowadays, parental verification in horses is done using MS genotypes. ISAG is currently working on a new SNP panel for parentage testing that will soon replace the microsatellite panel. Lab technologies to produce microsatellite and SNP genotypes are different so genotypes of these markers cannot be obtained at once. The objective of our study is to predict MS genotypes from SNP haplotypes using commercial SNP chips to perform parental verification.

Materials & methods

Data. IFCE (Institut Français du Cheval et de l'Equitation), INRAe and Fonds Eperon funded research programs such as Genequin, JumpSNP, SelGenEqui, GenEndurance and SoGen that provided horses with SNP genotypes used in this study. MS genotypes of the SNP genotyped horses and their parents from routine parental verification came from SIRE (equine information database). Horses with incompatibilities with their dam or sire or occurring as a parent of an incompatible foal were removed from the reference population. There were 5,892 horses with a genotype over at least one known MS and with SNP genotypes. The breeds were mainly Selle-Français (SF, 54%), French Trotters (TF, 22%), and Arabs (AR, 17%), with few Anglo-Arabs (AA, 3%) and other saddlebreds (SE, 4%).

As the data came from different research programs, horses were genotyped with three different SNP chips: 54K (54,602 SNPs, 29%), 65K (65,157 SNP, 15%) and 670K (670,806 SNP, 56%). SF were mostly genotyped with the 670K SNP chip, half of the TF were genotyped with the 54K and the other half with the 670K, and AR mostly with the 65K.

By investigating the MS genotypes, we observed that three MS over the 14 were missing for most of the horses, we had genotypes for only 11.4% of the horses for ASB17, 11.4% for ASB23 and 10% for HSM2. Result were therefore obtained for the 11 MS remaining

Method – correspondence table building. The method was based on McClure *et al.* (2012) and McClure *et al.* (2013) who worked on cattle. SNPs located within 500,000 base pairs on each side of the MS were

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_765, © H. Crichan *et al.* 2022

selected. We then phased MS alleles together with SNP genotypes using Fimpute3 (Sargolzaei *et al.*, 2014) by converting MS alleles into pseudo-SNP (Karimi *et al.* 2018, Teissier *et al.* 2020). This transformation was useful because FImpute3 only works bi-allelic markers. From the imputation, we obtained SNP haplotypes and MS alleles alongside. A correspondence table was then created between MS alleles and SNP haplotypes. The table was built so that one MS allele could have multiple correspondences with SNP haplotypes but a SNP haplotype had to correspond to only one MS allele. A second rule was that only the closest SNP constituted the haplotypes. Eight to 40 SNP located on either side of the MS constituted the haplotypes.

Method – validation. Horses were randomly split in five groups of equal sizes; each group was in turn the validation set and the training set. Using the training set, we built the correspondence table. The MS genotypes of the validation set were predicted using the correspondence table only. The partitioning of the validation sample was repeated 10 times. We then compared the predicted MS alleles with the actual MS alleles information. We measured ineffectiveness using the percentage of MS genotypes attributed with the correspondence table that were different from the original MS genotypes. The second measure of ineffectiveness was the number of MS found incompatible using MS parental information.

Results

Genotypes description. Over the 5,892 horses, parental verification was achievable for 96.1% of them (5,661). Of the 5.9% of the 5,661 horses with at least one MS incompatible, 5.3% had one and 0.6% had two MS incompatible. MS had a variable number of alleles in our dataset, ranging from six to 12, and recruited SNPs around them varied from 111 to 314. 1,908 SNPs were used in this study, the vast majority were in the 670K SNP chip (1,902), and only 10% of them were in the 65K SNP chip.

Training and validation sets. Rates of false genotypes were 0.6% for MS HTG6 and 8.1% for MS HMS3 with a 32 SNPs long haplotype. With the k-fold validation, false genotypes varied with the MS considered and with the length of the haplotype with a threshold observed at 32 SNPs (Figure 1). The proportion of horses with more than one MS incompatible increased from 0.6% initially to 12.4% with a 32 SNP

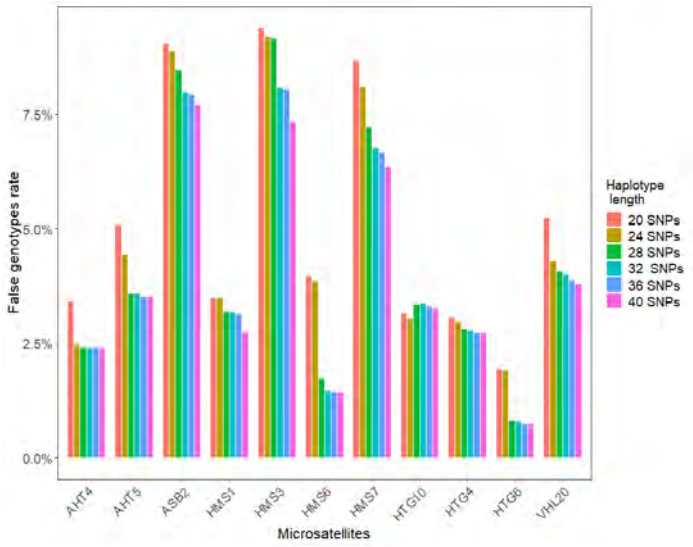

Figure 1. Average rates of false genotypes by MS and by haplotype length in the validation set (10-fold cross validation).

haplotype, the standard deviation of theses proportions between the random draws was 0.3%. For a 32 SNPs haplotype, we obtained 25% of one MS incompatible and 12% of 2 MS incompatible.

The error rate depended on the breed. Horses with more than one MS incompatible varied from 27.3% for AR to 7.3% for SF. A major difference between these breeds was the chip mainly used for the SNP genotyping.

As Figure 2 shows, the incompatibility differences were related to the density of the SNP chip used to genotype the horses. Only 3.4% of horses genotyped with the 670K SNP chip had more than one MS incompatible, whereas this percentage greatly increased to 32.1 and 21% with horses genotyped with the 65K SNP chip and the 54K SNP chip respectively. For horses genotyped with the 670K SNP chip, results were promising on the three breeds with only 4% for FR, 3.4% for AR and 3.2% for SF of horses with more than one MS incompatible.

Discussion

The method of SNP based MS imputation is recommended as a transition tool to save genotyping extra costs. There are some limitations regarding the results obtained from the correspondence table. First, there were three breeds in our study and we saw that the distribution of MS alleles differed across breeds; if we want to be able to predict MS alleles over all breeds, we will need more genotypes from different breeds to improve the corresponding table. This procedure may be difficult to manage and to automate, as some horses will need re-genotyping with MS. It will need to be accepted by breeders who are the primary clients for parental verification. If not, parental verification will need to be done by re-genotyping and/or double genotyping during the transition period. One of the questions is also the value of these results internationally. Horses that produce offspring or perform internationally will most likely be genotyped with both types of marker sets. Moreover, ISAG recommends only the re-genotyping in the first place as it was eventually done with cattle during their transition from MS to SNP. Finally, breeders' organizations will have to encourage their members to SNP genotype their horses so that the transition period is reduced to a minimum.

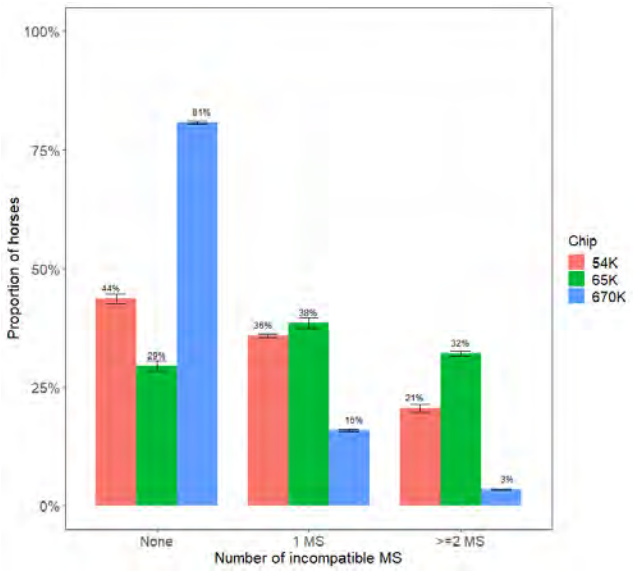

Figure 2. Average rates of incompatible MS by SNP chips in the validation set (10-fold cross-validation).

Abstract

In equine parentage control, the current common practice is the use of an internationally agreed upon microsatellite (MS) marker panel. In German horse breeding the goal is to transition to a SNP-based parentage control system. To facilitate the change from one method to another, an intermediate solution is the imputation of MS markers based on SNP genotypes. The feasibility and accuracy of such an imputation has been tested with a learning dataset of horses (n=2,607) from five different breeds. Horses have been genotyped for 11 to 17 MS markers, depending on studbook policies, and have been SNP-genotyped with an Illumina BeadChip (GGP Equine 70k or GGP Equine plus). The imputation has been conducted with Beagle 5. Results indicated that an average imputation accuracy 95.69% could be achieved for the 12 MS markers that belong to the mandatory panel of the International Society for Animal Genetics (ISAG).

Introduction

For more than two decades, the routine equine parentage control in Germany has been conducted via the microsatellite (MS) panel endorsed by the International Society for Animal Genetics (ISAG, https://www.isag.us/) (Bowling *et al.*, 1997). In the context of the planned introduction of genomic selection in German Warmblood horses by the International Association for Future Horse Breeding (IAFH), founded in 2017, a switch to a SNP based panel has become necessary. The advantage of using an SNP array lies in the diversity of its applications. Conditional on an appropriate number and selection of SNP markers, the information can be used not only for parentage control, but also for the determination of genomic breeding values for various traits. Compared to MS, SNPs have a better standardisation in genotyping and a lower mutation rate. At the same time, they are characterised by a lower cost per genotype, a higher throughput of data and an easier process to automate in the laboratory (McClure *et al.*, 2013).

In parentage control, it is essential that marker genotype information of the same category is available for both, parents and foals, i.e. MS or SNP information is required for both generations. To avoid double typing and the associated costs, time and effort in the future, foals should only be genotyped with a SNP array. As a consequence, it is necessary to obtain the MS information by imputation in order to be able to compare it with the parental generation. Imputation is the statistical determination, based on the SNP data, of the MS genotypes that an animal is most likely to carry. Before this process may be used routinely in practice, it is necessary to create a large learning dataset genotyped for both SNPs and MS. In cattle, the switch from the old MS system to a SNP panel has already been demonstrated and successfully applied (McClure *et al.*, 2012). The aim of this study was to impute MS genotypes in horses based on SNP genotypes and to assess the accuracy level of this approach in equines.

Materials & methods

The learning dataset used in this study consisted of 2,706 female horses that belong to the warmblood horse breeds Holsteiner (n=988), Trakehner (n=333), Westphalian (n=196), Oldenburg (n=926) and Oldenburg International (n=164). Hair samples have been collected by the studbooks during or as part of routine horse registration, identification or performance tests. Contract laboratories of the participating studbooks performed the MS genotyping according to their agreed upon panels, ranging from 11 to 17 MS markers. DNA extraction for the SNP genotyping was performed according to standard protocols at the Werlhof Institute (Hanover, Germany). Horses have been SNP genotyped with the Illumina GGP Equine 70k (n=715) or the GGP Equine plus (n=1,892) beadchip. All animals included here had a SNP call rate of ≥95%. SNPs were filtered for their minor allele frequency (≥0.01), a GC-Score (≥0.6), a call frequency (≥0.90), and Hardy-Weinberg-Equilibrium (≤0.001). MS genotypes and SNP genotypes were combined into one file in VCF-format. The imputation process was conducted with Beagle version 5.0 (Browning *et al.*, 2018). Default parameters were kept except for window size (200) and effective population size (30,000). All SNPs that are located on the same chromosome as the target MS were used for the imputation. In order to assess error rates of this method, a tenfold cross validation was performed in which 10% of the horses were masked for their MS genotype and imputed by means of the other 90% of the learning dataset. Ten percent of the horses from each of the five breeds were pooled to form a representative validation group. The imputed MS genotypes were then compared to the original (masked) data and scored for accuracy on a scale from zero to 100 as follows: 0 (both MS alleles incorrectly imputed compared to the original), 50 (one MS allele correctly imputed) and 100 (both MS alleles correctly imputed). Average accuracy scores were calculated per replicate, MS marker and breed. The error rate was calculated as 100 minus the respective imputation accuracy.

Results

The overall average imputation accuracy for all 17 MS markers was 96.17% (SD: 5.55), which corresponds to an error rate of 3.83% (Table 1). The error rates were higher in the set of mandatory markers (4.31%) than in the optional markers (2.68%). When evaluating the results separately for each breed, the Trakehner population had the lowest error rates with 2.40% for all 17 markers. The observation that the mandatory markers had a higher average error rate than the optional markers was made for each breed except for Westphalians. Overall, the group of Westphalian horses stood out because of comparatively high error rates for both mandatory markers (mean: 4.98%, SD: 6.37) as well as optional markers (mean: 22.45%, SD: 22.62). An assessment of the error rates on a MS marker level (Figure 1) revealed three markers that had high error rates in all breeds (ASB17, ASB23, AHT5) and three markers that only underperformed in Westphalian horses (HSM1, CA425, LEX3). An in-depth analysis of error rates and genotyping rates (GTR) for the MS markers showed that five out of the six problematic MS markers had low GTR (zero to 65%).

Table 1. Average imputation error rates for microsatellite markers by horse breed.

	Average imputation error rates in percent (%) for MS[1]-markers		
Horse breed	**17 markers**	**12 mandatory markers**	**5 optional markers**
all breeds	3.83	4.31	2.68
Holsteiner	3.32	4.47	0.58
Oldenburger	3.04	3.68	1.52
Oldenburg International	6.65	8.85	1.38
Trakehner	2.40	3.01	0.94
Westphalian	10.12	4.98	22.45

[1] MS = microsatellite.

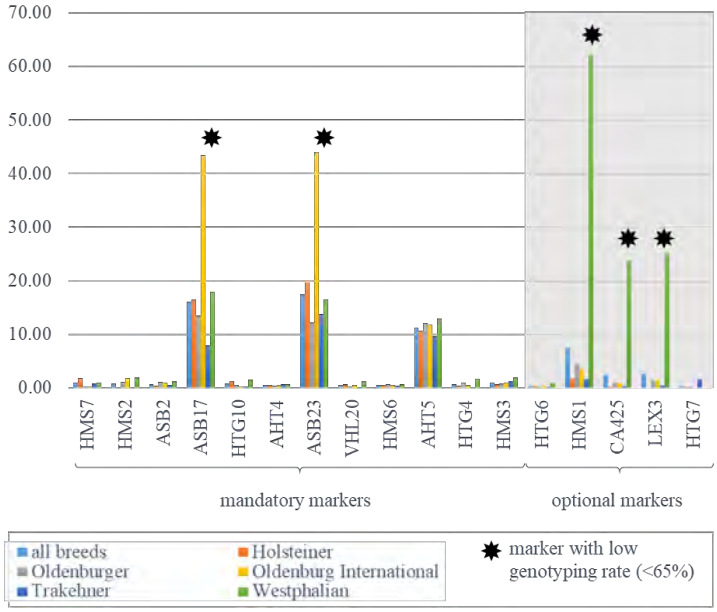

Figure 1. Imputation error rates in percent (%) for 17 equine microsatellite markers.

In Westphalians the GTR for HMS1, CA245, and LEX3 were 98.98, 22.96, and 22.45%, respectively. These markers had GTR below 1.5% in all other breeds. The markers ASB17 and ASB23 had GTR>98% in all breeds except for the Holsteiner horse, where this marker was only genotyped in single cases (GTR=0.20%.). As for AHT5, the GTR ranged between 99.40% (Trakehner) and 100% (all other breeds). An assessment of the chromosomal position of AHT5 showed that is marker is located at the telomeric end of the equine chromosome ECA8. Consequently, only eight SNPs were available for imputation upstream of the MS marker.

Discussion

Results from a ten-fold cross-validation scheme for a MS-marker imputation based on SNP-genotyped revealed that average imputation accuracies of 98% and beyond are feasible for certain markers. However, error rates increase when GTR are at a low level, especially when GTR are very heterogeneous between subgroups of a dataset. For Westphalian horses it could be observed, that the imputation accuracy for horses of this breed is greatly diminished when only few data points from horses of other breeds are also introduced, potentially representing haplotypes that are not present in the Westphalian group. Using an across breed imputation approach for markers of very unequal and low GTR cannot be recommended. We conclude that a high quantity of information leads to better imputation accuracies. However, optional markers of high GTR and high imputation accuracy, e.g. HTG6 and HTG7, are a valuable substitute for problematic markers such as AHT5. Compared to previous results in cattle, similar imputation accuracies were achieved within our study, particularly when considering MS markers with GTR above 90%. This is remarkable, especially because the reference panel in each replicate contained less than 2,500 animals, while McClure *et al.* (2014) used a reference panel of over 7,000 animals and reached accuracy levels of >98% in Irish cattle, which is similar to results in our study. With over 97% imputation accuracy, Marina *et al.* (2021) have also reported comparable magnitudes from Spanish Assaf sheep, following an experimental design, which was highly similar to the design in our study. Overall, our results can be considered highly encouraging and for a future routine application in practice.

767. Haplotype blocks and heterozygosity rich regions on ECA2 in Swedish Warmblood horses

Abstract

The Fragile Foal Syndrome (FFS) is a disease caused by a recessive lethal missense mutation in the *PLOD1* gene (ECA2). Despite its harmful effect, a relatively high frequency of the FFS allele carriers has been found in the Swedish Warmblood (SWB), suggesting a heterozygous advantage. Balancing selection can be further studied in haplotype blocks and increased heterozygosity around the target of selection. In this study we evaluated the presence of haplotype blocks and Runs of Heterozygosity on ECA2 in 380 SWB horses divided by sport discipline. In horses mainly bred for dressage a haplotype block comprising the FFS variant was found. On average 11.7 Runs of Heterozygosity were identified per horse on ECA2, with no significant difference in numbers between the sport disciplines. This study provides a preliminary characterization of haplotype blocks and heterozygosity rich regions on ECA2 which may further corroborate the potential presence of balancing selection for the FFS allele.

Introduction

Fragile Foal Syndrome (FFS) is a monogenetic disease caused by a recessive lethal missense point mutation in the *PLOD1* gene located on ECA2. Most FFS recessive homozygous foals are assumed to be lost by abortion during late gestation, whereas liveborn affected foals show severe skin fragility, joint hyper-elasticity, and need to be euthanized (Aurich *et al.*, 2019). Despite its harmful effect, a relatively high frequency of FFS carriers (7.4%) was found in the Swedish Warmblood breed (SWB), suggesting the presence of a heterozygous advantage. The presence of balancing selection in SWB was corroborated in a recent study where significant positive effects of the FFS allele were found mainly on movement related traits (Ablondi *et al.*, 2022). Balancing selection causes various types of signatures in the genome such as: increased diversity around the target of selection, differentiation between populations departing from the same genome wide background, and increased linkage disequilibrium around the target of selection (Fijarczyk and Babik, 2015). The advances in high throughput genotyping procedures permit further investigation of the presence of such signatures within animal species. In this study we aimed to explore the presence of haplotype blocks and heterozygosity rich regions on ECA2 in SWB horses to investigate if there is balancing selection acting on the FFS variant or on another closely located variant.

Materials & methods

A total of 380 SWB horses born 2010-2011 were genotyped using the 670 K Affymetrix® Axiom® Equine Genotyping Array. These horses were also genotyped for the XM_001491331: c.2032G > A variant in the *PLOD1* gene by a TaqMan genotyping assay on a StepOnePlus™ instrument (Applied Biosystems, Foster City, CA, USA). For the scope of this work, only SNPs on ECA2 (52,075 SNPs) were retrieved. The quality control (QC) was performed in PLINK v1.90 (Purcell *et al.*, 2007), based on the criteria: minor allele frequency (MAF) (<0.05), missing genotype per single SNP (GENO) (>0.10) and missing genotype per individual (>0.10). Haplotype blocks were defined as in Gabriel *et al.* (2002), considering the region including the *PLOD1* gene ± 1 Mbp, and detected using the Haploview software.

Runs of Heterozygosity (ROHet) were detected using the settings suggested by (Santos *et al.*, 2021) in the R package 'detectRUNS' (Biscarini *et al.*, 2019). ROHet within the ECA2 were considered as indicator of heterozygosity rich regions if they were shared by over 25% of the analysed horses. Haplotype blocks and ROHet detection was performed separately in two subgroups, defined as in Ablondi, *et al.* (2019), where horses with higher or lower EBV for show jumping than the reference population (mean EBV of 100) were classified as show jumping (SJ) and non-show jumping (NS) horses, respectively. Most NS horses had a dressage index above average. The Ensembl gene annotations EquCab3 was used to identify genomic elements extending 250 kb up- and downstream of the potential heterozygosity rich regions.

Results

A total of 31,122 SNPs and 380 horses passed the QC (189 NS and 191 SJ). Overall, 47 and 50 haplotypes were found in the NS and SJ horses, respectively, considering the region including the *PLOD1* gene ± 1 Mbp. These haplotype blocks were between 2 Kb to 115 Kb long. The haplotype with the greatest number of SNPs in the NS horses comprised 18 SNPs (40 Kb long) and was located 836 Kb upstream the FFS variant. For SJ horses, the highest number of SNPs within a haplotype was 19 (115 Kb long) and located 349 Kb downstream the FFS variant. In the NS, but not in the SJ, the FFS variant was in strong LD (D' equals to 1) with the closest downstream SNP (7 Kb apart), located within the *MFN2* gene (Figure 1).

On average 11.7 ROHet per horse were identified on ECA2, which was equal in both groups (SJ and NS horses). The ROHets had a length ranging between 12.6 Kb and 324 Kb and contained from 15 to 30 SNPs. On average ROHets were 69.5 Kb long and included 15.8 SNPs. A total of three ROHets were shared among

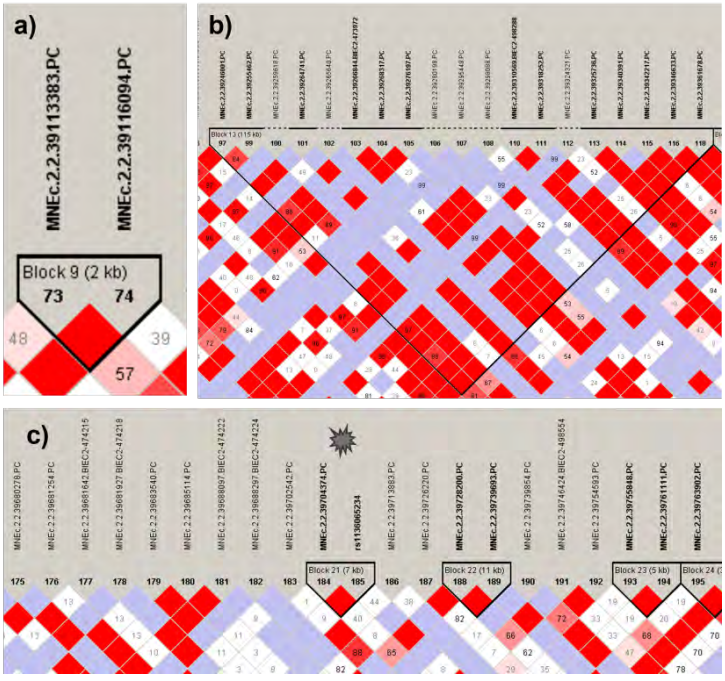

Figure 1. Examples of haplotype blocks in SWB within the *PLOD1* gene ± 1 Mbp: (a) haplotype block with minimum block size of 2 Kb, (b) haplotype block with maximum block size of 115 Kb in SJ horses, (c) haplotype block between FFS variant and the closest downstream SNP in NS horses which is highlighted with a grey star.

25% of the SWB horses: one in the SJ subgroups and two in the NS subgroup (Figure 2 and Table 1). In the case of NS horses, six lncRNA, five protein coding genes and one snRNA were found within the two heterozygosity rich regions shared in over 25% of the horses. In contrast in SJ, seven protein coding genes, two lncRNA and one miRNA were found.

Discussion

In NS horses, we found a haplotype block containing the FFS variant which was not detected in the SJ horses. A potential reason behind the failure to detect the haplotype in the SJ may be the lower frequency (5.8% in SJ vs 14.6% in NS) of the FFS variant in SJ horses as previously found by Ablondi *et al.* (2022) or that the selection pressure for heterozygosity in *PLOD1* is lower in SJ horses. In NS horses, the FFS variant was in strong LD with a SNP located within the Mitofusin 2 (*MFN2*) coding gene. The *MFN2* is involved in the regulation of vascular smooth muscle cell proliferation and has been found associated with disorders of the peripheral nervous system (Engelfried *et al.*, 2006), but is not known to be associated with joint

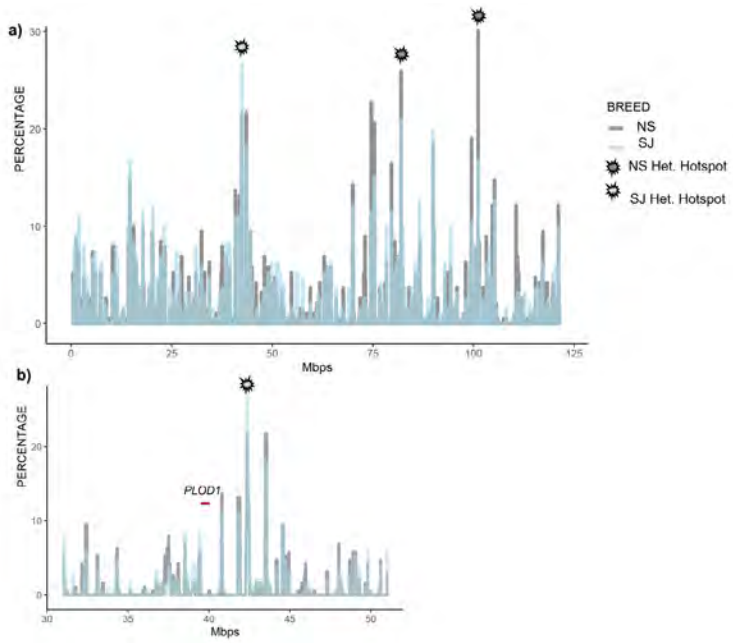

Figure 2. Proportion of times each SNP falls inside a ROHet in the two subgroups (SJ and NS) plotted against their position along the ECA2, with (a) showing the whole ECA2 and (b) showing a zoom-in representation on the *PLOD1* region ±10 Mb is shown.

Table 1. Heterozygosity rich regions on ECA2 shared in over 25% of the SWB horses divided into subgroups (SJ and NS) based on sport discipline.

Subgroup	Start (bp)	End (bp)	N. SNPs	Kb length	Percentage shared
NS[1]	81,932,632	81,972,128	16	39.5	25%
NS	101,054,766	101,088,692	12	33.9	32%
S[J]2	42,333,297	42,360,263	3	26.9	27%

[1] Non-show jumping SWB horses.
[2] Show jumping SWB horses.

elasticity or fragile skin. Interestingly, although for the *MNF2* SNP, the reference allele is the most common allele in the SWB, all FFS carriers horses among the NS horses carried the variant allele.

Compared to the length of runs of homozygosity (ROH) segments found in the SWB breed by Ablondi, *et al.* (2019) the ROHet investigated in this study were much fewer and detected more scarcely. This result was expected since polymorphic sites only account for a small portion of the whole genome. Nevertheless, the average number of ROHet found in the SWB ECA2 was more than three times higher compared to the one found in Mangalarga Marchador horse breed (Santos *et al.*, 2021). We did not find any clear signs of heterozygous rich regions next to the FFS variant. This can be expected if strong selection pressure is present around this locus, and heterozygosity advantage is only present for the FFS variant itself. We will further compare our findings on SWB ECA2 with the rest of the SWB genome to evaluate the potential role of balancing selection for the FFS variant.

Abstract

The structure of the equine sector implies the need for collaborative approaches to implement genomic applications in sport horse breeding. Based on a multi-breed reference population of 5,000 horses from five breeds, a single step genomic evaluation system for linear conformation and performance traits was developed. Using two different validation approaches, forward and cross validation, medium (around 0.6) to high (over 0.9) correlations of genomic estimated breeding values (GEBVs) indicated stability of the developed system. Different relatedness between the breeds was reflected in the results, but the benefit of available genotypic data with regard to the variance of the GEBVs was found for each breed. According to the findings of this study, single-step genomic evaluation using a multi-breed reference population is a feasible approach for routine implementation of genomic selection in sport horses.

Introduction

The introduction of genomic selection in animal breeding can be referred to as paradigm shift (Meuwissen *et al.*, 2016). For horse breeding, this method has great potential because it allows shortening the long generation interval and integrating traits with low heritability or which are difficult to record into the breeding programs. Although this has been recognized already years ago (Haberland *et al.*, 2012, Mark *et al.*, 2014), there is until today only one studbook for sport horses with officially published genomic breeding values for a single trait (Knaap, 2017). The major challenges of successfully implementing genomic selection in horse breeding relate to definition of suitable target traits and compiling of a sufficiently large reference population. The structure of the equine sector implies particular interest in genomic systems which allow use of data across studbooks and breeds of riding horses: individual breeding populations are often small, but breeding goals are overlapping and exchange of genetic material is existing worldwide. The aim of this study was to validate the across breed approach for single step genomic evaluation and perform detailed distribution analyses of GEBVs with focus on possible breed differences.

Materials & methods

The data basis for developing a genomic evaluation system for equine conformation and performance traits was from five breeding organizations of German riding horses: Oldenburg (OL), Oldenburg International (OS), Trakehner (TRAK), Holstein (HOL), and Westphalian (WESTF). Phenotypes were available from routine linear description of the respective studbooks for which they used the same comprehensive linear scheme. The about 41,600 linear profiles of foals and adult horses, which could be used for this work, had been recorded between 2012 and 2019 in connection with regular evaluation events. To implement a single step genomic evaluation system, pedigree data of all phenotyped horses plus four ancestral generations

were considered resulting in a relationship matrix of around 116,500 horses. The references population included 5,000 linearly described horses.

Genotyping was performed with commercially available single nucleotide polymorphism (SNP) arrays of medium density from Illumina (Illumina, 2015), GGPEquine (65,157 SNPs; 788 horses), and GGPEquinePlus (71,947 SNPs; 4,212 horses). After quality control with minor allele frequency of 0.01, call frequency of 0.1, call rate of 0.05 and a threshold of $P<0.001$ for Hardy Weinberg equilibrium test, n=4,964 horses and n=61,211 SNPs remained for analyses. The distribution of the different breeds in the dataset was: n=1,565 horses from OL, n=1,367 horses from HOL, n=829 horses from WESTF, n=778 horses from TRAK, and n=425 horses from OS. The genomic relationship between the five breeds included in the reference population was analyzed by principal component analysis (PCA plot, python version 3.8.1).

The 23 conformation and 18 performance-related linear traits were defined within age group and analyzed in pairs of analogous traits using the following linear animal models for foals (1) and adult horses (2).

$$Y_{ijklop} = \mu + SB_i + EVENT\text{-}TEAM_j + AGE_M_k + SEX_l + animal_o + e_{ijklop} \quad (1)$$

$$y_{ijmnop} = \mu + SB_i + EVENT\text{-}TEAM_j + AGE_Y_m + PTYP_n + animal_o + pe_o + e_{ijmnop} \quad (2)$$

where y is the phenotype; μ is the overall mean; SB is the fixed effect of the i^{th} studbook (i=1-5); EVENT-TEAM is the fixed effect of the combination of the event and team performing the linear description; AGE_M and AGE_Y are the fixed effects of the age of the foals in months (k=1-5; <1 month, 1-2 months, 2-3 moths., 3-4 months, >4 months) and of the adult horses in years (m=1-4; <3 years, 3-4 years, 4-5 years, >5 years); SEX is the fixed effect of sex for the foals (l=1-2; male female; distinct events for mares and stallions in the group of adult horses); PTYP is fixed effect of the presentation type for the adult horses (n=1-3; in hand, free, under saddle); animal is the random additive genetic effect; pe is the random permanent environmental effect; and e is the random residual effect. We used the software package MiX99 release XI/2019 version 19.1129 (Vuori *et al.*, 2006) for solving the equation model. GEBVs were standardized to a mean of 100 and a genetic standard deviation of 20.

The system was validated in two ways: Ten-fold cross-validation was performed by repeatedly choosing 15% of the genotyped and non-genotyped animals randomly per studbook, sex and trait as validation animals (VA); forward validation considered all horses linearly described in 2018 or later as VA. In each case, phenotypic data of the VA were excluded for the validation runs, and Pearson correlations between the GEBVs from the full run considering all available data and the validation run were determined (python version 3.8.1).

Distribution of the GEBVs were analyzed in more detail in the phenotyped horses born in 2007-2017 (approx. n=28,000). Descriptive statistics (mean, standard deviation, minimum, maximum) were generated for all horses and stratifying by studbook and availability of genotypic data.

Results

The principal component analysis of the genomic relationships among the five breeds in the reference population revealed three clusters. The first cluster comprised most of the horses from WESTF and OL, the second most of the horses from HOL and OS, and the third cluster included the horses from TRAK (Figure 1).

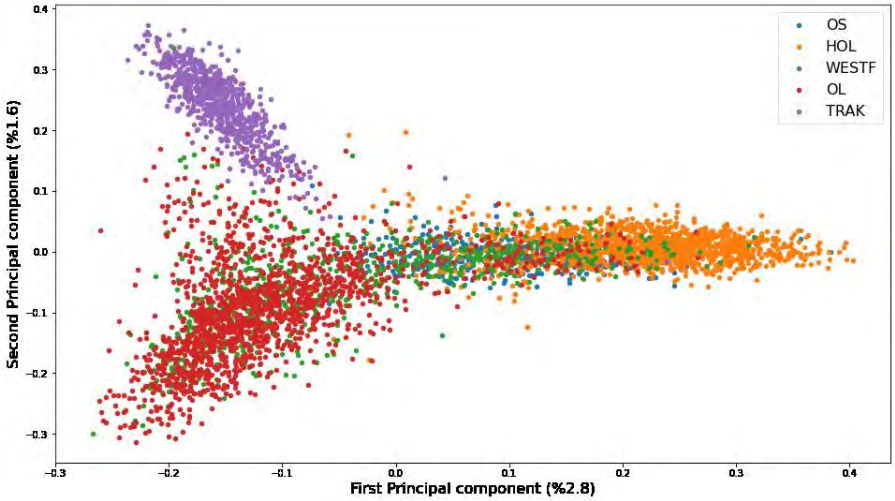

Figure 1. Principal component analysis of the n=4,964 horses in the reference population after quality check, showing the first two principal components.

The mean correlation coefficients between the GEBVs from the full run and the ten cross-validation runs were medium to high, with ranges of 0.60-0.95 for all VA and 0.86-0.99 for genotyped VA. Analyses of correlation coefficients for the genotyped VA by studbook revealed mostly minor differences, but with consistently higher figures for OL (0.88-0.98) and WESTF (0.86-0.99), followed by HOL (0.80-0.97) and OS (0.72-0.96), than for TRAK (0.63-0.94). The forward validation resulted in slightly lower GEBV correlations ranging between 0.56 and 0.89 for all VA and between 0.83 and 0.97 for the genotyped VA.

Analyses of the GEBV distributions showed clearly higher standard deviations in the genotyped horses than in the non-genotyped horses (on average +2.18 for the linear conformation traits and +2.30 for the linear performance traits). Similar results were obtained for each studbook with average differences between standard deviations of GEBVs in genotyped and non-genotyped horses ranging between +1.19 (TRAK) and +2.17 (OS) for conformation and between +1.30 (TRAK) and + 3.02 (OS) for performance traits. The standard deviations in all horses within studbook ranged between 8.68 (HOL) and 13.38 (TRAK) for conformation and between 7.84 (OS) and 11.47 (WESTF) for performance traits (Table 1).

Discussion

To meet the challenge of getting a sufficiently large reference population, German horse breeding organizations collaborated to assemble a 5,000 horse multi-breed training set for linear conformation and performance traits. The principal component analysis of the genomic relationships among the five included breeds reflected their relatedness. Different breeding focusses of studbooks on either of the two main disciplines of riding sport can explain the formation of two of the clusters, with one cluster including horses from studbooks with dressage as important breeding goal (WESTF, OL) and another cluster including horses from studbooks focusing on show-jumping (HOL, OS). The remaining cluster included TRAK horses, which is consistent with the breeding policy of a closed studbook where direct genetic links mainly exist through commonly used Thoroughbred or Arabian bloodlines and TRAK horses used in other studbooks. The expected closer relation of TRAK to the dressage cluster than to the cluster of studbooks with special focus on show-jumping was in accordance with other studies (Nolte *et al.*, 2019) also in our sample of genotyped horses.

Table 1. Means and standard deviations (std.) of GEBV across all performance traits (n=18) and all conformation traits (n=23) for the subset of phenotyped horses born between 2007-2017 by studbook and availability of genotypes.

	all	OL	HOL	WESTF	TRAK	OS
Conformation						
n	27,928	11,209	7,516	2,671	1,487	3,296
mean	100.19	100.73	99.95	100.06	100.15	99.26
std.	9.95	9.82	8.68	8.78	13.38	8.74
Conformation + genotype						
n	4,796	1,556	1,231	824	763	422
mean	100.28	101.02	100.10	100.10	99.80	99.31
std.	12.13	11.71	10.66	10.42	14.57	10.91
Performance						
n	28,560	11,343	7,599	2,874	1,497	3,356
mean	100.46	100.21	102.19	100.53	94.09	100.69
std.	11.27	9.93	8.07	11.47	11.01	7.84
Performance + genotype						
n	4,846	1,556	1,281	824	763	422
mean	100.12	100.67	102.22	101.22	93.67	101.18
std.	13.57	12.04	9.97	13.25	12.31	10.86

The reasonable variation of relatedness between the breeds included in the joint reference population implied the need of additional checks of the single step genomic evaluation system. Detailed analyses of the validation results by studbook showed lower GEBV correlations for TRAK than for the other contributing breeds. However, correlations were still in a range, indicating also for this studbook a satisfactory performance of the system for most of the linear target traits. In other species a multi-breed reference population has already proven to be a possible way for smaller populations to start with genomic selection if the respective breeds are related to each other (Lund *et al.*, 2014). This precondition is fulfilled for German warmblood horses. The analyses of the GEBV distributions showed in all breeds higher standard deviations for genotyped than for non-genotyped individuals indicating that genotyping benefits individual characterization of and differentiation between horses in a multi-breed single step genomic evaluation system for linear conformation and performance traits. With the transition to routine SNP genotyping with a medium density array as basis of parentage control, increasing proportions of genotyped horses will support future breeding progress in sport horse breeding.

769. Methodology to integrate pedigrees of two Belgian Warmblood studbooks and its importance for genetic evaluation

L. Chapard*, N. Buys and S. Janssens

KU Leuven, Department of Biosystems, Center for Animal Breeding and Genetics, Kasteelpark Arenberg 30, 3001 Leuven, Belgium; lea.chapard@kuleuven.be

Abstract

Most of the Warmblood studbooks allow for exchanges of genetic material with other studbooks. However, unique horse identification numbers are not consistently used across them, and an approved horse may have multiple identification numbers. This might cause problems because genetic evaluations are based on the use of pedigree information. In particular, the development of an across-breed evaluation becomes inaccurate when horse identification numbers are not unique. In this study, two pedigrees are concatenated and a semi-automated method based on string comparisons is developed to obtain an integrated pedigree. In test runs of genetic evaluations for a competition trait, this integrated pedigree is compared with an uncorrected and concatenated version of the pedigree. This uncorrected version of the pedigree resulted in a slightly higher heritability and also in differences in estimated breeding values compared to the integrated pedigree.

Introduction

European Warmblood studbooks which aim to breed successful show jumping horses are genetically connected (Thorén Hellsten *et al.*, 2008; Ruhlmann *et al.*, 2009). Hence, exchanges of genetic material are very common across these populations, and many well-known breeding sires (and also mares) are represented in several studbook pedigrees, i.e. they have offspring in different countries (Rovere, 2016). As most of the European studbooks are open studbooks and have similar breeding objectives concerning jumping performance (Koenen *et al.*, 2004), the development of joint genetic evaluations across two or more studbooks was often discussed. However, to develop such an evaluation for several breeding organizations, unique identification numbers used across organizations are essential. Indeed, unique numbers are needed to connect pedigrees and link phenotypes to individuals. For this, the horse identification number (Unique Equine Life Number, UELN) was created (as of 1999), but in practice they are often not unique across and even within studbooks. For example, once a foreign horse is approved for breeding in a studbook, often a new identification number is created which is different from its original one. So, when it comes to working with pedigree data coming from different studbooks with genetically connected horses, having an integrated pedigree free of duplicates and of horses with multiple UELN becomes a tedious task. The aims of this study were to present a method to obtain an integrated pedigree by detecting horses with multiple UELN and deleting duplicates, and to assess the impact of an inaccurate pedigree on genetic evaluation by comparing estimated variance components and breeding values obtained with a good quality pedigree on the one hand and with a pedigree that contains horses with multiple UELN and duplicates on the other hand. These methods were applied here to two Belgian Warmblood studbooks: the Belgian Warmblood horse (BWP) and Zangersheide (Z).

Materials & methods

Pedigree data. To perform a genetic evaluation across the studbooks BWP and Z, a combined pedigree which contains both BWP and Z horses is required. Although many horses were common to both pedigrees, several had different UELN. So for the sake of the study, two pedigrees were created: a joined pedigree (p_joined) which is BWP (314,582 records) and Z (115,760 records) pedigrees concatenated without making any edits (i.e. horses with multiple UELN and duplicates were kept) and an integrated pedigree (p_integr)

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_769, © L. Chapard *et al.* 2022

which is a combination of BWP and Z pedigrees, corrected for horses with multiple UELN. To create these two pedigrees, BWP and Z pedigrees were concatenated (p_joined). Then, to obtain p_integr, corrections were made on p_joined by creating a cross-reference (translation table) containing all the variants of UELNs present in the pedigree. In this table, the UELN variants, the name of the horse and the UELN considered as the reference key were stored. Duplicates were detected by pairwise comparisons based on string comparisons of horses' names and names of their parents. Those comparisons were performed with the R package RecordLinkage (Sariyar and Borg, 2020), and the records with a probability of match above 0.90 were kept. A check of the duplicates found via the pairwise comparisons was performed semi-manually by looking at the horse's name, its birthdate, its gender and its parents' names using a custom R script (R Core Team, 2020). Briefly, records with no matches were removed from this dataset, the confirmed matches were kept and a choice of the reference UELN of each horse was manually made and included in the translation table. Variants of UELNs in the pedigree were replaced by their reference UELN using the information from the cross-reference table. Next, duplicates based on UELNs were removed from the pedigree. This resulted in a cleaned pedigree free of duplicates: p_integr.

Competition data. K.B.R.S.F (Royal Belgian Sport Equestrian) provided 2,436,461 show jumping competition records from 50,913 Belgian events which were held between 2004 and 2019. These records contained the sport number of the horse (a unique number given by K.B.R.S.F), its UELN, its sex, its age, its ranking, the competition height, the fault(s), the time, the rider number, the year and place of the competition. UELNs in the competition data were 'cleaned' by using the cross-reference table. Then, the following criteria were applied to edit the raw data: competition records that could not be linked to a horse via a UELN in the pedigree file were discarded and records of horses that were ≤3 years old or older than 18 years were removed. In total, 674,527 records were kept for the analysis. Rankings in competition were transformed in a normally distributed variable using the Blom transformation as described by Foran *et al.* (1995). In this study, success in competitions was defined as the variable 'corrected fence height' (CFH) which is a 'combination' of fence height and ranking in competition, using the Blom scores previously defined with a factor 1.32 (Chapard *et al.*, unpublished data):

$$\text{CFH} = \text{Fence height} + 1.32 \times \text{Blomscore} \quad (1)$$

Statistical model. The following model was used for estimating genetic parameters of CFH using a restricted maximum likelihood approach implemented in the program REMLF90 (Mitszal I. *et al.*, 2018):

$$y_{ijkl} = \mu + sex_i + age_j + animal_k + c_k + rider_l + e_{ijkl} \quad (2)$$

Where y_{ijkl} is the value of the trait CFH of the k^{th} animal; μ is the population mean; sex_i is the fixed effect of the horse's sex (i= 1, 2, 3); age_j is the fixed effect of the age (j=4,…, 18); $animal_k$ is the random additive genetic effect of the animal (k=1,…, 80,897 for p_integr; k=1,…, 82,719 for p_joined); c_k is the random permanent environmental effect, $rider_l$ is the random effect of the rider (l= 1,…, 8,410) and e_{ijkl} is the random residual effect.

Results

The integrated pedigree contained less horses (393,719) than the joined one (430,342) as duplicates and redundant registries of horses with multiple UELN were removed from p_joined. 54,092 horses had multiple UELN in p_joined and were added to the cross-reference. The number of UELNs detected per horse in the concatenated pedigree ranged from 1 to 12. Due to the integration step, the number of 'informative' horses decreased from 82,719 (p_joined) to 80,897 (p_integr). Table 1 shows the estimated variance components of CFH obtained with each pedigree (p_joined and p_integr). Estimated heritability of CFH was higher with

Table 1. Estimated variance components for jumping performance expressed as corrected competition height (CFH), using two pedigrees of different quality (p_joined and p_integr).

	Variance				Share in the variance[1]		
	Residual	Rider	Permanent environment	Genetic	Rr^2	c^2	h^2
p_joined	47.03	103.10	25.74	28.40	0.51	0.13	0.14
p_integr	47.03	102.10	28.46	24.35	0.51	0.14	0.12

[1] Standard errors on the ratio's varied from 0.0048 to 0.0064.

p_joined (h^2=0.14) than with p_integr (h^2=0.12). Also a difference regarding the permanent environmental effect for CFH was seen: it was 0.13 with p_joined, whereas c^2 was slightly higher with p_integr (0.14). However, the proportion of the rider effect (Rr^2) for CFH was similar with the two pedigrees p_joined and p_integr. Therefore, an inaccurate pedigree led, in this case, to a slight over-estimation of the heritability of the trait of interest and a slight under-estimation of the permanent environmental effect. The estimation of the rider effect was not impacted.

Estimated breeding values (EBVs) of horses were also impacted by an inaccurate pedigree. EBVs of different subsets of animals were studied: all horses, horses with own performance(s) and stallions that had at least 5 offspring. Correlations between EBVs obtained with p_integr and EBVs obtained with p_joined were 0.91 for all horses, 0.97 for horses with own performance(s) and 0.94 for stallions with at least 5 offspring (Figure 1). The highest correlation was found for horses with own performance(s).

Differences were also seen in the ranking of the 10 best stallions with at least 5 offspring (Table 2). Eight stallions out of ten are common between the EBV-based rankings obtained with p_joined and p_integr. However, not all of them got the same rank with p_joined and p_integr, implying that a published index obtained with a non-edited pedigree would differ from an index obtained with an accurate one.

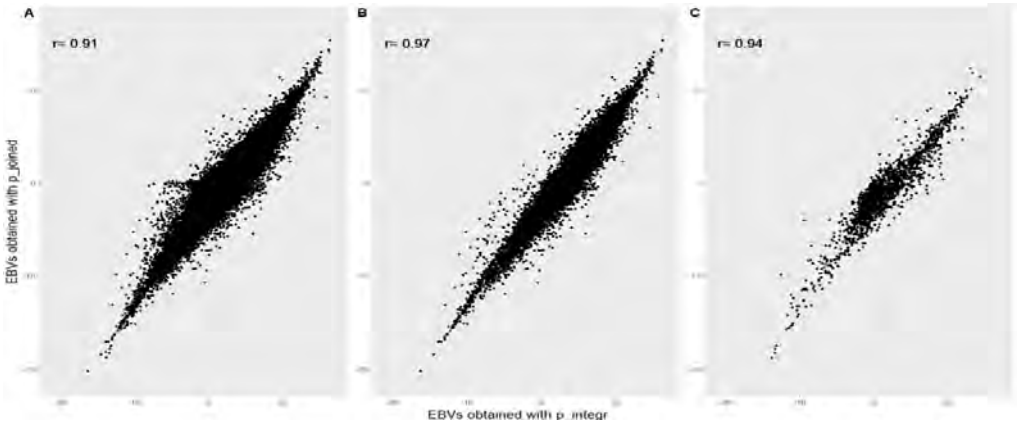

Figure 1. Relationships between EBVs obtained with two pedigrees (p_joined and p_integr). (A) all horses; (B) horses with own performance(s); (C) stallions with ≥5 offspring.

Table 2. Ranking of stallions with at least 5 offspring based on their EBVs.

Ranking stallions	CFH (p_integr)	CFH (p_joined)
1	Stallion 1	Stallion 2
2	Stallion 2	Stallion 1
3	Stallion 3	Stallion 6
4	Stallion 4	Stallion 4
5	Stallion 5	Stallion 3
6	Stallion 6	Stallion 11
7	Stallion 7	Stallion 5
8	Stallion 8	Stallion 21
9	Stallion 9	Stallion 9
10	Stallion 10	Stallion 10

Discussion

String comparisons of the names of horses and their parents proved to be a valuable tool to integrate pedigrees of different studbooks, although it was not always possible to detect matches. This was especially the case when the names of the horse were too different across studbooks and semi-manual editing was needed to obtain an integrated pedigree file. Hence, this method could be applicable to other horse populations and be an asset to develop across-breed evaluations. This study also showed that an inaccurate pedigree containing duplicates and animals with multiple identification numbers not only affected EBVs of individuals but also estimates of variance components which is in accordance with Senneke *et al.* (2004). EBVs can differ substantially between evaluations (accurate pedigree vs inaccurate pedigree) depending on the number of records of own performance linked to each UELN or/and numbers of offspring of each animal in the pedigree. Consequently, problems would certainly arise when publishing indices annually as there will be rank modifications caused by varying pedigree quality, and stallions may appear with multiple EBVs in the lists.

770. Estimation of genetic parameters and trends of reproduction traits of Korean Landrace and Yorkshire pigs

S.S. Lee*, M. Alam, H.K. Chang and T.J. Choi

Animal Breeding and Genetics Division, National Institute of Animal Science (NIAS), P.O. Box 31000, Cheonan-si, South Korea; genemap@korea.kr

Abstract

The study aimed to investigate the genetic parameters of the reproduction traits of Korean Landrace and Yorkshire breeds. Three reproduction traits, namely age at first farrowing (AFF), total number of piglets born (TNB) and number of piglets born alive (NBA), were analyzed. Genetic parameters were estimated from individual datasets using a multiple-trait animal model in AIREMLF90 software. The heritability values for AFF, TNB and NBA were 0.07-0.14, 0.09-0.11 and 0.09-0.10, respectively. Strong genetic correlations existed between TNB and NBA (0.90 to 0.96). The genetic responses were identified no distinct trends for TNB-EBVs in Landrace and Yorkshire pigs prior to 2014, after which they displayed noticeable upward trends.

Introduction

The Korean pig breeding industry has been developed by small and medium sized breeding farms, with variable population sizes and inbreeding frequencies (Seo *et al.* 2011). Korean purebred pigs are generally selected according to their reproduction traits in order to optimize commercial pig performance. It is crucial to assess the genetic parameters of these traits to understand their genetic potential. From 2012, the National Institute of Animal Science (NIAS) has organized a 'National swine genetic improvement network' with 17 breeding farms and implemented a nationwide pig breeding program for sire lines of Duroc and dam lines of Landrace and Yorkshire. The aims of this program are selection of superior breeding stock suitable for Korean breeding objectives and increasing the genetic connectedness across the breeding farms by allowing exchange of genetic resources.

Materials & methods

Animals, phenotypes, and pedigree. Data on three reproduction traits (age at first farrowing, AFF; total number of piglets born, TNB; number of piglets born alive, NBA) were provided by the Korea Animal Improvement Association, and Korea Pork Producers Association. The dataset of the three reproduction traits included first-parity phenotypes from gilts only. Reproduction records of 11,758 Landrace and 40,171 Yorkshire gilts, born between 1992 and 2020, were analyzed. The AFF of all of these gilts ranged between 324 and 438 days. We also defined TNB as the total number of piglets born during farrowing, which included all of the normal, stillborn, mummified, deformed and underweight piglets. However, NBA only accounted for live piglets during farrowing and excluded both stillborn and mummified piglets. The pedigrees for reproduction traits comprised 37,538 and 15,483 animals that were Landrace and Yorkshire pigs, respectively. In all three breeds, the number of generations traced back in the pedigree for reproduction datasets was 26, respectively.

Statistical analyses. The (co)variance components of traits were estimated through multiple-trait models using the AIREMLF90 software package (Misztal *et al.* 2021). The animal models for reproduction traits included a similar fixed effect of the herd, birth year and birth season (HYS) and a fixed effect of farrowing year-season, irrespective of breeds. Each model also included the random additive genetic effects of dams. We further obtained the approximated standard error (SE) of genetic parameter estimates from (co)variance components using the AIREMLF90 option (se_covar_function), which uses a Monte Carlo method for the

computation of SE, as proposed by Houle and Meyer (2015). The ratio of a trait's genetic standard deviation and its mean were expressed as the additive genetic coefficient of variation (CV_g), according to Houle (1992). We also obtained the genetic trend in traits using the averaged estimated breeding value (EBV) of animals based on their birth year.

Results

Table 1 presents the descriptive statistics of AFF, TNB and NBA for Korean Landrace and Yorkshire pigs. Landrace pigs showed the lowest average AFF value of 362.73±23.08 days. Despite some differences in average AFF, its CV values were smaller and similar across breeds. For TNB, the average of 12.07±3.40 piglets in Yorkshire was the highest. For the same trait, Landrace showed an intermediate mean to the other two breeds. Variations in TNB ranged between 27.60 and 28.13%. As for TNB, the mean NBA of 11.04±3.18 piglets was the highest in Yorkshire pigs.

Table 2 shows the variance components (genetic and residual), heritability (h^2) and genetic correlation (r_g) estimates of AFF, TNB and NBA traits. The h^2 value for the AFF trait 0.07±0.02 in Landrace and 0.12±0.01 in Yorkshire pigs. Genetic variation in AFF was relatively low, i.e. CV_g: 1%–2%. For TNB, our h^2 values in all pigs were low, ranging between 0.10 and 0.11. The h^2 of NBA was low in both breeds. The AFF-CV_g value was 8% in both breeds. For AFF and TNB, Yorkshire showed low, negative r_g values, such as -0.01, which were also not significantly different from zero. Landrace pigs exhibited a low and negative but slightly stronger association: -0.23±0.14. Landrace pigs also displayed a negative r_g between AFF and NBA (-0.21±0.14), in which another breed showed no significant association. On the other hand, the association between TNB and NBA was positive and strong in all pigs, i.e. 0.94 to 0.96.

Table 1. Descriptive statistics for reproduction traits in Korean Landrace and Yorkshire pigs.[1]

Breed	Trait	n	Mean	SD	Minimum value	Maximum value	CV
Landrace	AFF	11,758	362.73	23.08	324	438	6.36
	TNB	11,758	11.53	3.18	1	20	27.60
	NBA	11,757	10.63	2.98	0	20	28.02
Yorkshire	AFF	40,171	368.82	22.95	324	438	6.22
	TNB	40,171	12.07	3.40	1	20	28.13
	NBA	40,167	11.04	3.18	0	20	28.85

[1] AFF = age at first farrowing (day); TNB = total number of piglets born; NBA = number of piglets born alive; n = total sample size; SD = standard deviation; CV = coefficient of variation.

Table 2. Estimates of heritability (diagonals) and genetic correlations (upper diagonal), phenotypic correlation (lower diagonal) of reproduction traits with standard error in Landrace and Yorkshire pigs.[1]

Breed	Trait	Genetic parameter estimates			Genetic variance	Residual variance	CV_g
		AFF	TNB	NBA			
Landrace	AFF	0.07±0.02	-0.21±0.14	-0.23±0.14	21.08	261.40	0.01
	TNB	-0.01±0.01	0.10±0.02	0.94±0.02	0.87	7.83	0.08
	NBA	-0.03±0.01	0.90±0.00	0.10±0.02	0.77	7.08	0.08
Yorkshire	AFF	0.12±0.01	-0.01±0.06	-0.04±0.06	37.88	277.00	0.02
	TNB	0.00±0.01	0.11±0.01	0.96±0.01	0.99	8.35	0.08
	NBA	0.00±0.01	0.90±0.00	0.09±0.01	0.77	7.75	0.08

[1] AFF = age at first farrowing; TNB = total number of piglets born; NBA = number of piglets born alive; CV_g = genetic coefficient of variation.

The genetic response to AFF-EBVs was mainly inconsistent in all breeds, with no apparent visual trends. Similarly, we identified no distinct trends for TNB-EBVs in Landrace and Yorkshire pigs prior to 2014, after which they displayed noticeable upward trends. Moreover, Yorkshire TNB-EBVs were slightly higher than Landrace TNB-EBVs after 2002. With the two breeds, their NBA-EBV trends were similar to their TNB-EBV trends, even though Yorkshire pigs mostly performed better than Landrace pigs. Figure 1 shows the trends in animal estimated breeding value (EBVs) for NBA in Korean pig.

Discussion

AFF was found to be lowly heritable (0.07 to 0.14) across Korean breeds in our analysis. The low h^2 of AFF could be due to the lower genetic variability in Korean pigs. We suggest that necessary precautions be taken while considering the present AFF estimate for breeding decisions. We also found low heritability of TNB in Korean breeds. Using a single-trait repeatability model, Ogawa *et al.* (2019) obtained an h^2 of 0.12 for TNB in Landrace and Large White pigs, implying consensus. The NBA had low heritability in this study. In this respect, Ogawa *et al.* (2019) corroborated our study by reporting an h^2 of 0.12 in Landrace and 0.10 in Large White pigs. Ye *et al.* (2018), using multi-parity records in Large White pigs, also showed a lower NBA h^2 (0.06) in their pigs. A faster genetic improvement in any of the reproduction traits is not expected in Korean pigs due to their lower heritability values. Therefore, Korean pig breeding strategies should focus on increasing animals' genetic variabilities to achieve desirable selection responses, especially for the AFF trait.

In Korean pig breeds, the genetic association estimates of AFF with both TNB and NBA were lowly negative. However, most of these estimates were not significantly different from zero, except for Landrace pigs. This suggests that selection of Landrace pigs against AFF could increase TNB or NBA to some extent. Moreover, the non-significant correlation of AFF with TNB or NBA in Yorkshire pigs suggest no selection improvements in these breeds. The correlation between TNB and NBA was 0.90 or higher in our work. For this reason, both TNB and NBA could be assumed to have almost similar genetic bases, and an improvement in TNB could have subsequent desired effects on NBA.

For AFF, we observed no noticeable trend in EBVs in Landrace and Yorkshire pigs. No direct selection for AFF could explain. Another reason could be the genetic parameters of AFF, such as the low heritability, meaning greater environmental influences, and the lack of genetic correlations with TNB or NBA. Since 2014, we have also observed consistent improvements in TNB and NBA as they are directly targeted for reproduction improvement. According to recent statistics (KAIA, 2020), the average annual import between

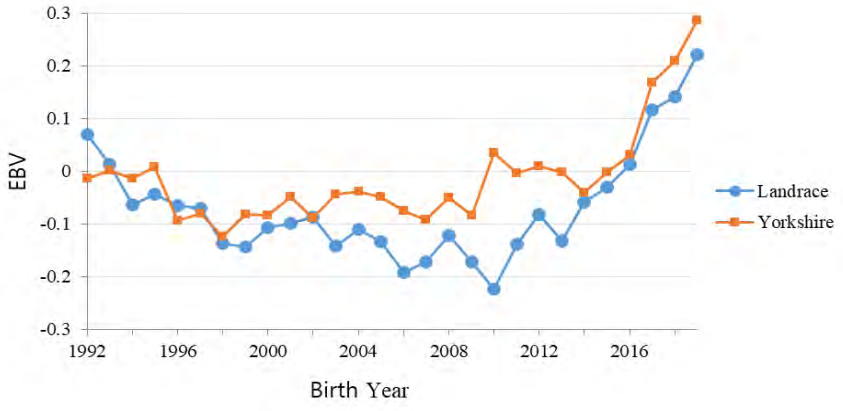

Figure 1. Trend of estimated breeding value (EBV) of NBA in Korean pigs.

2007 and 2010 was 1412 pigs, which increased by more than 4-fold between 2011 and 2012. Between 2011 and 2020, the average annual import was also reported as more than 2-fold greater than in previous years. In conclusion, most of our estimates suggested further improvement possibilities through selection. We argue that current genetic parameters could greatly assist future breeding and selection decisions for performance improvements in Korean pigs for specific purposes.

Abstract

This study aimed to investigate a suitable environmental indicator of heat stress on the number of born alive (NBA) and estimate the genetic variance components of a reproductive trait that reacts to heat stress. The data consisted of 26,770, 25,973, and 12,544 litters of Landrace, Large White, and Duroc sows, respectively, from four farms in Japan. The daily maximum ambient temperature was used as an indicator of heat stress. The correlation between the NBA and heat stress was estimated to determine a suitable period for heat load. The random regression model was fitted with heat load as random effects. Tolerance to heat stress was a heritable trait, but the variance was much smaller than trait performance in a standard environment. The heritability and additive genetic variance decreased as the heat load increased, implying that a lower heat load would be preferable for selection in NBA.

Introduction

Heat stress is one of the most important concerns in the pig industry, especially as global temperatures are rising. Heat stress decreases the number of piglets born alive (NBA), as well as the number of litters per sow per year. Therefore, it is necessary to improve genetically-determined tolerance to heat stress. The main objectives of this study were to investigate a suitable environmental indicator for expressing heat stress on NBA and to estimate the genetic parameters for heat stress.

Materials & methods

Data. The data consisted of 6,241 Landrace (26,770 litters), 5,861 Large White (25,973 litters), and 3,604 Duroc (12,544 litters) individuals from one breeding company with four farms in Japan. NBA was defined as the number of piglets alive at farrowing. Meteorological data were obtained from the Agro-Meteorological Grid Square Data, NARO, which can estimate the temperature and relative humidity for each 1-km square grid (Ohno *et al.*, 2016; https://amu.rd.naro.go.jp/). For each farrowing record, we obtained the daily maximum temperature (from days 140 to 0) and farrowing cycle of sows before the date of farrowing.

Statistical analysis. To identify the days in which heat stress during the reproduction cycle of the sow had the largest impact for each breed, NBA data were analysed for each breed using a three-step approach. First, the data were corrected for systematic and genetic effects using airemlf90 (Misztal *et al.*, 2018) with the following model:

$$y_{ijklmn} = parity_i + farm_j + year_k + cross_l + ss_m + a_n + pe_n + e_{ijklmn} \quad (1)$$

where y_{ijklmn} is the phenotypic value of NBA; $parity_i$ is the fixed effect of parity i (nine classes; one to eight and over nine); $farm_j$ is the fixed effect of farm j (four classes); $year_k$ is the fixed effect of the year of farrowing k (31 classes); $cross_l$ is the fixed effect of the type of crossing (two classes: pure or cross); ss_m is the random effect of service sire m; a_n is the random effect of the additive genetic effect of individual n; pe_n is

DOI: 10.3920/978-90-8686-940-4_771, © T. Okamura *et al.* 2022

the random effect of the permanent environmental effect of individual n; and e_{ijklmn} is the random residual term. The following assumptions regarding random effects were made:

$$\begin{pmatrix} \boldsymbol{a} \\ \boldsymbol{pe} \\ \boldsymbol{ss} \\ \boldsymbol{e} \end{pmatrix} \sim N\left[\begin{pmatrix} \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \end{pmatrix}, \begin{pmatrix} \sigma_a^2\boldsymbol{A} & \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \sigma_{pe}^2\boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \sigma_{ss}^2\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \sigma_e^2\boldsymbol{I} \end{pmatrix}\right]$$

where A is the additive relationship matrix, I is the identity matrix, and σ_a^2, σ_{pe}^2, σ_{ss}^2, and σ_e^2 are the additive genetic, permanent, environmental, service sire, and residual variances, respectively. The adjusted NBA records were obtained as estimated by e_{ijklmn}.

Second, to identify the day during the reproduction cycle of the sow heat stress that had a maximum influence on NBA performance, pairwise Pearson correlations between the adjusted observations and daily maximum temperature at each day of the cycle of the sow from 140 days before the day of farrowing were estimated.

Third, to identify the period (sequential days) during which the reproduction cycle of the sow heat stress had a maximum impact on NBA performance, pairwise Pearson correlations between adjusted NBA records and average daily maximum temperature in the interval centred on the estimated day of mating (114 days before farrowing) were estimated. The most impactful period that has the highest absolute value of the correlation coefficient was estimated for each breed.

To estimate the (co)variance components for the NBA and heat tolerance, the following random regression model was used:

$$y_{ijklmno} = \beta\varphi_{1o} + parity_i + farm_j + year_k + cross_l + ss_m + a_{0n} + a_{1n}\varphi_{1o} + pe_{0n} + pe_{1n}\varphi_{1o} + e_{ijklm} \quad (2)$$

where β is the fixed regression coefficient for the environmental covariate at the population level, φ_{1o} is the average daily maximum temperature during the best period for each breed as a covariate (standardised between 1 and 1) at value o, a_{0n} are a_{1n} random regression coefficients for the additive genetic effect of individual n for the intercept and slope terms, respectively, and pe_{0n} are pe_{1n} random regression coefficients for the permanent environmental effect of individual n for the intercept and slope terms, respectively. The following assumptions regarding random effects were made:

$$\begin{pmatrix} \boldsymbol{a_0} \\ \boldsymbol{a_1} \\ \boldsymbol{pe_0} \\ \boldsymbol{pe_1} \\ \boldsymbol{ss} \\ \boldsymbol{e} \end{pmatrix} \sim N\left[\begin{pmatrix} \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \\ \boldsymbol{0} \end{pmatrix}, \begin{pmatrix} \boldsymbol{G}\otimes\boldsymbol{A} & \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{P}\otimes\boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \sigma_{ss}^2\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} & \sigma_e^2\boldsymbol{I} \end{pmatrix}\right], \ \boldsymbol{G} = \begin{pmatrix} \sigma_{a0}^2 & \sigma_{a01} \\ \sigma_{a01} & \sigma_{a1}^2 \end{pmatrix}, \boldsymbol{P} = \begin{pmatrix} \sigma_{pe0}^2 & \sigma_{pe01} \\ \sigma_{pe01} & \sigma_{pe1}^2 \end{pmatrix}$$

where σ_{a0}^2 and σ_{a1}^2 are the additive genetic variances for the intercept and slope terms, respectively; σ_{a01} is the covariance between the two effects; σ_{pe0}^2 and σ_{pe1}^2 are the permanent environmental variances for the intercept and slope terms, respectively; and σ_{pe01} is the covariance between the two effects. Variance components were estimated using remlf90 (Misztal *et al.*, 2018). After obtaining the random-regression variance components, an additive genetic (co)variance matrix among the values of was calculated as follows:

$$\Gamma_a = \Phi'G\Phi, \Gamma_{pe} = \Phi'P\Phi$$

where G is the same as in model (2), and Φ is a matrix of the number of rows equal to the number of unique values of φ_1 in model (2) and two columns (a vector of 1 and φ_{1o}). The heritability of each value of o was calculated as follows:

$$h^2_{oo} = \frac{\Gamma_{aoo}}{\Gamma_{aoo} + \Gamma_{peoo} + \sigma^2_{ss} + \sigma^2_e}$$

where Γ_{aoo} and Γ_{peoo} are the o[th] values of the diagonal of Γ_a and Γ_{pe}, respectively.

