Abstract

Accurate and early identification of the likelihood of conception (LC) in cows is imperative for a profitable dairy farm. This study aims to use the milk mid-infrared (MIR) spectra in different intervals before the first insemination and partial least squares discriminant analysis (PLS-DA) to predict LC. The results show that the MIR data within 30 to 50 d after calving and close to insemination had a better prediction in LC (accuracy = 73.9 and 72.3%) than 0 to 30 d. And specificity (74.4 to 84.9%) was higher than sensitivity (67.8 to 73.1%). Once the expected date of insemination is given, the model can predict LC before the actual insemination, and intervene in advance for cows predicted poor LC such as delayed insemination and treatment can be initiated. The predicted LC also provide a novel and convenient way to accumulate extra reproductive phenotypes for genetic evaluation.

Introduction

As one of the most important factors in reproduction performance of dairy cow, the likelihood of conception (LC) has impact on the management and subsequent milk production of the herd because cows with more insemination or infertility are often culled and it does not fit the farms calving pattern or is not profitable, e.g. due to a prolonged dry period of the cow or lower milk revenues compared to a replacement heifer. Prior knowledge of the LC to a given insemination would enable farmers to optimize breeding decisions. The producer may decide not to use the cow where a poor LC is predicted but instead to wait for a subsequent estrus event or treatment. Sexed semen or expensive semen could be used where a greater LC is predicted. Thus, early diagnosis of LC in dairy cow needs to be investigated for defining more effective reproductive strategies. Dramatic changes in milk composition (e.g. sexual hormone) before insemination underlie the prediction of LC for the cows (Toledo-Alvarado *et al.*, 2018). And milk compositions are routinely quantified by mid-infrared (MIR) spectroscopy in many milk recording organizations (De Marchi *et al.*, 2014). In recent years, a few studies have attempted to calibrate milk spectra to predict LC in dairy cows before an insemination, reporting AUC of prediction results were 0.487 to 0.675 (Hempstalk *et al.*, 2015) and 0.66 to 0.75 (Ho *et al.*, 2019). The MIR predicted LC has greater heritability than true LC phenotypes (van den Berg *et al.*, 2021). These results highlighted the potential of milk MIR spectra as a predictor of LC, and MIR-predicted reproductive indicators can be used as a new trait for traditional reproductive phenotypes that are used in genetic evaluation. Nevertheless, there are no studies that determine which optimal time of milk testing after calving and before insemination to obtain the highest prediction accuracy. Therefore, this study aimed to: (1) using MIR spectra to classifying good and poor LC of the cow at the first insemination after calving and find the optimal test period; (2) identify the most relevant wavenumbers from MIR spectra that contribute to prediction accuracy of LC.

Materials & methods

Data. Original records of MIR spectra and reproduction from Chinese Holstein cows were obtained from December 2016 to March 2019 from 12 dairy farms located in Beijing, China. The MIR spectra were tested monthly using the machine FTS (Bentley, Chaska, USA) at the Beijing Dairy Cattle Centre. Spectra located in the infrared range from 649.03 to 3,999.59 cm^{-1} (i.e. containing 899 wavenumbers) were included. Only

cows within the range of 1 to 375 days in milk and up to 4 parities were selected. To ensure the cow had normal fertility performance, the records of gestation length ranging from 268 to 296 d, interval from calving to first insemination ranging from 20 to 230 d were included in the analysis. In this study, three-class of LC at first insemination were grouped: good (cow that conceived at first insemination), average (cows that conceived at 2 or more inseminations), and poor (cows with no conception event recorded and that had only 1 insemination). From an economic and breeding perspective, it would be very valuable to be able to predict cows with poor LC, thus the cows with good and poor LC were considered in this study.

Methods. Savitzky-Golay second-order derivative algorithm was used to eliminate the chaos and perturbations from water and others in milk (Grelet *et al.*, 2020). Based on previous studies and known water related regions, 538 spectral points (928 to 1,596 cm^{-1}, 1,693 to 3,025 cm^{-1}) out of the 899 wavenumbers were kept for further analyses. A further detection of outliers was performed using the standardized Mahalanobis distance combined with principal component analysis (Grelet *et al.*, 2020). Finally, 95% of data was kept according to the standardized Mahalanobis distance. Here, the dates of calving and first insemination were set on day 0 and the last day. MIR data in different intervals after calving include 0 to 30 d (early stage), 30 to 50 d (middle stage), 50 d to last day (late stage), 0 to 50 d, and 0 to last day were considered. The two time points 30 d and 50 d were chosen to ensure data balance. Based on previous results, MIR spectra, days in milk, parity, somatic cell count, milk yield, and interval from calving to first insemination were selected as the independent variables in the model.

In this study, PLS-DA was used to develop the prediction model. When one herd was used for external validation, then the remaining data was used for training model and internal validation (random, 10-fold cross-validation). Cross-validation was used to evaluate model performance and enable comparison between the different models. The indicators accuracy, area under the curve (AUC), specificity, and sensitivity were used to define which model performed best.

$$\text{Accuracy} = (TP+TN)/(TP+TN+FP+FN) \quad (1)$$

$$\text{Sensitivity} = TP/(TP+FN) \quad (2)$$

$$\text{Specificity} = TN/(TN+FP) \quad (3)$$

Where *TP*, *TN*, *FP*, and *FN* represent total numbers of true positives, true negatives, false positives, and false negatives as predicted by the model, respectively. Here, positive is the cow with good LC and negative is the cow with poor LC.

Results

The prediction results of external validation at different intervals before first insemination are shown in Table 1. The accuracies and AUCs ranged from 70.2 to 77.3% and 0.698 to 0.775, respectively. Sensitivity and specificity respectively represent the probability of correct prediction of individuals with good LC and poor LC in the real data. Specificity (74.4 to 84.9%) was higher than sensitivity (67.8 to 73.1%). In addition, the MIR data within 30 to 50 d after calving had best prediction of poor LC (accuracy = 73.9%) cows compared to that within 0 to 30 d and 50 to last d (Table 1).

To find out the most relevant wavenumbers that contribute to prediction in LC of the cows in this study, the regression coefficient in PLS-DA after normalization was considered for the different intervals (0 to 30 d, 30 to 50 d, 50 to last d). The wavenumbers that were the most relevant to predict the LC were found in five small regions, names from 936 to 1,189, 1,395 to 1,596, 1,693 to 1,790, 2,346 to 2,364, and 2,857 to

Table 1. The prediction results of herd-by-herd external validation based on mid-infrared data at different intervals before first insemination.

Interval	Records	No. cow	Accuracy[1]	AUC	Sensitivity[2]	Specificity[3]
0[4]-last[5] d	2,766	2,140	77.3%	0.775	73.1%	84.9%
0-50 d	1,886	1,422	74.3%	0.746	70.8%	78.5%
0-30 d	967	724	70.2%	0.698	67.8%	74.4%
30-50 d	956	727	73.9%	0.741	71.2%	76.9%
50-last d	955	725	72.3%	0.731	69.5%	75.3%

[1] Accuracy = (TP+TN)/(TP+TN+FP+FN).

[2] Sensitivity = TP/(TP+FN).

[3] Specificity = TN/(TN+FP). TP, TN, FP, and FN represent total numbers of true positives, true negatives, false positives, and false negatives as predicted by the model, respectively.

[4] The 0 day = the date of calving. [5]the last day = the date of first insemination. See main text for other abbreviations.

3,017 cm^{-1} (Figure 1). In addition, the regression coefficients after normalization of the three intervals had moderate to low Spearman correlations, ranged from 0.604 (0 to 30 d and 30 to 50 d) to 0.284 (0 to 30 d and 50 to last d).

Discussion

The innovation of this study is to defining the optimal test period to better classify good and poor LC based on MIR spectra. In addition, the MIR region associated with this reproductive trait was identified. The ability to accurately predict the conception outcome for a future mating would be of considerable benefit for producers in deciding what mating plan to implement for a given cow. The results of this study can be used in the development of a novel tool for monitoring the fertility and health in dairy cows before insemination. And accurate prediction implemented in current study also provide a new trait to accumulate reproductive phenotypes for genetic evaluation, especially before routine collection of reproductive information is established.

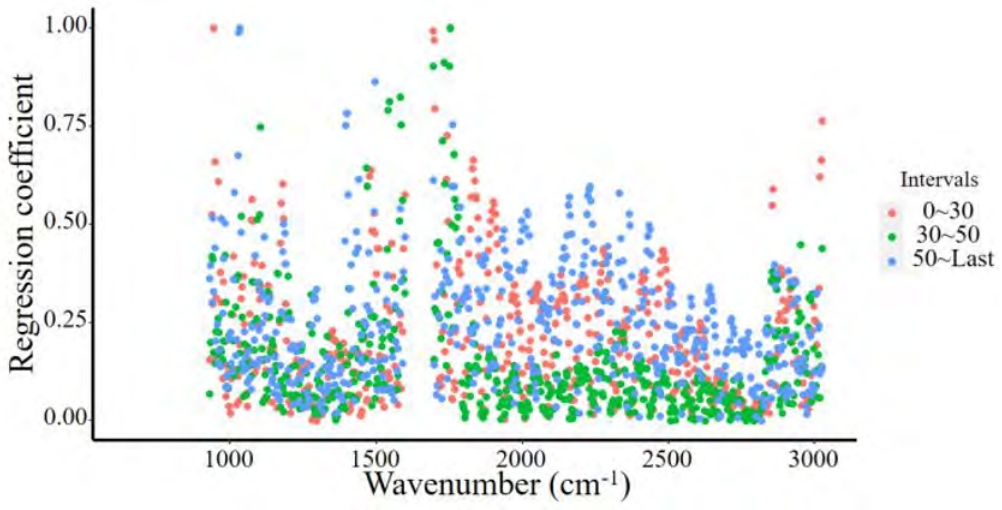

Figure 1. The regression coefficient after normalization for different wavenumbers in intervals of 0 to 30 (early stage), 30 to 50 (middle stage), and 50 to last (late stage) days.

Compared to the published studies, the accuracy (70.2 to 77.3%) and AUC (0.698 to 0.775) of external validation in this research are within these reported results (AUC: 0.487 to 0.750) (Hempstalk *et al.*, 2015; Ho *et al.*, 2019). Such differences among prediction is mainly due to differences in MIR data selection, spectral processing, and regression method employed. Specificity (74.4 to 84.9%) was higher than sensitivity (67.8 to 73.1%) in this study, which means the model has stronger ability to identify a cow with poor LC than a cow with good LC and this tendency is more important for reproductive management. The MIR data within 30 to 50 d after calving and close to insemination had the better prediction in LC (Accuracy = 73.9 and 72.3%) than 0 to 30 d. This indicated that collecting MIR spectra during these periods may obtain optimal prediction accuracy.

The most important wavenumbers of MIR may help in understanding why MIR spectra before insemination can predict LC. The regions from 936 to 1,189, 1,395 to 1,596, 1,693 to 1,790, 2,346 to 2,364, and 2,857 to 3,017 cm^{-1} are related to the chemical bonds including C-H, C-C, C=O, C-O-C, nitrogen-oxy compounds, aldehydes, and esters (Duffy, 1972). Many sex hormones (e.g. progesterone and follicle-stimulating hormone) contain the chemical bonds like esters, aldehyde, and nitrogen-oxy compounds. A previous study indicated that sex hormone exist in milk and that the level changes significantly before insemination (Toledo-Alvarado *et al.*, 2018), which means that MIR data before insemination contains information on sex hormone changes, especially within 30-50 d after calving and close to insemination. In addition, some studies found high concentration of blood ketone body before insemination will increase the risk of non-pregnancy (Walsh *et al.*, 2007), and MIR spectroscopy is a mature tool to qualify the concentration of ketone body in blood and milk (Benedet *et al.*, 2019). This indicated that the five spectral regions maybe reflect energy imbalance information, because the ketone body contain the chemical bonds like C-H, C-C, and C=O. The variation in other milk compositions could also be related to fertility and health of dairy cows. Given the most important wavenumbers in MIR data to predict LC, prediction based on MIR data before inseminations seems to be (partly) based on reflecting abnormal levels in sex hormones and energy imbalance. Meanwhile, the intervals of 30-50 d after calving and close to insemination might contain more changes in physiological state than the other periods, but it needs to be interpreted with caution.

146. Use of tracking technology for phenotyping laying hens within cage-free housing

C.M. Montalcini, M.B. Petelle, S.G. Gebhardt-Henrich and M.J. Toscano*

Center for Proper Housing: Poultry and Rabbits (ZTHZ), Division of Animal Welfare, VPH Institute, University of Bern, Burgerweg 22, 3052, Zollikofen, Switzerland; michael.toscano@vetsuisse.unibe.ch

Abstract

Our group has been tracking individual hen movements within a commercial aviary and identified consistent within- and among-animal movement and location patterns (MLPs). To examine the potential for breeding selection and health and welfare, we conducted two trials that tracked either 80 (Trial A) or 1,125 (Trial B) Dekalb White hens over a subset of the entire laying period during which data on health was assessed and related to movement. Results from principal component (PC) analysis within Trial A based on 13 movement variables collected during the first seven weeks in the barn demonstrated moderate repeatability (0.44 [CI: 0.43, 0.48]), temporal plasticity, and predictability (0.25 [CI: 0.21,0.31]) and a negative relationship between predictability of the first PC score and keel fracture. Using a population of crossbreds with known sires for Trial B, a low but present variance attributed to individual (~13-19%) and sire (~1%) was identified. Our effort details novel means to collect movement data towards development of stable phenotypes that can be used within laying hen breeding.

Introduction

Cage-free housing systems for laying hens provide superior welfare over cage systems by providing a rich array of resources such as outside areas and litter for dustbathing that allow animals to express their natural behaviours (Weeks and Nicol, 2006). Despite these benefits, many problems exist that unintentionally compromise the welfare of housed animals including those of behavioural (e.g. feather pecking and toe pecking), physical (e.g. keel bone fracture), and disease (e.g. Erysipelas) natures.

The problem is likely rooted in current laying hen breeding paradigms that target performance within small groups of hens. Consequently, available genetic hybrids are sub-optimal for cage-free housing systems with thousands of animals leading to the discussed poor welfare. Given the increasingly global trend towards cage-free housing, it is important to develop appropriate methods to assess phenotypes in commercially relevant cage-free systems. By use of a uniquely commercial aviary outfitted for research, our group has been able to combine traditional animal assessments (e.g. manual evaluation of feather quality) with sensor tracking technology to provide an accurate representation of an individual hen's health and movement. We previously demonstrated highly consistent MLPs over time that were nonetheless starkly different between hens (Rufener *et al.*, 2018) and that birds with more severe types of keel bone fracture spent a greater amount of time in the aviary's upper tiers (Rufener *et al.*, 2019).

Materials & methods

To understand selection for movement and location patterns for laying hens within cage-free housing systems, the current effort involved two projects that sought to yield a prospective suite of MLP-based traits that could be used within breeding paradigms of cage-free housed laying hens. The first project (Trial A) explored creation of an index of phenotypically correlated traits within a composite movement variable and its repeatability, plasticity, and predictability, as well as their relationship to traditional welfare measures. A second effort (Trial B) used a population with known 28 known sires (8-11 animals of each sire /pen) to focus on a narrower subset of traits based on the animal's presence within three specific areas believed to have particular health and welfare importance.

General. Two studies were conducted that tracked either 80 (Trial A) or 1,125 (Trial B) Dekalb White hens. In Trial A, hens were reared on site in one of four pens and in Trial B they were reared in eight pens with two different rearing aviaries (Rufener *et al*., 2019). At 17 weeks of age (WOA), hens were transferred to an on-site laying barn containing a Bolegg Vencomatic Terrace aviary (split into 20 identical pens separated by a vertical grid) and an outside winter garden accessible through a pop hole. Each pen contained 225 hens, of which eight were used for Trial A with 20 pre-selected focal hens. For Trial B, five pens were used of which all animals were tracked. Hens were a specialized crossbred where the sire of each was assigned a coded wingband at the hatchery. The wintergarden was initially closed (Trial A: 1 week; Trial B: 3 weeks) so that hens could acclimate to the nest boxes, perches, and the indoor area in general and thereafter opened and closed daily. Tracking data was collected near continuously by either a low-power active (Trial A) or radio frequency identification (Trial B) tracking system (Gantner Solutions GmbH, Schruns, Austria). Tracking tags were attached via a backpack or legband (Trial A and B, respectively). Each system was used to register the animal within five mutually exclusive zones containing key resources that together represented all places within the aviary: the three stacked tiers (top, middle, lower), as well as the littered floor and the wintergarden. For the work described here, data from between 19 to 25 WOA (Trial A) or 27 and 30 WOA was used for analysis.

Trial A. At 60 WOA, we assessed keel bone fractures based on radiographs with a scoring methodology used previously (Rufener *et al.,* 2018). Feather damage of the breast, tail, and neck was assessed using the Welfare Quality protocol (Welfare Quality Network, 2009). From the processed movement data, we extracted 13 daily variables per hen. Variables computed while artificial light was provided included: the percentage of time and the average number of stays per hour (to account for varying barn schedule) in each zone, the average realized vertical distance per hour, and whether the hen entered the winter garden within 15 min after access was possible. The sleeping height, measured by the number of stacked tiers underneath the zone where an animal was for most of the period when artificial light was off, was also calculated. We extracted a linear composite variable using PC analysis from psych package (Revelle, 2021). Linear mixed effect models were used to identify consistent individual movement differences in averages (individual intercept), temporal plasticity (individual slope), and predictability (individual variability). In a second step, we used bivariate models to evaluate if individual estimates of movements were associated with health assessments. Analyses were conducted using python for the data processing and R for statistics.

Trial B. Collected movement data was analysed using linear mixed models to relate daily duration in three of the five zones (continuous-Gamma distribution) with fixed (pen) and random (hen ID; sire without pedigree) effects. The three zones were targeted on a belief that they contain resources indicative of healthy behaviour (e.g. wintergarden and floor containing litter for dustbathing, foraging) and production (nestbox). Use of external areas (e.g. wintergarden) is also a trait of primary interest to consumers.

Results

Trial A. The first three PCs had eigenvalues >1. The first PC explained 41% of the variation with eight of the variables having a loading (in absolute value) >0.4 and six >0.7 (Table 1). The positive loadings on vertical distance/hour and number of stays/hour in zones other than the highest tier (where the majority of animals would sleep) suggested PC1 reflected general movement throughout the barn. A higher PC1 value would associate with animals that spent more time in the floor, lower tier, and wintergarden zones, but also transitioned more between these zones. In contrast, PC2, which explained 20% of total variation with four variables having an absolute loading value >0.4, had the greatest positive loadings on the middle tier which may reflect egg-laying behaviour. Lastly, PC3, which explained 14% of variation with three variables having an absolute loading value >0.4, was associated primarily with wintergarden presence. Focusing on the PC1, we found a repeatability estimate of 0.44 [CI: 0.43, 0.48] indicating that 44% of the remaining variance (after

Table 1. Loadings of a correlation-based principal components analysis within Trial A.

Wintergarden in 1st 15 min (Y/N)	0.39	-0.21	0.63

controlling for the external temperature downloaded from a local weather station and days post transfer) in PC1 can be attributed to differences between individuals. The degree of variation in predictability for PC1 among studied individuals was 0.25 [CI: 0.21, 0.31]. More predictable animals were associated with higher keel bone fracture scores.

Trial B. Examination of daily durations into each of the modelled aviary zones indicated that individual hens and sires composed a small but definitive amount of the phenotypic variance ranging from approximately 13-23 and 0.8-2.8%, respectively. Specifically for each zone (wintergarden, floor, and lowest, middle, and highest tiers) the variances for hens were 13.6, 15.0, 19.1, 23.4, and 28.2%, respectively. For sire, the variances (same zone order) were 1.1, 0.8, 0.8, 2.8, and 2.3%

Discussion

Our results demonstrate that continuous monitoring of individual hens' time entry/exit within a limited set of locations offers a valuable body of traits with relevance for breeding paradigms. While hens are remarkably homogenous in terms of phenotypes that were historically measured within cage housing (e.g. feed efficiency), they are relatively heterogenous in traits that are increasingly important for consumer demands (e.g. feather quality, presence outside). Our initial efforts indicate that some of the observed individual phenotypes can be quantified by average and temporal plasticity of early movements (PC score). In other words, our results offer a novel means to represent animals in a way that captures traits which previously could not be evaluated in a manner relevant for commercial housing. Sufficient sample sizes in future efforts will aim to link these phenotypes with pedigree information.

Individuals exhibited differences in the rate at which they adjusted movement over the observation period with a general increase in the PC1 value over the first weeks in the laying barn. For instance, some individuals exhibited an increased PC1 only after 35 days post-transfer while others did so almost immediately. Further examination suggested a variety of subtle MLPs that will need to be examined with larger datasets like that of Trial B. For instance, a degree of variation in predictability among studied individuals suggested that

some hens were more predictable (i.e. stronger daily routines) in their daily movements. Altogether, results found existence of individual differences in the variation of early movement.

In addition to the previously established link between daily duration in the upper tier and keel bone health, current results indicated a link between specific health indicators and behaviour shortly after transfer to the laying aviary. Therefore, behaviour shortly after transition may be useful as selection criteria to prevent development of poor health. For instance, we found that lower predictability of early movement was associated with reduced keel bone fracture severity later in life. Although such correlations would need to be investigated for causal relationships, animals exhibiting less predictability in movement may develop greater cognitive ability for movement leading to safer transitions between tiers. Alternatively, predictability and inactivity may be associated, although average PC1 value and predictability were only weakly correlated but need to be investigated further. Future analysis will seek to expand the movement variables identified in Trial A towards identifying variation across daughter-sires represented in Trial B.

Abstract

Automated milking systems (AMS) are of ever increasing relevance in dairy cattle housing. The systems automatically provide measurements and parameters that can be used as traits for genetic analyses. The present study exhibited estimates of heritabilities of moderate size around 0.14 for the number of visits to the AMS unit, the number of successful milkings as well as the difference between these two parameters, the number of refusals. This latter trait is highly influenced by the ability of the cow to adapt to the time limits set for subsequent milkings and thus is strongly determined by elements of learning behavior thus allowing for genetic selection. A GWAS for the trait refusals revealed a number of interesting chromosomal regions with several genes well known from model animal or human genomics. The results underpin the hypothesis that highly conserved genomic regions affecting behavioural traits exist across species.

Introduction

The use of automated milking systems (AMS) in dairy cattle housing steadily is increasing and considered to be the future standard procedure for milking of dairy cows. The ability of a cow to cope with the technological environment is largely determined by learning behavior. In model animals is has been shown repeatedly that learning behavior is a trait highly influenced by genetics. An AMS may be viewed as a test system that automatically is documenting and recording behavior in general and specifically learning behavior of a dairy cow. Wethal and Heringstad (2019) as well as Chang *et al.* (2020) emphasized the relevance of AMS-recorded traits as the recording: (1) does not interfere with the standard routine on-farm; (2) provides objective measurements; and (3) yields observational values with high phenotypic variance. In our data, amongst other parameters, the system recorded 'visits' and 'milkings' of cows as well as technical 'errors'. 'Visits' and 'milkings' differ as the AMS rejects milking of cows when they visit the AMS-unit too frequently, the difference between the two parameters is denoted as 'refusal'. For the latter trait, it was hypothesized that it likely is affected by the 'ability to learn'. All traits considered were averaged on a daily basis. Aim of the present study was to estimate genetic parameters as well as to identify chromosomal regions with putative influence on the traits studied.

Materials & methods

Data used originated from a large dairy herd equipped with 27 AMS units, each serving around 40 to 50 cows and covered a time span of 25 months in years 2017 to 2019 starting with the entrance of the entire herd to the newly AMS-equipped barn. Data comprised 2,245 cows with a total of 4,190 lactations. SNP genotypes from 50k arrays and 10k arrays imputed to 50k by Vereinigte Informationssysteme Tierhaltung w. V., Verden (Germany), were available for 1,566 cows. Milk yield for each milking was available from the AMS on farm and was converted to daily milk yield by own programming according to standard ICAR procedures. After edits, a total of 949,990 daily phenotypes were available for all traits. As behavior and specifically learning behavior is highly influenced by adaptation, the focus of attention was given to the time period of familiarity or 'experience' with the AMS. For modelling purposes, four classes of experience defined as days at AMS (DAA) were formed with class levels of 0-75, 76-150, 151-250, 251+ days and

combined with the effect of stage of lactation defined as days in milk (DIM) with three class levels of 0-100, 101-200, 201+ days, thus resulting in 12 class levels. The general mixed model applied was

$$y = Xb + Z_1u + Z_2pe + e \quad (1)$$

with y = vector of trait observations, X is the incidence matrix for fixed effects and b the vector of fixed effects to be estimated. X and b comprise the effect of season (4 classes), the combined DAA × DIM effect (12 classes), nested within parity class (4 levels), Z_1 is the incidence matrix for animals' additive genetic effects u, Z_2 is the incidence matrix for permanent environmental effects pe, and e is the vector of residuals. Estimation of LSMEANS for fixed effects and bivariate estimation of variance components for two traits at a time was conducted applying REML using ASREML. For these analyses, relationships between animals in u were considered via a pedigree-based relationship matrix comprising a total of 24,372 animals. Association analysis was carried out following the methodology of a single-step genomic association study (ssGWAS) approach proposed by Wang *et al.* (2012), based on the single-step genomic-BLUP method (ssGBLUP) (Aguilar *et al.*, 2010). The inverse of the H matrix was derived by combining inverses of the genomic relationship matrix G and the pedigree-based numerator relationship matrix A using the BLUPF90 family software as presented by Aguilar *et al.* (2018).

Results

LSMEANS for no. of visits per day initially, for low DAA, start at levels of around nine visits per day and drop to a level of around five for more experience while the number of successful milkings starts at a level of 3.6 and drops to around three for higher experience levels (not shown in table). Technical errors (not shown) occur at a low rate of around 0.14 and are unaffected by experience or stage of lactation or age. Refusals per day (RPD) start at a level of >5.0 for young cows without AMS experience and gradually drop to values around 2 for older and more experienced cows. It appears that learning to adapt to AMS ends with the midst of the second lactation. It should be noted that Table 1 also includes cows in later lactations but with little experience, i.e. they entered the AMS barn as older cows for the first time. For these cows, adaptation is relatively rapid.

Table 1. Least square means of refusals per day (RPD) by parity, stage of lactation, and experience level.

Parity class	DIM[1]	DAA[2]			
		0-75	76-150	151-250	251+
1	1-100	5.91	5.46		
	101-200	5.65	4.86	4.11	
	201+	5.57	4.38	3.77	3.18
2	1-100	2.80	3.05	2.33	2.77
	101-200	2.26	2.00	2.10	2.01
	201+	2.17	1.72	2.20	2.32
3	1-100	1.77	1.74	1.54	2.43
	101-200	2.13	1.41	1.57	1.73
	201+	2.70	1.79	1.98	2.06
4+	1-100	1.57	1.67	1.20	1.74
	101-200	2.04	1.16	1.51	1.46
	201+	1.82	1.43	1.91	1.95

[1] DIM = stage of lactation defined as days in milk.
[2] DAA = experience level defined as days at AMS.

Table 2 shows results from selected bivariate REML estimations of variance components. Estimates for the no. of visits and the no. of milkings per day as well as the no. of refusals per day (RPD) are on a moderate level of around 0.13 to 0.15. Technical errors exhibit very low heritabilities thus underpinning that their nature is purely technical and almost unrelated to genetic influences. However, errors appear to be cow-associated as indicated by the proportion of permanent environmental variance, c^2, of 0.49. Genetic correlations of visits × milkings as well as milkings × refusals are of substantial magnitude of around 0.80 due to the inherent autocorrelation.

Figure 1 displays results for GWAS as defined with -10log (pvalue) for SNP. Interesting chromosomal regions (-10log(pvalue) 4.0 to 6.0) appear to reside on chromosomes 3, 12, 18, and 19 with spurious elevated values for single SNP on other chromosomes.

Table 3 contains additional information for trait RPD and chromosomes 3, 12, 18, 19. It is striking to see that in all five regions genes are found that in mouse genetics and especially in human genetics are known to affect neuron development, intellectual ability or psychotic disorders. For sake of brevity, just a few publications in this regard will be mentioned here: Noh *et al.* (2019) emphasizes the role of NEGR1 in humans affecting hippocampal neurogenesis and behavior; Garcia-Corzo *et al.* (2013) underline the function of COCQ9 in encephalomyopathy in humans and a recent publication of a large international consortium highlights CNOT1 as a major factor in neuron development in humans (Vissers *et al.*, 2020).

Table 2. Estimates of heritabilities, proportion of permanent-environmental variance and genetic correlations from bivariate REML animal model analyses.[1]

Bivariate analysis		Trait 1				Trait 2				r_g (Trait 1 × Trait 2)	
Trait 1	Trait 2	h^2	SE	c^2	SE	h^2	SE	c^2	SE	r_g	SE
Vistits	Milkings	0.15	0.021	0.23	0.018	0.14	0.017	0.143	0.013	0.84	0.035
Visits	Errors	0.14	0.021	0.24	0.018	0.04	0.016	0.481	0.016	0.24	0.046

Discussion & conclusions

As hypothesized by Chang *et al.* (2020) and in this study, parameters automatically recorded in automated milking systems are valuable traits that could be used for genetic selection of adaptation to the technical environment of AMS. Furthermore, the amount of evidence for highly conserved genomic regions across species appears to be increasing. Costilla *et al.* (2020) in a meta study analysed the trait flight time frequently recorded in beef cattle and found that the genetic control of temperament in cattle at least partly is similar to neuron development function and autism spectrum disorders in humans. Alvarenga *et al.* (2021) in a further large-scale meta-analysis of studies of behavioural traits in cattle, sheep, and pigs found numerous links of chromosomal regions identified in livestock when compared to studies of human disorders. They concluded that a number of highly conserved genomic regions exist across species that are related to behavioural traits. Further studies in this field seem to be warranted.

Acknowledgements

Gratitude is expressed to Vereinigte Informationssysteme Tierhaltung w.V. for supplying imputed SNP genotypes and to the participating farm for making data available.

Abstract

Accelerometer sensors were attached to 147 Merino sheep for 26 days on a commercial farm in Victoria, Australia. Using a Support Vector Machine learning algorithm, 6 behaviours were defined, including grazing and rumination. The overall repeatability of grazing and rumination were 0.44±0.03 and 0.49±0.03, respectively. When repeatability was estimated on 2 consecutive days, it was approximately 0.7 for each trait and by increasing the interval between days (over 22) dropped to below 0.1. The heritability estimates for all grazing behaviour traits were close to zero, which is likely to be associated with the small sample size in our study and weak genetic connections between individuals. Nevertheless, the repeatability results were promising and suggested that animals maintain their ranking at least over short periods of time. These results were preliminary and from a small sample size. Hence, we recommend a larger sample size for estimating heritability of grazing and rumination traits.

Introduction

Grazing is commonly defined as the act of placing the head down and grasping grass whilst on pasture, while rumination is the process of regurgitating, chewing, salivation, and re-swallowing feed (Welch *et al.*, 1970). The physiological and nutritional aspects of these two traits have been investigated in ruminants (Beauchemin, 2018), but the genetic aspects of these traits have been rarely investigated, as the most of data has been obtained by visual observation, which are usually too few for quantitative genetics analysis. Since sensor technology has been used to measure the activity of ruminants, with commercial installations now common for management purposes, there is a growing interest in its application to the genetics of previously uninvestigated traits, such as grazing and rumination time. As grazing and rumination are the main activities of ruminant livestock, they have a major impact on growth and health (Hancock, 1954). The heritability of rumination in dairy cattle using sensor data was estimated at 0.30 and 0.34 (Byskov *et al.*, 2017; Moretti *et al.*, 2018), while the repeatability was substantially higher (Byskov *et al.*, 2017). To the best of our knowledge, the heritability and repeatability of grazing and rumination activity has not been estimated in sheep. Using sensor data from a Merino flock, the aim of this research was to estimate: (1) the repeatability of grazing and rumination activities between days and during the whole experiment; and (2) the heritability of grazing and rumination activities.

Materials & methods

This study was carried out on a commercial farm at Edenhope, Victoria, Australia. All the experimental procedures were approved by the Animal Ethics Committee, La Trobe University, Victoria, Australia (AEC number 17-09).

Animal and activity recording. The study was conducted on 147 Merino sheep with the average liveweight of 45.8±14 kg (mean ± S.D.) from 3rd to 29th of May 2020. The ram (n=67) and hogget (n=80)

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_148, © F. Almasi *et al.* 2022

sheep were grazed on separated pastures, that were 16 and 30 ha, respectively. ActiGraph (wGT3X-BT; ActiGraph, LLC, Pensacola, FL) accelerometer sensors were attached to the left side of the muzzle to record activities. The animal management details of this experiment were described in Almasi *et al.* (2022, in press). The activities of grazing sheep, including grazing, rumination, walking, licking, idle and other behaviours, were recorded using video cameras and compared with predicted activity trained through a support vector machine (SVM learning) algorithm. SVM was used as our data were not linearly distinguishable, and thus kernel space embedding was appropriate. The SVM classification was based on 5 s epochs to distinguish the activity of animals. Only grazing and rumination activities were used in this study. The concordance between visual and predicted behaviours using SVM method for grazing and rumination were 90%±11 and 95%±10 (± SD), respectively. The SVM validation and its features are explained in detail in Sohi *et al.* (2022, in press).

Statistical analysis. The data were analysed using ASReml-R (Butler *et al.*, 2017). The sum of each trait per day (e.g. minutes grazing) of each animal was calculated and used in the model. In total, 3,607 and 3,604 observations for 147 animals were recorded for grazing and rumination activities, respectively. The repeatability and heritability were estimated using a univariate model:

$$y = Xb + Zu + Wc, \quad (1)$$

where y is a vector containing the response variable (grazing or rumination time), b is the vector of fixed effects of overall mean, sex (male and female) and day of experiment (day 1 to 26); u ~N(0, $A\sigma^2_a$), c ~N(0, $I\sigma^2_c$) and e ~N(0, $I\sigma^2_e$) are the vectors of random animal effects, permanent environment effects and residual effects, respectively. A is the relationship matrix calculated from a pedigree of 351 animals which was traced back for 5 generations and I is the identity matrix. X, Z, and W are design matrices relating observations to the corresponding fixed or random effects.

The heritability was estimated by dividing the estimated genetic variance (σ^2_a) on the phenotypic variance ($\sigma^2_a+\sigma^2_c+\sigma^2_e$). The overall repeatability was calculating by dividing the sum of σ^2_a and permanent environment variance (σ^2_c) on the total phenotypic variance.

For calculating the repeatability of a trait over two days, or the interclass correlation between measurements for the same animals on two different days, the observations for just two days were included in the model.

Results

The mean ± S.D. of time spent grazing and ruminating were 404.4±41.9 min/d and 330.6±25.1 min/d (Table 1). Both grazing and rumination had an overall moderate to high repeatability (0.44 and 0.48, respectively), while their heritabilities were not significantly different to zero. The rams grazed 333 min/d less ($P<0.001$) but their rumination time was 25 min/d more than hoggets ($P<0.05$).

Figure 1a shows the repeatability between days, from 1 to 24 days interval. The repeatability with one day interval (e.g. day 2 to 3) for both activities was over 0.68. By increasing the interval, the repeatability for both traits dropped to below 0.1. Figure 1b shows the daily mean ± SD of both grazing and rumination

Table 1. The mean, SD, and repeatability of grazing and rumination activities.

Trait	Number of records	Mean (min/d)	S.D.	Repeatability ± S.E.
Grazing	3,607	404.4	41.9	0.44±0.03
Rumination	3,604	330.6	25.1	0.48±0.03

activity. There was considerable variation among days in the amount of time spent grazing and rumination. Day 23 with 491 min/d had the highest grazing activity, while day 19 had the highest rumination activity with 371 min/d. The lowest grazing activity (309 min/d) occurred on day 1 and the lowest rumination activity was on day 25 with 272 min/d (Figure 1b).

Discussion

The current study showed that the repeatability of grazing and rumination activity of pasture kept sheep grazing was moderate to high, while heritability estimates were close to zero. These results imply that while the sensor technology was a reliable tool to measure feeding activities and animals had repeatable behaviour within the same week, but then the repeatability dropped to below 0.50 when the interval between measurements were longer than a week. Therefore, many measurements in a week could help reduce residual variation, while over a longer period of time changes in behaviour can be detected. The repeatability of grazing and rumination suggests that there is a role for assessing these traits for quantitative genetic analysis. Although there was a significant difference in grazing and rumination time between rams and hoggets, they were grazing on different paddocks, which could also affect their grazing and rumination time.

Byskov *et al.* (2017) showed that the repeatability and heritability of rumination traits in research and commercial dairy cows at four different stages of lactation were high and moderate, respectively. The repeatability results of consecutive days for rumination trait in the current study were close to the Research herd (0.76 vs 0.75) in Byskov *et al.* (2017), but the heritability estimation for the same trait was completely different. Whereas, in the current study, the permanent environment, a short period of measurement (26 days), and small sample size and low genetic connectedness between animals could be the main factors that reduced the estimated additive genetic variance. Nevertheless, the sheep showed similar grazing and rumination patterns the next day, which means the sensor technology and the SVM method were reliable for ranking animals according to their feeding activities. According to the reported results by Byskov *et al.* (2017) and Morretti *et al.* (2018) rumination is a moderately heritable trait that can be considered for selective breeding. Further, it is important to estimate and understand the genetic correlations between grazing behaviour traits and other economically important traits such as feed efficiency or methane emissions.

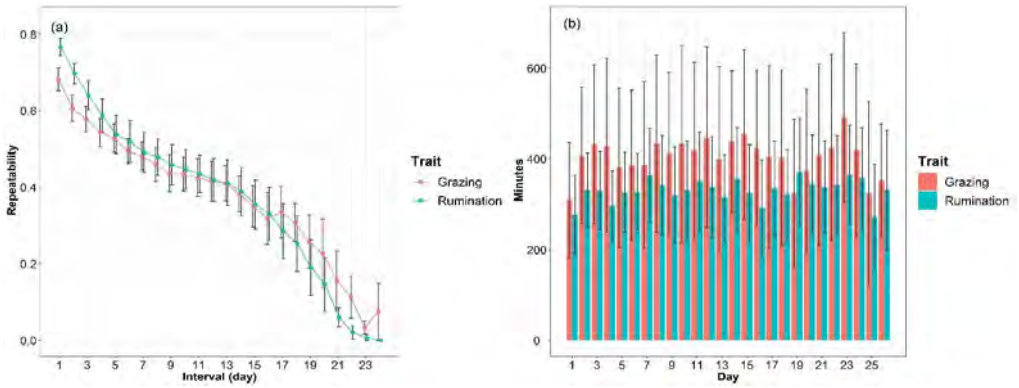

Figure 1. (a) The repeatability of grazing and rumination between days (from 1 to 24 days interval). The error bars represent SE. (b) The mean of grazing and rumination activity per day. The error bars represent SD.

Conclusions

Sensor technology and SVM method can be applied to determine grazing and rumination activities of sheep with potential application for breeding strategies. This is the first research study that has estimated the heritability and repeatability of these two traits in sheep. Further studies with a larger sample size are required to estimate the genetic variation in sheep in addition to correlations with traits of economic importance.

149. Deep data recording for developing resilience traits in Swiss cattle populations: a proof of concept and an application

B. Bapst*, P. von Rohr and F.R. Seefried

Qualitas AG, Chamerstrasse 56, 6300 Zug, Switzerland; beat.bapst@qualitasag.ch

Abstract

The number of automatic milking systems in Switzerland is increasing. This possibility of in-depth phenotyping was used to investigate whether resilience traits could also be developed in Switzerland, analogous to Dutch studies. Based on a data set of Holstein, Simmental, Swiss Fleckvieh and Montbéliarde dairy cattle, similar heritabilities have been estimated and breeding values subsequently predicted. Breeding value comparisons indicate that dual-purpose breeds may be superior to dairy breeds in terms of resilience traits developed. But further research is needed to validate the results presented in this study. Generally, in-depth phenotyping with automatic milking systems offers new opportunities to develop new resilience traits.

Introduction

Breeding objectives have been changed from a pure yield oriented objective to a balanced one by the inclusion of functional traits (Miglior *et al.*, 2005). This trend has continued into the present day (Miglior *et al.*, 2017), with the addition of resilience traits (Brito *et al.*, 2021), even though this group of traits is not easy to define and to collect (Berghof *et al.*, 2019; Colditz and Hine, 2016). Because environmental changes are observed in small time windows, the apparent effects on yield, health, or welfare are difficult to capture. To address these information deficits, more frequent environmental information is necessary and in-depth phenotyping is essential. Automatic milking systems (AMS) provide in-depth phenotypes and can therefore support the development of resilience phenotypes. Poppe *et al.* (2020a) developed resilience traits based on daily milk yield by fitting lactation curves of individual cows and then measuring various deviation values from these curves as resilience traits. They observed medium to high heritabilities. Some of these new traits showed moderate to high positive correlations with other functional traits closely related to resilience.

Since the number of AMS is increasing rapidly in Switzerland, we investigated the following two aspects:

1. The first aim was to set up a pipeline which processes data recorded by AMS on a daily basis in order to analyse resilience traits developed by Poppe *et al.* (2020a) in Swiss dairy cattle populations.
2. Milk prices for producers have been decreasing in Switzerland. As a result, producers tend to switch to dual-purpose breeds to achieve higher income from meat products and to lower costs due to more resilient dual purpose breed cows. While the dairy cow population in Switzerland has been declining over the past few years, the number of dual-purpose cows remains constant or is gradually increasing. Since resilience traits belong to the group of functional traits, the question of interest is whether dual-purpose breeds are also genetically superior to dairy breeds with respect to the traits developed under (1)?

Materials & methods

Since 2018, it has been possible for Swiss farms using AMS to have their basic milking data, such as milk yield, automatically stored in a central database at Qualitas AG (https://qualitasag.ch).

While at the beginning the number of farms with AMS was rather low, now a strong increase can be observed and currently more than 1000 farms with at least one AMS unit are registered. Of these, 433 use the automatic data transfer system. This incoming data had to be processed and validated with a data

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_149, © B. Bapst *et al.* 2022

pipeline. In addition to routine plausibility checks, the following issues had to be solved: Data records that exceeded the day change had to be assigned to the individual days based on the assignment of the milking time length. Additionally, missing daily data were filled in based on previous and subsequent days, and outliers were corrected using the same principle.

A data set of Holstein cows (red and black) as dairy cattle (DC) and all Simmental, Swiss Fleckvieh, Montebéliarde, Normand cows and their crosses as dual-purpose cattle (2C) were included in this study. After data curation, a set of 11,427 phenotypic records was available from 9,744 cows (Table 1). First of all, a data pipeline was set up to calculate the daily milk yields and to filter based on data plausibility. After that, resilience traits were developed using the methods by Poppe *et al.* (2020a). To compare the EBV of DC and 2C, only the following resilience indicator was calculated because it showed the highest correlations to important functional traits in the mentioned study: Log-transformed variance (LVA) of the deviations in the daily milk yield from individually modelled cow lactation curves. As an additional control, the trait raw variance (RVA) was also evaluated. These cow individual curves were modelled with a polynomial (fourth order) quantile regression. To collect as much data as possible and to follow the Swiss regulations for performance tests (swissherdbook, 2021), only cows with lactations of at least 270 days in milk (DIM) were included in the study. Variance components and breeding value (EBV) estimations as well as the preceding pedigree preparation and renumbering were performed with programs from the BLUPF90 package (Misztal *et al.*, 2018). For routine genetic evaluation in Switzerland, the breeds from this study and other additional breeds are combined to form a common pedigree. Crossbreeds connect the different pure breeds. Therefore, for this study, we used the data here in a common genetic evaluation for DC and 2C. Traits were analysed univariately using the following animal model with repeated measurements. This model was derived from the study of Poppe *et al.* (2020a) and slightly modified:

$$y_{ijkl} = hys_i + agca_j + lac_k + a_l + pe_{kl} + e_{ijkl} \quad (1)$$

where y_{ijkl} is the resilience trait of animal l in lactation k with age at calving j in herd year season i. hys_i is the fixed effect of herd year season, $agca_j$ the fixed effect of age at calving, lac_k the fixed effect of the lactation, a_l the random animal effect, pe_{kl} the random permanent environmental effect and e_{ijkl} the random residual effect.

Since more resilient animals have smaller variances of deviations from the standard curve, a lower EBV represents reduced deviations and lower EBV are therefore desirable.

Table 1. Cows with phenotypes.

Breed	n	%[2]	Purpose[1]	%[2]
Simmental	16	0.2	2C	
Swiss Fleckvieh	549	5.6	2C	9.3
Montbéliarde	330	3.4	2C	
Normande	12	0.1	2C	
Holstein	8,837	90.7	DC	90.7
Total	9,744	100.0	DC	100.0

[1] 2C = Dual-purpose cattle; DC = Dairy cattle with phenotypes in %.
[2] Breed proportion of cows.

The breeding values were transformed to a mean value of 100 with a standard deviation of 12. The differences of the EBV variances between DC and 2C were evaluated with a F-test.

Results

For the first time, a workflow was developed to process Swiss AMS data on a daily basis. The variance components and the heritabilities from the evaluated traits are in Table 2. For both traits, the estimated heritabilities were almost identical, while the variances were different, as expected. The genetic correlation (r_a) between RVA und LVA was 0.69.

The comparison between EBV of DC and 2C shows that the distributions of the EBV are not equal (Figure 1). F-statistics (*P*-value=0.012) confirm this difference. The difference of the means between the EBV of 2C and DC is 4.2.

Discussion

The developed data pipeline is a valuable tool to aggregate individual AMS data sets into daily information. Based on this, evaluations can be developed, such as resilience traits. Although the data set is small, we have obtained preliminary evidence that resilience traits based on daily AMS records can be evolved and that the methods of Poppe *et al.* (2020a) are applicable to other cattle populations. Heritabilities were in a similar range, but variances are different. Poppe *et al.* (2020a) estimated larger variances. Reasons for this could be the different models. With the integration of 2C data, the opposite would have been expected. However, further research is needed to explain these differences in variances and in the genetic parameters

Table 2. Estimated variance components and heritabilities (SE in brackets).[1]

Trait	σ^2_a	σ^2_{pe}	σ^2_r	σ^2_p	h^2
LVA	0.021 (0.004)	0.046 (0.004)	0.049 (0.002)	0.116	0.181 (0.030)
RVA	23.749 (4.222)	49.051 (4.559)	61.484 (2.487)	134.284	0.177 (0.037)

[1] LVA = log-transformed variance; RVA = raw variance; σ^2_a = additive genetic variance; σ^2_{pe} = variance of the permanent environment; σ^2_r = residual variance; σ^2_p = phenotypic variance; h^2 = heritability.

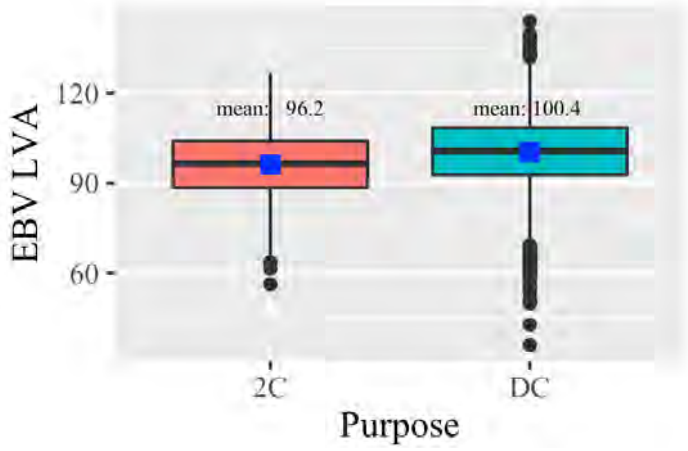

Figure 1. Comparison of the EBV distribution for 2C (dual-purpose cattle) and DC (dairy cattle) for the trait LVA; blue box: mean of the purpose groups.

derived from them. Additionally, it is surprising that r_a between RVA und LVA was larger in our study than in Poppe *et al.* (2020a). Therefore it needs to be verified that a model with repeated measurements gives the best fitting results. Poppe *et al.* (2020b) have found that LVA is not quite the same trait in second and higher lactations. Due to the limited data set, a repeatability model was used in this study. In addition, correlations with other functional traits need to be investigated. Cows with different breed proportions were included in the study. Therefore it must be checked whether non-additive effects should be taken into account (Van Der Werf and De Boer, 1989).

The current results suggest that 2C are better than DC in terms of the mean EBV of the resilience trait studied. Nevertheless, this needs to be validated with a larger data set and in addition, the differences between the levels of the EBV should be tested with a sensitive statistical procedure, such as a permutation test.

Abstract

This study aimed to explore a herd resilience indicator, LnVar, estimated from monthly test-day records. For each Holstein cow in first parity between 2014 and 2018, the expected milk yields were computed at each test-day, using the genetic and environmental effects estimated from a routine test-day genetic evaluation. LnVar was then estimated for each herd-year, as the natural logarithm of the variance within lactation of the deviation between the expected and the observed milk yields. LnVar presented a high variability and was quite repeatable between years. The herd-years with high LnVar were more productive and showed a greater risk of high somatic cell counts, clinical mastitis and short lactations. This study showed that LnVar is a relevant resilience indicator, even with monthly records. The genetic evaluations using test-day records could provide useful information for herd management.

Introduction

Cows are said to be resilient when they are able to maintain their performances throughout environmental disturbances or recover quickly if they are affected. Management practices can have an impact on these disturbances and the cows resilience. Poppe *et al.* (2019, 2020) showed that the variability of fluctuations around the expected lactation curve, measured through the natural logarithm of the variance of the deviation between the observed and the expected daily milk yields (LnVar) was a promising proxy to measure resilience at the cow and herd levels. However, these studies were based on daily records obtained by automatic milking systems, which limits the potential use of this indicator in commercial farms.

In France, expected lactations are provided by Institut de l'Elevage twice a year to the Milk Recording Organizations (MROs), in order to predict the production of each herd. Predictions use the genetic and environmental effects estimated from a genetic evaluation based on a test-day model. These effects can also be used to construct the expected lactation curve of the cows with past records and knowing their own parameters (year, age and season of calving).

In this study, a herd resilience indicator (LnVar) was estimated for each French Holstein herd using monthly test-day records. The objective was to assess to which extent the conclusions of Poppe's study were still valuable with less regular records, and whether a genetic evaluation could provide information to produce new herd management tools related to resilience.

Materials & methods

Description of the genetic evaluation. A genetic evaluation of Holstein cows was performed in October 2019 on milk yield, based on a test-day model described in Leclerc *et al.* (2008, 2009). This evaluation used all test-day records collected by MROs on Holstein cows in lactations 1 to 3 and having started their first lactation since September 1st, 1989 (more than 14 Mo cows). A random regression test-day model in which the first 3 lactations were considered as correlated traits was applied. In addition to a herd-test-day effect, the shape of the lactation curve defined by parity-region was taken into account, cumulating cubic splines of each level of the effects of calving month, calving age, length of dry period and gestation. Genetic and

permanent effects were included using a reduced rank model. Days in milk, region-year-parity and herd-year were used to model the residual variance.

Selection of cows and herd-years. We selected test-day records of French Holstein cows in first parity and included in the genetic evaluation. The lactations should have started between September 1st, 2014 and August 31st, 2018 and have at least 2 test-days. Cows should have performed their lactation in one single herd. Only performances observed before 350 days in milk (DIM) were considered and were assigned to a given year corresponding to the calving year (Year n from September n-1 to August n). Selected herd-years should have recording intervals of less than 5 weeks and at least 10 cows in first lactation.

35,719 herds-years met all requirements, corresponding to 711,485 cows (on average 19.9±10 cows per herd-year). Each cow had on average 10.3±1.4 test-day records.

Estimation of LnVar. For each herd-year, LnVar was estimated as follows: first, for a given cow j in herd i and with a performance recorded during the test-day k, the expected milk yield was estimated by the sum of all estimated effects affecting the cow at this test-day. Then the deviation δ_{ijk} was estimated between the observed and the estimated milk yields. The variance of these deviations was used to estimate the individual fluctuation of the lactation curve around its expectation. It was log-transformed in order to be normally distributed:

$$LnVar_{ij} = Ln\ (Var(\delta_{ij}))$$

Lastly, the indicator LnVar of the herd-year i was estimated as the mean of the individual fluctuations $LnVar_{ij}$ of the cows with test-day records in this herd-year.

Herd-year descriptors. Several descriptors were computed to describe herd-years regarding their production level (average milk yield within 305 days MY) and their resilience and health status (percentage of short lactations of less than 90, 120 and 200 days PSL90, PSL120 and PSL200, percentage of cows with at least one test-day above 300,000 somatic cells/ml P300kcel, or with at least one clinical mastitis observed by the farmers PMacl).

Analyses. Pearson correlations were estimated between consecutive years. The association between LnVar and the herd-year descriptors was studied through Pearson correlations and using a one factor linear model (SAS® GLM procedure), in which we tested the effect of classes of LnVar (5 classes, from very low to very high LnVar) on each herd-year descriptor.

Results & discussion

LnVar presented a high variability, with extreme values at more than 4 standard deviations from the mean and a coefficient of variation of 0.26 (Table 1). LnVar was quite repeatable across years (Table 2), which means that the profile of fluctuations in lactation curves of a given herd was only partially affected by one-time events.

Correlations between herd-year descriptors and LnVar were low or moderate (Table 3). Herd-years with high LnVar tended to be more productive and more vulnerable to udder infections (correlations of 0.27 and 0.21 between LnVar and MY and P300kcel respectively).

Table 1. Descriptive statistics of the herd resilience indicator LnVar.

	N	mean	std	min	max
LnVar	35,719	1.26	0.33	-0.12	2.97

Table 2. Correlations between LnVar estimated in consecutive years.

2015-2016	2016-2017	2017-2018
0.49	0.50	0.52

Table 3. General characteristics of herd-year descriptors and correlations with LnVar.

	Abbreviation	Unit	mean	std	Cor. with LnVar
Milk Yield	MY	kg	8,719	1,413	0.27
% of short lact. (<90 days)	PSL90	%	1.4	3.3	0.03
% of short lact. (<100 days)	PSL120	%	2.3	4.5	0.05
% of short lact. (<200 days)	PSL200	%	4.9	7.5	0.08
% of lact. with ≥1 test day with ≥300,000 cells	P300kcel	%	39.1	16.5	0.21
% of cows with ≥1 clinical mastitis within 1st parity	PMacl	%	11.1	13.4	0.04

All effects of LnVar classes on the herd-year descriptors were significantly different from zero (α<1‰). The tendencies mentioned before were confirmed, with large differences between classes illustrated by the contrasts with the middle class (Table 4). The average MY of the highest class was 1,742 kg higher than that of the lowest one and 523 kg higher than that of the middle one. The risk of having at least one test-day above 300,000 cells/ml was 1.55 times higher in herd-years with very high LnVar than in those with very low LnVar (52.1 vs 33.6%). Differences were observed for PMacl, even though the correlation with LnVar was weaker. The percentage of short lactations was higher for both extreme classes, but the risk increased more after 120 DIM for classes with high LnVar than for those with low LnVar (+2.1 vs +0.8% between 90 and 200 days for herd-year classes with very high vs very low LnVar).

Discussion

Our indicator was based on the same principles as described in Poppe *et al.* (2020), with several differences. The first one was the use of monthly test-day records instead of daily data. Large differences could be observed

Table 4. Means of herd performance indicators in different herd-year classes based on LnVar (compared to the middle herd-year class, standard errors within brackets).[1]

	Classes of herd-years based on the LnVar level [2]				
	Very low	Low	Middle	High	Very high
N	643	4,700	25,022	4,345	1,007

PSL200	+1.5 (0.30)**	+0.0 (0.12)	0.0	+0.9 (0.12)**	+2.4 (0.23)**
P300kcel	-4.9 (0.64)*	-4.1 (0.26)**	0.0	+6.2 (0.27)**	+13.5 (0.52)**
PMacl	-2.8 (0.53)**	-1.5 (0.21)**	0.0	+0.9 (0.22)**	+0.5 (0.43)

[1] * $P<10^{-3}$; ** $P<10^{-4}$.

[2] Very low: ≤0.6; low: [0.6; 0.93]; Middle: [0.93; 1.59]; high: [1.59; 1.92]; very high: >1.92.

between herd-years, even with less regular performances, and these differences were quite repeatable across years. The second originality was that the expected milk yields at each test-day were based on the effects estimated within a test-day genetic evaluation. Thanks to this approach, expected milk yields were adjusted for the cow genetic abilities (individual peak and persistency), and for the environmental effects estimated at a given stage of lactation. These parameters are currently available for any herd participating to milk recording and can be updated at each new evaluation.

The relationship between LnVar and herd descriptors were consistent with Poppe *et al.* (2020): the greater the fluctuations in lactations (higher LnVar), the more productive the herds and the greater the risk of udder health problems (high somatic cell counts and more clinical mastitis (CM) events). For PMacl, the low correlation with LnVar and the fact that the effect did not increase between the two highest classes of LnVar was probably due to a lack of comprehensiveness of registered CM events in some herds (Govignon-Gion *et al.* 2012).

The relationship between the percentage of short lactations and LnVar was more complex to interpret, since lactations may have been closed for many reasons. A large part of very short lactations were probably due to a low production level, particularly in the herds with a low productivity, and thus in the class with very low LnVar. But Beaudeau *et al.* (1995) showed that early lactation (before the peak of lactation) and end of lactation were the main periods of decision making for culling. Thus short lactations closed after the pick (between 90 and 200 days) likely corresponded to involuntary culling, and the increase in occurrences of short lactations with high LnVar could be interpreted as a lack of resilience.

Conclusions

This study showed that even with monthly data, it is possible to build herd resilience indicators based on the fluctuations of lactation curves, and that the results of a test-day genetic evaluation can provide useful information for herd management. Further investigations should be undertaken, in order to assess the genetic variability of LnVar estimated at the cow level and whether this proxy could be used to select more resilient cows.

151. Genomic selection of postpartum anoestrus recorded with accelerometer collars to improve beef cattle fertility

E. Fontanillas[1*], V. Prieur[2], A. Michenet[1], G. Auvray[1] and J. Mante[2]

[1]IngenomiX: Pôle de Lanaud, 87220 Boisseuil, France; [2]France Limousin Sélection: Pôle de Lanaud, 87220 Boisseuil, France; eric.fontanillas@ingenomix.fr

Abstract

A key genetic component of the female fertility, the calving-to-first-heat interval (CFHI), was evaluated on Limousin cattle. In a large-scale experimental design, 3,923 cows spread over 35 farms were phenotyped during 4 years. Accelerometer collars were used to detect first heat after calving. After determining the non-genetic effects on CFHI, the evaluation of the genetic potential of the animals was then carried out using a two-step genomic selection model. Heritability of the CFHI was evaluated at 6% and predictive ability, evaluated on cross validation on direct genomic values, was around 0.16. Regarding these results, together with the high variability of the phenotype and the substantial size of our reference population, we are able to set up a genomic selection program for CFHI on French Limousin breed.

Introduction

Cows' fertility is of major importance for the breeders' income in both beef and dairy cattle (Berry *et al.*, 2014; Taylor *et al.*, 2018). The reproduction efficiency is related to two aspects: the age at first calving and the calving interval (Berry and Evans, 2014; Roughsedge *et al.*, 2005). The age at first calving is genetically related to the age at puberty of the heifer. The calving interval (CI) can be impacted by breeding practices, like the management of cows by groups for natural service (insemination rate is 10% in the French Limousin breed). The CI can be split into several components (Burns *et al.*, 2010; Flores, 1971). First, the calving to first heat interval (CFHI) corresponds to the postpartum anoestrus. Second, the interval from the first heat to first mating is mainly related to breeding practices (Donoghue *et al.*, 2004). Then, the number of reproduction events until success is crucial. It is a very low heritable trait which is already evaluated from the French national records of inseminations (Idele, 2014). At last, the gestation length leads to the calving.

The CFHI is the most heritable trait among fertility predictors (Berry *et al.*, 2014). However, as studied by Mialon *et al.* (2000) in the Charolais breed, detecting the heat requires human observation or progesterone dosage which cannot be routinely recorded in commercial farms. Sensors can help to get more accurate heat detection (Schöpke and Weigel, 2014).

Since the last decade, the French Limousin breeding society has been developing on-farm data recording in collaboration with voluntary breeders gathered in a farm network. Several traits of particular interest for the breeders, like pelvis opening or udder shape, were recorded and led to the development of genomic selection on these traits. In 2016, an original project called 'COWnect' was launched with data collection of postpartum first heat using sensors. We report here results for heritabilities and genomic predictive ability for CFHI.

Materials & methods

Phenotype records. A total of 3923 cows from Limousin breed were recorded on the 35 farms of the 'COWnect' farm network over 4 years. The first component of CFHI is the calving date which is considered as a reliable record. The second component is the first heat event consecutive to calving, which was recorded by analysing onsets of activity using the accelerometer system collar (Heatime; SCR Engineers Ltd., Netanya, Israel). Quality controls were performed to keep realistic records of CFHI based on the

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_151, © E. Fontanillas *et al.* 2022

cyclicity of oestrus and the average gestation length. Twin calving records were discarded. After filtering steps and quality controls, 5,265 records of CFHI were collected for 3,181 cows between May 2017 and May 2021 (Figure 1a.). Two levels of filtering the CFHI records were tested: no filter and filtering with a minimum value of 20 days and a maximum of 160 days (Figure 1b.).

Genotypes. A total of 2,429 animals with performance were genotyped on 11 various chips from 26,151 SNP to 138,894 SNP. After quality control (call rate of 1%, Hardy Weinberg Equilibrium *P*-value 5%), these animals were all imputed to a target map of 43,784 SNP using Beagle v5.1 (Browning *et al.*, 2018).

Genetic model. The genetic model included repeated records from the same animals for successive calving records. A five-generation pedigree was extracted for each animal with a performance record. AIREML was run to estimate genetic parameters with sample standard deviation estimation (sd). Sensibility of the CFHI to the extreme values (below 20 days or above 160 days) was tested with heritability estimation on a non-filtered or filtered dataset (Table 1). Estimated breeding values (EBV) were computed with a pedigree BLUP (best linear unbiased predictor) based on filtered phenotypes. The BLUPF90 software package (Misztal *et al.*, 2002) was used for both purposes.

Genomic model. The EBV from 2,429 animals with phenotype and genotype were used as a reference population. A BayesC approach (Habier *et al.*, 2011) was used for the genomic model with a proportion of markers π assumed to have an effect at each iteration was fixed or estimated by the model. The π value was either estimated by the model, or fixed to several values: 0.01, 0.1, 0.2 and 0.5. A total of 100,000 iterations were performed with a burn-in period of 20,000. The GS3 software (Legarra *et al.*, 2013) was used for the analyses.

Accuracy of the genomic model was assessed using cross validation k-fold procedure including 8 validation population samples randomly defined. Pearson correlations were computed between direct genomic value (DGV) and phenotypes corrected from environmental effects (averaged for repeated measures).

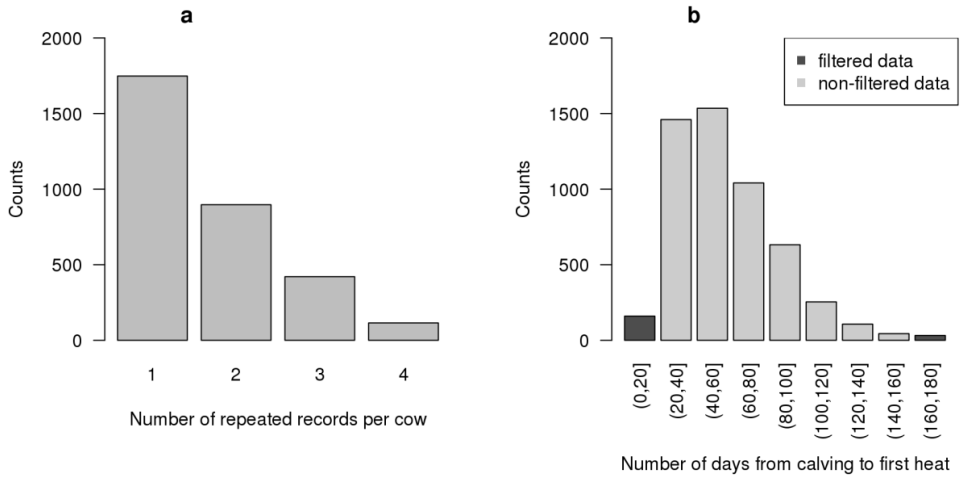

Figure 1. Description of the dataset: (a) counts of repeated records per cow; (b) distribution of calving to first heat intervals.

Results

Environmental factors detected as having a significant effect on CFHI were the contemporary group (made of herd × campaign of calving from September to August), the month of calving and the interaction of parity of the cow and its age at the first calving.

The removal of extreme CFHI values in the filtered dataset led to a lower phenotypic variance (Vp=706.2), a lower residual variance (Ve=546.2) and a slightly higher heritability (h^2=0.06) compared to the estimations made from non-filtered dataset (Vp=813.3; Ve=625.7 and h^2=0.05). The repeatability estimate was 0.07 in both cases. Moreover, the average reliability (i.e. CD) of the 2,429 EBV was 0.16 for the animals included in the genomic model.

Predictive ability of the genomic model, computed as correlation between predicted (DGV) and real information (deregressed phenotype) in cross-validation, was between 0.144 and 0.167 depending on the π parameter of the Bayes C model (Table 2.). The inclusion of the π as a random variable estimated by the Bayesian model gave the best accuracy. The posterior estimation of the π in this model is 0.29 with a sample standard deviation of 0.11.

Discussion

The CFHI trait definition implied several quality controls of the data which had a critical impact on heritability estimates. The assumption of non-realistic CFHI below 20 days related to the oestrous cycles (Forde *et al.*, 2011) led to slightly higher heritability but the estimates overlap given their standard deviations. Similarly, extremely long CFHI impacted the quantitative model while it might be more related to the breeding practices (based on breeder survey).

The best result of heritability estimated in this study is higher than the other traits of female fertility available until now for the French Limousin breed (Idele, 2014). The same trait studied in Holstein breed based on progesterone dosage as a proxy of commencement of luteal activity (Berry *et al.*, 2014) led to higher heritability (0.16-0.18). However, progesterone dosages are highly human-time consuming and are not sustainable for automated phenotypic recording. Similar results were observed by Mialon *et al.* (2000) on the Charolais breed, where CFHI (full-time human supervision) and postpartum-interval-to-

Table 1. Sensibility to extreme values of calving-to-first-heat interval (CFHI). In the filtered dataset, CFHI lower than 20 days and higher than 160 days were discarded from the analysis.

Datasets	Non-filtered	Filtered
Sample size	5,265	5,097
Heritability (standard deviation)	0.05 (0.02)	0.06 (0.02)
Repeatability	0.07	0.07

Table 2. Correlations from cross-validation for CFHI with a Bayes C model.

π value	Correlation from cross-validation (standard deviation)
0.01	0.144 (0.06)
0.1	0.162 (0.04)
0.2	0.162 (0.05)
0.5	0.159 (0.04)
Estimated	0.167 (0.04)

first-positive-progesterone test were measured on the same animals with respective heritability of 0.12 and 0.35. Heritability obtained in this study was lower but showed that the accelerometer system collar allows recording this performance in an automated way.

The precision of genomic selection is in the range of what is expected considering the heritability of the trait and the size of the reference population. Toghani *et al.* (2017), studied three fertility traits on composite beef cattle. Using the same Bayes Cπ model, validation correlations were equivalent for a trait with similar heritability.

These results are promising for the implementation of the genomic selection for female fertility which will become available in the next release for the French Limousin breed. This will be the first fertility trait genomic evaluation which exploits data from the 'COWnect' project. With low accuracy, extreme animals could be detected and culled. More data is needed to increase the reference population size. The development of sensors in commercial farms is a way to build up a larger database, considering that the long and thorough work of setting up the procedure of data exchange and collection has already been done.

To follow up on the topic, studying other components of the calving interval such as the gestation length or precocity is scheduled to build a package on genomic prediction for female reproduction.

Abstract

The objective of GenTORE is to develop innovative genome-enabled selection and management tools to optimise cattle resilience and efficiency in widely varying environments. These tools incorporate both genetic and non-genetic variables, aiming to increase the economic, environmental and social sustainability of European cattle meat and milk production systems. Using available on-farm technology allows large-scale phenotyping of resilience and efficiency that can be applied to evidence-based management, breeding and culling decisions. Veterinarians and other farm advisors are engaged with farm business drivers that are influenced by consumer and societal demands including the environment, human health concerns regarding antimicrobial resistance and animal welfare. Conflicts exist in balancing these factors. Evidence-based tools to support herd-level strategy are lacking. This work describes how multiple streams of sensor data can be combined to inform herd-level strategy in a time-efficient, automated and objective system to support advisor input to herd health.

Introduction

The GenTORE project aims to develop innovative genome-enabled selection management tools to optimise cattle resilience and efficiency in widely varying environments.

Current decision tools for breeding often fail because they ignore the complex interactions between production, health, genotypic predisposition, and reproduction performance at a specific herd population level; they also require significant time and are not user friendly for advisors or at farm level.

This paper outlines how the management tools developed through GenTORE can help farmers, veterinarians and other advisors to balance the four key drivers in sustainable dairy and beef farming (Figure 1).

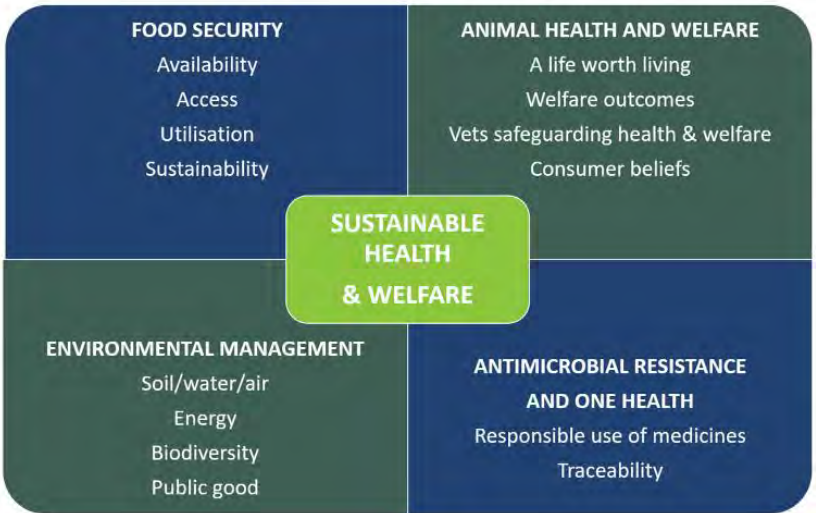

Figure 1. The sustainable herd health balance for farm advisors.

Balancing the drivers for evidence-based herd decision-making

Veterinarians and other farm advisors are engaged with the farm business drivers described below that are influenced by consumer and societal demands. Conflicts exist in balancing these factors. Precision Livestock Farming (PLF) offers opportunities for innovation in evidence-based decision-making for farmers, veterinarians and advisors. A balance must be achieved in sustainable dairy and beef farming between four key drivers (Figure 1):

1. 'One Health';
2. environmental impact;
3. animal health and welfare;
4. food security.

'One Health'. The concept of 'One Health' encompasses animal health, human health and the environment. One Health is ever present in the global fight against the development of antimicrobial resistance. It is already the cause of 700,000 human deaths every year (O'Neill 2016). Decisions to administer antimicrobials to cattle are critically important, but often highly subjective and not risk-based.

Environmental impact. The importance of mitigation of the impacts of dairy farming on the environment are increasingly recognised (Statham *et al.* 2017; Statham *et al.* 2020). In 2010 the Food and Agriculture Organization of the United Nations (FAO) produced a 'lifecycle assessment' of the dairy sector which was proposed to contribute 4% to the total global man-made greenhouse gas emissions. Improved efficiency of milk production will reduce negative environmental effects; if fewer cows (and replacements) are required and there are fewer 'lost' litres of milk and a reduction in greenhouse gases and resources per litre of saleable milk. 'Lost' milk here includes milk that does not enter the food chain following animal treatment or a reduction in yield that occurs following clinical or subclinical disease or poor reproductive performance. The difference in environmental impact between the best and poorest performing herds in terms of health and fertility is likely to be very large; in terms of fertility alone reductions in methane emissions of the order of 25% appear to be possible between the best and poorest herds (Garnsworthy 2004; ADAS 2013).

Animal health and welfare. It is important that the connections are clearly made for welfare as well as health in managing the sustainability of food production (Broom *et al.* 2013).

Food security. Food security is not limited solely to the quantitative aspects of food supply. Three fundamental dimensions are applicable to products of animal origin: availability of food, access to food, and effective and safe utilisation of food (Bonnet *et al.* 2011). Sustainability refers to the capacity for sustainably maintaining agricultural production (including animal production), national and international trade, storage and supply and food consumption that will meet the demand in the long term and even in the context of new constraints.

Herd level breeding and health decisions can be supported by on-farm sensor time series data presented as proxies of resilience and efficiency

Evidence-based tools to support herd-level strategy setting are lacking. However multiple streams of sensor data can be combined in a time-efficient, automated and objective system to support advisor input to herd health. Climate change, with its increasing frequency of environmental disturbances puts pressures on the livestock sector (Hansen *et al.* 2012). More complex traits such as resilience must be considered in our management strategies and breeding programs (Friggens *et al.* 2022). Resilient animals respond well to environmental challenges, are more likely to overcome them without assistance and therefore have better health and welfare. In practice there remains a lack of operational measures of resilience that can be deployed at large scale across different farm types and livestock species. Such measures are needed to provide more precise phenotypes of resilience for use in farm management and animal breeding decisions. Decisions can be made at individual animal level, but when combined can inform critical changes in herd level policies and protocols.

Cow resilience and efficiency are two key traits that can be used for decision making. Sensor-based proxies for phenotypes offer an important dimension to application of genomics data. Novel proxies for complex phenotypes were developed in Horizon 20-20 project 'GenTORE' for resilience using already existing at-market technology. Definitions and ways to calculate resilience outcomes were lacking; methodology had to be objective and valid so appropriate ranking of the cows for these traits on farm was possible (Adriaens *et al.* 2020). For resilience, a combination of longevity, health, robustness, production, and reproduction performance had to be considered. This resulted in the following definition for ranking cows: 'resilience is the cumulative result of a cow's ability to re-calve' (and thus extend her productive lifespan), supplemented with secondary corrections for age at first calving, calving intervals, 305-day milk yield, health events and number of inseminations. Different weightings of the included variables were proposed and cross-validated to produce a common equation to calculate the resilience scores. The highest weight was given to the number of parities. One of the main challenges in this work was the availability, completeness and reliability of the data (Adriaens *et al.* 2020).

Sensor technologies record parameters reflecting animals' performance, behaviours and physiological state. Besides the classical use for event detection and 'alerts', time series data from sensors can be characterized to provide information on how animals have performed over time. Two types of sensor features were defined. Type A sensor features generally characterize the sensor measurements relative to the herd peers, and include milk yield, body weight, rumination and activity. Type B sensor features specifically target the identification of dynamics in the time series indicating certain health or fertility events. Several primary algorithms to predict the resilience and efficiency rankings from the sensor features were tested. These algorithms were deployed to design software that could signal herd level change in resilience and thus provide an evidence base for practical changes in herd management policies.

Combining individual level data from multiple technologies in a form that is useable in real world situations in real time requires an additional integration step to deal with issues such as synchrony of multiple proxy indications at animal level. Statistical methods to deal with these issues and combine proxies into one reliable indicator have been proposed (Adriaens *et al.*, 2020). GenTORE partner 'Noldus' have developed a demonstration web framework using the software Blazor (https://demos.telerik.com/blazor-ui/; Microsoft, Redmond, USA) that outlines the potential of this combination of time-series sensor data as herd level resilience and efficiency based tools: Comparing herd resilience and efficiency score against a group benchmark; Visualization of four main component scores (Health, Fertility, Production and Herd Inventory) and a detailed view of underlying data for farm advisor or researcher.

Developing an advanced dairy cow decision-support tool prototype to optimize breeding decisions for dairy cows is a vital missing link in the industry today. So many PLF technologies operate in separate silos; opportunities to make evidence based breeding or culling decisions are essentially missed on many farms. GenTORE looks to integrate multiple sources of information including PLF sensor data, genomics and germplasm quality data (Spilman *et al.* 2017) to drive an opportunity to realise the wasted potential in commercial herds by targeting scarce resources and optimizing herd management decisions. The aim is to establish a practical approach to how the genetic potential offered by genomics can be optimally exploited in each individual herd environment.

Conclusions

Sustainable herd health would be supported by objective advice. Current decision tools for breeding often fail because: (1) they ignore the complex interactions between production, health, genotypic predisposition and reproduction performance at a specific herd population level; and (2) they require significant time and are not easy to use at farm level or for advisors. GenTORE aims to integrate multiple sources of information including PLF sensor data and genetics in order to deliver a herd level advisory tool that can inform a balanced herd sustainable management strategy.

Abstract

Influenza A virus (IAV) is one of the most important primary agents in porcine respiratory disease complex (PRDC). The gene expression profile was evaluated by RNA-Seq analysis in mediastinal lymph nodes from non-vaccinated and vaccinated pigs with a nanovaccine for IAV to clarify molecular mechanisms and genes involved in the protective immunity conferred by influenza vaccination. A total of 14,381 genes were expressed in the analysed tissue. From those, 564 were differentially expressed (DE) between the two groups. Eighteen biological processes (BP) were enriched in immune response, cell cycle regulation and reproductive processes. The defence response was the BP with more gene counts, including chemokines (*CXCL9, CXCL10, CCL8, CXCL8*), interleukin (*IL21, IL26*), interferons (*ISG20, IFN-alpha-8*), within others. The transcriptome analyses provided a better understanding of the immunogenicity in pigs induced by nanovaccination and could support the development and evaluation of better vaccines for swine and other animal species.

Introduction

Influenza A virus (IAV) is one of the most important primary agents in porcine respiratory disease complex (PRDC), causing a major economic concern for the swine industry and a pandemic threat for humans. Although the economic impact of influenza infection in pig farms is difficult to estimate, an influenza outbreak in a non-immune pig herd causes an acute respiratory disease (up to 100% morbidity), increased number of abortions and other bacterial secondary infections. In general, influenza outbreaks observed in pig farms over time increase the mortality rates (up to 2%) and cause a 10 to 30% reduction in piglet weaning weight (Gillespie *et al.* 1999; Torremorell *et al.* 2009).

In Brazil, IAV is the main virus detected in PRDC (Silva *et al.*, 2013). The genetic diversity of IAV in swine has increased since the emergence of pandemic H1N1 (pdm) virus in 2009 (Schaefer *et al.* 2015), introducing new challenges for the diagnostic and for the development of cross-protective vaccines. H1N1, H1N2 and H3N2 virus subtypes are prevalent in pig herds in Brazil, and they have distinct genetic and antigenic profiles. Hence, vaccination of swine with IAV strains that match the strains currently circulating in swine is the main strategy to control the disease in pig herds (Salvesen;Whitelaw, 2021). Although several influenza vaccines for pigs have been tested, and their efficacy proved in field trials, very few data are available on the immunological mechanisms underlying nanovaccine-induced protection. Previous study has shown a robust humoral immune response in pigs vaccinated with an influenza nanovaccine (Haach *et al.*, 2021). Therefore, we evaluated the gene expression profile in mediastinal lymph nodes (LMD) of pigs non-vaccinated and vaccinated with a nanovaccine for IAV containing the hemagglutinins of H1N1pdm, H1N2 and H3N2 viruses, to clarify the molecular mechanisms and genes involved with the immune response for a virosome-based influenza vaccine.

Materials & methods

Animals and sample collection. A total of 40 specific pathogen free (SPF) pigs were raised at the Embrapa Swine and Poultry National Research Centre, Concórdia, SC, Brazil, in a standard pig production system with water and feed *ad libitum*. The 28 days-old pigs were randomly distributed into two groups: G1: 10 non-vaccinated pigs, which received PBS injection and G2: 30 vaccinated pigs which received two doses (with 14 days of interval) of an IAV nanovaccine containing the hemagglutinins of H1N1pdm, H1N2 and H3N2. Animals were monitored for clinical signs, as well as for IAV or other virus and bacteria infection. Fifteen days after the second dose, all pigs were euthanized for mediastinal lymph node collection. LMD were stored in liquid nitrogen for gene expression analysis. The sample collection was performed according to the ethical guidelines of the Embrapa Swine and Poultry Ethics Committee on Animal Utilization, under the protocol number 001/2017.

RNA extraction, library preparation and sequencing. For the gene expression analysis, a total of 24 pigs (8 non-vaccinated, 5 females and 3 males and 16 vaccinated, 8 females and 8 males) were selected. The total RNA was extracted from approximately 100 mg of frozen mediastinal lymph node tissue using Trizol (Life Technologies), according to the manufacturer's protocol, followed by an RNA cleanup using the RNeasy mini kit (Qiagen). The RNA concentration was measured with Biodrop spectrophotometer (Biodrop) and the RNA integrity was verified using Bioanalyzer 2100 equipment (Agilent). The libraries were prepared using the Illumina Truseq Stranded mRNA (Illumina), with 1µg of total RNA, following the manufacturer's protocol. The sequencing was performed in Illumina NextSeq 2000 sequencer (lllumina, USA), using 2×100 bp paired-end reads, at the NGS Soluções Genômicas facility, in Piracicaba, São Paulo, Brazil.

Data analysis and functional annotation. The data were analysed using the Bioinformatics tools for quality control (QC) and mapping reads using BAQCOM pipeline available in the Github repository (Oliveira, 2022), which uses Trimmomatic (Bolger; Lohse; Usadel, 2014) to remove short reads (<70 bp), reads with low quality (QPhred <20) and adapter sequences, STAR (Dobin *et al.*, 2013) for mapping against the swine reference genome (Sscrofa 11.1, Ensembl release 104) and the HTseq-count (Anders *et al.*, 2015) for reads counting. The differentially expressed (DE) genes were obtained using the limma package (Ritchie *et al.*, 2015) and considered DE when a false discovery rate (FDR) was <0.05 and a logFC >|1|. Negative and positive fold-changes indicate down and upregulation of the genes in the vaccinated compared to non-vaccinated groups. The functional annotation of the DE genes was performed with clusterProfiler (Wu *et al.*, 2021) package from R language using gene ontology (GO), MSigdb and Reactome databases. Biological processes (BP) with FDR<0.05 were considered enriched. A Gene-Concept Network, which considers potentially biological complexities within genes and BP, was also constructed in the clusterProfiler.

Results

A total of 397,856,687 paired end reads were obtained for the 24 LMD samples. After QC, an average of 31.1±6.5 million paired-end reads per sample were kept, and 94.42% were uniquely mapped across the swine reference genome. Out of those, 80.63% were mapped in genes. A total of 14,381 genes were expressed in the swine mediastinal lymph node. From those, 564 were DE between groups: 316 were down and 248 were upregulated in the vaccinated group. A total of 481 genes had gene names assigned and were considered annotated, and therefore used for the enrichment analysis. After removing redundant GO terms, 18 BP were enriched in this dataset, where most of them were related to immune response, cell cycle regulation and reproductive processes. The defence response was the BP with more gene counts (25 genes), including chemokines (*CXCL9, CXCL10, CCL8, CXCL8*), interleukin (*IL21*), interferons (*ISG20, IFN-alpha-8*). In this BP, the activation induced cytidine deaminase gene (*AICDA*) gene was included,

which was the most upregulated gene in response to vaccination. Furthermore, it was possible to observe different BP that have genes with multiple functions, such as *CDC6, CDC20, CCNB1, RMI2, SGO1, TOP2A, BIRC5, ZWINT, AURKB, KIF18A, NUF2* and *HJURP*.

Using the immunologic signature of gene sets (C7) available in MSigdb, that are based on human and mouse datasets, 32 genes DE in our study have already been associated to the immune response to IAV: *MYBL2, RRM2, UBE2T, ASF1B, E2F2, CDC20, KIF2C, CDCA8, CDCA5, TOP2A, POLQ, HJURP, CENPE, BIRC5, NCAPG, KNL1, MKI67, ZWINT, GTSE1, AURKB, DLGAP5, KIF18A, E2F8, ESPL1, NCAPH, CDCA2, BUB1, CDCA7, LGI4, CKB, LPL* and *AZU1*.

Discussion

Nanovaccines can potentialize the immune response for a given antigen and could be one of the strategies to improve the performance of swine IAV vaccines (Salvesen; Whitelaw, 2021). In this study, the LMD gene expression profile in response to an IAV polyvalent nanovaccine developed by Embrapa Swine and Poultry was evaluated, evincing genes in several BPs related to the regulation of humoral immune response, immune cell migration and cell differentiation. These results corroborate with Haach *et al.* (2021), since a robust humoral immune response has already been described after vaccination of pigs with a polyvalent nanovaccine against IAV. Genes such as *AMCF-II, CXCL9, CXCL10* and *CXCL8*, known by their function in humoral response, were within the 40 genes most upregulated in the vaccinated group. The *AMCF-II*, an alveolar macrophage-derived chemotactic factor has antiviral activity (Borca *et al.*, 2021), and the *CXCL9* and *CXCL10* are activated in response to IAV in humans (Wang *et al.*, 2011).

The *AICDA* was the most upregulated (logFC=4.49) in response to the IAV nanovaccination. This gene is essential to generate high-affinity antibodies, robust humoral immunity and immune memory, and its activation in response to influenza vaccination has been observed in humans (Frasca *et al.*, 2015). It has been suggested that this gene could be a predictive marker of individual response to IAV vaccination (Frasca *et al.*, 2015). Other highly expressed genes, such as *IL26* and *IL21* are also involved in host defence and inflammatory response (Che *et al.*, 2020). Besides the functional candidate genes, which are potential markers for immune response, several genes that are important for the activation/proliferation of B and T cells were also highly expressed. Therefore, the transcriptome analyses provide a better understanding of the immunogenicity in pigs induced by nanovaccination and could support the development and evaluation of better vaccines for swine and other animal species.

154. Host variation in susceptibility to lumpy skin disease: gene expression analyses of experimentally infected cows

S. Van Borm[1], T. Klingström[2], A. Niazi[2], K. De Clercq[1], L. Mostin[1], A. Haegeman[1] and D.J. de Koning[2*]

[1]Sciensano, Rue Juliette Wytsmanstraat 14, 1050 Brussels, Belgium; [2]Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; dj.de-koning@slu.se

Abstract

Lumpy Skin Disease (LSD) is becoming a global threat to cattle and related species. It requires annual vaccination to prevent further outbreaks. There is host variation in the response to infection both in field studies and under carefully controlled artificial infections. Here, we study the gene expression response in whole blood at four time points before and after experimental infection with LSD virus in five cows with divergent disease outcomes. Differentially expressed genes (FDR<0.05) were identified for comparisons between LSD symptomatic and asymptomatic animals at all time points as well as between time points for symptomatic animals. Gene set enrichment showed a role of oxidative phosphorylation as well as a range of disease pathways. While preliminary, these results are the first ever study of host transcriptomes related to LSD.

Introduction

Lumpy skin disease (LSD) is endemic in Africa and an immediate and serious threat to cattle in Europe and eastern and central Asia. The disease is caused by the capripoxvirus Lumpy Skin Disease Virus (LSDV). The disease has spread steadily north over the past 10 years from Africa through the Middle East and the eastern Mediterranean region before entering Europe, the Balkans and Caucasus in 2014-16 (EFSA *et al.*, 2020). Several Balkan countries currently vaccinate against LSD but this is costly (reviewed by Tuppurainen *et al.*, 2021)). There is clear host variation in response to LSD infection: in field studies about 50% of the animals develop no clinical signs when a herd is infected with LSDV (EFSA *et al.*, 2020). This is confirmed by experimental challenges where animals are infected by direct injection of LSDV into the vena jugularis and the neck (Haegeman *et al.*, 2021). Here we show a first attempt to explore mechanisms behind divergent disease outcomes by studying gene expression after experimental LSDV infection in whole blood.

Materials & methods

Five approximately 6-month-old male Holstein bulls which were tested free of BVD and IBR were experimentally infected at Sciensano with LSDV via injection in the vena jugularis and the neck with a LSDV strain derived from Israel (Haegeman *et al.*, 2021). Blood samples were taken five days prior to infection, at day 1 post infection and subsequently at least every other day until day 15. Three animals were symptomatic for LSD while the other two were asymptomatic. Here we used whole blood stored in Tempus™ Blood RNA Tubes (Applied Biosystems™) from days -5, 3, 7, and 15. RNA was isolated using the Tempus™ Spin RNA Isolation Reagent Kit according to the manufacturer's instructions. RNA integrity was validated using high sensitivity RNA Screentape reagents (Agilent) yielding integrity scores (RQN)≥9.6 for all samples.

RNA Sequencing. RNA sequencing was performed at the Neuromics Support Facility of VIB University of Antwerp, Center for Molecular Neurology. RNA sequencing followed a QuantSeq approach where sequencing libraries were constructed near the 3′ end of polyadenylated RNAs (Moll *et al.*, 2014). This results in only a single fragment per transcript thus simplifying the quantification of gene expression. Libraries were sequenced with Illumina NextSeq500 using 150 HO sequencing kit.

RNA analysis. Bioinformatics analyses were performed by the SLU Bioinformatics Infrastructure (SLUBI). Quality control of sequencing data was performed using FastQC v0.11.8. Quality trimming and adapter removal was performed using bbduk.sh script available in BBMAP suite v38.94. After data pre-processing, the filtered data was input to STAR aligner v2.7.9a (Dobin *et al.,* 2013) for read mapping to *Bos taurus* reference genome. Top level assembly of the genome Bos_taurus.ARS-UCD1.2.105 and annotation in annotation v105 in GTF format was downloaded from ENSEMBL database. Differential Expression analysis was performed in R version 4.1.2 using DESeq2 v1.32.0 package (Love *et al.*, 2014). Comparisons were made between symptomatic and asymptomatic animals at each time points as well as within symptomatic animals between time points. Gene Set Enrichment Analyses were done for both gene ontology terms (GO) and KEGG pathways.

Results

All 20 libraries were sequenced successfully with an alignment rate of 90-93% of reads uniquely mapped to the reference genome. One sample of a symptomatic animal at day 3 was shown to be an outlier when doing a PCA plot of all the results. This sample also had the lowest RNA concentration and was hence removed from further analysis. When comparing the symptomatic animals to the asymptomatic animals at different time points the smallest number (17) of differentially expressed (false discovery rate (FDR)<0.05) genes was at 5 days prior to infection with the highest number (376) at 7 days post infection. At 3 days and 15 days post infection, we detected 36 and 40 differentially expressed genes, respectively. When comparing gene expression patterns over time within the symptomatic animals, the largest number of differentially expressed genes was between day 3 and day 7 post infection (81). The Venn diagrams in Figure 1 show limited overlap between different analyses, in particular when comparing symptomatic and asymptomatic animals. Table 1 shows the results for the functional annotation of the differentially expressed genes. While day 7 after infection showed the largest number of differentially expressed genes, day 3 after infection gives the clearest gene set enrichment related to disease response, both for GO terms and KEGG pathways. The GO terms point towards several metabolic processes while the KEGG pathways highlight a broad spectrum of disease-related pathways. While only nominally significant, the GO terms for day 7 post infection included terms like coagulation, platelet activation, wound healing and hemostasis. Both GO and KEGG point towards a role of oxidative (de-)phosphorylation.

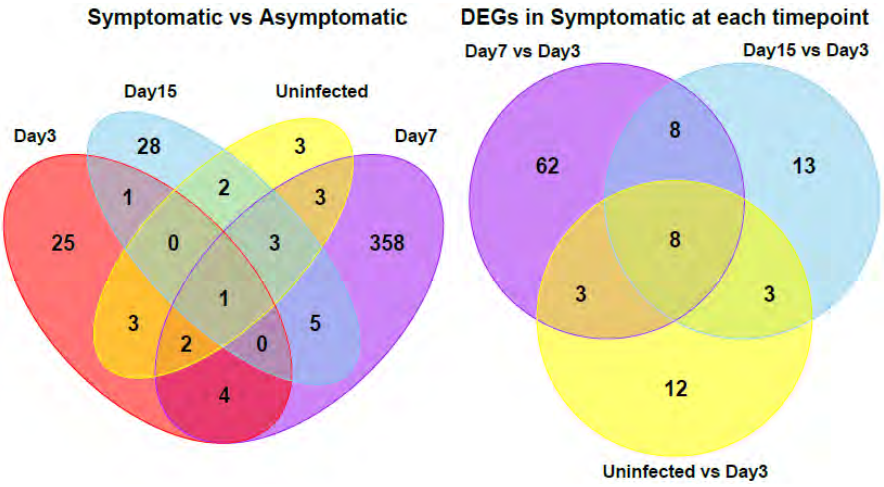

Figure 1. Differentially expressed genes between experimentally infected cows with different clinical outcomes (left), and within symptomatic animals over time (right).

Table 1. Functional annotation of differentially expressed genes.

Comparison	GO_Terms	FDR	KEGG Pathways	FDR
Symptomatic versus asymptomatic, day 3	ATP metabolic process	0.021	Oxidative phosphorylation	<0.001

	Positive regulation of dephosphorylation	0.08		
	Regulation of organ growth	0.08		
	Behavior	0.08		
	Bone morphogenesis	0.08		

Discussion

To the best of our knowledge this is the first study of host transcriptome response to infection with LSDV. While modest in terms of sample size, we could show clear differences between animals with different disease outcomes for all time points. The finding of differentially expressed genes, while only a handful, between symptomatic and asymptomatic animals at five days before infection is intriguing. While it may simply be an artifact, it could also reflect the prior immune status of animals that has a subsequent effect on the outcome of the infection. The most significant gene prior to infection, Interleukin 1 Receptor Accessory Protein (IL1RAP) is also significant at other time points, together with other genes related to interleukin. In further analyses we also look at genet works and pathways over time using the whole data. In order to make efficient use of limited blood volumes and other resources, we opted for a QuantSeq approach in this study. While this is an efficient way for gene counting, we did not capture any splice variants or get a complete whole blood transcriptome of LSDV response. In ongoing studies, we will perform whole transcriptome sequencing in a cohort of 15 animals which will facilitate a comparison with more statistical power and a more detailed analysis of the transcriptome itself.

Abstract

Nine hundred and fifty five rabbits were inoculated at 6 weeks of age with a pyogenic strain of *Pasteurella multocida* and were scored for resistance from 0 to 4 by taking into account post-mortem examinations. Fifty five sires having at least 10 inoculated offspring produced also 9,943 rabbits tested for health and growth and 1,468 females tested for reproduction in commercial farm conditions. Total number born and number born alive per litter were significantly lower in daughters of resistant sires (-0.27 and -0.41). Prevalence of digestive diseases and infectious diseases were significantly lower in the resistant growing rabbits than in the susceptible ones (-1.7 point and -3.0 points, respectively). This result suggests that resistance to pasteurellosis assessed by an experimental infection is favorably correlated to resistance to other infectious diseases.

Introduction

Pasteurellosis is one of the most common bacterial infection in commercial rabbit farms. The RELAPA project (Genomics for the Genetic Resistance of Rabbits to Pasteurellosis) aims at identifying genomic regions associated with the resistance to pasteurellosis. To establish a successful commercial breeding program to improve resistance to pasteurellosis, we need to evaluate the relationship between this trait and resistance to other diseases and production traits. This study aims at comparing production and health traits of growing rabbits and breeding does raised in commercial farms and produced from the resistant and susceptible sires having offspring tested through experimental inoculation with *Pasteurella multocida* in the RELAPA project.

Materials & methods

Sires evaluation. In the RELAPA program, 955 crossbred rabbits were inoculated at 6 weeks of age with a pyogenic strain *of Pasteurella multocida* and the response to inoculation was assessed during the following 14 days, the animals being sacrificed after 14 days (Shrestha *et al.*, 2018). These crossbreds are progenies from six sire lines (two lines each from breeding companies Eurolap, Hycole, and Hypharm) and one dam line (INRA 1777). The rabbits were scored for resistance to pasteurellosis from 0 to 4, by taking into account scores for extent of abscesses (0 to 4), scores of *P. multocida* presence (0 to 4), and status of the rabbits (dead/alive) at the end of the experiment. (Shrestha *et al.*, 2018). Among the sires used for RELAPA, 55 having produced at least 10 inoculated animals were classified as resistant (28 sires) or susceptible (27 sires) according to the mean resistance value of their inoculated offspring (Table 1).

Table 1. Means and standard deviation of the resistance score of resistant and susceptible sires calculated from their inoculated offspring score.

Group of sire	N	Mean resistance score	Standard deviation of resistance score
Resistant	28	1.57	0.16
Susceptible	27	2.03	0.26

DOI: 10.3920/978-90-8686-940-4_155, © H. Garreau *et al.* 2022

Animals and measured traits. The 28 resistant sires produced 4,991 growing rabbits (RG) and 884 breeding does (RD) while the 27 susceptible sires produced 4,952 growing rabbits (SG) and 712 breeding does (SD). Growing rabbits and does were raised in six commercials farms belonging to the three breeding companies partners of the RELAPA project. The does were raised in conventional housing, inseminated for the first time at 19 weeks of age and then every 42 days. Females produced 6,676 litters, or 4.2 litters per female on average. For each insemination, fertility was scored one (AI followed by a kindling) or zero (AI not followed by a kindling). For each litter, the number born alive and dead has been recorded. Stillbirth is calculated as the difference between the total number born and the number born alive divided by total number born. Nest mortality was calculated as the difference between the litter balance after adoption and the number of weaned rabbits divided by the litter balance.

The rabbits were weighed at weaning and at the end of the test. The weaning age ranged from 28 to 35 days, while the age of the end of fattening ranged from 66 to 70 days depending on the rearing farm. Mortality and clinical signs of diseases occurring in growing rabbits were recorded at the end of the test. The most likely cause of death of rabbits that died before the end of the test was also recorded. Disease traits were coded as 0 (absence) or 1 (disorder= morbidity or mortality). They were the following: (1) digestive disease, which includes diarrhea, bloated abdomen, and any form of digestive symptoms; (2) respiratory diseases which includes nasal discharge, pneumonia; (3) all infectious diseases, which combines digestive and respiratory diseases, abnormal low weights and other clinical signs of infectious origin. The basic statistics of growth and disease traits are given in Table 2.

The total prevalence of digestive, respiratory, infectious diseases and mortality recorded during the growing period are given in Table 3.

Table 2. Number of animals, mean and standard deviation (Std) for growth and reproduction traits.

Trait	Number of animals	Mean	Standard deviation
Weaning weight (g)	8,025	866	232
Final weight (g)	7,477	2,292	258
Fertility (0/1)	6,676	0.87	-
Total number born / litter	5,798	10.80	3.10
Number born alive / litter	5,798	10.09	3.57
Stillbirth (%)	5,137	7.35	-
Nest mortality (%)	5,069	9.81	-

Table 3. Mean prevalence (in %) of digestive, respiratory, all infectious diseases and mortality (%) recorded during the growing period.

Trait	Mean
Digestive diseases	8.7
Respiratory diseases	7.1
All infectious diseases	21.3
Mortality	5.3

Statistical analysis. The growth performances were analyzed with the PROC MIXED procedure of the SAS software (2008). The significant fixed effects ($P<0.05$) retained in the model were: the sire's resistance group (n=2), the combined effect batch × genotype (n=30), the litter size at birth (n=12), the litter size at weaning (n=10), the parity of the birth litter (n=4). The effect of weaning age was added to the weaning weight model while the end of fattening age effect was added to the final weight model. Health traits were analysed with the same procedure and the same fixed effects but without the litter size and the parity of the birth litter, which were not significant for this model. The random common environment of the litter effect was added for growth and health traits to the model.

The reproduction performances were analyzed with the PROC MIXED procedure of the SAS software (2008). The fixed effects retained in the model were: the sire's resistance group (n=2), the combined effect year × season × farm (n=26), the combined effect parity × physiological stage (lactating or not) (n=9). The random effect of the female was added to the model to take into account the repetition of female performances.

Ethics. All experiments were conducted in accordance with the guidelines of the Directive 2010/63/EU of the European Parliament and of the Council and were approved by the ethical review board (APAFIS#3866-2016020113447262).

Results & discussion

Differences in least squares means of traits are presented in Table 4. Weaning and final weight were not significantly higher in RG than in SG (+7 g, P=0.26 and +14 g, P=0.10 respectively). However Shrestha *et al.* (2018) estimated a favorable genetic correlation between resistance to pasteurellosis and average daily gain from birth to weaning recorded in inoculated animals of the same experiment. A moderate and favourable correlation between natural resistance to infectious diseases and weaning weight was also observed in another study carried in a commercial population (-0.34±0.12) (Gunia *et al.*, 2018). All together these findings suggest that breeding for pasteurellosis resistance is not detrimental to breeding for growth traits. On the contrary, total number born and born alive were significantly lower in litters of RD than in litters of SD (-0.27, P=0.02 and -0.41 P=0.003). These results suggest that breeding for resistance to pasteurellosis could decrease the prolificacy of does. However birth and nest mortality were not significantly different between litters of RD and SD.

Table 4. Differences in least squares means between offspring of resistant and susceptible sires for growth, diseases and reproduction traits, *P*-value of the sire group effect and standard error of least square means (LSM) differences.

Trait	Difference resistant-susceptible	*P*-value	Standard error of LSM difference
Weaning weight (g)	7	0.264	6
Final weight (g)	15	0.106	9
Digestive diseases (%)	-1.673	0.031	0.776
Respiratory diseases (%)	-0.698	0.284	0.652
Infectious diseases (%)	-2.991	0.008	1.121
Mortality (%)	-1.084	0.066	0.588
Fertility (0/1)	0.003	0.708	0.008
Total number born / litter	-0.270	0.023	0.119
Number born alive / litter	-0.410	0.003	0.137
Stillbirth (%)	1.547	0.056	0.809
Nest mortality (%)	-0.901	0.706	0.202

Prevalence of digestive diseases and infectious diseases were significantly lower in RG than in SG (-1.7 point, P=0.03 and – 3.0 points, P=0.008 respectively). This interesting result suggests that resistance to pasteurellosis assessed by an experimental infection using a single strain of *Pasteurella multocida* is favorably correlated to resistance to other infectious diseases. Gunia *et al.* (2015) demonstrated that a composite trait grouping all disease syndromes was heritable in rabbit. However, there was almost no genetic correlation between digestive and respiratory disease traits. This result can be partly explained by the fact only one syndrome was recorded per animal. The difference in prevalence of respiratory disease between RG and SG is not significant (-0.70 point, P=0.28). This could be explained by a lack of homogeneity in the recording of the trait between the different farms: some breeders considered only true respiratory symptoms (nasal discharges, pneumonia) while some others included some other symptoms related to pasteurellosis (abscesses, wryneck, eye infections).

156. Quantification of environmental management systems for U.S. Katahdin sheep producers

B.C. Arisman[1*], J.M. Burke[2], J.L.M. Morgan[3] and R.M. Lewis[1]

[1]Department of Animal Science, University of Nebraska-Lincoln, P.O. Box 830908, Lincoln, NE 68588, USA; [2]ARS, USDA, Dale Bumpers Small Farm Research Center, 6883 South State Highway 23, Booneville, AR 72927, USA; [3]Round Mountain Consulting, 18235 Wildlife Road, Fayetteville, AR 72701, USA; barisman2@huskers.unl.edu

Abstract

Gastrointestinal nematodes negatively affect the performance and wellbeing of sheep, encouraging producers to choose breeds that are naturally resistant. An example is Katahdin sheep. Katahdin are raised in various climates and management systems in the U.S., which can be combined into eco-management clusters. We hypothesized that gastrointestinal nematode challenge varies predictably based on the characteristics of the eco-management cluster. Katahdin producers from across the country were surveyed for management information. Body weights and faecal egg counts (FEC) were collected. Management and climate data were combined using a Factorial Analysis of Mixed Data approach to visualize ecomanagement clusters. The milder, drier, low input clusters had higher FEC while the colder, wetter, low input, clusters had a lower FEC ($P<0.05$). Through formation of ecomanagement clusters, an environmental variable can be specified for study of interactions or sensitivities of genotypes to their environment, potentially useful for identifying parasite-resistant sheep.

Introduction

The sheep industry contributed $5.8 billion to the United States (U.S.) economy in 2017 (Shiflett, 2017). Given the monetary impact, and for animal wellbeing, ensuring the good health and sound management of sheep is of utmost importance. A main factor negatively affecting the growth and health of sheep managed in a forage-based system is gastrointestinal nematode (GIN) parasites. GIN infection can cause weight loss, decreased appetite, and even death (Lôbo *et al.*, 2009). The inability to control GIN infection due to the prevalence of anthelmintic resistance has increased the popularity of breeds recognized as naturally resistant to parasites. Katahdin are a relatively prolific maternal composite hair breed that are comparable to other medium-sized maternal breeds in adult bodyweight (BW) and lamb growth (Ngere *et al.*, 2018). This breed is also known to potentially exhibit resilience and tolerance to GIN infection.

One approach to defining robustness is to characterize the sensitivity of individuals or families to environments varying in GIN infection challenge. The environment can be defined by differences among flocks in geographic location, with distinctive climates, and in management. Management differences among flocks, however, are often not considered when defining an environment due to the difficulty in quantifying management practices. The combination of the climate and management data can be referred to as ecomanagement groups or clusters.

Katahdin producers from across the U.S. were surveyed for management information, which was combined with U.S. Climate Normals data that captures precipitation, snowfall, and temperatures for the different flock locations. Performance data, including BW and faecal egg counts (FEC), were also available on the flocks. The aim of this study was to quantify ecomanagement clusters in Katahdin sheep with respect to their association with GIN challenge.

Materials & methods

Over three years (2017-2019), data were collected on 4,645 lambs from 17 flocks from across the U.S. as part of the National Sheep Improvement Program (Notter, 1998). The data considered included pedigree, BW (kg) and FEC (eggs/g) collected around 90-d of age [91.4 (SD 8.3) d], and drenching protocols. Only FEC from animals for which no anthelmintic was given 30 d prior to measurement were used, yielding 4,232 lambs with a valid FEC record. The FEC were transformed as log(FEC+25). Birth and rearing type measures were concatenated into a single variable (6 levels), and dam ages classified (5 levels). Contemporary groups (CG) were assigned based on birth year, management group, record date, sex, and age slice. Age slice was defined in 35-d intervals from the birth of the first lamb. CG with fewer than five individuals were discarded.

Environmental data. Climate data were obtained from the weather station closest to each flock's geographical location using the U.S. Climate Normals (1991 to 2020) published by the National Weather Service (2021). The weather data captured were monthly and yearly averages for precipitation, snowfall, and minimum and maximum temperature. Site elevation was also included.

Management data. A Qualtrics survey was distributed to 21 producers; 17 responded (81%), defining the flocks and data used in the study. The intent of the survey was to quantify differences in management practices. Practices of interest were grazing system, GIN impact, selection strategies to mitigate parasitism, feeding regime, and ewe flock and lamb management strategies. Survey responses were combined with climate data per a given flock's location.

Data analysis. The data were analysed using the Factoextra and FactoMineR packages in R (Lê *et al.*, 2008; Mundt and Kassambara, 2020). Using a Factorial Analysis of Mixed Data (FAMD) approach, a type of principal component analysis, groups of flocks with similar management practices and climate variables were grouped into ecomanagement clusters that define an environment. Using ANOVA (Fox and Weisberg, 2019), the systematic influences of ecomanagement cluster, CG, birth/rearing type, and dam ages in defining variation in FEC and BW were tested (α=0.05). Least square means were obtained for ecomanagement clusters and compared with the Fisher's least significant difference test (pairwiset.t.test; R Core team, 2020).

Results

The 17 producers answered all questions on the questionnaire. The greatest dissimilarity in responses were in feeding regime (from 0 to 100% pasture based) and sheep density per acre (from 2 to 27 ewes per acre). The greatest similarity in responses were regarding lambing season and selection for GIN strategy, where 94% of flocks lambed in the spring and used a combination of estimated breeding values and phenotypic performance records to select for GIN resistance.

Based on the FAMD analysis, ecomanagement clusters of flocks were formed (delineated by colour ellipses in Figure 1), where principal components 1 and 2 captured 13.5 and 11.2% of the variation, respectively. Any flocks not in an ellipse formed a standalone ecomanagement cluster. The three main factors discriminated the clusters were temperature, precipitation, and grain supplementation.