Results

The relationship between the adjusted NBA and the daily maximum temperature on a given day of the reproduction cycle is shown in Figure 1. For Landrace and Large White pigs, the absolute values of the correlation coefficients were highest around the estimated mating date (114 days before farrowing). In contrast, Duroc had negative correlation coefficients throughout the gestation period. To estimate correlations between adjusted NBA and average daily maximum temperature in the interval centred on the estimated mating date, the period between 130 days to 110 days, 130 days to 80 days, and 130 days to 0 days before farrowing had the highest absolute values of correlation in Landrace, Large White, and Duroc, respectively. The average daily maximum temperature over these periods could be the best indicator of heat load for each breed. Table 1 shows the variance components estimated for the NBA and heat tolerance. The additive genetic variance for tolerance to a given heat stressor is much smaller than that for trait performance in standard environments.

Figure 2 shows the estimates of heritability, additive genetic variance, permanent environmental variance, and phenotypic variance across the range of the average daily maximum temperature. Although these were constant for Duroc, the heritability and additive genetic variance decreased as the heat load increased for Landrace and Large White populations.

Discussion

Heat stress around the mating date strongly affects the reproductive performance of pigs and this pattern is consistent with a previous study of the total number of births (Bloemhof *et al.*, 2013). Previous studies (Silva *et a.*, 2014;) have reported that the tolerance component was slightly less than that in the standard environment, which is not consistent with our results. It is possible that the populations selected in hot regions have already acquired tolerance to heat stress and, consequently, the variability is small. The decrease of heritability and additive genetic variance as the heat load increased consistent with the previous studies (Tizzie *et al.*, 2020), which implied that selection in low heat load (comfortable to sows) is suitable for NBA.

Abstract

INGA FOOD, S. A. company has developed a crossbreeding scheme between two Iberian varieties (Retinto and Entrepelado) to generate a F_1 hybrid sow. A previous study has detected differences in the reproductive performance (litter size) across the two reciprocal crosses, suggesting the presence of imprinting effects. In this study, we developed a multivariate gametic model able to estimate the gametic correlations among the paternal and maternal effects generated from any of the two genetic origins. Gametic correlations significantly lower than one would explain the differences in performance across reciprocal crosses. The results indicated that, despite the small amount of available information, the estimates of the gametic correlation between paternal and maternal effects are smaller in the Entrepelado than in the Retinto populations. This would explain the differences in performance among the reciprocal crosses.

Introduction

The Iberian pig breed is recognized for their perfect adaptation to the 'Dehesa' environment and the high quality of its products (Serra *et al.*, 1998), Traditionally, the Iberian pig production was developed with purebred varieties and extensively. However, in recent decades, many traditional production systems have been replaced by intensive farms using crossbreeding with Duroc sires to improve growth and efficiency at final product (Serrano *et al.*, 2008). Regulatory norms of Iberian pig production allow this cross, as long as the sow is Iberian. The reproductive performance of the Iberian sows is lower than in white pig populations (Silio *et al.*, 2001). INGA FOOD, S. A. company developed a crossbreeding scheme between two Iberian varieties (Retinto and Entrepelado) to generate a F_1 hybrid sow associated with a relevant heterosis (Noguera *et al.*, 2019). However, that study identified strong differences in performance between both reciprocal crosses (Entrepelado × Retinto –ER- vs Retinto × Entrepelado –RE-). Therefore, the aim of this study is to develop a multivariate gametic model able to estimate the paternal and maternal gametic contributions of the Retinto and Entrepelado varieties in the ER and RE crosses and the correlations among them.

Materials & methods

Phenotypic and genomic data. The phenotypic data used in this study consisted of number of piglets born alive -NBA- from 206 Entrepelado × Retinto and 134 Retinto × Entrepelado sows. A summary of the data is presented in Table 1.

Genotypes for all sows were generated using the GeneSeek® GPP Porcine 70K HDchip (Illumina Inc., USA). The filtering consisted of excluding genotypes with a minor allele frequency lower than 0.05 and a SNP call rate less than 0.90 in the overall population. Subsequently, 33,875 SNP markers were used to calculate the paternal and maternal phases using the AlphaPhase software (Hickey *et al.*, 2011).

Table 1. Number of records (and sows between brackets), mean and standard deviation of the traits for Entrepelado × Retinto and Retinto × Entrepelado crosses.[1]

	Entrepelado × Retinto	Retinto × Entrepelado
N (NS)	1,258 (206)	700 (134)
NBA	8.77±2.24	8.84±2.37

[1] N = number of records; NS = number of sows; NBA = number born alive.

Statistical model. Data were analyzed with the following model:

$$\begin{bmatrix}\mathbf{y}_{ER}\\ \mathbf{y}_{RE}\end{bmatrix}=\begin{bmatrix}\mathbf{X}_{ER} & \mathbf{0}\\ \mathbf{0} & \mathbf{X}_{RE}\end{bmatrix}\begin{bmatrix}\mathbf{b}_{ER}\\ \mathbf{b}_{RE}\end{bmatrix}+\begin{bmatrix}\mathbf{W}_{ER} & \mathbf{0}\\ \mathbf{0} & \mathbf{W}_{RE}\end{bmatrix}\begin{bmatrix}\mathbf{s}_{ER}\\ \mathbf{s}_{RE}\end{bmatrix}+\begin{bmatrix}\mathbf{Z}1_{ER} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}1_{RE}\end{bmatrix}\begin{bmatrix}\mathbf{p}_{E}\\ \mathbf{p}_{R}\end{bmatrix}+\begin{bmatrix}\mathbf{Z}2_{ER} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}2_{RE}\end{bmatrix}\begin{bmatrix}\mathbf{m}_{\mathbf{R}}\\ \mathbf{m}_{R}\end{bmatrix}+\begin{bmatrix}\mathbf{e}_{ER}\\ \mathbf{e}_{RE}\end{bmatrix}$$

where y_{ER} and y_{RE} are the vectors of phenotypic records, b_{ER} and b_{RE} are systematic effects that include order of parity with 5 levels (first, second, third, fourth and five or more) and herd-year-season with 25 levels, s_{ER} and s_{RE} are the permanent sow environmental effects, p_E and p_R and m_E and m_R are the gametic paternal (p) and maternal (m) effects of Entrepelado and Retinto, respectively, and e are the vector of residuals. Further X, W, Z1 and Z2 are the corresponding incidence matrices. The prior distribution of the permanent sow environmental effects is:

$$\begin{bmatrix}\mathbf{s}_{ER}\\ \mathbf{s}_{RE}\end{bmatrix}=N(\mathbf{0},\mathbf{I}\otimes\mathbf{H}) \text{ where } \mathbf{S}=\begin{bmatrix}\sigma^2_{sER} & 0\\ 0 & \sigma^2_{sRE}\end{bmatrix}$$

and the prior distributions of the gametic effects are:

$$\begin{bmatrix}\mathbf{p}_{\mathbf{E}}\\ \mathbf{m}_{\mathbf{E}}\end{bmatrix}=N(\mathbf{0},\mathbf{G}_{\mathbf{E}}\otimes\mathbf{V}_{\mathbf{E}}) \text{ and } \begin{bmatrix}\mathbf{p}_{\mathbf{R}}\\ \mathbf{m}_{\mathbf{R}}\end{bmatrix}=N(\mathbf{0},\mathbf{G}_{\mathbf{R}}\otimes\mathbf{V}_{\mathbf{R}})$$

where G_E and G_R are the gametic relationship matrices of the Entrepelado and Retinto populations computed as defined by Nishio and Satoh (2015):

$$\mathbf{V}_{\mathbf{E}}=\begin{bmatrix}\sigma^2_{pE} & \sigma_{pmE}\\ \sigma_{pmE} & \sigma^2_{mE}\end{bmatrix} \text{ and } \mathbf{V}_{\mathbf{R}}=\begin{bmatrix}\sigma^2_{pR} & \sigma_{pmR}\\ \sigma_{pmR} & \sigma^2_{mR}\end{bmatrix}$$

where σ^2_{pX} and σ^2_{mX} are the paternal and maternal variances of the X={E,R} population, and σ_{pmX} is the covariance between them. The analysis was performed using the *gibbsf90* software (Misztal *et al.*, 2018) using a single chain of 5,000,000 iterations after discarding the first 1,000,000.

Results

The results of the posterior entail (and standard deviation) estimates of the variance components are presented in Table 2.

In addition, the posterior distribution of the genetic correlation between paternal and maternal effects in the Entrepelado and Retinto populations are presented in Figure 1.

The posterior mean (and mode) was 0.101 (0.245) for Entrepelado and 0.239 (0.461) for Retinto, and the posterior probability of a positive gametic correlation was 0.613 and 0.755 for Entrepelado and Retinto, respectively.

Discussion

The proposed bivariate model allows to estimate the gametic effects of each founder population acting as paternal or maternal as well as their correlation. In absence of paternal or maternal imprinting, the

Table 2. Posterior mean (and standard deviation) estimates of variance components.

Variance components[1]	Population	
	Entrepelado × Retinto	Retinto × Entrepelado

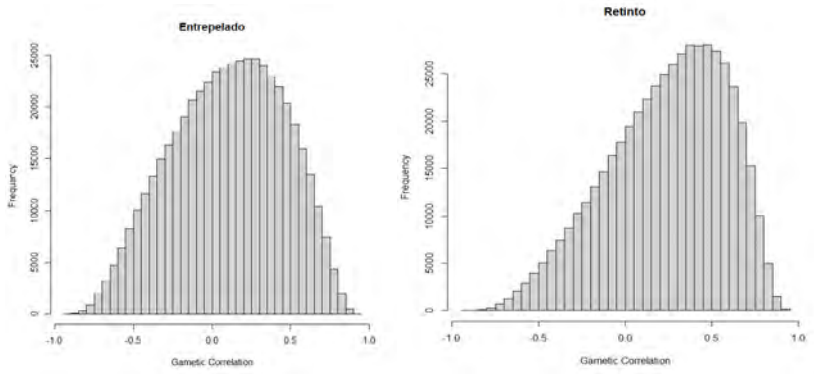

Figure 1. Posterior distributions of the correlations between paternal and maternal gametic effects in the Entrepelado and Retinto populations.

correlation among them should be perfect (one). A significant deviation from this perfect correlation would indicate differences in the performance of crossbred individuals depending on each of the population is acting as paternal (or maternal).

The results of the study are very preliminary, as the amount of phenotypic and genotypic information is very low. Differences in the posterior distribution of the correlation between gametic effects in Retinto and the Entrepelado varieties can be observed. The posterior distribution of the correlation in the Retinto variety is more positively skewed than the Entrepelado one. It suggests that the gametic contribution of Retinto individuals acting as boars or sows of the crossbred individuals are more similar, while the contribution of the Entrepelado individuals diverge greatly if they are used as boars or sows. This result may explain the differences in performance among the reciprocal crosses observed by Noguera *et al.* (2019) who propose using the Retinto variety as boar and the Entrepleado as sow providing a better performance that the opposite cross.

773. Heritabilities and genetic correlations of litter traits at farrowing and semen production traits in Duroc pigs

S. Ogawa[1*], M. Kimata[2], M. Tomiyama[2] and M. Satoh[1]

[1]Graduate School of Agricultural Science, Tohoku University, Sendai, Miyagi 980-8572, Japan; [2]CIMCO Corporation, Koto-ku, Tokyo 136-0071, Japan; shinichiro.ogawa.d5@tohoku.ac.jp

Abstract

We estimated heritabilities of semen production traits and litter traits and genetic correlations among them in purebred Duroc pigs. Semen production traits per ejaculate were semen volume, sperm concentration, proportion of morphologically normal sperms, total number of sperms, and total number of morphologically normal sperms. Litter traits at farrowing were total number born, number born alive, number still born, total litter weight, mean litter weight, and piglet survival rate. We used 45,913 records of 896 boars and 6,950 records of 1,400 sows. Estimated heritabilities ranged from 0.20 to 0.29 for semen production traits and from 0.06 to 0.25 for litter traits. Estimated genetic correlations between semen production traits and litter traits were weak, except for those of NSB and SVB with CON, NUM, and NUMF absolute values of which were higher than 0.3 in this study.

Introduction

Genetic parameters of semen production traits have been estimated (e.g. Wolf, 2010; Brinke *et al.*, 2020), but information on their genetic relationship with other economically important traits is limited. In particular, no study has reported the genetic parameters of semen production traits in Japanese pig population. Heere, we estimated the heritabilities and genetic correlations of semen production traits and litter traits at farrowing in a Japanese purebred Duroc pig population.

Materials & methods

Approval of Animal Care and Use Committee was not required for this study because the data were acquired from an existing database.

Phenotype and pedigree data. We analysed 45,913 semen production records of 896 Duroc boars and 6,950 farrowing records of 1,400 Duroc sows provided by CIMCO Corporation (Tokyo, Japan), which operates great-grandparent (GGP) and grandparent (GP) farms by Specific Pathogen Free system in northern to southern parts of Japan, were analysed. Pedigree data covered 67,993 animals. Sows were serviced by artificial insemination (typically three times using semen from the same boar).

Semen production traits per ejaculate were semen volume (VOL), sperm concentration (CON), proportion of morphologically normal sperms (PROP), total number of sperms (NUM) = VOL × CON, and total number of morphologically normal sperms (NUMN) calculated as NUM × PROP. Litter traits at farrowing were total number born (TNB), number born alive (NBA), number still born (NSB), total litter weight at birth (LWB), mean litter weight at birth (MWB) = LWB ÷ NBA, and piglet survival rate (SVB) = NBA ÷ TNB.

Numerical analyses. Genetic parameters were estimated, according to Wolf (2010) and Ogawa *et al.* (2019), using the following repeatability animal model:

$$y = Xb + Za + Wpe + e \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_773, © S. Ogawa *et al.* 2022

where y is the vector of phenotypic records; b is the vector of fixed effects; a is the vector of breeding values; pe is the vector of permanent environmental effects; e is the vector of random errors; and X, Z, and W are the design matrices. The vector b for semen production traits contains the effects of year at ejaculation (18 levels: 2000 to 2017), month at ejaculation (12 levels), farm (6 levels: two GGP and four GP farms), age at ejaculation (43 levels: 6 to 48 months), and interval between present and the previous semen collections (13 levels: up to 3, 4, …, 14 days, and ≥15 days). The vector b for litter traits contains the effects of farrowing year (18 levels: 2001 to 2018), farrowing season (4 levels: spring [March to May], summer [June to August], autumn [September to November], winter [December to February]), farm (6 levels: two GGP and four GP farms), and dam parity (10 levels: 1st to 9th and ≥10th).

Heritability was estimated by single-trait analysis. Genetic correlation was estimated by two-trait analysis. Non-zero covariances between two semen production traits and between two litter traits were assumed for all random effects. Non-zero covariance between semen production and litter traits was assumed for only for breeding values. Variance components were estimated using AIREMLF90 software (Misztal *et al.*, 2002). Standard errors were calculated according to Klei and Tsuruta (2008).

Results

Estimated heritabilities of semen production traits ranged from 0.20 for PROP to 0.29 for VOL, equal to or greater than those for litter traits, which ranged from 0.06 for SVB to 0.25 for MWB (Table 1). Estimated repeatabilities of semen production traits ranged from 0.41 for CON to 0.49 for VOL, greater than those of litter traits, which ranged from 0.08 for SVB to 0.32 for LWB.

Among semen production traits, estimated genetic correlations of VOL were positive with NUM and NUMN (0.48 and 0.51) and negative with CON (-0.66) (Table 2). That of PROP was positive with VOL (0.18) and negative with CON (-0.33). Those among litter traits agreed with those in Landrace and Large White populations of the same company (Ogawa *et al.*, 2019). Those between semen production and litter traits were weak in many cases, except for those of NSB and SVB with CON, NUM, and NUMF absolute values of which were higher than 0.3.

[1] See Table 1 for abbreviations of trait names.

Seasonal variations in phenotypic records were observed. Figure 1 shows examples of semen production traits; values of VOL and NUM were lower in hotter months (especially August to October). This might reflect in part the effect of heat stress on boars before semen collection.

Figure 2 shows the effects of farrowing season on NBA in different pig breeds; values were lower in autumn and winter, probably reflecting in part the effect of heat stress on sows just before service by artificial insemination.

Discussion

Previous studies using repeatability animal models estimated the heritability of semen production traits to range from 0.1 to 0.3, higher than those of TNB and NBA in different Landrace and Large White populations (Wolf, 2010; Brinke *et al.*, 2020). Genetic improvement of semen production traits, therefore, seems to be possible. As far as we know, this is the first study to estimate the genetic correlations between

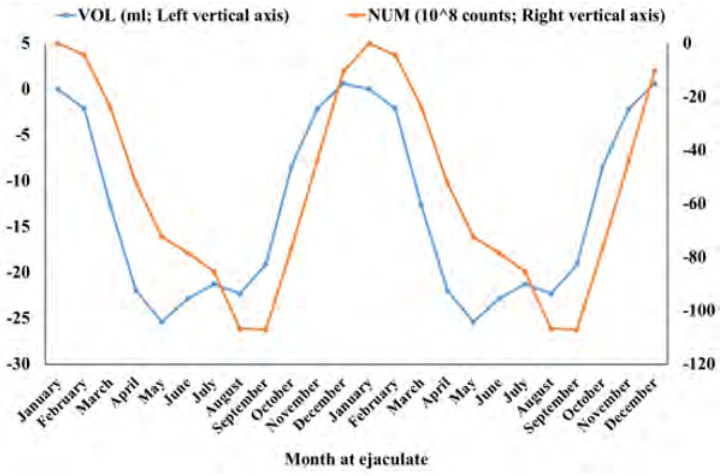

Figure 1. Estimated values of effects of month at ejaculate on semen volume (VOL) and total number of sperm (NUM).

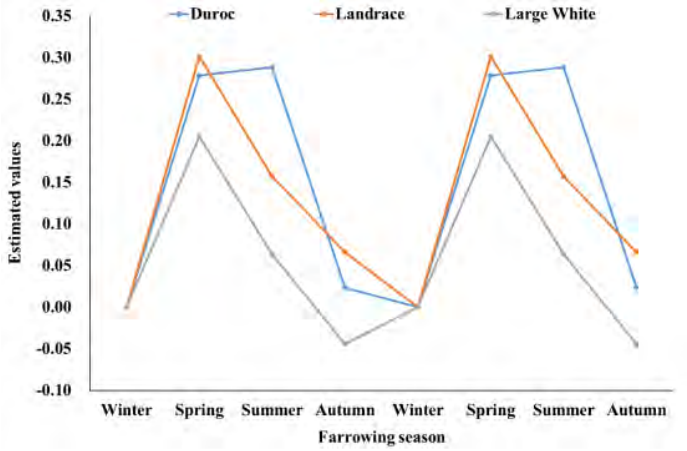

Figure 2. Estimated values of effects of farrowing season on number born alive for different pig breeds. Results for Landrace and Large White breeds were from Ogawa *et al.* (2019).

semen production and litter traits in purebred Duroc pigs. Wolf (2010) and Brinke *et al.* (2020) estimated genetic correlations between semen production and litter traits in different Landrace and Large White pig populations, the consistency of the results was poor, perhaps because, as Wolf (2010) stated, no animal has both records on semen production and litter traits, and therefore, genetic correlations could be estimated only via relatives.

Heat stress due to seasonal variation in climatic factors including temperature, as well as global warming, harms the efficient pork production system (Mayorga *et al.*, 2019). We to observed seasonal variation in semen production traits and NBA, which seems to be the heat stress. Therefore, we are now trying to establish a breeding scheme for improving heat tolerance in Japanese pig populations to confront the anticipated effects of heat stress.

774. Genomic analysis of quality and morphological sperm parameters in Piétrain breeding boars

C. Groβe-Brinkhaus[1,2*], Z.M. Kröhl[1], M. Friedrichs[3] and E. Tholen[1]

[1]University of Bonn, Institute of Animal Science, Endenicher Allee 15, 53115 Bonn, Germany; [2]Association for Bioeconomy Research (FBF), Adenauerallee 174, 53113 Bonn, Germany; [3]GFS-Cooperation, Zum Pöpping 29, 59387 Ascheberg, Germany; cgro@itw.uni-bonn.de

Abstract

Artificial insemination is essential for breeding progress and economic success in pig production. The aim of this study was the estimation of genetic parameter and to perform a genome-wide association study (GWAS) for traits recorded with the computer assisted semen analysis system in Piétrain breeding boars. Beside sperm volume, the fresh semen was evaluated for five sperm quality traits. In total 72,370 records of 958 Piétrain boars were available for variance component estimation. The h^2 ranged from 0.048 for motility to 0.284 for plasma droplets. The environmental effect of the repeated semen collection was highest for motility with 0.260. The genetic correlations met biological expectations and ranged from -0.912 to 0.933 among the sperm quality traits. First GWAS allowed to detect 21 chromosome-wide significant associations for motility, total number of sperm cells and sperm morphological abnormalities. Most of the identified regions have been already reported in other studies.

Introduction

Artificial insemination (AI) is essential for breeding progress and economic success in pig production. The selection of AI boars mainly based on breeding values for production and female reproduction traits (Wolf 2009), whereas the selection of young boars on semen quality is still not a common practice (Marques *et al.* 2017). In Germany, based on pedigree information an indirect selection is realized before an AI-boar is bought or performed based on phenotypes during semen production (M. Friedrichs, personal communication).

In the recent years the evaluation of the sperm quality in AI-stations has been changed from a subjective inspection to the computer assisted semen analysis (CASA). Compared to a subjective evaluation this system allows to record sperm motility and morphological abnormalities with a high measurement accuracy(e.g. Amann and Waberski 2014). Occurrence of morphological abnormalities and cytoplasmatic droplets can determine the quality of an ejaculate due to their negative impact on motility and fertility of sperm (Gruhot *et al.* 2019).

For semen quantity and sperm quality traits low to moderate heritabilities (h^2) have been reported (Marques *et al.* 2017; Wolf 2010). Several studies investigated candidate genes affecting subjective evaluated sperm quality traits (e.g. Kaewmala *et al.* 2011). But, because of the limited number of boars with phenotypic and genotypic data, only few studies have performed genome-wide association analyses (GWAS) for male reproduction traits (Marques *et al.* 2018; Gao *et al.* 2019; Diniz *et al.* 2014).

The aim of this study was the estimation of genetic parameters and to perform a genome-wide association study for CASA traits in Piétrain AI- boars, used as nucleus and terminal sires.

Materials & methods

All investigated animals belong to the breed Piétrain owned by the AI-station GFS. These boars are part of the breeding program of a German herdbook organisation (German Genetic) and were used as terminal

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_774, © C. Groβe-Brinkhaus *et al.* 2022

sires in production as well as breeding boars in the nucleus of the herdbook organisation. Data of 958 breeding boars housed on six AI-station of the GFS from March 2018 to March 2021 were available. In total 72,370 ejaculates were considered for investigation. Boars with less than ten ejaculates, were removed from the analyses.

The fresh semen was evaluated immediately after ejaculation using the CASA eFlow system Androvision® (Minitüb GmbH, Tiefenbach, Germany). Following five traits were recorded in a semen sample: sperm morphological abnormalities (ABN, %), cytoplasmic droplets (CD, %), total number of sperm cells (Ncell-T, Mrd), total number of intact sperm cells (Ncell-I, Mrd), sperm motility (MOT, %). In addition, the collected semen was weighted (semen volume, VOL, ml). Because of the skewness of ABN, the values were log-transformed into logABN.

Furthermore, boars were genotyped with the 60K Illumina bead chip. After quality control (call rate >0.95, minor allele frequency >0.05 and deviation from Hardy Weinberg Equilibrium $P<0.001$) 43,483 SNPs of 754 boars with 67,561 phenotypes were available for further investigations.

Variance component estimation. In a first step, environmental effects influencing the semen quality and sperm morphology were identified. Variance components were estimated using the VCE5 package (Kovač and Groeneveld 2003). The following multi-trait repeatability model in matrix form was used:

$$y = Xb + Za + Wpe + Ie \quad (1)$$

where y displays sperm quantity and -quality traits; X, Z, and W denoted the design matrices, I The identity matrix; b was the solution vector of the fixed effect including station-year-season of ejaculation, collection interval (days) and age in days of the boars when ejaculating (covariate, quadratic form); $a \sim N(0, A\sigma^2_a)$ was a vector of genetic values; $pe \sim N(0, I\sigma^2_{pe})$ was a vector of random permanent boar effect $e \sim N(0, I\sigma^2 e)$ denoted the residuals and I denoted the identity matrix. A series of tri-variate model analyses were applied, which comprised all possible three trait combinations. Heritability (h^2), permanent environmental effects (pe^2), phenotypic (r_p) and genetic (r_g) correlations are presented by calculating the mean of all particular estimations.

Genome-wide association study. For GWAS Equation 1 was extended by a single SNP as additional fixed regression coefficient, where the particular SNP was additively coded {0,1,2}. Possible effects through population stratification were visually proven by calculating a genomic relationship matrix following VanRaden (2008) and plotting the first two principal components. In order to control the relatedness between the animals, the additive genetic relationship was considered (Equation 1) and the genomic control method was applied. Significant associations were detected using a conditional Wald F statistic. Resulting *P*-values were transformed by calculating the false discovery rate to avoid error accumulation by multiple testing (Storey 2002). Markers with an adjusted *P*-value<0.05 were handled as chromosome wide significant. The GWAS was performed with ASreml (Gilmour *et al.* 2006).

Results

In total 72,370 ejaculation records of 958 Piétrain boars were available for analyses. The investigated traits revealed averaged mean values and standard deviations: VOL 245.69±72.62; MOT 88.83±5.31; ABN 2.78±2.8; PD 9.66±5.39; Ncell-T 73.74±25.61; Ncell-I 57.84±20.49.

In Table 1 and 2 an overview of the estimated h^2, pe^2 and correlations is given. The h^2 ranged from 0.048 for MOT to 0.284 for CD. The pe^2 reflects the permanent environmental repeatability of the measurements and

Ncells-I	0.258	0.493	-0.133	-0.207	0.907	0.142±0.026

[1] h^2 (± standard error) on the diagonal, r_p phenotypic correlation under the diagonal, r_g genetic correlation above the diagonal; VOL: volume; MOT: motility; logABN: log-transformed sperm morphological abnormalities; CD: cytoplasmic droplets; Ncell-T: total number of sperm cells; Ncell-I: number of intact sperm cells.

were moderate for all traits. The highest pe^2-values were observed for MOT (0.260) and Ncel-I (0.243). The effect of the general repeated effect ω^2 (h^2+pe^2) of the semen was highest for CD with 0.450.

The observed phenotypic and genetic correlations followed according to the sign biological expectations (Table 2). The semen amount revealed a positive r_g of 0.22 and 0.32 with Ncell-T and Ncell-I traits, but was negatively correlated the morphological traits ABN and PD. A strong negative r_g was found between MOT and ABN as well as MOT and CD of -0.91 and -0.82, respectively.

In a first GWAS, we identified 21 chromosome-wide significant SNPs comprising six QTL of three sperm quality traits. For MOT two QTL located on *Sus scrofa chromosome* (SSC) 6 and SSC7 were detected. On SSC5 13 SNPs located within three chromosomal regions revealed significant effects on logABN.

Discussion

The observes values for the mean and standard deviations of the investigated phenotypes are comparable to the reports in literature. The proportion of the CD were higher comparted to the ABN. This result can be expected, because CD are the most recent sperm abnormalities in boar semen (Briz and Fàbrega 2013). The trait ABN comprises several sperm abnormalities, like head or tail deformations, which can originate in the spermatogenesis or the maturation in the epididymidis (Briz *et al.* 1996). Plasma droplets, separated in cytoplasmic or terminal droplets and have been described as part of the sperm maturation, but have a negative impact on the fertilization (Briz and Fàbrega 2013).

The estimated h^2 and r_g of the investigated traits were in accordance with reports from literature (Wolf 2009; Diniz *et al.* 2014; Marques *et al.* 2017; Brinke *et al.* 2020). Only a limited number of studies investigated the genetics of CD so far (Zhao *et al.* 2019; Gruhot *et al.* 2019). In the recent work, the h^2 of CD (h^2: 0.28) was higher compared to ABN (h^2: 0.15).

The identified genomic regions have been reported in previous studies (Marques *et al.* 2018; Kaewmala *et al.* 2011). The limited number of six identified QTL met expectations, because the data set does not cover the complete phenotypic variance. The investigated boars were indirect selected for a high sperm quality and the number of low-quality ejaculates was below 5%.

775. Differential expression in the porcine thymus upon infection by PRRSV, influenza B or their coinfection

K.M. Sarlo Davila[1,2*], Y. Sang[3], W. Ma[4] and L.C. Miller[2]

[1]Oak Ridge Institute for Science and Education, Oak Ridge Associated Universities, Oak Ridge, TN 37830, USA; [2]Virus and Prion Research Unit, National Animal Disease Center, USDA, Agricultural Research Service, Ames, IA 5061, USA; [3]Department of Agricultural and Environmental Sciences, College of Agriculture, Tennessee State University, Nashville, TN 37209, USA; [4]Department of Veterinary Pathobiology Department of Molecular Microbiology & Immunology, University of Missouri, Columbia, MO 65211, USA; kaitlyn.sarlodavila@usda.gov

Abstract

Porcine Reproductive and Respiratory Syndrome (PRRSV) causes large economic losses and suppresses the host immune system, impairing thymus function and leaving pigs susceptible to secondary infections such as zoonotic Influenza B (IBV). Seronegative pigs at 3-4 week-old were split into four treatment groups: control; infected with Type 2 PRRSV NPB strain; infected with B/Brisbane/60/2008 virus; or coinfected with both viruses. Pigs from each of the four treatment groups were necropsied at 3-, 5- and 7-days post-infection(dpi) and thymus samples were collected for transcriptomic analysis. Differentially expressed gene (DEG) analysis was carried out using DeSeq2 and g:Profiler was used to identify significantly enriched pathways. Several pathways related to immune function were detected in the PRRSV and coinfected but not IBV samples, indicating that PRRSV infection persist and subvert the host immune system by downregulating genes involved in cytokine and interferon signalling and monocyte and macrophage signalling with the thymus.

Introduction

Infectious diseases are one of the primary constraints of swine production, resulting not only in production and economic losses but also in some cases impacting human health (VanderWaal and Deen, 2018). Worldwide PRRSV is the most economically important infectious swine disease, estimated to result in a loss of $664 million annually in the US alone (Lunney *et al.*, 2016). One component of PRRSV economic devastation is its ability to suppress the host immune system, including impairing thymus function, leaving pigs susceptible to secondary infections (Wang *et al.*, 2020). Influenzas are common secondary infections to primary PRRSV infections: a serological survey of U.S. Midwest domestic swine herds from detected IBV in 38.5% of sampled farms and observed that herds infected with PRRSV had a higher prevalence of IBV compared to herds without PRRSV (Ran *et al.*, 2015). IBV is of concern not only to swine production but also human health as it is pathogenic to humans.

Materials & methods

Animals. Samples were provided by Dr Wenjun Ma, Kansas State University. The animal study was reviewed and approved by the Institutional Animal Care and Use Committee at Kansas State University (IACUC #3821). Briefly, 36 pigs (3-4 week-old) seronegative for influenza A, influenza B, and PRRSV were split into 4 groups: one blank control group and three infected groups (PRRSV, IBV, and PRRSV/IBV coinfection). Each pig from the PRRSV and coinfected group were intranasally infected with Type 2 PRRSV NB strain at a tissue culture infectious dose (TCID) of 2×10^5 $TCID_{50}$/ml. Control and IBV pigs were mock inoculated with virus free minimum essential medium (MEM) through the same route. At 14 days post infection with PRRSV each pig from coinfected and IBV group was inoculated intratracheally (1 ml) and intranasally (1 ml) with B/Brisbane.60/2008 virus at 10^6 $TCID_{50}$/ml. Pigs from the other two groups were inoculated with same volume of virus free MEM through the same routes. Three pigs from each of

the four groups were necropsied at 3-, 5-, and 7-days post IBV inoculation(dpi). The objective of this study was to investigate host transcriptomic response in the thymus following PRRSV and IBV infections as well as their coinfection

Sample preparation and sequencing. Thymus samples were collected from three pigs in each of the four treatment groups (Control, PRRSV, IBV and PRRSV/IBV) at each of the three time points (dpi, 5 dpi, and 7 dpi) with the exception IBV 7 dpi pigs at which time point samples were only collected from two pigs. Total RNA was extracted from the samples, preparation was performed the 3' Quantseq fwd kit, and 100 bp paired end reads were generated utilizing the Illumina Hiseq 6000.Tools present at galaxy.scinet.usdagov were utilized to analyze the sequenced reads. FastQC was used to perform quality control for reads and examine raw read data and counts. Trimmomatic (version 0.38.1) was used to remove adapters and reads with a phred score below 20 prior to alignment on the Sscrofa 11.1 genome with HiSat2 (version2.1.0). Raw counts were generated with the default parameters of FeatureCounts. Differential gene expression (DEG) was performed using DeSeq2 (version 2.11.40.6) utilizing a parametric fit type and poscounts to account for genes with zero counts. DEG analysis was based on the model treatment + dpi + treatment: dpi +E. Statistically significant (FDR<0.15) genes were reported for the interaction effect of treatment: dpi. Further analysis was performed on significant genes from each dpi and treatment group interaction for significantly enriched pathways using the g: Gost function of g: Profiler. A Benjamini Hochberg FDR<0.05 was used as the significance threshold for KEGG pathways. A network representing overlaps among enriched pathways was created utilizing the EnrichmentMap plugin of CytoScape. DEGs within KEGG pathways were visualized using PathView.

Results

PRRSV. Comparison of the PRRSV infected samples vs control samples resulted in a total of 3 statistically significant DEG (false discovery rate (FDR)<0.15) (2 downregulated,1 upregulated) for 3 dpi and did not result in any significantly enriched pathways. Expression levels peaked at 5 dpi with 253 significant DEG (196 downregulated, 57 upregulated) which were significantly enriched for 4 KEGG pathways: Influenza A, viral protein interaction with cytokine and cytokine receptor, cytosolic DNA-sensing pathway, and natural killer cell mediated cytotoxicity. Expression levels decreased at 7 dpi with 27 significant DEG (12 downregulated, 15 upregulated) which were not significantly enriched for any pathways.

Influenza B. Influenza B-infected samples showed the least expression overall but a similar pattern over time to PRRSV-infected samples, with the highest expression levels occurring at 5 dpi, which was also the only timepoint having pathways that were significantly enriched. Comparison of the Influenza B-infected samples vs control samples resulted in a total of 3 DEG (1 downregulated, 2 upregulated) for 3 dpi, 5 DEG (4 downregulated, 1 upregulated) for 5 dpi, and 4 DEG (1 downregulated, 3 upregulated) for 7 dpi. The 5 DEG at 5 dpi were over enriched for the KEGG pathway: autophagy-animal.

Coinfection. In contrast to either single infection when compared to the control samples the coinfected samples showed the greatest expression levels at 3 dpi. In total, 314 genes were differentially expressed (261 downregulated, 53 upregulated) at 3 dpi and were significantly enriched for 9 KEGG pathways: Influenza A, RIG-1-like receptor signalling pathway, viral protein interaction with cytokine and cytokine receptor, cytosolic DNA-sensing pathway, Hepatitis C, Herpes 1 simplex virus infection, Measles, Coronavirus disease-COVID 19 and Epstein-Barr virus infection. Only 4 DEG (1 downregulated, 3 upregulated) were significant at 5 dpi. Expression levels increased slightly at 7 dpi with 26 significant DEG (14 downregulated, 12 upregulated) but no pathways were significantly enriched at either time point.

Discussion

An enrichment map representing the overlap of enriched pathways across samples is shown in Figure 1. The PRRSV single infection and PRRSV/IBV coinfection share several enriched pathways yet neither infection overlaps with the IBV single infection, which may give insight into the ability of PRRSV infections persist in lymphoid tissues. This pattern from of expression differs significantly from that in the lung as Fleming *et al.* (2020) reported shared DEGS among the 3 infection groups in the lung. The DEGs from both PRRSV and coinfected samples were significantly enriched for the Influenza A pathway which has been very well annotated. The differential regulation of genes within this pathway for both the PRRSV and coinfected samples are shown in Figure 2. PRRSV has previously been reported to induce abnormal innate and adaptive immune responses, suppress interferon (IFN) induction, dysregulate cytokine expression and

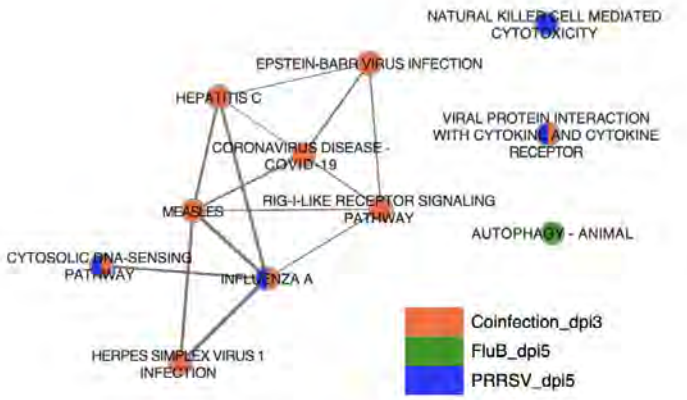

Figure 1. Cytoscape network of significantly enriched pathways. Pathways are represented as circles and connected with lines sized based on the number of genes shared by the connected pathways.

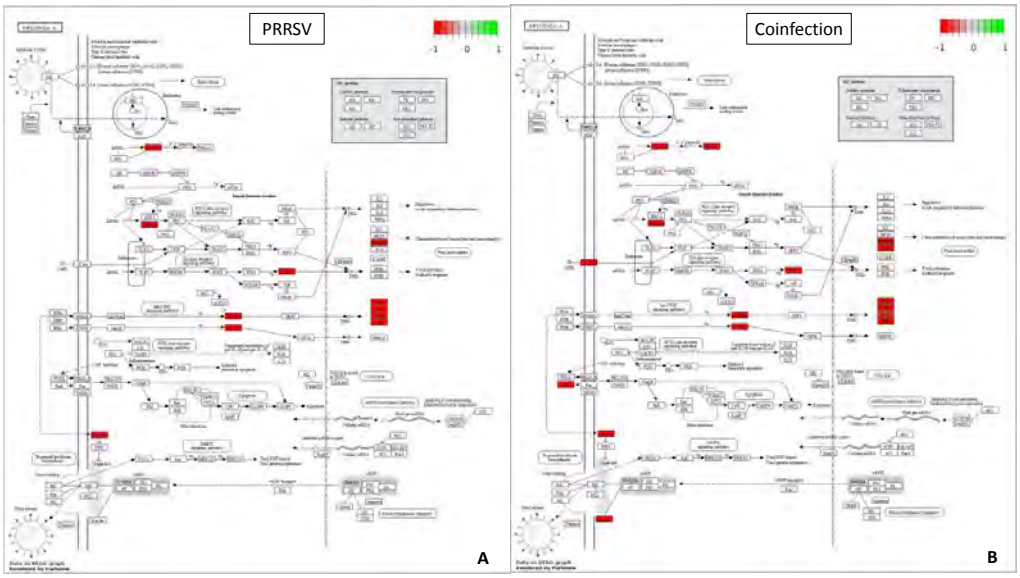

Figure 2. Enriched KEGG pathway Influenza A with downregulated genes highlighted in red and upregulated genes highlighted in green. (A) Differential regulation in the PRRSV samples. (B) Differential regulation in the coinfected samples.

atrophy the thymus but the mechanisms by which this occurs are not yet fully understood (Wang *et al.*, 2020). In both the PRRSV and coinfected samples several key genes in IFN induction were downregulated, including *MDA5* and *IRF7* as well as IFN induced genes *STAT1, MXA, OAS, ADAR, PML* and *Viperin,* all of which are key genes in antiviral activity (Stelzer *et al.*, 2016). *RANTES,* a chemokine signallign gene, was also downregulated. This downregulation may be unique to lymphoid tissues as Fleming *et al.* (2020) reported that *IRF* genes were upregulated in PRRSV infected lung samples across all three timpoints. Additionally *IP10, TLR4, FASL,*and *β-actin* were downregulated in the coinfection but not the PRRSV single infection. *IP10* is also an IFN induced gene which stimulates monocytes, *TLR4* is essential in pathogen recognition, *FASL* induces apoptosis and *β-actin* is crucial for intercellular signalling (Stelzer *et al.*, 2016). The downregulation of these genes provides insight into the mechanism by which PRRSV establishes multi-pathogen coinfection and persistent viral infection in lymphoid tissues.

776. Genetic associations between survival at different parities in commercial crossbred sows

B.G. Poulsen[1,2*], N.G. Leite[3] and D. Lourenco[3]

[1]Danish Pig Research Centre, Danish Agriculture & Food Council, Axelborg, 1609 Copenhagen W, Denmark; [2]Quantitative Genetics and Genomics, Aarhus University, Blichers Allé 20, 8830 Tjele, Denmark; [3]Department of Animal and Dairy Science, University of Georgia, Athens, GA 30602, USA; bgp@lf.dk

Abstract

We investigated whether sow survival is genetically associated across parities. Sow survival was investigated through five stayability traits and a five-trait animal model: The first stayability trait was survival from first service to first farrowing. The fifth stayability trait was survival from fourth farrowing to fifth farrowing. All sows were commercial and either F1 or rotationally crossbred between Landrace and Yorkshire. All stayability traits were favourably genetically correlated in both Landrace and Yorkshire. Stayability from first service to first farrowing was moderately to strongly genetically correlated with other stayability traits (0.26-0.73). The remaining four stayability traits were strongly genetically correlated with each other (0.63-0.88). Therefore, survival from first farrowing to fifth farrowing can be regarded as similar traits, while survival from first service to first farrowing is relatively different from later survival.

Introduction

Promoting meaningful genetic progress for sow survival is challenging. One reason is that sow survival is a biologically complex trait. Sows are culled for multiple reasons, and the risk for culling due to any of these reasons depends on the parity (Engblom *et al.*, 2007). Because frequencies of specific reasons for culling differ across parities, the rankings between genetic merits for sow survival likely also differ across parities. Genetic associations between sow survival at different time points have been estimated in purebred (Abell *et al.*, 2016; Plaengkaeo *et al.*, 2020; Ogawa *et al.*, 2021) and crossbred sows (Engblom *et al.*, 2009; Abell *et al.*, 2016; Poulsen *et al.*, 2020). However, results on sow survival from purebred populations may not be extrapolatable to crossbred populations (Abell *et al.*, 2016; Poulsen *et al.*, 2020). Furthermore, the studies on crossbred sows have neither provided comprehensive insights into genetic associations across parities (Poulsen *et al.*, 2020) nor used adequate sample sizes (Engblom *et al.*, 2009; Abell *et al.*, 2016). Improved knowledge on the genetic associations between commercial sow survival at different parities can contribute to better breeding procedures for sow longevity. The objective of this study was to investigate whether sow survival is genetically associated across parities in commercial and rotationally crossbred sows. This was examined by estimating (co)variance components for five survival traits with a multi-trait animal model. We hypothesized that the five survival traits are moderately to strongly genetically associated.

Materials & methods

Animal Care and Use Committee approval was not required for this study as data were obtained from an existing database.

Phenotype data. The sows were crossbred between the DanBred Landrace and DanBred Yorkshire populations. All sows produced on commercial breed-to-wean farms located in Denmark. The phenotype data consisted of farrowing records from sows born between January 1st, 2015, and December 31st, 2017. The farrowing records included service dates, farrowing dates, litter sizes, litter sire, and breed.

Traits. We investigated sow survival through five sequential stayability traits: stayability from the first service to first farrowing (Stay1), from first farrowing to second farrowing given survival in Stay1 (Stay2),

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_776, © B.G. Poulsen *et al.* 2022

from second farrowing to third farrowing given survival in Stay2 (Stay3), from third farrowing to fourth farrowing given survival in Stay3 (Stay4), from fourth farrowing to fifth farrowing given survival in Stay4 (Stay5). All traits have binary outcomes where '1' denotes survival and '0' denotes death. The survival rates ranged from 0.74-0.93 across traits (Table 1)

Partial additive relationship matrices. The additive genetic covariance between animals was modelled with the partial additive relationship matrices (Lo *et al.*, 1993; García-Cortés and Toro, 2006) because some sows and gilts with phenotypes were rotationally crossbred. With this method and two-way rotationally crossbred animals, additive genetic effects are split into three components: a breed-specific effect for Landrace, a breed-specific effect for Yorkshire, and a segregation effect between Landrace and Yorkshire. However, preliminary analyses showed that the segregation effects were not significant for this combination of population and trait. Therefore, segregation effects were not included in the statistical model.

Statistical model. Stay1, Stay2, Stay3, Stay4, and Stay5 were simultaneously analysed using a five-trait linear mixed model:

$$\mathbf{y} = \begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \\ \mathbf{y}_3 \\ \mathbf{y}_4 \\ \mathbf{y}_5 \end{bmatrix} = \mathbf{Xb} + \mathbf{Wh} + \mathbf{Ql} + \mathbf{Z}_L\mathbf{a}_L + \mathbf{Z}_Y\mathbf{a}_Y + \mathbf{e} \quad (1)$$

Where y_1, y_2, y_3, y_4 and y_5, are vectors of phenotypes for Stay1, Stay2, Stay3, Stay4, and Stay5, respectively; b is a vector of fixed effects for herd-year at birth, and month at birth, and regression coefficients of age at first service (linear and quadratic), fraction of Yorkshire, fraction of heterosis, and reproductive performance (permanent sow effect from a mixed linear model; zero for y_1); h is a vector of random effects for combinations of the herd, year, and month at birth; l is a vector of random effects for litters; a_L and a_Y are vectors of partial additive genetic effects for breed-specific terms from Landrace and Yorkshire, respectively; e is the residual; X, W, Q, Z_l and Z_y are design matrices of proper dimensions. In Equation 1, the effects within all vectors are nested within traits.

The statistical model contains two random environmental effects, two additive genetic effects, and one residual effect which were assumed to be distributed as:

$$\begin{bmatrix} \mathbf{h} \\ \mathbf{l} \\ \mathbf{a}_L \\ \mathbf{a}_Y \\ \mathbf{e} \end{bmatrix} \sim \text{MVN}\left(\begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \begin{bmatrix} \boldsymbol{\Sigma}_H \otimes \mathbf{I}_H & & & & \\ \mathbf{0} & \boldsymbol{\Sigma}_L \otimes \mathbf{I}_L & & \text{Symm.} & \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Sigma}_{AL} \otimes \mathbf{A}_L & & \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \boldsymbol{\Sigma}_{AY} \otimes \mathbf{A}_Y & \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \boldsymbol{\Sigma}_E \otimes \mathbf{I}_E \end{bmatrix} \right) \quad (2)$$

where Σ_H, Σ_L, Σ_{AL}, and Σ_{AY} are 5×5 covariance matrices where each element is an estimable parameter; Σ_E is a 5×5 diagonal covariance matrix; I_H, I_L, and I_E are identity matrices; A_L and A_Y are partial additive

Table 1. Number of animals and phenotypic mean for each trait.

	#Animals	Mean
Stay1	112,373	0.93
Stay2	104,009	0.85
Stay3	88,501	0.85
Stay4	75,355	0.81
Stay5	60,691	0.74

relationship matrices for breed-specific terms from Landrace and Yorkshire, respectively; 0's are vectors or matrices with zeros; and ⊗ is the Kronecker product.

Covariance components were estimated using the average-information restricted maximum likelihood algorithm in the DMU software (Madsen *et al.*, 2006). The standard errors of covariance components were approximated using their asymptotic normal distribution. The standard errors of heritability statistics and correlations were approximated with the Delta Method (Dorfman, 1938; Oehlert, 1992). Heritabilities and correlations were assumed normally distributed when statistically tested.

Results

Estimated genetic correlations were favourable and moderate to strong (0.26±0.17-0.88±0.18; Table 2). Subsequent stayability traits tended to be more strongly associated than non-consecutive stayability traits (0.54±0.16-0.88±0.18 vs 0.26±0.17-0.84±0.11). Stay3, Stay4, and Stay5 were strongly associated (0.73±0.18-0.88±0.18).

The heritabilities were low for all traits (0.01±0.00-0.05±0.01). Heritabilities were larger for later-in-life stayability than those measured earlier in life, except for in Yorkshire where Stay3 was as heritable as Stay1.

Discussion

Most stayability traits were favourably and moderately to strongly genetically associated in the Landrace and Yorkshire populations. Thereby, the genetic background for sow survival is similar across most parities.

Other studies have estimated genetic associations between survival at different parities in commercial and crossbred animals (Engblom *et al.*, 2009; Abell *et al.*, 2016; Poulsen *et al.*, 2020). These studies also found that survivals at different parities are moderately to strongly genetically associated. This may be because of the overlap in culling reasons as reproductive failure persists as the predominant reason for culling until the fifth parity (Engblom *et al.*, 2007; Malanda *et al.*, 2019). Of the traits investigated, only Stay1 was not consistently strongly genetically correlated with the other stayability traits.

We found that Stay1 is often only moderately genetically associated with the later-in-life stayability traits. However, it is important to note that Stay1 is defined differently than the other stayability traits. In other

[1] Not statistically significantly different from zero.

words, Stay1 is defined as the survival between a service and a farrowing, whereas the other stayability traits are defined as the survival between one farrowing and another farrowing. This difference in definition may contribute to a weaker genetic association between the stayability traits if the genetic background differs for voluntary and involuntary culling.

The heritabilities were low (<0.10) for investigated traits in both the Landrace and Yorkshire populations. Previous studies on genetic parameters for stayability do not agree on whether the heritability for stayability is low or high (0.01-0.98) (Engblom *et al.*, 2009; Abell *et al.*, 2016; Plaengkaeo *et al.*, 2020; Poulsen *et al.*, 2020; Ogawa *et al.*, 2021). However, there is a tendency that studies on stayability in purebred animals estimate higher heritabilities than studies in crossbred animals (purebred: 0.10-0.36; crossbred: 0.01-0.06) (Engblom *et al.*, 2009; Plaengkaeo *et al.*, 2020; Poulsen *et al.*, 2020; Ogawa *et al.*, 2021). Composite traits, such as survival, are expected to have low heritability (Price and Schluter, 1991). Furthermore, it is common procedure to use crossbred animals in commercial herds. Therefore, we argue that the lower heritabilities in crossbred animals are more representative of the heritability in commercial herds than heritabilities in purebred animals.

Most survivals at different parities were moderately to strongly genetically correlated. Therefore, the high parametrisation of multi-trait models may not contribute to an increase in prediction accuracy compared to parametrically simpler models, e.g. random regression- or repeatability models. However, it is worth noting that Stay1 was less genetically associated with later-in-life stayability.

777. Piglet Survival is lowly heritable in DanBred Landrace pigs

X. Guo[1,2*], A.C. Sørensen[1], M. Henryon[1] and T. Ostersen[1]

[1]Danish Pig Research Centre, Danish Agriculture & Food Council, 1609 Copenhagen V, Denmark; [2]Center for Quantitative Genetics and Genomics, Aarhus University, 8830 Tjele, Denmark; xguo@lf.dk

Abstract

We tested the premise that piglet survival at day 5 is a lowly-heritable trait in DanBred Landrace pigs. We did this by fitting a bivariate animal model to piglet survival and total number of piglets born. Our results showed that piglet survival was lowly heritable in Landrace pigs. The direct and maternal heritabilities were 0.018 and 0.020; the total heritability was 0.030. Heritability for piglet survival is clearly low in DanBred Landrace pigs, but there should be enough genetic variation to increase piglet survival.

Introduction

The proportion of live piglets has increased since selection for litter size at day 5 after farrowing was implemented in DanBred's pig breeding program for Landrace and Yorkshire pigs (Nielsen *et al.*, 2013). Survival is an important trait in pig production systems for ethical and economic reasons (Amer *et al.*, 2014). Direct and maternal heritabilities for piglet survival have been reported as low. They tend to range from 0.01 to 0.24 when estimated using threshold-liability models (Su *et al.*, 2008; Ibáñez-Escriche *et al.*, 2009; Roehe *et al.*, 2010; Kapell *et al.*, 2011) and from 0.00 to 0.05 using linear models (Knol *et al.*, 2002). This suggests that piglet survival at day 5 is also a lowly-heritable trait in DanBred pigs. We tested this premise by fitting a bivariate animal model to DanBred Landrace pigs.

Materials & methods

Experimental design. We estimated the additive-genetic variation, heritability, and prediction accuracy for survival in DanBred Landrace pigs. We did this in two parts. First, we estimated additive-genetic variation and heritability by fitting a bivariate linear model to piglet survival at day 5 (SURV) as a trait of the piglet and total number of born piglets (TNB) as a trait of the sow. Second, we estimated prediction accuracy using breeding values derived from the bivariate linear model in a validation analysis. We did this using SURV and TNB records from 537,746 Landrace piglets from 35,127 first parity litters, and 568,629 animals were included in pedigree. All the piglets were born between January 2016 and April 2021. SURV was recorded on a binary scale, 0 for dead and 1 for alive. The descriptive statistics of the two traits are shown in Table 1.

Genetic variation and heritability. The bivariate model fitted to estimate additive-genetic variation and heritability was:

$$\begin{bmatrix} \boldsymbol{y}_S \\ \boldsymbol{y}_T \end{bmatrix} = \begin{bmatrix} \boldsymbol{X}_S & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{X}_T \end{bmatrix} \begin{bmatrix} \boldsymbol{b}_S \\ \boldsymbol{b}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z}_{a_S} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{bmatrix} \begin{bmatrix} \boldsymbol{a}_S \\ \boldsymbol{a}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z}_{u_S} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_S \\ \boldsymbol{u}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z}_{m_S} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}_{m_T} \end{bmatrix} \begin{bmatrix} \boldsymbol{m}_S \\ \boldsymbol{m}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z}_{l_S} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}_{l_T} \end{bmatrix} \begin{bmatrix} \boldsymbol{l}_S \\ \boldsymbol{l}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}_{s_T} \end{bmatrix} \begin{bmatrix} \boldsymbol{s}_S \\ \boldsymbol{s}_T \end{bmatrix} + \begin{bmatrix} \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}_{c_T} \end{bmatrix} \begin{bmatrix} \boldsymbol{c}_S \\ \boldsymbol{c}_T \end{bmatrix},$$

where y_S and y_T were observations of SURV and TNB, b was fixed effects including year-month, herd-year, and also regressions on age at first farrowing (age and age^2); a was direct genetic effects of the piglet, u was non-genetic effects of the piglet, m was maternal genetic effects for SURV and direct genetic effects of the sow for TNB, l was birth litter effects, s was service sire genetic effects, c was non-genetic effects of service sire; u_s and l_t were the random residuals. X and Z were incidence matrices relating the observations to the fixed and random effects, respectively.

Table 1. Descriptive statistics.

Trait[1]	No. Obs	Mean	SD	Min	Max
SURV	537,746	0.794	0.404	0	1
TNB	35,127	15.309	4.201	1	32

[1] SURV: piglet survival at day 5; TNB: total number born.

The random effects were assumed to follow multi variate normal distributions:

$$\begin{bmatrix} \boldsymbol{a_S} \\ \boldsymbol{m_S} \\ \boldsymbol{m_T} \\ \boldsymbol{s_T} \end{bmatrix} \sim MVN \left(0, \begin{bmatrix} \sigma^2_{a_S} & \sigma_{a_S,m_S} & \sigma_{a_S,m_T} & \sigma_{a_S,s_T} \\ \sigma_{a_S,m_S} & \sigma^2_{m_S} & \sigma_{m_S,m_T} & \sigma_{m_S,s_T} \\ \sigma_{a_S,m_T} & \sigma_{m_S,m_T} & \sigma^2_{m_T} & \sigma_{m_T,s_T} \\ \sigma_{a_S,s_T} & \sigma_{m_S,s_T} & \sigma_{m_T,s_T} & \sigma^2_{s_T} \end{bmatrix} \otimes \boldsymbol{A} \right),$$

$$\begin{bmatrix} \boldsymbol{u} \\ \boldsymbol{l_S} \\ \boldsymbol{l_T} \\ \boldsymbol{c_T} \end{bmatrix} \sim MVN \left(0, \begin{bmatrix} \sigma^2_u & 0 & 0 & 0 \\ 0 & \sigma^2_{l_S} & \sigma_{l_S,l_T} & 0 \\ 0 & \sigma_{l_S,l_T} & \sigma^2_{l_T} & 0 \\ 0 & 0 & 0 & \sigma^2_{c_T} \end{bmatrix} \otimes \boldsymbol{I} \right),$$

where A was the matrix of additive genetic relationships constructed based on the pedigree, and I was an identity matrix. The model was fitted using the DMU software (Madsen and Jensen, 2013)

Variance components, genetic correlations and corrected phenotypic values (y_c) were estimated using the full data. Following a previous study (Eaglen and Bijma, 2009), phenotypic variance (σ^2_p) of SURV was calculated as $\sigma^2_{p_S} = \sigma^2_{a_S} + \sigma^2_{m_S} + \sigma_{a_S,m_S} + \sigma^2_u + \sigma^2_{l_S}$. The direct heritability of SURV ($h^2_{a_S}$) was calculated as $h^2_{a_S} = \frac{\sigma^2_{a_S}}{\sigma^2_{p_S}}$, the maternal heritability of SURV ($h^2_{m_S}$) was calculated as $h^2_{m_S} = \frac{\sigma^2_{m_S}}{\sigma^2_{p_S}}$, and the total heritability of SURV was calculated as $h^2_{t_S} = \frac{\sigma^2_{a_S} + \sigma^2_{m_S} + 2\sigma_{a_S,m_S}}{\sigma^2_{p_S}}$.

Prediction accuracy. Prediction accuracy was calculated by dividing the population into training and validation data sets. Breeding values for SURV were derived from the bivariate linear model fitted to SURV and TNB. The birthdate of 1st July, 2020 was chosen as the cut-off date. The predictive accuracy was evaluated as $\sqrt{cor^2(EBV, y_c)/h^2_{t_S}}$.

The y_c were raw phenotypic records corrected for fixed effects including year-month, herd-year and regressions on age at first farrowing (age and age^2).

Results

Survival. SURV was lowly heritable in Landrace pigs. The direct-genetic and maternal-genetic variances were similar (Table 2). Their heritabilities were 0.018 and 0.020. The total heritability was 0.030.

Genetic correlations. A negative genetic correlation between direct genetic and maternal genetic effects was observed at -0.215 for SURV. The unfavourable genetic correlation was significantly different from 0.

Prediction accuracy. As shown in Table 3, the accuracy was 0.17 for prediction of direct genetic values, 0.23 for prediction of maternal genetic values, and 0.31 for total genetic values.

Discussion

Our findings showed unequivocally that piglet survival is lowly heritable in the DanBred Landrace pigs. Even though it was low, the 3% total heritability that we estimated should allow selection to increase piglet survival. Our heritability estimates were generally supported by estimates for other pig populations

Table 2. Estimates of genetic (co)variance and heritabilities for piglet survival.

Parameter[1]	σ^2_{as}	σ_{a_s,m_s}	$\sigma^2_{m_s}$	h^2_{as}	h^2_{ms}	h^2_{ts}
Estimates	0.0030	-0.0007	0.0033	0.0183	0.0202	0.0300

[1] σ^2_{as}: variance of direct genetic effects; σ^2_{ms}: variance of maternal genetic effect; σ_{a_s,m_s}: covariance between direct and maternal genetic effects; h^2_{as}: direct heritability; h^2_{ms}: maternal heritability; h^2_{ts}: total heritability.

Table 3. Prediction accuracy of piglet survival.

Trait[1]	Direct	Maternal	Direct + Maternal
SURV	0.17	0.23	0.31

[1] SURV: piglet survival at day 5.

(Grandinson *et al.*, 2002; Knol *et al.*, 2002). We also found that approximately half of the genetic variation for piglet survival was direct-genetic variation, the other half was maternal-genetic. This is important because it means that breeders need to utilise both sources of variation to maximise genetic gains for piglet survival. The potential for increasing piglet survival by utilising both sources was highlighted by our prediction accuracies. Prediction accuracy of 0.31 is particularly high for a trait with a heritability of 3%. The high accuracy partly reflects the DanBred pig breeding system, where large litter sizes have resulted in each pig in the breeding population having many close relatives. So, even though the heritability for piglet survival is low, there should be enough genetic variation and sufficient prediction accuracy to increase piglet survival in DanBred Landrace pigs.

The high prediction accuracy probably also reflects the bivariate model we fitted to piglet survival. A preliminary analysis showed that it was worthwhile including TNB in this model because it resulted in larger estimates of direct and maternal genetic variances for piglet survival than a univariate model fitted to piglet survival. The most likely reason for the larger estimates was that the bivariate model fitted genetic and non-genetic correlations between SURV and TNB. For example, we detected a negative genetic correlation between direct and maternal-genetic effects for survival. Direct-genetic effects for survival also showed negative genetic correlations to both sow and service-sire effects for TNB (results not shown). These correlationsprovide additional information sources that increases the prediction accuracy for piglet survival. Therefore, fitting bivariate models that include TNB provide additional sources of information that increase prediction accuracy and help to utilise the genetic variation for piglet survival in pigs.

778. Feasibility of reducing mortality of pigs from birth to slaughter by genetic selection

G. Su[1*], T. Liu[1,2], O.F. Christensen[1], M.S. Lund[1] and B. Nielsen[1,3]

[1]Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark; [2]Institute of Animal Science, Guangdong Academy of Agricultural Sciences, Dafeng 1st Street 1, Wushan, Tianhe District, 510640 Guangzhou, China; [3]SEGES Pig Research Centre, Axelborg, Axeltorv 3, 1609 Copenhagen, Denmark; guosheng.su@qgg.au.dk

Abstract

Pig mortality is a big welfare and economic challenge. This study investigated the feasibility of reducing mortality of pigs from day 5 to slaughter and from birth to slaughter by breeding. Data of 163,782 female pigs were from DanBred Yorkshire breeding herds. Variances and breeding values were estimated using a linear, a logit and a probit model based on mortality record (0, 1) at individual level. Estimates of direct heritabilities ranged from 0.013 to 0.017 and maternal heritabilities from 0.005 to 0.017. Estimated breeding values (EBVs) from the three models were highly consistent. Although low heritabilities, validation accuracies of EBVs ranged from 0.415 to 0.420 for direct EBVs, from 0.192 to 0.392 for maternal EBVs, and from 0.357 to 396 for total EBVs. The results indicate that reducing pig mortality by breeding is feasible, and linear model is efficient for genetic evaluation of pig mortality.

Introduction

Pig mortality in modern pig production has become a major welfare and economic concern. It has been reported that pre-weaning mortality rates vary between 12 and 25% (Alonso-Spilsbury *et al.*, 2007). In addition to pre-weaning mortality, previous studies have shown that mortality rates ranged between 1.9 and 4.2% in nursery phase, and between 1.6 and 4.6% in finisher phase (USDA, 2015; Christiansen, 2018). In Denmark, selection for number of piglets alive at day 5 has been implemented since 2004, which is expected to improve both litter size and piglet survival before day 5 (Su *et al.*, 2007). However, the mortality from day 5 to slaughter has not directly been taken into account yet. So far, the knowledge in efficiency of breeding for reducing pig mortality is very rare, especially for mortality after weaning.

Pig mortality is usually recorded at litter level and considered as a trait of sow. However, mortality is a complex trait that is also affected by the pig's own genotype. It may therefore be more appropriate to perform genetic evaluation of mortality at pig individual level using a model including direct and maternal additive genetic effects. Furthermore, since pig mortality at individual level is a binary trait, a standard linear Gaussian model may be not appropriate for analysing such data, and more sophisticated models should be considered.

The objective of this study is to evaluate feasibility of reducing mortality of pigs before slaughter by estimating variance components and heritability of pig mortality and validating accuracy of genetic evaluation of mortality using a linear, a logit and a probit model, based on data from Danish Yorkshire breeding herds.

Materials & methods

Population and data. The data used in this study included 163,782 female pigs, collected from DanBred Yorkshire breeding herds from October 2018 to November 2021. Male pigs were not used in this study since relevant information was missing, e.g. castration. The traits in the analysis were mortality from day 5 to slaughter (Mort5S), and mortality from birth to slaughter (MortBS). Since all females were born in nucleus herds, slaughter age was set to 150 days for all pigs. A pig was scored 1 if the pig died before slaughter, otherwise 0. Based on the data, Mortality rate was 16.6% for Mort5S and 23.8% for MortBS in this population.

DOI: 10.3920/978-90-8686-940-4_778, © G. Su *et al.* 2022

Statistical models. Variance components and breeding values of mortality were estimated using the following single-trait models.

Linear mixed model: $y = Xb + Z_c c + Z_l l + Z_d a_d + Z_m a_m + e$

Logit model: $\eta = Xb + Z_c c + Z_l l + Z_d a_d + Z_m a_m$

Probit model: $\rho = Xb + Z_c c + Z_l l + Z_d a_d + Z_m a_m$

In the models, y is the vector of binary observations $y_i = \{0,1\}$, η is the vector of logits with $\eta_i = \log(\pi_i / (1 - \pi_i))$ where π_i is probability of death of animal i, and ρ is the vector of expected liabilities of death with $\rho_i = \Phi^{-1}(\pi_i)$ where Φ is cumulative normal distribution function, b is the vector of fixed effects including parity, herd, and year-month, c is the vector of random herd-year-month effects, l is the vector of random litter effects, a_d is the vector of direct additive genetic effects, a_m is the vector of maternal additive genetic effects. The scales of b, l, c, a_d and a_m in the three models are different. It is assumed that $c \sim N(0, I\sigma_c^2)$, $l \sim N(0, I\sigma_l^2)$, $\begin{bmatrix}\mathbf{a_d}\\ \mathbf{a_m}\end{bmatrix} \sim N\left(\mathbf{0}, \begin{bmatrix}\sigma^2_{ad} & \sigma_{adam}\\ \sigma_{adam} & \sigma^2_{am}\end{bmatrix} \otimes \mathbf{A}\right)$. The residuals are assumed to $e \sim N(0, I\sigma_e^2)$ in the linear model, set to $e \sim N(0, I)$ in the probit model, and logistic distribution with variance ≈ 3.29 in the logit model. Phenotypic variance was defined as $\sigma_p^2 = \sigma_l^2 + \sigma_{ad}^2 + \sigma_{am}^2 + \sigma_{adam} + \sigma_e^2$ (Willham, 1972). The models were implemented using DMU package (Madsen *et al.*, 2010).

Validation of genetic prediction. For validation of genetic prediction using the above models, the full data were divided into reference data and validation data by dam's birth date with 2019-10-01 as a cut-off date. Accuracy of EBV was measured as the correlation between EBV and corrected phenotype (y_c) divided by accuracy of y_c. EBV from all three models were compared with the y_c from the linear model. The y_c was defined as $y_c = \hat{a}_d + \hat{a}_{m(dam)} + \hat{l} + \hat{e}$. By the definition, the accuracy of y_c was $r_{yc} = \sqrt{\frac{\sigma^2_{ad} + \sigma^2_{am} + \sigma_{adam}}{\sigma^2_l + \sigma^2_{ad} + \sigma^2_{am} + \sigma_{adam} + \sigma^2_e}}$. Dispersion bias for each model was measured by the regression of EBV from full data on EBV from reference data.

Results

For all traits and models, the estimates of direct and maternal heritabilities were very low, ranging from 0.005 to 0.017 (Table 1). For MortBS, direct heritabilities in underlying scale from the logit and the probit model were not higher than those in observed scale from the linear model, which was unexpected, indicating a challenge of analysing binary traits. Maternal heritabilities for MortBS was higher than those for Mort5S. The correlations between direct and maternal additive genetic effects was low and not significantly different from zero.

Table 1. Phenotypic variance, proportion of litter variance, direct (a_d) and maternal (a_m) heritability, correlation between a_d and a_m, as well as their standard error (±).

Trait	Model	σ_p^2	lit^2	h_{ad}^2	h_{am}^2	r_{adam}
Mort5S	Linear	0.134	0.051±0.0021	0.015±0.0026	0.005±0.0017	-0.119±0.1747
	Logit	3.648	0.071±0.0038	0.017±0.0033	0.010±0.0031	0.006±0.1884
	Probit	1.107	0.069±0.0039	0.016±0.0030	0.010±0.0031	0.032±0.1879
MortBS	Linear	0.177	0.061±0.0021	0.015±0.0026	0.010±0.0022	-0.182±0.1451
	Logit	3.665	0.076±0.0031	0.013±0.0024	0.014±0.0031	-0.069±0.1613
	Probit	1.128	0.084±0.0035	0.014±0.0025	0.017±0.0034	-0.050±0.1608

Although variance components and heritabilities were somewhat different among the three models, the EBVs from the three models are highly consistent (Table 2). For the validation animals, correlations between EBVs from logit and probit model were higher than 0.998. Correlations between EBVs from the linear model and the other two models were about 0.990 for direct EBVs and total EBVs, and ranged from 0.928 to 973 for maternal EBVs.

Regression coefficients of the EBVs obtained from full data on the EBVs from reference data for validation animals ranged from 0.932 to 1.194 (Table 3), indicating that dispersion bias was small for all models and traits. Regression coefficients for the logit and probit models were slightly less far from 1 than the counterparts from the linear model, indicating slightly less bias.

Despite low heritability, accuracy of EBV were not low (Table 4). Validation accuracies ranged from 0.415 to 0.420 for direct EBVs, from 0.192 to 0.392 for maternal EBVs, from 0.357 to 0.396 for total EBVs. The validation accuracies were very similar between the three models, except that accuracy of maternal EBV from the linear model was lower than those from the other two models. According to the results from the linear model, the total genetic variance for observed phenotypic values ($\sigma^2_{ad} + \sigma^2_{am} + \sigma_{adam}$) was 0.00248 for Mort5S and 0.00398 for MortBS. Selection on the sum of EBV_{ad} and EBV_{am} would reduce mortality by 1.95% for Mort5S, or 2.25% for MortBS, given selection intensity of 1.

Table 2. Correlations (upper diagonal for Mort5S and lower diagonals for MortBS) between EBVs from different models.

Model	EBV_{ad}			EBV_{am}			EBV_{ad+am}		
	Linear	Logit	Probit	Linear	Logit	Probit	Linear	Logit	probit

Discussion

This study assessed feasibility of reducing pig mortality before slaughter by investigating genetic parameters and selection accuracy using three models. With the binary output of mortality at individual level, it was expected that the logit model and the probit model would perform better than the linear model in which the normality assumption is violated. However, the results showed that the EBVs from the linear model were highly consistent with the EBVs from the logit and probit models. The validation accuracies of the three models were also similar to each other. The negligible difference in prediction accuracy between linear model and probit or logit model have been found in simulation studies (e.g. Meijering and Gianola, 1985) and in the studies on mastitis in cattle (e.g. Koeck *et al.*, 2010). These results indicates that linear model is robust to violation of normality hypothesis, and thus it could be a good choice for genetic evaluation of pig mortality because it is simple to implement.

Heritabilities for the two mortality traits were lower than 0.02. However, accuracies of EBVs were moderate for direct EBV and total EBV, though relatively low for maternal EBV. This could be due to large information from relatives contributing to the estimation of breeding values. In the current study, an individual had, on average, about seven full-sibs and about 200 half-sibs in the data. According to the genetic parameters and accuracy of EBV obtained in this study, selection on total EBV would reduce mortality by $i\times1.95\%$ for Mort5S, and $i\times2.25\%$ for MortBS, where i is selection intensity. The realized reduction of mortality by including mortality in selection index will depend on the weight on mortality and the relationship of mortality with the other traits in the selection index.

Accuracies of EBV and expected genetic gains presented above are based on conventional selection. Genomic selection has been widely used in pig breeding. It has reported that selection accuracy and genetic gain increased up to 50% when changing conventional selection to genomic selection (e.g. Knol *et al.*, 2016). In most pig breeding companies, pure pigs in test are genotyped. When genomic information is used for prediction of pig mortality, the accuracies of EBV and the genetic progress in reducing mortality is expected to increase largely.

We conclude: even though heritability for mortality traits is low, accuracy of EBV is acceptable for selective breeding; linear mixed model is efficient for predicting breeding value of mortality traits; and selection to reduce pig mortality before slaughter is feasible.

Abstract

A premise was tested that genotyping both surviving and dead pigs will realise more genetic gain in post-weaning survival (PWS) than genotyping only surviving animals. Stochastic simulation was used to estimate the rate of true genetic gain in different genotyping scenarios that differed in varying proportions of genotyping dead animals. Selection was for only PWS that had heritability of 0.02. Mortality was assumed 10%. The trait was controlled by 7,702 biallelic quantitative trait loci distributed across a 30 Morgan genome. We used 54,218 biallelic single nucleotide polymorphisms (SNPs) that were used in genomic prediction. Genotyping both surviving and dead animals realised 12 to 24% more genetic gain than genotyping only surviving animals. The power of detecting SNP effects increased when animals of extreme phenotypes are genotyped. Therefore, genotyping both surviving and dead pigs realised more genetic gain than genotyping only surviving animals.

Introduction

Post-weaning survival (PWS) is an economically important trait for growing pigs (Knol *et al.*, 2016; Hermesch *et al.*, 2014). The trait is easy to record but is lowly heritable (h^2=0.02-0.06) with low prediction accuracy (Leite *et al.*, 2021; Harper *et al.*, 2019). It can particularly benefit from genomic selection as shown by an increase in the prediction accuracy of genomically estimated breeding value (GEBV) for PWS from 20 to 50% when prediction included genomic information (Leite *et al.*, 2021; Knol *et al.*, 2016). However, one of the challenges when applying genomic selection to survival is that, for practical reasons, only surviving animals may be genotyped. This has the potential to introduce prediction bias and reduce accuracy (Leite *et al.*, 2021). In general, genotyping phenotypically contrasting animals can increase the genetic gain, accuracy of GEBV and decrease the bias of GEBV for continuous trait in comparison to genotyping only top animals because information on phenotypically extreme values results in more accurate estimates of SNP effects (Gowane *et al.*, 2019, Chu *et al.*, 2020). For the case of PWS, genotyping phenotypically contrasting animals refers to the scenario of genotyping both surviving and dead animals. This indicates that genotyping both surviving and dead animals is expected to realise more genetic gain than genotyping only surviving animals. Based on this reasoning, it was tested if genotyping all animals in the birth cohort realises more genetic gain (ΔG) for PWS than genotyping only surviving selection candidates.

Methods

Procedure. Stochastic simulation was used to estimate the ΔG_{true} realised for PWS. All surviving animals and 0, 20, 40, 60, 80, and 100% of randomly selected dead animals were genotyped. Genomic breeding values (GEBVs) were used in optimum contribution selection (OCS), and pedigree information was used to constrain inbreeding to 0.01 per generation. Post-weaning survival had an initial value of 90% and heritability of 0.02 on the observed scale (Harper *et al.*, 2019). It was controlled by 7,702 biallelic QTL distributed across a 30M genome. The genome contained 54,218 biallelic genetic markers that were used to calculate GEBV. Simulation of genomes in a founder population was detailed in the study by Henryon

et al. (2019). Breeding schemes were run for 10 discrete generations and replicated 30 times. Each replicate was initiated by sampling a unique base population from the founder population. Animals in the base populations were randomly selected in generation $t = 1$. In generations $t = 2 \ldots 10$, selection candidates were allocated matings by OCS.

Breeding scheme. Population consisted of 20 sires and 300 dams that were selected in every generation. Each sire was randomly mated with 15 dams. Each dam produced six progeny with a sex ratio of progeny of one to one.

Simulating phenotype. The true breeding value (TBV) was calculated as the sum of additive genetic effects at the 7,702 QTLs. Its residual value e_i was sampled from $e_i \sim N(0, \sigma_e^2 = 0.79$ on the underlying scale). The target observed-scaled heritability (h_o^2=0.02) was transformed to heritability on underlying scale (h_l^2 =0.06) according to the following formula (Dempster and Lerner, 1050):

$$h_l^2 = \frac{h_o^2 K(1-K)}{z^2} \quad (1)$$

Where K is the proportion of survivability incidence which was assumed 90% in this study, z is the height of normal distribution curve at threshold.

The liability of animal i was calculated as $l_i = a_i = e_i$, where a_i is the animal's TBV and e_i is the residual value. Phenotype of individual animal i, y_i was assigned as $y_i = 1$ when liability exceeded the threshold value for survivability of 90% and otherwise $y_i = 0$.

Genomic prediction. A liability threshold (probit) model was used to estimate the breeding value for the post-weaning survival trait.

$$l = Xb + Z_1 a + Z_2 c + e \quad (2)$$

where b is the fixed generation effect, a and c are vectors of random additive genetic effect and random common environmental effect respectively, e is the vector of random residual error. The co(variance) structure of the random effects was:

$$\begin{pmatrix} \boldsymbol{a} \\ \boldsymbol{c} \\ \boldsymbol{e} \end{pmatrix} \sim N\left(\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \boldsymbol{A}\sigma_a^2 & 0 & 0 \\ 0 & \boldsymbol{I}\sigma_c^2 & 0 \\ 0 & 0 & \boldsymbol{I}\sigma_e^2 \end{bmatrix} \right)$$

Where I is an identity matrix, σ_a^2=0.06 is the additive genetic variance on the underlying scale, σ_c^2=0.15 is the common litter variance and σ_e^2=0.79 residual variance on the underlying scale that was used to sample phenotype. Single-step genomic breeding value (ssGBLUP) was estimated using H matrix instead of A.

Comparisons. Rate of true genetic gain (ΔG_{true}) was calculated in each replicate as a linear regression of average true breeding values of animals born in generations $t = 5$ to 10 (G_t) on time t. Accuracy of GEBV was calculated in each generation as the correlation between true breeding values (TBVs) and GEBV of surviving animals. Generation averages were averaged across the 30 replicates. Bias of GEBV in each replicate was calculated as the regression of TBV on GEBV of surviving animals. All results are presented as the mean of 30 replicates.

The ADAM software (Pedersen *et al.*, 2009) was used for simulating a breeding program. The DMU package (Madsen *et al.*, 2006) was used for predicting GEBV and OCS was carried out by the EVA software (Berg *et al.*, 2009).

Results

Compared to traditional pedigree selection, the addition of genotype information on all surviving animals resulted in 70% more true genetic gain. Genotyping both surviving and dead pigs realised a higher ΔG_{true} compared with genotyping only surviving pigs (Table 1). Genotyping all surviving pigs and 20-100% of the dead pigs realized 12-23% more genetic gain than genotyping only surviving animals. Compared to only genotyping surviving animals, the greatest realised gains were made when 20% of dead animals were also genotyped (a 12% increase). Thereafter, increasing genotyping dead animals by 20% only resulted in a realised 4-6% increase.

Genotyping both surviving and dead animals increased accuracy of GEBVs. Genotyping all surviving pigs and 20-100% of the dead pigs generated GEBVs that were 12.5 to 18% more accurate respectively, than genotyping only surviving animals (Table 1). Meanwhile, bias was reduced by 7% when also genotyping all dead pigs.

Discussion

In this simulation study, the benefits of genotyping both surviving and dead pigs were assessed based on changes in genetic gain, prediction accuracy and bias of GEBV for PWS in surviving animals as compared to the genotyping only surviving pigs and pedigree selection. Since single-step method was used in this simulation, relationship information about ungenotyped dead pigs was available from the genotyped surviving pigs. As a result, genotyping only surviving pigs provided additional genetic gain and increased prediction accuracy compared to the pedigree selection. However, genotyping both surviving and dead pigs refers to the genotyping phenotypically contrasting animals and that realised more genetic gain and increased prediction accuracy in comparison to genotyping only surviving animals. The finding in this study is in agreement with other studies using continuous trait (Gowane *et al.*, 2019; Chu *et al.*, 2020). When animals of extreme phenotypes are genotyped, the power of detecting SNP effect increased because most of the genetic information is captured in animals of extreme phenotypes (Huang and Lin, 2007). This resulted in higher genetic gain in PWS when both surviving and dead animals were genotyped in this simulation study. One might argue that additional genetic gain in PWS due to genotyping dead pigs might be because of genotyping additional animals not because of dead animals specifically. To explore

Table 1. Rate of true genetic gain (ΔG_{true}, expressed on underlying scale), prediction accuracy and bias of estimated breeding value for post-weaning survival in different proportion of genotyping dead animals. Standard error is shown in parenthesis.[1]

Genotyping strategy	ΔG_{true}	Accuracy	Bias
Pedigree selection only	0.051 (0.002)	0.199 (0.007)	1.20 (0.05)
Genotype all surviving animals	0.087 (0.003)	0.264 (0.008)	1.22 (0.04)
Geno surviving + 20% dead	0.097 (0.004)	0.297 (0.007)	1.24 (0.03)
Geno surviving + 40% dead	0.101 (0.003)	0.317 (0.006)	1.29 (0.03)
Geno surviving + 60% dead	0.105 (0.002)	0.318 (0.006)	1.19 (0.03)
Geno surviving + 80% dead	0.107 (0.003)	0.322 (0.006)	1.23 (0.02)
Geno surviving + 100% dead	0.104 (0.003)	0.312 (0.006)	1.13 (0.02)

[1] Geno surviving = all surviving animals were genotyped. Results were the mean of 30 replicates.

this hypothesis, additional scenarios were simulated where equal number of live or dead animals were genotyped in addition to genotyping fixed numbers of live animals. Findings of additional simulations (results not shown) clearly indicated that additional genetic gain was achieved from genotyping both live and dead animals. Therefore, the hypothesis turned out to be true that genotyping both surviving and dead animals realised more genetic gain as compared to genotyping only surviving animals.

This study assumed PWS to be 90% so that the benefit of genotyping different proportions of dead animals could be shown. In reality, PWS is greater than 90% because of high biosecurity in nucleus populations. Variation of a binary trait depends on proportion of incidence. If the mortality rate ranges from 3 to 5% in the nucleus population, data will lack enough variation for breeding value estimation. The low incidence of PWS in nucleus populations could be circumvented by adding mortality information from commercial herds. Genotyping commercial dead pigs could be used to add crossbred pigs in the reference population, since relationships between animals can be efficiently estimated with genomic data instead of keeping pedigree. If the commercial dead pigs are genotyped and added in the reference population for selection in nucleus, prediction accuracy of GEBV for post-weaning survival may increase. However, the benefit of genotyping commercial population depends on the correlation between purebred and crossbred populations (Van Grevenhof and Van der Werf, 2015). Therefore, it is worth investigating the benefit of genotyping commercial dead pigs to increase the accuracy of GEBV for PWS in the nucleus.

780. GBP5 PRRSV resistance gene had no effect on pigs' infectivity or susceptibility in a trial simulating natural infections

Abstract

A bespoke small-scale porcine reproductive and respiratory syndrome virus 2 (PRRSV2) transmission experiment was designed to gather evidence on whether the previously identified *GBP5* PRRS resistance gene also confers lower susceptibility and/or infectivity of pigs under natural PRRSV transmission. Commercial full- and half-sib piglets (n=164) were assigned as either inoculators, shedders, or contact pigs. Pigs were grouped according to their relatedness structure and their *GBP5* genotype, and barcoding of the PRRSV2 strain (SD09-200) was applied to track pig genotype-specific transmission. Blood samples were collected on consecutive trial days and the area under the curve (AUC) of the $\log TCID_{50}$ viral load using rt-PCR was used as response variable general linear mixed model analyses. These provided no supportive evidence that the *GBP5* resistance gene confers differences in host susceptibility or infectivity. However, variation in AUC among sibling groups does provide evidence that PRRSV2 transmission is partly genetically controlled.

Introduction

Porcine reproductive and respiratory syndrome (PRRS) arguably remains one of the most important infectious diseases for the pig industry worldwide. Despite biosecurity measures and vaccination, PRRS prevalence continues to be high, with estimated production losses of around 664 million US dollars per year (Holtkamp *et al.*, 2013). The disease is commonly associated with reproductive failure, and respiratory disease, fever, reduced growth, and mortality in piglets and breeding animals. Quantitative genetics studies have identified substantial genetic variation in the resistance of pigs to PRRS, with a single gene on pig chromosome 4 (*GBP5*, encoding guanylate-binding protein 5) explaining 15% of the genetic variation in viral load and 11% of the genetic variation for growth rate in nursery pigs infected with PRRSV2 (Boddicker *et al.*, 2014; Koltes *et al.*, 2015). Although these results offer promising opportunities for mitigating PRRS through genomic selection, predicting the impact of such selection on PRRS prevalence is difficult, as the role of host genetics and in particular of the *GBP5* resistance gene in PRRSV transmission is currently not known.

The overall aim of this study was to determine the role of the *GBP5* resistance gene on PRRSV2 transmission. To this purpose, a bespoke PRRSV transmission experiment was designed. The experiment differed from conventional transmission experiments in two key aspects: (1) a specific genetic-relatedness structure and *GBP5* genotype composition of pigs in the different contact groups to maximise statistical power for estimating genotype effects on PRRSV transmission,;and (2) barcoding of the PRRS virus to trace pig genotype specific transmission routes.

Materials & methods

Transmission experiment and statistical models. A total of 164 commercial cross-bred pigs (full-sibs or paternal half-sib progeny from ~70 sows, post weaning, up to 42 days old) were used in this study. Approximately half of the pigs from each sibling group carried (R+) or did not carry (R-), a copy of the dominant *GBP5* resistance allele. The study design consisted of two steps (Figure 1): step 1 involved infection of shedder pigs through natural exposure to PRRSV infected inoculation pigs, while step 2 was the main transmission trial to assess genotype effects on shedder pig infectivity and contact pig susceptibility. After considering parentage and *GBP5* genotype (Figure 1 and as outlined below), pigs were randomly assigned to one of the following roles: (1) Inoculation pig (n=20); (2) Shedder pig (n=48); (3) Contact pig (n=96). Full-sib inoculation pigs (all R-, from 10 unrelated parents) were split into two rooms, where they were inoculated with either a bar-coded (room A, blue, Figure 1) or a non-barcoded (room B, red, Figure 1) version of a virulent PRRSV2 strain circulating in North American pig farms (SD09-200; infection dose 10^5 $TCID_{50}$). Previous infection trials confirmed that barcoding had no effect on the infectivity or pathogenesis of the virus. One day later, 24 sibling pairs of shedder pigs were introduced into the two rooms (each consisting of equal proportion of pigs of each genotype and with sibs of the same R genotype split across

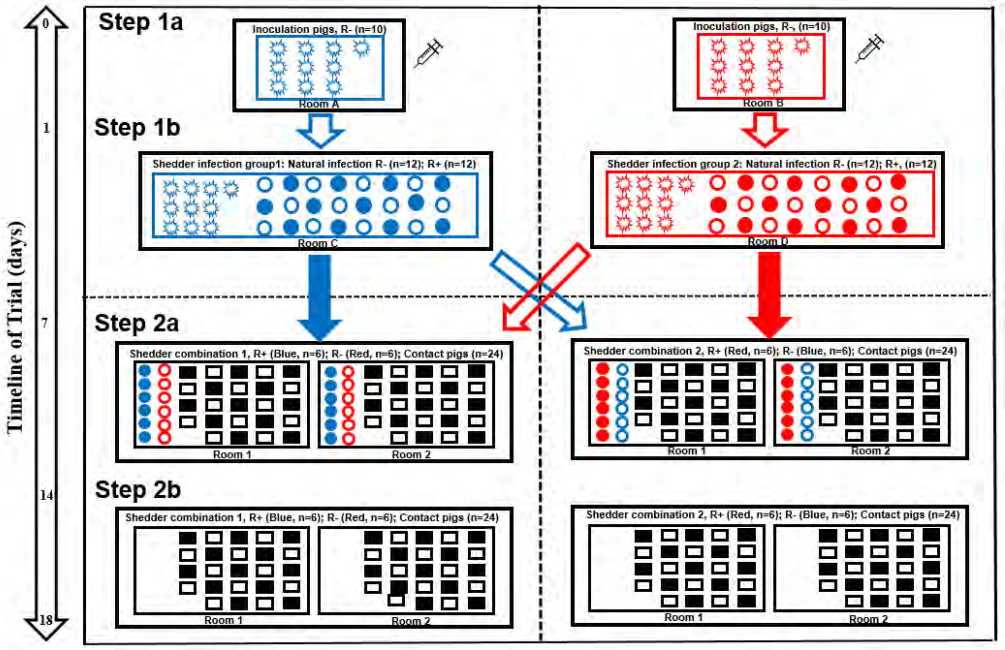

Figure 1. Experimental design. Schematic of the design of the trial comprising creation of the shedder pigs (Step 1) for use in the main transmission trial (Step 2). Step 1, a. direct infection of the inoculation pigs (day 0; challenge dose was 10^5 $TCID_{50}$ in a total volume of 4 ml, and the challenge route was intramuscularly (IM) and intra-nasally (IN) with 2 ml IM and 1 ml for each nostril) and b. infection of shedder pigs through natural transmission (day 1 to day 6); and Step 2, a. re-assortment of the naturally infected shedder pigs and placement in rooms with naive contact pigs (day 7) and b. removal of the shedder pigs (day 14). Jagged circles, directly inoculated pigs; Smooth circles, naturally infected shedder pigs; Squares, contact pigs; closed symbol R+ genotype, open symbol R-; Blue, Shedder infection group 1; Red, Shedder infection group 2. Arrows indicate the direction of the movement of pigs (R+ solid arrows; R- open arrows).

rooms), where they were in direct contact with the inoculated pigs. At day 7, infected shedder pigs were transferred into 4 new rooms, according to their genotypes and relatedness (sibs of the same R genotype split across rooms to avoid confounding between relatedness and R genotype effects), where they could transmit PRRSV2 to resident naïve contact pigs (24 per room, 12 pigs per R genotype; pigs of the same R genotypes from different sibling groups, and sibs of different R genotypes in the same room).

To minimise re-infection of shedder pigs, they were removed at day 14. The trial lasted only 18 days, enough time to ensure contact pigs were infected by shedders, and contact-contact pig transmission was limited. Sampling involved collecting blood samples on trial day (d) d6, d8, d9, d10, d14 and d17. For statistical analyses, the area under the curve (AUC) of the log$TCID_{50}$ viral load derived from rt-PCR of the serum samples of all shedder and contact pigs was generated using the spline rule (R version 4.1.0). To determine genetic and R genotype effects on contact pig susceptibility and shedder pig infectivity, multivariable models were fitted to the data using General Linear Mixed Models (GLMM, SAS Proc Mixed), with the shedder or contact pig's AUC as dependent variables and the shedder and contact pig R genotypes, the shedder infection group, shedder combination, and interactions as fixed effects. Sibling-group and room (step 2, contact pigs only) were added as random effects.

Results

Shedder pigs. All but 2 shedder pigs were viraemic at d6, d8, d10, and d14. All pigs were infected by pigs within the same shedder infection group (step 1b, Figure 1). Analysis of AUC showed that there was no significant R genotype effect on shedder infection level, regardless of the shedder infection group the pigs originated from (shedder infection group×shedder genotype, P=0.49; Figure 2A).

Contact pigs. All but 1 contact pig was viraemic at some point in the transmission trial. Only eleven (11%) were viraemic at d9 (2 days post contact (dpc) with the shedder pigs), however 96% (n=92) were viraemic at

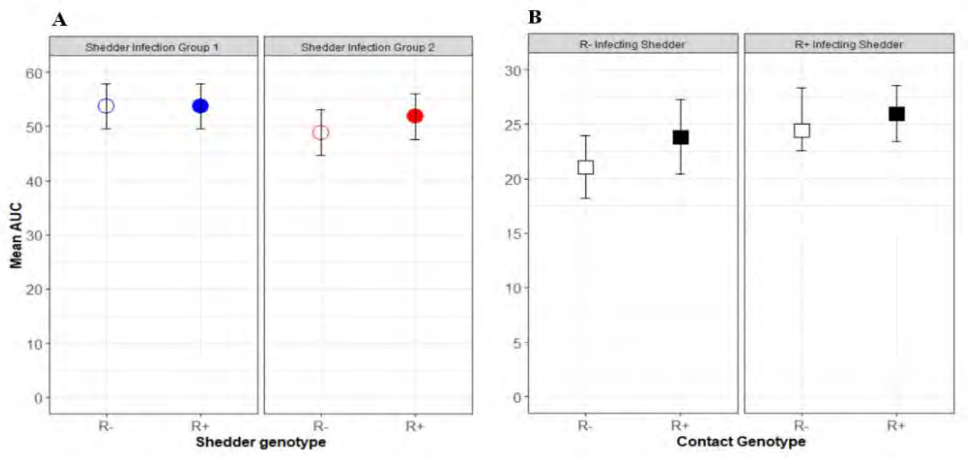

Figure 2. GLMM results for shedder pig (A) and contact pig (B) models of serum Area Under the Curve (AUC) representing the level of infection. For shedder pigs the results are displayed with respect to the shedder infection group they originated from and their *GBP5* genotype (R-, R+). For contact pigs the results are displayed with respect to the genotype of the shedder pig (R-, R+) they were infected by (indicating genotype effect on shedder infectivity) and their own genotype (R-, R+) (indicating genotype effect on contact pig susceptibility). Error bars are 95% confidence intervals.

d14 (7dpc). Multiple infections from shedder groups with different R genotypes were detected in only three pigs. Analysis of AUC showed that there was no significant R genotype effect on contact pig infection level, regardless of the R genotype of the contact pig or of the shedder pig that transmitted the infection (Infected by R+ shedder×contact genotype, P=0.46; Figure 2B).

Variation between sibling groups. The study design relied on the use of full- or half-sibs with contrasting R genotypes. Figure 3 shows the area under the curve for the shedder (Figure 3A) and contact (Figure 3B) sibling groups. There was considerable variation between sibling groups for both the shedder and contact pigs, and the addition of sibling-group improved the fit of the GLMM (lower BIC), significantly for contact pigs (log-likelihood ratio (P<0.025).

Discussion

This pilot study introduces a novel experimental design to assess genetic effects on disease transmission. However, it provides no supportive evidence that the previously identified *GBP5* resistance gene confers differences in host susceptibility or infectivity under natural PRRSV transmission. However, recent research (Jeon *et al.*, 2021) found that the *GBP5* resistance gene also confers differences in pigs' resilience when subjected to a natural polymicrobial disease challenge. Hence, given the relatively small scale of the present study, and the potential implications of the results to the pig industry, it is paramount for the results of this study to be validated. Finally, although the present study did not identify significant associations of *GBP5* with PRRSV transmission, it did provide strong evidence that PRRSV transmission is under host genetic control, as evidenced by the significant sibling-group effects in the models. Future studies should focus on investigating the genetic architecture underlying PRRSV transmission as an important component for reducing PRRS prevalence through genetic selection.

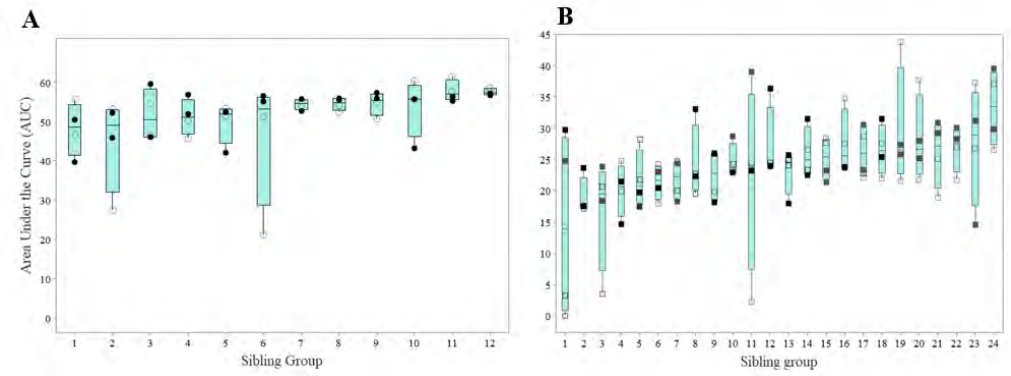

Figure 3. Differences in viral load as measured by Area Under the Curve (AUC) for the A. shedder (n=12) and B. contact pig (n=24) sibling groups. Data is organized based on increasing median AUC. Open circles/squares, R- genotype; closed circles/squares, R+ genotype

Abstract

We present a first catalogue of genetic variants influencing the porcine metabolome and an *in silico* reconstruction of metabolic pathways in two pig breeds: Large White and Duroc. For about 1,300 pigs, targeted metabolomic profiles (186 metabolites each), were used for modelling metabolite relationships via Gaussian Graphical Models. Metabolic networks presented breed similarities as well as specific features. Coupling via genome scans the metabolomic and the genomic profiles (>60,000 variants each), we identified >50 DNA markers and >20 candidate genes controlling the plasma concentrations of about 40 metabolites. Overall, these results pointed out several similarities between the porcine and the human metabolism, that strength the usefulness of the pig as animal model. The obtained catalogue of genomic variants, in addition to the medium-high genomic heritability obtained for several metabolites (h^2>0.50-0.60), represents a relevant source of information for the use of metabolomic markers as intermediate phenotypes to explain more complex traits.

Introduction

The genome of an organism, its proteome and metabolome represent the simplest biological layers that interact each other and generates networks of biological functions (Fontanesi 2016). Processes and pathways established in this additional complex layer talk to each other and define cell types, organs and the organism itself. It is noticeable that also a small alteration of any biological layers can generate altered phenotypes. In livestock, these includes exterior, production, reproductive and pathological (or disease related) traits. Hence, there is a strong interest in disentangling such biological complexity to develop tools for nutrigenomics and genomic selection as well as for precision livestock feeding and breeding goals.

The introduction of high-throughput sequencing and phenotyping technologies has made it possible to rapidly obtain near complete readouts of the different molecules and features characterizing each layer. This in turn has led to the development of phenomics, that is the use of large scale approaches to study how genetic instructions translate into a final phenotype/trait (Houle *et al.* 2010; NIFA-NSF Phenomics Workshop Report 2011). In its simplest form, gene variants are responsible for protein (enzyme) forms that differ in the processing of metabolites lastly impacting metabolic pathways and defining a phenotype. Therefore, metabolites represent internal (or intermediate) phenotypes used to dissect more complex phenotypes like performance traits (Suhre and Gieger 2012). This changed the paradigm of linking genetic variants to performance traits (e.g. Bertolini *et al.* 2018) via genome wide association studies (GWAS) to linking genetic variants to metabolite levels (m) representing a final phenotype via mGWAS.

With a set of pilot studies, we previously showed that different porcine metabolic routes are established by the different sexes or pig breeds (Bovo *et al.* 2015, 2016). Here, by merging genomic and metabolomic profiles (>60,000 variants and >180 metabolites) of about 1,300 pigs, we present a first catalogue of genetic

variants influencing the porcine metabolism plus its *in silico* reconstruction. This catalogue represents a great source of information that can be used to improve and develop additional tools in the fields of precision livestock feeding and breeding.

Materials & methods

Animals. About 1,300 performance tested pigs, including 900 Italian Large White (ILW) and 400 Italian Duroc (IDU) animals, were used in this study. Animals were from triplets of siblings from the same litter (two females and one castrated male) which were individually performance tested for genetic evaluation of a boar from the same litter (sib-testing). Animals were fed with a standard commercial feed and at the end of the test they were slaughtered after overnight fasting. Blood was collected just after jugulation into a tube with EDTA. Samples were refrigerated, processed and stored at -80 °C.

Phenotypes, genotypes and data processing. The abundance level of 186 metabolites covering five compound classes (acylcarnitines, amino acids, biogenic amines, glycerophospholipids and sugars) was determined via mass spectrometry-based targeted metabolomics of plasma samples using the Biocrates AbsoluteIDQ p180 Kit. For each breed, data quality checks considered the percentage of missing points per sample, the presence of outliers and the evaluation of inter-plate coefficients of variation. Abundances were normalized via the Box-Cox transformation. Confounding effects were removed via linear models (LMs). Analyses run in R v.3.4.4 (https://www.r-project.org).

All pigs were genotyped with the Illumina PorcineSNP60 BeadChip v.2 (61,565 SNPs). PLINK v.1.7 (Purcell *et al.* 2007) was used for within breed quality checks, including the evaluation of the call rates, Minor Allele Frequency and Hardy Weinberg Equilibium.

Metabolic network generation. The dependence between metabolite concentrations was investigated with a Gaussian Graphical Model (GGM; Krumsiek *et al.* 2011). Briefly, residuals of the LMs were used to compute partial correlations coefficients (PCC). After having computed the statistical significance of each PCC, Bonferroni correction with α=0.05 was applied to retain reliable relationships. Networks were annotated with Cytoscape v.3.0.1 (Shannon *et al.* 2003).

Genome scans. GWAS were carried out via Linear Mixed Models (LMM) as implemented in GEMMA (Zhou and Stephens 2012). Briefly, residuals of the LM were used as input phenotype and additive genetic models were tested. A genomic relatedness matrix was included in the model. The proportion of variance in phenotype explained by a given variant (PVE%) and the genomic heritability were concurrently calculated. Single metabolites concentrations and metabolites ratios were evaluated. Bonferroni correction with α=0.05 was applied to retain reliable associations. For metabolite ratios we used the *p-gain* statistics (Petersen *et al.* 2012). Meta-GWAS were carried out with METAL (Willer *et al.* 2010).

DNA sequencing. Two DNA pools (one for ILW and one for IDU; 35 pigs each) and 50 single animals (25 ILW and 25 IDU) were subjected to 40× and 20× whole genome sequencing (WGS), respectively. Reads were aligned over the Sscrofa11.1 reference genome with BWA tool 0.7.17 (Li and Durbin, 2009) and variants were called with GATK4 (McKenna *et al.* 2010).

Results

The quality control led to retain 169 and 164 metabolites for ILW and IDU, respectively. The merged dataset counted 160 metabolites.

The porcine metabolic network. A total of 160 metabolites entered in the network reconstruction process. The resulting GGM (Figure 1) counted 283 edges. No singletons were obtained. PCC values ranged from 0.15 to 0.78 and were computed both within the single breed and in the whole population. Few PCC were statistically significant only within a specific breed: no. 5 for IDU and no. 20 for ILW. The network was characterized by modules that clearly represented the specific metabolism of the different metabolite classes, poorly interconnected each other. The highest PCC was obtained between metabolites separated by one reaction step.

Genome scans. Genome wide association analyses of single metabolite concentrations (Figure 2) identified at least one association for 29 and 23 metabolites in ILW and IDU, respectively. The most significant association (p=1.83×10^{-32}) was detected for Kynurenine levels in ILW pigs. Analysis of metabolites ratios (Figure 2) pointed out several other associations; the most significant one (p-$gain$=7.37×10^{47}) was a metabolite of the PC group. Genomic heritability was in the ranges 0.0-0.52 (mean=0.22) and 0.0-0.62 (mean=0.15) for ILW and IDU, respectively. Candidate genes were further globally evaluated via sequencing for the detection of possible causative mutations.

Discussion

The reconstruction of porcine plasma metabolite networks led to evaluate several features of the pig metabolism. One of them is its similarity (considering the top PCC) to the GGM presented in human by Krumsiek *et al.* (2011), that remarks how the porcine metabolism is genetically governed similarly to what is known in humans. The results open new research routes for translational sciences. It was interesting

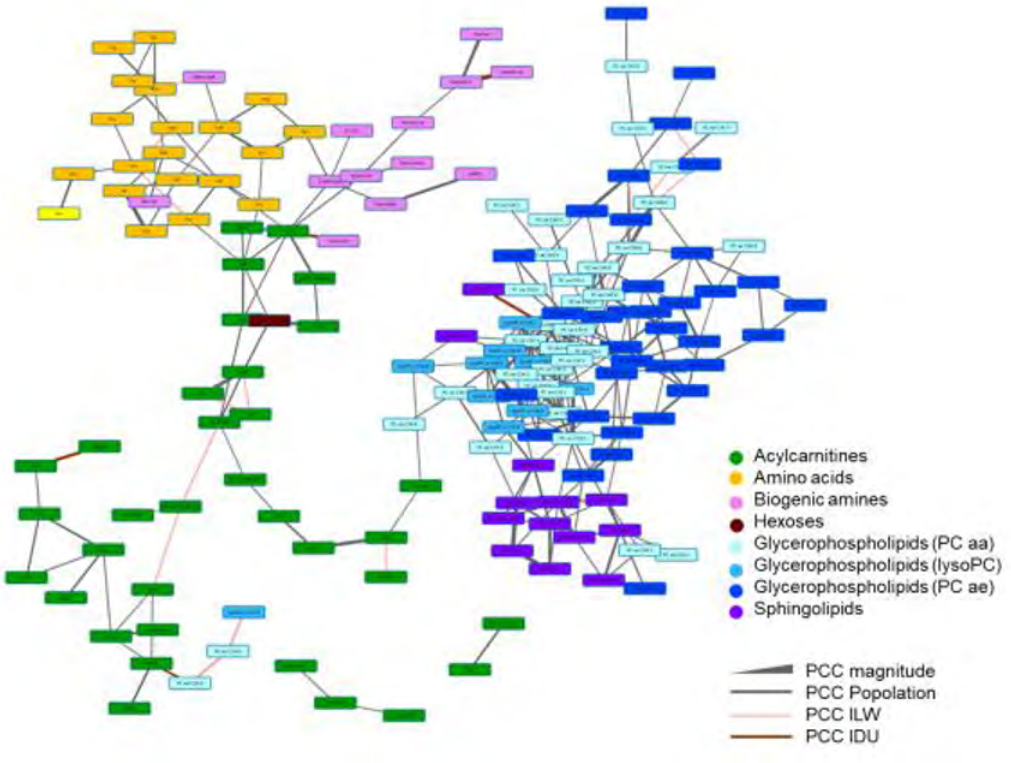

Figure 1. Reconstructed porcine metabolic network (Gaussian Graphical Model).

to note the presence of breed specific metabolite relationships, suggesting that attention should be given when developing strategies and tools for precision livestock feeding and breeding. To further boost such strategies/tools, we have disclosed a several genomic markers, candidate variants and genes controlling up to 40 metabolite levels (21% of the metabolic profile). Together, the knowledge of both metabolite-metabolite relationships and the effect that variants can have on them gives the possibility to fine tune breeding programs using metabolites as internal phenotypes to improve animal productivity, welfare and obtain sustainable productions.

782. The value of innate sow appetite as a model trait for maternal breeding objectives

L. Vargovic*, K.L. Bunter and S. Hermesch

AGBU a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia lvargov2@une.edu.au

Abstract

The concept presented here evaluated benefits of including 'innate appetite' as an additional source of information to enhance response within a maternal breeding objective. The term 'innate appetite' refers to (heritable) feed intake (or comparable feeding behaviour) data recorded at any point in a sows' life-cycle, reflecting an animals desire to eat. When 'innate intake' was included as a selection criterion, the overall response increased from $41.98 to $47.31. The main proportion of the overall response was attributed to traits recorded on growing pigs. At the same time, farrowing and pre-weaning survival, wean-to-conception interval and longevity improved. Maternal breeding objectives in pigs can be extended by using innate appetite data, provided that uncertainty of genetic parameters, in particular between traits of growing pigs and sows is clarified.

Introduction

Data on feed intake is typically recorded on growing pigs from terminal lines only. As an alternative, data reflecting a sows' desire to eat (i.e. innate appetite), recorded during some period of the sows' life-cycle, can potentially provide information correlated to feed intake. Data recorded on sows can be obtained from electronic sow feeding systems, potentially providing an additional source of readily available information for all breeding female relatives of selection candidates. The usefulness of this information for breeding purposes depends on the genetic variability of these phenotypes and their relationship to feed intake. Feed intake in growing and mature animals is moderately correlated (Bunter *et al.* 2010), when circumstances enable appetite to be expressed. When feeding is *ad libitum,* feed intake traits are moderately heritable in both growing pigs and sows (Bunter *et al.* 2010; Bergsma *et al.* 2013). In contrast, when feed intake is restricted, the heritability for feed intake in growing pigs (Hermesch *et al.* 1999) and gestating sows is reduced but heritability of feeding behaviour traits is seen, which also contribute to feed intake (Bunter *et al.* 2018; Vargovic *et al.* 2021b).

Feed intake, or a correlated feeding behaviour trait, can be recorded at any stage of a sows' life-cycle, and therefore this study refers to this trait generically as reflecting 'innate' appetite. It was assumed that this appetite trait is present generally throughout an animals' entire life, and used it as a model trait. The aim of this study was to investigate the impact of recording an 'innate appetite' trait on sows for response in a maternal breeding goal. The hypothesis was that data recorded on dams would improve selection in a maternal breeding objective.

Materials & methods

Traits. A maternal breeding objective (BO), including production and reproductive traits, has been previously derived for the Australian pig industry (Amer *et al.* 2014). This BO was adapted to replace feed conversion ratio with average daily feed intake (Table 1). The BO traits were average daily gain (ADG: g/day), backfat thickness (BF: mm), average daily feed intake (ADFI: kg/day), piglets born alive (NBA: pigs/litter), farrowing survival (FS: 0/1 for survival), pre-weaning survival (PWS: 0/1 for survival), wean to conception interval between the first and second parity (WCI: days), longevity (LONG: parities) and sow mature weight (MWT: kg). A consensus of assumed genetic parameters was adapted from several

[1] ADG = Average daily gain (g/day), BF = Backfat thickness (mm), ADFI = Average daily feed intake (kg/day), NBA = Born alive piglets (piglets/litter), FS = Farrowing survival (0/1 for survival), PWS = Pre-farrowing survival (0/1 for survival), WCI = Wean to conception interval (days), LONG = Longevity (parity), MWT = Sow mature weight (kg), IAP = Innate sow appetite (kg/day)

Australian studies (Tholen *et al.* 1996; Bunter *et al.* 2008; Bunter *et al.* 2010) and one Dutch study (Bergsma 2011). The initial genetic parameters for innate sow appetite (IAP, kg/day) were adapted from data for lactation feed intake (Bunter *et al.* 2010; Bergsma 2011).

Breeding schemes and analyses. Trait responses were obtained by using the MTIndex program (van der Werf 2021). Predicted responses were for a single generation of selection with a selection intensity of one. It was assumed that ADG and BF were available at selection on the selection candidate, dam, sire, six full-sibs and 40 half-sibs. For NBA, FS, PWS, WCI and IAP, dams had two records (one record for WCI) and three half-sibs. For LONG and MWT dams had one record. The first scenario (Base0) included recording all traits, except ADFI and IAP. The Base1 scenario included recording on all traits, except ADFI. The Base1 scenario was also used for simple sensitivity analyses, to investigate the impact of uncertain correlations between IAP and the other traits for responses in the individual traits and the overall index. Sensitivity analyses were conducted by changing genetic correlations (r_g) between IAP and other traits, keeping heritability constant, one at a time, by plus or minus 0.10, where possible, as shown in Table 3 and Figure 1. This change was only considered possible if correlations between all other traits combinations remained constant.

Results

Adding data for IAP increased the overall selection response by 13% (Base0 vs Base1: $41.98 vs $47.31/gilt, Table 2) with the assumed genetic parameters. Recording IAP (Base1) resulted in additional desired response for all traits, except ADG and NBA. The largest improvements were for ADFI (Base0 vs Base1: $22.69 vs $26.32) and LONG (-$5.43 vs -$2.61). Modifying r_g between IAP and BO traits was conducted within boundaries to keep the variance-covariance matrix positive definite, and for each trait was possible in only one direction (Table 3). These modifications of r_g between IAP and BO traits had an impact on the overall response relative to Base1 (Table 3). Changing r_g of IAP with ADG or ADFI had the largest impact on the overall response (97.13 and 104.55%) and for individual traits (Figure 1). Traits that were the most sensitive to this change were ADFI, BF, NBA and LONG (Figure 1). When r_g with other BO traits were changed, the overall responses varied less.

Table 2. Responses in breeding objective traits ($/gilt) for Base0 and Base1 scenarios.

Scenario	ADG[1]	BF	ADFI	NBA	FS	PWS	WCI	LONG	MTW	Total

[3] Response relative to Base1.

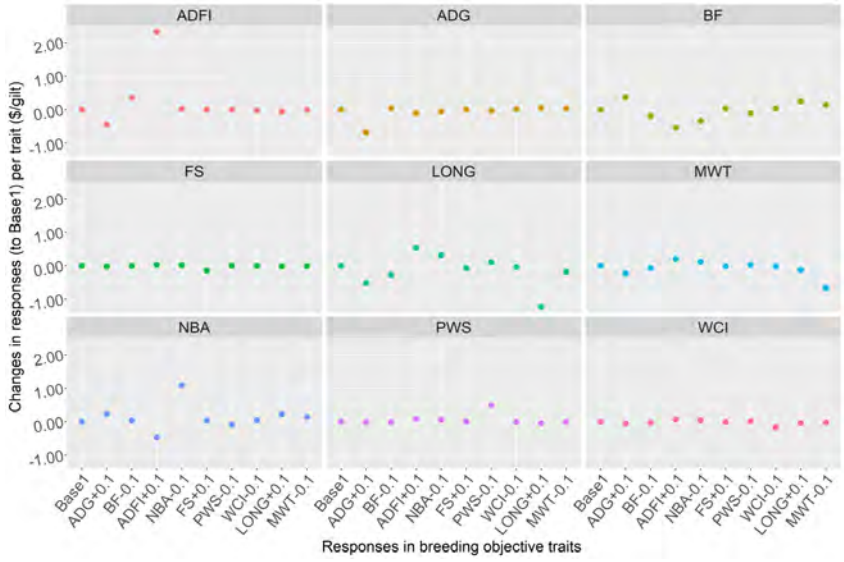

Figure 1. Changes in response for breeding objective traits ($/gilt), relative to Base1, when genetic correlations between innate sow appetite (IAP) and each trait change by ±0.10 (x-axis).

Discussion

A maternal breeding objective attempts to balance traits on growing animals with reproductive traits. With the assumed goal, data recording and Base1 parameters, results supported the hypothesis generally that traits representing IAP added as a selection criterion contribute to an increased overall response, due to genetic correlations between IAP and other traits. This supports the concept that sow feed intake can theoretically be recorded at any point in a sows' life-cycle, providing an opportunity to utilise already

recorded data. Therefore, the generic term 'innate' was used, reflecting any stage of a sows' life-cycle when the data can become available. In practice, the information on intake is not readily available in all stages of a sows' life, due to the limitations imposed by the high cost of recording. In this study lactation feed intake was used as an illustration, because of data availability (Bunter *et al.* 2010; Bergsma *et al.* 2013). The alternative traits reflecting 'innate appetite' are feed intake or feeding behaviour recorded during gestation (Vargovic *et al.* 2021b), or appetite before farrowing (Vargovic *et al.* 2021a). Changing the correlations between IAP and the other traits, whilst keeping the heritability constant, was done with the aim to mimic the alternative sow feed intake traits. None of the BO traits could have correlations changed by 0.10 in both directions as the variance-covariance matrix was no longer positive definite, demonstrating that the direction/magnitude of change was unlikely. Possible direction of change was not consistently favourable or unfavourable for each trait. Although the added information resulted in enhanced response, varying the correlations from the assumed baseline parameters affected the overall results. This demonstrated the effect of uncertain genetic parameters on the overall response, in particular between growing pigs and sows, and therefore requires clarification.

Abstract

The aim of this study was to perform genome-wide association analyses for backfat thickness and osteochondrosis in Landrace pigs and to fine map pleiotropic genomic regions. In order to characterise genomic regions, phenotypic information of 5,000 animals with osteochondrosis scored from CT images and 40,000 animals with backfat thickness scored from CT or ultrasound images were analysed. All animals were genotyped with a medium density SNP chip and a subset of them were genotyped with a high-density SNP chip as well, allowing for imputation. Two genomic loci were found in common for osteochondrosis and backfat thickness, one on chromosome 5 and one on chromosome 14. For both regions, an antagonistic relationship was found. Fine mapping using an impact score approach identified the *CCND2* gene as the most likely causal gene on chromosome 5, whereas a mutation in *CRTAC1* had the highest impact score in the chromosome 14 region.

Introduction

Osteochondrosis (OC) is a developmental disease usually occurring in joints in an early stage of life in pigs as well as other domestic animals. It is characterised by a disturbed endochondral ossification in the articular cartilage and the epiphyseal growth plates and is most likely caused by failure of blood supply to the growing cartilage (e.g. Ytrehus *et al.*, 2007). OC is the most important cause of leg weakness in pigs and is therefore an important trait due to both animal welfare concerns and economic reasons. In Norwegian Landrace pigs, the heritability of OC was shown to vary from 0.06-0.21 depending on anatomical location, and the total OC score had a heritability of 0.31 (Aasmundstad *et al.*, 2013). Genomic studies have been conducted to elucidate the mechanisms causing OC. Quantitative trait loci (QTL) regions associated with OC have been identified on *Sus scrofa* chromosome (SSC) 2, 3, 5, 13 and 15 (Andersson-Eklund *et al.*, 2000; Laenoi *et al.*, 2011).

Backfat (BF) is an important carcass composition trait in pig production. Lean meat is the most valuable product so breeding programs have aimed for more growth of lean meat and reduced levels of BF (Lonergan *et al.*, 2001). Heritability of BF in Landrace pigs is 0.42 (unpublished data, H. C. Oliveira). Genomic studies have showed numerous candidate genes influencing backfat thickness and QTLs identified over the years can be found in the animal QTL database (https://www.animalgenome.org/QTLdb).

The aim of this study was to detect genomics regions contributing to BF in Landrace pigs and to fine map regions showing pleiotropy with OC.

Materials & methods

Animals. The animals included in this study were purebred Landrace boars and sows born between 2013 and 2020 in Norway. Animals used in the OC analysis were boars from the nucleus boar testing station in Hamar, Norway, that entered the testing station at approximately 30 kg live weight and lived in groups of 12 pigs per pen. At the end of the test period (at approximately 120 kg live weight), boars were subjected

DOI: 10.3920/978-90-8686-940-4_783, © M. van Son *et al.* 2022

to a CT scan for measurement of OC as well as body composition traits. Prior to scanning, the boars were sedated using Azaperone (Stresnil Vet ®, Janssen-Cilag Ltd., Buckinghamshire, UK), which was injected intramuscularly. OC was scored from CT images as described in detail by Aasmundstad *et al.* (2013). For eight anatomical locations (distal and lateral humerus and femur, right and left side), a score for OC between 0 and 5 was assigned and the sum of phenotypes from all the locations, the total score, was used as the OC phenotype. A total of 5,000 animals were included for the OC association analysis.

Animals used in the BF analysis were boars from the boar testing station as well as boars and sows from Norwegian nucleus farms. BF measurements were done using CT data on boars from the boar testing station and ultrasound on the other animals. Backfat was measured in millimeter and 40,000 animals were included in the BF association analysis.

Genotyping. Ear samples for DNA extraction were collected and stored at -20 °C until used (Caisley ear sampling protocol). DNA for genotyping was extracted from the ear samples using BioSprint DNA Kit (Qiagen, Hilden, Germany) by BioBank (Hamar, Norway). DNA concentration and quality was measured using a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, DE, USA). The genotyping was performed at CIGENE, University of Life Sciences, Norway and at NEOGEN, Scotland, UK. All the animals in this study were genotyped using Illumina porcine medium-density SNP chips (50K, 80K) (Illumina, San Diego, USA) or a custom made 25K SNP chip (Illumina and Neogen). Some of the boars were also genotyped using the Axiom porcine 660K array from Affymetrix (Affymetrix Inc., Santa Clara, CA, USA). All genotypes were filtered based on call rate>0.97 and minor allele frequency (MAF)>0.01. Imputation of all animals to 660K was performed using FImpute v3 (Sargolzaei *et al.*, 2014) with default settings and the complete pedigree as additional information. SNPs that were shared between the SNP chips were checked for matching genotypes and allele frequencies before imputation.

Genome wide association study and fine mapping. Genome-wide association study (GWAS) was performed using the GCTA software (Yang *et al.*, 2011). The total OC score and the backfat measurements were included as phenotypes using a linear animal model.

Fine mapping was conducted using the porcine combined annotation dependent depletion (pCADD) method (Derks *et al.*, 2021). The pCADD pipeline takes the top SNP as input and identifies SNPs from whole genome sequence (WGS) data that are in high linkage disequilibrium (LD; >0.7) with the top SNP. SNPs from WGS data are then ranked based on the pCADD scores, chromatin data information (liver) and gene expression data. The output from the pipeline is a list of likely causal variants. WGS and gene expression data from the Landrace population were available from previous studies (e.g. Van Son *et al.*, 2017a,b).

Results

GWAS were conducted using 660K imputed genotypes to identify genomic regions associated with OC and BF in Landrace boars. The prevalence of OC for the animals included in this study ranged between a total score of 0-19 with mean=2.81 (SD=2.54). BF ranged from 2 to 18 mm with mean=7.44 (SD=1.82). The GWAS detected significant loci for both OC (Figure 1) and BF (Figure 2) (corrected *P*-value<1.0^{-10}) on SSC5 at 66 Mb and on SSC14 at 109 Mb. For BF, additional significant loci were detected on SSC2 44 Mb (highly significant), SSC4 1 Mb, SSC5 15 Mb and SSC18 11 Mb.

The top SNP of the SSC5 QTL is AX-116685771 for both traits, showing opposing effects where the A allele increases BF and decreases OC. The SNP explains 0.5% of the genetic variance for OC and 0.1% for BF. Fine mapping of this region returned 47 variants in LD with the top SNP. The variant with the highest impact

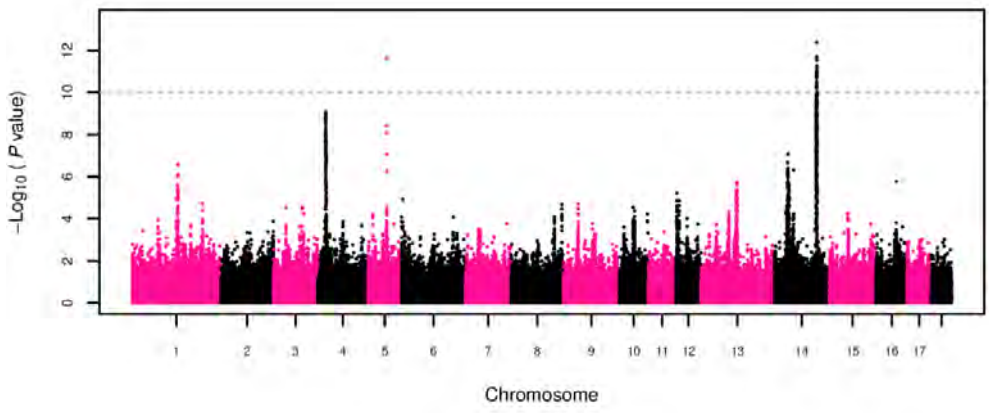

Figure 1. GWAS results of OC in Landrace pigs.

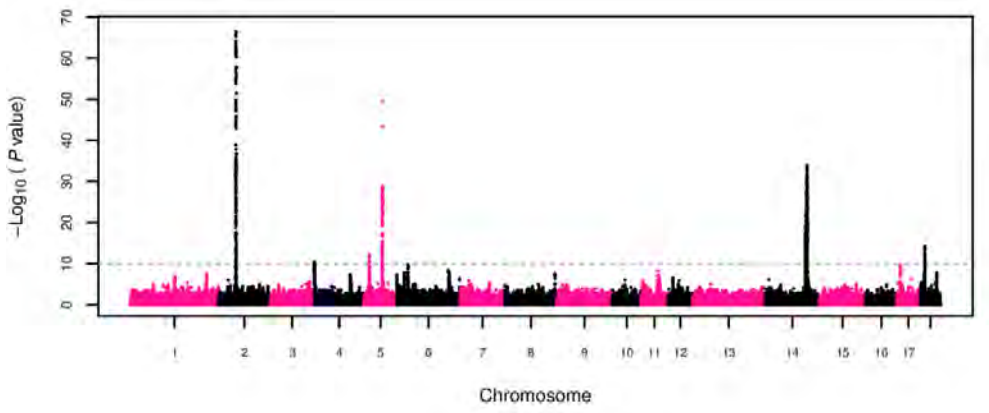

Figure 2. GWAS results of BF in Landrace pigs.

score was an intronic variant in the cyclin D2 gene (*CCND2*) with a pCADD score of 13.5. All 47 variants from this region were located in *CCND2* or downstream of this gene.

For the SSC14 QTL, AX-116521996 is the top SNP for OC whereas AX-116659727 is the top SNP for BF (LD between these two SNPs is 0.9). AX-116659727 is also highly significant for OC and the SNP shows opposing effects for the two traits in the same manner as on SSC5. The top SNPs explains 0.1% of the genetic variance for both OC and BF. Using AX-116659727 as top SNP, fine mapping of this region returned 319 variants in LD. The variant with the highest impact score was an intronic variant in cartilage acidic protein 1 (*CRTAC1*; pCADD=17.8).

Discussion

Breeding for increased growth rate and more lean meat has reduced the level of BF. However, pigs that grow faster are also more susceptible to OC and by including phenotypes on OC in the breeding goal, it is possible to balance the selection. Genomic information can be useful to identify genes showing pleiotropic effects on different traits and this study identified two QTL regions in common for OC and BF; on SSC5 and 14.

A previous study also identified the region on SSC5 for BF in four different breeds (Gozalo-Marcilla *et al.*, 2021). They suggested a causal role for the fibroblast growth factor 23 (*FGF23*) gene as its expression in osteocytes is linked to adipose tissue secretion of proteins. In this study, fine mapping identified *CCND2* as the most likely causal gene on SSC5. It is involved in the control of the cell cycle (Chiles, 2004) and knock-out studies in mice show numerous consequences in development of organs and functions. The two genes *FGF23* and *CCND2* are located just 50 kb apart and both genes are good biological candidates for both traits. It is also possible that the two genes are somehow interacting or that one gene is affecting BF and the other OC.

On SSC14, a mutation in *CRTAC1* showed the highest impact score. This gene is an extracellular matrix protein of articular cartilage (Steck *et al.*, 2007) and a promising candidate gene for OC, however, a function related to BF is not clear. It is also possible that two closely linked genes are causing the common QTL region on SSC14. The fine mapping of this region also listed several other potential candidate genes with high impact score, but further studies are needed to pinpoint the causal gene.

Abstract

We hypothesized that: (1) non-genetic correlations between litter size (LS) and daily gain are different from zero; and (2) modelling non-genetic correlations changes estimates of genetic (co)variances of the traits compared to when they are ignored. We tested these hypotheses using a new multi-trait model that separates genetic and non-genetic correlations by fitting correlations between the residual effects for one trait and non-residual effects of the other trait. We estimated variances by fitting models with and without these non-genetic correlations to LS and daily gain in DanBred Landrace pigs. We found that all non-genetic correlations between LS and daily gain were significantly different from zero. Estimates of genetic (co)variances changed significantly when non-genetic correlations were ignored. Clearly, multi-trait models with production traits and litter size traits should include correlations between residual effects for one trait and non-residual effects of the other trait to separate genetic correlations from non-genetic correlations.

Introduction

Multi-trait models are state-of-the-art for breeding value estimation (Mrode, 2014, p. 70). They provide more unbiased and accurate predictions than single-trait models when non-genetic correlations among traits differ from genetic correlations (Mrode, 2014, p. 70). Modelling non-genetic correlations is clearly important for prediction. However, some of these correlations are often neglected because the model framework has not been developed. An example is when a single phenotype is available for a trait(s) and multiple phenotypes are available for another trait(s). In pig breeding, daily gain and litter size are examples of such traits. Daily gain is often recorded as a single phenotype per animal. Litter size is recorded for each farrowing and each sow can have multiple phenotypes for litter size. A further complication is that two possible non-genetic correlations may exist. First, an animal's record of daily gain can be affected by the litter size in its birth litter. Second, a female's daily gain can affect its non-genetic permanent ability to produce large litters. Standard multi-trait models cannot cater for correlations between the residual effect for one trait and a non-genetic non-residual effect for another trait. The challenge is that neglecting them risks that they are captured by genetic correlations during REML estimation (Walter and Mao, 1985). Clearly, a new model framework that separates non-genetic correlations from genetic correlations is needed. We propose such a model and in doing so, hypothesize that: (1) the non-genetic correlations between litter size and daily gain are different from zero; and (2) modelling non-genetic correlations changes the estimates of genetic (co-)variances of the traits compared to when they are ignored.

Materials & methods

Experimental design. We estimated (co)variances using two trivariate models fitted to litter size at day 5 (LS), average daily gain until 30 kg (G1) and average daily gain from 30 to 100 kg (G2) in DanBred Landrace pigs. The two models were with and without non-genetic correlations between LS and the production traits.

Data. There were 93,408 records of LS from 45,973 purebred Landrace sows and 64% of the litters were crossbred with DanBred Yorkshire sire and the others were purebred litters. There were 203,411 records of G1 (g/day) and 212,191 records of G2 (g/day) all from purebred DanBred Landrace animals (Table 1).

Table 1. Descriptive statistics.

Trait[1]	No. Obs	Mean	SD	Min	Max
LS	93,408	14.2	4.1	0	32
G1	203,411	382	37	295	579
G2	212,191	1,080	109	680	1,609

[1] LS: litter size at day 5; G1: average daily gain (g/day) from birth to 30 kg; G2: average daily gain (g/day) from 30 kg to 100 kg

The pedigree included 237,500 purebred Landrace animals. The data we used was from litters born between January 2016 and April 2021.

Model. The tri-variate model to estimate variance and covariance components was:

$$\begin{bmatrix} \boldsymbol{y_{LS}} \\ \boldsymbol{y_{G1}} \\ \boldsymbol{y_{G2}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X_{bLS}} & 0 & 0 \\ 0 & \boldsymbol{X_{bG1}} & 0 \\ 0 & 0 & \boldsymbol{X_{bG2}} \end{bmatrix} \begin{bmatrix} \boldsymbol{b_{LS}} \\ \boldsymbol{b_{G1}} \\ \boldsymbol{b_{G2}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z_{aLS}} & 0 & 0 \\ 0 & \boldsymbol{Z_{aG1}} & 0 \\ 0 & 0 & \boldsymbol{Z_{aG2}} \end{bmatrix} \begin{bmatrix} \boldsymbol{a_{LS}} \\ \boldsymbol{a_{G1}} \\ \boldsymbol{a_{G2}} \end{bmatrix} +$$
$$\begin{bmatrix} \boldsymbol{Z_{cLSp}} & \boldsymbol{Z_{cLSc}} & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \boldsymbol{Z_{cG2}} \end{bmatrix} \begin{bmatrix} \boldsymbol{c_{LSp}} \\ \boldsymbol{c_{LSc}} \\ \boldsymbol{c_{G2}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z_{pLS}} & 0 & 0 \\ 0 & \boldsymbol{Z_{eG1}} & 0 \\ 0 & 0 & \boldsymbol{Z_{eG2}} \end{bmatrix} \begin{bmatrix} \boldsymbol{p_{LS}} \\ \boldsymbol{e_{G1}} \\ \boldsymbol{e_{G2}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z_{eLS}} & 0 & 0 \\ 0 & \boldsymbol{Z_{lG1}} & 0 \\ 0 & 0 & \boldsymbol{Z_{lG2}} \end{bmatrix} \begin{bmatrix} \boldsymbol{e_{LS}} \\ \boldsymbol{l_{G1}} \\ \boldsymbol{l_{G2}} \end{bmatrix}$$

where y_{LS}, y_{G1} and y_{G2} are vectors of records for LS, G1 and G2; b_{LS} is a vector of fixed effects for LS including herd-year, year-month-litterbreed, year-parity, and first and second order regressions on the sow's age at first farrowing as well as time interval between farrowings; b_{G1} is a vector of fixed effects for G1 including herd-year-month, sex and birth-parity as well as a regression on the age of the sow at farrowing; b_{G2} is a vector of fixed effects for G2 including herd-year-stable, sex, and birth-parity. The vectors a_{LS}, a_{G1} and a_{G2} contain the genetic effects of the sow on LS, the genetic effect of the pig on G1 and the genetic effect of the pig on G2. The vectors c_{LSp} and c_{LSc} contain non-genetic random service sire effects on LS for purebred and crossbred litters. The vector c_{G2} contains random effects of pen on G2. The vector p_{LS} contains permanent non-genetic effects of the sow on LS, whereas the vectors l_{G1} and l_{G2} contained non-genetic random effects of birth-litter. Vectors e_{G1} and e_{G2} contain the residuals for G1 and G2 following the individual animal, whereas e_{LS} contains the residual for LS following the individual litter. All X and Z matrices are design matrices. The random effects are distributed as:

$$\begin{bmatrix} \boldsymbol{a_{LS}} \\ \boldsymbol{a_{G1}} \\ \boldsymbol{a_{G2}} \end{bmatrix} \sim MVN(0, \boldsymbol{G_0} \otimes \boldsymbol{A}); \ \boldsymbol{c_{LSp}} \sim N(0, \boldsymbol{I}\sigma^2_{cLSp}); \ \boldsymbol{c_{LSc}} \sim N(0, \boldsymbol{I}\sigma^2_{cLSc});$$

$$c_{G2} \sim N(0, \boldsymbol{I}\sigma^2_{cG2}); \begin{bmatrix} \boldsymbol{p_{LS}} \\ \boldsymbol{e_{G1}} \\ \boldsymbol{e_{G2}} \end{bmatrix} \sim MVN(0, \boldsymbol{RP_0} \otimes \boldsymbol{I}); \begin{bmatrix} \boldsymbol{e_{LS}} \\ \boldsymbol{l_{G1}} \\ \boldsymbol{l_{G2}} \end{bmatrix} \sim MVN(0, \boldsymbol{RL_0} \otimes \boldsymbol{I}),$$

where G_0 is a 3×3 additive-genetic covariance matrix; RP_0 is a 3×3 non-genetic covariance matrix related to animals; RL_0 is a 3×3 non-genetic covariance matrix related to litters; I is an identity matrix and A is the numerator relationship matrix.