All systematic effects fitted in the statistical model defined variation in FEC and BW (P<0.05). In Table 1, mean FEC and BW are summarized relative to ecomanagement cluster. The FEC means ranged from 2.34 to 2.96 eggs/g while BW ranged from 17.0 to 27.3 kg.

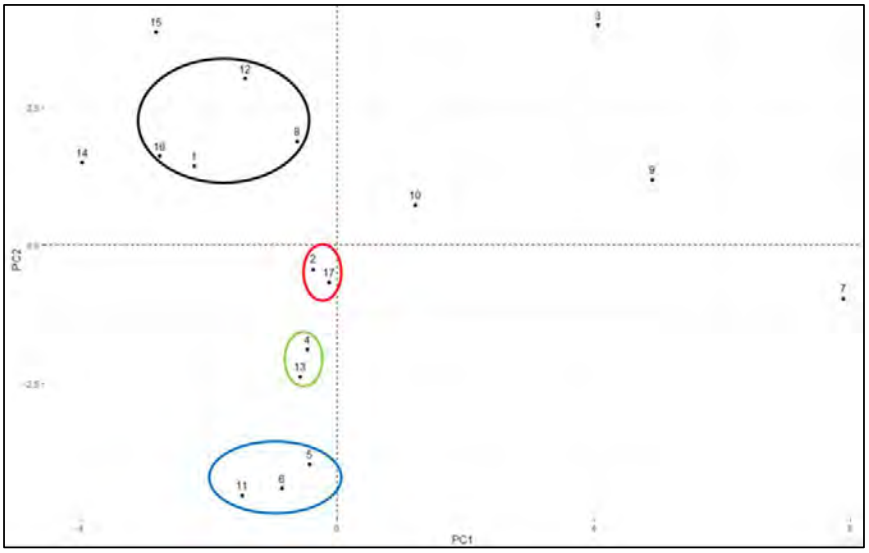

Figure 1. Principal component analysis plot derived from the Factorial Analysis of Mixed Data approach (PC1 – first principal component; PC2 – second principal component).

Table 1. Descriptions and least square means (± s.e.) for log transformed faecal egg count [(Log(FEC+25)] and bodyweight for ecomanagement clusters.

Ecomanag. cluster	Climatic and management variables defining cluster	Log(FEC+25)		Bodyweight	
		No.	Mean, eggs/g[1]	No.	Mean, kg[1]

Discussion

In previous research, climate and management practices were considered separately to quantify the environment. U.S. Climate Normals were used to define ecoregions in beef cattle, while surveys were used to quantify management practices in sheep (Rowan *et al.*, 2021; Stewart *et al.*, 2020). However, our combining climate with management data allowed identification of ecomanagement clusters improving the description of the overall environment. Of the factors considered in the FAMD analysis, temperature appeared to affect the pattern of the clustering more substantially. This is logical since GIN development relies on temperature and humidity (Lôbo *et al.*, 2009). The clusters with milder and drier climates, and

low grain supplementation, suffered from a greater FEC. Conversely, the colder and wetter climates, with low grain supplementation, benefitted from a lower FEC. There was no clear association of parasite load with BW.

Although the climate and management practices of only 17 flocks were considered in the study, they represented the full geographic distribution of Katahdin flocks in the U.S. The ecomanagement clusters were defined using management practices present during the time span of the study. Re-analysis of the clusters would need to be completed on a periodic basis, accounting for changes in management practices that may occur over time. The next stage of this research is to determine if sufficiently strong familial relationship exist across ecomanagement clusters to connect them genetically. If so, the clusters could be used as an environmental variable to investigate genotype by environment interactions, or in a reaction norm analysis to identify superior individuals or families able to tolerate variable GIN challenges.

157. Bias and heritability of the autocorrelation based on longitudinal data used as resilience indicator

H.A. Mulder

Wageningen University & Research Animal Breeding and Genomics, P.O. Box 338, 6700 AH Wageningen, the Netherlands; han.mulder@wur.nl

Abstract

To genetically improve resilience, the autocorrelation between subsequent deviations from fitted curves of longitudinal data was proposed. Autocorrelation is related to the speed of recovery after a disturbance: a high autocorrelation means slow recovery, while a low autocorrelation means fast recovery. It is known that estimated autocorrelations are biased, while the genetic properties of the autocorrelation are largely unknown. The aims of this research were to investigate the bias and the heritability of the autocorrelation. Deterministic expressions were derived and evaluated with Monte Carlo simulation. The estimated autocorrelation was 0.2-0.3 lower than the true value when the number of records was 10. The heritability was between 0.05 and 0.10 in most situations. It is recommended to have at least 50 records per animal. This shows good opportunities for genetic improvement. This study is a first step towards better understanding of the mathematical and genetic properties of the autocorrelation.

Introduction

In recent studies on genetics of resilience indicators, the lag-one autocorrelation, or simply called autocorrelation, based on subsequent deviations from fitted curves of longitudinal data from an animal, was found to be a promising resilience indicator. Berghof *et al.* (2019) and Poppe *et al.* (2020, 2021a) showed that the autocorrelation is a heritable trait, with a heritability between 0.05 and 0.1. Autocorrelation based on milk yield deviations was related to recovery from environmental perturbations, e.g. from a heat wave or an unspecified herd disturbance (Poppe *et al.*, 2021b). Cows with genetically a low autocorrelation had a faster recovery than cows with a high autocorrelation. This means that cows with a low autocorrelation need less time until their milk yield reaches normal levels after a disturbance than cows with a high autocorrelation. Genetic correlations between the autocorrelation based on milk yield deviations and health and longevity traits were weak in dairy cattle (Poppe *et al.*, 2020). No relationships were found between the autocorrelation based on body weight deviations and lesion scores or mortality upon a disease challenge in chickens (Berghof *et al.*, 2019). These weak or absent relationships may be partly due to properties of the autocorrelation.

The autocorrelation is new to quantitative geneticists, although it has been studied for many years in resilience research (Scheffer *et al.* 2015) or in research using time series (Arnau and Bono, 2001). It is already known for many years that estimates of autocorrelation are biased, especially with a small number of records (Kendall, 1954; Marriott and Pope, 1954; Arnau and Bono, 2001). The mathematical properties of the autocorrelation are largely unknown for geneticists. Furthermore, there is no equation to understand the relationship between the heritability of the autocorrelation and the number of records. Such an equation would help in optimizing breeding schemes to genetically improve resilience.

The aim of this study was to investigate the bias and the heritability of the estimated autocorrelation. Monte Carlo simulation was used to evaluate the deterministic equations.

Materials & methods

Genetic model and Monte Carlo simulation. Phenotypes were generated following a Markov process with autoregressive environmental effects. For simplicity, the phenotype was equal to the environmental effects and did not include additive genetic effects on the level of the phenotype, i.e. the normal additive genetic variance utilized in breeding programs:

$$P_{i,t} = \mu_P + E_{i,t} = \mu_P + r_{a_i} E_{i,t-1} + e_{i,t} \quad (1)$$

where $P_{i,t}$ is the phenotype at time t of individual i, μ_p is the mean of the trait and assumed to be zero, r_{a_i} is the lag-one autocorrelation, or simply called autocorrelation, of individual i, $E_{i,t} = r_{a_i} E_{i,t-1} + e_{i,t}$ is the environmental effect at time t and $e_{i,t}$ is the random environmental effect specific to time t. Since $\mu_p = 0$, $E_{i,t} = P_{i,t}$ here. The initial environmental variance σ^2_E, e.g. for the first environmental effect to be sampled $E_{i,l}$, was 1.0. The variance of $e_{i,t}$ was $1 - r^2_{ai}$, so that the phenotypic variance is one. The r_{a_i} had a mean μ_{r_a} a random additive genetic effect A_{r_i} ($N(0, \sigma^2_{A_r})$) and a random environmental effect E_{r_i} ($N(0, \sigma^2_{E_r})$):

$$r_{a_i} = \mu_{r_a} + A_{r_i} + E_{r_i} \quad (2)$$

Monte Carlo simulations were used to evaluate the deterministic expression for the estimated autocorrelation $\widehat{r_a}$. In the simulations to evaluate the expression for the estimated autocorrelation, $\sigma^2_{A_r} = 0$ and $\sigma^2_{E_r} = 0$, while μ_{r_a} was varied between -0.9 and 0.9 and the number of records was varied between 10 and 300. In the simulations to evaluate the simple expression for heritability, the maximum heritability was set to 0.1 and $\sigma^2_{A_r} = 0.003$ and $\sigma^2_{E_r} = 0.027$, which approximately resemble estimated parameters by Poppe *et al.* (2020). The results were averages of 100 replicates.

Deterministic equation for the estimated autocorrelation. The estimated autocorrelation $\widehat{r_a}$ can be approximated with a Taylor series approximation (Lynch and Walsh, 1998):

$$\widehat{r_a} \cong \frac{\sigma_{E_t \widehat{E_{t-1}}}}{\widehat{\sigma^2_E}} \left(1 + \frac{var(\widehat{\sigma^2_E})}{\widehat{\sigma^2_E}} - \frac{cov(\widehat{\sigma^2_E}, \sigma_{E_t \widehat{E_{t-1}}})}{\widehat{\sigma^2_E} \sigma_{E_t \widehat{E_{t-1}}}}\right) \quad (3)$$

where $var(\widehat{\sigma^2_E})$ is the variance of $\widehat{\sigma^2_E}$, i.e. the variance of a variance estimate, $cov(\widehat{\sigma^2_E}, \sigma_{\widehat{E_t E_{t-1}}})$ is the covariance between $\widehat{\sigma^2_E}$ and $\sigma_{\widehat{E_t E_{t-1}}}$ i.e. a covariance between a variance and a covariance estimate. The required expressions for $\widehat{\sigma^2_E}$, $\sigma_{\widehat{E_t E_{t-1}}}$, $var(\widehat{\sigma^2_E})$ and $cov(\widehat{\sigma^2_E}, \sigma_{\widehat{E_t E_{t-1}}})$ were derived and will be shown in a full paper.

Simple equation for the heritability. The heritability of the autocorrelation $h^2_{r_a}$ is a function of the number of records. The number of records determines the sampling variance of the autocorrelation, which can be approximated as $\sigma^2_{r_a} \cong \frac{(1 - r^2_a)^2}{n - 2}$ (Lynch and Walsh, 1998), where n is the number of records. The heritability can therefore be approximated as:

$$h^2_{r_a} = \frac{\sigma^2_{A_r}}{\sigma^2_{A_r} + \sigma^2_{E_r} + \sigma^2_{r_a}} = \frac{\sigma^2_{A_r}}{\sigma^2_{A_r} + \sigma^2_{E_r} + \frac{(1 - r^2_a)^2}{n-2}} \quad (4)$$

Equation 4 makes it feasible to quickly evaluate the effect of the number of records on the heritability of the autocorrelation and therefore also the accuracy of selection when used as selection criterion.

Results

The estimated autocorrelation was substantially lower than the true autocorrelation, indicating bias, as shown in Figures 1A and 1B. The curves show that the bias was as large as 0.2-0.29 when the number of records was 10. The bias decreased slowly when the number of records increased, but even with 200-300

records the bias was 0.005-0.013 when the autocorrelation was 0.3 or 0.5. The bias was larger when the autocorrelation was larger. The deterministic prediction using Equation 3 resembled results from Monte Carlo simulation, while a small deviation was observed when the number of records was 10. If an acceptable bias is smaller than 0.05, the minimum number of records is 40 when the autocorrelation is 0.3 and >50 when the autocorrelation is 0.5. In summary, the estimated autocorrelation can be substantially lower than its true value; therefore it is recommended to have at least 50 records per individual.

The simple equation for heritability (Equation 4) accurately predicted the heritability when the number of records was large, e.g. 80-100, or when the autocorrelation was 0.1 (Figure 2A). However, when the number

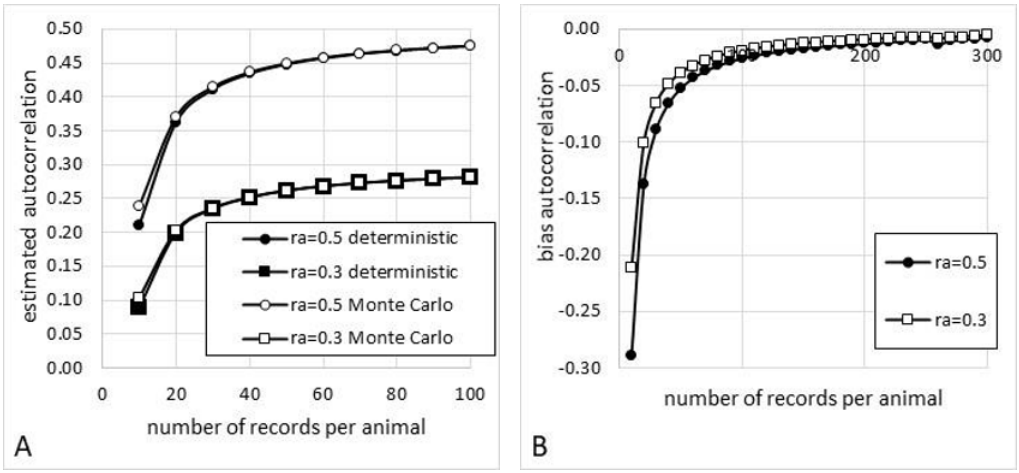

Figure 1. The estimated autocorrelation (panel A) and its bias (estimated − true autocorrelation; panel B) as a function of the number of records per animal when the true autocorrelation (ra) is 0.3 and 0.5 using deterministic Equation 3 (panel A and B) or Monte Carlo simulation (panel A).

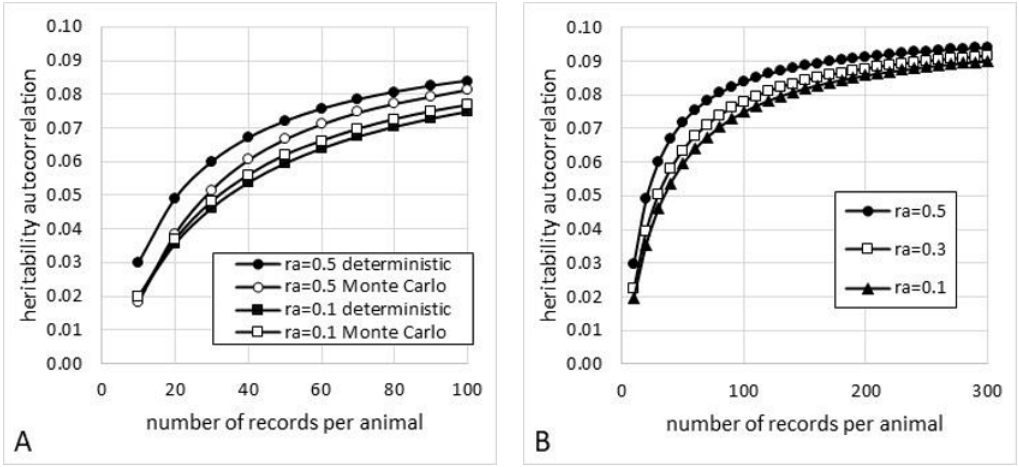

Figure 2. The heritability of the autocorrelation as a function of the number of records when the mean autocorrelation is 0.1, 0.3, 0.5 and the maximum heritability is 0.1 using the deterministic Equation 4 or Monte Carlo simulation.

of records was smaller than 50 and the autocorrelation was 0.5, the simple equation overpredicted the heritability by 8-65%. Figure 2B shows that the heritability was larger when the mean autocorrelation was higher. Given a number of records, the heritability was lowest when the mean autocorrelation was zero. The increase in heritability was small when the number of records was larger than 200. Figure 2B shows that the heritability was between 0.06 and 0.1 when the number of records was at least 50 and when the maximum heritability was 0.1.

Discussion

In this study, the bias in the autocorrelation and the heritability of the autocorrelation were investigated and deterministic equations were presented. The bias in the autocorrelation was already studied in detail by Marriot and Pope (1954) and Kendall (1954). The bias is due to the dependency between the estimated covariance and the estimated variance, which is shown in Equation 3 by the term $\frac{cov(\widehat{\sigma_E^2},\widehat{\sigma_{E_{t,E_{t-1}}}})}{\widehat{\sigma_E^2}\widehat{\sigma_{E_{t,E_{t-1}}}}}$. The estimated autocorrelation may be corrected by adding the predicted bias based on the number of records (Arnau and Bono, 2001). Alternatively, a fixed polynomial regression on the number of records may be included in the model to account for the non-linear effect of number of records on the estimated autocorrelation.

The bias in the mean autocorrelation also affects the heritability of the autocorrelation, because the genetic covariance between the breeding value for the autocorrelation and the estimated autocorrelation, i.e. the numerator of the heritability, was smaller than the true value. Furthermore, the variance of the autocorrelation, the denominator, was underestimated in Equation 4. However, the simple equation gave a very good prediction of the heritability when the number of records was larger than 50. The equation can be used to get more insight in the accuracy of selection for different types of longitudinal data in animal breeding. In general, given the range of heritabilities between 0.05 and 0.10, there are good opportunities for genetic improvement of resilience by selecting on a lower autocorrelation. This study is a step forward in quantitative genetic understanding of the autocorrelation used as resilience indicator in breeding.

158. The possibilities of estimating relationships between traits with and without micro-genetic environmental sensitivity

M.D. Madsen*, J.H.J. van der Werf and S. Clark

[1]*School of Environmental and Rural Science, University of New England, Armidale, NSW 2351, Australia; mmadsen3@myune.edu.au*

Abstract

Genotype by environment interaction due to short term, localised differences in environmental conditions is caused by the animal's underlying micro-genetic environmental sensitivity (GES). Many traits across a variety of livestock species exhibit micro-GES, however little is known about the genetic relationship between environmental sensitivity in a statistical sense e.g. estimated micro-GES and more direct measure of sensitivity such as disease resistance. This paper investigated the possibility of using multi-trait models including a double hierarchical generalised linear model to examine the genetic relationships between a trait with and a trait without micro-GES. A simulation study was conducted with varying genetic parameters and data structures. Results showed that non-zero genetic correlations had the greatest impact on the accuracy of the estimated parameters, and resulted in an overestimation of the non-zero genetic correlations themselves.

Introduction

Genetic variation in micro-genetic environmental sensitivity (GES) is the underlying cause of genotype by environment interactions (G×E) in response to short-term or localized environmental differences impacting individual animals (termed micro-environments) (Hill and Mulder, 2010). Micro-GES results in variability of phenotype, e.g. a sire with high micro-GES would have offspring with more variable phenotypes than the offspring of a sire with low micro-GES when reared in the same macro-environment (definable environments often containing multiple animals). Micro-GES have been found in multiple species and traits (see e.g. Rönnegård *et al.*, 2010; Felleki *et al.*, 2012). It remains to be determined whether there is a genetic relationship between micro-GES of routinely measured traits and traits, such as disease resistance, which is more expensive to measure and less extensively measured. If such relationships exists, micro-GES of routinely measured traits could potentially be used as indication of for direct measurements of disease resistance. Obtaining the genetic relationship would require estimating the genetic correlation between the breeding values for micro-GES of one trait and the additive genetic value of a second trait, which can be estimated by fitting a multi-trait model with a double hierarchical generalised linear model (DHGLM) fitted for one trait. We propose to investigate the accuracy of this estimate and how this estimate depends on genetic parameters and data structure.

Materials & methods

Simulations. In all scenarios, two traits were simulated. Trait 1 (T1) could be considered a disease resistance trait or a similar trait that did not exhibit micro-GES. Trait 2 could be considered a production trait or similar trait with both a mean genetic potential (T2) and genetic component due to micro-GES (T2d) expressed as a genetic heterogeneity of the environmental variance. Phenotypes were simulated following

$$y_{\mathrm{T1},i} = \mu + a_{\mathrm{T1},i} + e_{\mathrm{T1},i} \quad (1)$$

$$y_{\mathrm{T2},i} = \mu + a_{\mathrm{T2},i} + \exp\left(0.5\, ln\left(\sigma^2_{e_{\mathrm{T2}_d}}\right) + 0.5 a_{T2_d,i}\right)\varepsilon_i \quad (2)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_158, © M.D. Madsen *et al.* 2022

where $y_{T1,i}$ and $y_{T2,i}$ were the phenotypes of animal i for T1 and T2 respectively, $a_{x,i}$ was the true breeding value (TBV) of animal i for trait x ($x \in \{T1, T2, T2d\}$). The residual of T1 ($e_{T1,i}$), and the animal specific random environmental variable (ε_i) were independently distributed following $N(0,1)$. The environmental variance of the exponential model ($\sigma^2_{e_{T2_d}}$) was 1.

The TBVs were drawn from $MVN(0, \begin{bmatrix} \sigma^2_{a_{T1}} & r_{a_{T1}a_{T2}}\sigma_{a_{T1}}\sigma_{a_{T2}} & r_{a_{T1}a_{T2_d}}\sigma_{a_{T1}}\sigma_{a_{T2_d}} \\ & \sigma^2_{a_{T2}} & r_{a_{T2}a_{T2_d}}\sigma_{a_{T2}}\sigma_{a_{T2_d}} \\ & & \sigma^2_{a_{T2_d}} \end{bmatrix} \otimes A)$, where A is the additive genetic relationship matrix derived from the pedigree. $\sigma^2_{a_{T1}}$, $\sigma^2_{a_{T2}}$ and $\sigma^2_{a_{T2_d}}$ were the additive genetic variance of T1, T2 and T2d, respectively, while $r_{a_{T1}a_{T2}}$, $r_{a_{T1}a_{T2_d}}$ and $r_{a_{T2}a_{T2_d}}$ were the genetic correlations between the TBVs for T1 and T2, T1 and T2d and T2 and T2d, respectively.

For both traits 20,000 phenotypes were simulated on the offspring of 200 sires (100 offspring per sire). The percentage of records kept for analysis of T1 ($n_{T1\%}$) was varied to investigate the model's sensitivity to unequal information availability amongst the traits. All combinations of $\sigma^2_{a_{T1}} = \{0.5, 0.3, 0.2\}$, $r_{a_{T1}a_{T2}} = \{0, 0.5\}$, $r_{a_{T1}a_{T2_d}} = \{0, 0.5\}$ and $n_{T1\%} = \{100\%, 50\%, 10\%\}$ were simulated, resulting in a total of 36 scenarios. For all scenarios $\mu_{T1} = \mu_{T2} = \mu_{T2_d} = 0$, $\sigma^2_{a_{T2}} = 0.3$, $\sigma^2_{a_{T2_d}} = 0.1$ and $r_{a_{T2}a_{T2_d}} = 0.3$ were used.

Statistical analysis. For all scenarios the phenotypes were analysed using a multivariate model, combining a linear mixed model and a DHGLM, both fitted at the sire level.

$$\begin{bmatrix} \boldsymbol{y}_{T1} \\ \boldsymbol{y}_{T2} \\ \boldsymbol{y}_{T2_d} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\mu}_{T1} \\ \boldsymbol{\mu}_{T2} \\ \boldsymbol{\mu}_{T2_d} \end{bmatrix} + \begin{bmatrix} \boldsymbol{Z}_{T1} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}_{T2} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{Z}_{T2_d} \end{bmatrix} \begin{bmatrix} \boldsymbol{s}_{T1} \\ \boldsymbol{s}_{T2} \\ \boldsymbol{s}_{T2_d} \end{bmatrix} + \begin{bmatrix} \boldsymbol{e}_{T1s} \\ \boldsymbol{e}_{T2s} \\ \boldsymbol{e}_{T2s_d} \end{bmatrix} \quad (3)$$

where $\boldsymbol{y}_{T1}$, $\boldsymbol{y}_{T2}$ and $\boldsymbol{y}_{T2_d}$ were vectors containing the response variables for T1, T2 and T2d, respectively, $\boldsymbol{\mu}_x$, $\boldsymbol{Z}_x$, $\boldsymbol{s}_x$ and $\boldsymbol{e}_x$ were the population mean, design matrices relating phenotypes to sires, additive genetic effect of sires, and residuals of trait x, respectively. The distribution assumptions for the additive genetic sire effects were:

$$\begin{bmatrix} \boldsymbol{s}_{T1} \\ \boldsymbol{s}_{T2} \\ \boldsymbol{s}_{T2_d} \end{bmatrix} \sim MVN\left(\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma^2_{s_{T1}} & \sigma_{s_{T1}s_{T2}} & \sigma_{s_{T1}s_{T2_d}} \\ & \sigma^2_{s_{T2}} & \sigma_{s_{T2}s_{T2_d}} \\ & & \sigma^2_{s_{T2_d}} \end{bmatrix} \otimes \mathbf{A} \right)$$

where A is the additive genetic relationship matrix among sires and ⊗ was a Kronecker product. The distribution assumptions for the residuals were:

$$\begin{bmatrix} \boldsymbol{e}_{T1s} \\ \boldsymbol{e}_{T2s} \\ \boldsymbol{e}_{T2s_d} \end{bmatrix} \sim MVN\left(\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \mathbf{I_{T1}} & 0 & 0 \\ 0 & \boldsymbol{W}^{-1} & 0 \\ 0 & 0 & \boldsymbol{W}_d^{-1} \end{bmatrix} \right),$$

$\mathbf{I_{T1}}$ was a $n_{T1} \times n_{T1}$ identity matrix ($n_{T1} = \frac{n_{T1\%}}{100} * 20000$), $\boldsymbol{W} = diag(\widehat{\boldsymbol{y_d}})^{-1}$ and $\boldsymbol{W}_d = diag\left(\frac{1 - \boldsymbol{h}_{T2}}{2}\right)$. $\boldsymbol{h}_{T2}$ was the diagonal element of the part of the hat-matrix corresponding to $\boldsymbol{y}_{T2}$. The response variables in $\boldsymbol{y}_{T1}$ and $\boldsymbol{y}_{T2}$ were the simulated phenotypes and $y_{T2_d} = \frac{\hat{e}^2_{T2}}{1 - h_{T2}}$, where $\hat{\boldsymbol{e}}_{T2}$ was the estimated residual of $\boldsymbol{y}_{T2}$ (Rönnegård *et al.*, 2010). The AI-REML package of DMU (Madsen and Jensen, 2013) was used to estimate both variance components. The model in (3) was iterated until convergence and $\boldsymbol{y}_{T2_d}$, $\boldsymbol{W}$ and $\boldsymbol{W}_d$ was updated in each round.

Post-analysis calculations. The additive genetic variances and estimated breeding values (EBVs) were converted from the level of sire to the animal level as described by Madsen *et al.* (2021). The sensitivity of the model to the varied parameters were assessed as the magnitude of any deviation in the means of the estimated variance parameters across converged replicates from their true values and whether the means deviated significantly from the true values. Significances were based on the 95% confidence interval derived from the empirical SEM across converged replicates. The convergence percentage was also assessed.

Results

The alternative genetic parameters used to simulate each traits had minimal impact on the estimated genetic variance of T1 and T2, and the estimated additive genetic variances of T1 was within -0.01 to 0.02 of the true value (corresponding to 2 to 10% of the true value) across all scenarios. The estimated additive genetic variance of the mean of T2 was within ±0.01 (3%) of the true value. There was a tendency for the estimated genetic variance of the dispersion of T2 to be overestimated in scenarios where the true genetic variance of T1 was 0.2 or 0.5 and the true genetic correlation between T1 and T2d was 0.5. The overestimation of the estimated additive genetic variance of the dispersion of T2 was at most 0.01 (10%) of the true value for the dispersion. The SEMs of the estimated additive genetic variances ranged from 0.00 to 0.01, regardless of the varied parameters. In the scenarios where the true genetic correlation between T1 and the mean of T2 or between T1 and the dispersion of T2 was 0, the estimated genetic correlation ranged from -0.04 to 0.03. If the true genetic correlation was 0.5 instead, the estimates ranged from 0.50 to 0.55. The true genetic correlation between the mean and dispersion of T2 was fixed at 0.3 across all scenarios and the estimates ranged from 0.30 to 0.35. The number of records used for analysis of T1 did not systematically impact any of the estimated parameters, except the convergence percentage. 50% of the scenarios where only 10% of the records were used for analysis had <100% convergence (range 93-99) and one scenario where 50% of the records were used had 99% convergence.

Discussion

In general, the presence of non-zero genetic correlations between T1 and either mean or dispersion of T2 caused the estimates of non-zero genetic correlations to be up to 10% overestimated. Estimation of the additive genetic variance of T1 and T2 was generally accurate. The additive genetic variance for dispersion (T2d) tended to be overestimated when the true genetic variance of T1 was not equal to 0.3 (i.e. $\sigma^2_{s_{T1}} \neq \sigma^2_{s_{T2}}$), and the genetic correlation between T1 and T2d was 0.5. However, this overestimation was slight and the estimates ranged from 0.10 to 0.11. The convergence percentage was generally high, except in a proportion of scenarios where not all of T1 records were used. In summary, it is possible to obtain accurate measurements of additive genetic variances from a multi-trait model with a routinely measured trait exhibiting micro-GES and less extensively measured trait such as disease resistance. In the presence of a genetic correlations between the non-GES trait and the mean or dispersion of the micro-GES trait, the model will estimate a genetic correlation, though it may be slightly overestimated. Similarly, if there is no genetic correlations the model will indicate so. This allows for identifying traits that could be used to shed light on traits, like disease resistance, which are harder to obtain.

The family structure in the current study was very well balanced with sires having 200 offspring each and thus the same amount of information to base their EBVs on. Further research should be done to investigate the impacts of unbalanced data structures. However it has been shown that DHGLMs are more sensitive to average family size than variability in family size (Madsen *et al.*, 2021). Similar results would be expected for multi-trait models including DHGLMs.

Abstract

Vibrio harveyi is a major pathogen affecting aquaculture. Selective breeding could be a strategy to improve European sea bass resistance but genetic parameters are unknown. Additionally, the on-going replacement of marine-based ingredients by plant-based ingredients in fish diets could affect the efficiency of a breeding program due to genotype-by-diet interaction (G×D). Hence, we estimated the genetic parameters and G×D of survival to *V. harveyi*. Two groups of 1,200 seabass were fed (A) a custom feed enriched with plant-based ingredients and (B) a commercial feed. Then, the fish were injected with a *V. harveyi* suspension, mortality was recorded and fish were genotyped. With both diets, survival was moderately heritable (0.16 and 0.18, respectively), and the genetic correlation for survival between diets was 0.88, indicating that G×D was low. These results are encouraging to develop robust breeding program for survival to *V. harveyi*.

Introduction

Vibrio harveyi is considered as a highly problematic pathogen in aquaculture across species and countries as it cannot be efficiently controlled by commercial vaccines, due to low antigen specificity. In commercial farms, the mortality caused by *V. harveyi* can reach 50% in case of an outbreak. In this context, selective breeding could be an effective strategy to improve fish resistance to *V. harveyi*. Indeed, selective breeding has become a prime strategy to tackle disease resistance in fish species and many breeding programs include disease resistance in their breeding goals (Chavanne *et al.*, 2016).

In parallel, fish farming is facing another challenge: the replacement of fish meal and fish oil in the diets by plant-based ingredients (soy, corn gluten, etc.). Such replacement could have several impacts on farmed fish. First, it could affect the sensitivity of fish to pathogens. Second, it could decrease the efficiency of fish breeding programs due to genotype-by-diet interactions (G×D). When G×D occurs, the ranking of families fed a diet A differs from the ranking of families fed a diet B. More generally, genotype-by-environment interactions (G×E) have already been observed on fish reared in different farming systems (e.g. Gulzari *et al.*, 2022). In their review paper, Sae-Lim *et al.* (2016) reported substantial re-ranking for growth-related traits (average genetic correlation=0.72) and for survival-related traits (average genetic correlation=0.54). The consequence of re-ranking due to G×D is of great concern because the selection of the nucleus would lead to lower genetic responses in commercial environments where fish are reared and grow with a different feed than in the nucleus. Our goal was therefore to estimate the genetic parameters of survival to *V. harveyi* and to study potential G×D in seabass to develop a robust and efficient breeding program improving the survival to *V. harveyi*.

Materials & methods

Animals. Seabass from 225 families were produced from three full factorial mating design (5 dams crossed with 15 sires each) using artificial fertilization by the EMGI breeding company. The fish were split in two groups and fed with two different iso-lipidic, iso-energetic and iso-proteic feeds. The first group (A) was fed a custom feed, produced by Nireus, using a formulation developed in the Arraina EUproject, with a high level of vegetal ingredients, including wheat protein extract to limit gut injury often caused by soy-based ingredients. The second group (B) was fed a commercial feed (Biomar).

***Vibrio harveyi* challenge.** 1,186 and 1,211 fish from group A and B were challenged to *V. harveyi* in the SYSAAF-ANSES Fortior Genetics platform (Plouzané, France) at 345 days post fertilization. The fish were split into 12 tanks (5 test tanks and 1 control for each group A and B). All fish were injected with 100 µl of bacterial suspension. The negative controls were injected with a solution containing sterile cell culture medium. The mortality was recorded each day during the 14-days challenge period.

Statistical analysis of phenotypes. To test whether the type of feed influences mortality due to *V. harveyi*, we applied a binary logistic regression model using glm function in R. The following model was fitted:

$$log\left[\frac{P(y_i = 1)}{1 - P(y_i = 1)}\right] = \mu + \text{Group}_i + \beta_0 \times \text{BW}_i + \beta_1 \times (\text{BW}_i \times \text{Group}_i) \quad (1)$$

Where y_i is the variable of interest, dead or alive, for fish i. Group_i is the fixed effect of the type of feed (A or B) and BW_i is the body weight of fish i at the start of the challenge.

Genetic analysis. A total of 942 fish from group A and 895 fish from group B were genotyped the 57k SNP array DlabChip (Griot *et al.*, 2021). The genomic data were then used to compute variance components and estimated breeding values for survival using THRGIBBSF90 (Tsuruta and Misztal, 2006). The survivals in each group A and B were considered as different traits to estimate the genetic correlation between both groups. Variance components were estimated using the following bi-variate model:

$$y = Xb + Zu + e \quad (2)$$

Where y is the vector of phenotypes (survival as binary trait; 1 = dead, 2 = alive), X is the design matrix for intercept and regression on initial body weight, b is the vector of intercept and regression coefficient estimates, u is the vector of breeding values and Z the corresponding incidence matrix. It is assumed that u follows a multivariate normal distribution $N(0, G\sigma^2_g)$ with G the genomic relationship matrix proposed by VanRaden, (2008) and σ^2_g is the additive genetic variance. e is the vector of the random residual errors that follows a normal distribution $N(0, I\sigma^2_e)$ with σ^2_e the residual variance and I the identity matrix. The variance components (σ^2_g and σ^2_e) were estimated using a Gibbs sampler with 500,000 iterations, 100,000 of burn-in and one sample was kept every 20 iterations for posterior analysis.

Results

First significant mortality occurred the day after the injection and reached a peak 2 days after the injection (Figure 1). At the end of the challenge, the mortality rate reached 38% for the group fed diet A (dead 468 fish) and 48% for the group fed diet B (dead 546 fish) (Figure 2a).

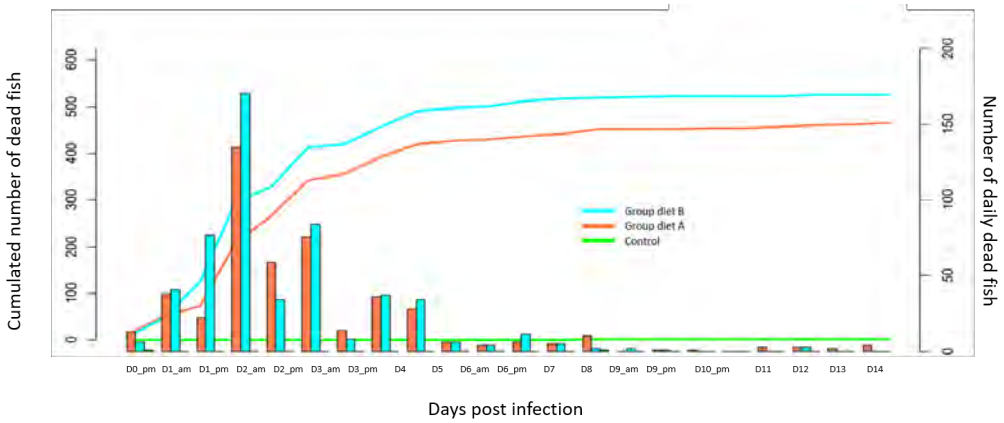

Figure 1. Barplot of the number of dead fish per day (or half day) after *V. haveyi* injection for the group fed diet A and the group fed diet B. The lines represent the cumulated mortality for both groups.

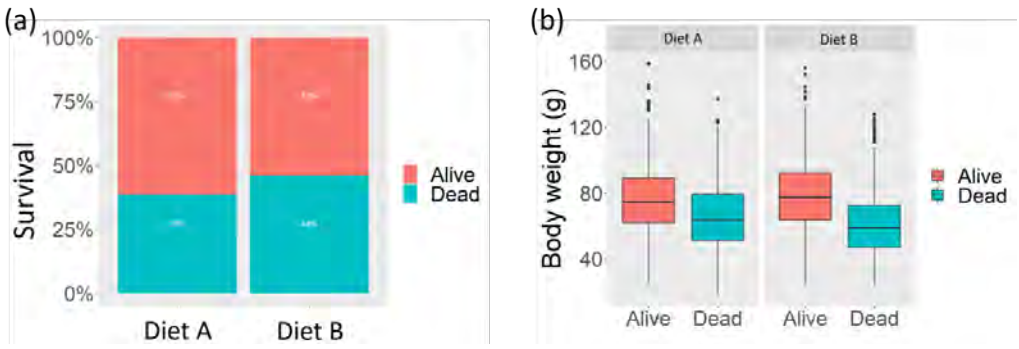

Figure 2. Panel (a) represents the mortality and survival rate at the end of the challenge for both diets A and B. Panel (b) is the boxplot of the body weight at the start of the challenge for surviving and dead fish in both groups.

The logistic regression showed that feed and body weight significantly affected the survival rate of the fish. Fish fed diet B were more likely to die from the infection compared to fish fed diet A (P<0.0001). Also, bigger fish were less likely to die from the infection compared to smaller fish (P<0.0001). The interaction between the type of feed and the weight was also significant (P=0.0001). Survival to *V. harveyi* was moderately heritable, h^2=0.18 (0.07) in the group fed diet B and 0.16 (0.07) in the group fed diet A. Furthermore, we found that the genetic correlation of survival to *V. harveyi* between diet A and B was high (0.88).

Table 1. Heritabilities (on the diagonal) of survivals to *Vibrio harveyi* when fed diet A and when fed diet B. Above the diagonal is the genetic correlation between the two traits.

	Survival with diet A	**Survival with diet B**
Survival with diet A	0.16 (0.07)	0.88 (0.10)
Survival with diet B		0.18 (0.07)

Discussion

G×D has already been investigated in aquaculture (e.g. Le Boucher *et al.*, 2013) but to our knowledge, this study is the first investigating the interaction between the type of feed and the genetic component of resistance to a specific pathogen, i.e. *V. harveyi*. First, we observed differential mortality between small and large fish that could be explained by the injection of the same bacterial dose to all fish. This is why body weight was included as covariable in the genetic model. Then, we found that the type of feed significantly affected the mortality at the challenge. However, the genetic correlation of survival between each diet group was high, indicating that G×D was low and that the type of feed only marginally affected the ranking of families. Additionally, the heritabilities of survivals to *V. harveyi* in both feeding environments were moderate, and substantial variation in the survival of the progeny of the 45 sires used in the mating was observed. These results are encouraging to develop a breeding program specifically targeting survival to *V. harveyi* in seabass. The results are also encouraging for breeding companies that could select fish for better resistance to *V. harveyi* without losing efficiency across feeding environments, which is essential to design an efficient and robust breeding program.

160. Can we prevent pathogen adaptation when breeding disease resistant livestock?

A.D. Hulst[1,2*], P. Bijma[2] and M.C.M. De Jong[1]

[1]Quantitative Veterinary Epidemiology, Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Animal Breeding and Genomics, Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; dries.hulst@wur.nl

Abstract

Recent research shows that genetic selection has high potential to reduce the prevalence of infectious diseases in livestock. However, as with all interventions targeted at infectious diseases, pathogens might evolve strategies to escape the resistance. Thus, for sustainable breeding, strategies that prevent the invasion of these escape mutants are needed. Here we use a mathematical model of infection transmission that accounts for genetic selection in hosts and pathogens to investigate the conditions under which escape mutants can invade. The results show that genetic selection for resistance typically leads to an 'invasion window', the range in host resistance in which an escape mutant can invade. This window is smallest when resistance is strong. To prevent the invasion of escape mutants, host resistance should be increased fast through the invasion window. This raises questions about the sustainability of the common multi-trait approach when the breeding goal includes infectious disease resistance.

Introduction

Genetic selection has long been considered a potential strategy to combat infectious diseases in livestock (Bishop *et al.,* 2010). Recent theoretical studies show that the response to genetic selection to reduce the prevalence of infectious diseases should be much larger than predicted by common quantitative genetic models (Bijma *et al.,* 2021; Hulst *et al.,* 2021). With each intervention targeted at infectious diseases, however, comes the risk that pathogens evolve strategies to escape the effects of that intervention, with the widespread antibiotic resistance as the most prominent example (Davies and Davies, 2010). Thus, questions arise whether and when pathogens can evolve escape strategies to genetically selected animals, and how this can be prevented.

For some other interventions, strategies exist to prevent the evolution of pathogen escape. An example is the restricted use of antibiotics. antibiotics are preferably used as little as possible, and when used, this should be in sufficiently high dose to kill all bacteria. In this way development of bacterial escape is prevented or at least largely delayed (Walsh, 2003).

For genetic selection of livestock for increased resistance against infectious diseases, however, strategies to prevent pathogen escape have not been investigated as far as we know. In this paper, we use a mathematical model of infection transmission that accounts for artificial genetic selection in the host (i.e. livestock) population and for the evolution of escape by natural selection in the pathogen population, to investigate the conditions under which escape mutants of a pathogen can invade a livestock population. Furthermore, we investigate how such invasion of an escape mutant is influenced by the strength of resistance of the host. Ultimately, we try to find strategies for genetic selection of livestock that limit or prevent the risk of pathogen escape.

Methods & results

In this section we briefly describe and analyse a mathematical model of infection transmission that is tailored to the invasion of escape mutants in a host population under genetic selection for increased resistance (for details see Hulst *et al.,* 2022, in preparation). The starting point of our analysis is a local host population

endemically infected with the wild type pathogen. We first describe how we model genetic selection for resistance in this host population and show how this affects the prevalence of the wild-type infection for different strength of resistance. Next, we model the invasion of escape mutants in the endemically infected host population and show how the opportunity for invasion depends on the frequency of resistant hosts and the strength of resistance.

Genetic variation in host resistance to wild-type infection. We assume that host resistance is defined by a single locus, which is either fully dominant or fully recessive, such that the host population consists of two types: resistant (with fraction f_R) and non-resistant ($1 - f_R$). Here resistant merely means that animals are less susceptible to the infectious disease, not that they cannot get infected at all.

We model differences in resistance between the two host types through the basic reproduction ratio, which is a key parameter in epidemiology and is defined as the average number of secondary infections caused by a single infected individual in an otherwise fully susceptible population (Diekmann *et al.*, 1990). R_0 has a threshold function; when it is above one an infection may persist in the population, while when R_0 is below one an infection will die out with certainty. Thus, to eradicate an infectious disease, it is essential that genetic selection reduces R_0 below a value of one.

In our case, each of the two host types has its own R_0. For infection with the wild-type (W) pathogen, these are denoted R_{NW} for non-resistant hosts, and R_{RW} for Resistant hosts. Because resistant hosts are less likely to become infected, $R_{RW}<R_{NW}$. The R_0 of the population is a weighted average of these the values, $R_0 = (1 - f_R)R_{NW} + f_R R_{RW}$.

The model tends to an equilibrium, where the number infected individuals of both host types do not change. Figure 1 shows the prevalence of the infection in this equilibrium over the frequency of resistant hosts (f_R), for R_{RW} of 1.1, 0.8 and 0.1. For R_{RW} of 0.1 and 0.8, the prevalence decreases to 0 at a certain f_R, meaning that the disease dies out. This point of dying out occurs at lower f_R for stronger resistance (i.e. lower R_{RW}). When R_{RW} is 1.1, the infection can persist in a fully resistant population, reflected in the nonzero prevalence at f_R=1. In the next section we investigate whether an escape mutant can invade a population that is endemically infected with the wild type pathogen, assuming this population is in the equilibrium as shown in Figure 1.

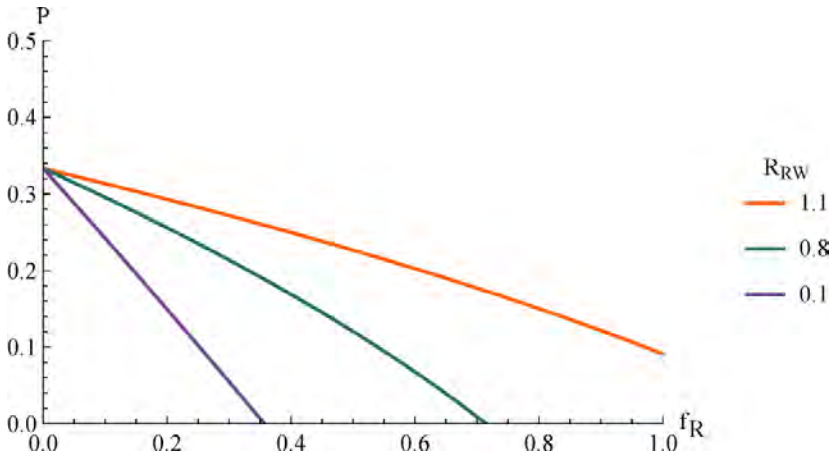

Figure 1. Equilibrium prevalence as a function of the frequency of resistant hosts. R_{NW}=1.5.

Escape mutant invasion. Escape mutants are, by definition, better able to infect resistant hosts than the wild-type pathogen. Furthermore, we assume that the escape mutation comes with a cost in pathogen fitness for infection of non-resistant hosts. We model this again through the reproduction ratios; R_{NE} for infection of non-resistant host with the escape mutant and R_{RE} for infection of resistant hosts with the escape mutant. The conditions above imply that $R_{NE}<R_{NW}$ and $R_{RE}>R_{RW}$.

We assume that escape mutants arise continuously as long as the wild type is present, so we look at their invasion rather than their emergence. Furthermore, we will only look at the invasion of a single type of mutant, with certain R_{NE} and R_{RE}, at a time. Since the mutant arises in a host population that is already infected with the wild type, to determine whether it can invade we need to derive a reproduction ratio for invasion (R_{INV}) in a host population in which the wild type is at endemic equilibrium. This can be done by multiplying the reproduction ratios of the escape mutant with the fraction of non-infected individuals of each type in the equilibrium,

$$R_{INV} = R_{NE}[(1 - f_R) - P_{NW}] + R_{RE}(f_R - P_{RW}) \quad (1)$$

where P_{NW} and P_{RW} denote the endemic prevalence of the wild type in non-resistant and in resistant hosts. If $R_{INV}>1$ the escape mutant can invade, whereas if $R_{INV}<1$, the escape mutant can emerge, but not invade because it is outcompeted by the wild type.

Figure 2 shows R_{INV} as a function of f_R (dashed line) for R_{RW} of 0.8 (green lines) and 0.1 (purple lines). The prevalence of the wild type over f_R is also shown (similar to Figure 1). The threshold value for R_{INV} of 1 is indicated by the dotted line. The invasion possibility of the escape mutant is restricted by two bounds: (1) the lower bound where R_{INV} becomes above 1, the escape mutant can invade from that point; and (2) the upper bound at which the wild type dies out (P=0), from that point the escape mutant cannot emerge anymore because there are no wild-type pathogens to mutate from. We call the range in f_R between these bounds the 'invasion window'. It is clearly visible in Figure 2 that this window is smaller with lower R_{RW} (i.e. stronger resistance). Thus, stronger resistance not only results in faster eradication of the infection, but also corresponds to a lower risk of escape mutant invasion.

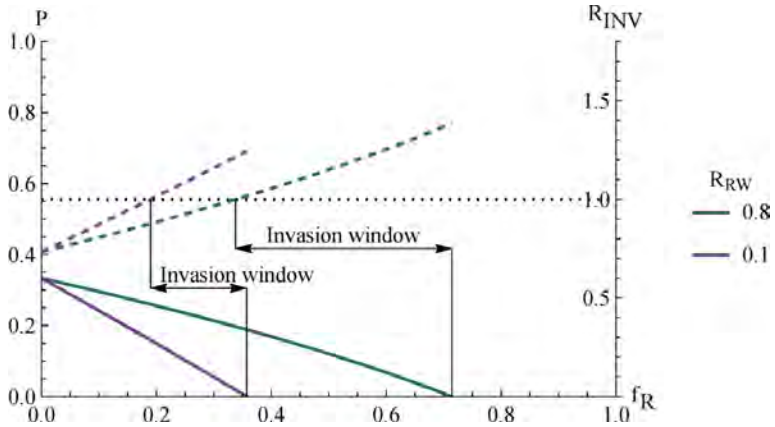

Figure 2. Invasion window for R_{RW} of 0.8 and 0.1. R_{NE}=1.1, R_{RE}=1.5, R_{NW}=1.5.

Discussion

We have demonstrated that an infectious disease can be eradicated from a local population by increasing the frequency of genetically resistant hosts sufficiently. For eradication, it is necessary that the reproduction ratio of the infection in resistant hosts (R_{RW}) is lower than one. Eradication occurs as a consequence of herd immunity, not because resistant individuals cannot become infected. As long as the infection is not eradicated, escape mutants of the pathogen might emerge and invade the host population. The invasion window is bounded by the frequency of resistant hosts from which the escape mutant can outcompete the wild-type pathogen ($R_{INV}>1$) and the frequency of resistance at which the wild type dies out. This window is smaller with lower R_{RW}.

For animal breeding, the above implies that to increase infectious disease resistance sustainably, without escape mutants invading and diminishing the effects of selection, the frequency of resistant hosts in the local population should be increased as fast as possible through the invasion window. A possible strategy to achieve that is by basing herd composition on the resistance status of the animals, such that herds are either on the left (no invasion) or on the right (eradication) side of the invasion window. This is most feasible in species where the animals in production herds are replaced all at once, such as in poultry or fattening pigs.

In genetic improvement of livestock, multi-trait selection has become the standard, because it is superior to other selection strategies for ordinary quantitative traits (Hazel *et al.*, 1994). However, improvement happens typically in small steps for each trait with multi-trait selection, which creates ample opportunity for escape mutants to invade. A relevant question is thus whether the current approach in animal breeding of gradual weak selection for infectious disease resistance is sustainable. On the one hand, it might be more difficult for pathogens to evolve escape strategies when resistance is polygenic, especially if this entails multiple resistance mechanisms. While on the other hand there are clear parallels with the long-term use of low-doses of antibiotics, which has strongly supported the evolution of antibiotic resistant bacteria (Olofsson and Cars, 2007). Further research into this is needed, but if the latter holds, it might be better to use a high dose for a short time, which corresponds to applying a large selection differential for infectious disease resistance within a single or a few generations.

Abstract

This study estimates heritability of complete blood count (CBC) and *in vitro* immunoassay traits. The traits were measured from blood samples of young-healthy nursery animals that then survived to slaughter during a natural polymicrobial disease challenge in the grow-to-finish stage but had variable production performance. Genetic correlations of CBC and immunoassay traits with performance traits collected from grow-to-finish pigs exposed to the challenge were also estimated, including carcass, average daily gain, and feed intake traits. Most CBC and several immunoassay traits had heritability estimates ranging from 0.11 to 0.46. Several CBC and immunoassay traits showed moderate to high positive (0.25 to 0.51) or negative (-0.92 to -0.37) genetic correlations with performance traits under disease. These results suggest that some CBC and immunoassay traits collected from young-healthy animals before exposure to disease challenge are potential indicator traits for selecting disease resilient pigs that can maintain better performance under pathogen exposure.

Introduction

Infectious diseases have steadily increased morbidity and mortality in multiplication and production herds of the pig industry, which causes significant productivity and economic losses. The current challenge in the pig industry is the hard-to-manage disease caused by a multitude of infectious pathogens that exist around the world. Thus, there is increased interest in selecting disease resilient pigs that can maintain undepressed performance under pathogen exposure, resulting from a combined optimal balance of disease tolerance and resistance mechanisms (Albers *et al.*, 1987, Mulder and Rashidi, 2017). Improving disease resilience can deliver multiple benefits to the pig industry, including more sustainable production, improved animal health, and the potential for managing the polymicrobial challenge common in pig production to reduce antimicrobial use.

Multiple immune traits collected from vaccinated or disease challenged pigs, including antibody titers, immune cell counts, and cytokine levels, have shown relatively high estimates of heritability and genetic correlations with performance (Clapperton *et al.*, 2009; Flori *et al.*, 2011; Bai *et al.*, 2020; Blanc *et al.*, 2021). However, the value of using immune traits collected from young healthy pigs as indicators of disease resilience remains largely unknown. Thus, the objective of this study was to investigate CBC traits and *in vitro* immunoassay traits collected from young-healthy pigs before exposure to disease challenge as potential indicator traits for the selection for disease resilience.

Materials & methods

The study was carried out in accordance with the Canadian Council on Animal Care guidelines. The protocol was approved by the Animal Protection Committee of the Centre de Recherche en Sciences

Natural polymicrobial disease challenge model. This study is derived from a research project that aimed to investigate indicators and the genetic basis of disease resilience in a wean-to-finish polymicrobial natural disease challenge model (NDCM). The NDCM was established to mimic severe disease challenge in a commercial production environment, as a combination of the circulating pathogens, together with the environment, management, and veterinary strategies; details can be found in Putz *et al.* (2019). Briefly, the NDCM consisted of three phases, the pre-challenge quarantine nursery (19 days on average beginning at ~21 days of age), the challenge nursery (~27 days) and the finishing (~100 days) phases. Every three weeks, a batch of 60 or 75 weaned crossbred (Landrace × Yorkshire) barrows from a high-health multiplier farm were introduced into the NDCM in a continuous flow manner, with approximately 3,300 pigs entering between 2015 and 2019.

Common disease-causing pathogens found in Canadian commercial farms were the primary target of the NDCM, including multiple strains of porcine reproductive and respiratory syndrome virus-2 (PRRSV2), *Mycoplasma hyopneumoniae* (MHP), and various other systemic, respiratory, and enteric pathogens. The challenge nursery was established by introducing pigs from commercial units with known diseases together with the first few batches of healthy pigs. Each subsequent batch of pigs was challenged by exposure to pigs introduced three weeks earlier. After one week of exposure, the older pigs were moved to the finisher. Not every batch was exposed to the same types or doses of pathogens, as disease pressure varied by batch and season, except every batch was confirmed to have been exposed to PRRSV2 and MHP.

Performance traits. Performance traits were collected from grow-to-finish barrows that survived to slaughter from all batches, including average daily gain in the challenge nursery (cNurADG) and in the finisher (FinADG); slaughter traits of carcass weight (CWT), carcass backfat (CBF), carcass loin depth (CLD), dressing percentage (DRS), and lean yield (LYLD); finishing feed intake traits of average daily feed intake (ADFI) and duration (ADFD), feed conversion ratio (FCR), residual feed intake (RFI), the proportion of off-feed days based on feed intake (OFF_{FI}) or feed intake duration (OFF_{DUR}), and day-to-day variation in feed intake (VAR_{FI}) or feed intake duration (VAR_{DUR}). Details of the traits collection, number of records, derivation, and genetic parameters of these traits can be found in Cheng *et al.* (2020).

CBC and *in vitro* immunoassay traits. CBC (n=2,036) from all batches and *in vitro* immunoassays of phagocytosis (n=736) and blood cell stimulation (n=775) from selected batches (Lim *et al.* 2021) were collected from barrows that survived to slaughter when they were in the pre-challenge quarantine nursery at ~26 days of age. Details of the CBC traits are in Bai *et al.* (2020). The phagocytosis assay quantified the percentage of leukocytes showing phagocytosis of FITC-labelled opsonized *E. coli* bacteria by flow cytometry (Phagotest, Glycotope). The percentages of phagocytosis of leukocyte subpopulations were also quantified based on cell morphology. Blood cell stimulation detected and quantified nine cytokines (IL-4, IL-2, IL-8, IL-13, IL-6, IFNg, IL-10, IL-17 and IL-1b) under non-stimulation, and LPS (lipopolysaccharide at 1 μg/ml) and PI (phorbol myristate acetate at 50 ng/ml and ionomycin at 1 μg/ml) 24h-stimulation conditions.

Genotyping and quality control. Genotyping used the 650 K Affymetrix Axiom® Porcine Genotyping Array. Details of genotype quality control are in Putz *et al.* (2019) and the genomic relationship matrix construction are described in Cheng *et al.* (2020).

Variance component analyses. Variance components were estimated by GBLUP using ASReml 4.1 (Gilmour *et al.*, 2015). The general models used in univariate and bivariate analyses were described in Chen *et al.* (2020).

Results

Most CBC and immunoassay traits were estimated to be low to moderately heritable: estimates for CBC traits ranged from 0.11±0.05 to 0.40±0.06, phagocytosis test traits ranged from 0.19±0.09 to 0.48±0.10, and blood cell stimulation traits ranged from 0.01±0.08 to 0.46±0.13. Some CBC and immunoassay traits showed significant (P<0.05) genetic correlations with performance traits and were summarized in Table 1. CBC and phagocytosis test traits were primarily found to be genetically correlated with carcass and feed intake traits, respectively. However, blood stimulation with LPS was genetically correlated with multiple categories of performance traits, including DRS, cNurADG, and ADFI.

Discussion

The significant heritabilities and genetic correlations for CBC and immunoassay traits collected from young-healthy animals with performance under pathogen exposure suggest that they can be indicators for selection of disease resilience in commercial farms. Higher CBC traits of LYM and HCT associated with improved DRS and CWT under disease. However, the greater CBF associated with higher HCT must be noted, indicating decreased lean meat yield. Putz *et al.* (2019) and Cheng *et al.* (2020) showed

Table 1. Significant (P<0.05) estimates of heritability (h^2) and genetic correlations for CBC and immunoassays traits with performance traits (SE in parentheses).

Traits[1]	h^2 (SE)	r_g (SE) with performance traits	
CBC			
LYM	0.28 (0.05)	DRS	0.48 (0.16)
HCT	0.12 (0.05)	CWT	0.45 (0.23)
		CBF	0.37 (0.17)
		LYLD	-0.37 (0.17)
PLT	0.27 (0.05)	ADFD	0.25 (0.12)
Phagocytosis test			
PHAGO	0.48 (0.10)	ADFD	0.32 (0.15)
GRAN_PHAGO	0.33 (0.10)	ADFD	-0.48 (0.16)
		OFF_{DUR}	0.51 (0.22)
NEU_PHAGO	0.19 (0.09)	ADFD	-0.61 (0.22)
LYM_PHAGO	0.48 (0.10)	ADFD	0.31 (0.15)
EOS_PHAGO	0.29 (0.09)	OFF_{DUR}	-0.49 (0.25)

		cNurADG	-0.92 (0.34)
		ADFI	-0.49 (0.25)
IFNg_LPS	0.30 (0.13)	cNurADG	-0.46 (0.24)
		ADFI	-0.44 (0.22)
IL6_LPS	0.21 (0.10)	cNurADG	-0.72 (0.26)

[1] LYM (10^3/μl): lymphocyte concentration; HCT (%): hematocrit; PLT: platelet concentration; PHAGO (%): phagocytizing cells among total cells; GRAN/NEU/LYM/EOS_PHAGO (%): phagocytizing cells among granulocytes/neutrophils/lymphocytes/eosinophils; IL8/IFNg/IL6_LPS (pg/ml): IL8/IFNg/IL6 concentration under LPS stimulation.

that higher ADFD and ADFI, but lower OFF_{DUR} were proxy traits of improved disease resilience in the NDCM. Therefore, the higher CBC trait of PLT and phagocytosis test traits of PHAGO, LYM_PHAGO and EOS_PHAGO, but lower GRAN_PHAGO or NEU_PHAGO tended to be associated with greater disease resilience. For blood stimulation traits, lower cytokine levels of IL8, IFNg, and IL6 after LPS stimulation correlated with greater DRS, cNurADG, and ADFI, and therefore, tended to be associated with improved disease resilience.

Immune traits have the potential to be further explored as indicators of disease resilience because the ability to produce effective and appropriate immune responses is closely associated with disease severity and tissue damage, which may be a key player in balancing between immune responses and tissue damage to maintain an animal's performance in response to the disease challenge (Hine *et al.* 2014). The present work contributes to our knowledge of the genetic parameters of immune traits collected from young healthy pigs and their relationships with multiple production performance traits under disease. Further studies are warranted to validate these traits as genetic indicators of resilience and further determine the role of these immune traits in disease resilience.

Abstract

The objective of this study was to estimate genetic parameters for traits recorded on finishing pigs reared under commercial conditions and experimentally inoculated with porcine reproductive and respiratory syndrome virus (PRRSV). Pigs (n=1,446) were vaccinated for PRRS and inoculated with PRRSV four weeks later. Individual body weights were recorded at 0, 13, and 42 days post-infection (dpi) and at marketing. Individual clinical scores were recorded at 0, 13, and 42 dpi and mortality was recorded from 0 dpi to market. Heritability estimates for average daily gain, clinical score at 13 dpi, clinical score at 42 dpi, and mortality were 0.26(0.05), 0.15(0.04), 0.09(0.04), and 0.10(0.07), respectively. In conclusion, data collected from this study can be used as a training data set for immediate implementation of genetic selection to breed pigs for improved, natural robustness to disease challenge in high disease pressure environments.

Introduction

Disease has a major impact on the cost, efficiency, and welfare of pig production. Biosecurity practices and vaccination may be used to control the incidence of disease outbreaks or severity of infection upon exposure. However, these approaches are not effective for all diseases or in all situations. Therefore, using genetic approaches to produce animals with enhanced robustness to disease is an attractive, additional disease control strategy.

One approach is to use genetic engineering to introduce novel genetic variation associated with enhanced robustness to disease. Research conducted by Whitworth and others (2015) showed that gene-editing technology can be used to introduce a novel mutation within the *CD163* gene, which confers complete resistance to PRRSV-infection. An alternative genetic solution is to use existing genetic variation within a population to breed pigs for enhanced robustness to disease challenge. Evidence of naturally occurring genetic variation in response to challenge has already been detected for purebred and crossbred sows following a PRRS outbreak (Herrero-Medrano *et al.*, 2015; Mathur *et al.*, 2014; Serão *et al.*, 2014) and commercial pigs when housed in a closed research facility and inoculated with PRRSV (Boddicker *et al.*, 2012; Dunkelberger *et al.*, 2017; Hess *et al.*, 2016). Results from these studies suggest that genomic selection, which capitalizes on existing genetic variation within a population, can be used to breed pigs for enhanced, natural robustness to disease as a viable, alternative PRRS control strategy. However, naturally occurring genetic variation in host response to experimental PRRSV-challenge for pigs reared under commercial conditions has not yet been evaluated. Therefore, the objective of this study was to estimate genetic parameters for host response to disease challenge for finishing pigs reared under commercial conditions and experimentally inoculated with PRRSV.

Materials & methods

The South Dakota State University (SDSU) and Pipestone Applied Research (PAR) institutional animal care and use committees (SDSU IACUC 18-030A and PAR IACUC 1-18) reviewed and approved the trial protocol, mortality standards, and caretaker handling certification.

Animals. Commercial crossbred (Synthetic boar × [Landrace × Large White]) (n=1,446) pigs were used for this study. Ear tissue was collected from each pig at birth and used for genotyping with a custom single nucleotide polymorphism (SNP) panel. Pigs were transported to a commercial research barn at weaning and placed into pens balanced by sex, with 27 pigs housed per pen. Post-arrival, each pig was vaccinated for PRRS using a PRRS modified live virus vaccine (IngelVac ATP, Boehringer Ingelheim), according to the label instructions. Four weeks later, each pig was experimentally inoculated with $1\times10^{3.5}$ TCID50 of the 1-7-4 PRRSV isolate via intramuscular injection (SDSU, South Dakota, USA) and followed until marketing.

Traits. Various phenotypes were recorded throughout the study, including individual body weights at 0, 13, and 42 dpi, which were used to calculate average daily gain (ADG) as the slope of body weight regressed on day from 0 to 13 dpi, 13 to 42 dpi, 0 to 42 dpi, and 0 dpi to market. Clinical scores were recorded for each individual at 0, 13, and 42 dpi using a subjective, 6-point scoring system, based on the method described by Pantoja *et al.* (2013). Mortality was recorded from 0 dpi to slaughter.

Genotypes. Genotypes across 45,577 SNPs were available on 1,419 pigs to construct a genomic relationship matrix according to the method of VanRaden (2008).

Statistical analyses. All statistical analyses were conducted using ASReml 4.0 (Gilmour *et al.*, 2015). Variance components and heritability estimates were derived for each trait using a single record per individual. Average daily gain and clinical score were analyzed using a mixed linear model with sex (barrow or gilt), room (East or West), age at 0 dpi (covariate), and weight at 0 dpi (covariate) fitted as fixed effects. Animal, litter, and pen were fitted as random effects to account for genetic, maternal, and environmental effects, respectively. Mortality was analyzed as a binary variable (0/1) using both a LOGIT and linear model.

Results

Although pigs tested positive for swine influenza virus at weaning and for *Salmonella* and rotavirus post-placement, most pigs (69.05%) appeared physically healthy and without signs of disease (clinical score = '1') at PRRSV-inoculation (Figure 1). This percentage dropped to 47.77% at peak challenge (13 dpi) and returned to baseline by 42 dpi (70.08%) (Figure 1).

Overall mortality rate (from wean to market) was 13.5%, indicating severe disease, thus maximizing phenotypic variation and, therefore, expression of genetic variation, in host response to challenge. The high mortality rate observed for this trial was likely due to a combination of factors, including: flu-positive status at weaning, inoculation with a highly pathogenic PRRSV strain, co-infection with numerous, opportunistic pathogens post-challenge, and intentionally withholding antibiotic treatment from 0 to 21 dpi, in adherence of microbiome analyses to be conducted using fecal samples collected during this time period. Examples of opportunistic pathogens detected post-challenge include: *Haemophilus parasuis, Actinobacillus suis, Streptococcus suis, Salmonella, Pasteurella multocida,* and *Escherichia coli.*

Results of genetic parameter estimation show that breeding pigs for improved overall response to disease challenge is possible. Heritability of ADG post-challenge was estimated at 0.27(0.05), 0.16(0.05), and 0.24(0.05) when calculated from 0 to 13 dpi, 13 to 42 dpi, and 0 to 42 dpi, respectively (Table 1). Similar heritability estimates were obtained for ADG from birth to market, wean to market, and 0 dpi to market at 0.24(0.05), 0.25(0.05), and 0.26(0.05), respectively (Table 1). Clinical score was not heritable when evaluated prior to challenge (0.03[0.03]). Post-challenge, heritability was estimated at 0.15(0.04) for clinical score evaluated at 13 dpi, 0.09(0.04) for clinical score evaluated at 42 dpi, and 0.10(0.07) for mortality from 0 dpi to market (Table 1).

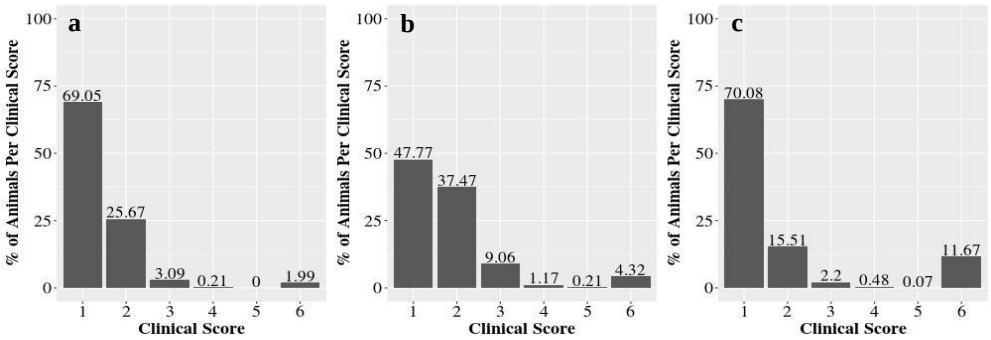

Figure 1. Percent of pigs per clinical score assigned at (a) 0, (b) 13 and (c) 42 days post-infection with porcine reproductive and respiratory syndrome virus. Individual clinical scores were assigned according to the following scale: '1' = healthy, no signs of disease; '2' = early signs of disease; '3' = moderate signs of disease; '4' = advanced clinical disease; '5' = candidate for euthanasia; and '6' = mortality.

Table 1. Variance components and heritability estimates (SE) for traits evaluated following experimental infection with porcine reproductive and respiratory syndrome virus.

Discussion

Genetic parameters for traits evaluated in this study provide evidence of substantial, naturally occurring genetic variation in host response to challenge with a highly pathogenic PRRSV strain. Further, genetic correlations between traits evaluated post-challenge (results not shown) were in the expected direction. Previous studies conducted to investigate the role of genetics on host response to PRRS challenge used data collected following an outbreak or following experimental infection with PRRSV in a closed research facility. Therefore, this is the first study to evaluate host response to experimental PRRSV-challenge for pigs reared under commercial conditions. Detection of numerous opportunistic pathogens throughout this study, a reflection of the immunosuppressive effect of PRRSV, is consistent with presentation of PRRS in the field. An experimental challenge model was used for this study to maximize the accuracy of genetic

parameters estimated for traits recorded under challenge. Variability in exposure, which is typical during an outbreak, leads to underestimation of heritability for traits recorded under challenge (Bishop, 2014). Experimental inoculation, which standardizes the level, timing, and route of pathogen exposure across individuals, can be used to avoid this issue.

In conclusion, the combination of genotypic and phenotypic data collected from this study can be used as a training data set for immediate implementation of genetic selection to breed pigs for improved, natural robustness to disease challenge in commercial, high disease pressure environments. Genomic selection is the ideal methodology to facilitate genetic improvement of traits controlled by multiple genes, which is typical of disease-related traits. Therefore, breeding pigs for enhanced, natural robustness to challenge should be considered a viable, alternative PRRS control strategy to introducing novel genetic variants for PRRS resistance using genetic engineering technologies.

163. A quantitative genetic theory for infectious diseases

P. Bijma*, A.D. Hulst and M.C.M. de Jong

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; piter.bijma@wur.nl

Abstract

We integrated quantitative genetics and epidemiology to develop a quantitative genetic theory of the prevalence of endemic infectious diseases. Results show that infectious diseases respond very differently to selection than common non-communicable traits, and strongly suggest that the genetic variance determining the potential response of prevalence to selection must be much larger than currently believed. Moreover, heritable variation and response to selection increase significantly when the prevalence of the infection decreases, ultimately leading to local extinction of the infection due to herd immunity. These results change our perspective on the prospects of genetic selection against infectious diseases.

Introduction

A reduction of the prevalence of infectious diseases in livestock is highly desirable. Individual disease status, however, measured as $y = 0$ or 1 indicating non-infected vs infected, typically shows low heritability (h^2). Moreover, the classical threshold model predicts that h^2 goes to zero when a disease becomes rare. Hence, genetic selection against infectious diseases seems difficult. This perspective, however, ignores that infectious diseases rely on transmission between individuals. Here we present a quantitative genetic theory for response to selection and heritable variation in the prevalence of endemic infectious diseases.

Methods & results

The endemic prevalence (P) of an infectious disease is the average fraction of the population that is infected, and is equal to the mean of individual disease status (P = avg(y)). Standard epidemiological theory shows that the endemic prevalence follows from the basic reproduction number (R_0; Weiss and Dishon 1971; Figure 1),

$$P = 1\text{-}1/R_0 \quad (1)$$

R_0 is the number of individuals that gets infected by a single typical infected individual in a naive population. For example, with $R_0 = 3$, an infected individual would on average infect three others. However, if 2/3 of the population is infected already, then only a single new infection will occur on average. Hence, prevalence reaches an equilibrium at $P = 1 - 1/3 = 2/3$. To reduce prevalence, therefore, breeders should lower R_0. At low R_0, prevalence is very sensitive to changes in R_0 (Figure 1), which has significant implications for response to selection.

Breeding values for R_0, prevalence and disease status. R_0 is the product of the contact rate between individuals, the *sus*ceptibility of individuals to become infected, the propensity of individuals to infect others (*inf*ectivity) and the duration of the infectious period (*t*). Because R_0 is a product and because it takes strictly positive values, we define an additive model with normally distributed genetic effects for the logarithm of R_0,

$$A_{\ln(R0)} = A_{\ln(sus)} + A_{\ln(inf)} + A_{\ln(t)} \quad (2)$$

We assume that additive genetic (co)variances are constant on this log scale, i.e. are independent of the level. (This implies that additive genetic variance in R_0 decreases as R_0 decreases). Connecting Equation 1

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_163, © P. Bijma *et al.* 2022

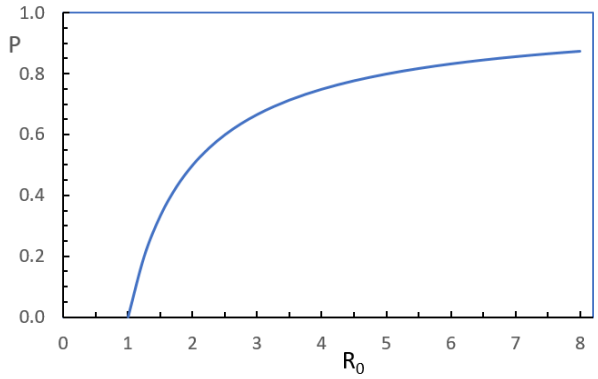

Figure 1. Prevalence as a function of R_0 (from Bijma *et al.* 2022).

and 2 leads to a breeding value for individual disease status (A_y) and a breeding value for prevalence (A_p; Bijma *et al.* 2022; here assuming no genetic variation in infectivity),

$$A_y = P(1\text{-}P)\, A_{\ln(R0)} \quad (3a)$$

$$A_P = (1\text{-}P)\, A_{\ln(R0)} \quad (3b)$$

A_y is the ordinary ('direct') breeding value for the disease status of the individual itself, while A_p is a total breeding value that measures the total effect of an individual's genes on the prevalence in the population. Hence, response of prevalence to selection equals the per generation change in mean A_P. Note that A_p is a factor 1/P greater than A_y. Moreover, for a constant $A_{\ln(R0)}$, A_y has a maximum for P=0.5, while A_p increases when P decreases. Thus, the common h^2 of individual disease status (y=0,1) has a maximum at P=0.5, similar to the threshold model (Robertson 1950), but the additive genetic variance that breeders can use for response to selection increases significantly as prevalence falls (Figure 2). This result is a consequence of the increasing slope of the relationship between P and R_0 at lower values of R_0 (Figure 1).

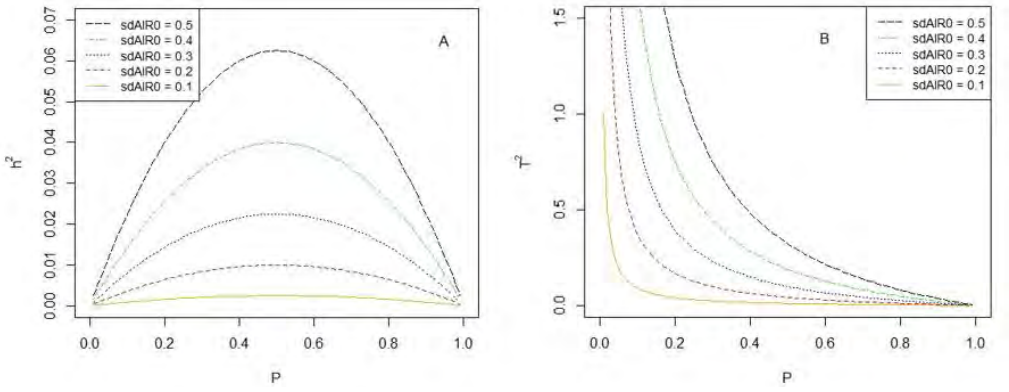

Figure 2. Heritability of individual disease status (h^2, panel A), and additive genetic variance in the endemic prevalence as a fraction of phenotypic variance (T^2, panel B), as a function of prevalence (P). For different additive genetic standard deviations in $\ln(R_0)$, and without genetic variation in infectivity (from Bijma *et al.* 2022).

Figure 2 shows that common heritabilities of disease status correspond to a large additive genetic variance in prevalence, particularly when prevalence is small. For example, for P=0.2 and sd($A_{ln(R0)}$)=0.4, the common observed-scale heritability of binary disease status is only 0.026, while the additive genetic variance that can be used for response to selection is 64% of phenotypic variance (T^2=0.64). Hence, for this scenario, the additive genetic standard deviation in prevalence is sqrt[0.64×0.2×(1-0.2)] = 0.32, which is very large.

Response to selection. Figure 2B shows a strong increase in additive genetic variance as prevalence falls, suggesting that response to selection for lower prevalence should accelerate over generations. Figure 3 shows response to selection observed in simulations following standard methods in epidemiology, not using any of the above theory. Figure 3 also shows the mean breeding values for prevalence (A_p) and for individual disease status (A_y), expressed as deviations from prevalence in the first generation. As expected based on Figure 2, the response accelerates as prevalence decreases. In the final generations (t=16, and t=70) the infection disappears due to herd immunity in the local population, not because individuals are fully resistant to infection. The mean breeding value for prevalence (Equation 3b) closely matches the observed response, while the mean breeding value for individual disease (Equation 3a) deviates more and more from the observations as prevalence decreases. Hence, response in Figure 3 is significantly greater than the common breeding values for individual disease status suggest.

Discussion

We developed a quantitative genetic theory of infectious diseases, focussing on R_0 and on the endemic prevalence of the infection. The breeding value for the logarithm of R_0 is central to the theory, and is the sum of the breeding values for the logarithms of susceptibility, infectivity and duration of the infectious period. From the breeding value for ln(R_0) we derived a breeding value for individual binary disease status

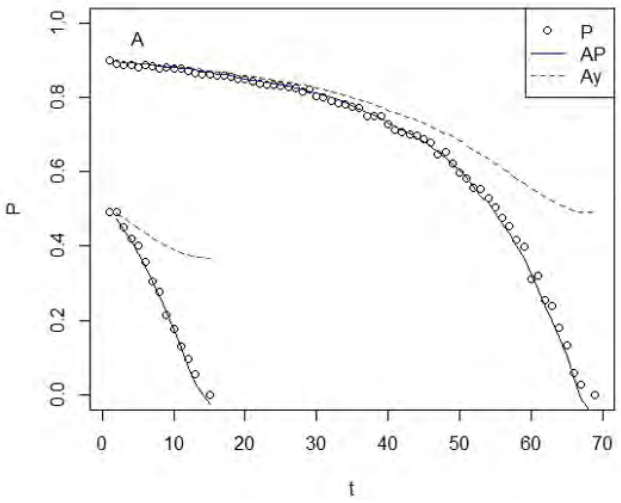

Figure 3. Response to mass selection against an infectious disease; observed response (small circles), mean breeding value for prevalence in (A_p, solid blue line) and mean breeding value for individual diseases status (A_y, dashed red line). For two populations, one starting at a prevalence of 50%, and the other at 90%. With genetic variation in susceptibility only, with var($A_{ln(R0)}$) = var($A_{ln(sus)}$) = 0.3^2, and a selected proportion of 0.5. The common observed-scale heritability for individual disease status in any generation can be read from Figure 2A, using an x-axis value corresponding to the prevalence in that generation, and does not exceed 0.022 (from Bijma *et al.* 2022).

and a breeding value for the prevalence of the infection in the population. The first relates to ordinary h^2 of individual disease status, while the second relates to response to selection. Without genetic variation in infectivity, the breeding value for prevalence is a factor $1/P$ greater than the breeding value for individual disease status. This is a general result, and does not rely on the assumption of an additive model on the log scale. For this reason, both the additive genetic variance for prevalence and the response of prevalence to selection increase when prevalence goes down (Figure 2B, 3).

The large difference between the h^2 of individual disease status and the total additive genetic variance in prevalence as a fraction of phenotypic variance (T^2) shown in Figure 2 indicates the presence of considerable indirect genetic effects (IGE). The h^2 reflects the variance of only the direct genetic effect of individuals on their own disease status. The T^2 reflects the variance of the full effect, i.e. of the sum of the effects on the disease status of the individual itself and on the disease status of its herd mates. Diseases that rely on transmission generate considerable IGE because an individual who does not become infected itself also cannot infect other individuals (simply because it is not infected). Hence, the direct effects for susceptibility and for duration of the infectious period are fully correlated to the corresponding indirect effects, resulting in positive feedback and an increase in the total additive genetic variance. This positive feedback effect increases strongly when prevalence decreases, which causes IGE to make up an increasing proportion of the total effect, and explains the difference between h^2 and T^2 in Figure 2 A vs B.

The results shown here apply to endemic microparasitic infections, and where the pathogen relies on the host individual (i.e. the livestock) for its replication. Hence, we assume absence of an external reservoir of pathogens, such as a second host species (for example badgers in the case of bovine Tb). Note that temporary survival of the pathogen in the environment does not violate this assumption. This assumption implies that a reduction in, e.g. susceptibility translates fully into reduced exposure in the local population (because of fewer infected individuals). Example traits include mastitis, infectious claw disorders, respiratory infections in young animals (young replacement stock, meat calves, fattening pigs), faecal-oral transmitted infections causing gastro-intestinal diseases, and several zoonosis.

In conclusion, our results show that the quantitative genetics of infectious diseases is very different from the quantitative genetic theory for ordinary, non-communicable, traits, and that prospects for genetic improvement are much better than currently believed, as was also proposed by Bishop and Stear (1997). These findings, coupled with the high importance of infectious diseases for animal health and welfare, and also for human health in the case of zoonoses, suggest that breeders should become familiar with basic concepts in epidemiology, such as R_0. Together with recent advances in sensor technology and AI, which will enable us to collect large-scale high-quality data on individual disease status, these findings facilitate artificial selection against infectious diseases.

Abstract

We performed a selection experiment to investigate the possibility to improve resistance to non-specific diseases in rabbits. The selection criterion was a binary trait (healthy versus sick or dead) obtained from clinical signs of diseases occurring naturally on farm. A herd of 116 to 132 does and 30 bucks was bred based on this selection criterion. The heritability of the trait was 0.035±0.009. After four generations of selection, the genetic progress was 1.5 genetic standard deviation, indicating that breeding for general disease resistance is feasible.

Introduction

Livestock populations are exposed to a variety of pathogens, not always identified, resulting in multifactorial diseases that are difficult to eradicate. For this reason, animal breeders and farmers are searching for robust strains of animals, able to cope with environmental stresses and to resist epizootics. However, a measure of individual responses to diseases resistance that is accurate, cheap, heritable and easy to perform on farm is difficult to obtain (Davies *et al.*, 2009; Bishop and Woolliams, 2014). In this study, we performed a selection experiment to improve the general resistance of animals to the various diseases they may encounter. The selection criterion was a binary trait (healthy versus sick or dead) based on clinical signs of diseases occurring naturally on farms. The aim of our project was to investigate if selection for non-specific disease is possible based on this criterion in rabbits.

Materials & methods

Trait. The selection criterion was a binary trait (0 = morbid, sick or dead from digestive, respiratory, or other diseases, mostly from infectious origin; 1 = healthy). Clinical signs were recorded at the INRAE experimental rabbit farm at a single time point toward the end of growth (63 days of age). The most likely cause of death was also recorded for rabbits that died between weaning and the end of the test. Clinical signs of diseases were recorded once in the young rabbit life, at 63 days of age, but not between weaning and the end of the test. Thus, rabbits categorized as healthy at 63 days of age might have been sick (exposed) individuals which recovered before recording (resistant or tolerant individuals). During the two years of the experiment, 10,169 rabbits were recorded individually.

Animals. A foundational herd of 132 females and 30 males was constituted from the INRA1777 rabbit line, a maternal line selected for litter size and for direct and maternal effects on weaning weight. Throughout the experiment, animals were not exposed to any sort of antibiotic treatments. Reproducers were vaccinated against myxomatosis and Rabbit Hemorrhagic Disease (RHD). The herd was conducted with overlapping generations. The number of reproducing does varied between 116 to 132, while the number of available bucks was kept to 30. The reproduction interval was of 42 days. Between 300 to 900 kits were born in each batch. They were weaned at 35 days old and reared in groups of 5 kits during the fattening period. Litters

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_164, © M. Gunia *et al.* 2022

were split after weaning to mix the genetic origins in each group. Weaned rabbits were fed *ad libitum* a commercial diet for growing rabbits (STABI-GREEN G, Terrya, Rignac, France).

The first 2 generations (10 batches) were reared in old facilities with standard cages (38×90×32 or 40×100×38). Then, the herd was moved to new facilities (renovated buildings, new housing systems: 46×90×70 or 46×90×60) from the eleventh batch.

Every 42 days, the best 30 females and 10 males were selected based on our selection criterion to become reproducers, with a constraint to limit inbreeding increase at 1% per generation, by using the Gencont software (Meuwissen, 2002). The selection was based on the genetic merit of the individuals, estimated from the information collected on all relatives tested in the pedigree to achieve the best possible accuracy.

Genetic analyses. Variance components were computed with a restricted maximum likelihood method, using a single-trait animal linear model and a threshold model with a logit link function. Breeding values were estimated with the BLUP method using the linear model. Variances components and genetic values were estimated together with the ASReml 3.0 software (Gilmour *et al.*, 2009). The models included a random additive polygenic effect and a random common litter effect. The significant fixed effects were the batch, parity of the dam, and gestation length. The estimated breeding values were used to estimate the genetic gain on the selection criterion. The linearity of the relationship between the means of the estimated breeding value per batch and the batch number was tested using a Fischer test from the Proc Reg of the SAS software.

Ethics. All experiments were conducted in accordance with the guidelines of the Directive 2010/63/EU of the European Parliament and of the Council and were approved by the ethical review board (no. 115, under the code APAFIS#1812-201812121652792 v4).

Results & discussion

In total, 14.9% of the rabbit showed clinical signs of diseases. The proportion of the main syndromes are shown in Table 1. Animals mostly suffered from digestive symptoms (in 68% percent of the cases), which could be related to Epizootic Rabbit Enteropathy (a gastrointestinal disorder of unknown aetiology) or to other digestive diseases caused by various pathogens.

The heritability of the selection criterion was low (Table 2), with a low genetic variance. This value was in the same range as previous studies in other rabbit lines (Gunia *et al.*, 2015, 2018), where the heritability estimates ranged from 0.03±0.003 to 0.10±0.02.

Table 1. Main disease syndromes recorded.

Syndromes	Number of rabbits	Proportion
Digestive symptoms	1,024	68%
Poor body condition	324	21%
Rabbit Haemorrhagic Disease (RHD)	139	9%
Other clinical signs	28	2%
Total	1,512	100%

Table 2. Genetic components of the non-specific disease status.

	Threshold model (underlying scale)		Linear model (observed scale)	
	Value	Standard-error	Value	Standard-error
Genetic variance	0.140	0.068	0.003	0.001
Heritability	0.027	0.013	0.032	0.009
Common litter effect	0.152	0.012	0.128	0.006

We observed a linear (P<0.001) increase of the estimated selection response (Figure 1), reaching 1.5 genetic standard deviation after 18 batches (approximately 2 years, a batch being 42 days). The first generation (batch 1 to 5) was a transition from the foundational herd (batch 0) conducted with separated generation to the herd selected on disease resistance with overlapping generation. It explains why the genetic level remained stable from batch 1 to 5, before increasing at batch 6.

The percentage of sick or dead rabbits was on average 14.9% per batch. The very low percentage of sick rabbit in batch 11 (0.1%) was related to the installation of the herd to the renovated facilities. In batch 13, an outbreak of RHD occurred. This disease is lethal and highly contagious. Sick rabbits were euthanised and all the other rabbit of this batch were culled to prevent contamination risk between batches and herds at the experimental facility. The culled rabbits were not considered in the experiment. The room and parcs were disinfected before introducing the next batch, and all fattening rabbits were vaccinated against RHD from batch 14.

Phenotypically, we did not see any progress or reduction in the number of sick rabbits (Figure 1). It is probably be due to the various pathogens that rabbits encountered in each batch. In addition, the type of pathogen and the pathogen loads may vary from batch to batch.

The first results of the selection experiment are promising. We did not perform a divergent section for ethical reasons. However, a comparison with a control herd is planned by the end of 2022. Embryos of

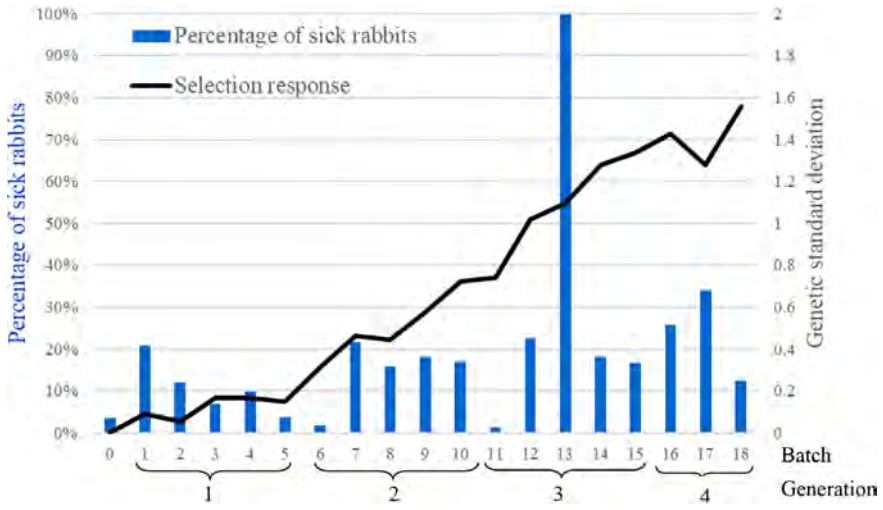

Figure 1. Proportion of sick rabbits (in percentage) per batch and predicted selection response for the proportion of healthy rabbit (in genetic standard deviation units).

the founder herd (before selection) were frozen. This final experiment will allow assessing the effect of selection by comparing the selected and control groups together in the same environment. Two contrasted environments (indoor in cages and outdoor on pasture) will be tested. Selected and control groups will be naturally exposed to the same pathogens within the same environment and thus will be able to express their various degree of disease resistance and/or tolerance.

Our results show that selection for health, without targeting any specific disease, is possible. We will assess if the results of selection in a specific environment are also validated in a different environment with different pathogens challenges.

Analyses on immune response traits and gut microbiota will now be performed to get a first insight into the mechanisms underlying this general disease resistance.

Abstract

Bovine paratuberculosis, or Johne's disease (JD), is a contagious, incurable and very difficult to control disease due to *Mycobacterium avium* subsp. *paratuberculosis* (MAP). Using a single step GBLUP, including candidate SNPs for resistance to JD, applied to a pedigree of 161,253 Holstein animals (56,766 with serological phenotypes and 12,431 with genotypes), we estimated a moderate heritability value (0.14) of this trait and detected genomic regions associated to resistance to JD on chromosomes 23, 21, 12, 3, 7, 27, 5, 10, and 20. We also estimated a slightly favorable genetic trend of resistance to JD over the last two decades and relatively reliable genomic predictions (CD=0.55) in a validation population allowing the identification of cows at high risk of infection. Genomic predictions should therefore rapidly become an effective tool for controlling paratuberculosis in French Holstein cow farms.

Introduction

Bovine paratuberculosis, also referred as Johne's disease (JD), is a contagious and incurable disease, caused by *Mycobacterium avium* subsp. *paratuberculosis* (MAP). After being contaminated *in utero* or more frequently via the intake of MAP-infected feces as a young calf, animals undergo a long latency phase that can last several years. Subclinical symptoms of JD are weight loss and reduced milk production together with an inconsistent humoral immune response and fecal shedding. Subclinical cases can therefore contaminate their environment. Clinical cases finally develop chronic diarrhea and severe emaciation, ending in death. JD, which has adverse effects on animal welfare and serious economic consequences, has no effective treatment and access to vaccines is restricted, it is therefore very difficult to control. A number of studies have shown the role of host genetics in resistance to MAP (Brito *et al.*, 2018) but their results are not fully consistent mainly due to the various definitions of the MAP-resistant phenotype.

In genome-wide association studies (GWAS) conducted on imputed whole genome sequences of 1,644 Holstein cows with an accurately defined status for MAP, we previously identified various candidate SNPs explaining around 20% of the phenotypic variance of resistance to MAP infection (Sanchez *et al.*, 2020; 2021). Using these data together with additional data collected in infected herds and a ssGBLUP model including the best candidate SNPs, we investigate here the genetic determinism of resistance to JD and estimate genetic trends, reliability and risk factors associated to genomic predictions.

Materials & methods

Phenotypes and genotypes. Data of 247,375 Holstein cows were collected in northwestern French herds enrolled in JD control plans. These data included MAP statuses of 4,100 cows obtained from serum ELISA and PCR on faeces in the PARADIGM project (see details in Sanchez *et al.*, 2020) and MAP statuses of 243,275 cows deduced from serological data (Idexx or Idvet ELISA test, Montpellier, France) routinely recorded since 2015. These cows were non-infected (NI; n=228,337) or infected (I; n=19,038) by MAP. We applied different filters to these data. First, to exclude cows still potentially in the latency period, I and NI cows younger than 24 and 36 months old, respectively, were discarded. Then, to maximize the probability

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_165, © M.P. Sanchez *et al.* 2022

of exposure to MAP, we kept only cows in herds with at least one I cow and one NI cow born in the same year. These filters resulted in a drastically reduced dataset, which ultimately contained 56,766 Holstein cows (42,829 NI and 13,937 I) from 3,114 herds. The pedigree was traced over four generations and contained 161,253 animals, including 12,431 genotyped individuals, among which 4,031 had phenotypes (2,787 NI and 1,244 I). The 12,431 animals were genotyped with different SNP Beadchip versions, including the EuroGMD Beadchip that contains an add-on for selected SNPs predictive for resistance to JD. In total, 53,469 SNPs were imputed using FImpute (Sargolzaei *et al.*, 2014).

Model and methods. To estimate ssEBVs, resistance to JD was modelled as follows:

$$y = X\beta + Za + e \quad (1)$$

where y is the vector of phenotypes, i.e. 1 for NI cows and 0 for I cows, $a \sim N(0, H\sigma_a^2)$ is the vector of random additive genetic effects and $e \sim N(0, I\sigma_e^2)$ is the vector of random residual effects. The β vector included the fixed effects of herd × birth year, birth month, and ELISA test to account for variability of exposure to MAP in the environment between farms and in time, and for differences in test sensitivities and specificities. X and Z are incidence matrices, H is the relationship matrix among individuals and I the identity matrix, σ_a^2 and σ_e^2 are the additive genetic and residual variances, respectively. Model (1) was applied to the Hybrid Single Step method, proposed by Fernando *et al.* (2016) and implemented in the HSSGBLUP software (Tribout *et al.*, 2020). This method directly provides SNP effect estimates and ssEBVs of all animals in the pedigree, genotyped or not. ssEBVs were then expressed in genetic standard deviation units by dividing predictions on the raw scale by 0.15.

Variance components were estimated with WOMBAT software (Meyer, 2007) using a similar model but only with pedigree information to build the relationship matrix A. Heritability h^2 for resistance to JD was calculated as follows: $h^2=\sigma_a^2/(\sigma_a^2+\sigma_e^2)$.

Genetic trends of resistance to JD in females and males were assessed separately by the annual average ssEBVs of cows with phenotypes born between 2008 and 2018 and of bulls born between 2000 and 2014 with at least 10 daughters with MAP statuses.

Reliability of ssEBVs was estimated in a validation (VAL) population of 907 cows with phenotypes (715 NI and 192 I) and genotypes born between 2015 and 2018. For this study, model (1) was run on a truncated dataset constituted by phenotypes of the 41,774 cows (31,115 NI and 10,659 I) born before 2015, among which 3,118 had genotypes (2,069 NI and 1,049 I). Reliability was estimated by $CD=r^2/h^2$, with r the correlation between phenotypes adjusted for non-genetic effects estimated with model (1) on the complete dataset and genomic predictions (GP) of VAL animals predicted using the truncated dataset. Risk factor was also assessed in the VAL set. GP were grouped in 0.5 point classes and the relative risk factor in class i was estimated by the ratio of the proportion of infected animals in class i to that in the central 0 class.

Finally, considering SNP effects (ŝ) estimated in HSSGBLUP, the % of genetic variance explained by the i^{th} genomic region of 25 adjacent SNPs was calculated as $var(\hat{a}_i)/\sigma_a^2$ where $\hat{a}_i = M_i\hat{s}_i$ is the vector of genomic values for the i^{th} region, M_i the matrix of SNP content in region i, and $\hat{s}_i$ the effects of the 25 SNP of the region.

Results

Estimates of genetic and residual variances were 0.019 and 0.113, respectively, corresponding to a moderate h^2 estimate of 0.143±0.01 for resistance to JD.

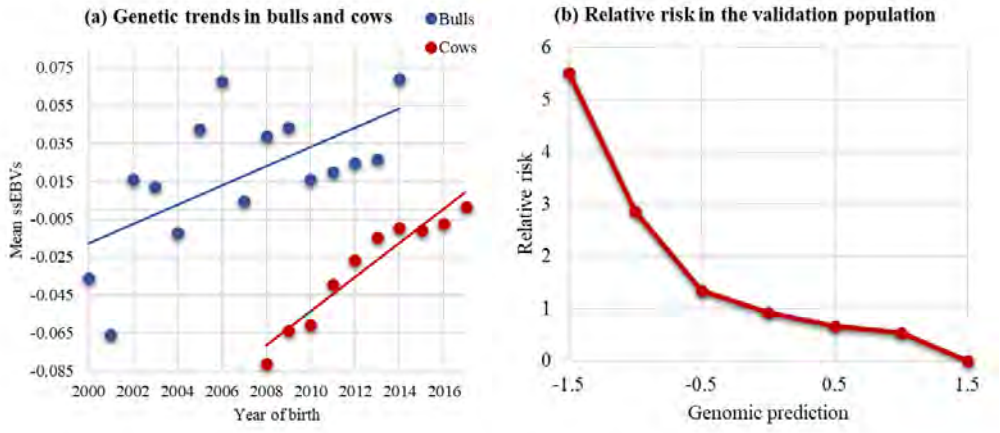

Figure 1. Evaluation results: (a) genetic trend of resistance to JD and (b) relative risk of being infected by MAP.

Estimated genetic trends of resistance to JD in bull and cow populations (31 to 117 bulls and 2,356 to 8,674 cows depending on the year of birth) were favourable (+0.6 σ_a and +0.8 σ_a, respectively over the period considered), the younger animals being genetically more resistant than the older ones (Figure 1a). Correlation between (GP) and phenotypes adjusted for fixed effects in VAL was equal to 0.28 (SE=0.03); the corresponding reliability was therefore ~0.55.

To illustrate the effect of genetics on the phenotype, we used the VAL population to estimate the relative risk for cows to be infected based on their GP (Figure 1b). A strong effect of genetics was observed in this validation dataset. Assuming the relative risk equal to 1 for GP=0, this risk was half as big and three times higher for cows with GP=1 and -1, respectively. Although numbers are limited, effects were even much stronger for cows with GP equal to ±1.5.

The estimation of percentage of genetic variance explained by overlapping genomic regions of 25 SNPs revealed a high peak on chromosome 23 (max. 0.32%) and lower peaks explaining between 0.10 to 0.15% of the total genetic variance, on chromosomes 21, 12, 3, 7, 27, 5, 10, and 20 (Figure 2).

Discussion

This study, based on a single step SNP GBLUP including candidate SNPs for resistance to JD, provides new insights into the genetic determinism of this trait and gives very encouraging results for the implementation of a genomic evaluation in Holstein cows using MAP statuses deduced from serological data routinely recorded.

With respect to the genetic determinism of resistance to JD, we herein obtain results quite different from those found in our previous study conducted on imputed whole-genome sequences of 1,644 Holstein cows with accurate extreme phenotypes (Sanchez *et al.*, 2020; 2021). In the present study, we first estimated a moderate h^2 value (0.14) much lower than the one we reported before (0.57) but which agrees with h^2 values reported in various studies (0.03-0.27; Brito *et al.*, 2018). The multi-SNP GWAS approach taking into account a total of 161,253 animals in the pedigree – 56,766 with phenotypes and 12,431 with genotypes – confirms effects of genomic regions located on chromosomes 23, 12, 3, and 5 and revealed new regions affecting resistance to JD on chromosomes 21, 7, 27, 10, and 20. However, the major effect detected on chromosome 13 in our previous single-SNP GWAS is not confirmed here.

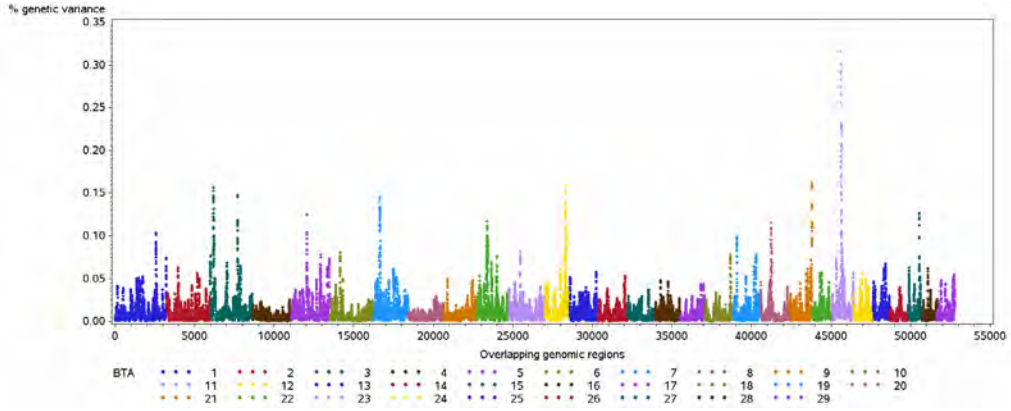

Figure 2. Percentage of genetic variance explained by overlapping regions of 25 adjacent SNPs.

Trends of genomic predictions, estimated over the last two decades, show a favourable genetic evolution of resistance to JD. In a validation population, we highlight relatively reliable genomic predictions for resistance to JD (CD=0.55) estimated from a reduced reference population and we show that genomic predictions can already be of great help in identifying cows at high risk of infection. These breeding values can be used at two levels: (1) in infected herds, this information will allow orientating early culling of highly susceptible animals and planning matings with resistant bulls; (2) at the breeding scheme level, these breeding values can be integrated into the breeding goal and, more importantly, used to produce resistant artificial insemination bulls for matings in infected herds. We can anticipate that as the number of genotyped and phenotyped cows increases continuously, genomic predictions will rapidly become an effective tool for controlling paratuberculosis in French Holstein farms. The same strategy is currently being developed in the Normande breed and could be extended to other populations in the future.

Abstract

The aims of this study were to estimate genetic parameters and to identify genomic regions associated to the host's immune response against *Mycobacterium avium* subsp. *paratuberculosis* (MAP). Three thousand eighty eight ewes, genotyped with the OvineSNP50 Beadchip, were subjected to repeated serum ELISA tests over time in an experimental flock. Two different variables were derived from the original ELISA results. A genomic relationship matrix was used to estimate variance components with variable-specific animal models. QTL mappings were performed by a combined linkage and linkage disequilibrium method using a principal component analysis to synthesize identity-by-descent matrix information. Results were similar for both the variables. Heritability of MAP status was approximately 0.2 and a significant QTL was detected on OAR 20 at about 24.8 Mb for both the variables. The QTL region overlaps some MHC II genes and will be further investigated by using whole genome sequence data.

Introduction

Paratuberculosis (PTB), is a contagious disease caused by infection with the Gram-positive bacteria *Mycobacterium avium* subsp. *paratuberculosis* (MAP). It affects ruminant species and can manifest as chronic granulomatous enteritis. PTB infection, results in significant negative effects both on the animal welfare and on farm profitability. Moreover, several studies suggested the implication of MAP in the Crohn's disease (Sechi *et al.* 2005). There are no effective treatments against MAP infection and vaccination does not guarantee the elimination of MAP shedding. Control strategies based on culling seropositive animals are very expensive and have a limited effectiveness. The role of host genetics in the susceptibility to MAP infection have been largely studied in dairy cattle, where low-to-moderate heritabilities were estimated and numerous Quantitative Trait Loci (QTL) were mapped. In sheep, the few studies on the role of genetics on resistance to PTB, suggest a moderate heritability with differences between breeds (Hick*ey et al.*, 2003; Sechi *et al.*, 2011). Moreover, studies on association between genetic polymorphisms and PTB susceptibility are very rare and usually based on experiments of limited size. In this work the genetic resistance to PTB in sheep was studied on the basis of data collected on a large sheep experimental flock. Ewes were genotyped with the OvineSNP50 Beadchip and repeated enzyme-linked immunosorbent assay (ELISA) tests have been performed over time. The main goals were to estimate genetic parameters of proxy traits for PTB resistance and to identify genomic regions associated to the host's immune response against MAP. Selected regions will be further investigated through association and functional annotation analysis of polymorphisms identified by whole genome sequence data (Casu *et al.* this congress).

Materials & methods

Experimental population. The experimental flock was set in 1999 with the first generation of ewes consisting in 928 back-cross Lacaune × Sarda. The following generations were obtained by mating adult ewes with rams from the Sarda Herd Book. The average size of the flock has been about 800 ewes with a replacement rate of 25%. The flock is managed by the farming system commonly adopted by commercial farms and is raised in an experimental farm in the south of Sardinia. Animals of the nucleus flock were

naturally exposed to the MAP infection and no control practice, treatment or vaccination against PTB have been applied.

Phenotypes. From 2001 to 2012, 3,088 ewes from the experimental population, born from 1999 to 2011 were blood sampled with lags between consecutive samplings ranging from 5 to 12 months. On the whole, 14,482 blood samples were collected: on average 4.7 per head ranging from 1 to 8. Blood samples were tested using ELISA screening test (IDvet, France or Pourquier ELISA, France). Test results were expressed on the base of the percentage of the sample-to-positive ratio (SP) calculated as 100 × [OD of the sample – OD of the negative control] / [OD of the positive control – the OD of the negative control], where OD is the optical density. A test was definite positive when SP was ≥70%.

Genotypes. All the 3,088 phenotyped ewes, their 100 sires and 10 Sarda grandsires were genotyped with the Illumina Inc. OvineSNP50 Beadchip. SNP editing was performed using call rate and MAF thresholds of 95 and 1%, respectively. The ovine genome assembly v4.0 was used to construct the genetic map by assuming 1 Mb=1 cM. Unmapped SNPs and SNPs on sex chromosomes were not included. Finally, 43,390 SNPs were retained.

Genetic analyses. The definition of the susceptible/resistant status with the antibody levels assessed by the ELISA test is questionable, due to the lack of sensitivity (Mathevon *et al.*, 2019). Thus, to check the overall consistency of results, we performed the genetic analyses with two different variables. The first one assigns the susceptible status to animals showing at least one positive test along the recording period (CAR). However, CAR roughly approximates the status for those animals that showed at least one negative test after a positive one (41%) or those with just one test in the recording period (5%). Thus, the quantitative variable SP was considered to avoid the use of thresholds to define the PTB status. Heritability estimate for the binary variable CAR (coded as 1 for susceptible and 0 for resistant) was realized through an animal model with no fixed effect other than the mean and the random animal genetic effect. The quantitative variable SP was analyzed with a single trait repeatability animal model including the fixed effect of the age of the animal at the date of sampling as covariate and the ELISA plate, the animal non genetic effect and the animal genetic effect as random. In both the analyses, genetic relationships were taken into account by calculating the genomic relationship matrix (Van Raden, 2008) among genotyped animals. Variance components were estimated by a REML procedure through airemlf90 software (Misztal *et al.*, 2002). For the QTL detection on CAR, the original variable was used. For the QTL detection on SP, pseudo-phenotypes were obtained by averaging individual animal residuals and summing-up the genetic and non genetic animal effects of the previous model. QTL mappings were performed by the method proposed by Usai *et al.* (2019) which uses principal components to summarize Identity-by-Descent probabilities (IBD) between gametes of genotyped individuals. IBD were estimated at each position *l* of the OvineSNP50 SNP (IBD_l) by combining linkage disequilibrium and linkage analyses. In addition, the QTL detection model included a genome-wide IBD matrix calculated by averaging all the IBD_l to account for the polygenic effects. In this study, only QTL segregating within gametes of Sarda origin were tested by F-test at each SNP position. The 5% genome-wide significance threshold was determined by a Bonferroni correction for the 43,390 tests, which resulted in $-\log_{10}$ (*P*-value) = 6. Moreover, the ratio between the ANOVA estimators of the QTL variance and the total phenotypic variance was calculated (Casu *et al.*, 2022).