The second model ignoring non-genetic correlations between production traits and litter size is as above, but with the off-diagonal elements of the first row and column of RP_0 and RL_0 equal to zero. (Co-)variance components in the above models were estimated with REML using DMU (Madsen and Jensen, 2013)

Results

Non-genetic correlations. All non-genetic correlations between LS and the two growth traits were significantly different from zero (Table 2). The correlations between residuals for the two growth traits and the permanent non-genetic effect of the sow on LS were favourable 0.21 and 0.12 for G1 and G2, whereas the correlations between the residual for LS and the non-genetic birth litter effects were unfavourable -0.29 and -0.11 for G1 and G2.

Genetic variances. The genetic variances changed significantly when the non-genetic correlations were ignored (Table 3). The genetic variance of LS increased from 1.03 to 1.30 and the genetic correlations between LS and the two growth traits weakened. The correlation between LS and G1 changed from -0.11 to -0.04, and the correlation between LS and G2 changed from -0.24 to -0.16.

Discussion

Our findings supported our hypothesis that non-genetic correlations between litter size and daily gain are significant. We found significant and favourable correlations between the residuals for the two growth traits and the non-genetic permanent effect of the sow on LS. We found significant and unfavourable correlations between the residual for LS and the non-genetic birth litter effects on the two growth traits. Our findings also supported our second hypothesis that modelling these correlations changes the estimates of genetic variances compared to when they are ignored. We found significant changes in both the genetic variance of LS and the genetic correlations between LS and the two growth traits. Clearly, multi-trait models with production traits and litter size traits should include correlations between residual effects for one trait and non-residual effects of the other trait to separate genetic correlations from non-genetic correlations.

Table 2. Non-genetic variances for residual, permanent non-genetic sow effect and birth-litter effect (correlations above diagonal).

	RP_0[1]			RL_0[2]		
	LS	**G1**	**G2**	**LS**	**G1**	**G2**
LS	1.15	0.21	0.12	11.5	-0.29	-0.11
G1	5.3	557	0.06	-12	148	0.28
G2	8.4	98	4,425	-7.6	71	421

[1] RP_0 contained variances for the animal-level non-genetic variances – i.e. permanent non-genetic sow effect for litter size and residual for the two growth traits. Standard errors of correlations were within the range 0.01 to 0.02, standard errors of diagonal elements were 0.07, 5 and 37.

[2] RL_0 contained variances for the litter-level non-genetic variances – i.e. residual for litter size and birth-litter variance for the two growth traits. Standard errors of correlations were within the range 0.01 to 0.02, standard errors of diagonal elements were 0.07, 3 and 14.

Table 3. Genetic variances for models with and without non-genetic correlations between litter size and production traits (correlations above diagonal).

	With non-genetic correlations[1]			**Without non-genetic correlations**[1]		
	LS	**G1**	**G2**	**LS**	**G1**	**G2**
LS	1.03	-0.11	-0.24	1.30	-0.04	-0.16
G1	-1.8	234	0.37	-0.74	230	0.37
G2	-13	299	2,787	-9.5	292	2,774

[1] Standard errors of correlations were within the range 0.02 to 0.04, standard errors of diagonal elements were 0.1, 10 and 80 for LS, G1 and G2.

The change in genetic variances and correlations was likely caused by both the non-genetic correlations on animal-level as well as on litter-level. Models, where only litter-level non-genetic correlations were ignored, caused inflated genetic variance for LS as well as very strong negative genetic correlations between LS and the two growth traits (results not shown). Oppositely, models, where only animal-level non-genetic correlations were ignored, did not cause inflated genetic variance for LS, but instead genetic correlations between LS and the two growth traits became closer to zero (results now shown). So, it seems that modelling both animal-level and litter-level non-genetic correlations are of importance for these traits.

The multi-trait model that we developed is novel because it handles non-genetic correlations between traits, where the levels of observation are different. We fitted our model to litter size, measured at the litter level, and daily gain, measured at the individual level. Not only is the model relevant for these traits, it may also be relevant for other traits on the same levels, for other mammalian species, where litter size is larger than one (Mínguez *et al*., 2015), and for traits on different levels. Examples of traits on different levels include non-genetic correlations between group recorded traits and individually recorded traits (Ma *et al*., 2021) and between longitudinally recorded traits and individually recorded traits (Shirali *et al*., 2017). So, our model is not only relevant to litter size and production traits in pigs, but also litter traits and individual traits in other species. It is also relevant for other scenarios, where the level of observation differs among traits analysed.

Abstract

We tested the hypothesis that selection for component traits of live piglets at day 5 (LP5) realises more genetic gain (ΔG) for piglet survival than selection for LP5 while maintaining ΔG for LP5. We tested this premise by stochastic simulation of the breeding scheme for Danbred's Landrace pigs. We estimated ΔG for LP5 and piglet survival realised by selection for: (1) an index for LP5; and (2) an index for TNB and piglet survival at 1% rate of inbreeding. Selection for index TNB and survival realised about 30% more ΔG for piglet survival than selection for the LP5 index while realising the same ΔG for LP5. Clearly, it is worthwhile separating LP5 into its component traits: it realises more ΔG for piglet survival while maintaining ΔG for LP5.

Introduction

Number of live piglets in a litter on day 5 after farrowing (LP5) is a key trait of DanBred's pig breeding program in Denmark (Su *et al.*, 2020). LP5 is considered a trait that is expressed by the sow of each litter. It is a composite of total number of piglets born (TNB) and survival of individual piglets within litters until day 5 after farrowing (piglet survival). Breeding for increased LP5 has been remarkably successful in DanBred's two maternal breeds: Landrace and Yorkshire (Nielsen *et al.*, 2013; Su *et al.*, 2020). Breeding has realised genetic gain (ΔG) for LP5 by allocating selection pressure to TNB and piglet survival. The drawback is that breeding for LP5 does not allow breeders to control the amount of selection pressure allocated to TNB and piglet survival. Both TNB and piglet survival are economically important because they contribute to LP5. However, there is good reason to allocate more selection pressure to piglet survival: piglet survival is also a proxy for animal welfare and consumer acceptance. One way that we could breed for LP5 while allocating more selection pressure to piglet survival is to separate LP5 into its component traits and select for an index of these components. We could shift selection pressure from TNB to piglet survival by increasing the index weight for piglet survival. This led us to hypothesise that selection for component traits of LP5 realises more ΔG for piglet survival than selection for LP5 while maintaining ΔG for LP5. We tested this hypothesis by stochastic simulation of the breeding scheme for Danbred's Landrace pigs.

Materials & methods

Procedure. We used stochastic simulation of the breeding scheme for Danbred's Landrace pigs to estimate ΔG for LP5 and piglet survival realised by selection for an index for LP5 – referred to as I_{LP5} – and an index for TNB and piglet survival (I_{TNB+S}) at 1% rate of inbreeding. Selection index I_{TNB+S} was tested with different relative index weights for TNB and piglet survival. We also selected for TNB (I_{TNB}) and piglet survival (I_S) as extreme indices of I_{TNB+S}. The simulations were carried out by: (1) sampling unobserved underlying liabilities for TNB and piglet survival; (2) expressing and phenotyping LP5, TNB, and piglet survival on their observed scales based on the liabilities; (3) predicting EBV for LP5, TNB, and piglet survival by fitting animal models to the phenotypes on the observed scales; (4) using the EBV to construct selection indices; and (5) selecting breeding animals by optimum-contribution selection (OCS) with the index values as estimates of genetic merit. All animals were phenotyped for piglet survival before EBV prediction and selection. Surviving animals were candidates for selection. Dams that were selected in each generation were phenotyped for LP5 and TNB after selection. Breeding schemes were run for 16 discrete generations ($t = 1$

… 16) and replicated 300 times. Selection for the indices was carried out in generations t = 12 … 16. The first 11 generations were used to establish a pedigreed population with phenotypes.

Breeding scheme. Each replicate was initiated by sampling a unique base population of 100 sires and 1000 dams. One-hundred sires and 1000 dams were randomly selected and mated in generations t = 1 … 11. In generations t = 12 … 16, 1000 matings were allocated to selection candidates by OCS. The number of matings allocated to each male varied from 0, 1, 2 … to 50 matings. One thousand females were allocated a single mating. The 1000 sire and dam matings were paired randomly. Litter size of each mating (dam) was the dam's phenotype for TNB on the observed scale. Offspring were assigned as males or females with probability 0.5.

Sampling underlying liabilities. Unobserved underlying liabilities for TNB and piglet survival (ℓ_T and ℓ_S) were sampled as:

$$\begin{bmatrix}\boldsymbol{\ell}_T\\ \boldsymbol{\ell}_S\end{bmatrix} = \begin{bmatrix}\mathbf{1} & \mathbf{0}\\ \mathbf{0} & \mathbf{1}\end{bmatrix}\begin{bmatrix}\mu_T\\ \mu_S\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_{a_d} & \mathbf{Z}_{a_s} & \mathbf{0} & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{Z}_{a_{id}} & \mathbf{Z}_{a_m}\end{bmatrix}\begin{bmatrix}\mathbf{a}_d\\ \mathbf{a}_s\\ \mathbf{a}_{id}\\ \mathbf{a}_m\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_s & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{s}\\ \mathbf{0}\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_l & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_{ls}\end{bmatrix}\begin{bmatrix}\mathbf{l}\\ \mathbf{ls}\end{bmatrix} + \begin{bmatrix}\mathbf{0} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_e\end{bmatrix}\begin{bmatrix}\mathbf{0}\\ \mathbf{e}\end{bmatrix} \quad (1)$$

where m_T=15.3 and m_S=0 are mean liabilities for TNB and piglet survival, a_d and a_s are vectors of true genetic sow and service-sire effects for TNB, a_{id} and a_m are vectors of true direct-genetic effects and maternal-genetic effects for piglet survival, s is a vector of non-genetic service-sire effects for TNB, l is a vector of litter effects for TNB that can also be interpreted as a vector of residuals, ls is a vector of litter effects for survival, e is the vector of residuals for piglet survival, 1 are vectors of 1's, 0 are vectors and matrices of 0's, and Z_{a_d}, Z_{a_s}, $Z_{a_{id}}$, Z_{a_m}, Z_s, Z_l, Z_{ls}, and Z_e are design matrices. Effects for animals in the base populations were sampled as:

$$\mathbf{a} = \begin{bmatrix}a_d\\ a_s\\ a_{id}\\ a_m\end{bmatrix} \sim N\left(\begin{bmatrix}0\\0\\0\\0\end{bmatrix}, \mathbf{G} = \begin{bmatrix}1.367 & 0.231 & -0.036 & -0.094\\ 0.231 & 0.508 & -0.078 & 0.066\\ -0.036 & -0.078 & 0.003 & -0.008\\ -0.094 & 0.066 & -0.008 & 0.003\end{bmatrix}\right), \; s \sim N(0, 0.63), \begin{bmatrix}l\\ ls\end{bmatrix} \sim N\left(\begin{bmatrix}0\\0\end{bmatrix}, \begin{bmatrix}14.98 & -0.58\\ -0.58 & 0.14\end{bmatrix}\right),$$

and $e \sim N(0, 0.78)$. True genetic effects of animals in subsequent generations were sampled as $\mathbf{a}_i \sim N(½ \cdot (\mathbf{a}_{\text{sire}i} + \mathbf{a}_{\text{dam}i}), ½ \cdot (1 - \bar{F}_i) \cdot \mathbf{G})$, where $a_{\text{sire}i}$ and $a_{\text{dam}i}$ are additive-genetic values of the sire and dam of animal i and $\bar{F}_i$ is the average inbreeding coefficient of the sire and dam.

Observed phenotypes. TNB and piglet survival were expressed and phenotyped on their observed scales. TNB was transformed from the unobserved underlying liability scale to the observed scale by rounding elements of ℓ_T to the closest integer. Piglet survival was assumed to follow a threshold-liability model. Animal I survived (y_{Si}=1) if its liability, $\ell_{Si} > k$, and died (y_{Si}=0) if $\ell_{Si} \leq k$, where k=-0.82 is a fixed threshold derived from the mean probability of piglet survival 0.79 for DanBred Landrace. LP5 were expressed for each litter as $\text{LP5}_j = \sum_{i=1}^{\text{TNB}_j} y_{Sij}$, where y_{Sij} refers to piglet I in litter j.

Prediction. Animal models were fitted to the observed phenotypes to estimate (co)variances and predict EBV. The models were: (1) LP5: $\mathbf{y}_{\text{LP5}} = \mathbf{1}\nu_{\text{LP5}} + \mathbf{Z}_{a_d}\mathbf{a}_d + \mathbf{Z}_s\mathbf{s} + \mathbf{e}$; (2) TNB and survival: $\begin{bmatrix}\mathbf{y}_T\\ \mathbf{y}_S\end{bmatrix} = \begin{bmatrix}\mathbf{1} & \mathbf{0}\\ \mathbf{0} & \mathbf{1}\end{bmatrix}\begin{bmatrix}\nu_T\\ \nu_S\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_{a_d} & \mathbf{0} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_{a_{id}} & \mathbf{Z}_{a_m}\end{bmatrix}\begin{bmatrix}\mathbf{a}_d\\ \mathbf{a}_{id}\\ \mathbf{a}_m\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_s & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{s}\\ \mathbf{0}\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_l & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_{ls}\end{bmatrix}\begin{bmatrix}\mathbf{l}\\ \mathbf{ls}\end{bmatrix} + \begin{bmatrix}\mathbf{0} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_e\end{bmatrix}\begin{bmatrix}\mathbf{0}\\ \mathbf{e}\end{bmatrix}$; (3) TNB: $\mathbf{y}_T = \mathbf{1}\nu_T + \mathbf{Z}_{a_d}\mathbf{a}_d + \mathbf{Z}_s\mathbf{s} + \mathbf{e}$; and (4) Survival: $\mathbf{y}_S = \mathbf{1}\nu_S + \mathbf{Z}_{a_{id}}\mathbf{a}_{id} + \mathbf{Z}_{a_m}\mathbf{a}_m + \mathbf{Z}_{ls}\mathbf{ls} + \mathbf{e}$, where y_{LP5}, y_T, and y_S are vectors of observed phenotypes for LP5, TNB, and piglet survival, $\hat{\nu}_{\text{LP5}}$, $\hat{\nu}_T$, and $\hat{\nu}_S$ are means for LP5, TNB, and piglet survival, e are residuals, and all other effects are as defined for Equation 1.

Selection indices. The selection indices were: (1) LP5: $\mathbf{I}_{\text{LP5}} = \hat{\mathbf{a}}_d$; (2) TNB and survival: $\mathbf{I}_{\text{TNB+S}} = \hat{\mathbf{a}}_d + \omega \cdot (½ \cdot \hat{\mathbf{a}}_{id} + \hat{\mathbf{a}}_m)$, ω=10, 15, 16, 18, 20, 25, 30, 40; (3) TNB: $\mathbf{I}_{\text{TNB}} = \hat{\mathbf{a}}_d$; and (4) Survival: $\mathbf{I}_S = ½ \cdot \hat{\mathbf{a}}_{id} + \hat{\mathbf{a}}_m$. EBV used in indices (1)-(4) were predicted by corresponding animal models (1)-(4). We use the circumflex '^' to denote EBV predicted by the models. The effects and weights in the selection

indices reflected Landrace's genetic contribution to Duroc × (Landrace × Yorkshire) pigs that are used in production.

Optimum-contribution selection. OCS solved $U_t(\mathbf{c}) = max\{\mathbf{c}'\mathbf{I}_j | \mathbf{c}'\mathbf{A}\mathbf{c} \leq C_{t+1}\}$ with respect to c, where c is a vector of genetic contributions to the next generation, I_j is a vector of index values ($I_j = I_{LP5}$, I_{TNB+S}, I_{TNB}, I_S), A is a numerator-relationship matrix, and C_{t+1} is the pre-defined average relationship in generation t+1 (Meuwissen, 1997). C_{t+1} was a function of average relationship in generation t and the pre-defined 1% rate of inbreeding.

Genetic gain and rate of inbreeding. We plotted ΔG for LP5 against ΔG for piglet survival for the four selection indices based on Landrace's genetic contribution to production pigs. ΔG for LP5 and piglet survival were calculated as the linear regression of $LP5_t$ and S_t on t, where $LP5_t$ and S_t are the average true breeding values for LP5 and piglet survival of animals born at generation t = 12 … 16. The true breeding values for LP5 and piglet survival of animal I born at generation t were estimated as $LP5_i = (\mu_T + a_{di}) \times S_i$ and $S_i = 1 - \Phi(k = -0.82, \text{mean} = ½ \times a_{idi} + a_{mi}, \text{sd} = 1)$, where a_{di}, a_{idi}, and a_{mi} are the i^{th} elements of a_d, a_{id}, and a_m, and Φ(.) is the cumulative standard-normal distribution. Rate of inbreeding was calculated as 1-exp(β), where β is the linear regression of $\ln(1-F_t)$ on t and F_t is the average coefficient of pedigree inbreeding for animals born at times t = 12 … 16.

Results

Selection for index TNB and survival, I_{TNB+S}, with index weight ω=20 applied to piglet survival realised about 30% more ΔG for piglet survival than selection for index LP5, I_{LP5}, while realising the same ΔG for LP5 (Figure 1). Increasing the weight in I_{TNB+S} to ω=25 realised about 73% more ΔG for piglet survival for only a 3.7% decrease in ΔG for LP5. Selection for I_{TNB+S} did not realise more ΔG for LP5 than I_{LP5} at the same ΔG for piglet survival. Selection for the first of our extreme indices, I_{TNB}, realised negative ΔG for piglet survival and 36% less ΔG for LP5 than selection for index I_{LP5}. Selection for I_s realised 174% more ΔG for piglet survival than I_{LP5}, but 65% less ΔG for LP5.

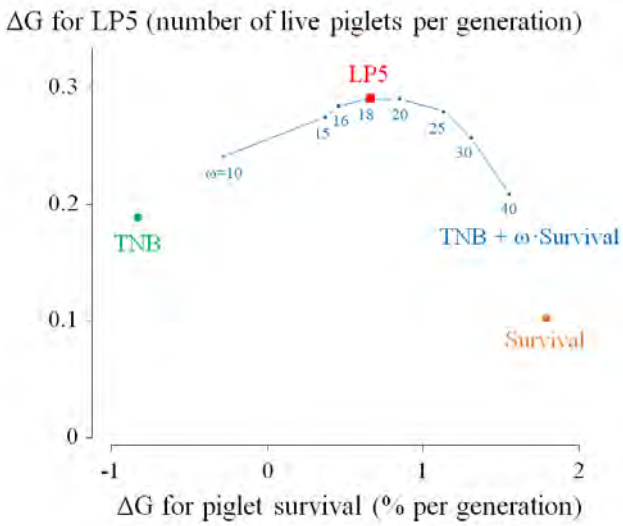

Figure 1. ΔG for LP5 against ΔG for piglet survival realised by selection for four indices at 1% rate of inbreeding. Rates are means of 300 simulation replicates. SD between replicates ranged from 0.059-0.069 (ΔG for LP5) and 0.27-0.46 (ΔG for piglet survival).

Discussion

Our findings supported our hypothesis that selection for component traits of LP5 realises more ΔG for piglet survival than selection for LP5 while maintaining ΔG for LP5. The additional 30% ΔG for piglet survival that we simulated in Landrace pigs while maintaining ΔG for LP5 makes it worthwhile separating LP5 into its component traits. We could realise even more ΔG for piglet survival if we are prepared to accept a small decrease in ΔG for LP5. Separating LP5 into its component traits and selecting for an index of these traits realised more ΔG for piglet survival because it shifted selection pressure from TNB to piglet survival. It must have shifted selection pressure, given that we realised more ΔG for piglet survival while maintaining ΔG for LP5. There will probably always be an incentive to increase ΔG for piglet survival given that piglet survival is economically important and a proxy for animal welfare and consumer acceptance. However, separating LP5 into its component traits does come with challenges. It can increase the number of traits that need to be recorded, increase the dimension of multi-trait prediction models, and require reliable estimates of heritabilities and genetic and residual correlations between the component traits and all other traits included in these prediction models. These challenges could persuade some pig breeders to continue selecting for LP5. So, provided it does not burden breeding schemes, it makes perfect sense to separate LP5 into its component traits because it realises more ΔG for piglet survival while maintaining ΔG for LP5.

We were surprised to find that separating LP5 into its component traits did not realise more ΔG for LP5 than selection for LP5 at the same ΔG for piglet survival. Clearly, the animal model that we fitted to TNB and piglet survival did not provide additional benefits beyond allowing us to shift selection pressure to piglet survival. The model was designed to cater for differences in heritabilities of the traits and to differentiate between genetic and residual correlations. TNB and piglet survival have similar heritabilities in Landrace pigs when assessed as traits of the sow of the litters; and the genetic correlation between the traits is similar to their residual correlation. However, the model could still provide additional benefits in other pig breeds and animal species where heritabilities of component traits are different and genetic correlations differ from residual correlations. This leads us to speculate that separating composite traits into component traits realises more ΔG for both component traits than selection for composite traits when the components differ for heritability and genetic and residual correlations.

786. Phenotyping strategies for an efficient and holistic approach to reduced boar taint through genomic selection

A. Markey*, C. Burgeon and N. Gengler

Gembloux Agro-Bio Tech, University of Liège, Passage des Déportés 2, 5030 Gembloux, Belgium; alice.markey@uliege.be

Abstract

Surgical castration without anaesthesia or analgesia of boars is about to be banned in Europe. This ancestral practice avoids the development of boar taint (BT), an unpleasant smell found in cooked meat of some uncastrated male pigs, mainly due to the accumulation of skatole and androstenone in adipose tissue. Animal breeding and especially genomic selection in the context of whole-male rearing has been recognised as a potentially promising strategy to avoid BT. However, challenges exist to define and to record BT associated traits. Required phenotypes must be cheap, available in routine as close as possible to the slaughterline and repeatable. This review will also cover new opportunities through different and innovative aspects of BT phenotype definitions allowing the potential identification of underlying genetic architecture and its use in the breeding against BT.

Introduction

Boar taint (BT), found in uncastrated male pigs, is a complex hormonal odour caused in majority by androstenone and skatole (Rius *et al.*, 2005) that give respectively an urine and faecal odour to cooked meat (Font-i-furnols, 2012). Androstenone (i.e. *5α-androst-16-en-3-one*) is a testicular steroid that is synthesized in Leydig cells from pregnenolone (Squires *et al.*, 2020) and in high concentrations since puberty (Bonneau, 1998). Skatole is an alkaloid derived from tryptophan (Claus *et al.*, 1994; Jensen *et al.*, 1995a). They are produced in the colon by the breakdown of indigestible fermentable food and dead intestinal cells by microbiota (Jensen *et al.*, 1995b; Wesoly *et al.*, 2012). Androstenone and skatole can be found in various tissues and fluids such as in fat and blood (Wesoly *et al.*, 2012; Squires *et al.*, 2020). Other compounds could contribute to BT (e.g. 2-aminoacetophenone) (Rius Solé *et al.*, 2001; Fischer *et al.*, 2014) or could be correlated (e.g. presence of high levels of saturated fatty acids (Mörlein *et al.*, 2014)). Moreover, the odour intensity is affected by several factors such sexual maturity which particularly affects androstenone production, husbandry practices (e.g. nutrition particularly involves in skatole synthesis), the health and the raising environment, but also breed and genetics (Li *et al.*, 2019; Squires *et al.*, 2020), and lastly the interaction of all these. From one individual to another, the tainted characterisation is therefore highly variable. Despite extensive knowledge that was established about BT in the last years and related phenotypes based on biological and chemical facts, work is ongoing to advance on required phenotyping strategies for an efficient and holistic approach to do genomic selection for reduced BT while considering pig breeding as a whole.

Phenotypes

Direct classification of BT phenotypes. Phenotypes are characterised when boars are slaughtered as carcasses have to be checked for BT to determine what will be there use later on in the meat processing (e.g. consumption of pork chops for untainted boars or dilution of the meat in the case of tainted meat). Throughout Europe, the 'human nose' method is generally used by trained operators online or at line except in Denmark where a colorimetric method is used to detect and quantify indolic compounds (European Commission, 2019). From an animal breeding perspective this type of field data based on the current detection methods has the advantage of being fast, easily performed in routine and cheap, therefore on a large scale, but has the weakness of unreliability left by the subjective identification of an operator even if

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_786, © A. Markey *et al.* 2022

he is trained for 'human nose method' and the lack of specificity for the colorimetric method (Burgeon *et al.*, 2021a).

Detection of BT generating compounds in fat. An alternative to sensory analysis is accurate chemical analysis of odorous compounds. This implies normally that animal are dead but a biopsy tool has been developed by Baes *et al.* (2013) to test live boars and determine from their phenotype of BT compounds. Many chromatographic techniques have been developed that allow a high level of robustness, reliability, accuracy and sensitivity in the detection of BT compounds often found in trace amounts. Their disadvantages are in particular their rather high price, the difficulty of setting up such an instrument in terms of space and technical training in the slaughterhouse, and the lack of speed (including preparation). Portable instrumental methods such as biosensors, surface-enhanced Raman scattering, and Rapid Evaporative Ionisation Mass Spectrometry technologies are being studied but still required sample preparation. These research include the detection well-known BT compounds (e.g. androstenone and skatole) but can also be based on volatile organic compounds profile as Burgeon *et al.* (2021b) recently explored (Font-i-furnols *et al.*, 2020; Burgeon *et al.*, 2021a). Finally the Laser Diode Thermal Desorption–Tandem Mass Spectrometry is currently being tested in slaughterhouses in Denmark, probably to replace the colorimetric method, meeting the requirement of cost and reliability (Font-i-furnols *et al.*, 2020; Burgeon *et al.*, 2021a). Most of current detection methods are based on the detection of these compounds in fat matrix. However, other matrices could be studied such as blood or plasma and saliva since the presence of skatole and androstenone these matrices have been previously observed (Bone *et al.*, 2019; Dubois *et al.*, 2021).

Indirect traits used to detect risk of BT. Other traits related to sexual maturity were also studied although they were not always considered satisfactory for classification. Weight is used in the UK as an indicator of puberty implying slaughter below 110 kg (European Commission, 2019) but this method is at risk for pigs with early age maturity. Bernau *et al.* (2018) also correlated greater testicular volume and body fat with abundant androstenone content. If body fat is routinely assessed on slaughterlines measuring testis volume may present a greater challenge. Fatty acids have also been identified as potential indicators of BT. It would appear that tainted fats are significantly richer in saturated fatty acids and poorer in unsaturated fatty acids than an untainted subcutaneous adipose tissue (Mörlein *et al.*, 2014; Liu *et al.*, 2017). Measuring fatty acids using appropriate techniques may be reliable in routine using appropriate tools (e.g. near-infrared reflectance spectrometry) (Font-i-Furnols *et al.*, 2020).

Classical breeding against boar taint

Classical genetic tools. Breeding programmes need to use different precited phenotypes to identify boars with a low risk of transmitting odour development to their offspring (Drag *et al.*, 2017). In Europe, there are various BT selection programmes (e.g. Topigs Norsvin, Nucleus) (Squires *et al.*, 2020) often nowadays exploiting genomics (Drag *et al.*, 2017).

Holistic approach towards pig breeding. If the previously mentioned indirect traits were relatively, but not totally, i.e. body fat, in neutral relationships to breeding objectives, BT is suspected to have negative genetic correlations with meat quality, including intramuscular fat and fat thickness, and fertility and that selecting for reduced BT incidence would deteriorate the selection response in these traits. Genetic correlations of reproductive and aggressiveness traits, aspects concerning farmers for breeding, with BT compounds have been reported as related by Duarte *et al.* (2021). However, these correlations depend on the breed and the gender and their capacity to develop associated traits to BT compounds development.

Future opportunities and challenges

Innovative phenotypes. BT is complex. Its compounds, some of which are well known, are widely studied. Currently, genetic and genomic studies for selection against BT generally focus on the main compounds responsible for BT (skatole, androstenone and indole at a smaller extent) as well as on sexual maturity related traits. To characterise BT and optimize selection to make it fast and cheap for use in routine, research should open up to other ways of working or go down again paths that are sometimes abandoned due to lack of funds or technological resources. For example, the study of volatile organic compounds related to BT (e.g. Burgeon *et al.*, 2021b) is a path that is again being opened in particular through the development of more refined and potentially faster chemical techniques. Technological phenotyping has to explore the BT characterization in fat and other matrices which contain these compounds. BT compounds could be related in particular to the physiology of boars and sows and indicator traits (traditional and novel ones). Finally, this innovative phenotyping is a gateway to genetics, genomics and gene expression studies for known and currently undetermined BT molecules. Where fundamental science brings technologies to phenotyping, these could be linked to establish the most accurate genetic selection possible to respond to producers and consumers requirements.

Gene pathways. Skatole and androstenone have been extensively studied, including at genomic level to determine which genes are involved in the physiological pathways (e.g. Squires *et al.*, 2020). As genome wide association studies (GWAS) on skatole, androstenone, indole and other usual BT traits have already identified candidate genes, research could also find new gene pathways from exploiting these novel phenotypes. These new identified biomarkers could be then used.

Gene expressions. The study of these genes and their expression in different tissues could bring new opportunities to define expression quantitative trait loci (eQTL) of interest. Drag *et al.* (2018) have already characterised eQTLs function according to regulation systems of traditional BT compounds. However, since BT reduction is desired, it is necessary to monitor possible overlaps for other traits as highlighted by Drag *et al.* (2018).

787. Genome-wide association study for oxidative stress indicators in replacement gilts

S.A. Breuer[1*], J. Chinchilla-Vargas[2], B.J. Kerr[3] and K.J. Stalder[1]

[1]Department of Animal Science, Iowa State University, 806 Stange Rd, Ames, IA 50011, USA; [2]PIC North America, 100 Bluegrass Commons Blvd #2200, Hendersonville, TN 37075 USA; [3]USDA-ARS-NLAE, 1015 N. University Blvd., Ames, IA 50011, USA; sabreuer@iastate.edu

Abstract

Oxidative stress (OS) may be an important contributor to sow longevity, but little is known about OS variation or its genetic implications for commercial swine production. The goal of this study was to assess OS levels in gilts prior to breeding and identify possible genomic relationships to OS using genome wide associations (GWAS). Blood was collected from 318 crossbred gilts to perform reactive oxygen species (ROS) and serum antioxidant capacity (SAC) analyses. Following a GWAS analysis, one window of interest explainied 0.67% of variation for SAC. Two biologically relevant genes, monoamine oxidase (MAO) A and B were identified. Behaviour traits may be associated with MAOA which may be impactful as the US swine industry moves to group sow housing. Estimates from this analysis should be viewed cautiously due to the small numbers of animals included. Further research is warranted to evaluate MAO's potential impact on sow behaviour and longevity.

Introduction

OS is described as an imbalance between oxidants and antioxidants at the cellular level (Lykkesfeldt and Svendsen, 2007). ROS, commonly referred to as free radicals, are produced at the cellular level through electron transport chain leakage as part of an animal's energy metabolism. However, there are instances that may exacerbate this phenomenon in swine production such as pregnancy (Covarrubias *et al.*, 2008), lactation (Zhao *et al.*, 2013), poor nutrition (Kim *et al.*, 2013), environment (Wang *et al.*, 2021), and management (Buchet *et al.*, 2017). Uncontrolled ROS production can cause damage to cellular components such as DNA, RNA, cholesterol, lipids, carbohydrates, and proteins (Celi and Gabai, 2015). In contrast, antioxidants are used to neutralize ROS before cellular damage occurs. Two key components associated with neutralizing ROS at a cellular level are antioxidant networks and SAC. To this end, the ratio of ROS to SAC has been used to calculate an oxidative stress index (OSi) which has been suggested to characterize the animals' overall stress level (Abuelo *et al.*, 2013).

Narrow-sense heritability estimates for the oxidative stress biomarker, glutathione peroxidase, has been reported to be high at 0.55 (±0.05) in studies involving slaughter pigs (Ntawubizi *et al.*, 2020). While narrow-sense heritability helps determine the proportion of phenotypic variance dictated by additive genetic variance, GWAS aim to identify specific relationships between genomic regions and phenotypes. Single nucleotide polymorphisms were used in this study to isolate specific genomic windows that might be useful in identifying a specific gene to improve traits that are economically and biologically important in commercial swine production. With growing concern for sow longevity, measuring stress that animals experience has become a focus for researchers to combat the associated negative effects of such stress, which is increasing because of the industry shift to group sow housing. Sows have shown a difference in various oxidative stress parameters due to different housing scenarios and social ranking. Zhao *et al.* (2013) reported that sows exhibiting a lower social ranking in a group housing system had increased levels of stress biomarkers indicating aggression and behaviour could contribute to oxidative stress status.

Because the relationship between oxidative stress status in breeding animals and genetics is lacking, the goal of this study was to determine baseline oxidative stress status for gilts, post puberty but prior to mating, and determine if any genomic regions are related to these measurements.

Materials & methods

The experiment was carried out according to the guidelines of the Institutional Animal Care and Use Committee of Carthage Innovative Swine Solutions for the humane use and care of swine in research.

Animals and biological sampling. A total of 318 crossbred replacement gilts (PIC 1050) on a commercial farm in Illinois (US) were involved in this study. Gilts were sourced from the same multiplier and born within the same week. All gilts were provided *ad libitum* access to the same diet, similar housing conditions, and managed (boar exposure, vaccinations, etc.) following the company's standard operating procedures. At 23 weeks of age, two blood samples were taken via jugular puncture from each gilt with one sample tube containing sodium heparin to analyse OS parameters and one sample tube containing EDTA for genetic analysis. Serum samples were obtained from the blood in sodium heparin tube after centrifugation at 2,500×*g* and 20 °C for 15 min and stored at -80 °C until analysis.

Oxidative stress status analyses. ROS were assayed using the spectrophotometric d-ROM test (Diacron International, Grosseto, Italy) as described by Trotti *et al.* (2001). The d-ROM assay determines hyper peroxides through a reaction with the chromogen. Results are expressed as 'Caratelli units' (CarrU) where 1 CarrU is equivalent to the oxidizing power of 0.08 mg H_2O_2/ml. SAC was assayed with the OXY-Adsorbent Test (Diacron International, Grosseto, Italy) (Trotti *et al.*, 2001). The SAC assay utilizes a hypochlorous acid (HClO) solution to oxidize antioxidant pools (albumin, bilirubin, uric acid, thiol groups, vitamins, glutathione peroxidase, superoxide dismutase, catalase, etc.) within the serum, yielding the cumulative antioxidant potential action relative to the sum of all antioxidants. Results are expressed as μmol HClO/ml. Directions for both assays were followed according to the kit booklet and adapted to a 96 well plate absorption spectrophotometer (BioTek Cytation15, Santa Clara, CA). While both methods have been used in bovine (Abuelo *et al.*, 2013) and human studies, they have not been used in swine.

Variance component estimation and genome-wide association study. ROS and SAC traits were analysed using a linear model that contained a single fixed effect of plate number consisting of 10 and 12 levels, respectively. The plate effect was included because of known differences in standardization of kit calibrators. In the case of OSi, two fixed effects accounting for the plate level for ROS and SAC respectively were included. A genomic relationship matrix was constructed as described by VanRaden (2008) and used to account for genetic correlations between genotypes and phenotypes. Given the small sample size, variance components were estimated using a Bayesian inference of 150,000 iteration, burning 25,000, and thinning every 50. These estimations were performed with Thrshgibbs1 and postgibbs1, members of the blupf90 suite of programs (Misztal *et al.*, 2018). A single step genomic best linear unbiased (GBLUP) method under a Bayesian approach was used to identify 1.0 Mb candidate genomic regions associated with the three traits based on the percentage of additive variance they explained, using PostGSf90 (Aguilar *et al.*, 2014). Because of the relatively small animal numbers involved in this study, it was decided that GO would not be beneficial so the focus would be on windows that explained a proportion of GV that was markedly greater than others. Additionally, the genes that were included in those windows along with 1 mb up and downstream from the specific gene location were evaluated in the present analyses.

Results

Descriptive statistics and genetic parameter estimates are provided in Table 1 for OS traits. As shown in Figure 1, window (19_38)[1] explained 0.67% of variation in SAC. There were two genes of interest annotated as MAO A and MAO B and will be referred to as the MAO system.

Discussion

Metabolism of neurotransmitters involved in aggressive behaviour include dopamine, adrenaline, noradrenaline, histamine, and serotonin (Kolla and Bortolato, 2020). These compounds are degraded by the enzymes, MAO A and B, encoded by the MAO genes. During MAO catalysis, H_2O_2, NH_4^+, and aldehydes are products that remain, where H_2O_2 is known for being an agonist of ROS production (Edmondson and Binda, 2018). MAO A and B have demonstrated to be related to stress in many trials involving mice (Cases *et al.*, 1995; Doyle *et al.*, 1996). Overall, OS is biologically associated with increased MAO expression in mammals and could be used to further investigate stress in swine production settings. However, low activity of MAO results in increased aggressive behaviour (Mentis *et al.*, 2021) indicating that a balance

Table 1. Descriptive statistics and heritability estimates for each OS trait.

Trait	Unit	N	Mean	Min	Max	SD	Heritability
ROS	CarrU	318	792.1	547.6	1,119.4	112.7	0.08
SAC	µmol HClO/ml	318	382.7	91.9	950.6	174.2	0.12
OSi	CarrU/(µmol HClO/ml)	318	2.5	0.9	8.7	1.3	0.16

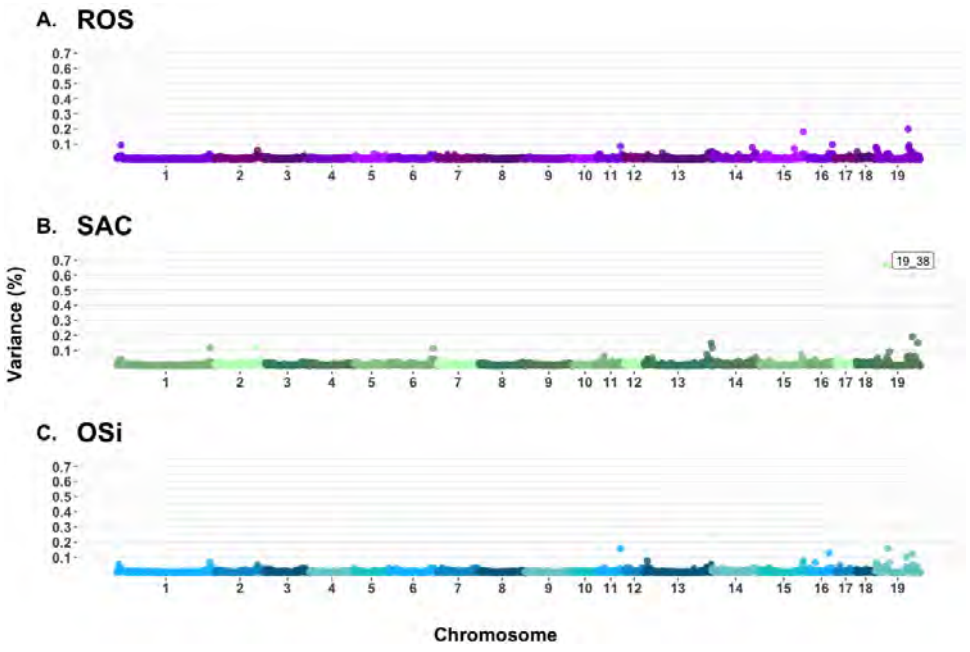

Figure 1. Manhattan plot indicating the proportion of window variance by genome location for ROS, SAC, and OSi traits.

[1] Chromosome X is written as 19 in the plot.

of MAO gene and enzyme expression is necessary to achieve optimal oxidative stress homeostasis and behavioural disposition. Estimates of this study, while encouraging, should be interpreted with caution due to the small sample size used in the genomic analysis. Therefore, research with an increased sample size is needed to determine how useful this information is in a breeding program to reduce oxidative stress and prolong cellular efficiency in breeding swine.

788. Genetic determinism of boar taint in the French Landrace pig breed

C. Larzul[1*], M.-J. Mercat[2], C. Hassenfratz[2], C. Carillier-Jacquin[1], R. Comte[3], B. Blanchet[4], I. Louveau[3], S. Boulot[2] and A. Prunier[3]

Abstract

Since pig breeds differ in their risk of developing boar taint, it is important to consider line-by-line selection by estimating genetic parameters of odorant compounds in relation to sexual development and production traits. The present study focused on French Landrace, one of the main French maternal lines. More than 1000 non-castrated males were measured for growth rate, body composition and meat quality, fat-odorant compounds, androstenone and skatole, and four steroid hormones. As expected, heritability values were high for androstenone (h^2=0.69) and estradiol (h^2=0.79). Genetic correlations of boar taint compounds were moderate to high with testosterone and estradiol but close to 0 with progesterone and cortisol. Genetic correlations of these compounds were low with growth rate, ultimate pH or color, but moderate and favorable with carcass leanness. It is therefore possible to include fat-odorant compounds in selection objectives, either directly or via sex hormones, while controlling their impacts on production performance.

Introduction

In France, male piglet castration without anaesthesia has been prohibited since January 1st, 2022. One of the primary motivations for castration of male pigs is to improve the quality of the meat, mainly to prevent the appearance of an odor defect known as boar taint. The two main components responsible for this defect are skatole (produced by bacteria in the digestive tract) and androstenone (a steroid produced by testes) which accumulate in fatty tissue. Reducing the level of these two compounds largely resolves the occurrence of the defect.

To promote the breeding of uncastrated male pigs, several pig lines have been developed under the label 'low boar taint' (Larzul, 2021). Most of the effort has focused on the paternal lines. However, the influence of maternal lines should not be overlooked. In that respect, maternal lines are more at risk than paternal lines (Larzul, 2021). Specifying the genetic determinism of boar taint compounds in maternal lines is therefore an essential prerequisite for implementing selection strategies aimed at limiting boar taint without penalizing production traits. We estimated the genetic parameters of the boar taint compounds, in relation with growth, feed efficiency, body composition and meat. Steroid hormones have also been included in the study in order to clarify the genetic relationships between boar taint and testicular and adrenal metabolism and, possibly, to propose alternative selection criteria to reduce the risk of boar taint.

Materials & methods

Animals. Between two and three weeks of age, male French Landrace piglets were transferred from their birth farm to the Rheu phenotyping station in 14 piglet post-weaning pens (UE3P, https://doi.org/10.15454/1.5573932732039927E12). Around 26 kg, all the pigs of the pen were simultaneously transferred to the fattening pens to start the control at 35 kg live weight. The animals were slaughtered at the Cooperl Arc Atlantique slaughterhouse (Montfort, 35). At slaughter, the average body weight was 117±6 kg, for a median age of 168 days. During the control period, the pigs were fed *ad libitum* with a feed with a net

R.F. Veerkamp and Y. de Haas (eds)

energy content (NE) of 9.6 MJ/kg, digestible lysine content of 0.94 g/MJ EN, and of digestible tryptophan of 1.7 g/kg. A total of 1,084 animals, from 249 sires, were bred in 33 batches between June 2018 and April 2021.

Measures. The average daily gain (ADG) was calculated from the weights at the start and at the end of the control period. The feed conversion ratio (FCR) and the average daily feed intake (DFI) were calculated from the consumption recorded by the feeding device. A day before departure to the slaughterhouse, a blood sample was collected in heparinized tubes from the jugular vein. The blood samples were then centrifuged and the plasma was stored at -20 °C until the concentrations of testosterone, estradiol, progesterone and cortisol were measured. Concentrations were measured using ELISA kits (ST AIA-Pack Testosterone, ST AIA-Pack hsE2, ST AIA-Pack CORT, ST AIA-PackPROGIII, Tosoh Corporation, Tokyo, Japan) developed for an automatic analyzer (AIATosoh Corporation, Tokyo, Japan). Dressing percentage (DY) is the ratio between the weight of the carcass with head 24 hours after slaughter and the weight before departure to the slaughterhouse after fasting. Carcass leanness (%M) was automatically estimated at the slaughterhouse (CSB Image-Meater®). The pH was measured (Sydel pHmeter, Xerolyt electrode) in the semimembranous muscle 24 hours post mortem (pH24). The day after slaughter, the colour parameters (L*a*b*) were measured (Minolta CR300 chromameter) on a fresh section of the *gluteus superficialis*. Finally, a sample of backfat was taken from the neck and frozen for subsequent determination of androstenone and skatole (Batorek *et al.*, 2012).

Statistical analyses. Androstenone and skatole contents lower than 0.2 and 0.03 µg/g, respectively, can't be precisely measured. All values below these thresholds have been brought back to the threshold values. To normalize the distributions, the measurements obtained from the assays were transformed before analysis with the log function, except for the measurement of testosterone (square root transformation). All variables were then reduced and centered. For the dosages and the meat quality characteristics, the model included the effect of the weight at the end of the control period and the date of slaughter, equivalent to the batch of measurement. For the growth and food consumption traits, the model included the weight at the start of the control, the batch effect and the fattening pen as a random effect. For body composition measurements, the model took into account the weight before departure and the batch effect. The animal effect was added as a random effect in order to estimate the additive genetic variance. Six generations were considered to build the kindship matrix. The analyses were carried out with the VCE6 software (Neumaier and Groeneveld, 1998). Estimates of the variance components were performed jointly for the six assays. Other genetic correlations were estimated by two-trait analyses including one of the traits obtained from the assays and one of the other traits.

Results

The estimated heritabilities for these traits are all moderate to high. The highest heritabilities are observed for plasma estradiol level (h^2=0.80) and androstenone level in back fat (h^2=0.83). The lowest heritabilities were observed for the level of testosterone (h^2=0.26) and progesterone (h^2=0.34). The estimated heritabilities for cortisol (h^2=0.54) and skatole (h^2=0.50) were medium. The genetic correlations between compounds and production traits are reported in Table 1.

Discussion

Heritabilities. The estimated heritability for androstenone is in the upper range of previously published values (Larzul, 2021). The heritability value of skatole content was expected to be lower, according to results published in the literature (Larzul, 2021). It is recognised that skatole is more subject to environmental effects than androstenone. The heritability of estradiol is higher than those estimated in a population of Landrace (h^2=0.65) in Norway (Grindflek *et al.*, 2011) and much higher than the values estimated in German Landrace (h^2=0.09) (Brinke *et al.*, 2021). The result can probably be explained by a stricter

standardisation of the sampling and/or by the higher age and weight of the animals in the present study. The lower heritability of testosterone compared to estradiol (Grindflek *et al.*, 2011; Dugué *et al.*, 2020), confirmed by this study, is explained by a production of testosterone that is pulsatile and more sensitive to changes in the environment and stress. Few published results exist for the heritability of plasma cortisol in pigs In Landrace, at the end of fattening, Kadowaki *et al.* (2012) estimated a plasma cortisol heritability value of 0.2 and Brinke *et al.* (2021) of 0.11. The differences with the present study could be explained by breed or age at sampling. Knowing that cortisol heritability seems higher in a stressful situation (Larzul *et al.*, 2015), it is possible that the measured level does not reflect the basal level, as at the time of blood sampling, the animals were already isolated, for their departure to the slaughterhouse.

Genetic correlations. As expected, the genetic correlations between testosterone, estradiol and androstenone are high and in agreement with the published values (Larzul, 2021). Grindflek *et al.*, 2011 estimated much higher correlation values between these traits (from 0.8 to 0.95) in Landrace populations than those of the present study. In contrast, Brinke *et al.* (2021) published correlations of the same magnitude (from 0.49 to 0.89). These high correlations reflect the common metabolic pathways for these steroids (Robic *et al.*, 2014). The genetic correlations between, on the one hand, the steroids produced by the testes (androstenone, estradiol and testosterone) and, on the other hand, the steroids produced mainly by the adrenal glands (progesterone and cortisol) are weak (from zero to 0.34). Considering Brinke *et al.* (2021) and present results, it can be assumed that the steroid activity of the adrenal glands and testes are poorly genetically related.

Growth rate is not genetically related to any of the measurements except with progesterone (r_g=0.23). FCR and DFI are positively correlated not only with testicular hormones but also with progesterone, suggesting an overall genetic relationship with steroid metabolism. In contrast, %M is negatively correlated with testicular hormones, and more particularly with testosterone. This result is contrary to expectations, given that testosterone is known to have an anabolic effect on muscle. However, it should be considered that the animals were in the process of puberty and low levels of testosterone and estradiol indicate an early stage of sexual maturity for individuals just starting to deposit fat. The negative genetic correlations between %M and androstenone or skatole are consistent with the fact that the leaner lines are less at risk of developing boar taint (Larzul, 2021). The negative and moderate genetic correlation between yield and skatole might be related to viscera development. The pH measured 24 hours post mortem is not genetically linked to steroid hormones and odorant compounds as already shown by Dugué *et al.* (2020) in Pietrain. As for the colour parameters, they are moderately correlated with estradiol and testosterone (around 0.3) as well as with androstenone for the red index (r_g=0.31). The links between steroids and meat quality could result from the pubertal stage of development of the animals. In general, less mature stages are associated with lighter

and less red meat, thus individuals more advanced in their pubertal development would have darker meat with a higher red index.

The estimation of the genetic parameters on boar taint related traits in one of the main French maternal lines shows that overall selection against boar taint will have indirect responses similar to those of the sire lines. However, in these maternal lines, it is also imperative to estimate the genetic relationships between boar taint risk (in males) and reproductive traits (in related females).

789. A comprehensive overview of mitochondrial DNA insertions in the nuclear genome of the pig

M. Bolner*, M. Ballan, S. Bovo, G. Schiavo and L. Fontanesi

Department of Agricultural and Food Sciences, Division of Animal Sciences, University of Bologna, Viale Giuseppe Fanin 46, 40127 Bologna, Italy; matteo.bolner2@unibo.it

Abstract

The integration of nuclear mitochondrial DNA into the mammalian genomes is an ongoing but rare evolutionary process that produces nuclear sequences of mitochondrial origin (NUMTs). In this study we identified and analysed NUMTs of the porcine genome. We first constructed a comparative distribution map of NUMTs in the Sscrofa11.1 reference genome and in other 14 assembled and drafted pig genomes (of Asian and European origin). Then, a total of 581 whole genome sequencing datasets, from 35 different breeds or populations, were analysed for the discovery of recently integrated and polymorphic NUMT positions. Overall, we built a comprehensive catalogue of more than 500 NUMTs, some of which were not included in the assemble genomes. Breed-specific NUMTs as well as segregating NUMTs were also identified. This work lays the base for in-depth studies on the phylogeny of *Sus scrofa* populations.

Introduction

Nuclear sequences of mitochondrial origin (NUMTs) are insertions of mitochondrial DNA (mtDNA) into the nuclear genome of an eukaryotic organism through horizontal transfer mechanisms (Lopez *et al.* 1994). NUMTs are sequence fossils that provide phylogenetic information among related species, sub-species and lines and, for this reason, can be useful to reconstruct the history of animal domestication (Schiavo *et al.* 2017). The integration of NUMTs into the nuclear genome is still an ongoing, even if rare, evolutionary process.

The recent rise in genomic data available for livestock has allowed the discovery of NUMTs in different species (e.g. Pereira and Baker 2004; Schiavo *et al.* 2018, 2019). NUMTs in the genome of the pig (*Sus scrofa*) were recently investigated by Schiavo *et al.* (2017) using a LAST-based (Kiełbasa *et al.* 2011) pipeline and the Sscrofa10.2 reference genome. However, a new version of the pig genome (Sscrofa11.1), constructed from the same Duroc pig of the previous version, has been released in 2017. This is the current standard reference genome. Therefore, it would be needed to redefine the NUMT map in this new version and evaluate the differences between the two reference genomes (Sscrofa10.2 *vs* Sscrofa11.1) and obtain an updated catalogue of NUMTs present in the pig genome.

Over the last few years, many whole genome sequencing (WGS) datasets have been produced in all livestock species, including the pig. These datasets can be mined to detect additional NUMT regions, not included in the reference genome and other NUMT sequences that might have been recently inserted in the genome of some breeds, populations or individuals.

Here, we built a comprehensive catalogue of porcine NUMTs by analysing the novel Sscrofa11.1 reference genome, 14 additional drafted pig genomes (of Asian and European origin) and about 600 WGS datasets.

The results of this study could be useful for gaining a better understanding of the phylogenetic history of the domestic pig, the relationships between breeds and, eventually, the impact of polymorphic NUMTs in affecting phenotypic traits in this species.

Materials & methods

Reference genomes and WGS datasets. The reference pig genome (Sscrofa11.1) and the drafted genome reference sequence of 14 different pig breeds (Table 1) were downloaded from the National Center for Biotechnology Information (NCBI, https://www.ncbi.nlm.nih.gov/). Data included both the nuclear and mitochondrial genomes. Moreover, WGS data of 464 pigs from 35 pig breeds and populations were retrieved from the European Nucleotide Archive (ENA; https://www.ebi.ac.uk/ena/browser/). This dataset was enlarged by including additional 117 WGS data obtained from individual pigs of the three Italian heavy pig breeds (Italian Large White, Italian Landrace and Italian Duroc).

Detection of NUMTs in the reference and drafted genomes. The pipeline followed what previously proposed by Schiavo *et al.* (2017). Briefly, the mitochondrial genome was circularized by concatenating two copies of the complete mtDNA in order to capture matches extending over the boundaries of the linear sequence. LAST software (Kiełbasa *et al.* 2011) was used to query the Sscrofa11.1 reference genome and the additional 14 reference genomes. Then, alignments pointing out putative NUMTs were retained considering the E-value statistics. A threshold of E-value = 55 was obtained based on the method proposed by Tsuji *et al.* (2012). A comparative analysis and mapping of NUMTs included in Scrofa11.1, in Sscrofa10.2 and in all 14 drafted genome versions was obtained by aligning the flanking regions (1000 bp each) of each detected NUMT with all the other genomes.

NUMT detection from WGS dataset. The pipeline followed, with some adjustments, the approach described by Ju *et al.* (2015). Reads were initially mapped over the reference genome with BWA (Li and Durbin, 2009). Then, the genome was divided in windows of 500 bp that were evaluated for the presence of discordant reads (i.e. one mate aligned to mtDNA and the other one aligned to a nuclear chromosome). BLASTN (Altschul *et al.* 1990) was then used to realign reads contained in windows presenting discordant reads and to confirm those regions/windows representing NUMTs. Then, windows containing soft clipped reads were evaluated for the possible alignment of the clipped portion, via BLASTN, to the porcine mtDNA.

[1] Fraction of the nuclear genome covered by NUMTs.
[2] Sscrofa11.1 reference genome.

This led to the identification of *de novo* insertions as well as the portion of inserted mtDNA and the location of the breakpoints at the nuclear level.

Results

Detection and comparative evaluation of NUMTs from reference genomes. The number of NUMTs detected in the reference genome (Duroc) as well as in the other drafted genomes is reported in Table 1. The number of matches resulted similar across all breeds, with an average ± standard deviation of 466±15. The size of these NUMTs ranged from 56 bp to 10,996 bp. Of the identified NUMTs, 293 are shared between all breeds. We also detected private NUMTs (i.e. breed specific) in the range of 0 to 3 per breed. NUMTs on the same chromosome (or scaffold) within 20 kb of each other were annotated as part of the same NUMT region, which is expected to be derived by the same insertional events followed by subsequent mutations that divided the integrated mtDNA. Across the 15 analysed reference or drafted genome sequences we detected from 199 to 261 NUMT regions. Figure 1 shows the distribution of the different NUMT length classes in the two reference genomes (Sscrofa10.2 and Sscrofa11.1). The two distributions resulted similar, with the majority of NUMTs covering the class of 100-500 bp.

Detection and evaluation of NUMTs from WGS datasets. The comprehensive evaluation of WGS datasets led to confirm the existence of most NUMTs (those retrieved from the evaluation of the reference genome) as well as the detection of *de novo* NUMT insertions (i.e. NUMTs not included in the reference or drafted genome versions). For example, the analysis based on Italian heavy pig breeds detected a total of 383 NUMTs, 80% of which were already annotated in the reference genomes (they overlapped with known NUMTs). Moreover, the evaluation of soft-clipped reads led to the discovery of about 50 breakpoints in the nuclear genomes pointing out novel NUMTs, not included in the reference genome. This pipeline also led to evaluate the zygosity state of the NUMTs as well as their segregation across breeds.

Discussion

We present for the first time a comprehensive catalogue of porcine NUMTs detected using the combination of different approaches. We started by annotating NUMTs in the Sscrofa11.1 reference genome and

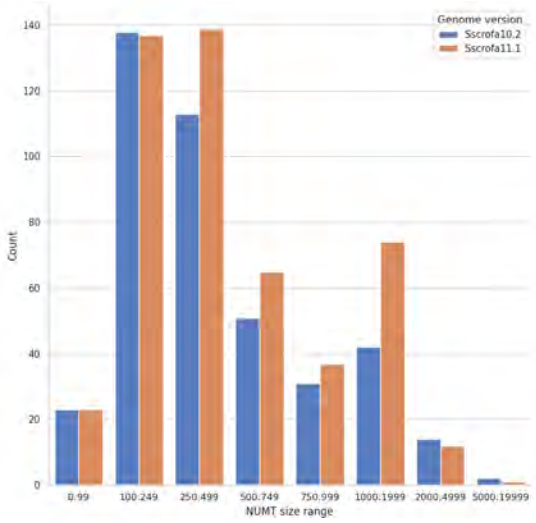

Figure 1. Comparison of NUMTs size distribution across the two pig reference genome versions.

then this information was integrated with NUMTs detected in drafted genomes of different breeds and unassembled WGS datasets. Most of NUMT positions were confirmed across all assembled genomes. In a few cases, partial overlapping of NUMT positions across the assembled genomes might be due to potential chimeric misassembled positions, incomplete sequences and polymorphic regions (i.e. presence/absence of the insertion), as determined when WGS datasets were used. All three zygosity states were identified using WGS datasets. That means that, as already demonstrated (Schiavo *et al.* 2017), some NUMT positions are polymorphic within and across breeds. Some of the polymorphic NUMT sites could be quite recent in terms of integration into the genome of some pigs whereas for others, the integration event probably occurred a few millions of years before present (MYBP). This might suggest that their polymorphic state is derived from relatively more recent (compared to the insertion event) interspecies admixture that contributed to shape the *S. scrofa* genome. These NUMTs can be very informative to reconstruct the genetic events that constituted the modern pig breeds and lines through different waves of gene flux and introgression, particularly, between European and Asian pig populations. Other NUMTs might be breed-specific. Direct PCR validation in a larger number of animals would be needed to confirm these results that can lead to the development of breed-specific markers.

790. To Box-Cox or not to Box-Cox: phenotypic and genomic evaluation of litter size variability in Landrace pigs

G. Cieleń[1*], E.F. Knol[2], M.S. Lopes[2,3] E. Sell-Kubiak[1]

[1]Poznań University of Life Sciences, Department of Genetics and Animal Breeding, Wołyńska 33, 60-637 Poznań, Poland; [2]Topigs Norsvin Research Centre, Schoenaker 6, 6641 SZ Beuningen, the Netherlands; [3]Topigs Norsvin, R. Visc. do Rio Branco, 1310 Centro, Curitiba, PR, 80420-210, Brazil; cielengabriela@gmail.com

Abstract

This study aims to evaluate phenotypic and genomic background of variability of litter size obtained from data without and with Box-Cox transformation. We used 67,500 records on total number born (TNB) from Landrace pig population. Since the original data presented skewness the decision was made to perform Box-Cox transformation (bcTNB). Phenotypic variability was estimated as log-transformed variance of residuals (LnVar) for both TNB and bcTNB. EBVs obtained with LnVar were used to calculate the deregressed EBV, which were further used in genome-wide association study (GWAS) on ~5,000 sows and boars genotyped or imputed to 660K SNP-chip. The final GWAS results are still to be developed.

Introduction

Reproduction traits are highly important in livestock production and play an essential role in management and economic profits (Rempel *et al.*, 2010). Thus litter size in pigs has been intensively selected for decades in many breeding systems (Zhang *et al.*, 2019). Constant genetic improvement of this trait is possible thanks to existence of substantial genetic variation (Samorè *et al.*, 2016). However, due to confirmed genetic correlations (0.5) with increase of litter size also its variably is increasing (Sell-Kubiak *et al.*, 2015). The traits variability, can be measured by the heterogeneity of residual variance (Hill and Mulder, 2010).

Some authors (Rönnegård and Valdar, 2011; Yang *et al.*, 2011; Khaw *et al.*, 2016, Iung *et al.*, 2018) indicated that the data transformation can substantially affect the traits variability. Thus, it is suggested to use e.g. Box-Cox transformation instead of working with raw data. Moreover, the data transformation by affecting the estimates of trait variability can also lead to association with different genomic regions. So far only two studies on Large White pigs data (Sell-Kubiak *et al.* 2015;2022) indicated genomic regions involved in variability of litter size. Those previous studies, however, did not apply the data transformation.

Therefore, our study aims to evaluate the effect of Box-Cox transformation on trait variability and its phenotypic and genomic characteristics. In order to perform that we use Landrace pigs population and focus on total number born (TNB) and its variability estimated as log-transformed variance of residuals (LnVar).

Materials & methods

Phenotypes. Data for this study were obtained from the multiplication farm of the Topigs Norsvin (Vught, the Netherlands). In total 73,035 litter size (total number born, TNB) observations were available from 21,244 Landrace sows. After data editing, 67,500 litters from 16,273 Landrace sows remained for the analysis. The final TNB data presented skewness (Figure 1a), thus it was decided to perform the Box-Cox transformation. This was done using the MASS package in the R-program (R Development Core Team, 2011). For the estimation of λ, the fixed effects of parity of the sow, year and season of the farrowing and age at first insemination of a sow were used. Data after transformation are presented on Figure 1b and will be referred to as bcTNB.

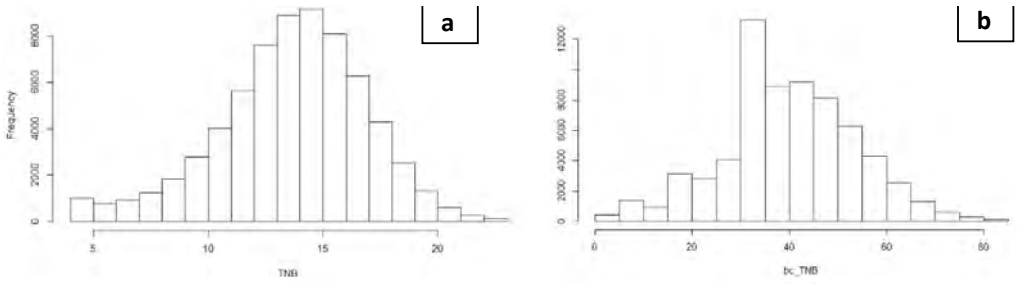

Figure 1. Distribution of raw litter size (TNB) and after Box-Cox transformation (bcTNB).

Statistical analysis. The animal model used for TNB and bcTNB in ASReml 4.1 (2015) was:

$$y = Xb + Za_d + Za_s + Upe + Vs + e \quad (1)$$

where y is a vector of observations on TNB or bcTNB; X, Z, U and V are known incidence matrices relating observations to fixed or random effects; b is a vector of fixed effects of parity of the sow, year and season of the farrowing and age at first insemination of a sow; a_d is a vector of dam additive genetic effect, with $a_d \sim N(0, A\,\sigma^2_{ad})$; a_s is a vector of random sire genetic effects with $a_s \sim N(0,A\,\sigma^2_{as})$; pe is a vector of random non-genetic effect of the sow (permanent sow effect), with $pe \sim N(0, I_{pe}\,\sigma^2_{pe})$; s is a vector of random non-genetic sire effect (service sire effect), with $s \sim N(0, I_c\,\sigma^2_c)$; e is a vector of residuals, with $e \sim N(0,I_e\,\sigma^2_e)$.

The residuals obtained for TNB and bcTNB were used to estimate log-transformed variance of residuals (LnVar). Then the variance components for LnVar were estimated with the model:

$$y_v = X_v b_v + Z_v a_{dv} + e_v \quad (2)$$

where y_v is a vector of observations on LnVar_TNB or LnVar_bcTNB; X_v and Z_v are known incidence matrices relating observations to fixed or random effects; b_v is a vector of fixed effects of year and season of the first farrowing; a_{dv} is a vector of dam additive genetic effect, with $a_{dv} \sim N(0, A\sigma^2_{adv})$ and e_v is a vector of residuals, with $e_v \sim N(0,I_{ev}\sigma^2_{ev})$. In this model variance was assumed heterogenous.

Genome-wide association study. The EBVs obtained for LnVar's were deregressed following Garrick *et al.* (2009) and used in GWAS. In total, ~5,000 sows and boars genotyped with Axiom porcine 660K array from Affymetrix (Affymetrix Inc., Santa Clara, CA, USA) or imputed to 660K using Fimpute v2.2 (Sargolzaei *et al.* 2014) were available. A single-SNP GWAS was performed with the following linear animal model in GCTA (Yang *et al.*, 2011):

$$y_k^* = \mu + X^*\hat{\beta} + u_k^* + e_k^* \quad (3)$$

where y_k^* is the deEBV of the k^{th} animal for LnVarTNB or varTNB; μ is the average of the deEBV; X^* is the genotype (0, 1, 2) of the k^{th} animal for the evaluated SNP; $\hat{\beta}$ is the unknown allele substitution effect of the evaluated SNP; u_k^* is the random additive genetic effect, assumed to be distributed as $\sim N(\mathbf{0}, \mathbf{G}\sigma^{2*}_a$, which accounts for the (co)variances between animals though the formation of a genomic numerator relationship matrix (G), constructed using the imputed 660K genotypes, σ^{2*}_a is the additive genetic variance; and e_k^* is the random residual effect, which was assumed to be distributed as $\sim N(\mathbf{0}, \mathbf{I}\sigma^{2*}_e)$.

Results

The significant difference in skewness, was observed after data transformation with the change from -0.469 to -0.02. Table 1 shows the variance components and heritability for litter size (TNB), whereas Table 2 for log-transformed variance (LnVar) of litter size before and after Box-Cox transformation (bcTNB). The data transformation did affect the variance components estimates for litter size and its variability. Heritability for TNB was 0.118 vs 0.125 for bcTNB, whereas for LnVar_TNB it was 0.0025 vs 0.0055 for LnVar_bcTNB. This indicates a larger proportion of additive genetic variance in entire variance based on transformed data. The change in magnitude of genetic variance was even more apparent when comparing GCV_{SDe} for LnVar's without and with transformation (2% vs 4%).

Figure 2 presents preliminary GWAS results for LnVar's that did not include in the litter size models variance components coming from the sire and before transformation of the data.

Discussion

As indicated by previous studies (Rönnegård and Valdar, 2011; Yang *et al.*, 2011; Khaw *et al.*, 2016; Iung *et al.*, 2018) the transformation of the data can have a substantial effect on the phenotypic variability of the trait of interest. This was confirmed here as the estimate of GCV_{SDe} for LnVar's changed from 0.02 to 0.044 after transformation. Moreover, the genetic correlation between mean TNB and LnVar's increased from 0.38 to 0.64 after data transformation (analysis not shown), which is surprising as usually Box-Cox transformation leads to decrease of correlation between mean and variability of a trait (Yang *et al.*, 2011; Iung *et al.*, 2018). Still the genetic correlations between LnVar's was 0.96 (analysis not shown). Data transformation also affect TNB variance components. Again the higher heritability was observed for bcTNB than TNB. This confirms that in case of skewed data of Landrace pigs, the transformation is necessary to reduce variation caused by distribution of the data.

Table 1. Variance components (with SE) for litter size (TNB) without or with Box-Cox transformation (bc) in Landrace sows.

Estimate	TNB	bcTNB
Additive genetic variance	1.13 (0.08)	21.33 (1.45)
Sire additive genetic variance	0.16 (0.08)	2.66 (1.37)
Permanent sow variance	1.11 (0.06)	19.92 (1.11)
Service sire variance	0.31 (0.08)	4.67 (1.39)
Residual variance	8.23 (0.05)	192.12 (1.47)
Heritability	0.118 (0.007)	0.125 (0.007)

Table 2. Variance components (with SE) for log-transformed variance (LnVar) of litter size (TNB) without or with Box-Cox transformation (bc) in Landrace sows.

Estimate	LnVar_TNB	LnVar_bcTNB
Additive genetic variance	0.005 (0.002)	0.008 (0.002)
Residual variance	0.32 (0.004)	0.30 (0.004)
GCV_{SDe} [1]	0.020	0.044
Heritability	0.0025 (0.0007)	0.0037 (0.0008)

[1] Genetic coefficient of variation at residual standard deviation level: $GCV_{SDe} \approx ½\sigma_{av}$.

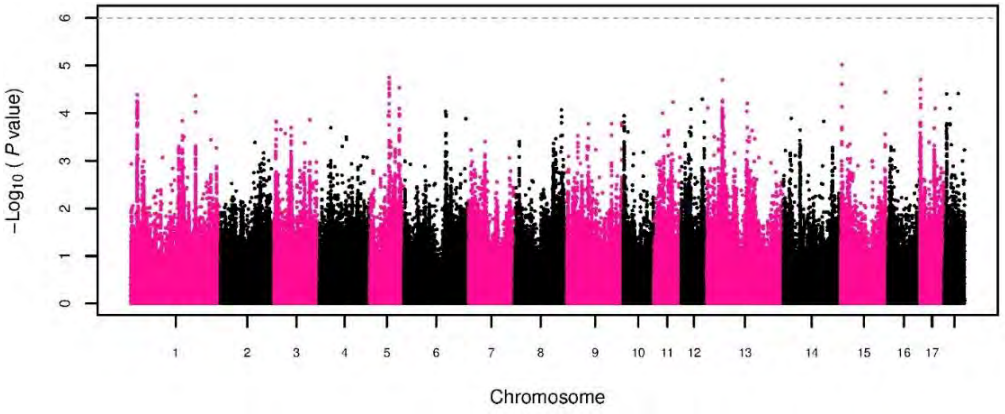

Figure 2. Preliminary GWAS results for the variability of litter size in Landrace pigs.

Previous studies focused on genomic background of litter size variability did not include data transformation since a Normal distribution of the raw data was indicated (Sell-Kubiak *et al.*, 2015; 2022). Moreover, variance components estimation for litter size in Landrace pigs included an additive genetic sire and non-genetic service sire components. This was not necessary e.g. in Large White pigs (Dobrzański *et al.*, 2019), where those variances were close to 0. Thus litter size data coming from Landrace pigs present substantially different properties than those of different breeds.

Our initial analysis did not include variance components coming from the sire (as genetic or non-genetic effect). Thus GWAS results present at the current stage need to be repeated using the deEBVs for LnVar's coming from models with the best fit to the litter size data and also separately for the data after Box-Cox transformation.

Conclusions

The results of this study indicate a substantial change in variability estimates when Box-Cox transformation is applied on data presenting skewness. Further analysis focused of genomic background of LnVar's will bring more insight into those differences.

Abstract

Precision Livestock Farming technologies applied to pig production has enabled to measure individual consumptions and feeding behaviour. The objective of this study was to estimate the heritability of feeding behaviour and feed efficiency traits at different periods and their genetic correlations in a Pietrain sire line. The database contained records of 933 pigs. The feeding behavioural and feed efficiency traits analysed showed high heritability (from 0.35 to 0.56) except for daily feed intake (0.26) and average daily gain (0.10). The genetic correlation of feeding behaviour traits between periods was close to one. Also, relevant correlations between traits were found, such as feeding rate with average daily gain (-0.78) and with feed conversion (0.47). These partial results indicated that including feeding behavioural traits in the breeding programme could be beneficial. However, more accurate correlations are expected as more data from the test station will be added.

Introduction

Pork meat is one the most widely consumed and its production has been steadily increasing. Feed cost represents the major proportion of the total costs of pig production, so improving feed efficiency traits is key to obtaining acceptable profitability. Feed conversion rate (FCR) and residual feed intake (RFI) are the most widely used efficiency traits in selection indexes, but they are difficult to measure, while average daily gain (ADG) is easier to measure but does not consider the feed consumed. The development of precision livestock farming technologies has made possible to monitor individual weight and feeding behaviour, such as consumption, duration and frequency of visits. These behavioural traits can be measured early in life, and if they are correlated with feed efficiency traits can be used as an early selection criterion (Kavlak and Uimari, 2019). For instance, pigs with unfavourable feeding behaviour at the early stages of the test could be removed and replaced by other test pigs, and it could reduce costs considerably. The aim of this study was to estimate the heritability of feeding behaviour and the feed efficiency traits at different periods and their genetic correlations in a Pietrain sire line.

Materials & methods

Field data were obtained from the test station of the Pietrain selection program of Selección Batallé company (Girona, Spain) from June 2019 until April 2021. The pigs started the test with an initial body weight (IBW) of 53.6±7.6 kg at the age of 96.8±10.0 days and ended with 111.4±11.6 kg at the age of 166.0±7.6 days. Pigs were fed *ad libitum* on a high protein diet, and the feedings were recorded automatically with Pig Performing Test (PPT) stations (Nedap, Groenlo, the Netherlands) along with data of feed intake, duration, and body weight for each visit. Each pen was equipped with a single-space feeder, and the mean of pen occupation was 12.8±2.35 pigs per pen. The raw data included 523,195 observations of 933 animals. Data of feed intake equal to zero or animals with less than 95 days of age at the start of the test or less than 50 total days were removed. After filtering, 459,519 observations from 790 males and 32 females were grouped by animal to compute: total number of visits, the median number of visits per day (NVD), time spent in feeding per day (TPD), daily feed intake (DFI), median of time spent per visit (TPV), median feed intake per visit (FPV), median feeding rate per visit (FR), average daily gain (ADG), feed conversion rate (FCR) and residual feed intake (RFI). FR (g/min) was calculated as the median of the ratio between FPV and TPV.

The RFI was calculated as the residual term of the adjusted DFI (amount of feed consumed during the whole period, divided by the number of days):

$$DFI_{ijk} = sex_i + pb_j + b_1(IBW)_{ijk} + b_2(ADG)_{ijk} + b_3(BF)_{ijk} + b_4(LT)_{ijk} + e_{ijk}, \quad (1)$$

where sex_i is the sex effect (i= male, female), pb_j is the interaction between pen and slaughter batch (j= 1, …, 69), b_1, b_2, b_3, b_4 are partial regression coefficients of IBW, ADG, BF (Back-fat thickness) and LT (Loin muscle depth), respectively. BF and LT were measured at the end of the test with a PIGLOG 105® (Frontmatec, Kolding, Denmark), at the last rib level and 6.5 cm off the midline.

Bayesian univariate and bivariate models were performed for all studied traits and the same effects were considered in all models: sex (2 levels), pb (69 levels), common litter effects (346 levels) and the additive genetic effect (822 levels). The models assumed multinormal distributions for the common litter (l), additive genetic (a) and residual effects (e): $l \mid L_0 \sim N(0, L_0 \otimes I)$, $e \mid R_0 \sim N(0, R_0 \otimes I)$ and $a \mid G_0 \sim N(0, G_0 \otimes A)$, respectively, where I represents identity matrices, A is the numerator relationship matrix, $\otimes$ denotes Kronecker product, L_0, G_0 and R_0 are covariance matrices of each effect of one dimension for the univariate and two dimensions for the bivariate models. Bounded flat priors were considered for the systematic effects (sex and pb) and co(variances). The marginal posterior distributions of all unknown parameters were obtained using Gibbs Sampling with the programme gibbs1f90 (Misztal *et al.*, 2002). Chains of 1,000,000 samples were run, and the first 50,000 iterations were discarded. Then a sample was obtained every 100 iterations. The heritability and corresponding variance components for behavioural and efficiency traits were computed for the whole period and for two periods groups according to the phenotypic differences found between the 96-132 days of age (n=819) and 132-182 days of age (n=812).

Results

The heritability and HPD 95% for behavioural and production traits are listed in Figure 1. The posterior means of the heritability were higher for the first period than for the second period for NVD (0.48 to 0.35), DFI (0.32 to 0.26), TPV (0.52 to 0.37), FPV (0.59 to 0.38), FR (0.50 to 0.33); the only exception was TPD which increased from 0.41 to 0.52. The genetic correlations of each behavioural trait between the whole and first period were high with a range of 0.88 to 0.99. The posterior mean of the heritability for FCR, RFI, BF and LT were moderately high (0.35, 0.43, 0.43 and 0.41, respectively) and low for ADG (0.10). The heritability for the feed efficiency traits within period did not properly converge.

Genetic correlations between feed efficiency and behaviour traits are shown in Table 1. The most relevant genetic correlations (HPD95% not included zero) were found between NVD and FCR (-0.44), TPD and ADG (0.74), TPD and BF (0.37), DFI and FCR (0.81), DFI and RFI (0.78), DFI and BF (0.43), TPV and BF (0.39) and FR with ADG (-0.78). The genetic correlations within feeding behaviours traits were also calculated. NVD was inversely correlated with TPV, FPV and FR, their respective posterior mean values and HPD 95% (between brackets) were -0.64 (-0.85, -0.4), -0.92 (-1, -0.83) and -0.42 (-0.78, -0.08). On the contrary, FPV was positively correlated with TPV and FR, with values 0.68 (0.46, 0.87) and 0.46 (0.11, 0.75). For feed efficiency traits, FCR showed two important positive correlations with RFI, and BF with values of 0.70 (0.37, 0.96) and 0.53 (0.09, 0.99), respectively. The genetic correlation between ADG and FCR was not relevant with a value of -0.15 (-0.99, 0.67). All genetic correlations between traits exhibited a wide HPD95%.

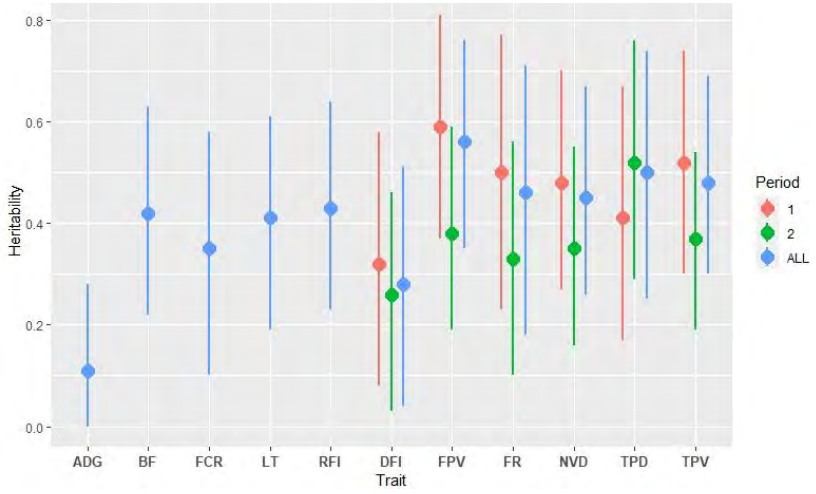

Figure 1. Posterior mean of the heritability and its HPD 95% for feed efficiency and behaviour traits. (Average daily gain (ADG), backfat thickness (BF), daily feed intake (DFI), feed conversion rate (FCR), feed intake per visit (FPV), feeding rate (FR), loin muscle depth (LT), number of visits per day (NVD), residual feed intake (RFI), time spent in feeding per day (TPD), time spent in feeding per visit (TPV).

Table 1. Posterior mean of genetic correlations [HPD95%] between feed efficiency and behaviour traits.

Trait[1]	FET[2]

[1] Feeding behaviour traits (NVD=number of visits per day, TPD=time spent in feeding per day, DFI=daily feed intake, TPV= time spent in feeding per visit, FPV=median of feed intake per visit, FR=feeding rate).

[2] Feed efficiency traits (ADG=Average daily gain, FCR=Feed conversion rate, RFI= residual feed intake, BF=Backfat thickness, LT= loin muscle depth).

Discussion

The heritability of behaviour traits found in this study ranged from 0.28 (DFI) to 0.56 (FPV). These values were slightly higher than those obtained by Chen *et al.* (2010) in Duroc with estimates ranging from 0.18 (TPD) to 0.42 (FR), and similar to Kavlak and Uimari (2019) in Finnish Yorkshire with estimates ranging from 0.17 (DFI) to 0.47 (TPV). Nevertheless, there is a great variability of the heritability reported for

behaviour traits (Hall *et al*., 1999). The heritability of feed efficiency traits was similar to other studies except for ADG (0.10) which was lower than those obtained by Herrera-Caceres *et al.* (2019) and Kavlak *et al.* (2021) (0.19 and 0.29, respectively). However, there were also differences in the number of days of recording data. In our study were 65 days, whereas in Herrera-Caceres *et al.* (2019) and Kavlak *et al.* (2021) studies were 107 and 95 days. In contrast, the heritability for ADG was similar than in Chen *et al.* (2010) who obtained 0.21, 0.11 and 0.10 in three testing periods with 64 days of total recording. As expected, negative correlations were obtained for NVD with TPV, FPV and FR, (-0.64, -0.92 and -0.42, respectively) in agreement with Do *et al.* (2013) and Santiago *et al.* (2021). DFI was strongly positively correlated with FCR and RFI and moderately with BF (0.81, 0.78 and 0.43, respectively). These results are in line with those reported by Kavlak and Uimari (2019). A positive correlation was found for TPD with ADG (0.74) and BF (0.37), agreeing with Do *et al.* (2013) in the direction but with a different magnitude. In addition, a negative correlation was found between NVD and FCR (-0.44), in contrast to those positive correlations observed in Landrace, Yorkshire and Duroc by Do *et al.* (2013) and Duroc by Santiago *et al.* (2021) (0.35 and 0.34, respectively). These earlier observations suggest that Pietrain pigs with more NVD, have lower FR, TPV and FPV. At the same time, higher NVD may result in lower FCR. Considering the moderate to high heritability of NVD (0.45) and its strong correlation shown between the first period and the whole period (0.97), it could be useful to incorporate NVD in selection criteria to improve the accuracy of selection for FCR in Pietrain pigs. However, all the correlations between behavioural and feed efficiency traits in this study have a broad 95% HPD and will become more accurate as more data from the test station will be added.

792. Genetic analysis of hoof colour in Duroc pigs

J. Vila, O.O.M. Iheshiulor, M.C.A.M. Bink and A.E. Huisman*

Hendrix Genetics, P.O. Box 114, 5830 AC Boxmeer, the Netherlands; abe.huisman@hendrix-genetics.com

Abstract

Hoof colour is an important characteristic for the Spanish producers of the cured hams and shoulders. The colour of the hoof is one of the quality requirements for high-value product ranges. Within this niche industry the Duroc breed is used as terminal sire line. The blackness of the hooves is used as a selection criterion for Duroc boars entering into Iberian production. To accommodate for this in the Hypor breeding program, the colour of the hooves in the Duroc breeding lines is recorded. Based on the original phenotypes new colour traits were defined. A genetic analysis was performed to estimate variance components and their ratios to investigate the genetic background of the colour of hooves. Heritabilities were in the mid to high ranges (0.06-0.50), in addition a GWAS was performed, resulting in identified peaks on chromosomes 1, 5, and 7. The results presented here are preliminary results.

Introduction

Hoof colour is an important characteristic for the Spanish producers of the cured hams and shoulders. The colour of the hoof is one of the quality requirements for high-value product ranges. Within this niche industry the Duroc breed is used as terminal sire line to produce final products which are a cross between the Duroc breed and the Iberian breeds. According to Iberian producers, the most important characteristic is colour homogeneity, and colour intensity is less relevant. The blackness of the hooves is used as a selection criterion for Duroc boars entering Iberian production. Scientific reporting on inheritance of colour is scarce and dated, but in a series of seven papers Hetzer described colour inheritance for crosses between a variety of breeds (Hetzer, (1945-1948), reviewed by Legault, 1998). Remarkably, there was no mentioning of hoof colour in these papers.

Different classes of Iberian hams are produced, varying in degrees of Iberian breed present in the final product. The other breed making up the final product is the Duroc breed. Since 2014 the Spanish government is tagging products based on these specifications (http://www.aeceriber.es/). Although no direct relationship between hoof colour and ham quality has been reported, in the production of Iberian ham special emphasis is put on the colour of the hoofs attached to the hams. Black hoofs stand for quality, deviations from this black colour result in a perceived lower quality of the ham. Therefore, a requirement for the Duroc sires used to produce Iberian hams is the presence of black hooves. The purpose of this study is to investigate the genetic background of hoof colour in purebred Duroc animals.

Materials & methods

Phenotypes for hoof colour were collected at one of the Hendrix Genetics, Hypor nucleus facilities. The colour of the hoofs was assessed at birth for Duroc sire line. The phenotypes were defined as percentages black, completely black: 100%, the absence of black: 0%. For ease of registration, the percentages black does not cover the whole range of 0-100%, but five classes: 100, 75, 50, 25 and 0% (Figure 1). The scoring was done by a trained technician. To note, 0% does not mean completely white, it means that the black part is less than 25%, and for example 50% mean greater than 50% but less than 75%.

The original classification levels were arbitrarily chosen, and we apply a re-classification, by merging various levels, into fewer levels as this may further our understanding of the genetic background of the trait (Table 1).

DOI: 10.3920/978-90-8686-940-4_792, © J. Vila *et al.* 2022

Figure 1. Images on hoof colour that illustrate the original five classification levels.

Table 1. Number of observations per class[1]

Trait[1]	0%	25%	50%	75%	100%	Levels
Original score	4,863	2,793	1,213	459	115	5
White versus rest	4,863	4,580				2
Black versus rest	9,328				115	2
Extremes narrow	4,863	4,465			115	3
Extremes wide	7,656		1,213	574		3

[1] Cells in grey represent merged classes.

The model used for the analysis of the defined traits was the same for all five traits. After testing several fixed and random effects, the final model:

$$y = Xb + Za + Wc + e$$

where y is vector of observations, b is vector of fixed effects, including breed, sex, year-quarter of birth, a is vector of random animal effects, c is vector of common environmental effects, e is vector of random residual effects, and X, Z, and W are incidence matrices relating records to fixed, animal and common environmental effects, respectively. It is assumed that the common environmental effects and the residual effects are independently distributed with means of zero and variance σ_c^2 and σ_e^2, respectively; therefore var(c) = $I\sigma_c^2$; var(e) = $I\sigma_e^2$; and var(a) = $A\sigma_a^2$.

The number of observations in total was 9,443; the number of observations per class is given in Table 1. Pedigree was traced back for 10 generations and included 13,656 animals. The number of observations per trait and class combination is presented in Table 1. Obviously, the number of observations reduces with the level of blackness of the hooves, i.e. black hooves are the least prevalent phenotype in the dataset.

Single trait analyses were performed, using the airemlf90 program out of the BLUPF90 suite of programs (Misztal *et al.* 2014), to estimate variance components for the different traits. While traits defined on a categorical scale, the models were analysed assuming a normal distribution. Subsequently a GWAS was performed using only data from 1,806 genotyped animals. The GWAS was performed using the GCTA software (Yang *et al.* 2014). A series of quality control steps (missing SNP, MAF and Hardy-Weinberg equilibrium) resulted in a genotype of 31,111 SNP available for 1,806 animals.

Results

The estimated variance components and their ratios are presented in Table 2. For trait Black versus the rest the results are unreliable, most likely due to the limited number of observations in the 100% class. Heritabilities for the different traits are in the mid to high ranges and vary from 0.322 for Extremes wide to 0.502 for Original score, except for trait 'Black versus the rest'.

Figure 2 shows the GWAS results for the different traits. For the original score 3 peaks were identified, located on chromosomes 1, 5 and 7 (Figure 2A). Not for all trait definitions peaks were found, i.e. for black versus rest (Figure 2C) no significant peaks were detected. Whereas for other trait definitions peaks appear to be in line with the peaks found for the original score.

Table 2. Phenotypic variance (σ^2) and estimated heritability (h^2) and common environment (c^2) for the five hoof colour traits[1]

Trait	σ^2	h^2	c^2
Original score	0.87	0.50	0.17
White versus rest	0.24	0.47	0.07
Black versus rest	0.01	0.06	0.10
Extremes narrow	0.27	0.46	0.08
Extremes wide	0.31	0.32	0.21

[1] Standard errors on h^2 ranged from 0.02 to 0.04; standard errors on c^2 from 0.01 to 0.02.

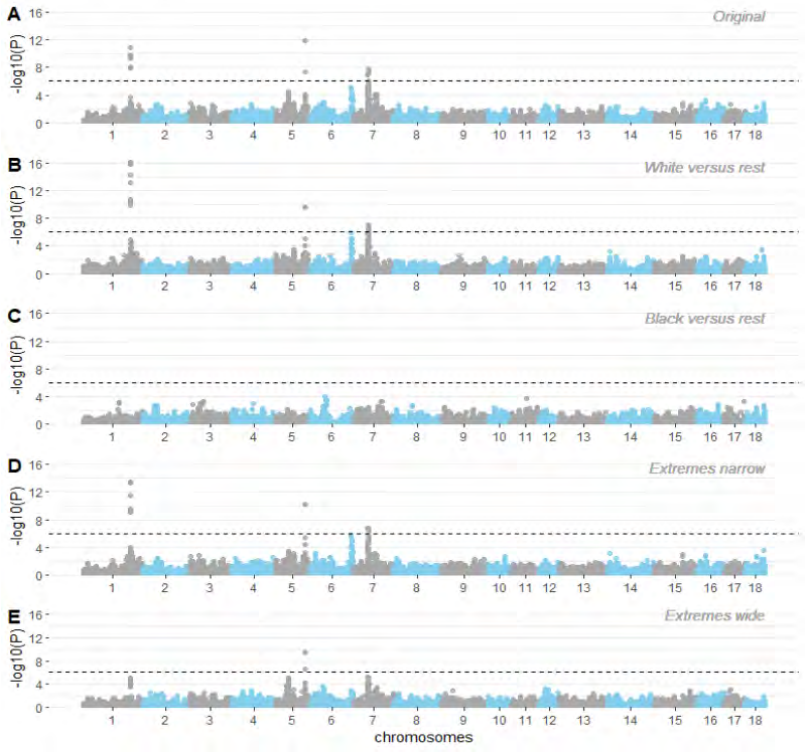

Figure 2. Manhattan plots on the GWAS results for the five hoof colour traits.

Discussion

The trait analysed has been recorded as a categorical trait, whereas there is a range in blackness of the hooves. The phenotypes have been scored visually, a possible better way of scoring could be the use of cameras or other visual tools. Given the nature of the trait definition a threshold model might have been the more appropriate choice of model. However, for ease of analysis and given the stage of this research we opted for the mixed linear model. Running a threshold model for the original score resulted in much higher heritability (0.68) whereas the litter component is similar (0.14). Other colour phenotypes such as coat colour and eye colour seem to be polygenic, even though there are a few genes with very large effects (KIT, MC1R, etc). Surprisingly, that's not what we found for hoof colour. The peak explaining the largest amount of variance was like ~5%. It seems to be rather polygenic. Incomplete penetrance could also play a role in the inheritance of hoof colour.

Next steps in the analysis will include investigating different modelling options and collecting more phenotypes, also at different ages to see how this trait evolves over time, i.e. is hoof colour seen at birth representative for hoof colour at older ages.

Abstract

Economically relevant traits are often not included in genetic evaluations because the animals that express them lack pedigree ties to selection candidates. Simulations produced three purebred (PB) breeds (A, B and C), an F_1 and a 3-way crossbred (CB). Breeds A, B and F_1 expressed lowly heritable traits with moderate genetic correlations between them. Selection was practiced for four generations with the goal of improving F_1 performance. Genotypes of F_1 dams were imputed using FImpute. Scenarios differed by number of CB genotyped per generation and knowledge of F_1 mates. When mates were known and >3 progeny were genotyped per generation, the phenotypic response in F_1 did not differ (P>0.05) from when the true genotypes were used. Un-genotyped F_1 animals can be imputed such that their phenotypes can be used in genetic evaluations but the benefit depends upon the number of CB progeny genotyped, parity and completeness of CB pedigree.

Introduction

With advancements in genotyping technologies, swine breeders are limited not by genotypes but by phenotypes which represent goal traits of the breeding program. Goal traits in swine breeding programs are often observed in animals outside of the nucleus and have a genetic correlation to nucleus traits which is often below unity. Previous reports have investigated CB genotyping and phenotyping strategies to improve genetic gain in PB selection candidates for CB performance with favorable results (Duenk *et al.*, 2021). Since the structure of most swine breeding programs consists of large full- and half-sib families (Badke *et al.*, 2012), a large degree linkage disequilibrium (LD) exists which can be exploited to impute genotypes of non-genotyped animals. Previous reports show that non-genotyped animals can have genotypes accurately imputed using greater than 10 genotyped progeny (Pimentel *et al.*, 2013; Berry *et al.*, 2018). Objectives of the present study were: (1) evaluate the accuracy of imputed genotypes of non-genotyped F_1 dams of CB animals; and (2) to quantify the response to selection for F_1 performance using imputed genotypes.

Materials & methods

Simulation and evaluation. Data were simulated using the AlphaSimR package (Gaynor *et al.*, 2019) in R. The genome consisted of three chromosomes each 1 CM in length with 11,100 evenly spaced bi-allelic markers. The historical population began with an effective population size of 12,000 which was gradually reduced to 250. Following historical founder development (n=1,500), founders were randomly assigned with equal numbers of males and females to three PB breeds (hereafter breeds A, B and C). Recent LD and PB breed differentiation was achieved by random mating during a genetic bottleneck (10 generations), with constant population size (30 generations), and followed by population expansion (10 generations). Males and females (25 and 425, respectively) were chosen to be breed founders. Dams produced one litter per generation and PB and CB matings produced 8 and 10 progeny, respectively. The 3-way crossbreeding program was achieved by crossing 25 sires from A with 400 dams from B to produce AB females. CB progeny were simulated by crossing AB females (n=1000) with sires from C (n=50).

A subset (n≈9,000) of markers was chosen to be included on the SNP chip used for imputation and genetic evaluations. Three phenotypes were simulated by randomly selecting 300 markers, which were not SNP,

to be quantitative trait loci which acted additively. Simulated variance components for breeds A, B and AB were chosen to mimic reproductive traits in swine (h^2=0.2, 0.2 and 0.15, respectively) which were moderately correlated to each other (r_a=0.65). The only female animals which produced offspring expressed a phenotype and the phenotype was considered as expressed only at the first parity.

Selection and genetic evaluation. The goal of the selection scheme was to improve performance in AB by using estimated breeding values (EBV) produced from either single- or two-trait animal models. Prior to the simulation of CB animals, candidates from breeds A and B were chosen by EBV produced from single-trait models for within breed performance. After CB animals were produced, selection candidates were chosen by EBV for AB performance. EBV were produced by two-trait models including breeds A and AB, or breeds B and AB.

Single- and two-trait single-step genomic best linear unbiased prediction models were fitted using the BLUPf90 application programs. Single- (PB performance) and two-trait (PB and AB performance) models contained effects of the overall mean, generation (class effect), additive genetic (random) and residual (random). Variance components were those initially simulated.

Imputation strategies. Imputation of non-genotyped AB dams was done using FImpute V3 using both family- and population-based imputation (Sargozaei *et al.*, 2014). Genotypes (MAF>0.05) used to impute AB dams were from breeds A, B, C and CB progeny. Pedigree information used for imputation included relationships within PB breeds and AB dam relationships to CB progeny. Sire relationships with CB progeny were considered to be either known (knownSire) or unknown (unknownSire). The number of genotyped CB progeny per generation (2, 3, 4 or 6) was also investigated. Given the minimum number of progeny required to impute non-genotyped parents in FImpute is 4, genotyping 2 or 3 CB progeny per generation resulted in imputed genotypes after two parities resulting in fewer AB records in genetic evaluations. Comparisons across imputation strategies were made using mean genotype concordance (GC), defined as the proportion of correctly imputed genotypes. Response to selection using imputed genotypes was compared to selection when either no genotypes (noGeno) or the true genotypes (trueGeno) of AB animals were used. The cumulative phenotypic response in AB performance (CPR) was calculated per replicate as the difference between mean phenotype of AB dams from the final generation and mean phenotype in the first generation. Least squares (LS) means were then calculated for the CPR using the *emmeans* package in R by fitting a linear model including fixed effects of replicate, sire relationship status and number of genotyped CB. The analysis was then replicated 20 times.

Results

Summary of simulated animals. The degree of LD and distribution of MAF produced in breeds B and C was similar to A. In breed A, pairwise estimates of r^2, averaged across replicates, in the range of genomic distance in kb of 0-25, 50-120, 200-500, and 1000-2,000 was 0.49, 0.41, 0.28, and 0.14, respectively. The correlation of LD phase between PB breeds (Bladke *et al.*, 2012) averaged over pairwise PB breed comparison and replicate, within a range of genomic distance in kb of 0-100, 200-300, 500-600 and 700-800 was 0.72, 0.50, 0.32 and 0.23, respectively. In general, distributions of allele frequencies were near uniform. The number of alleles with extreme frequencies tended to be greater than those with intermediate frequency, but distributions varied by replicate.

Imputation accuracy. The mean GC of imputed AB genotypes in the final generation under knownSire using 2, 3, 4 or 6 CB progeny genotypes per generation was 0.96, 0.98, 0.96 and 0.97, respectively. However, relative to the cumulative number of genotyped CB, GC increased as the number of genotyped CB increased.

Once 9 CB progeny were genotyped little benefit in GC was achieved for an additional genotyped progeny (Figure 1A). In general, parity had little effect on GC under knownSire (Figure 1B).

The average GC of imputed AB genotypes in the final generation under unknownSire using 2, 3, 4 or 6 CB progeny genotypes per generation was 0.80, 0.82, 0.71 and 0.73, respectively. Breeding scheme factors such as the total number of genotyped CB progeny (Figure 1A) and parity (Figure 1B), impacted genotyped concordance using unknownSire. For every additional genotyped CB animal beyond 8, the corresponding gain in GC was negligible. Significant improvement in GC was achieved when genotyped CB progeny were from multiple parities. The average increase in GC when genotyped CB progeny were from 2 or 3 parities compared to one was 0.14 and 0.19, respectively. Parity 3 dams with less than 3 mates and parity 2 dams with one mate comprised 1.05 and 0.58% of all AB matings, respectively.

Response to selection. The CPR, expressed as LS means, is presented in Figure 1C. When noGeno and trueGeno were used the LS means for CPR were 0.32 and 1.26, respectively. As the number of genotyped CB progeny increased CPR also increased. Whether CB sires were included in the pedigree or not impacted the CPR differentially according to the number of genotyped CB progeny used for imputation. The CPR was not different when 2 or 3 CB progeny were genotyped per generation between knownSire and unknownSire, yet the increase in CPR was greater between generations 3 and 4 under knownSire compared to unknown sire. When the number of CB progeny genotyped per generation increased to 4 or 6, knownSire produced a greater CPR compared to unknownSire. CPR when sire was known and 4 or more CB genotypes per generation were used for to impute AB did not differ ($P>0.05$) compared to using trueGeno. However, using as few as 3 genotyped CB per generation, regardless of CB sire status, provided a greater response ($P<0.05$) in CPR than noGeno.

Discussion

The trend in LD phase between breeds in current study was similar to those previously reported in real swine breeds (Badke *et al.*, 2012). Previous reports suggest that imputation accuracy increases as MAF becomes more extreme (Pimentel *et al.*, 2013). Thus, imputation accuracy could be inflated upwards compared to previous reports with normally distributed allele frequencies.

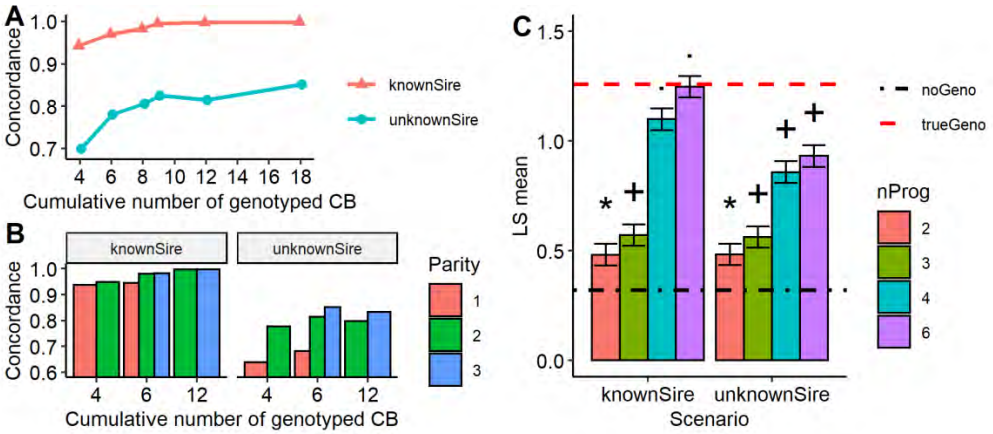

Figure 1. Factors affecting GC and CPR expressed as LS means. (A) Impact of the cumulative number of genotyped progeny on GC. (B) Impact of parity on GC. (C) CPR where * and + denotes significantly different ($P<0.05$) from noGeno, trueGeno and both noGeno and trueGeno, respectively.

In the current study, the simulation was designed to mimic a breeding scheme where CB genotyping decisions were made prior to the imputation of AB dams. Factors related to the design of the breeding scheme, including total number of genotyped progeny and parity of the dam (number of mates), contributed to GC. As expected, as the total number of CB progeny genotyped increased the accuracy of imputation also increased regardless of CB sire pedigree status, in agreement with previous reports (Berry *et al.*, 2018). The relationship between parity and GC has not been previously reported. The increase in GC due to parity is likely driven by the increase in the number of mates per AB dam. In the case where 2 or 3 CB progeny were genotyped per generation, AB dams with imputed genotypes had more parities and benefited from a larger reference population which led to an increase in GC compared to when 4 or 6 CB progeny were genotyped per generation. Increases in GC led to differences in CPR across imputation strategies. When genotyping 4 or 6 CB progeny per generation the CPR was greater than noGeno, regardless of CB sire pedigree inclusion. However, only under knownSire using 4 or 6 CB genotypes per generation was the CPR using imputed genotypes not different from trueGeno. Combined results suggest that imputed AB genotypes can be used to inform genetic evaluations and selection decisions. For entities that genotype CB, this study demonstrates an avenue to improve genetic gain in F_1 performance without the requirement of additional genotyping or pedigree tracking through the use of imputed genotypes.

794. Distinctive gene-expression profiles characterise tail-biting precursors in pigs under dietary protein restriction

L. Couteller[1,2], L. Roch[2,3] and C. Kasper[2*]

[1]École Supérieure d'Agricultures, 55 Rue Rabelais, 49007 Angers, France; [2]Agroscope, Tioleyre 4, 1725 Posieux, Switzerland; [3]Animal Welfare Division, Veterinary Public Health Institute, University of Bern, Länggassstrasse 120, 3012 Bern, Switzerland; claudia.kasper@agroscope.admin.ch

Abstract

Tail biting is a common problem in pig production, but genetic studies are impeded by the difficulty of observing it. It is a broader phenomenon that begins before lesions manifest. Therefore, precursors of tail biting, such as oral and nasal manipulation of conspecifics, should be studied. However, the molecular physiology underlying those behaviours is not well understood. Here we show that gene expression profiles in the hypothalamus of 73 non-tail-docked pigs fed a protein-reduced diet differed between individuals showing abnormal and normal behaviours. We found that differences in the expression of genes involved in neurotransmission, notably in dopamine, serotonin and GABA, and G-protein coupled signalling, energy metabolism and appetite. Our results demonstrate that abnormal behaviours have distinct signatures in the brain, which could be partly caused by genomic variation. These insights can lead to a better understanding of the biological mechanisms involved and thus may ultimately inform genomic selection programmes.

Introduction

Damaging behaviours such as tail biting are a common problem in pig production, compromising animal welfare and causing economic losses. A previous study found low to zero heritability for tail biting (Breuer *et al.*, 2003). Genetic studies are impeded by the enormously complex phenotyping, because tail biting often cannot be observed directly. Tail biting is thought to be a broader phenomenon, and behavioural problems caused by various stressors begin before escalating into damaging behaviour where serious injuries occur (Valros, 2018). Therefore, it useful to study the precursors of tail biting, which are behaviours that are termed 'abnormal' such as belly nosing, ear biting and 'tail-in-mouth' (Brunberg *et al.*, 2011) to gain insights into the molecular physiology of tail biting.

Poor sanitary conditions in combination with dietary protein reduction increase the prevalence of tail biting (Van der Meer *et al.*, 2017). Since restricting the protein content in the diet is a promising way to reduce nitrogen emissions in pig manure, it is important to investigate whether this measure can lead to a reduction in animal welfare. Even if essential amino acids are substituted, the overall reduction in dietary protein could lead to an increase of abnormal behaviours due to neurotransmitter system dysfunction because of the reduced availability of amino acids required for neurotransmitter synthesis. Pigs differ in their ability to utilise dietary proteins, which has been shown to be heritable (Kasper *et al.*, 2020). Therefore, we expect that individuals are not equally affected by protein reduction. Here, we investigate whether, under protein-restricted feeding with essential amino-acid substitution, gene expression profiles reflect differences in behaviour. Furthermore, we explore the genes and their functions as well as the pathways that are affected by abnormal behaviours.

Materials & methods

Animals. Ninety-five non-tail-docked pigs were reared on a diet formulated to contain 80% of crude protein of the recommendation. Between day 98 and 115 after birth, all instances of nasal and oral manipulation behaviours towards conspecifics (biting, seizing and nosing), classified as 'abnormal' behaviours, were recorded during five-min observations at four occasions. The protein efficiency of each pig was calculated

R.F. Veerkamp and Y. de Haas (eds)

as the amount of protein in the carcass after slaughter divided by the amount of protein ingested. The effect of protein efficiency and sex on abnormal behaviours was analysed with generalized mixed-effects models with a Poisson and binomial family. The individual ID as well as the sire ID were added as random effects to correct for multiple observations and the family structure.

Brain extractions, RNA preparation and sequencing. The brains of the remaining 94 pigs (one died before slaughter) were extracted around 20:33±01:50 min after the start of exsanguination. The hypothalamus was dissected, immediately frozen in liquid nitrogen and stored at -80 °C until RNA extraction. The brains of the first eight pigs and further six samples were discarded as the training set for the sampling procedure and because of bad sampling quality. RNA extraction and sequencing of 80 hypothalamus samples (from 38 females and 35 males) were carried out by an external provider (Alithea Genomics, Lausanne, Switzerland). RNA-seq was done using the BRB-seq method (Bulk RNA Barcoding and sequencing, Alpern *et al.*, 2019), in which samples are multiplexed after the first reverse-transcription step.

Differential gene expression and network analysis. We removed genes with zero variance, genes with zero counts in more than 90% of samples and genes with a low expression (i.e. less than 10 counts) and samples with sequencing depth of <1M. We applied a multiple regression design, which included manipulation behaviour towards conspecifics, protein efficiency and sex, to control for additional variance, in DESeq2 (Love *et al.*, 2014). *P*-Values and fold-changes of the differential gene expression analysis were computed using the negative binomial GLM fitting and Wald statistics. GO-term enrichment of differentially expressed genes (DEG) was performed in ToppGene Suite (https://toppgene.cchmc.org). Weighted gene co-expression network analysis in WGCNA (Langfelder and Horvath, 2008) was carried out on the filtered read count matrix after variance-stabilizing transformation. To divide the co-expressed genes into modules, we chose a maximum block size of 10,000, a soft power threshold of 10 and 'signed' as the topological overlap matrix type. The modules enriched for DEG related to abnormal behaviour were determined with least-square linear models, an empirical Bayes moderation of standard errors in the R package limma (Ritchie *et al.*, 2015). The same procedure for GO-term enrichment as described above was applied to the genes contained in the significant modules. All *P*-values were corrected with a Benjamini-Hochberg FDR (a=0.05).

Results & discussion

Behavioural observations. Only three pigs were involved in tail biting (3.2%, two biters, one individual was both biter and victim). Even though the majority of pigs performed nasal or oral manipulation behaviour towards conspecifics, 16 pigs (17%) did not show these behaviours in any of the four observations. The number of abnormal behaviours was not influenced by protein efficiency or sex (GLMM with Poisson family: P=0.194 for protein efficiency, P=0.836 for sex), nor was the probability to engage in those behaviours (GLMM with binomial family: P=0.190 for protein efficiency, P=0.672 for sex).

Differential gene expression. Sequencing produced a read count matrix of 31,908 genes by 80 individuals. Filtering resulted in the removal of 13,775 genes. Sequencing depths ranged from 0.56M to 3.57 M reads per sample (1,774,168±649,509 reads). Seven individuals were removed because their sequencing depth was <1M reads. We found 23 genes differentially expressed between behaviourally abnormal and normal pigs ($P \leq 0.05$), of which 17 were up-regulated in abnormally behaving pigs compared to normally behaving ones and six genes were down-regulated (Table 1). In the set of DEG, 23 GO terms were enriched, most notably pertaining to G protein-coupled activities, amino acid binding, neurotransmitter and synaptic vesicle transport. The heterotrimeric G-protein signalling pathway-Gq alpha and Go alpha mediated pathway and the 5HT2 type receptor mediated signalling pathway were also significantly enriched.

[1] Mean expression across samples.

[2] Hochberg-Benjamini adjusted FDR.

[3] Originally unknown gene in the Sscrofa11.1 assembly. A search for orthologs in the Expression Atlas (https://www.ebi.ac.uk/gxa/home) yielded PRKCHA.

Weighted gene co-expression network analysis. The genes were divided into 20 modules, of which only one was significantly enriched for DEG related to manipulation behaviour (logFC=0.11, t=3.08, adj. *P*=0.04). This module contained 30 genes, which were down-regulated in abnormally behaving relative to normally behaving pigs (Figure 1). Only three genes in the module overlapped with the list of significant DEG (*CCK*, *SLC18A2* and *DDC*). Among the genes contained in the module were six transcription factors (*NR2F2*, *FOXA1* and *FOXA2*, *EN1* and *EN2*, and *LMX1B*). Eight genes were involved in neurotransmitter metabolism (*DRD2*, *CHRNB3, CHRNA6, SLC6A3. SLC18A2, DDC*, *ALDH1A1* and *TH*). Three genes coded for proteins involved in the regulation of feed intake and energy metabolism (*RET*, *CCK* and *INS*). The other genes were related to cell migration (*PRPRU* and CD164), G-protein-coupled receptors (*GPR26* and *TRPC6*), dopaminergic neuron differentiation (*RSPO2*), regulating mitochondrial Ca2+ uptake in neurons (*PDZD8*), synaptic vesicle formation (*CPLX2*) and genes with other functions (*SLC10A4*, *ZAR1, LRRC3B, GSTO1, SFRP4* and *MXRA7*). We found 71 GO terms significantly enriched, most notably dopamine and catecholamine binding, neurotransmitter transport, neurotransmitter metabolic processes, synaptic vesicle transport, neuron generation and differentiation, behaviour and response to drugs.

Conclusions

As expected, tail biting was very rare. Classifying animals into groups based on their oral and nasal manipulation behaviour towards conspecifics (i.e. abnormal behaviour) is therefore useful and offers

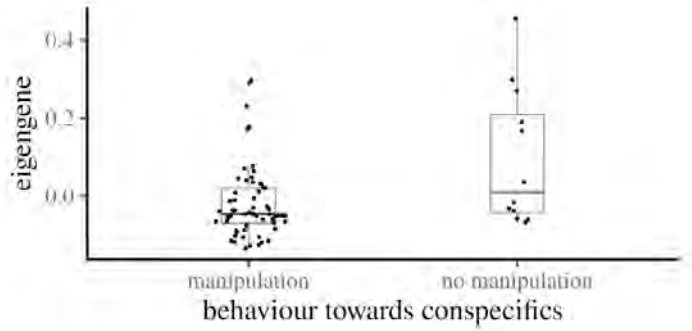

Figure 1. Eigengene values in the module that is significantly enriched for genes related to manipulation behaviour.

interesting insights. Here, we found evidence that abnormal behaviour in pigs is associated with gene expression profiles that are implicated in neuropsychiatric disorders in humans. Genes related to the synthesis, synaptic transmission and uptake of neurotransmitters, notably GABA, glutamate, dopamine, acetylcholine and serotonin, were differentially expressed in pigs showing abnormal behaviour. This was corroborated with the findings from pathway enrichment analysis. Interestingly, some of the DEG have been associated with energy metabolism, feed intake and appetite. Especially in the context of protein-efficiency studies, this warrants further investigation. As of now, it is unclear whether the differences in expression found in this study are caused by genetic variants, DNA methylation or other modifications, or short-term environmental influences. A better knowledge of these causes could inform genomic selection programs and allow the inclusion of welfare in the breeding goals.

Abstract

Iberian pigs are well-adapted to high temperatures, however, detrimental effects on reproductive traits have been reported. We evaluate the effect of heat stress on farrowing rate (FR) of Iberian sows. Data included 13,290 first insemination records from 3,009 sows. Temperature-humidity index (THI) was calculated using records from the closest weather station. Heat stress was defined trough heat load, as the number of degrees surpassing a particular threshold (THI0) affecting farrowing rate. Cycle number, heat load (THI0=16) and breed sire effects on FR were assessed and heritability using a threshold model was estimated. Heritability of FR was low 0.039 (0.018/0.065) and heat load, cycle number and sire effects were detected. Heat stress affects the farrowing rate of Iberian sows since the liability for this trait was lower with higher heat loads. Therefore, THI has to be taken into account for improving the farrowing rate.

Introduction

It is well known that global warming affects livestock species. High environmental temperatures can produce heat stress on animals, modifying their physiology through a decrease of their prolificacy and an increase of the mortality at birth (Hoffmann, 2010). High temperatures can reduce oestrous behaviour, alter the ovarian follicular development, compromise the competence of oocyte and inhibit the development of embryo (Hansen *et al.*, 2001). Farrowing rate is an interesting reproductive trait in porcine livestock that can be defined as getting pregnant from first insemination and maintaining this pregnancy until farrowing. Bloemhof *et al.* (2012) estimated heritability values for farrowing ranged from 0.05 to 0.19 in different purebred and crossbred pig lines. They also observed that farrowing rate can be affected by high temperatures.

Iberian pigs are well adapted to high temperatures, since they have been living in the Southwest of the Iberian Peninsula where the temperatures on summer (June-August) can reach up during several days between 35 and 45 °C. However, negative effects of high temperatures on farrowing rate, total piglets born and piglets born alive have been reported (Piñán *et al.*, 2021).

Therefore, the objective of the current study was to analyse the effect of heat stress on farrowing rate of an Iberian commercial line and to estimate the genetic parameters for this trait.

Materials & methods

Data. In the present study, data of Iberian pigs from a closed commercial population (SRC line) fattened in an extensive traditional system was used. A total of 13,290 first insemination records from 3,009 sows inseminated between August 2009 and February 2020 with semen of Iberian or Duroc sires was available. Iberian semen was collected from sires living in the same farm that sows that were inseminated the same day or the day after the semen was collected. However, semen from Duroc was bought to artificial insemination centres, therefore the semen, after being collected, had to be cooled and shipped from the insemination centre to the farm. Farrowing rate was defined as a binary trait being 1 when the first insemination resulted in a pregnancy with a gestation length between 108 and 117 days and a total number of piglets born alive

between 1 and 13. On the other hand, farrowing rate was defined as 0 when the first insemination did not result in a pregnancy. The records not fulfilling these conditions were removed and, therefore, 9,838 and 3,153 records registered as 1 and 0, respectively, were available.

The sows were allocated on farrowing houses on a farm situated in the north of Huelva province (Spain). Although the insemination was carried out into sheds, the sows were located in outdoor ground parks. Temperature (T°) and relative humidity (RH) at insemination was collected from the closest public weather station (*El Campillo;* https://n9.cl/g4xdl). The daily temperature-humidity index (THI) measured in degrees Celsius (°C) was estimated based on the following formula according to Ravagnolo and Misztal (2000):

$$THI(°C) = T(°C) - [0.55 - (0.0055 \times RH)] \times [T(°C) - 14.5]$$

Heat load quantification. Heat stress effects were estimated through heat load (H). Daily heat load is defined as the number of degrees surpassing a given threshold of THI (THI0) on the insemination day. Heat stress effects on farrowing rate were assessed using the following generalized mixed model with binomial distribution:

$$y_{ijk} = C_i + S_j + H_k + e \quad (1)$$

where y_{ijk} is the farrowing rate of the individual y at the oestrus cycle number i, sire j and heat load k, C_i is the insemination cycle number (1, 2, 3, 4, 5, 6, 7, ≥8), S_j is the sire type used for the insemination (Iberian or Duroc) and H_K is the heat load (up to 11 levels). Four models were fitted according to four different THI0 (16, 18, 20 and 22 °C) and the most adequate model was selected through an Akaike Information Criterion (AIC) analysis. The statistical analyses were carried out using *glmer* function in Rstudio (RStudio Team., 2020).

Genetic parameter estimation. The following Bayesian threshold animal model was fitted for liability (L)

$$L = Xb + Z_d a_d + W_p p_p + e \quad (2)$$

where L is the liability for farrowing rate, b are the systematic effects of the insemination cycle number, sire and heat load, a_d is the vector of the direct additive genetic effects, p is the vector of the maternal permanent random effects and e the vector with the residual effects. X, Z_d and W_p are the incidences matrix. The analyses were carried out using the software TM (Legarra *et al.*, 2011) and convergence were assessed by visual inspection and estimating the Z criterion of Geweke.

Results

Average farrowing rate was equal to 0.76 in the whole population. The farrowing rate was lower when Duroc sires were used for insemination (0.64) than when Iberian sires were used (0.79). A total of 19 sires did not have breed information available. It is worth to mention that Duroc sires were less used for insemination than Iberian ones (2,974 vs 10,002) and the use of these breeds was not uniform along the year (Figure 1A) or at a particular THI value (Figure 1B).

The AIC values for different THI0 ranged from 13,789.98 to 13,929.37. The optimal AIC value was the one for a THI0 equal to 16 °C. According to this, heat load fitting a threshold of 16 °C was used for estimating heritability and permanent environmental parameters for farrowing rate (liability). As a result, low values

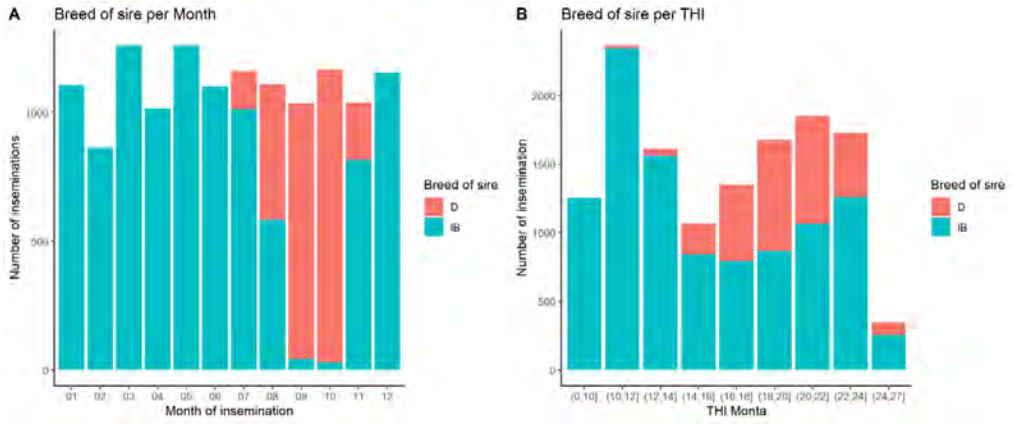

Figure 1. Number of inseminations per sire breed (Duroc or Iberian) (A) along months of insemination or (B) per THI.

were observed for both parameters, being h^2 equal to 0.039 (95% HPD: 0.018/0.065) and the permanent environmental effects of the sow (p^2) equal to 0.026 (95%HPD: 0.006/0.053).

Cycle number effects were inferred as difference from the first one. First cycle showed a higher liability than the second one, however, for cycle numbers greater than 6, their liability increased compared to the first cycle number.

The difference in liability for farrowing rate of Duroc respect Iberian sires was equal to -0.396 (95%HPD = -0.458/-0.334). There was also an effect of heat load on the liability for farrowing rate being lower when the heat load increases (Figure 2).

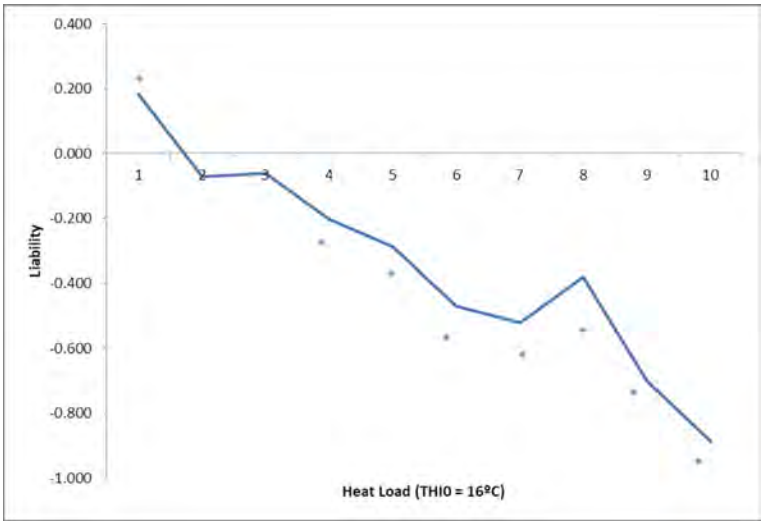

Figure 2. Posterior means of heat load (THI0 = 16 °C) deviated from the lowest category (heat load = 0) on liability for farrowing rate. *Bayesian posterior probability greater or lower than zero (PProb>0).

Discussion

In the population analysed, we observed a 76% of farrowing rate after the first insemination, this is a relevant trait because it is a direct measure of non-productive sow days when a sow is not lactating or gestating (Wilson *et al.*, 1986). Therefore, it is important to improve it. The heritability of liability for FR observed in the present study is low (0.03) and it agrees with the values reported by other authors (Holm *et al.*, 2005 and Bloemhof *et al.*, 2012).

The AIC analyses showed that a model including heat load with a THI0 of 16 °C had a better quality than those with THI0 of 18, 20 or 22 °C. The inclusion of heat load in the Bayesian threshold model revealed that heat load affects the farrowing rate. Although an increase in liability was observed when heat load was equal to 1 °C respect heat load equal to 0 °C. The liability for farrowing rate heavily decreases for heat load values equal or higher than 4 °C which agrees with the results reported by Bloemhof *et al.* (2012) in other pig breeds.

In addition to this, a lower farrowing rate was associated to Duroc semen. Duroc semen unlike the Iberian one, was refrigerated and then shipped to the farm, therefore, it cannot be discriminated whether the effects observed on the farrowing rate are due to Duroc breed itself or the semen handling. The results showed here point out that THI has to be taken into account for improving farrowing rate and other reproductive traits in Iberian pigs.

796. Whole-genome screening for resilience against PRRSV outbreaks in breeding sows

M. Laplana*, R. Ros-Freixedes, J. Estany, L.J. Fraile and R.N. Pena

Department of Animal Science, University of Lleida-Agrotecnio-CERCA Center, 25198 Lleida, Catalonia, Spain; marina.laplana@udl.cat

Abstract

The porcine reproductive and respiratory syndrome virus (PRRSV) has a world-wide impact in health and productivity of growing pigs and sows. A genetic component in the resilience of sows facing a PRRSV outbreak has been reported. In this study, we aimed to identify genetic variants associated with resilience in sows using data on the stability of reproductive performance (SRP) during a PRRSV outbreak as a proxy for resilience. Forty-eight Landrace × Large White sows with extreme SRP phenotypes underwent whole-genome sequencing at a coverge of 7X. A genome-wide association study (GWAS) for the SRP phenotype identified 44 variants associated with the 'stable' phenotype. Some candidate genes are related to disease, cell structure, proliferation and migration and immune response. The identification of genetic markers can be useful to identify resilient sows that can successfully cope with a PRRSV outbreak without compromising their health status or productivity.

Introduction

Pork is one of the most common sources of animal protein for human consumption, thus, making necessary a sustained increased in pig production to provide the growing global food demand. One strategy to achieve this is improving the efficiency of the pork production sector with animals that can face stressors and recover in a short period of time without altering their normal physiology and their productivity, also known as resilient animals.

Among the potential stressors that can challenge a farm, infectious agents can have dramatic consequences leading to large losses and compromising pig welfare. One of the common viral pathogens circulating in the swine production systems is the Porcine Reproductive and Respiratory Syndrome Virus (PRRSV), which can cause endemic and/or epidemic infections. In sows, PRRSV infection can lead to respiratory problems as well as reproductive failure, including embryonic death in early gestation (Lunney *et al.* 2010; Chand *et al.* 2012), foetal death and abortions in late gestation, early farrowings, and elevated preweaning mortality (Karniychuk *et al.* 2011; Karniychuk and Nauwynck 2013). Although a PRRSV vaccination scheme is a common control measure, vaccines have a limited power to control this disease (Nan *et al.* 2017) due, in part, to the high mutation rate of the virus and the kinetic of the immune responses.

The role of genetic variability of the host in the outcome of PRRSV infection in pregnant sows has been demonstrated (Serão *et al.* 2014; Abella *et al.* 2019; Pena *et al.* 2019). In addition, several DNA markers associated with resilience to PRRSV infection in reproductive sows have also been reported (Laplana *et al.* 2020). In this line, we aimed to provide a global characterization of the genetic variability of pig resilience to PRRSV infection and their combined effect in reproductive traits. For this, we used a low-coverage (7X) whole-genome sequencing approach to unravel to most promising genetic DNA markers that could be implemented in the future in selection or crossbreeding schemes to improve resilience under the challenge of a PRRSV outbreak.

Materials & methods

Animals. A group of 305 Landrace × Large White sows from a PRRSV-positive stable production farm were included in the study. Main characteristics of the animals and farm have been previously described (Abella *et al.* 2019). Reproductive data was collected from 2016 to 2018, with no major pig diseases with the exception of a PRRSV outbreak at the end of the screened period, which lasted 15 weeks. PRRSV exposure during the outbreak was confirmed by antibody detection in all sows as previously described (Abella *et al.* 2019). Data on 1,464 parities were recorded including the number of stillborn (NSB) and mummified (NMU) piglets per litter. The total number of lost piglets per litter (NLP) was calculated as the sum of NSB and NMU.

In order to discover genetic markers related to resilience, the stability of reproductive performance (SRP) was used as a proxy of PRRSV resilience. SRP was assessed by the ability of maintaining stable NLP during the PRRSV outbreak. SRP score was calculated for each sow as follows: NLP in outbreak – mean NLP in non-outbreak farrowings. Animals were ranked according to their SRP score and were classified as 'stable' sows when SRP score <1 and 'non-stable' sows when SRP score >1. Finally, a total of 48 sows with extreme reproductive phenotypes, including 22 stable and 26 non-stable sows, were selected from the top and bottom of the ranking for whole-genome sequencing (WGS).

Sequencing. Low-coverage (7X) WGS was performed in NovaSeq 6000 sequencing system (Illumina) with 150 bp paired-end reads using standard Illumina protocols for library preparation, sequencing and initial quality check in the Centro Nacional de Análisis Genómico (CNAG-CRG, Barcelona, Spain). Sequence reads were processed with Trimmomatic (Bolger *et al.* 2014) to remove adapter sequences and mapped to the reference genome *Sscrofa11.1* using the BWA-MEM algorithm (Li 2013). Duplicates were marked with Picard. Single nucleotide polymorphisms (SNPs) and short insertions and deletions were identified with the variant caller GATK HaplotypeCaller (GATK 3.8.0) (DePristo *et al.* 2011; Poplin *et al.* 2017) using default settings separately for each individual. After filtering out variants with a mean coverage 3 times greater than the average global coverage with VCFtools (Danecek *et al.* 2011), we retained biallelic variant positions for further analyses.

Genome-wide association analysis and annotation. Plink software version 1.9 was used to filter out variants with minor allele frequency below 0.1 and call rate below 0.8. Next, a relatedness matrix was constructed in GEMMA v0.98.1 software from a reduced Plink dataset pruned based on linkage disequilibrium (windows of 200 variants, sliding by 25, linkage disequilibrium r^2 of 0.1 and genotyping rate ≥99.99%). Two genome-wide association analyses (GWAS) were performed in GEMMA including 14,689,130 variants. The first GWAS (GWAS-1) was performed considering SRP as a categorical score (stable and non-stable). The second GWAS (GWAS-2) was performed using the quantitative value of SRP. Variants were considered associated with the phenotype when P-value$<10^{-6}$. Genomic regions were defined by the overlap of associated variants expanding the variant coordinates ±1 Mb. Genes were retrieved using Biomart tool from Ensembl (EMBL-EBI), release 104, and Pig Sus scrofa 11.1 genes and annotated with Ensembl Variant Effect Predictor and the Enrichr tool.

Results

We identified a total of 25,568,592 biallelic variants, adding up to a total of 21,469,571 SNPs and 4,099,571 indels in the sequenced animals. With the GWAS-1 we identified 44 variants associated with the classification by the stability of reproductive performance (SRP) distributed in 13 chromosomal regions (Figure 1). To note that 27.3% of the associated variants have not been previously annotated in the Ensemble database.

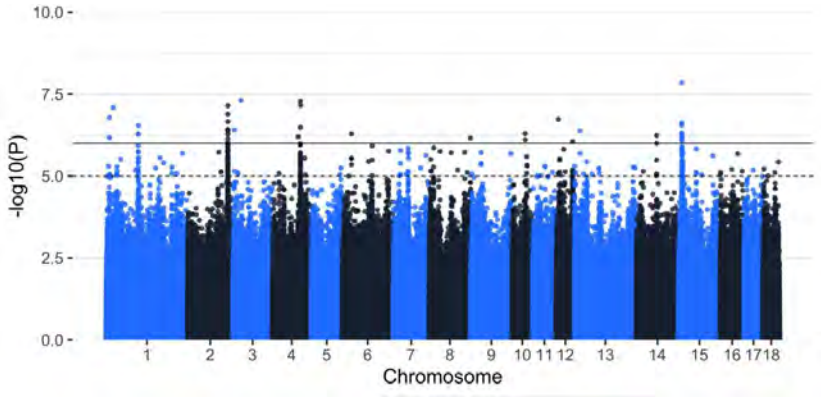

Figure 1. Manhattan plot of genome-wide -log10(*P*-values) for the stability of reproductive performance (SRP) in GWAS-1 (stable vs non-stable sows). The horizontal solid line represents the significance threshold (*P*-value=10^{-6}), the dashed line represents the suggestive threshold *P*-value (10^{-5}).

Next, associated variants were summarized in 16 genomic regions. Four regions had the strongest evidence of association. Briefly, in region 3 (1:9887943-11899689) the lead SNP, 1:107892069, also known as rs329563388, is located in the third intron of the *peptidylprolyl isomerase B* gene (*PPIB*) and is also a 3'UTR variant of *sorting nexin 22* gene (*SNX22*), which is related to intracellular trafficking, degradation of the extracellular matrix and collagen chain trimerization pathways as well as to osteogenesis imperfecta disease among others. Region 4 (2:133860837-136261458) contains twelve variants associated with SRP. The lead SNP in this region is 2:135261458, known as rs336589103, and located in the second intron of *AF4/FMR2 family member 4* gene (*AFF4*). Region 8 (4:93237379-96309123) contains 3 associated variants and expands 3.07 Mb. The lead SNP is 4:94237379 or rs322037463, which is located in intron 23 of *Gon 4 like* gene (*GON4L)* and relates to transcriptional repressor activity, which is required for B cell lymphopoiesis. Finally, region 16 (15:10187282-12903678) contains twelve associated variants. The lead SNP, 15:11187282, also known as rs692795800, is located in intron 42 of the *LDL receptor related protein 1B* gene (*LRP1B*). This gene has been reported as a putative tumor suppressor gene in humans as it is involved in cell proliferation and migration. All these genes are positional and functional candidates for SRP.

In order to identify more candidate genes for reproductive performance stability, we studied the functional annotation of genes positioned in the 16 genomic regions. GO analysis reported enrichment of genes that participated in immunoglobulin and other immune and growth factor receptor activity, catalytic activity acting on tRNA and ephrin receptor binding. Furthermore, we found enrichment in KEGG pathways involved in the regulation of the immune response and cell proliferation, division and survival, growth, angiogenesis and immunity.