Results

Sixteen % of the ELISA tests were positive and 29.7% of the 3,088 ewes investigated in this study had at least one positive test during the observation period. Heritabilities estimated with the specific animal models were 0.20 for both CAR and SP with standard errors of 0.029 and 0.024 respectively. Repeatability estimate for SP was 0.68. Significance profiles obtained for CAR (Figure 1) and SP (Figure 2) were very similar. SNPs

exceeding the 0.05 GW significance threshold were 116 and 156 for SP and CAR respectively and 112 were significant for both the variables. All the significant positions were located on OAR 20 within a region from 23 to 35 Mb. For both the variables, the phenotypes predicted by the QTL effects at each significant SNP positions were strongly correlated (r>0.45) to the phenotypes predicted by the QTL effects at the position of the peak. The most significant position for the two variables corresponds to two close SNPs located at around 24.8 Mb (Table 1). ANOVA estimators of QTL variances at the peak positions were 4.1 and 4.7% of the phenotypic variance for SP and CAR respectively. Moreover, further positions close to WGS significance threshold were detected: for CAR on OAR18 at ~30 Mb; for SP on OAR1 at ~200 Mb and on OAR15 at ~62 Mb for both the variables.

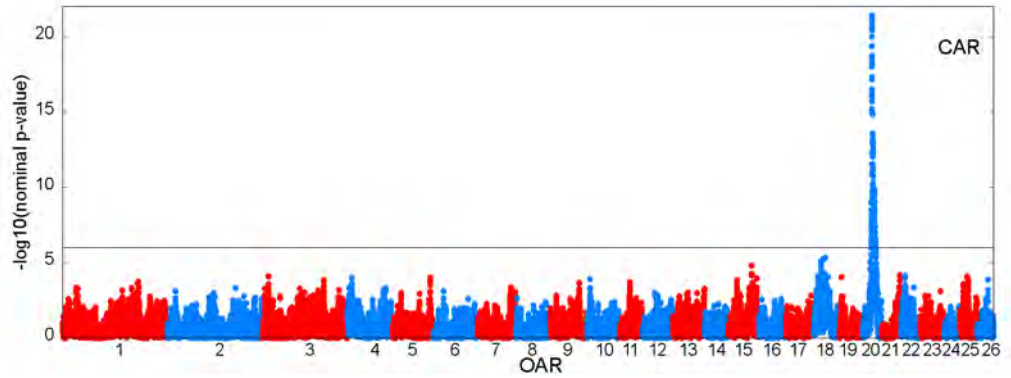

Figure 1. Manhattan plots corresponding to the QTL mapping carried out on CAR.

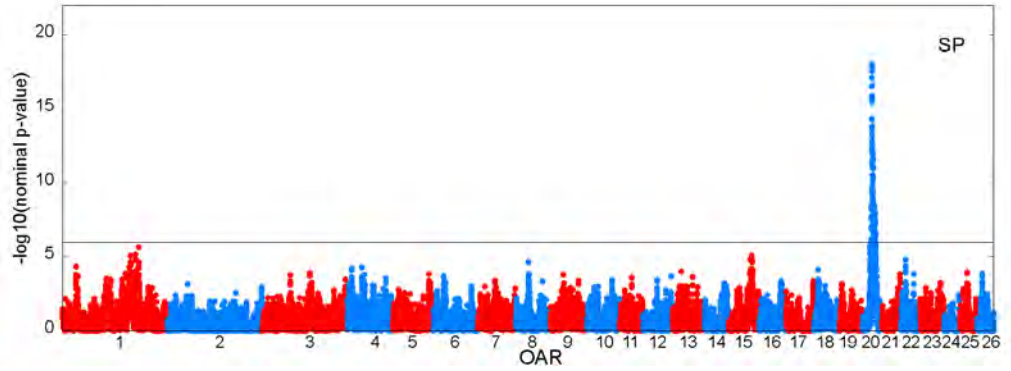

Figure 2. Manhattan plots corresponding to the QTL mapping carried out on SP.

Table 1. Details of the QTL regions that include SNP positions exceeding the 0.05 genome-wide significance threshold.

Variable	OAR	Significant SNP (n)	Range (Mb)	Highest peak		
				SNP name	Position (bp)	– log10 (*P*-value)
CAR	20	156	23.12-35.13	rs413015672	24860179	21.396
SP	20	116	23.49-35.13	rs419287784	24791184	18.025

Discussion

In our study, the two different variables led to very similar results in terms of heritability estimates and QTL detection profiles. CAR slightly outperformed SP in the significance level of the QTL on OAR 20 and further few differences were detected for some positions close to significance. Overall, heritabilities of serological response to PTB estimated by a genomic relationship matrix were moderate and consistent with previous studies, although they may be biased upwards by vertical transmission (Hickey *et al.*, 2003; Sechi *et al.*, 2011). This result suggests that selective breeding based on large scale ELISA tests may be an option to enhance resistance of sheep to MAP infection. The QTL on OAR20 identified in this study maps close to a region affecting the resistance to gastro-intestinal nematodes identified in the same experimental population (Casu *et al.*, 2022). The phenotypic variance explained by the QTL is equivalent to about 20% of the heritability of the two variables. This result seems promising for the potential application of a marker-assisted selection approach. The QTL region on OAR20, and especially its most significant segment (about 23-25 Mb), overlaps locations of some genes belonging to MHC II that are already known as involved on the genetic resistance to PTB (Kravitz *et al.*, 2021). With the aim of searching for potential causative mutations, this region was deeply investigated by using whole genome sequence data (Casu *et al.* this congress).

167. The genetic basis of sex differences in immune responses in wild Soay sheep (*Ovis aries*)

E.A. Wimborne[1], A.M. Sparks[1,2], K. Watt[1], R. Sinclair[1], J.G. Pilkington[1], J.M. Pemberton[1], T.N. McNeilly[3], D.H. Nussey[1] and S.E. Johnston[1*]

Abstract

Sex differences in immune responses are widely observed in nature. Females have stronger innate and adaptive immune responses with higher rates of autoimmunity, whereas males have reduced resource allocation to immunity. If immune traits share a genetic basis between the sexes, sexual conflict may prevent each sex from reaching their optimal phenotype, maintaining variation at immune loci. We investigated sex differences in genetic basis of immune traits in wild Soay sheep (*Ovis aries*) using sex-stratified genome-wide analyses of IgA, IgE and IgG antibody levels against the nematode *Teladorsagia circumcincta*. We found a strong genetic constraint between the sexes (r_A=0.87-0.99), indicating a strong potential for sexual conflict. We identified increased maternal effects in female lambs and sex-specific variants in the male lamb genome near the candidate genes *SHARPIN*, *LRRC14* and the IL-9 cytokine gene, indicating moderate effect alleles contributing to sex differences in immune trait variation in Soay sheep.

Introduction

Sex differences in immune responses are widely observed in nature and are likely to be source of evolutionary trade-offs (van der Most *et al.* 2011; Metcalf *et al.* 2020). Females typically have stronger innate and adaptive immune responses, with higher rates of autoimmunity due in part to the immune-enhancing effects of oestrogen (Klein and Flanagan 2016). This may enhance female reproductive success through longevity, whilst investing heavily in each reproductive effort (Zuk 2009). Conversely, males tend to have reduced resource allocation to immunity, instead improving their fecundity through mating frequency, with testosterone having a suppressive effect on immune responses (Kanda *et al.* 1996). If immune responses are heritable and share a genetic basis between the sexes, then these differences can create an opportunity for sexual conflict to prevent each sex from reaching their optimal immune phenotype (Rowe *et al.* 2018). Indeed, despite infection imposing strong selection pressures, substantial genetic variation underpinning immune responses often persists in human and livestock studies (Liston *et al.* 2016; Denholm *et al.* 2017). Yet, few studies have specifically investigated sexual conflict in immunity in vertebrate populations. Soay sheep are a primitive breed of domestic sheep that have lived wild on the St Kilda archipelago in Scotland since the Bronze age and have been intensively studied since 1985. They are infected with several gastrointestinal strongyle nematodes common to domestic sheep, predominantly *Teladorsagia circumcincta*, *Trichostrongylus axei* and *Trichostrongylus vitrinus* (Craig *et al.* 2006). A recent genome-wide association study found large-effect loci associated with anti-*Teladorsagia circumcincta* IgA, IgE and IgG at the MHC, *CIITA*/*CLEC16A* and the IGH complex loci (Sparks *et al.* 2019). Here, we investigate the potential for sexual conflict by characterising genetic correlations between the sexes and conducting sex-stratified variance component and genome wide association analyses of Ig levels in this population.

Materials & methods

Study population and data sets. The Soay study population is in the Village Bay of the island of Hirta, St Kilda, Scotland (57°49'N, 8°34'W). There is a comprehensive genomic pedigree and 7,691 individuals have been genotyped at 417,373 polymorphic SNP loci (see Stoffel *et al.* 2021 for full details). Antibody levels were previously assayed and quantified by Sparks *et al.* (2019); IgA, IgE and IgG levels were measured against *Teladorsagia circumcincta* third larval stage (L3) somatic antigens using direct (IgA, IgG) and indirect (IgE) ELISA. This was done using blood samples taken each August between 1990 and 2015.

Genetic architecture of Ig levels. Sex-specific restricted maximum likelihood animal models were run in in ASReml-R v4.1 for IgA, IgE and IgG levels in lambs and adults. Fixed effects included age in days for lambs and years for adults. Random effects included the additive genetic component, birth year, mother identity, individual identity (permanent environment) ELISA plate number and run date. Genetic correlations between the sexes were fit in bivariate models using the CORGH and IDH functions for each age class using the same fixed and random effect structures. Sex-specific genome-wide association studies (GWAS) were carried out using the rGLS function in RepeatABEL v1.133, including a genomic kinship matrix and the same model structure defined as above. This approach fit SNPs as an additive effect (0, 1 and 2) for each genotype as a fixed covariate. The significance threshold at α=0.05 was set at P=2.245×10^{-6} as in Johnston *et al.* (2016). Gene by sex interactions were investigated using bivariate linkage disequilibrium score regression analysis (Bernabeu *et al.* 2021):

$$t = \frac{b_{males} + b_{females}}{\sqrt{SE^2_{males} + SE^2_{females} - 2r \cdot SE_{males} \cdot SE_{females}}}$$

where b is the estimated SNP effect sizes from the GWAS, SE is the standard error of b and r is the Spearman rank correlation (r).

Results

IgA, IgE and IgG levels were significantly heritable and were similar between the sexes within each age class (Figure 1 and 2). IgA had the greatest additive genetic effects (h^2=0.45-0.61), whereas IgE ranged from 0.19-0.46 and IgG from 0.18-0.26. The presence of high inter-individual variation, demonstrated by the permanent environmental and additive genetic effects, suggests repeatability of the antibody levels across the individual's lifetimes (repeatabilities of IgA: 0.74 and 0.77, IgE: 0.70 and 0.80, IgG: 0.51 and 0.48 for male and female adults; Figure 1 and 2). Generally, there were no significant maternal effects with the exception of female lamb IgA antibody levels. Other random effects including birth year, capture year, ELISA plate identity and run date explained between 1-8% of the phenotypic variance. Genetic correlations were strongly positive between the sexes for all three antibody traits in both lambs and adults, with rA ranging between 0.87 and 0.99.

Both male and female lambs confirmed previous associations with *CIITA/CLEC16A* (females: oar3_OAR24_10616039, P=1.18×10^{-17}; males: oar3_OAR24_10712874, P=1.70×10^{-15}). Male lamb IgE levels were significantly associated with *oar3_OAR9_12632265* on chromosome 9 (P=1.35×10^{-06}), ~1.05 Mb upstream from the candidate genes *SHARPIN* with mutations associated with IgA, IgE and IgG level variation in mice (Wang *et al.* 2012), and ~0.75 Mb upstream *LRRC14*, which is involved in NF-kB and TLR immune signalling (Wu *et al.* 2016). Male lamb IgG levels were associated oar3_OAR5_45528930 on chromosome 5 (P=1.67×10^{06}), located ~0.8 Mb downstream of the IL-9 cytokine gene, which is associated with IgG antibody production and decreased parasitic infection susceptibility in mice and humans (Petit-Frere *et al.* 1993; Dugas *et al.* 1993). No significant sex by genotype interactions effects (P<0.05) were observed for any Ig traits in either age or sex class.

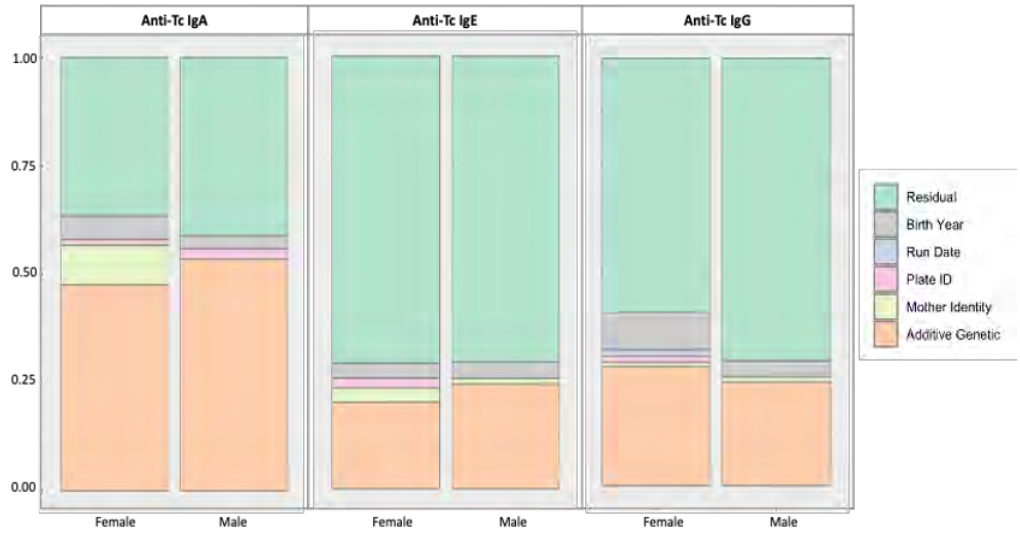

Figure 1. Proportion of phenotypic variance attributed to each random effect in lambs.

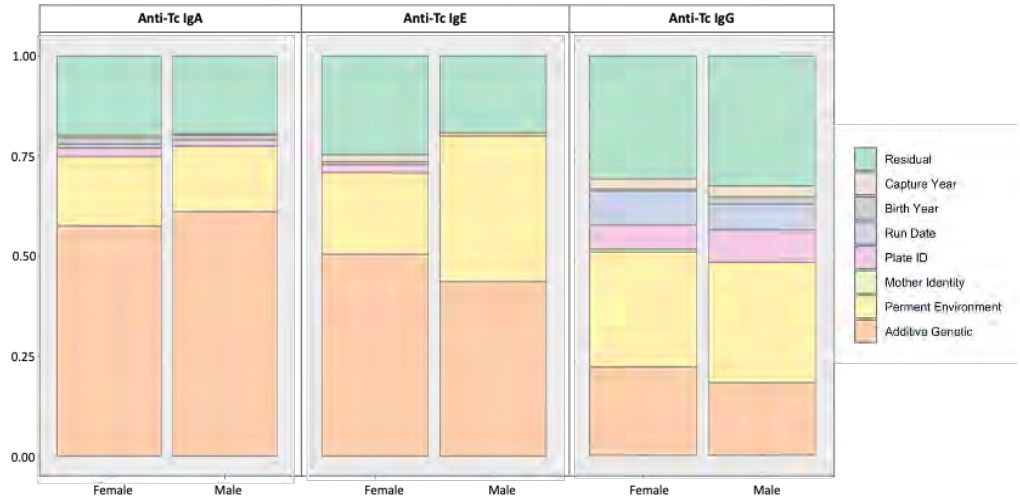

Figure 2. Proportion of phenotypic variance attributed to each random effect in adults.

Discussion

Soay females were previously shown to have higher IgA, IgE and IgG antibody levels, following trends of enhanced female innate and adaptive responses in other vertebrate species (Sparks *et al.* 2019). Nevertheless, we observed strong genetic correlations (r_A<0.867) and similar levels of trait heritability between males and females for IgA, IgE and IgG levels in Soay sheep, indicating a similar genetic basis between the sexes. High genetic correlations imply a genetic constraint, reducing the evolvability of sexual dimorphism in these traits and potentially explaining the maintenance of genetic variation (Rolff *et al.* 2005). However, the contributions of environmental heterogeneity should also not be overlooked in this analysis, especially considering the extreme variation in weather, population density and nutritional supply on St Kilda.

The loci *SHARPIN*, *LRRC14* and *IL-9* were associated with male Ig levels. It should be noted that despite occurring up to 1 Mb away, high linkage disequilibrium in this population indicates potential for these candidate regions to have an effect on immune phenotype (Sparks *et al.*, 2019), but should be confirmed with functional studies. Future work will also investigate associations between previously and currently identified immune loci with sex-specific reproductive success and survival, and explore how further mechanisms maintain variation, such as frequency-dependent selection, age, and parent-offspring conflict.

168. New tools and insights to enable breeding for reduced disease transmission

A. Doeschl-Wilson[1*], G. Marion[2] and C.M. Pooley[1,2]

[1]The Roslin Institute, University of Edinburgh, Easter Bush EH25 9RG United Kingdom; [2]Biomathematics and Statistics Scotland, The King's Buildings, Edinburgh EH9 3FD, United Kingdom; andrea.wilson@roslin.ed.ac.uk

Abstract

Theoretical and empirical evidence indicates there is far more host genetic variation underlying infectious disease prevalence than currently utilized in breeding programmes. In particular, genetic variation in host propensity to transmit infection is rarely fully captured. This paper describes methods now available for estimating genetic effects underlying infectious disease transmission, and novel insights regarding genetic (co-) regulation of the corresponding host epidemiological traits from empirical studies. Results show we now have the tools available to obtain reliable estimates for genetic effects for host susceptibility, infectivity and recovery or death rates from individual disease data, given the appropriate experimental or field study design. Substantial genetic (co-)variation appears to exist for all three epidemiological host traits and previously identified resistance genotypes may also confer genotypic differences in at least one if not all of these traits, thus holding great promise to drastically improve the effectiveness of genetic disease control.

Introduction

Reducing the transmission of infectious pathogens is a critical component of sustainable livestock production (Doeschl-Wilson *et al.*, 2021). Yet, it is currently not known how to breed animals for low disease transmission, as quantifying the underlying host genetic contributions remains a long-standing challenge. Epidemiological theory points to three key host traits regulating infectious disease transmission: susceptibility (propensity to acquire infection), infectivity (propensity to pass on infection to others) and recovery or death rate post infection, which affects the duration that an infected animal can transmit infection (Pooley *et al.*, 2020; Bijma *et al.,* 2021). Despite increasing empirical evidence for substantial genetic variation in these traits (e.g. Welderufael *et al.*, 2018, Anacleto *et al.,* 2019; Chase-Topping *et al.*, 2021; Prentice *et al.,* 2022), genetic parameter estimates for these traits rarely exist. Furthermore, the effects of previously identified resistance genotypes (e.g. based on single SNPs or estimated breeding values) on these epidemiological traits are largely unknown. Therefore, it is difficult to predict to what extent genetic selection for disease resistance also reduces disease transmission and prevalence (Hulst *et al.*, 2021; García-Ballesteros *et al.,* 2022).

In this paper we give an overview of recently developed methods and data requirements for estimating genetic parameters and genotypic effects for these three host epidemiological traits. We collate key insights about their genetic (co-)regulation gained from experimental and field studies in different host and pathogen species. We conclude by outlining further research needs to transform livestock breeding programmes to not only reduce the direct impact of infectious disease on individuals' production and health, but also their transmission and prevalence.

Materials & methods

Methods and software for estimating genetic effects underlying disease transmission. Compared to conventional genetic analyses of disease resistance phenotypes, models for estimating genetic effects underlying disease transmission need to incorporate epidemiological concepts (Pooley *et al.*, 2020; Bijma *et al.*, 2021). These concepts have been recently implemented in the open-source Bayesian inference software called SIRE (Susceptibility-Infectivity-Recoverability Estimator) which provides simultaneous estimates of

genetic effects on host susceptibility, infectivity and recovery / death rates from various types of individuals' disease records from epidemics that can be represented by an epidemiological susceptible-infectious-recovered (SIR) model (Pooley *et al.*, 2020, 2022a). SIRE implements three hierarchical models: (1) a genetic model for the three host epidemiological traits, which incorporates either the effects of a specific SNP or genotype (e.g. known to be associated with resistance) under consideration (Pooley *et al.*, 2020) or additive genetic (co)-variance for polygenic traits (SIRE 2.0; Pooley *et al.*, 2022b), together with other fixed and random effects; (2) an epidemiological model that links the three epidemiological traits to individuals' (usually unobservable) infection and recovery/death times; and (3) an observational model that links individuals' infection status to their disease records. The software has been validated with different types of data from a large range of simulated epidemics, which also provided insights into data requirements for obtaining sufficiently precise estimates for the genotypic effects (Pooley *et al.*, 2020) or genetic parameter estimates, and for achieving high prediction accuracies for the epidemiological traits (Pooley *et al.*, 2022a).

Methods and software to aid experimental designs. First empirical estimates of genetic effects for the epidemiological host traits may be best derived from controlled disease transmission experiments (Doeschl-Wilson *et al.*, 2021). We recently developed an open source online software tool SIRE-PC, (SIRE Precision Calculator) to assist with the design of these in the case of a single SNP under investigation (e.g. one already known to be associated with disease resistance) (Pooley *et al.*, 2022b). SIRE-PC provides precision estimates for SNP substitution and dominance effects for all three host epidemiological traits depending on experimental designs specified by the user, and optimal solutions for different types of experimental designs. These estimates are based on analytical expressions for the precision of estimated SNP substitution and dominance effects for the three epidemiological traits, and have been validated with simulated experiments using the above described SIRE software (Pooley *et al.*, 2022b).

Results

Software validation and insights from simulation studies. Extensive validations of both versions of the SIRE software show that it is possible to obtain accurate and unbiased estimates of genetic effects (e.g. SNP effects and genetic parameter estimates) associated with all three epidemiological host traits from individual temporal epidemic data, even when that data is incomplete (Pooley *et al.,* 2020, 2022b) for detailed assessment of influencing factors on these estimates). To summarize: inference of genetic parameter estimates and SNP effects for all three traits is possible even when only recovery (or death) times of individuals are known, or when measures of individuals' infection status are infrequent or censored. Unsurprisingly this requires larger datasets to gain equivalent precision and prediction accuracies compared with perfect data. For genetic infectivity effects, a large number of contact groups with few individuals generally provides better estimates than the converse.

Optimal designs for transmission experiments. Maximising analytical expressions for the precision on SNP effects led to three distinct 'experimental' designs (potentially consisting of several replicates), each specifying a different set of ideal SNP genotype compositions across contact groups: (1) appropriate for a single contact-group per replicate; (2) a multi-group 'mixed' design; and (3) a multi-group 'pure' design, where 'mixed' and 'pure' refer to contact groups consisting of contact individuals with different (mixed) or same genotypes, respectively (Figure 1). Precision estimates for infectivity were found more sensitive to the experimental design than those for susceptibility or recovery/death rate. The multi-group designs provide more precise estimates for infectivity effects than the single-group design containing the same number of individuals and records (e.g. standard deviation for the optimal single group design in Figure 1 was 1.5 higher than for the multi-group designs). Whilst the multi-group pure and mixed designs are predicted to yield similar precisions (results not shown), the pure design may be more intuitive and robust to stochastic

effects. In contrast, the mixed design may be preferable if the number of contact groups is limited or if artificially infected seeder animals are used.

Insights from disease transmission experiments and field studies. Table 1 shows summary results from various experiments that assessed the effects of known disease resistance genotypes on disease transmission. Most of these applied the 'multi-group pure design' (Figure 1). The studies confirm the predictions from simulation studies, that it is possible to obtain informative estimates for the genetic effects for all three epidemiological traits even from relatively small scale transmission experiments and incomplete data. There was a large difference between estimated genotypic effects on the diverse epidemiological host traits across studies, with e.g. genotypic differences in host infectivity ranging from negligible to large (Table 1). The same is true for the first published genetic parameter estimates for polygenic epidemiological host traits obtained from field and experimental studies (Welderrufael *et al.*, 2018; Biemans *et al.*, 2019; Prentice *et al.*, 2022; Sanchez-Molano *et al.*, 2022), which indicate that substantial genetic variation and co-variation could exist in any or all epidemiological traits.

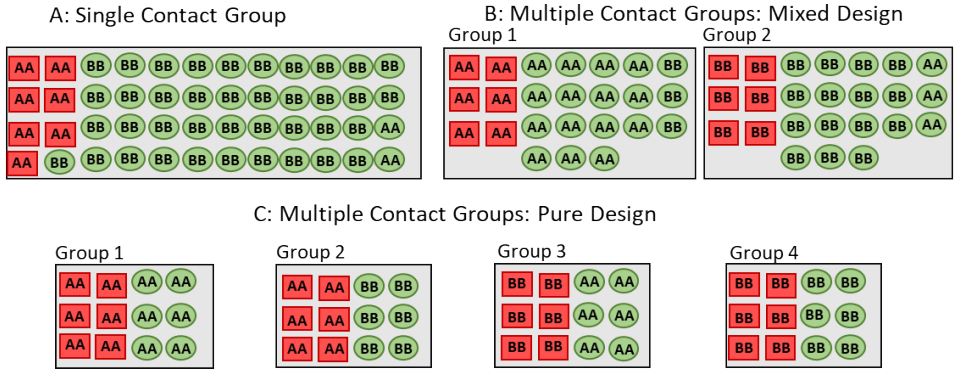

Figure 1. Optimal experimental designs for estimating genotype effects on host infectivity without compromising estimation of susceptibility and recovery rate. Assumptions underlying the analysis shown here: bi-allelic SNPs (A,B), only additive genotypic effects, random distribution of individuals regarding other influencing factors (e.g. family structure), fixed number of individuals (here n=48) per replicate. Red boxes: individuals infected at the start of the experiment; green circles: initially uninfected individuals.

Table 1. Empirical estimates of resistance genotype effects on transmission parameters.

Discussion

Genetic infectious disease control would strongly benefit from shifting the current focus on improving individuals' disease resistance towards reducing disease transmission in populations (Bijma *et al.* 2021; Doeschl-Wilson *et al.* 2021). Estimating genetic effects for the three epidemiological host traits is now possible and constitutes an important step towards this goal. Necessary future developments include improvements in the existing computational inference methods to accommodate a larger variety of genomic and epidemic models and data, as well routine implementation of genetic-epidemiological models to predict response to selection (Bijma *et al.*, 2021; Doeschl-Wilson *et al.*, 2021; García-Ballesteros *et al.,* 2022).

Abstract

Evolutionary theory predicts substantial genetic variation in host infectivity influences infectious disease spread and mortality rates in populations. This study combined data from a bespoke transmission experiment in turbot, and novel inference software (SIRE 2.1) to provide empirical genetic parameter estimates for host infectivity, in addition to susceptibility and infection induced mortality. Validation of SIRE 2.1 with simulated disease and survival data mimicking the experimental design provided reliable (co-) variance estimates and high prediction accuracies for all three traits. Confirming theoretical expectations, posterior means for genetic variance in host infectivity, estimated from the experimental data, were at least twofold higher than those for susceptibility and mortality respectively. Infectivity was positively genetically correlated with mortality. The results highlight the huge potential to reduce infectious disease transmission in livestock through genetic selection.

Introduction

Infectious diseases can cause high loss of animals in livestock production. To mitigate its impact on animal health and welfare, many breeders of aquatic and terrestrial livestock species tend to select animals that are genetically more likely to survive when exposed to infectious pathogens (Saura *et al.*, 2019). However, it is currently unknown to what extent this selection strategy reduces disease transmission, as survivors may still become infected and transmit infections, becoming 'tolerant super-spreaders' in the worst case scenario.

Determining animals' genetic contribution to infectious disease transmission, requires understanding the genetic (co-)regulation of three key epidemiological host traits: susceptibility (propensity to acquire infection), infectivity (propensity to pass on infection to others), and recovery or mortality post infection, which affects the duration that an infected animal can transmit infection (Pooley *et al.*, 2020). In line with the common genetic architecture of conventional disease traits, these traits are also expected to be polygenic. Furthermore, evolutionary theory suggests that genetic variation may be higher for host infectivity than for the other epidemiological host traits (Lipschutz-Powell *et al.*, 2012). However, to date no empirical genetic parameter estimates for these three traits exist despite strong evidence that the traits are under genetic control (Doeschl-Wilson *et al.*, 2022).

This study uses data from a bespoke transmission experiment for parasite infections in turbot fish (*Scophthalmus maximus*) that had been specifically designed to provide empirical genetic parameter estimates for all three epidemiological host traits (Anacleto *et al.*, 2019). The parasite was *Philasterides dicentrarchi*, which is the causative agent of scuticociliatosis, which manifests itself with the onset of visual signs, and is a common cause of mortality in turbot farming. Previous analyses of this experimental data provided evidence that genetic variation in host infectivity, in addition to variation in the time to onset of clinical signs (termed resistance) and the time from onset of signs to death (termed endurance) exists and

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_169, © J.C. Prentice *et al.* 2022

affects disease spread and survival of fish (Anacleto *et al.*, 2019). Furthermore, estimates for heritabilities and candidate SNPs for resistance and endurance traits by Saura *et al.* (2019), showed no significant genetic correlation between them.

The aim of this study was to estimate genetic parameters for the three unobservable host epidemiological traits (susceptibility, infectivity, and mortality post infection) from these data. For this purpose, we adapted our recently developed Bayesian inference software SIRE (Susceptibility-Infectivity-Recoverability Estimation) (Pooley *et al.*, 2022) to fit the data. To validate the empirical results, we evaluated the software first on simulated data.

Methods & materials

Experimental design and data. We refer to Anacleto *et al.* (2019) and Saura *et al.* (2019) for a detailed description of the experimental design and data. Briefly, the experiment consisted of two consecutive trials, each comprising ~900 turbot from 22 (Trial 1) and 23 (Trial 2) full-sibling families generated from 29 sires and 25 dams, respectively. Fish in each trial were distributed into 36 isolated tanks, each comprising 25 fish (5 initially infected seeder fish, 20 naive contact fish; 5 individuals per full-sib family; families were assigned to tanks to maximise statistical power for parameter estimation). In each tank the infection was seeded by inoculating the seeder fish at the start of the experiment, with the 50,000 (Trial 1) and 56,000 (Trial 2) ciliates of *Philasterides dicentrarchi* diluted in 200 µl saline (Anacleto *et al.*, 2019). Infected fish that developed scuticociliatosis were identified by the development of visible signs such as changes in colour or behaviour (Anacleto *et al.*, 2019). The phenotypic data used for the genetic analyses in this and previous studies consisted of individual records of the time (days post exposure) at which visual signs were first observed (t_S, which is different to the time of infection), and time of death (t_D). Sire and dam information was available for all individuals, and used to generate the numerator relationship matrix (A).

Bayesian inference of genetic parameter estimates for the epidemiological host traits. The recently developed Bayesian inference software SIRE 2.0 (Pooley *et al.*, 2022) was adapted to infer genetic parameter estimates for the three epidemiological host traits from this data. The software has been specifically designed to produce posterior parameter estimates for these traits from a wide range of individual disease records (Pooley *et al.*, 2020, 2022). Central to the inference process is to specify the underlying epidemiological model that links the epidemiological host traits to individual infection status, combined with the genetic models for each trait. The infection profiles of the seeder and contact fish strongly indicated that fish were infectious before they developed visual signs. Hence, an epidemiological model that fits this infection pattern is the SIDR model, where *S* refers to the susceptible state, *I* is infectious but undetectable, *D* is infectious and detectable, and *R* is removed (dead).

The rate of new infections S→I is described by the force of infection $\lambda_i = \beta \exp(g_i) \sum_j \exp(f_j)$ (summed over all infectious individuals *j* in the same group as *i*). The times taken for individual *i* to transition I→D and D→R are gamma distributed with means $1/\rho$ and $\exp(r_i)/\mu$, and shape parameters k_{ID} and k_{DR} respectively. Here β is the mean *per capita* transmission rate for the disease, ρ is the mean *per capita* detection rate, and μ is the mean *per capita* infection induced mortality rate, g_i, f_i, and r_i represent fractional deviations in the susceptibility, infectivity, and infection induced mortality rates of individual *i* compared to a population-wide reference. The phenotypic fractional deviations in susceptibility, infectivity, and infection induced mortality were defined as x = a + e, where x refers to the phenotypic vector for the three epidemiological traits, the additive genetic effect $a \sim \text{MVN}(0, \text{A}\otimes\Omega)$, where A and Ω are the numerator relationship matrix and is a 3×3 genetic trait covariance matrix, and the random environmental effects $e \sim \text{MVN}(0, \text{I}\otimes\Psi)$, where I and Ψ denote the 3×3 identity and environmental trait covariance matrices.

Validation of SIRE 2.1 with simulated data. To validate SIRE 2.1's ability to provide reliable estimates for genetic parameters and high prediction accuracies for the epidemiological traits, we first simulated the above experimental design (using the same pedigree, group layout, assignments, and population size), and generated simulated data for t_S and t_D using a stochastic implementation of the SIDR epidemiological model described above (algorithm described in Pooley *et al.* 2020). The values for the epidemiological trait means were chosen to provide similar population profiles for t_S and t_D as those observed in the experiment, the genetic and environmental trait variances were arbitrarily assumed to be 0.5 (h^2=0.5), and genetic correlations were set to 0.4. A total of 20 epidemiological replicates were simulated and the A-matrix, tank ID, and simulated times t_S and t_D for each individual were passed to SIRE 2.1 for inference. SIRE 2.1 was run to generate 10^7 samples, sufficient to ensure convergence (estimated sample size >200 for each parameter). Precision for variance and covariance estimates was assessed by comparing the posterior means and the 95% credible intervals (C.I.) with the true values, and prediction accuracies were estimated as the Pearson correlation between the true and estimated breeding values.

Application of SIRE 2.1 to experimental data. The procedure described above was applied to the experimental data for individuals' t_S and t_D. These were rounded to the nearest day, and t_S was adjusted to be one day earlier if both days coincided. Both trials were analysed separately, as their epidemic profiles differed substantially (Anacleto *et al.*, 2019).

Results

Validation of SIRE 2.1 with simulated data. SIRE 2.1 was able to provide reliable estimates for the genetic variances and correlations for all three epidemiological host traits (Figure 1). The results suggest that despite high uncertainties in the variance component estimates, the experimental design would allow detection of genetic variance and correlations between the traits, if they exist. Similarly, reasonably high prediction accuracies (95% C.I.) were obtained for all three traits. These were 0.594 (0.314, 0.795) for susceptibility *g*, 0.455 (0.209, 0.770) for infectivity *f*, and 0.772 (0.659, 0.871) for mortality *r*.

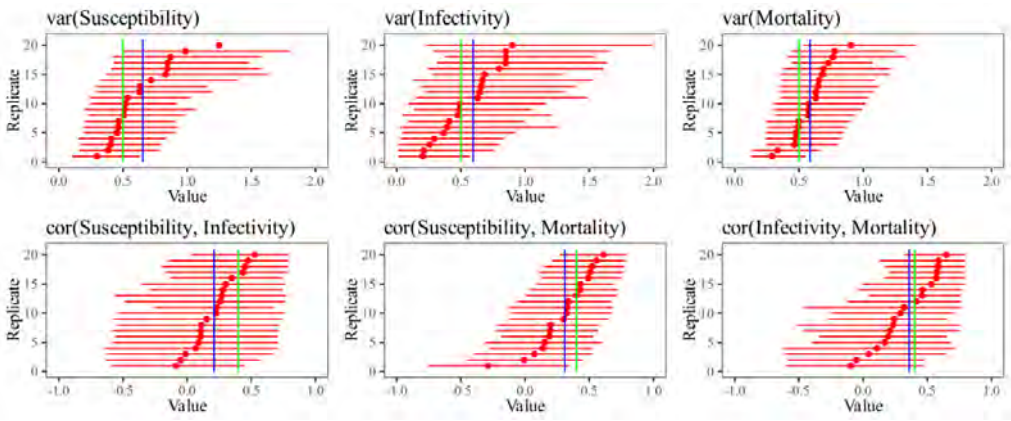

Figure 1. Validating estimated trait variance-covariances: Tornado plots showing estimated posterior means (red dots) with 95% C.I. (red horizontal lines) for additive genetic variances and correlations for the three epidemiological traits. Green vertical lines show the true parameter value, blue lines refer to the estimated mean across all 20 replicates. Each line refers to one replicate.

Genetic parameter estimates for host susceptibility, infectivity, and mortality from experimental data. Significant positive additive genetic variance was found for all three traits, with genetic variance in infectivity substantially larger than for susceptibility or mortality, respectively (Table 1). Despite substantial uncertainty in the estimates, genetic correlation between the traits seems to be weak to moderate.

Table 1. Estimated Ω: genetic variance (along diagonal) and correlation (off diagonal) estimates (95% C.I.) for log-normally distributed host traits, for Trials 1 and 2.

		Susceptibility	Infectivity	Mortality
Trial 1	Susceptibility	0.08 (0.00, 0.24)	-0.29 (-0.50, 0.26)	0.39 (0.01, 0.50)
	Infectivity		1.51 (0.63, 2.67)	0.24 (-0.16, 0.49)
	Mortality			0.66 (0.39, 0.96)
Trial 2	Susceptibility	0.06 (0, 0.24)	-0.07 (-0.48, 0.45)	0.08 (-0.46, 0.49)
	Infectivity		2.78 (2.28, 2.99)	-0.29 (-0.49, 0.17)
	Mortality			0.05 (0.00, 0.19)

Discussion

This study demonstrates that it is possible to obtain reliable genetic parameter estimates for three epidemiological traits controlling disease transmission given appropriate experimental design, and produces the first empirical estimates for all three traits. These findings support previous hypotheses that there is substantially more host genetic variation underlying disease prevalence than currently utilised in breeding programmes, and in particular in host infectivity (Bijma *et al.*, 2021; Lipschutz-Powell *et al.*, 2012). Further validation of these results is required by including additional effects and fitting a wider range of genetic and epidemiological models. However these preliminary results suggest that it may be possible to select turbot that not only have higher genetic resistance and endurance to scuticociliatosis infection, as previously suggested (Saura *et al.*, 2019), but are also less likely to transmit it.

170. Impact of selection for disease resistance on the spread of infection in a simulated aquaculture population

Abstract

Disease resistance is a common breeding objective in aquaculture selection programmes. The main phenotype recorded is the time of death, which depends on three underlying epidemiological host traits: susceptibility, infectivity and infection induced mortality. The aim of this simulation study was to predict the impact of selection for time of death on these underlying traits and on the spread of the disease in a fish population. The time of death phenotypes were obtained by simulating virus transmission in a disease challenge experiment for Atlantic salmon with genetic variation assumed in the three epidemiological traits. Three scenarios varying in the point where the challenge test was stopped were simulated. Selection for time of death reduced disease spread evaluated through the basic reproductive ratio in all scenarios. However, the greatest decrease in the basic reproductive ratio (reaching values <1) was when the challenge test continued until mortality naturally levels off.

Introduction

Infectious disease outbreaks are a major threat to the economic and environmental sustainability of the aquaculture industry and it is accepted that selective breeding could be a key factor to prevent these outbreaks (Houston *et al.* 2020). In fact, disease resistance (the ability to survive when exposed to the pathogen) is included as a breeding objective in species with advanced selective breeding programmes.

In aquaculture programmes, disease resistance is often recorded on sibs of selection candidates in challenge tests, and the main phenotype is time of death (Doeschl-Wilson *et al.* 2021). However, it is unknown whether selecting directly on time of death reduces pathogen transmission and, thus, the incidence and severity of outbreaks (Doeschl-Wilson *et al.* 2021). This is because the spread of the disease is affected by three underlying epidemiological host traits, which are difficult to record: susceptibility (the propensity of an uninfected individual to become infected when exposed to infectious material), infectivity (the ability of an individual, once infected, to transmit the infection) and mortality (the propensity of an infected individual to die).

The objective of this study was to predict, through computer simulations, the impact of selection for disease resistance measured as time to death on the three underlying traits and, therefore, on the spread of the disease by mimicking a selective breeding programme for Atlantic salmon.

Materials & methods

Genetic and population models. The genome simulated was composed of 30 chromosomes of 1 Morgan each, approximating the salmon genome. A total of 31,500 evenly spaced biallelic loci (including 1,500 SNP markers to be used in genomic evaluations) were simulated per chromosome. The base population was created in a two-step process. Firstly, a large population in mutation-drift equilibrium was generated by randomly selecting 500 males and 500 females across 4,000 discrete generations. Secondly, once the equilibrium was reached, 100 males were randomly mated with 200 females (200 full sib families) in order to simulate a base population with family structure. Each mating produced 30 fish (10 selection candidates and 20 sibs to be used in the challenge test).

Underlying traits. Three uncorrelated traits (susceptibility, infectivity and mortality) were considered. A total of 1000 loci (randomly sampled from the 31,500 loci) affected simultaneously the three traits for which the initial phenotypic variance and the heritability (h^2) were 1 and 0.5, respectively, leading to a h^2 for the observed trait (time of death) of 0.2. The phenotypic value was obtained by adding to the true breeding value an environmental deviation sampled from a normal distribution with mean 0 and variance 0.5.

Observed trait. The observed trait was time of death (day when an individual dies from the beginning of the challenge test) which depends on infection and, once infected, death times. These times were obtained assuming a stochastic compartmental Susceptible-Infected-Removed epidemiological model. The algorithm used (based on Anacleto *et al.* 2015) specifies inter-event times which determine the transition rates of individuals to move between susceptible to infected determined by the force of infection (the infection rate of an individual j) $\lambda_j = \beta \exp(S_j) \sum_i \exp(I_i)$ and to move between infected to dead $w_j = (\gamma \exp(M_j))$, where β is a mean *per capita* transmission rate for the disease, γ is a mean *per capita* infection induced death rate, S_j and M_j represent fractional deviations in the susceptibility and infection induced mortality rates of individual j compared to a population-wide reference, and I_i represents the fractional deviation in infectivity of individual i (the sum goes over all infected individuals sharing the same contact group as j at any given point in time). Estimates for β and γ were obtained by matching simulated infection and survival profiles to those from published studies of ISA virus challenge experiments in Atlantic salmon with fast transmission (Ødegård *et al.* 2007; Chase-Topping *et al.* 2021). Simulated challenge tests consisted of 20 groups, each of 200 fish (one from each family). The infection was seeded by randomly choosing five fish per group as initially infected. The rest of the individuals were considered susceptible. Three scenarios varying in the point where the challenge test was stopped were simulated. The test was stopped when the cumulative mortality reached an asymptote, which occurred at ~60 days with 80% of dead fish (scenario A), when 50% of the fish per group were dead, which occurred on day ~16 (scenario B) or when 25% of the fish per group were dead, which occurred on day ~7 (scenario C). The survivors' phenotype was assumed to be the last day of the challenge test plus one (i.e. day 61, 17 and 8 for A, B and C, respectively).

Genetic evaluation and selection. Standard genomic evaluation (GBLUP) using 1,500 SNPs/Morgan was implemented to obtain estimates of breeding values for the observed trait. The BLUPf90 software (Misztal *et al.* 2015) was used for carrying out GBLUP evaluation. The 100 males and the 200 females with the highest estimated breeding value for time of death were selected each generation. Each selected male was randomly mated with two females and each mating produced 30 fish (10 selection candidates and 20 sibs to be used in the challenge test). Selection was practised for 10 discrete generations.

Parameters evaluated. For each generation t, the cumulative genetic gain for each underlying trait was calculated as the true breeding value averaged across all fish born in t. The basic reproductive ratio (R_0) was also evaluated as a measure of the impact of selection for disease resistance (time to death) on the spread of the disease. Extrapolating from Hyman and Li (2000) the expected theoretical R_0 was estimated for each group by randomly choosing an individual as infected index case (IC) in an otherwise susceptible population:

$$R_0 = (\beta/\gamma) * \left(\sum_{i=1}^{n} (\exp(S_i)) \Big/ n \right) * \left(\exp(I_{IC}) / \exp(M_{IC}) \right),$$

where β and γ (defined above) are 0.8 and 0.4 respectively, n is the total number of susceptible fish per group (excluding the fish chosen as IC), S_i is the susceptibility phenotype of fish i and I_{IC} and M_{IC} are respectively the infectivity and mortality phenotypes of the fish chosen as IC. For each group, R_0 was computed as the average R_0 calculated with the five initially infected fish as IC. Finally, for a given generation, R_0 was calculated as the average R_0 across groups. A total of 25 replicates were simulated and the results presented are averages over replicates.

Results

Selection for disease resistance (time of death) led to a reduction in all three underlying traits although the magnitude of the response for each trait differed across the scenarios considered (Figure 1). In scenario A, the genetic gain was mainly for susceptibility. As the duration of the challenge test decreased, the gain of the three traits became more similar, although in the three scenarios the lowest response was obtained for infectivity. At t=10, the genetic gain for susceptibility was 30% (scenario B) and 47% (scenario C) lower than in scenario A. However, the gain for mortality and infectivity was about double in scenarios B and C than in A.

Selection for time of death decreased R_0 in all scenarios (Figure 2). However, only scenario A led to an R_0 value below 1 and this was reached at t=5. Reducing R_0 below 1 is an important objective, as it implies that the disease cannot spread.

Discussion

In this study, we have simulated a disease leading to high mortality within a 60-day time window with mortality profiles similar to those found in some diseases of great importance such as infectious salmon anaemia (Ødegård *et al.* 2007, Holborn *et al.* 2020). We show that selection for disease resistance (measured as time of death) not only increases survival (Houston *et al.* 2020, Doeschl-Wilson *et al.* 2021), but also contributes to reducing disease transmission in a severe outbreak when the underlying traits are assumed to be uncorrelated.

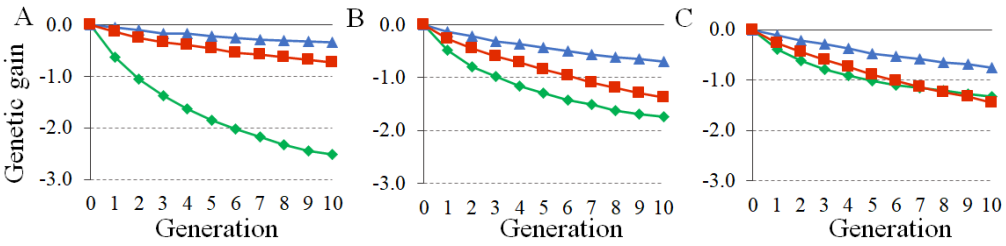

Figure 1. Cumulative genetic gain across generations for each trait (susceptibility in diamonds, infectivity in triangles and mortality in squares) for scenarios varying in the proportion of cumulative mortality at the end of the challenge (scenarios A, B and C).

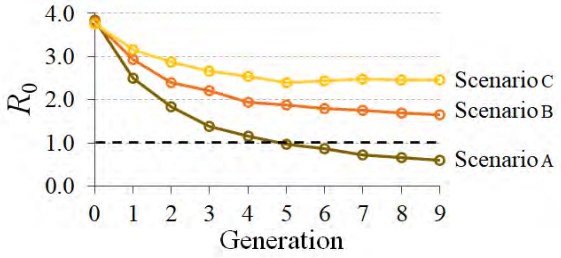

Figure 2. Basic reproductive ratio (R_0) across generations for scenarios varying in the proportion of cumulative mortality at the end of the challenge (scenarios A, B and C).

The genetic response for each underlying trait and R_0 depended on when the challenge test was stopped. The closer the end of the challenge test was to the point where cumulative mortality rate reached an asymptote, the greater the response in susceptibility and the greater the decrease in R_0. In this case, the survivors at the end of the test were mainly fish with low susceptibility (they were not infected or they were infected late and did not die before the end of the test). However, when the challenge test was stopped before the asymptote in the cumulative mortality rate was reached, the genetic response in susceptibility and the decrease in R_0 were lower and the response in infectivity and infection induced mortality was higher. In this case, the survivors were fish with low susceptibility, but also fish with medium and high susceptibility and medium and low mortality (i.e. fish that were infected but survived with the infection for a long time and had not yet died when the challenge test was stopped) and also fish with high and medium susceptibility that coexist with groups of infected fish with less infectivity (in scenarios B and C, fish with low infectivity and low mortality have less chance/time of infecting).

In summary, our results highlight the fact that, if the selection objective is to control the spread of the disease, the challenge test should continue until mortality naturally levels off.

Abstract

We assessed the usefulness of defining kinship based on the combinations of alleles (haplotypes) instead of individual alleles for genomic predictions of milk traits. The accuracy and bias of predictions were calculated when pure Holstein (H), pure Jersey (J) and/or H×J crossbred cattle were included in the reference set. For within-breed predictions, using haplotypes marginally improved the accuracy by 1%. For across-breed predictions, using haplotypes of 5 adjacent markers increased the accuracy of prediction for fat yield for H and J by 4 and 2%, respectively. The most consistent gains for H (1.8%) and J (1.5%) were achieved when all pure and crossbred animals were included in the reference. The change in accuracy of predictions for crossbred animals was not consistent, which could be associated with shorter haplotypes and lower accuracy of phasing. Generally, the bias of predictions was lower when haplotypes were used in the relationship matrix.

Introduction

Genomic prediction relies on linkage disequilibrium (LD) between single nucleotide polymorphism (SNP) markers and causal variants. However, this LD could be different across breeds mainly due to crossing over and change in allele frequency after breed formation. Consequently, the accuracy of across-breed predictions is lower than within breed predictions (Khansefid *et al.*, 2020). To avoid this problem, the causal mutations, or the SNPs close to them should be used to build the genomic relationship matrix (GRM). However, finding all of the causal mutations is difficult because most of them have very small effects (Xiang *et al.*, 2021). Using haplotypes instead of SNPs might better describe the relationship between individuals of different breeds in admixed populations because it could distinguish identity by descent from identity by state to some extent (Ferdosi *et al.*, 2016). In this study, we calculated the accuracy and bias of genomic estimated breeding values (GEBV) for milk traits by replacing the GRM with a haplotype relationship matrix (HRM). We assessed the usefulness of the HRM for within-breed, across-breed and crossbred genomic prediction.

Materials & methods

Phenotypes and genotypes. The data used in this study were described by Khansefid *et al.* (2020). The animals were recorded for milk traits in New Zealand. For milk, fat and protein yields, the de-regressed proofs (DRP) for bulls and their equivalent records for cows (adjusted fixed effects) were calculated by DataGene (all cow phenotypes were processed on the Australia scale). The animals had XT_50k imputed genotypes which consisted of 46,516 SNPs enriched for causal variants (Xiang *et al.*, 2021). In total, 14,987 pure H and 5,016 pure J bulls and cows as well as 20,281 crossbred cows were used in this study. The crossbred cows were divided into three subgroups according to their breed proportions (~75%H:25%J,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_171, © M. Khansefid *et al.* 2022

~50%H:50%J, and ~25%H:75%J). The genotypes of all animals were phased using Eagle v2.4.1 with default parameters (Loh *et al.*, 2016).

Reference and validation sets. Four reference sets in our study were R_1 (13,985 pure H), R_2 (4,484 pure J), R_3 ($R_1 + R_2$) and R_4 ($R_1 + R_2$ + 18,469 H×J crossbred). The validation sets consisted of 1,002 pure H, 863 75%H:25%J, 868 50%H:50%J, 324 25%H:75%J and 532 pure J cows which were selected to avoid high relationships with animals in the reference sets.

Prediction model. MTG2 (Lee and van der Werf, 2016) was used to calculate GEBV when the same validation set but different reference sets were included in the model (Equation 1).

$$y = Xb + Zu + e \quad (1)$$

where y contains DRP for milk, fat, or protein yields for the animals in the reference; b, $u \sim N(0, A\sigma^2_a)$ and $e \sim N(0, E\sigma^2_e)$ are the vectors of fixed effects (mean and sex-breed group), random effects (GEBV) and random residual effects, respectively; X and Z are design matrices. The genetic variance (σ^2_a) in this model was estimated when the relationships between animals in matrix A were defined by either a GRM (Yang *et al.*, 2010) or HRM. The HRM was calculated using the sliding window algorithm (Ferdosi *et al.*, 2016) and three haplotype sizes (5, 10 and 15). The error variance (σ^2_e) was estimated considering the weighting coefficients in diagonal E matrix (Garrick *et al.*, 2009).

Accuracy and bias of genomic predictions. The accuracy (correlation coefficient between GEBV and DRP), and the bias (regression coefficient of DRP on GEBV) of genomic predictions were calculated and reported separately for each of the validation breed groups.

Results

The accuracy and bias of the GEBV were shown in Figure 1 and Figure 2, respectively. Replacing the GRM with the HRM: (1) marginally improved the accuracy of within-breed predictions for milk traits (i.e. using R_1 to predict H and R_2 to predict J) and generally reduced the bias except for fat yield in J. (2) The accuracy and bias of across-breed predictions (i.e. using R_1 to predict J and R_2 to predict H) was only improved for fat yield. (3) In R_3 (i.e. H+J purebred reference), the accuracy and bias of predictions generally improved for milk traits in purebred cows. (4) In R_4, (i.e. purebred and crossbred animals in the reference), the accuracy of predictions improved for milk traits in purebred cows but marginally improved just for protein yield in crossbred cows.

Using HRM instead of GRM in the prediction model increased the estimated σ^2_a because HRM absorbed some of the variance explained by breed groups which was fitted as a fixed effect. However, the estimated σ^2_e was reduced by 1 to 27%, where larger reductions were associated with the size of the haplotypes used to build HRM. The average reduction in the estimated σ^2_e was smaller in R_2 (6%) compared to others references (16%).

The goodness of fit of the models (i.e. log likelihood) was only improved for protein yield and in R_1, R_3 and R_4 ($P<0.01$). Furthermore, haplotype sizes of 5 and 10 outperformed haplotype size of 15 in terms of the model goodness of fit.

Discussion

The usefulness of replacing the GRM with HRM in the prediction model was not consistent across different traits and haplotype sizes. In a within breed context Ferdosi *et al.* (2016) also reported that optimum

haplotype length for each trait and dataset could be different. This could be associated with the distribution of causal mutations and SNPs across the genome as well as the relationship between animals. Hence, for the closer relatives, the larger haplotype sizes may perform better. As we selected the validation set to be least related to the reference set, the improvement in predictions was limited. Nevertheless, there was a small consistent improvement in accuracy for within-breed genomic prediction. We found that using HRM was not promising for crossbred prediction. This could be associated with different optimum length of haplotype to define relationships in crossbred and purebred animals. Further, the phasing in crossbred animals could be less accurate compared to purebred animals because of expected higher imputation errors and larger effective population size in crossbred animals.

The application of HRM was most useful for genomic prediction of protein yield according to the goodness of fit in the model. However, the accuracy of across-breed prediction was almost zero when GEBVs of pure J were calculated from R_1 (i.e. pure H). Haile-Mariam *et al.* (2019) also reported the lowest correlation between milk traits across different breed groups was for protein yield. Hence, probably the effect of haplotypes on protein yield was largely breed specific. As identity by descent is considered in defining the relationships in HRM, the accuracy of across-breed predictions was reduced but was generally improved in R_4 (i.e. multibreed reference) for all validation breed groups.

In conclusion, HRM has limited benefits such as marginal increase in accuracy and reduction of bias of predictions compared to GRM. The advantages of using haplotypes instead of SNPs to define relationships could be potentially higher using standard Bovine 50k instead of a chip already enriched for causative mutations. However, XT_50k genotypes were used in this study because we wanted to find whether replacing the GRM with HRM could improve the accuracy and reduce the bias of prediction when the best

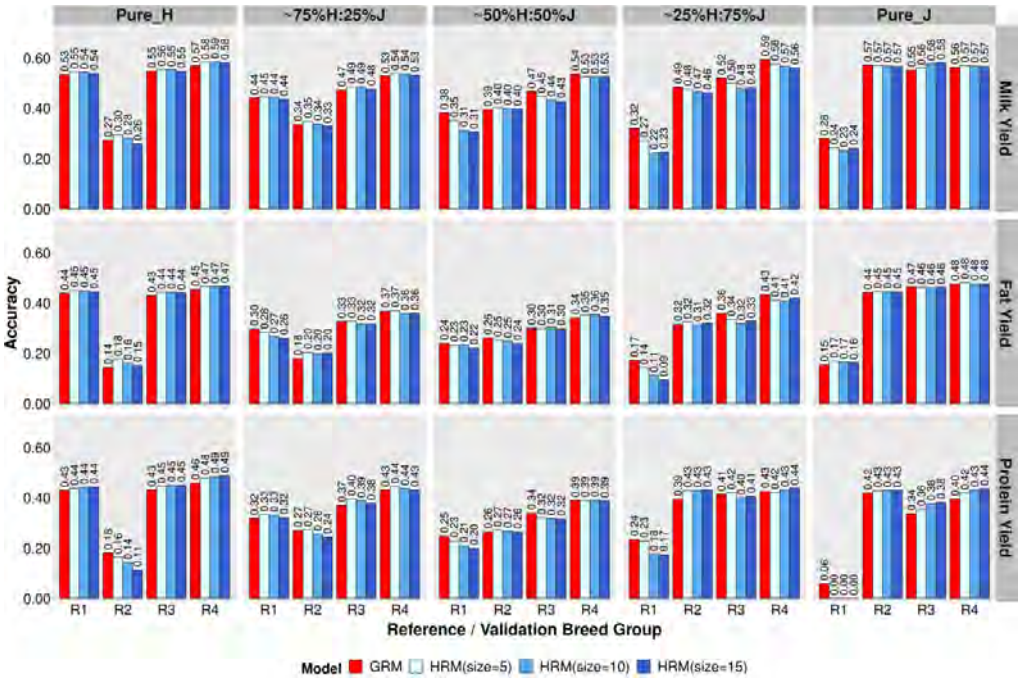

Figure 1. Accuracy of genomic prediction for milk, fat and protein yields in five validation breed groups using different reference sets and relationship matrices.

available set of SNPs were used in genomic prediction (Khansefid *et al.*, 2020). Considering the haplotype frequency in calculating HRM may improve the accuracy of predictions and reduce the inflated estimation of σ^2_a. Otherwise, HRM could explain the variance associated with population structure better than the fixed effects such as breeds groups. Nevertheless, the reduction in σ^2_e and improved log likelihood could be still useful to assess the improvement in goodness of fit of the model.

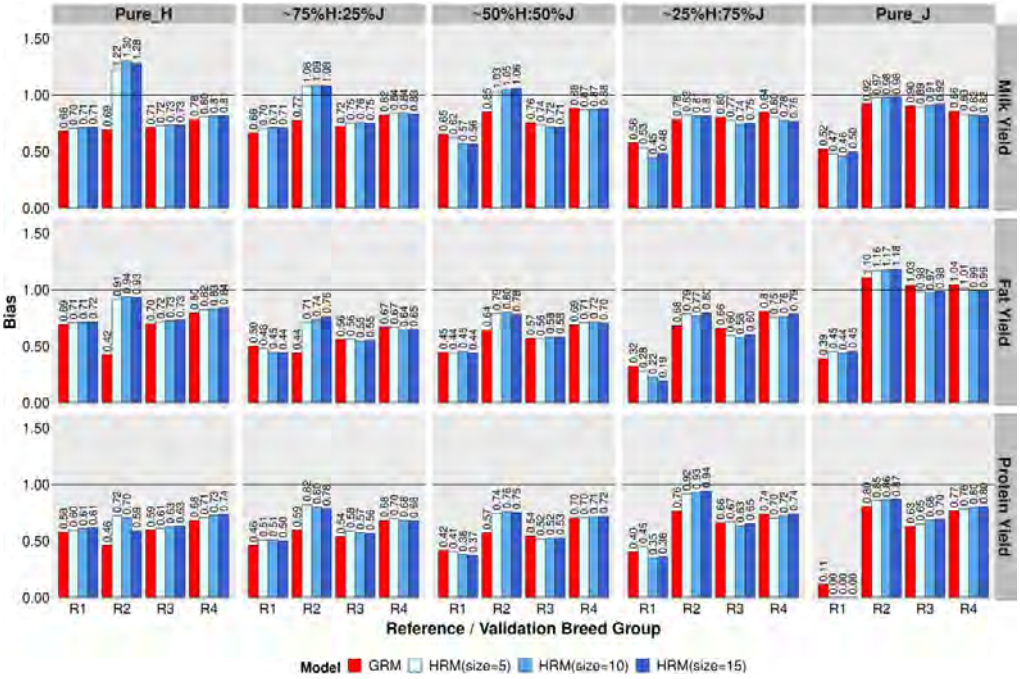

Figure 2. Bias of genomic prediction for milk, fat and protein yields in five validation breed groups using different reference sets and relationship matrices.

Abstract

Bos indicus and *Bos taurus* subspecies possess distinct morphological traits as a consequence of artificial selection and environmental adaptation. However, the impact of epigenetic contribution in relation to breed adaptation in the two subspecies has not been explored. In this work, Reduced Representation Bisulfite Sequencing (RRBS) profiling of the indicine Nellore (N) and the taurine Angus (A) cattle breeds was compared to identify CpG methylation differences in the two subspecies. A total of 134,553 methylated regions (MRs) were detected across all 20 samples (5 N and 5 A in two seasons). Approximately one third of them show differences in the two breeds in genes which function is related to sensory perception of chemical stimulus, development process and regulation of cellular organization. Further investigation is necessary to understand the real impact of epigenetic differences in the two breeds and how they can regulate genes important for cattle adaptation.

Introduction

Cattle belong either to the Indicine or the Taurine subspecies, the results of two independent domestication processes. Indicine breeds are more adapted to semi-arid, arid and tropical wet/dry climates and to parasites, and possess specific distinct morphological traits, as a cervico-thoracic hump, large ears and excess skin (Utsunomiya *et al.*, 2019, Verdugo *et al.*, 2019). European taurine breeds are characterized by high milk production potential or excellent carcass and meat yield and quality, but poor adaptation to hot environments (Manirakiza *et al.*, 2017; Rodrigues *et al.*, 2017). Both cattle subspecies have been extensively characterized at the genome-wide level and at specific loci (Bolormaa *et al.*, 2013; Pérez O'Brien *et al.*, 2014; Hu Y *et al.*, 2020; Barbato *et al.*, 2020) but few studies have focused on epigenomic diversity. Recently, we reported genome-wide DNA methylation changes in blood samples from indicine (Nellore) and Taurine (Angus) breeds under heat stress (Del Corvo M, *et al.*, 2021). After stressful period, a breed specific response was observed. Significant changes in methylation were observed in genes related to stress response and cellular defence in Nellore, whereas the response was less focused in Angus. Although heat stress seems induces changes in methylation patterns at specific loci, a remarkable diversity in methylation pattern was observed comparing the overall methylation of the two subspecies independently on the environmental challenge, presumably related to their origin and breed characteristic. In this paper, reduced representation bisulfite sequencing (RRBS) data from Nellore and Angus breed collected in different seasons, were analysed to investigate in more detail the epigenetic differences between the two subspecies.

Materials & methods

Data were obtained for ten half-sibs males of 15 months of age: an indicine breed (5 Nellore) and a Taurine breed (5 Angus) were reared at the UNESP Aracatuba (Sao Paulo state, Brazil) experimental station (located at -21.186244 latitude and -50.439053 longitude) during the hot Winter (C= Challenge period, heat stress)

and until the following cooler Spring (R=Recovery period) (del Corvo *et al*., 2021). DNA was isolated with QIAamp DNA Blood Midi Kit (Qiagen) following manufacture instruction. One µg of genomic DNA was used for RRBS libraries preparation. Illumina sequence reads were analysed using nf-core (Ewels *et al*., 2020), via the nf-core/methylseq v1.5 pipeline (https://github.com/nf-core/methylseq) selecting Bismark v0.22.3 (https://www.bioinformatics.babraham.ac.uk/projects/bismark/) as aligner. To evaluate the epigenetic variation in the two sub-species, sequence reads were aligned to the bisulfite-converted *Bos taurus* reference genome (ARS-UCD1.2: GCF_002263795.1), and methylation calls were extracted using the Bismark methylation extractor v0.22.3 function. The Seqmonk (https://www.bioinformatics.babraham.ac.uk/projects/seqmonk/) software v1.47.1 was used for visualization and analysis of the Bismark output. Methylated regions (MRs) were detected by dividing the genome in 400bp tiles with sliding windows of 200bp and analyzing average methylation for tiles containing at least three mutually covered 5× Cs in CpG context per position. Differentially methylated regions (DMRs) between Angus and Nellore were calculated for 5 A and 5 N in the two seasons using the logistic regression filter in R (FDR≤0.05, absolute cut-off of 10%). MRs and DMRs were investigated for 5' UTR, 3' UTR, exons and introns. Hierarchical clustering was calculated for all MRs detected. Methylation percentage was used for clustering using the Genesis software (Sturn *et al.*, 2002). Gene Ontology analysis was performed with PANTHER (Mi *et al.*, 2021).

Results

Sequencing statistics are reported in Table 1. The average number of reads per sample was 14.8 M (range: 9.2-25.M). About 73.7 and 77.6% cytosines in the CpG enriched regions were methylated in *B. taurus* and *B. indicus*, respectively. A slight difference was observed in the two season with 3 out of 5 A showing a methylation decrease and 3 out of 5 N a methylation increase from challenge to recovery period. A total

of 134,553 methylated regions (MRs) were detected across all 10 samples in two conditions. Hierarchical clustering of MRs in Angus and Nellore animals considering the heat-stress treatment and recovery period (C= Challenge period, heat stress and R=Recovery period) is in Figure 1.

About 30.22% of MRs were differentially methylated (DMRs n=51,421) between Angus and Nellore (LR FRD<0.05). Compared to MRs, the number of DMRs was slightly higher in non-coding regions and slightly lower in exons and 5'UTRs. GO analysis of a subset of genes (n=606) showing the higher methylation variation (DMRs with FDR<10^{-40}) showed enrichment in biological processes related to sensory perception of chemical stimulus, development process and development and regulation of cellular organization and signalling.

Discussion

In the current study, blood collected from taurine and indicine cattle subspecies was profiled by RRBS. Blood from Angus and Nellore showed an average level of CpG methylation of about 74%, not very consistent with previous data obtained by RRBS profiling of blood from tropical bovine breeds and their main ancestors, ranging from 51 to 57% (Sevane *et al.*, 2018), probably due to differences in the protocol procedure in size selection during library preparation. Although, the epigenomic comparison of Colombian Creole cattle breeds and their putative Spanish ancestors identified only 334 DMRs by RRBS (Sevane *et al.*, 2018), in our study the CpG methylation comparison between A and N showed a high diversity (DMRs n=51,421), with

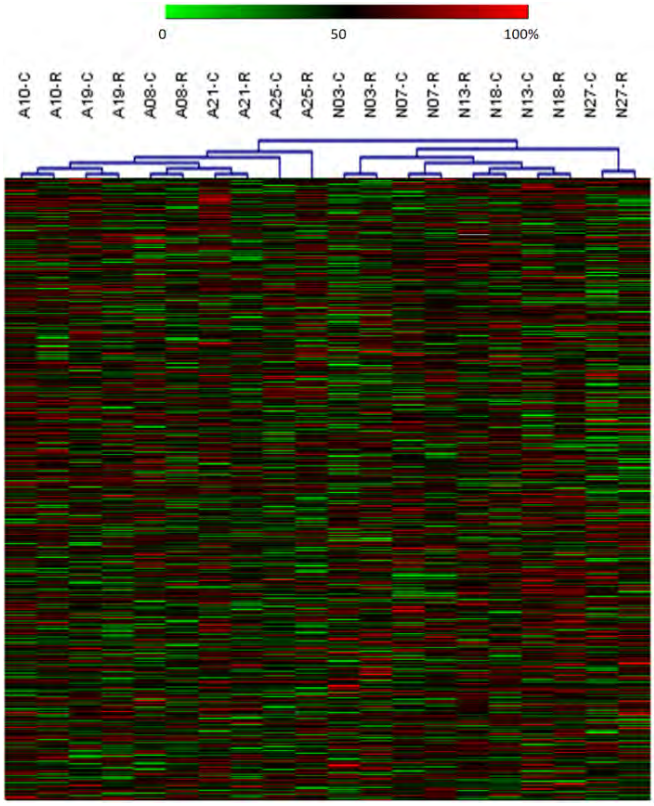

Figure 1. Hierarchical Clustering for 134,553 methylated regions (MRs) in the 20 samples mapped on *Bos taurus*. A=Angus; N=Nellore; C=Challenge; R=Recovery.

about 30% of the total identified MRs that differ between the two subspecies. The inconsistency between these two studies can probably be related to differences in experimental design. Only 2 animals from Costeño con Cuernos and one from San Martinero from Colombian Creole cattle breeds and one animal from each Asturiana de los Valles, Lidia and Retinta breeds from Iberian cattle were compared in Sevane *et al.*'s study, whereas we compared five animals from same indicine and taurine breeds. Important changes in the level of muscle methylation between different breeds was also observed in pigs, probably indicating the result of long-term selection for quantitative traits involving a very high number of genes (Ponsuksili *et al.* 2019). In conclusion, RRBS profiling of A and N animals showed a high epigenetic diversity between two subspecies, certainly not influenced by external environmental condition but related to evolutionary trajectories, that probably affects genes implicated in important pathways for cattle adaptation.

173. Evaluating the use of genotype information for the prediction of breed composition in purebred and crossbred cattle

C.A. Ryan[1,2*], D.P. Berry[1], T. Pabiou[3] and D.C. Purfield[2]

[1]Teagasc, Moorepark, Fermoy, Co. Cork, Ireland; [2]Munster Technological University, Cork, Co. Cork, Ireland; [3]Irish Cattle Breeding Federation, Bandon, Co. Cork, Ireland; cliona.ryan@teagasc.ie

Abstract

The ability to accurately predict breed composition using genomic information has many potential uses including increasing the accuracy of genetic evaluations, designing mating plans, traceability and genotype quality control. While software exists to estimate breed composition, the ability to exploit existing pipelines used in genomic evaluations for breed prediction could be advantageous. Utilising 49,213 single nucleotide polymorphisms (SNPs), the breed composition of 3,146 purebred and 4,330 crossbred cattle was estimated using both SNP-BLUP and Admixture. The accuracy of low-density panels to predict breed composition was also evaluated. The average mean difference in predicted breed composition between SNP-BLUP and Admixture was 0.000 and 0.048 for purebreds and crossbreds, respectively. Both methods accurately assigned ≥98% of the purebred validation population to the correct breed. SNP-BLUP required 2,000 and 3,000 SNPs to accurately predict purebred and crossbred breed composition, respectively; the respective values for Admixture was 500 and 1000 SNPs.

Introduction

In the absence of genomic data, an animal's breed proportion is assumed to be the average breed composition of both parents (Sölkner *et al.*, 2010). However, due to parental chromosomal recombination during gametogenesis, the breed composition of the offspring from a crossbred parent may differ from the expectation. Genomic information has the potential to more precisely determine the breed composition of animals due to its capacity to establish parental contribution, and therefore can help correct pedigree errors and estimate kinships when pedigree data is missing. While software exists to estimate breed composition (e.g. Admixture; Alexander *et al.*, 2009) the potential to exploit existing pipelines used in genomic evaluations for breed prediction could be more computationally efficient and be utilized for quality control, ensuring no mislabelled genotypes enter the database. The objective, therefore, of this study was to use a large database of genotyped purebred and crossbred cattle to compare breed composition predictions using a freely available software, Admixture, with those from SNP-BLUP. An additional objective was to determine the accuracy and general robustness of low-density genotype panels for breed prediction which was achieved by varying: (1) the SNP density; and (2) the selection strategy of SNP for alternative custom-derived low-density panels.

Materials & methods

Genotypes from 49,213 single nucleotide polymorphisms (SNPs) were available post quality control for 703,078 dairy and beef cattle; sporadically missing genotypes were imputed using FImpute (Sargolzaei *et al.*, 2014). A total of 13 breeds were included in this study, and purebreds from each breed were verified using both a principal component analysis and having a breed composition of >0.9 assigned in an unsupervised Admixture analysis (Alexander *et al.*, 2009). Within breed identity-by-state (IBS) clustering was undertaken on all purebred animals to identify the 500 least similar animals within each breed to represent the training population. A validation population of 3,146 verified purebred and 4,330 two and three-way crossbred animals with no direct relationship to the training population was chosen at random. An additional purebred independent population of 9,955 animals was also created to determine, and

subsequently rank, SNPs by informativeness for the development low-density panels; these animals were not included in either the training or the validation populations.

The allele substitution effect per SNP for each breed was estimated using SNP-BLUP (MIX99 Development Team, 2017), where all SNPs were fitted as random effects within a linear mixed model:

$$\mathbf{y}_i = \mu + \sum_{i=1}^{n} \mathbf{X}_j \mathbf{g}_{ij} + \mathbf{e}_i \quad (1)$$

where the dependant variable y_i was recorded as either one if animal i had a breed proportion of >0.9 in unsupervised admixture and was in the training population for the breed under investigation, zero if the animal was in the training population but not for the breed under investigation, or -99 if the animal was in the validation population; μ refers to the overall mean, X_j is the allele substitution effect of SNP_j; g_{ij} is the genotype of animal i at locus j and e_i is the residual term for animal i. The phenotypic variance for the dependent variable varied per breed and was estimated as pq, where p was the proportion of animals which were verified to be the breed under investigation (i.e. coded as 1); q was 1 minus this proportion. The resulting allele substitution effects were then summed to generate an estimate of the proportion of each breed in each animal. A supervised analysis in Admixture with 13 breed clusters (K=13) was then performed using the same training and validation animals and their estimated breed composition were compared with estimates from SNP-BLUP.

Development of low-density genotype panels. Seven lower-density panels (i.e. 500, 1000, 2,000, 3,000, 5,000 and 7,500 SNPs) were generated using six different SNP selection strategies. All low-density panels were compared to SNP-BLUP breed estimations based on all 49,213 SNPs, which were considered the gold standard prediction due to the fact that SNP-BLUP was computationally less intensive than Admixture and breed predictions from both software's were very similar. For purebred animals, breed assignment was assumed to have occurred if the prediction of breed composition was ≥0.90 for any single breed. The six alternative methods used to rank SNPs for the generation of the low-density panels were:

1. *Fixation Index* (F_{st})*:* The global F_{st} was estimated across all 13 breeds from the independent population using all 49,213 SNPs.
2. *PCA:* SNP weightings for each principal component were calculated using the 'smartpca' algorithm in Eigensoft v7.2.1 (Patterson *et al.*, 2006) on the independent population. The greater the difference in allele frequency between the breeds the greater the SNP weighting.
3. *SNP-BLUP variances:* SNP effects for breed prediction were estimated from SNP-BLUP using all 49,213 SNPs in the independent population. The standard deviation of these SNP effects were estimated across breeds and this was used to rank the SNPs.
4. *Random Forest (RF):* The RF analysis was conducted in the R package randomForest (Liaw and Wiener, 2002) using the genotypes of the purebred independent population. SNPs were ranked according to their relevance for breed prediction using the Mean Decrease in Gini Index. The higher the value of each SNP's Mean Decrease in Gini score, the more informative the SNP should be for breed prediction.
5. *Partitioning-around-mediods (PAM):* The partitioning-around-mediods (PAM) algorithm clusters SNPs on each chromosome together based on their proximity in genomic position. The number of clusters created per chromosome was set to the number of predefined SNPs for that chromosome. The SNP located in the middle of each cluster was selected.
6. *Random Selection:* The number of predefined SNP required per chromosome was randomly selected until each of the respective panel densities was obtained.

The number of SNP chosen per chromosome remained constant for each selection methods evaluated and was proportional to the genome length of each chromosome. The F_{st}, SNP-BLUP variances and RF methods

all ranked SNPs for the generation of low-density panels, and SNPs in the nth highest ranking for each SNP selection method were chosen per chromosome where n was the number of predefined number of SNPs for that chromosome.

Results

As there is no gold standard for genomic breed prediction, we tested the precision of SNP-BLUP by comparing the breed estimates with breed estimates from the well-established Admixture method. When 49,213 SNPs were included in the analysis, both SNP-BLUP and Admixture accurately assigned ≥98% of the purebred validation population to the correct breed. For crossbreds, the average mean difference in breed proportion predictions using SNP-BLUP and Admixture was 0.060 with a root mean square error of 0.08. For the low-density panels, the mean accuracy of breed composition predictions improved with increasing panel density (Figure1). In general, purebreds and crossbreds required 2,000 and 3,000 SNPs, respectively for accurate prediction of breed composition when using SNP-BLUP. There was a minimal difference in prediction accuracy across the various SNP selection methods when employing SNP-BLUP at panel densities ≥3,000 SNPs, with a mean difference of 0.021 between gold standard predictions and those made at panel densities ≥3,000 SNPs (Figure 1), but at panel densities below this, the F_{st} method was the most accurate at predicting breed composition. For comparison purposes, the SNPs selected using the three most accurate SNP selection methods (i.e. F_{st}, PCA and PAM) were used for breed prediction in Admixture and the predictions of breed composition were compared to those from SNP-BLUP. Using the same low-density panels, Admixture predicted breed composition more accurately than SNP-BLUP, with 500 and 1000 SNPs sufficient to accurately predict the breed composition of purebred and crossbred cattle, respectively (Figure 2).

Discussion

The root mean square error for breed predictions made using Admixture and SNP-BLUP across purebreds and crossbreds when 49,213 SNPs were used was 0.08, indicating a high degree of similarity between the two methods. As suggested by others (Bjørnstad and Røed, 2002), when predicting breed composition, some animals may never be correctly assigned regardless of the number of SNPs used because individuals are

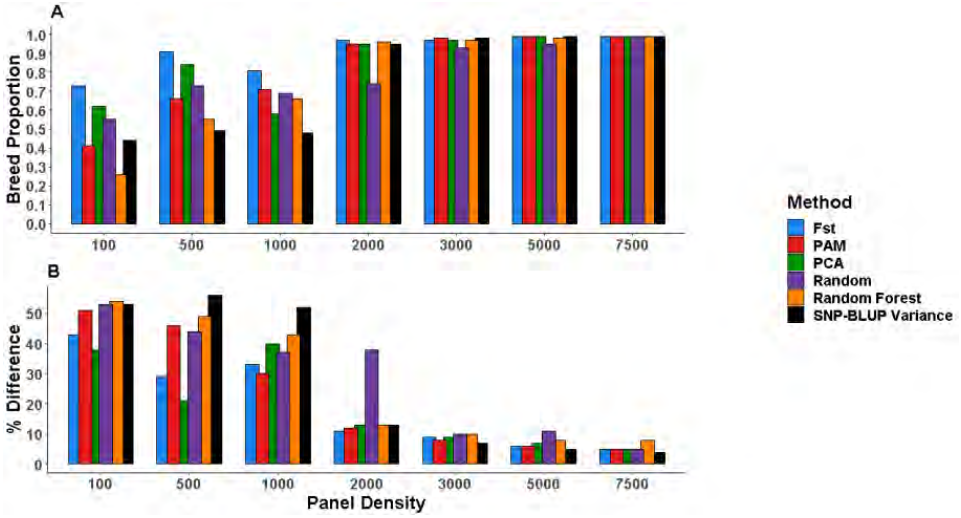

Figure 1. (A) Purebred breed proportion estimates across all low-density panels, (B) The ±% difference between gold standard and low-density breed estimates for crossbreds.

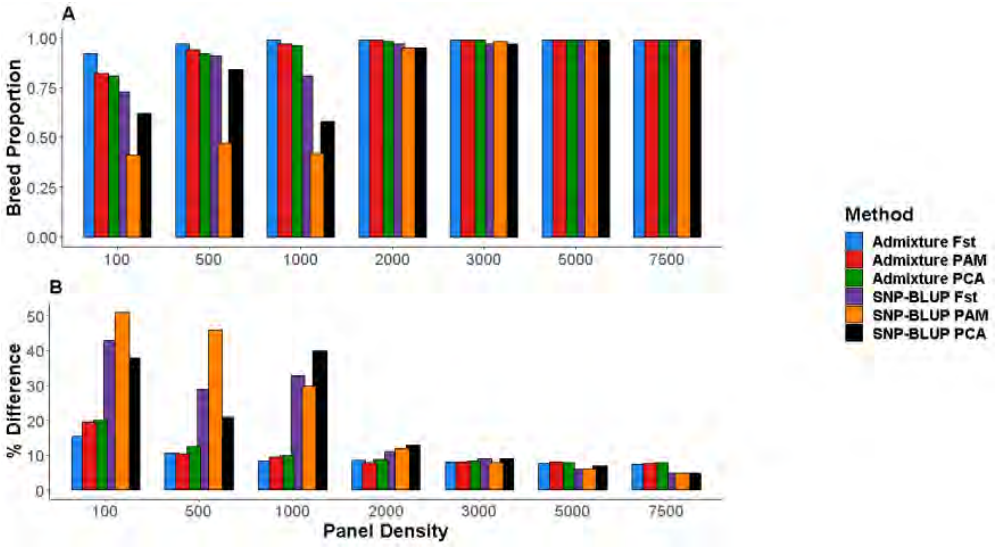

Figure 2. (A) Purebred breed proportions estimates from Admixture and SNP-BLUP, (B) The ±% difference between gold standard and low-density breed proportion estimates from Admixture and SNP-BLUP.

genetically uncharacteristic of their breeds. To avoid the latter from occurring, the training population in the present consisted of a large population of animals, thus increasing the within-breed variability. Purebreds required 2,000 SNPs to accurately predict their breed composition, whereas 3,000 SNPs were required to predict animals in the crossbred validation population, corroborating results of Bjørnstad and Røed (2002) in that predicting the breed composition of crossbreds is more challenging than that for purebreds. Despite choosing SNPs located in close proximity to each other on each autosome, the Fst method proved to be the best SNP selection method for low-density panels. This suggests that informative SNPs for the prediction of breeds may cluster together, which could potentially be reflective of positive selection as result of modern breeding programmes. The strong similarity between SNP-BLUP and Admixture breed predictions when panel density ≥3,000 SNPs suggests that breed prediction could be readily integrated into the SNP-BLUP pipelines used for genomic evaluations, thus replacing stand-alone software.

174. Genomic prediction using breed origin of alleles model accounting for probabilities in the assignment of the alleles

A. Guillenea*, G. Su, M.S. Lund and E. Karaman

Center for Quantitative Genetics and Genomics, Aarhus University, 8830 Tjele, Denmark; ana.guillenea@qgg.au.dk

Abstract

This study investigates genomic prediction using a breed origin of alleles (BOA) model which accounts for BOA with a (1) definitive assignment to a breed; or (2) probabilities of assignments to each breed. Our BOA model estimates breed-specific marker effects based on genotypic and phenotypic information from the purebred and crossbred animals. A traditional combined analysis of all breeds' data implicitly assumes a correlation of one between the marker effects of the breeds, whereas our BOA model allows the estimation of these correlations. We used de-regresed proofs of production traits from the admixed Nordic Red Cattle population to evaluate the model and performed the analysis assuming marker effects between breeds are correlated or assuming they are uncorrelated. We found that using probabilities in the BOA model outperformed the BOA model, assuming the origin of each marker is known with certainty, especially when the marker effects were assumed uncorrelated between breeds.

Introduction

The implementation of genomic prediction (GP) is challenging in admixed populations since the same allele of a given marker might have a different effect on the phenotype according to its breed of origin. Accuracy of GP relies on the linkage disequilibrium (LD) between single nucleotide polymorphisms (SNP) and quantitative trait loci (QTL). In multi-breed reference populations, accuracy of GP relies on the LD phase between SNP and QTL being conserved across breeds, but LD may be different, or phase may be even reversed across breeds. QTL effects might also vary between breeds if there are interactions between QTL and genetic background (Calus *et al.*, 2018). Several methods have been proposed recently to account for breed origin of alleles (BOA) in GP, and several methodologies/software have been developed to infer BOA (Lawson *et al.*, 2012; Vandenplas *et al.*, 2016; Eiriksson *et al.* 2021). For GP, Karaman *et al.* (2021) developed a method that allows to include purebred and crossbred animals, estimating SNP effects considering correlation of SNP effects between the breeds. This method includes breed-specific matrices and thus, relies on the correct assignment of the alleles. Some of the existing software to infer BOA provide the probabilities of belonging to each breed for each allele, and others provide the probabilities of belonging to each breed for alleles that could not be assigned to a specific breed. Including these probabilities in the models, instead of assigning an allele to one particular breed, could improve reliabilities because they may account for some uncertainty in the assignments, especially for highly admixture populations. The objective of this study was to compare GP for a BOA model using either assignment of an allele to a specific breed or probabilities of an allele from the possible breeds, based on data from the Nordic Red dairy cattle (RDC) population, which is an admixture of Danish Red (RDM), Swedish Red (SRB) and Finnish Ayrshire (FAY) dairy cattle, which have strong ties due to the use of common bulls.

Materials & methods

Genotypic and phenotypic data. We used de-regressed proofs (DRP) of 51,336 animals (5,104 bulls and 46,232 cows) of the RDC population for milk, fat and protein as response variables to predict direct genomic breeding values (DGV). The Nordic Cattle Genetic Evaluation provided the data. The bulls in the data set were genotyped using the Illumina Bovine SNP50 chip (50K). For cows, 23,245 were genotyped with the standard Illumina Bovine low-density Chip and 22,987 with the EuroGenomics customized chip,

which, in addition to the previous, includes SNPs selected from imputed whole-genome sequencing data that were not used in this study. In addition, 3,000 HOL bulls were included as an ancestral population as a preliminary pedigree analysis showing ties of HOL with RDM. The genotypes of all animals (RDC and HOL) were imputed to 50K and phased. Finally, 42,470 SNPs common to RDC and HOL were used in this study.

Estimation of breed origin. First, we used all genotyped RDC bulls to perform an ancestry analysis to identify purebred animals, regardless of the presence of DRP. In total, 8,356 bulls were included in this analysis (5,356 RDC and 3,000 HOL). The bulls were allocated to purebred and admixed groups based on the breed proportions predicted using ADMIXTURE v1.30 software with k=4 (k = ancestral populations). In total, in this step 1,820 bulls were selected as purebred (751 HOL, 244 RDM, 760 FAY and 65 SRB). Second, BOA was inferred for the rest of the RDC animals with ChromoPainterV2 software (Lawson *et al.*, 2012) using the haplotypes of purebred animals of each breed, selected in the ADMIXTURE analysis, as donor haplotypes of their corresponding breed. The expected probability of each SNP coming from each of the purebred populations was used to infer the BOA in two ways: (1) each allele was assigned to one purebred population for which the expected probability was the highest, or (2) each allele was assigned to each population as a product of the allele count (0, 1 or 2) and the expected probabilities. Breed proportions were inferred by summing the alleles from each breed.

Statistical model. The BOA model to estimate breed-specific SNP effects is as follows (Karaman *et al.*, 2021):

$$y = 1\mu + Xb + Z_D u_D + Z_F u_F + Z_S u_S + Z_H u_H + e$$

where y is the vector of DRP of milk, fat or protein for the reference animals, 1 is the vector of 1s, μ is the overall mean, X is the matrix of breed proportions, b is the vector of fixed breed effects, and e is the vector of random residuals. Z_D, Z_F, Z_S, and Z_H are the matrices of breed-specific content of SNP for RDM, FAY, SRB, and HOL, u_D, u_F, u_S and u_H are vectors of SNP effects for RDM, FAY, SRB, and HOL, respectively.

Two approaches to construct Z matrices were used. For the first approach, the Z matrices were formed by assigning each allele to a certain purebred population for which the expected probability is the highest (BOAg). The entry at a locus in an Z matrix, for instance, Z_D, were the number of '*A*' alleles (0, 1 or 2) originating from RDM for an animal. Consequently, if an animal had '*aa*' genotype or had no allele originating from RDM, the corresponding entry in Z_D was zero. The same applies to other Z matrices for each breed. For the alternative approach, each allele was assigned to all original populations according to expected probabilities (BOAp). Thus, the Z matrices were achieved by taking the sum of the product of the allele count (0 or 1) and the expected probabilities over the two alleles at each locus. The Z matrices were centered by subtracting the mean of the column prior to analysis.

For the analysis assuming breed-specific SNP effects uncorrelated across the breeds (Uncor), each vector of SNPs was assigned a prior of a normal distribution separately for each breed (i = D,F,S,H): $u_i|\sigma^2_i \sim N(0, \sigma^2_i)$. Here, σ^2_i is the SNP variance for breed i, obtained from a preliminary analysis using only bulls' data. For the analysis assuming correlated breed-specific SNP effects (Cor), a multivariate normal distribution was assigned for the vectors of SNP effects: $[u'_D, u'_F, u'_S, u'_H]' \mid B \sim N(0, B \otimes I)$, where I is an identity matrix, and B is as in (Guillenea *et al.*, 2022). Briefly, the diagonals are the breed-specific SNP variances and off-diagonals of B are covariances. Random residuals were assumed to follow a normal distribution, $e \sim N(0, D\sigma^2_e)$, where σ^2_e is the residual variance, and D is a diagonal matrix with elements $d_{ii} = 1/w$, w is the weighting factor for the ith DRP. More details of priors are given in Guillenea *et al.* (2022). Fixed effects were assigned to

having flat priors. The analyses were written and carried out in Julia programming language (Bezanson *et al.*, 2017).

Model validation. The validation consisted of 11,786 cows, while reference consisted of 5,104 bulls and 34,446 cows. Both populations were made based on groups of half-sibs with a cut-off birth date July 1, 2015. The DGVs of validation animals were calculated by multiplying the breed-specific matrices with breed-specific SNP effects and adding a fixed breed contribution. The prediction reliability was calculated as the squared correlation between DGV and DRP divided by the reliability of DRP for the validation animals. We used a bootstrap procedure sampling 10,000 times to calculate reliabilities and the standard errors of each model.

Results

Reliabilities of GP are presented in Figure 1. Using probabilities of assignments improves prediction reliabilities for the three traits in Uncor, but not in Cor. On average, the increase of BOAp over BOAg was 1% for the correlated analysis and 33% for the uncorrelated analysis. Regarding the production traits under study, milk presented the highest reliabilities and the patterns over the traits were similar.

Discussion

The performance of models based on the breed origin of the alleles depends, among other factors, on the precise estimation of the origin of each allele, which is used to construct the breed-specific allele matrices. The RDC is a highly admixed breed, which made it difficult to define purebred animals of the three Nordic original breeds, and consequently, the assignments of the alleles in ChromoPainterV2 showed a distribution of probabilities, in which only 40% were assigned to their breed origin with probability >0.9. This means that in our first approach (BOAg) if one allele had a probability of, for instance, 30% of coming from RDM and the probabilities for the other breeds three were lower, the allele was assigned to RDM. In the second approach (BOAp), the same allele was assigned to all breeds with the expected probabilities. The

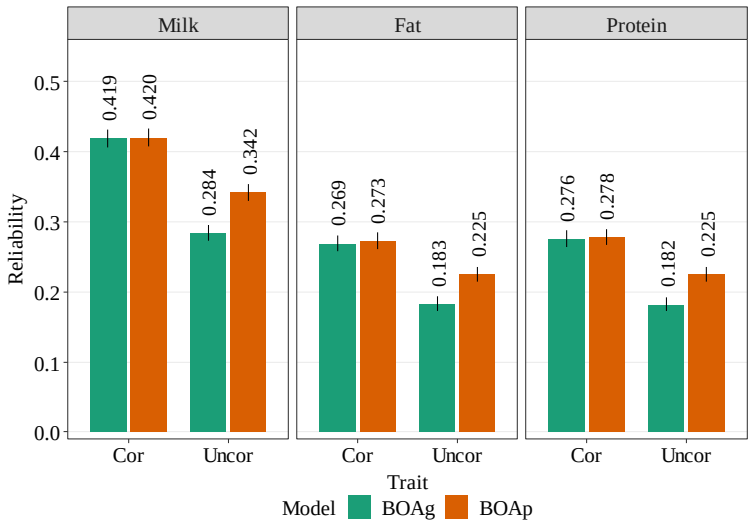

Figure 1. Reliabilities and standard errors of BOA with definitive assignment to a breed (BOAg) (Guillenea *et al.*, 2022) or probabilities of assignments to possible breeds (BOAp) for a scenario of correlated (Cor) or a scenario of uncorrelated (Uncor) SNP effects between breeds.

uncorrelated analysis obtains more gains for using the probabilities because it depends more on intra-breed information. In this population, in which breeds were found to be highly related, the impact of accounting for probabilities was small for the correlated analysis. However, it is expected that the improvement of predictions by using probabilities would be more in a correlated analysis for the breeds which are more distantly related. For such breeds the use of BOA models would also become more important.

Conclusions

This study compared GP of BOA with two types of breed-specific genotypic matrices: (1) each allele was assigned to only one specific breed; and (2) probabilities in the assignments were taken into account in the matrices. We conclude that the BOA model benefits from the use of probabilities in the construction of the breed-specific matrices, so it is a more precise approach to assign alleles that can be implemented in models with breed-specific matrices.

Abstract

Combining data from different breeds into a genetic evaluation can have several benefits, especially when there is a close evolutionary relationship as in Iberian dairy sheep breeds. This work explores the benefits on prediction reliability of combining genomic and phenotypic data into a multi-breed genomic evaluation for milk yield in four Iberian dairy sheep breeds: Assaf, Churra, Latxa, and Manchega. The phenotype was the estimated breeding value by classic BLUP evaluation and together with genomic information, single- and multi-breed evaluations were run. No gain in prediction reliability of multi-breed genomic evaluations was found, probably related to differences between linkage disequilibrium patterns and genetic differentiation between concerned breeds. The relationship among these breeds is probably not close enough to increase prediction reliability into a multi-breed genomic evaluation. Additional studies need to be done to confirm that.

Introduction

Multi-breed genetic evaluations can improve prediction reliability due to a bigger reference population (RP) size that increases the accuracy of determining the relationship between phenotypes and SNP markers (Lund *et al.*, 2014). Dairy sheep breeds are characterized by the presence of a wide range of breeds, with an adapted production system, small population size, heterogeneous data recording system and lower economic value per individual, that difficult a join evaluation, but at the same time makes it more interesting. The relationship among Iberian dairy sheep breeds has been previously studied based on morphological characters and molecular data (microsatellites and mitochondrial DNA), and although genetic differentiation exists, a close relationship has been described (Jordana and Ribo, 1991; Pedrosa *et al.*, 2007; Legaz *et al.*, 2008). Currently, the implementation of genomic schemes into these breeds is ongoing work at different stages, while farmers' attitude towards genomic breeding tools seems to be positive (Martin-Collado *et al.*, 2021). However, the size and composition of their RP are highly varying, which makes comparison difficult between breeds. This situation provided the stimulus for our work to explore the impact on prediction reliability of joining phenotypic and genomic data of four Iberian dairy sheep breeds (Assaf, Churra, Latxa, and Manchega) into a multi-breed genomic evaluation for the main breeding objective, milk yield.

Materials & methods

Phenotypic, genealogic and genomic data. The concerned Assaf, Churra, Latxa, and Manchega breeds, have considered 120 days standardized milk yield records as initial phenotype; the number of records and animals in the pedigree is highly different across breeds, as well as the size and sex composition of the genotyped population, as shown in Table 1. The genotyping was carried out using different platforms: Affymetrix 50K, Custom Affymetrix 50K ULE, AxiomTM Ovine Genotyping Array (Thermo Fisher Scientific Inc., Waltham, MA, USA), and Illumina Ovine SNP50 Bead Chip (Illumina Inc., San Diego, CA,

[3] Milk daily controls.

USA); that brings between 49,702 and 63,679 markers, and after quality controls the common markersacross breeds were included (21,787 SNP).

Based on the available genomic data, to explore the existing relationship across breeds, we applied principal component analysis (PCA) on the VanRaden (2008) matrix of genomic relationships, which was computed as $G = ZZ' / 2\Sigma p_i q_i$, where Z is a matrix of centered genotypes and $p_i = 1 - q_i$ is the allelic frequency for the i^{th} marker based on observed genotypes. Moreover, we studied the conservation of linkage disequilibrium (LD) patterns across these sheep breeds, estimated as the set of correlations of genotypes across all possible pairs of SNP loci (Hill and Robertson, 1968), considering a ranges of distance of 0.05, 0.5 and 5 Mb.

Single breed estimates. Classic BLUP evaluations considered the phenotypic information and routinely used models to obtain estimated breeding values (EBV) of genotyped individuals. No information was available to estimate de-regressed proofs, so EBV provided by breeders associations were used as pseudo-phenotypes despite their limitations. These EBV were used as phenotypes for genomic BLUP evaluations (GBLUP; Habier *et al.*, 2007; VanRaden, 2008) to obtain single-breed genomic estimated breeding values (GEBV). For all breeds Blupf90 family programs (Misztal *et al.*, 2002) were used.

Multi breed pooled estimates. As phenotype, the estimated classic EBV was used. It was combined with the genomic information of concerned breeds into a multi-breed GBLUP evaluation (multiGBLUP), where the breed was considered as a fixed effect. Variance component estimates and evaluations in all cases were run with Blupf90 family programs (Misztal *et al.*, 2002). We estimated correlations among GEBV obtained from different analysis and we also compared mean reliabilities from each method calculated as $\sqrt{1 - \frac{PEV}{\sigma_u^2}}$, being PEV the prediction error variance and σ_u^2 the genetic variance.

Results

The projection of each individual on the three main principal components is shown in Figure 1. The two first principal components (PC) explained 38 and 14% of the covariance across individuals, while the PC3 explained 10%. We can see that the PC1 distinguished Churra, Latxa and Manchega populations from the Assaf population, whereas the PC2 distinguished Assaf and Churra from Manchega and Latxa and PC3 distinguished Latxa subpopulations.

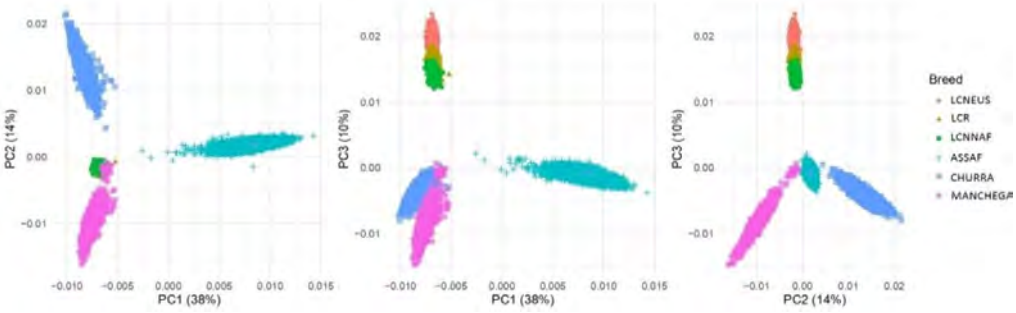

Figure 1. Principal component analysis based on common SNPs across breeds.

The linkage disequilibrium (LD) patterns varied across breeds. At 0.05 Mb the mean LD value was similar for all the studied breeds (~0.16), but when the distance increased, there was a significant drop in mean LD in Assaf, Churra and Manchega breeds (0.06 and 0.03, at 0.5 Mb and 5 Mb) but not in Latxa populations (0.15 and 0.13, at 0.5 Mb and 5 Mb). Regarding the correlation between breeding values estimated by classic BLUP, GBLUP and multiGBLUP, all concerned breeds showed a higher correlation between BLUP and GBLUP estimates (~0.98) than between BLUP-MultiGBLUP (~0.92) or between GBLUP-MultiGBLUP (~0.91) based estimates. Finally, mean reliability values for each genetic prediction method are shown in Table 2. Reliabilities increased to almost one in all breeds with genomic predictions (GBLUP). When the information was combined into a multi-breed evaluation (multiGBLUP), Assaf, Churra and Manchega breeds had higher reliabilities than BLUP evaluations. However, they were lower than GBLUP evaluations in all cases. Latxa populations showed similar reliabilities in BLUP and multiGBLUP evaluations.

Discussion

The lack of gain in prediction reliability of multi-breed genomic evaluations could be related to using EBVs as phenotypes, which were estimated differently in each of the breeds. Even though EBVs represent the ability of animals to transmit their milk yield ability, the variability across breeds is highly different, and the additive variances result in accuracy loss. Possibly using pseudo-phenotypes as daughter yield deviations (VanRaden and Wiggans, 1991) or de-regressed proofs (Garrick *et al.*, 2009) appropriately weighted would be more suitable. Moreover, the different number of genotyped animals across breeds could have affected results, obtaining higher prediction reliabilities of multiGBLUP evaluations within-breed with more genotypes (Assaf, Churra, and Manchega) and being less gain in Latxa populations. Also,

Table 2. Mean reliability for the three evaluation methods: classic BLUP, single breed genomic BLUP (GBLUP) and multi breed genomic BLUP (MultiGBLUP).

Breed[1]	BLUP	GBLUP	MultiGBLUP
Assaf	0.673	0.995	0.809
Churra	0.363	0.999	0.795
LCNEUS	0.738	1.000	0.729
LCR	0.732	0.995	0.724
LCNNAF	0.735	0.988	0.718
Manchega	0.510	0.952	0.761

[1] Latxa Cara Negra from Euskadi (LCNEUS), Latxa Cara Rubia (LCR), and Latxa Cara Negra from Navarre (LCNNAF).

the number of common markers fulfilling all requirements in all breeds could be small to pick up the LD that goes across breeds and increases reliabilities. The PCA has shown that the concerned breeds are genetically differentiated and display differences between LD patterns. Therefore, the relationship among these breeds is probably not close enough to increase prediction reliability into a multi-breed genomic evaluation. Similar results have been previously reported in related sheep breeds (Legarra *et al.*, 2014), highlighting the necessity of a closer genetic relationship to take advantage of a common RP (Lund *et al.*, 2014). The exception could be Latxa populations; given the closer relatedness, it might be worth analysing if combining only them improves prediction accuracy.

In conclusion, we did not find the expected gain in prediction reliability from a multi-breed genomic evaluation. This might be related to the genetic differences between breeds, LD differences and the use of EBVs as phenotypes. Moreover, breeding programs have varying breeding criteria and follow different strategies, making a multi-breed evaluation less suitable. Further studies are needed to test the use of more suitable phenotypes to take advantage of a joint RP of Iberian dairy sheep breeds.

Acknowledgements

The authors thank the breeders' associations for providing phenotypic and genomic data. This work would not have been possible without the funding of the Spanish Ministry of Agriculture, Fisheries and Food by the proposed ENCOMIENDA DE GESTION (2017-2020) and the support of the project ARDI (EFA208/16), funded by INTERREG POCTEFA with the European Fund for Regional Development (FEDER).

176. Online Mendelian Inheritance in Animals (OMIA) – future proofing of a globally used animal genetics knowledgebase

I. Tammen[1*], M. Mather[2], Z. Li[2], J. Nothman[2], D.P. Vanichkina[2] and F.W. Nicholas[3]

[1]The University of Sydney, Faculty of Science, Sydney School of Veterinary Science, PMB 4003, Narellan, NSW 2567, Australia; [2]The University of Sydney, Sydney Informatics Hub, Darlington, NSW 2008, Australia; [3]The University of Sydney, Faculty of Science, Sydney School of Veterinary Science, Sydney, NSW 2006, Australia; imke.tammen@sydney.edu.au

Abstract

Online Mendelian Inheritance in Animals (OMIA) is a freely available curated knowledgebase that contains information and facilitates research on inherited traits and disorders across more than 300 species. It is used by animal geneticists, breeders and veterinarians worldwide as a definitive source of information on single-locus traits (especially disorders) in all relevant animal species. Increase in curation capacity and funding for software engineering support have resulted in software upgrades and commencement of new initiatives. We provide here an overview of information contained in OMIA, routine curation activities and key user statistics. A review and update of hyperlinks between OMIA and Online Mendelian Inheritance in Man (OMIM) is reported. Ongoing initiatives including updates of likely causal variant table information, submission of variant information to the European Variation Archive (EVA), introduction of Mammalian Phenotype Ontology (MPO) categories and planned introduction of breed and phene ontologies into OMIA are briefly discussed.

Introduction

OMIA (Online Mendelian Inheritance in Animals 2022, https://omia.org) is a freely available, curated, online knowledgebase which provides users with up-to-date summary information on the known harmful and beneficial variants in animals, together with background information on known inherited disorders and beneficial traits. OMIA is modelled on and reciprocally hyperlinked to OMIM (https://www.omim.org), and provides links to the National Center for Biotechnology Information (NCBI, https://www.ncbi.nlm.nih.gov/), and the European Bioinformatics Institute's Ensembl (http://asia.ensembl.org/index.html).

To facilitate across species analysis, OMIA has a hierarchical structure of traits ('phenes') in one or more species. This structure is reflected in the OMIA ID, which has the form OMIAxxxxxx-yy…yy, where xxxxxx is the 6-digit phene ID and yy…yy is NCBI's species taxonomy ID. Thus an OMIA ID signifies a phene-species, i.e. a particular phene in a particular species. Phenes that have been reported in multiple species, often using different synonyms for the trait or disease, can thus be easily explored using comparative biology approaches.

OMIA focuses on phenes with confirmed and suspected Mendelian modes of inheritance. However, several phenes with unknown or complex modes of inheritance and phenes caused by somatic mutations, genetic modifications or genome editing are also included. Furthermore, OMIA provides references for landmark and review articles and for papers describing genetic maps and reference genomes in animals. While the vast majority of OMIA entries are for the major domesticated animal species, entries for all animal species, except for humans and common model organisms such as mice, rats, and zebrafish, are included.

Since the beginning of 2021, the curation team has increased from one to two main curators and bequest funding has enabled software engineering support. Ongoing curation work, software updates, and several new initiatives are discussed below.

Materials & methods

Routine curation activities. A daily automated PubMed (https://pubmed.ncbi.nlm.nih.gov/) search including key genetics terms, all publications of key animal genetics journals and of key authors with a track record in the field is conducted. Identified papers are reviewed based on title and abstract information, and selected papers are added to OMIA via PMID upload as references to existing or new phene-species, and/or added as landmark, mapping or review papers. If relevant, text fields in phene-species entries are updated, hyperlinks to NCBI genes are added, OMIM phene and/or gene hyperlinks are added or updated and likely causal variant information is added to variant tables using Human Genome Variation Society (HGVS) nomenclature (http://varnomen.hgvs.org/).

OMIA software upgrade. Since August 2010, the OMIA database and website have been using Django software, a high-level Python Web framework. In July 2021, software packages were upgraded from Python 2 to 3 (https://www.python.org/) and from Django 1.9 to 3.2 (https://www.djangoproject.com/), and coding was refined with the aim to future-proof OMIA and improve homepage response times. Several additional changes were implemented: new site administration tools were introduced to facilitate 'liftover' of variant information to newer reference genome assemblies, and to enable export of variant information for submission to EVA (https://www.ebi.ac.uk/eva/). A new literature search tool was trialled; separate fields for 'OMIM phene' and 'OMIM gene' hyperlinks were included; and 'Variant ID' and 'Source of Genetic Variant' fields were added to provide unique numerical variant identification and to facilitate inclusion of variant information for genome-modified or edited variants.

Review of OMIA-OMIM hyperlinks. Since 1997, OMIA has been reciprocally hyperlinked to OMIM. OMIM links are identified by OMIA curators when new phenes are entered into OMIA. OMIM downloads OMIA phene IDs with an OMIM ID link once a week and updates OMIM accordingly. We reviewed OMIA-OMIM hyperlinks for all OMIA phenes for which a likely causal variant has been identified. OMIM links were confirmed, deleted, or added.