Moreover, in GWAS-2 using SRP phenotype values we identified 4 variants associated with the reproductive outcome of the sow during the PRRSV outbreak, which overlapped with the region in chromosome 2 (2:133598288-135771079) associated with the SRP categorical classification.

Conclusions

Our study provides evidence of the genetic background on reproductive stability during a PRRSV outbreak. Identified associated genomic regions contain genes with functions related to immune response regulation, cell proliferation, division, survival and growth, all of them with putative impact on reproductive outcome.

Further studies are required to refine and validate these findings in larger populations, as well as their applicability to identify the sows that can be more resilient against PRRSV infection.

Abstract

This study estimates phenotypic and genetic correlations of different components of the immune system of young healthy pigs, evaluated by various immunoassays, with an aim towards revealing a deeper understanding of the immune system of pigs and the role of immunoassays in predicting disease resilience. The composition of circulating immune cells, their phagocytic activity, and immune response measured by the High Immune Response (HIR™) technology were found to be heritable. The percentages of granulocytes and neutrophils in blood had high positive phenotypic and genetic correlations with each other and with the percentage of cells that showed phagocytosis activity. The HIR tests showed antibody-mediated immune response to be positively genetically correlated with cell composition traits, while cell-mediated immune response had a positive genetic correlation with only % eosinophils. These results suggest that immunoassays conducted on young healthy pigs provide important genetic information on their immune response profiles.

Introduction

Infectious diseases reduce animal welfare and disrupt production goals in pork production, thereby imposing a significant economic challenge to the industry. Thus, selecting pigs that are more resilient to disease i.e. with the ability to maintain performance while diseased (Albers *et al.*, 1987, Mulder and Rashidi, 2017), has gained traction. Over the years, many immunoassays have been developed that evaluate different aspects of the immune system, either *in vitro*, such as phagocytosis tests, or *in vivo*, such as the High Immune Response (HIR™) technology, which measures both antibody-mediated immune response (AMIR) and cell-mediated immune response (CMIR) (Schmied *et al.*, 2018), capturing critical aspects of the immune system to improve resilience (Wilkie and Mallard, 1999). Schmied *et al.* (2018) showed that HIR tests can identify pigs with superior capacity for immune response, and decreased mortality when disease challenged. Gorlov *et al.* (2021) showed that high phagocytic activity of cells is associated with a high innate immune status. Against this background, the objective of this study was to estimate phenotypic and genetic correlations among immune response traits in young healthy pigs based on various immune assays, to enhance our knowledge of the different aspects of the immune system regarding their potential as genetic indicator traits for disease resilience.

Materials & methods

The data used were obtained in a large research project that aims to understand the genetic basis of, and identify indicators of, disease resilience in a wean-to-finish polymicrobial natural disease challenge model (Putz *et al.*, 2019, Cheng *et al.*, 2020). The immune assays investigated here were conducted on young healthy Landrace × Yorkshire barrows from seven breeding companies, comprising PigGen Canada, while housed in a quarantine nursery before disease challenge. All pigs were genotyped using a 650K Affymetrix Axiom Porcine Genotyping Array. Details on genotype quality control are in Putz *et al.* (2019).

Immunoassays. The immunoassays investigated in the quarantine nursery were: the proportion of immune cells in blood, the phagocytotic activity of those cells, and the HIR test. Blood samples for cell composition and phagocytosis tests were collected on the 994 pigs described by Lim *et al.* (2021) at ~26 days of age. Using flow cytometry, the phagocytosis test quantified the % of cells able to capture FITC-labelled opsonized *Escherichia coli* bacteria (Phag%) and phagocytic activity of those cells based on mean fluorescence intensity (PhagMFI). Based on morphology, leukocyte subpopulations of monocytes, lymphocytes, neutrophils, granulocytes, and eosinophils were also quantified and analyzed for phagocytic activity. For the HIR test, AMIR was evaluated by an enzyme linked immunosorbent assay and CMIR by measuring the change in skin-fold thickness due to cutaneous delayed-type hypersensitivity (Schmied *et al.*, 2012,2018). HIR phenotypes of 1397 pigs (cycles 5-7 of Cheng *et al.*, 2020) were used. In total, 708 pigs had both phagocytosis and HIR data.

Statistical analyses. Variance components and correlations were estimated by GBLUP using ASReml 4.1, with the fixed effect of batch, the covariate of entry age, and random effects of pen by batch, additive genetics, and litter, with the genomic relationship matrix of Cheng *et al.* (2020). For phagocytosis test traits, the fixed effect of assay date was also included. Technician was included as a fixed effect for AMIR and CMIR, along with serum antibody activity before antigen injection as a covariate for AMIR and a negative control for CMIR.

Results & discussion

Table 1 shows estimates of heritability and of phenotypic and genetic correlations among the cell composition and phagocytosis traits. Heritability estimates were similar to those reported on the same data by Bai *et al.* (2022). The phenotypic correlation of % lymphocytes was highly positive with % granulocytes (the genetic correlation estimate did not converge) and highly negative with % neutrophils, as was the genetic correlation. These findings agree with Koomkrong *et al.* (2017), who found a highly negative relationship between % neutrophils and % lymphocytes. Within cell type, %Phag and PhagMFI showed moderate positive phenotypic and genetic correlations (green cells in Table 1). The only strong positive genetic correlation of cell composition with phagocytic activity was observed for monocytes (0.39 for % and 0.49 for MFI). Phenotypic correlations were low between most phagocytosis traits, but genetic correlations ranged from low to high, but with generally high SE. Phenotypic and genetic correlations of the % phagocytizing cells were highly positive with % granulocytes and % neutrophils, and highly negative with % lymphocytes. Thus, it is consistent with Uribe-Querol and Rosales (2020) that show the essential role of granulocytes and neutrophils is that of phagocytosis.

Both AMIR and CMIR had weak phenotypic correlations with cell composition and phagocytosis traits (Table 2). However, AMIR showed moderate positive genetic correlations with most cell composition traits, while CMIR was moderately genetically correlated with only % eosinophils (0.24±0.30). Both AMIR and CMIR had moderate genetic correlations with phagocytizing activity of eosinophils (% and MFI) but low genetic correlations with phagocytizing activity of other cells. Note that, although AMIR is based on circulating antibody levels, AMIR itself occurs in secondary lymphoid organs and, therefore, may not relate directly with cell composition and phagocytosis activity in blood.

Significant estimates of heritability and of genetic correlations of immunoassay traits collected on young healthy pigs clearly indicate the substantial genetic variation that exists for immune response. Uncovering immune traits measured on young healthy pigs that are indicators of resilience will allow for the selection of pigs capable of maintaining performance traits during disease. Ongoing analyses investigate genetic relations with other immunoassay traits that were measured on young healthy pigs in this project, such as proliferation of peripheral blood mononuclear cells after mitogen stimulation (Jeon *et al.*, 2021) and natural antibody levels (Chen *et al.*, 2020) to provide a full understanding of all aspects of a young healthy pig's immune system.

798. Sequencing-based genome-wide association study for resilience indicators in growing pigs

H. Laghouaouta*, R.N. Pena, R. Ros-Freixedes, L. Fraile and M. Laplana

Department of Animal Science, University of Lleida-Agrotecnio-CERCA Center, 25198 Lleida, Catalonia, Spain; houda.laghouaouta@udl.cat

Abstract

Resilience refers to the ability of animals to withstand stressors and rapidly recover their production. There is a growing interest in the improvement of resilience through selective breeding. However, there is no straightforward quantifying method. The body weight deviation and the increment of the acute-phase protein haptoglobin after applying a common vaccine challenge were used as resilience indicators in growing pigs. We assumed that resilient pigs would maintain their productivity and show a low activation of haptoglobin. Whole-genome sequencing-based association analyses were performed for the suggested resilience indicators of the most resilient (n=40) and susceptible (n=40) pigs. We identified a total of 28 associated genomic regions harbouring relevant candidate genes involved in the immune response (*CCL20*, *CD82*, *INAVA*…) and growth (*IGFBPL1*) pathways. Our study advances our understanding of the genetic background of resilience and corroborates the strong relationship between resilience, immune response and growth.

Introduction

Selective breeding for improved resilience would provide resistant animals with robust phenotypes (Mulder and Rashidi, 2017), reducing the economic losses and increasing the profitability of the production systems. However, there is no direct measure of resilience. Productivity-related traits and immunophenotypes reflecting perturbations caused by stressors have been proposed as resilience indicators in several livestock species (Berghof *et al.*, 2019; Chen *et al.*, 2020; Poppe *et al.*, 2021; Putz *et al.*, 2019). We suggested the body weight deviation (ΔBW) and the increment of the acute-phase protein haptoglobin (ΔHP) after applying a common vaccine challenge as resilience indicators in growing pigs. Pigs that maintained a steady production (high ΔBW) and had a minor activation of haptoglobin (low ΔHP) were deemed resilient. In contrast, pigs with a depressed production (low ΔBW) and a high activation of haptoglobin (high ΔHP) were deemed susceptible (Laghouaouta *et al.*, 2021). Heritability estimates were moderate for ΔBW (0.33) and low-to-moderate for ΔHP (0.16), indicating that they are genetically controlled and may be improved through selective breeding.

There is scarce information about the genetic background of resilience. A few association analyses were performed using resilience indicators in pigs such as antibody levels (Chen *et al.*, 2020; Sanglard *et al.*, 2020) and health-related traits (Ballester *et al.*, 2020). These studies detected promising candidate genes related to the immune response pathway. In this study, we used whole-genome sequencing data of pigs with extreme resilience indicators (ΔBW and ΔHP) to unravel the genetic background of resilience by identifying associated genomic regions and candidate genes.

Materials & methods

Animals and phenotypes. A total of 540 Duroc pigs at 10 weeks of age (71.4±2.4 days) were randomly placed into five batches of 104 to 111 pigs each. Pigs were reared under the same conditions and had *ad libitum* access to commercial diets. After two weeks (85.6±2.4 days of age), 445 pigs were challenged with an attenuated Aujeszky vaccine (Auskipra, Laboratorios Hipra, Amer, Girona) and 95 control pigs were inoculated with phosphate-buffered saline. The resilience indicators ΔBW and ΔHP were calculated for each challenged pig as described in Laghouaouta *et al.* (2021).

DOI: 10.3920/978-90-8686-940-4_798, © H. Laghouaouta *et al.* 2022

Both ΔBW and ΔHP were simultaneously considered to select 80 pigs with extreme response towards the challenge (40 resilient and 40 susceptible). For each batch, the eight most resilient pigs with the highest ΔBW and the lowest ΔHP values and the eight most susceptible pigs with the lowest ΔBW and the highest ΔHP values were selected.

Genotypes and quality control. Pigs with extreme response to the challenge were sequenced with paired-end reads using the NovaSeq 6000 platform (Illumina, San Diego, CA, USA) at an average coverage of 8.5X. Adapter sequences were removed using Trimmomatic (Bolger *et al.*, 2014). Reads were aligned to the *Sscrofa11.1* reference genome using the BWA-MEM algorithm (Li, 2013) and duplicates were tagged using Picard Tools. Variant calling was performed with the GATK Haplotype Caller to identify single nucleotide polymorphisms, insertions and deletions (Depristo *et al.*, 2011). Further, variants with a minor allele frequency below 0.2 and a missing genotyping frequency above 0.1 were filtered out using PLINK (Chang *et al.*, 2015). After quality control, a total of 80 individuals and 7,986,234 variants remained in the dataset.

Whole-genome association study. Association analyses were performed for the resilience indicators by fitting a univariate linear mixed model using GEMMA (Zhou and Stephens, 2012). Data from the extreme pigs were analysed to investigate the genetic background of resilience using the continuous resilience indicators (ΔBW and ΔHP) and the categorical pigs' response to the challenge (resilient or susceptible). Phenotypes were adjusted for the batch fixed effect (5 levels). Associated variants were identified at a *P*-value threshold of 10^{-5}. Associated genomic regions were determined by grouping significant variants within 500 kb and extending each genomic region by 200 kb on each side to consider nearby genes. Candidate genes within the associated genomic regions were retrieved from the Ensembl database. Gene ontologies were investigated using DAVID database (Jiao *et al.*, 2012) and a literature search.

Results

Whole-genome association analyses identified 61, 32 and 69 associated variants with ΔBW, ΔHP and the classification of each pig by their response to the challenge (resilient/susceptible groups), respectively (Figure 1). Six genomic regions at pig chromosomes (SSC) 2, SSC3, SSC9, SSC14, SSC15 and SSC18 were associated with ΔBW and 13 genomic regions at SSC1, SSC2, SSC4, SSC8, SSC9, SSC10, SSC11 and SSC15 were deemed associated with ΔHP. Among them, two genomic regions at SSC9 (27.4-27.8 Mb) and SSC15 (128.8-129.2 Mb) were associated with both ΔBW and ΔHP. Besides, sixteen genomic regions were found to be associated with the pigs' response to the challenge, some of which overlapped with the associated genomic regions obtained for ΔBW (27.4-27.8 Mb at SSC9 and 128.6-129.2 Mb at SSC15) and ΔHP (238.9-239.3 Mb at SSC1, 18.2-18.9 Mb, 58.7-59.3 Mb and 129.0-129.7 Mb at SSC8, 27.4-27.8 Mb at SSC9, 22.6-23.4 Mb at SSC10, 64.8-65.2 Mb at SSC11 and 128.6-129.1 at SSC15). The associated genomic regions harbour several candidate genes involved in immune response and growth pathways such as C-C motif chemokine ligand 20 (*CCL20*), CD82 antigen (*CD82*), innate immunity activator (*INAVA*) and insulin-like growth factor binding protein-like 1 (*IGFBPL1*).

Discussion

The aim of this study was to unravel the genetic background of resilience in pigs by identifying genomic regions and candidate genes associated with resilience indicators. Association analyses were conducted using whole-genome sequencing data of the most resilient and susceptible pigs to increase the detection power of associations between variants and phenotypes.

A total of 28 associated genomic regions were detected across the pig genome, indicating the polygenic nature of resilience. That was expected since resilience is a complex trait regulated by various biological processes (Colditz and Hine, 2016). Since pigs were selected using simultaneously ΔBW and ΔHP, there

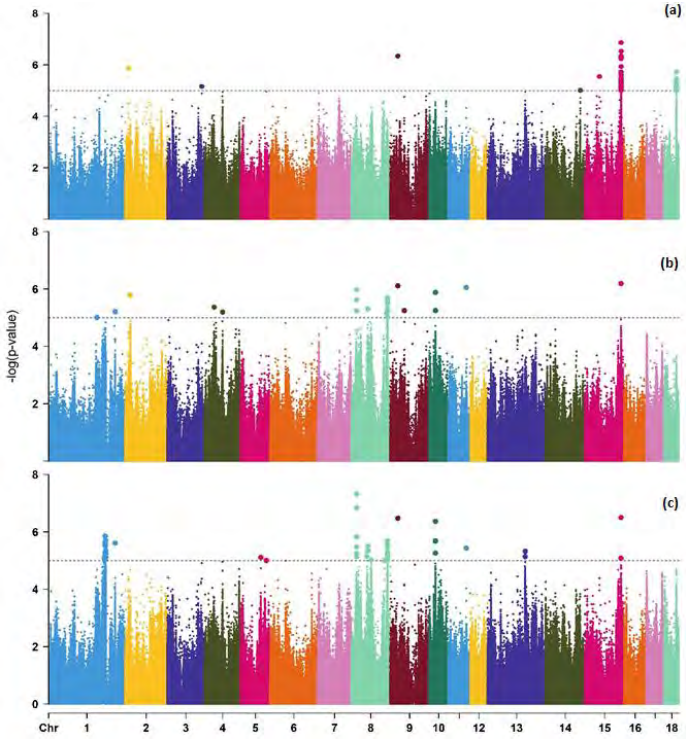

Figure 1. Manhattan plot for the genome-wide association study for (a) the body weight deviation (ΔBW), (b) the haptoglobin increment (ΔHP) and (c) the pigs' response after the vaccine challenge.

was a partial overlap between the associated genomic regions. The associated genomic regions harboured relevant candidate genes related to the immune response and growth pathways, which corroborates the relationship between resilience, the immune system and growth (Dantzer *et al.*, 2018; Zheng *et al.*, 2021). In addition, the associated genomic regions at SSC5 (71.8-72.2 Mb) and SSC8 (18.2-18.9 Mb, 55.4-55.8 Mb and 58.7-59.3 Mb) overlap with haptoglobin concentration QTL in pigs (Wimmers *et al.*, 2009). Further validation of the identified associations is needed in order to apply these markers in selection breeding programs under field conditions.

799. First parity indicator traits for longevity in crossbred sows

M.W. Iversen* and E.G. Enger

Norsvin, Storhamargata 44, 2317 Hamar, Norway; maja.iversen@norsvin.no

Abstract

Longevity is an important trait in sows, for economical as well as animal welfare reasons. Due to early replacement based on breeding values, longevity data collected in purebred nucleus populations is often useless. Collecting data in crossbreds is an alternative. This study looked at alternative traits measured in first parity crossbred sows and their genetic correlations to longevity traits. Traits investigated were litter size, weight and fat depth at insemination and farrowing. Results show positive genetic correlations (range 0.38-0.76) between longevity and first parity observations of litter size, backfat and weight at insemination, backfat at farrowing, and gain in backfat during pregnancy. A reduction in backfat during first lactation had a negative correlation with longevity. These results indicate that backfat and weight at first insemination, or backfat at first farrowing can be used as indicator traits for longevity in sows, in addition to performance traits such as litter size.

Introduction

Longevity in sows is a very important trait because keeping the sow in the herd for an extra parity is cheaper than replacing it (Hoge and Bates, 2011), provided it still performs adequately. It is challenging to measure in purebred nucleus herds however, because sows are often replaced based on breeding values early in life, before they have a chance to show their potential for longevity. Therefore, collecting longevity information in crossbred sows may be a good alternative. Indicator traits measured early in life that are correlated to longevity may also be a good alternative and will improve the accuracy of the breeding values of related purebreds for longevity. Another challenge with longevity or culling is that it is affected by many factors other than genetics such as health, behaviour and reproduction, as well as production traits having an influence on culling decisions (Yazdi *et al.*, 2000). The aim of this study was to investigate new potential indicator traits for longevity in crossbred sows.

Materials & methods

Animals and data. Data was from one purebred dam line (A) and their F1 crossbred (X) with purebred dam line B. For purebred animals (A), only longevity data was used (53,186 animals). Longevity was defined as; LGY12 – whether (0 or 1) the sow was inseminated for a second litter within 85 days after first farrowing, LGY13 – how many litters the sow had within 270 days after first farrowing (1-3), and LGY14 – how many litters the sow had within 420 days after first farrowing (1-4). Crossbred sows had data from five farms on total number born (1,805 animals), total number born alive (1,805 animals), weight (in kg, 874 animals) and backfat (in mm, 858 animals) at insemination, backfat at farrowing (in mm, 1,016 animals), and longevity (69,595 animals) as described above.

Statistical analysis. All models were analysed in ASReml (Gilmour *et al.*, 2009). Pedigree-based relationships were used for variance component estimation. Traits were analysed by single-trait models to determine initial variance components, and then each of the first-parity crossbred traits were analysed bivariate with each of the longevity traits. The following model was applied:

$$y = Xb + Zu + Vv + e,$$

R.F. Veerkamp and Y. de Haas (eds)

where y was a vector of observations, X, Z, and V, known incidence matrices; b, a vector of fixed effects (Table 1); u, a vector of random additive genetic effects, with $u \sim N(0, A\sigma_u^2)$, where σ_u^2 was the additive genetic variance and A was the additive relationship matrix (pedigree); v, was a vector of common litter effects, with $v \sim N(0, I_v\sigma_v^2)$, where σ_v^2 was the variance of common litter effects; and e, a vector of residuals, with $e \sim N(0, I_e\sigma_e^2)$, where σ_e^2 was the residual variance. Matrices I_v and I_e were identity matrices of the appropriate dimensions.

Results

Weight of the sows increased over time, with drops in weight after each farrowing due to piglets being born and loss of weight during lactation (Figure 1). All farms had similar trends, but one farm had lower weights on average compared to other farms. Backfat decreased with time (within pregnancy-phase) and was always highest at first insemination compared to later inseminations (Figure 2). Farm 2 had higher variations in changes in backfat and higher levels overall than other farms, and Farm 1 had lower variation and levels.

Using only crossbred data, estimates of heritability for the longevity traits were between 0.01 and 0.025. When purebred data was included, heritabilities for longevity were in the range 0.06-0.08. Genetic correlations between the longevity traits were 0.87 (0.06), 0.85 (0.07) and 0.99 (0.01) for LGY12 with LGY13, LGY12 with LGY14 and LGY13 with LGY14, respectively. Litter size, backfat depth at farrowing and insemination, weight at insemination and fat gain in pregnancy were positively correlated to longevity (Table 2). Fat reduction during first lactation was negatively correlated to LGY13 and LGY14 but did not have a significant correlation to LGY12.

Discussion

This study investigated the use of data from first parity crossbred sows as indicators for longevity. Backfat depth at first insemination and farrowing had a positive genetic correlation with longevity traits. This agrees with findings by others (Knauer *et al.*, 2010; Stalder *et al.*, 2005), who found that sows with higher

Table 1. Fixed and random effects[1] for all traits.

Trait[2]	Litter nr dam	Farm	Year first insemination	Age (days)	Days weighing to insemination	Animal	Year-season farrowing	Litter id
LGY12	F	F	F			G		R
LGY13	F	F	F			G		R
LGY14	F	F	F			G		R
TNB	F	F		FR		G	R	
NBA	F	F		FR		G	R

BFI	F	F		FR		G		R
WI	F	F		FR	FR	G		
FGP		F		FR		G	R	
FLL		F		FR		G	R	

[1] F = fixed effect; FR = fixed regression; R = random effect; G = genetic effect.

[2] Trait: LGY12, whether (0 or 1) the sow was inseminated for a second litter within 85 days after first farrowing; LGY13, how many litters the sow had within 270 days after first farrowing (1-3); and LGY14, how many litters the sow had within 420 days after first farrowing (1-4). TNB = total number born, NBA = number born alive, BFF = backfat depth at farrowing (mm), BFI = backfat depth at insemination (mm), WI = weight at insemination, FGP = backfat gain in pregnancy (mm), FLL = fat loss in lactation.

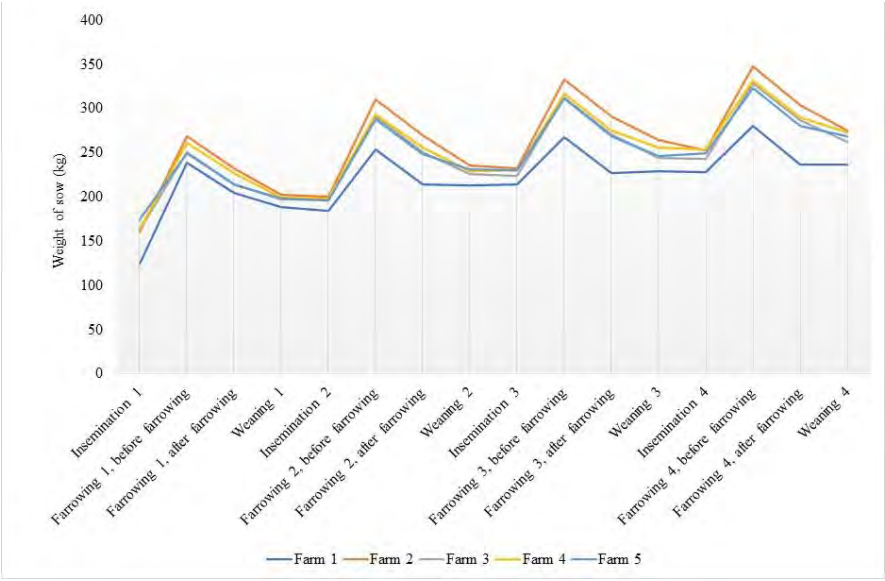

Figure 1. Average weight (kg) of sows measured for 4 litters across 5 farms.

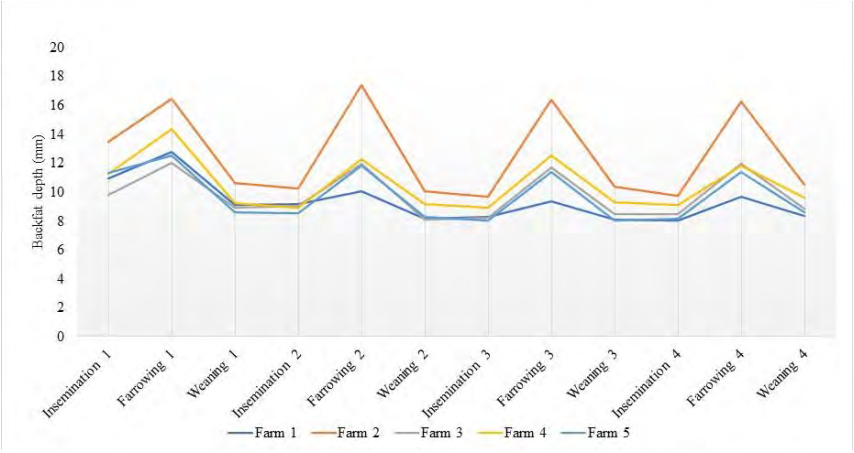

Figure 2. Average backfat depth (mm) of sows measured at different times for 4 litters across 5 farms.

backfat scored higher for number of lifetime litters and stayability. Backfat of sows decreased with age, and therefore, a focus on getting sows sufficiently fat before first insemination seems important to support longevity. Weight at first insemination was also positively correlated with longevity, thus larger sows (within age) may be favoured to improve longevity. However, selecting for these traits would result in larger adult size of sows, which is not necessarily positive. Fat reduction in lactation did not have a significant genetic correlation to LGY12 but was significant (and negative) for later parities. This may suggest that this is not an important factor for whether the sow gets inseminated for a second litter, but because backfat of sows decrease with time, it may have a bigger impact later in life. High weight loss in first lactation may lead to a smaller second litter (Schenkel *et al.*, 2010), which may influence selection decisions between second and third parity. Litter size at first parity was positively correlated with longevity and agrees with results found

Table 2. Heritabilities and genetic correlations (s.e.) between first parity traits and longevity.

Trait[1]	LGY12	LGY13	LGY14	h^2
Total number born	0.469 (0.170)	0.385 (0.174)	NS[2]	0.11 (0.04)
Number born alive	0.504 (0.177)	0.480 (0.178)	0.457 (0.184)	0.10 (0.04)
Backfat farrowing (mm)	0.487 (0.154)	0.426 (0.171)	0.469 (0.169)	0.38 (0.11)
Backfat insemination (mm)	0.569 (0.287)	NS	NS	0.16 (0.12)
Weight insemination (kg)	0.594 (0.116)	0.461 (0.140)	0.498 (0.136)	0.41 (0.11)
Fat gain pregnancy (mm)	NS	0.677 (0.230)	0.762 (0.229)	0.20 (0.10)
Fat loss lactation (mm)	NS	-0.5305 (0.186)	-0.588 (0.179)	0.32 (0.12)

[1] Traits: LGY12, whether (0 or 1) the sow was inseminated for a second litter within 85 days after first farrowing; LGY13, how many litters the sow had within 270 days after first farrowing (1-3); and LGY14, how many litters the sow had within 420 days after first farrowing (1-4).
[2] NS = not significant (estimates not significantly different from zero).

by others (Guo *et al.*, 2001). Not surprising, as sows with small litters at first parity are less likely to be inseminated for a second parity. In conclusion, backfat depth and weight at first insemination, and backfat depth at first farrowing are moderately to highly genetically correlated to longevity in sows and could be used as indicator traits to select for longevity.

800. protiPig: Genomic analyses of traits related to nitrogen utilisation efficiency in pigs

M. Schmid*, R. Weishaar, D. Berghaus, E. Haese, N. Sarpong, A. Kurz, J. Seifert, A. Camarinha-Silva, M. Rodehutscord and J. Bennewitz

Institute of Animal Science, University of Hohenheim, Garbenstrasse 17, 70599 Stuttgart, Germany; markus_schmid@uni-hohenheim.de

Abstract

One important goal of sustainable pig production is to reduce nitrogen emissions by improving the protein utilisation efficiency of the pigs. The presented study investigated the suitability of traits related to protein efficiency for pig breeding as well as their genetic architecture. A total of 508 F1-crosses descending from 20 Piétrain sires and Landrace dams were generated and phenotyped for nitrogen utilisation efficiency, blood urea nitrogen, and production traits including feed intake and conversion and daily gain. All individuals were genotyped for 60k SNPs. Variance components were estimated by applying mixed linear models and revealed moderate heritabilities for all traits. Significant genomic regions were mapped for blood urea nitrogen traits in genome-wide association studies. It appeared that measuring the blood urea nitrogen might be a suitable indicator trait to breed for an improved nitrogen utilisation efficiency.

Introduction

Nitrogen (N) emissions have negative impact on the environment and the health of individuals as they lead to air pollution, water eutrophication as well as many more consequences on ecosystems which compromise e.g. biodiversity. In agriculture, a great proportion of N emissions result from N excretion of farmed animals such as pigs. Ammonia is the major product of metabolic amino acid degradation and it is transformed into urea in the liver and excreted via the urine of pigs. Measuring the N intake and excretion enables to calculate the N retention and the N utilisation efficiency (NUE). Thereby, the blood urea nitrogen (BUN) concentration provides a relatively easy-to-measure indicator trait of NUE (Kohn *et al.* 2005). Besides effects of the diet, age and sex, NUE is moderately impacted by the genetics of the individuals (Ruiz-Ascacibar *et al.* 2017, Kasper *et al.* 2020).

protiPig is a multi-disciplinary project at the University of Hohenheim with the overall aim to improve the protein efficiency in order to reduce the negative impacts of N emissions and simultaneously reducing the required amount of feed protein that is edible for humans. As breeding for an improved protein efficiency of the animals is expected to be one potential way of achieving such goals (e.g. Sorg *et al.* 2021), first results regarding the genetic architecture and genetic parameters of traits related to this subject obtained in a large experimental study are presented.

Materials & methods

Experimental design and data set. A F1 cross population consisting of 508 individuals (females:barrows = 1:1) that descended from 20 sires of the German Piétrain population and German landrace sows was established within a period of 2.5 years and using 21 cohorts of pigs. The animals were born and housed at the Hohenheim University's experimental station Unterer Lindenhof under standardised conditions. Between 76 days of age and the day of slaughtering (on average 149 days), they were kept in single cages and fed *ad libitum* with barley-wheat-soybean meal-based diets with marginal lysine concentration in a 2-phase fattening period. The feed intake (FI) was recorded during the whole experimental phase. Body weights were determined was well as blood samples at three consecutive days were taken for BUN measuring in week 3 and 6 of the experiment. Thus, the sampling periods were placed in feeding-phase 1 and 2, respectively. The

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_800, © M. Schmid *et al.* 2022

average BUN value across the three samples in sampling period 1 (2) were considered as phenotypes and are denoted as BUN1 (BUN2) in the following. Further, the feed conversion rate (FCR) and daily gain (DG) were calculated. The NUE of all individuals was approximated by using formulas derived from N-balance data and blood metabolites of a subset of 56 individuals for which N input and output was quantified. All individuals were genotyped using the Illumina PorcineSNP60 BeadChip (Illumina, San Diego, CA). After data filtering, the phenotypes for the traits FI, FCR, DG, BUN and NUE of 475 individuals and their genotype information of 48,748 SNPs remained as the data basis for further analyses.

Statistical analyses. The variance components of the traits were estimated using ASReml (Butler *et al.* 2009) and the following mixed model:

$$y = X_b b + Z_{co} co + a + e \quad (1)$$

Thereby, y denotes the vector of phenotypic records, vector b contains the fixed effects (sex and age at slaughtering) and co the random cohort effects. The design matrices X_b and Z_{co} relate the effects to the observation and vector e contains the residuals. The random animal effect a was modelled as $a \sim N(0, G \times \sigma_a^2)$, with σ_a^2 being the additive-genetic variance and G the genomic relationship matrix according to VanRaden (2008). In order to estimate genetic correlations between the traits, the model was extended towards a bivariate model. The likelihood-ratio test was applied to test the significance of the heritabilities. Single marker genome-wide association studies (GWAS) were conducted for the N related traits by means of GCTA software (Yang *et al.* 2011). The model was

$$y = X_b b + g + e, \quad (2)$$

where b contains the fixed effect of the SNP to be tested, the effects of the sex, cohort and age at slaughtering, $g \sim N(0, G \times \sigma_g^2)$ denotes the random polygenetic effect and e is the residual vector. A leave-one-chromosome-out approach was applied to avoid a double-fitting of the tested SNP. Because a genome-wide significance level using Bonferroni methods is very stringent, additionally a nominal significance threshold was defined. SNPs were considered to be significantly trait associated when their *P*-values were $P<5\times10^{-5}$ or they exceeded the Bonferroni genome-wide threshold.

Results

All investigated traits were significantly heritable ($P<0.001$), with heritabilities ranging from $h^2=0.25$ for NUE to $h^2=0.47$ for DG. Because the heritability of BUN1 and BUN2 did not differ ($h^2=0.41$) and their genetic correlation was 0.99, the average values of all 6 BUN measures were also treated as one single trait (meanBUN). The heritability of meanBUN and its genetic and phenotypic correlations to the other traits as well as the standard errors are presented in Table 1. A significant negative genetic correlation was observed between meanBUN and NUE.

Genome-wide association studies revealed typical quantitative traits. Three genome-wide significant SNPs on chromosome 7 were detected for BUN2 and meanBUN, respectively. When the nominal significance level was applied, 26 SNPs were significantly associated with BUN2, of which 24 were located on chromosome 7. The other were on chromosome 2 and 5. All 16 nominally significant SNPs for meanBUN were detected on chromosome 7. Figure 1 shows the GWAS results for the BUN traits. No SNP was significantly associated with the trait NUE.

Table 1. Heritabilities[1] (diagonal), genetic[2] (below diagonal) and phenotypic (above diagonal) correlations as well as their standard errors (in parentheses) of the investigated traits average blood urea nitrogen (meanBUN), efficiency of nitrogen utilisation (NUE), feed intake (FI), feed conversion rate (FCR) and daily gain (DG).

	meanBUN	NUE	FI	FCR	DG
meanBUN	0.49 (0.09)	-0.39 (0.07)	0.07 (0.08)	0.15 (0.08)	0.18 (0.08)
NUE	-0.60* (0.13)	0.25 (0.07)	-0.13 (0.07)	<0.01 (0.08)	-0.11 (0.19)
FI	0.44* (0.14)	-0.29* (0.20)	0.40 (0.09)	-0.25 (0.07)	0.75 (0.03)
FCR	-0.06 (0.17)	0.01 (0.21)	<0.01 (0.19)	0.27 (0.07)	0.44 (0.06)
DG	0.33* (0.14)	-0.24 (0.19)	0.86* (0.05)	0.52* (0.14)	0.47 (0.09)

[1] Obtained from univariate analyses.

[2] Obtained from bivariate analyses.

* Significant genetic correlation ($P<0.05$).

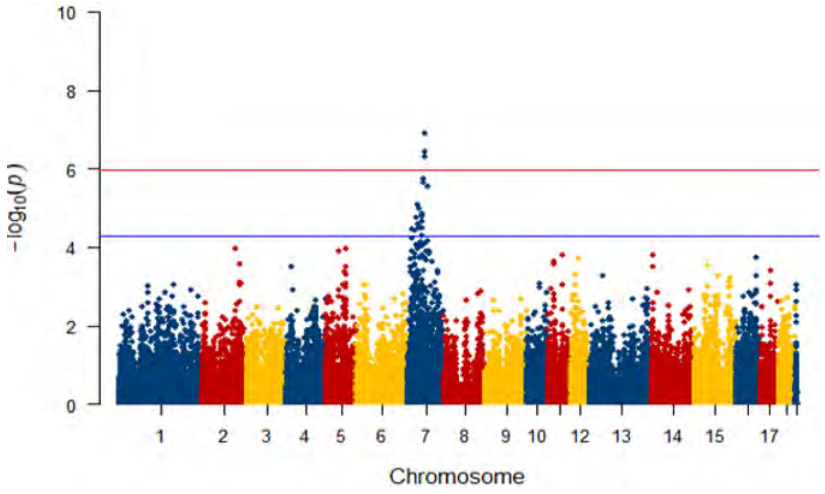

Figure 1. GWAS results of the blood urea nitrogen (averaged values across the two sampling periods, meanBUN).

Discussion

Moderate heritabilities with low standard errors were estimated for the N related traits BUN1, BUN2 and NUE, indicating that these traits have the potential as selection traits to breed for an improved utilisation of N and hence for protein efficiency in pigs. This agrees with Klindt *et al.* (2006) who estimated heritabilities for BUN at different timepoints and Kasper *et al.* (2020) who estimated population genetic parameters for NUE. However, due to the high degree of standardisation in the present study it should be further evaluated whether the findings are also valid in field data or in purebred populations. Of note, the present study implied a marginal lysine supply in order to allow the animals for expressing their potential of N utilisation. The genetic correlations between BUN1 and BUN2 were close to unity implying that the timepoint of phenotyping animals for BUN is less relevant. The results showed that low BUN levels come along with an increased NUE and are also correlated on a genetic scale which underlines the suitability of BUN as a heritable indicator trait for NUE. Genome-wide association studies revealed a polygenic architecture of the traits with many genomic regions, each having a small effect on the phenotype expression. Although strong

association signals were detected for BUN2 and meanBUN, suggesting candidate genes is not possible at this stage as the mapping precision was very low.

Adding gut microbiota data to further zoom into the mechanisms of protein efficiency in pigs is in progress within the *protiPig* project.

801. Genomic prediction of ham weight loss during dry-curing in heavy pigs

V. Bonfatti*, S. Faggion and P. Carnier

Department of Comparative Biomedicine and Food Science, University of Padova, viale dell'Università 16, 35020 Legnaro, Italy; valentina.bonfatti@unipd.it

Abstract

Excessive ham weight losses during dry-curing (WL) represent a loss of marketable product, hindering the quality of dry-cured hams. Bayesian regression models were developed for observed (OB) and infrared-predicted WL (IR), from the EBV of 640 and 956 crossbred pigs, respectively. The accuracies of direct genomic values of the purebred sires (DGV-PB) of crossbred pigs were estimated in a leave-one-family-out validation scheme. Accuracies were satisfactory and very similar for both traits. The correlation between the DGV-PB for IR and sire EBV for OB was slightly lower (0.318) than the correlation between the DGV-PB for OB and the sire EBV for OB (0.383). While genomic prediction of OB and IR can be equally suggested to be incorporated in future selection programs aiming at reducing WL, the use of IR allows a reduction in phenotyping costs, favouring the establishment of larger reference populations, with accuracies comparable to those achievable using OB phenotype.

Introduction

Genetic selection of pigs aiming at reducing excessive ham weight losses (WL) during dry-curing is challenging because measures of WL: (1) require the establishment of ham individual traceability systems throughout the dry-curing process, largely limiting the availability of phenotypes; and (2) can be obtained only after the completion of the entire dry-curing process, resulting in long generation intervals, with consequent penalizing effects on the response to selection. Recently, on-site infrared spectroscopy has demonstrated its effectiveness as a large-scale phenotyping tool for WL, by enabling cost-effective, high-throughput, early predictions of WL, using spectral data acquired at the slaughterhouse on green hams, combined with carcass and green ham quality traits (Bonfatti and Carnier, 2020). In addition, it provides infrared predictions of WL (IR) that are highly genetically correlated with the measured trait (OB) and characterized by a higher heritability than the corresponding measured trait (Bonfatti and Carnier, 2020). The incorporation of IR into pig genomic selection programs aiming at reducing WL might be a promising alternative to the genomic prediction of OB, as it would allow periodical phenotype collection at virtually no additional costs and the creation of larger reference populations. The objective of this study was to compare the accuracy of genomic prediction models for OB and IR and evaluate the ability of genomic predictions for IR to predict the genetic merit for OB.

Materials & methods

Phenotypes. A measure of WL was obtained on the left ham at the end of dry-curing (12 mo) from 1,888 crossbred (CB) pigs produced in the sib-testing program of the C21 Goland sire line (Gorzagri, Fonzaso, Italy). Age at slaughter and body weight were those typical of heavy pigs (270 days, and 167 kg, respectively). Of these pigs, 1,624 had also spectra records and were used to develop infrared prediction models for WL, as detailed by Bonfatti and Carnier (2020). Briefly, the prediction model included the following explanatory variables: (1) visible-infrared spectra, collected at the slaughterhouse on the transversal section of the subcutaneous fat of the raw ham using a LabSpec®5000 (ASD Inc., Boulder, Colorado, USA) equipped with a fibre optic contact probe; (2) sex; (3) carcass traits (carcass weight, backfat depth, lean meat content, weight of the hams); (4) green ham quality traits (ham subcutaneous fat depth, and linear scores for ham round shape, subcutaneous fat thickness, and ham marbling).

DOI: 10.3920/978-90-8686-940-4_801, © V. Bonfatti *et al.* 2022

To obtain the IR values for the 1,624 pigs with available records of OB, a set of prediction models was developed excluding, at each round, all the samples from a given slaughter batch from the training set and applying the obtained model to the samples of the batch that was left out. The process was repeated until all the slaughter batches (n=25) were used in prediction. Finally, a model trained on the entire dataset (n=1,624) was applied to obtain records of IR in a larger dataset, extracted from the historical database of the genetic evaluation program of the Goland C21 sire line. The larger dataset included records of carcass traits, green ham quality traits and spectral variables from 8,048 CB pigs. Hence, a total of 9,672 records of IR were available for this study.

Pseudo-phenotypes. Genomic prediction models were developed following a multiple-step genomic evaluation approach, where the estimated breeding values (EBV) of the CB pigs were used as pseudo-phenotypes. The EBV for OB and IR were obtained using BLUPF90 (Misztal *et al.*, 2002). The complete pedigree information was available for all CB pigs with phenotypic records and all their purebred (PB) C21 Goland sires. The model included the fixed effect of sex (female and castrated male) and slaughter batch and the random additive genetic effect of the animal.

Genotypes. Genotypes were available for 1,029 CB pigs, spanning four generations. Of these, 640 had a record of OB and were offspring of 57 sires, and 956 had a record of IR and were offspring of 104 sires. Sire families with records of both OB and IR were 53. Genotypes of the sires were also available. Genotypes at 8,826 SNP were obtained using the GGP Porcine LD chip (Genomic Profiler for Porcine LD, GeneSeek Inc., a Neogen Co., Lincoln, NE) according to the manufacturer's protocol, and subsequently imputed to the GeneSeek® Genomic Profiler™ Porcine 50K (Neogen, Lansing, MI, USA) using Fimpute v. 2.2 (Sargolzaei *et al.*, 2014). All genotypes were then subjected to quality control using PLINK v. 1.9 software (http://www.cog-genomics.org/plink2). After editing, a total of 29,559 SNPs were retained for the genomic prediction models.

Genomic prediction model. Bayesian Ridge Regression was fitted to the CB data using the BGLR package (De los Campos and Rodriguez, 2021) in the R software (R Core Team, 2021). A total of 500,000 iterations were generated to estimate the parameters of the models, with a burn-in period of 100,000 iterations, and a thinning interval of 100 samples. To simulate a scenario under which a reference population including only CB pigs with phenotypic information is used to provide genomic predictions of the genetic merit of PB candidates, the estimated SNP substitution effects were used to calculate the direct genomic values of the PB sires (DGV-PB) of the CB pigs.

In particular, models were trained on the EBV of CB pigs and tested on the EBV of PB sires (EBV-PB) according to the following scenarios:

1. The model was trained on the EBV of CB pigs for OB and tested on the EBV-PB for OB;
2. The model was trained on the EBV of CB pigs for IR and tested on the EBV-PB for IR;
3. The model was trained on the EBV of CB pigs for IR and tested on the EBV-PB for OB.

For each scenario, a leave-one-family-out training-validation scheme was performed: models were trained excluding, at each round, the members of a sire family, a Bayesian Ridge Regression model was fitted to the training set, and the estimated SNP substitution effects obtained at each round were used to calculate the DGV-PB of the sire that was excluded from training. The correlation between EBV-PB and DGV-PB was used as a measure of model accuracy. The bias was calculated as the regression coefficient of the EBV-PB on DGV-PB.

Results

On average, OB was 27.8±2.4%, whereas IR averaged 26.5%, and exhibited a lower variability (SD=1.8%) compared to the corresponding measured trait. The accuracies of the genomic predictions obtained for the investigated traits are summarized in Table 1. Values of accuracies were very similar for OB and IR (0.383 and 0.396, in scenarios 1 and 2, respectively), whereas a lower accuracy (0.318) was obtained in scenario 3. All the correlation coefficients were significantly different from 0. Regression coefficients were highly variable across cross-validation folds and not significantly different from 1.

Discussion

The leave-one-family-out training-validation scheme allowed to mimic as far as possible the circumstances under which models are going to be applied in practice, where selection is based on the DGV estimated for PB breeding candidates and estimates are based on a reference population of CB finishing pigs belonging to families related to, but different from, those of the PB candidates.

Scenario 1 had the aim to evaluate the accuracy attainable by models exploiting OB phenotyping, whereas scenario 2 allowed testing the ability of models trained on IR pseudo-phenotype to predict the EBV-PB for the same trait. Results obtained in the two scenarios were comparable, probably due to the larger training set and higher heritability of IR compared to OB (0.39 vs 0.31, data not reported in tables).

The correlation between DGV-PB and EBV-PB in scenario 3 corresponds to the accuracy of models in predicting the genetic merit of PB sire from a reference population based on CB pigs with no close relationships with the sires, thus representing the most realistic scenario. The accuracy under this scenario was lower than the accuracy achievable if the model was trained on OB (scenario 1), but comparable to that value for practical applications. In pigs the accuracy of the DGV tends to decline rapidly over generations, and periodical phenotype collections, especially in animals related to selection candidates, are likely to be needed to update genomic prediction models (van Grevenhof and van der Werf, 2015). Routine phenotyping for OB is currently unfeasible, and the periodical phenotype collection is expensive. In addition, when the target is the prediction of PB genetic merit for CB animals, an increased number of training animals with phenotypes is needed. Under these circumstances, the use of IR in place of OB can allow a reduction of the phenotyping costs, favouring the construction of larger reference populations, a greater flexibility in the collection of phenotypes, with only a minimal impact on model accuracy compared to the use of OB phenotypes.

Considering the limited phenotyping costs for IR and the relatively short generation length achievable using IR phenotypes, the genetic gain attainable by a genomic selection program based on IR phenotyping

Table 1. Accuracy of direct genomic values of sires (DGV-PB) for observed ham weight loss (OB) or its infrared prediction (IR) in predicting the EBV of sires (EBV-PB) for OB or IR.[1]

Scenario	DGV-PB	EBV-PB		Accuracy		Bias	
			n	*r*	*P*-value	B	*P*-value[2]
1	OB	OB	57	0.383±0.125	<0.01	1.190±0.387	0.626
2	IR	IR	104	0.396±0.091	<0.001	0.838±0.192	0.400
3	IR	OB	104	0.318±0.094	<0.001	0.739±0.218	0.234

Abstract

Breeding against boar taint becomes more important since surgical castration of young piglets was banned by law in Germany from 2021. Main compounds responsible for boar taint are androstenone and skatole. Previous studies underline the polygenetic background of at least androstenone in the genome and pointed out breed-specific differences. Genotype data from previous genome wide association studies were used to perform meta-analyses in order to identify overlapping gene regions between lines, associated with androstenone and/or skatole. Data from three different origins was used: two maternal purebred breeds (Landrace and Large White) and a Piétrain-sired commercial endproduct population (Piétrain×F1/F2 sow). Results of the meta-analyses showed eleven overlapping markers for skatole in all three populations in a previously identified region on *Sus scrofa* chromosome (SSC) 14 around 141 Mega base pairs (Mb) which underlines the importance of this region for skatole for further analyses.

Introduction

Castration of young male piglets in their first week of life without anaesthesia to avoid boar taint is banned by law in Germany from 2021 (Deutscher Bundestag 06.11.2018). Boar taint is mainly caused by two compounds: androstenone (AND) (Patterson 1968), a sex steroid hormone which is produced in the Leydig cells of a boars' testis, and skatole (SKA), which is synthesized as a metabolite of the amino acids tryptophan in the colon (Yokoyama und Carlson 1979). Accumulation of both compounds in the backfat starts with the puberty as the sexual maturation begins (Bonneau 1982). Breeding against boar taint is a sustainable and beneficial long-term alternative to surgical castration regarding animal welfare, resource efficiency (Lundström *et al.* 2009) and carbon footprint (Stefanski *et al.* 2018).

Both compounds were identified to be moderate to high heritable with a range of 0.25 to 0.88 for AND and 0.19 to 0.54 for SKA as reviewed by Robic *et al.* (2008) To establish breeding against boar taint in modern breeding programmes, it is mandatory to identify causal gene regions or quantitative trait loci (QTL) that are responsible for the formation, metabolism or degradation of AND and SKA. For AND, previous studies showed significant regions across the whole autosome within and above different breeds (Große-Brinkhaus *et al.* 2015), which underlines the polygenetic genetic architecture of this trait. In contrast to that, SKA is assumed to have a more monogenetic background with focus on SSC 6, 7, 10 and 14.

The aim of this study was to conduct meta-analyses from data and results of earlier genome-wide association studies (GWAS) in different pig populations to identify overlapping regions for AND and SKA.

Materials & methods

The datasets for this study were based on 3,211 boar taint phenotypes of the purebred nucleus populations Landrace (LR) and Large White (LW) and a Pi-sired crossbred (Pi×$F_{1/2}$) population. The crossbred sows had different compositions: a 2-way cross of type LW×LR and a 3-way cross of type LW×(Leicoma×LR) (Große-Brinkhaus *et al.* 2015). All AND and SKA concentrations of the nucleus populations were analysed from backfat tissue samples by using a standardized stable isotope dilution analysis-headspace solid-phase microextraction-gas chromatography / mass spectrometry (Fischer *et al.* 2011). For the Pi×$F_{1/2}$ trials, AND and SKA were

evaluated from backfat tissue samples using gas chromatography/mass spectrometry (GC/MS) (García-Regueiro und Diaz 1989), as this data was analysed before the method of Fischer *et al.* (2011) was established. All animals were genotyped with the Illumina PorcineSNP60 Bead Chip (Illumina, San Diego, CA, USA).

Genome wide association study. GWAS was performed univariate per trait and population by using the R-package GenABEL (Aulchenko *et al.* 2007b). Concentrations of AND and SKA were used as log-transformed values. SNPs and individuals with a call-rate of less than 0.95 and SNPs with a minor allele frequency less than 0.05 were excluded from further analyses. In the nucleus populations, population stratification was corrected by application of the GRAMMAR approach (Aulchenko *et al.* 2007a) whereas the stratification in the crossbred population was corrected by the genomic control approach by Devlin und Roeder (1999). Association analyses were performed under the following model for the nucleus populations:

$$y = X\beta + Zu + e \quad (1)$$

where y contains the phenotypes AND and SKA. The Equation 1 consisted of year-season of slaughter as fixed environmental effect (β) and animal (u) and error (e) as random effects. Age and weight at slaughter were used as fixed covariates. The model for the Pi×$F_{1/2}$ data differs only slightly with a combined factor including the effects testing station-year-season and housing system (group- or single-penned).

Meta-analysis. For the meta-analysis, the results of the performed GWAS described above, were compared trait specific among the populations. Therefore, a weighted inverse variance method was used, as implemented in the R-package MetABEL (Aulchenko *et al.* 2007b). In brief, the weight (w_i) for each GWAS study (i) was equal to one over the square of the standard error (s_i^2) of the estimate for that GWAS study:

$$w_i = \frac{1}{s_i^2} \quad (2)$$

The pooled effect estimate was then calculated by multiplying the GWAS study effect estimate (β_i) by the GWAS study weight (w_i, Equation 2), summing over all GWAS studies (Equation 3).

$$\beta_{pool} = \sum_{i=1}^{N} w_i \beta_i \quad (3)$$

In the last step, the pooled effect estimate (β_{pool}, Equation 3) was divided by the sum of the GWAS study weights in order to calculate the χ^2 statistics of the meta-analysis (Equation 4) (Hartung *et al.* 2008).

$$\chi^2 = \frac{\beta_{pool}}{\sum_{i=1}^{N} w_i} \quad (4)$$

As the datasets were already corrected for population stratification for the GWAS, further correction for stratification was not necessary. Results from the meta-analyses were corrected after Bonferroni.

Only the results of two GWAS studies were investigated at once within the meta-analysis, leading to following comparisons: {LR:LW}, {LR:Pi×$F_{1/2}$} and {LW:Pi×$F_{1/2}$}.

Results

The number of animals, overall means and standard deviations of raw phenotypes are shown in Table 1, separated by population.

Population specific GWAS for AND revealed nine significant associations on SSC 5 in the LR nucleus population whereas no significant associations were found for the other populations. All markers were

Table 1. Descriptive statistics of the analysed traits.[1]

	LR			LW			Pi×$F_{1/2}$		
Trait	n	x̄	SD	n	x̄	SD	n	x̄	SD
AND	1,293	1,923	1,433.29	1,317	1,305	1,107.46	601	569	664.05
SKA	1,293	203.8	221.67	1,317	84.79	122.58	601	169.4	182.84

[1] AND = androstenone in ng/g fat; SKA = skatole in ng/g fat; x̄ = mean; SD = standard deviation.

located in a region from 21.5 to 22.3 Mb. For SKA, five significant associations were found on SSC 6 and 14 in LR, 15 in LW on SSC 14, and none in the Pi×$F_{1/2}$ population. The most prominent region was at SSC 14 around 141 Mb where 15 of the 19 significant markers of both breeds were located.

A considerable larger number of QTLs were found by applying the meta-analyses using the combined results of two breeds. In total meta-analyses for SKA revealed 27 markers for {LR:LW} (24 located on SSC 14, three on SSC 6), 5 or 10 markers for {LW:Pi×$F_{1/2}$} and {LR:Pi×$F_{1/2}$} respectively (Figure 1b). Of particular importance are three markers which were found in all combined breed scenarios. These QTL were located on SSC 14 around 141 Mb which covers the well-known CYP2E1 gene. Moreover, six identical QTL were found in the meta-analysis of the {LR:LW} and {LW:Pi×$F_{1/2}$} combinations. These novel SKA influencing QTLs were located on SSC 6 and 14. For SKA, nine markers were found in meta-analyses but not in single analyses (0 vice versa).For AND one significant marker was found in the combined analysis {LR:LW}, seven for {LR: Pi×$F_{1/2}$} (all located on SSC 5 in a 21.5 to 22.3 Mb interval) and 35 for {LW:Pi×$F_{1/2}$}(Figure 1a). Only one QTL was found in the meta-analyses of {LR:LW} as well as in {LR:Pi×$F_{1/2}$}. This novel QTL is located on SSC 5 at 21.5 Mb. Meta-analyses for AND revealed two markers, that were only found in the single analyses but not in the meta-analyses (0 *vice versa*).

Discussion

Breeding against boar taint is an appropriate method to replace surgical castration without anaesthesia if the amount of odorous boars at slaughterhouse can be reduced. The descriptive summary (Table 1) showed that concentrations of AND and SKA in fat were on average greater in LR than in LW. The Pi×$F_{1/2}$ population revealed the lowest AND concentration, but was situated between LR and LW regarding the mean SKA concentration.

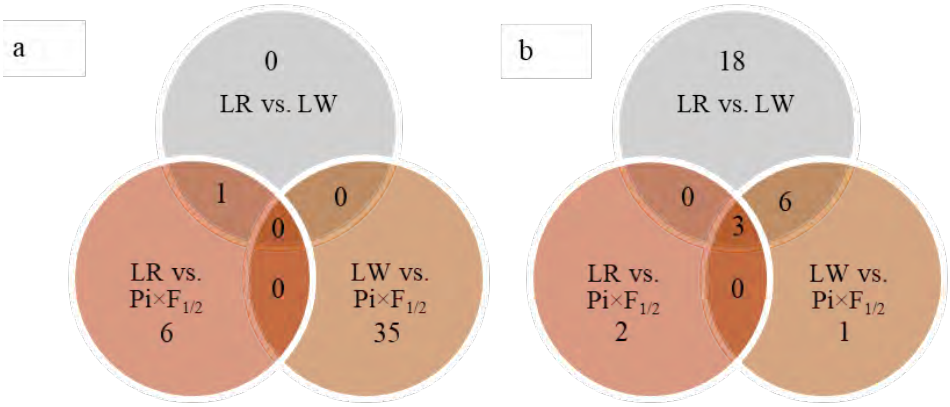

Figure 1. Number of shared significant markers in meta-analyses between the three datasets for androstenone (a) and skatole (b).

Different studies identified an extensive range of QTL associated with AND across the whole genome which differs among breeds as summarised by Robic *et al.* (2008), not including the region at 21.5 to 22.3 Mb that was identified in this study. In contrast to that, a candidate gene for SKA metabolism (CYP2E1) in the liver is already identified on SSC 14 in several purebred and crossbred lines (Squires und Lundström 1997; Skinner *et al.* 2005; Moe *et al.* 2009; Mörlein *et al.* 2012; Wiercinska *et al.* 2012). Meta-analyses in this study confirmed this region to be involved with SKA as 15 of a total of 19 significant associated markers were located in the promoter region of CYP2E1 on SSC 14 at ~141 Mb. This shows the potential of this QTL for breeding against boar taint as this region seems to be highly conserved among breeds. Further analyses, especially multivariate GWAS is necessary to further evaluate this regions potential on SSC 14 for further (genomic) selection against boar taint. In a next step, a pooled meta-analysis of all three populations {LR:LW:- $Pi \times F_{1/2}$} will be proven.

803. A data-architecture to monitor and collect cow-individual methane emissions real-time from commercial dairy farms

I. Hulsegge*, D. Schokker, G.G.J. Klandermans and C. Kamphuis

Wageningen University & Research, Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, the Netherlands; ina.hulsegge@wur.nl

Abstract

Real-time monitoring and collecting cow-individual methane emissions will help individual farmers in identifying which management interventions affect methane emissions, and the dairy sector in developing strategies to reduce methane emissions. To achieve this real-time monitoring and collecting of cow-individual methane data, an architecture was developed that automates both aspects in a commercial setting. The first step in the data architecture was to collect the analogue signal of sniffers real-time, and transform this signal into methane concentrations. Because these sniffers do not record cow identification, the second step was to combine the methane concentration data with real-time cow identification. The cow identification is retrieved by automatically detecting the ear tag in a live-stream video footage, to subsequently 'read' the 4-digit number of that ear tag. With the deployed architecture, we developed a universal, low-tech, and scalable method to collect cow-individual sensor data real-time for technologies that do not record cow identification by default.

Background

Precision Livestock Farming (PLF) includes the integration and interpretation of relevant sensor information leading to new opportunities in the management and breeding of livestock through continuous real-time monitoring of health, behaviour, production, reproduction, and environmental impact (Berckmans 2017; Herlin *et al.* 2021). PLF technologies are entering the livestock domain in a fast pace, offering the potential to collect information that was not possible a decade ago (Buller *et al.* 2020). Currently, PLF technologies are available to monitor greenhouse gasses (GHG) emissions at cow-individual level (de Haas *et al.* 2021). One of these technologies is a non-dispersive infrared unit or 'sniffer' to measure GHG emission (de Haas *et al.* 2021). These relatively cheap sniffers offer opportunities to meet the Dutch government's objective to reduce GHG emissions by 49% by 2030, compared to 1990 levels (Goverment of the Netherlands 2021). Real-time monitoring of cow-individual methane emissions will help in identifying which management interventions affect methane emissions (e.g. new feeding ration), and in developing strategies to reduce methane emissions in the dairy sector (e.g. through breeding). Currently, the methane emission measurements with sniffers take place in the milking robot as described by Huhtanen *et al.* (2015), which enables information to be collected on each individual cow. The sniffer monitors a constant analogue signal that is linearly related to gas concentrations, which can be transformed into a methane and carbon dioxide concentration. The sniffer measures continuously, and the assumption is that when a cow is in the milking robot and eating her concentrates while being milked, that the sniffer is measuring that cow's methane concentration. At a later stage, sniffer data and robot data are combined to add cow identification to sniffer data. To collect sniffer information real-time, the first step of our data-architecture involves the connection of the sniffer to an Arduino, a small and inexpensive computer and accompanying software to program this computer (https://www.arduino.cc). The Arduino is programmed to push the sniffer data to the cloud service platform Azure (https://azure.microsoft.com) via the Internet of Things (IoT) network. This IoT system was selected to avoid potential problems with low coverage of e.g. a WIFI signal (Schokker *et al.* 2020), allowing future upscaling independent of WIFI coverage. In Azure, an IoT hub was built which was subscribed to the data stream. This means that this IoT hub was used to acquire and ingest (load), and transform the raw sniffer analogue signal into a methane concentration data point. At this stage, we

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_803, © I. Hulsegge *et al.* 2022

thus have cow-individual methane concentrations measured and collected in real-time. However, sniffers do not record cow identification, and thus, the next step of our data-architecture involved the real-time information which cow the sniffer is actually monitoring.

Automatic and real-time animal identification

Animal identification, which refers to the process of accurately recognizing individual animals, plays an important role in automatic and real-time analysis of activities and productivity in PLF. All cows in the Netherlands are uniquely identified with a lifetime registration number at birth. This number is printed on the ear tags that cows are obligatory to wear. Four digits of this ear tag are highlighted using a larger font size. These four digits are typically used by farmers as the cow's work number. In addition to these mandatory ear tags, Radio Frequency Identification Device (RFID) transponders that are connected to the neck-collar of the cow are also a method readily used to identify cows (e.g. RFID is used by milking robots for cow identification). However, not all farmers have milking robots. Also, milking robots may store the transponder identification together with a datetime stamp, but accessing and matching this identification to other data is not always straightforward, and therefore error-prone. Identification of animals by automatically reading the ear tags may be a more universal solution in precision dairy farming. This automation can be done using video footage or camera images. Methods for individual cow identification system using ear tags were described by Ilestrand (2017) and Zin *et al.* (2020). These methods have been applied on a static dataset of previously collected images. But for PLF, a system is required that continuously reads the ear tag number and makes this cow identification available real-time. The use of video is an attractive approach to achieve this because it offers 24/7 monitoring, and is a relatively cheap investment. We developed a system that enables real-time cow identification through the use of vision technology and artificial intelligence (AI). The system was developed and implemented in Python 3.8 using the Open Computer Vision Library (OpenCV 4.1.2), an existing library for the analysis of image or video datasets in AI and deep learning (Culjak *et al.* 2012). The system 'detects' the ear tag area from a live-stream, 'segments' the ear tag area from the live-stream, 'improves' the image quality using image processing techniques, 'rotates' the ear-tag such that the baseline of the tag is horizontal in the image, and subsequently 'reads' the 4-digit number of the ear-tag by applying a number recognition model. This whole process is depicted in Figure 1. The number recognition model was developed by transfer learning of a pre-trained household number model (Goodfellow *et al.* 2014), a Convolutional Neural Network (CNN) classifier. Recognizing house numbers is a quite similar problem to recognizing ear tag numbers. The house number model is retrained with ear tag numbers, which increased the accuracy of a test set from 80% using the pre-trained model to 87% using the retrained model. The developed data-infrastructure consists of a video station involving a Raspberry Pi 4 Model B (a small, inexpensive computer developed by the Raspberry Pi Foundation in the United Kingdom), connected to a security camera (DS-2CD2T43G0) via ethernet (LAN) connection. The video station is installed in the milking robot as a place where also the sniffer sensor is continuously recording the analogue signal. The Raspberry Pi is programmed to collect, and process the live-stream of the camera, to push just the ear tag number together with a timestamp to the Arduino where the methane data is also collected. From the Arduino the methane data, ear tag number and timestamp are streamed onto the Azure cloud platform using Azure Streaming Analytics (Figure 1). Streaming Analytics is a querying, alerting and monitoring tool that monitors data streams.

Challenges

At this stage, sniffer and ear tag data streams come-in simultaneously and (near) real-time in the cloud platform. However there are still challenges to overcome. The next step will be to integrate and synchronize the sniffer- and ear tag data streams real-time. Furthermore, during a cow's visit to the milking robot the ear tag is not always (clearly) visible, especially if the cow is moving her head. As a result, ear tag recognition is not robust enough to deduct the starting- and/or end-time of the robot visit. To overcome this problem

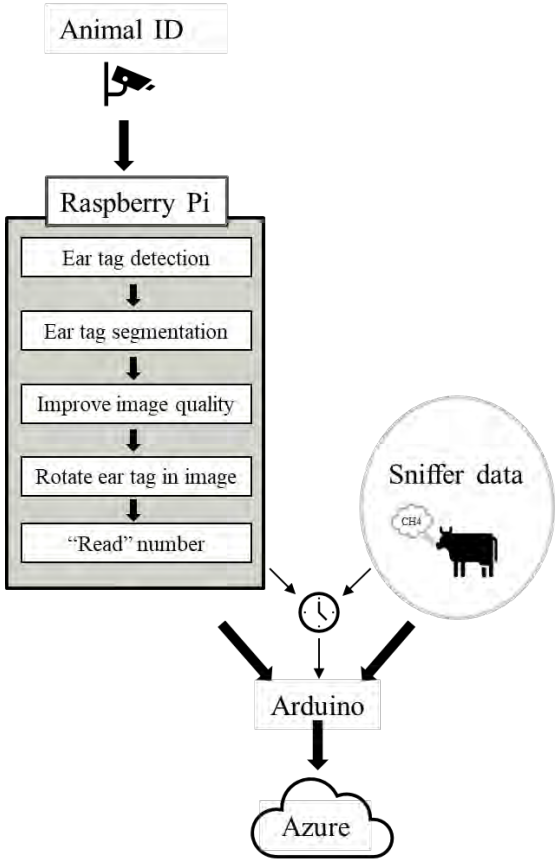

Figure 1. Schematic overview infrastructure.

template matching will be used to check if there is a cow in the milking robot, and to signal the starting and endpoint of a cow visit. Improvement in the downstream process, after 'reading' the 4 digits need also to be investigated. One of current investigation is to improve the number recognition by comparing consecutive predicted numbers in time. Such a system could be developed by using a majority vote of the prediction for in a sliding window of consecutive frames. Other improvements could be made by comparing the predicted number with a list of all cow ear tag numbers present in the herd.

Conclusions

A universal, low-tech and scalable method to collect cow-individual sensor data real-time for technologies that do not record cow identification by default is developed and deployed in a commercial setting. The system can be applied anywhere on a farm, not just in the milking robot as described in this paper. The method offers perspective to be used by other PLF techniques that do not register animal IDs by default. The data architecture is flexible in accepting additional data streams, e.g. other sensor data, but also animal and farm data that are often stored in separate farm management systems. Another part of the flexibility of the infrastructure links to the scalability, i.e. handling data from new farms in case the number of farms where methane is monitored, increases (Schokker *et al.* 2020).

Abstract

The aim of this study is to propose a new approach for the collection of data from genetic traits and milk proteins and to manage this information in a unique virtual environment. Information about genetic traits and milk proteins can come from different sources and can be determined using different types of genetic tests. All input data are recorded in the database with a priority that is defined by the database update algorithm, taking into account the source of the data and the type of genetic test. In this way, the most reliable information is considered official herd book data, according to the established priorities. In conclusion, this new management of genetic traits and milk proteins aims to lay the foundations for a process of harmonization that supports international exchanges of data and that makes the interpretation of genetic traits clearer, in particular for breeders and for the livestock industry.

Introduction

In recent years, the advent of genomic analysis, new technologies and advanced automated systems have completely changed the way we approach livestock data, allowing an increasing exchange of genetic trait information on a global scale (Gutierrez-Reinoso *et al.*, 2021). Today millions of data on genetic traits (monogenetic traits) are available but only through an efficient management and sharing system can this information be a real resource for breeders, for the livestock industry and for the international scientific community (Niklitschek *et al.*, 2016). The creation of this new database for the collection and management of data on genetic traits and milk proteins genetic variants, arises from the need to make this information always available and clear, in order to promote the exchange of data and harmonization with international standards. The management of genetic traits implemented until now allowed to record only the diagnosis of the genetic trait (e.g. tested carrier or free), neglecting other information, such as the source and the historicization of the type of genetic tests, which can have an important influence on the reliability of the data. Aim of this project is to design, with an ontology approach, a new database for management and tracking of the source of the data and the type of analyses.

Materials & methods

The new database (DB) is designed to manage data on genetic traits and milk proteins in a unified virtual environment, using an ontology approach. An ontological approach looks at the things (entities) the data is about and uses them as the basis for the structure of the data. If the things that are important to the activities and the relationships between them are correctly identified, then the data model is universally useful (Cui and O'Brien, 2000). Being a relational database the key element for its operation are the entities. The DB entities have specific properties some of which relate entities to each other.

The entities. The ontology DB has five entities: Gene entity, Diagnosis entity, Source entity, Analysis entity and Exposition sequence entity. The entity Gene contains the list of genetic traits and milk proteins and identifies them with a unique progressive code. The genetic traits are divided into two categories according

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_804, © C. Franzoni Migliorati *et al.* 2022

to the type of genetic test: the Gene category is assigned to diagnoses resulting from direct tests while the Haplotype category is assigned to diagnoses resulting from indirect tests. At the moment 30 genes and 21 haplotypes are included. The diagnosis entity lists all possible diagnoses for each genetic trait and milk protein and establishes the nomenclature with which the result of the analysis is identified. Both the international nomenclature of WHFF (World Holstein Friesian Federation) and the nomenclature used today in Italy are provided. A total of 164 diagnoses are expected, including those identified by imputation. The Source provides a list of sources from which data can be received and each of them is assigned a unique code. Each source is assigned a priority level; a higher priority is given to more reliable data sources (Table 1).

In the entity Analysis all incoming analyses are recorded and each is assigned a unique code. For each incoming analysis, the serial number of the animal, the unique code related to the genetic trait or milk protein, the unique code of the diagnosis, the unique code of the source are recorded and it is specified when the analysis comes from imputation. The entity Exposition sequence establishes the sequence in which diagnoses are to be displayed on official documents. The results of genetic traits will be presented first, then coat colour genes followed by milk proteins.

The database update algorithm. Each animal can have one or more tests for the same genetic character. All of them must be entered in the DB with the priority determined at the time of entry. For each test to be entered, the algorithm considers 3 different priority levels:

1. Direct/indirect test: for tests involving the same genetic traits the gene category always has priority over the haplotype category whatever the source.
2. Sources: analysis of the same category (gene or haplotype) the algorithm establishes priority according to the data source.
3. Imputation: when the analysis is determined without having the animals' genome but based on ancestry, it is considered 'from imputation'. These analyses are identified in the Analysis entity and the algorithm considers them with the lowest priority level so that they are not exposed on official documents.

Results

The new ontology DB is structured to handle millions of records and tests to verify its performance were carried out by loading batches of data. As shown in Table 2, the data loading tests included 497,097 records from genomic files and 110,591 records from the old genetic traits management system, for a total of 607,688 incoming data. 598,815 analyses were correctly registered in the database (488,979 from genomics and 109,836 from the old management system). There were 8,873 records that the update algorithm correctly did not include in the database because they were already present with the same source and the same diagnosis. 2,743 records were indicated with a different result from the one already in the database. In this case, the algorithm inserts the data but indicates as official analysis the one with the most reliable source, according to the established priorities. Correctly, for the 2,737 records from genomic files the DB reports

Table 1. Source and priority level.

Source	Priority level
Specific test by accredited laboratories	100
Genomic test files	90
Official documents by foreign herdbooks	70
Old genetic traits management system	50
Unofficial documents or self-declarations	30

Table 2. Results of data uploading tests.

Source	Genomic files			Old genetic traits management system	Total
	Marker-based tests	Haplotypes	Both		
No. of input data	188,627	308,470	497,097	110,591	607,688
No. of data entered	180,509	308,470	488,979	109,836	598,815
No. of data not entered because already present	8,118	0	8,118	755	8,873
No. of data notified for different diagnosis in DB	2,737	0	2,737	6	2,743

that the official diagnosis has been changed because a higher priority is assigned to that source. While for the 6 records derived from the old system was notified that there is a different diagnosis but the official diagnosis is still the one in the DB. The haplotypes were all correctly entered into the database (308,470 records) without any analyses already in the database or analyses notified due to different results.

Discussion

The new ontology database makes it possible to keep track of all the tests registered for the same animal and for each type of test it is possible to consult, through a web application: the genetic trait, the result, the source, the type of test, the priority and the date of inclusion in the database. Priority levels have been designed to represent the reliability of the data based on the type of genetic test and the source of the data. Taking into account the scientific evidence, types of direct analysis (marker-based tests) have been considered more reliable (and therefore with higher priority) than indirect tests that do not detect the causal allele, such as haplotypes (Sonstegard *et al.*, 2013). Even lower priority has been assigned to imputation analyses that are determined without having the animals' genome but based on ancestry (Nicolazzi *et al.*, 2013). Concerning the source of the incoming data, it was decided to give the highest priority to genomic test files (Italian or from data exchanges with other countries) and to the results that come from official documents issued by internationally accredited laboratories because these sources certify the scientific evidence of the execution of the test. It should be emphasized that the diagnoses derived from genomic files are considered more reliable also because our procedure, before uploading the data in DB, provides Mendelian controls that compare, for biallelic genes, the genotype of the animal with that of the verified parents (if available). Slightly lower priority has been assigned to the information reported on official documents by foreign herdbooks because in this case we do not have an analysis or a genome of the animal but only an information and human error cannot be excluded. Data from the old genetic traits management system were given lower priority because the source cannot be traced. Tracking all analyses for the same genetic character allows the analysis with the highest priority, and therefore the most reliable, to be automatically considered official. In addition, the recording of all incoming data allows immediate and automatic identification of any conflicting results for the same animal. The nomenclature used to identify genetic traits was a central element of the project; the new management system includes both the nomenclature used today in Italy and the international WHFF standard with the aim of encouraging future use of the international nomenclature in Italy. Furthermore, the algorithm of the database makes it possible to determine the genetic traits that must be included in official documents and the expression codes with which they must be displayed. Analyses that are not to be displayed in official documents (e.g. non-royalty free genetic traits, haplotypes or imputation analyses) are determined, but it is a flexible system that allows them to be exposed in the future if necessary. The flexibility of the system is decisive because it is designed to allow technical staff to choose and change, autonomously and without acting on the software, but only a change into the reference DB table, which genetic traits are to be displayed on official documents and

on our online consultation applications, ensuring that the order in which genetic traits are displayed can be chosen and changed to highlight, for example, the diagnoses of genetic traits deemed most interesting.

Conclusions

In conclusion, the new ontology data management system enables automatic acquisition of information on genetic traits and reduces human errors as much as possible. The reliability of the data is the key element to ensure a process of international harmonisation and data exchange for the benefit of the breeders, the livestock industry and the scientific community.

805. Genotyping errors in SNP markers: types, consequences, and a novel detection method

W.M. Rauw*, M.G. Gil, O. Torres and L. Gomez-Raya

Departamento de Mejóra Genética Animal, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA-CSIC), Ctra de la Coruña km 7.5, 28040 Madrid, Spain; wendy.rauw@csic.es

Abstract

Genotyping errors consist in misclassification of genotypes at a genetic marker. Most research using genotyping arrays only report generic screening of SNPs due to low calling rate, departures of Hardy-Weinberg equilibrium or because of reduced allele frequency (Minimum Allele Frequency, MAF). Detection of genotyping errors for a particular experimental dataset remains generally unreported. We propose to relate the probability of genotyping errors to the probability of the rate of rejection of true parent-offspring. Only single nucleotide polymorphisms (SNPs) at intermediate frequencies are useful to determine genotyping errors. Genotyping errors are detected mostly for SNPs at allele frequencies between 0.18 and 0.50. Our method can estimate the probability of generic (across all SNPs) and specific (affecting some SNPs) genotyping errors. For the rate of rejection of 0.000735 in a porcine HD array we estimated a genotyping error of 6 out of 1000 SNPs.

Introduction

SNPs are distributed throughout the genome at a rate of approximately 1 in 1000 base pairs, and may be located within a gene locus (thus altering amino acids), but are mostly located in the non-coding DNA between genes (Shastry, 2002). Because the dense coverage of the genome by SNPs, they can be used for linkage disequilibrium mapping of SNP markers that are in close proximity to (or are themselves) the causal mutation. To accomplish this, the vast amount of SNPs detected by recent cost-effective advances in next-generation sequencing (NGS) technologies can be used in the development of SNP arrays that are used to interrogate the entire genome for associations between the phenotype and around 50.000 to one million SNPs at a time in Genome Wide Association Studies (GWAS). In genomic selection, estimates of the effects of all genotyped markers across the genome are used to estimate an individual's breeding value, rather than estimates only of the effects of significant markers. In addition, pedigree-based relationships among animals can be replaced by genomic relationships that are computed based on SNP genotypes in genomic best linear unbiased prediction (GBLUP). Virtually every genetic study includes genotyping errors, quantified by the Quality scores probability of error provided by genomics companies, resulting from calling algorithms that misidentify and misclassify the individual's genotype. It is likely that genotyping errors vary between experiments due to variation in DNA quality or problems associated to lab sample handling; genotyping errors are usually not reported in scientific studies. We define genotyping errors as the misclassification of genotypes. Our goal is to determine the probability of genotyping errors in large scale genotyping experiments.

Calculation of the genotyping errors in genetic research

In the last decades, the number of animals being genotyped as well as the number of SNPs typed per animal has increased dramatically. Genotyping and/or DNA sequencing is now the gold standard for genetic research. For example, a porcine High Density SNP array provided by ThermoFisher has more than 600K SNPs, however, genotyping errors reduce the true total number of available SNPs for data analysis. After cleaning data based on calling rate, genotyping errors are typically approached by excluding SNPs that deviate from Hardy-Weinberg Equilibrium and those with minor allele frequency (MAF) (Fialkowski *et al.*, 2019).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_805, © W.M. Rauw *et al.* 2022

Two types of genotyping errors can be distinguished: generic errors affect all SNPs randomly and equally, while specific errors are inherent to the marker itself, i.e. they do not affect all SNPs equally. The latter may influence GWAS when a particular erroneously typed SNP rejects a truly existing association to a causal mutation, while generic errors may particularly influence genomic selection accuracy because it results in erroneous estimation of the effects associated with an individual's genotype at the affected SNP markers (the impact on genomic evaluations should be small if a genotyping error probability is not large and a large number of SNPs is used). It is possible to test for genotyping errors through repeated testing with the same or different molecular genotyping methods. However, this is unpractical for most routine genotyping operations. Alternatively, genotyping errors can be detected using inconsistencies in Mendelian inheritance between parents and offspring (not common for most GWAS studies). There are two possibilities to detect erroneously genotyped parent-offspring: a) detection based on rejection of a parent-offspring relationship if one parent and its offspring are homozygous for alternative alleles (Gomez-Raya *et al.*, 2022), and 2) detection based on rejection of a parent-offspring relationship if both parents are homozygous for the same allele while progeny is heterozygous. We will focus on the first, because it is the easiest and more common situation.

Inconsistent Mendelian inheritance between a parent and its offspring

In livestock production, genotyped individuals in a population are often related. A first-degree relative is an individual that shares ~50% of their alleles with a particular other individual: parent-offspring and full-sibs. In most cases, individuals with first-degree parent-offspring relationships are part of the same selection candidates in genomic selection or crossbreeding programs. Under strict Mendelian inheritance, individuals with a first-degree parent-offspring relationship cannot be homozygous for alternative alleles at a given locus. For example, an individual offspring cannot be homozygous CC at a locus, when a parent is GG at the same locus. Following Gomez-Raya *et al.* (2022), inconsistent Mendelian inheritance between parents and offspring can be used to assign true maternities and paternities based on the rate of rejection of parent-offspring relationships. Furthermore, this method can be used to detect genotyping errors after true parent-offspring relationships are resolved, i.e. two individuals appear to be homozygous for alternative alleles at a SNP marker when in reality they are not.

Rate of rejection of first-degree relationships and probability of genotyping errors

The probability of rejecting a true first-degree relationship at a locus is related to genotyping errors and can easily be measured when parents and offspring co-exist in a genotyped data set (Gomez-Raya *et al.*, 2022). A model of genotyping errors for parents with genotype *AA* is given in Table 1; models for parents with genotypes *Aa* or *aa* are constructed in the same fashion. Parents with genotype *AA* will be at a population frequency of f_{AA}. The probability of a genotyping error, *ge*, results in erroneously observed genotypes *AA*, *Aa,* and *aa*, at frequencies f_{AA}, f_{Aa}, and f_{aa}, respectively. Note that this model assumes that erroneous genotyping occurs given the probability of the genotype frequencies in the population; that is, misclassification of genotypes depends on the population frequency. True *AA* parents produce two types of offspring: *AA* at frequency f_A, and *Aa* at frequency f_a. True *AA* offspring with a probability of genotyping error *ge* will appear in the population at genotype frequencies $ge\,f_{AA}$, $ge\,f_{Aa}$, and $ge\,f_{aa}$. Using probabilities in Table 1, the probability of rejection for parents with true genotype *AA* is:

$$r_{AA} = gef_{aa}[(1-ge) + 2ge\ f_{AA} + (1-ge)f_A\ + gef_Af_{AA}]$$

The same arguments can be used to relate rate of rejection of parents with true genotypes *Aa* and *aa*:

$$r_{Aa} = gef_{AA}[ge\ f_{aa} +\ 0.5f_a(1-ge)] + gef_{aa}[ge\ f_{AA} +\ 0.5f_A(1-ge)]$$

Table 1. Modeling genotyping errors for parents with genotype *AA*. Frequencies of genotypes are between brackets; *ge*: genotyping error or probability of incorrect genotype.

True genotype parent (freq)	Prob. of error	Observed genotype parent (freq)	True genotype offspring (freq)	Prob. of error	Observed genotype offspring (freq)
AA (f_{AA})	*1-ge*	*AA* (1)	*AA* (f_A)	*1-ge*	*AA* (1)
	ge	*AA* (f_{AA})		*ge*	*AA* (f_{AA})
	ge	*Aa* (f_{Aa})		*ge*	*Aa* (f_{Aa})
	ge	*aa* (f_{aa})		*ge*	*aa* (f_{aa})
			Aa (f_a)	*1-ge*	*AA*
				ge	*AA* (f_{AA})
				ge	*Aa* (f_{Aa})
				ge	*aa* (f_{aa})

$$r_{aa} = ge f_{AA}[(ge\ f_{aa}) + (1 - ge) f_a\ + (1 - ge) + ge\ f_{aa}]$$

The joint rate of rejection for the three parental genotypes is $r_r = r_{AA} f_{AA} + r_{Aa} f_{Aa} + r_{aa} f_{aa}$. Figure 1 shows that the relationship between the rate of rejection of first-degree relationships in Equation 1 depends strongly on the allele frequency. Only SNPs at intermediate allele frequencies are likely to reject true parent-offspring relationships. The rate of rejection is a lower bound of the true genotyping error.

In an example of nine Duroc sires, 55 Iberian dams, and 214 Duroc × Iberian offspring genotyped with the HD porcine Affymetrix array (658,692 SNPs), true paternity of 75 and maternity of 85 piglets were established with a rate of rejection of 0.000735 (Gomez-Raya *et al.*, 2022). Figure 2B shows that those SNPs do not correspond to the genotyping errors detected by the Inconsistent Mendelian Inheritance method, instead, genotyping errors are detected mostly for SNPs at allele frequencies between 0.18 and 0.50. On the contrary, the distribution of the allele frequencies of 592,053 autosomal SNPs in the array shows a typical U distribution, with a majority of SNPs close to fixation (Figure 2A).

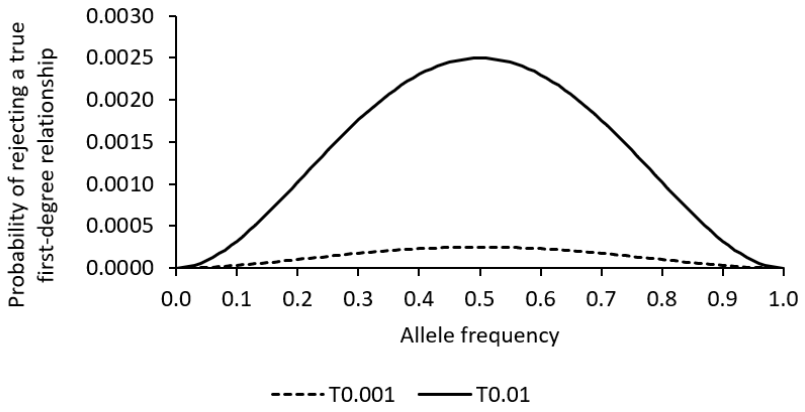

Figure 1. The probability of rejecting a true first-degree relationship as a function of allele frequency when the true probability of genotyping error is 0.001 or 0.01%.

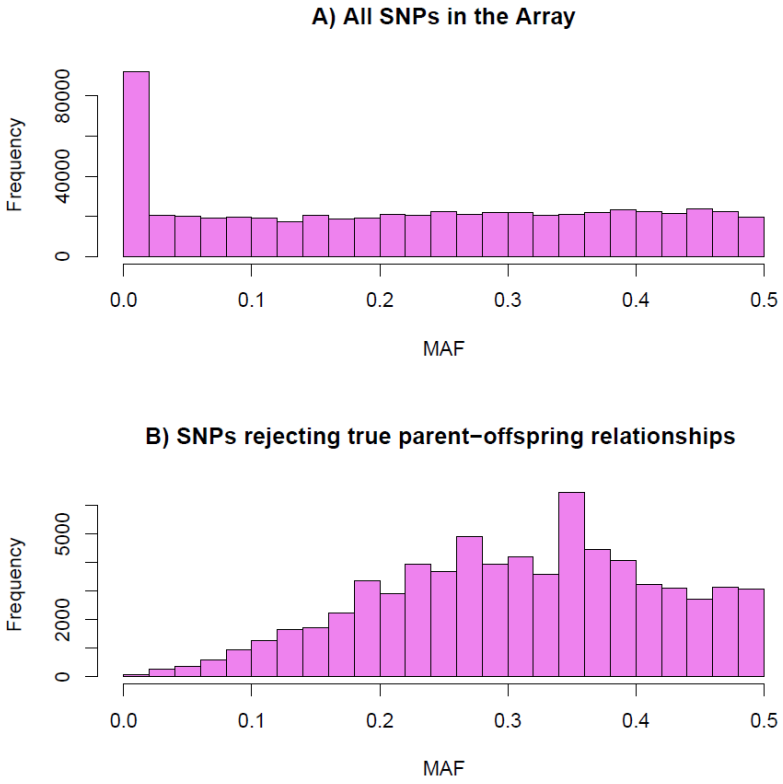

Figure 2. Distribution of SNPs as a function of minimum allele frequency (MAF). (A) Allele frequency distribution of 592,053 autosomal SNPs in the array; (B) Allele frequency distribution of 69,882 SNPs rejecting true parent-offspring relationships.

The generic genotyping error of an array can be computed by setting *ge* at an initial value and by computing the average r_r using all SNPs and their frequencies in the array. If the average r_r differs from that observed in our dataset, then *ge* is increased or reduced until the average r_r approaches the approximate same value as the actual estimated value in data r_r. For the rate of rejection of 0.000735 we estimated a *ge* = 0.006. That is, six out 1000 genotypes were genotyping errors. In addition to the generic genotyping errors we can identify specific SNPs that repeatedly reject true parent-offspring relationships. In our analysis we identified 7,744 SNPs rejecting ≥5 true parent-offspring relationships (Gomez-Raya *et al.*, 2022). Discarding SNPs based merely on MAFs implies profiling based on the fact that clustering algorithms are more prone to error with SNPs at low MAF. Instead, SNPs detected by the Inconsistent Mendelian Inheritance method should be the result of true genotyping errors.

Abstract

Recently, numerous studies including various tissues have been carried out on long non coding RNAs (lncRNAs) but still, lncRNAs variability has not yet been fully understood. In this study, we characterized the interindividual variability of lncRNAs in pigs, in the context of number, length, and expression. Six transcriptomes of Polish Landrace boars (S1-S6), including half-brothers (S1-S3), were investigated using bioinformatics (lncRNAs identification) and statistical methods (lncRNAs variability). The number of lncRNA ranged from 1,289 to 3,500 per animal. The number, length, and expression of lncRNAs significantly varied between individuals. S1 exhibited significantly higher, while S3 and S6 exhibited lower expression than other animals. Based on the pairwise analysis two groups with no difference in expression level were distinguished: S2, S4, and S5 as well as S3 and S6. No consistent pattern has been found between pairs of half-brothers. This work might contribute to further research leading to understanding the role of lncRNA variability.

Introduction

Long non coding RNAs (lncRNAs) are RNA molecules longer than 200 nucleotides that are not translated into functional proteins. According to Statello *et al.* (2020) lncRNAs play a role in gene expression regulation by affecting transcription, DNA replication, and the response to DNA damage and repair. Other functions involve structural and regulatory roles in mRNA metabolism, including splicing, turnover and translation, as well as signaling pathways. Since alterations in lncRNAs expression affect important cellular functions they have the potential to contribute to a phenotypic variation including numerous diseases (Statello *et al.* 2020). Domestic animals are an essential resource in studies involving RNA, including lncRNAs (Lagarrigue *et al.* 2021). Still, lncRNAs have not yet been fully characterised in pig genomes. In our study, we investigated interindividual variability of lncRNAs in pigs, in the context of number, length, and expression.

Materials & methods

RNA-seq data. Transcriptomes were collected from muscle tissue (*longissimus dorsi*) samples, which were taken from six Polish Landrace boars (S1-S6), where three boars were half-brothers (S1-S3). DNA isolation and reverse transcription were performed to obtain DNA and cDNA templates required for library preparation. Libraries were generated from 50 ng of RNA fragments using the KAPA RNA HyperPrep Library Preparation Kit (Roche) and then sequenced using the Illumina NovaSeq 6000 in a paired-end mode with the designated single read length of 101 bp. The number of raw reads per individual ranged from 120,802,823 to 168,508,615.

Bioinformatic pipeline. Quality control of raw reads was carried out for each sample using the FASTQC software (Andrews, 2020). Data cleaning was done by Trimmomatic (Bolger *et al.* 2014). Edited reads were then mapped to the Sscrofa11.1 reference genome (Warr *et al.* 2020) using HISAT2 (Kim *et al.* 2019). The Samtools package (Li *et al.* 2009) was used for post-alignment processing. The next step comprised the quantification of gene expression with the StringTie software (Kovaka *et al.* 2019) based on information from aligned reads, reference genome, and reference gene annotation (Warr *et al.*, 2020), which resulted in

transcripts abundances expressed in Fragments per Kilobase Million (FPKM). Transcripts were then filtered out to retain only putative lncRNA by applying the following sequence of removal criteria: (1) transcripts containing a single exon using the gffread tool from GFF Utilities (Pertea and Pertea, 2020); (2) transcripts shorter than 200 bp or longer than 10,000 bp; (3) transcripts consisting of at least 50% of low complexity regions identified using the sDUST software (Morgulis *et al.* 2006); (4) transcripts with an expression lower than 0.3 FPKM (Cai *et al.* 2018); (5) transcripts containing known protein-coding domains; and (6) transcripts with high coding potential using the Coding Potential Assessment Tool (CPAT) software (Wang *et al.* 2013). Among the remaining transcripts that represent lncRNA, the novel lncRNAs were identified by comparing sequences with the non-coding RNA sequence database RNA-Central (Petrov *et al.* 2015).

Interindividual variability of number, length, and expression level of lncRNAs. The χ^2 of the goodness of fit test was used to test whether the *number* of lncRNA is uniformly distributed between individuals. The normality of the distribution of both the length of lncRNA and the expression level measured by FPKM was assessed with the Kolmogorov-Lilliefors test. The underlying null hypothesis was defined as: lncRNA length/expression follows a normal distribution. Due to the non-normality of considered data, non-parametric methods were applied. The underlying null hypothesis assuming that the distributions of lncRNA *lengths* were the same for all animals was verified using the Kruskal-Wallis test, which is a rank test dedicated to independent samples. Then the Dunn test was used to compare the distribution of lncRNAs in pairs of animals. The nonparametric Quade test for dependent data was used to verify if there is interindividual variability in the *expression* level between all individuals. To check if any boar has a higher/lower expression of lncRNA than other individuals the pairwise comparison using Wilcoxon signed-rank test was performed. In both cases the length and expression analysis the Bonferroni procedure was applied for multiple testing correction across all pairs of individuals.

Results

The number of lncRNAs significantly varied between individuals ($P<2.2\times10^{-16}$) and ranged from 1,289 to 3,500 (Figure 1). Moreover, only 232 lncRNAs were common among all boars (Figure 2). Not only the counts but also lncRNA lengths significantly varied between individuals ($P<2.2\times10^{-16}$) (Figure 3).

In particular, individual S1 differed from the other boars. Moreover, there was significant interindividual variability in the expression level ($P=8.43\times10^{-266}$ in the Quade test). Pairwise Wilcoxon test with Bonferroni correction showed that lncRNAs of S1 exhibit higher expression than those belonging to the other boars (P varied from 5.48×10^{-89} to 2.22×10^{-139}), while S3 and S6 exhibit much lower expression than 4 other animals

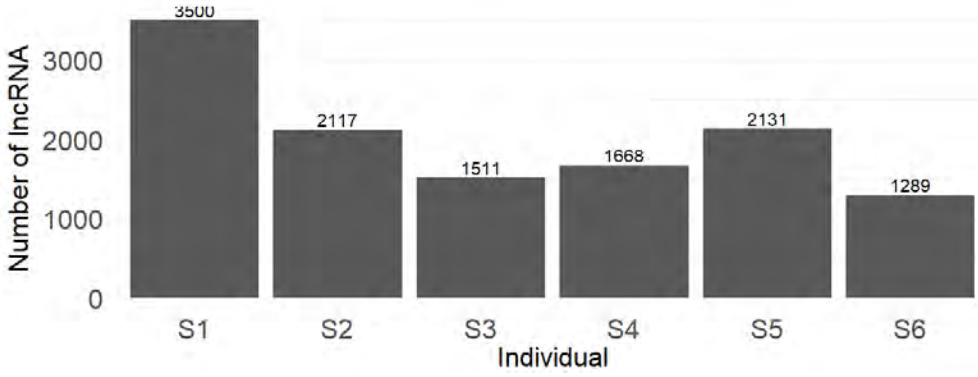

Figure 1. The total number of lncRNA per individual.

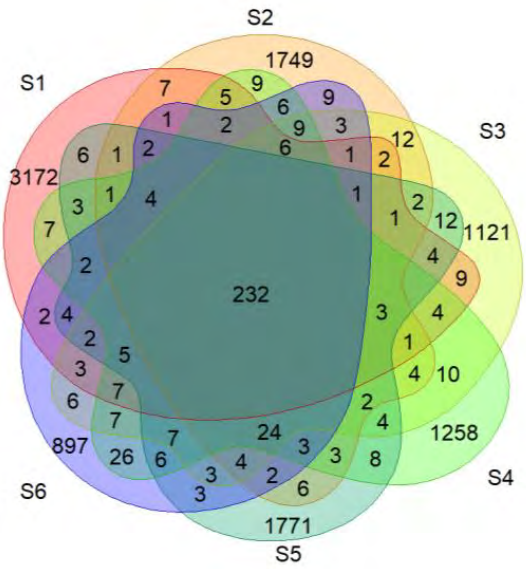

Figure 2. The number of common LncRNAs between boars.

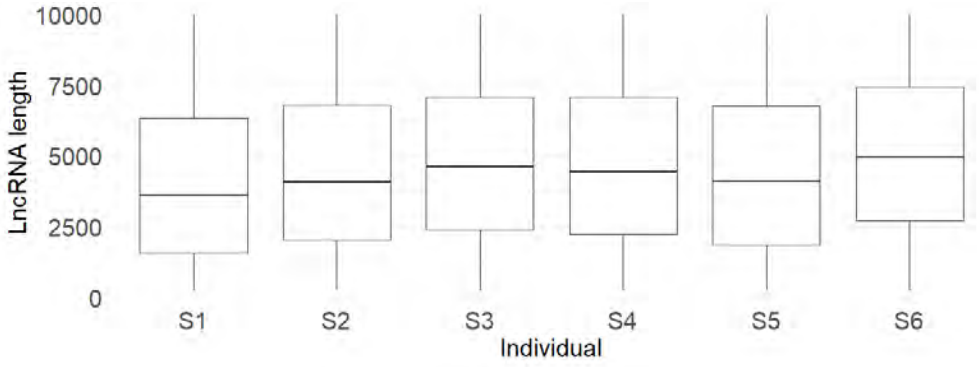

Figure 3. The lncRNA length per individual.

(*P*-values varied from 0.001 to 9.4×10^{-135} for pairs including S3 animal and from 1.11×10^{-139} to 1.21×10^{-7} for pairs including S6). Based on the pairwise analysis two groups with no difference in expression level were distinguished: S2, S4, and S5 as well as S3 and S6.

Discussion

It is already known that lncRNAs are abundant in multiple organisms, e.g. human, other vertebrates, plants and simple model species such as *C. elegans* and yeast (Kornienko *et al.* 2016). Multiple studies including numerous tissues have been carried out on lncRNAs also in pigs (Kosinska-Selbi *et al.* 2020, Yang *et al.* 2021) and the improvements in the understanding of non-coding RNAs variation has been observed by e.g. recognizing that lncRNAs display higher expression variation than protein-coding genes (Hu *et al.* 2020, Kornienko *et al.* 2016). Nevertheless, not much is known about the interindividual variability of lncRNA number, length and expression. In this work, we found that individuals significantly varied in all three

terms. Moreover, no consistent pattern has been found between pairs of half-brothers. This work might be a good start to understanding lncRNA variability between individuals and contribute to further research pointing to the role of this variability.

Acknowledgements

807. Inclusion of average rainfall in genetic evaluation of SA Holsteins to mitigate genotype by environment interaction

M. van Niekerk[1,2*], F.W.C. Neser[1], J.B. van Wyk[1] and V. Ducrocq[1,2]

[1]Department of Animal, Wildlife and Grassland Sciences, University of the Free State, 205 Nelson Mandela Drive, Park West, Bloemfontein 9301, South Africa; [2]Université Paris-Saclay, INRAE, AgroParisTech, UMR GABI, 78350 Jouy-en-Josas, France; michiel@ganna.co.za

Abstract

Genetic improvement for persistency of milk production in South African Holstein cattle in a total mixed ration or pasture production system will be impeded because of the existence of genotype by environment interaction between the production systems. Previous studies where herds' production system were known (unlike reality) showed that rainfall level indicate the production system preferred by producers. The study aimed to determine the effect of including average rainfall in a random regression model as a possible proxy for production system used. The animal-additive-genetic effect due to annual rainfall (class) was added to the existing additive-genetic-average-production and -persistency effect. Heritability estimates of rainfall class 1 ('low' rainfall) coincided with total mixed ration estimates while rainfall class 5 ('high' rainfall) coincided with pasture estimates in later lactations. Results suggest that genetic background responsible for average production level and persistency over the lactations are not consistent over different rainfall areas.

Introduction

Genotype by environment interaction has been shown to exist in South African (SA) Holstein dairy cattle in previous studies by Ducrocq *et al.* (unpublished data) and Van Niekerk *et al.* (2019, 2021). In the latter two studies, clear differences in genetic parameters between herds using a total mixed ration (TMR) or pasture (PSTR) production system were shown. Specifically, genotype by environment interaction for persistency of production between the two production systems were indicated with genetic correlations for the first three lactations being below 0.64 throughout (Van Niekerk *et al.*, 2021). This mean that animals whose progeny perform well in TMR will not necessary perform well under PSTR conditions with regards to milk production (MilkPr) traits. Selecting sires whose progeny will perform satisfactory or superior in both or one of the production systems will thus not be accurate, as the production system used by herds are not known and thus ignored in genetic evaluations of SA Holsteins. Ducrocq *et al.* (2015) showed that the production system used by herds are dependent on the rainfall (long term annual average) of the herd's location (nearest town) in SA. They also showed that rainfall had the largest effect on the genetic variability of MilkPr using a reaction norm model. The aim of this study was to investigate the effects of including average rainfall of the towns nearest to the applicable herds as a proxy for the production system used, utilising a previously developed alternative random regression model (aRRM; Van Niekerk *et al.*, 2019).

Materials & methods

Full access to the complete pedigree and milk recording data that were used in this study were given by the SA Holstein Cattle Breeders' Society.

Data. Test-day (TD) records of MilkPr (kg) from 1988 to 2016 were used for the analysis. The dataset consisted of the first three lactations of cows from 37 herds, of which 26 utilize a TMR and 11 a PSTR production system. Cows with seven or more TD records per lactation and who completed their first lactation were used in the study. Sires with less than 10 daughters and contemporary groups with less than five cows were excluded from the dataset.

Statistical analyses. Restricted maximum likelihood was used to analyse the data, making use of the Wombat software (Meyer, 2007). MilkPr was analysed using multi-lactation records and the aRRM (Van Niekerk *et al.* (2019). This model was created as a better substitute to the fixed regression model used for genetic evaluations of SA Holsteins (Interbull, 2022). In the aRRM the animal-additive-genetic random effects were defined as separate for each lactation and expressed as a function of days in milk, containing a constant plus a regression slope multiplied by current days in milk. Consequently, each lactation is a combination of an (additive) genetic-average-production (GPr) and -persistency (GPe) effects (first and second eigenvector per lactation, respectively). In the analysis for this study, a third term (regression) over each day in milk was added for the animal-additive-genetic effect (third eigenvector). This term represents the genetic effect due to rainfall (GR), as a proxy to dominant production system. Rainfall level (long term annual average) was categorised in five classes as follow: Class 1: 413 to 492 mm; Class 2: 493 to 597 mm; Class 3: 598 to 672 mm; Class 4: 673 to 787 mm; Class 5: 788 to 1,008 mm. Classes were defined according to a relative balanced distribution of herds over rainfall level. The permanent environmental effect was included in the same way as the animal-additive-genetic effect. Residual variance was considered heterogeneous over and between lactations and partitioned in 10 classes per lactation. This aRRM, TD and multi-lactation model that included the GR effect (GR model) for MilkPr can be described as follows:

$$y = Tt + Ss + Hh + Ll + Mm + Aa + Cc + Qu + Zp + e \quad (1)$$

where y is a vector of 24-h test-day MilkPr observations for the lactations; t is a vector of fixed Herd × Test-day × Number of milkings interaction (contemporary group) effects; s is a vector of fixed Herd × Calving year × Calving season × Lactation number interaction effects. The following vectors of fixed regression coefficients are included in Equation 1: h for Herd effects; l for Calving year × Lactation number interaction effects; m for Calving month effects; a for Calving age class effects (8 classes); c for previous calving interval class effects (8 classes). The random regression coefficients for the animal additive genetic and permanent environmental effects were u and p, respectively and e is a vector of residual effects. The matrices T, S, H, L, M, A, C, Q and Z are incidence matrices that relate observations to their respective effects.

Results & discussion

The model that included the GR effect in this study did not have a better Bayesian Information criterion (increase of 27,316.38) compared to results from Van Niekerk *et al.* (2021), where the TD records from TMR and PSTR were treated as different traits (i.e. multi-trait analyses) and without the GR effect (TMR-PSTR model). However, there was an improvement of the Bayesian information criterion (decrease of 2,879.55) compared to results from Van Niekerk *et al.* (2021), where TD records from TMR and PSTR were treated as the same trait, also without the GR effect. This model can be seen as a 'national SA Holstein genetic evaluation' (nGE model). The addition of the GR effect in the current model explained 7.8% of the animal-additive-genetic effect for MilkPr in lactation 1 and decreased to 0.9 and 0.0% for lactation 2 and 3, respectively.

In lactation 1 (Figure 1), heritability estimates from the GR model were similar between ('low') rainfall classes 1, ('medium) 3 and ('high') 5, and in close agreement to TMR and nGE estimates. In lactation 2 the rainfall class 1 and 3 estimates were still close to each other and to TMR and nGE estimates. However, rainfall class 5 estimates were higher during early- to mid-lactation and closer to heritability estimates from the PSTR production system. In lactation 3 the differences between the heritability estimates of rainfall class 1, 3 and 5 are more pronounced during mid- to late-lactation with estimates from rainfall class 5 being closest to PSTR estimates, and rainfall class 1 estimates still being closest to TMR estimates (as in lactation 1 and 2). (Van Niekerk *et al.*, 2021).

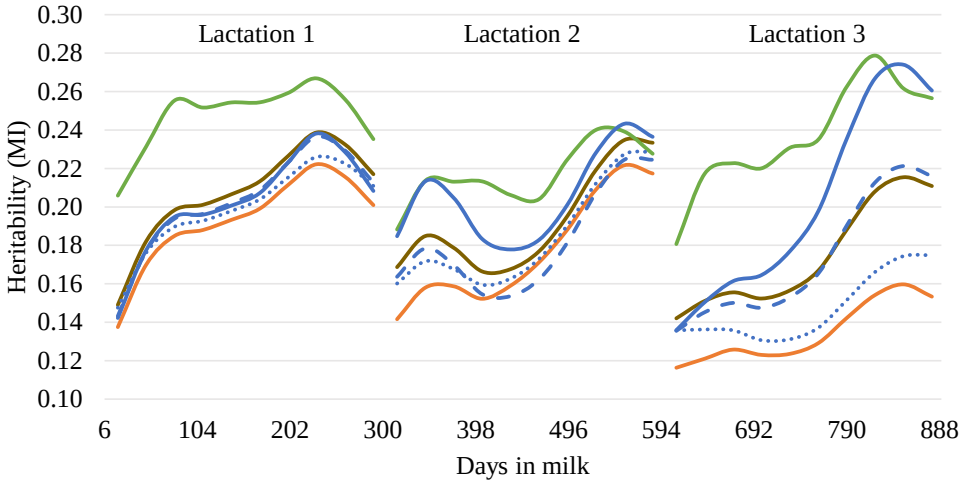

Figure 1. Heritability estimates for milk production over the first three lactations using the model including the genetic effect due to rainfall (class 1: blue dotted; class 3: blue dashed; class 5: blue solid; GR model), compared to a previous model where the two production systems were defined as different traits (total mixed ration: orange; pasture: green; TMR-PSTR model), as well as a 'national SA Holstein genetic evaluation' model excluding the genetic effect due to rainfall and TD records undefined for production system (brown; nGE model).

The nGE heritability estimates are similar to the TMR estimates as most records analysed with the nGE model came from herds using a TMR production system (Van Niekerk *et al.*, 2021). Rainfall class 1 heritability estimates being close to previous TMR heritability estimates make sense as 100% of herds in this class use a TMR production system. This also make sense to a lesser degree, for rainfall class 3 estimates as 78% of herds utilise a TMR production system. 75% of herds employing a PSTR production system in rainfall class 5 explains the similarity of these estimates with previous PSTR estimates. Rainfall classes 3 and 5 heritability estimates seem to follow nGE and PSTR estimates more precisely in later lactations, specifically lactation 3. (Van Niekerk *et al.*, 2021).

Genetic correlations (Table 1) between the GR and GPr effects were positive but weak, ranging from 0.43 to 0.32 for lactation 1 and 2, and 0.19 for lactation 3. The genetic correlation between the GR and GPe effects were negative and also weak for lactation 1 and 2 (-0.28 and -0.30, respectively), but positive and close to zero for lactation 3 (0.10).

The GPr and GPe components are made up of the average-additive-genetic level and persistency respectively, of performance of animals and their progeny, irrespective of the rainfall area(s) in which they produce and are measured in, over each of the lactations. When the additive-genetic performance of animals and their progeny are further regressed for average rainfall, the genetic correlations mentioned suggest that the genes involved in MilkPr are not consistent and reliable over different rainfall areas.

Conclusions

Considering the heritability estimates in this study and supported by previous research, including rainfall level as an important climatic variable in the proposed aRRM for MilkPr seem to be a good proxy for production system used by Holstein herds in SA, especially for later lactations. The way in which the rainfall classes are constructed may have an important effect on the heritability estimates. More herds in

Abstract

Intramuscular fat content (IMF) is an important trait to estimate in order to select meat quality in pigs. The IMF estimation, using ultrasound measurement on live pigs (IMFref), is a suitable method but partly manual and so, too time consuming for field application. From a first dataset with 2,311 pigs, we developed an automatic method based on several steps to estimate IMF value from raw ultrasound pictures (IMFauto). This method permitted to obtain high corelations between values obtained by IMFref and IMFauto methods, 0.65 at picture level and 0.83 at animals' ranking within batch level. A genetic parameters estimation was done to validate the two traits (IMFref and IMFauto) using 1,544 animals evaluated from 2020 and 2021. The two traits were genetically identical with genetic corelation equal to 1. The automated estimation gave a more accurate estimation with higher heritability and less rejected pictures. The trait IMFauto is validated to be used routinely in selection but correlation between this trait and IMF measured on meat have to be validated.

Introduction

The intramuscular fat level (IMF) is related to the meat quality in pork due to association with tenderness and juiciness of the meat (Ragland *et al.*, 1998). AXIOM, a pig breeding company, decided to integrate IMF trait in breeding goal of its Duroc line in 2015. The IMF level is estimated on the *longissimus dorsi* muscle by using ultrasound measurements on live animals around 100 kg liveweight. Routinely, the IMF estimation (IMFref) is done using BioSoft Toolbox® II for Swine 2.5 developed by Biotronics company (Newcom *et al.*, 2002). This method is partly manual. Indeed, technician has to done several actions and choices to estimate IMF: image quality control and selection of the area to analyse on ultrasound picture. This process requires 1 week between animal ultrasound measurement and integration of IMF estimation in the BLUP genetic evaluation. This process is not efficient due to this delay. In order to improve efficiency and save, AXIOM decided to develop an automatised method for IMF calculation. To estimate IMF value with ultrasound pictures, several approaches have been studied for the last years. Ragland *et al.* (1998) used multiple regression to predict IMF using linear model. Aass *et al.* (2006) used stepwise regression procedures to develop prediction models. In 2020, AXIOM had estimated more than 2,500 raw ultrasound pictures and values of IMF calculated from linear regression using BioSoft Tollbox ® II for Swine 2.5 (IMFref). At this stage, no IMF measurements on meat were available. The aim of this study was to develop an automatic method to estimate IMF content in a short time and to validate that the new trait estimated was genetically similar to IMFref.

Materials & methods

Animals. Animals used were males and females from AXIOM Duroc line, born in one nucleus farm and raised at the original farm or at the boar testing station of AXIOM. Two datasets were created to develop this method. The first one used to develop the method of the automatic IMF (IMFauto) estimation was composed with 2,311 animals tested from 2016 to 2019. The second dataset, used for genetic parameters estimation on of IMFauto was composed of 1,544 pigs recorded from 2020 to 2021. The pedigree file was traced back 24 generations corresponding to 88,974 animals born between 1994 and 2020. All the known ancestors were integrated in the pedigree file.

Ultrasound measurements. All pigs, around 100 kg liveweight, were weighted and 6-10 ultrasound images were taken using EXAGO ultrasound system (IMV Imaging; Angoulême, France) equipped with a linear transducer. Measurement site was on the *longissimus dorsi* muscle between the 10th and 13th vertebrae on the left side at almost 7 cm from the dorsal line. Operators who recorded measurements on pigs were AXIOM technicians, trained together at least one time per year to record IMF pictures. All pigs from one batch were tested the same day by the same operator in one group of control (batch).

IMF reference estimation. The reference value of IMF (IMFref) was calculated using a linear regression with BioSoft Toolbox® II for Swine 2.5. In average 5.2 (±1.5) pictures / animal were considered as acceptable after quality control done by the technician. Then operator positioned a 1 square centimeter area on each picture to estimate IMFref (Newcom *et al.*, 2002). The IMFref value considered for each animal was the average of values estimated for all pictures measured from this animal, from 1 to 11 pictures for this study.

IMFauto development. Automatic process of IMF estimation was developed (IMFauto). Each raw ultrasound picture was segmented using scikit-image library on Python software (van der Walt *et al.*, 2014). Firstly, a Canny filter function (Canny,1986 cited by van der Walt *et al.*, 2014) was used to highlight in a binary picture the muscle edge. Secondly, the transform hough line function (Van der Walt *et al.*, 2014) used the result of the Canny filter function to create automatically the limit of the muscle area. From this segmentation, muscle area was extract from the original picture. From muscle area, the parameters described by Newcom *et al.* (2002) were extracted from each picture, representing 50 variables for each picture. From those variables, a random forest analyze was proceeded using the randomForest package (Liaw and Wiener, 2002) on R (R Core Team, 2018) to estimate the best coefficients of the linear equation to predict IMFref from automatic picture treatment. Best model was validated using Spearman corelation using package stats on R (R Core Team, 2018). Several levels of validation have been done: picture level, animal level and ranking within batch. Picture quality control was also automatically done on picture size after segmentation.

IMFauto calculation. IMFauto calculation was done on all the historical data of ultrasound pictures from AXIOM (first dataset). The IMFauto value considered for each animal was the average of values estimated for all pictures validated by the method. IMFauto calculation take less than 1 second per picture and around 15 minutes per batches (30 animals with 6 pictures/animals) for all the process.

Genetic parameters estimation. Genetic parameters were estimated using ASReml 3.0 software (Gilmour *et al.*, 2009) with the restricted maximum likelihood methodology applied to a multitrait animal model with two traits, IMFref and IMFauto. Fixed effects were tested at an α-risk of 5% using the Wald test on ASReml (Gilmour *et al.*, 2009). Testing farm with 2 levels, sex with 2 levels (male and female) and batch of control with 37 levels were significant and included as fixed effect in models. The number of pictures taking in account to calculate IMFauto or IMFref and the weight at testing were significant and added as covariate. Litter effect used as contemporary group effect, was added as random effect. Dataset for genetic validation was composed with 1,544 Duroc animals

Results

Linear equation. The best linear model obtained by random forest to predict IMFref from automatic treatment showed a Spearman correlation of 0.65 at picture level and 0.74 at animal level (Table 1). Correlation of animal's ranking from highest to lowest estimation of IMF value within batch between IMFref and IMFauto was 0.83.

Table 1. Descriptive statistics for both IMF.

	Number of animals	Average weight at testing (kg)	Average number of pictures / animal	Average IMF (%)
IMFref	1,082	105.1	5.2	1.99
IMFauto	1,474	105.6	5.7	1.96

Phenotypic means and distributions. On the dataset used for genetic parameters estimation 70% of animals have value for IMFref and 95% for IMFauto. The difference was due to quality control process with 30% of animals rejected for IMFref and only 4.5% for IMFauto method. The IMF trait was tested at 102 kg for IMFref and 106 kg liveweight for IMFauto with close average estimates (1.99 vs 1.96%).

Genetics parameters. Heritability of IMF calculated was quite high with 0.52 for IMref and 0.66 for IMFauto but could not considered as different due to standard error (Table 2). Genetically, the two traits could be considered as identical, genetic correlation was 0.99, not significatively different from 1. Whereas, absolute value of the phenotype could differ between the two methods with the phenotypic correlation significatively different from 1 (0.84).

Litter effect was similar for both IMF, with 1 and 2% of the total variance explained for IMFref and IMFauto. They were not difference from 0 with a standard error of 0.02.

Discussion

Linear model for prediction seems to be the best approach in the AXIOM's context, it was previously used by Ragland *et al.* (1998) and Aass *et al.* (2005). Kvam *et al.* (2017) showed that deep learning applied to ultrasound images can predict accurately IMF as long as sufficient image quality and large number of images were available. To develop this kind of method AXIOM should invest in a large database with IMF from meat whereas, for a linear approach, row pictures and IMF calculation were already available in AXIOM's databases. Therefore, predicting IMFauto from IMFref appears as the best option. Nevertheless, IMFauto was developed to predict IMFref but not to estimate the real value of intramuscular fat in pork meat. It will be necessary to validate IMFauto with chemical value of IMF or at least visual ranking of IMF realised directly on meat.

Genetic validation of IMFauto. IMFauto and IMFref had very similar values (1.99 vs 1.96% of IMF). Maignel *et al.* (2009) showed that correlation between IMF obtained *in vivo* by ultrasound measurement and IMF on pork meat using chemical analysis was around 0.62, value higher than the study done by Newcom in 2002. In fact, absolute value obtain by ultrasound technology is lower than value in the meat but the rank between animals is correct and permitted to select animals on IMF (Maignel *et al.*, 2009). IMFauto method has to be validated with samples of IMF from chemical analysis of the meat.

Table 2. Genetic parameters of IMFref and IMFauto with heritability on diagonal, phenotypic corelation down to the diagonal and genetic corelation up to the diagonal.

	IMFref	IMFauto
IMFref	0.52 (±0.08)	0.99 (±0.02)
IMFauto	0.84 (±0.02)	0.66 (±0.08)

Heritability estimates of IMFauto and IMFref were close to values found by Maignel *et al.* in 2009 (0.52 and 0.66 vs 0.66), with Duroc and dataset size very similar. Won *et al.* in 2017 found IMF heritability at 0.52 but it was estimated on Yorkshire animals.

Corelation between IMFauto and IMFref was close to 1, meaning that the both approaches evaluated the same trait. Heritability was higher for IMFauto and phenotypic variance were smallers than IMFref. Probably, the automatized process produced less bias than operator evaluation. In the same time, less pictures were rejected during quality control. Indeed, automatic quality control is more objective than human evaluation.

AXIOM developed an automatic process to estimate IMF using ultrasound measurement. Linear equation was based on IMFref which was not an estimation of intramuscular content of the meat but estimation of it using ultrasound pictures. Genetic parameters have shown that IMFauto and IMFref were genetically the same trait. The automatization reduced variability of the estimation and bias due to operators' decisions. IMFauto was a good solution to select animal instead IMFref with less time between measurement and more accuracy. However, no validation has been done on real IMF value in pork meat. The next step will be to evaluate IMF on meat using chemical estimation on animals previously evaluated alive.

809. Assessing genomic prediction of economic trait in alpacas: a simulation study

G.C. Mamani[1*], B.F. Santana[2] and D. Jarquin[3]

[1]Instituto Nacional de Innovación Agraria, Av. La Molina N° 1981, 2791, Lima, Peru; [2]University of Connecticut, Storrs, CT 06269, USA; [3]University of Florida, Gainesville, FL 32611, USA; gerardocmamani@gmail.com

Abstract

The objective of this study was to assess the prediction accuracy of genomic breeding values using different methods. The data were simulated containing phenotypic, pedigree and genomic information mimicking an alpaca population. A total of 70,000 SNP markers were simulated considering the 36 alpaca chromosomes. The heritability of the simulated phenotypic trait (fiber diameter trait) was set to 0.41. Three prediction methods were considered: BLUP, GBLUP and ssGBLUP. The genomic prediction accuracy was computed as the correlation between the true genetic values and the predicted values, also the expected accuracy was estimated via the prediction error variance. GBLUP provided the highest prediction accuracy for non-phenotyped young animals followed by ssGBLUP and BLUP. The obtained results indicate that in the absence of animal performance data, the genomic information allows us to obtain a higher accuracy of breeding values which can be leveraged to obtain greater genetic gains.

Introduction

In animal breeding, the selection of genetically superior individuals is crucial to improve trait performance of populations. The estimation of breeding values through a predigree-based best linear unbiased prediction (BLUP) which method is widely applied, both in academia and for commercial purposes. Recently, the availability of dense molecular markers (genomic data) has revolutionized conventional breeding strategies. However, the high initial cost for implementing this methodology could discourage its use. The use of simulation studies helps to assess the potential of this methodology to take more informed decisions before making a large investment.

Genomic selection (GS) proposed by Meuwissen *et al.* (2001) aims to estimate the genomic breeding values (GEBV) of non-phenotyped individuals and to carry out the selection of the animals using GEBV. This method initially requires the availability of phenotypic and genomic information for a set of already observed individuals to be used from model calibration then the genomic breeding values of non-phenotyped individuals are estimated using exclusively their maker profiles.

The alpaca is an important specie for many farmers in Peru due cultural, economic, and social aspects. To our knowledge, as today there are no alpaca breeding programs using genomic information in the selection process. The objective of this study is to compare the accuracy of estimated breeding values obtained with three prediction methods using simulated alpaca genomic data.

Materials & methods

Simulation. The phenotypes, pedigree and genomic data were generated using QMSim software (Sargolzaei, 2014). The historical population consisted of 100 generations with a gradual decrease in size from 3,000 to 640 individuals. A total of 600 females and 40 males of the last generation of the historical population were the founders of the recent population. The population was expanded by 10 generations based in phenotypic selection. The simulated genome considers the 36 alpaca autosomes. Genotypes were simulated for 70,000

bi-allelic markers for the five last generations (3,000 individuals). Phenotypic measures were simulated based on real heritability estimates for fiber diameter (0.41, Gutiérrez *et al.*, 2009).

Statistical analysis. *BLUP (Best linear unbiased prediction).* The following model was used to predict the breeding values when using pedigree data solely:

$$y = 1u + Za + e \quad (1)$$

where, y represents the response of the trait, u is the general mean and it is common to all genotypes, Z is the incidence matrix that connects phenotype with additive genetic effects, a is the vector of additive genetic effects with $a \sim N(0, A\sigma^2_a)$ and e is the vector of residuals such that $e \sim N(0, I\sigma^2_e)$ where, A is the numerator relationships matrix, I is the identity matrix, σ^2_a is the additive genetic variance, and σ^2_e is the residual variance.

GBLUP (genomic best linear unbiased prediction). The direct genomic value (DGV) is estimated for all genotyped individuals using the following equation:

$$y = 1u + Zg + e \quad (2)$$

where, DGV (*g*), $g \sim N(0, G\sigma^2_g)$, G is the genomic relationship matrix whose entries contains the genomic similarities between pairs of individuals, σ^2_g is the additive genetic variance explained by markers, and the remaining terms as previously defined. The G matrix was calculated according to VanRaden (2008). The GBLUP analysis was implemented using the Blupf90 program (Misztal, 2014).

ssGBLUP (Single-Step genomic best linear unbiased prediction). The ssGBLUP was implemented to combine the information of genotyped and non-genotyped individuals using the inverse of the hybrid matrix H $(H)^{-1}$ (Aguilar *et al.*, 2010) which joins the matrix of the numerator relationship matrix (A) with the genomic relationship matrix obtained with maker data (G). The ssGBLUP analysis was performed using the same parameterization as the BLUP, only replacing the matrix A^{-1} by H^{-1}. This method was also implemented in the Blupf90 program (Misztal, 2014).

Accuracy. The model's predictive ability was measured by computing the Pearson's correlation between the predicted and the true breeding values for the different prediction methods. In addition, we also measured the expected accuracy by computing the Predicted Error Variance (PEV).

Results

The highest accuracy was obtained with GBLUP method. The density plot (Figure 1) shows the empirical distribution of the estimated breeding values obtained with the three different methods implemented. These empirical distributions are mound shaped and close to a normal distribution. The BLUP method provided EBV with less variability, also the empirical distributions derived from the GBLUP and ssGBLUP methods are overlapped also showing a slightly smaller variance.

Table 1 shows the average, minimum and maximum prediction accuracy for the last two simulated generations (9 and 10). Predicting the breeding values for young genotyped animals without phenotypic records, the GBLUP method returned the highest average correlation (0.82 and 0.81) for these generations compared with the other two alternatives. The BLUP returned the smallest accuracy (0.56 and 0.50) while the ssGBLUP returned intermediate results (0.67 and 0.63). Thus, the relative improvements in predictive ability using GBLUP compared with ssGBLUP were 22 and 29% for generations 9 and 10, respectively.

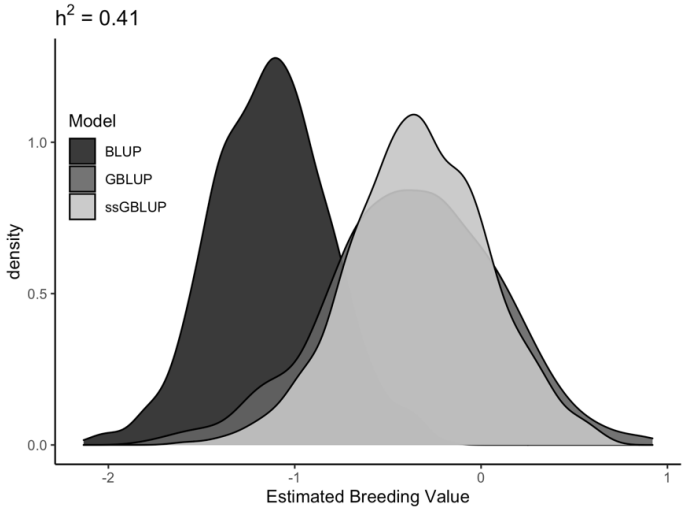

Figure 1. Density of estimated breeding values obtained using BLUP (best linear unbiased prediction), GBLUP (genomic beast linear unbiased prediction), and ssGBLUP (single-step genomic best linear unbiased prediction) methods.

Table 1. Average accuracy values obtained with different methods using A matrix (BLUP), G matrix (GBLUP) and H matrix (ssGBLUP) of the last two generations (9 and 10).

Generation	n	BLUP	GBLUP	ssGBLUP
9	600	0.56	0.82	0.67
10	600	0.5	0.81	0.63

However, the animals without genomic information but with pedigree data are excluded of analysis, except when using the ssGBLUP.

Discussion

The GBLUP method returned the highest mean accuracy, but it only can consider individuals with genomic data while the method that only uses pedigree data (BLUP) produced the lower results. On the other hand, the ssGBLUP had higher accuracies than BLUP, confirming that the integration of maker and pedigree data can be beneficial.

This comparison is between the last two generations of non-phenotyped but genotyped individuals. Garrick (2011), in beef cattle, showed that genomic prediction offers accuracies that exceed those of pedigree-based parent average of young selection candidates, and it can be equivalent to progeny tests based on up to 10 offspring. In addition, the ssGBLUP permits the estimation of genetic values for non-genotyped animals, which is not possible in GBLUP analysis (Tsuruta, Misztal, Aguilar, Lawlor, 2011) and also allows increasing training sets sizes by including genotypes with pedigree and phenotypic data only. The obtained results using BLUP, GBLUP and ssGBLUP of this study are in agreement with those reported by Daetwyler, Villanueva and Woolliams (2007). These authors found that higher accuracies when the heritability of the traits was high due to a high contribution of gene effects for phenotypic variation.

Conclusions

The prediction of breeding values using genomic information showed accuracies higher than pedigree-based estimations in animals without phenotypic information. Between the two methods that use genomic information, the ssGBLUP allows obtaining breeding values for un-genotyped individuals as well.

810. Somatic cell count and its relationship with udder type traits in Italian Mediterranean Buffaloes (*Bubalus bubalis*)

M.M. Gómez[1], R. Cimmino[1], Y. Gombia[1], G. Zullo[1] and S. Biffani[2*]

[1]Italian National Association of Buffalo Breeders (ANASB), Via Petrarca 42-44, 81100 Caserta, Italy; [2]National Research Council (CNR), Institute of Agricultural Biology and Biotechnology (IBBA), Via Edoardo Bassini 15, 20133 Milano, Italy; stefano.biffani@ibba.cnr.it

Abstract

Mammary infections in livestock are a major problem which affects animal health, resulting in significant economic losses in the dairy industry. Among the factors which can mitigate or increase the rate of intramammary infections, udder morphology plays a substantial role. The somatic cell score (SCS) is commonly used as predictor in selection for mastitis resistance. The aim of this study was to investigate the relationship between SCS and udder traits in the Italian Mediterranean Buffalo (IMB). A total of 122,717 lactations, SCS and type traits (one composite trait and six linear traits) records from 16,627 primiparous buffalo cows were used. The relationship was investigated fitting two mixed models. Analysis of variance suggested that SCS were significantly (P<0.001) affected by both udder morphology and milk yield. Least square means clearly indicated that having a morphologically correct udder contributes significantly to reducing SCS level in milk.

Introduction

Mastitis is an infection of the mammary gland, a disease of great economic importance resulting in significant economic losses in the dairy industry. Indeed, the economic costs caused by mastitis are of different nature, for example the reduction in milk production, the discarded milk, the increased culling, the increased costs of health care and labour, and the reduced milk quality. Therefore, strategies to control mastitis must include preventive health care, hygiene, veterinary remedies and genetic selection (Juozaitiene *et al.*, 2006). A commonly used phenotypic indicator of udder health is somatic cell count (SCC) (Tiezzi *et al.*, 2020). After being log-transformed to SCS, it is used as a predictor in the selection for mastitis resistance (Martin *et al.*, 2018, Parker Gaddis *et al.*, 2020). Some studies in the buffalo species (Dhakal, 2006, Piccinini *et al.*, 2006) confirmed that the threshold value of 200×103 cells/ml in buffalo milk was indicative of the presence of inflammation. Moreover parity, calving age, stage of lactation, season, stress, milking interval are additional features which can affect SCC level in buffalo milk (Singh and Ludri, 2001). Among the factors which can mitigate or increase the incidence of intramammary infections, udder morphology plays a substantial role (Pantoja *et al.*, 2020). However, few studies have been performed to investigate the relationship between SCS and udder morphology in the buffalo species. Hence, the purpose of this study was to evaluate the relationship among traits related to the mammary system, milk yield and SCS in the Italian Mediterranean Buffalo.

Materials & methods

Data. Three sources of data were available, namely milk yield data, SCC data and type trait data. The production data set included a total of 6,576,041 milk test day samples collected between 1982 and 2019 from 262,254 buffaloes, the SCC file included 2,348,632 records, corresponding to 175,362 buffaloes and the type trait dataset was composed of 81,537 records collected between 2004 and 2020. After joining and editing these three sources of information, only primiparous buffalo cows were retained and the final dataset was composed of 122,717 records from 16,627 primiparous buffalos. The variable SCC was log-transformed into SCS by using the formula SCS = log2(SCC/100,000) + 3 (Ali and Shook, 1980). The udder traits, which included a udder score (US) as composite trait and six linear traits were: fore udder attachment

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_810, © M.M. Gómez *et al.* 2022

(FUA), rear udder width (RUW), udder depth (UD), teat placement (TP), teat length (TL) and teat position (TPOS). US was scored using a scale from 65 to 99, while all linear traits were scored on a scale with 1 and 50. Finally, all traits were transformed into classes, with an interval of 5.

Model. The relationship between SCS and udder traits was investigated fitting the following mixed model:

$$y_{ijklmn} = \mu + DIM30_i + YM_j + MT_k + b_1MP_l + HYS_m + A_n + e_{ijklmn} \quad (1)$$

where y is the dependent variable (SCS test-day); μ is the general mean; DIM30 is the fixed effect of the i^{th} stage of lactation; YM is the fixed effect of the j^{th} year-month combination of milk recording; MT is the fixed effect of the k^{th} score of the morphological trait; b1 is the linear regression coefficient of daily milk production (MP). Animal (A) and Herd-year-season (HYS) were random effects; and e was the random residual term. Furthermore, backward elimination was used to eliminate non-significant effects from the model. Analysis of variance and least square means (LSM) were calculated to identify possible relationships between morphological traits and SCS.

Results

The results of the analysis of variance for SCS based on a model with the composite trait as explanatory variable (M1) and a model with all linear traits as explanatory variables (M2) are in Table 1. All effects included in the model were significant ($P<0.001$). These findings confirm the hypothesis that SCS are significantly affected by both the morphology of the mammary system and the production level.

LSM for both composite and linear traits can be observed in Figure 1a and 1b, respectively. An increase in US score has a favourable effect on SCS, which decrease by approximately 1 unit. Indeed, an udder score higher than 80 reflects a functional udder with strong ligaments, appropriate teat size and position, and proper volume. These findings are also confirmed when the relationship between SCS and morphology is analysed using three udder-related linear traits, namely TP, UD and TL. As expected, an increase in both TP and UD score has a favourable effect on SCS (decrease) while an intermediate score for TL (higher scores = longer teats) is more effective.

Table 1. Analysis of variance for SCS based on a model with the composite trait (M1) and linear traits (M2).

Factor[2]	DF	M1[1]		M2[1]	
		Mean	F value	Mean	F value

Discussion

Milk production is a complex process which can possibly exacerbate stress responses. This is particularly true in specialized dairy breeds where udder health problems and the detriment of its conformation have been observed (Sartori *et al.*, 2018). This is the case of the IMB, where an impressive increase in milk production over the last 15 years has been observed (ANASB, 2021). Alongside milk production, an increase in SCS has also been observed, being steeper in buffalo cows born before 2011 than in recent years (Costa *et al.*, 2021). Type traits appraisal in the IMB started at the early 2000s and in 2018 udder and feet score have been included in the IMB breeding objective (Biffani *et al.*, 2021). From the results observed in this study, an udder with the correct length, direction and position of the teats favors low SCC values during lactation. Present findings are also supported by earlier studies, where deeper udders or udders presenting an incorrect teat position were found to be at higher risk of developing mastitis (Juozaitiene *et al.*, 2006, Singh *et al.*, 2014). Moreover, we identified longer teats as potential risk factor for mastitis. This is in agreement with the findings of Berry *et al.* (2004) who also showed that dairy cows with longer teats were genetically predisposed to a higher incidence of mastitis. Rogers and Hargrove (1993) reported that Holsteins with shorter teats were associated with lower SCC showing a lower incidence of mastitis. Accordingly, the overall udder morphology and some additional udder traits such as US, TP, UD or TL could have some degree of association with the udder health in the buffalo cows. Hence, their inclusion in breeding programs as indicator traits may help to control and possibly reduce the incidence of mastitis in the IMB.