Results

At the beginning of 2022, OMIA included information on 2,195 phenes across 319 species, contained 4,030 phene-species entries and included a total of 28,184 references. The references include 90 landmark publications, 816 review publications and 428 reference genome or mapping publications. Core statistics for key livestock species are summarised in Table 1.

On average, each phene has reports in 1.9 species, ranging from 1 to 47 species per phene. Of the 33 phenes with reports in 10 or more species,10 phenes are pigmentation traits, which are easy to phenotype. Susceptibility or resistance to spongiform encephalopathy, a zoonotic disease, is the phene reported in the greatest number of species (n=47).

Table 1. Summary of OMIA information relating to key livestock species (9/1/2022).

	Cattle	Pig	Sheep	Horse	Chicken	Goat	All
Total phenes	583	329	291	251	232	99	4,030
Mendelian phenes	272	118	114	61	134	23	1,680
Phenes with at least one known likely causal variant	175	57	48	47	56	17	1,012
Likely causal variants known	235	65	80	101	70	30	1,368
Likely causal variants with EVA ID[1]	73 (134)	18 (20)	26 (41)	16 (50)	15 (12)	8 (10)	197 (506)

[1] Number of variants submitted to EVA in October 2021 for assignment of EVA IDs shown in brackets.

Google analytics (https://analytics.google.com) data for 2021 identified 36,786 users from 161 countries. The majority of users were located in the USA (20%), followed by Russia (5%), Spain (5%), Brazil (5%), Mexico (4%), Australia (4%), Germany (3%) and the UK (3%).

During 2021 the daily automated PubMed literature search resulted in 16,081 hits, of which 778 papers were identified to be added to OMIA (average daily hits =44, and average daily additions = 2.1). Additional references were added as part of other curation activities. We trialled other literature search strategies, including use of the machine learning tool LitSuggest (Allot *et al.* 2021), but further work is required to optimise the search strategy.

A performance review after completion of the software upgrades and refinements to coding confirmed vast improvements to search and homepage response times.

The review of the OMIA-OMIM hyperlinks for phenes in OMIA that had at least one causal variant identified, resulted in confirmation of 607 OMIM links, addition of 683 OMIM links and deletion of 46 OMIM links. Most of the added OMIM links were OMIM gene IDs (n=493), as these were in the past not routinely added to OMIA. OMIA currently lists 2,283 models of human traits. 1,369 OMIM phenes and 645 OMIM genes (14.3 and 3.9% of all OMIM phene and gene entries, respectively) have a link to OMIA.

Discussion

OMIA is a globally used knowledgebase. Until recently, curation was predominately conducted single-handedly by one curator, and limited funding restricted access to urgently needed software upgrades and modifications. Increased curation capacity and bequest funding support to upgrade and refine the underlying software is improving curator and user experiences and has resulted in the commencement of several new innovations while maintaining ongoing curation activities.

We reported the introduction of variant tables to OMIA (Tammen and Nicholas 2018) and indicated that the aim would be to provide EVA IDs to provide standardised nomenclature for all variants. However, EVA (https://www.ebi.ac.uk/eva/), the global resource for animal variant information since NCBI's dbSNP phased out support for non-human animals, does not accommodate all types of variants and only very few authors of OMIA-relevant papers submit variant information to EVA. We therefore have started to review and standardise all historic variant information in OMIA using HGVS nomenclature, with the aim to report location information based on a recent reference genome assembly (Shields *et al.* 2021; Tammen *et al.* 2021a). Software upgrades to site administration tools have further facilitated this process by inclusion of an integrated 'liftover' pipeline. In October 2021, variants listed in OMIA that were lacking an EVA ID but had standardised location information were submitted to EVA using a new OMIA pipeline for export of variant information to EVA. EVA RS IDs for these variants are expected to be released in 2022 and will further facilitate integration between OMIA and other online resources. Variant tables and variant information in VCF format can be downloaded from OMIA, providing valuable resources for researchers and genotyping service providers and enable use of OMIA data as a reference when interpreting high-throughput genomic studies. The need for more standardised nomenclature for variants has been recently discussed to ensure greater transparency in relation to DNA testing. The constantly rising number of causal variants, the increase in genes which are reported to have multiple causal variants, the fact that variants that are initially reported as breed-specific are later found across several breeds and in cross bred animals, as well as use of different nomenclature to describe a variant, can create challenges in how to identify which variants are included in various diagnostic panels. To this end, OMIA numerical variant IDs are now presented in the first column of all OMIA variant tables. An OMIA variant ID provides a unique unchanging ID for each likely causal variant, including those complex variants for which there is no EVA ID.

The revision of OMIA-OMIM hyperlinks will facilitate comparative-medicine-related research approaches. However, a large list of OMIA phenes without known likely causal variants have not been reviewed so far, as it is more speculative to identify homology between human and animal phenes if the underlying genetic cause is unknown. Similarly, due to lack of standardised nomenclature, newly reported animal diseases or traits, for which the underlying genetic cause is unknown, can sometimes be difficult to allocate to a specific phene in OMIA.

Two major current projects relate to the introduction of breed and phene ontologies to OMIA. This work is being conducted in collaboration with colleagues from the Monarch initiative (https://monarchinitiative.org/), as previously outlined (Tammen *et al.* 2021b). The vertebrate breed ontology (VBO) will combine breed information from various resources using the Domestic Animal Diversity Information System (https://www.fao.org/dad-is/en/) as a starting point, with the aim of harmonizing breed definitions (while allowing for the use of country or language specific synonyms) in a computer-accessible format. VBO will improve the currently limited options to analyse breed predispositions in OMIA, and will be publicly available as a resource for any across breed analysis. The phene ontology will enable integration of OMIA with other global online resources and ultimately enable mechanistic discovery and diagnostics of Mendelian diseases. As an interim step, Mammalian Phenotype Ontology (Smith and Eppig 2009) 'major biological system headers' have replaced existing OMIA 'categories' in advanced searches and in the OMIA browse page (https://omia.org/browse/).

Sustainability of curation efforts is an ongoing concern, and we encourage authors to use HGVS nomenclature wherever possible, and to include EVA IDs when publishing new variants, to facilitate the curation process. OMIA curators (frank.nicholas@sydney.edu.au or imke.tammen@sydney.edu.au) welcome feedback on current information presented in OMIA.

Abstract

In previous work, we theoretically derived expressions for an upper and lower bound of the correlation between purebred and crossbred performance (r_{pc}), using only variance components of the parental purebred lines. In the current study, we validated these expressions in real data of pigs by comparing predicted bounds of r_{pc} with the estimated r_{pc}. We compared three methods to approximate the required variance components. The results suggest that the most useful method is to use ordinary REML estimates. If confirmed in other datasets, this approach may help breeders to predict the value of r_{pc} based only on parental line information, or to determine the relative contributions of genotype by genotype and genotype by environment interactions to the value of r_{pc}. We therefore advise studies estimating r_{pc} with genotype data to also estimate and report genetic variance components within and between the parental lines, estimated as described in this study.

Introduction

The genetic correlation between purebred (PB) and crossbred (CB) performance (r_{pc}) is an important parameter in crossbreeding programs, because the r_{pc} determines the response in CB performance when selection is based on PB performance in the parental lines (Smith 1964; Wei *et al.* 1991). A low value of r_{pc} may therefore indicate the need for collecting CB information when the aim is to improve CB performance.

The r_{pc} can be estimated from phenotypes measured on PB and CB animals that are genetically related, and when the pedigree-based relationships between these animals are known (Wei and van der Werf 1995; Lutaaya *et al.* 2001). In practice, however, collecting CB phenotypes can be costly, and the pedigree of CB animals is often difficult to record. The need for a pedigree can be alleviated by genotyping the PB and CB animals that have phenotypes. Although this approach can lead to accurate estimates of r_{pc} (Duenk *et al.* 2019), it may not justify the large investment that is needed for phenotyping and genotyping the required number of CB animals, in particular because the value of CB information for genetic improvement has not yet been determined. Breeders may therefore benefit from predicting the r_{pc} beforehand, based only on information from the parental lines, which is readily available in ongoing breeding programs.

In a previous study, we derived expressions for bounds of r_{pc} based on true variance components computed from QTL effects and genotypes in the parental lines (Duenk *et al.* 2021). These expressions predict the bounds of r_{pc} when only genotype by genotype interaction (G×G) due to dominance and epistasis, and no genotype by environment interaction (G×E) is present. Although obtaining the required variance components is straightforward when QTL effects and genotypes in the parental lines are known (Duenk *et al.* 2021), it is not yet clear how they can be estimated from phenotypes and marker genotypes in the parental lines. In this study, we compare three methods to approximate the variance components required to predict bounds of r_{pc}. For this purpose, we compared predicted bounds of r_{pc} with the estimated r_{pc} in empirical data of pigs.

Materials & methods

Data. We used phenotypic and genotypic data from three PB lines and their three-way CB, provided by Topigs Norsvin and Norsvin. In total, we used 17,100 animals from a synthetic sire line (S), 6,611 animals from a Landrace (LR) line, 8,587 animals from a Large-White (LW) line, and 4,173 three-way CB. The LR and LW lines were crossed to produce F1 sows, which were crossed with the sires from S to produce the three-way CB. Purebreds were housed in a nucleus environment, and crossbreds in a commercial environment. Phenotypes were pre-corrected for fixed effects using a larger dataset during the routine genetic evaluation of Topigs Norsvin. Traits included were test growth (TGR), lifetime daily gain (LGR), daily feed intake (DFI), backfat (BFE) and loin depth (LDE). All animals were genotyped with the Illumina 50K SNP chip or the Illumina Custom 25K SNP chip. After quality control, all genotypes were imputed to 50K using Fimpute v2.2 (Sargolzaei *et al.* 2014). Markers with MAF<0.01 in any of the lines were excluded, yielding a total of 35,595 markers that were used for analyses.

Estimating r_{pc}. We estimated r_{pc} in line S using a bivariate model that treats PB and CB performance as different, but genetically correlated traits. The statistical model was:

$$\begin{bmatrix}\mathbf{y}_{\mathrm{PB}}\\ \mathbf{y}_{\mathrm{CB}}\end{bmatrix} = \begin{bmatrix}\mathbf{1}_{\mathrm{PB}} & 0\\ 0 & \mathbf{1}_{\mathrm{CB}}\end{bmatrix}\begin{bmatrix}\mu_{\mathrm{PB}}\\ \mu_{\mathrm{CB}}\end{bmatrix} + \begin{bmatrix}\mathbf{Z}_{\mathrm{PB}} & 0\\ 0 & \mathbf{Z}_{\mathrm{CB}}\end{bmatrix}\begin{bmatrix}\mathbf{u}_{\mathrm{PB}}\\ \mathbf{u}_{\mathrm{CB}}\end{bmatrix} + \begin{bmatrix}\mathbf{e}_{\mathrm{PB}}\\ \mathbf{e}_{\mathrm{CB}}\end{bmatrix} \quad (1)$$

where y is a column vector of corrected phenotypes, μ is the mean, 1 is column vector of 1's, u is a column vector of additive genetic values with incidence matrix Z, and e is a column vector of random residuals. The distribution of additive genetic values for PB and CB performance was:

$$\begin{bmatrix}\mathbf{u}_{\mathrm{PB}}\\ \mathbf{u}_{\mathrm{CB}}\end{bmatrix} \sim N\left(\begin{bmatrix}\mathbf{0}\\ \mathbf{0}\end{bmatrix}, \begin{bmatrix}\sigma^2_{u_{PB}} & \sigma_{u_{PB}u_{CB}}\\ \sigma_{u_{PB}u_{CB}} & \sigma^2_{u_{CB}}\end{bmatrix} \otimes \mathbf{G}\right) \quad (2)$$

where G is the genomic relationship matrix, constructed following Wientjes *et al.* (2017). Estimated variance components were obtained using restricted maximum likelihood (REML) in MTG2 (Lee and van der Werf 2016).

Predicted bounds of r_{pc}. Bounds of r_{pc} were predicted based on parental line information only, using the expressions derived in Duenk *et al.* (2021). The expression for the lower bound of r_{pc} in line S for a three-way CB is:

$$r^L_{pc} = \frac{\sigma_{S(S),S(LW)} + \sigma_{S(S),S(LR)}}{\sigma_S\sqrt{\left(\sigma^2_{S(LW)} + \sigma^2_{S(LR)} + 2\sigma_{S(LW),S(LR)}\right)}} \quad (3)$$

where σ_S is the standard deviation of additive genetic values of individuals in line S for the trait expressed in line S, $\sigma^2_{S(b)}$ is the variance of additive genetic values of individuals in line S for the trait expressed in line *b*, where *b* is LW or LR, and $\sigma_{S(b),S(c)}$ is the covariance between additive genetic values of individuals in line S for the trait expressed in line *b* and *c*. The expression for the upper bound of r_{pc} uses the same parameters, and is

$$r^U_{pc} = \frac{\sigma^2_S + 0.5\sigma_{S(S),S(LW)} + 0.5\sigma_{S(S),S(LR)}}{\sigma_S\sqrt{\left(\sigma^2_S + 0.25\sigma^2_{S(LW)} + 0.25\sigma^2_{S(LR)} + \sigma_{S(S),S(LW)} + \sigma_{S(S),S(LR)} + 0.5\sigma_{S(LW),S(LR)}\right)}} \quad (4)$$

Approximating variance components. Equations (3) and (4) show that we need genetic variance components of parental lines that are usually not available, such as the additive genetic standard deviation in line S for the trait expressed in line LW ($\sigma_{S(LW)}$). Such a component cannot be estimated directly, because there are no phenotypes of individuals from line S for the trait expressed in line LR. Instead, we approximated these components using three different methods. With the first method (M-GEBV), we obtained genomic estimated breeding values (GEBV) of individuals in line S using univariate genomic analyses for each line separately, and computed the (co)variances between these GEBV to approximate the parameters in (3) and

(4). For example, $\sigma_{S(LW)}$ was approximated as the standard deviation of GEBV of individuals in line S for the trait expressed in line LR, and $\sigma_{S(LW),S(LR)}$ was approximated as the covariance between GEBV of individuals in line S for the traits expressed in line LW and line LR. With the second method (M-GEBV-S), we used the same approach, but we corrected for shrinkage of GEBV by dividing the GEBV by the square-root of their reliabilities before using them to approximate the variance components. With the third method (M-REML), we used ordinary genomic REML estimates of variance components within and between lines. For example, $\sigma_{S(LW)}$ was approximated as the ordinary REML estimate of the additive genetic standard deviation in line LW, and $\sigma_{S(LW),S(LR)}$ was approximated as the ordinary REML estimate of the additive genetic covariance between line LW and LR.

Results

The estimated r_{pc} ranged from 0.76 (LGR and DFI) to 0.79 (BFE), with standard errors that ranged from 0.04 (DFI and BFE) to 0.07 (LDE) (Figure 1). With M-GEBV, the estimated r_{pc} was always between the predicted lower and upper bound. However, the difference between the lower and upper bound of r_{pc} (i.e. the range) was large (0.57 on average). Correcting GEBV for shrinkage (M-GEBV-S) resulted in a smaller range (0.40 on average), but the estimated r_{pc} was sometimes higher than the upper bound. Finally, with M-REML, the estimated r_{pc} was usually between the bounds, except for BFE. Furthermore, M-REML resulted in the smallest range (0.22 on average).

Discussion

In this study, we predicted bounds of r_{pc} based on approximated genetic variance components of parental lines. We compared three methods to approximate the required variance components. The results suggest that the most useful method is M-REML, because this method resulted in the smallest range between the lower and upper bound, and in correct bounds for four out of five traits. For one trait (BFE), the estimated r_{pc} was lower than the predicted lower bound, but this difference was smaller than the standard error of r_{pc}.

Based on theory, the variances and covariances in (3) and (4) should be obtained from true breeding values of S individuals, for the trait expressed in the three parental lines. We therefore expected that method M-GEBV-S would yield the most useful predictions, because this method ensures that (1) approximated variance components refer to the individuals in the focal line, and (2) the GEBV are corrected for shrinkage. The difficulty of this method lies in accurate estimation of GEBV (and their reliabilities) for traits expressed in the mated lines. As a result, estimates of variances and covariances may be inaccurate. In contrast, with M-REML, variance components are estimated directly from phenotypes of the trait of interest, making them more accurate. However, with M-REML, the variance components do not refer to the individuals in

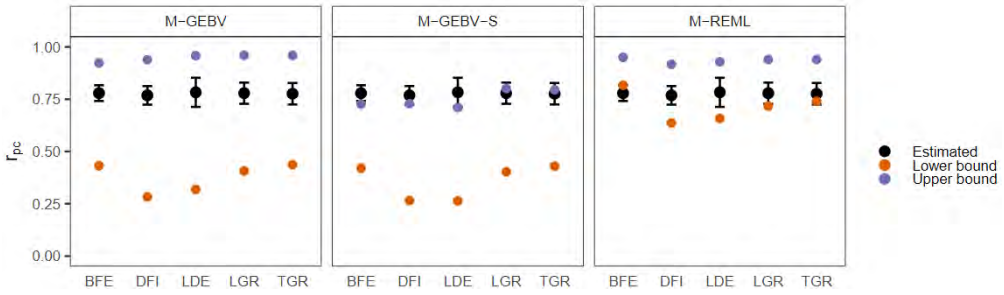

Figure 1. Estimated r_{pc} and predicted bounds of r_{pc} in line S. Facets indicate the method that was used to approximate variance components. BFE=backfat, DFI=daily feed intake, LDE=loin depth, LGR=lifetime daily gain, TGR=test growth rate.

the focal line, but to the individuals in the mated line. For the line and traits that were used in this study, M-REML seemed to give more accurate predictions than M-GEBV-S, suggesting that the assumptions of M-REML have a smaller impact on predicted r_{pc} than those of M-GEBV-S.

The expressions to predict bounds of r_{pc} assume that the value of r_{pc} is determined only by non-additive effects in combination with allele frequency differences between parental lines (i.e. G×G interaction), and not by G×E interaction. In this study, G×E interaction may be present, because the PB animals were housed in a nucleus environment, while the CB animals were housed in a commercial environment. Hence, the value of r_{pc} may be lower than 1 due to both G×E and G×G.

In conclusion, we empirically validated that bounds of r_{pc} can be predicted from ordinary REML estimates of variance components in the parental lines. If confirmed in other datasets, this approach may help breeders to predict the value of r_{pc} based only on parental line information, or to determine the relative contributions of G×G and G×E to the value of r_{pc}.

178. Multi-breed genomic predictions from commercial crossbred data

B.J Hayes*, J. Copley, E. Dodd, E.M. Ross and G. Fordyce

Centre for Animal Science, Queensland Alliance for Agriculture and Food Innovation, University of Queensland, St Lucia, QLD 4067, Australia; b.hayes@uq.edu.au

Abstract

Ideally genomic estimated breeding values would be accurate regardless of breed or breed composition (crossbreds, composites) of the selection candidates. Additionally, it would be an advantage if commercial (potentially crossbred) animals could be used in the reference population, as this would potentially allow for very large reference populations. Here we propose a model for such data, using marker heterozygosity (to model heterosis) and breed composition derived from markers, as covariates in the model. Using a tropical beef data set of close to 30k purebred, crossbred and composite commercial animals, we demonstrate moderately-accurate (0.3-0.43) genomic estimated breeding values can be predicted from this model. Finally, a method for estimating the number of effective genome comparisons for each breed combination within contemporary groups is derived.

Introduction

Multi-breed genomic evaluations are desirable as they allow producers to select sires and dams across breeds, crossbreds and composites, increasing selection intensity. The advantage of multi-breed evaluations for increasing accuracy of genomic prediction, particularly for breeds with smaller reference set sizes, has been demonstrated in dairy cattle (Khansefid *et al.* 2020), sheep (Brito *et al.* 2017, Moghaddar *et al.* 2013) and beef cattle (Hayes *et al.* 2019).

There are a number of challenges to overcome for multi-breed predictions. In particular, multiple breeds must be measured in the same contemporary groups in order to disentangle contemporary group effects from breed effects.

Using commercial data from purebred, crossbred and composite animals (rather than data collected on studs) in multi-breed evaluations is attractive, as such data may be abundant. Such data is also recorded in the target environment for production, so that genotype by environment interaction between stud and commercial environments is no longer an issue. However often little is known about breed composition or heterosis of these animals.

Here, we propose a model for multi-breed genomic prediction based on large scale commercial data that overcomes at least some of these problems.

Methods and materials

Animals and phenotypes. Fifty-four collaborator herds from across northern Australia participated in data collection (the 'Northern Genomics project'). The 28,250 heifers enrolled included crossbred and in approximately 8,000 purebred heifers from at least 14 breeds. Importantly, producers in this project committed to having bulls in the paddock for approximately 6 weeks. Traits measured on the heifers included weight, height and body condition score at an average of 600 days, and a heifer puberty trait. The heifer puberty trait was cycling or not cycling by an average of 600 days (CLscore) assessed by ovarian scanning, as described by (Corbet *et al.* 2018). To maximise genetic variation, the trait is actually measured when an estimated 50% of heifers are pubertal, i.e. at 1.0-2.5 years of age.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_178, © B.J Hayes *et al.* 2022

Genotypes. All heifers were genotyped with the 35k or 50k tropBeef SNP array by Neogen, Australasia. Genotypes were imputed up to 709,768 SNP (Bovine HD array) using the findhap software (VanRaden *et al.* 2013), and a panel of 4,650 cattle of relevant breeds genotyped for the Bovine HD array.

Statistical analysis. We first estimated breed proportions of each heifer for each of the 14 breeds known to be in the data set (using the 35K array data only). Previously, a separate large data set consisting of only purebred cattle was used to estimate SNP effects for breed composition. A GBLUP model was fitted, where the phenotype was 1 if the animal was of that breed and 0 if not (Dodds *et al.* 2014). The effect of each SNP for the proportion of each breed was then derived by back-solving for the SNP effects (Yang *et al.* 2011), and the resulting prediction equations for each breed were used to estimate breed proportions in the heifers.

Then the model fitted to the CLScore, height, body condition score and weight data was:

$y = \mu + cohort + year + het + breedprop + animal + \varepsilon$

Where: y is a vector of trait records (CLscore, weight, hip height or body condition score); μ is the population mean; cohort is the property+yeardrop+paddock that the heifers were in prior to mustering for trait recording; year is the year of recording; het is the heterozygosity of each heifer as measured by the proportion of markers that were heterozygous (to capture heterosis effects) fitted as a liner effect; breedprop is a series of 15 covariates (14 breeds and *Bos indicus* content), measuring the proportion of each breed in the heifers as described above; animal is a vector of random effects ~ $N(0, \mathbf{G}\sigma_g^2)$, with G the genomic relationship matrix among all heifers (Yang *et al.* 2011) and σ_g^2 the genetic variance captured by the SNP markers; ε is a vector of random deviations ~ $N(0, \mathbf{I}\sigma_e^2)$. There were at least 50 animals in each contemporary group. To report heterosis, which ranges in the data from marker heterozygosity ~0.25 (purebred) to 0.5 (F1), we have re-scaled the estimate to be on the scale of purebred to F1 (e.g. ¼ of the actual estimate of marker heterozygosity which is scaled 0 to 1). Variance components were estimated in GCTA (Yang *et al.* 2011), and the heritability of the traits (actually the proportion of phenotypic variance captured by the SNP) was estimated as $h^2=\widehat{\sigma_g^2}/(\widehat{\sigma_g^2}+\widehat{\sigma_e^2})$.

The accuracy of GEBV was evaluated by dropping out 10 of the 2018 cohorts (the latest birth year of heifers for which data was captured) at random. The breed composition within the 10 herds (3,790 heifers) ranged from purebred Brahman to crossbreds of *Bos taurus* breeds. There were 24,561 heifers in the reference population. GEBV were predicted for the heifers in the 10 excluded herds, then the GEBV were correlated with the actual phenotypes (adjusted for fixed effects) of the heifers within each herd. This correlation was divided by the square root of the heritability of the trait to get the accuracy of genomic prediction. We also assessed accuracy of genomic prediction in a completely independent data set, the Beef CRC cohort of 894 and 1,088 Brahman and Tropical composite cattle (respectively). These cattle were phenotyped for a different fertility trait than we have used, age at first corpus luteum, assessed by ultrasound scanning at six-week intervals (Johnston *et al.* 2013). Genotypes for these cattle were imputed to the same 709,768 SNP used in the genomic predictions.

Ultimately for multi-breed evaluations, head-to-head comparisons of breeds in the same herd/environment are necessary. We assessed how many head-to-head comparisons as $\sum_i^n X_i' X_i$ where for each of *n* cohorts in the data set, X_i is a matrix of breed proportions in cohort *i*, of dimensions number of heifers in the cohort × number of breeds.

Results

Heterosis had a positive effect on all traits, increasing height, weight, body condition and a substantial effect on the chance of being pubertal at scanning, Table 1. The heritability of the traits estimated from the genomic data was moderate for heifer puberty and body condition score, and higher for weight and hip height (Table 1).

Table 1. Number of phenotypes, heterosis effect (scaled purebred to F1 of *Bos indicus* × *Bos taurus*; trait range for reference in body condition score is 1 to 5, for heifer puberty 0 to 1), trait genomic heritabilities (± standard errors) and accuracy of genomic predictions (across 10 herds).

Trait	Number of records	Heterosis	Heritability	Accuracy of genomic prediction
Weight	24,528	40.5 kg	0.29±0.02	0.31±0.04
Hip height	24,261	43.8 mm	0.39±0.02	0.43±0.04
Body condition score	24,537	0.25 units	0.22±0.02	0.33±0.04
Heifer Puberty	28,351	0.27 units	0.22±0.03	0.42±0.05

Accuracies of GEBV in the 10 validation herds were moderate, and fairly consistent across herds, reflected in the relatively low standard error on these accuracies.

The number of head-to-head comparisons possible from the data set, which enables estimates of breed effect, was reasonable for Angus versus Brahman (337), Brahman versus Droughtmaster (924) and Brahman versus Santa Gertrudis (421), but was lower for other breed combinations.

Discussion

This study demonstrates that moderate accuracies of multi-breed genomic prediction can be achieved from reference sets derived from large scale commercial data. Genomic heritabilities were consistent with previous estimates for these traits in tropical beef cattle data sets derived from pedigree (e.g. Corbet *et al.* 2018), as were heterotic effects (e.g. Frisch and Vercoe 1984). The challenges of unknown breed composition and level of heterosis can be solved using estimates of these parameters obtained directly from the genotype data (e.g. Dodds *et al.*, 2014, Akanno *et al.* 2016). Using crossbred data allows head-to-head comparison of chromosome segments derived from different breeds, disentangling breed effects from contemporary group effects, at least to some extent. This suggests the data set will contribute to multi-breed genomic evaluations for many, but not all breeds used in northern Australia.

Acknowledgements

The authors gratefully acknowledge the participation and efforts of the 54 northern herds in the Northern Genomics Project, and assistance from various DAF staff at various stages of the project. We are grateful for funding from the MLA Donor Company and University of Queensland through project P.PSH.P0833.

Abstract

Beef cattle breeds in North Australia originate from two subspecies, *Bos indicus* and *Bos taurus*. Development of accurate genomic evaluations for this industry will require models that can accurately predict across all breeds and cross-breeds of these two subspecies in this industry. As these subspecies are genetically diverse, it will be essential to understand if there are differences in genomic architecture of quantitative traits between these subspecies. We propose a novel method of using haplotypes to define subspecies of origin in a multi-breed, multi-subspecies population of heifers with no available pedigree. Results from this method show that subspecies specific genomic architecture exists in this population of heifers, and further research is required to develop methods to account for this population structure in genomic evaluations.

Introduction

Many livestock breed and crop varieties are actually hybrids of species or subspecies. For example, tropical beef and dairy cattle are often hybrids of *Bos indicus* and *Bos taurus* (Achilli *et al.*, 2008, Bolormaa *et al.*, 2011). Accurate genomic selection and QTL mapping relies upon sufficient linkage disequilibrium (LD) between SNP on the marker panel and the quantitative trait loci (QTL) affecting the trait of interest (Meuwissen *et al.*, 2001, de Roos *et al.*, 2008). For subspecies that diverged many generations ago, it is unlikely that the same QTL segregate in both subspecies (Bolormaa *et al.* 2011). When genomic selection and or QTL mapping is applied in such populations, ghost QTL, where a SNP tracks a QTL in a subset of the population but not the rest of the population, may result (Kemper *et al.* 2015). This reduces the accuracy of genomic predictions and reduces mapping precision. Here we propose a new method for genomic prediction that accounts for the possibility of different LD between SNP and QTL in haplotypes derived from the different subspecies that make up a hybrid population.

Methods and materials

Genotypes and phenotypes. In order to assign SNP alleles in the reference population to subspecies of origin, genotypes from 1,182 purebred *B. indicus* and *B. taurus* animals were obtained from the 1000 Bulls Genome Project Run 6 (Hayes and Daetwyler, 2019). In total there were 868 *B. indicus* animals from a single breed, Brahman, and 313 *B. taurus* animals from five breeds, Angus (n=100), Hereford (n=43), Limousin (n=62), Shorthorn (n=95) and Charolais (n=13).

The genomic prediction reference population consisted of 3695 heifers from three breeds. There were 979 Brahman heifers, which is a *B. indicus* breed, 914 Santa Gertrudis and 1802 Droughtmaster heifers, which are both stabilised composites of *B. indicus* × *B. taurus* origin. All heifers were genotyped with the Geneseek GGP-LD array consisting of 21,121 SNP (Hayes *et al.*, 2019) that was then imputed up to the Bovine HD array of 728,785 SNP (800K panel) using the FImpute software (Sargolzaei *et al.*, 2014). All heifers were phenotyped for reproductive maturity score (RMS) which is a single-ultrasound measure of puberty that has been shown to be moderately heritable (20%) in this population of heifers (Warburton *et al.*, 2020). Full details of heifer management and recording have been described previously (Corbet *et al.*, 2018).

Subspecies of origin assignment. Both datasets were phased using Eagle version 2.4.1 (Loh *et al.*, 2016) and haplotypes were generated using fixed, non-overlapping windows of 100 kb from in-house scripts using Julia (Bezanson *et al.*, 2017). A second Julia function was developed to calculate subspecies specific haplotype frequencies from the reference population. Subspecies of origin was assigned using a method derived from Bolormaa *et al.* (2011). For each animal in the validation population, each haplotype in the genome was assigned a b-value, which is the probability that the haplotype is *B. indicus* in origin (Bolormaa *et al.* 2011).

$$b = \frac{pBi_j}{pBi_j + pBt_j} \quad (1)$$

Where *pBi* is the frequency of the j^{th} haplotype in the *B. indicus* 1000 Bulls Genomes data and *pBt* is the frequency of the j^{th} haplotype in the *B. taurus* 1000 Bulls Genomes data. If a $b \geq 0.5$ the haplotype was considered to be *B. indicus* in origin and if $b < 0.5$ it was considered *B. taurus*. In the instance a haplotype from the validation population did not exist in the reference, Hamming distance methods were used to calculate *b* in that subspecies using Julia (Gomez, 2015, Van der Loo, 2014). Each animal has two haplotypes per locus *j* and b-values were used to estimate if an animal is homozygous *B. indicus* (BiBi), homozygous *B. taurus* (BtBt) or B. *indicus* × *B. taurus* (BiBt) composite for each SNP within a haplotype. After assigning subspecies of origin to each animals SNP's, *B. indicus* content was averaged for all animals within a breed. The estimated *B. indicus* content from haplotypes was compared to theoretical *B. indicus* content for each of the breeds, derived from known breed history, to assess the accuracy of subspecies assignment using haplotypes.

X-matrix construction. We designed a subspecies-specific X-matrix, with dimensions of $n \times 3m$ where *n* is the number of animals in the validation population, and *m* is the number of SNP on the marker panel used to construct haplotypes. Each SNP from the 800K panel has three columns in the X-matrix, one for BiBi, one for BtBt and one for BiBt. After subspecies assignment, the X matrix was populated with phased genotype data (0, 1 or 2) using subspecies of origin assignment (BiBi, BtBt, BiBt) to allocate the appropriate X-matrix column for each SNP and animal.

Bayesian analysis. BayesR analyses used the model in Equation 2.

$$RMS = 1n\mu + cg + age + Xg + e \quad (2)$$

Where RMS is a vector of reproductive maturity score phenotypes, 1n is a vector of ones, cg is contemporary group defined as herd, year and season fitted as a fixed effect and age is age at measurement fitted as a covariate. As there were no mixed breed contemporary groups in this dataset, breed was not fitted as a covariate in the model as contemporary group described all variation due to breed. X is the X-matrix described above and g is a vector of SNP effects with a distribution $g \sim N(\mathbf{0}, \sigma_i^2$ where σ_i^2 belongs to one of four distributions: $\sigma_i^2 = \{0, 0.0001, 0.001, \text{or } 0.01\} \times \sigma_g^2$ and σ_g^2 is the genetic additive variance. Full details on the BayesR model can be found in Erbe *et al.* (2012). We used 50,000 Gibbs chain iterations, with the first 20,000 iterations discarded as burn-in.

Subspecies genome mapping. The X-matrix used in this BayesR analysis allowed us to simultaneously estimate subspecies effects for each SNP on the 800K marker panel. Subspecies specific genomic architecture for the RMS trait was investigated by identifying differences in subspecies specific SNP effects for each of the SNP on the 800K marker panel. The estimated subspecies SNP effects were plotted using the CMplot package in R (Yin 2021).

Results

Results in Table 1 show the average *B. indicus* content of each of the breeds of heifers, estimated using haplotypes (observed) and theoretical known breed history (expected). These results show that there are no significant differences in *B. indicus* content between theoretical estimates and haplotype subspecies assignment. This suggests that haplotype assigned subspecies of origin is able to detect and trace subspecies specific genomic architecture accurately throughout the genome.

Figure 1 shows that there are distinct subspecies differences in the genetic architecture for RMS in this population of heifers. There are very few instances where SNP are explaining variation in both subspecies. Furthermore, in the few regions where SNP are explaining variation in multiple subspecies, the estimated SNP effects are often quite different between the subspecies.

Discussion

To our knowledge, this is the first attempt using BayesR to map QTL in multiple subspecies in a hybrid population. Our results suggest the method can identify distinct subspecies differences. In some instances, the estimated subspecies SNP effects showed opposing effects with other subspecies, which may suggest that associations (phase) between SNP and QTL differ between the subspecies. It has been estimated that the *B. indicus* and *B. taurus* subspecies diverged from a common ancestor approximately 332,000 years ago (Achilli *et al.*, 2008). Thus, these observed differences in genomic architecture are not unexpected.

Table 1. Average *Bos indicus* content of Brahman, Droughtmaster and Santa Gertrudis heifers estimated from known breed origins (expected) and from haplotype subspecies mapping (observed).

Breed	Expected *B. indicus* %	Observed *B. indicus* %
Brahman	90	89
Droughtmaster	50	54
Santa Gertrudis	34	39

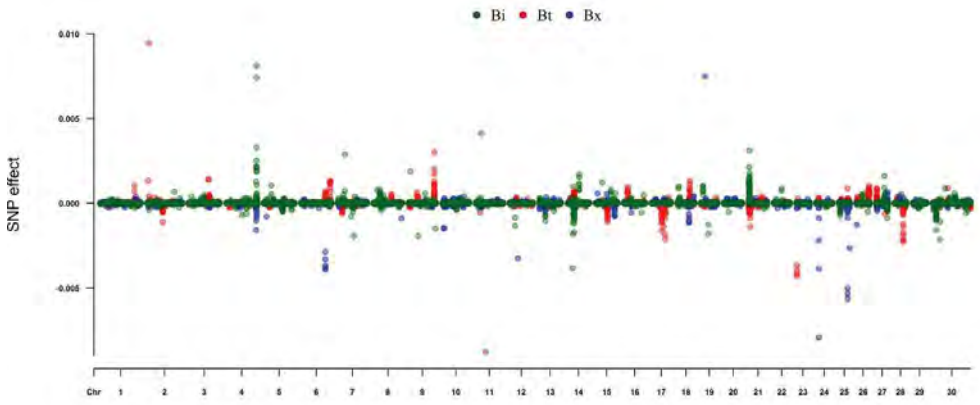

Figure 1. Estimated SNP effects (y-axis) from BayesR analysis using haplotypes to allocate subspecies of origin across all chromosomes (x-axis). Estimated homozygous *Bos indicus* (Bi) SNP effects in green, homozygous *Bos taurus* (Bt) effects in red, and *B. indicus* × *B. taurus* (Bx) effects in blue.

Accurate genomic evaluations rely upon maintenance of LD-phase between SNP and QTL (de Roos *et al.*, 2008). In a study of multi-breed *B. taurus* dairy and beef cattle, de Roos *et al.* (2008) showed that high density (~300,000) marker panels would be required to accurately perform genomic evaluations between these breeds due to differing LD associations. It must be noted that in the paper by de Roos *et al.* (2008), all of the breeds studied were from a single subspecies, *B. taurus*. In our study we have shown that LD phase between SNP and QTL is unlikely to be conserved across subspecies, *B. indicus* and *B. taurus*. Failure to take this into account may generate ghost QTL, and decrease the precision of QTL mapping. More work is required to investigate methods to use subspecies specific SNP effects in genomic evaluations, with the aim of improving prediction accuracy in hybrid populations.

Abstract

The lack of large reference populations has limited the accuracy of genomic prediction for dairy cattle breeds with small populations. We review strategies to improve multi-breed genomic prediction. Several studies show that multi-breed reference populations can increase accuracy for minor breeds. Evidence suggests sequence and functional genomics can get us closer to causal variants, and thus improve multi-breed prediction. However, we know little about the sharing of causal variants across breeds. We carried out a case study comparing direction of effect of variants selected from within-breed genome-wide association studies (GWAS), a meta-GWAS, or a combination of functional, evolutionary, and pleiotropic information. Variants selected from a meta-GWAS were most likely to have the same direction of effect in different populations. Selecting variants from a meta-GWAS with the same direction of effect in multiple breeds may be a suitable strategy to select sequence variants that increase the accuracy of multi-breed genomic prediction.

Introduction

Genomic prediction has revolutionised the dairy cattle industry in the last decade. This is especially true for breeds with large reference populations, such as Holstein cattle. However, the uptake of genomic prediction has been challenging for breeds with smaller populations. The size of the reference population is a major factor determining the accuracy of genomic prediction (Liu *et al.*, 2011), and the lack of sufficiently large reference populations has been an obstacle for some breeds. For example, in Australia, genomic prediction for Holstein has been implemented in 2011, yet genomic estimated breeding values (GEBV) for Australian Red dairy cattle (a minor breed) were first released only in August 2021, 10 years later. Furthermore, even though Australian Reds now have GEBV for milk, fat, protein and somatic cell count; Holsteins have GEBV for a wider range of traits, such as fertility, survival, feed efficiency and heat tolerance. Hence, for breeds with smaller population sizes obtaining a sufficiently large reference population for all traits, the dairy industry does not have access to the same level of genomic and phenotypic information as breeds with larger datasets. For closely related populations, sharing reference populations can increase prediction accuracy. However, the benefit declines as breeds become more distantly related (Lund *et al.*, 2016). In this paper, we reviewed factors impacting the accuracy of multi-breed genomic prediction in dairy cattle, and future opportunities. Furthermore, we carried out a case study comparing the direction of effect in three dairy cattle breeds of preselected sequence variants.

Composition of multi-breed reference population

Larger reference populations tend to increase genomic prediction accuracy (Liu *et al.*, 2011). However, this is not necessarily true for multi-breed prediction. A multi-breed reference population dominated by one breed can actually reduce the prediction accuracy in smaller breeds (Khansefid *et al.*, 2020; van den Berg *et al.*, 2020a). In Australian Reds, prediction accuracies increased substantially when a small number of Holstein bulls was included in the reference population, but further increasing the number of Holsteins

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_180, © I. van den Berg *et al.* 2022

reduced the accuracy, sometimes below that achieved within-breed (van den Berg *et al.*, 2020a). Similar results were obtained for genomic prediction of crossbred dairy cattle (Khansefid *et al.*, 2020). Hence, rather than using all available data, multi-breed reference populations need to be designed cautiously.

Selection of sequence variants

Various studies have shown that using preselected sequence variants can help to increase the accuracy of genomic prediction (e.g. Brøndum *et al.,* 2015; VanRaden *et al.*, 2017), and can be especially beneficial for across-breed prediction (Raymond *et al.*, 2018). The optimal set of prediction markers may, however, vary between traits and breeds (van den Berg *et al.*, 2016). Additionally the increasing availability of 'omics phenotypes, such as metabolomics and transcriptomics, provides opportunities to detect likely causal variants. For example, Prowse-Wilkins *et al.* (2021) showed that variants under ChIP-seq peaks were enriched for quantitative trait loci (QTL) associated with milk production traits, as well as for expression QTL (eQTL). Littlejohn *et al.* (2016) reported an eQTL in *MGST1* associated with milk production traits. Xiang *et al.* (2019) developed the Functional and Evolutionary Trait Heritability (FAETH) score, that integrates functional, evolutionary, and pleiotropic information of variants and can be used to select prediction markers than can increaseprediction accuracy in multiple breeds (Xiang *et al.*, 2019). A custom chip of approximately 50,000 variants, of which three-quarters were selected using sequence and multi-omic approaches, increased the accuracy of genomic prediction in a multi-breed setting (Khansefid *et al.*, 2020).

Multi-breed GWAS

While long-range linkage disequilibrium (LD) can be beneficial for genomic prediction, it reduces precision of within-breed GWAS. When a large section of the genome is in high LD, many sequence variants are highly significant in a GWAS. While many of these variants could be good prediction markers within-breed, this is not necessarily true across breeds, where LD is only conserved over a shorter distance. Including multiple breeds in the GWAS to select sequence variants may, therefore, help to identify variants that are in consistent LD with the causal variant in multiple breeds. Even for within-breed prediction, variants selected from multi-breed GWAS resulted in a higher prediction accuracy than variants selected from within-breed GWAS (van den Berg *et al.*, 2016). In practice, sharing genotypes and phenotypes for a multi-breed GWAS can be challenging. However, a multi-breed GWAS can be approximated with a meta-GWAS, by combining only summary statistics of multiple GWAS, and increase power and precision compared to within-breed GWAS (van den Berg *et al.*, 2020b).

Models suited for multi-breed prediction

While GBLUP assumes all variants have a small effect, using a weighted genomic relationship matrix (GRM) (Zhang *et al.*, 2010), or fitting multiple GRMs (van den Berg *et al.*, 2016) allows preselected sequence variants to have larger effects than standard prediction markers. However, the effects are often assumed to be the same across breeds. Using haplotypes instead of variants to define the relationships between individuals within and across breeds in multi-breed predictions was found to marginally improve the accuracy of predictions (Khansefid *et al., 2022*). Bayesian variable selection models assume most variants have no or very small effects and allow some markers to have larger effects. BayesRC is especially suitable for the analyses of preselected sequence variants, as it uses prior biological information to define classes of variants that are expected to be enriched for causal variants (MacLeod *et al.*, 2016). Alternatively, intermediate omics data can be integrated directly in genomic prediction models alongside prediction markers (Christensen *et al.*, 2021). Multi trait genomic prediction models that consider the same trait in different breeds as different but correlated traits can result in higher accuracies than single trait models and are less sensitive to the composition of the reference population (van den Berg *et al.,* 2020a).

Case study: causal variants sharing across breeds

A potential explanation for the limited success of multi-breed prediction to date could be inconsistent LD between prediction markers and causal variants across breeds. Identifying causal variants, and using models that can allocate an appropriate effect to the variants closest to causal variants, may therefore increase the accuracy of multi-breed genomic prediction. However, this assumes that the majority of causal variants are shared across breeds. Only a few causal variants are identified in dairy cattle, making it challenging to estimate how many causal variants are shared across breeds. The large variation in sample size across breeds makes it challenging to set a threshold to detect QTL and determine whether QTL are shared or not.

Here we evaluated differences in variant effects across breeds by comparing the direction of effect in GWAS in Holstein, Jersey and Australian Red cows. To this end, we undertook within-breed and sex GWAS and a multi-breed meta-GWAS using imputed whole genome sequence data and protein percentage records of 6,323 Holstein bulls, 56,843 Holstein Cows, 1,476 Jersey bulls, 10,210 Jersey cows and 3,080 Australian Red cows. The top 1000/500/100 variants were selected as follows: (1) variants were ranked based on *P*-value or FAETH score; (2) the most significant variant or variant with highest FAETH score genome-wide was selected; (3) variants within 1 Mb of selected variant were discarded; (4) repeat until the desired number of variants was selected. We then estimated the proportion of variants with the same direction of effect (pSDE) in different populations for all variants and the top variants. While pSDE in different breeds increased when variants were more significant in within-breed GWAS (Table 1), pSDE remained substantially lower than for bulls and cows of the same breed. The pSDE across populations was larger for top variants selected from the meta-GWAS than the within-breed GWAS, because *P*-values in the meta-GWAS decrease when the direction of effect is consistent in all populations. Variants selected based on their FAETH score tended to have a higher pSDE than all variants, though the difference was smaller than for variants selected from within-breed GWAS or meta-GWAS. This is not surprising, given that the FAETH variants are not specifically selected for protein percentage. Selecting variants based on their *P*-value in a meta-GWAS and the direction of effect in different populations showed promising results for genomic prediction of milk urea nitrogen using a multi-breed and multi country reference population (van den Berg *et al.*, 2022), and may be a suitable method to select variants for a specific multi-breed reference population and trait. The effect direction meta-analysis developed by Xiang *et al.* (2020) uses direction of effect in multiple GWAS to select pleiotropic variants rather than trait specific variants.

Table 1. Proportion of variants with the same direction of effect across populations[1] for different sets of variants2 (effect direction assessed based on within-breed GWAS).

			GWAS			meta-GWAS			FAETH

JC	RC	0.50	0.52	0.54	0.66	0.80	0.83	0.93	0.51	0.47	0.46

[1] Populations tested were Holstein bulls (HB), Holstein cows (HC), Jersey bulls (JB), Jersey cows (JC) and Australian Red cows (RC); [2] the 1000/500/100 most significant QTL regions in GWAS or meta-GWAS, or with highest FAETH score

Conclusions

To date, implementing routine multi-breed genomic prediction remains challenging. Further identification of causal variants and integration of multi omics data looks promising to increase the accuracy of multi-breed prediction, but we need to better understand the proportion of causal variants shared across breeds. Selecting sequence variants based on multi-breed GWAS or meta-GWAS with consistent direction of effect in different breeds may be a useful strategy to select variants for multi-breed genomic prediction.

Abstract

Crossbred dairy cattle populations have different proportions of parental breeds. However, individuals who display the same breed composition could exhibit remarkable differences in the distribution of local ancestry across the genome. Thus, this study examined the distribution of local ancestry blocks using Illumina BovineSNP50 genotypes and correlated them to key production traits. Two rotational crossbred populations, referenced as ProCROSS and Grazecross were assessed. The results showed higher performance ProCROSS animals in milk fat production more commonly have Holstein ancestry on BTA 2, 6, 13, 22 and 23, where the genes Prion, Lactotransferrin, and Cytochrome P450 reside. We found evidence of an excess proportion of Viking Red ancestry and decreased Jersey ancestry on BTA 1, 10, 12, 14 and 25 at known health QTL in the Grazecross population. In conclusion, we believe that localized breed ancestry plays an important role; thus, selecting and maintaining particular ancestry blocks is crucial to ensure optimal trait performance in crossbred cattle.

Introduction

Generally, crossbreeding is the breeding among individuals from at least two distinct populations. The admixed individuals will inherit haplotype blocks that contain genetic variants of one or more populations. The melding of these haplotype blocks increases the heterozygosity level that contributes to heterosis or hybrid vigour in the admixed offspring. However, this heterozygosity may not always exist, as recombination events occur randomly in gamete formation, creating unique combinations of chromosome segments from each population. Due to this, admixed individuals may display the same breed composition but exhibit differences in the distribution of local ancestry blocks that directly affect complex production trait performance. Mapping local ancestry composition instead of global ancestry could aid in identifying causal variants in complex traits, especially ancestry-specific traits in admixed individuals (Ding *et al.*, 2011). Therefore, our primary goals were to describe the distribution of local ancestry blocks across the genome of the ProCROSS and Grazecross dairy cattle populations. Furthermore, we aimed to explore the correlation of the local ancestry blocks with various production traits.

Materials & methods

Study population. The University of Minnesota (UMN) granted access to ProCROSS and Grazecross datasets. The datasets included 378 ProCROSS and 229 Grazecross cattle genotypes and four traits (milk yield (MY), fat yield (FY), protein yield (PY) and somatic cell score (SCS). To compare ancestry variation for trait performance, the top 20% high-performance animals were compared to the lowest 20% low-performance animals for each trait. To investigate admixture of the ProCROSS and Grazecross, genotypes representing the purebred and admixed breeds used in the two rotational systems were needed for comparison. ProCROSS are a product of rotational crossbreeding of Viking Red (VKR), Holstein (HOL), and Montbeliarde (MON). In contrast, Grazecross consists of VKR, Normande (NOR), and Jersey (JER). VKR breeds were represented by 3 genotype breeds Danish Red (DNR, n=4), Swedish Red

(SWD, n=32) and Finnish Ayrshire (FAY, n=27) (Upadhyay *et al.*, 2017; Iso-Touru *et al.*, 2016, Viking Genetics, Denmark). HOL genotypes (n=92) were provided by UMN obtained from animals directly used in the development of these two admixed populations. Jersey (JER, n=73), Montbeliarde (MON, n=34), and Normande (NOR, n=35) genotypes were obtained from the Gautier *et al.* (2010) publication and represented purebred animals from the USA (JER) and Europe (MON & NOR), respectively. SNP data of all animals were obtained through bovine genotyping array kits BovineHD DNA Analysis Kit (HD150K), BovineSNP50 DNA Analysis BeadChip (50K) and CLARIFIDE® 50k (ZL5) (Illumina- Neogen, Lansing, MI, USA; Clarifide-Zoetis, San Diego, CA, USA).

Filtering and quality control of genomic data. Quality control (QC) analyses for both sets of autosomal SNPs were calculated using SNP and Variation Suite (SVS) v8.x (Golden Helix, Inc., Bozeman, MT, USA). SNPs were excluded if they were unmapped to the UMD 3.1 bovine genome assembly (Zimin *et al.*, 2009) or mapped to the sex chromosomes, had a call rate less than 0.95, or a minor allele frequency less than 0.05. SNPs were further pruned for linkage disequilibrium (LD) using a threshold of r^2>0.75, leaving 9,792 SNPs and 10,795 SNPs for ProCROSS and Grazecross analysis respectively. Overall, SNPs used provided relatively clear separation between ancestral and admixed populations.

Admixture analysis. The global breed composition was estimated from genomic data using a maximum likelihood model implemented in ADMIXTURE 1.23 software. The datasets were analyzed using unsupervised clustering analysis with K=3, where K represented the expected number of ancestral populations in the 3-breed rotational crossbreeding systems. Average global ancestry was determined for each extreme trait performance group with significance in ancestry variation between performance groups assessed using a T-test.

Local ancestry. The pipeline established by Martin *et al.* (2017) was used in developing the local ancestry inference. Crossbred individuals were first phased based on their respective reference population using SHAPEIT2 (v.2) before all haplotypes were merged using custom scripts. These combined phased haplotypes were used as input into the PopPhased version of RFMix v.1.5.471 with the following flags: -w 0.2, -e 1, -n 5, – use-reference-panels-in-EM, and – forward-backward EM. Node size was set to five to reduce bias in random forests resulting from unbalanced reference panel sizes (HOL panel n=92, MON panel n=34, and VKR panel n=63). Several methods were assessed to determine the best representation of local ancestry for each extreme performance group. The method shown here calculated the number of occurrences of the particular breed ancestry for each SNP within each performance group. The ancestry having the highest number of occurrences was considered the ancestry origin for a SNP within a specific performance group.

Results & discussion

Global ancestry composition. Admixture analysis was run to assess the global ancestry composition of ProCROSS and Grazecross. The admixture plots (Figure 1) for both populations revealed proportions of ancestral breeds between 23 and 34%, expected with the 3-breed crossbreeding system. Comparing the average of global ancestry composition between high- and low-performance animals showed that HOL composition plays a significant role in MY and FY in ProCROSS populations, while in the Grazecross population, VKR and NOR composition play a significant role in SCS performance (*P*-value<0.05). This finding provided the basis for understanding the impact of breed-specific ancestry on the performance of crossbred cattle.

Local ancestry. Local ancestry karyograms representing each extreme group were plotted for significant production traits in each admixed population (Figure 2) so that a comparison can be made to identify several potential regions correlated to the performance. A set of breed-specific QTL was extracted from

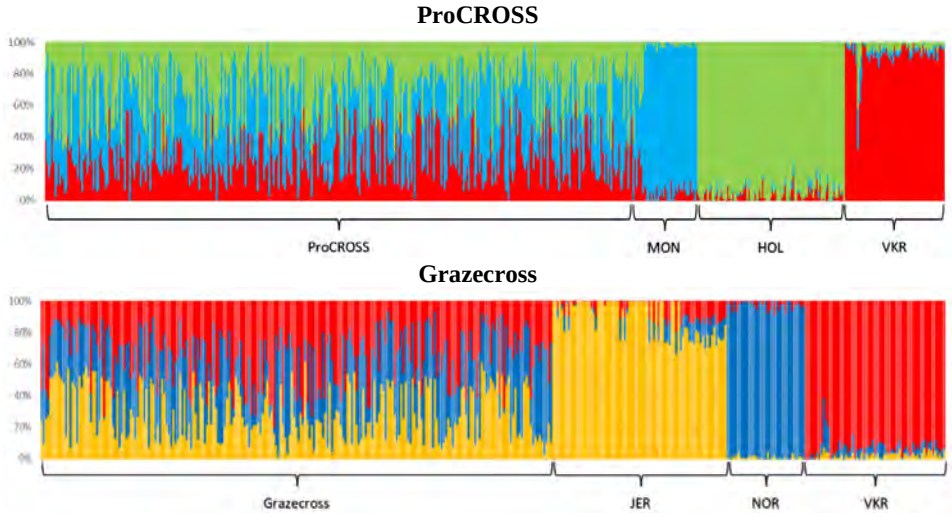

Figure 1. Admixture analysis reflecting global ancestry of breeds for both ProCROSS and Grazecross admixed individuals and all parental populations for K=3.

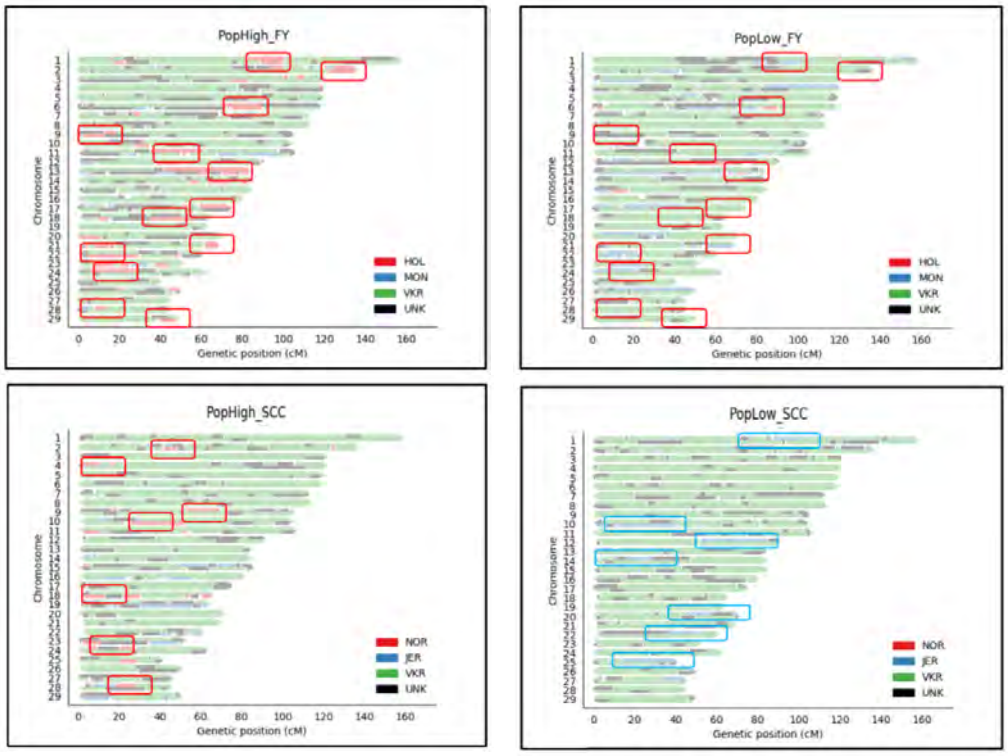

Figure 2. Local ancestry analysis compares high-performance groups (Left side diagrams) and low-performance groups (Right side diagrams) for both ProCROSS (Top) and Grazecross (Bottom) populations.

the Animal QTL database (https://www.animalgenome.org) and several recent publications. Higher ProCROSS FY production animals more commonly have visually larger HOL ancestry on BTA 2, 6, 13, 22 and 23, where genes for Prion, Lactotransferrin, and Cytochrome P450 reside and are denoted by the red box in Figure 2 (top). On the other hand, we found evidence of an excess proportion of VKR ancestry (red box) together with a decrease of Jersey ancestry (blue box) on BTA 1, 10, 12, 14 and 25 at known health QTL for high- and low-performance Grazecross animals respectively (Figure 2 bottom). These findings agreed with the global ancestry results but warrant further investigation to determine if the local ancestry variation visually seen is significantly different between performance groups. In addition, approaches for defining local ancestry for a performance group is still being assessed so that haplotype blocks define group ancestry as opposed to individual SNPs.

182. DNA pooling is a cost effective method of including commercial crossbred data in selection of purebreds

Abstract

It is generally economically unviable to individually genotype large quantities of commercial crossbred broilers to predict purebred breeding values for crossbred performance. Pooling DNA of crossbreds with similar phenotypes, and genotyping the pool, could be a cost-effective alternative. To test this hypothesis, we used a dataset from a broiler three-way cross experiment consisting of ~9,000 individual genotypes and constructed pools of four different sizes (5, 10, 25, and 50 individuals). Estimated SNP effects and predicted sire breeding values from pooled genotypes were compared to results from individual genotypes, where number of individual genotypes was equal to number of pools. The pool size of 50 and 58 pools had a reasonable accuracy and bias (0.45 and 0.76, respectively) compared to 58 genotyped individuals (0.14 and 0.24). Our results indicate that DNA pooling may be used as a cost-effective means to obtain information on commercial crossbreds for selection in purebreds.

Introduction

Production, health, and welfare traits are routinely recorded on commercial crossbred broilers. Due to cost and logistics, it is not viable to link information from individual commercial crossbred animals to purebred selection candidates. Nevertheless, it is desirable to include these traits in selection of purebreds for crossbred performance. Particularly traits measurable at point of slaughter, observable only on animals raised in a commercial environment, or traits for which genetic correlation between purebred and crossbred performance is low. A potential solution is DNA pooling, where individuals with a similar phenotype are grouped together, and then genotyped as one sample. DNA is extracted from each individual, and amplified to a known concentration. A pool is formed by combining equal contributions of DNA, and then the pool is genotyped. In our previous study we showed that the genotypes of DNA pools are a good representation of individuals within the pool (Marjanovic *et al.*, 2020). DNA pooling can be used to estimate sire breeding values (GEBVs) by building a pseudo genomic relationship matrix (Bell *et al.*, 2017). However, this approach would be difficult to implement with complex crossbreeding structures, as relationships between pools and each sire would be relatively equal. Alternatively, SNP effects could be estimated, from which GEBVs of purebred selection candidates can be predicted. Our objective was to determine if DNA pooling of crossbred genotypes and estimation of SNP effects could be used to accurately and unbiasedly predict GEBVs for crossbred performance in purebred animals.

Materials & methods

Available data. Cobb Vantress provided a dataset from a broiler three-way cross experiment. From a single generation and across five batches, 156 genotyped purebred sires (A) were mated with 1,027 crossbred dams (BC). In total there were 9,262 crossbred progeny (A(BC)) that had a body weight recorded at 35 days after hatching (BW35) and each crossbred animal was genotyped (50,961 SNPs). The crossbred progeny were raised in an environment with 'commercial-like' properties, and each batch was divided across five pens.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_182, © M.N. Aldridge *et al.* 2022

Sampling scenarios. In total, 40 contemporary groups were formed based on the fixed effects batch×pen×sex×age, with between 108 and 408 individuals in each. The majority of a sire's offspring within a batch were housed in the same pen, and each pen represented multiple sires, this means sires were not equally distributed across all contemporary groups. Each contemporary group was divided into a high end and a low end (top and bottom 25% performing animals based on BW35, respectively). From the high end of one contemporary group, five individuals were randomly sampled, forming one high pool. Each individual could only appear in one pool, and a pool would only be formed if it could be filled completely (each pool must have 5 individuals). This sampling was repeated for the low end and all contemporary groups. In total, 890 pools were formed (445 high pools and 445 low pools). Pool sizes of 10, 25, and 50 were tested with the same sampling method, which resulted in 426, 158, and 58 pools respectively. For each pool a pseudo genotype was created by calculating the allele frequency of individual genotypes in that pool (pools were not actually genotyped). The phenotype for the corresponding pool was calculated as the mean BW35 for the individuals within the pool. To compare pooling and individual genotyping, three sampling methods were tested. Individuals were selected randomly from the full population (Full), randomly from animals in the high end (High only), or randomly from animals in either the high or low end (High/Low). The number of individuals genotyped was equal to the total number of pools. For the larger individual sampling sizes (890, 426, 158) each contemporary group was represented. In addition, one analysis used all 9,262 individual crossbred genotypes as the golden standard.

Estimating SNP effects. Previously parameter estimates for BW35 were estimated with the same dataset (Duenk *et al.* 2019). They were used as input for the program MiXBLUP with the 'hpblup solver', which was used to estimate SNP effects (Ten Napel *et al.*, 2017). For scenarios that included pools, the pseudo genotypes were treated as if they were imputed genotypes. For scenarios that used the individual genotypes (no pooling), the actual genotypes were used. For the 156 line A sires, the SNP genotypes were used to predict GEBVs following Meuwissen (2001). For each scenario with pooling (5, 10, 25, and 50) and individual genotyping (Full, High only, High/Low), the sampling of individuals and estimation of SNP effects and GEBVs were repeated ten times. In addition, GEBVs were estimated using SNP effects for the golden standard.

Accuracy, bias, and cost. Accuracy and bias were calculated for each scenario and presented as means of the ten replicates. Accuracy was estimated as a weighted correlation between the predicted sire GEBV and the mean offspring performance (Calculated from the full dataset for each sire). Bias was calculated using R (Team R Core, 2013), as a weighted regression of the mean offspring performance on the sire GEBVs, and multiplied by two (for an expectation of 1.00, rather than 0.5 of just the sire). Weighted correlations and regressions were used because some of the sires had significantly more crossbred offspring than others. The weights used, were reliabilities of corrected offspring performance, estimated following Cameron (1997), as:

$$(1/4nh^2) / (1+1/4(n\text{-}1)h^2), \quad (1)$$

where n is the number of offspring and h^2 is the estimated heritability.

The cost for each sampling method, was set at € 28 per sample to be genotyped and an additional 20 cents per DNA extraction.

Results

When the full population of crossbred progeny (9,262) were genotyped, the highest accuracy (0.88) and no bias (1.00) were achieved, but at the highest cost (€ 259,336). With less than 10% of those costs, a reasonable accuracy (0.62) and bias (0.98) was achieved by genotyping 890 individuals (Table 1), but only if genotyped animals were sampled from both the high and low performing end (High/Low). Sampling from the Full population or just the High end, reduced accuracy (Full: 0.49 and High: 0.29) and increased bias (Full: 0.85 and High: 0.51). The High/Low sampling was optimal regardless of the number of individuals genotyped. Therefore, the comparison between pooling and individual sampling is made with High/Low.

With a pool size of 5 (4,450 individuals in 890 pools), the accuracy and bias (0.51 and 0.87) was lower than High/Low sampling. The pool size of 10 (4,260 individuals in 426 pools) outperformed individual High/Low sampling for both accuracy (Pool size 10: 0.49 and High/Low 426: 0.42) and bias (Pool size 10: 0.83 and High/Low 426: 0.74). Due to the cost of extracting additional DNA samples, the cost of 426 pools (€ 12,780) is slightly higher than individual genotyping (€ 11,928). With large pool sizes (25 and 50) and small number of pools (158 and 58), pooled sampling significantly outperformed accuracy and bias of the equivalent number of individual genotypes, at a lower cost (€5,214 and €2,204). With pools of 25, the accuracy was higher (Pool size 25: 0.48 and High/Low: 0.24) and bias lower (Pool size 25: 0.82 and High/Low: 0.42) than 158 individual genotypes. The extreme pooling of 50 individuals in 58 pools had a higher accuracy than 58 individual genotypes (Pool size 50: 0.45 and High/Low 58: 0.14) and less bias (Pool size 50: 0.76 and High/Low 58: 0.24).

Discussion

Pooling individuals based on phenotypic performance within contemporary groups, and then estimating SNP effects from the DNA pools, is an effective method of estimating GEBVs for a sire line. This is in line with the results of Bell *et al.* (2017) with a different approach where a pseudo G-matrix is formed instead. If there is sufficient budget, individual genotyping is preferred. However, to maximise accuracy and reduce bias, animals from both the low and high performing end should be included. Pool size and the number of pools had limited impact on accuracy and bias. The purpose of DNA pooling is cost saving, when the budget is limited, maximising pool size and minimizing number of pools is preferential.

Table 1. Estimated accuracy, bias, and economic cost of individual or pooled genotyping.

Sampling method	Number of individuals	Accuracy[1]	Bias[2]	Cost per sample genotyped	Number of samples genotyped	Total cost
Population	9,262	0.88	1.00	€ 28	9,262	€ 259,336
Full 890	890	0.49	0.85	€ 28	890	€ 24,920
High 890	890	0.29	0.51	€ 28	890	€ 24,920
High/Low 890	890	0.62	0.98	€ 28	890	€ 24,920
High/Low 426	426	0.42	0.74	€ 28	426	€ 11,928
High/Low 158	158	0.24	0.42	€ 28	158	€ 4,424
High/Low 58	58	0.14	0.24	€ 28	58	€ 1,624
Pool size 5	4,450	0.51	0.87	€ 29	890	€ 25,810
Pool size 10	4,260	0.49	0.83	€ 30	426	€12,780
Pool size 25	3,950	0.48	0.82	€ 33	158	€ 5,214
Pool size 50	2,900	0.45	0.76	€ 38	58	€ 2,204

[1] SE for individual genotyping methods ranged between 0.01 and 0.03, and for pooling were all <0.01.

[2] SE for individual genotyping methods ranged between 0.01 and 0.04, and for pooling were all <0.01.

It is worth noting that we formed pseudo genotypes as allele frequencies, rather than actually genotyping pools as it would be required in practice. Previously we showed small differences depending on how the pseudo genotype is calculated and some differences compared to real genotyping of pools (Marjanovic *et al.*, 2020). Therefore, our method of obtaining pseudo genotypes may have influenced our findings. Furthermore, our cost analysis only considered the additional cost of extracting DNA, while there would be other additional costs. Finally, we acknowledge that the accuracies are likely to be spurious (important for EBVs of the high performing end), as the relationship between sires and crossbred progeny are likely to be different across strategies. A cross-validation will be performed to confirm our findings.

Regardless of limitations, in the most extreme scenario (58 pools with 50 individuals in each pool), the accuracy and bias outperformed most individual genotyping scenarios. The accuracy and bias from 58 pools suggests substantial genetic progress could be made using predicted GEBVs in the sire line. On the other hand, selection based on information from 58 individual genotypes would result in poor outcomes due to low accuracy. DNA pooling and estimating SNP effects is a promising method for situations with limited resources but there is a desire to include traits in selection, which is often the case with commercial crossbreds.

Challenges – understanding and utilizing genetic diversity

183. Genetic variability in the individual inbreeding load: genomic prediction for artificial purging

Abstract

Inbreeding is caused by mating between related individuals and it is associated with inbreeding depression. Recently, some models have been described to predict individual inbreeding depression loads with the aim of avoiding undesirable mating and to perform artificial purging. In this study, those models were implemented using a single-step GBLUP approach with two main objectives: (1) to evaluate the increase of accuracy of the prediction of inbreeding loads thanks to genomic information; and (2) to use the equivalence between GBLUP and SNP-BLUP to estimate the SNP effects and to identify the genomic regions associated with the largest variance of inbreeding loads. The results of this study revealed that the increase of accuracy was only relevant for genotyped individuals, and that the inbreeding load variance is heterogeneously distributed along the genome, indicating that the procedure may be adequate to detect potential candidate genes which explain the phenomenon of inbreeding depression.

Introduction

Inbreeding is caused by mating between related individuals and it is associated with inbreeding depression, understood as a reduction in the phenotypic yield (Charlesworth and Willis, 2009) that has been widely observed in animals, plants and humans (Charlesworth and Willis, 2009; Leroy, 2014). Inbreeding depression is brought about by the higher degree of homozygosity in inbred individuals that lose the advantage of over-dominance at heterozygous loci or increase the probability of the presence of recessive alleles. Over the last few years, some models (Casellas, 2018, Varona *et al.*, 2019) have been developed for the prediction of individual hidden inbreeding depression loads that can be used to predict the expected inbreeding depression of each potential inbred cross in the population and to perform individual purging by selecting those with the best inbreeding loads. One limitation to this approach is that most of the inbreeding is caused by a small number of ancestors. Therefore, the accuracy achieved for most of the individuals in the population is very low. However, the approach described above has been developed using only genealogical and phenotypic information. Here we include the genotypic information provided by SNPs device using a single-step approach (Aguilar *et al.*, 2010) with the aim of: (1) evaluating the increase of accuracy for the prediction of the inbreeding loads of younger genotyped animals; and (2) identifying the genomic regions associated with the largest variance of inbreeding loads in order to disentangle the genetic basis of the inbreeding depression.

Materials & methods

Data. The dataset used in this analysis included 91,412 records for cold carcass weight and a pedigree of 141,399 individual-sire-dam entries for the Rubia Gallega beef cattle breed. The average weight was 223.5 kg. with a standard deviation of 40.38 kg. Additionally, 3,441 individuals were genotyped with Axiom Bovine platform (*Axiom_BovMDv3*) from ThermoFisher (Waltham, MA USA). After a standard filtering (95% of individual and population call rate and MAF>0.5), 36,429 SNP for the autosomal chromosomes were used.

Inbreeding. The average inbreeding in the 91,412 phenotyped individuals was 0.027. The great majority of them has a null (35,572) or below 0.05 (42,222) inbreeding coefficient. However, 12,608 of them have an inbreeding coefficient greater than 0.05 and 2,015 of them larger than 0.25. The maximum inbreeding coefficient was 0.46875. The total inbreeding coefficient was decomposed using the Mendelian decomposition proposed by Caballero and Toro (2000) as well as the algorithm described by García-Cortés *et al.* (2010). We were able to decompose the total inbreeding in 1,646,121 partial inbreeding coefficients generated by 2,136 ancestors. The contributions of these ancestors to the total inbreeding were very heterogeneous as 104 ancestors contributes to more than 1000 inbred descendants. Among the ancestors generating inbreeding 475 of them were genotyped.

Model. The model of analysis was:

$$\boldsymbol{y} = \boldsymbol{f}g + \boldsymbol{t}c + \mathbf{Xb} + \mathbf{Wh} + \mathbf{Zu} + \mathbf{Ki} + \boldsymbol{e} \quad (1)$$

Where y is the vector of phenotypic records, *g* is a covariate with total inbreeding, *c* is a covariate with age of recording, b is the vector of systematic effects than includes sex -2 levels- and slaughterhouse –29 levels-, h is the random herd-year-season effects with 14,687 levels, u is the vector of the additive genetic effects, i is the vector of individual inbreeding loads and e is the vector of residuals. The vectors f and t include the genealogical inbreeding and the age of recording, respectively. Lastly, X, W, Z and K are the corresponding incidence matrices. The prior distribution of the herd-year-season was univariate Gaussian and the prior distribution of the additive breeding values was defined with two alternatives: model 1) $\begin{pmatrix}\boldsymbol{u}\\ \boldsymbol{i}\end{pmatrix} \sim N\left(\begin{matrix}0\\ 0\end{matrix}, \boldsymbol{G} \otimes \boldsymbol{A}\right)$ and model 2) $\begin{pmatrix}\boldsymbol{u}\\ \boldsymbol{i}\end{pmatrix} \sim N\left(\begin{matrix}0\\ 0\end{matrix}, \boldsymbol{G} \otimes \boldsymbol{H}\right)$ with $\boldsymbol{G} = \begin{pmatrix}\sigma_u^2 & \sigma_{ui}\\ \sigma_{ui} & \sigma_i^2\end{pmatrix}$. σ_u^2 is the additive genetic variance, σ_i^2 is the inbreeding load variance and σ_{ui} is the covariance between them. Furthermore, A is the numerator relationship matrix and H is the matrix that combines the genomic relationship matrix with A as described by Aguilar *et al.* (2010). The analysis was performed through a Bayesian approach with the Gibbs sampler using a single long chain of 500,000 iterations, having discarded the first 50,000.

Once the analysis was performed, the accuracy (r_i) of the predicted inbreeding loads was approximated in both models by:

$$r_i = \sqrt{\frac{(1+F_i)\hat{\sigma}_i^2 - \mathrm{PSD}(i_i)^2}{(1+F_i)\hat{\sigma}_i^2}} \quad (2)$$

Where F_i is the total inbreeding coefficient of the i^{th} individual and $PSD(i_i)$ is the posterior standard deviation of its inbreeding load. Lastly, we used the predictions of breeding values under model 2 to estimate the SNP effects for the individual inbreeding load following Wang *et al.* (2012). We later used the predictions of SNP effects to estimate the percentage of the total variance explained by segments of 50 consecutive SNP along the autosomal chromosomes.

Results

The estimates of the variances components with model 1 and 2 were very similar. The posterior means (and posterior standard deviations) estimates under model 2 were -56.66 (3.50), 731.55 (17.47), 6,829.71 (2,005.91), -1,531.59 (263.38), 180.79 (4.25) and 223.50 (10.57) for *g*, σ_u^2, σ_i^2, σ_{ui}, σ_h^2 and σ_e^2 respectively. The predictions of the individual inbreeding loads under model 2 are presented in Figure 1, where they are compared with minus the posterior mean estimate of the average inbreeding depression (*-g*).

It must be noted that the model provides estimates of the inbreeding loads that must be understood as the inbreeding depression achieved by a fully inbred descendant. It is worth to highlight that 9.92% of individuals get a prediction of inbreeding load bigger than *–g*, suggesting that inbreeding generated by them will increase the phenotypic performance of their inbred descendants.

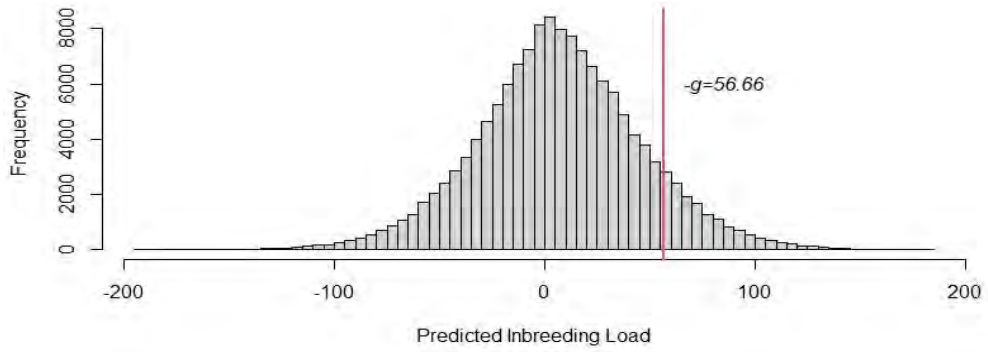

Figure 1. Distribution of the prediction of inbreeding loads compared with minus the posterior mean estimate of the average inbreeding depression (in red).

Later, we investigated the accuracy of the predicted inbreeding loads under models 1 and 2. The average repeatability achieved for all individuals in the pedigree was very similar (0.558 vs 0.562). Only an increase of 2.6% was detected for the genotyped individual (0.606 vs 0.632). Moreover, the difference increased up to 3.7% (0.548 vs 0.585) for genotyped individuals born after 2016.

Finally, Figure 2 presents a Manhattan plot of the percentage of the inbreeding load variance explained by genomic segments of 50 consecutive SNP. The distribution of the inbreeding load variance is heterogeneous along the autosomal genome, and two genomic regions in chromosomes 21 and 28 can be highlighted.

Discussion

The model proposed by Varona *et al.* (2019) allows to estimate the individual inbreeding loads using genealogical and phenotypic information. In this study, it is confirmed that the model is able to detect genetic variation on the inbreeding load and to predict phenotypic consequences in future inbred individuals. Those predictions can be used to avoid undesirable mating and to perform artificial purging by selecting the individuals with the best inbreeding loads. Moreover, we proved that the genomic information can be used to improve the accuracy in the predicted inbreeding loads. However, the use of genomic information has only provided a relevant increase of accuracy in genotyped individuals, with more evidence in young

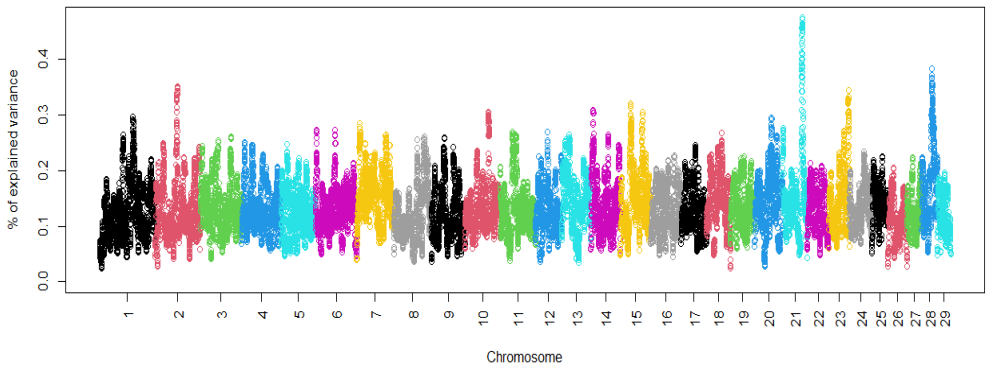

Figure 2. Manhattan plot of the percentage of the inbreeding load variance explained by genomic segments of 50 SNP.

individuals that have no inbred descendent. Additionally, the equivalence between GBLUP and SNP-BLUP models (Wang *et al*., 2012) can be used to estimate the SNP effects associated with the inbreeding load and to calculate the amount of inbreeding load variance explained by each specific genomic segment. As an illustrative example, we calculated the amount of variance explained by genomic segments defined by 50 consecutive SNP and we were able to identify two genomic regions in chromosomes 21 and 28. Nevertheless, these results must be taken as preliminary, and further research has to be done to define more precisely the genomic regions and to identify potential candidate genes within these regions.

184. Inbreeding depression in livestock: comparing trait groups and inbreeding measures

H.P. Doekes*, P. Bijma and J.J. Windig

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; harmen.doekes@wur.nl

Abstract

Inbreeding depression has been documented for many livestock populations. We compared inbreeding depression estimates (1) between trait groups, and (2) between different pedigree-based and genomic inbreeding measures. Inbreeding was found to affect all sorts of traits to a similar extent, independent of heritability and of whether a trait is a primary fitness trait or not. Inbreeding depression estimates were moderately to highly correlated between different pedigree-based and genomic inbreeding measures, but those based on genomic measures tended to have lower *P*-values, suggesting more power to detect inbreeding depression with genomic measures (assuming there is a true inbreeding depression effect). Among different genomic measures (based on genomic relationship matrix, regions of homozygosity, or percentage of homozygous markers), there were no consistent differences in *P*-values.

Introduction

Inbreeding reduces the mean performance of animals, a phenomenon known as inbreeding depression. Based on theory and laboratory experiments, inbreeding mostly affects primary fitness traits such as survival and fertility (Lynch and Walsh, 1998). These traits are under directional selection and the average dominance effect is expected to be favourable, because fixation occurs more quickly for loci with an unfavourable dominance effect (Lynch and Walsh, 1998). For livestock populations, one could argue that traits related to e.g. production may equally qualify as fitness traits, since there has been (artificial) selection for these traits for many generations. Hence, one may expect a similar degree of inbreeding depression for a wide range of traits in livestock.

The degree of inbreeding depression is typically quantified by linear regression of phenotypes on inbreeding coefficients. Inbreeding coefficients can be estimated from pedigree data, but are increasingly derived from genomic information, particularly SNP data. An advantage of genomic measures is that they provide estimates of realized inbreeding, instead of genealogical probabilities (Wang, 2016). Therefore, using genomic inbreeding coefficients may result in more accurate estimates of inbreeding depression (Caballero *et al.*, 2021). Among SNP-based measures, some may better capture inbreeding depression than others.

Many studies have reported (pedigree-based, and more recently genomic) estimates of inbreeding depression. In this paper, we summarize our recently published meta-analysis (Doekes *et al.*, 2021) and extend it with some additional literature and analyses. The aim was to determine and compare inbreeding depression estimates between different trait groups, as well as between different pedigree-based and SNP-based approaches.

Materials & methods

Data. A literature search in Web of Science and Scopus on inbreeding depression in cattle, pig, chicken, sheep, goat, horse and rabbit resulted initially in 766 studies published between 1990 to 2020. After filtering (for details, see Doekes *et al.* 2021) 154 studies remained with inbreeding depression estimated as linear regression coefficients (*b*-values), i.e. as the change in phenotypic mean per 1% inbreeding. From these studies, 2321 *b*-values were extracted. For each trait, the favourable phenotypic direction was determined,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_184, © H.P. Doekes *et al.* 2022

and the sign of *b*-values was changed if needed to ensure that negative values reflected unfavourable effects. Estimates for traits with an optimum or an unclear favourable direction were removed (n=197).

Comparison between trait groups. Traits were divided into six groups: reproduction/survival, weight/growth, production, conformation, health and other traits (details on classification, see (Doekes *et al.* 2021)). For the comparison between traits and trait groups, *b*-values were divided by the corresponding trait mean (to get b_m) or trait standard deviation (to get b_s) and only pedigree-based estimates were used (n=1,818 for b_m and n=1,259 for b_s). A general linear model was run, in which a population effect (combined effect of study and breed) was fitted in addition to the trait group effect. Estimated marginal means (EMMs) for the different trait groups were obtained and compared. In addition, h^2-estimates were extracted when available (n=490), compared across trait groups and correlated to b_m- and b_s-estimates.

Comparison between inbreeding measures. Inbreeding depression estimates were compared within 11 studies and within traits between pedigree inbreeding (F_{PED}), inbreeding based on ROH (F_{ROH}), inbreeding derived from a GRM (F_{GRM}, from VanRaden's method 2 and Yang's method), inbreeding derived from a GRM computed with allele frequencies of 0.5 ($F_{GRM0.5}$) and the percentage of homozygous SNPs (*HOM*). To account for scale differences of inbreeding measures, b_m and b_s were standardized, by multiplying them by the SD of the inbreeding measure in the corresponding population, such that they were expressed per 1 SD increase in inbreeding (rather than per 1%). Significance of *b*-values was also compared across inbreeding measures, with smaller *P*-values indicating a more significant association between inbreeding and phenotypic value.

Results

Across all studies and traits, the mean (median) pedigree-based b_m and b_s were -0.22 (-0.13) and -0.71 (-0.59), respectively. Distributions for b_m and b_s were roughly similar for different trait groups (Figure 1). The mean and median b_m and b_s were negative for each trait group, except for 'other traits'.

When correcting for population and ignoring the 'other traits', the EMM of b_m was most negative for production traits (-0.31) and reproduction/survival traits (-0.30), and least negative for conformation traits (-0.14). For b_s, the EMM was most negative for weight/growth traits (-1.07) and least negative for

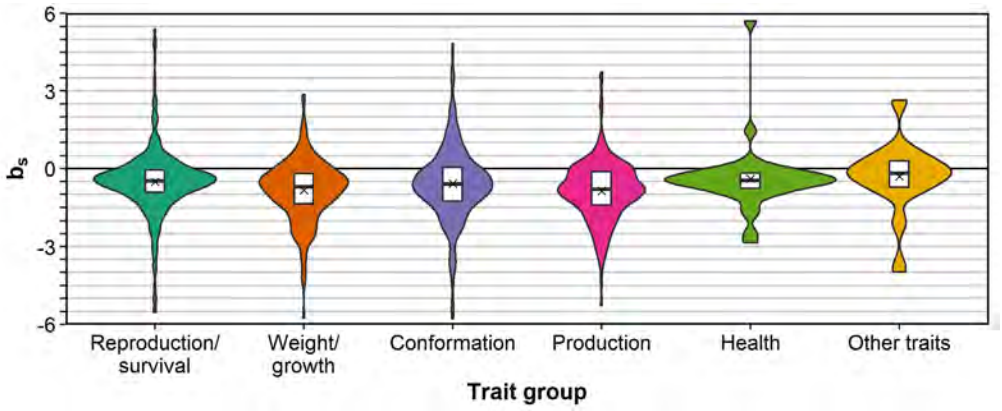

Figure 1. (adapted from Doekes *et al.*, 2021) Violin plots of inbreeding depression estimates per trait group, expressed as percentage of a trait's SD (b_s). Boxplots and the mean (×) are also shown. There were 39 outliers outside the range of this figure.

reproduction/survival traits (-0.41). Pairwise differences of EMMs across trait groups were generally not significant.

Heritability estimates were on average 0.07 for reproduction/survival traits (n=141), 0.30 for weight/growth traits (n=126), 0.29 for production traits (n=109), 0.27 for conformation traits (n=95) and 0.17 for health traits (n=9). Correlation coefficients between inbreeding depression estimates and heritability estimates were close to zero (Figure 2).

Standardized b_m- and b_s-estimates generally showed moderate to (very) high correlations between different inbreeding measures. Correlations of b-values between $F_{GRM0.5}$ and *HOM*, between F_{PED} and F_{GRM}, between F_{ROH} and *HOM*, and between F_{GRM} and $F_{GRM0.5}$ were all ≥0.9. Correlations were lowest between F_{ROH} and F_{GRM} (0.27 for b_m and 0.52 for b_s) and between F_{GRM} and *HOM* (0.24 for b_m and 0.47 for b_s).

Inbreeding depression estimates for SNP-based inbreeding measures had lower *P*-values than estimates based on pedigree inbreeding in more than 80% of direct comparisons (Table 1). Among the SNP-based measures, there were no consistent trends, i.e. which measure had the lowest *P*-value largely differed across studies and also across traits within studies.

Discussion

The mean (median) b_m of -0.22% (-0.13%) and b_s of -0.71% (-0.59%) are similar to the mean b_m of -0.14% and b_s of -0.56% that were previously reported by Leroy (2014) for a subset of 57 studies. Across trait groups, there were some small differences, but those differences were not consistent for b_m and b_s and did not suggest that primary fitness traits such as survival and reproduction exhibit more inbreeding depression than other traits.

Inbreeding depression estimates for SNP-based inbreeding were generally more significant than those based on pedigree inbreeding. Some other studies, which were not included in our analysis, also support this finding. Baes *et al.* (2020), for example, reported more significant inbreeding depression for genomic inbreeding than for pedigree inbreeding for six traits in a sample of ~15,000 Holstein cows (genomic inbreeding was most likely F_{GRM}, though this is not explicitly stated). Lozada-Soto *et al.* (2021) recently estimated inbreeding depression for heifer pregnancy and weight/growth traits in American Angus cattle and found smaller credible intervals for F_{GRM} and F_{ROH} than for F_{PED}. Thus, SNP-based measures appear promising for accurately estimating inbreeding depression.

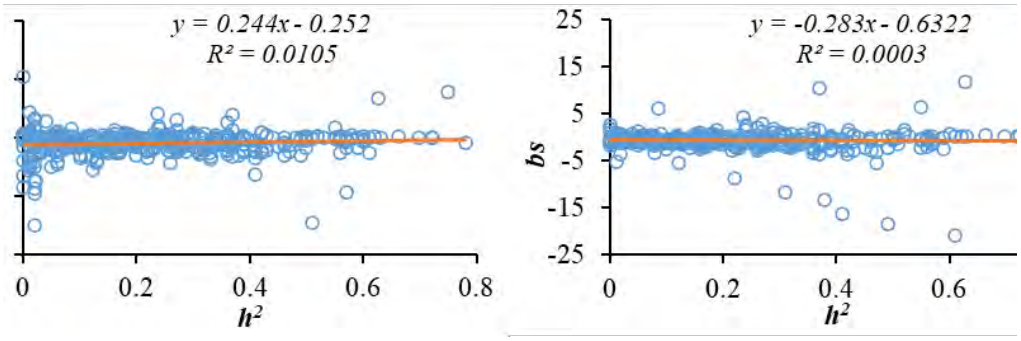

Figure 2. Relationship between inbreeding depression estimates expressed as percentage of a trait's mean (b_m; left) or SD (b_s; right) and heritability estimates (h^2).

Table 1. (adapted from Doekes *et al.*, 2021) Comparison of *P*-values of inbreeding depression estimates within 11 studies and within traits for each combination of two inbreeding measures, where both inbreeding measures had an unfavorable effect on the phenotype. There were no comparisons between F_{GRM} and $F_{GRM0.5}$ in the data set.[1]

				Comparisons where *P2*<*P1*	
Measure 1	**Measure 2**	**N studies**	**N comparisons**	**N**	**% of total**
F_{PED}	F_{ROH}	8	38	30	79
F_{PED}	F_{GRM}	1	7	7	100
F_{PED}	$F_{GRM0.5}$	4	26	21	81
F_{PED}	*HOM*	4	18	15	83
F_{ROH}	F_{GRM}	1	7	4	57
F_{ROH}	$F_{GRM0.5}$	5	40	15	38
F_{ROH}	*HOM*	4	34	19	56
F_{GRM}	$F_{GRM0.5}$	1	3	3	100
F_{GRM}	*HOM*	2	14	4	29
$F_{GRM0.5}$	*HOM*	1	20	10	50

[1] *P*1 = *P*-value of measure 1; *P*2 = *P*-value of measure 2.

Among the SNP-based measures, there were no consistent trends with regard to which measure yielded the lowest *P*-values. Caballero *et al.* (2021) performed a set of computer simulations to shed more light on the question which SNP-based measures are more accurate for estimation of inbreeding depression. They found that the answer largely depends on the population parameters. For example, while F_{ROH} is appropriate for populations with a small effective population size (in which relationships are tight and there is relatively less intense selection), it may be less appropriate for populations of larger effective population size.

Overall, we conclude that inbreeding depression in livestock populations is present for all sorts of traits to a similar extent and that SNP-based inbreeding measures tend to have more predictive power than pedigree-based measures.

Abstract

Information about patterns of genetic ancestry in admixed livestock populations provide insights on past introgression events and genomic regions under selection. The Tunisian Noire de Thibar sheep is an ideal model of composite breed between local and European stocks. Using genome-wide SNP data, we evaluated patterns of global and local ancestry in this breed. Global ancestry analysis confirmed the introgression of Merino d'Arles to improve the wool fiber quality and at a lower extent, the Black Brown Swiss, used to fix the black color. Therefore, we estimated marker average ancestry at each locus, to identify genomic regions shaped by ancestral Merinos. Surprisingly, we detected a high signal of 'Merinization' on chromosome nine harbouring the *SULF1* gene involved in the pathway of primary wool follicle induction. These results provide new insights of exotic allele's diversity in local sheep, which could be utilized for rapid introgression of novel alleles through genomics-assisted breeding.

Introduction

Information about patterns of genetic ancestry in admixed livestock populations provide insights on past introgression events and genomic regions under selection. Recent advances in genomic technologies and molecular data analysis allow for accurate detection of ancestry at the genome level by identifying genomic fractions originating from ancestral populations. There are currently two different approaches to determine ancestry inference: 'global ancestry' and 'local ancestry'. The main objective of global ancestry inference is to estimate the average ancestry contributed by each population, over the whole genome, useful for studying admixture populations. In contrast, local ancestry inference provides the same information but for each locus of the genome in order to detect ancestry at each locus (Maples *et al.* 2013). Different methods to detect local inference have been used mainly to study recent admixed populations (Tang *et al.* 2006; Sankararaman *et al.* 2008; Maples *et al.* 2013). The Tunisian Noire de Thibar sheep, also known as 'Black Thibar', a local synthetic breed, created through a reciprocal cross between an Algerian thin tailed, known as Queue Fine de l'Ouest in Tunisia and the imported Merino d'Arles (Porter *et al.* 2016), which is originated from local ewes crossed with Spanish Merino rams. In 1945, Noire de Thibar sheep was officially registered in the national Herd book and was recognized as a local breed in Tunisia. In the 1970s, a new gene pool was introduced into the breed using the Swiss Brown-Black sheep breed, mainly to avoid consanguinity, fix the black coat colour and improve meat and wool quality (Kallal 1968). Indeed, the black coat Noire de Thibar animals are tolerant to toxic '*Hypericum perforatum*' weeds, which causes skin photosensitization in white sheep, causing a major economic loss to sheep farmers (Baazaoui *et al.* 2020). Now, Noire de Thibar flocks represents only 2% of national sheep flock and are characterized by lower fat meat and high wool quality. A study of genetic structure of Tunisian sheep at global scale highlighted a clear differentiation of the Noire de Thibar breed from local sheep populations and a genetic proximity to Northern Mediterranean breeds explained by introgression of European genetic stocks (BAAZAOUI *et al.* 2018). However, this European ancestry is still unknown at the genome level, just as its contribution to shaping regions under selection. Thus, the aim of this study is to estimate global and local ancestry of Noire de Thibar breed to infer patterns of European (Merinos d'Arles and Swiss Black Brown breeds) ancestry using genome-wide SNP data.

Materials & methods

Animals and data genotyping. Animals were genotyped with the Illumina Ovine BeadChip (Kijas *et al.* 2009) according to the manufacturer's protocol. Raw material of 13 Tunisian Noire de Thibar (NDT) animals was genotyped in a previous study (Bedhiaf-Romdhani *et al.* 2020). SNP data of 18 French Merinos d'Arles (MER) and 23 Swiss Black Brown (SBB) were obtained respectively from previous published studies (Tortereau *et al.* 2017) and (Kijas *et al.* 2012). Genome coordinates for all SNP were based on the OAR version 3.1 ovine genome assembly.We used PLINK 1.9 (http://www.coggenomics.org/plink 2) (Purcell *et al.* 2007) for data merging and quality checks. The combined raw dataset was filtered to exclude poorly genotyped individuals (<90% of SNPs). SNP markers located on sex chromosomes, genotyped in <90% of individuals and with rare alleles (MAF<0.01). We retained 37,776 SNPs after linkage disequilibrium filtering using the following parameters: 50 SNPs per window, a shift of 5 SNPs between windows and a variation inflation factor's threshold of two (corresponding to r^2>0.5).

Genetic relationship among breeds. To better visualize the genetic relationship and complex population network of NDT animals and its three parental breeds (QFO, MER and SBB), we used a network-based approach implemented in NetView v.1.1 software (Neuditschko *et al.* 2012) using identity by state (IBS) distance matrix. Thus, we adopted an increasing K (parameter determining the number of mutual nearest neighbors) values up reaching an arbitrarily sufficient level of connectedness among samples. Global patterns of ancestry and admixture was assessed using unsupervised and supervised hierarchical clustering of NDT individuals, at K=2, with prior information given to its European ancestors (MER and SBB) implemented in the Admixture software v1.3.0 (Alexander and Lange 2011) by applying the default settings.

Inference of European local ancestry in Noire de Thibar sheep. The local ancestry was inferred using LAMP (Local Ancestry in adMixed Populations) software (Sankararaman *et al.* 2008) to estimate ancestries at each locus in a population of admixed individuals. On the light of previous results, we assumed that NDT animals were the result of crossbreeding between local QFO and MER. Thus, we estimated the individual's local ancestry of MER breed proportion in NDT animals. For each locus, LAMP analysis provides the marker average ancestry (MAA) related to considered ancestral populations (QFO and MER). The software operates on sliding windows of contiguous SNPs and assigns ancestries by combining the results with a majority vote. The following default settings were adopted: number of generations since admixture (g) = 32 and recombination rate (r) =10^{-8}. The fraction of global admixture (α) related to MER was assigned to α=0.1, using the Admixture software (Alexander and Lange, 2011). The highest MAA values related to MER are considered as significant genomic regions supposed to be under selection. We conducted a comprehensive search in the available literature and public databases to investigate the biological function of each annotated gene.

Results

Analysis of ancestry using Network-based approach (Figure 1A) has shown that MER is strictly linked to NDT and the influence of SBB is just manifested through two NDT samples at K=25 and 30, probably *via* recent crossbreeding. These findings are confirmed by results of supervised and unsupervised admixture results at K=2 (Figure 1B) where samples from NDT breed show high proportions of MER ancestry.

The results of MER marker-ancestry repartition on autosomes of NDT animals revealed that of MAA values ranged between 0.07 and 0.33. Therefore, the highest signal defined a putatively regions under selection, located on chromosome 9 spanning the genomic region 45.9-46.3 Mb including eight adjacent SNPs (MAA=0.33) harboured two candidate genes (*SULF1* and *SLCO5A1*) (Figure 2).

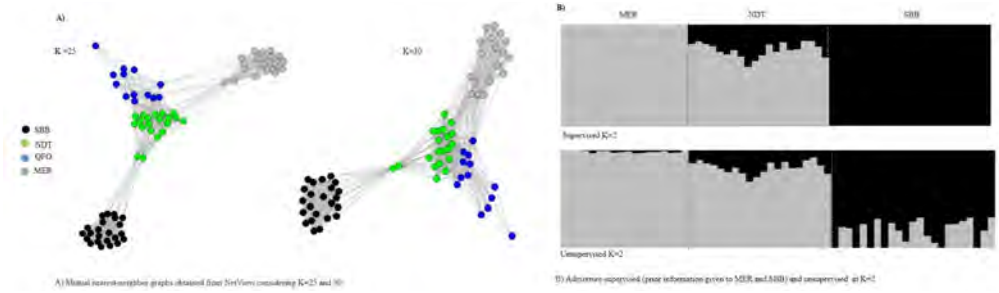

Figure 1. Inference of global ancestry of Noire de Thibar animals.

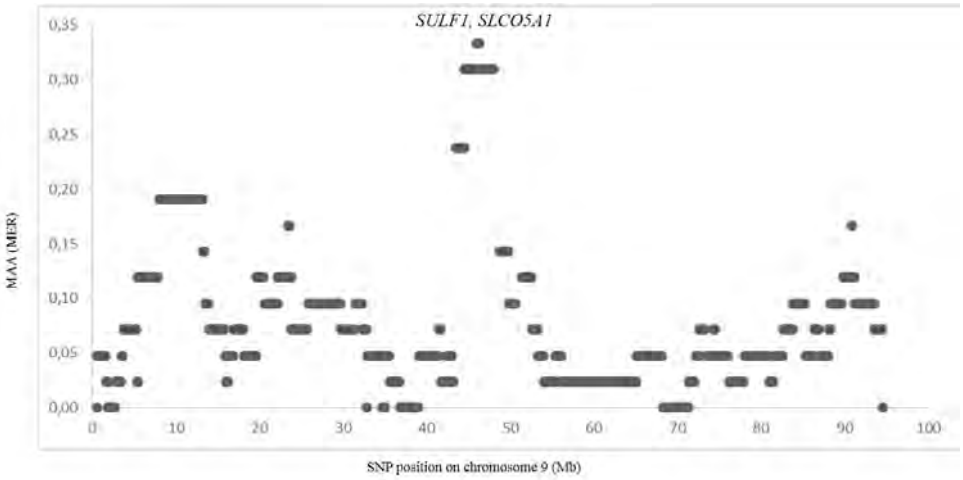

Figure 2. MAA of MER on chromosome 9.

Discussion

Our results are in line with historical origin of NDT evidenced by past introgression of Merinos gene flow through artificial selection for black coat colour (Kallal 1968). These findings could explain the Merinos ancestry from the Spanish Merino ancestors from which MER was derived (Ben Jemaa *et al.* 2019). Local ancestry analysis revealed a high signal of MER ancestry in the genomic region containing the *SULF1* gene which is a candidate gene involved in primary wool follicle induction and skin development (Nie *et al.* 2018). Indeed, *SULF1* is an enzyme of the sulfatase class able to alter the sulfation patterns of proteoglycans and consequently the binding site of many growth factors, among them WNT, BMP and FGF, which are known to play major roles during embryogenesis, and among others, during the hair follicle development. Therefore, the assumed origin of NDT as a composite breed was supported here, with clear influence of MER breed, likely introduced at the beginning of the last century to improve wool quality. Our results provide a genetic base reference to establish molecular marker-assisted selection to improve the production performance of natural coloured wool, which represent a niche market for top quality fleeces in the world. We should mention that wool from coloured sheep is a valuable genetic resource in high demand by handcrafts and wool crafters for its natural look and its freedom from dye chemicals.

186. Common heterozygosity-rich regions across the genomes of commercial and local goat breeds

F. Biscarini*, A. Manunza, P. Cozzi and A. Stella

Institute of Agricultural Biology and Biotechnology (IBBA), National Research Council, Via Edoardo Bassini 15, 20133 Milan, Italy; filippo.biscarini@ibba.cnr.it

Abstract

Heterozygosity-rich regions (HRRs) are still under-characterized in animal genomes. In this work, we detected HRRs in goat samples from 6 breeds, both commercially widespread (ALP, BOE, SAA) and local (BRK, CRE, LNR), specifically looking for HRRs common across breeds. In total, 79 common HRRs have been detected; in particular, a region on chromosome 12 (49.9-51.6 Mbps) was shared by over 35% of the goats in 5 breeds. The imputation of missing SNP genotype data did not have a significant impact on results.

Introduction

Contiguous segments ('runs') of diploid genomes may be characterised by higher than average values of homozygosity or heterozygosity. Runs of homozygosity (ROH) have been extensively studied in animal populations, e.g. for the quantification of inbreeding or the detection of selection signatures (Peripolli *et al.* 2017). Runs of heterozygosity, better known as heterozygosity-rich regions (HRRs), are a more recent concept (Williams *et al.* 2016), and are still largely uncharacterized in animals. A handful of studies described HRRs in cattle (Ferenčaković *et al.* 2016, Biscarini *et al.* 2020), sheep (Tsartsianidou *et al*., 2021), turkeys (Marras *et al.* 2018) and horses (Bizarria dos Santos *et al.* 2021). In this study we looked for HRRs in the goat genome, specifically looking for HRRs common across commercial and local breeds. The impact of imputing missing SNP genotypes was also assessed.

Materials & methods

SNP genotype data. For this study, we used SNP genotype data provided by the AdaptMap (Stella *et al.*, 2018) and SMARTER (https://www.inrae-transfert.fr/en/showroom/439-smarter) projects. With the aim of including both widely distributed commercial breeds ('commercial') and locally adapted breeds ('local'), samples from the Barki (BRK), Creole (CRE) and Landrace (LNR) (local), and from the Alpine (ALP), Boer (BOE) and Saanen (SAA) (commercial) breeds were selected, for a total of 1,072 goats. SNPs were obtained from the GoatSNP50 BeadChip (Illumina Inc., San Diego, CA) which includes 53,347 SNPs (mapped on ARS1.2). Only SNP loci on the goat autosomes (chromosomes 1-29) were used, and they were filtered for MAF>0.05 and call-rate (>95% locus-wise, >80% sample-wise). After filtering, 1,051 goats and 47,689 SNPs were left for the analysis (per-breed data breakdown is reported in Table 1). Plink v.1.9 was used for data management and filtering (Chang *et al.* 2015). To evaluate the impact of SNP genotype imputation on HRR detection, missing data were imputed in a separate run using the LHCI (localized haplotype clustering imputation) method implemented in Beagle v.5.1 (Browning and Browning 2009).

Detection of heterozygosity-rich regions (HRR). HRR were detected in the goat genome by scanning the ordered sequence of SNP loci with the window-free method described by Marras *et al.* (2015). The following parameters, derived from Biscarini *et al.* (2020), were used for the detection of HRR: minimum 15 SNPs and minimum length of 250 kbps to define a HRR; maximum gap 1e+03 kbps between adjacent SNPs in a HRR; maximum 3 homozygous SNPs and 2 missing SNPs in a HRR. The R package detectRUNS was used for the detection of HRR (https://cran.r-project.org/web/packages/detectRUNS/). HRR islands have been defined as HRR found (identical) in at least 20% of the samples (within breed).

Table 1. Descriptive statistics of filtered genotype data per breed.

	Breed	n_ind	n_snp	missing_rate	MAF
Commercial	ALP	211	47,689	0.003	0.372
	BOE	251	47,689	0.002	0.368
	SAA	145	47,689	0.005	0.374
Local	BRK	146	47,689	0.019	0.363
	CRE	179	47,689	0.012	0.353
	LNR	120	47,689	0.001	0.356

[1] n_ind: number of goats per breed; n_snp: number of SNPs; MAF: minor allele frequency.

Results

MAF was slightly higher in commercial goat breeds compared to local breeds (0.371 vs 0.357); conversely, missing rate was higher in local breeds (e.g. 1.9% in BRK, 1.2% in CRE; see Table 1). Both findings likely relate to the ascertainment bias of the GoatSNP50 array, developed based mainly on commercial breeds. From non-imputed data, a total of 73,173 HRRs were detected in the 1,051 goats remaining after filtering (69.6 HRRs per goat, on average). More HRRs have been detected in commercial breeds than in local breeds, both overall (50,477 vs 22,696) and per goat (83.3 vs 51). The average length of detected HRRs was 805.7 kbps in commercial breeds and 794.5 kbps in local breeds. With imputation of missing SNP genotypes, similar results in terms of HRRs have been obtained: overall, slightly fewer and shorter HRRs have been detected in all breeds. Descriptive statistics of HRR per breed are reported in Table 2.

Looking at HRRs shared by individual goats, 79 HRR islands (HRRs in 20% of the samples) have been identified. Figure 1 shows HRR islands in chromosomes harbouring more than one island. Common HRR islands are found on chromosomes 1, 10 and 14 (across 3 breeds), chromosomes 3, 13 and 18 (across 4 breeds), and on chromosome 12 (across 5 breeds). The HRR islands most shared across breeds is the one found on chromosome 12 at 49.884-51.611 Mbps. Figure 2 shows a visualization of this common HRR island across samples (B, right), and the corresponding peak of SNP loci found to be lying inside it (A, left).

Discussion

This is the first report on HRR in the goat genome. Like ROH, HRRs can provide insights into the demographic history of populations (e.g. admixture or introgression events) or help detect genomic regions under balancing selection. In particular, HRR common across breeds may indicate regions which

Table 2. Summary of detected HRR in the base scenario (left: selected parameters, no imputation), and with imputed data (same parameters, right).

Group	Breed	Non-imputed[1]			Imputed[1]		
		n_hrr	avg_n	Length	n_hrr	avg_n	Length
Commercial	ALP	15,439	73.17	807.20	15,419	73.08	803.78
	BOE	24,611	98.05	802.85	24,384	97.15	802.13
	SAA	10,427	72.41	807.97	10,323	71.69	806.38
Local	BRK	6,481	44.39	789.39	6,019	41.23	787.95
	CRE	9,725	54.32	795.17	9,339	52.17	792.50
	LNR	6,490	54.08	798.17	6,403	53.36	797.51

[1] n_hrr: total number of of HRRs per breed; avg_n: average number of HRR per goat; length: average length of detected HRRs (in kbps).