811. Estimating vertical path coefficients of transmission of non-genetic inherited effects from a similarity matrix

Abstract

In addition to DNA, non-genetic information, that can cause phenotypic differences between animals (microbiota, epigenetic), can be transmitted physically from one generation to the next, thus contributing to the inheritance of a trait. The path coefficients of transmission of these non-genetic inherited factors are unknown. We propose a method to estimate them from the similarity matrix between individuals. This matrix can be derived from the direct measurements of the transmitted factors. The method provided consistent estimates on simulated and real data.

Introduction

Animal selection in livestock species is based on genetic inheritance. However, non-genetic information, that can cause phenotypic differences between animals, can also be transmitted from one generation to the next, thus contributing to the inheritance of a trait. As the genetic information, the non-genetic inherited information can be transmitted physically across generations. This is the case for epigenetic marks (epigenetic inheritance) and other media such as metabolites and symbionts (microbiota inheritance). Because the laws of transmission of the non-genetic inherited factors are unknown, disentangling the different sources of inheritance involved in the phenotypic resemblance between relatives is challenging. To overcome this difficulty, David and Ricard (2019) proposed to combine the different inherited values into a single one in the transmissibility model in the case when phenotypic and pedigree information are available. With the development of new molecular measurement methods, additional low-cost information on inherited factors becomes available, offering new possibilities to study the non-genetic inheritances. The objective of the study is to propose a method to extract, from this additional information, knowledge on the vertical transmission of non-genetic factors useful for selection. The method is evaluated on simulated and real data.

Materials & methods

Methods. Let's consider a similarity matrix B. This similarity matrix is a matrix of resemblance between individuals for a given phenomenon. It can be obtained from knowledge about the law of transmission of a specific phenomenon and population structure or from direct measurements of the transmitted information (measurements of genomic, microbiota or epigenetic information on several individuals). The similarity matrix can be decomposed into 3 parts:

$$B = B_t + B_e + B_E \quad (1)$$

where B_t is the expected vertical transmission relationship matrix, B_e a matrix that accounts for the variability around the expected transmission, and B_E a covariance matrix accounting for the external factors shared by individuals influencing the transmitted inherited factor. The vertical transmission relationship matrix B_t is a symmetric matrix with 1's on the diagonal (without inbreeding) and r_{ij} as off-diagonal entries. For the case of 2 animals i and j with n common ancestors ($l = 1,n$) $r_{ij} = \sum_{l=1}^{n} r_{ij,l}$ with $r_{ij,l} = \lambda_s^{k_{ij,l}} \lambda_d^{q_{ij,l}}$, $k_{ij,l} = k_{il} + k_{jl}$, $q_{ij,l} = q_{il} + q_{jl}$, where k_{il} and q_{il} are the number of sire and dam

transmissions between ancestor *l* and animal *I*, respectively; λ_s and λ_d are the sire and dam path coefficients of transmission, respectively. Their values are useful to evaluate if selection is possible (i.e. is the factor transmitted to the next generation? by which way (sire, dam or both)? and with which intensity (value of the path coefficients)?). Depending on the information used to build the similarity matrix and the inherited factor under consideration, all or only part of the decomposition in Equation 1 is to be taken into account. Indeed, to study genetic inheritance, the genetic relationship matrix A is a similarity matrix derived from the pedigree knowing that an animal received half of its DNA from its father and half from its mother (both path coefficients equal to 0.5). It corresponds to the expected Identical-By-Descent relationships (IBD), i.e. the average relationships assuming infinite number of loci: $A = B_t$. Using SNP markers, the 'real' IBD relationships matrix (genomic relationship matrix G) is computed, resulting in a similarity matrix slightly different from A, given the finite genome size (Hill and Weir, 2011), $G = B_t + B_e = A + B_e$. Conversely to genetic, non-genetic inherited factors may be modified by the environment and/or are not stable over time. Thus, microbiota (M) or epigenetic (Γ) similarity matrices, obtained from dedicated measurements (OTUs or methylation) (Camarinha-Silva *et al.*, 2017), include the 3 parts in their decomposition: $M \text{ or } \Gamma = B_t + B_e + B_E$.

The objective of the study is to estimate B_t and its components (the sire and dam path coefficients of transmission) from the similarity matrix B. To estimate components of B_t, the chosen method was to apply the transmissibility model to a realization of pseudo phenotypes y generated by $y \sim N(0,B)$. The transmissibility model is: $y_i = y_i\beta + t_i + e_i$, with $\mathbf{t} \sim N(0, \mathbf{B_t}\sigma_t^2)$ and $\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2)$, where B_t is the previously defined transmission relationship matrix whose unknown components (path coefficients of transmission) are to be estimated and I the identity matrix. Variance components and path coefficients of the transmissibility model are estimated with ASReml and the freely available OWN Fortran program developed by David (2018). Pseudo phenotypes simulation and estimation of the path coefficients from the transmissibility model are repeated in order to obtain the distribution of the path coefficient estimates.

Application to simulated similarity matrix B. A population consisting of four non-overlapping generations without selection was simulated. The founder generation comprised 6 sires and 50 dams that were randomly mated to give birth to 400 offspring (sex-ratio 0.5). Among the progeny, 6 males and 50 females were sampled randomly to be the parents of the next generation. The same process was repeated until the last generation. The final population comprised 1,256 individuals. The transmission relationship matrix B_t was built based on the corresponding pedigree and considering three different sets of sire and dam path coefficients of transmission ({sire,dam}={0.56,0.30},{0.40,0.40} or {0.25,0.50}). The matrix B_e was set to 0.04I. To structure the B_E matrix, the 1,256 animals were randomly grouped into 6 different groups mimicking different environmental effects influencing the inherited factors. The covariances between animals in the same environment were sampled in a uniform distribution]0,1[. The B_E matrix then consisted in 1's on the diagonal and the value of the sampled covariance as off diagonal entries between animals sharing the same environment. We then considered same weight of the environment and transmission on the inherited factors to build the similarity matrix, i.e.: $B = 0.5B_t + B_e + 0.5B_E$. Pseudo phenotypes were simulated using this similarity matrix.

Application to real similarity matrix B. A first population of 660 genotyped animals was used. They were sires and dams of pigs divergently selected for residual feed intake (Gilbert *et al.*, 2017). After quality control, genotypes for 64,487 SNPs were available to compute Ω as $\frac{\mathbf{ZZ^T}}{k}$ where k is twice the sum of heterozygosities of the markers and Z the matrix of genotypes centered by allele frequencies (VanRaden, 2008). Then the genomic relationship matrix G was obtained by scaling Ω, to make the means of the diagonal and off-diagonal elements of G and A matrices equal to each other. We simulated pseudo phenotypes using the similarity matrix A or G (2 different datasets) and, to prevent convergence issues of the transmissibility

model due to no residual variation, added noise (e ~ $N(0, 0.04I)$) to obtain noised pseudo-phenotypes.

A second population consisted in 801 Large White pigs from a divergent selection on microbiota composition (Larzul *et al.*, 2021). The gut microbiota was characterized by sequencing the V3-V4 variable region of the 16S rRNA gene from fecal samples collected on 60-day-old piglets. From the initial 147 genera, unknown classified genera and genera with more than 50% of missing value were removed. The relative abundances of the 65 remaining genera were used to build the similarity matrix B. Missing values (i.e. zero) were imputed using non-parametric multiplicative simple imputation (Martín-Fernández *et al.*, 2003). Then isometric log-ratio (ilr,(Egozcue *et al.*, 2003)) transformation was applied and B was computed as $\frac{\mathbf{XX^T}}{64}$ where X is the 801×64 matrix of by column scaled ilr coordinates (i.e. $X_{ij} = \frac{ilr_{ij} - \overline{ilr_{.j}}}{sd(ilr_{.j})}$). Pseudo phenotypes were simulated using this similarity matrix.

In each case, path coefficients of B_t were estimated by applying the transmissibility model to the simulated (noised) pseudo phenotypes. Fixed effects included in the model were the environment for *simulated* B, a general mean only for *real* B with the A or G matrix, the batch effect for *real* B with the microbiota similarity matrix. Simulation of (noised) pseudo phenotypes and estimation with the transmissibility model were repeated 100 times.

Results

Variance component and path coefficient estimates obtained for pseudo phenotypes generated using simulated and real similarity matrices are presented in Table 1. For simulated B, real A and G matrices, the true values of the path coefficients to estimate are known (equal to the simulated value or to 0.5 for genetic inheritance). In such cases, path coefficient estimates were close to their true value and had low standard errors (0.03 to 0.08). For A and G matrices, the estimated residual variance was equal to 0.04, which corresponds to the value of the variance of the added noise. Transmissibility variance estimates were in line with simulated values (0.50 for simulated B, 1.00 for A and G). Applied to the similarity matrix based on microbiota data, the method provided estimates of path coefficient equal to 0.34 and 0.48 for the sire and dam, respectively. The residual variance estimate was large (0.72) and consequently the transmissibility variance reduced to 0.21.

Table 1. Path coefficient and variance estimates (s.e. in bracket).

	Expected transmission coefficients		Estimated transmission coefficients		Estimated residual variance	Estimated transmissibility variance
	Sire	Dam	Sire	Dam		
Simulated B	0.56	0.30	0.56 (0.08)	0.30 (0.05)	0.36 (0.09)	0.55 (0.12)
	0.40	0.40	0.40 (0.07)	0.41 (0.06)	0.31 (0.07)	0.53 (0.08)
	0.25	0.50	0.25 (0.06)	0.49 (0.05)	0.30 (0.06)	0.50 (0.07)
Pedigree	0.50	0.50	0.49 (0.04)	0.49 (0.03)	0.04 (0.03)	1.02 (0.34)
Genomic	0.50	0.50	0.49 (0.03)	0.49 (0.03)	0.04 (0.03)	0.99 (0.42)
Microbiota	Sire < Dam		0.34 (0.21)	0.48 (0.19)	0.72 (0.22)	0.21 (0.13)

Discussion

From the results, we show that applying the transmissibility model to pseudo phenotypes is efficient for estimating the path coefficients of transmission from a similarity matrix. Other methods could have been used, such as gradient-based descent minimization applied to the inverse of the similarity matrix, but results (not shown) were not satisfactory. Applied to a real microbiota similarity matrix, results were consistent with expectations: a sire path coefficient of transmission lower than that of the dams. Indeed, in livestock, the transmission from one generation to the next of all or part of the intestinal microbiota is most likely the result of physical contact between newborns and the dam (David *et al.*, 2019). But there is also a resemblance between the microbiota of the sire and the offspring because the genetics of the host may also have an influence on the microbiota (Goodrich *et al.*, 2016). It should be noted that results obtained should be considered with caution since microbiota information at the genus level was used to build the similarity matrix while information at the OTUs level is usually preferred to capture the similarity between individuals (Camarinha-Silva *et al.*, 2017). The estimate of the residual variance of the transmissibility model applied to the microbiota similarity matrix was large, suggesting that important related environmental effects were unaccounted for in the model. In the proposed method, the environmental effects influencing the non-genetic inherited factors are not taken into account in the estimated transmission relationship matrix. It is thus hypothesized that modifications of the transmissible potential due to environmental effects occur after the transmission of the non-genetic factors. Studies are underway to include transmitted environmental effects in the estimated transmission relationship matrix.

812. Building on Falconer's work on environmental sensitivity and scale

D.L. Waters*, J.H.J. van der Werf and S.A. Clark

School of Environmental & Rural Science, University of New England, Armidale, NSW, 2351, Australia; dwaters9@myune.edu.au

Abstract

Reaction norms are popular for analysing the genetics of environmental sensitivity in animals. The slope of the reaction norm is directly used as a measure of sensitivity. However, some of the variation in slope might be due to differences in the scale of the genetic variance. This problem was considered in 1990 by Falconer in the context of phenotypic reaction norms. This paper extends his work into the current use of genetic random regression reaction norms. A simple post-hoc method to estimate breeding values for environmental sensitivity independent of scale effects while accommodating for higher-order polynomials is proposed. A small example is used for illustration.

Introduction

There are two classes of genotype by environment interaction (G×E). Rank-type G×E occurs when the ranking of genotypes change in different environments, while scale-type G×E occurs when the genetic variance changes in different environments. In the context of breeding programs, rank-type G×E is more important as it means selection candidates change depending on the environment. In contrast, the effect of scale-type G×E can be completely removed by using an appropriate transformation (Falconer and Mackay, 1996). Both types of G×E often act simultaneously in a population (Falconer, 1990).

Reaction norm models (RNMs) estimated via random regression capture both rank and scale-type G×E. This approach uses a covariate, such as the mean performance of a contemporary group, to measure the environmental quality for each animal. The breeding value of each animal is then calculated as a function of the covariate, using the performance of relatives in different environments to infer how it changes. A linear function is often used, resulting in estimated breeding values (EBVs) for the intercept and slope for each animal. It is popular to treat the slope as an EBV for how sensitive a genotype is to different environments i.e. it's environmental sensitivity (ES) (Knap, 2005). However, it could be important to consider that the variation in slope arises from both rank and scale-type G×E (Falconer, 1990).

Falconer (1990) noted that many traits have higher variances when the means are higher. The consequence of this in a reaction norm model is illustrated in Figure 1. As the environmental mean increases, the genotypes spread out. While the rankings of genotypes do not change, there is still variation in the slope of genotypes. In this case, does the slope represent the ES of a genotype? If we assume it does, we would note that animals with a larger intercept have a larger slope. This frequently results in the conclusion that higher performing animals are more sensitive (Rauw and Gomez-Raya, 2015). However, animals with negative intercepts of the same size have equivalently large slopes (i.e. equally as sensitive), just in the opposite direction. Also, a scale transformation that equalises the variance across the environments would completely remove the variation in slope. If we ascribe the correlation between intercept and slope (r_{IS} = ~0.99) to a scale effect, the variation in slope due to re-ranking would be ($1 - r_{IS}^2$) (Falconer, 1990), or effectively to zero.

Falconer did not offer a strong opinion on the treatment of scale in reaction norms, other than to say scale effects should be considered in the analysis of environmental sensitivity (Falconer, 1990). However in Falconer and Mackay (1996), it is recommended that by recognising a true scale effect, such as larger variances

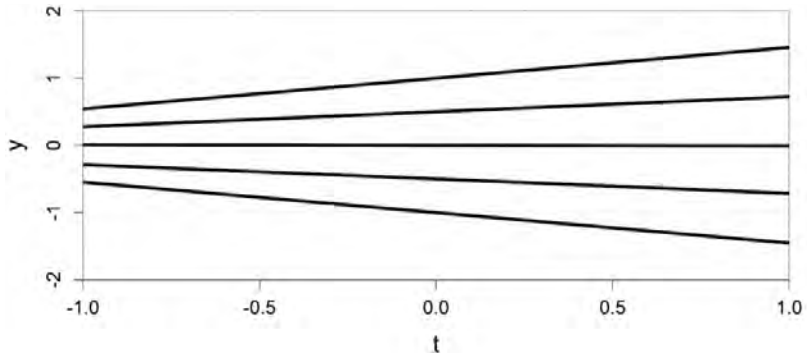

Figure 1. Reaction norm where the variance of y increases with t.

associated with higher body weights in mice, '… there is no need to look deeper into the genetic properties of the character for explanation.' This logic could be applied to the treatment of slope variance in Figure 1.

Hayes *et al.* (2003) accounted for scale in RNMs using a log transformation on phenotypic data. However, if the ratio of genetic and phenotypic variance changes across environments, the genetic variance might not be properly scaled this way (Falconer, 1990). Since random regression RNMs separate genetic and residual variance, a post-analysis focusing only on the genetic variance might be a better course of action. The following method corrects for heterogenous genetic variance on estimates of ES. Ordinary polynomials are used, although it can be easily modified for other polynomials such as Legendre.

Scale-correction method

Consider a random regression reaction norm model that estimates K, a $p \times p$ matrix containing the genetic variances and covariances between the intercept, slope and higher order regression coefficients up to p-1. This also model also estimates breeding values for the intercept (a_0), slope (a_1) and higher order coefficients for each animal. The EBV for animal i in environment j with score t is given by: $\boldsymbol{EBV_{i,j} = a_{0_i} + a_{1_i} \times t_j + \cdots + a_{p-1_i} \times t^{p-1}}$

The genetic variance and covariance matrix (G) between j environments across the trajectory can be obtained by: G = ΦKΦ', where Φ is an $j \times p$ matrix containing a vector of 1's in the first column and a vector of the j environmental scores in the second. The remaining p-2 columns of Φ are given by: $\Phi_{i,q-2} = (\Phi_{i,2})^q$, where q is the order of the polynomial. The diagonal of G gives the genetic variance for each environment. The EBVs for all animals can be standardised (SEBV) within environments based on the diagonal of G:

$$SEBV_{i,j} = \frac{EBV_{i,j}}{\sqrt{G_{j,j}}} \quad (1)$$

When plotted, the SEBVs preserve the points of reranking, but are not affected by scale effects. The SEBVs will not be linear with respect to $\boldsymbol{t}$ (even when using a linear reaction norm), so the average of the first derivative of the curve can be used to approximate the absolute change in SEBV:

$$ES_i = \frac{SEBV_{i,\max(t)} - SEBV_{i,\min(t)}}{\max(t) - \min(t)} \quad (2)$$

This can be interpreted as the 'real' environmental sensitivity (ES_i) of genotype i, representing the change in performance relative to its contemporaries in the absence of heterogenous genetic variance. Another advantage is that it permits higher-order reaction norms to be modelled while still capturing the ES into a single value. The average first derivative could also be explored over different segments of the trajectory.

Applied to a small example

Genetic reaction norms were simulated under zero, medium and high scale effects across environments (t) -1 to 1 units. The variance in intercept and slope was fixed to 1 and 0.4, while the correlation between them was 0, 0.5 and 0.95 for low, medium and high scenarios respectively. For each scenario, 1000 reaction norms were simulated and adjusted for scale following the scale-correction method. A subset of 5 genotypes were drawn from the population in the medium scenario and plotted in Figure 2a. This scenario represented a modest G×E interaction; the genetic correlation between environments -0.75 and 0.75 units was 0.62, while the genetic variance increased from 0.79 to 1.37. For a study with similar G×E levels, see (Madsen *et al.*, 2018). Equation 1 was applied to the population, which created Figure 2b. In this plot, the points of re-ranking were the same as in Figure 2a, however the variance of the SEBV was constant over t and the reaction norms were non-linear. The absolute change in SEBV was then calculated using Equation 2 and is illustrated in a sensitivity plot (Figure 2c). The sensitivity plot should not be interpreted directly as a reaction norm, as it is a linear approximation of the true reaction norm in Figure 2b. Rather, it is only used to visualise the sensitivity of each genotype.

Based on the original reaction norm, genotype 1 would be considered more robust than genotype 2, as it has a flatter slope. However, this is interpretation reverses after correcting for scale effects. This is best explained by looking at the standard deviation (SD) bands in Figure 2a. Genotype 1 is approximately 2.73 SDs above average when t=-1, but this reduces to 1.68 SDs when t=1. Therefore, its performance is relatively more sensitive compared to genotype 2, which is consistently 2.1 SDs above average across the environments. Despite a flat slope in the original reaction norm, genotype 5 improves in rank as t increases and therefore has a positive slope after correction. Meanwhile, genotypes 3 and 4 are not greatly affected by the scale correction, as the effect of scale is not as large closer to the mean.

The relationships between slope before and after correction under the three scenarios are plotted in Figure 3. The scale-correction did not affect the slope when there were no scale effects. As scale effects increased, the correlation between slope before and after correction decreased.

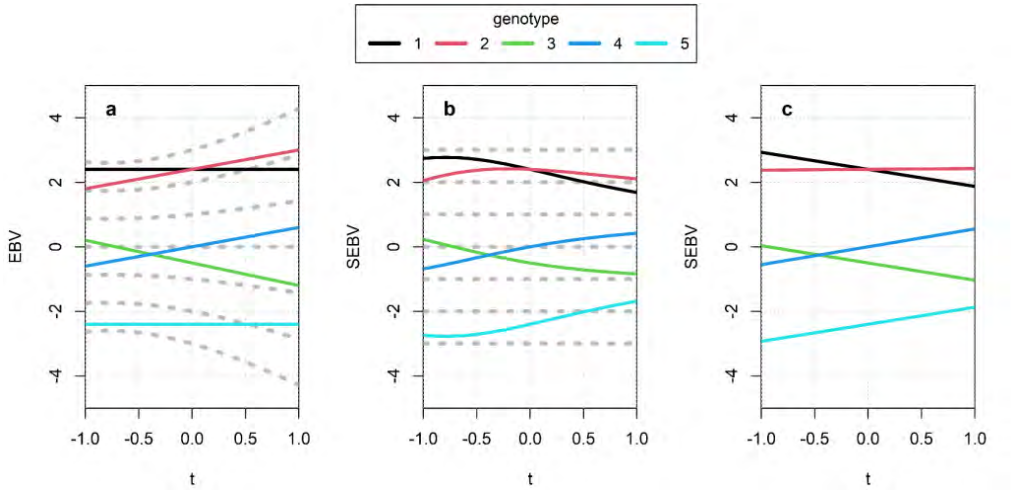

Figure 2. Reaction norms of 5 genotypes coloured individually, with ± standard deviation bands of EBVs given by the broken grey lines a: reaction norms before correction, b: reaction norms with variance standardised, c: sensitivity plot demonstrating change in slope.

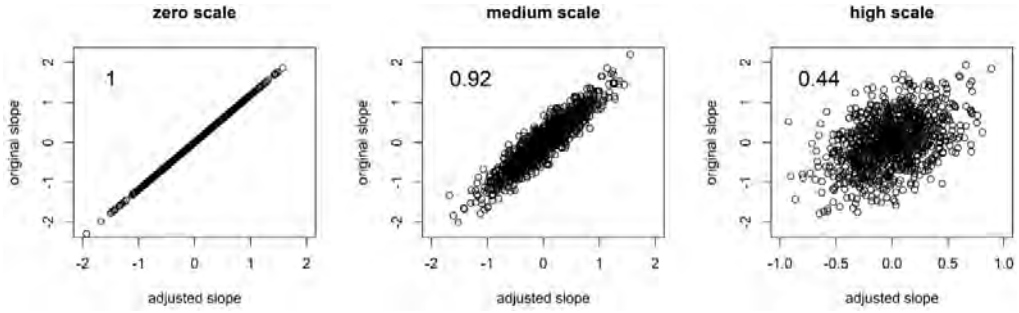

Figure 3. Scatterplot between slope EBVs before (original slope) and after (adjusted slope) being corrected for scale. The correlation is given in the top left.

The method could also be used in the analysis of longitudinal traits, where scale effects are very important. For instance, there is far less variation in weaning weights than in adult weights in livestock. In a linear random regression over time, this would bias the slope of high-weaning weight animals upward and low-weaning weight animals downward. Applying the scale correction would remove this bias and help identify animals that increase in ranking over time (i.e. faster growing animals).

Conclusions

To make progress in genetic selection, it is important to have a clear understanding of the trait being selected for. Environmental sensitivity derived from the slope of a reaction norm was previously not clearly defined, due to the impact of scale effects. A simple method for adjusting for scale effects is given. The resulting estimate of ES captured variation between genotypes in the degree of re-ranking, which could be used directly in breeding programs. The scale-correction could also be useful in longitudinal traits.

Abstract

In multiple-trait animal models, variance components are frequently estimated using Restricted Maximum Likelihood method (REML). Such an approach assumes the multivariate normality for the phenotype even if, in practice, this hypothesis is not always realistic. We assessed, using simulation, the impact of a non-Gaussian distribution for the residual term of the mixed model, on the REML estimations. The non-Gaussian distributions were simulated using a copula-based approach. Large populations over 8 generations were simulated using random selection for the 3 first generations and using a truncation selection for the following. Results obtained highlighted the robustness of REML when random selection is performed. On the contrary with a truncation selection process, we observed significant differences with the true parameters, particularly with asymmetric bivariate distributions on the residual part.

Introduction

In a genetic animal context, mixed models are widely used to dissociate the genetic and environmental variance part on the studied phenotypes and perform selection. Extension to the multiple trait model permits to consider the correlations between traits (Meyer (1991), Mrode (2014)).

The principal assumption of this model is the multi normality for the observed phenotype vectors. Since Henderson (1975), the variance-covariance parameters of the model are frequently estimated by REstricted Maximum Likelihood (REML) method, that, under the Gaussian assumption, provides unbiased estimators. However, even if the marginal distributions are Gaussian, the distribution of the multivariate phenotype can be non-Gaussian due to a non-Gaussian dependence structure between the components of the residual vectors of the mixed model.

More precisely let $X = (X_1, X_2)$ be a random vector with cumulative distribution function (c.d.f.) F and marginal c.d.f.s F_1 and F_2 assumed to be continuous. According to Sklar's theorem (Sklar, 1959), it exists a unique function C: $[0,1]^d \rightarrow [0,1]$ such that:

$$F(\boldsymbol{x}) = C\{F_1(x_1), F_2(x_2)\}, \qquad \boldsymbol{x} = (x_1, x_2) \in \mathbb{R}^2$$

The function C is called the copula of the random vector X and characterizes the dependence structure of the vector X. Typical examples of copulas are normal copula (C^N), Clayton copula (C^C), Frank copula (C^F) or Joe copula (C^J), see Nelson (2007). The contour plot of the bivariate distributions with C^C, C^F and C^J copula and Gaussian margins are given in Figure 1. Clayton and Joe distribution are asymmetric (radial sense), and have high dependence in the tail (resp. lower and upper) of the distribution. Frank distribution (with Gaussian margins) is symmetric with slightly more variation in the tails than the Gaussian distribution.

The aim of this paper is to assess the effect of a Gaussian misspecification for the residual part on the REML estimations of the heritabilities and correlations (genetic and residual), when the copula is C^C, C^F or C^J but the margins remain Gaussian.

Materials & methods

We simulated simplified pig breeding schemes, following Gonzales *et al.* (2020). The total number of animal animals over 8 generations, including founders was 19,800. In the first 3 generations, choice of reproducers was carried out at random. In the following 5, reproducers were chosen by truncation selection (intra-family selection) from a combination of their 2 breeding values (BVs) estimated by BLUP, with equal weight for each trait, that is to say, from the 3rd generation to the 8th, REML estimation of the variance components and BLUP of the BVs were performed using ASReml software (Gilmour *et al.*, 2015). All the progeny had 2 observed phenotypes and were candidates for selection. Selection rate of 2.9% for the males and 10% for the females were considered (204 breeder females and 10 breeder males by generation including founders). Full-sibs and half-sibs were never mated to limit the inbreeding.

For the founders, the BVs $a_{i,1}$, $a_{i,2}$ for the i^{th} animal were simulated according to a bivariate Gaussian distribution with fixed covariance matrix G. For the other generations, the BVs were simulated through a Mendelian sampling term: $a_{i,j} = 0.5\left(a_{i_f,j} + a_{i_m,j}\right) + M_{ij}$, j = 1,2, where i_f and i_m were respectively the indices of the sire and dam of the i^{th} animal, and $(M_{i,1}, M_{i,2})$ followed a bivariate Gaussian distribution with covariance matrix $G/2$. The residual vectors $(\varepsilon_{i,1}, \varepsilon_{i,2})$ were sampled from a bivariate distribution with standard Gaussian margins and C^N, C^C, C^F or C^J copula whose Kendall's correlation was 0.7 (corresponding Pearson's correlations respectively were 0.891, 0.846, 0.852 and 0.850).

We carried out 1000 Monte Carlo simulations and estimated the heritabilities for the two traits and the genetic and residual correlations. The true genetic variances were 0.18 or 0.67 leading to low and medium heritabilities of 0.153 or 0.401. The true genetic correlations ρ_a were 0.309 or 0.588.

Results

At the end of the 3rd generation (where reproducers were carried out at random), the absolute bias for the heritabilities ranged between 6.77×10^{-6} and 1.43×10^{-3} with SEs between 0.020 and 0.030. The absolute bias for the correlations ranged between 2.4×10^{-7} and 0.010 with SEs between 0.004 and 0.093. No differences were significant (for the t-test at level 5%). The average estimation biases and SEs for the heritabilities evaluated at the end of the 8th generation are shown in Table 1.

When the residual terms followed a bivariate distribution with C^C or C^J copula, we observed significant difference with the true heritability on the trait with medium heritability as soon as the heritability for the two traits are different. In this case, REML over-estimated the heritability for C^J copula and under-estimated the heritability for C^C copula. For C^F copula, we did not observe any significant difference with the theoretical values. The average estimation biases and SEs for the correlations evaluated at the end of the 8th generation are shown in Table 2.

'*': significant difference between estimated and true correlations for the t-test at level $\alpha = 0.05$

Table 2. Table of bias and SE of estimated correlations.

Concerning the residual correlations, as soon as at least one of the heritability was medium (0.401), all the non-normal copulas led to significant differences with the true residual correlation. In theses case, C^F and C^C copula led to an under-estimation of the residual correlations and C^J led to an over-estimation. Concerning the genetic correlation, as soon as the theoretical heritabilities were equal, we observed significant under-estimation with C^J copula and over-estimation with C^C copula. Using C^F copula, the difference with the theoretical values appeared significant (over-estimation) for medium heritability only.

Discussion

To qualify the robustness of the REML facing deviation from normality in the bivariate case, we look for symmetric (C^F), and asymmetric bivariate distributions (C^C and C^J) for the residual term.

With random selection, the robustness of the REML was remarkable despite the non-Gaussian distribution on the residuals; neither the asymmetry nor the heaviness of the distributions affected the REML estimations.

At the end of the 8th generation (truncation selection from the 3rd generation), we observed systematic bias for the variance-covariance parameters using asymmetric distribution: for the estimated heritability when the true heritabilities for the 2 traits were different and for the estimated correlation, when the true heritabilities were the same and medium. Even for the symmetric non-Gaussian distribution (C^F), we observed significant differences with the true parameter for the estimated correlations. Hence, with truncation selection based on EBVs of 2 observed phenotypes, the asymmetry of the residual part but also the heaviness of the upper tail affects the REML estimations. Clearly, the estimation biases are caused in particular, by the selection process carried out in the upper right tail of the distribution. In the case of same heritability for the 2 traits, high (resp. low) dependences in the upper right tail of the residual distribution (using C^I resp. C^C) will lead to an overestimation (resp. underestimation) of the residual correlations and consequently an underestimation (resp. overestimation) of the genetic correlations. In the case of different heritability for the 2 traits, presumably the selection alters the variance of the BV for the trait with medium heritability which causes under or over estimation of the heritability using C^I and C^C.

[1]Institute of Animal Science, Guangdong Academy of Agricultural Sciences, Dafeng 1st Street 1, Wushan, Tianhe District, 510640 Guangzhou, China; [2]Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark; [3]SEGES Pig Research Centre, Axelborg, Axeltorv 3, 1609 Copenhagen, Denmark; liutfei@gmail.com

Abstract

This study compared four genotyping scenarios of genomic prediction for survival in a simulated pig population with survival rate of 80%. Breeding values were predicted using a linear mixed model and a logit model, based on individual records. The scenarios in order of prediction accuracy were: genotyping all individuals, randomly genotyping 80% individuals, genotyping alive individuals, and no genotyping. Using variance components estimated from pedigree-based model, genomic predictions with genotypes only from alive animals were unbiased. Given the same number of genotyped individuals, random genotyping 80% individuals led to higher prediction accuracy than only genotyping alive individuals, indicating the importance of genotype information of dead pigs. Moreover, the linear and the logit models achieved similar accuracy. We conclude that genotyping dead individuals should be considered, and a linear model can be used for predicting breeding values of survival in pigs.

Introduction

Survival rate can affect not only economic efficiency, but also welfare in pigs. Genetic improvement will be a good solution to improve pig survival. Compared with traditional pedigree-based selection, genomic selection can increase of accuracy of estimated breeding value (EBV) of mortality rate up to 50% (Guo *et al.*, 2015;Knol *et al.*, 2016). Usually, survival rate is recorded as phenotypes of sow. However, survival rate is a complex trait that is also affected by the pig's own genotype. It may therefore be more appropriate to perform genetic evaluation of survival at individual level. Genomic prediction for survival at individual level may encounter problems in the case where dead individuals do not have genotypes. Using only the genotyping data of living individuals may cause bias of genomic prediction. Furthermore, at individual level, survival is a binary trait, and therefore a logit model could be more appropriate, and thus may lead to higher accuracy than a linear mixed model. The objective of this study was to: (1) investigate genetic parameters estimated using a linear model and a logit model; (2) explore the impact of genomic information of dead individuals on genomic prediction; (3) compare the accuracy of genomic prediction of a linear model and the logit model for survival in pigs.

Materials & methods

Data simulation. The data was simulated using QMSim software (Sargolzaei and Schenkel, 2009) mimicking a pig population. We simulated 18 chromosomes, each 100cM with 3,100 markers and 50 QTLs. The simulation started with a founder population of 200 males and 200 females, and went through 300 historical generations to generate linkage disequilibrium between markers and QTLs. After historical generations, a base population was created and went through eight non-overlapping generations. In each generation, 30 sire and 300 dams were randomly selected from alive animals, a sire mated 10 dams randomly, and each dam produced one litter. The litter size was not generated as a genetic trait but randomly assigned to 10, 12, 14, 16, or 18 with the probabilities 0.02, 0.14, 0.68, 0.14, 0.02, and sex ratio was 1:1.

The liability of an individual to be alive was generated as the sum of direct additive genetic effect (a) of the individual, maternal additive genetic effect (m) of the dam, litter effect and random residual, and independent of litter size. The heritabilities in terms of *a* and *m* as well as proportion of litter variance were all set as 0.04, and genetic correlation between *a* and *m* was 0.3. The phenotype on observed scale was scored as 1 if the liability was the top 80%, and otherwise 0. Four genotyping scenarios were studied: (1) all pigs were genotyped (G_all); (2) only alive pigs (80%) (G_alive); (3) 80% of pigs randomly selected from the whole population (G80_ran); (4) no pig was genotyped (G_none). In total, 30 replicates were simulated for the four scenarios. The reported results were the mean and standard deviation of the 30 replicates.

Statistical analysis. The data were analyzed using a linear mixed model and a logit model.

The linear mixed model is:

$$y = 1\mu + W_l l + Z_a a + Z_m m + e \quad (1)$$

where y is the vector of the observed phenotypes (0 or 1), 1 is a vector of 1s, μ is overall mean, l is the vector of litter effects, a is the vector of direct additive genetic effects, m is the vector of maternal additive genetic effects, and e is the vector of random residuals. W_l, Z_a, Z_m are incidence matrixes associating l, a, m with *y*.

The logit model is:

$$\eta = 1\mu + W_l l + Z_a a + Z_m m \quad (2)$$

where η is the vector of logit function of probabilities of surviving, $\eta_i = \log_e \frac{\mu_i}{1-\mu_i}$ and μ_i is the expected value of y_i. The other notations are the same as in the linear model, but in logit scale.

For both modes, it was assumed that l, a and m have the following distributions: $\boldsymbol{l} \sim N(\mathbf{0}, \boldsymbol{I}\sigma_l^2)$ and $\begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{m} \end{bmatrix} \sim N\left(\mathbf{0}, \boldsymbol{G_0} \begin{bmatrix} \sigma_a^2 & \sigma_{am} \\ \sigma_{am} & \sigma_m^2 \end{bmatrix} \otimes \mathbf{K}\right)$ where σ_l^2, σ_a^2, σ_m^2 and σ_{am} are the variance of *l, a, m* and covariance between *a* and *m*, respectively, and K is an additive genetic relationship matrix. When using traditional BLUP method, K was constructed from pedigree information. When using single-step GBLUP model (ssGBLUP), K was constructed from pedigree and genotypes (Christensen and Lund, 2010). It was assumed that in the linear model, $\boldsymbol{e} \sim N(\mathbf{0}, \boldsymbol{I}\sigma_e^2)$ and in the logit model residuals followed a standard logistic distribution with variance of $\pi^2/3$. In this study, total phenotypic variance was defined as $\sigma_p^2 = \sigma_l^2 + \sigma_a^2 + \sigma_m^2 + \sigma_{am} + \sigma_e^2$.

The variance components estimated from the model with pedigree-based relationship matrix based on data of generations 5-8 were used for prediction of breeding values in all models. The estimation of variances and breeding values were performed using the DMU software (Madsen *et al.*, 2010).

Evaluation of genomic prediction. A validation procedure was performed to assess genomic prediction using different genotyping strategies and statistical models, in which the 5~7th generations were used as reference population, and the 8th generation as validation population. Genomic predictions were evaluated using the following criteria: (1) The correlation between EBV and the true breeding value to assess prediction accuracy; (2) Average true breeding value of the top 5% of individuals in EBVs to assess the realized selection differential; (3) Regression of EBV from whole data on the EBV from reference data (Legarra and Reverter, 2018) to evaluate dispersion bias. Here, EBV from whole data was defined as the EBV obtained from the whole data with genotypes of all individuals.

Results

As shown in Table 1, estimates of parameters were different between the two models due to different scales. By a transformation, the estimates in observed scale from the linear model were consistent with those used in the simulation. For the logit model, the estimated h_a^2 was much lower than the estimated h_m^2, which was unexpected since direct and maternal heritabilities were the same in the simulation. For both models, the estimates of genetic correlations between *a* and *m* (around 0.4) were higher than correlation used in simulation (0.3), and also had large standard error.

Accuracies measured as correlation between total EBV (EBV_a+EBV_m) and total true BV are shown in Table 2. The scenario of G_all had the highest accuracy, and the scenario of no genotyping had the lowest. With the same proportion of genotyped pigs (80%), the accuracy of G80_ran was 4.73 to 11.2 percentage points higher than G_alive, indicating that the genotypes of dead pigs greatly increased the accuracy of EBV. The regression coefficients were around 1 for all genotyping scenarios including G_alive, indicating that genotyping only for alive animal did not lead to biased prediction when using variances estimated from the model with pedigree-based relationship matrix. The results from the logit model were almost the same as those from the linear model.

The 5% top animals selected from the scenario of G_all has the highest true breeding value, followed by G80_ran, then G_alive, and then G_none (Table 3). The results of the linear model and the logit model were very similar, and the difference in true total breeding value of top 5% EBV individuals between the two models was less than 1%.

Discussion

In this study, we compared four genotyping scenarios for the accuracy of predictions of survival in pigs. In a pig breeding program, dead animal is usually not genotyped, which may lead to biased estimation of variance components and breeding values when using a genomic model. We carried out a pilot study, and found that a ssGBLUP model with genotypes only from alive animals severely overestimated additive genetic variance and led to a residual variance near to zero (results not shown). Similarly, Wang *et al.* (2020) reported that selective genotyping severely overestimated additive genetic variance. Therefore, in the case of no dead animals being genotyped, genomic prediction should use the variances estimated from the model with pedigree-based relationship matrix to avoid or reduce bias of genomic prediction due to selective genotyping.

With the same size of genotyped individuals, genotyping both alive and dead pigs (G80_ran) has a higher accuracy than genotyping only for alive pigs (G_alive), indicating that the genotypes of dead pigs has an important influence on prediction accuracy. Therefore, it could be a good strategy to genotype dead animals. The predictive powers of the linear model and the logit model are similar, suggesting that linear mixed model is robust to predict breeding value of survival traits. We conclude that the genomic information of dead individuals is very useful, and linear model is a good choice for genomic prediction of survival in pigs.

Abstract

The aim of the current study was to confirm and characterise the effect of a polymorphism in the Toll-like receptor 1 family member A (*TLR1A*) gene on levels of natural antibodies (NAb) in poultry. The study population consisted of a base population and 7 generations of birds from a High and Low selection line. Genotypes for a polymorphism in *TLR1A* were available for chickens in generations 5, 6 and 7. The TLR1A polymorphism had large and significant effects on total NAb levels (IgTotal) and IgM NAb, with full dominance of the *TLR1A* C allele. Significant (*TLR1A*×Generation) interactions were detected for IgM and IgTotal. The frequency of the *TLR1A* C allele was 0.45 in the base population (based on imputed genotypes), 0.66 and 0.04 in generation 7 of the High and Low line, respectively. Results confirm the major effect of this polymorphism in *TLR1A* on NAb levels suggest high sensitivity of the effect to environmental factors.

Introduction

Diseases pose a serious and increasing challenge to livestock production. In recent years, poultry layer production in several countries shifted from battery cages to free roaming housing systems. This increased the number of contacts between chickens, resulting in a higher risk of pathogen spreading. Another recent trend is the restricted use of antibiotics in order to reduce the risk of antibiotic resistance. These developments require other ways to limit the impact of diseases on poultry production and selective breeding might be part of an integrated animal health management approach.

Selective breeding for disease resistance is challenging. Preferably, selection should not be for resistance to one or a few diseases, but for enhanced immune competence resulting in a broad (general) disease resistance. Furthermore, traits that reflect general disease resistance should be easy and cheap to measure and ideally early in the animal's life. NAb could be of value in selection for general disease resistance. NAb show a broad specificity repertoire and act as a first line of defence against infections (Palma *et al.,* 2018). NAb can be measured relatively easily and at a young age in blood samples. We showed in previous studies that selection for high NAb against keyhole limpet hemocyanin (KLH) leads to a higher survival in chickens which are challenged with avian pathogenic *Escherichia coli* (Berghof *et al.,* 2019). Therefore, selection for high NAb levels might contribute to improved general disease resistance in poultry.

In a Genome-Wide Association Study (GWAS) we identified a genomic region on chromosome 4 with a major effect on IgM NAb. This chromosomal region contains the Toll-like receptor 1 family member A (*TLR1A*) gene and a polymorphism in this gene was identified as being the most likely causal variant affecting NAb levels (Berghof *et al.*, 2018). The aim of the current study was to confirm and characterise the effect of this polymorphism in the *TLR1A* gene.

Materials & methods

Birds used in this study were from a commercial pure-bred elite white leghorn layer line provided by Hendrix Genetics (Boxmeer, the Netherlands). The study population consisted of a base population, which was unselected for NAb, and 7 subsequent generations of birds from a High and Low selection line. Birds were divergently selected for total KLH-binding NAb titers (IgTotal). Blood plasma samples were taken at 16 weeks of age. An ELISA was performed to determine IgTotal, and KLH-binding IgM and IgG isotypes. A detailed description of the procedure is given by Berghof *et al.* (2018).

The single nucleotide polymorphism (SNP) in *TLR1A* consists of a cytosine (C)/guanine (G) polymorphism, and results in a phenylalanine (F)/leucine (L) amino acid substitution in *TLR1A* at protein position 126. Imputed genotypes for this *TLR1A* SNP were available for the base population (Berghof *et al.,* 2018). These imputed genotypes were used to derive the allele frequency in the base population but were not used in the current study to estimate the effect of the *TLR1A* polymorphism. Genotypes for the *TLR1A* SNP of chickens in generation 5, 6 and 7 of the selection experiment were determined based on a TaqMan assay.

To estimate the effect of the *TLR1A* polymorphism, genotypic and phenotypic information from chickens in generation 5 (n=1105), 6 (n=681) and 7 (n=978) of the selection experiment were available. Genetic differences between selection lines were accounted for in the model by including a line effect. Genotypic effects were estimated using the following model:

$$y_{ijklmn} = \mu + Plate_i + Sex_j + Line_k + TLR1A_l + a_m + d_n + e_{ijklmn} \quad (1)$$

where y_{ijklmn} is IgTotal, IgM, or IgG titer, μ is the mean, $Plate_i$ is the fixed effect of ELISA plate effect (with i = 1 to 166), Sex_j is the fixed effect of sex (with j = 1,2; male or female), $line_k$ is the fixed effect of selection line (with k=1,2; High or Low), $TLR1A_l$ is the effect of the polymorphism in the *TLR1A* gene (with l=1,3; genotypes CC, CG, or GG), a_m is the random additive genetic effect of the m^{th} animal, which is assumed to be distributed as $N(0,A\sigma_A^2)$, d_n is the random effect of the n^{th} dam, which is assumed to be distributed as $N(0,I\sigma_m^2)$, and e_{ijklmn} is the random residual term, which is assumed to be distributed as $N(0,I\sigma_e^2)$. To build the A matrix, pedigree information of 12,443 individuals from 14 generations were used. Generation effects are confounded with ELISA plate effects and therefore 'Generation' was not included as a separate effect in the model.

Additive genetic and maternal environmental variances in these analyses were fixed at the values obtained using all data from the selection experiment consisting of 10,878 birds; heritabilities were fixed at 0.30 for IgM, 0.12 for IgG and 0.12 for IgTotal, maternal environmental effects were fixed at 0.03 for IgM, 0.02 for IgG and 0.03 for IgTotal. Additional analyses were performed to test for possible interactions between *TLR1A* and Sex, TLR1A and Line and TLR1A and Generation. All statistical analyses were performed using ASREML 4 (Gilmour *et al.* 2015).

Theoretically expected changes in *TLR1A* frequencies due to mass selection for IgTotal were approximated using Falconer and Mackay (1996). The coefficient of selection was approximated as:

$$s = i_r \left(\frac{2a}{\sigma_p}\right) \quad (2)$$

where i_r is the standardized realized selection differential, a is the estimated additive genetic effect of the *TLR1A* polymorphism on IgTotal and σ_p is the phenotypic standard deviation of IgTotal. The estimated additive genetic effect of the *TLR1A* polymorphism on IgTotal and the phenotypic standard deviation were

obtained from analyses using model (1). The theoretically expected change in *TLR1A* G frequency was calculated as (Falconer and Mackay, 1996):

$$\Delta q = -sq^2(1 - q) \quad (3)$$

Changes in *TLR1A* G frequency were calculated separately for males and females and subsequently averaged. Approximate changes in *TLR1A* frequencies assume that effects are constant over generations and show complete dominance i.e. assuming that effects of CC and GC on IgTotal are identical.

Results

Table 1 shows that the *TLR1A* polymorphism had a highly significant effect on IgM and IgTotal NAb titers. The CC and CG genotypes had more than 1 titer point higher IgM NAb levels than the GG genotype. The difference between the CC and CG genotypes for NAb IgM titers was small and not significant, suggesting full dominance of the C allele. Similar as for IgM, CC and CG genotypes had higher IgTotal NAb titers than the GG genotypes and the difference between CG and GG genotypes was not significant.

For IgG no significant interactions between the *TLR1A* polymorphism and Sex, Line or Generation were detected.The *TLR1A* effect on IgM and IgTotal suggested full dominance of the C allele and therefore for the interaction analyses we only distinguished two genotype classes: CC/CG and GG. For IgTotal no significant (TLR1A×Sex) interaction was detected. For IgM a significant (TLR1A×Sex) interaction was detected (P=0.004); the effect of the *TLR1A* polymorphism (CC/CG versus GG) in males (1.15) was larger than in females (0.92). No significant (TLR1A×Line) interactions were detected indicating that effects do not differ significantly between the High and Low selection line. Highly significant (TLR1A×Generation) interactions were detected, both for IgM (P<0.001) and IgTotal (P=0.008). For IgTotal the difference between CC/CG and GG was 0.43 titer points in generation 5, 0.23 titer points in generation 6 and 0.71 titer points in generation 7. For IgM the difference between CC/CG and GG was 0.70 titer points in generation 5, 1.22 titer points in generation 6 and 1.28 titer points in generation 7. The frequency of the *TLR1A* C allele was 0.45 in the base population (based on imputed genotypes). The frequency of the C allele in the High line was 0.71 in generation 5, 0.64 in generation 6 and 0.66 in generation 7 (Figure 1). In the Low line the frequency of the C allele was 0.09 in generation 6, 0.06 in generation 6 and 0.04 in generation 7. In generation 5 of the Low line there were 5 chickens with genotype CC and in generation 6 and 7 of the Low line there were no chickens left with the CC genotype. In generation 7 the selection response for IgM due to *TLR1A* allele frequency changes was -0.65 titer points in the Low line and +0.21 titer points in the High line. The segregation of the TLR1A polymorphism therefore resulted in an asymmetrical selection response for IgM.

Table 1. Estimated effects of the *TLR1A* polymorphism on NAb titers based on chickens in generation 5 (n=1,105), 6 (n=681) and 7 (n=978) of a selection experiment.

	IgTotal	IgM	IgG
GG	0	0	0
GC	$0.49_{(0.09)}$	$1.01_{(0.07)}$	$0.22_{(0.10)}$
CC	$0.44_{(0.11)}$	$1.12_{(0.09)}$	$0.07_{(0.13)}$
P	<0.001	<0.001	0.048

Discussion

Highly significant effects of *TLR1A* on IgTotal and IgM reported by Berghof *et al.* (2018) were confirmed in the current study. Estimated genotypic effects of *TLR1A* on IgM and IgTotal were larger than those reported by Berghof *et al.* (2018). The current data allowed testing for the interaction between *TLR1A* and sex, line or generation. Surprisingly, we detected highly significant *TLR1A* by generation interactions for IgM and IgTotal. In the selection experiment, conditions were kept as stable as possible. However, despite this standardization generation-specific variation cannot be avoided. Each generation was raised as a single batch and therefore several factors might be responsible for the observed *TLR1A* by generation interactions. Despite high sanitary status of the research facility, immune status and presence of pathogens can be other major effectors of TLR expression. As far as we know such strong genotype by environment interaction effects have not been reported before for disease resistance-related traits. Possibly because such effects were either not present or not investigated, but it does highlight the importance of the test environment when selecting for KLH-binding NAb, and possibly for disease resistance-related traits in general.

Highly significant effects of *TLR1A* on IgTotal were also confirmed based on the observed allele frequency changes in the High and Low selection line. Results provided unique experimental verification of changes in allele frequencies at a major gene with dominant gene action affecting a quantitative trait that is subjected to mass selection. Theoretically, allele frequencies might not only change due to selection but also due to drift. Increase of inbreeding per generation is low; on average 0.26% in the Low line and 0.31% in the High line.

Therefore, allele frequency changes due to drift are expected to be small. If NAb play an important role in the immune defence of poultry one might expect that purifying (natural) selection would remove alleles with deleterious effects. However, if pure line individuals are kept under strict hygienic conditions in breeding nuclei, their immune response is not seriously challenged, and purifying (natural) selection will not be effective. Reciprocal recurrent selection also might not be effective in removing deleterious alleles

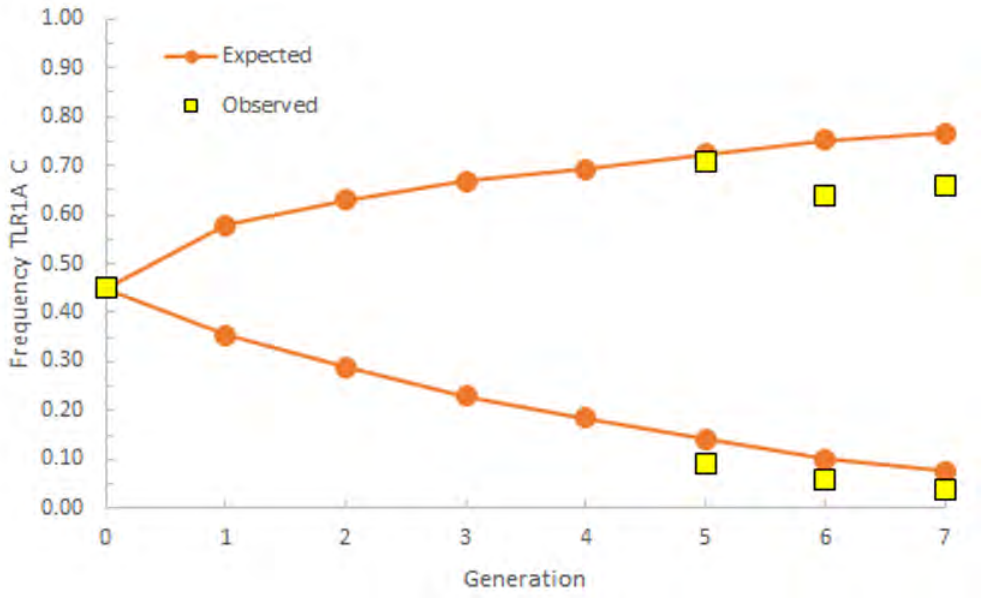

Figure 1. Realized and theoretically expected changes of *TLR1A* C allele frequencies in a High and Low selection line for NAb.

when the other parental line is homozygous for the favourable *TLR1A* allele (CC). Therefore, for situations with genotype by environment interaction and complete dominant mode of gene action, the crossbreeding system might be 'hacked' by deleterious mutations.

Abstract

Geometry of vector spaces is modeled to deal with genomic information. A vector of additive values deviating from the mean is constructed for each SNP (Single Nucleotide Polymorphism). The norm of this vector (length) is the additive standard deviation. We propose the term 'angular linkage disequilibrium (LD)' as the angle, φ_{AB}, between two vectors of additive values corresponding to loci *A* and *B*. In this model, $\cos\varphi_{AB} = r_{AB}$, where r_{AB} is the square root of the standard r^2 measure of LD. Applications of geometry of vector spaces include: (1) the Gram-Schmidt process to eliminate redundant LD information in genomic selection, and (2) estimation of angular and traditional (r^2) LD with a hand calculator. Simulation results showed a full agreement between simulated and estimated LD parameters using either the Expectation-Maximization algorithm or the method using genotype counts suitable for computation with a hand calculator.

Introduction

Geometry is one of the oldest branches of mathematics. Geometry has evolved to include applications in almost all sciences, including art and architecture. One of its most important applications is the geometry of vector spaces. Genomics is the study of genomes. In livestock improvement, this includes genome-wide identification of allelic variants associated with production or resistance to disease (genome-wide association studies, GWAS) and breeding value estimation based on genomic information (Genomic Selection). The objective of this study is to show applications of the geometry of vector spaces to genomics. Linkage disequilibrium (LD) is defined as the angle between two vectors of additive value deviations.

Geometry of abstract vector spaces to define vectors of additive values

A vector is an object that has both a magnitude and a direction. A vector in an *n*-dimensional Euclidean vector space (or R^n) is defined as $\vec{a} = (a_1, a_2, a_3, \ldots, a_n)$, where $a_1, a_2, a_3, \ldots, a_n$ are the components of the vector. We propose to create vectors of additive values $\vec{u}_A$ and $\vec{u}_B$ for two loci *A/a* and *B/b*. For locus *A/a*, genotypes *AA*, *Aa* and *aa* have additive genotypic values α_A, 0, $-\alpha_A$ with frequencies f_{AA}, f_{Aa} and f_{aa}, respectively. The genotypic mean of locus A/a is $\mu_A = \alpha_A f_{AA} - \alpha_A f_{aa} = \alpha_A (f_{AA} - f_{aa})$. The same approach can be used to model locus B/b with effects α_B and with genotypic mean $\mu_B = \alpha_B (f_{BB} - f_{bb})$, where f_{BB} and f_{bb} are the frequencies of genotypes *BB* and *bb*, respectively. When implementing genotypic information in the language of vector spaces in R^n, the components of $\vec{u}_A$ and $\vec{u}_B$ are centered additive genotype values (additive genotype value for the corresponding genotype minus the genotypic mean). The components of vectors $\vec{u}_A$ and $\vec{u}_B$ for individuals with genotypes *AA*, *Aa*, and *aa* or *BB*, *Bb*, *bb* at two loci *A/a* and *B/b* are:

$$u_{AA} = \big(1 - (f_{AA} - f_{aa})\big)\alpha_A;\ u_{Aa} = -(f_{AA} - f_{aa})\alpha_A;\ \ u_{aa} = (-1 - (f_{AA} - f_{aa}))\alpha_A$$

$$u_{BB} = (1 - (f_{BB} - f_{bb}))\alpha_B;\ u_{Bb} = -(f_{BB} - f_{bb})\alpha_B;\ u_{bb} = (-1 - (f_{BB} - f_{bb}))\alpha_B \quad (1)$$

CC BY

DOI: 10.3920/978-90-8686-940-4_816, © L. Gomez-Raya *et al.* 2022

The norms or length of $\vec{u}_A$ and $\vec{u}_B$ are the square root of the additive variance of markers *A/a* and *B/b*, respectively. The direction of a vector is the measure of the angle with a horizontal line. The cosine of the angle, φ_{AB}, between two vectors of additive values, $\vec{u}_A$ and $\vec{u}_B$, is:

$$\cos \varphi_{AB} = \frac{\vec{u}_A \cdot \vec{u}_B}{\|\vec{u}_A\| \|\vec{u}_B\|} \quad (2)$$

where $\vec{u}_A \cdot \vec{u}_B$ is the dot product of vectors $\vec{u}_A$ and $\vec{u}_B$, and $\|\vec{u}_A\|$ and $\|\vec{u}_B\|$ are the norms of vectors $\vec{u}_A$ and $\vec{u}_B$, respectively. Equation 2 is the correlation coefficient between a pair of loci A and B, and is usually expressed as its square, r^2_{AB} (Hill and Robertson, 1968).

We define, angular LD, as the angle, φ_{AB}, between vectors $\vec{u}_A$ and $\vec{u}_B$ with value:

$$\varphi_{AB} = arc\ cos\left(\frac{\vec{u}_A \cdot \vec{u}_B}{\|\vec{u}_A\| \|\vec{u}_B\|}\right) \quad (3)$$

Angle φ_{AB} in Equation 3 is in radians but it can be converted to degrees by multiplying φ_{AB} by 180/π. For $\varphi_{AB} = 90^0$, the two vectors are orthogonal and in linkage equilibrium. For $\varphi_{AB} \neq 90^0$, the two vectors are non-orthogonal and the level of dependency is larger for values of φ_{AB} near 0^0 or 180^0; we say that the two loci are in linkage disequilibrium.

To illustrate estimation of angular LD, let us use an example of 10 Iberian sows as shown in Table 1. Columns 2 and 3 list genotypes for two SNPs in positions 17702032 and 18169229 located on SSC1. The vector components for each individual are in columns 4 and 5. The other columns provide dot products and the square of each vector components for the two SNPs necessary to compute angular LD, respectively. From Table 1, we can compute genotype frequencies for the two positions: $f_{AA}^{17702032} = 0.4$; $f_{AG}^{17702032} = 0.5$; $f_{GG}^{17702032} = 0.1$ and $f_{AA}^{18169229} = 0.5$; $f_{AG}^{18169229} = 0.2$; $f_{GG}^{18169229} = 0.3$. The genotypic means in the two positions are $\mu_{17702032} = 0.3\alpha_{17702032}$, and $\mu_{18169229} = 0.2\alpha_{18169229}$, where α_i is the effect of the SNP in position *i*. For this example, the cosine of the angular LD is:

$$\cos \varphi_{AB} = \frac{\vec{u}_A \cdot \vec{u}_B}{\|\vec{u}_A\| \|\vec{u}_B\|} = \frac{2.76}{\sqrt{(4.1)(7.6)}} = 0.494$$

Table 1. Genotypes for 10 individuals at two loci in SSC1 in positions 17702032 and 18169229 of reference map SScroffa v11.1.

Individual	Genotype position		Vector components		Dot product	Square of each vector component in position	
	17702032	18169229	17702032	18169229		17702032	18169229
1	AG	GG	-0.3	-1.2	0.36	0.09	1.44
2	AG	GG	-0.3	-1.2	0.36	0.09	1.44
3	AA	AA	0.7	0.8	0.56	0.49	0.64
4	AG	AA	-0.3	0.8	-0.24	0.09	0.64
5	AG	GG	-0.3	-1.2	0.36	0.09	1.44
6	GG	AG	-1.3	0.2	-0.26	1.69	0.04
7	AA	AA	0.7	0.8	0.56	0.49	0.64
8	AA	AA	0.7	0.8	0.56	0.49	0.64
9	AG	AG	-0.3	0.2	-0.06	0.09	0.04
10	AA	AA	0.7	0.8	0.56	0.49	0.64
Sum					2.76	4.1	7.6

The angular LD is $\varphi_{AB} = arc\ cos(0.494) = 1.054$. In degrees, $\varphi_{AB} = 60.39^0$. It can be shown that under Hardy-Weinberg conditions the equivalence between angular and traditional LD (r^2) is:
$\varphi_{AB} = arc\ cos\left(\frac{\vec{u}_A \cdot \vec{u}_B}{\|\vec{u}_A\|\|\vec{u}_B\|}\right) = arc\cos(r_{AB})$, where r_{AB} is the correlation between additive values for loci A and B (Hill and Robertson, 1968). Some properties of the geometry of vector spaces can be useful when analyzing genomic information. We explore: (1) The Gram-Schmidt process to eliminate redundant LD information in genomic selection; and (2) Estimation of angular and traditional (r^2) LD with a hand calculator.

Gram-Schmidt process to eliminate redundant LD information in genomic selection

Current GBLUP incorporates SNP information independently of other SNPs, ignoring linkage disequilibrium between them. Geometry of vector spaces can mitigate redundant LD information by the so-called Gram-Schmidt process. For example, we can extract information associated to one SNP that is in LD with another SNP. The first step in the Gram-Schmidt process is to create orthogonal vectors $\vec{v}_A$ and $\vec{v}_B$ as follows:

$$\vec{v}_A = \vec{u}_A;\ \vec{v}_B = \vec{u}_B - \left(\frac{\vec{v}_A \cdot \vec{u}_B}{\|\vec{v}_A\|}\right)\vec{v}_A$$

For the example with 10 Iberian genotypes (Table 1), $\vec{v}_B = \vec{u}_B - 0.67317\,\vec{v}_A$ and $\vec{v}_B = (-0.998, -0.998,\ 0.328,\ 1.002, -0.998, 1.077,\ 0.328, 0.328, 0.402, 0.328)$. The Gram-Schmidt process can be applied to multiple SNPs but it is problematic with rounding errors, even with the modified Gram-Schmidt process. We are currently investigating the application of the Gram–Schmidt process removing dependences due to LD locally (affecting a few SNPs in the neighborhood).

Estimation of angular and traditional (r^2) LD with a hand calculator

LD is usually estimated using the Expectation-Maximization (EM) method proposed by Excoffier and Slatkin (1995), which is an iterative method that may be time consuming when estimating LD for hundreds of thousands or millions of SNP pairs. Geometry of vector spaces can facilitate calculations requiring just genotype counts and Equation 1. The dot product $\vec{u}_A \cdot \vec{u}_B$, and the norms of $\|\vec{u}_A\|$ and $\|\vec{u}_B\|$ can be obtained easily after realizing that only three types of elements, corresponding to each of the three genotypes in vectors $\vec{u}_A$ and $\vec{u}_B$, are required. Thus, the dot product in Equation 1 is:

$$\begin{aligned}\vec{u}_A \cdot \vec{u}_B = {} & n_{AABB}(1-\alpha_A)(1-\alpha_B) + n_{AABb}(1-\alpha_A)(-\alpha_B) + n_{AAbb}(1-\alpha_A)(-1-\alpha_B) \\ & + n_{AaBB}(-\alpha_A)(1-\alpha_B) + n_{AaBb}(-\alpha_A)(-\alpha_B) + n_{Aabb}(-\alpha_A)(-1-\alpha_B) \\ & + n_{aaBB}(-1-\alpha_A)(1-\alpha_B) + n_{aaBb}(-1-\alpha_A)(-\alpha_B) + n_{aabb}(-1-\alpha_A)(-1-\alpha_B)\end{aligned} \quad (4)$$

Where n_{ij} is the count of genotypes *ij* (*AABB*, *AABb*, *AAbb*, *AaBB*, *AaBb*, *Aabb, aaBB*, *aaBb*, *aabb*), $\alpha_A = f_{AA} - f_{aa} = \alpha_B = f_{BB} - f_{bb}$. Also, for Equation 1, norms of $\|\vec{u}_A\|$ and $\|\vec{u}_B\|$ can be obtained as:

$$\|\vec{u}_A\| = \sqrt{N[f_{AA}[1-\alpha_A]^2 + [-f_{Aa}(\alpha_A)^2] + f_{aa}[-1-(\alpha_A)]^2]}$$
$$= \sqrt{N[f_{AA} + f_{aa} - [(\alpha_A)]^2]}, \text{ and}$$

$$\|\vec{u}_B\| = \sqrt{N[f_{BB} + f_{bb} - [(\alpha_B)]^2]} \quad (5)$$

where $N = n_{AABB} + n_{AABb} + n_{AAbb} + n_{AaBB} + n_{AaBb} + n_{Aabb} + n_{aaBB} + n_{aaBb} + n_{aabb}$. Therefore, the nine genotypic counts can be used to directly estimate angular and traditional (r^2) LD requiring just a hand calculator when estimating LD for a pair of SNPs. For a large number of SNPs, computation time is much reduced. An example with genotype counts for 435 Iberian sows for genotypes at SNP positions 17702032 and 18169229 on SSC1 (Table 2) yielded an estimate of cos $\varphi_{AB} = 0.3213$ using the method proposed in this study, and

r^2 = 0.1046022 when using the EM algorithm proposed by Excoffier and Slatkin (1995). The angular LD between these two SNPs is 71.26^0.

Results & discussion

Results of a computer simulation with 10,000 replicates for two scenarios regarding allele frequencies and r^2 are given in Table 3. Sample sizes of 100 and 1000 are used. The method using Equations 4 and 5 into 2 and termed *HC-r²* yields the same results as the EM-algorithm (*EM-r²*), and as the simulated parameters. The standard deviation between replicates is slightly higher in method *HC-r²*. Angular LD provides LD information as an angle of the departure of orthogonality, which is 90^0. There is a potential range of applications of geometry of vector spaces to genomics that we are just beginning to delve into, from removing LD in nearby SNPs from Genomic Selection using the Gram-Schmidt process, to construction of blocks of haplotypes using properties of the vector spaces. For example, vector spaces in R^n have the additional property allowing to sum groups of markers that can have an angular LD with the sum of other groups of markers. In a recent paper, we have applied geometry of vectors spaces to construct additive and dominance genomic relationship matrices including orthogonalization by the Gram-Schmidt process (Gomez-Raya *et al.*, 2021).

Table 2. Genotype counts of 435 sows at two loci in in SSC1 in positions 17702032 and 18169229 of reference map SScroffa v11.1.

	BB	*Bb*	*bb*
AA	25	61	26
Aa	77	114	25
aa	68	35	4

Table 3. Average estimates (± s.e.) of angular LD (φ_{AB}), and traditional r^2 estimated by the EM algorithm (*EM-r²*) and by the method in equations (4) and (5) suitable for analysis with a hand calculator (*HC-r²*) in the simulation of 10,000 replicates. The simulated conditions for two loci A and B are: r^2_{AB} = 0.9, f_A = 0.5, f_B = 0.5 and r^2_{AB} = 0.5, f_A = 0.5, f_B = 0.4. n = the total number of individuals.[1]

	n=100			n=1000