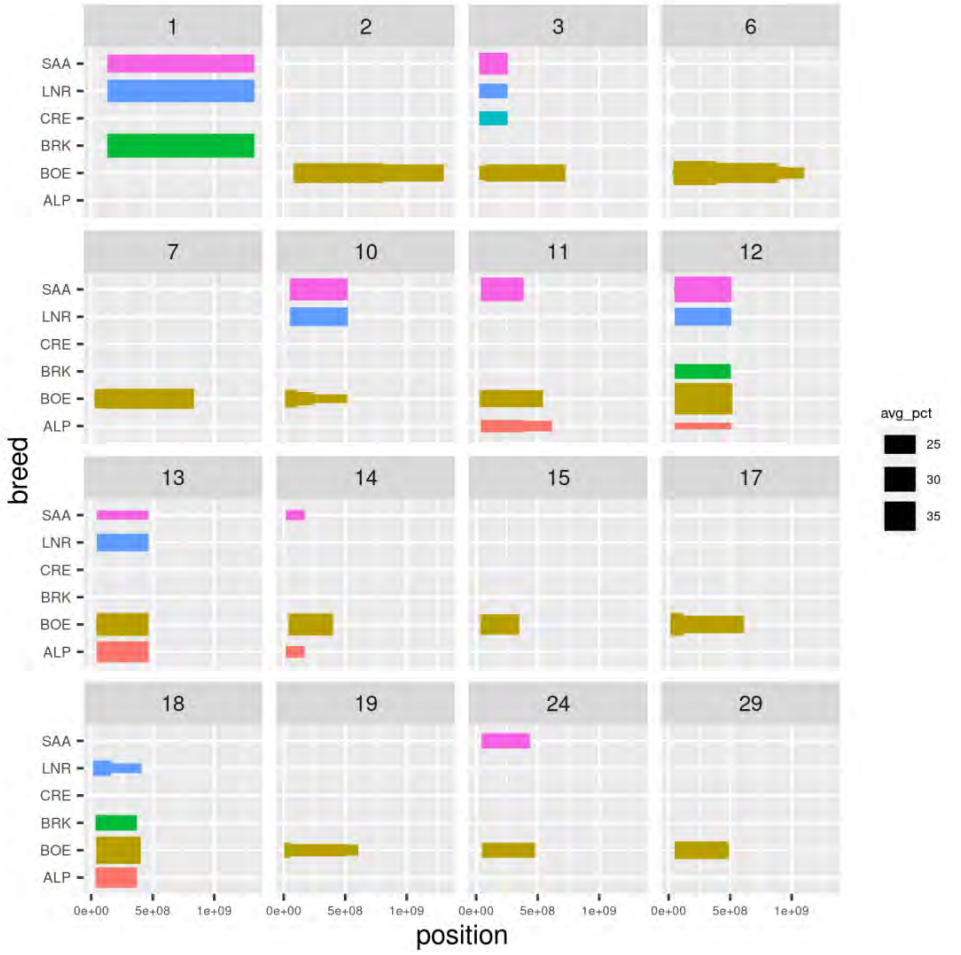

Figure 1. Visualization of HRR islands detected in the genome of commercial (ALP, BOE, SAA) and local (BRK, CRE, LNR) goat breeds. Chromosomes with only one HRR have been excluded. The thickness of the HRR is proportional to the percentage of samples in which it has been detected (avg_pct). The length of the HRRs has been artificially extended (multiplied by 10) for the sake of visualization.

are conserved for biological or evolutionary reasons. This may be the case for the 49.9-51.6 Mbps region on chromosome 12, which harbours about 20 annotated genes, among them IL17D known to be associated with the immune response in humans (Huang *et al.* 2021). Overall, the imputation of residual missing SNP genotypes does not appear to influence results, though this may depend on the initial missing rate and the accuracy of imputation. A systematic analysis of the parameters used to detect HRRs and of the threshold to identify HRR islands still needs to be carried out.

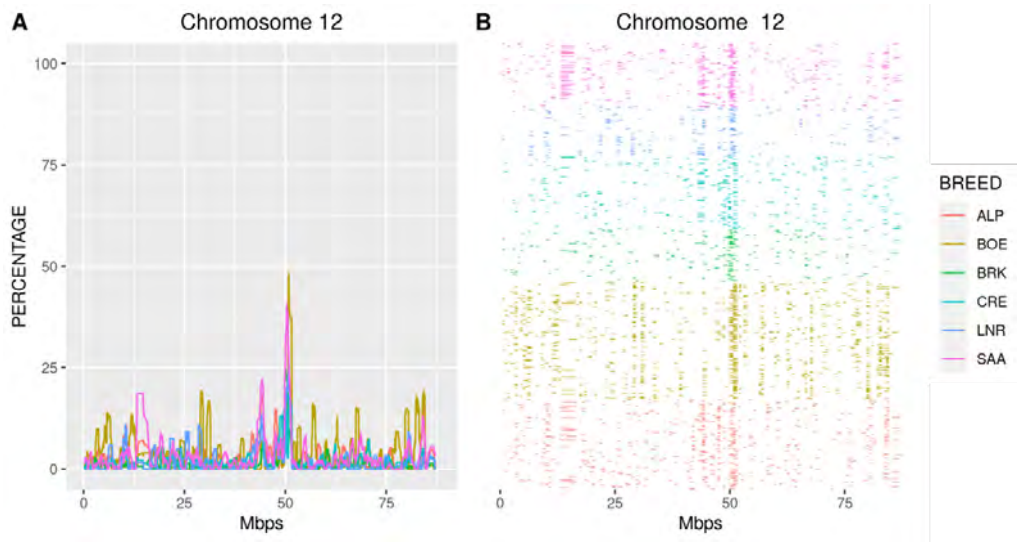

Figure 2. HRR island on goat chromosome 12. (A) proportion of times SNP loci fall within HRRs in the analysed goat samples (across breeds); (B) distribution of HRRs on chromosome 12 in goat samples (a clear signature of heterozygosity is visible at 49.9-51.6 Mbps).

187. Markhor-derived introgression of *PAPSS2* confers high-altitude adaptability in Tibetan goats

Abstract

Understanding the genetic mechanism of how animals adapt to extreme environments is fundamental to unriddle the relationship between molecular evolution and continuous climate change. After domestication, goats have developed strong adaptation to various environments, including harsh conditions at high-altitudes with low temperature and reduced oxygen concentrations. Here, we utilized 331 genomes of goats living at varying altitudes (high >3,000 m above sea level and low <1,200 m) as well as wild caprid species to precisely dissect genetic determinants underlying the adaptation to high altitudes on the Qinghai-Tibetan Plateau (QTP). Population genomic analyses combined with genome-wide association testing revealed that the *PAPSS2* locus confers adaptability to high altitudes in Tibetan goats. Additionally, this gene harbours significant signatures of interspecies introgression from a wild caprid species, markhor (*Capra falconeri*). We further demonstrated a functional role for *PAPSS2* in response to hypoxia using *PAPSS2*-deficient cells. In conclusion, our results suggest a hitherto unknown contribution of *PAPSS2* to high-altitude adaptation and showed that interspecific introgression contributed to the adaptation of goats to the harsh conditions at the Tibetan Plateau.

Introduction

Goats (*Capra hircus*) are believed to be one of the first domesticated livestock species, dating back to ~10,000 years ago (Daly *et al.*, 2021; Zeder, 2000). Goats have developed rapid and strong physiological and genetic adaptation to various environments along with human civilization and migration (Daly *et al.*, 2018). This includes adaptation to some challenging agro-ecological conditions, such as high-altitude environments. Adaptive introgressions had occurred in humans (Huerta-Sánchez *et al.*, 2014) and other mammals native to the QTP, such as Tibetan Mastiff (Miao *et al.*, 2017), cattle (Chen *et al.*, 2018) and sheep (Hu *et al.*, 2019). These studies focus on the genetic basis of adaptive traits. However, how Tibetan goats acquired this adaptability is still unknown. In this study, large-scale genomic and transcriptomic data were systematically compared between goats from the Tibetan Plateau and low-altitude regions to provide new insights into the evolutionary origins of high-altitude adaptability in mammals.

Methods

Blood samples from 91 goats (83 from Tibet, 4 from low altitude, and 4 Siberian ibex) were collected for short-read genome sequencing.

The genomic short-read sequencing data were mapped to the goat reference genome using BWA-MEM (Heng L. 2013), and SNPs were discovered and genotyped using GATK (McKenna *et al*., 2010). The F_{ST}, *XP-EHH*, and GWAS statistics were calculated between 76 high- and 80 low-altitude animals. The *D*-statistics (Martin *et al.* 2015) and Q95 (Racimo *et al.* 2017) analyses were used to conduct a genome-wide screening of putative introgression events from the markhor.

We used CRISPR/Cas9 to knock out the murine *papss2* gene in NIH/3T3 cells. The *papss2* mRNA expression in the NIH/3T3 cells was determined by quantitative PCR (qPCR). The *papss2* deficient cells were incubated in a humidified atmosphere under normal (21% O_2) and hypoxic (3% O_2) conditions at 37 °C (Thermo Scientific HERAcell 150i), respectively. Then the expression of *papss2* was measured alongside changes in cell phenotype using quantitative PCR (qPCR). Differentially expressed genes (DEGs) by RNA-sequencing reads were calculated using cufflinks (Trapnell *et al.* 2012).

Results

We used three complementary approaches (GWAS, F_{ST}, *XP-EHH*) to identify genes potentially involved in high-altitude adaptation (Figure 1A-B). Positively selected haplotypes encompassing *PTEN*, *ATAD1*, *PAPSS2,* and *DSG3* were significantly associated with high-altitude adaptation (Figure 1C). *PTEN* contributes to regulating hematopoiesis and leukemogenesis (Wu *et al.*, 2020). A previous study suggested *PTEN* to likely be under selection in the Tibetan human (Simonson *et al.*, 2010). *ATAD1* plays a critical role in regulating synaptic plasticity, learning, and memory (Ahrens-Nicklas *et al.*, 2017). *PAPSS2* was also previously identified as the major selective gene for high-altitude and cold environment adaptation in horses (Librado *et al.*, 2015; Shi *et al.*, 2019). *DSG3* was previously highlighted as a candidate gene for hypoxia adaptation in Tibetan goats (Kumar *et al.*, 2018). *PAPSS2* has not been implicated in high-altitude adaptability so far.

The *D*-statistic was used to detect the ancestral origin of the selected region and to screen the Tibetan goat genomes for signatures of markhor introgression. The analysis revealed a strong signature of introgression at Chr26:42,070,001-42,120,000 (f_d=0.7634; Figure 2A) which overlapped with *PAPSS2* locus and which was also supported by the Q95 (Figure 2A) and a phylogenetic analysis. The genomic region encompassing

The dotted horizontal line indicates the threshold (-Log10(*P*)=8.65). (B) The strategy used to identify a list of genes related to high-altitude adaptation. It relies on three sets of genes, derived from the F_{ST} (blue), *XP-EHH* (red), and GWAS (yellow) analyses. F_{ST} and *XP-EHH* selection candidate sets include genes in the top 0.5% of the empirical distributions of F_{ST} and *XP-EHH* results, respectively. (C-D) Comparison of genomic regions identified in selection scans between high- and low-altitude goats. EAS-H, East Asian high-altitude goats, and EAS-L, East Asian low-altitude goats.

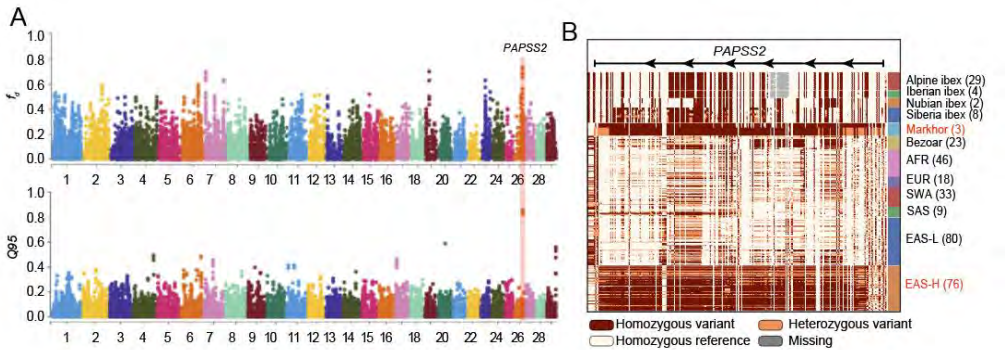

Figure 2. A genomic region encompassing *PAPSS2* was introgressed into Tibetan goats from markhor. (A) Genome-wide distribution of *D*-statistics (top) and Q95 (bottom) values calculated for 50-kb windows with a 10-kb step across the genome. Each dot represents a 50-kb window. (B) Haplotype structure for *PAPSS2*. Rows represent individuals and columns represent SNPs positions in the genome. AFR, African goats; EUR, European goats; SWA, Southwest Asian goats; SAS, South Asian goats.

PAPSS2 had a high similarity between Tibetan goats and markhor but was substantially different in other domestic goat populations and wild caprid species (Figure 2B). The functional role of *PAPSS2* in the adaptation to hypoxia was further confirmed with the *papss2*-deficient cells.

Discussion

In this study, we leveraged a large caprine whole-genome and transcriptome data set encompassing 331 goats and 13 tissues to localize signatures of high-altitude adaptation in Tibetan goats. Collectively, both positively selected haplotypes and expression patterns suggest genomic regions encompassing *PAPSS2* and *DSG3* to be significantly associated with high-altitude adaptation in Tibetan goats.

Although harsh environments may promote the accumulation of adaptive mutations in animals, it is unlikely that many de novo mutations can emerge at the same site during a short period of time (Hu *et al.*, 2019; Jeong *et al.*, 2016; Zhao *et al.*, 2017). Adaptive introgressions from other geographically close species may contribute to the process of adaptation that occurred in humans and many animals native to the QTP. In this study, we revealed that Tibetan goats carry specific adaptive introgressions derived from markhor (*C. falconeri*), a wild goat species native to high Himalayan mountains, including a haplotype encompassing *PAPSS2*. This region showed the strongest signature of both adaptive introgression and selection. A relatively long haplotype (chr26:42,077,488-42,179,191) also indicated that the area was introgressed rather recently.

Several studies have shown that the kidneys and the spleen may play a critical role in human oxygen-sensing (Schodel and Ratcliffe, 2019) and mammalian physical activity (Storz and Cheviron, 2021). Through multi-tissue transcriptome data comparison, we found that the *PAPSS2* gene was differentially expressed in the kidney and spleen between Tibetan and other domestic goats. The functional role of *PAPSS2* in the adaptation to hypoxia was further confirmed by our functional validation assay. Thus, it is plausible that the unique but recent introgression from the markhor may have conferred the adaptability of Tibetan goats to survive over the harsh environment on the QTP.

Our data provide new insights into the role of genetic introgression from wild relatives on environmental adaptation in livestock. We showed that the establishment of the genetic mechanism of plateau adaptation in Tibetan goats had occurred by the combined effects of gene introgression and natural selection. This

enabled Tibetan goats to adapt to the hypoxic environment in a relatively short period of time and continues to strengthen this ability until now.

Wallace Beltsville Agricultural Research Service, USDA, Beltsville, MD 20705, USA; ealozada@ncsu.edu

Abstract

The main objective of this study was to leverage genomic information to ascertain patterns of inbreeding and selection in five North American dairy cattle populations. We obtained genotypes for over 4 million individuals of the Ayrshire, Brown Swiss, Guernsey, Holstein, and Jersey breeds. Inbreeding based on runs of homozygosity was calculated in each population. The average inbreeding ranged from 0.11 for Ayrshire to 0.17 for Jersey. We calculated a coefficient of homozygosity for each marker. Highly homozygous markers were joined into larger genomic segments of interest that ranged from 0.08 to 7.83 Mb in length and spanned 14 chromosomes across breeds. Annotation of genes and QTLs in the highly homozygous regions revealed selection for economically important traits, notably for udder and cow health, productive life, and reproductive traits. We found differences across breeds on inbreeding load, genomic regions of high inbreeding, and selection signatures.

Introduction

Runs of homozygosity (ROH) are continuous stretches of markers in a homozygous state in the genome of an individual. The characterization of the length, number, and genomic distribution of ROH allow us to ascertain the level of inbreeding in individuals and decipher the inbreeding history of populations (Gibson *et al.*, 2006). The proportion of the autosomal genome covered by ROH segments has been routinely used as a measure of inbreeding in cattle populations (Howard *et al.*, 2015; Makanjuola *et al.*, 2020) due to its high correlation with other inbreeding coefficients and autozygosity (Peripolli *et al.*, 2017). We can also use the level of homozygosity at the marker level to identify regions of selection within a population and uncover differences in the selection history of multiple populations. Therefore, our aim was to characterize ROH segments, calculate the level of inbreeding, and identify regions of high homozygosity as selection signatures in the five major breeds of North American dairy cattle.

Materials & methods

Animals and genotypes. Imputed genotypes were obtained for 76,389 autosomal markers of 4,173,679 animals of the Ayrshire (AY), Brown Swiss (BS), Guernsey (GU), Holstein (HO), and Jersey (JE) breeds. Quality control of the genomic data was first performed within each breed, including the removal of animals with a marker call rate lower than 95%, markers with a minor allele frequency lower than 0.01%, and markers with Mendelian error rates larger than 10%. Subsequently, we removed markers with an across-breed call rate lower than 95%. After genomic quality control, a total of 4,010,718 animals (8,413 AY, 39,040 BS, 3,834 GU, 3,525,992 HO, and 433,439 JE) and 62,546 markers remained for subsequent analyses.

Detection of ROH and calculation of segment-based inbreeding. Runs of homozygosity (ROH) were detected using a sliding window approach with the PLINK v.1.9 software (Chang *et al.*, 2015). Parameters to define windows and detect ROH were the following: a minimum window size of 20 markers, at most 1 heterozygote call in a window, at most 2 missing calls in a window, a minimum physical length of 1 Mb for ROH, a maximum gap of 0.5 Mb between consecutive markers, a minimum marker density of 1 marker

per 0.1 Mb, a minimum number of 60 markers to declare a ROH. Parameters were chosen according to previous results (Purfield *et al.*, 2012; Forutan *et al.*, 2018; Meyermans *et al.*, 2020). Descriptive statistics of the detected ROH were calculated for each breed. A segment-based inbreeding coefficient (F_{ROH}) was calculated for each animal as the proportion of the autosomal genome covered by ROH.

Region-specific homozygosity and ROH islands. A coefficient of homozygosity ($F_{ROH.i}$) was calculated for each i^{th} marker as the proportion of animals (within breed) for which the marker is within a ROH segment. Afterwards, we identified markers that fell at or above the 99.5th percentile for $F_{ROH.i}$ and joined significant adjacent markers into larger segments, henceforth identified as ROH islands.

Annotation of genes and QTLs located within ROH islands. Annotation of genes located within the identified ROH islands was done using the 'btaurus_gene_ensembl' (ARS-UCD1.2 genome assembly) database with the 'biomaRt' R package (v.2.48.3) (Durinck *et al.*, 2009). We utilized the GALLO R package (Fonseca *et al.*, 2020) to query the Animal QTLdb (https://www.animalgenome.org/cgi-bin/QTLdb/index) for quantitative trait loci (QTL) that have been previously identified in the regions of interest. Furthermore, a trait enrichment analysis was performed on the annotated QTLs to identify traits whose presence is not due to chance (FDR adjusted *P*-value<0.05).

Results & discussion

Descriptive statistics of detected ROH per individual are presented in Table 1. The average number of ROH ranged from 39.20 for AY to 65.87 for JE, the average length ranged from 6.48 Mb in GU to 7.31 Mb in BS, and the average combined length ranged from 268.39 Mb in AY to 431.77 Mb in JE. The inbreeding followed a similar trend with AY having the lowest average inbreeding (0.11) and JE having highest average inbreeding (0.17).

Region-specific homozygosity for every marker across the genome for the five breeds is presented in Figure 1. We found significant markers in chromosomes 4, 5,6, and 8 for AY; 5, 6, and 16 for BS; 6, 11, 13, 15, and 19 for GU; 10 and 20 for HO; and 2, 3, 7, and 20 for JE. ROH islands ranged from 0.08 to 7.83 Mb in length. We found two overlaps between ROH islands in different breeds, a 3.44 Mb overlap in chromosome 6 (BTA6: 86.76-90.1) between AY and BS, and a 2.57 Mb overlap in chromosome 20 (BTA20: 25.61-28.17) between HO and JE. We found a total of 26 genes shared between AY and BS, most notably *ADAM metallopeptidase with thrombospondin type 1 motif 3* (ADAMTS3). The ADAMTS3 gene has been linked to longevity (Mészáros *et al.*, 2014), embryonic development (Janssen *et al.*, 2016), and milk and milk component yield (Costa *et al.*, 2019) in cattle. The region that overlapped between HO and JE contained 5 genes, most notably *ISL LIM homeobox 1* (ISL1) and *pelota mRNA surveillance and ribosome rescue factor* (PELO). Both of these genes have been associated with spermatogenesis (Fernández *et al.*, 2014). The most

Table 1. Descriptive statistics of detected ROH per individual and average F_{ROH} in 5 breeds.[1]

Breed[2]	Avg. n.	Avg. length (Mb)	Avg. combined length (Mb)[3]	F_{ROH}
AY	39.20 (8.47)	6.78 (1.36)	268.39 (85.11)	0.11 (0.03)
BS	49.58 (8.72)	7.31 (1.08)	363.55 (87.12)	0.15 (0.04)
GU	57.39 (7.71)	6.48 (1.03)	371.99 (79.22)	0.15 (0.03)
HO	42.03 (8.66)	7.24 (1.17)	305.88 (87.68)	0.12 (0.04)
JE	65.87 (8.52)	6.55 (0.90)	431.77 (83.49)	0.17 (0.03)

[1] Standard deviation shown within parenthesis.

[2] AY= Ayrshire; BS= Brown Swiss; GU=Guernsey; HO= Holstein; JE= Jersey.

[3] Average combined length of genome in ROH.

gene-dense island was found for Jersey cattle in chromosome 7 (BTA7: 39.76-45.56), where we identified a total of 167 genes. A notable gene found in this region was *NLR family pyrin domain containing 3* (NLRP3), this gene has been previously associated with resistance to *Mycobacterium avium* ssp. paratuberculosis (MAP) infection (Mallikarjunappa *et al.*, 2018).

The top 10 (based on *P*-value) enriched traits from the annotated QTLs are presented for each breed in Figure 2. Milk production traits were found to be enriched in all five breeds, including milk or milk protein yield in AY, BS, HO, and JE. Other traits that were found enriched in two or more breeds included productive life, immunoglobin G level, clinical mastitis, and ketosis. This highlights the high selective pressure that has been put on traits that increase the health, reproductive ability, and length of productive life of U.S. dairy cows. Interestingly, 7 out of the top 10 enriched traits in the Guernsey breed related to meat and carcass traits, mainly content of saturated and monounsaturated fatty acids.

In summary, the differences observed in the genomic patterns of homozygosity suggest substantial heterogeneity in the management and selection strategies implemented in the different populations of U.S. dairy cattle.

189. Exploring genetic diversity and selection signatures in indigenous African cattle breeds

J. Friedrich[1*], R. Bailey[2], A. Talenti[1], K. Marshall[3], J. Prendergast[1] and P. Wiener[1]

[1]Division of Genetics and Genomics, The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Midlothian, EH25 9RG, United Kingdom; [2]Department of Ecology and Vertebrate Zoology, University of Łódź, 90-237 Łódź, Poland; [3]Centre for Tropical Livestock Genetics and Health (CTLGH), ILRI Kenya, P.O. Box 30709, Nairobi, Kenya; juliane.friedrich@roslin.ed.ac.uk

Abstract

African cattle are a fascinating resource for exploration of genetic diversity due to their complex history and their adaptation to diverse environments. As a consequence of taurine and indicine ancestries and selection pressure from various environments as well as from humans, over 150 African cattle breeds exist today with remarkable genotypic and phenotypic diversity. We analysed whole-genome sequence data of over 100 African cattle comprising 9 breeds and calculated within- and between-breed population statistics to characterise genetic diversity and identify selection signatures. We found overlapping selection signatures between indigenous African breeds, with the longest selection signature on BTA10. The greatest genetic differentiation from other breeds was observed for the N'Dama and Boran breeds, potentially mirroring their high proportion of taurine and indicine ancestry, respectively. Genomic regions that are highly differentiated between breeds suggest candidate regions for associations with important adaptation and production traits.

Introduction

Indigenous African cattle with their complex evolution, migration and admixture history are a unique resource to explore genetic diversity and identify selection signatures for adaptation to diverse environments. Indigenous African cattle descended from *Bos taurus taurus* and *Bos taurus indicus* subspecies: from their respective domestication centres, taurine cattle migrated to Europe and subsequently first entered the African continent from the North, while indicine cattle migrated later to Africa from the East (Mwai *et al.*, 2015). The ancestors of indigenous cattle were exposed to considerable environmental and disease challenges that led to evolutionary genetic adaptations. Nowadays, it is estimated that around 150 indigenous cattle breeds inhabit the African continent (Gebrehiwot *et al.*, 2020) that can be roughly grouped into breeds with high proportions of indicine background (Zebu), high proportions of taurine background ('African taurine') and cattle with a mixture of taurine and indicine ancestries (Kim *et al.*, 2020). A number of traits have been associated with genetic ancestry, including the hump, large ears and excess skin indicative of indicine ancestry. These characteristics are thought to provide heat tolerance and thus contribute to adaptation to semi-arid and desert climates (Hansen, 2004). Disease resilience is another ancestry-related factor: e.g. African taurine cattle are considered to be more resistant to trypanosomiasis (Berthier *et al.*, 2015) than those with substantial indicine ancestry. Adaptation to these environmental challenges can improve animal performance and fertility and hence, indigenous African cattle are an important socio-economical resource for the African population, particularly for smallholder farmers. The aims of this study are to use genetic diversity patterns of African cattle breeds to improve understanding of the genetic basis of important traits and to contribute to conservation and breeding strategies.

Materials & methods

Whole-genome sequence data of African cattle. Illumina sequencing data for multiple global cattle genomes was prepared as described in Dutta *et al.* (2020). We retained all African cattle samples with a sequencing depth of ≥8. The biallelic variants were filtered for a call rate ≥95% and genotyping quality

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_189, © J. Friedrich *et al.* 2022

(QG) >20. Samples with a call rate <75% or a 1st-degree relationship to another sample were excluded. After removal of breeds with fewer than 7 samples, the following samples remained: 7 Ankole, 7 Baoule, 47 Boran, 7 Djakkore, 9 Kenana, 27 N'Dama, 8 Ogaden and 7 Zebu Gobra.

Determining the genetic structure of African cattle breeds. The genetic structure and admixture of samples was analysed using principal component analysis (PCA) in Plink (Chang *et al.*, 2015) and the ADMIXTURE (Alexander *et al.*, 2009) software. The genotype data was pruned for high linkage disequilibrium in Plink, leaving a pruned dataset of 4,902,838 variants. For the ancestry estimation in ADMIXTURE, the best number of clusters (K) was determined by comparing 5-fold cross-validation (CV) errors for K=2-10.

Comparative analysis of selection signatures. Signatures of selection *within* breeds were identified using the integrated haplotype score (iHS) statistic. Genotypes were phased in Beagle version 4.173 (Browning and Browning, 2007) and marker-wise iHS were calculated according to Voight *et al.* (2006) using the hapbin software (Maclean *et al.*, 2015). Correlations between marker-wise iHS statistics across breeds were calculated and the top 0.01% iHS per breed were selected to identify signatures shared across breeds. To determine signatures of selection *between* breeds, a windows-based fixation index (F_{ST}) was estimated between each breed and all others. The mean F_{ST} for windows of 50 kb with an overlap of 25 kb was determined using vcftools (Danecek *et al.*, 2011). Windows with fewer than 30 variants were excluded.

Results

The underlying genomic population structure for all African cattle breeds was explored using PCA and Admixture analysis. The PCA indicated a separation according to the longitudinal geographical origin of the samples, which also correlates with the occurrence of more taurine (West Africa) or more indicine (East Africa) breeds (Figure 1A). The lowest CV error in the Admixture analysis was calculated for K=3. Breeds with the greatest ancestry proportions for the three clusters were N'Dama and Baoule (red cluster), Kenana (dark blue cluster) and Boran (light blue cluster) (Figure 1B). To detect recent and incomplete selective sweeps within breeds, we calculated the iHS score for each marker and identified the markers belonging to the top 0.01% of the iHS for each breed. The correlation between iHS scores for the African breeds was highest for Kenana and Ogaden (corr=0.27) and Kenana and Djakkore (corr=0.22). The lowest correlation was observed between N'Dama and Boran (corr=0.03). We grouped variants within 50 kb of each other that were detected as within the top 0.01% in at least two breeds into windows. We detected 78 windows including at least two selection candidate variants; these spanned 51.8 kb on average. The longest candidate window was found on BTA10 (233-237 kb; 54 SNPs), with top 0.01% variants for all African breeds except Boran. This region included one gene: the T cell receptor alpha variable 24 (*TRAV24*) gene.

genetic differentiation between African breeds, we calculated window-based F_{ST} between each breed and all others. The genome-wide average F_{ST} was highest for N'Dama (0.10), followed by Boran (0.07), Baoule (0.06), Kenana (0.04), Ogaden (0.03), Ankole (0.02), Zebu Gobra (0.02) and Djakkore (0.01). The highest windows-based F_{ST} differed across breeds and included regions on BTA6, 7, 9, 15 and 20 (Figure 2). The window with the highest F_{ST} across all breeds was identified for N'Dama on BTA7, and included the coding region for one gene, the pleckstrin and Sec7 domain containing 2 (*PSD2*) gene.

We checked for coincident variants between top 0.01% F_{ST} windows and top 0.01% iHS for every breed, but detected no overlaps.

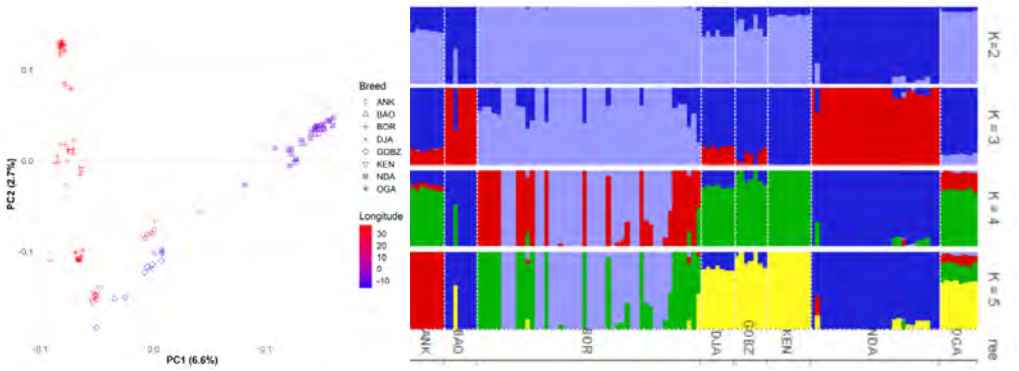

Figure 1. Genomic population structure analysed by PCA (A) and Admixture analysis (B). Samples are coloured according to the longitude of the capital of the country of origin. ANK = Ankole; BAO = Baoule; BOR = Boran; DJA = Djakkore; GOBZ = Zebu Gobra; KEN = Kenana; NDA = N'Dama; OGA = Ogaden.

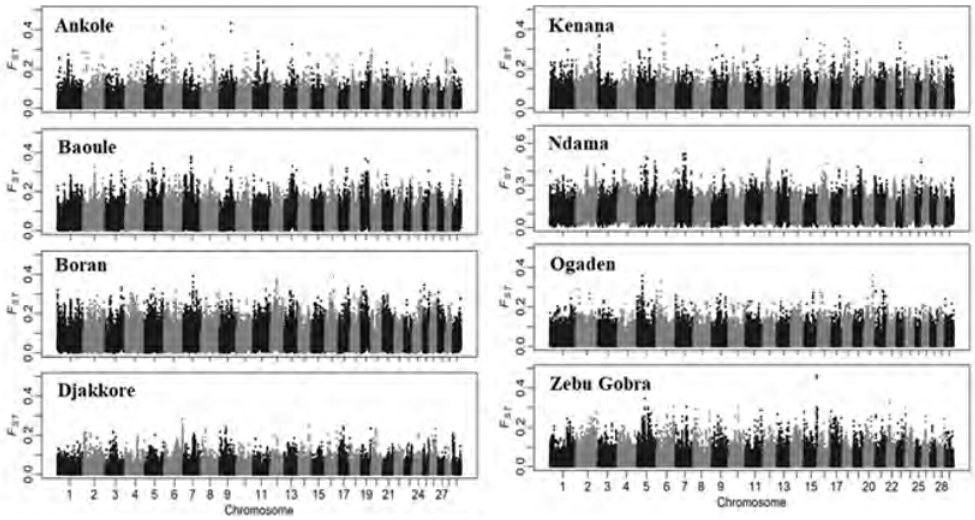

Figure 2. Window-based F_{ST} across the genome for African breeds.

Discussion

African cattle represent a valuable genetic resource to study both artificial and natural selection. Characterising the selection signatures and genetic differences between breeds will provide insights into genomic regions associated with environmental adaptation. PCA and admixture analyses showed a clear separation between cattle with higher proportions of taurine and indicine ancestry, reflecting the domestication and evolutionary history of indigenous African cattle and their geographical origins (Mwai *et al.*, 2015). The highest genetic differentiation from the remaining breeds was observed for N'Dama and Boran, which had the highest proportion of taurine and indicine ancestry, respectively. Furthermore, the selection signature results suggest the potential to identify regions associated with breed-specific adaptation or production traits, e.g. a genomic region on BTA10 harbouring the *TRAV24* gene emerged from the iHS results as a candidate region under selection in all African breeds except Boran. *TRAV24* is involved in adaptive immunity and the wider region on BTA10 overlaps with the multi-gene TRA/TRD

cluster (Connelley *et al.*, 2014). Furthermore, the F_{ST} results highlighted the locus on BTA7 (harbouring the *PSD2* gene) as a region for which N'Dama is highly differentiated from all other breeds. Previously, Kim *et al.* (2020) identified this as a region showing an excess of indicine ancestry in admixed African cattle. *PSD2* has also been suggested as a selection target related to fat deposition in sheep (Mastrangelo *et al.*, 2019). These two examples demonstrate that identification of selection signatures across multiple breeds has the potential to shed further light into gene functions and the genetic basis of phenotypic variability in indigenous African cattle breeds.

Abstract

Dual-Purpose Blue in Belgium and northern France is a local breed that is currently in the focus in order to understand its genetic distinctiveness and its use for local products. Its genomic evaluation systems are evolving, and its specific genetic distinctness was here studied for type traits. Results showed that throughout the 23 traits, there were two distinguishable genomic regions (BTA2 and BTA26) where BTA26 was associated with development traits and BTA2 was associated with muscularity traits, but also with associated traits as overall rump, udder depth, overall udder, and rear udder. Given these results future genomic evaluation systems should consider the segregating *MSTN* (myostatin), which is located on BTA2.

Introduction

Blue cattle in Belgium, but also in neighbouring northern France, originated from the crossbreeding between local dairy cattle and imported Durham (Shorthorn) bulls during the 1850-1880. Even if the presence of blue cattle in the low countries is attested by paintings from the 17th century, this crossbreeding mostly created the blue colour pattern. This pattern is a variant of the Shorthorn pattern where black replaces red leading to three colours: black (and white), white and blue roan. During the early 1900's this breed evolved into a local dual-purpose breed. In Belgium, since the 1950's, most breeders favoured the beefier type leading to the Beef Belgian Blue (BBB) breed. In France political circumstances let few farmers continue keeping blue cattle local known as the dual-purpose 'Bleue du Nord'. For many years, French breeders have been joining forces with fellow dual-purpose breeders in the 'Belgian Blue' Herdbook in Belgium who have recently changed the name of their Belgian Blue strain to 'Dual Purpose Blue' (DPB), a name used hereafter for the whole population. Several projects have led to common genetic evaluations for several traits and a common understanding of the needs in this breed (BlueSter 2021). General efforts will be reported to exploit genomics as a tool and its use in the of context of DPB cattle. The specific objective will be to illustrate this by estimating genomically enhanced estimated breeding values (GEBV) and by performing genome wide association studies (GWAS) for linear type traits.

Materials & methods

DPB populations. The DPB are present in the southern Belgian (Walloon) part (~80%), as mentioned in France (~15%) and the remaining animals are in Flanders, around Brussels. This third population is not providing data to the joint DPB breeding program but selected young bulls are entering it, also based on genomic predictions. Flemish breeders can also access DPB AI sires. In total approximately 3,000 cows are (milk) performance recorded.

Genotyping. Extensive efforts are ongoing to genotype a large part of the currently active DPB population. This study, which used data available in May 2021, had access to 1,772 genotypes. The DPB population is rather unique as it has a tradition of testing for the *MSTN* (myostatin) mutation that is segregating in its population since it was discovered (Grobet *et al.* 1997). Also, given this fact, there is a large acceptance for genomic testing, it is expected that genotyping will cover nearly the whole population in a few years.

Performance recording and type data. Milk performance recording is well established, and individual data was available down to the 1970s in Wallonia. This is relevant as the DPB population was larger at that moment and semen of AI sires from this period is still being used. Recently, a transnational type recording program was initiated addressing the complexity of the needs for this dual-purpose breed. Therefore, the 23 traits scheme includes 18 individual traits: five udder traits, three muscularity traits, but also body development, including stature, rump, feet and legs and other traits and five additional overall traits that are scored and not computed from individual traits: udder, development, feet and legs, muscularity, and rump. These traits allowed the inclusion of less recent data from a simplified system previously used in France which handled only stature and these overall traits. Results reported in this study labelled udder, development, feet and legs, muscularity, and rump refer always to those 5 overall traits.

A total of 1,746 French and 10,701 Belgian records from 10,134 cows scored until the beginning of 2021 were included in this study. All traits are scored from 1 to 9 except stature which is measured. Normally, cows needed to be scored at least once in first or second lactation but could then be rescored. For this reason, 50.7 and 37.6% of the records were scored in first or second lactation, respectively. The remaining were animals that were rescored, mostly in the third lactation (10.0%), however late rescoring was also used because DPB breeding strives to obtain a high longevity.

Generating genomically enhanced estimated breeding values (GEBV). A transnational genomic evaluation system is currently under development for type traits. This system is based on two steps. In a first step, as there were missing traits, it was preferable to use a multiple-trait model allowing missing values. Moreover, tests showed that a full multiple-trait model had convergence issues. However, the use of a canonical transformation adopted for multiple diagonalization (Misztal *et al.* 1995) was able to handle easily the required 23 trait repeatability model. Associated (co)variance components were estimated as outlined by Misztal *et al.* (1995) on a subset with no missing values. These computations were based on 9,777 Walloon and 934 French records of 7,514 DPB cows. The used model was very close to the model used for Holstein cattle in the Walloon region of Belgium (Croquet *et al.* 2006) but without heterogeneous variance adjustments. The model had five fixed effects with a herd-year-month of classification x classifier-system contemporary group effect where classifier-system distinguished between classifiers working in the three recognized systems (Walloon, France-old and France-new). Also included were age and lactation stage effects distinguishing between fine overall effects and larger classifier-system specific effects. A direct implementation of a genomic single-step model in this setting was however not available. Therefore, in a second step, using estimated breeding values (EBV) and associated reliabilities (REL) generated in the first step, the Bayesian approach as proposed by Vandenplas *et al.* (2014) and used by Colinet *et al.* (2018), but only limited to local data, was used. Conceptually, this is equivalent to replacing the pedigree-based relationship matrix A by a combined matrix H transforming EBV into GEBV and REL into genomically enhanced REL (GREL) thus approximating closely an ssGBLUP.

Genome wide association study (GWAS). The SNP effects were estimated individually for each of the 23 traits using the postGSf90 software (Aguilar *et al.* 2014). The vector animal effects (GEBV) was separated in genotyped (a_g) and ungenotyped animals (a_{ng}). The GEBV of genotyped animals were considered being a function of the SNP effects, $a_g = Zu$, where Z is a matrix relating genotypes of each locus to SNP marker effect and u is a vector of the SNP marker effect. The variance of animal effects was assumed as:

$$\mathrm{Var}\left(\mathbf{a}_g\right) = \mathrm{Var}\left(\mathbf{Zu}\right) = \mathbf{ZDZ}'\sigma_u^2 = \mathbf{G}\sigma_a^2$$

where D is a diagonal matrix of weights for variances of markers (D = I), σ_u^2 is the genetic additive genetic variance captured by each SNP marker when the weighted relationship matrix (G) was built with equal weights.

The SNP effects were obtained using the following equation:

$$\hat{\mathbf{u}} = \lambda \mathbf{DZ}'\mathbf{G}^{-1}\hat{\mathbf{a}}_g = \mathbf{DZ}'\left[\mathbf{ZDZ}'\right]^{-1}\hat{\mathbf{a}}_g$$

where λ was defined as a normalizing constant (VanRaden 2008) and the percentage of genetic variance explained by the ith genomic region was estimated as:

$$\left(\mathrm{Var}\left(\mathbf{a}_i\right)/\sigma_a^2\right)\times 100 = \left(\mathrm{Var}\left(\sum_{j=1}^{25}\mathbf{Z}_j\hat{\mathbf{u}}_j\right)/\sigma_a^2\right)\times 100$$

where a_i is the genetic value of the ith region that consists of 25 adjacent SNPs, σ_a^2 is the total genetic variance, Z_j is the vector of the SNP content of the jth SNP for all individuals, and $\hat{\mathbf{u}}_j$ is the marker effect of the jth SNP within the ith region. The results were presented by the proportion of variance explained by each window of 25 adjacent SNPs and windows explaining for at least 1.0% of the total additive genetic variance were identified.

Results

Heritabilities, repeatabilities and correlations. Heritabilities across all 23 traits ranged from 0.15 for foot angle to 0.74 for stature. Repeatability ranged from 0.28 for foot angle to a very high 0.84 for stature. Table 1 shows heritabilities and correlations among the 5 overall traits.

Genome wide association studies (GWAS). Throughout the 23 traits, there were two important genomic regions. The genomic region located between 20.8 to 22.9 Mb on BTA26 was associated with traits including chest width, overall development (Figure 1), and stature. A region located between 5.3 to 7.3 Mb on BTA2 was associated with muscularity traits, but also with overall rump, overall udder (Figure 1), udder depth, and rear udder.

Table 1. Genetic (above diagonal) and phenotypic (below diagonal) correlations, and heritabilities (diagonal) for overall traits.

	Udder	Development	Feet and legs	Muscularity	Rump
Udder	0.37	0.15	0.10	-0.66	0.48
Development	0.08	0.63	0.26	-0.19	0.47
Feet and legs	0.10	0.15	0.19	0.00	0.12
Muscularity	-0.36	-0.08	0.01	0.60	-0.65
Rump	0.28	0.28	0.06	-0.39	0.42

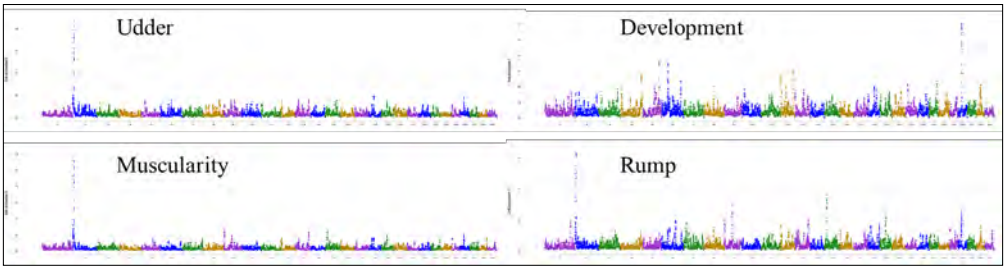

Figure 1. Additive genetic variance explained by windows of 25 adjacent SNP across chromosomes for the 4 overall traits udder, development, muscularity, and rump in Dual-Purpose Blue cows.

Discussion

Heritabilities, repeatabilities and correlations. Heritabilities were, as expected, with a tendency on the upper bound compared to those reported in literature. In general, repeatability tended to be high too. On a genetic level, an expected strong opposition between udder and muscularity appeared clearly, underlying the importance to include both in an adapted breeding objective for this dual-purpose breed.

Genome wide association studies (GWAS). At least one study in a completely different breed (Holstein) has associated BTA26 with an overall development trait (body form composite index) (Ashwell *et al.* 2005). Previous studies showed that SNPs inside the region on BTA2 position 5.3 to 7.3 Mb in various breeds of dairy and beef cattle were linked to mutations in *MSTN* (myostatin), the cause of the double-muscled phenotype in cattle, in general considered as the most important functional gene in the region found on BTA2. A visible distinct muscular hypertrophy (mh) occurs with high frequency in the DPB breed, linked to a specific deletion (Grobet *et al.* 1997), without being homozygous as in BBB. As explained previously, a large part of the DPB population is genotyped for this mutation. Given the large variance on BTA2, strategies may be useful to include mh in the future genomic evaluation system as already proposed for calving difficulty and associated traits (Mota *et al.* 2017).

191. Genetic background of productive and adaptive features in the West African indigenous cattle breeds in Benin

S.F.U. Vanvanhossou[1*], T. Yin[1], I.J. Giambra[1], K. Brügemann[1], L.H. Dossa[2] and S. König[1]

[1]Institute of Animal Breeding and Genetics, Justus-Liebig-University Gießen, 35390 Gießen, Germany; [2]School of Science and Technics of Animal Production, Faculty of Agricultural Sciences, University of Abomey-Calavi, Abomey-Calavi, 03 BP 2819 Jéricho Cotonou, Benin; seyi.f.vanvanhossou-2@agrar.uni-giessen.de

Abstract

This study aimed to investigate the genetic patterns underlying productive and adaptive features in West African indigenous cattle breeds. Multi-breed genome-wide association studies for two morphometric traits (height at withers and sacrum height) were performed considering 449 animals from four indigenous cattle breeds (Lagune, Somba, Borgou and Pabli) in Benin. In addition, 67 animals were selected from the previous sample for next-generation sequencing targeting six milk protein genes (*CSN1S1, CSN2, CSN1S2, CSN3, LALBA, LGB*). A total of eight single nucleotide polymorphisms were associated with the morphometric traits. The loci and the potential candidate genes were not only involved in conformation, growth or carcass traits, but also in adaptive trait mechanisms including response to heat stress, immune functions or disease resistances. Furthermore, high genetic polymorphism was observed in the milk protein genes, and a total of 17 milk protein variants including four previously undescribed variants ($CSN3^{K}$, $LALBA^{F}$, LGB^{B1}, LGB^{K}) were identified.

Introduction

African animal genetic resources are highly diverse and represent a valuable asset for food security and the livelihood of farmers (Mwai *et al.,* 2015). Unfortunately, they are increasingly threatened by several factors including climate change, diseases and lack of adequate management policies (Mwai *et al.,* 2015). In addition, the lack of proper genetic characterization impedes their promotion, genetic amelioration and sustainable use. Recent genetic studies on some African breeds confirmed their richness and valuable features including resistance to disease, heat stress as well as their economic potential (e.g. Kim *et al.,* 2020). Novel genomic statistical methods offer new possibilities to investigate African breeds and to unravel their genetic potential.

The aim of this study was to use up-to-date genomic tools to characterise West African indigenous cattle breeds in Benin. For this purpose, morphometric traits, known as proper early indicators for animal growth, health, welfare and longevity (Kominakis *et al.,* 2017) were targeted, and their genomic architectures were investigated in genome-wide association studies (GWAS). In addition, four casein genes (*CSN1S1, CSN2, CSN1S2, CSN3*) on *Bos taurus* autosome (BTA) 6, and two whey protein genes (*LALBA* and *LGB*) on BTA5 and BTA11, respectively, were characterized, because they are associated with milk production traits in several cattle breeds (Caroli *et al.,* 2009). Genetic polymorphisms in milk proteins genes and milk protein variants were detected using next-generation sequencing.

Materials & methods

Animal genotyping and multi-breed GWAS for morphometric traits. In total, 449 animals from four indigenous cattle breeds (Lagune, Somba, Borgou and Pabli) were sampled in Benin and genotyped using the Illumina BovineSNP50 BeadChip. SNP with a minor allele frequency <5%, genotyping call rate <90% and which are in Hardy-Weinberg equilibrium ($P \geq 10^{-6}$), as well as animals with genotyping call rate <95%, were excluded. The final genotype data were used to perform GWAS for the morphometric traits in PLINK (Purcell *et al.,* 2007), including height at withers (HAW) and sacrum height (SH). The genetic structure

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_191, © S.F.U. Vanvanhossou *et al.* 2022

of the animal population was estimated applying a discriminant analysis of principal components. The genetic-statistical model was defined as follows:

$$y = Xb + Wg + e$$

where y was a vector of observations for HAW and SH; b was a vector of fixed effects including age, sex, the origin (agro-ecological zone), breed, and linear discriminant functions; g was a vector for the SNP fixed effects; e was a vector of random residual effects with $\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2)$; and X, W were incidence matrices for b and g, respectively.

Significantly and suggestively associated SNP were identified using the Bonferroni-corrected significance threshold (P=1.55×10^{-6}) and chromosome-wide Bonferroni-corrected significance thresholds (pc = 0.05/m_c, with m_c = effective number of SNP for each chromosome).

Animal sequencing and detection of milk protein variants. Next-generation sequencing was performed using 67 animals selected from the previous samples. For this purpose, genotyping-in-thousands by sequencing (GT-seq) using the Illumina MiSeq V3 platform targeted the exon sequences, flanking intron sequences and parts of the 5′-upstream regions of milk protein genes (*CSN1S1, CSN2, CSN1S2, CSN3, LALBA, LGB*). The generated raw sequence data were processed to identify SNP, insertions and deletions (InDel). Variants detected in the coding regions were considered to annotate milk protein variants following the existing nomenclature (Caroli *et al.,* 2009; Gallinat *et al.,* 2013) and referring to the amino acid (AA) position in the mature proteins.

Results

Genomic regions associated morphometric traits. The multi-breed GWAS for HAW identified one significantly associated SNP (rs109126926 on BTA1, P=1.12×10^{-6}) and five chromosome-wide suggestively associated SNP (on BTA3, 17, 19 and 21, P=6.44×10^{-6}-5.04×10^{-5}) (Figure 1). The significantly associated SNP for HAW on BTA1 is located in the *VEPH1* gene. The SNP rs110369628 and rs109889052 on BTA19 are positioned close to each other (7.41 Mb), within the genes *PIK3R6* and *SSH2*, respectively. In addition, the SNP rs4163436 is positioned in the gene *CCDC117* on BTA17, whereas the two remaining associated SNP are not located in the vicinity of any gene. Sacrum height was associated with two suggestive SNP (P=2.35×10^{-5}-3.86×10^{-5}) and each is located in close distance to a gene (Figure 1). The SNP rs111001850 is positioned near the *LYPD8* gene on BTA7, and the SNP rs110441360 is mapped in relative proximity to the *PIK3R1* gene on BTA20.

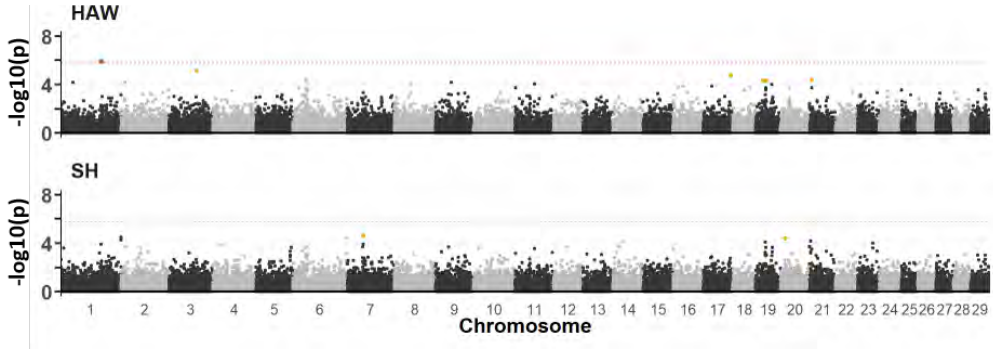

Figure 1. Manhattan Plots displaying GWAS results for height at withers and sacrum height in Beninese indigenous cattle breeds. Genowe-wide significant SNP are in red and chromosome-wide suggestive SNP are in yellow.

Milk protein variants in the Beninese indigenous cattle breeds. Within the coding regions, a total of 12 DNA polymorphisms caused 17 milk protein variants. The distribution of the milk protein variants in the investigated breeds is presented in Table 1. Two casein variants were identified for *CSN1S1 (CSN1S1^{B}* and *CSN1S1^{c}).* They were due the SNP rs43703010A>G located in exon 17. The variant *CSN1S1^{B}* and *CSN1S1^{C}* were associated with the reference alleles rs43703010A and rs43703010G, respectively. For *CSN2,* the casein variants *CSN2^{A1}*, *CSN2^{A2}* and *CSN2^{L}*, were identified. *CSN2^{A1}* corresponds to the reference sequence and was differentiated from *CSN2^{A2}* with the SNP rs43703011A>C. *CSN2^{L}* is due to the SNP rs715383373T>C in exon 7. In the *CSN1S2* gene, only one missense variant (rs441966828C>T) was identified, and is associated with the *CSN1S2^{B}* and *CSN1S2^{A}* protein variants. With regard to *CSN3,* three milk protein variants (*CSN3^{A,} CSN3^{B}, CSN3^{K}*) were detected. The *CSN3^{A}* and *CSN3^{B}* were associated with the SNP rs43703015T>C and rs43703016C>A in exon 4. The third detected milk protein variant was previously undescribed and was named *CSN3^{K}*, following the previous nomenclature in cattle. *CSN3^{K}* is caused by a novel SNP (BTA6:85656526C>T) in exon 4. Moreover, three known (*LALBA^{A}*, *LALBA^{B}*, *LALBA^{E}*) and one novel (*LALBA^{F}*) milk protein variants were detected in *LALBA*. *LALBA^{A}* differs from the reference variant *LALBA^{B}* with the SNP rs722550244G>C in exon 1. Near this SNP, another SNP rs7144688595C>T induces a new milk protein variant previously undescribed and therefore named *LALBA^{F}*. In addition, the variant *LALBA^{E}* due to the SNP rs465119286A>G was idenified. A missense SNP (rs109625649C>T) and a frameshift insertion induced one known (*LGB^{B}*) und two novel milk protein variants (*LGB^{B1}*, *LGB^{K}*) for *LGB*. *LGB^{B}* is associated with the reference allele rs109625649C, whereas the alternative allele rs109625649T is responsible for a novel milk protein variant called *LGB^{B1}*. *LGB^{K}* is induced by a frameshift insertion causing the emergence of a premature stop codon, and resulting in the reduction of the coding sequence of the *LGB* gene from a total of 178 to 104 AA with a complete exchange of the protein sequence from AA 92 to 104.

Discussion

The rather small number of detected SNP for the moderately to highly heritable polygenic traits is in line with our small sample size and its diversity (multi-breed), and is most likely due to a lack of power to detect variants with smaller effects. However, the functional annotation of the identified genes and comparison with previous studies confirm the association of the detected loci with conformation, growth and carcass traits in cattle or in other species. For instance, the *VEPH1* gene affects rump fat thickness in Nellore

Table 1. Distribution of milk protein variants in the Beninese indigenous cattle breeds.

Genes	Variants [1] (Ref. / Alt.)	Protein exchange	Variant Frequency (Ref. / Alt.)

[1] The variants in bold have been newly annotated.

cattle (Santana *et al.,* 2015). The *PIK3R6* gene was previously related to body size in sheep (Kominakis *et al.,* 2017). In addition, the *CCDC117* gene associated with HAW is implicated in feed intake and heat stress regulation in cattle (Lindholm-Perry *et al.,* 2016). Similarly, *PIK3R1* is associated with resistance to disease infections in cattle (Marino *et al.,* 2017). The observed overlap of genomic regions associated with morphometric and adaptive traits is reported in previous studies, and is in line with the selection strategies for animal adaptation using morphometric traits in African cattle herds.

The results of this study also show that the milk protein gene regions display several known and previously unknown polymorphisms in the Beninese cattle breeds (Caroli *et al.,* 2009; Gallinat *et al.,* 2013). The identified variants confirm the distribution of previously described milk protein alleles in Beninese and African cattle breeds (Moazami Goudarzi *et al.,* 2001). However, the detection of several previously unknown milk protein variants (*CSN3*^{K}, *LALBA*^{F}, *LGB*^{B1}, *LGB*^{K}) support the unicity and genetic diversity of the West African cattle breeds. The identified variants are expected to be further investigated for potential association with milk quantity and quality in the Beninese indigenous breeds. This study corroborates the necessity to enhance genetic studies in local breeds from tropical countries, contributing to a deeper understanding of genetic mechanisms for adaptation and the identification of novel genes for productive performances.

Abstract

Genomic analyses in livestock animals, beside the obvious contribution to applications in agriculture, provide important insights into biodiversity research and species conservation. The Drežnica goat (*Capra hircus*) is the only Slovenian local goat breed with critically endangered status. Its robustness and adaptability to the hard Alpine environment are important traits worth preserving especially in light of climate changes to even harsher conditions. The aim of the study was to analyse the genetic structure of the breed and its independent origin within other goat breeds. We genotyped Drežnica goats with an Illumina 50K SNP chip and analysed the genetic diversity and population structure within the breed and genetic relatedness to other breeds from the Alpine region. The results showed that the breed had a large number of private alleles and retained moderate to high genetic variability. Estimates of genetic distances showed Drežnica goat's distinct genetic origin and the admixture with foreign breeds is extremely low.

Introduction

In the era of preferential rearing of high-performance breeds, local breeds are slowly being recognised as an important source of phenotypes with good production potential in environments with harsh conditions. Due to high selection pressure for economically important traits associated with indoor housing system, cosmopolitan goat breeds have diminished or lost alleles for adaptation to extreme environments like high-altitude areas. On the other hand, low pressure of artificial selection and high pressure of natural selection are two possible reasons why local goat breeds maintain those adaptive traits (Marsoner *et al.*, 2018). In Slovenia, the only local goat breed is called Drežnica goat. Because of its small population size, the breed is at high risk of extinction. Based on production purpose, the population is divided into dairy and meat production type. The dairy subpopulation is mainly widespread around the Bovec region (upper dot in Figure 1), while the meat type is concentrated in the Drežnica-Kobarid region (bottom dot in Figure 1). Drežnica goat is reared according to traditional alpine production system with short span of indoor rearing in the winter and free-range grazing on mountain pastures from spring to autumn. Adaptation to the hard conditions of the Alpine environment allows the breed to survive without human help, which are important traits worth conserving. Nevertheless, this breed lacked genetic analyses on which breeding and conservation programmes could be based. Additionally, the variability in coat colour raised doubts that the breed is rather a genetically mixed population of different breeds. For this reason, we genotyped Drežnica goats with an Illumina goat chip containing ~50.000 SNP markers (Tosser-Klopp *et al.*, 2014) to analyse the parameters of genetic diversity, population structure, and possible occurrence of crossbreeding with other breeds.

Materials & methods

We selected and sampled 133 representative animals of Drežnica goat and acquired six goat breeds from neighbouring countries Austria and Italy (Pogorevc *et al.*, 2021). Goats were genotyped with the Illumina Goat SNP50 BeadChip (Tosser-Klopp *et al.*, 2014). Additionally, we included the genome-wide genotypes of 16 goat breeds from the Alpine area available in the DRYAD repository. After forming the dataset

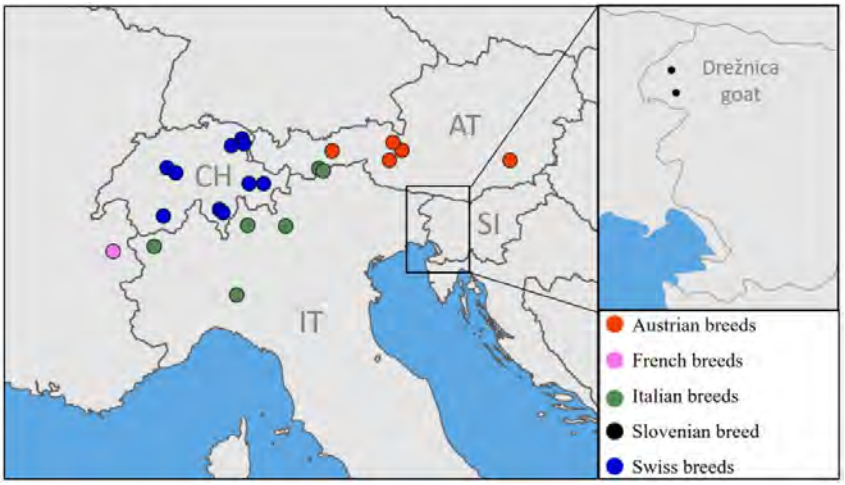

Figure 1. Geographic locations of 23 alpine goat breeds included in our datasets.

(Figure 1, Table 1), we performed quality control excluding SNPs with unknown chromosomal positions, inconsistent information according to relatives, a call rate <95%, and a minor allele frequency <0.025. We imputed missing genotypes for 48,297 autosomal SNPs that passed quality control (Browning *et al.*, 2007). For optimization, genetic diversity estimation, and genetic distance calculation described below, we used 5,658 short haplotypes consisting of four adjacent SNPs, each less than 50 kb apart.

To obtain objective results we optimized the dataset by excluding goats with admixture signatures from other breeds. We used a multivariate outlier test (Filzmoser *et al.*, 2005) and excluded outliers that had weaker genetic relationships with individuals from the same breed, stronger genetic relationships with individuals from other breeds, and a larger proportion of foreign alleles. Based on identity by descent we estimated unified additive relationships (UAR) and excluded closely related goats with UAR>0.25 (Yang *et al.*, 2010). After both optimization steps, we estimated genetic diversity parameters by calculating the number of private alleles and mean allelic richness. Genetic relationships between the breeds were calculated with Nei's distances (Nei *et al.*, 1983), which were used for the construction of a phylogenetic neighbour net with the program SplitsTree4 (Huson and Bryant, 2006). To determine the population structure, we used single-SNP alleles and analysed them with the programs SmartPCA (Price *et al.*, 2009) and Admixture (Alexander *et al.*, 2009).

Results

With allele count parameters based on haplotypes, we analysed genetic diversity within the breeds (Table 1). Drežnica goat had 301 private alleles, which is the second highest number. In terms of allelic richness, the Drežnica goat was positioned in the middle of breeds from the Alpine environment with a mean value of 7.86. The neighbour net tree of Nei's distances placed the distinct branch of Drežnica goat close to geographically neighbouring breeds from Austria and Italy (Figure 2B). These results were consistent with principal component analysis (PCA), which distinguished three major groups (Figure 2A). The cosmopolitan breeds from four countries (Camosciata Alpine and Chamois Coloured) formed one cluster, Austrian, Italian and Swiss breeds formed the second and the third cluster was the Drežnica goat. Austrian breeds were closest

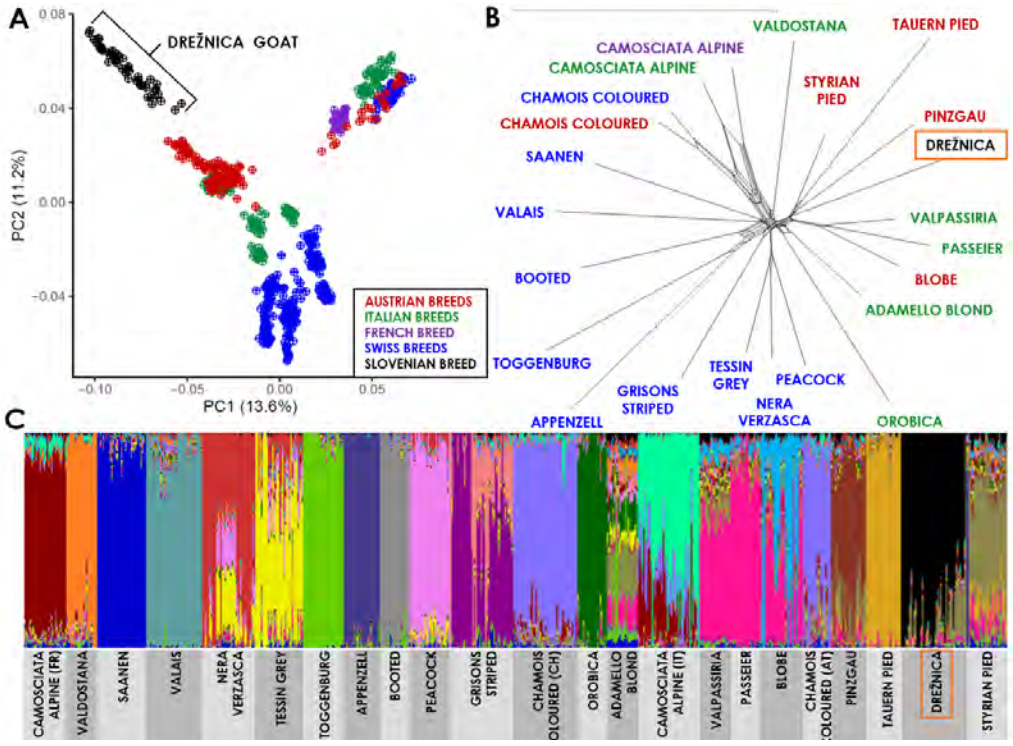

Figure 2. Genetic relationships of alpine breeds based on PCA analysis (A), Nei's distances (B), and their population structures of admixture analysis (C).

to the Drežnica goat, followed by Italian and then Swiss breeds. The lowest cross-validation error of the admixture analysis determined the optimal number of 21 hypothetical populations for our dataset (Figure 2C). There were 11 breeds that formed homogeneous clusters, while some individuals or whole populations of other breeds were slightly admixed, resulting in rather heterogeneous clusters. Drežnica goats showed mainly homogeneous blocks with traces of admixture in few individuals. With admixture plot, we obtained more detailed population structures, further supporting previous results observed in PCA and neighbour net graphs.

Discussion

Genomic characterization of endangered local breeds is essential for their efficient breeding and conservation programs. To achieve this, we compared the Drežnica goat with genotypes of 22 goat breeds from the Alpine environment. From the high number of private alleles and average allelic richness, we can conclude that the Drežnica goat retained distinct genetic signature. With the neighbour-joining tree, we demonstrated that this high diversity is not primarily due to admixture but to the distinct genetic origin of the Drežnica goat with its own branch. This supported the PCA analysis, where the Drežnica goat formed its own cluster clearly separated from other alpine breeds. An admixture analysis revealed that several Drežnica goats contained some admixture signatures, else the breed had a uniform population structure without clear separation of both production types. Since the breed has experienced bottlenecks in the past and the population size is low today, these diversity results are encouraging for future breeding and conservation programmes. Our study demonstrating distinct genetic identity therefore places the Drežnica goat on the world map of goat breeds.

Abstract

In this study, genomic information was used to evaluate the genetic composition and characteristics of a composite beef cattle population. This composite population consisted of 50% Red Angus, 25% Charolais, 25% Tarentaise. The results showed an increase in the proportion of Tarentaise to approximately 57% while Charolais decreased to approximately 5%, and Red Angus decreased to 38%. Evaluating runs of homozygosity showed the formation of new haplotypes in the composite population around the sixth generation. The study showed that progenitor combinations are not stable over generations and that either direct or natural selection plays a role in modifying the proportions. Furthermore, the results showed that Tarentaise contributed useful attributes to the composite in a cool semi-arid environment and suggests a re-exploration of this breed's role may be warranted.

Introduction

Composite breeds are traditionally developed by combining two or more breeds that have complementary traits. In 1979, the USDA Agricultural Research Service's station in Miles City, Montana, US developed a composite population using *Bos taurus* breeds with distinct production characteristics. For this cold semi-arid environment, a three-breed composite (50% Red Angus, 25% Charolais, 25% Tarentaise) was formed to evaluate its performance in a limited nutrient production system. In brief, the CGC was started with breeding 300 Red Angus dams to either 14 Charolais sires or 12 Tarentaise sires using artificial insemination. The F1 individuals were produced between years 1980 to 1984. Crossing of F1 individuals began in 1981 and F_2 individuals were generated from 1982 until 1988. The F3 generation was produced between 1984 and 1990. With this mating plan the CGC effective population size was computed to be 95.7. Subsequent generations have been produced since 1987.

The objective of this study was to evaluate the genetic composition of CGC, if changes have occurred, what parental populations were favored/disfavored and given the small population size can it adequately be a research model for composite beef populations.

Materials & methods

The dataset consisted of a total of 248 animals, where 10 were founder crosses to form CGC, 69 were CGC, 61 Red Angus, 79 Charolais and 29 Tarentaise. The ten early founder crosses were born in 1980 and were 50% Charolais and 50% Red Angus or 50% Tarentaise and 50% Red Angus. The CGC animals were born between 1986 and 2017. All animals were genotyped with High-density SNP panel (777,962 SNP, BovineHD Beadchip, Illumina, San Diego, CA, USA). Markers with minor allele frequency lower than 1% were removed. In addition, markers with a call rate lower than 95% or not physically mapped to the bovine genome assembly UMD3.1 were discarded from the analyses. Markers on sex chromosomes were also removed, the final number of SNP genotypes used was 203,297.

To evaluate the genetic relationship between the pure breeds and CGC, principal component and ADMIXTURE (Alexander *et al.* 2009) analyses were conducted. Additionally, runs of homozygosity (ROH) analysis was conducted using PLINK (Purcell *et al.* 2007). The parameters were set to be a minimum run length equal to 1 Mb with a minimum of SNP markers calculated using the equation in Lencz *et al.* (2007) and allowing runs to contain up to two heterozygotes and five missing genotypes with a maximum gap equal to 50 kb and a minimal SNP density of 1 SNP per 50 kb.

Results

The principal components analysis showed population divergence with CGC clustered intermediately among the progenitor breeds (Figure 1). Furthermore, the progenitor breed proportions of CGC animals were estimated by ADMIXTURE and evaluated according to the generation number. The results showed decreased proportions of Charolais and Red Angus and an increase in Tarentaise in subsequent generations of CGC. As shown in Figure 2, there was an increase in the proportion of Tarentaise to approximately 57% while Charolais decreased to approximately 5%, and Red Angus decreased to 38%.

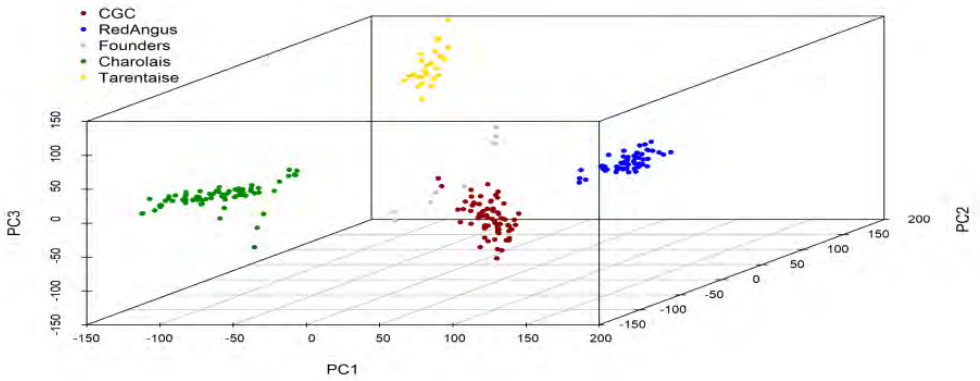

Figure 1. PCA plot for CGC founders, CGC, Red Angus, Charolais and Tarentaise.

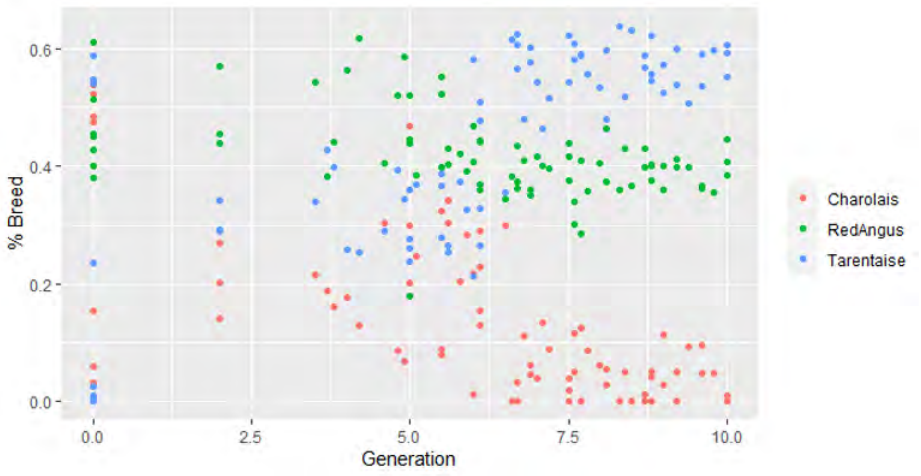

Figure 2. Genomic breed composition of CGC animals according to their equivalent generation number using Admixture analysis.

The ROH analysis showed Red Angus to have the highest number of ROH per animal and the longest total length of ROH (Table 1). Additionally, runs of homozygosity were classified according to the expected number of prior generations tracing back to a common ancestor. Figure 3 shows the change in the average ROH length according to the equivalent generation number of animals. Around the sixth-generation formation of longer ROH was observed.

Table 1. Summary description of the number, individual and total length of ROH segments (in Mb) per animal.

Parameters[1]	Breeds	Mean	SD	Min	Max
ROH_n	*CGC*	40.76	10.86	2	65
	Charolais	45.21	9.80	19	78
	Red Angus	92.26	12.09	70	127
	Tarentaise	70.72	10.99	50	98
ROH_L	*CGC*	3.33	3.60	1	55.41
	Charolais	3.70	4.40	1	100.54
	Red Angus	3.79	3.99	1	85.66
	Tarentaise	2.97	3.22	1	52.87
ROH_T_L	*CGC*	141.10	56.93	4.55	262.47
	Charolais	172.46	88.49	37.99	525.16
	Red Angus	349.92	81.52	226.98	738.47
	Tarentaise	209.27	44.21	115.42	304.64

[1] ROH_n = number of individual ROH segments per animal, ROH_L = length of individual ROH segments in Mb, ROH_{TL} = total length of ROH segments in Mb per animal.

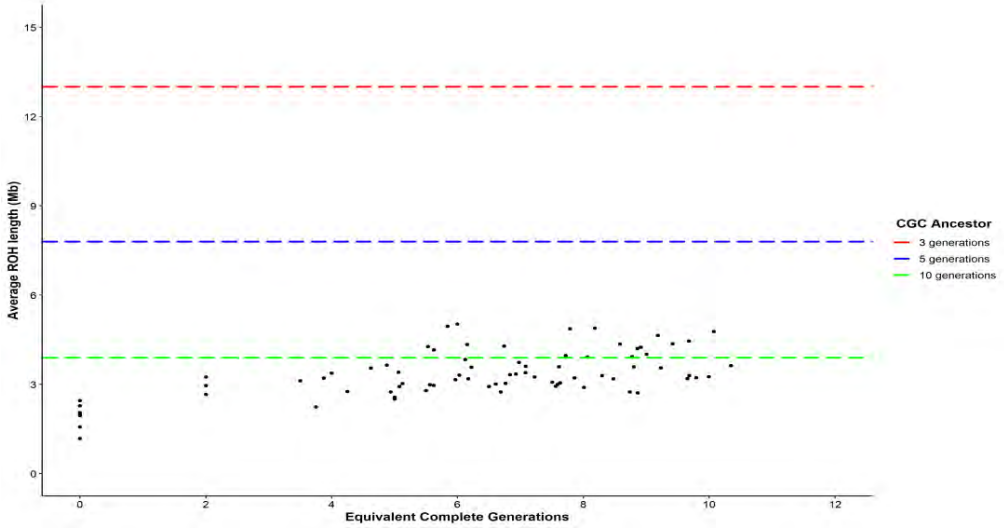

Figure 3. Runs of homozygosity observed in CGC cattle according to the equivalent generation number. Dashed lines indicate the length threshold for ROH that relates to a common ancestor at 3, 5, and 10 prior generations (red, blue, and green, respectively).

Discussion

Our results suggest several points about composite population development and potential use. As with other studies (Blackburn *et al.* 2017; Paim *et al.* 2020a; Paim *et al.* 2020b) with advancing generations the composite population develops its own unique cluster when compared to progenitor breeds (Figure 1). The formation of CGC cluster (generation 6) appears to be in concordance with previous work where a Brangus cluster occurred between generation 5 and 6 (Paim *et al.*, 2020a).

Evaluating runs of homozygosity showed new islands in CGC formed around generation 6 (Figure 3). This could be interpreted as when new breed formation occurred. The ROH based genomic inbreeding also showed a sharp increase to 10% in generation 6 and is different than the UN Food and Agriculture Organization (FAO) Guidelines for *in vivo* conservation of animal genetic resources (FAO 2013) which suggest three generations of inter se mating are required to establish a new composite breed after the initial crosses have been made.

The CGC population was constructed for increased cow productivity with the ability to perform in the northern Great Plains and has not been selected for meat quality, feedlot performance, nor increased mature size. Rather, the emphasis on selection tended to focus upon cow fertility and calf weaning weight. Given these selection objectives it is not surprising that the composition of the progenitor breeds shifted with time for CGC. Specifically, the proportion of Tarentaise shifted from a target of 25% to an average 57% in the last two generations, Red Angus decreased from a target of 50% to approximately 38%, and Charolais decreased from a target of 25% to approximately 4% (Figure 2).

194. Variation in patterns of recombination result in genetic variation in intrachromosomal shuffling in the domestic pig

C. Brekke[1*], S.E. Johnston[2], A.B. Gjuvsland[3] and P. Berg[1]

[1]Norwegian University of Life Sciences, Oluf Thesens vei 6, 1433 Ås, Norway; [2]University of Edinburgh, EH9 3FL, Edinburgh, United Kingdom; [3]Norsvin SA, Storhamargata 44, 2317 Hamar, Norway; cathrine.brekke@nmbu.no

Abstract

Meiotic recombination leads to shuffling of loci located on the same chromosome. The amount of intrachromosomal shuffling from one generation to the next is affected by the number of crossovers, location of crossovers and crossover interference. In the domestic pig, *Sus Scrofa*, genome wide recombination rates are higher in females than in males. However, in this study we find that the genome wide intrachromosomal shuffling between pairs of loci is higher in males than in females due to difference in distribution of crossovers along the chromosome in the sexes. We show that this pattern is consistent in four of five different pig breeds and that there is a genetic component to the variation in genetic shuffling.

Introduction

An important part of meiosis is the exchange of genetic material between homologues chromosomes through meiotic recombination, which results in gametes with novel haplotypes. This event breaks down linkage disequilibrium and lead to haplotypic diversity that can be exploited in selection. Recombination also has a vital role in the proper alignment and segregation of homologues chromosomes. (Sherman *et al.*, 1991; Koehler *et al.*, 1996; Hassold *et al.*, 1995; Fledel-Alon *et al.*, 2009). Recombination can however also break up beneficial linkage previously built up by selection (Charlesworth and Barton, 1996), and there is evidence for increased mutation rates in recombination hotspots (Halldorsson *et al.*, 2019; Arbeithuber *et al.*, 2015). Recombination rates vary between taxa and species, and even within and between closely related populations (reviewed in Ritz *et al.*, 2017; and Stapley *et al.*, 2017). Most species show some level of heterochiasmy (Burt *et al.*, 1991) and in some species there is also a substantial sexual dimorphism in the distribution of crossovers along the genome (Sakamoto *et al.*, 2000; Lien *et al.*, 2011; Tortereau *et al.*, 2012; Johnston *et al.*, 2016). In breeding this variation is of interest because it affects the production of novel allelic combinations. Veller *et al.* (2019) suggests shuffling of maternal and paternal alleles from one generation to the next as an alternative measure that pics up both the number and distribution of crossovers. The aim of this study was to compare our previous results of variation in recombination rates within and between five domestic pig breeds with measures of intrachromosomal genetic shuffling and investigate whether there is variation between sex and breeds.

Materials & methods

Data. This study focused on five purebred commercial breeding populations with pedigree and genotype data: two sow breeds, Landrace (LR) and Large White (LW); and three boar breeds, Duroc (DU), Synthetic (SY) and Pietrain (PI). The genotype data and filtering are described in detail in Brekke *et al.* (2022).

Linkage mapping and crossover detection. Detailed description of linkage mapping, gamete phasing, crossover detection and fine scale recombination mapping can be found in Brekke *et al.* (2022).

Genetic shuffling within individuals. Genetic shuffling was calculated as the probability that a randomly chosen pair of loci was shuffled during gamete production following the method suggested by Veller *et al.*

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_194, © C. Brekke *et al.* 2022

(2019). We defined the parameter $\bar{r}$ as the probability of two alleles on a chromosome being shuffled due to recombination, i.e. excluding the part due to independent assortment in Equation 4 in Veller *et al.* (2019):

$$\mathbb{E}[\bar{r}] = \sum_{k=1}^{n} 2p_k(1-p_k)\,L_k^2$$

where k is the chromosome number (1-18), p is the proportion of grandpaternal alleles, $1\text{-}p$ is the proportion of grandmaternal alleles and L is the length of the chromosome as a fraction of the total length of the genome. For each phased gamete transmitted from a mother or father to an offspring, shuffling was calculated following Equation 1 and assigned as an observation to the parent, resulting in multiple observations for the phenotype 'genetic shuffling', hereafter referred to as $\bar{r}$, for each parent (hereafter focal individual, or FID).

Genetic variation. We estimated variance components for individual $\bar{r}$ with a repeatability model using the restricted maximum likelihood (REML) method and average information (AI) algorithm in DMU v 6 (Madsen *et al.*, 2014). The following model was used:

$$\bar{r} = id1 + id2 + e$$

where id1 is the random additive genetic effect of the FID, id2 is the random effect of the FID permanent environment (i.e. individual and/or environmental effects affecting all gametes from an FID) and e is the residual effect. The narrow-sense heritability (h^2) was defined as the proportion of phenotypic variance explained by the additive genetic effect and was estimated separately for each breed and sex.

Results

Mean $\bar{r}$ is significantly higher in males than in females in the LR (P=3.12e^{-105}), DU (P=2.51e^{-85}), PI (P=3.70e^{-72}) and SY (P=2.38e^{-53}) breed. In the LW line $\bar{r}$ is only slightly, but significantly (P=1.40e^{-21}) higher in females. Means and distribution are plotted in Figure 1. Intrachromosomal shuffling is a heritable trait in females in all breeds, but only in the LR breed in males. These results are presented in Table 1.

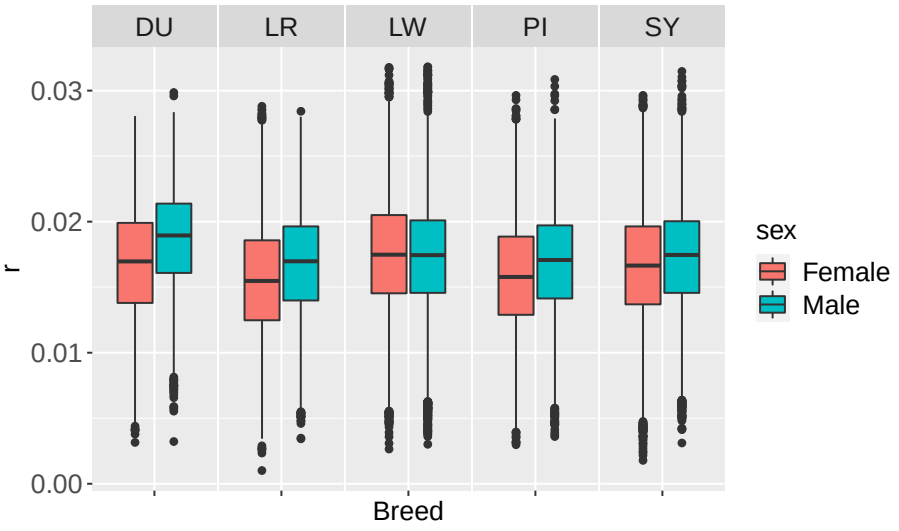

Figure 1. Sex difference in mean and distribution of shuffling.

Table 1. Results from variance component estimation of $\bar{r}$.

Breed	Sex	Mean(SD)	h^2(SE)	No obs[1]	No ind[2]

(B) Example of crossover positions and the resulting number of pairs of loci shuffled (modified from Veller *et al.* (2019)).

Discussion

Our results show that the probability of shuffling between two loci on the same chromosomes is low relative to the shuffling of alleles at different chromosomes (average of 0.5 due to Mendelian segregation), but also that the intra-chromosomal shuffling differs between breeds and sexes and is a heritable trait in the domestic pig. Genome wide recombination rates in these pig breeds are higher in females than in males, and rates tend to be elevated in the telomeric regions in both sexes (Brekke *et al.* 2022). In some chromosomes this pattern is more extreme in females, i.e. recombination rates are higher than males in the telomeric regions, but lower than in males closer to the centromere (e.g. as in Figure 2a). This could explain why $\bar{r}$ is lower in females despite higher genome wide recombination rates. Figure 2b illustrates why a central crossover leads to more shuffling and why the position of the crossover may have a higher impact on the probability of shuffling between two loci than the number of crossovers. It is however puzzling that one of the breeds show the opposite sex difference in $\bar{r}$ (Figure 1). This breed (LW) is the breed with the highest genome-wide recombination rate (Brekke *et al.* 2022). More evenly spread crossovers lead to more shuffling (Figure 2b).

Differences in genetic shuffling can thus also be caused by differences in crossover interference between the breeds, explaining part of the difference in $\bar{r}$. Our results show that even if overall levels of sex-differences in recombination is the same in closely related populations, the shuffling might be different, potentially because of rapidly evolving hotspot usage (Paigen and Petkov, 2010; Weng *et al.*, 2014, 2019). It is not clear, however, how the difference between the sex is maintained in a population from generation to generation as each offspring receives a paternal and maternal gamete. Even if a different number of unique sires and dams mated in each generation, the number of maternal and paternal gametes in each generation is always exactly the same. A next step could be to look at differences in recombination and genetic reshuffling between X and Y paternal gametes. The population level shuffling might be more influenced by variation in $\bar{r}$ within the sex, and in males in particular in pigs as the selection pressure is higher. In conclusion this study shows that variation in crossover distribution affects the production of novel haplotypes from one generation to the next and that there is variation in the shuffling caused by recombination between breeds, sex and individuals in the domestic pig.

195. Identification of runs of homozygosity islands and functional analysis for Caqueteño Creole cattle

A.M. Toro-Ospina[1*], J.A.II.V. Silva[2,4], G.P. Schettini[3], V.H. Vallejo[1] and E.G. Ortiz[1]

[1]Universidad de la Amazonia, Sede Porvenir Calle 17 Diagonal 17 con Carrera 3F, 180001, Florencia Caqueta, Colombia; [2]School of Veterinary Medicine and Animal Science, Unesp, 18618-307 Botucatu, SP, Brazil; [3]Virginia Polytechnic Institute and State University 24061, Blacksburg, Virginia, USA; [4]National Council for Scientific and Technological Development, CNPq, Brasília, 71605-001, Brazil; toroospina92@gmail.com

Abstract

The study aimed to identify genomic regions of ROH hotspots/islands and genes of interest in Colombian Creole cattle. The Caqueteño Creole population used belongs to the University of Amazonia, Caquetá, Colombia. The dataset consisted of the genotypes of 127 animals genotyped with the Bovine HD 777,000 SNPs chip. The ROH islands were measured by the PLINK 1.9 program. Since genomic regions with the highest frequency of ROH occurrence are called hotspots. The present study identified ROH hotspots in BTA3, BTA5, BTA6, BTA8, BTA16, and BTA20 chromosomes. The identified genes associated with fertility, reproduction, muscular development, environmental resistance, and immunity traits suggest a natural selection effect on Caqueta creole breed over the years. Notwithstanding, more research needs to be carried out on the Caqueteño Creole breed to identify the specialized production traits of the population.

Introduction

The diversity and genetic adaptation of *Bos taurus* and *Bos indicus* subspecies in the American continent provided changes in their genomes, forming new breeds. Colombia is, in Latin America, one of the countries with more creole breeds adapted to humid tropics performing rusticity and good reproductive features (Bejarano *et al.*, 2012). Originated in the Caquetá department (Colombia), the Caqueteño creole is a breed adapted to tropical conditions. Nowadays, this breed has a low specimen number, and it has been a poorly studied, which becomes it essential to preserve this valued genetic resource for native Colombian breeds. With the advancement of genomics applied to cattle, it was possible to carry out genomic studies with high-density SNP chips among several breeds. Also, this tool made it feasible to perform studies in native breeds without any knowledge *a priori* about the population structure or information at the genome level (McKay *et al.*, 2008). Runs of homozygosity (ROH) have been used extensively in livestock to characterize their population structure and demographic history (Mastrangelo *et al.*, 2018). Furthermore, the ROH analysis can assist in identifying regions associated with economically important traits. Homozygous regions are desirables since they can contribute to breed conservation and recovery. Therefore, the study aimed to identify genomic regions of ROH hotspots/islands and genes of interest in Colombian Creole cattle.

Materials & methods

The Caqueteño Creole population assessed in this study comprises a little herd from three farms in the Caquetá department (Colombia), and a Creole population belonged to the University of Amazonia, Colombia. A total of 127 animals genotyped with the HD Bovine 777,000 SNPs chip (Illumina, San Diego, CA) composed the present study dataset. Through a quality control carried out by the PLINK 1.9 program, the genotypes were filtered with MAF<0.01, a call rate for SNPs <0.90, and a call rate for samples <0.98.

ROH hotspot. The ROH islands were calculated via PLINK 1.9 program (Purcell *et al.*, 2007) using the command *--homozyg-group--*. After, ROH hotspot/island segments with a higher frequency in shared regions were identified in the population. Also, the linkage disequilibrium average was estimated. Genes and orthologs that were settled within the standard limits were pointed out through the *BiomaRt* package in the R-environment.

Results

The genomic regions with the highest frequency of ROH occurrence are called hotspots. In this sense, we identified six genomic regions located on the BTA3 (29615176-98903642), BTA5 (62276336 -87155753), BTA6 (38632996-116998306), BTA8 (65897661-105645859), BTA16 (43074568-454221344) and BTA22 (674568-45422124) with one ROH hotspot in each chromosome. In addition, on the BTA 20, we got four ROH hotspots (20114020-63708551, 38347984-40037991, 12658291-51430813, 10769304-63708551) (Figure 1).

Discussion

The genomic regions with the highest frequency of ROH islands identified in the Caqueteño Creole population (Figure 1) suggest a relationship with genes associated with important economic traits. Identified in BTA3, the PHTF1 gene was associated with the fertility index in Holstein cattle (Mesbah-Uddin *et al.*, 2021). The ROH region in the BTA6, the NUP54 gene was associated with body fat deposition, and muscle development (Nolte *et al.*, 2019). According to these genes, it is possible to suggest the Creole Caqueteño has some important features which are supported by their phenotypic performance, precocity, and fertility rates (Celis Parra, Chinguad Taramuel and Garcia Bustos, 2020).

The TUT7 gene located in BTA8 was responsible to regulate the response of the immune cells, meanwhile, the PEX14 and CORT genes located in BTA16 were related to environmental adaptation and stress response (Singh *et al.*, 2020). These traits have valuable importance for cattle breeds to resist environmental changes. Some identified genes are in concordance with Colombian breed traits, such as rusticity and adaptability to tropical regions. The SPEF2 and PRLR putative genes, highlighted in BTA20, were associated with an important effect on cattle coat length, related to SLICK phenotype, as well as being linked to cattle thermal regulation in tropical climates (Huson *et al.*, 2014). Single nucleotide variants have the potential to assist, through genomic selection, to obtain shorter coat animals, which will lead to better thermotolerance and, consequently, higher production levels in hot and humid climates.

The identified genes associated with fertility, reproduction, muscular development, climate resistance, and immunity traits, lead us to suggest that it could be present in the Caqueta creole breed provided by the natural selection over the years. It should be noted that it is the first study that includes genomic information to understand the selection and history of the Caqueteño Creole population. Thus, these results suggest potential genes associated with immunity, adaptation, and fertility traits that could be manifested in the

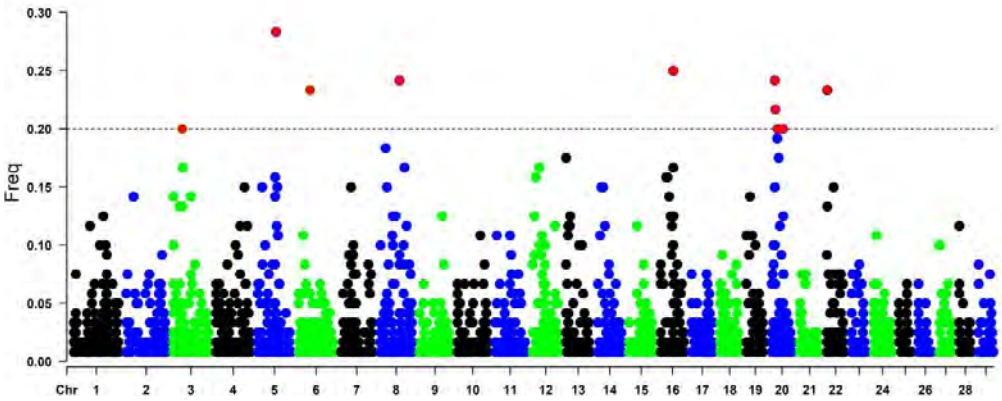

Figure 1. Manhattan plot of the distribution of ROH islands in population Creole Caqueteño cattle.

population. However, more research needs to be carried out on the Creole Caqueteño breed and native breeds in tropical countries, since livestock faces daily challenges, such as those associated with global climate changes that affect animal production.

196. Candidate genes related to signatures of selection for body weight and harvest length in American mink

D.N. Do*, K. Karimi, G. Hu and Y. Miar

Department of Animal Science and Aquaculture, Dalhousie University, Truro, NS B2N 5E3, Canada; duy.do@dal.ca

Abstract

Mink is a major animal used in the fur industry worldwide, and growth is an economically important trait for mink farmers. Mink farmers select animals with better growth traits, such as longer body length (pelt size), but little is known about the genetic mechanisms underlying growth traits in mink. This study examined the signatures of selection for body weight (BW) and body length (BL) in mink using whole-genome sequence data. We identified several genes, such as *PHF3* and *EYS* that may influence variation in BW and BL in overlapping extremes of fixation index and nucleotide diversity results. Enrichment of positional candidate genes indicated that genes involved in lipid metabolism, hormone secretion, and IL-17 signaling pathways might be related to the selection of these traits. This study provides a better understanding of the genetic background of BW and BL variations in mink.

Introduction

Growth is an economically important trait for farm animals, and better knowledge of animal growth is necessary for optimized management and feeding practices. Artificial selection leads to better growth performance in farm animal species. Exploring the genetic mechanisms underlying domestication and phenotypic variation using signatures of selection has been performed in various species using different statistics (reviewed in Saravanan *et al.*, 2020). Mink is a major animal used in the fur industry worldwide. Body weight (BW) and length (BL) are correlated traits and important for mink farmers as they are related to the pelt price. Generally, mink farmers select their animals with better reproductive performance, growth (longer BL), and fur quality. This selection has increased the body length of mink and led to better reproductive performance. However, little is known about the genetic mechanisms underlying the selection of growth traits in mink. The first study for selection signatures in American mink was performed for Aleutian disease by Karimi *et al.* (2021a), which detected 63 genes associated with the mink's response to the disease infection. Identified genetic markers involving selection signature of BL and BW could be used for genetic or genomic selection; therefore, this study examined the potential genes or markers for the signature of selection of the traits in American mink raised in Canada.

Materials & methods

Animals and samplings. The studied animals were raised under standard farming conditions in two farms (the Canadian Center for Fur Animal Research (CCFAR) at Dalhousie Faculty of Agriculture (Truro, NS, Canada) and Millbank Fur Farm (Rockwood, ON, Canada)). Details of 100 animals used for the whole genome sequencing in this study has been given in Karimi *et al.* (2021b). Mink were fed *ad libitum* with the commercial feed and their BW and BL were measured at the harvesting time in December 2018. Tongue samples were collected after humanly euthanization for DNA isolation.

Whole genome sequencing and variant calling. Genomic DNA was extracted from tongue tissues using DNeasy Blood and Tissue Kit (Qiagen, Hilden, Germany) following the manufacture protocol. DNA samples were then sequenced (100 bp pair-end reads) using the BGISEQ-500 platform at Beijing Genomics Institute (BGI, Guangdong, China). After sequencing, SOAPnuke software was used to remove adapters and low-quality reads. Then, high-quality reads were aligned against the last American

R.F. Veerkamp and Y. de Haas (eds)

mink reference genome (https://www.ncbi.nlm.nih.gov/assembly/GCF_020171115.1/) using Burrows-Wheeler Aligner (BWA) 0.7.17 with default options. The aligned files were converted to binary alignment map (BAM) format and sorted using SAMtools 1.11. Potential PCR duplicates were removed using the MarkDuplicates command tool of Picard (http://broadinstitute.github.io/picard/). The BAM files were then indexed by SAMtools software. Variant calling was performed with two pipelines of (1) 'mpileup' module of SAMtools/BCFtools and (2) Haplotype caller using Genome Analysis Toolkit 4.1.9.0 (GATK) pipeline (https://gatk.broadinstitute.org/). To increase the accuracy of SNP calling, the overlapping SNPs between two conducted SNP calling pipelines were extracted. Then the final SNPs obtained by GATK pipeline were filtered using the following criteria: phred-scaled quality score <80.0, quality by depth <2.0, phred scaled *P*>60.0, mapping quality <40.0, strand odds ratio >4.0, mapping quality rank sum test <-12.5, read position rank-sum test <-8.0, minor allele frequency (MAF) >0.05, call rate <0.9, and Hardy-Weinberg Equilibrium with *P*<0.000001. Moreover, only biallelic and autosomal SNPs were kept for further analyses. After quality control, a total number of 9,758,965 SNPs from 100 animals was remained for signatures of selection analyses.

Detection of signature selection. The top 20 mink (10 males and 10 females each) with the highest and lowest values of BW and BL were selected for the signature of selection analyses. Fixation index (F_{ST}) and nucleotide diversity ($\theta\pi$) were used to detect selection signatures for BW and BL. Both $\theta\pi$ and F_{ST} values were calculated using vcftools 0.1.16 in a window size of 100 kb with a step size of 25 kb. To normalize the F_{ST} values, Z-transformation was performed using the scale function in the R program, and genomic windows harboring the top 5% Z-transformed F_{ST} values ($Z(F_{ST})$) were identified. The $\theta\pi$ ratios were computed as $\theta\pi$ high BW or BL divided by $\theta\pi$ low BW or BL. The $\theta\pi$ ratios were then log-transformed. The overlapped windows harboring the top 5% values from both methods were considered as significant windows for the traits. The most recent American mink genome assembly and bedtools 2.30.0 software were used for gene annotation. To identify the biological pathways enriched in the candidate gene lists, gene enrichment analysis was performed using clusterProfiler R package for Gene ontology and Kyoto Encyclopedia of Genes and Genomes (KEGG) terms. Overrepresented annotated genes were identified by Fisher's exact test, considering the *P*<0.05 as the threshold.

Results & discussion

The largest numbers of significant SNPs for both traits, regardless of methods, were located on chromosome 1 (Figure 1a and b). Notably, chromosome 1 was the longest chromosome in the mink genome. A total of 1,058 and 1,691 overlapping windows between the top 5% of F_{ST} and $\theta\pi$ was detected for BW and BL, respectively (Figure 1c). A similar ratio (around 20%) of overlapping windows between F_{ST} and $\theta\pi$ was also reported by Salek *et al.* (2020) when they analyzed the signature of selection for pony and light horse types. A total of 411 windows were involved in the selection for both BW and BL (Figure 1c), which might be due to the fact that the two traits had a high genetic correlation of 0.78 (Do *et al.*, 2021); therefore, sharing common genetic mechanisms.

The $Z(F_{ST})$ of these overlapping windows ranked from 1.92 to 10.24 for BW and 1.79 to 17.36 for BL, respectively. The windows with $Z(F_{ST})$ >7 with the positional candidate genes for BW were listed in Table 1. A novel gene *LOC122901584* was the only gene located in the window with the highest $Z(F_{ST})$ value at 172.73 MB on chromosome 2. Some other positional candidate genes for BW included *PHF3, EYS, TRNAK-CUU, TFAP2D,* and *TFAP2B* on Chromosome 1, *CCDC7* on Chromosome 12, or *USP3, FBXL22,* and *HERC1* on chromosome 13. For BL, the most significant region was centered at 105.88 Mb on chromosome 1, where *PHF3, EYS,* and *TRNAK-CUU* were considered as the positional candidate genes. Multiple windows with $Z(F_{ST})$ >7 and candidate genes were found around the regions of 105.88 Mb on chromosome 1. Another important window region for BL was at 74.88 Mb on chromosome 10 since several windows with $Z(F_{ST})$ >7

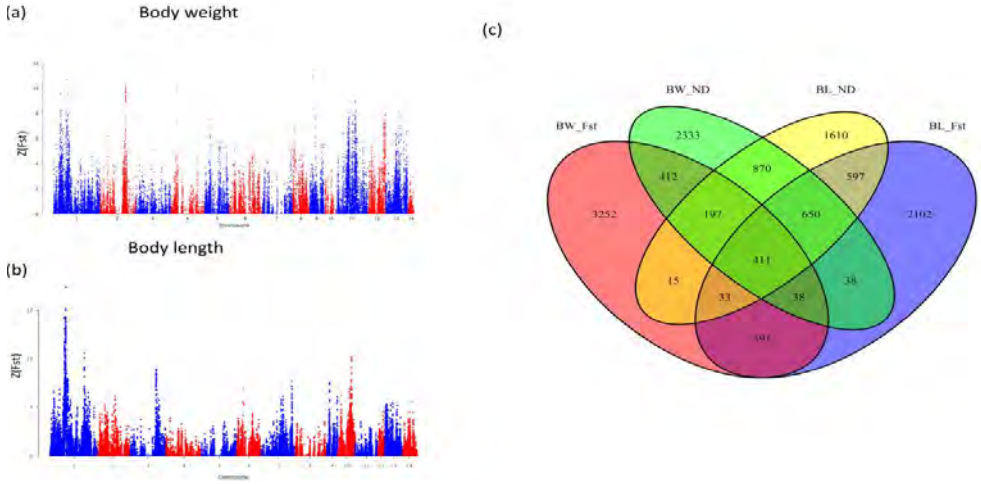

Figure 1. Manhattan plot of $Z(F_{ST})$ values for (a) BW and (b) BL, and (c) Venn diagram of overlapping windows. BW_Fst, BL_Fst, BW_ND and BL_ND were the top windows for BW and BL based on the $Z(F_{ST})$ and θπ ratios, respectively.

Table 1. The top windows based on $Z(F_{ST})$ for body weight.

Chromosome	Start (Mb)	End (Mb)	$Z(F_{ST})$	Log(θπ ratios)	Genes
2	172.73	172.83	10.24	1.71	*LOC122901584*
1	105.88	105.98	7.99	1.16	*PHF3, EYS,* and *TRNAK-CUU*
1	96.93	97.03	7.90	0.46	*TFAP2D* and *TFAP2B*
12	116.93	117.03	7.90	0.51	*CCDC7*
1	46.75	46.85	7.83	0.40	*LOC122905089*
13	105.25	105.35	7.80	1.38	*USP3, FBXL22,* and *HERC1*
2	170.35	170.45	7.67	4.31	*LOC122899239*
1	89.6	89.7	7.44	0.80	*PTK7, SRF,* and *CUL9*
12	107.3	107.4	7.15	0.39	*LOC122892061*
12	117.08	117.18	7.12	0.47	*LOC122891753*
1	89.55	89.65	7.02	0.88	*KLHDC3, CUL7, MRPL2, KLC4,* and *DNPH1*

were located in this region. *RASSF5, EIF2D, IKBKE, LAX1,* and *ZC3H11A* were potential candidate genes for BL in this region.

The functional enrichment analyses showed ubiquitin-like protein transferase activity, motor activity, and epidermal growth factor receptor binding were the three most significant GO terms enriched for BW. The protein phosphatase regulator activity, Rac GTPase binding, and rRNA methyltransferase activity were the three most significant GO terms enriched for BL. A total of 27 and 17 KEGGs pathways were significantly ($P<0.05$) enriched for candidate genes of BW and BL, respectively. Sphingolipid and IL-17 signaling pathways were among the two of the three most significant KEGG pathways enriched for both BW and BL. Some other significant enriched pathways included Parathyroid hormone synthesis, secretion and action, Wnt signaling pathway or Cytokine-cytokine receptor interaction for BW and ABC transporters, Thyroid hormone signaling pathway, and Glycerophospholipid metabolism for BL, respectively.

Although more than hundreds of genes were annotated as potential candidate genes for these traits, many genes such as *LOC122901584*, *LOC122905089,* and *LOC122899239* (Table 1) were novel genes with no known functions in mink. The functions of these genes were inferred based on the information from human studies. *PHF3* and *EYS* might involve the selection signatures for both BW and BL as they were located in the window associated with both traits. *PHF3* might function as a transcription factor, while *EYS* was known for its roles in retinal degeneration. There are no functional studies of these genes in mink so far. The functional enrichment indicated that BW candidate genes are involved in growth factor binding, which is one of the important functions of growth development. The involvement of BW candidate genes was also supported by the results of KEGG pathways enrichment. The enriched pathways, including Sphingolipid signaling pathway or Parathyroid hormone synthesis, secretion, and action pathway, were involved in lipid metabolism or hormone secretion – the important processes for regulating body weight. Interestingly, the IL-17 signaling pathway was enriched for both candidate genes of BW and BL. The IL-17 genes family is primarily involved in the host defense mechanisms against infection of bacteria, fungi, and helminth (Chung *et al.*, 2021); therefore, the enrichment results of the IL-17 signaling pathway might reflect the selection of higher BW or longer BL might be related to the health status of animals.

197. Maintenance of genetic diversity in subdivided populations using different genomic coancestry matrices

E. Morales-González[1*], B. Villanueva[1], M.Á. Toro[2] and J. Fernández[1]

Abstract

The main objective in conservation programs of subdivided populations is to maximize the global genetic diversity while restricting the levels of inbreeding within subpopulations. This can be achieved using the Optimal Contribution method that originally relied on pedigree-based coancestries. However, marker-based coancestries could lead to a more efficient management although different marker-based measures can have different effects on the diversity maintained. In this simulation study, we evaluated the potential benefit of using different marker-based genomic coancestry matrices in terms of global genetic diversity and its distribution within- and between-subpopulations. Our results show that using the genomic matrix describing the excess in the observed number of alleles shared by two individuals relative to the expected number under Hardy–Weinberg equilibrium could be the best option for managing subdivided populations as it maintains more global diversity and leads to less inbreeding within subpopulations.

Introduction

Most populations of endangered species or breeds within species are subdivided into different separated breeding groups. This fragmentation implies a reduced census in each subpopulation that leads to strong genetic drift and, thus, to fast increases in inbreeding and decreases in local genetic variability.

The consensus method to maintain genetic variability is the Optimal Contribution (OC) method that was extended by Fernández *et al.* (2008) to optimally manage subdivided populations. Their method determines the optimal number of offspring (contribution) of each individual to the next generation to maximize the global genetic diversity while balancing the relative levels of coancestry between and within subpopulations (and therefore the levels of inbreeding within subpopulations) and optimizes migration between subpopulations. As originally proposed, the method of Fernández *et al.* (2008) used pedigree-based coancestries. However, in undivided populations, it has been shown that the use of marker-based genomic coancestries leads to a more efficient maintenance of genetic diversity (e.g. Gómez-Romano *et al.* 2013) although different genomic coancestry matrices may lead to different levels of genetic variability (Meuwissen *et al.* 2020; Morales-González *et al.* 2021).

The objective of this study was to evaluate, via stochastic simulations, the global levels of genetic diversity maintained, its distribution within- and between-subpopulations and the migration flow between subpopulations when using different genomic coancestry matrices in the OC method for managing subdivided populations.

Materials & methods

The genome was composed of 20 chromosomes of 1 Morgan each. Two types of biallelic loci (500,000 SNPs and 500,000 'unobserved loci' per chromosome) were simulated. SNP loci were used for computing the genomic coancestry matrices involved in the management and the unobserved loci were used for calculating the different parameters evaluated. The conservation program started from a base population (t=0) made up of 100 individuals, which was created in three steps. Firstly, a population at mutation-drift equilibrium was generated by simulating 10,000 discrete generations of random mating for a population

of n=100 as described in Morales-González *et al.* (2021). Secondly, the population was expanded in order to have enough individuals for sampling 100 replicates (n=25,600). Then, five panmictic generations were performed with a small group of individuals (10 ♂ and 10 ♀) isolated from the rest of the population (40 ♂ and 40 ♀). Afterwards, the large group was randomly divided into four groups of 10 ♂ and 10 ♀ each. Thus, at the beginning of the management (t=0), one of the subpopulations was genetically differentiated and more inbred than the others. At t=0, the average number of SNPs and unobserved loci still segregating was 48,519 and 48,376, respectively. Management was performed during 10 discrete generations following the OC method of Fernández *et al.* (2008) that maximizes the global genetic diversity but balancing the relative importance of within-subpopulation coancestry by a factor λ. Values of λ tested were 1 and 5. A restriction on the maximum number of migrants between subpopulations (M=5) was also included. The method was implemented using the pedigree-based coancestry matrix (Θ_P) and two matrices based on genomic information (i.e. on SNPs segregating at t=0): the matrix describing the excess in the observed number of alleles shared by two individuals relative to the expected number under Hardy-Weinberg equilibrium (Li and Horvitz 1953), Θ_L, and the genomic relationship matrix obtained using method 2 described in VanRaden (2008), Θ_V. Base population frequencies were used to compute both matrices. Mating was at random within subpopulations.

Management scenarios were compared in terms of the genetic variability retained in the global population and its distribution between and within subpopulations. The amount of genetic variability retained in the global population was measured as the expected heterozygosity (H_T). The genetic variability within subpopulations was measured as the average expected heterozygosity across subpopulations (H_S) and the genetic variability between subpopulations was calculated as $D = H_T - H_S$ (also referred to as the average distance between subpopulations). Given that matings within subpopulations were random, the average molecular inbreeding for subpopulation i was $F_{Si} = 1 - H_{Si}$, where H_{Si} is the expected heterozygosity for that subpopulation. Additionally, scenarios were compared in terms of the particular flow of offspring from and to subpopulation 1 (i.e. the number of migrants involving this particular subpopulation). Results presented for all parameters are averages across the 100 replicates.

Results

Table 1 shows a decrease in H_T across the 10 generations when the management was based on Θ_P or Θ_V for both values of λ, while H_T increased when using Θ_L for λ=1. This increase in H_T with Θ_L was accompanied by a higher reduction in H_S and a higher increase in D. However, for λ=5 (i.e. giving a higher weight to within-subpopulations variability), management using Θ_L was able to keep higher levels of diversity both in the global population (H_T) and within subpopulations (H_S) than when using Θ_P or Θ_V.

As expected, inbreeding was practically the same for subpopulations 2 through 5 and it was lower for λ=5 than for λ=1 (Table 2). For λ=1, the lowest levels of F_{S1} and $F_{S2\text{-}5}$ were obtained when using Θ_P and the highest levels were obtained when using Θ_L (the matrix giving the lowest H_S).

For λ=1, on average, each subpopulation sent 1 individual and received 1 individual from other subpopulation across generations (results not shown). However, for λ=5 (Figure 1), whatever the matrix used in OC (Θ_P, Θ_L or Θ_V), subpopulation 1 sent ~1 migrant and received 3-4 migrants at t=0 and, as the generations go by, the number of migrants received decreased (1 migrant after 4-5 generations). This is a reflection of λ=5 implying a higher pressure to increase the originally lower levels of diversity in subpopulation 1 compared to other subpopulations. In fact, due to the differential migration between subpopulations, Fs_1 decreased from t=0 to t=10 until it reached a value close to $Fs_{2\text{-}5}$ (Table 2).

Table 1. Expected heterozygosity in the global population (H_T), average expected heterozygosity in subpopulations (H_S) and distance between subpopulations (D) across generations (t) when contributions were optimized using pedigree-based (Θ_P), Li and Horvitz (Θ_L) and VanRaden (Θ_V) coancestry matrices.[1]

Discussion

The highest global genetic diversity maintained was obtained when using Θ_L. This result was also observed when dealing with undivided populations (Meuwissen *et al.* 2020; Morales-González *et al.* 2021). However, when giving the same weight to between- and within-subpopulation coancestry (λ=1), the higher global diversity obtained with Θ_L was at the cost of an increase in the genetic distance between subpopulations (D) and an increase in local inbreeding (lower H_S). This agrees with theory that predicts that the maximum global genetic diversity is achieved when the population is composed by many isolated inbred subpopulations (i.e. low local genetic diversity). However, when giving more weight to the within-subpopulation coancestry (λ=5), the use of Θ_L in OC not only led to higher global genetic diversity, but also to lower local inbreeding than the use of Θ_P or Θ_V. As expected, for all matrices lower levels of inbreeding were achieved for λ=5 than for λ=1, mainly due to the increase of migrants sent to subpopulation 1. This shows the ability of the methodology to detect the differences in genetic diversity between subpopulations and correct them by optimising the contributions and the migration flow. Allowing a higher number of migrants would probably lead to low inbreeding values in fewer generations. However, this is not a realistic scenario due to the cost and risk of moving animals between subpopulations.

In conclusion, it seems that Θ_L could be the best option for managing subdivided populations as it maintains more global diversity and leads to less inbreeding.

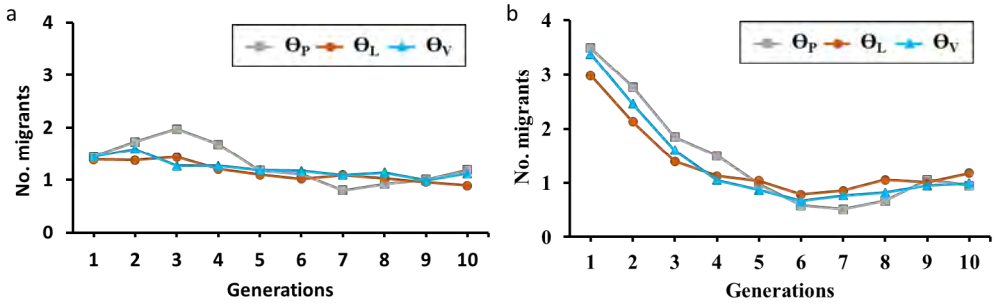

Figure 1. Number of individuals sent (a) and received (b) by subpopulation 1 across generations when contributions were optimized using pedigree-based (Θ_P), Li and Horvitz (Θ_L) and VanRaden (Θ_V) coancestry matrices for λ=5.

Abstract

The infinitesimal model assumes that polygenic traits are influenced by (infinitely) many quantitative trait loci with (infinitely) small effects and that selection on such traits has minimal impact on the frequency of alleles at individual loci, hence minimal impact on genetic variance. Here we evaluated trends in genetic mean and genic variance for milk yield over 25 years in 9,403 proven and genotyped bulls from the Canadian Dairy Network. The results showed significant change in genetic mean and minor change in genic variance, supporting the infinitesimal model. A detailed analysis of SNP marker allele frequencies indicated sizeable changes at individual loci. We grouped the SNP markers by their initial allele frequency and direction of change, to indicate how these groups of makers contribute to changes in mean and variance in the analysed period of 25 years and predictions for the next 75 years showing sizeable changes in mean and variance.

Introduction

Animal breeding programmes focus on additive genetic values that represent the sum of allele substitution effects over all quantitative trait loci for the trait of interest. Much of the theory and estimation of additive genetic values is based on the infinitesimal model. The infinitesimal model assumes that polygenic traits are influenced by (infinitely) many quantitative trait loci with (infinitely) small effects (Fisher, 1918). Consequently, this model implies that selection on polygenic traits has (infinitely) small impact on allele frequency changes at individual loci (Fisher, 1918). Despite the (infinitely) small impact on allele frequency changes, selection can have a significant cumulative change across all loci, as manifested by breeding programmes.

Since the infinitesimal model predicts (infinitely) small allele frequency changes under selection, this implies (infinitely) small short-term changes in genetic variance. This prediction is in line with observations that response to selection in most breeding programmes are not levelling off (e.g. Hill, 2016). There are reports that recent introduction of genomic selection has sped up the rate of change in genetic mean and variance (Jannink, 2010; Hidalgo *et al.*, 2020; Wientjes *et al.*, 2021), which could also be due to the Bulmer effect, negative linkage-disequilibrium component of genetic variance (Bulmer, 1971; Lara *et al.*, 2021).

Abundant genome-wide marker data is enabling rapid genetic improvement via genomic selection, but also detailed dissection of underlying genome changes that drive the rapid genetic improvement. Compared to phenotypic selection, genomic selection is increasing the risk of losing favourable alleles (Jannink, 2010; Wientjes *et al.*, 2021), particularly for the rare alleles or those alleles that are in unfavourable linkage-disequilibrium with genomic selection markers. A systematic evaluation of the change in past and predicted future allele frequencies and their relation to genetic mean and variance is lacking and the aim of this contribution.

Materials & methods

Data. We used data from the routine milk yield genetic evaluation of the Canadian Dairy Network – Lactanet (Guelph, ON). The data comprised 9,403 proven bulls, born between 1989 and 2014. We retrieved

R.F. Veerkamp and Y. de Haas (eds)
CC BY

de-regressed estimated breeding values and associated reliabilities for the bulls. We also retrieved their single nucleotide polymorphism (SNP) marker genotypes. We retained 40,448 SNP markers from the autosomes having minor allele frequency above 0.05.

Estimation of marker effects. We estimated allele substitution effects of the SNP markers using the Bayesian ridge-regression model $y = Xb + M\alpha + e$, where y is a vector of de-regressed estimated breeding values for milk yield scaled to mean zero and unit variance, b is a vector of fixed effects (the intercept), α is a vector of allele substitution effects, e is a vector of residuals, X is an incidence matrix linking y with b, and M is a matrix of SNP marker genotypes. The model assumptions were $\boldsymbol{\alpha} \sim N(\mathbf{0}, \boldsymbol{I}\sigma_\alpha^2)$ and $\boldsymbol{e} \sim N(\mathbf{0}, \boldsymbol{W}\sigma_e^2)$, where W is a diagonal weight matrix with values equal to (1-Reliability$_i$)/Reliability$_i$ (for the i-th bull) adjusting heterogeneous residual variance in the de-regressed estimated breeding values.

We inferred the model parameters using the Gibbs sampler implemented in the JWAS package with default prior specifications (Cheng *et al.*, 2018). We obtained 100,000 samples from posterior distribution of allele substitution effects and saved every 100th sample. We also obtained posterior samples of breeding values (a) for the i-th sample using $a^i = M\alpha^i$.

We further obtained samples from posterior distribution of the mean of breeding values $\mu_{a,k}^i = E(\boldsymbol{a}_k^i)$ and variance of breeding values $\sigma_{a,k}^{2,i} = Var(\boldsymbol{a}_k^i)$ for each (k-th) year of birth. Summarising the $\mu_{a,k}^i$ and $\sigma_{a,k}^{2,i}$ samples and plotting the summaries against the year gives time trends in genetic mean and variance. Lara *et al.* (2021) showed that changes in genetic variance are driven by changes in genic variance (function of allele frequencies and allele substitution effects at the causal loci; $\sigma_{a,l}^2 = 2p_l(1-p_l)\alpha_l^2$ for the l-th locus and $\sum_{l=1}^{n_l} \sigma_{a,l}^2$ for all n_l loci) and in linkage-disequilibrium covariance (function of correlation between causal locus genotypes and their allele substitution effects). Here we focus only on genic variance. Preliminary analysis showed minor changes in genic variance in the period between 1989 and 2014, despite significant changes in genetic mean, corroborating the infinitesimal model. To further analyse these results, we analysed changes in allele frequencies of the SNP markers.

Estimation of allele frequency time trends. We calculated allele frequency of the SNP markers for each year of birth (1989 to 2014) and estimated their rate of change with beta regression (*betareg* R package; Cribari-Neto and Zeileis, 2010), independently for each SNP marker. We have then predicted change in allele frequency from the fitted beta regression model for each SNP marker for 100 years $\hat{p}_{l,k}$ for the k-th year), including the observed period (1989 to 2014).

To further analyse change in genetic mean and no apparent change in genic variance we have grouped the SNP markers according to the initial allele frequency (in year 1989) (above or below 0.5) and change in allele frequency (increasing or decreasing). The rational for this grouping is that following the $2p_l$ (1 – p_l) expression we expect that 'InitialAFAbove0.5IncreasingAF' markers will show decrease in genic variance, 'InitialAFBelow0.5IncreasingAF' markers will show increase in genic variance until frequency of 0.5, 'InitialAFAbove0.5DecreasingAF' markers will show increase in genic variance until frequency of 0.5, and 'InitialAFBelow0.5DecreasingAF' markers will show decrease in genic variance. For each of the groups we plotted predicted allele frequencies and showed their contribution to predicted genetic mean ($\hat{\mu}_{a,k} = \sum_{l=1}^{n_l} 2\hat{p}_{l,k}\hat{\alpha}_l$) and genic variance ($\left(\sum_{l=1}^{n_l} \hat{\sigma}_{a,l}^2\right)_k = \sum_{l=1}^{n_l} 2\hat{p}_{l,k}(1-\hat{p}_{l,k})\hat{\alpha}_l^2$), with $\hat{\alpha}_l$ being mean of the 1000 samples α_l^i.

Results

Figure 1 shows the predicted changes in allele frequency for the SNP markers over 100 years. The change of allele frequencies in each of the four groups of course match the grouping based on the estimated rate of

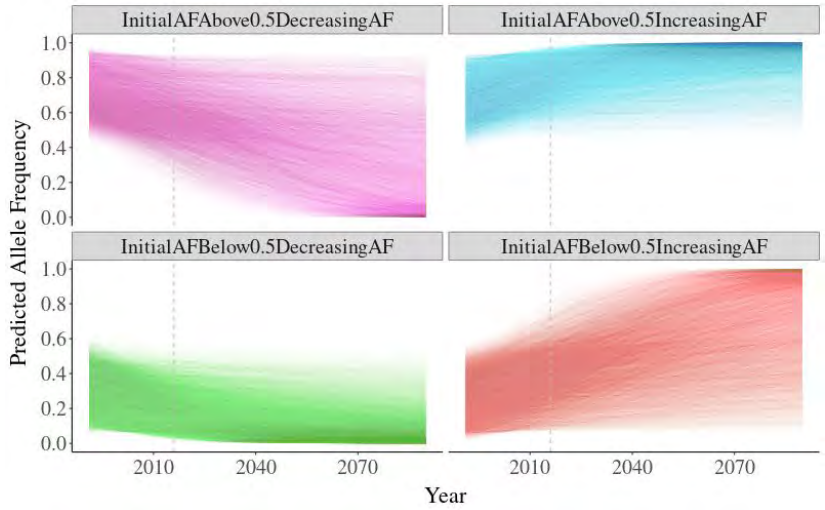

Figure 1. Predicted allele frequencies over 100 years for the four groups of SNP markers.

change, but there is considerable variation within each group. Some SNP markers are predicted to fixate, but many allele frequency changes are small.

Figure 2 shows the predicted genetic mean over 100 years and contribution of the four groups of SNP markers to the genetic mean. Genetic mean increased over the initial period and is predicted to increase in the future, above 6 genetic standard deviations of genetic gain. The largest contribution is from the 'InitialAFAbove0.5IncreasingAF' group, followed by the 'InitialAFBelow0.5IncreasingAF' group, with a considerably smaller contribution of the other two groups of SNP markers.

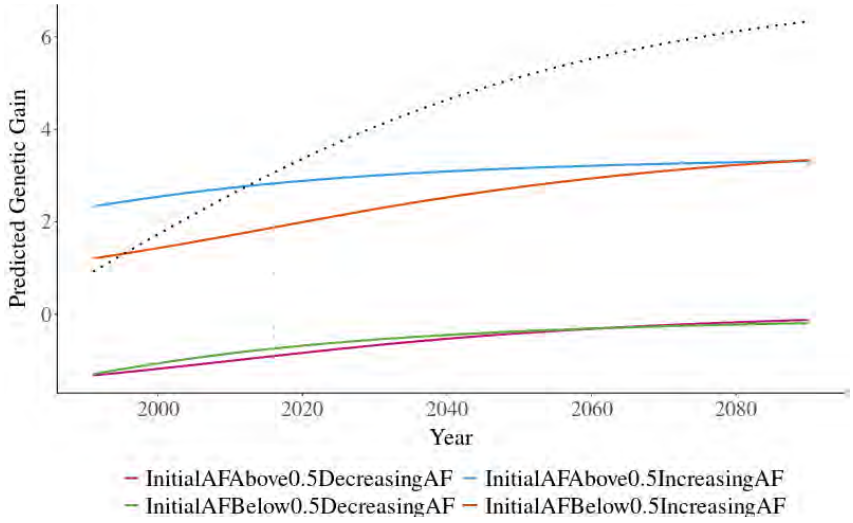

Figure 2. Predicted genetic mean over 100 years and contribution of the four groups of SNP markers to the genetic mean.

Figure 3 shows the predicted genic variance over 100 years and contribution of the four groups of SNP markers to the genic variance. Genic variance was almost constant during the initial period but is predicted to decrease for about a third in future. Contribution of the four groups varied over time, with relatively similar contributions in the initial period and the largest contribution of the 'InitialAFBelow0.5IncreasingAF' and 'InitialAFAbove0.5DecreasingAF' groups for most of the period, though these contributions decreased after some point. This result is in line with the expectation according to the $2p_i(1 - p_i)$ expression.

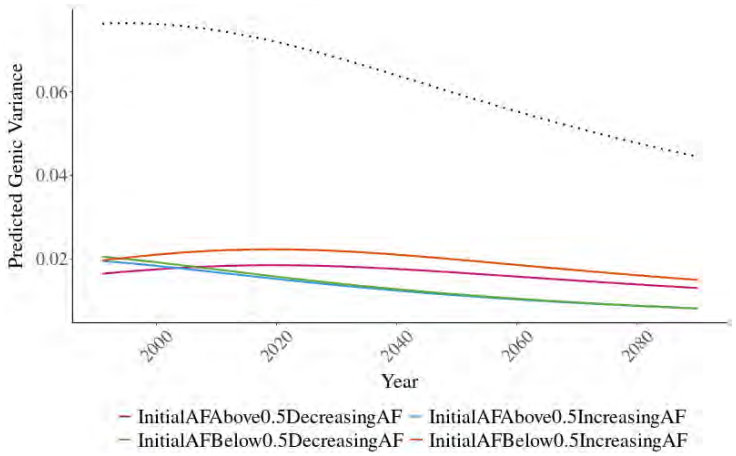

Figure 3. Predicted genic variance over 100 years and contribution of the four groups of SNP markers to the genic variance.

Discussion

We analysed change in genetic mean and variance over 25 years as well as underlying changes in SNP marker allele frequencies and predicted the trends in the same quantities for further 75 years. Results show that allele frequencies of the SNP markers changed sizeably during the analysed period of 25 years, and are predicted to change even more in the future, though arguably over a long period. The results suggests that there is considerable dynamics at individual loci that is not seen at the cumulative level. The results also give insights into the assumptions of the infinitesimal model and its predictions for changes in genic variance. The results also clearly showed different contribution of the four groups of SNP markers, both to genetic mean and genic variance. All these predictions assume that estimated rate of allele frequency changes in the initial period will hold in the future, that allele substitution effects will not change, hence that there are no non-additive genetic effects and that we have stable linkage-disequilibrium between the SNP markers and causal loci, and that there will be no mutations. These are clearly strong assumptions. The presented analysis nevertheless enables in-depth study of genetic changes in breeding populations.

Abstract

Allele frequencies change due to drift and selection. We investigated those changes for different selection methods. We simulated a livestock population with 50 generations of selection for an additive trait controlled by 2,000 segregating loci at the start of selection. Our results show that the average absolute change in allele frequency with genomic selection was slightly higher than with pedigree selection, and considerably higher than with mass selection. Genomic and pedigree selection both resulted in fixation of roughly three times more loci than mass selection, and roughly five times more loci became fixed for the unfavourable allele. While this was mainly a result of increased genetic drift, genomic selection also lost additional favourable alleles due to hitchhiking. This suggests that genomic selection can limit long-term genetic gain.

Introduction

Despite the sometimes strong selection pressure in animal breeding programs, genetic variation and rates of genetic gain have been stable for many generations in several animal populations (Beniwal *et al.*, 1992; Havenstein *et al.*, 2003). Therefore, these pedigree-based selection methods have proven to be sustainable so far.

Implementation of genomic selection has increased the rates of genetic gain in the short term. Moreover, it has likely accelerated the changes in allele frequencies across generations in certain regions on the genome (Heidaritabar *et al.*, 2014; Doekes *et al.*, 2018) and has increased the risk of losing rare favourable alleles (Jannink, 2010; Liu *et al.*, 2014). However, the long-term consequences of genomic selection are still largely unknown.

The current availability of genomic information has also opened up the possibility to investigate the changes in allele frequency as a result of selection, which is essential for understanding the long-term effects of selection. The vast majority of causal loci are, however, unknown. Therefore, our aim is to investigate and quantify the allele frequency changes at causal loci and how this is affected by selection methods using simulations.

Materials & methods

We simulated a livestock population under 50 generations of selection. First, we simulated a historical population in QMSim software (Sargolzaei and Schenkel, 2009) that showed a linkage disequilibrium pattern and allele frequency distribution comparable to livestock populations. Then we used our own developed Fortran program to generate the next 50 generations of selection. In every generation, the best 100 females and 100 males were selected and randomly mated using a mating ratio of 1:1 and a litter size of 10 (5 females and 5 males). Each scenario was replicated 20 times. For more details, see Wientjes *et al.* (2021).

Genome and phenotypes. The simulated genome had 10 chromosomes of 100 cM each. At the end of the historical population, 20,000 segregating loci with a uniform allele frequency distribution were selected as marker, and 2,000 segregating loci with a U-shaped allele frequency distribution were selected as causal

loci with an effect on the simulated trait. Moreover, 4,000 non-segregating loci were randomly selected as locations for causal mutations, which started to affect the trait when the locus was segregating after a mutation took place. The number of new mutations for each individual was sampled from a Poisson distribution, with an average of 0.6, which resulted in a mutational variance of ~$0.001\sigma_e^2$ per generation.

Phenotypes were simulated based on an additive model. For all causal loci and mutations, an additive effect was sampled from $N(0,1)$. The additive effects and genotypic information of causal loci were used to calculate the true breeding value for each individual. Finally, a non-genetic residual was added to the true breeding value, to obtain a heritability of 0.4.

Selection process. We compared five methods to select the parents of the next generation:

1. RANDOM, which randomly selected the animals.
2. MASS, which selected the animals with the best phenotypes.
3. PBLUP_OP, which selected the animals with the best pedigree based estimated breeding value, estimated including own performance information.
4. GBLUP_NoOP, which selected the animals with the best genomic estimated breeding value (GEBV), estimated excluding own performance information.
5. GBLUP_OP, which selected the animals with the best GEBV, estimated including own performance information.

With PBLUP, the last eight generations of pedigree and last three generations of phenotypes were used. With GBLUP, the last three generations of genotypes and phenotypes were used. Breeding values were estimated with the MTG2 software (Lee and van der Werf, 2016), using a model including a fixed mean, a random additive genetic effect and a residual.

Allele frequency changes and fixation of loci. We compared the average change in allele frequency and the number of loci that became fixed during the 50 generations of selection, requiring a minimal change in allele frequency of 0.2 to disregard loci that initially were already close to fixation. For the loci that became fixed, we investigated the average additive effect and starting allele frequency and whether the favourable alleles was fixed or lost.

To disentangle the impact of drift and selection, additional simulations were run with random selection using a population with the same effective population size (N_e) as in the selection scenarios. For each scenario, the N_e was estimated using the pedigree kinship coefficient based on the off-diagonal elements of the pedigree relationship matrix. Then we measured the effect of selection as the additional number of loci that became fixed in the selection scenarios compared to the drift scenario.

Results

All scenarios with selection resulted in an improvement of the phenotype over the 50 generations. This improvement was largest for GBLUP_OP and lowest for GBLUP_NoOP (Table 1). Both GBLUP methods lost ~82% of the genetic variance, which considerably reduced the rate of genetic gain across generations. The loss in genetic variance was considerably less with MASS (~60%). Therefore, the rate of genetic gain after 50 generations was highest for MASS. The average change in allele frequency was 2-3 times larger with selection than with RANDOM, and largest for the GBLUP scenarios, followed by PBLUP_OP and finally MASS. Compared to RANDOM (N_e=222), selection reduced N_e most for PBLUP_OP (46), followed by the GBLUP scenarios (74-82), and finally MASS (136).

Table 1. Change in average phenotype, genetic variance and allele frequency across 50 generations of selection[1].

	Phenotypic change[2]		Proportion of genetic variance lost		Average change in allele frequency		Effective population size	
RANDOM	0.02	(0.11)	0.03	(0.03)	0.023	(0.000)	222	(0.8)
MASS	27.31	(0.44)	0.60	(0.01)	0.054	(0.001)	136	(1.8)
PBLUP_OP	27.02	(0.46)	0.79	(0.01)	0.062	(0.000)	46	(0.9)
GBLUP_NoOP	25.25	(0.45)	0.82	(0.01)	0.063	(0.001)	74	(1.4)
GBLUP_OP	29.37	(0.42)	0.83	(0.00)	0.065	(0.001)	82	(1.5)

[1] Results are shown as averages across replicates with standard errors across replicates between brackets.

[2] Expressed in base generation additive genetic standard deviations.

With RANDOM, very few loci became fixed, and there was an equal chance of fixing or losing the favourable allele (Table 2). Selection resulted in fixation of a considerable number of loci, being similar for PBLUP_OP, GBLUP_NoOP and GBLUP_OP, which was ~2.7 times higher than with MASS. With selection, more loci became fixed for the favourable allele than for the unfavourable allele, which was more emphasized with MASS (~89%) than with the other selection scenarios (~80%).

With selection, the average additive effect of the loci where the favourable allele became fixed was larger than for an average locus (average α across all loci was 0.041), and was largest with MASS. The average starting allele frequency of those loci was lower with selection, and lowest for GBLUP_OP, GBLUP_NoOP and PBLUP_OP. In contrast, the loci where the unfavourable allele became fixed had on average a lower additive effect than an average locus (0.024 vs 0.041). Moreover, the average starting allele frequency at those loci was largest for GBLUP_OP, GBLUP_NoOP, PBLUP_OP, followed by MASS and lowest for RANDOM.

For all selection methods, more loci became fixed for the favourable allele due to selection than due to drift, while more loci became fixed for the unfavourable allele due to drift. Both GBLUP methods and PBLUP_OP fixed a similar number of loci, but the impact of selection on the fixation of loci was higher for the GBLUP methods. Moreover, with both GBLUP methods, an additional number of loci became fixed for the unfavourable allele as a result of selection.

Table 2. Characteristics of loci that became fixed over 50 generations of selection[1].

			Favourable allele			Unfavourable allele		
	Total nr.[2]	Prop. fav.[3]	Avg. α[4]	Start freq.[5]	Sel.[6]	Avg. α[4]	Start freq.[5]	Sel.[6]

[6] Proportion of loci segregating in generation 0 that became fixed due to selection.

Discussion

The loss in genetic variance was considerably larger with the BLUP methods than with MASS, and MASS had the highest rate of genetic gain in the last generations. Therefore, for the longer term, MASS is expected to outperform GBLUP_OP in terms of cumulative genetic gain. The BLUP methods also showed a faster change in allele frequency and a greater rate of fixation of favourable alleles than MASS, which can be explained by the higher accuracy of the BLUP methods (Liu *et al.*, 2014).

The N_e was lowest for PBLUP_OP, which is a result of more family selection with PBLUP compared to GBLUP (Liu *et al.*, 2014; Wientjes *et al.*, 2021). So even though the average change in allele frequency and total number of loci becoming fixed was similar for GBLUP and PBLUP_OP, this was more due to drift and less due to selection with PBLUP_OP (21% due to drift and 25% selection) than with GBLUP (15% due to drift and 31% due to selection).

With the two GBLUP scenarios, an additional number of unfavourable alleles became fixed over and above the effect of drift. This was surprising, since selection was expected to prevent loss of favourable alleles on top of the effect of drift. An additional loss of favourable alleles due to selection did not happen with MASS and PBLUP, indicating that GBLUP resulted in greater fixation of unfavourable alleles due to genetic hitchhiking (Smith and Haigh, 1974; Barton, 2000).

Overall, GBLUP resulted in slightly larger and faster changes in allele frequencies of causal loci than PBLUP, and much larger and faster changes than MASS. As a consequence, GBLUP lost more favourable alleles. Maintaining rare favourable alleles is especially important for long-term genetic gain (Jannink, 2010), suggesting that GBLUP can limit the long-term genetic gain and should be accompanied by a management of genetic diversity.

200. The effect of recombination rate on genomic selection in simulation

M. Johnsson[1*], A.M. Johansson[1], T. Klingström[1] and E. Rius-Vilarrasa[2*]

[1]Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; [2]Växa Sverige, P.O. Box 30204, 104 25 Stockholm, Sweden; martin.johnsson@slu.se

Abstract

Genome features such as recombination rate vary between different regions of the genome and affect the distribution of genetic variation, thus potentially affecting the response of the genome to selection and the accuracy of genomic selection. In this paper, we build a quantitative genetic simulation with variable recombination rate based on real linkage maps. It confirms that higher recombination rate causes a somewhat higher long-term genetic gain due to preservation of additive genetic variance, and that high recombination rate lowers the accuracy of genomic selection. While the benefit happens in the long term, the decreased accuracy is immediate.

Introduction

In this paper, we build a quantitative genetic simulation with variable recombination rate in order to explore the effect of recombination rate on genomic selection in simulation. Features of the genome such as recombination rate, mutation rate and historical natural selection vary along the genome, and shape the distribution of genetic variation as they affect the supply of standing variation (Corbett-Detig *et al.* 2015, Harpak *et al.* 2016) and the extent of selective interference between variants (Hill and Robertson 1966).

Simulations are widely used in animal genetics to test the performance of analysis methods, understand the response to selection in breeding program designs, but also for mechanistic modelling of genetic variation. These simulations make many simplifying assumptions, including, often, abstracting away genome features and treating the genome as a more or less uniform grid of markers. Some of these assumptions may be entirely warranted, relying on the generality of quantitative genetic theory, but others may not.

In our research on the genome dynamics of livestock breeding, we hypothesise that there is additional knowledge about genetic architecture, and potentially genomic selection accuracy, to be gained by modelling the relationship between variation and features of the genome in more detail. This paper presents some of our pilot work on the effect of recombination rate on selection, using published physical and genetic maps of the cattle and chicken genomes.

Materials & methods

We used AlphaSimR (Gaynor, Gorjanc and Hickey 2021) to build a simulation of a closed breeding population with different karyotypes and recombination rate variation based on real linkage maps from cattle and chickens.

Simulation of population and traits. The founder population was generated using the coalescent simulator MaCS within AlphaSimR, using the 'GENERIC' population history, which models a large historical population size decreasing during domestication, and a final effective population size of 1000. We simulated one quantitative trait with either 100, 1000 or 10,000 causative variants drawn at random, proportioned to chromosomes based on their physical length. Additive genetic coefficients were drawn from a standard normal distribution. Dominance degrees were drawn from a normal distribution with mean 0.2 and variance 0.1, similar to values estimated by Bennewitz and Meuwissen (2010). Normally distributed noise was added to the phenotypes to achieve a heritability of 0.4.

Chromosomes and linkage maps. Chromosomes were either based on the cattle karyotype, the chicken karyotype or were 20 chromosomes of equal size. Table 1 describes the different genomes simulated, with number of chromosomes, physical and genetic sizes. We only included autosomes that were included in the linkage map, meaning that the X and Z chromosome are missing, respectively, as well as some chicken microchromosomes. We used linkage maps from Ma *et al.* (2015) for cattle and Elferink *et al.* (2010) for the chicken. In order to update the physical coordinates, we used the UCSC LiftOver service to sequentially lift the physical position to ARS-UCD1.2 for cattle and GRCg6a for the chicken. We filtered the lifted maps to remove markers that caused disagreements in marker order, leaving a total of 58,010 in cattle and 12,907 in the chicken. We adjusted the genetic maps from coalescent simulation, which have uniform recombination rate, to correspond to the real linkage maps before breeding. We converted the initial genetic position of each site to a physical position, and linearly interpolated the new genetic position on the real linkage map based on that physical position. Linkage maps and code are available at https://github.com/mrtnj/lifted_recombination_maps.

Breeding structure. Each generation, 50 males (10%) and 100 females (20%) were selected to be the parents of next generation, and mated to produce 1000 offspring, half of each sex. The first ten generations of each replicate used phenotypic selection, and for the next ten generations, we either ran another ten generations of phenotypic selection or ten generations of genomic selection. In order to measure the decline in genomic accuracy, training was performed once using data from generation 6-9. The genomic selection model was SNP-BLUP based on 50,000 SNP markers randomly chosen but equally proportioned to chromosomes based on physical length. We evaluated accuracy as the correlation between true and the estimated breeding value. Each simulation case was run for 50 replicates. The simulation code is available at https://github.com/mrtnj/wcgalp_recombination.

Simulation with linkage equilibrium. For comparison, we created a simulation where the causative variants had the same starting frequencies, and distributions of additive and dominance coefficients, but where the loci were made to be in linkage equilibrium independently sampling the genotypes from a binomial distribution each generation. The linkage equilibrium simulation also used the same heritability, population size and a sex-averaged selection intensity as the AlphaSimR simulation.

Results

High recombination rate led to a lower loss of additive genetic variance on average (Figure 1). This effect was noticeable when there were many causative variants (i.e. not in the case with 100 loci), at later generations, but the difference was small compared to the variation between replicates. This was accompanied by somewhat higher genetic mean. Considering the case with 10,000 loci, in generation 20, the genetic mean was 4.4% higher for 1 M chromosomes, 6.4% higher for 2 M chromosomes, 3.6% higher for the cattle genome and 4.0% higher for the chicken genome compared to the shortest genome (0.5 M chromosomes).

Table 1. Genomes simulated.

Case	Physical length (Mbp)	Genetic length (M)	Chromosomes
0.5 M chromosomes	2,000	10	20
1 M chromosomes	2,000	20	20
2 M chromosomes	2,000	40	20
Cattle genome	2,489	24	29
Chicken genome	941	27	27

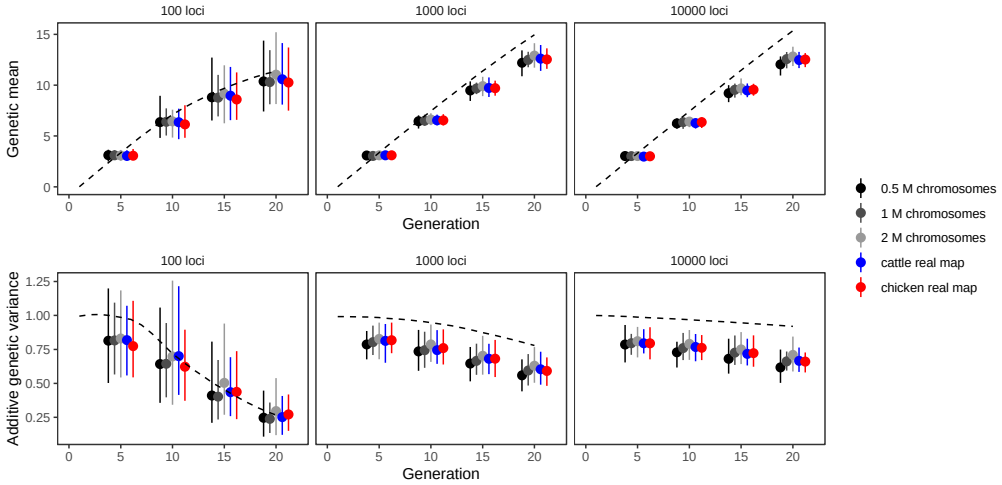

Figure 1. Changes in additive genetic variance with different recombination rates. The dashed line is the average from a simulation where causative variants are in linkage equilibrium.

On the other hand, higher recombination rate caused a decrease in genomic prediction accuracy (Figure 2). Considering the case with 10,000 loci, the first generation of genomic selection, average accuracies after one generation were 19% lower for 1 M chromosomes, 36% lower for 2 M chromosomes, 25% lower for the cattle genome, and 22% for the chicken genome compared to the most accurate 0.5 M chromosome case. When the genomes used the real cattle or chicken karyotype but had uniform recombination rate, the reduction was somewhat greater than with real linkage maps (27% for cattle and 26% for the chicken).

Discussion

The slight increase in genetic gain due to higher recombination is consistent with results from Battagin *et al.* (2011), who found that higher recombination rate led to higher genetic gain due to a smaller reduction in additive genetic variance, though the effect was small. The quantitative results are not comparable, as they used a different breeding structure, and selection on true breeding value. With genomic selection, the benefit from high recombination rate would be offset by a decreased genomic selection accuracy; while the improvement due to higher recombination happens in the long term and is small, the decrease in accuracy is immediate.

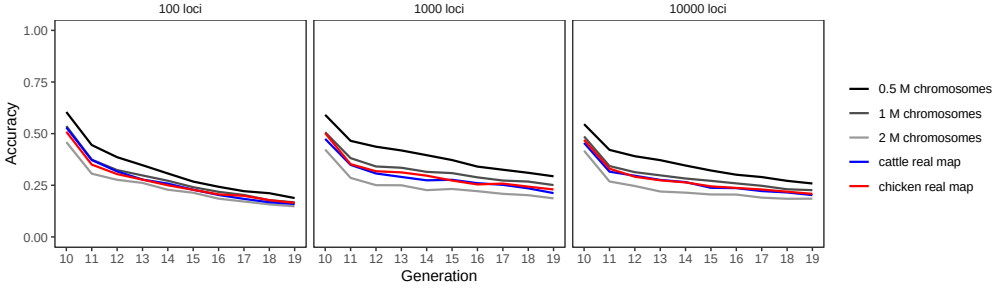

Figure 2. Decline in genomic selection accuracy over generations increasingly removed from a constant reference population, with different recombination rates.

As there is substantial variation within the genome in recombination rate, different regions of the genome should display local variation in its contribution to genomic selection accuracy, and to a lesser extent to long term gain. In the linkage maps used here, the 25 and 75% quantiles of recombination rate in between-marker intervals were 0.060 and 1.6 cM/Mbp for the cattle linkage map and 0.0 and 4.1 cM/Mbp for chicken linkage map.

Except for the real linkage maps, most aspects of these simulations were highly simplified. These are some avenues for development: the simulations used a generic population history, with a domestication bottleneck and large ancestral population. Work is ongoing to infer population history, and synthesise that with published estimates. As the real linkage maps were only introduced after the coalescent simulation of the founder population, the regional variation in linkage disequilibrium was only built up during the simulated breeding. Also, the real recombination rate landscape is more punctuated, with short 'hotspots' of a few kilobasepairs. Work is ongoing to infer fine-scale recombination rate and use it to improve the realism of the founder simulation. Finally, we used a generic breeding structure of a small closed population. The flexibility of AlphaSimR as well as recent developments to communicate and visualise breeding structures (Simianer *et al.* 2021) will be helpful for improving this aspect.

Abstract

We herein characterized fine-scale meiotic recombination rate (RR) variation in a whole-genome sequenced cattle pedigree including 264 individuals. With a family-based approach, we identified 6,644 cross-over (CO) events (median length: 3.9 kb) whereas with a population-based method, we observed the presence of 12,776 recombination hotspots (median length: 1.5 kb). Although these hotspots represented only 0.97% of the genome, 38.3% of the CO overlapped with these hotspots (40.6% in males, 34.8% in females), suggesting that they might still be in use in the current population. Subsequently, we determined that RR was higher in open chromatin regions, in CpG islands, and in predicted PRDM9 motifs. Conversely, lower RR were estimated close to genes except in the transcription start sites. Finally, higher RR were estimated around H3K4me3 histone mark in testis, further supporting the implication of the PRDM9 zinc finger protein in meiotic recombination in cattle.

Introduction

Meiotic recombination is an important biological process as it ensures the proper segregation of homologues during meiosis and it shapes the patterns of linkage disequilibrium (LD) by creating new combinations of alleles (see for instance Coop and Przeworski, 2007, Baudat *et al.*, 2010, and Peñalba and Wolf, 2020, for reviews). Two approaches can be used to study meiotic recombination from genotypes (Peñalba and Wolf, 2020). First, family-based approaches allow to identify sex-specific cross-over (CO) events and provide current recombination rates (RR). Second, population (or LD)-based approaches provide historical sex-averaged RR. These latter maps represent relative estimates as they are influenced by other parameters such as past effective population size or selection intensity. Two mechanisms directing recombination are currently known (Baudat *et al.*, 2010). The first one is PRDM9-independent, where recombination is concentrated at TSS and CpG islands, and where we observe stable patterns of recombination across generations, as seen in yeasts, plants, and vertebrate species such as birds. In contrast, in most mammals such as in human, recombination is PRDM9-directed, that is, concentrated at the positions where PRDM9 protein is binding, away from genes, and where we observe a fast evolution of PRDM9 binding-motifs and a divergence between close species (Baudat *et al.*, 2010). Here, we take advantage of a unique sequenced cattle pedigree to characterize the patterns of RR in the bovine genome and to study the relationship between recombination and genomic features.

Materials & methods

Sequence data. Whole-genome sequence data was available for a small pedigree containing 264 Holstein-Friesian individuals. Based on filtering and processing steps described in Oget-Ebrad *et al.* (2021), we selected 8.4 million SNPs for further analysis.

CO events identification. We used the family-based approach implemented in LINKPHASE3 (Druet and Georges, 2015) to identify CO events in the sequence data. We removed double CO occurring within 1 Mb, and multiple identical CO within a family to remove putative errors. CO intervals were then refined using ShapeIT4.1 (Delaneau *et al.*, 2019).

LD-based RR and hotspots. We used LDhelmet (Chan *et al.*, 2012) to estimate population-based RR and sequenceLDhot (Fearnhead, 2006) to identify recombination hotspots.

PRDM9-related features. We predicted the PRDM9 binding-motifs for each allele of the BTA1 paralog previously characterized for the Holstein breed (Zhou *et al.*, 2018), using the approach from Persikov and Singh (2014). We scanned the genome for potential binding locations of each of these predicted motifs with FIMO (Grant *et al.*, 2011).

Other genomic features. We used available public database to locate genomic features such as the transcription start sites (TSS) (Goszczynski *et al.*, 2021), and CpG islands (https://hgdownload.soe.ucsc.edu/goldenPath/bosTau9/database/). Functional annotation was available from experiments performed in testis, including an Assay for Transposase-Accessible Chromatin using sequencing (ATAC-seq), and epigenetic data for histone marks (H3K27me3, H3K4me3, H3K4me1, H3K27ac) and for one DNA-binding protein (CTCF).

Results

Broad-scale variation of RR. We identified 6,644 CO events (3,895 for males and 2,749 for females; median length: 3.9 kb) with the family-based approach and characterized 12,776 LD-based hotspot regions (median length: 1.5 kb; RR=4.1/kb in the hotspots vs 0.18/kb as whole-genome average), the latter representing 0.97% of the genome. Thirty-eight percent of the CO overlapped with LD-based hotspots (40.6% in males, 34.8% in females) and more than 50% were within 5 kb from the hotspots (Figure 1). This proportion was highly significant compared to random sets of CO events ($P<0.001$; 2.4% overlap on average with 1000 simulations). We also observed that both CO and hotspots density were higher at telomeres.

Fine-scale variation of RR. In our population, we observed the five alleles of the BTA1 *PRDM9* paralog previously described by Zhou *et al.* (2018) at following frequencies: 12.3% for allele 1, 51.1% for alleles 2 and 3, 23.1% for allele 4, and 13.4% for allele 5. A total of 149,620 PRDM9 predicted motifs were identified in the genome. Although we observed increased RR around these motifs (Figure 2a), only 11.3% of the LD-based hotspots contained at least one motif. We observed reduced RR close to TSS (Figure 2b) and increased

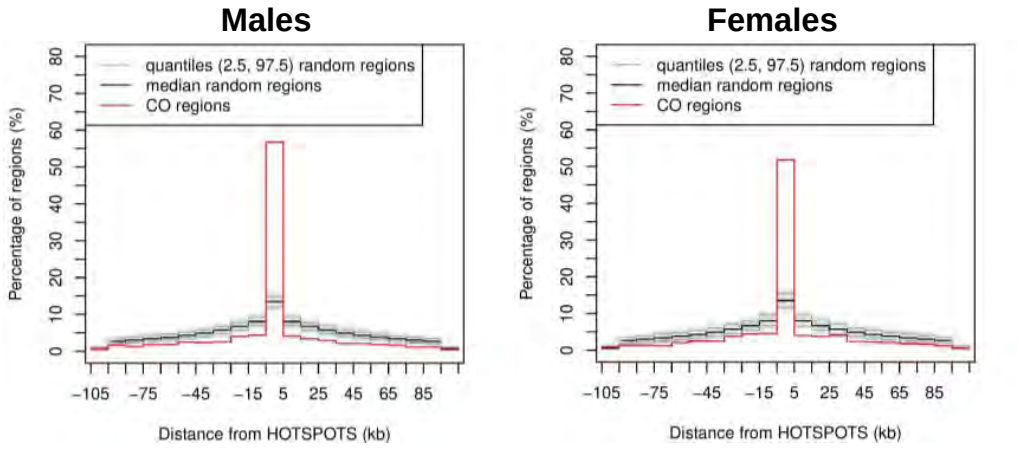

Figure 1. Percentage of CO events (red) identified with the family-based approach in males and females as a function of the distance (in kb) from the closest hotspot from the population-based approach, compared to 1000 simulated random sets of CO matching in number and size (grey for quantiles, black for median).

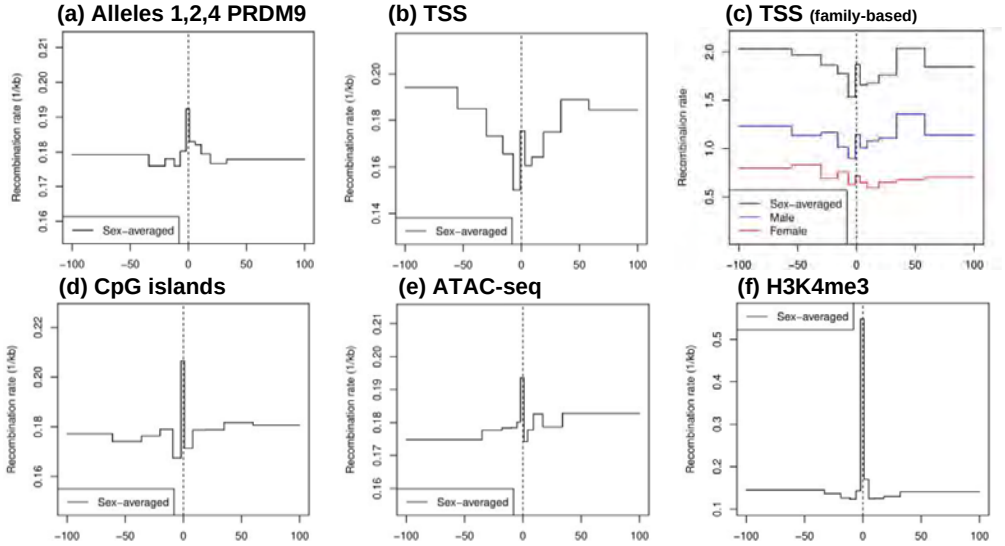

Figure 2. Recombination rates (RR) as a function of the distance (in kb) from the closest (a) BTA1 PRDM9 predicted binding-motif for alleles 1, 2 & 4, (b-c) transcription start site (TSS), (d) CpG island, (e) ATAC-seq peak, and (f) H3K4me3 signal. RR were estimates from the population-based approach, except in (c).

RR in CpG islands (Figure 2d). RR were higher in accessible DNA regions (ATAC-seq peaks, Figure 2e) and in CTCF signals. Methylation marks from active promoters (H3K4me1 and H3K27ac) presented lower RR. We observed a strong increase of RR in the H3K4me3 methylation mark (Figure 2f). This was specific to assays performed in testis and not observed with ATAC-seq data from other tissues (e.g. liver). Some of these associations were also observed with the set of identified CO (Figure 2c), with no striking difference between males and females, although the patterns were less clear than with the population-based approach.

Discussion

In cattle, association between PRDM9 and individual RR and CO events location (at relatively broad scale) has been previously reported, as in human and mice. Meiotic recombination has been indeed previously studied in cattle with sparser marker maps (Ma *et al.*, 2015). Based on whole-genome sequence data, our findings further support the role of PRDM9 in this species. First, we observed the presence of recombination hotspots (median length: 1.5 kb) in cattle, as in human and mice (Baudat *et al.*, 2010). These recombination hotspots represent 0.97% of the genome (1.7-1.9% in human (Kong *et al.*, 2010)). They were significantly overlapping with identified CO, suggesting that the historical hotspots are still in use in the present population. Then, we observed increased RR around BTA1 PRDM9 binding-motifs, as well as a small proportion of hotspots (11.3%) containing at least one PRDM9 binding-motif. This relatively low proportion (10.1% expected with random location) might result from inaccuracies in hotspots identification or in binding-motif predictions. The hotspots might also be associated with other *PRDM9* alleles that we did not identify, for instance alleles associated with the *PRDM9* paralogue on BTAX or alleles that are no longer present in the population. Overall, when multiple *PRDM9* alleles contribute to recombination hotspots, motifs enrichment analysis might fail to identify specific *PRDM9* alleles. Finally, a strong increase of RR in the H3K4me3 methylation mark was observed. This mark is known to be deposited by PRDM9 after binding DNA and is mandatory for the initiation of the recombination process (Diagouraga *et al.*, 2018), further supporting the implication of PRDM9 in meiotic recombination in cattle.

More generally, we found that RR increased in CpG islands and in open chromatin regions as seen in human (Halldorsson *et al.*, 2019), and decreased in regions associated to active promoters. CO would thus be kept away from genes and motifs should evolve rapidly; the recombination landscape could thus differ among breeds or between closely related species.

Abstract

Recombination is a fundamental biological process for the reproduction and evolution of species. Recombination phenotypes have been shown to exhibit large inter-individual variation with a significant genetic determinism. Here we make use of large genotyping datasets in the Sheep to: (1) study the distribution of recombinations along the genome (recombination maps); and (2) evaluate its inter-individual variation using a phenotype termed *hotspot usage* (HSU). We precisely estimated sex specific recombination maps and found that sex differences in recombination rates are concentrated in 16% of the genome, mostly at chromosome extremities. Individual variation in HSU is dominated by a large difference between sexes: males are found to preferentially use recombination hotspots contrary to females. This difference is most pronounced in regions with large sex differences in recombination rate. This suggests that sex difference in recombination maps in Sheep could be due to different crossover determination processes in male and female meioses.

Introduction

Recombination is a fundamental biological process that exhibits variation among species, populations and individuals. Two main recombination phenotypes have been studied at the individual level: recombination rate and recombination localisation. Individual recombination rates can be measured by counting the number of crossovers per meiosis (using pedigree or cytogenetic approaches). However, individual variation in crossover localisation is more difficult to measure as it requires data from a large number of meioses per individual and/or a very precise localisation of individual crossovers. One of the individual phenotypes that can be measured to evaluate variation in recombination maps is *hotspot usage (HSU)*. It is the propension for an individual to recombine in small genomic regions of high average historical recombination rate called hotspots. In this study we used a new dataset of precisely localised crossovers in sheep families to estimate HSU in multiple individuals and investigate its variation between the sexes.

Materials & methods

Datasets. This study exploits three datasets. First, two previously published datasets of medium density genotypes (~50K SNPs) in large pedigrees in Lacaune (Petit *et al.* 2017) and Soay (a primitive breed of domestic sheep; Johnston *et al.* 2016) sheep populations to build sex-specific recombination maps. Second, a new dataset of small nuclear families in a Romane population genotyped for a high-density SNP array (HD; ~600K SNPs) and used to study HSU variation. Datasets were phased and crossover positions identified using the software yapp (https://yapp-doc.netlify.app/).

Sex specific recombination maps. Recombination maps were estimated for each sex using poisson regression on crossover (CO) counts observed in non-overlapping 1 Mb intervals along the genome using the glm procedure in R. Sex-specific recombination maps were estimated considering each population by sex as a group in a Poisson-Log-Normal Model framework using the PLNmodels R package (Chiquet, Mariadassou, and Robin 2021). An extension of the model allowing for a mixture of poisson distributions assigned each 1 Mb interval to a specific mixture component and identified intervals with clear differences in recombination rates between sexes.

Hotspot usage estimation. Hotspot usage was estimated in individuals from the HD Romane dataset and hotspots identified in Petit *et al.* (2017) using the procedure described in Coop *et al.* (2008). Briefly, this method estimates HSU in a collection of crossovers as the proportion that use a hotspot, adjusted for the size of the crossover localisation interval and the local hotspot density. First the probability that each crossover overlaps a hotspot by chance is estimated by randomly shifting its position locally. This allows to account for the size of the localisation interval (crossovers with large intervals have a higher probability of overlap by chance) and the local recombination rate (crossovers located in regions of high hotspot density have higher probability of overlap by chance). Then given a set of crossovers (for an individual, a sex …), the HSU is estimated by maximizing the likelihood that depends on these overlap probabilities (see Coop *et al.* (2008) for details).

Results

Table 1 summarises the crossover data for the three datasets. The two medium density datasets identify a large number of crossovers and can be used to precisely estimate average recombination rates. The HD dataset resolves crossovers in intervals roughly 10 times smaller and allows estimation of HSU.

Sexes differ in their recombination maps in few genomic intervals. Statistical analysis of crossover counts in the two MD datasets reveals that genomic intervals can be separated into 2 components in terms of recombination rate variation between groups. The majority component I (84% of the genome, green on Figure 1) exhibits essentially the same recombination rate in males and females. The minority component II (16% of the genome, purple on Figure 1) corresponds to intervals with large between sex variation, most of them located at the extremities. In both classes, the Soay and Lacaune populations have essentially the same recombination rates in males and females, despite their large genetic distance.

Hotspot usage exhibits strong sex differences and within sex variation. Pooling all crossovers from the Romane dataset, the HSU estimate is 59% with 95% confidence interval [57-61]. Males had significantly higher HSU (72%, CI [70-75]) than females (29%, CI [24-34]) (LRT=207.67 (1 df), P=4.5×10^{-47}). Figure 2 left shows that there is a large variation in individual estimates of HSU but mostly due to the large difference between sexes. However, a few outliers can be identified (two females with HSU>75 and 3 males with HSU<60) and the likelihood ratio tests on individual variation within each sex are significant (for females LRT=57.34 (27 df) P=5.8×10^{-4}, for males LRT=52.36 (28 df) P=3.5×10^{-3}).

Sex difference in hotspot usage and recombination rate are associated. Estimating hotspot usage in component II vs component I intervals reveals that females have an extremely low hotspot usage in intervals of class II while males have the same high hotspot usage in both components (Figure 2 right).

Table 1. Crossover data used in this study.

Population	Sex	# Parents	# Meioses	# CO	CO localization size (kb)[1]
Lacaune	Female	286	483	13,789	715 (249-4,168)
Lacaune	Male	542	8,991	325,487	687 (202-6,311)
Soay	Female	1,001	4,471	123,852	1,204 (266-9,614)
Soay	Male	631	4,157	144,237	829 (160-8,129)
Romane	Female	28	59	2,665	82.3 (18-2,605)
Romane	Male	29	166	6,433	91.7 (17-4,012)

[1] Median size (lower – upper 5% quantiles)

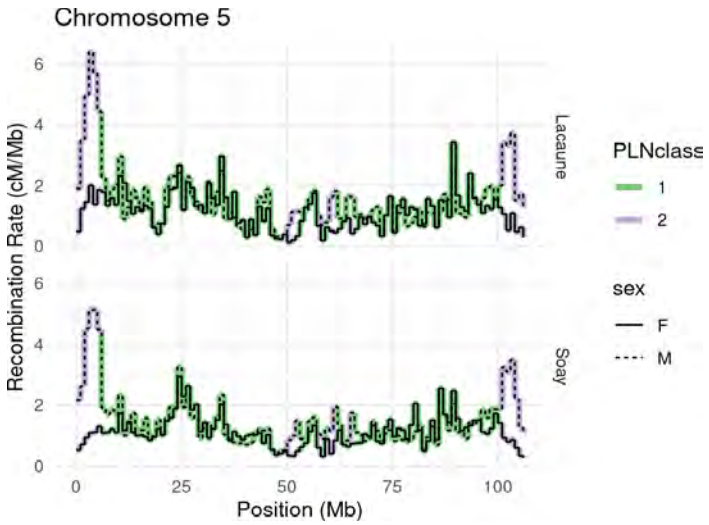

Figure 1. Example of recombination maps along chromosome 5 in two sheep populations and two sexes. Genomic intervals are coloured according to their mixture component (PLNclass).

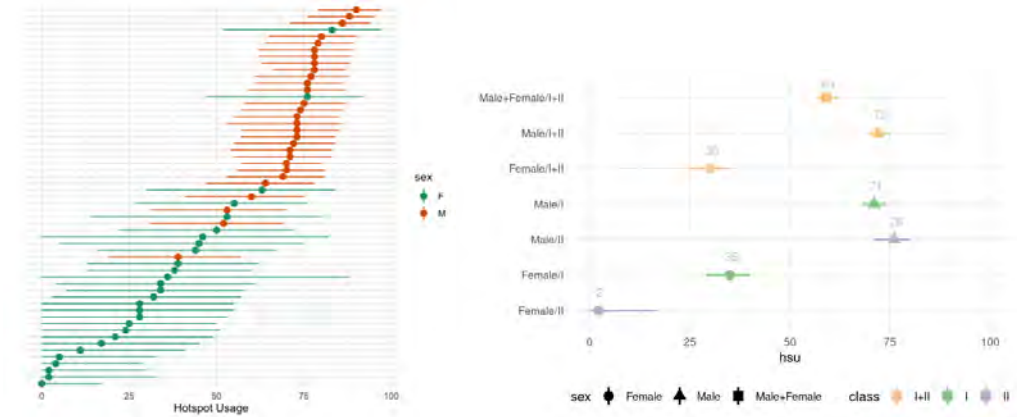

Figure 2. Hotspot Usage in the Romane population. Left panel: individual estimates of HSU Right panel: HSU in different genomic interval components and sex.

Discussion

We have established precise recombination maps in males and females in two highly differentiated populations of sheep. While sex differences in the recombination landscape are large, within sex between population variation is mostly negligible at the megabase scale so maps established here can be generally useful in many sheep populations. However, our results suggest that genetic analysis of segregation in pedigrees or genomic selection methods exploiting gametic variance, e.g. Bijma *et al.* (2020), should take account of between sex variation in recombination.

The sex difference in recombination rate between males and females in sheep is characterized by females recombining less than males due to a lower recombination rate in a small part of the genome mostly located at chromosome extremities. This is consistent with previous results in many mammals including cattle

(Ma *et al.* 2015), mouse (Peterson and Payseur 2021) and human (Broman *et al.* 1998) but different from red deer (Johnston *et al.* 2017) or pig (Tortereau *et al.* 2012) where females rather than males tend to have elevated recombination rates at chromosome ends.

Analysis of inter-individual variation in recombination localisation (HSU) show that the sex-difference in the recombination landscape in sheep is associated with a lower overall hotspot usage in females, particularly in the genomic intervals that exhibit large sex-differences in recombination rates. These differences could be due to differential use of crossover resolution pathways as was shown recently in the mouse (Brick *et al.* 2018; Powers *et al.* 2020).

203. Is it possible to differentiate meat products of a local breed from those of its sister breed based on genotypes?

H. Wilmot[1,2*], G. Glorieux[3], X. Hubin[3] and N. Gengler[2]

[1]National Fund for Scientific Research (F.R.S.-FNRS), Rue d'Egmont, 5, 1000 Brussels, Belgium; [2]Gembloux Agro-Bio Tech, University of Liège, Passage des Déportés, 2, 5030 Gembloux, Belgium; [3]Walloon Association of Breeders, Rue des Champs Elysées, 4, 5590 Ciney, Belgium; helene.wilmot@uliege.be

Abstract

To maintain endangered breeds and preserve their intrinsic diversity, it is often advocated to develop derived labelled products and the related certification process. However, this certification process is not always easily implemented if the endangered breed is closely related to another one. The breed traceability is only possible if the genetic diversity between those breeds is high enough. In this study, it was determined if meat of Dual-Purpose Blue (DPB) animals can be differentiated from meat of its sister breed, the Beef Belgian Blue (BBB), by the application of a genomic test. The results showed that the meat of DPB was completely distinguished from the meat of BBB, and this, with a probability of one for all meat samples. It therefore seemed possible to differentiate the DPB derived products from those of BBB with a high accuracy, meaning the implementation in routine of a certification process seemed possible.

Introduction

The Dual-Purpose Blue (DPB) breed can be considered as the old type of the previously called Mid and Upper Belgium Breed, from which the well-known Beef Belgian Blue (BBB) also derived. Both branches (DPB and BBB) separated during the seventies (Mota *et al.*, 2017). However, from this point, the BBB gained popularity while the number of DPB decreased to the point it is now considered an endangered breed. The BlueSter project (BlueSter, 2021) aimed to maintain this breed by, among other measures, *in situ* conservation and the development of local products. The consumer confidence can be ensured through a certification process using a genomic breed assignment tool for breed derived-products (e.g. Judge *et al.*, 2017). However, implementing this kind of certification is not always easy if the endangered breed is closely related to another one, as it is in our case. The objective of this study was therefore to determine if it was possible to differentiate meat products of the endangered DPB breed from those of its mainstream sister breed, the BBB, by the use of a genomic breed assignment test previously developed.

Materials & methods

All computations were run on R v.4.1.2 (R Core Team, Vienna, Austria, 2021) and visualized on R Studio (R Studio Team, Boston, USA, 2020).

Breeds. The two main breeds of interest in this study were the DPB, a transboundary dual-purpose breed of Southern Belgium and the North-East of France, and the BBB, a beef breed mostly located in Belgium. Whereas all BBB animals are homozygous for a partially recessive allele 'mh' resulting in muscular hypertrophy, a disparity is found in the DPB population where the wild type of the allele '+' is still existing (Mota *et al.*, 2017). In other words, depending on the selection objective of the breeder, DPB animals can be 'mh/mh' (in farms with a more meat-orientated breeding goal, mostly found in Belgium), 'mh/+' or '+/+' (in farms with a more dairy-orientated breeding goal, as most French breeders), and two or three genotypes can be coexisting in the same farm.

Datasets. Two different datasets were used in this study: the first one was used for the principal component analysis, aiming to determine if the breeds of interest can be differentiated, and the second one was used by the breed assignment model. For the principal component analysis, 60 DPB and 60 BBB, considered as the reference population of their respective breed, were studied. Both Belgian (n=52) and French animals (n=8) were represented in the DPB population. For the breed assignment model, a total of 32 samples of meat pieces, coming from three breeds, were genotyped with the EuroG MD v2 (Illumina, San Diego, CA, USA). The three breeds included were the BBB (n=8), the DPB (n=16) and the Holstein (HOL, n=8). The BBB animals were born in four different farms but all fattened at the same place. The DPB animals came from two different breeders in a balanced manner (n=8 for each breeder). One of the breeders was located in Belgium and only provided 'mh/mh' animals to be slaughtered. The other one was located in France and raised both 'mh/+' and '+/+' animals. It was thus considered that the DPB breed was well represented as animals from the three genotypes were sampled. The HOL animals were also raised by different breeders and were considered as a 'control' for the study.

Principal component analysis. The PCA was based on a total of 17,667 SNPs as in a previous study (Wilmot *et al.*, 2022) and on the first dataset. Missing values per individual were imputed following a procedure of the missMDA v1.18 R package (Josse and Husson, 2012), related to PCA, and described in Wilmot *et al.* (2022). The FactomineR v.2.4 R package (Lê *et al.*, 2008) was used to perform the PCA on the matrix of correlations.

Breed assignment model. The breed assignment model used in this study to determine the breed of origin of meat samples for each of the 32 slaughtered animals was previously described in Wilmot *et al.* (2021) as the second best model to be used for breed assignment. Because the second best model used less SNPs than the first one (2,005 vs 7,153), it was preferred for routine analyses. In brief, the chosen model was based on 2,005 SNPs and used the Nearest Shrunken Centroids method to classify each individual. Twelve breeds can be detected with this model of which the BBB, the DPB and the HOL. Each meat sample was assigned to the breed for which it had the highest probability to belong to.

Results

Principal component analysis. The first two dimensions of the PCA are illustrated in Figure 1. There was a gap between animals from both breeds, even if one BBB animal was closely related to the DPB cluster. Therefore, it seemed possible to differentiate DPB from BBB. Moreover, as expected because of the different selection objectives and the three muscular genotypes existing in the DPB breed, there was a greater diversity in the DPB population compared to BBB animals i.e. DPB animals were more widespread than BBB animals in Figure 1.

Breed assignment of meat samples. A model based on 2,005 SNPs and on the Nearest Shrunken Centroids method was used to classify all the meat samples in the breed they were supposed to belong to. From the 2,005 SNPs, 167 were used to differentiate DPB from the other breeds existing in the reference population and 173 were used to differentiate BBB from the other reference breeds. An overlap of seven SNPs was observed between both SNP panels. The confusion matrix of the breed assignment test is available in Table 1. All meat samples were correctly attributed to their breed of origin, and this, with the maximum probability.

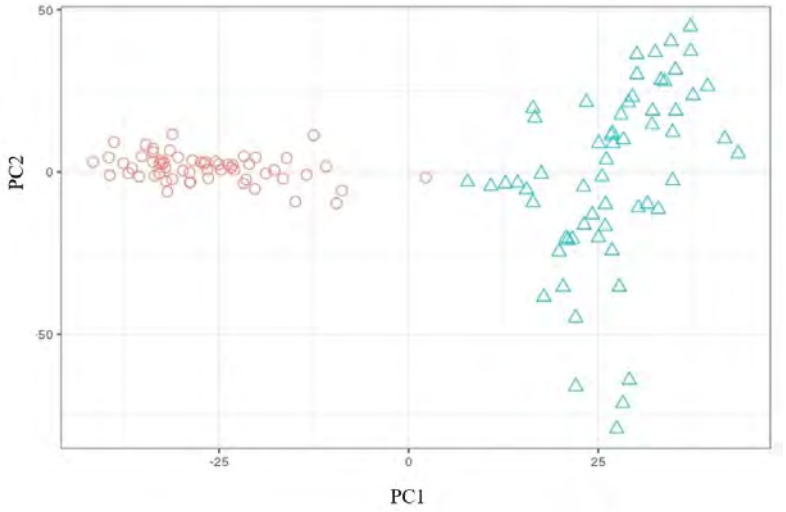

Figure 1. First two dimensions of the principal component analysis based on genotypes of reference Dual-Purpose Blue and Beef Belgian Blue. O = Beef Belgian Blue; Δ = Dual-Purpose Blue.

Table 1. Confusion matrix of meat samples based on the breed assignment test.

Predicted breed	Breed of origin		
	Beef Belgian Blue	Dual-Purpose Blue	Holstein
Beef Belgian Blue	8	0	0
Dual-Purpose Blue	0	16	0
Holstein	0	0	8

Discussion

The possibility to distinguish local meat products of an endangered breed, the DPB, from a mainstream sister breed, the BBB, based on genotypes, was studied. The breed assignment test allowed to perfectly differentiate the DPB meat samples from the BBB meat samples, with a probability of one for all meat samples, even those of DPB animals carrying the 'mh/mh' genotype, highlighting the high accuracy of the test.

This high accuracy can be partially explained by the fact that the SNPs used by the model were selected to differentiate each breed in the reference population from the others. Therefore, the panel comprised SNPs dedicated to differentiate DPB animals from BBB animals. It is then expected that significant phenotypic and genetic differences have arisen between both breeds since their divergence in the seventies, even for 'mh/mh' DPB animals. It has for example been suggested that the dairy performances were not necessarily inconsistent with the 'mh/mh' genotype as the more dairy DPB cows ('+/+') were producing on average 5,000 litres whereas the meat producing-DPB cows ('mh/mh') were still able to produce 4,000 litres (BlueSter, 2021). Moreover, it has been reported that, even when DPB animals carry the 'mh/mh' genotype, caesarean sections were more frequent in BBB than in DPB. It seemed that DPB breeders selected more for decreased birth weight and decreased calving difficulties, even within the 'mh/mh' animals, than BBB breeders (Mota *et al.*, 2017).

The fact that the breed assignment test can make the difference between genotypes of these two very closely related breeds, that diverged only from each other less than 50 years ago, is not trivial. It means that the genetic diversity between DPB and BBB was sufficiently high to differentiate these breeds. As a counter-example, the Angus and Red Angus cattle could not be effectively assigned to their respective breed in the study of Kuehn *et al.* (2011), even if both breeds started to separate much earlier (Márquez *et al.*, 2010) than DPB and BBB breeds. Besides, whereas the same three colour patterns (black-pied, blue-pied and white) are co-existing both in DPB and BBB, Angus and Red Angus clearly segregate from this point of view. However, the method chosen by Kuehn *et al.* (2011) was based on a regression of allelic frequencies and their objective was slightly different: determining breed composition instead of assigning animals to a breed.

Finally, the results showed that it would be possible to use the studied breed assignment test in routine as one step of a certification process of local products, especially if a SNP chip containing all the selected SNPs is used.

Part 14

Genetic diversity and inbreeding

204. Assessing existing admixture in indigenous veld ecotypes and non-descript goat populations of Southern Africa

C. Visser* and S.F. Lashmar

University of Pretoria, Private Bag X20, 0028, Hatfield, Pretoria, South Africa; carina.visser@up.ac.za

Abstract

Indigenous goat populations play an important role in food security and livelihoods of resource-poor communities in Southern Africa. These adapted animal resources could contribute significantly to future food production strategies, but limited research has been performed on their genomic architecture. A total of 192 indigenous goats, comprising of three recognized ecotypes (n=92), as well as five non-descript, communal populations (n=100) were genotyped using the Illumina® Goat SNP50 version 2 single nucleotide polymorphism (SNP) genotyping panel. Genome-level genetic relatedness analyses indicated that population differentiation was driven by both genetic distinctness and geographic isolation. Some of the communal individuals clustered with previously recognized ecotypes, while others indicated unique and distinct ancestry. Elevated inbreeding levels could probably be ascribed to artificial selection in commercial ecotypes, and small communal population sizes. A conservation through utilization approach could benefit the genetic diversity of these populations.

Introduction

Approximately 70% of Southern African goats are kept in non-commercial production systems and contribute to the nutritional and financial security of resource-poor households and communities (Monau *et al.*, 2020). Goats farmed in smallholder and communal farming systems are typically kept in small herds of less than 20 animals and are often confronted with environmental stressors and nutritional inadequacies, with little to no management inputs or supplementation (Chokoe *et al.*, 2020; Monau *et al.*, 2020). The endurance of these goats within different agroecological zones, and their subsequent development into uniquely adapted breeds or ecotypes, is believed to be a result of natural (rather than artificial) selection pressures. As a result of their exposure to these pressures, indigenous goats have acquired anatomical and physiological adaptive mechanisms to tolerate heat and drought, resist parasites (external and internal) and reduce their maintenance requirements.

Indigenous goat ecotypes and non-descript populations represent an important genomic reservoir for local chevon production and have served as a foundation for the development of commercial breeds, largely due to their adaptive traits (Mdlala *et al.*, 2016). The Indigenous Veld Goat (IVG; https://www.indigenousveldgoats.co.za/) society was recently established to improve pedigree and performance recording efforts for recognized ecotypes that are distinguished based on their morphological features (e.g. Nguni, Cape Lob Ear, Cape Speckled). Communally farmed goat populations are, however, for the most part non-descript with an increased number of community-based breeding programs (CBBP) being established to facilitate improved productivity and profitability (Mtshali *et al.*, 2021). The relevance of the breed concept is increasingly being brought into question, specifically for locally adapted goat populations, and there is a tendency towards advocating conservation through utilization of existing admixtures that were historically introduced (e.g. do Prado Paim *et al.*, 2019).

In order to capitalize on their adaptive traits for improved sustainability of future goat production strategies, it is necessary to profile the existing population structure and elucidate between-population relationships of local goat genetic resources. The aim of this research was to report on the genetic diversity and population structure of recognized indigenous goat ecotypes and non-descript populations occurring in Southern Africa.

Materials & methods

Ethical approval was granted by the Ethics Committee of the Faculty of Natural and Agricultural Sciences, University of Pretoria, for the use of the genotypes in this study (Ethics number: NAS313/2021). Single nucleotide polymorphism (SNP) data was available for 192 indigenous southern African goats comprised of three recognized ecotypes namely the Cape Speckled (n=30), Nguni (n=20) and Xhosa Lob Ear (n=42), as well as five non-descript, communal populations (Cedara, Jozini, Mboza, Msinga and OSCA; n=20 each). Within the Cape Speckled and Xhosa Lob Ear populations eight and ten animals, respectively, originated from Namibia (NM); the remaining samples originated from South Africa (SA), with the communal populations all originating from different regions in the KwaZulu-Natal (KZN) province. Genotyping was conducted using the Illumina® Goat SNP50 version 2 genotyping panel (59,727 SNPs), and data was subjected to quality control procedures in PLINK software (Purcell *et al.*, 2007). Mapped, autosomal SNPs were removed based on low call rate (<90%), low minor allele frequency (MAF<5%) and violation of Hardy-Weinberg Equilibrium (HWE; $P<0.001$). Linkage disequilibrium-based filtering was additionally applied (LD; $r^2>0.2$), where after a final set of 26,792 independent SNPs were retained.

Genome-level genetic relatedness between individual goats was estimated by means of principal component analysis (PCA) derived eigenvectors calculated using GCTA software (Yang *et al.*, 2011). A model-based clustering algorithm, applied using default ADMIXTURE 1.23 software (Alexander *et al.*, 2009) settings, was used to determine the most likely number of ancestral contributors (K-value) for each population. The K-value with the lowest cross-validation (CV) error was chosen as the most probable one, and population structure bar plots were visualized using Genesis version 0.2.3 software (Buchmann and Hazelhurst, 2014). The inbreeding levels of the various populations were quantified using PLINK's SNP-based F-statistic (F_{SNP}).

Results & discussion

The within and between population differences observed from the PCA analysis was seemingly driven by two factors namely genetic distinctness and geographic isolation (Figure 1). The three recognized ecotypes i.e. the Nguni (Mbuzi), Speckled and Xhosa types formed separate clusters, albeit dispersed. The Cedara and Msinga populations, which were previously described as non-descript, clustered with the Nguni type suggesting that these animals might belong to this ecotype. Interestingly the Jozini, Mboza and OSCA populations formed a distinct cluster from the recognized ecotypes, indicating possible association with a different ecotype. The sampling locations supported geographic isolation as a contributor to genetic distinctness as the Jozini and Mboza populations are located in northern parts of the KwaZulu-Natal (KZN) province, whereas the OSCA population is more centrally located and the Cedara and Msinga populations are found in the south of the province. An example of within-ecotype genetic isolation was observed for the Speckled goats; the Namibian samples subclustered, indicating a greater genetic distance from South African samples. The dispersed patterns of clustering are consistent with Chokoe *et al.* (2020) that genetically characterized communal, indigenous goat populations in other provinces of South Africa.

When ADMIXTURE's model-based algorithm was applied, a K-value of three (CV error=0.618) separated the recognized Speckled and Xhosa Lob Ear ecotypes from the remaining goats, which displayed varying proportions of a third predominant ancestor. The most likely number of inferred ancestral populations (K=6; CV error=0.613) revealed unique ancestry for the Namibian Speckled goats (mean proportion shared=0.900±0.086), different from that of SA Speckled goats. This observation was in concordance with an African-wide trend identified by Colli *et al.* (2018) that goat genepools are more associated with geographical areas than single populations. Similarly, the OSCA population that is geographically separated from populations in the north (Jozini and Mboza) and south (Cedara and Msinga) of KZN, largely derived its genetic composition from a completely unique ancestor (mean proportion shared=0.740±0.239). The Jozini and Mboza populations, which are in close proximity to one another, shared 0.487 and 0.821 proportion

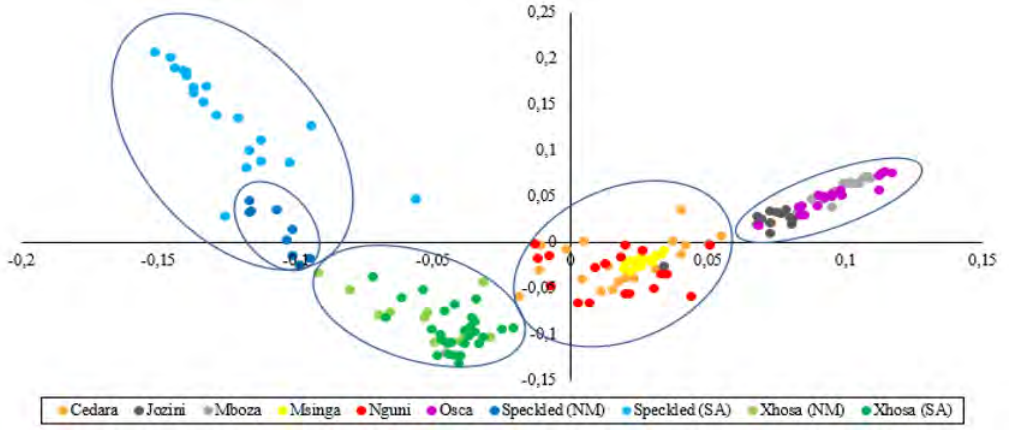

Figure 1. Principal component analysis (PCA) of genetic relatedness between indigenous South African goat populations. NM=Namibian; SA=South African.

units of a distinct ancestral population. One predefined Mboza animal, shared 90% of its ancestry with the Xhosa Lob Ear population, and this may have resulted from the tendency in the communal sector to purchase live animals and resell them in other areas (Gwaze *et al.*, 2008).

The SNP-based inbreeding coefficients (F_{SNP}) ranged from -0.030 (Nguni) to 0.146 (Speckled). In the case of the Speckled goat, a higher level of inbreeding may have resulted from its introduction to breed improvement, and hence pedigree- and performance-based selection (Indigenous Veld Goats, 2018). Higher levels of inbreeding in communal populations e.g. the Mboza (F_{SNP}=0.140) and OSCA (F_{SNP}=0.079) may be due to small census and effective population sizes, and may pose a risk to the existing genetic diversity.

Conclusions

Results from the present study indicated genome-level relatedness of communal goats previously described as non-descript with recognized goat ecotypes. The PCA and model-based clustering analyses additionally

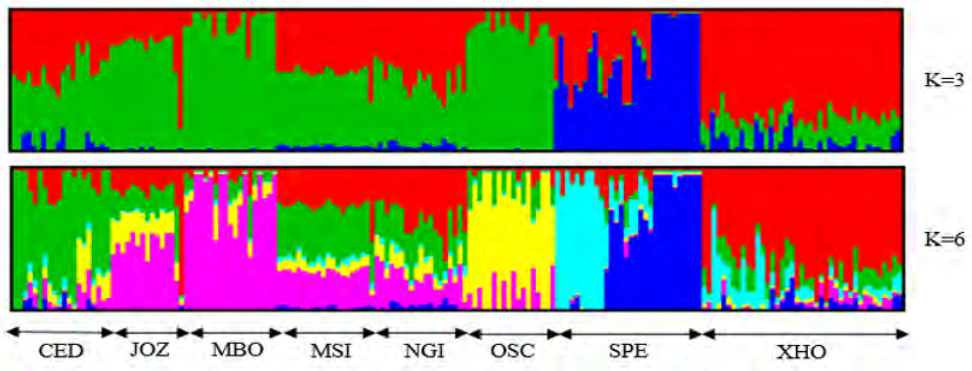

Figure 2. Model-based clustering of indigenous southern African goat populations. CED=Cedara, JOZ=Jozini, MBO=Mboza, MSI=Msinga, NGI=Nguni, OSC=OSCA, SPE=Speckled, XHO=Xhosa.

indicated unique and distinct ancestry, not common to existing, recognized ecotypes which may convey the presence of previously unrecognized ecotypes. It is recommended that existing admixture be conserved for future utilization, as some ancestral genomic segments may contribute to the expression of adaptive traits.

205. Estimation of sex chromosome inbreeding depression on milk production in cattle

I. Curik[1*], H. Vostra-Vydrova[2], M. Shihabi[1], J. Sölkner[3] and L. Vostry[2]

[1]University of Zagreb – Faculty of Agriculture, Svetošimunska 25, 10000 Zagreb, Croatia; [2]Czech University of Life Science Prague, Kamycka 129, 16500 Prague, Czech Republic; [3]University of Natural Resources & Life Sciences Vienna, Gregor-Mendel-Strasse 33, 1180 Vienna, Austria; icurik@agr.hr

Abstract

Inbreeding depression in dairy production is an extensively studied phenomenon. However, we are not aware of a single study that has estimated inbreeding depression concerning sex-chromosome. Using Bayesian inference, we analyzed inbreeding depression in milk yield (4,749 Czech Holstein cows genotyped for >40,000 SNPs with milk yield in the first lactation) in terms of the combined effect of inbreeding (per 1% increase) obtained from autosomes and sex-chromosome. We used three models, each based on different estimated inbreeding coefficients (pedigree, ROH>4Mb, or ROH>8Mb). Significant inbreeding depression estimates for autosomes were observed in all three models (medians; bF_{PED}=-13.2 kg, $bF_{ROH>4Mb}$=-30.0, and $bF_{ROH>8Mb}$=-34.4 kg), while significant inbreeding depression was observed only for pedigree sex-chromosome estimates (medians; $bF_{PED\text{-}sex}$=-7.6 kg, $bF_{ROH>4Mb\text{-}sex}$=-0.1 kg, and $bF_{ROH>8Mb\text{-}sex}$=3.9 kg). Low genomic correlations between inbreeding estimated from autosomes and sex-chromosome argue for the need to estimate inbreeding depression from sex-chromosome.

Introduction

Inbreeding depression is defined as a reduction in the population mean for quantitative traits such as reproduction, fecundity, survival, and other traits (Leroy 2014; Doekes *et al.*, 2021). In genetically small populations, inbreeding and consequently inbreeding depression cannot be avoided, especially in populations subject to strong artificial selection, as is the case with dairy cattle populations. Inbreeding depression estimated from pedigree or genomic data (Curik *et al.*, 2017) is a well-documented phenomenon in dairy cattle (Miglior *et al.*, 1995; Pryce *et al.*, 2014; Doekes *et al.*, 2019). However, we are not aware of a single study that estimated inbreeding depression in relation to sex chromosome, either from inbreeding estimated from pedigree or inbreeding estimated from genomic data.

The main objective of this study was to estimate the joint effect of inbreeding (per 1% increase) of sex and autosomal chromosomes on milk yield in the Czech Holstein population.

Materials & methods

Animals, phenotypes, pedigree, and genotypes. Milk yield data were analysed for a total of 4,749 first lactation cows that calved during 2018-2021 (first lactation only). The total pedigree included 54,196 individuals and is of good quality with a mean complete generation equivalent of 12.3 (range 8.6 to 14.2). Most cows (4,478) were genotyped with the Illumina BovineSNP50 BeadChip (versions v3_A1), while 205 and 67 individuals were genotyped with the CRV-developed 60 k Illumina Panel (versions v2) and the Illumina EuroGMD Chip (EuroGenomics), respectively. Our analysis was based only on SNP with known positions on autosomes and sex chromosomes. Quality control was performed using PLINK v1.9 software (Chang *et al.*, 2015), and we removed all SNPs with a call rate <90% and SNPs that deviated from Hardy-Weinberg equilibrium with $P<10^{-7}$. After removing individuals with a call rate <95%, we estimated ROH-based inbreeding coefficients for 4,749 cows with different SNP numbers. Milk data, pedigrees, and genotypes were kindly provided by the Holstein Cattle Breeders Association of The Czech Republic.

Calculation of relationship matrices and inbreeding coefficients. The pedigree-based additive relationship matrices, autosome A (Tier, 1990) and sex-chromosome A-sex (Fernando and Grossman, 1990), were estimated using our code. In contrast, the related inbreeding coefficient F_{PED} and $F_{PED\text{-}sex}$ were calculated from the diagonal of the relationship matrices (diagonal minus one). The genomic relationship matrices for autosomes (G) and sex-chromosome (G_X) were calculated using the first model proposed by VanRaden (2008). All ROH-based inbreeding coefficients (FROH>4Mb, FROH>8Mb, FROH>4Mb-sex, and FROH>8Mb-sex) were calculated using the approach described in McQuillan *et al.* (2008) and Curik *et al.* (2014). ROHs were estimated for each individual with the R package 'detectRUNS' (Biscarini *et al.*, 2019) using the consecutive method with the following parameters: maxgap = 2 Mb, minSNP = 15, one heterozygote and one missing allowed.

Estimation of inbreeding depression. Inbreeding depression was estimated by the following model:

$$y_{Milk} = HY_i + Month_j + b_1 Age + b_2 F_X + b_3 F_X\text{-sex} + cow_X + cow_{X\text{-}Sex} + e, \quad (1)$$

where HY is a fixed effect of Herd by Year of birth; Month is a fixed effect of birth month; b_1Age is a regression coefficient for cow age; b_2F_X is a regression coefficient for autosomal inbreeding coefficient (X is F_{PED}, $F_{ROH>4Mb}$ or $F_{ROH>8Mb}$); b_3F_X-sex is a regression coefficient for the sex-chromosome inbreeding coefficient (X is $F_{PED\text{-}sex}$, $F_{ROH>4Mb\text{-}sex}$ or $F_{ROH>8Mb\text{-}sex}$; cow_X is a random effect of cow for autosomes (X is autosomal relationship matrix, additive A or genomic G); $cow_{X\text{-}sex}$ is a random effect of cow for sex-chromosome (X is sex relationship matrix, additive A-sex or genomic G-sex); and e is a random residual effect. Our estimation followed the Bayesian inference approach using gibbs2f90 software (Misztal, 2003) with two parallel Gibbs sampling chains with 250,000 iterations, as described in Farkas *et al.* (2007). The convergence of the Gibbs sampling chains was analysed using the ARIMA procedures of the SAS software and additionally examined using the Z-criterion of the Geweke analysis (Geweke, 1992). The first 50,000 iterations (burn-in period) were shifted and only every 150th iteration (tinning) was sampled to reduce dependence between successive iterations. Descriptive statistics and graphical representations of posterior distributions were obtained using the tidyverse package collection (Wickham *et al.*, 2019) from Rstudio (R Core Team, 2019; RStudio Team, 2020).

Results & discussion

Descriptive statistics for milk yield and various inbreeding estimates are provided in Table 1. In contrast to the ROH-based estimates, where much higher estimates were observed for the sex-chromosome, lower estimated inbreeding was observed for the pedigree sex-chromosome. Variation in sex chromosomal inbreeding was always more variable than variation in autosomal inbreeding (Table 1).

The correlation of 0.534 was observed between pedigree inbreeding coefficients (F_{PED} and $F_{PED\text{-}sex}$), while very low correlations were observed between ROH-based inbreeding coefficients, 0.08 between $F_{ROH>4Mb}$ and $F_{ROH>4Mb\text{-}sex}$ and 0.05 between $F_{ROH>8Mb}$ and $F_{ROH>8Mb\text{-}sex}$. Such low correlations suggest that the effects of genomic inbreeding estimated from autosomes do not account for the deleterious load that may be present on the sex chromosome.

The distributions of estimates of inbreeding depression obtained by three models, each based on differently defined inbreeding coefficients, using the Bayesian inference approach are shown in Figure 1.

Table 1. Descriptive statistics of the milk production, inbreeding coefficients and pedigree quality.

Variable	Median	Mean	Range	SD[1]
Milk yield (kg)	9,902	9,925	4,852-15,315	1,768
F_{PED} (%)	6.1	6.3	0.9-23.1	1.8
$F_{ROH>4Mb}$ (%)	10.5	10.7	0.2-28.7	3.0
$F_{ROH>8Mb}$ (%)	6.8	7.1	0.0-25.5	2.7
$F_{PED-sex}$ (%)	4.2	5.2	0.2-29.8	3.5
$F_{ROH>4Mb-sex}$ (%)	20.0	22.0	0.0-78.6	10.7
$F_{ROH>8Mb-sex}$ (%)	6.3	9.2	0.0-74.2	11.8

[1] SD represents standard deviation.

[2] CGE is complete generation equivalent.

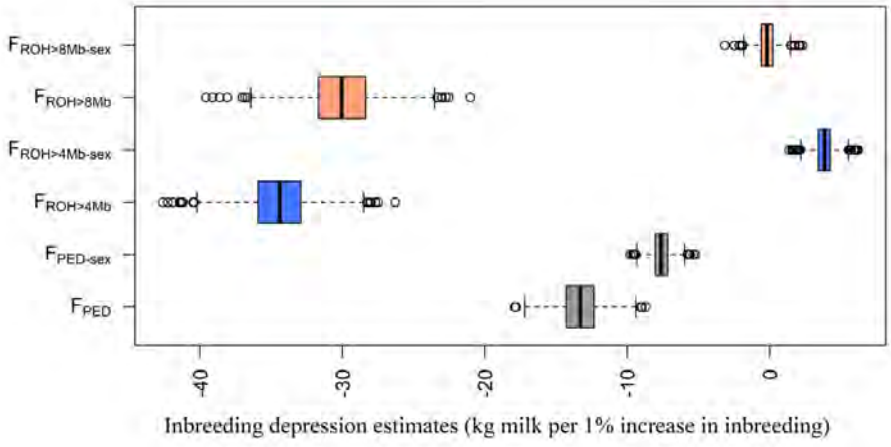

Figure 1. Box-plot distribution of estimates of inbreeding depression (Bayesian inference) resulting from three models, each based on differently defined inbreeding coefficients: (1) pedigree (F_{PED} and $F_{PED-sex}$); (2) ROH>4Mb ($F_{ROH>4Mb}$ and $F_{ROH>4Mb-sex}$); and (3) ROH>8 Mb ($F_{ROH>8Mb}$ and $F_{ROH>8Mb-sex}$).

According to Figure 1, significant inbreeding depression estimates for autosomes were observed in all three models (medians; bF_{PED}=-13.2 kg, $bF_{ROH>4Mb}$=-30.0, and $bF_{ROH>8Mb}$=-34.4 kg), while significant inbreeding depression was observed only for pedigree sex-chromosome estimates (medians; $bF_{PED-sex}$=-7.6 kg, $bF_{ROH>4Mb-sex}$=-0.1 kg, and $bF_{ROH>8Mb-sex}$=3.9 kg).

We were unable to explain the difference between pedigree and genomic estimates of inbreeding depression for the X chromosome. At the same time, little is known about the effects of inbreeding on X chromosome inactivation. Our knowledge of the interplay of inbreeding, selection, and accumulation of deleterious load on the X chromosome in animal populations is also insufficient. However, to our knowledge, this is the first estimate of inbreeding depression with respect to the X chromosome in livestock populations, and further research is needed to properly assess the potential negative consequences of X chromosome inbreeding in dairy cows.

Abstract

The genetic integrity of southern African Nguni ecotypes is under potential threat due to both indiscriminate crossbreeding and uncontrolled inbreeding. This study aimed to assess the transboundary genetic diversity and heterozygosity-rich regions of 192 South African (half stud, half research herds) and 96 eSwatini Nguni cattle. A set of 40,930 common single nucleotide polymorphisms (SNPs) were used to study their population structure and runs of heterozygosity (ROHet) profiles. Principal component analysis (PCA) and population structure (K=5) analyses illustrated genomic distinctiveness between South African (SA) and eSwatini (ES) populations, greater admixture for SA research (shared ancestry=0.631±0.353) compared to SA stud (shared ancestry=0.741±0.123), and three subpopulations for ES. The largest proportion (0.650) of the 935 ROHet segments fell within the 0.5-1 Mb length category. Overall, results illustrated that genetic distinctiveness resulted from geographic isolation and production strategies. Although no impending threat to genetic diversity was observed, further loss should be monitored to prevent possible ecotype endangerment.

Introduction

The Nguni cattle breed is classified as an indigenous Sanga breed (*Bos taurus africanus*) and a transboundary animal genetic resource that manifests unique adaptation abilities across distinct agroecological zones. Nguni cattle are known for their relatively low maintenance requirements (Musemwa *et al.*, 2010), longevity and high calving rates (Matjuda *et al.*, 2014), heat tolerance (Katiyatiya *et al.*, 2017) as well as resistance to ticks and tick-borne diseases (Mapholi *et al.*, 2014), which deem them adaptable to the diverse production environments characteristic of southern Africa. Accompanying the settlement of several ethnic groups in different geographic and climatic regions of southern Africa, distinct Sanga cattle ecotypes, phenotypically distinguishable by coat colour variations, developed over time (Bester *et al.*, 2003) which include the Shangaan, Pedi and Nkone (van Marle-Köster *et al.*, 2021).

In the early 1930's, South African (SA) Nguni cattle populations were classified as non-descript and an official breed society was only established in 1986. The SA Nguni is most popular in the regions with higher temperature and humidity in both commercial and smallholder production systems but has a relatively short history of animal recording and objective selection (van Marle-Köster *et al.*, 2021). In eSwatini (ES), Nguni are found in all six ecological regions of the country where they play a significant role in the economy of rural communities. The mandate of the four existing conservation and breeding stations changed in 1975 from conservation alone to a combined focus on conservation and improvement for beef cattle production. The improvement program consists of inter-crossing of the six different indigenous lines for multiplication purposes and up-grading of selected populations with exotic breeds that include the Angus and Brahman (Food and Agriculture Organization, 2004).

Uncontrolled breeding and the approved influx of exotic genetic material for crossbreeding and upgrading of indigenous populations is considered a threat to adapted local breeds, such as the Nguni. This study

aimed to assess the genetic diversity and heterozygosity-rich regions that exists both across countries (ES: eSwatini; SA: South Africa) and within-country (SA), between purebred stud animals (SA-S) and research herds (SA-R).

Materials & methods

Ethical approval was granted by the Ethics Committee of the Faculty of Natural and Agricultural Sciences, University of Pretoria, for the use of external data (EC-180000097) and written consent was provided by the University of eSwatini's UNESWA Research Board. Subsets of 96 SA purebred stud animals (SA-S), 96 SA animals from research stations (SA-R) and 96 eSwatini cattle from three governmental breeding stations (ES) were studied. Deoxyribonucleic acid (DNA) was extracted from hair (ES, and SA-S) and/or blood samples (SA-R). Post-quality control, 40,930 common, autosomal SNPs were retained after the exclusion of non-autosomal, unmapped and duplicated SNPs. Using PLINK software (Purcell *et al.*, 2007) exclusion of samples and SNPs was based on sample call rate (<90%), SNP call rate (<95%), low minor allele frequency (MAF<1%) and Hardy-Weinberg Equilibrium (HWE; P<0.001). Liberal linkage disequilibrium (LD) based filtering was additionally employed (r^2>0.5) before genetic relatedness and population structure analyses.

To assess the genetic relatedness, a genomic relationship matrix (GRM) was constructed using GCTA software (Yang *et al.*, 2011) and used in principal component analysis (PCA) to estimate eigenvectors. The cross-validation (CV) procedure was used to identify the most likely number of ancestral populations (K) in ADMIXTURE software (Alexander *et al.*, 2009). The K-value producing the lowest CV error was considered ideal and visualized with GENESIS software (Buchmann and Hazelhurst, 2014). Heterozygosity-rich segments were identified using the R package *detectRUNS* (Biscarini *et al.*, 2019) by executing the consecutive-SNP-based detection method (Marras *et al.*, 2015). A minimum of 10 SNPs and length of 10 kb was required to constitute a segment. The number of opposing (homozygous) and missing genotypes allowed were zero and two, respectively. In contrast to what is suggested by Meyermans *et al.* (2020) for ROH (i.e. no MAF filtering), MAF filtering was applied prior to runs of heterozygosity (ROHet) analyses to prevent underestimation of segment lengths as low-MAF SNPs tend to have homozygous genotypes, which may partition longer ROHet segments (i.e. more but smaller ROHet are identified). No LD filtering was applied prior to ROHet analysis.

Results & discussion

The PCA analysis (Figure 1a) indicated a clear separation of ES and SA populations, with more dispersion observed within the ES population than the overall SA population, and is consistent with a longer history of methodical within-breed selection for SA overall (since 1986) compared to a longer history of indiscriminate crossbreeding with exotic breeds for ES (since 1975). The tighter cluster observed for SA-S than SA-R supports more intense exposure to artificial selection and the utilization of high-impact animals across herds. Population structure results (Figure 1b) supported the clustering patterns depicted in the PCA. The ideal number of ancestral populations (K) estimated, with the lowest cross-validation error (CV=0.499), for the merged Nguni data set was five. The genomic composition of the SA Nguni population was largely derived from two ancestral populations, with SA-S being more uniform (mean proportion shared=0.741) and SA-R displaying a higher degree of admixture (mean±standard deviation proportion shared=0.631±0.353). The three distinct ancestral contributors observed for ES (shared genetics=0.404 for yellow, 0.249 for pink and 0.286 for green) supported the existence of three separate breeding lines (consistent with sampling), however, the degree of admixture illustrated increased crossbreeding across lines and individual ecotypes could be at risk of genetic erosion.

Runs of heterozygosity (ROHet) are genomic regions where diversity might be beneficial (e.g. adaptive traits) and may indicate balancing selection events (Biscarini *et al.*, 2020). The sum totals of ROHet

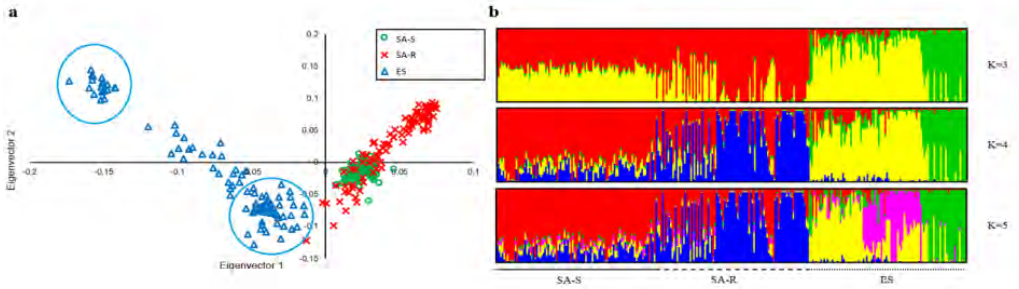

Figure 1. Genetic structure of southern African Nguni cattle, according to principal component analysis (a), and model-based clustering (b).

segments were 343, 309 and 283 for the ES, SA-R and SA-S populations, respectively, which was within the range of per-population numbers observed in other studies (e.g. 2 for Creolo from Guadalupe to 1,702 for Montana Tropical composite; Mulim *et al.*, 2021). The mean ROHet segment length was 0.63 megabase pairs (Mb) across the three populations. Albeit complex to compare (due to differing criteria for defining ROHet segments), the mean length was similar to a mean ROHet length of 0.70 Mb reported by Biscarini *et al.* (2020) for semi-feral Maremanna cattle. Similar to the afore-mentioned authors, and depicted in Figure 2, the 0.5-1 Mb length category ranked the highest in terms of mean proportion of ROHet segments (0.650 across populations). The most prevalent consensus ROHet segment was identified only in the SA-R population and encompassed 26 *Ensembl* (https://www.ensembl.org/index.html) protein-coding genes assembled to the ARS-UCD 1.2 cattle assembly. The 0.35 Mb ROHet region on BTA18 (base pair position range: 34,817,149-35,163,513), present in 19.5% of the SA-R animals, includes genes that may play a role in cilium biogenesis (e.g. *ATP6V0D1*), cellular response to starvation (e.g. *RIPOR1*) and phagocytosis (e.g. *ELMO3*). Identifying regions of conserved genomic diversity may be advantageous in characterizing adaptive traits and the identification of shared ROHet segments in regions containing, for example, immune response related genes may facilitate better elucidation of disease resistance, which is one of the proxy-indicators of adaptive ability (Mulim *et al.*, 2021). These results should, however, be interpreted with caution and a larger data set, in terms of sample size and marker density (or whole-genome sequencing), is expected to provide improved resolution.

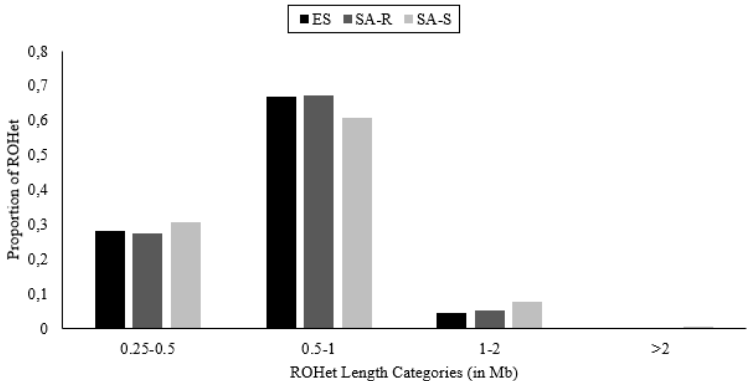

Figure 2. The proportion of heterozygosity-rich segments (ROHet), within different length categories, identified for eSwatini and South African Nguni cattle.

Conclusions

The genomic information proved useful to provide insight into the genomic diversity and heterozygosity-rich regions among the three Nguni populations. The SA and ES populations could be distinguished as separate clusters and require further investigation for potential ecotypes. Breeding strategies for ES populations should be monitored to prevent genetic erosion of subpopulations. Higher resolution genomic profiling (e.g. with whole-genome sequencing information) of a broader spectrum of Nguni populations, in both countries, will provide a more comprehensive picture of the genes included in consensus ROHet region(s). These regions of conserved genome-level variability may pinpoint genes that will assist in better describing the Nguni's adaptive mechanisms (e.g. disease resistance).

Abstract

We developed infographics explaining inbreeding and genetic management for breeders, breeding organisations and the general public. Infographics are illustrations combined with text to obtain clear communication and understanding of concepts. The infographics consisted of three parts: (1) what is inbreeding and what are the consequences; (2) how to manage inbreeding for animal breeders and owners; (3) how to manage inbreeding for breeding organizations. The infographics can be downloaded for free and are available in several languages.

Introduction

Genetic diversity is vital for animal populations to respond to selection and adapt to changing environments. Many breeds, however, have become small in number, with the associated risk of loss of genetic diversity and a parallel increase in inbreeding. This implies potential detrimental consequences such as inbreeding depression and expression of genetic defects. Many breeds, especially in Northern Europe, are managed by small holders and hobby breeders. In these cases, their breeding organisations are often run by volunteers without a professional education in animal breeding. Even though other rare breeds, especially in Southern Europe, are kept at professional farms, inbreeding and kinship are concepts that are difficult to fully grasp. Consequently, there is a great need for information for non-professionals and professionals on how to manage genetic diversity, inbreeding and relationships.

Genetic management is riddled with pitfalls and misunderstanding. For example, many breeders do not realise that inbreeding is not heritable and that a ban on breeding with inbred animals is, therefore, unnecessary. At the same time it can be a challenge to explain why breeders should not all go for a superior sire in terms of the breed standard, top production or championships. These superior sires tend to be highly related which is a threat for the breed in the long term. On the other hand, an explanation on the use of the mean kinship (MK) of an animal with all other animals in the breed can be an eye-opener, leading to better management and maintenance of genetic diversity in the long term.

The theory of what inbreeding is and its relation to genetic diversity, the occurrence of genetic defects and inbreeding depression is well developed in population genetics (Falconer and Mackay 1996, Frankham *et al.* 2010, Lynch and Walsh 1998). Moreover, guidelines have been developed on how to manage populations (e.g. FAO 2013). This, however, is a vast body of material directed towards professional researchers and breeders. A comprehensive summary targeted to a broad audience is needed to reach practitioners and policy makers. To do so, we have developed some infographics that explain principles and practices with colourful graphics that are attractive to read.

Development of the infographics

Infographics are visuals (such as illustrations) combined with text to obtain clear communication on complicated matters. The infographics were developed in cooperation with a professional company specialised in visual communication. The aim of infographics is to inspire the viewer and reader to gain new insights and draw practical conclusions. In order to do so, good infographics take into account how the human brain works to distinguish and to group objects guided by their colour and by the background. The general reading direction in Western culture from left to right and top to bottom is important as well for the design of infographics.

The set of infographics were developed in a process that combined the expertise of the population geneticists with the designers of the agency. First, to get the designers acquainted with the problem, explanations such as those used by the population geneticists over the years for training students and breeding organisations were presented and discussed. Next, all relevant information on the topic was analysed and filtered to keep only the essential concepts. Next, initial sketches were made, texts added, discussed and adapted and, finally, the design was elaborated in full colour.

The first set of infographics was produced in Dutch and presented in an on-line series of seminars for an audience of animal breeders, breeding organisations and other people interested in breeding and inbreeding. Next, the infographics were translated into English, in consultation with experts from different countries. Currently versions in other languages are in preparation.

Structure of the infographics

The information was split into three infographics (Figure 1) in order to avoid too dense information to better communicate the most important messages towards three different target groups. The first infographic describes the basics of inbreeding and is targeted to anyone interested in inbreeding. The second infographic is targeted to animal owners and breeders and shows how to deal with inbreeding at the level of individual selection and mating. The third infographic is targeted to breeding organisations and population managers and visualizes how to deal with inbreeding and relationship at the population level.

Infographic 1: basics of inbreeding. The basic rule that an animal receives half of its DNA from the mother and the other half from the father is the starting point of this infographic. The definition of inbreeding is given and the fact that inbreeding leads to more homozygosity and less diversity is illustrated as well. Furthermore, the problem of recessive genetic defects is treated and why inbreeding can lead to their expression explained. Finally, examples of traits affected by inbreeding depression and common genetic defects are illustrated.

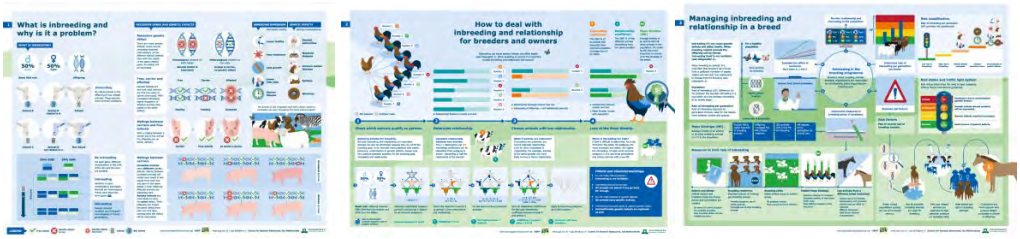

Figure 1. Thumbnails of infographics in English.

Infographic 2: managing inbreeding for breeders and owners. How to choose mates is the main question breeders and owners are faced with, when it comes to managing inbreeding. A flow chart is presented to illustrate the steps to take. It starts with a hen and seven roosters from which its mate can be chosen. Some mates may be unsuitable, because of other reasons besides inbreeding (such as health and breeding goal), and these are discarded in step 1. In step 2 relationship coefficients are determined. At this point, to facilitate the comprehension, the calculation of inbreeding and relationship coefficients is illustrated in the lower part of the infographic. In step 3 mates with a high relationship coefficient (i.e. between close relatives) are discarded. And in the 4th and final step an extra factor is introduced which makes the animal with a low MK to be favoured and chosen. The infographic ends by pointing out four common pitfalls or misunderstandings around inbreeding and providing the correct interpretation.

Infographic 3: managing inbreeding at population level. The information for population managers and breeding organisation is based on the cycle used in animal breeding education (Oldenbroek and De Waay, 2015) with the following steps: (1) Monitor the population by determining average inbreeding and relationship coefficients. (2) Determine the inbreeding rate (ΔF) per generation. (3) Analyse risk factors for the population. (4) Take measures and set up rules to counteract risk factors. (5) Set up communication. (6) Evaluate results. The inbreeding rate is the main indicator tool here, which is illustrated with a traffic light in vibrant colours for each of the categories (Table 1). The term effective population size is avoided because this generally gives a lot of confusion, requiring lengthy explanation to make general public aware of the fact that census size is only one, and often a minor, factor determining effective population size. Instead, risk factors for high inbreeding rates are illustrated. Possible actions to decrease inbreeding rates, such as the use of MKs and a breeding circle, are illustrated as well, with special emphasis on MKs as this is one of the most effective tools.

Discussion

Frequently, there is a rather incomplete understanding of inbreeding. This can lead, on the one hand, to attributing everything that is wrong to inbreeding and, on the other hand, to a denial of any detrimental effect of inbreeding. Consequently, this has led to heated debates and even splitting of breeding organisations of already small populations. The infographics are designed to increase the knowledge of breeders and breeding organisations. The use of social media and other actions may enhance their distribution even further. Evaluation of the effect of infographics on the practices of breeders and breeding organisations will be a next step.

Infographics may be useful for other concepts in animal breeding that are used widely but not always well understood by the general public. Examples can be breeding against diseases or genomic selection. The development of infographics also forces the designers and scientists to evaluate what are the core concepts needed for a proper understanding of the issue, and as such can be a useful exercise for teachers and students as well.

Table 1. Risk assessment based on inbreeding rate.

ΔF per generation	Assessment	Risk	Colour
>1%	Critical	Extinction due to accumulation of genetic defects	Red
0.5-1%	Endangered	Genetic defects almost certainly will be expressed	Orange
0.25-0.5%	Vulnerable	Genetic defects might be expressed	Yellow
<0.25%	Normal	Small chance of genetic defects	Green

Conclusions

The infographics clearly fill in a gap. In the Netherlands, they were readily picked up and links soon appeared after the introduction on websites of several breeding organisations. Three video presentations were made containing elements of the infographics, the first one about the basics of inbreeding has (12/12/2021) over 500 views on YouTube (https://youtu.be/OSzCsI4UOjs). This shows the need for this information and that the developed infographics turned out to be really helpful to get the message across.

The infographics can be downloaded from www.fokkenmetverstand.nl (Dutch) and the ERFP website https://www.animalgeneticresources.net/index.php/publications/ (English). At the time of writing, other languages are in preparation, and links will be made available on the ERFP website.

Acknowledgements

Development of the infographics was financially supported by the Dutch Ministry of agriculture, nature and food quality (projects KB-34-013-002 and WOT-03-003-056) and the European Regional Focal Point for Animal Genetic Resources (ERFP). We also would like to thank Eline de Kool for translating most parts from Dutch to English and Marleen Hijlkema for initial discussions on the set up of the infographics.

Abstract

By its paternal transmission, Y-chromosomal haplotypes are sensitive markers of population history and male-mediated introgression. We used whole-genome sequences (WGSs) of 386 domestic goats from 75 modern breeds and 7 wild goat species generated by the VarGoats goat genome project. Phylogenetic analyses indicated five domestic haplogroups Y1AA, Y1AB, Y1B, Y2A and Y2B. Haplogroup distributions for 180 domestic breeds indicate ancient paternal population bottlenecks during the migration into northern Europe, southern Asia and Africa. Sharing of haplogroups reveals male-mediated introgressions: from Asia into Madagascar and, more recently, into the South-African Boer goat; then from this breed into other southeastern African goats; and from Europe into native Korean and Ugandan goats. This study illustrates the power of the Y-chromosomal variation for the reconstructing the history of domestic species with a wide geographic range.

Introduction

The genetic diversity of goats has been reported to show a weak phylogeography of the mtDNA (Luikart *et al.*, 2001), but a strong geographic partitioning of the autosomes (Amills *et al.*, 2017; Colli *et al.*, 2018; Zheng *et al.*, 2020). This is in sharp contrast to similar studies of sheep (Kijas *et al.*, 2012; Ciani *et al.*, 2020), but has been confirmed by studies of ancient DNA (Daly *et al.*, 2022). However, the goat Y-chromosome as a marker for the paternal lineages has not yet been studied at a worldwide scale. For many species, Y-chromosomal variants have proved to be highly informative markers for paternal origin, which generally show a much stronger phylogeographic differentiation than mitochondrial or autosomal variants (Jobling and Tyler-Smith, 2017).

Previous analyses of Y-chromosomal diversity in European and Asian goats on the basis of low number of SNPs defined four haplotypes Y1A, Y1B, Y2A and Y2B, which have a strong geographic differentiation (Lenstra and the Econogene Consortium, 2005; Tabata *et al.*, 2018). Here, we use WGS data from the VarGoats project for a broad sample of European, Asian and African goats in order to define the major haplogroups, their phylogeny and the relationships with haplotypes from Iranian and Anatolian bezoar. After combining with data from other sources, we characterize the phylogeographic patterns across the three continents. We present evidence for population bottlenecks during the ancient migration of domestic goat and for more recent introgressions within and between continents.

Materials & methods

We extracted SNPs from four contigs in the male-specific part of the Y-chromosome, which after quality control were used for constructing Neighbour-Joining (NJ) trees and a Median-Joining Network of bezoars and domestic goats. We identified Y-chromosomal haplogroups for 2,214 goats on the basis of: (1) the VarGoats WGS data; (2) dideoxy sequencing of DNA segments covering SNPs that are diagnostic for the haplogroups; (3) published data for French, Swiss, Turkish and South-Asian goat breeds; (4) KASP genotyping of diagnostic SNPs; and (5) SNP alleles extracted from WGS data.

Results

Neighbour-Joining phylogenetic trees (not shown) and a Median-Joining Network (Figure 1) on the basis of the VarGoats data gave completely consistent patterns of clustering and show five domestic haplogroups that correspond to the previously found haplotypes: Y1AA, Y1AB (both representing a distinct cluster of Y1A haplotypes), Y1B, Y2A and Y2B. All domestic haplotypes differ from the Iranian or Anatolian bezoar haplotypes, which also differ from each other. The bezoar haplotypes are associated with the domestic Y1AA (CaY1AA) or Y2B (CaY2B) clusters, are linked to the Y1 or Y2 roots (CaY1 and CaY2) or are between the Y1 and Y2 haplogroups (Y0, in the NJ tree close to the root).

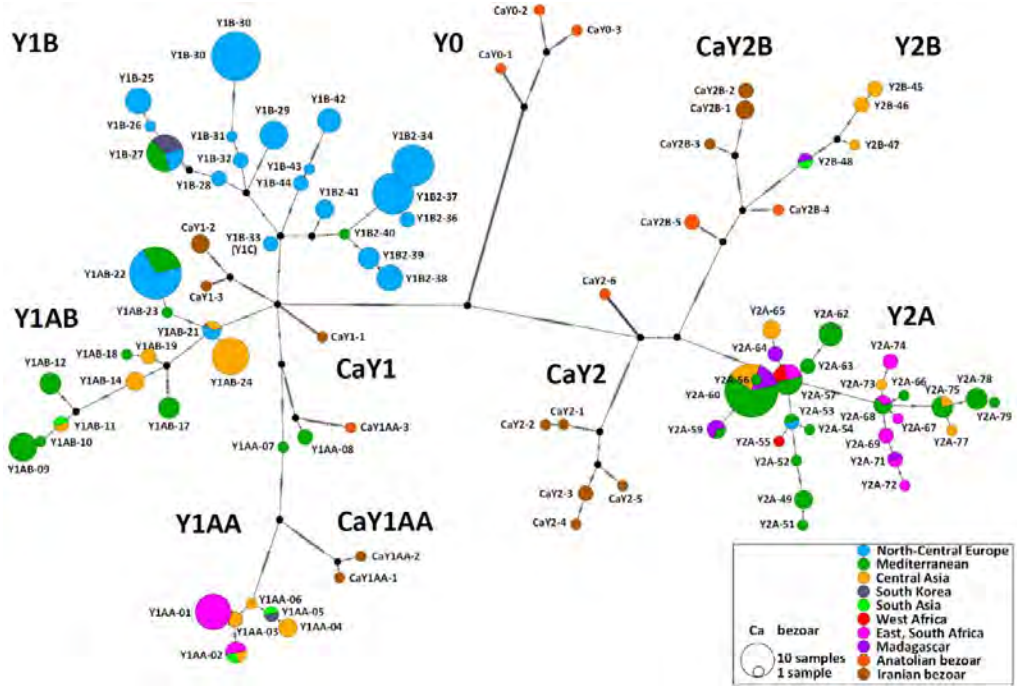

Figure 1. Median-Joining Network of 286 male domestic goats and 27 bezoars.

The network further shows a remarkable geographic differentiation:

1. Haplogroup Y1B is predominant in central and northern Europe, but is also found in South Korea and Uganda.
2. Y2A is almost absent in central and northern Europe, but is the predominant haplogroup in Spain, Anatolia and Africa. The British Anglo-Nubian (not shown) carries Y2A and Y1AA because of its Asian and African ancestry. Remarkably, most Y2A haplotypes on Madagascar are more related to Asian than to continental-African Y2A haplotypes.
3. Y2B does not occur in Europe, continental Africa or west Asia, but is a major haplotype in east and southeast Asia. It was also found in a single goat from Madagascar.
4. Y1AA is sporadic in Europe, but is a major lineage in Asia. Two Y1AA haplotypes in East and South Africa are closely related to Asian haplotypes. This reflects the Asian ancestry of the popular Boer breed, which has been crossed into other southeastern African goats.

Discussion

We propose that the phylogeographic pattern is the result of ancient population bottlenecks and recent introgressions (Figure 2). The Y-chromosomal link between Madagascar and Asia is in line with the genomic composition of the Malagasy zebu (Magnier *et al.*, 2022) and the Austronesian origin of the Malagasy language.

We conclude that the Y-chromosomal variation of goats reveals bottlenecks, expansions and introgressions, illustrating the power of Y-chromosomal markers for inferring the genetic origin of mammalian populations.

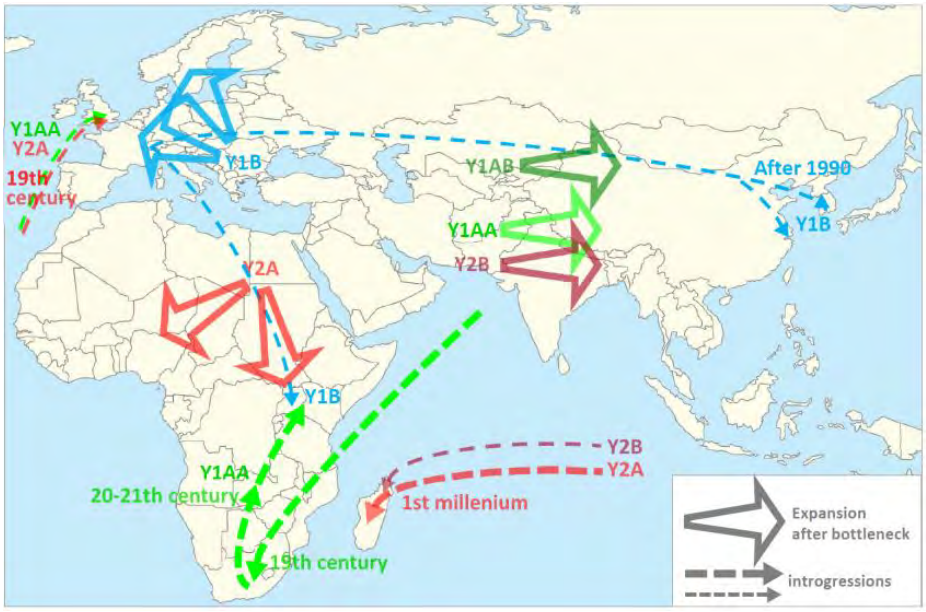

Figure 2. Bottlenecks, expansions and migrations inferred from the distribution of Y-chromosomal haplotypes.

Abstract

The objective of this study was to evaluate the effect of inbreeding, through pedigree and genomic-based inbreeding coefficients, on the selection (postweaning) weight (WSel), scrotal circumference (SC), and days to calving (DC) and to evaluate the effect of recent and ancient inbreeding in these traits in Nellore cattle. A total of 1,446 animals genotyped was used. Individual inbreeding coefficients were estimated based on pedigree (FPED), runs of homozygosity (ROH, FROH) and diagonal of the H matrix (pedigree-genomic relationship matrix) (FH). For each 1% increase in FPED, FROH and FH a decrease of 1.29, 1.27 and 1.31 kg in WSel and an increase of 1.48, 1.35 and 0.55 days in the DC were observed, respectively. However, there were no clear patterns of the effect of inbreeding in the SC. Especially for DC, ancient inbreeding was less harmful compared to recent inbreeding. In conclusion, inbreeding negatively affects postweaning weight and female fertility trait in Nellore cattle.

Introduction

Mating between related animals increases the proportion of homozygous genes associated with inbreeding, which can lead to inbreeding depression (Doekes *et al.*, 2021). Inbreeding coefficient (F) is commonly used to describe the proportion of autozygosity in an individual's genome and can be estimated from pedigree information or genomic data (e.g. Ferenčaković *et al.*, 2013).

The objective of this study was to assess the estimated inbreeding levels in an experimental herd of Nellore cattle, by using three methods. In addition, the effect of inbreeding on the selection (postweaning) weight (WSel), scrotal circumference (SC) and days to calving (DC) and the effect of recent and ancient inbreeding was evaluated.

Materials & methods

All management procedures followed animal welfare guidelines and were conducted in accordance with the State Law No. 11,977 of the State of São Paulo, Brazil. The database refers to Nellore cattle from a selection experiment established in 1980 at the Institute of Animal Science (IZ), Beef Cattle Research Center, Sertãozinho, SP, Brazil (Benfica *et al.*, 2020).

Genomic data of 1,446 animals born from 1983 to 2019 were available, with 757 animals being genotyped with GGPHD 75K (GeneSeek® Genomic Profiler Indicus) and 689 with HD (High-Density Bovine BeadChip, Illumina Inc., San Diego, CA) panels. Genotypes obtained with the lower density panel were imputed to the high definition (HD) panel using the FImpute v.3 software (Sargolzaei et. al., 2014). Quality control (QC) was performed by excluding SNPs with no defined position or located on the sex chromosomes, with a call rate lower than 0.85, and the SNPs that deviate from Hardy-Weinberg expectation ($P<1\times10^{-5}$). After QC a total of 612,154 SNPs were available. Pedigree file included 3,075 animals (378 bulls and 1,510 dams) and 8 generations. The traits considered were the selection (postweaning) weight adjusted to 378 days of age for

R.F. Veerkamp and Y. de Haas (eds)

males and postweaning weight adjusted to 550 days of age for females (WSel), the scrotal circumference at yearling (SC), and the repeated days to calving considering all breeding seasons in which the female participated (DC). Days to calving were obtained for all females that calved as the difference between the calving date and the date of the beginning of that breeding season. Cows that did not calve were penalized by adding 21 to the largest days to calving value within the breeding group (Ferreira Júnior *et al.*, 2018).

Three methods were used to calculate the inbreeding coefficient: Pedigree-based inbreeding coefficient (FPED) was calculated using the BLUPF90 family programs (Misztal *et al.*, 2009). Plink 2.0 software (Purcell *et al.*, 2007) was used to identify the ROH. Following criteria were adopted to define a ROH: a minimum physical length of 1 Mb; a maximum gap of 500 kb between two successive SNP; a minimum of 50 consecutive homozygous SNP and a minimum density of one SNP per 100 kb. After identification, the ROH were classified into five length classes: (1) 1-2 Mb (FROH1); (2) 2-4 Mb (FROH2); (3) 4-8 Mb (FROH3); (4) 8-16 Mb (FROH4); and (5) >16 Mb (FROH5). These length classes indicate inbreeding resulting from ancient to most recent ancestors. A total inbreeding coefficient based on all ROH classes (FROH) was also estimated. Inbreeding coefficient based on pedigree-genomic relationship matrix (FH) was obtained by diagonal of the matrix H minus 1 (Legarra *et al.*, 2020) using preGSf90 (Misztal *et al.*, 2009).

The effect of inbreeding on phenotypes was estimated using BLUPF90 family of programs (Misztal *et al.*, 2009) including inbreeding coefficient as a linear covariate in single-trait analysis. The model for WSel was previously described by Benfica *et al.* (2020), and the models for SC and DC were described by Ferreira Junior *et al.* (2018).

Results

Descriptive statistics for the traits evaluated are in Table 1. Pearson correlations between all estimated inbreeding coefficients are presented in Figure 1A. The correlation coefficients between pedigree-based inbreeding and genomic-based inbreeding were moderately high, of 0.62 (FPED × FROH) and 0.58 (FPED × FH). The highest correlation was observed between FROH and FH (0.77). Classical estimates of inbreeding (FPED, FROH, FH) and FROH classes were positively and moderately correlated, however inbreeding based on smaller ROH segments were weakly correlated with inbreeding based on larger ROH segments.

The variation of the three inbreeding estimates, FPED, FROH and FH, over the years of selection for postweaning weight, and more recently for postweaning weight and feed efficiency (Benfica *et al.*, 2020) were shown in Figure 1B. FPED showed an increasing tendency over the years from 1982, during the first decade of the selection experiment. A greater number of inbreeding events was captured by ROH that kept mean values higher than the other inbreeding measures.

The regression coefficients of inbreeding effect are shown in Table 2. In general, inbreeding depression was observed for WSel and DC, but not for SC.

Table 1. Number of animals (and records) (N), mean, standard deviation (SD), minimum and maximum values for selection (postweaning) weight (WSel), scrotal circumference (SC) and days to calving (DC).

Trait	N	Mean	SD	Min	Max
WSel, kg	1,446	354	53.0	136	512
SC, cm	982	23.1	2.72	14.5	32.5
DC, day	452 (1,604)	344	33.6	263	417

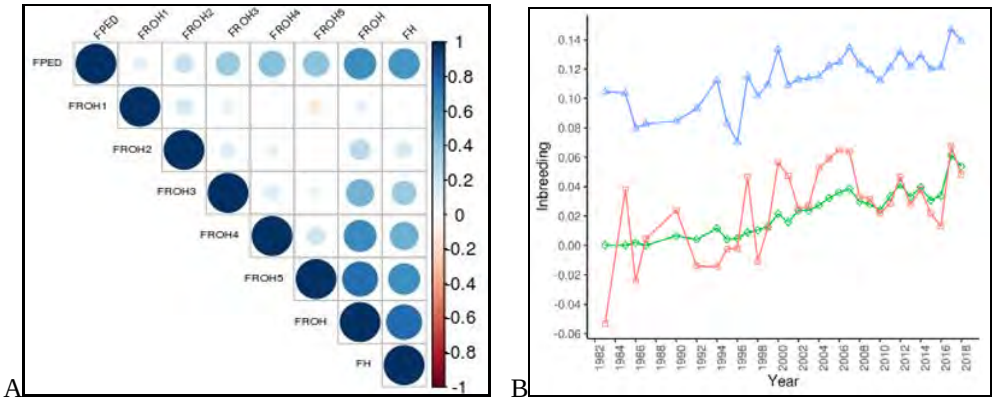

Figure 1. (A) Pearson's correlations between inbreeding measures; (B) Mean of FPED (green), FROH (blue) and FH (red) by year of birth.

Table 2. Estimates of inbreeding depression for selection (postweaning) weight (WSel), scrotal circumference (SC) and days to calving (DC), expressed as the change in phenotype per 1% of increasing in inbreeding.

Inbreeding method[1]	Trait					
	WSel, kg		SC, cm		DC, day	
	Estimate	SE	Estimate	SE	Estimate	SE
FPED	-1.29	0.85	0.09	0.07	1.48	0.84
FROH1 (0-2 Mb)	0.19	2.96	-0.39	0.24	-4.28	3.07
FROH2 (2-4 Mb)	-4.16	1.83	-0.11	0.14	-2.59	2.01

FROH (total)	-1.27	0.37	-0.03	0.03	1.35	0.42
FH	-1.31	0.30	-0.001	0.02	0.55	0.33

[1] FPED: pedigree-based inbreeding; FROH: inbreeding based on runs of homozygosity; FGRM: inbreeding based on genomic relationship matrix.

Discussion

In the present study, as well as in previous studies (Doekes *et al.*, 2019; Makanjuola *et al.*, 2020), FPED was moderately to highly correlated with FROH. The higher correlation between FPED and FROH5 may be a direct reflection of pedigree depth, as ROH reflect past and recent relatedness and FPED estimates are based on pedigree records, which may not extend back many generations (Ferenčakovic *et al.*, 2013).

The inbreeding age can be derived from the length of ROH, with shorter lengths reflecting more ancient inbreeding, as it has already gone through the process of breakdown and recombination. Theoretically, ancient inbreeding should be less harmful, as a decrease in the frequency of deleterious alleles over time is expected as a result of natural selection (Doekes *et al.*, 2019; Makanjuola *et al.*, 2020). For WSel trait, there was no clear difference between effect of long ROH (recent inbreeding) and short ROH (ancient inbreeding). For DC, the results are in accordance with theory and ancient inbreeding even caused a favorable result in the trait, reducing the number of days to calving. Overall, both long and short ROH appear to contribute to inbreeding depression.

Inbreeding influenced the reproductive performance of females. Increasing 1% in FPED, FROH and FH increased 1.47, 1.35 and 0.55 days in DC. Martikainen *et al.* (2017) reported a 0.4 day increase in interval between inseminations for 1% increase in FROH of dairy cows. Overall, the increase in inbreeding had an unfavorable effect on productive and fertility traits, except for SC. Recent inbreeding is more harmful for female fertility trait than ancient inbreeding. Hence, the management of inbreeding should be highlighted in breeding programs for Nellore cattle.

Abstract

Due to that Czech indigenous goat breeds, together with Slovak indigenous goat breeds, are closed population, face this population loss of genetic diversity, because these populations are closed. The aim of this study was to perform a genome-wide diversity characterization using Illumina GoatSNP50 BeadChip of indigenous Czech Braun Shorthair and White Shorthair goat breeds together with international Alpine goat from Czech Republic and indigenous White Shorthair goat breed from Slovak Republic. For comparison was in this analysis included indigenous alpine goat breed from Austria and Switzerland. To determine key conservation risk parameters, we estimated inbreeding (F_{ROH}) and current and historical effective population size (Ne). The observed estimates for Czech and Slovak indigenous breed show similar values as other alpine goat breeds. In addition, by comparing genetic differences by Neighbour-net, no differences were recorded between the Czech-Slovak WSG. The study provides data and information utilizable in the management of conservation programs planned to reduce inbreeding and to minimize loss of genetic variability.

Introduction

The main aim of the conservation of the livestock population is maintaining genetic diversity. This is mainly because about one-fifth of livestock breeds became extinct during the second half of the twentieth century and a large part of these breeds are endangered (Hodges 2006). Much of the lost genetic variability was mostly unknown and undocumented (Bruford *et al.*, 2003). For these reasons, it is necessary to study and documented genetic diversity by local breeds, which can be used in future breeding with commercial breeds, especially when future breeding goals differ from those of today (Woelders *et al.* 2006).

White Shorthair goat (WSG) and Brown Shorthair goat (BSG) are local breeds of domestic dairy goats from the Czech and Slovak Republic. The WSG was created by crossing the native Czechoslovak landrace goats crossed with Saanen goats from Switzerland and Germany. The BSG was created by crossing the Czech native breed with non-uniform colour with German Brown bucks in the period between 1900 and 1930, mainly in the Czech-German borderlands.

The aim of this study was to analyse the genetic diversity and conservation status of Czech and Slovak native goat breed.

Materials & methods

Data collection and genotyping. Our dataset, contained samples of two Czech indigenous breeds Brown Shorthair (CZ_BSG) and White Shorthair (CZ_WSG), one international breed Alpine goat (CZ_A) collected in the Czech Republic and one Slovak indigenous breed White Shorthair (SK_WSG) collected in the Slovak Republic, we genotyped 121 individuals. In addition to our original data, the dataset of Austria and Switzerland was used. The five breeds from Austria (Blobe – AT_BLB, Chamois Coloured – AT_CHA,

R.F. Veerkamp and Y. de Haas (eds)

Pinzgau – AT_PNZ, Styrian Pied – AT_STP, Tauern Pied – AT_TAP) and ten Switzerland were: (Appenzell – CH_APP, Grisons striped – CH_GST, Chamois Coloured – CH_CHA, Nera Verzasca – CH_NVR, Peacock – CH_PEA, Saanen – CH_SAA, Booted – CH_BOT, Tessin grey – CH_TSG, Toggenburg – CH_TGB, Valais – CH_VAL) In these breeds a historical admixture with Czech-Slovakia indigenous breeds is expected. The animals were genotyped with the Illumina goat SNP50 BeadChip. Data cleaning was performed using software PLINK 1.9 (Chang *et al.*, 2015) to select only common autosomal SNP markers with known chromosomal positions. Then, only animals and common autosomal SNP markers with a call rate higher than 95% across all breeds were retained in the database.

Runs of homozygosity inbreeding. Runs of homozygosity (ROH) segments were detected using detectRuns (Biscarini *et al.* 2018). The ROH segments were defined with a specific minimum length (>4 Mbp, >8 Mbp) reflecting different generations of ancestors in the past. The different proportions of missing calls within homozygous regions were allowed depending on the ROH length class (>4 Mbp 1 call, >8 Mbp 2 calls). No heterozygous call was allowed for all ROH segments.

Population structure and gene flow. Inference of the phylogenetic relationship between 20 goat breeds was represented as the Neighbour-net network inferred from pairwise Nei's genetic distances (Nei, 1972). Nei's distances were calculated using the R package StAMPP R (Pembleton *et al.*, 2013). A NeighborNet network was created and represented using SplitsTree4 software.

Results

Genotype data of Alpine goat breed with a substantial number of genotypes available were selected to compare the genetic diversity of Czech and Slovak native goat breeds.

The relatedness between analysed breeds was evaluate by Neighbour-net (Figure 1) based on pairwise Nei's genetic distances. As expected, the results showed that CZ_WSG and SK_WSG create together separated cluster within the main reticulation. The CZ_BSG create separate cluster on separate reticulation. The CZ_A created cluster together with AT_CHA and CH_GST.

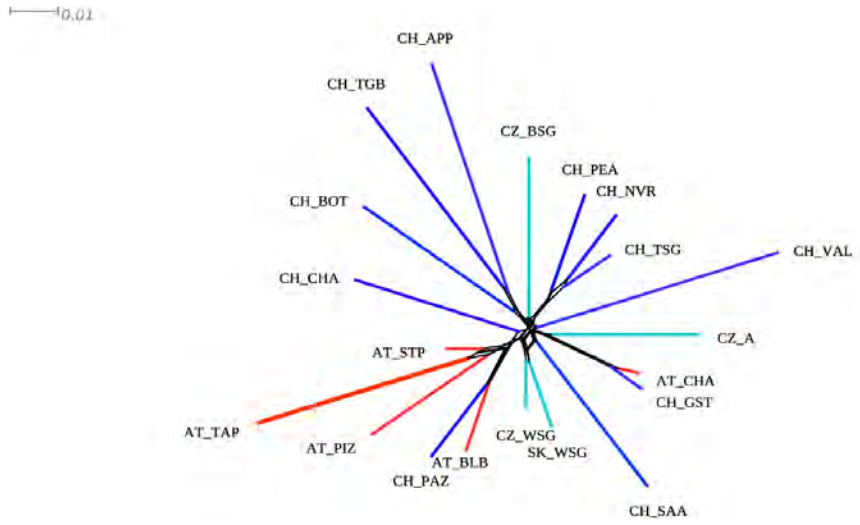

Figure 1. Neighbour-Net graph of Nei's distances between breeds. Each color represent one country: Austria, Czech and Slovak Republic, Swizerland.

The estimation inbreeding coefficient based on ROH>4 and >8 Mb and effective population size across Czech and Slovak native goat and representative Apline goat breed from each cluster are presented in Table 1. While Czech breeds have a higher value of current and historical inbreeding in comparison with other breeds. For Slovak goat breeds was estimated two times the lower value of both inbreeding with comparison to the same breeds keep in the Czech Republic. The highest value of inbreeding from Czech breeds based on different length of ROH was estimated in BSG and the lowest value in WSG. The overall highest value of inbreeding was observed in the AT_TAB breed. The highest value of inbreeding based on a short length of ROH ($F_{ROH>4Mb}$) points to more frequent mating of related individuals in the history than in current breeding.

The estimates of current effective population size indicate that analysed populations are not at risk of loss of genetic diversity. The lowest value of the current population size of Czech and Slovak native goats was found in breed SK_WSG (N_e=127) and the highest in breed CZ_WSG (Ne=267). A comparison of the current Ne and Ne 10 generations ago shows that most breeds have decreased Ne. On the contrary, in breeds CZ_BSG there was an increase in the effective size of the population.

Discussion

The study of genetic diversity in Czech and Slovak native goat breeds confirm that breeds are affected by the loss of genetic diversity, especially CZ_BSG. The estimated genomic inbreeding coefficient (FROH) of Czech native breeds, show a higher value than the inbreeding coefficients estimate based on pedigree data (CZ_WSG – 0.02 and CZ_BSG – 0.05, Vostra-Vydrova *et al.*, 2020). Contrariwise, the current effective population size estimated in this analysis shows a smaller value than Ne estimated on pedigree data (311-CZ_WSG and 87 – CZ_BSG). Thy higher N_e value of CZ_BSG compared with CZ_WSG and SK_BSG are affected by a smaller number of individuals of analyzed the breed. Increased Ne by CZ_BSG is affected by expected improving other breeds during 10 generation ago.

Our study points to tendency clustered CZ_WSG and SK_WSG between Austria and alpine goat. The Neighbour-net indicated the close genetic distance between CZ_WSG and SK_WSG breed and higher distance of CZ_BGB and Czech and Slovak WSG. This higher similarity between WSG depends on the

Table 1. Inbreeding coefficient, effective population size and number of animals for Czech and Slovak native breeds and selected Alpine breeds.

[1] Standard deviation.

historical development of these breeds. Until 1993, breeds CZ_WSG and SK_WSG were considered as one breed. After the division of Czechoslovakia were these breeds split into two populations. The close relatedness between CZ_WSG, SK_WSG and CH_SAA presented by Neighbour-net confirms the expectations that CH_SAA was used for improvement of the WSG in the past. The study provides data and information utilizable in the management of conservation programs planned to reduce inbreeding and to minimize loss of genetic variability.

211. Population structure of U.S. Holsteins allows for a snapshot of allele frequency changes and family specific SNPs

Abstract

Genetic change occurs in the U.S. Holstein population through the heavy use of specific bulls for a relatively short period of time. By focusing on a specific time-period, we were able to group a high percentage of the descendants of several prominent bulls into five different clusters. The average F_{st} across clusters was 0.03. Comparison between clusters revealed a heterogeneous mixture of allele frequency changes with varying degrees of magnitude and direction. Non-parallel responses between families suggests alternative goals and/or non-additive gene action. SNP effects for the trait stature were estimated independently for the five clusters and used to predict additive breeding values (BV). Correlations of within-cluster BVs with BVs based upon all animals combined varied from 0.70 to 0.88. By stratifying a population into subpopulations, family specific SNPs can be identified and used to increase or maintain genetic diversity.

Introduction

A top dairy bull can have tens of thousands of daughters and an even larger number of granddaughters. These family members, with similar degrees of relationship, appear at different time periods. For example, the first group of descendants of a young prominent bull will be his daughters. They have an additive genetic relationship of 0.5 with their sire. After another year or two, the sons of this prominent bull will start producing granddaughters, and there will be a mixture of both daughters and granddaughters in our population. And after another couple of years, the additive genetic relationship will drop to 0.25 as almost all the living descendants will be granddaughters. As we move through time, the average relationship of this prominent bull with our active breeding population will decrease as his descendants become more distant.

K-mean clustering results in animals with similar relationships being grouped together. By focusing on a specific time-period, the descendants of certain bulls are clustered together. That is the progeny of the most prominent young sires are clustered together, descendants of the slightly older sires with breeding age sons are grouped into a separate cluster, and so on down to the final cluster of animals with the lowest average relationship amongst the current breeding population. When looking at GWAS results of prominent Holstein sires, Ma *et al.* (2012) stated:

> Artificial insemination and genetic selection are major factors contributing to population stratification in dairy cattle. Artificial insemination has been widely used and this has increased the likelihood of the presence of related individuals in randomly selected samples and the presence of large half-sib families; both of which contribute to population stratification.

Materials & methods

A total of 20,099 genotyped Holstein animals were used as target population of breeding animals born between 2010 and 2012. They included 3,902 males with at least 25 progeny and 16,197 females with a classification score. K-means clustering with a built-in R package (kmeans) was applied on the genomic relationship matrix (G) to separate the population into five separate clusters. The pedigrees of the target animals were traced back for 10 generations. The frequency of each SNP was calculated for each generation. Changes in allele frequency (AF) is defined as the difference in frequency of each SNP between

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_211, © T.J. Lawlor *et al.* 2022

two successive generations. The F_{st} across clusters, a measure of the variation in allele frequencies among subpopulations, was calculated as in Bonhomme *et al.* (2010).

Expected inbreeding within or across cluster was calculated based on pedigree information assuming non-zero inbreeding for unknown parents (Aguilar and Misztal, 2008) with the INBUPGf90 package within the BLUPF90 software suite (Misztal *et al.*, 2014). The genetic correlations across clusters were estimated using stature as trait and the method by Duenk *et al.* (2020). This correlated the additive breeding value of a cluster using the SNP effects of the same cluster, or when using the SNP effects of another cluster. Female animals of each cluster were used to estimate SNP effects with the POSTGSF90 package (Misztal *et al.*, 2014) and applied on the males of each cluster. Unlike the method by Duenk *et al.* (2020), the correlations were adjusted using the method by Calo *et al.* (1973). Assuming a heritability of 0.45 in all clusters, this adjustment factor is 1/0.45.

Results & discussion

Successful population stratification was confirmed in several ways. PCA analysis validated the clustering of target animals into five different but overlapping subpopulations. Inbreeding analysis showed higher within cluster relationships and lower relationships between clusters. Average inbreeding by cluster was 0.22, 0.20, 0.18, 0.17 and 0.10; with average between cluster inbreeding of 0.11. A multi-modal distribution of inbreeding values within the first three clusters indicated the inclusion of daughters and granddaughters of the prominent bulls. Average F_{st} value across all cluster was 0.03. Indicating allele frequency differences between the clusters. The age of the prominent bull for each cluster was associated with its average inbreeding Table 1.

All clusters combined. Alternative procedures for identifying the top SNPs associated with selection were investigated. Grouping all target animals together increases the likelihood of identifying those SNPs with a similar and consistent allelic change across all clusters. The method of Rowan *et al.*, 2020, which looks for the SNPs that are highly associated with changes over time was investigated. Most of the top 100 SNPs identified by this method could be described as changing in a parallel way across all clusters. Interpretation of these allele frequency changes are consistent with a polygenic shift.

Separate clusters. Clustering similarly related descendants of a unique bull into individual groups provides a snapshot of the genotypic makeup of different families at a specific point in time. With alternative sources of genetic drift and linkage disequilibrium, each cluster may exhibit its own unique trajectory of AF changes. Three procedures were utilized to determine the most significant family specific SNPs. Two procedures involved comparing within-cluster AF changes and then looking for SNPs with the largest between cluster contrast. The 100 SNPs exhibiting the greatest range or the greatest variance between clusters were selected. The third method involved selecting the 100 SNPs with the highest $F_{st.}$

Table 1. Association of the average inbreeding value of the animals within the cluster with the age of the most prominent ancestor for that cluster.

Cluster description[1]	Most prominent ancestor[2]	Birthdate of bull	Average inbreeding of the cluster

B.	Goldwyn	January 2000	0.20
C.	Shottle	July 1999	0.18
D.	O Man	March 1998	0.17
E. Lowest	Many	---	0.10

[1] Clusters are ranked by the average additive relationship of its members.

[2] Most prominent ancestor was identified as the bull with the largest numbers of descendants within a cluster.

The starting allele frequency for each cluster was similar with all animals tracing back to a common group of ancestors. The SNPs with the highest $F_{st.}$ would usually have one cluster exhibit a sharp change in its trajectory in the final generation. This is an indicator of genetic drift and a strong association between a cluster and a specific family. The genotype of the prominent sire causes a dramatic shift in the allele frequency.

Two procedures aimed at contrasting AF changes between clusters identified rapid directional changes, dramatic reversals in direction, and a mixture of parallel and non-parallel responses across clusters. Replicate Frequency Spectrum (Barghi *et al.* 2019) indicated that individual SNPs that showed a large directional change in AF for a specific cluster were replicated in the other clusters approximately 60% of the time. Heterogeneous changes in AF across clusters indicates genotypic redundancy whereby a variety of different genotype combinations provide different genetic solutions to the selection goals in a specific time-period.

Although we can only speculate on the reasons that may be involved in these non-parallel changes across clusters, two possible explanations would be differences in selection goals in different families and/or non-additive gene actions. The most prominent sires of families 1 and 2 are Planet and Goldwyn who are known to differ dramatically for fat and protein yield. The trajectory of the DGAT gene which has a significant genetic effect on fat and protein changes accordingly Figure 1.

Several known candidate genes identified by Ma *et al.* 2019 as having large AF in a very similar population were investigated. We also observed AF changes of a similar magnitude for the same identical alleles. However, their trajectories are not always the same for all families. For example, *ERBB4* (Chromosome 2) does show a shared and parallel change in AF across all families. Whereas the AF for *SPATA6* (chromosome 3) and *USP13* (chromosome 1) changed in a non-parallel way in the different families.

Population stratification caused by prominent sires allows for the investigation of alleles with strong LD (Barton, 2017). The fate of individual alleles is highly contingent on the allelic makeup at other loci. SNPs

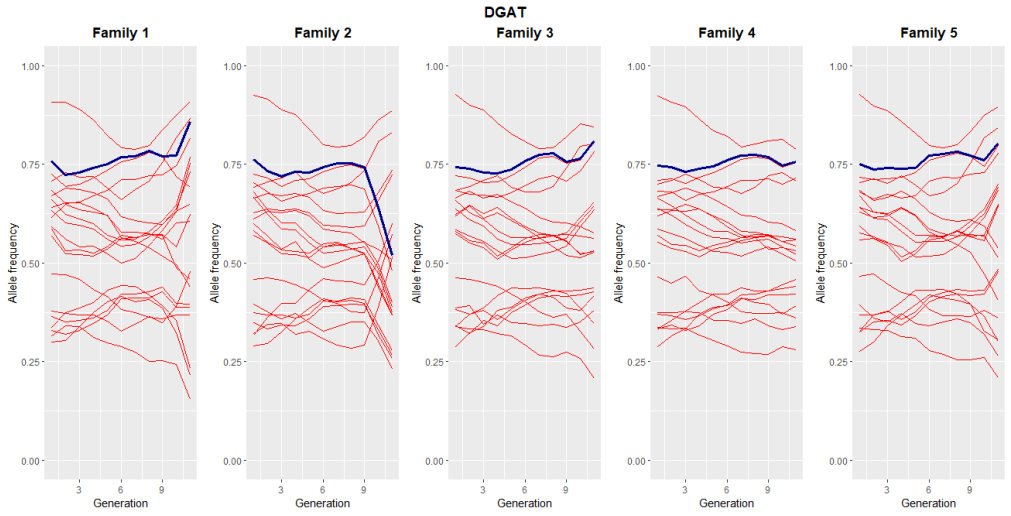

Figure 1. The allele frequency of the SNP that showed the *DGAT* gene (blue) and the surrounding 20 SNP markers (red) per generation within each family.

with an AF trajectory that includes a reversal in direction (or flip) are good candidates for the investigation of epistasis. Using the criteria of an overall reversal in direction of 0.1, we observed 11% or approximately 6,300 SNPs changing direction. In comparison, fixation of alleles was infrequent across the whole population (3 alleles). Number of alleles that became fixed within each family were 38, 22, 22, 59, and 40, respectively.

Conclusions

This study identified different subpopulations within the Holstein breed for a specific time-period. These clusters are associated with unique and identifiable families. AF changes between clusters involved rapid directional changes, dramatic reversals in direction, and a mixture of parallel and non-parallel responses. Heterogeneity in AF changes across families is an indicator of genotypic redundancy and a source of genetic variation.

212. Genome-wide evaluation of runs of homozygosity in Indian Sahiwal cattle

S.K. Illa[1], S. Mumtaz[2], S. Mukherjee[3], S. Nath[3] and A. Mukherjee[3*]

[1]Livestock Research Station, Garividi, Andhra Pradesh, 535101, India; [2]State Animal Husbandry, Kolkata, West Bengal, 700106, India; [3]ICAR-National Dairy Research Institute, Karnal, Haryana, 132001, India; writetoanupama@gmail.com

Abstract

Genome wide scan of ROH provide information on inbreeding, population history and genes under selection. The present study aimed: (1) to validate PLINK input settings and characterization of ROH patterns; (2) to assess the ROH islands to identify the major genes and gene hubs; and (3) to compare different inbreeding measures in the selected population in Sahiwal cattle. The study revealed optimum thresholds as gap (250 KB), density (120 KB/SNP), window-snp (10) and window-threshold (0.05) and based on this ROH patterns were assessed. The ROH islands revealed hub genes i.e. *ACAD11, RFX4*and *BANP* controlling various traits. The values of mean F_{PED}, F_{ROH}, F_{HOM}, F_{GRM} and $F_{GRM0.5}$ were 0.009, 0.091, -0.001, -0.104 and -0.009 respectively and the correlations ranged from -0.03 to 0.90among inbreeding measures. The ROH estimates helps in understanding the evolutionary mechanism and planning sustainable breeding programme in Sahiwal breed.

Introduction

The Sahiwal cattle was distributed around the globe especially the tropical countries and is known for their milk attributes (Ilatsia *et al.*, 2011). The Sahiwal herd was established at National Dairy Research Institute (NDRI)in 1955 and from 2010 genetic improvement and propagation of superior germplasm under All India Coordinated Research Projects (AICRP)was initiated. The selective breeding was followed since then in the herd and optimum level of inbreeding based on pedigree (<10%) was maintained. But due to incomplete and lack of ancestor information for few animals pedigree based method may not be accurate and it is important to estimate autozygosity at genomic level for genetic improvement in the herd. Thus, monitoring of genetic diversity and genomic inbreeding is a key for sustainable breeding programme in Sahiwal cattle.

ROH are the contiguous homozygous stretches of genotypes transmitted to offspring from parents through the common ancestor (Broman *et al.*, 1999; Gibson *et al.*, 2006). The ROH estimates elucidates about the population structure, demography history of individuals (Purfield *et al.*, 2012) estimate level of autozygosity and differentiate identical by state with descent (Curik *et al.*, 2014). Although many studies have been reported (Mukherjee *et al.* 2018; Martikainen *et al.*, 2020; Peripolli *et al.*, 2020),inconsistent choice of parameter settings makes difficult to compare the values across the studies(Meyermans *et al.*, 2020). Thus, present study was undertaken to develop guideline for uniform, reliable ROH parameter and its validation on SNP data prior to analysis. The study aimed: (1) to validate PLINK input settings and characterization of ROH patterns; (2) to assess the ROH islands to identify the major genes and gene hubs; (3) to compare different inbreeding measures in the selected population in Sahiwal cattle.

Materials & methods

The study was conducted on 193 Sahiwal cows from NDRI herd and pedigree based inbreeding coefficient was estimated. The equivalent complete generations (ECG) ranged from 1 to 5 and average ECG of individuals was 2.29±0.92, the inbreeding coefficients and the average relatedness were in the range of 0 and 0.06, 0.0002 and 0.032, respectively. The maximum 13 generations was found in the study. The

Sahiwal cows were genotyped with a medium-density INDUSCHIP2, a customized Illumina Bovine SNP chip developed by National Dairy Development Board (NDDB), India (Annual Report, 2018) consisted of 52,363 SNPs with the approval by Institute Animal Ethics committee (NDRI approval 43-IAEC-18-8). The quality control of genotypic data with flag --geno 0.1 and --mind0.1 was performed by PLINK v1.9 (Purcell *et al.*, 2007) software. A total of 739 SNPs were removed; no individuals were excluded and remaining 49,697 SNPs were used for downstream analysis. The sliding window approach was used to validate the various parameters settings i.e. density, maximum gap (Kb), minimum SNP per window, minimum length (Kb),window size (SNP) and threshold on detection of ROH. Each parameter is validated by keeping other parameters as default and the genomic coverage percent was calculated for each validation. The genomic coverage percent is expressed as the per cent of largest ROH identified to the total length of genome (autosome) that was utilized in the validation of ROH analysis. Finally, the parameters with greater genome coverage percent were utilized in the estimation of ROH segments. The ROH segments were grouped into five classes based on the length: 0-2 Mb, 2-4 Mb, 4-8 Mb, 8-16 Mb and >16 Mb. The --homozyg-group function in PLINK was used to identify ROH islands shared among at least 25% of individuals. Candidate genes within ROH islands were ascertained using Ensembl Biomart tool (Haider *et al.*, 2009). Significant GO terms and KEGG pathways were obtained by DAVID (Huang*et al.,* 2009). The genomic inbreeding estimates F_{ROH}(based on ROH), F_{HOM} (ratio of observed to expected homozygous genotypes), F_{GRM}($F_{GRM} = 1/n \sum_{i=1}^{n} \frac{(x_i - 2p_i)^2}{h_i} - 1$), $F_{GRM0.5}$ (estimated from diagonal of GRM with allele frequencies as 0.5) (Bjelland *et al.*, 2013; Doekes *et al.*, 2019) and F_{PED} (pedigree based) were estimated and compared.

Results

In this study, observed better genome coverage at the density of 120 kb/SNP, maximum gap of 250 kb, window SNP of 10 with 0.05 threshold were identified (Table 1). The greater portion of genome consisted of medium size segments (2-4 Mb) with corresponding length as 37.70% whereas; with shorter and longer ROH segments was 0.19 and 5.68% respectively (Table 2). The genome coverage (%) due to longer ROH segments was higher than other segments.

Table 1. Validation of parameters for ROH analysis using 50K SNP array.

Parameter	Value	Genomic coverage %	Number	Average length
Maximum gap	250	3.64	8.49	9.68
Density	120	7.477	14.25	12.05
SNP	50	4.01	11.77	7.82
KB	30	3.45	7.34	10.62
--homozyg-window -snp	10	3.63	7.86	10.52
--homozyg-window -threshold	0.05	3.45	7.34	10.62

Table 2. Summary of runs of homozygosity, number and length (Mb) by ROH length class.

Class	n ROH	Percent	Cumulative (%)	Mean length	SD length	Total length	Genome coverage%
ROH_{0-2}	334	5.65	5.65	1,417.01	284.63	473,282.06	0.19
ROH_{2-4}	1,893	32.04	37.69	3,054.41	489.64	5,782,005.62	2.30
ROH_{4-8}	1,873	31.70	69.39	5,614.43	1,127.15	10,515,843.09	4.19
ROH_{8-16}	1,207	20.43	89.82	11,086.93	2,229.55	13,381,924.50	5.33
$ROH_{>16}$	600	10.18	100	23,776.74	11,679.50	14,266,045.53	5.68

The mean F_{PED}, F_{ROH}, F_{HOM}, F_{GRM} and $F_{GRM0.5}$ were 0.009, 0.091, -0.001, -0.104 and -0.009, respectively with coefficient of variation from35.73 to 65.01%. The high correlations found for F_{PED} with F_{HOM} (0.90); medium of F_{PED} with F_{GRM} (-0.43) and with $F_{GRM0.5}$ (0.21) (Table 3).

The most frequent ROH islands were located on BTA5 and BTA7containing 113 genes related with milk production, fertility, body conformation, stress tolerance and host immunity. The effect of various density values on genomic coverage revealed that genomic coverage spiked up significantly between 40 and 70 Kb/SNP of SNP density and in agreement to Meyermans *et al.* (2020). The maximum genome coverage achieved at 120 Kb/SNP in our study. It was challenging to obtain maximum genome coverage with higher gap threshold. The shorter segments (<1 Mb) couldn't be detected with default gap settings (1000 Kb). A gap of 250 Kb setting was found to be optimum for ROH analysis in medium dense array.

Discussion

The genomic coverage percent was considered as a best indicator for the validation procedure. Different parameters such as density (Kb/SNP), maximum gap (Kb), window size and threshold were validated. The maximum gap of 250 Kb parameter was better thresholds and confirms Meyermans *et al.* (2020) to skip pruning genotypes for LD and MAF as it would extremely affect ROH analysis with negligible gain in ROH detection.

In this study, the inbreeding was due to the presence of longer ROH segments that are contributed by recent ancestors. The recombination events were unable to break the segments that might result the longer segments (Kirin *et al.*, 2010). The similar results were reported in tropical cross bred cattle and mithun (Mukherjee *et al.*, 2018; Peripolli *et al.*, 2020). The low average F_{PED} and F_{ROH} values observed contrary to these Dixit *et al.* (2020) and Peripolli *et al.*(2020) reported higher estimates. The study revealed common ROH islands on chromosome 5 and 7(40% similarity) against earlier report of 92, 90 and 93%, respectively in Gyr, Piedmontese and other indicine cattle (Karimi, 2013; Marras *et al.*, 2015; Peripolli *et al.*, 2018). The *ACAD11* (Acyl-CoA dehydrogenase family member 11) has significant effects on average daily gain, dry matter intake and residual feed intake traits in cows. *RFX4* (Regulatory factor X4), located on the chromosome 5 is important and supposed to affect 21 different traits in dairy cattle (Hu *et al.*, 2019). *BANP* (BTG3 associated nuclear protein) gene is related with somatic cell score (*VT:1000072, LPT:1000072, CMO:0000793*) of dairy cows (Jiang *et al.*, 2019).This study provided the insights of the ROH role in detecting the selection foot prints and genomic inbreeding in the Sahiwal population. This is probably the first study to compare genomic inbreeding with pedigree based estimate with characterization of

Table 3. Inbreeding based on Pedigree(F_{PED})on ROH lengths(F_{ROH}), F_{HOM} and F_{GRM}.

Abstract

The aim of this study was to assess the genetic diversity and the degree of introgression of foreign alleles into autochthonous goat genomes following putative land and maritime routes of human migrations. Genotypic data from sixteen populations were analysed for diversity statistics and admixture. Results show genetic fingerprints of old gene flow that could be related to past human expansions for explorations, raids or demographic reasons. In addition, this study could add missing pieces to indirectly recreate historically and still uncertain human land and maritime routes.

Introduction

Archaeological and historical sources have driven the reconstruction of human migrations. Recently, cutting-edge genomics and bioinformatics analysis has contributed to this field. Since their domestication, small ruminants constituted an irreplaceable source of food and ecosystem services for humans and their small size made them ideal for carrying them by land and sea, following human migratory routes (Amills *et al.*, 2017). A deeper analysis of literature (Colli *et al.* 2018, Cardoso *et al.*, 2018), investigating the genetic diversity in several breeds from the five continents, led us to catch subtle but intriguing similarities among geographically distant populations. In this study, we aimed to infer signs of gene flow following putative routes of human migrations by analysing the genomes of native modern goat populations. In particular, we focused on two prolonged migration events that occurred between the 500 BCE and the 900 CE: the Celtic expansion from Continental Europe and the Viking diaspora from Scandinavia (Viking Age, VA).

Materials & methods

Our dataset includes data from Stella *et al.* (2018): ARR = Traditional Aran, BLB = Bilberry and OIG = Old Irish (Ireland), BAG = Bagot and OEG = Old English (UK), DNK = Danish Landrace (Denmark), FIN = Finnish landrace (Finland), ICL = Icelandic landrace (Iceland), NLD = Dutch Landrace (the Netherlands), NRW =Norwegian Landrace (from Tanzania); from Berg *et al.* (2020) (SKO = Skorpa coastal goat, SEL = Sejle coastal goat) (Norway); from Cortellari *et al.* (2021) (ORO = Orobica, NVE = Nera Verzasca and VLS = Vallesana (northern Italy); from Smarter project, https://www.smarterproject.eu/) SWE = Swedish landrace (Sweden). Genotype data were from Illumina GoatSNP50 BeadChip (Tosser-Klopp *et al.*, 2014). Data were remapped against ARS1.2 assembly. Quality control was performed using PLINK v1.9 (Chang *et al.* 2015). We used Arlequin v.3.5 (Excoffier *et al.*, 2010) to calculate the pairwise Fst values and the SNPrelate R package (Zheng *et al.*, 2012) to perform the Principal Component Analysis (PCA). We inferred the estimation of individual ancestries using ADMIXTURE v.1.3 with K ranging from 2 to 30 (Alexander *et al.*, 2009). To make a comparative dataset considering the maternal contributions, we selected from GenBank the HV1 control regions (392 bp) of 63 domestic goats (Scandinavia, British Isles and northern Italy). A Maximum-Likelihood (ML) phylogeny analyses using Tamura-Nei and 1000 bootstrap was carried out with MEGA v.11 (Tamura *et al.*, 2021) and the resulting tree was drawn using iTOL v.6.4.3 program (Letunic and Bork, 2021).

Results

F-statistics highlighted a surprisingly low genetic diversity that characterizes some populations, considering a European continental context. Fst ranged from 0.071 to 0.621. The NVE breed shows the lowest Fst values in all pairwise comparisons and a close similarity with all populations from Scandinavia (above all DNK, 0.096) and secondarily with the British Isles (0.143-0.193). The ICL breed differentiates in a well-defined cluster (ADMIXTURE and PCA analysis). It presents Fst values a little lower of 0.3 with the Scandinavian breeds, definitely a lower value in comparison with British breeds (0.6) and slightly higher with Italian breeds (0.4). The breeds from the British Isles are quite similar to each other but show a lower genetic distance with DNK and NRW (0.159-0.208) followed by the Italian populations (0.184-0.217). The cross-validation method in the ADMIXTURE (Figure 1) analysis indicates K=19 as the most probable number of ancestries. Figure 1A shows a significant level of admixture in most of breeds, except for ICL, ARR, SKO and NLD. A small introgression level is detected among some populations from Scandinavia, British Isles and Italy. The genetic clustering analysis by PCA (Figure 2) groups the populations in three clusters: Icelandic breed is closer to Scandinavian breeds; British Iles forms a unique cluster with Italian breed near to NLD, whereas DNK is a bit far from the rest making a single cluster Also, we can see a certain level of overlapping between NVE with BLB and among SKO, SEL and SWE (dotted circle in the Figure 2).

The control region tree depicts an interesting link across populations. Individuals are coloured depending on their geographical origin and the groups of interest are highlighted in different colours. Six well-established groups are identified, whose nodes are supported by a bootstrap value around 50% or higher. mtDNA analysis confirms a certain degree of past introgression between NVE and DNK, Norwegian

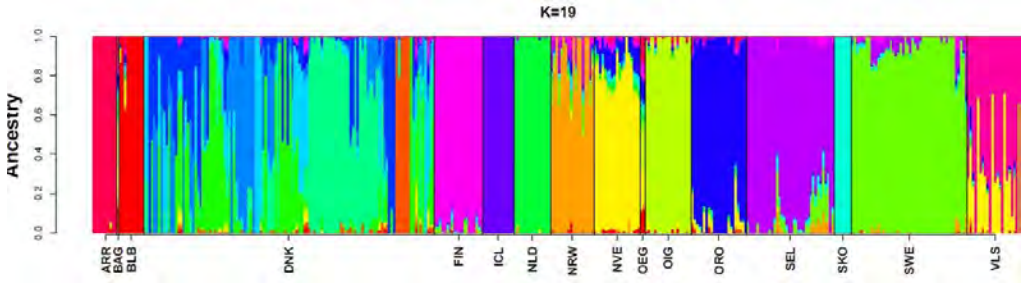

Figure 1. Individual ancestries inferred by ADMXTURE analysis: different colours refer to different ancestries.

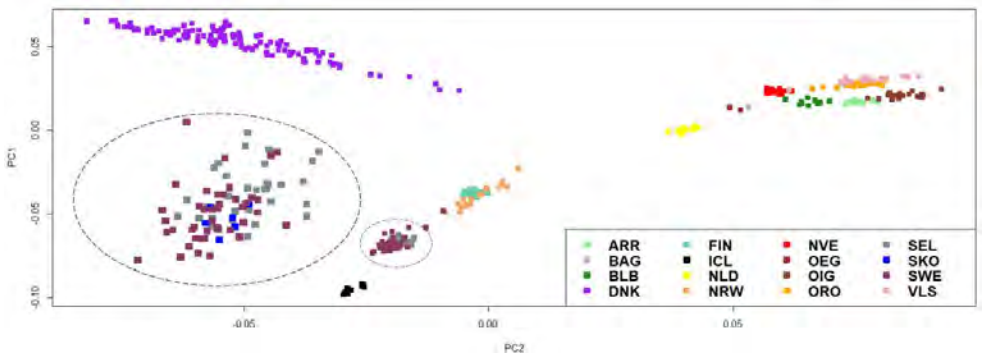

Figure 2. PCA analysis: the first two PCs explain the 10.3% of variance.

with British Iles individuals (with historical samples in the same branches) and Icelandic with NVE. The ancient samples from the British Isles are also clustering together. H= historical and M=modern prefix ID of samples as in Cassidy *et al.* (2017).

Discussion

All our findings suggest that crossing and introgression events among these native breeds occurred in the past, possibly following human migrations. The BLB breed for example, seems to have contributed to the genetic composition of both Italian and Scandinavian breeds, during two different and temporally separated contacts or through a slow but continued genetic exchange. We can speculate that the foreign fingerprint found in these populations is traceable back to the Celtic migration from central Europe towards Ireland and Britain and later with the Viking diaspora, spanning from the 500 BCE to the 900 CE. A previous study on the historical gene flow based on mtDNA of British Isles breeds (Cassidy *et al.*, 2017) found that ancient samples from the islands of Scotland clustered together with modern Irish goats and a Norwegian landrace goat. Another interesting grouping contains a modern British goat from central-east Ireland alongside Welsh, English and Icelandic goats. Both results suggest a genetic link with native goats from Scandinavian countries and settlements. In our mtDNA analyses, we included more individuals from Scandinavian countries, Iceland and northern Italy. It is noteworthy that a deeper inspection of the inferred ancestries and the goat haplotypes distributions reveals additional similarity between Scandinavian breeds and the rest of breeds. This suggests a bidirectional introgression and that a common situation has emerged in the genetic composition of modern Scandinavian and British Isles human populations. In fact, two studies aiming to explore the genomic history of the Celtic insular origin and the VA (Byrne *et al.*, 2018; Margaryan *et al.*, 2020), showed that the genetic composition of modern individuals from Scandinavia and Ireland exhibited different degrees of admixture that mirror the most famous expansion routes (Norwegian-like haplotypes into peoples from British Isles and Iceland, Danish-like haplotypes into Britain). In addition, several individuals with large amounts of South European ancestry in Denmark and southwest Sweden were retrieved during the VA, supporting our findings. Considering these results in the context of historical recorded raids and human demographic movements, we can postulate that the genome

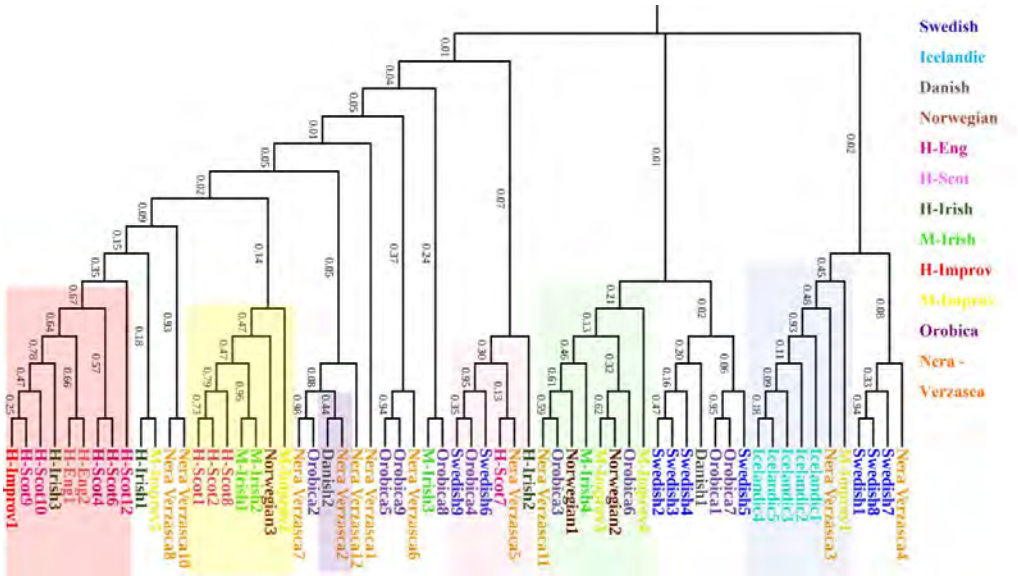

Figure 3. Phylogeographic analysis of 63 control regions of native goat breeds.

of modern indigenous goats could retain clues of old foreign genetic contribution as a consequence of an extensive trade and transport of goats in their history.

Abstract

Estimates of the inbreeding coefficient based on runs of homozygosity (F_{ROH}) are widely used in population genetics and livestock studies. The accuracy of F_{ROH} estimates is determined in part by the density of the genotyping chip. Compared with high density (HD) chips, low density (LD) chips tend to overestimate F_{ROH} in shorter homozygous segments. It is unclear whether imputation of genotypes from LD to HD would reduce or eliminate this overestimation. Our goal was to determine whether F_{ROH} calculations based on imputed LD genotypes are accurate. To this end, F_{ROH} estimates were determined for Nelore cows using HD or LD imputed genotypes (F_{ROH_HD} and F_{ROH_LDimp}). Our results showed that LD imputed genotypes reduced but did not eliminate differences between estimates. Differences were observed in both directions, with under- and overestimates of F_{ROH}. This suggests that imputation errors can either disrupt or generate homozygous segments.

Introduction

Runs of homozygosity (ROH), which are continuous segments of homozygous genotypes, have a variety of applications in population genetics and livestock breeding (McQuillan *et al.*, 2008; Curik *et al.*, 2014). Because they do not rely on 'complete' and correct pedigree information, are not based on expected values, and account for recent and remote inbreeding depending on segment size, inbreeding coefficient estimates based on ROH (F_{ROH}) may be expected to estimate autozygosity more precisely than traditional inbreeding coefficient estimates derived from pedigree data (Keller *et al.*, 2011; Peripolli *et al.*, 2016).

The density of the SNP chip influences the quality and precision of F_{ROH} estimates, as low density (LD) chips tend to overestimate F_{ROH} in shorter ROH segments compared to high density (HD) chips (Ferenčaković *et al.*, 2013; Hillestad *et al.,* 2017; Ceballos *et al.,* 2018). To reduce genotyping costs, it is common practice in animal breeding to genotype a portion of the individuals with an LD chip and impute their missing HD genotypes using information from a reference population genotyped with an HD chip (Khatkar *et al.*, 2012). Although this strategy has been shown to be cost-effective in providing accurate genomic predictions, among other applications, it is unknown whether F_{ROH} estimates from imputed genotypes are reliable. The goal of this study was to compare F_{ROH} estimates based on HD and LD imputed genotypes using Nelore (Bos indicus) cattle genotypic information.

Materials & methods

F_{ROH} estimates were first calculated for 1,221 Nelore cows genotyped with the Illumina® BovineHD chip (HD). These cows were born in six different herds between 1993 and 2008 and were part of the DeltaGen® breeding program's genomic selection reference population (Carvalheiro *et al.,* 2014). Only SNPs from autosomes and with call-rates greater than 0.95 were considered, totaling 660,297 SNPs. The proportion of the autosomal genome covered by ROH segments was calculated as F_{ROH} (McQuillan *et al.,* 2008).

ROH were identified using the SNP & Variation Suite v.8.9.0 (Golden Helix, Bozeman, MT, USA) under the following conditions: 15 or more consecutive homozygous SNPs with gaps of no more than 1000 kb between SNPs, at a density of at least 1 SNP every 100 kb. Due to the possibility of genotyping errors, a limited number of heterozygous and missing SNPs were permitted within ROH segments, with the number varying according to the length of the ROH segment (Ferenčaković *et al.*, 2013).

To assess the quality of autozygosity estimates from imputed genotypes, F_{ROH} was recalculated assuming that cows were genotyped with LD chips and their genotypes were imputed on HD. To do this, partial information from the HD chip was used to simulate the possibility that cows were genotyped with the following LD chips: Illumina® BovineLD (7k), Illumina® BovineSNP50 v2 (50k) and two other simulated/customized LD chips (21k and 52k) tested in the imputation study conducted by Carvalheiro *et al.* (2014). The number of SNPs from each LD chip corresponded to 6,848 (7k), 39,642 (50k), 21,570 (21k) and 52,590 (52k). The imputation process from LD to HD was performed using FImpute v.2.2 software (Sargolzaei *et al.,* 2014) and HD genotypes from 994 influential Nelore bulls as reference population.

Finally, for each cow, differences in F_{ROH} estimates obtained with the HD (F_{ROH_HD}) and imputed LD (F_{ROH_LDimp}) genotypes were computed, taking into account overall ROH segment lengths (>1 Mb) and specific ROH segment lengths (1-2 Mb, 2-4 Mb, 4-8 Mb, 8-16 Mb, and >16 Mb). F_{ROH_HD} was also compared to FROH from 50k that was not imputed to HD (F_{ROH_50k}).

Results & discussion

For the studied Nelore cattle population, the mean, median, minimum, and maximum values of overall (>1 Mb) F_{ROH_HD} were 0.0516, 0.0497, 0.0001, and 0.2380, respectively. Zavarez *et al.* (2015) present a more detailed description of this population's ROH pattern. The mean value of F_{ROH_50k} was 0.2843, indicating that autozygosity was overestimated when compared to F_{ROH_HD}. Ferenčaković *et al.* (2013) discovered a similar pattern in taurine breed cattle. This overestimation occurred primarily at smaller (1-2 Mb) ROH (Table 1), indicating that the 50k chip lacks sufficient coverage in these small segments to detect heterozygous SNPs, which the HD chip detects. The greatest autozygosity estimate difference was found in a cow with F_{ROH_HD} and F_{ROH_50k} values of 0.0268 and 0.3347, respectively.

Imputed genotypes provided F_{ROH} estimates that were comparable to HD genotypes on average. In comparison to F_{ROH_HD}, the 7k imputed genotypes had a slight overestimation of F_{ROH}, with a mean F_{ROH} of 0.0640. The remaining LD imputed genotypes had mean F_{ROH} values of 0.0534 (21k), 0.0546 (50k), and 0.0526 (52k), all of which were very close to the mean value of F_{ROH_HD} (0.0516). Aside from having comparable average F_{ROH} values, some cows had differences in F_{ROH_HD} and F_{ROH_LDimp} estimates. The minimum and maximum differences shown in Table 1 indicate that the discrepancies occurred in both directions, implying that the imputed LD chips underestimated or overestimated the autozygosity of some cows when compared to F_{ROH_HD}. Increasing the SNP chip density from 7k to 21k, 50k, or 52k reduced the percentage of cows with a discrepancy between F_{ROH_HD} and F_{ROH_LDimp} estimates but had almost no effect on the range between minimal and maximal F_{ROH} estimate differences (Table 1).

It is critical to note that the imputation accuracies were high, with average values of 0.9268 (7k), 0.9826 (21k), 0.9761 (50k), and 0.9909 (52k). A cow's minimum imputation accuracy was 0.8077 (7k), 0.9186 (21k), 0.9002 (50k), and 0.9486. (52k). There was no correlation found between imputation accuracy and differences between F_{ROH_HD} and F_{ROH_LDimp} estimates, indicating that imputation errors could either break or create ROH segments (data not shown). We were unable to predict or diagnose individuals with differing F_{ROH_LDimp} compared to F_{ROH_HD} because no pattern of differences was observed. Additional analyses will be carried out in order to determine the source of these discrepancies. In conclusion, our findings show

Table 1. Summary statistics of the differences[1] of autozygosity estimates obtained with the HD chip (F_{ROH_HD}) and lower density chips[2] (F_{ROH_LD}), for different ROH segment lengths.

that F_{ROH} estimates from imputed genotypes are, on average, comparable to F_{ROH} estimates based on HD chip. Nonetheless, some animals had very different autozygosity estimates when comparing F_{ROH_HD} and F_{ROH_LDimp}. Despite having the potential to influence selection and mating decisions, it is unclear to what extent these differences influence the results of other studies, such as those related to genomic inbreeding depression (Stoffel *et al.*, 2021) or the detection of signals of positive selection (Cheruiyot *et al.*, 2021). Further research into this subject is advised. While the reasons for the differences in F_{ROH} estimates remain unknown, higher density LD chips (e.g. ≥21k) should be preferred over lower density LD chips (e.g. 7k) to obtain more reliable F_{ROH} estimates based on imputed genotypes if HD genotyping of all individuals is not possible.

This study was supported by the ANAGRAMS-IP-2018-01-8708.

Abstract

Resistance to mastitis is a difficult trait to improve due to its multifactorial causes. The objective was to characterize a Mexican Braunvieh cattle population for genetic resistance to mastitis. We used 22 SNP markers for 19 candidate genes in 150 animals. Average heterozygosity was 0.468±0.034, a value higher than those reported for other European breeds. The inbreeding coefficient was low, 0.057±0.066, similar to those reported for tropical breeds. The genotypic profiles for the candidate loci per K-means group were obtained, as well as the group's distribution through the graphics of the principal component analysis. The genotypic profiles showed high genetic diversity among groups. There are highly heterozygous groups, a favourable indicator of the presence of genetic diversity. The results of this study constitute evidence of the genetic potential of the Mexican Braunvieh population to improve resistance to mastitis.

Introduction

Resistance to mastitis is a complex trait that is multifactorial in nature and, thus, difficult to improve. According to Haugaard *et al.* (2013), the genomic prediction ability for clinical mastitis is low, 0.19, compared to that reported by Brunes *et al.* (2021) for traits like dry matter intake (0.52±0.04). The conventional selection scheme for resistance has not been effective against mastitis due to the large number of candidate genes related to several non-immune factors that influence it (Meier *et al.*, 2020), and the low heritability reported for the resistance to mastitis (Kašná *et al.*, 2018). In addition to the control of environmental factors to prevent it at the farm level, genomic methods have been used as an alternative solution to the problem of increasing resistance to mastitis. The aim is to obtain animals that are immune to the main mastitis-causing pathogens and have the ability that allow them to adapt to the environmental factors that cause mastitis (Suleiman *et al.*, 2018).

According to Ali *et al.* (2019), manipulation of genetic variation is key to the development and use of any genetic improvement program for dairy and beef cattle breeds. Genetic diversity has been studied in the original Braunvieh and derivative breeds aiming to disentangle the genetic basis of their adaptation to diverse environments and increasing productive performance. The objective of this study was to determine the genetic diversity and structure of a Braunvieh population in terms of mastitis resistance.

Materials & methods

Source of information, quality control and candidate markers. Genomic information was obtained using hair samples from 150 animals born between 2001 and 2016 on five farms of the Mexican Association of Braunvieh Purebred Breeders. The samples were genotyped at GeneSeek (Lincoln, NE, USA, http://genomics.neogene.com) using the Genomic Profile Bovine LD chip with 50,000 SNP markers. The missing genotypes were imputed using the observed allele frequencies. Additionally, a 0.05 threshold for the minor allele frequency was considered. The candidate genes associated with resistance to mastitis in *Bos taurus* were identified (197), according to literature reports. The position ranked by base pairs were obtained from

the Gene Library (Gene, 2021). All the analyses were carried out using the R software, version 4.0.4 (R Core Team, 2021). With this information, the intragenic loci were searched (±25 kb), 22 markers associated with resistance to mastitis were found and the 10% most informative markers were determined using the Shannon index (Sherwin, 2010).

Population genetic structure and multivariate analyses. Expected (He) and observed (Ho) heterozygosity, and Hardy-Weinberg equilibrium were estimated using the adegenet package (Jombart and Ahmed, 2011). The inbreeding coefficients by individual with respect to the population (F_{IT}) were calculated with adegenet and a histogram including a nonparametric estimate of the density function was obtained (Jombart and Ahmed, 2011). The differences in the genotypic profile of individuals were identified with the K-means algorithm included in the stats and factoextra packages in R (Kassambara and Mundt, 2020). The optimum number of groups to be formed was obtained with Silhouette and Elbow of factoextra. The principal component analysis (PCA) was performed using adegenet package (Jombart and Ahmed, 2011) using the sample covariance matrix obtained with the candidate SNP. The groups of K-means were used to identify divergent genotypes among groups of animals and to characterize genetic diversity based on the PCA.

Results

Candidate markers and population genetic structure. Table 1 shows the markers obtained after filtering with the Shannon Index. Their candidate genes, chromosome, and the number assigned to visualize the results in the graphs are shown. For resistance to mastitis, 19 genes with 22 loci were obtained. All loci were in Hardy-Weinberg Equilibrium.

The He and Ho were 0.495±0.006 and 0.468±0.034, respectively. The *P*-value with the Bonferroni correction showed non-significant difference between He and Ho. The genomic coefficient of inbreeding was 0.057±0.066. Figure 1 shows the distribution of the animals according to their individual F_{IT}.

Clustering and principal component analysis. The optimum number of groups to equilibrate the silhouette width and the means of squared errors for K-means converged at 11 groups, Figure 2. Silhouette width and the average proportion of variability among groups relative to the total variability (Elbow method) were 0.08 and 34.9%, respectively.

Discussion

In México, studies using genomic information from large animal populations are scarce. Usually, the main restriction is the availability of economic resources for animal genotyping. (Mrode *et al.*, 2019). Despite having used only 150 animals in our study, the sample size was enough to detect significant differences with an effective size of 0.4 (*P*=0.05). The power of 0.87 for the Xi^2 test obtained in the present study is adequate to obtain conclusive, reliable results (Khalilzadeh and Tasci, 2017).The estimates for Ho obtained in our study for mastitis (average 0.468±0.034) are above those obtained in breeds derived from the original Braunvieh, but below those reported for some *Bos taurus* breeds, with adaptation to the tropics. In Colombia, Creole cattle (Ocampo *et al.*, 2021) reported Ho of 0.66. This Ho estimate are quite different from those reported by (Mocarelli *et al.*, 2020), who found an average of 0.35±0.167 for Ho in populations related to Braunvieh. This suggests that the Mexican Braunvieh population studied has increased its genetic diversity. The overall average for F_{IT} was 0.057±0.066 for resistance to mastitis. This value is similar to those found (0.07-0.09) for the African tropical breeds King *et al.* (2021) and Creole Colombian cattle (Ocampo *et al.*, 2021). In contrast, the F_{IT} for Gyr (0.013±0.106), and Guernsey (0.02±0.217) (Strucken *et al.*, 2021) was 30% lower than that found in our study. The distribution of animals by their F_{IT} value can be observed in Figure 1. In general, animals fall in the range of 0 to 0.3 F_{IT}. The average F_{IT} is lower than those reported

[1] Candidate genes reported by Chen *et al.* (2015), Cai *et al.* (2018), Kurz *et al.* (2019), and Moretti *et al.* (2021).

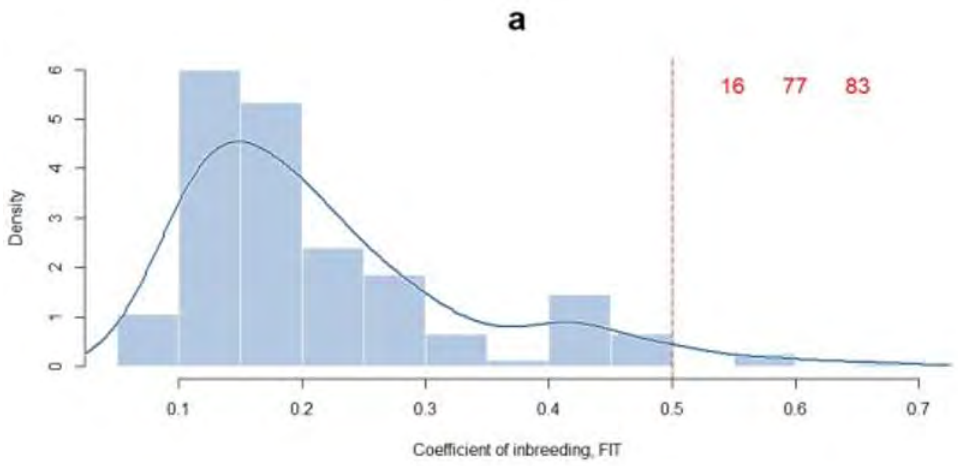

Figure 1. Histogram and density plot (cosine Kernel Function) of the coefficient of inbreeding (F_{IT}) for resistance to mastitis in a Braunvieh cattle population. bw= Bandwidth. Animals with a F_{IT} greater than 0.5 are shown in red.

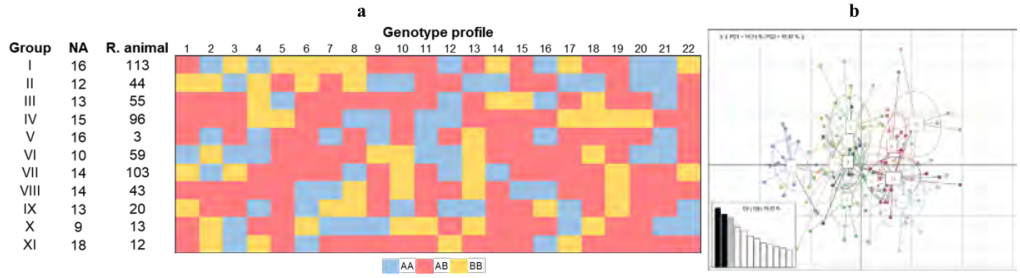

Figure 2. Clustering results (a) for 150 individuals and graphic representation of the principal components analysis (b) for resistance to mastitis in a Braunvieh cattle population. NA = Number of animals in the group. R. animal = representative animal (the closest to the centroid). PC1/2 = percentage of variability explained by dimension one (x-axis) and two (y-axis). Note: the names of each locus are indicated in Table 1.

by Signer-Hasler *et al.* (2004) for *Bos taurus* breeds (0.071), Brown Swiss (0.071), Braunvieh (0.059), and Original Braunvieh (0.023) (Moscarelli *et al.*, 2020).

The K-means algorithm and PCA are good statistical tools to visualize groups of animals with different genotypic profiles. Figure 2 shows the high genetic diversity of the Braunvieh population, since AB genotypes are abundant, especially in group XI (a). PCA chart (b) suggests that there are clear differences between the groups formed by K-means.

The results of our research give evidence of the genetic potential of the Mexican Braunvieh population for the improvement of mastitis-related traits in the tropic.

Abstract

Local cattle breeds are an important part of genetic diversity, but due to globalization and industrialization of production, they are often marginalized. Istrian cattle is a local breed that almost became extinct three decades ago. Active measures have been taken to protect the Istrian cattle and the population has increased, gaining a new economic importance. The objective of this study was to analyze the status and trends of Istrian cattle using pedigree information. The population of Istrian cattle has stabilized trends in the number of animals and herds, although it requires constant monitoring. The levels of relatedness and inbreeding have plateaued (at 4.00 and 3.14%, respectively) and bottleneck in the population has not been observed. The mean number of equivalent generations is relatively low (2.99) and further systematic monitoring is important.

Introduction

Genetic diversity is one of nine control variables in the planetary boundaries framework (Steffen *et al.*, 2015). The genetic diversity of cattle, the most important domestic species in terms of global production of food of animal origin, is gradually being depleted (FAO, 2015). Of the total number of breeds of mammalian species used for agriculture worldwide, cattle breeds account for 22.90% (FAO, 2019). Although the number of extinct cattle breeds is relatively low (12.8%), a large number of breeds are endangered (21.1%) and only 12.3% of cattle breeds are in 'not endangered' status. For most cattle breeds, their endangered status is unknown (53.8%) (FAO, 2019).

Istrian cattle is one of the three Croatian local cattle breeds. The primary breeding area of Istrian cattle is the Istrian peninsula and the neighboring island, and in last ten years has been extended to karst area (Lika, Dalmatia). It belongs to the Podolian group of cattle breeds and is very similar to the Italian Podolian and Maremmana breeds (Maretto *et al.*, 2012). Until the early twenties of the 20th century, cattle production in Croatia was based on local cattle breeds. Due to the modernization of agricultural production, the use of mechanization and the introduction of allochthonous breeds, local breeds were marginalized, and their survival was in danger. In the nineties of the 20th century, the program of protection of Istrian cattle was launched and the initial population included 103 cows and eight bulls (Ramljak *et al.*, 2011). According to the Croatian Agency for Agriculture and Food (2021), the current population of Istrian cattle is 1,118 adult animals (65 bulls and 1,053 cows) housed in 174 breeding farms. Previous studies on Istrian cattle included phenotype analysis and genetic analysis (Ivanković *et al.*, 2007; Ramljak *et al.*, 2011; Maretto *et al.*, 2012), but pedigree analysis was not performed. Pedigree information is a useful source for conservation programs to maintain genetic variability and minimize inbreeding (Santana *et al.*, 2016), and to analyse the breeding status of population (Jarnecka *et al.*, 2021). Therefore, the objective of this study was to describe the population structure and trends of the Istrian cattle population through pedigree analysis.

Materials & methods

The database of Istrian cattle includes 7,399 animals born between 1971 and 2020, belonging to 174 herds located mainly on the Istrian peninsula. For each animal in the database, information such as the

identification number, date of birth, sex, sire, dam, and herd were recorded. In this study, active (alive) animals of both sexes were selected as reference population (REF 01). Demographic and population parameters are presented for the last two decades, because Herdbook was closed in 2000. Pedigree analysis was performed using ENDOG v4.8 software (Gutiérrez and Goyache, 2005). Pedigree completeness was determined using the mean number of complete generations, mean number of maximum generations, and mean number of equivalent generations (Boichard *et al.*, 1997). Parameters related to inbreeding (mean inbreeding coefficient (*F*), mean average relatedness coefficient (*AR*), effective population size (*Ne*)), probability of gene origin (effective number of founders (f_e), effective number of ancestors (f_a), effective number of founder herds (f_h)), and generation interval (*GI*) were assessed. The effective population size was estimated via an individual increase in inbreeding per generation (Gutiérrez *et al.*, 2008). The average relatedness coefficients and individual inbreeding coefficients were calculated based on Gutiérrez and Goyache (2005). The generation intervals were calculated for the four paths: sire-son, sir-daughter, dam-son and dam-daughter.

Results

Demographic trends in the Istrian cattle population are shown in Figure 1. The number of cows has been constant1y increasing per year. According to Figure 1, the number of herds and number of new registered animals (offspring's included in the Herdbook per year) have increased from 2000 to 2011 and have only been roughly stable in the last decade.

An analysis of all pedigree entries revealed 6,756 animals for which both parents were known. The active living population consisted of 2,207 active animals and the effective population size is 91.92 (Table 1). The number of founder animals was 235 and the mean number of equivalent complete generations was 2.99.

The ratio between effective number of founders and effective number of ancestors is 1.03, The average generation interval was 5.93±3.65 years and ranged from 4.77±3.07 (sire – son) to 6.69±3.84 (dam – son). The average inbreeding coefficient in the REF 01 population was 3.14%, ranging from a minimum of 1.41% (2002) to a maximum of 3.19% (2018) (Figure 2). The *AR* in the population was 4.00%, ranging from 3.31% (2008) to 4.27% (2000).

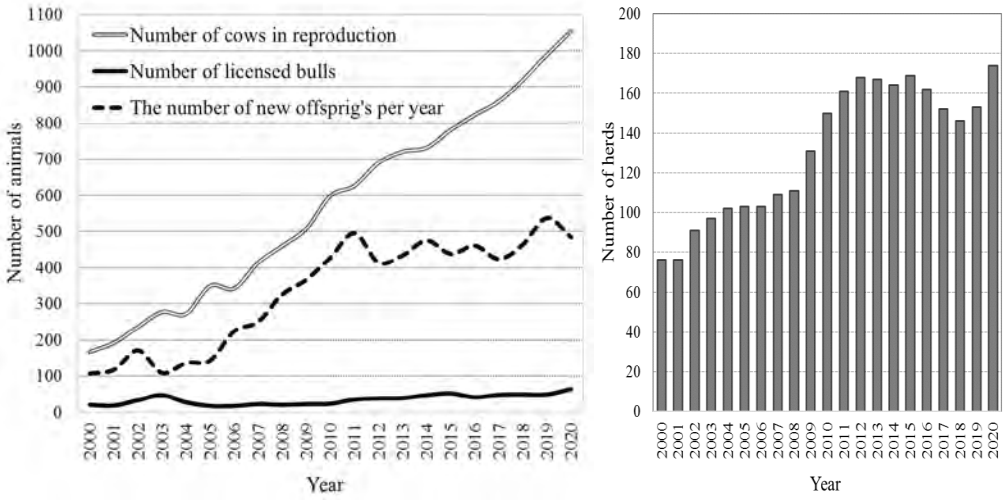

Figure 1. Population trends in the Istrian cattle population in the last two decades.

Table 1. Population size and genetic diversity indices of the Istrian cattle.

Item	Total
Original dataset (TP; total population)	7,399
Reference population 1 (REF 01; live animals)	2,207
Mean inbreeding coefficient (*F*)	3.14
Mean Average Relatedness coefficient (*AR*)	4.00
Effective population size (N_e)	91.92
Mean number of complete generations (*MCG*)	1.79
Mean number of equivalent generations (*MEG*)	2.99
Mean number of maximum generations (*MMG*)	5.81
Number of founders contributing to reference population	235
Effective number of founders for the reference population (f_e)	36
Effective number of ancestors for the reference population (f_a)	35
Effective number of founder herds (f_h)	17.10
Effective number of founders/effective number of ancestors (f_e/f_a)	1.03

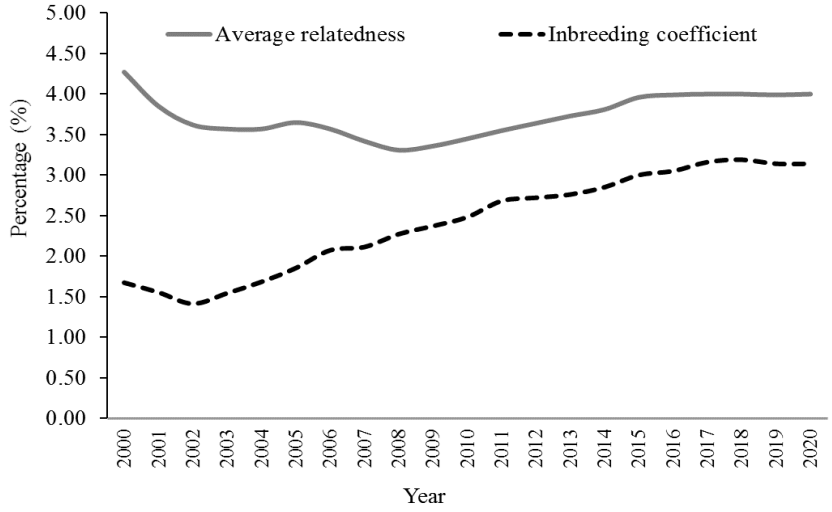

Figure 2. Level of inbreeding coefficient and average relatedness (in %) in the Istrian cattle from 2000 to 2020.

Discussion

The Istrian cattle population is subject to a systematic protection program, and an economic revitalization program has been implemented in the last decade. Considering the number of animals, the population trend is positive, as well as the increase in the average size of the herd from 2.5 adult animals (in 2000) to 6.4 (in 2020). The sex ratio in the population (cows/bulls) increased from 8.0 (in 2000) to 16.2 (in 2020). In the last ten years, the growth of the inbreeding level has slowed down, while in the last five years it has stagnated around 3.14%. The level of inbreeding observed in Istrian cattle is not alarming, but requires constant monitoring. We need to be careful in monitoring the level of inbreeding because Boichard *et al.* (1997) pointed out that the *F* trend has some limitations, especially when pedigree completeness is low. It should consider the fact that pedigree completeness is still low in the Istrian cattle population (*MCG*=1.79). The relationships between N_e, f_e and f_a provide information about the occurrence of bottleneck in a population.

For example, a f_e/f_a ratio close to 1 suggests that bottlenecks have not occurred in the population (Boichard *et al.*, 1997). A high f_e/f_a ratio indicates disproportionate use of breeding animals (Stephens and Splan, 2013). The f_e/f_a ratio in Istrian cattle is currently 1.03, indicating that there is no obvious bottleneck in the population. We assume that this is a consequence of the higher presence of natural mating compared to artificial insemination in practice.

217. Population dynamics of a long-term selection experiment in chickens divergently selected for high or low body weight

S.J. Harrison[1*], P.B. Siegel[2], C.F. Honaker[2] and R.M. Lewis[3]

[1]The University of Zambia, P.O. Box 32379, 10101 Lusaka, Zambia; [2]Virginia Polytechnic Institute and State University, 2170 Litton Reaves Hall, Blacksburg, VA 24061, USA; [3]University of Nebraska-Lincoln, P.O Box 830908, 68583-0908, Lincoln, NE, USA; sylvia.harrison@unza.zm

Abstract

The population dynamics of two lines of chickens from a long-term selection experiment was assessed. White Plymouth Rock chickens were selected for high or low 8-week body weight for 59 generations. The objective was to determine whether the two lines maintained similar population structures over the selection horizon. A complete pedigree of 30,943 birds was available: 102 founders, 16,292 low weight select (LWS), and 14,549 high weight select (HWS). Average inbreeding rates per generation were less than 1% in both lines. At generation 59, average relatedness coefficients were 0.53 (SD 0.001) for LWS, and 0.66 (SD 0.001) for HWS. Effective population size, whether based on inbreeding or coancestry, was 39 in LWS and 33 in HWS. Effective number of founders, ancestors, and genome equivalents were 17, 12.3, and 2.5 in LWS; correspondingly, in HWS they were 15, 8.4, and 1.9. Since the two lines had similar population structures, selection responses can be reliably compared.

Introduction

Population dynamics refers to the way in which the size and age structure of populations change over time, and the characterization of that change in mathematical terms. Such change is brought about by selection, as individuals that differ in viability and fertility contribute differently to the next generation. A long-term selection experiment in chickens based on high and low body weight (BW) at 8-wk of age provides a clear illustration of response to artificial selection (Márquez *et al.*, 2010). In a closed population, such as this one, inbreeding is inevitable, which effects the variance of gene frequency from one generation to the next (Konig *et al.*, 2010). There also are impacts on the structure of the population, manifest in its effective population size and contributions of founders, ancestors, and genetic drift. Gutiérrez *et al.* (2003) reported that genetic variability and evolution can be explained by a well-documented pedigree. The objective of this study was to assess population dynamics and genetic diversity in the high and low BW lines now after 59 years of selection, using pedigree data.

Materials & methods

Data and husbandry. Data were from 59 discrete generations. The two selection lines were established from a cross of 7 inbred lines of White Plymouth Rock chickens. Fifteen roosters and 87 hens from this cross were the founders of both lines. Their heavier offspring were selected as parents of the high weight select (HWS) line while their lighter offspring were selected as parents of the low weight select (LWS) line. From that 1,957 hatch, 8 sires and 48 dams were selected to establish the parental generation for each line. A complete pedigree, including sex, generation, and selection line, was constructed for each bird. The data analysed included 102 founders, 16,292 LWS and 14,549 HWS birds.

Inbreeding and average relatedness. The analyses were conducted using ENDOG v4.8 (Gutiérrez and Goyache, 2005). Individual inbreeding coefficients (F_t), and changes in inbreeding over time, were computed to deduce trends and infer the remaining heterozygosity. The inbreeding rate statistic was calculated as:

$$\Delta F_t = (F_t - F_{t-1}) / (1 - F_{t-1}) \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_217, © S.J. Harrison *et al.* 2022

where ΔF_t was the change in mean inbreeding between successive generations, and F_t was the mean inbreeding coefficient in generation *t*. Coancestry coefficients (f_{ij}) between each pair of individuals, *i* and *j*, were obtained and used to calculate Wright's F-statistics (F_{IS}, F_{ST}; Wright, 1978). The average relatedness coefficient (*AR*) was computed as explained by Dunner *et al.* (1998) accounting for both inbreeding and coancestry.

Effective population size. The effective population size describes the effective number of breeding individuals responsible for observed inbreeding rates if the population was randomly mated. It was calculated as:

$$N_e = 1 / (2 \times \Delta F_\mu) \quad (2)$$

where ΔF_μ was the average:

$$\Delta F_i = 1 - (\sqrt[t-1]{(1 - F_i)}) \quad (3)$$

of the birds in generation 59, and *t* was the number of equivalent complete generations (Gutiérrez *et al.*, 2009). Additionally, such realized effective population size was computed in a similar way but based on coancestry (N_{ec}; Cervantes *et al.*, 2011).

Effective number of founders, ancestors and genome equivalents. The effective number of founders (f_e) was computed to deduce the number of individuals that would be expected to produce the observed genetic diversity in a population if all the individuals had contributed equally to the population, as:

$$f_e = 1/\Sigma_{(i = 1,f)} q^2_i \quad (4)$$

where q_i was the proportion of genes originating with the i^{th} founder, and *f* was the total number of founders. The effective number of ancestors (f_a), was computed to account for unbalanced use of potential parents resulting in losses in genetic diversity producing bottlenecks (Boichard *et al.*, 1997), as:

$$f_a = 1 / \Sigma_{(j = 1,a)} p^2_j \quad (5)$$

where p_j was the marginal genetic contribution of the j^{th} ancestor, and *a* was the total number of ancestors. Founder genome equivalents (f_g) were obtained to quantify the number of equally contributing founders that would lead to the same level of genetic diversity as seen in the population under study assuming no random losses of founder alleles (Lacy, 1989).

Results

Inbreeding and average relatedness. Mean inbreeding coefficients per generation are shown in Figure 1 as the regression of $\log(1 - F_t)$ on *t* (R^2>0.98). The slope for LWS of -0.58±0.19% and for HWS of -0.68±0.32% approximated the -*ΔF* for each line. Maximum and average inbreeding rates per generation were similar in both lines. The population-level F_{ST} was 0.1202, suggesting that 12% of the total variation in the population was due to line differences. That finding was consistent with the pairwise F_{ST} between lines of 0.1215, implying that the selection lines had diverged substantially genetically. The maximum inbreeding coefficient and average relatedness in each line at generation 59 is summarized in Table 1.

Table 1. Summary statistics for genetic diversity measures at generation 59.

Parameter	Low weight select	High weight select
Number	193	185
Maximum F_i	0.64	0.63
Mean *AR* (SD)	0.53 (0.001)	0.66 (0.001)
N_e	39.3	33.2
N_{ec}	38.6	32.9
f_e	17	15
f_a	12.3	8.4
f_g	2.5	1.9

[1] F_i is individual inbreeding coefficient; *AR* is average relatedness coefficient; N_e is realized effective population size based on inbreeding; N_{ec} is realized effective population size based on coancestry; f_e is effective number of founders; f_a is effective number of ancestors; f_g is founder genome equivalents.

Effective population size. The realized effective population sizes at generation 59, whether based on inbreeding or coancestry, were similar in both lines at about 39 in the LWS and 33 in the HWS (Table 1). This coincided with their similar rates of inbreeding.

Effective number of founders, ancestors and genome equivalents. The effective number of founders, ancestors, and genome equivalents at generation 59 are shown in Table 1. Their values were similar for both lines. In Figure 2, the cumulative marginal contributions of ancestors to genetic diversity in each line at generation is 59 plotted. Fewer than 33 ancestors contributed to a line. In the LWS, five males and one female ancestor explained 50% of the genetic variation at generation 59. In the HWS, only three male ancestors explained that same amount of variation.

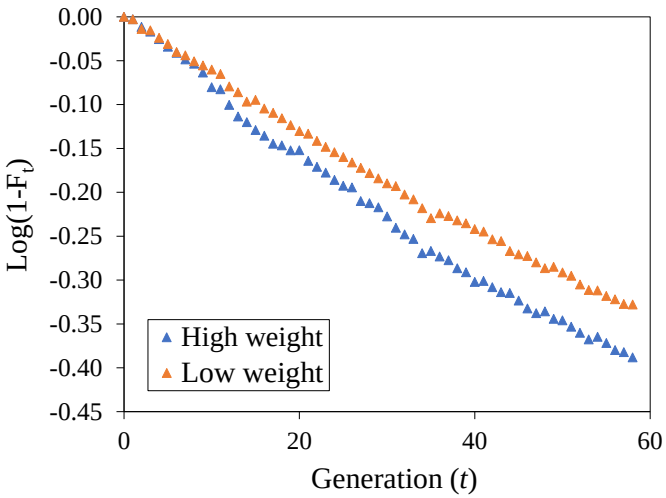

Figure 1. Plot of log(1-F_t) against *t* by line across 59 generations, where F_t was the mean inbreeding coefficient at generation *t*.

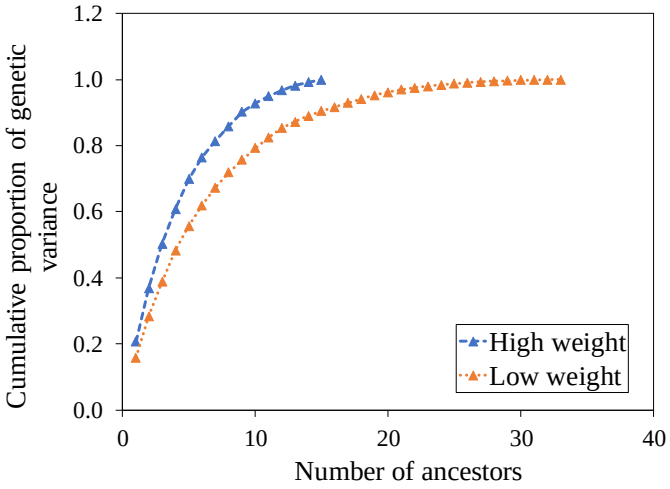

Figure 2. Cumulative marginal contributions of ancestors to genetic diversity in each line at generation 59.

Discussion

Inbreeding. A gradual increase in inbreeding coefficients in the LWS and HWS lines was observed. Because inbreeding increases the frequency of homozygous genotypes in a closed population, expression of deleterious recessive alleles can lead to inbreeding depression, which may negatively affect fertility and survivability. This population was propagated by short generation intervals, which is the case with chickens. The moderate levels of inbreeding identified were inevitable, with individuals became more closely related with increasing generations. However, the risk of inbreeding depression was less drastic in this population because the founders were entirely unrelated, and selection and mating decisions consciously avoided accumulating inbreeding. With on average less than 1% increase in inbreeding per generation, there was relatively low risk of inbreeding depression or loss of a line.

Effective population size. The N_e observed was similar in both lines and this similarity can be attributed to the relatively constant rate of inbreeding across generations. At generation 59, the N_e was about 60 and 68% of the actual population size (number of selected parents) in the LWS and HWS lines, respectively. Franklin and Frankham (1998) reported a critical N_e of 500 to maintain adequate genetic variation in natural populations. However, that study did not indicate whether that threshold was specific to a particular species or breed, or due to biological differences such as reproductive rate. Smaller livestock populations (e.g. N_e>100) were considered viable to maintain long-term selection responses (Goddard, 1992; Weigel, 2001).

Effective number of founders, ancestors and genome equivalents. The f_e measures the expected founder contributions to descendants across generations. However, the f_a is more befitting for a population that has undergone bottlenecks, which risks a potential loss of alleles. In generation 59 of this study, the f_a [12 (LWS); 8 (HWS)] was relatively low compared to the actual number of founders (102), taking note that an ancestor many not necessarily be a founder. The cumulative marginal contribution of the ancestors showed that few ancestors were most influential in genetic contribution to descendants, as was the case with founders. Similar percentages were observed with regards the number of equally contributing founders that would lead to the same level of genetic diversity.

Based on various statistics that characterize the dynamics of a population, the LWS and HWS lines were similar in their genetic architecture. Robust comparisons of the performance of these two lines over the entire selection profile therefore can be made with confidence.

218. Genetic management meets genomics

J.A. Woolliams[1*] and T.H.E. Meuwissen[2]

[1]The Roslin Institute, Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush Campus, Midlothian EH25 9RG, United Kingdom; [2]Norwegian University of Life Sciences, P.O. Box 5003 NMBU, 1432 Ås, Norway; john.woolliams@roslin.ed.ac.uk

Abstract

Genomics opens the opportunity for observing multiple genetic perspectives but genetic management requires decisions that resolve them towards desired outcomes. Management using alternative genomic relationship matrices (G) may create a covariance between drift and initial allele frequency and this creates a distinction between natural measures of inbreeding based on drift (F_{drift}) and homozygosity (F_{hom}). These measures coincide when inbreeding management is based on identity by descent (IBD), with more gain relative to either F_{drift} or F_{hom} when G was based on IBD compared to drift or homozygosity. The covariance implies that management based on drift or homozygosity drives rare alleles respectively towards extinction or intermediate frequencies either of which may be undesired. Management by IBD allows frequency changes to be as expected with random drift, separating out the management of diversity from the selective advantages arising from artificial or natural selection.

Introduction

Genomics opens a window on the diversity that delivers gain in breeding schemes, and so offers opportunities for re-imagining them. The key to sustaining more than short-term gain is the diversity itself, both for traits underlying productivity and those underlying robustness, encompassing health and welfare in livestock and companion animals. Therefore management of diversity, and understanding how genomics may play a role, is important in re-imagining. A crucial perspective is that managed populations in their current form have value, e.g. productivity in livestock, temperament in companion animals, feral traits in zoo populations; consequently many attributes are to be maintained alongside desired improvements. Therefore the current population is a reference point framing the objectives for managing diversity.

In the absence of genomics the ideas of diversity were built upon IBD referring back to a base population, a reference point (so well-suited to the management needs) where all alleles are considered distinct irrespective of their identity by state (IBS). In this inbreeding framework, core concerns in managing diversity coincide: genetic drift from the reference, which may promote lethal recessives, and loss of heterozygosity, in turn associated with loss of genic variance and increased risks of fixing deleterious and losing desired alleles. These are all predictable from the classical F, and controlling the rate of inbreeding (ΔF) provides a means to managing diversity. Control is achieved with optimum contributions (OC; e.g. Meuwissen, 1997) which, in one form, maximises rates of gain (ΔG) for a given ΔF, using the NRM (A).

The problem with this framework is that the classical theory refers to neutral and selection-free loci, and genomics has demonstrated that while there may be many neutral loci, these are likely linked to loci affecting selection. Routine prediction of EBVs using a G based on dense chips of primarily *a priori* neutral SNPs compounds this problem as these SNPs do not remain neutral. Furthermore, the genomic data for these SNPs allows direct observation of heterozygosity and drift from their frequencies in a reference population. Therefore the simple substitution of G for A in OC, as in BLUP, offers a viable solution (Sonesson *et al.* 2012). However Beukelaer *et al.* (2017) hint that with this solution the coincidence of drift and loss of heterozygosity may disappear. Furthermore, while there is one A, there are many possible G, raising the possibility that what may be true for one G may not be true for another. To resolve these issues extensive

simulation studies were conducted and reported by Meuwissen *et al.* (2020) and what follows is a summary of their findings with special attention for the discrepancies between drift and homozygosity inbreeding in genomic diversity management.

Materials & methods

Genomes and SNPs. The genome was 10 simulated chromosomes, each 1M, and developed over 400 generations with N_e=100, and a mutation rate of 10^{-8}/base pair/generation to achieve drift-mutation-linkage disequilibrium (LD) balance. This resulted in 33k SNPs in a base population with allele frequencies (p_{0k} for SNP k) distributed comparably to whole genome sequence (WGS). Four separate panels of 7k SNPs were randomly sampled: M, used for predicting EBVs and (in most results) also constructing G to manage diversity; Q, used as QTLs with a Normal distribution of substitution effects, with variance independent of p_{0k}, and combined with environmental variance to give a trait for selection with breeding values g and h^2=0.4; N, used as truly neutral loci to assess outcomes; and D, used (for some results) in conjunction with M to separate genomic data for predicting EBVs and managing diversity.

Predicting EBV. A ridge regression model on scaled allele counts was used to predict EBV

$$y = 1m + Xb + e \quad (1)$$

where y is a vector of phenotypes, m a fitted mean, 1 a vector of 1's, b a vector of coefficients for panel M markers, assumed MVN(0,σ^2I), X their design matrix, and e a vector of residuals. X contained the counts of a random chosen alternative allele at SNP k scaled by $[2p_{0k}(1-p_{0k})]^{1/2}$. The use of p_{0k} was maintained across generations. The scaling leads to models analogous to Model 2 of Van Raden (2008). EBVs were then predicted as $g^{hat}=Xb^{hat}$.

Diversity management. OC was simulated with a number of different relationship matrices G. Genomics vastly expands possible G, and can be classified by their underlying target. A: drift, exemplified by G_{VR1} and G_{VR2}, based on methods 1 and 2 of Van Raden (2008), but with frequencies remaining 'centred' on p_{0k}; and $G_{i(p)}$ based on transforming a change in allele frequency from p_{0k} to a scale of total intensity applied, whether or not random (Liu *et al.*, 2008). B: homozygosity, exemplified by $G_{0.5}$, constructed as a Van Raden matrix with all frequencies 'centred' on 0.5. C: IBD, exemplified by A, and G_{FG} using genomics to aggregate IBD across the genome by linkage analysis (Fernando and Grossman, 1989). A hybrid of B and C using ROH is also feasible, G_{ROH}. All were considered by Meuwissen *et al.* (2020), including details of their calculation, but only a subset will be described in these results.

Simulations and summaries. OC schemes were run for 19 generations after a generation of random selection in a dioecious population with ΔF=0.005 (N_e=100), although exact values cannot be guaranteed when using e.g. A or $G_{0.5}$. In one scenario the EBVs in each generation were randomly generated. Each form was replicated 100 times and averaged. In each replicate ΔG was calculated, together with 2 natural measures of inbreeding coefficient following Wright: if p_{tk} is the allele frequency of locus k at time t, H_{tk} = $2p_{tk}(1-p_{tk})$, and $\delta p_{tk} = (p_{tk}-p_{0k})$, these were $F_{hom} = 1- \Sigma_{loci} H_{tk}/[H_{0k}N_{loci}]$ and $F_{drift} = \Sigma_{loci} \delta p_{tk}^2/[p_{0k}(1-p_{0k})N_{loci}]$. Corresponding rates were calculated using -1x the slope of the regression of $\log_e(1-F)$ on t.

Results

With these definitions of F_{hom} and F_{drift}, then their difference is twice the covariance of the allele frequency change δp_{tk} for locus k and its initial deviation from ½, standardising both terms by $[p_{0,k}(1-p_{0,k})]^{1/2}$, which is the genic s.d. for individual allele frequency in fully inbred individuals, i.e. $F_{hom}-F_{drift}=2\text{cov}(\delta p_{tk}/[p_{0,k}(1-p_{0,k})]^{1/2},(p_{0k}-½)/[p_{0,k}(1-p_{0,k})]^{1/2})$. This is the covariance of Beukelaer *et al.* (2016). Compared to classical drift

Table 1. Observed ΔF measured by drift or homozygosity and the difference between total F in SNP panels M and N after 20 generations of OC selection.

		EBV predictors: Panel M			Neutral loci: Panel N		
Scheme[1]	Type[2]	ΔF_{hom} [3]	ΔF_{drift} [3]	F_{hom}-F_{drift} [3]	ΔF_{hom} [3]	ΔF_{drift} [3]	F_{hom}-F_{drift} [3]
G_{VR2}(M,M)	A	0.0146	0.0050	0.147	0.0103	0.0068	0.054

[1] G_{VR2}(M,D) denotes SNP panel M used to predict EBVs, and SNP panel D used to construct G_{VR2} for use in OC. Others follow by analogy, with ~ indicating no panel required either due to random EBVs or use of A.

[2] Target for controlling diversity (see text): A, drift; B, homozygosity; C, IBD.

[3] Standard errors $<2.5\times10^{-5}$ for ΔF_{hom} and ΔF_{drift} and $<2.2\times10^{-4}$ for F_{hom}-F_{drift}.

where F_{hom}=F_{drift}, a covariance >0 indicates minor alleles are more likely to be lost, and <0 indicates they are more likely to be retained but drift towards 0.5 and further from p_{0k} (especially in WGS data).

Distinction between F_{hom} and F_{drift}. Table 1 shows that with genomic management of diversity the classical coincidence of F_{hom} and F_{drift} is no longer automatic. Diversity management based upon VR1 or VR2 resulted in $F_{hom}>F_{drift}$, from promoting the loss of minor alleles and reducing the larger magnitude drift towards fixation through penalties based on δp_{tk}^2. $F_{hom}>F_{drift}$ was also observed in the unmanaged neutral panel N, but less strongly, as these are driven by LD with the managed panel M. This phenomenon is not due to directional selection as $F_{hom}>F_{drift}$ was observed with random selection (G_{VR2}(~,M)), and it is not due to the use of the same marker panel for predicting EBV and diversity management as $F_{hom}>F_{drift}$ was observed with G_{VR2}(M,D). The converse, $F_{drift}>F_{hom}$, was observed when diversity management was based on homozygosity, with larger magnitude changes in allele frequency permitted to reduce the loss of alleles. As observed with $G_{0.5}$(M,M), a low ΔF_{hom} in the managed panel is not necessarily replicated in an unmanaged panel of neutral loci. However when the diversity management was tracking IBD the difference between F_{hom} and F_{drift} was much smaller than for all other schemes. For G_{FG}(M,M) most of the observed difference was explained by the non-random mating arising from the 2 sexes; F_{hom} is defined for HWE whereas in the simulations F_{hom} was as observed in the simulated population.

Gain in relation to F_{hom} and F_{drift}. Figure 1 shows gain achieved as a function of F_{hom} or F_{drift} over the 20 generations for 5 schemes in Table 1, with the target F=0.1 highlighted. Maximum gain was achieved using IBD for management when assessed per unit of either F_{drift} or F_{hom}. The two G_{VR} schemes gave very similar trajectories of gain, slightly lower than $G_{0.5}$(M,M) per unit of F_{hom} but greater than $G_{0.5}$(M,M) per unit of F_{drift}.

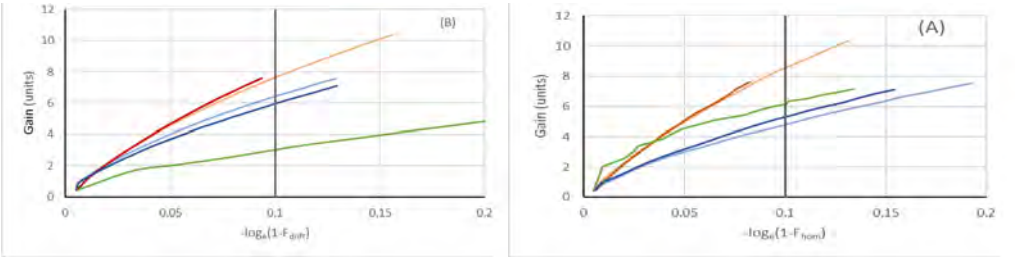

Figure 1. The trajectory of total gain as a function of different measures of inbreeding: (A) related to F_{hom}; (B) related to F_{drift}. Schemes shown are: G_{FG}(M,M) dark red; A(M,~) light red; $G_{0.5}$(M,M) green; G_{VR1}(M,M) dark blue, and G_{VR2}(M,M) light blue.

Discussion

The near coincidence of F_{hom} and F_{drift}, showing at most small covariance between MAF and drift is justified from theory as classical inbreeding can be imagined as arising from a set of 2N alleles at each locus for the N individuals in the base. Hence, all alleles at all loci used for management have frequency $(2N)^{-1}$ and the covariance will be 0, and equivalence follows. In turn, this offers an explanation as to why gain is greater when G was based on IBD, as the selective advantages of the QTL and EBV markers will be influenced through LD by the covariance in promoting changes not beneficial to the trait: either by resisting desired movement towards intermediate frequencies when using G_{VR1} or G_{VR2}, or resisting desired movement away from intermediate frequencies when using $G_{0.5}$. The effects observed are potentiated by $|p_0$-½| and suggests that using G_{VR1} rather than G_{VR2} may be preferable for generating gain as it weights G towards intermediate p_0 rather than equally irrespective of MAF, but the results for ΔG do not support this despite the reduced magnitude of F_{hom}-F_{drift}.

For breeding and generating directional gain the most attractive option was using IBD for managing diversity. Note that A does not offer control of inbreeding, as the true ΔF will always exceed the target to an unknown degree; G_{FG} overcomes this but computation remains challenging. Objectives may solely concern protecting diversity in the valued reference population and $G_{0.5}$ may appear attractive, but purging will be hindered, IBD increased, and epistatic variance promoted. In conclusion, the pre-genomic idea of IBD management allows allele frequency changes to be as expected under random drift, separating out the management of diversity from the selective advantages arising from artificial or natural selection.

Abstract

The primary objective of this study was to determine the levels of genetic variability and inbreeding within the different ecotypes found north and south of the Veterinary Cordon Fence (VCF). Hair samples from the Kavango- (n=124), Caprivi- (n=135), Ovambo- (n=269), Kunene- (n=118), Herero (n=17) Sanga ecotypes as well as Nguni (n=148) cattle were collected and analysed using a 150K Single Nucleotide Polymorphism (SNP) chip. Marker and individual quality control, and linkage disequilibrium (LD) filtering were performed on a total of 120,700 markers and 837 animals. Observed (Ho) and expected (He) heterozygosities, and inbreeding coefficients (*F*) were calculated. Except for the Herero ecotypes, low positive *Fs* for the other ecotypes were observed. Expected heterozygosity values for Kavango = 0.325±0.0001, Caprivi = 0.316±0.00006, Nguni = 0.322±0.0002, Kunene = 0.331±0.0004, Ovambo = 0.321±0.0001 and Herero = 0.346±0.00004 were observed. PCA scatter plots and admixture (*K=9*) showed four (4) cluster groups, despite some admixture being reflected. *Fst* coefficients between pairs of populations were calculated and low *Fst* coefficients were however observed when compared to PCA plots.

Introduction

Cattle are usually grouped into two major categories namely *Bos Taurus* (taurine) and *Bos Indicus* (indicine) (Meyer, 1984; Groeneveld *et al.* 2010; Horsburgh *et al.,* 2013; Mwai *et al.* 2015; Madilindi *et al.,* 2020). Indigenous cattle such as the Nguni, Pedi, Tuli, Afrikaner, is collectively known as Sanga cattle (Meyer 1984; Strydom, 2008; Els *et al.* 2000). Sanga cattle are a combination of African taurine and African indicine (Makina *et al.*, 2016). Namibia does not have its own suitable name for the indigenous cattle and as such are also referred to as Sanga cattle (Els *et al.* 2000).

Most of the Namibian indigenous Sanga cattle are found in the Northern Communal Areas (NCA) of Namibia. According to Els (2001), the indigenous Sanga cattle are divided into different ecotypes namely Kunene, Ovambo, Kavango and Caprivi. Due to the presence of Foot and Mouth Disease (FMD) and Contagious Bovine pleurophneumonia (CBPP) or Lungsickness in the NCA, the North-South movement of all cloven-hoofed animals in Namibia are controlled by the Veterinary Cordon Fence (VCF). Thus creating isolated cattle populations of the same breed. Hanotte *et al.* (2010) is of the opinion that livestock that experienced selection pressure due to environmental conditions such as drought, display a greater genetic diversity across habitats when compared to a 'neutral' genomic background.

Very little information is available on the phenotypic and genetic levels of diversity of indigenous livestock in Africa (Rege, 1999; Mwai *et al.,* 2015) and in Namibia only Notier *et al.* (2002) looked at genetic diversity levels in indigenous Sanga cattle using 10 microsatellite markers. Recently the government of Namibia embarked on a genetic diversity study using SNPs (150K) aimed at characterizing the indigenous Sanga cattle of Namibia to further support the conservation of the vulnerable indigenous animals.

Materials & methods

Sample collection. A total of 837 hair samples were collected from unrelated indigenous Sanga/Nguni cattle ecotypes in all fourteen (14) regions in Namibia. The ecotypes included, Kavango (n=124), Caprivi (n=135), Nguni (n=148), Kunene (n=118) and Ovambo (n=269). An additional ecotype, Herero Sanga (n=17), was also collected. Most of the indigenous Sanga/Nguni ecotypes (Kunene, Ovambo, Kavango and Caprivi) occur in the NCAs, north of the VCF, while the Nguni and Herero ecotypes were collected south of the VCF. All the hair samples from the NCA stood a quarantine period of three (3) months and were baked in an oven for 30 minutes at 72 °C to sterilize the samples from FMD and CBPP as per requirements import permit.

Analysis of hair samples. All hair samples were analyzed at GeneSeek/Neogene (Nebraska, USA) and the Agricultural Research Council (ARC) in South Africa using a 150K Single Nucleotide Polymorphism (SNP) chip (Igenity and Illumina). Sample analysis was performed as described by King *et al.* (2021). Briefly, PLINK (1.07) (Purcell, 2010) software was used to perform statistical analysis. SNP quality control was performed where SNPs with missing genotypes in more than 5% individuals or less than 95% (--geno 0.05), with a minor allele frequency (MAF) of less than 10% (--maf 0.01) and that deviated from the Hardy-Weinberg equilibrium (--hwe 0.001) were excluded from the analysis. Observed (Ho) and expected (He) heterozygosities as well as inbreeding coefficients were calculated; highly inbred and crossbred animals were also removed. A total of twenty six (26) animals were excluded after quality control. Principle Component Analysis (PCA) scatter plots were done using R-Studio, an integrated development environment (IDE) for the programming language R (R Core Team, 2021). Admixture (1.3) (Alexander *et al.* 2020) (*K=9*) was used to determine the genetic relationship between and among populations. *Fst* coefficients were calculated using PLINK (1.9) (Purcell and Chang, 2019).

Results

Table 1 shows that low positive inbreeding coefficients *(F)* were observed for all the ecotypes, except for the Herero Sanga (exhibiting more heterozygous animals than inbred). Expected heterozygosities (He) varied from 0.316±0.00006 to 0.346±0.00004; Caprivi ecotype being the least heterozygous while the Herero Sanga cattle were the most heterozygous. The Kavango, Nguni, Kunene and Ovambo ecotypes were very similar in heterozygosity. Studies done by Makina *et al.* (2016), Madilindi *et al.* (2020) and King *et al.* (2021) showed Sanga breeds showed similar trends as seen with this data.

Four cluster groups were observed when using PCA scatter plots. The Kunene and Ovambo ecotypes clustered as one group, while the Kavango and Caprivi ecotypes clustered as another group. Nguni and Herero Sanga also cluster separately from the previous groups. Admixture (Figure 2) confirms similar results as seen with the PCA scatter plot (Figure 1). In a study by Madilindi *et al.* (2020) on three Nguni populations it was found that they did cluster independently even though there was some admixture.

Table 1. Inbreeding Coefficients, Observed (Ho) and Expected (He) Heterozygosities of the Indigenous Sanga of Namibia.

Ecotype	n	F	Ho ± std	He ± std
Kavango	124	0.0097	0.322±0.0141	0.325±0.0001
Caprivi	135	0.0113	0.313±0.0118	0.316±0.00006
Nguni	148	0.0110	0.318±0.0167	0.322±0.0002
Kaoko (Kunene)	118	0.0002	0.331±0.0158	0.331±0.0004
Ovambo	269	0.0045	0.319±0.0163	0.321±0.0001
Herero	17	-0.0515	0.364±0.0144	0.346±0.00004

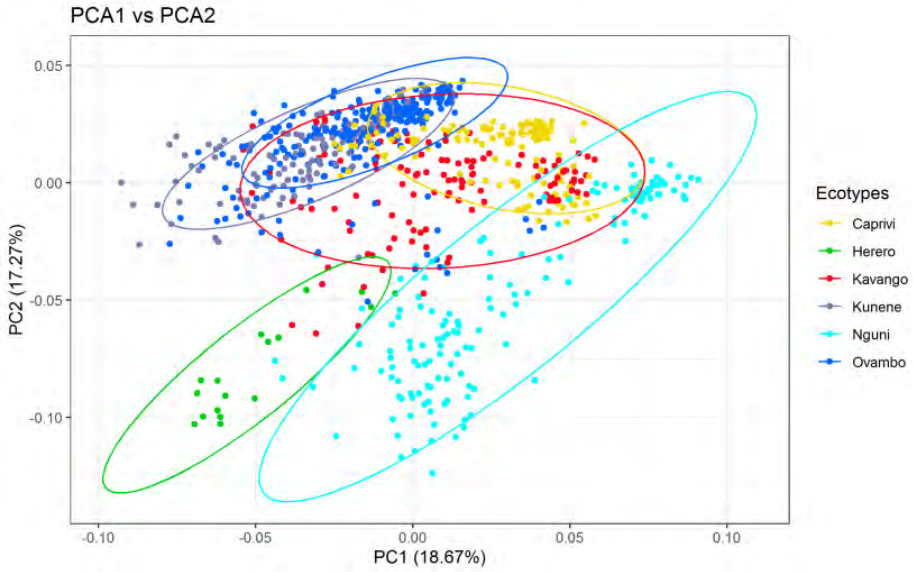

Figure 1. Cluster groups of the Indigenous Sanga cattle of Namibia.

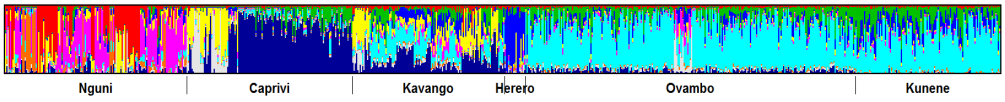

Figure 2. Admixture of Indigenous Sanga cattle in Namibia (*K*=9).

Low *Fst* coefficients showed a low level of differentiation (Table 2). This could possibly be ascribed to that all these Sanga ecotypes belong to one breed that has common ancestory (Maiorano *et al.*,2018; Bhuiyan *et al.*, 2021).

Discussion

The natural environment in which these ecotypes exist clearly plays a role in the genetic diversity of the animals. The Nguni and Herero Sanga cattle are found south of the VCF, the FMD free area where no restrictions on animal movement exist. The remaining ecotypes (except for those at the government research stations) are in the NCA. Caprivi ecotype is in Zambezi region, where animal movement to other regions are restricted (due to FMD). In the NCA, the cattle have adapted to different climates, from dry harsh north-

Table 2. Fst coefficients between the six Sanga ecotypes in Namibia.

	Kavango	Caprivi	Nguni	Kunene	Ovambo	Herero
Kavango						
Caprivi	0.0065					
Nguni	0.0097	0.0133				
Kunene	0.0081	0.0139	0.0165			
Ovambo	0.0058	0.0093	0.0142	0.0041		
Herero	0.0351	0.0513	0.0386	0.0347	0.0421	

western Namibia to wet north-eastern Namibia. In the NCA no direct selection for genetic improvement is practiced, thus natural selection occurs mostly. This is because subsistence farming is practiced, and no clear breeding plans and objectives exist. The result is that populations subjected to similar environments cluster closer together. Hanotte *et al.* (2010), Madilindi *et al.* (2020) and King *et al.* (2021) confirm these results in terms of adaptability to natural environment and selection due to the environment in which the animals exist. However, more genetic exchange also occurs between these regions.

220. Hedging genetic diversity using a similarity matrix based on Mendelian sampling

A.A. Musa* and N. Reinsch

Research Institute for Farm Animal Biology (FBN), Institute of Genetics and Biometry, Wilhelm-Stahl-Allee 2, 18196 Dummerstorf, Germany; musa@fbn-dummerstorf.de

Abstract

A major limitation of genomic selection criteria is the trade-off between short- and long-term genetic gains. A similarity matrix based on Mendelian sampling was recently proposed as an additional criterion to optimise this trade-off while hedging genetic diversity. However, its effect on genetic gain and diversity in breeding programmes under recurrent selection has not been investigated. Here the effects of the similarity matrix in conjunction with breeding value and an index combining breeding value and Mendelian sampling variance on genetic gain and diversity are investigated. We found no apparent effects of including the similarity matrix on genetic gains over generations. However, compared to the conventional breeding value and index selection, its inclusion preserved up to 6 and 19% of genetic diversity, respectively. This result is due to the similarity matrix's diversifying effect, which enables the selection of an optimal set of genetically diverse parents that maximises genetic gain in the next generations.

Introduction

Selecting parents of future generations based on their genomic breeding values (BV) maximise short-term genetic gains. Continuous selection on BV, on the other hand, accelerates the loss of genetic diversity, jeopardising long-term genetic gains. An index combining BV and Mendelian sampling variance (MSV) was recently proposed to optimise the trade-off between short and long term gains (Bijma *et al.*, 2020). MSV quantifies the expected variability among full-sibs and is vital if offspring variability is of interest. Under high selection intensity, the index tends to choose similar parents with high MSV potential, resulting in unintended losses of genetic diversity.

To hedge genetic diversity, a similarity matrix based on the Mendelian sampling values of parents was developed, in which the diagonal elements represent the similarity of a parent to itself, which equals its MSV (Musa, 2021; Reinsch and Musa, 2021). A high similarity between parents indicates that they share many heterozygous quantitative trait loci (QTL), with large effects on a trait in the same linkage phase. Similar to how the covariance and correlation matrices of asset prices are used for portfolio diversification in finance (Markowitz, 1952), the similarity matrix can be combined with selection criteria to obtain an optimal set of genetically diverse parents with high expected returns (Musa, 2021; Reinsch and Musa, 2021). However, its effect on genetic gain and diversity in a breeding programme under recurrent selection is yet to be investigated. Using a simulated cattle breeding programme, we investigate the potential of the similarity matrix combined with BV and an index comprising BV and MSV for increasing genetic gain and hedging genetic diversity in future generations. The results are compared to those obtained using BV and the index.

Materials & methods

Simulation of a cattle breeding programme. A base population of 1000 animals with 500 cows was simulated with a predefined parameter set for cattle using a coalescent process in AlphaSimR (Gaynor *et al.*, 2020). An average genetic map for both sexes with an architecture of 10 chromosomes with an average length of ~100 cM was assumed. For each chromosome, 1,200 segregating sites were assigned, from which 200 were QTL affecting a trait. The QTL effects are assumed to be additive, with a mean of

zero and a variance of 100. The heritability of the trait was assumed to be 0.25. Then we performed 20 generations of selection using various criteria. Each generation included the following steps: (1) calculation of selection criterion; (2) selection of the top 1% of bulls and 50% of cows as parents; (3) allotting mates with a maximum allocation of cows to a bull of 20%; and (4) mating to form a new generation of animals with four offspring per mate-pair, while maintaining a constant population size of 1000. Genetic gain and diversity of true breeding values were derived using 1000 animals. The entire simulation was repeated 100 times. The simulations and subsequent statistical analyses were performed in R software (R Core Team, 2020).

Selection criteria – BV. Let $\mathbf{z}_i'$ be a row vector of QTL genotype indicators (coded 1, 0, and -1 for respective genotypes *AA*, *AB* or *BA*, and *BB* at each locus) and m a vector of population additive QTL effects, then the BV of animal i is computed as $bv_i = \mathbf{z}_i'\mathbf{m}$ and for mate-pair ij as the mean BVs of animals i and j.

Selection criteria – Index. The index I_i of animal i is calculated according to Bijma *et al.* (2020) as $I_i = bv_i + \sqrt{2} \cdot x_p \cdot \sigma_{g_i}$ and for mate-pair ij as mean the mean indices of animals i and j. Here, x_p is the standardised truncation point belonging to the selected proportion p, and σ_{g_i} is the square root of MSV for animal i. Then MSV of additive genetic values of gametes produced by animal i is obtained using and $\sigma^2_{g_i} = \sum \left(\boldsymbol{m}_i^c\right)' \boldsymbol{R}^c \boldsymbol{m}_i^c$, where and $\boldsymbol{m}_i^c$ is the parent-specific vector of additive QTL effects for parent i on chromosome c and R^c is the expected within-family linkage disequilibrium matrix of QTL on the same chromosome (Bonk *et al.*, 2016; Musa, 2021). The element m_{ik}^c of the parent-specific vector $\boldsymbol{m}_i^c$ is given by the formula $m_{ik}^c = \delta_{ik} m_k^c$, where δ_{ik} and m_k^c are the phase indicator and QTL effect at locus k. If the standard allele is observed on the first haplotype, the phase indicator δ_{ik} is 1; otherwise, it is -1. For each homozygous genotype, the indicator is set to zero $\delta_{ik} = 0$. The element ρ_{kl}^c of R^c is calculated as $\rho_{kl} = \exp(-2d_{kl}^c)/4$ (Haldane, 1919), where d_{kl}^c is the genetic distance (Morgan) between QTL k and l on chromosome c.

Computation and application of similarity matrix. Let $\boldsymbol{m}_i^c$, $\boldsymbol{m}_j^c$, $\boldsymbol{m}_u^c$, and $\boldsymbol{m}_v^c$ be the parent-specific vector of QTL effects for parents i, j, u, and v, then the similarity $s_{ij,uv}$ between the Mendelian sampling values of zygotes produced by parent pairs ij and uv is given for a single trait as $s_{ij,uv} = \sum_c \left(\left| \left(\boldsymbol{m}_i^c\right)' \boldsymbol{R}^c \boldsymbol{m}_u^c \right| + \left| \left(\boldsymbol{m}_j^c\right)' \boldsymbol{R}^c \boldsymbol{m}_v^c \right| \right)$ (Musa, 2021). A similarity matrix S can be derived by assembling $s_{ij,uv}$. The diagonal and off-diagonal elements of matrix S represent MSVs and similarities between Mendelian sampling values of zygotes produced by mate pairs, respectively. Finally, matrix S was standardised to obtain a correlation matrix K within the range of $0 \leq k_{ij,uv} \leq 1$ (Musa, 2021).

The matrix K was then used in the same way as in the portfolio diversification approach in finance (Markowitz, 1952), in which the similarities between mate pairs were minimised for a given level of expected returns to obtain a portfolio that contains the optimal set of mate pairs. The expected genetic return of a portfolio was defined as $\Psi = n'p$, where vector p is the vector of BV or index for mate pairs ij and n is a vector of the relative weights allotted to mate-pairs ij. The optimisation problem can be stated as:

$$\min_n \boldsymbol{n'Kn}$$

Subject to $\Psi = \boldsymbol{n'p} \geq 0$

$$\boldsymbol{n'1} = q$$

$$n_{ij} \in \{0,1\}, _{ij} \in \{1, \ldots, N\}$$

where l is a vector of ones, q is the number of mate pairs to be selected, n_{ij} is a binary decision showing whether mate pair ij is selected (n_{ij}=1) or not (n_{ij}=0), and N is the total number of all possible mate pairs. The minimum and maximum allocations were set to 0 and 1, respectively, for unbiased comparison with other criteria. This optimisation was solved using *gurobi* (Gurobi Optimisation LLC, 2021) to obtain vector n at varying levels of expected return Ψ to derive an efficient frontier (EF). The EF offers several portfolios containing a set of optimal allocations of mate pairs with the lowest possible risk of losing genetic diversity (low similarities) for each level of expected returns.

Results & discussion

Figure 1A shows a subset of a similarity matrix for mate pairs, with the red boxes separating one bull from the other. Due to differences in heterozygosity and QTL linkage, some families have larger MSVs and thus produce more variable offspring than those with smaller MSVs, as indicated by the diagonal elements. Large MSVs are typically caused by heterozygous QTL that have large effects on a trait, whereas small effects cause small MSVs (Musa, 2021). Consequently, small-effect QTL may be lost by only selecting mate pairs with high MSV potentials. Mate pairs with large MSVs are more similar than those with small MSVs (see off-diagonals) because they share many heterozygous QTL with large effects on a trait in the same linkage phase. Hence, the similarity matrix is of practical importance for hedging and visualising genetic diversity. The standardised similarity matrix (Figure 1B) contains the same information as Figure 1A, except that the diagonals are one, and the off diagonals better highlight small similarities between mate pairs (Musa, 2021; Reinsch and Musa, 2021).

Figure 1C shows the EF, which provides several portfolios (blue and red points) containing an optimal set of genetically diverse mate pairs at a given expected return. Additionally, the EF illustrates the trade-off between expected returns and diversity (similarity), with expected returns increasing as the similarity between mate pairs and, consequently, among offspring increases. The choice of a portfolio depends on the breeders' goals and objectives. Nonetheless, the EF enables breeders to make the most informed decisions regarding the genetic diversity they are willing to sacrifice for greater genetic gain (Musa, 2021; Reinsch and Musa, 2021). Here we chose the portfolio in red with the highest similarity and expected returns.

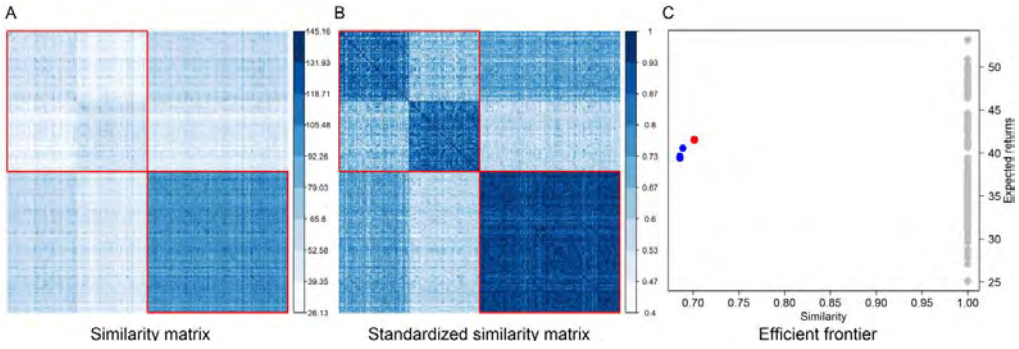

Figure 1. Similarity matrix (A), standardised similarity matrix (B) and efficient frontier (C) of matings. The red boxes on the similarity matrices (A and B) separate matings between bulls. The grey points represent the expected returns of each mate-pair. The blue and red coloured points (efficient portfolios) are called the efficient frontier (C), which provide a set of diverse mate pairs with low haplotype similarities at a given expected return level. The portfolio in red is the chosen portfolio in this study.

The genetic gains over generations (Figure 2A) were nearly identical for BV and index selection, with minor differences occurring only in later generations. There were no apparent effects of including the similarity matrix on genetic gains. Genetic diversity, however, was better preserved (10-55%) by index selection compared to selection solely on BV (Figure 2B). This effect was amplified by 3-19% when the index was combined with a similarity matrix (INDEX_SIM). In the case of BV selection, including the similarity matrix (BV_SIM) also had a beneficial effect, albeit to a much lesser extent (1-6%). These results are due to the similarity matrix' diversifying effect, allowing for the selection of a genetically diverse set of parents that maximises genetic gain while hedging genetic diversity in subsequent generations.

The similarity matrix can be included as an additional GS criterion to optimise the trade-off between short and long term genetic gains while hedging genetic diversity to sustain longer-term genetic gain.

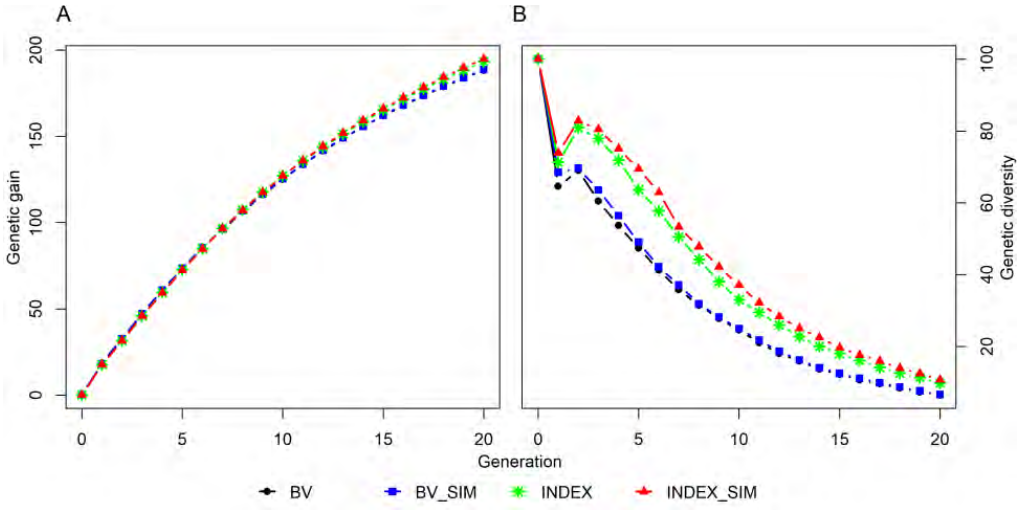

Figure 2. Genetic gain (A) and diversity (B) of true breeding values over 20 generations.

221. Genetic basis of sexually divergent early life survival in red deer (*Cervus elaphus*)

L. Peters[1,2*], J.M. Pemberton[1] and S.E. Johnston[1]

[1]Institute of Evolutionary Biology, School of Biological Sciences, University of Edinburgh, Edinburgh, EH9 3FL, United Kingdom; [2]Laboratoire de Genetique Cellulaire, INRAE, 31320 Auzeville-Tolosane, France; lucy.peters@inrae.fr

Abstract

Males and females largely share the same genome, but the optimal value of a trait can differ between the sexes. If these traits share a genetic basis between the sexes, intra-locus sexual conflict can prevent them from reaching their optima. Here, we explore the genetic basis of sex-specific early life survival in wild red deer, a species with extensive sexual dimorphism, using a genomic dataset of >38,000 genotyped SNPs for 3,067 individuals. We conducted a variance component analysis using a Bayesian mixed model approach. Males were ~14% more likely to die before the age of two. Early life survival was significantly heritable (h^2=~0.1) and influenced by maternal effects. No SNPs were significantly associated with sex-specific survival to the second year and a polygenic genetic architecture is likely. Overall, this study gives valuable insight into the genetic architecture of sexually-dimorphic traits and its contribution to maintaining genetic variance.

Introduction

In species with separate sexes, males and females often follow very different life-history strategies. In many species, females invest more heavily in parental care compared to males, e.g. through gestation and food provisioning, whereas males invest more heavily in maximising their reproductive success (Clutton-Brock, 1991; Schärer *et al.*, 2012). This can lead to diverging fitness optima in the two sexes (where fitness is defined as total lifetime breeding success or its components such as survival and fecundity) and results in males and females differing substantially in a range of physical and behavioural traits. As a result, the genetic architecture of such traits can be sex-specific and play an important role in maintaining genetic polymorphisms, which has been documented for some major effect loci (Barson *et al.*, 2015; Rostant *et al.*, 2015). However, in most cases the genetic architecture of sexually divergent traits and thus their effect on genetic variance is unknown.

Red deer show extensive sexual dimorphism in morphology. Due to intense male competition, traits such as body size and fighting ability are important in stags, leading to significantly higher birth weight and faster growth rates in male calves (Clutton-Brock, 1985; Kruuk *et al.*, 1999). However, male calves also have lower fat storage compared to female calves, and consequently often much lower first winter survival (Clutton-Brock, 1985; Gauzere *et al.*, 2020). As a result, male and female red deer have different fitness optima for a number of traits, including those affecting survival. Here, we use long-term individual data on survival and a genomic dataset from red deer on the Isle of Rum, Scotland, to investigate the genetic basis of sexually divergent early life survival and its role in maintaining genetic variance.

Materials & methods

Study system and genomic data-set. The red deer study population is situated in the North Block of the Isle of Rum, Scotland (57°02'N, 6°20'W) and has been subject to individual monitoring since 1971. Deer calves are marked with ear tags shortly after birth to enable recording of detailed life histories of individuals. DNA is routinely extracted from neonatal ear punches. DNA samples were genotyped on the Cervine Illumina BeadChip (Brauning *et al.*, 2015) using an Illumina genotyping platform and Illumina GenomeStudio software (Illumina Inc., San Diego, CA, USA). A total of 3,067 pedigreed individuals

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_221, © L. Peters *et al.* 2022

genotyped at 39,587 polymorphic SNP loci were available for analysis. In addition, a linkage map specific to the Rum population is available, with 38,083 SNPs assigned to linkage groups corresponding to the 33 deer autosomes and X chromosome (Johnston *et al.*, 2017).

Imputation of missing genotypes. Missing genotypes in the genomic dataset were imputed using AlphaImpute version 1.98 (Hickey *et al.*, 2012) to prepare the dataset for subsequent analyses. The following parameters were used: threshold of non-missing SNPs for an animal to be included in high density group = 50%; threshold for allowed disagreement between cores of two surrogate parents = 0.5; five phasing iterations were run, the size of cores including tails being 100, 200, 300, 400 and 500 and the respective core sizes 50, 150, 250, 350 and 450.

Bayesian mixed model analysis of early life survival. To identify sexually antagonistic SNPs that affect early life survival, a Bayesian general linear mixed model approach was adopted using the R package *BGLR* version 1.0.8 (Pérez and De Los Campos, 2014). Survival to the second year of life was used as a binomial response variable, coded 1 if the animal survived and 0 if it died. All models employed the following formula:

$$y = Xb + Z1\ a + Zr\ ur + e \quad (1)$$

where y is a vector of survival to the second year, X is an incidence matrix relating individual measures to the vector of fixed effects b; Z1 and Zr are incidence matrices relating individual measures to additive genetic and other random effects respectively; a is a vector of SNP effects or the genomic co-variance matrix; ur is a vector of additional random effects; and e is a vector of residual effects. Models were run both with sex as a fixed effect and as separate models for each sex. Models were selected based on their genomic prediction accuracy i.e. the ability of an individual's genotypes to predict its phenotype. The genomic prediction accuracy was calculated as the area under the curve (AUC) of a Receiver Operating Characteristic (ROC) curve. AUC calculation and significance testing was performed in R using the *pROC* package version 1.17.0.1 (Robin *et al.*, 2011). The genetic priors tested were the BayesA model, which assumes all markers have non-zero effects and uses a scaled-t distribution, and the BayesB model, which implements a mixture of a distribution with highest density at 0 and a scaled-t distribution (Meuwissen *et al.*, 2001). The additional random effects tested included birth year, second winter year, and mother ID. For the non-genetic random effects, a Bayesian Ridge Regression (BRR) model was chosen, which uses a Gaussian prior. Additionally, Bayesian Reproducing Kernel Hilbert Spaces Regressions (RKHS) models using a genomic co-variance matrix was run to determine the heritability of early life survival; a full model with both sexes and two sex specific models were run. All models were run with the default parameters except for the number of iterations, which was set to 120,000 with a burn-in of 20,000; the thinning interval was kept the default value of 5.

Results

After model selection the best model was a BayesB model with additional random effects to account for the influence of common environment (birth year) and maternal effects (mother ID). Males had on average a ~14% lower probability of survival to the second year compared to females (effect = -0.1407, 95% confidence interval (CI) = [-0.1998; -0.0807]). The heritability of early life survival was substantial (0.10) as estimated by the RKHS model, which included sex as fixed effect and the environmental and maternal random effects. The maternal effect on survival explained ~14% of total phenotypic variance, which was slightly larger than the additive genetic effect. The environmental effect of birth year had larger uncertainty associated with its estimate. Sex specific variance components suggested maternal effects have a stronger effect on male than on female survival (Table 1). None of the SNP effect sizes in either the model containing

Table 1. Variance components of the RKHS *BGLR* model for early life survival.

Variable	Variance (95% CI)	Proportion Vtotal[1](95% CI)
Additive genetic	0.3184 (0.1410; 0.5697)	0.1024 (0.0496; 0.1664)
Mother ID	0.4037 (0.2357; 0.6201)	0.1320 (0.0746; 0.2020)
Birth year	1.3810 (0.7087; 2.4529)	0.4350 (0.2983; 0.5821)
Additive genetic female	0.3487 (0.1390; 0.6910)	0.1446 (0.0649; 0.2525)
Mother ID female	0.3198 (0.1297; 0.6195)	0.1340 (0.0571; 0.2381)
Birth year female	0.7078 (0.3466; 1.3113)	0.2916 (0.1757; 0.4332)
Additive genetic male	0.3077 (0.1136; 0.6567)	0.1128 (0.0464; 0.2126)
Mother ID male	0.5055 (0.2255; 0.9057)	0.1867 (0.0910; 0.3003)
Birth year male	0.8818 (0.4438; 1.6066)	0.3208 (0.2024; 0.4649)

[1] Total phenotypic variance.

sex as fixed effect or in the two sex specific models had 95% CIs that did not contain zero, and therefore no SNP could clearly be identified as having an effect on survival (Figure 1).

Discussion

Survival to the second year in red deer was significantly heritable, with additive genetic variance explaining about 10% of the total phenotypic variance. This was similar to previous findings for this population that showed first and second winter survival separately each had a heritability of about 5% (Gauzere *et al.*, 2020). However, no individual loci with significant effects on post-natal early life survival were identified. Therefore, although early life survival clearly has a genetic component, the trait is likely polygenic with many loci of small effect rather than a small number of loci explaining most of the genetic variance. This kind of genetic architecture is typical for fitness-related traits, where additive genetic variance is thought to be maintained by high mutational variability due to large number of loci influencing survival (Houle *et al.*, 1996; Merilä and Sheldon, 1999). Thus, genetic variance can be maintained even in the face of strong selection if a trait is highly polygenic (Barton and Keightley, 2002). There was a strong sex effect on early life survival probability, with female offspring ~14% more likely to survive to their second year compared to their male counterparts, confirming earlier findings on sex differences in early life survival in the red deer (Clutton-Brock, 1985). Additionally, maternal effects were also found to play a significant role in offspring survival, explaining ~14% of the overall phenotypic variance in the model including both sexes and this effect was stronger for males in the sex specific models than in females (~19% compared to ~13%). This is in line with earlier findings that mothers invest more heavily in their male offspring (Clutton-Brock, 1991).

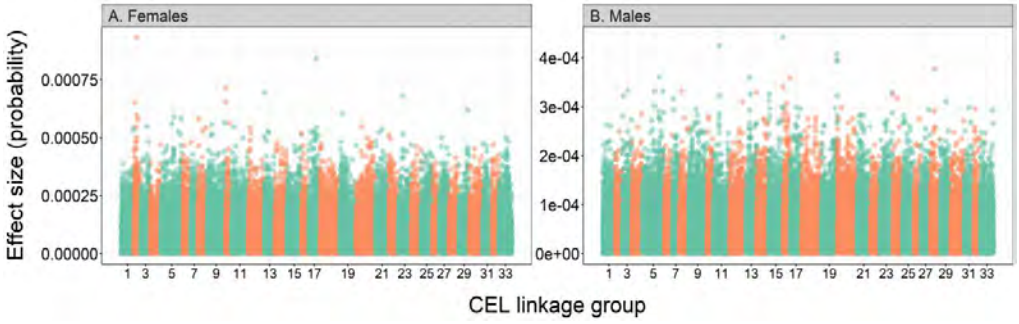

Figure 1. SNP effect sizes from sex-specific BGLR models for females (panel A) and males (panel B). Effect sizes are given as absolute change on a probability scale.

Maternal effects can weaken the link between an individual's genotype and their phenotype, thus adding to the conservation of genetic variance by moderating the influence of selection (Yamamichi and Hoso, 2017). A polygenic architecture together with maternal effects likely contributes to the maintenance of genetic variance for early life survival in this population.

222. Changes in genomic inbreeding over half a century in Swedish Red and Swedish Holstein cattle

S. Eriksson*, E. Strandberg and A.M. Johansson

Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, P.O. Box 7023, 75007 Uppsala, Sweden; susanne.eriksson@slu.se

Abstract

Over the last half century, new artificial insemination technology, methods for genetic evaluation, and breeding material from other countries have been introduced in Swedish cattle breeding. In this study, we aimed at investigating changes in homozygosity and genomic inbreeding over time in commercial dairy breeds. Genotype data from 50K and 150K SNP arrays for in total 5,636 Swedish Red and 3,115 Swedish Holstein bulls born 1956-2015 were analysed. The highest levels of both average homozygosity and inbreeding coefficient based on runs of homozygosity were seen in the earliest period of the data, although rapidly decreasing until the 1980s. After a period of more stable estimates, the inbreeding coefficients increased in both breeds after the introduction of genomic selection around 2010. Principal component analysis of relatedness showed a gradual transition over time for both breeds, but most pronouncedly for Swedish Holstein that was much influenced by foreign Holstein bulls.

Introduction

Commercial dairy cattle breeds are intensively selected to suit current or predicted future market needs. At different time periods, new techniques and breeding regimes have been implemented for Swedish dairy cattle, such as the use of frozen semen for artificial insemination in the 1950s, and the introduction of the Interbull genetic evaluation of bulls in 1994 and the joint Nordic breeding values in 2005. The method best linear unbiased prediction (BLUP) was implemented for genetic evaluation in 1984, and in more recent years, genomic selection has been implemented as an even more efficient selection tool (Bengtsson *et al.*, 2020). Along with these improvements, the need to monitor genetic diversity has increased (Forutan *et al.*, 2018).

Today, the Swedish Red (SR) is a synthetic breed, largely influenced by Finnish, Norwegian and Danish red breeds, but that also shows genetic similarities to some old native Swedish cattle breeds (Upadhyay *et al.* 2019). The Swedish Holstein (SH) started as a strain of Friesian cattle (SLB), but the influence of Holstein increased from the 1960s until an almost complete Holsteinization of the breed. With the aim to study consequences of such developments, we estimated and compared different measures of genetic diversity, and inbreeding in Swedish commercial dairy bulls during different time periods since the 1950s.

Materials & methods

In total 5,636 SR and 3,115 SH bulls born from 1956 to 2015 were genotyped (Table 1). Most bulls (3,032 SH and 5,545 RDC) were genotyped using the 50K Illumina SNP array (v1 or v2) and their genotypes were obtained from the Nordic Cattle Genetic Evaluation (NAV). In addition, 83 old HOL and 90 old SR bulls were genotyped using the 150K Genomic Profiler SNP array from GeneSeek®. In total 39,161 autosomal SNPs overlapping between the different arrays, with a non-zero minor allele frequency, were kept for further analyses.

Calculation of expected and observed level of homozygosity (Ho_{exp} and Ho_{obs}), runs of homozygosity (ROH), ROH-based inbreeding coefficient F_{ROH}, inbreeding coefficient based on deviation of observed from expected homozygosity (based on allele frequencies of bulls born before 1980) (F_{dev}), and principal

Table 1. Number of genotyped bulls born in different years for Swedish Red (SR) and Swedish Holstein (SH).

	Birth year								
Breed	<1965	1965-1979	1980-1984	1985-1989	1990-1994	1995-1999	2000-2004	2005-2009	2010-2015
SR	33	54	42	266	425	383	351	452	3627
SH	25	33	19	60	90	146	177	592	1973

component analysis (PCA) was done using PLINK v1.9 (Purcell *et al.*, 2007). Ho_{obs} was defined as the proportion of homozygous SNPs and the deviation from expected homozygosity was estimated using the --het command, using the allele frequencies of bulls born before 1980. For ROH definition, a window size of 40 SNPs within 1000 kb, minimum SNP density of 75 (kb/SNP), up to 500 kb allowed gap between SNPs, 0.08 as proportion overlapping windows required to be homozygotic, 1 missing and 0 heterozygotic SNPs allowed per window, were used. F_{ROH} for each individual was calculated as the aggregate length of ROH segments in kbase pairs divided by the total length of the genome covered by SNPs, and the resulting value was adjusted by dividing with the F_{ROH} (0.9197) that a simulated completely inbred individual would get in the analysis.

A random subset of 395 SR and 236 SH bulls per birth decade starting from 1990 and 2000, respectively, were used in the PCA, to avoid bias due to the large number of genotyped individuals born in later years.

Results

Higher average homozygosity was estimated for SR than SH bulls in all studied time periods, but the difference was very small in later years (Figure 1). The inbreeding coefficient based on deviation from expected homozygosity (F_{dev}) was positive in the earliest years in both breeds, then negative after 1980, but increasing towards 0 from 1990s in SH (Figure 1). The F_{ROH} were similarly showing a higher level of inbreeding before the 1980s, that rapidly declined until the 1990s, stayed rather stable until 2009 and then started to increase again in both breeds in the last time period (Figure 1). This measure of inbreeding was higher for SR than SH before the 1980s, but from the 1990s the F_{ROH} was slightly higher in the SH than in the SR bulls.

The PCA-plot for each breed showed a gradual but distinct pattern related to the birth time periods of the bulls, from until the mid-1960s to 2015 (Figure 2). This pattern in relatedness within breed was mainly explained by the first principal component, and was more marked for the SH than for the SR bulls.

Discussion

The reduction in generation interval as a consequence of the introduction of genomic selection has been suggested to be the main cause of increased inbreeding rates per year in dairy cattle in recent years. In contrast, the use of pedigree-based BLUP would theoretically give a higher inbreeding rate per generation (Forutan *et al.*, 2018). In the Swedish commercial populations, a more rapid increase in F_{ROH} was as expected seen after 2009, following the introduction of genomic selection. It is noticeable that the highest levels of F_{ROH} were seen in the oldest bulls when breeding was a local business, but declined rapidly when the international exchange of genetic material increased. In practice, the old Swedish Friesian cattle (SLB) was crossbred with, and gradually replaced by, American Holstein (Bett *et al.*, 2010), and this transition is visible in the PCA plot.

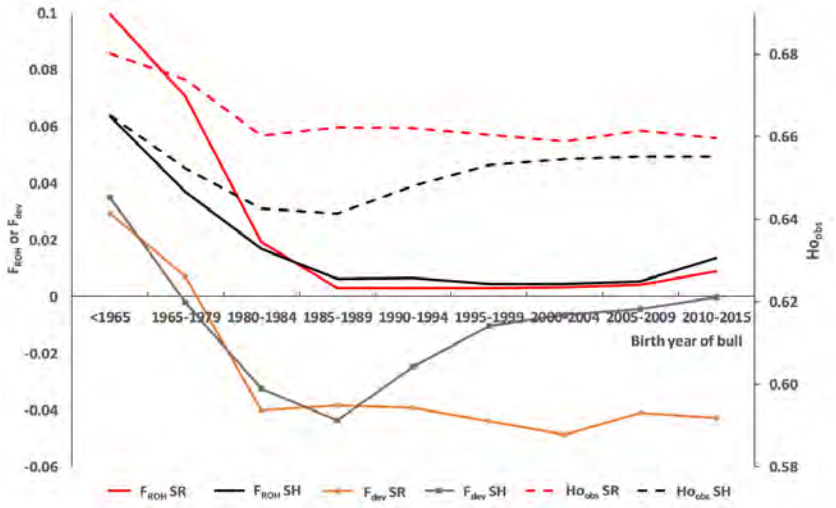

Figure 1. Average inbreeding coefficient based on runs of homozygosity (F_{ROH}), and on deviation from expected homozygosity (F_{dev}), and average observed homozygosity (Ho_{obs}) for Swedish Red (SR) and Swedish Holstein (SH) bulls born in different time periods.

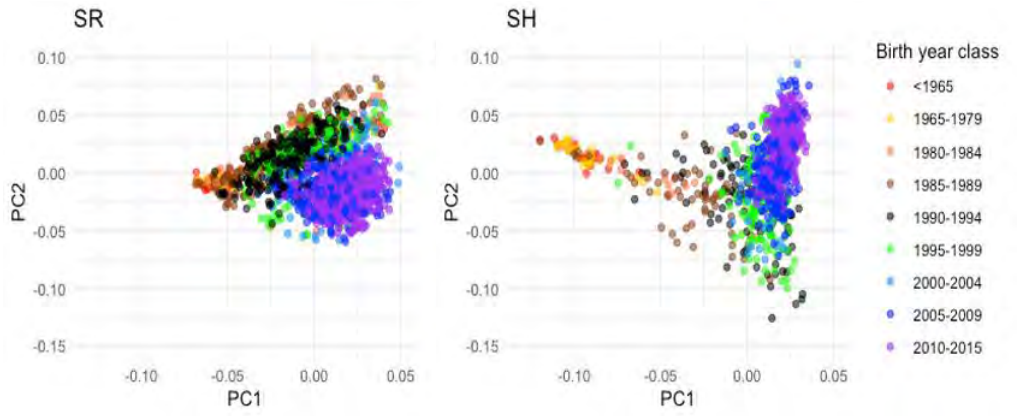

Figure 2. Principal component (PC) analysis of genetic relatedness between bulls born in different years, for Swedish Red (SR) and Swedish Holstein (SH). PC1 and PC2 explained 2.1 and 1.2% of the variation for SR, and 2.9 and 1.1% for SH, respectively.

At about the same time that BLUP was introduced in Swedish cattle breeding, the decrease in average F_{ROH} stopped, and the trend became more stable. This could also be due to a reduced effect of crossbreeding, especially in the SH in which the proportion of Holstein at that time was large. The continued transition also in later years shown mainly in the second principal component in the PCA-plot would thus likely be due to intensive selection for favourable genotypes.

Most studies of inbreeding trends that go far back in time are based on pedigree information. The low pedigree completeness in historical data, such as illustrated by Makanjuola *et al.* (2020), may cause under-estimation of inbreeding levels in the oldest animals, which can be avoided by using genomic information. Due to recombination, old inbreeding is seen as shorter ROH than recent inbreeding, and

genomic measures such as F_{ROH} do not accumulate inbreeding over time to the extent that homozygosity and pedigree-based measures do (Meuwissen *et al.*, 2020). The current levels of F_{ROH} in both SR and SH appear to be considerably lower than in the Canadian Holstein population studied by Makanjuola *et al.* (2020), where it increased from around 0.1 in 1990 to around 0.17-0.19 in 2018. Martikainen *et al.* (2017) found F_{ROH} ranging from 0.04 to 0.09 in Finnish Red cows born 2002-2014, which is more comparable, but still higher than our results. However, their estimate of Ho_{obs} was 0.63, which was lower than our values. The actual level notwithstanding, our results show that the inbreeding level was considerably higher half a century ago than at present, but that the inbreeding level in both SR and SH is currently increasing, which should be considered in breeding strategies.

Abstract

Runs of homozygosity (ROH) are used in livestock research for identification of homozygous genomic regions and are valuable to characterize inbreeding. The aim of this study was to use BovineSNP150K data to investigate inbreeding levels and occurrence of ROH in indigenous Bonsmara and Nguni cattle populations. 506 genotypes were included for analysis. Quality control was performed using PLINK. ROH were computed using the R package detectRUNS. A total of 17,411 ROH in total with mean number of ROH per individual per breed ranging from 203 to 397 were obtained. Both breeds displayed low ROH based inbreeding (F_{ROH}) of 0.003±0.002 for Nguni and 0.012±0.005 for the Bonsmara population. Within the reported ROH, genes relating to heat tolerance and immunity were detected in both breeds, while those relating to growth was found only in the Bonsmara population. These breeds provide valuable insights for understanding the genetic basis of adaptive traits.

Introduction

Runs of homozygosity (ROH), an indicator of genomic autozygosity, are defined as long and continuous stretches of homozygous genotypes (Ku *et al.*, 2011). ROH results from parents transmitting identical haplotypes to their offspring. This autozygosity may be present in inbred as well as non-inbred populations due to several population occurrences such as inbreeding, genetic drift as well as natural and artificial selection. Over the past two decades, there has been a rapid development of high-throughput genomic analysis methods, including next-generation sequencing (NGS) and genotype-based microarrays. Both methods allow for effective identification of ROH. However, single nucleotide polymorphisms (SNP) microarrays remain most popular for determining ROH due to its lower cost and less-time consuming analysis, compared to NGS. SNP arrays in cattle have been successfully used to estimate inbreeding (Zhang *et al.*, 2013). In addition, ROH was found to be effective in distinguishing non-autozygotic identical by state (IBS) segments from autozygotic identical by descent (IBD). The frequency and length of ROH are important parameters in determining the causative forces of genomic change. Therefore, the identification of ROH may assist in revealing the population structure of a population. The Nguni, an indigenous South African (SA) breed has many beneficial traits such as parasite resistance, heat and drought tolerance. Bonsmara, a composite breed performs well in beef production systems due to its high fertility, calm temperament and easy handling (van Marle-Köster *et al.,* 2021). Thus, the aim of this study was to determine ROH in indigenous Nguni and Bonsmara cattle populations.

Ethical approval. Ethical approval was obtained from the Agricultural Research Council, Animal Production Ethics Committee (APIEC21/06).

SNP data and quality control. Raw SNP data using GeneSeek Genomic Profiler 150K was obtained for two SA cattle breeds. The quality control parameters involved removing SNPs with less than 95% call rate, SNPs less than 2% minor allele frequencies (MAF), samples with more than 10% missing genotypes and SNPs that deviated from Hardy Weinberg Equilibrium using PLINK (*P*£0.001) (Purcell *et al.*, 2007). Closely related individuals with a PI_HAT value greater than 0.25 were removed. Following quality control,

27 individuals and 40,224 SNPs were removed from the Nguni population, while 32 individuals and 28,409 SNPs removed from the Bonsmara population.

ROH analysis and Gene annotation. ROH were determined using the R package detectRUNS (Biscarini *et al.*, 2018). The minimum length that constituted the ROH was set to 1 Mb. The following parameters were used to define the ROH: (1) one missing SNP and up to one possible heterozygous genotype was allowed in the ROH; (2) the minimum number of SNPs that constituted the ROH was set to 50; (3) the minimum SNP density per ROH was set to one SNP every 100 Kb; and (4) the maximum gap between consecutive homozygous SNPs was 250 Kb. The inbreeding coefficient (F_{ROH}) was estimated based on ROH for each animal and averaged per breed. F_{ROH} was calculated within detectRUNS using the following formula:

$$F_{ROH} = L_{ROH} / L_{AUTO}$$

where L_{ROH} is the total length of ROH on autosomes and L_{AUTO} is the total length of the autosomes covered by SNPs (Biscarini *et al.*, 2018). Analyses of common ROH revealed SNPs most common in both populations by using the tableRUNS function with the threshold set at 0.2 found in the detectRUN R package. Results indicated the top ROH island positions and number of SNPs. Genes within these islands were identified using Ensembl BioMart (Kasprzyk, 2011). The enrichment analysis was performed using PANTHER with Bonferroni correction ($P<0.05$) to group genes based on function or processes unique to each population.

Results

In Table 1, the number of animals and SNPs remaining after quality control along with the inbreeding coefficient is shown.

The genes that are unique to the two breeds are shown in Table 2 and the enrichment analysis of gene ontology terms for biological processes and molecular function are shown in Table 3.

Discussion

ROH provides useful information with regard to genetic relatedness among individuals, assisting in managing the inbreeding rate in a population, revealing possible deleterious variants in the genome. The calculation of the inbreeding coefficient (F_{ROH}) from ROH was reported to be more accurate for estimating autozygosity and detecting historic and recent inbreeding effects, rather than estimating inbreeding from pedigree data (Alemu *et al.*, 2021). F_{ROH} for the Nguni was lower than the Bonsmara. This may be attributed to Nguni being an indigenous breed with higher genetic diversity than Bonsmara cattle (van Marle-Köster *et al.,* 2021). Other studies reported higher levels of inbreeding in cattle (Dixit *et al.*, 2020). Findings in this study are consistent to that reported by Soma *et al.*, 2021, whereby low levels of inbreeding were detected using microsatellite data. Genes relating to heat tolerance (*DNAJCB5, DNAJB1*) and immunity (*IRF1, STING1*), were detected in both populations, while growth (*GHR*) related genes were identified in the Bonsmara. DNAJC18 gene, plays a role in heat stress, was detected only in Nguni. The gene ontology term chaperone-mediated protein folding (GO: 0061077) and unfolded protein binding (GO:0051787) present in the Bonsmara population, supports the presence of heat shock proteins (*HSPH1, HSPB2, HSPA9*). While the

Abstract

Inbreeding caused by the mating of animals related through a recent ancestor is expected to have more pronounced effects on traits than old inbreeding. Estimating these effects requires a clear definition of new (recent) and old (ancient) inbreeding. Current methods to classify inbreeding are largely based on heuristic criteria. The subjectivity of the thresholds used to distinguish between ancient and recent inbreeding has led to inconsistency in results. To remedy this situation, we developed a new method to classify inbreeding based on a search algorithm driven by the hypothesis that new inbreeding tends to have a more pronounced effect on traits. Four growth traits were used to quantify the effects of old and new inbreeding in a Hereford herd. Thresholds to classify inbreeding varied across traits and sources of information. Using pedigree information, inbreeding generated in the last 10 to 11 generations was considered recent. When genomic information was used, thresholds ranged between 4 to 7 generations. In general, the proposed method seemed to have similar performance compared to existing approaches using ROH segments and to be slightly better using pedigree information.

Introduction

Although genealogy information has been traditionally used to estimate individual level of inbreeding (F), the pedigree-based measure of inbreeding (F_{ped}) is highly influenced by the quality of the pedigree and its completeness (Cassell *et al.*, 2003). The availability of high-density single nucleotide polymorphisms (SNPs) provides an alternative to quantify the genome-wide homozygosity through runs of homozygosity (ROH) segments. Several studies showed that inbreeding coefficients calculated based on ROH (F_{ROH}) are more accurate, and they are more powerful in assessing the effects of inbreeding (Keller *et al.* 2011). The distribution of ROH segment length could be a valuable resource to distinguish between new and old inbreeding. Long ROH segments are likely produced by recent common ancestors (recent inbreeding), whereas shorter segments are generated many generations in the past (older inbreeding). Knowing the distribution of ROH segments will provide a useful tool to understand the purging of deleterious alleles and to assess inbreeding depression. Several approaches based on tracing the pedigree back to a pre-specified number of generations (threshold) to identify recent inbreeding were proposed (Doekes *et al.* 2019). Unfortunately, the threshold is arbitrarily set, and it is likely to be population or even breed dependent. Additionally, multiple studies have recently attempted to discriminate between recent and ancient inbreeding using genomic autozygous segments. Several approaches have been proposed to categorize ROH segment length into different age-classes based on arbitrary thresholds. These approaches to discriminate between recent and old inbreeding have led to inconsistent results. It was hypothesized that recent inbreeding has a greater impact on traits compared to inbreeding due to distant common ancestors. Ancient inbreeding allows selection to have enough time to purge deleterious recessive mutations. The ability to identify inbreeding classes associated with a greater impact on phenotypes could be useful not only for quantifying its impact on phenotypes, but also for better herd management. The objectives of this study are to: (1) develop a new method to distinguish between recent and old inbreeding using pedigree and ROH information; and (2) compare the performance of the proposed approach with existing methods.

Materials & methods

Data used in this study was collected from purebred Line 1 Hereford cattle herd maintained at USDA-ARS, Fort Keogh Livestock and Range Research Laboratory, Miles City, MT. Although the population was historically selected for increased yearling weight, since 2011, the selection was primarily focused on improving calving ease. A complete pedigree comprising 10,478 animals was used. Pedigree analyses of the Line 1 population showed relatively complete, deep genealogical records with an average of 17.15 equivalent complete generations for all animals. A subset of 797 animals born between 1953 and 2016 was genotyped with different density panels (3k to 50k markers). Imputed genotypes for 30,220 SNPs on 29 autosomal chromosomes for 785 animals, generated as described in Sumreddee *et al.* (2019), were used.

Grid search approach to discriminate between old and recent inbreeding. We developed a grid search algorithm to determine the appropriate threshold for discriminating between new and old inbreeding based on the basic assumption that recent autozygosity has more harmful effects than old inbreeding (Sumreddee *et al.*, 2019). Thus, the threshold separating old and recent inbreeding can be identified by comparing their effects on traits. By varying the threshold to cluster ROH into short and long segment classes, the optimal cut-off-point (threshold) can be inferred. Standardized coefficients for new and old inbreeding based on varying thresholds (ROH length or number of generations) were included as covariates in the model for analyzing inbreeding depression. The magnitudes of the estimated inbreeding effects associated with partial inbreeding were then compared, and a threshold for recent inbreeding was determined. The threshold was defined as the minimum number of ancestral generations (t) or the longest length m (in Mb) used to classify ROH segments that resulted in a larger negative effect of recent inbreeding compared to its old counterpart. The resulting new and old inbreeding are denoted hereafter as $F_{new\,t}$ and $F_{old\,t}$ using pedigree information and F_{long_m} and F_{short_m} using ROH segments. The proposed method was compared to several existing approaches used to partition inbreeding into new and old classes.

Results

Figure 1 presents the correlations between different estimates of new and old inbreeding. In general, F_{ped} has moderate to high correlation (r=0.63 to 0.91) with old age-class inbreeding (e.g. $F_{old\,t}$, $F_{anc\,Kal}$). However, it was weakly correlated (r=0.24 to 0.41) with recent inbreeding (e.g. $F_{new\,t}$, $F_{new\,Kal}$). Different patterns were observed between F_{ROH} and partial inbreeding coefficients derived based on different definitions of ROH segment length classifications. F_{ROH} was in general highly correlated with both short and long ROH-based inbreeding coefficients (r=0.69 to 0.98). However, high correlations were observed only between F_{ROH} and old inbreeding derived based on pedigree (r=0.47 to 0.62). Correlation between F_{ROH} and pedigree based new inbreeding ranged between 0.15 to 0.24. The higher correlations of both F_{ped} and F_{ROH} with pedigree based old inbreeding seem to suggest that the majority of autozygosity in the used pedigree is ancient. Moderate negative correlations (r=-0.45 to -0.55) were observed between pairs of new and old inbreeding based on pedigree using our proposed thresholds (10 and 11 generations), while almost no linear relationships were observed between pairs of new and old inbreeding using a 5 generations literature threshold (r=-0.18) and between Kalinowski's new and ancestral inbreeding (r=0.09).

Inbreeding depression based on new and old pedigree-based inbreeding. The effects of new and old inbreeding based on pedigree information were present in Table 1. Using the proposed method, the threshold for discriminating between new and old inbreeding was 10 (for BW, WW and YW) and 11 (for ADG) generations. An additional 1% of new inbreeding resulted in a loss of 1.78 kg and 8 gram/day in YW and ADG, respectively. Old inbreeding also showed a significant negative effect of 5.5 gram/day on ADG but was not significant for YW. All growth traits consistently showed a larger negative effect of new inbreeding compared to its old counterpart. The proposed method yielded consistent results with those using the ancestral inbreeding approach ($F_{new\,Kal}$ and F_{anc_Kal}) based on Kalinowski *et al.* (2000) in terms

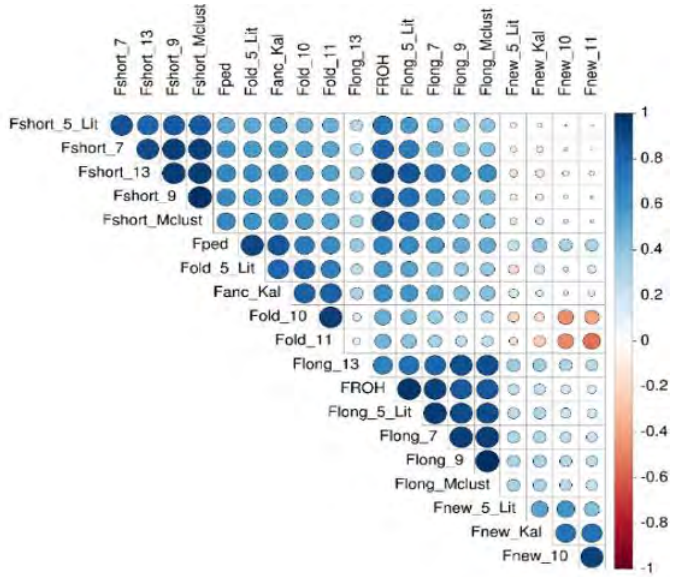

Figure 1. Correlations between different estimates of inbreeding coefficients with hierarchical clustering order. Blue and red circles represent positive and negative correlations, respectively. Color intensity and the size of the circle are proportional to the correlation coefficients. F_{ped} = pedigree-based inbreeding from the full pedigree; F_{old_t}, F_{new_t} = old and new inbreeding based on tracing the pedigree back to t ancestral generations; $F_{old\ 5\ Lit}$ and $F_{new\ 5\ Lit}$ = old and new inbreeding based on 5 generations for recent generations according to the literature; F_{anc_Kal}, $F_{new\ Kal}$ = ancestral and new inbreeding based on Kalinoski *et al.* (2000); F_{ROH} = genome-wide ROH-based inbreeding; F_{short_Mclust} and F_{long_Mclust} = inbreeding due to short and long ROH based on model-based clustering method; $F_{short_5_Lit}$ and $F_{long_5_Lit}$ = inbreeding due to short and long ROH based on 5 Mb as defined from the literature; F_{short_m} and F_{long_m} = inbreeding due to short and long ROH determined using proposed method with *m* Mb threshold.

[1] Significant effects are indicated by a bold font. The estimates of inbreeding effects from the proposed method are shown only for specific traits due to a trait-specific threshold to define new inbreeding.

[2] $F_{old\ 5\ Lit}$ and $F_{new\ 5\ Lit}$ = old and new inbreeding based on 5 generations for recent generations according to the literature; F_{anc_Kal} and $F_{new\ Kal}$ = ancestral and new inbreeding based on Kalinowski *et al.* (2000); $F_{old\ t}$ and $F_{new\ t}$ = old and new inbreeding based on tracing the pedigree back to t ancestral generations determined using the proposed method.

[3] BW = birth weight (kg); WW = weaning weight (kg); YW = yearling weight (kg); ADG = average daily gain (kg/d)

of inbreeding depression, especially for YW and ADG. Kalinowski's new inbreeding (F_{anc_new}) was more harmful than ancestral inbreeding (F_{anc_Kal}) for most of the growth traits; however, the significant effects were found only for YW and ADG. Using the literature-defined threshold of 5 generations to separate new and old inbreeding only the latter ($F_{old\ 5\ Lit}$) showed a significant unfavorable effect on both YW and ADG. Although a greater harmful impact would be expected for a very recent inbreeding (5 generations), this small threshold value favored older inbreeding to capture the majority of the genome-wide inbreeding. In fact, about 93% of the total inbreeding (F_{ped}) was captured by old inbreeding when the threshold was fixed at 5 generations. Consequently, magnitudes of effects of $F_{old\ 5\ Lit}$ and F_{ped} on YW and ADG were similar. In this respect, although the old inbreeding is likely to have a small deleterious effect, the accumulation of a relatively larger number of old genetic variants could dominate the overall inbreeding depression. Likewise, a smaller effect of new inbreeding obtained using 5 recent generations ($F_{new\ 5\ Lit}$) could be due to its minimal contribution (about 7%) to the total inbreeding. These results are concerning regarding the potential bias in the estimation of inbreeding depression using an arbitrary threshold.

Inbreeding depression based on recent and ancient ROH-based inbreeding. Partitioning of ROH segments into long and short classes offers the opportunity to assess the unfavorable effects of recent (F_{long}) and ancient (F_{short}) inbreeding. Using the proposed method, both inbreeding coefficients had negative effects on growth performances; however, the effects are statistically significant only for YW and ADG. Inbreeding based on ROH segments longer than 7 Mb (F_{long_7}) estimated using the proposed method resulted in a significant decrease in ADG (4.4 gram/day per 1% increase in inbreeding). Overall, the differences in the effects of new and old inbreeding based on the length of ROH segments were less evident compared to those observed using pedigree information. The proposed method seemed to have similar performance compared to existing approaches using ROH segments and to be slightly better using pedigree information.

225. Genome wide characterisation of runs of homozygosity on the main indigenous goat breed of Botswana

P.I. Monau[1*], K. Raphaka[2] and S.J. Nsoso[1]

[1]Botswana University of Agriculture and Natural Resources, Faculty of Animal and Veterinary Sciences, Department of Animal Science, Private Bag 0027, Gaborone, Botswana; [2]National Agricultural Research & Development Institute, Private Bag 00177, Gaborone, Botswana; pmonau@buan.ac.bw

Abstract

Runs of homozygosity (ROH) provides knowledge on the demographic history and management of livestock. The aim of this study was to characterise the distribution of runs of homozygosity (ROH) in Tswana goat genome. The Illumina Goat SNP50 Bead Chip was used to genotype 192 Tswana goats. Quality control and detection of ROH were analysed using Plink software. A total of 2,486 ROH were detected in Tswana goat population and the average number of ROH per animal was 13.08±8.71. The mean length was 7.18±7.89 and ranged from 3.02 Mb to 28.06 Mb. The majority of ROH segments for Tswana goats were shorter and accounted for approximately 77% in contrast to 10% of segments longer than 16 Mb. The highest chromosomal inbreeding levels were found on chromosome 6 with about 7.8%. The findings form a base for future goat genomics research and goat breeding programs in Botswana.

Introduction

Tswana goat is the predominant ancient genetic resource valuable for sustainable production and nutrition of poor-resource farmers in Botswana. It constitutes about 70% of the 1.3 million goat's population kept extensively under traditional management systems (Statistics Botswana, 2019). The traditional sector consists of approximately 96% of goat production (Statistics Botswana, 2019). This breed has been exposed to natural selection over time, enforced by environmental changes, breeding conditions and different husbandry practices, resulting in a wide range of adaptability such as low feed intake, heat, and disease resistance. Selection of certain characters over time often leads to reduced genetic diversity and autozygosity. Autozygosity generally occurs when individuals possess identical haplotypes from common ancestors resulting in long incessant homozygous segment known as runs of homozygosity (ROH) (Nosrati *et al.*, 2021). The length and frequency of ROH play a major role in shaping the genomic change of livestock (Dixit *et al.*, 2020). The short ROH may arise because of ancient consanguinity from genetic drift and founder effect whilst longer ROH may reveal recent common ancestor (McQuillan *et al.*, 2008). The distribution and size of ROH provide insights on individual autozygosity, evolution history and demography, diseases, and traits architecture, ultimately assisting on guiding breeding strategies and sustainable genetic improvement.

Molecular genetics has facilitated in scanning the genome for ROH in different livestock species using high-density markers. The extent of ROH across different goat genome is however, limited particularly for indigenous goats in the tropics including the indigenous Tswana goat. It is necessary to assess autozygosity of indigenous goats to implement relevant breed improvement and design breed conservation programs to cope with current and future environmental changes. The aim of this study was therefore, to characterise genome wide patterns of runs of homozygosity of indigenous Tswana goats of Botswana.

Materials & methods

Animals, genotyping and quality control. Animal sampling was conducted in conformity with the guidelines of Botswana University of Agriculture and Natural Resources ethical committee (BUANEC). A total of 96 goat hair samples were randomly collected from traditional farms in all different agro-ecological regions of Botswana and the other 96 from Agricultural Research Stations. The hair samples were

despatched to Animal Genetic Laboratory in France, Labogena DNA platform (Domaine de Vilvert, CS 80009, 78353 Jouy en Josas cedex), for DNA extraction and genotyping with the Illumina Goat SNP50 Bead Chip. All quality control procedures were carried out using PLINK v1.07 software (Purcell *et al.*, 2007). Only autosomal SNPs were included in the analysis and markers that did not map to any chromosome were discarded. SNPs with minor allele frequency (MAF) greater than 0.05, call rate and genotyping rate greater than 95%, Hardy-Weinberg equilibrium $>1\times10^{-4}$ and individuals with missing genotyping rate of more than 15% were excluded from the analysis. The ultimate dataset retained for down streaming analyses included 190 animals and 47,040 markers.

Detection of runs of homozygosity. Runs of homozygosity (ROH) were detected using PLINK v1.07 software (Purcell *et al.*, 2007). To define the ROH, a sliding window of 50 SNPs was used, and the following parameters were used: the minimal number of SNPs in ROH was set to 20; the maximal gap between the adjacent SNPs was set to 2 Mb; the minimum SNP density per ROH was set to 1 SNP every 100 kb; one heterozygote genotype allowed, and 5 missing genotypes allowed. To characterize the ROH distribution, the following parameters were estimated; the average ROH per individual, the number of ROH, the mean total length of ROH, and the genomic inbreeding coefficient (F_{ROH}). The genomic inbreeding coefficient based on ROHs ($F_{ROH)}$ was computed following the method proposed by McQuillan *et al.* (2008). The detected ROHs were specified based on length to four categories: 2-4 Mb, 4-8 Mb, 8-16 Mb, and >16 Mb recognised as $ROH_{2\text{-}4}$ Mb, $ROH_{4\text{-}8}$ Mb, $ROH_{8\text{-}16}$ Mb, and $ROH_{>16}$ Mb, respectively. All ROHs per individual were summed and averaged to calculate the mean sum of ROH length.

Results

A total of 2,486 ROH were detected across the autosome of 190 Tswana goats and the average number of ROH per animal was 13.08±8.71, with values ranging from 2 to 59. The descriptive statistics for runs of homozygosity of indigenous Tswana goats are summarised in Table 1. The mean length was 7.18±7.89 and ranged from 3.02 Mb to 28.06 Mb. The longest segment of 66 Mb constituting of 1,258 SNPs was found on chromosome 2 (CHI2). The majority of ROH segments for Tswana goats were shorter (2-8 Mb) and covered relatively small part of the genome. These segments accounted for approximately 77% in length in contrast to 10% of ROH segments longer than 16 Mb that covered a higher proportion of the genome (Table 1). The genomic inbreeding coefficient (F_{ROH}) was 0.005.

The relationship among animals regarding the number of ROH and the length of the genome covered by them is portrayed in Figure 1. Most of the individuals clustered close to the beginning of coordinates because each one carried 2 to 20 ROH with a total length less than 300 Mb. The highly inbred animal displayed a ROH genome coverage of 315.31 Mb of the total autosomal genome with 51 number of ROH found within a range of 2-8 Mb and a mean length of 5.34 whilst the least inbred animal exhibited a ROH genome coverage of 8.05 Mb and a mean length of 4.0 with all ROHs found within a range of 2- 8 Mb.

Table 1. Descriptive statistics for runs of homozygosity for indigenous Tswana goat.

Class length (Mb)	No of ROH[1]	Percentage	Mean length	Standard deviation	Genome coverage
$ROH_{2\text{-}4}$	1,147	46	3.02	0.48	0.14
$ROH_{4\text{-}8}$	763	30	5.54	1.15	1.69
$ROH_{8\text{-}16}$	353	14	11.0	2.23	1.55
$ROH_{>16}$	223	10	28.06	11.11	2.51

[1] Number of runs of homozygosity.

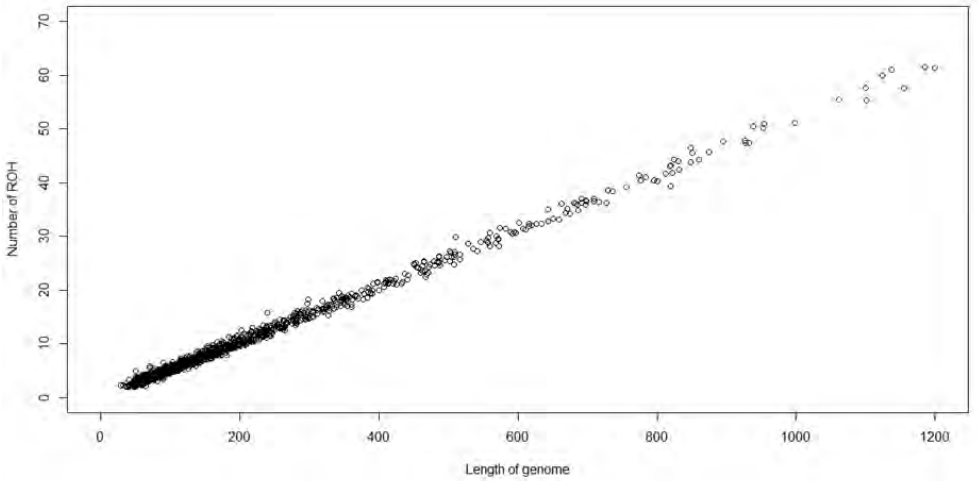

Figure 1. Number of runs of homozygosity per individual Tswana goat and the length of the genome covered by ROH (Mb).

The frequency of ROH per chromosomes are presented in Figure 2. ROH segments were identified on all 29 autosomes and the percentages of ROH declined as the number of chromosomes increases. Major fraction of ROH was observed on chromosome 6 with about 7.8%.

Discussion

Genomic inbreeding based on runs of homozygosity (ROH) provides an important information due to non-existent pedigree information of goats kept under traditional management system. The abundance of short ROH measuring up to 8 Mb segments in Tswana goat population demonstrate that the breed has been formed by small founding populations. The substantial low contribution of short ROH to the genome could indicate differences in selection events in ancestral populations. The long ROH that covered most of the genome though in small percentiles reflect low possibility of recombination and recent inbreeding of

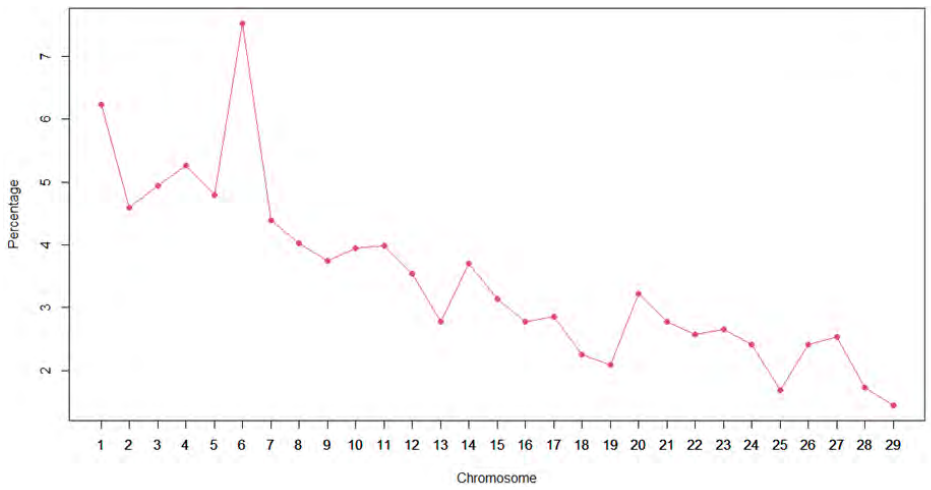

Figure 2. Percentage of SNPs in a ROH for each chromosome of Tswana goats.

3-5 generations ago (Onzima *et al.*, 2017). Recent inbreeding is more destructive than ancient inbreeding because selection lessens the frequency of harmful alleles over generations (Zhao *et al.*, 2021). The pattern of ROH coverage observed in this study is in line with other studies of goats (Brito *et al.*, 2017; Onzima *et al.*, 2018; Manstrangelo *et al.*, 2021). The low genomic inbreeding coefficients provides the opportunity for better management and designing appropriate conservation programs to preserve genetic diversity to cope with current and future predicted effects of climate change. The findings of the study will advance our understanding on the adaptation and functional traits of Tswana goats.

Conclusions

Runs of homozygosity are randomly distributed across Tswana goat genome. The population is not highly affected by recent inbreeding and the ancient haplotypes may have a major positive impact on the functional traits of Tswana goats. The findings provide insight for future goat genomics research, goat breeding program, and sustainable utilization of the breed.

Abstract

Native Portuguese cattle breeds are a 'biodiversity deposit' resulting from genetic and environmental effects accumulated over the years. We assessed two cattle breeds representative of Portuguese native cattle (Barrosã – BAR and Brava de Lide – BRA) aiming the evaluation of ROH across populations, identification of ROH islands and functional analysis of the identified genes. The pattern of ROH differed across breeds mainly from short to median range. Based on ROH islands analysis, three regions were observed to be shared by more than 35% of the individuals in the two breeds. Besides, gene networks highlighted biological associations based on genes found on ROH islands with biological processes related with reproductive traits (*RBM19*) and immune systems (*DTX1*) in BAR breed, and immune systems and adipogeneses processes (*ZBTB16*) in BRA breed.

Introduction

Native Portuguese cattle breeds are a 'biodiversity deposit' resulting from genetic and environmental effects accumulated over the years, namely, geographical, edapho-climatic, land, historical, cultural, political-economic, among others. In the middle of the 20th century, with the implementation of the first Herd Books and the reorientation of production, mainly for beef, the current native bovine populations became properly organized. Since the 1990s, according to the size of the herd and the priorities defined by breeders for each breed, they have been included in conservation or genetic improvement programs. Except for the Brava de Lide breed, whose selection is oriented towards behavioural traits, the other breeds have been selected essentially for maternal and reproductive traits.

History of the population, breeding system, and pattern of geographic subdivision may be reflected in runs of homozygosity (ROH) patterns throughout the genome. ROH are continuous homozygous segments of DNA (Gibson *et al.*, 2006), and its calculation is essential to identify islands. The islands of homozygosity shared among individuals, may be helpful in identify possible results of selection events (Zhang *et al.*, 2015). Moreover, genes identified in those regions can be functionally analysed through gene networks (Verardo *et al.*, 2021) aiming to a better understand of their biological role in each population. Thus, we assessed two cattle breeds representative of Portuguese native cattle, with different breeding goals (Barrosã – BAR and Brava de Lide – BRA) aiming the evaluation of ROH across populations, identification of ROH islands and functional analysis of the identified genes.

Materials & methods

The cattle breeds of Portugal used in this study are representative of the two trunks of cattle that were formed in the westernmost region of the Iberian Peninsula and classified by Miranda do Vale (1949), according to their ethnic characteristics and geographical distribution: Mauritanian or *Bos taurus mauritanicus* (Barrosã – BAR) and Iberian or *Bos taurus ibericus* (Brava de Lide – BRA). Animals were genotyped using the commercial genotyping array of Affymetrix (60k). SNP genotypes from sexual chromosomes were excluded from the analysis. Also, genotypes were excluded when the call rate <0.95 and minor allele frequency <0.01.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_226, © M.V.G.B. Silva *et al.* 2022

In addition, samples showing overall call rates <0.90 were excluded from further analysis. A total of 96 and 94 animals were analysed after quality control with 34,997 and 33,482 SNPs in the genotypes of BAR and BRA, respectively.

The ROH approach using the software PLINK v1.07 (Purcell *et al.*, 2007) for each population with the following parameters were used: minimum window length of 120 SNPs, maximum gap size between two SNPs of 1000 kb, minimum ROH length of 1000 kb, minimum number of potential marked SNPs of 50, one heterozygote allowed per window, maximum of five missing calls per window, sliding window length of 50 SNPs and proportion of overlapping windows that must be a homozygous >0.05. To identify ROH islands throughout the genome, the most observed homozygous segments shared by individuals in each breed were considered as an indication. The '--homozyg-group' function implemented in PLINK was used to assess ROH islands shared among individuals. The GenBank annotation based on the ARS-UCD1.2 assembly of the bovine genome was used to identify genes in ROH regions.

Gene networks highlighting biological processes among the gene sets identified for each breed were generated using the ClueGO plugin for Cytoscape (Bindea *et al.*, 2009). This procedure allowed the creation of gene networks highlighting biological roles, and the comparison of gene clusters by visualizing their functional differences or similarities.

Results

The pattern of ROH differed across breeds mainly from short to median range (Figure 1A). BAR and BRA breeds showed similar percentage of long-range ROH (>31 Mb; <5%), while BAR showed higher percentages of short range ROH (<5 Mb; >50%). In addition, based on ROH islands analysis, three regions were observed to be shared by more than 35% of the individuals in the two breeds (Table 1). Gene networks highlighting biological associations were generated based on genes found on ROH islands (Figure 1B). Several biological processes were highlighted, including Regulation of T cell differentiation and positive regulation of embryonic development.

[1] BAR: Barrosã; BRA: Brava de Lide.

Discussion

We first aimed to evaluate the run of homozygosity in two Portuguese breeds, Barrosã and Brava de Lide. A run of homozygosity is the probability that all consecutive markers on a pair of homologous chromosome segments, in the same or different individual(s), display identical alleles (Hayes *et al.*, 2003). The extent and frequency of ROH may provide information about the ancestry of an individual and its population. Moreover, inbreeding may be inferred from the presence of long ROH, with longer segments indicating recent inbreeding within a population (Kirin *et al.*, 2010). We observed that both breeds showed small and similar occurrence of longest ROH found in this study (<5%). This indicates a proper matting scheme in those breeds to prevent higher inbreeding. Besides, BAR showed higher prevalence of small ROH indicating more genetic diversity.

Moreover, both breeds showed ROH islands. It is important to note that with few sampled genotypes, it is quite likely that some ROH are artifacts. This is particularly important when pointing to specific candidate regions/genes as these might be misleading. In this study, genes and their biological processes were analysed aiming to understand their roles in each breed. In BAR, we identified an island in chromosome 17 with genes associated, for example, with positive regulation of embryonic development (*RBM19*) and negative regulation of lymphocyte activation (*DTX1*) in the biological process network. *RBM19* encoding for RNA binding motif protein 19, may be involved in regulating ribosome biogenesis and was previously reported to be essential for preimplantation during mouse embryonic development (Zhang *et al.*, 2008). *DTX1* encode for deltex E3 ubiquitin ligase 1 protein being reported to play a regulatory role in immune responses in teleost fish (Zheng *et al.*, 2021). Thus, these two genes may play a role on reproductive traits (*RBM19*) and immune systems (*DTX1*) in BAR breed.

Also, ROH islands were observed on chromosome 15 of BRA breed. In those islands, based on biological process network, we observed a gene (*ZBTB16*) related with regulation of T cell differentiation which is also shared with the previous discussed gene of BAR breed (*DTX1*). The *ZBTB16* gene encodes for the zinc finger and BTB domain containing 16 protein and have been related with innate and innate-like lymphoid lineage development in mouse (Mao *et al.*, 2017) and defense response to gram-positive bacteria in goat (Rout and Verma, 2021). Also, its overexpression is suggested to promote white adipogenesis and induce brown-like adipocyte formation in bovine white intramuscular preadipocytes (Wei *et al.*, 2018). It suggests a role of this gene in immune systems and adipogeneses processes of BRA breed.

In this study, short ROH were observed in both Portuguese Iberian breeds BAR and BRA, suggesting a successful matting scheme, also highlighted by a lower occurrence of long ROH. Genes located in ROH islands were evaluated and explored throughout their biological processes, which provided genetic insights about the breeds. Genes were associated with important traits (e.g. *RBM19* with reproductive traits and

DTX1 with immune systems in BAR breed; and *ZBTB16* with immune systems and adipogeneses processes in BRA breed).

Abstract

Runs of Homozygosity (ROHs) are extensively found in the genomes of farm animals. The genes contained in these regions are important for the selected traits, having reached fixation through selective breeding, but also as a result of inbreeding. Two essential goals of breeding programs are to increase reproductive fitness and muscle growth, both of which are largely determined by ROHs and the genes therein. In this study, the genomes of pigs selected primarily for reproductive (Large White (LW), n=10) or growth (Pietrain (PI), n=10) traits were sequenced, and ROHs were detected. In both breeds, approximately one third of the genome was found to be homozygous. Although breed-specific genes overlapping ROHs were not significantly enriched for biological functions related to reproduction or growth, five genes were associated to muscle biology. Furthermore, these genes were affected by non-synonymous mutations, which may result from selection.

Introduction

Though maintaining genetic diversity is a priority of any breeding program, regions of homozygosity are prevalent in the genomes of farm animals, resulting from selection and inbreeding (Maltecca *et al.*, 2020). These regions are mostly studied in the form of Runs of Homozygosity (ROHs), relying on single nucleotide variants (SNVs) for their detection (Ceballos *et al.*, 2018).

High reproductive performance and high lean body weight are two important goals in pig breeding. Under commercial conditions, it is common to cross highly prolific females with highly muscular males, in order to obtain a large number of piglets that will meet market standards. This is known as terminal crossing and it often involves Large White (LW) females and Pietrain (PI) males. Therefore, these two breeds offer a convenient model to explore fertility and growth's genetic background.

This study aimed to identify regions of homozygosity in ROHs and detect genes associated with reproduction and growth by sequencing the genomes of pigs highly selected for maternal (LW) and paternal traits (PI). Results from these analyses provide insights into the genetic diversity of these two important commercial pig breeds.

Materials & methods

Sample collection and whole genome sequencing. Genomic DNA was extracted from blood (10 animals per breed) using QIAamp DNA Mini Kit (Qiagen, Hilden, Germany). Blood samples were collected

R.F. Veerkamp and Y. de Haas (eds)

in accordance to the health and hygiene monitoring at the German Federal Hybrid Breeding Programme (BHZP) (for more details see (Dauben *et al.*, 2021)). Sequencing libraries were prepared with the Illumina® TruSeq® Nano DNA Library Prep kit. Sequencing was done with Illumina® NovaSeq6000 generating paired end reads of 151 bp length.

Read processing and SNV calling. Adapter removal and quality trimming were performed with FASTP (Chen *et al.*, 2018). Read quality was evaluated with FastQC (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/). Reads were aligned to the pig genome build Sscrofa11.1 using the Burrow-Wheeler Aligner software in MEM mode (Li and Durbin, 2010).

Alignment processing and SNV calling followed GATK best practices (4.0.6.0) (Depristo *et al.*, 2011; McKenna *et al.*, 2010; Poplin *et al.*, 2017; Van der Auwera *et al.*, 2013). Only bi-allelic SNVs were retained. Sites were filtered by removing 5-10% of the poorest-scoring variants according to the following annotations: QualByDepth, FisherStrand, StrandOddsRatio, RMSMappingQuality, MappingQualityRankSumTest and ReadPosRankSumTest. SNVs were genotyped as missing if the depth of coverage was either too low (<4 reads), too high (3 standard deviations higher than the sample mean depth), or if the genotype quality was too low (<20 in Phred scale). Variants missing in at least one sample were removed. Annotations were done using SnpEff v4.3t (Cingolani *et al.*, 2012).

Detection of runs of homozygosity. ROHs were estimated using the ROH extension (Narasimhan *et al.*, 2016) in SAMtools/BCFtools v1.5 (Li *et al.*, 2009). For this, allele frequencies at each SNV site and a constant recombination rate of 0.7 cM/Mb were provided. Genes overlapping ROHs were detected, transformed into human gene identifiers and characterized based on Gene Ontology Biological Process (GOBP) annotations using enrichr (Xie *et al.*, 2021).

Data handling and visualization. Genomic intervals (genes, SNVs and ROHs) were overlapped using GenomicRanges (Lawrence *et al.*, 2013). Data processing and visualizations were done using R (R Core Team, 2020) and the tidyverse package (Wickham *et al.*, 2019).

Results

Average genome coverage was ~50× and a total ~16M SNVs were detected. Levels of homozygosity were similar in both breeds, with approximately 35% of the genome covered by ROHs (Figure 1). Genomic homozygosity was largely (~23%) composed by medium size ROHs between 100 Kb and 5 Mb. Small ROHs less than 100 Kb spanned only 5% of the genome in both breeds. In Pietrain, a slightly higher genomic fraction was covered by large ROHs (>5 Mb).

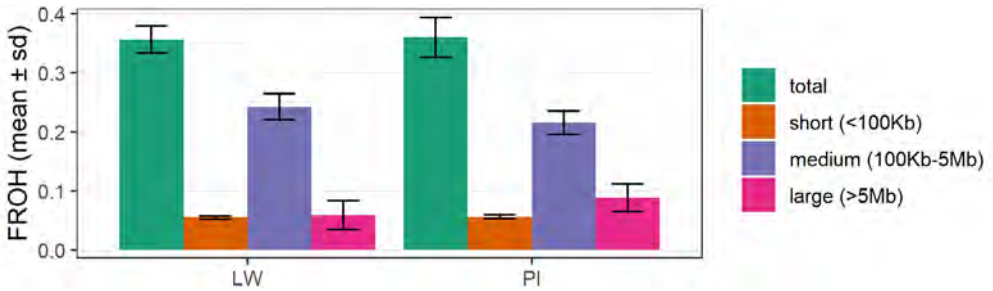

Figure 1. Mean genomic fraction covered by ROHs (FROH). For each breed the total FROH is shown and next decomposed into subcategories according to ROH size.

For each animal, genes overlapping ROHs were detected and breed-specific gene lists were created: LW-private with 216 genes and PI-private with 393 genes. Reproductive functions were not represented by LW-private genes, but significant enrichments (FDR<0.05) were found for 'ephrin receptor signaling pathway' (GO:0048013), 'positive regulation of cytoskeleton organization' (GO:0051495) and 'axon guidance' (GO:0007411). PI-private genes did not produce significant enrichments. However, for 14 genes, GOBPs included functions related to muscle growth. Five of these genes were affected by at least one missense or stop-gained homozygous SNV (Table 1).

Discussion

Although ROHs have been studied in LW and PI, this was so far done via SNP-arrays (Gorssen *et al.*, 2020; Shi *et al.*, 2020; Zhan *et al.*, 2020) or low-mid coverage WGS (Bosse *et al.*, 2012; Nosková *et al.*, 2021). In this study, samples were sequenced at an average coverage of ~50×, which allows to obtain a dense SNV set and to genotype heterozygous variants with high accuracy. These two attributes are critical to get a detailed view of the ROH landscape.

Private genes overlapping ROHs in LW were not involved in reproductive processes. Interestingly, the significantly enriched term 'ephrin receptor signalling pathway' (GO:0048013) has been reported to mediate FSH signalling in granulosa cells (Buensuceso and Deroo, 2013), which could be important for ovarian follicle development and ovulation. On the other hand, muscle function associated genes were found in the PI-private gene list, carrying mutations predicted to disrupt translation and altering the amino acid protein sequence. Since neither of these mutations have been reported within Pietrain ROHs, it is possible that they were missed by previous studies due to a lower SNV density than the present study.

This study provides new insights into the footprints of selection and inbreeding in the genomes of commercially important pig breeds. The genes spanned by ROHs may have important functions for the selected traits, but they may also represent the consequences of inbreeding.

Funding

This study was funded by the Leibniz Collaborative Excellence programme (K52/2017, SOS-FERT).

Abstract

The genome of the current cattle breeds has been shaped by domestication, adaptation, and by artificial selection. In this study, genomic data of 3,177 animals from 205 different Taurine and Indicine breeds spread worldwide were used to investigate the Runs of Homozygosity (ROH) pattern among three different climatic zones (North, Temperate and Tropics). Our findings confirmed that *Bos taurus* presents the lowest number of ROH per animal, *Bos indicus* the largest, and hybrids (*B. taurus* × *B. indicus*) have intermediate values, respectively. ROH tend to be longer in the temperate areas and shortest in the tropics.

Introduction

Modern cattle breeds originated from the extinct wild Auroch (*Bos primigenius*), that has been domesticated about 8.500 years ago in the Fertile Crescent (Magee and Bradley, 2006). The first hypothesis is that *Bos taurus* derived from *B. primigenius*, and then *Bos indicus* would have been derived from *B. taurus* during early pastoral movements to India, at 4000 BC approximately (Magee and Bradley, 2006). The second hypothesis, which is largely accepted, is that modern cattle arose from two different domestications of aurochs: *B. indicus* would derive from a southern Asian subspecies of Aurochs, the *B. primigenius namadicus* (Bradley *et al.*, 1998). In any case, the modern breeds originated from a complex interaction between natural and artificial selection, and adaptation to environment (Gautier *et al.*, 2010). *B. indicus* is spread in Eurasia and eastern Africa, whereas *B. taurus* is diffused mainly in Europe, North and West Africa, and Middle East (Bruford *et al.*, 2003).

The genomes of these two subspecies and of their crosses (hybrids) can provide interesting insights about their different evolution histories. Among genomic metrics able to highlight these signals, Runs of Homozygosity (ROH) are increasing in popularity. ROH are continuous homozygous chromosomal segments (Gibson *et al.*, 2006) whose length is used as a temporal indicator of the inbreeding events: ROH due to recent inbreeding tend to be longer, whereas ROH due to remote inbreeding are shorter ones. Because homozygous genotypes could be due also to fixation of favorable alleles, ROH occurrence can be the result of both artificial and natural selection (Macciotta *et al.*, 2021).

The aim of this study was to analyze the distribution of ROH in different types of cattle (*B. taurus*, *B. indicus*, and hybrids) raised worldwide, and to assess whether the ROH composition would differ in different climatic regions.

Materials & methods

In this study, genotypes of 3,177 cattle (2,689 *B. taurus*, 330 *B. indicus*, and 158 Hybrid) belonging to 205 different breeds were available from a merge of SNP data conducted in previously published work (Mastrangelo *et al.*, 2020). After edits, 23,313 SNPs mapping on the 29 autosomes were retained for the analysis. The average number of animals per breed was 16±7 (range from 3 to 30). For each breed, the latitude and longitude of country of origin were retrieved from online databases. Breeds were then grouped

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_228, © L. Falchi *et al.* 2022

into three zones according to the latitude of their countries of origin: (1) North, latitude≥45°; (2) Temperate, 45°<latitude>23.26°; (3) Tropics, latitude≤23.26° (including also negative latitudes).

Runs of homozygosity. Consecutive ROH were computed using the '*detectruns*' R package (Biscarini *et al.*, 2018). The following parameters were adopted to define a ROH: at least 15 homozygote SNPs in a row covering a minimum of 2 million base pairs, with no heterozygote or missing allowed. Number of ROH per animal (nROH) and average (meanMb) ROH length were computed. A ROH that started and finished at exactly the same positions within chromosome was defined as unique (Cesarani *et al.*, 2018; Macciotta *et al.*, 2021).

Statistical analysis. The effects of Type (subspecies) and Zone on nROH were tested using the following generalized linear model with a lognormal distribution:

$$nROH = \mu + TYPE + ZONE + e \quad (1)$$

where:

μ is the overall mean; TYPE is the fixed effect of the type (i.e. *B. taurus*, *B. indicus*, and hybrids); ZONE is the fixed effect of the zone (i.e. Tropics, Temperate, and North); e is the residual term.

ROH length was analyzed with the following model:

$$y = \mu + TYPE + CHROM + ZONE + ANIM + e \quad (2)$$

where:

CHROM is the fixed effect of chromosome (29 levels); ANIM is the random effect of the animal, added to model the repeated measurements within animal (3,177 levels); and e is the random residual. The two random effects were assumed to be normally distributed with parameters $N(0,I\sigma_a^2)$ and $N(0,I\sigma_e^2)$, where I is an identity matrix and σ_a^2 and σ_e^2 the variances associated with the animal and the residual random effects, respectively. Both models (1 and 2) were run also including ZONE×TYPE, i.e. the interaction between Zone and Type, removing North because only *B. taurus* animals were present in that area. Mixed models were computed using SAS PROC GLMMIX (SAS Inc. 2012).

Results

A total of 136,922 ROHs were found in 3,177 animals. Removing the duplicated regions, 94,925 unique ROH were found: 1,453 ROH were highlighted at least one time in all the 3 zones, whereas only 649 were found in all the three considered Types. Table 1 shows the four unique ROH that have been found to be shared by more than 70 animals.

Table 1. ROH shared by more than 70 animals.

BTA	Region (Mb)	N°	Animals per zone[1]			Animals per type		
			Temperate	North	Tropics	Taurus	Indicus	Hybrid
12	63.40-69.68	94	51	38	5	86	6	2
16	1.03-4.77	91	52	32	7	80	10	1
27	0.43-6.04	86	45	34	7	81	4	1
15	1.03-6.30	77	40	32	5	62	9	6

[1] Nord = Latitude≥45°; Temperate = 45°<Latitude>23.26°; Tropics = Latitude≤23.26°.

Table 2 shows the results of the mixed model analysis. ZONE affected both nROH and meanMB. Animals farmed in the Tropics showed the highest nROH and the lowest meanMb, whereas lowest nROH and the highest meanMb were found for the Temperate zone, respectively. All the three types differed significantly for nROH, with *B. indicus* having the largest value and *B. taurus* the smallest, respectively. In the model for meanMb CHROM was highly significant. Repeatability for meanMb was 0.09 and 0.13 for the model without and with interaction, respectively.

LS means of the interaction between Zone and Types are reported in Figures 1a and 1b.

The *indicus* showed the highest nROH ($P<0.001$) in both climate regions whereas differences between *taurus* and *hybrids* ($P<0.001$) can be found only in the temperate zone.

Discussion

An effect of the farming zone and, to a lesser extent, of the subspecies on ROH features of the investigated sample of cattle, has been detected. Tropics exhibited the largest number of ROH per animal and the

Table 2. Least squares means of number of ROH and average ROH length per animal.

Taurus	28.61 ± 1.02^{C}	4.28 ± 1.02^{A}

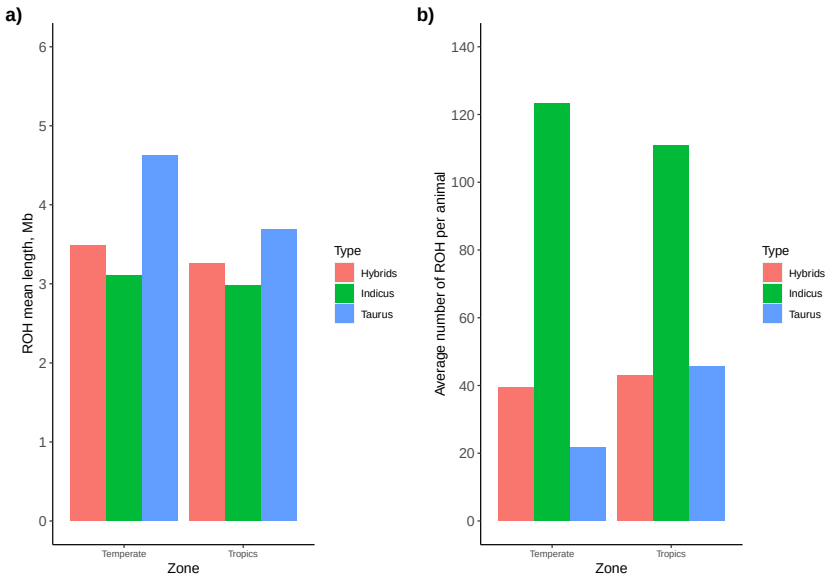

Figure 1. Least squares means of the Zone×Type interaction for the average number of ROH per animal (a) and the average ROH length (b).

smallest average ROH length. Effects of geographical area on the number and length of ROH have been recently reported, albeit in a more limited geographical context, for goats (Cortellari *et al.*, 2021) and sheep (Cesarani *et al.*, 2022). Geographical clines in ROH distributions have been reported also for human populations (Nothangel *et al.*, 2010). A study on mammalian species has evidenced a relationship between ROH length and latitude of farming area (Bruniche Olsen *et al.*, 2018). The higher nROH observed in *B. indicus*, especially due to a larger occurrence of short ROHs (<4 Mb), could be at least partially ascribed to ascertainment bias in genotyping of this subspecies. However, this issue has been at least partially addressed by the criteria here adopted for ROH detection. A larger ROH length was observed for *B. taurus* only in temperate climate (Figure 1b). Usually longer ROH are interpreted as evidence of a stronger selection (Purfield *et al.*, 2012). Thus, results here obtained seems to highlight an effect of selection in favor of *B. taurus* mainly in temperate areas. Finally, an interesting result is represented by the sharing of same unique ROHs across zones and, especially, subspecies.

Abstract

Inbreeding is an important parameter that should be monitored in livestock populations under selection. The traditional inbreeding coefficient (F_{PED}) is based on pedigree data. Runs of homozygosity (ROH) can be used to define one of the most accurate genomic inbreeding parameters, defined as the proportion of the autosomal genome covered with ROH (F_{ROH}). The aim of this work was to evaluate how 25 years of selection have shaped the inbreeding level of the three heavy pig breeds raised in Italy: Italian Large White, Italian Landrace and Italian Duroc. For all breeds, the average F_{ROH} increased over time, as expected in populations under selection. What was interesting is that the rate of inbreeding was higher for F_{PED} than for F_{ROH}. This might mean that the rate of inbreeding could be overestimated by using only pedigree information. F_{ROH} can complement traditional F_{PED} coefficient to monitor inbreeding in these populations.

Introduction

In livestock populations under selection, inbreeding increases as an inevitable consequence of the selection program. Therefore, inbreeding should be monitored to avoid the negative effects, such as inbreeding depression. The traditional inbreeding coefficient (F_{PED}) is calculated using pedigree data (Falconer and Mackay, 1996). This way to calculate inbreeding has several limitations. For example, it needs complete and correct pedigree registrations, it does not account for the true relatedness of the founder animals of the base population, and it does not consider the stochasticity of the recombination events over generations.

High throughput genotyping data can be used to calculate several genomic inbreeding parameters. One of these parameters is based on the identification and then of the sum over the whole animal genome of runs of homozygosity (ROH). ROH are long and continuous stretches of homozygous chromosome regions in which all adjacent single nucleotide polymorphisms (SNPs) are homozygous. The proportion of the autosomal genome covered by ROH can be used to define F_{ROH}, that is considered a good estimation of the true level of inbreeding in an individual animal, which can be averaged over all animals of a population (Ferenčaković *et al.* 2013).

Italian Large White (ILW), Italian Duroc (ID) and Italian Landrace (IL) are the main breeds raised in Italy for the production of heavy pigs. Animals from these breeds are slaughtered at about 160 kg of live weight when they are at least 9 months old and are raised for the production of Protected Designation of Origin (PDO) products. Their breeding programs started in the second half of 1980s.

Genomic inbreeding based on ROH and other parameters has been preliminarily evaluated in several Italian pig breeds by Schiavo *et al.* (2020). ROH have been also analysed in many other European pig breeds, with useful results for the inference of the genetic history and genetic events of these autochthonous pig genetic resources (Schiavo *et al.* 2021).

In this study, to have a general overview of the inbreeding trend in the Italian heavy pig breeds, we evaluated their average inbreeding level (calculated using pedigree and ROH data) over the last 25 years.

Materials & methods

Animals and data. A total of 6,982 pigs of the ILW, ID and IL breeds, born between 1995 and 2019, registered in their breed herd books managed by the Italian Pig Breeders Association (ANAS), were included in this study. The average pedigree minimum depth for these pigs was 5.28± 1.64 for ILW, 4.80±1.627 for ID and 3.43±2.44 for IL. The same animals were genotyped with the GeneSeek® GGP Porcine HD Genomic Profiler SNP chip for a total of 68,516 SNPs. Quality check and filtering of the genotyping data was performed with PLINK 1.9 (Chang *et al.* 2015), with the following parameters: Hardy Weinberg Equilibrium *P*-value>0.001; call rate >0.9. No filter was applied for minor allele frequency. The final dataset included 3,540 ILW, 1,201 ID and 1,969 IL pigs with 51,930 SNPs.

Inbreeding coefficients. Two methods for estimating F_{PED} were used: F_{PEDW}, according to Wright's coefficient with the algorithm proposed by Meuwissen and Luo (1992), and F_{PEDR}, with the recursive method proposed by VanRaden (1992). This last method takes into consideration individuals with unknown relatives, which by definition have a F_{PEDW} coefficient equal to 0, and recursively updates their inbreeding coefficient with the average coefficient of their year of birth. Both methods are implemented in Inbupgf90 (Aguilar and Mizstal, 2008). ROH were computed using PLINK 1.9 with the following parameters: at least 15 consecutive homozygous SNPs; ROH length of at least 1 Mb; no heterozygous SNPs allowed; minimum density of SNPs in a genome window of 1 SNP every 100 kb. F_{ROH} was defined as the sum of ROH of an individual over the autosome size. Different F_{ROH} parameters were estimated according to the minimum length of ROH considered. Namely F_{ROH1} was defined with ROH with minimum length of 1 Mb, F_{ROH4} with a minimum length of 4 Mb, and F_{ROH16} with ROH longer than 16 Mb.

Comparison between coefficients. Pairwise Pearson's correlations between the three inbreeding coefficients were calculated. The correlation values between all methods are reported in Table 1. For the three methods and for each breed, the average inbreeding per year was calculated. Breed-year combinations with more than 15 animals were considered for the analyses. Inbreeding rates of the coefficients from the

three different methods were defined as the opposite slope of the regressed values of ln(1-F) on the years of birth, where F was the average value for the related year, as described for example in Doekes *et al.* (2018).

Results

The average inbreeding value (calculated considering all animals included in this dataset) was higher in ID with respect to the other two breeds. In particular, the average F_{PEDW} was 0.054±0.07 in ID, 0.052±0.05 in ILW and 0.033±0.06 in IL. Similar results were obtained with F_{PEDW}, for which the average value was 0.058±0.07 for ID, 0.062±0.05 for ILW and 0.045±0.06 for IL. The average F_{ROH1} was 0.241±0.05 in ID, 0.152±0.05 in IL and 0.139±0.45 in ILW. The trends of F_{ROH1} and F_{PEDW} coefficients are shown in Figure 1. When comparing F_{PEDR} and F_{PEDW}, along with a very high correlation coefficient (R>0.94), also the trends resulted to be very similar. F_{ROH1} was highly correlated with F_{ROH4} (R>0.98), while F_{ROH16} had a R>0.93 with the other two F_{ROH} coefficients. The Pearson's correlations between a genomic-based and a pedigree-based measures ranged from a minimum of 0.5 in ILW to a maximum of 0.58 in IL. All genomic-based values were better correlated with F_{PEDW} than with F_{PEDR}. All correlations are reported in Table 1. The comparison between the slopes of the regressed ln(1-F) on years of birth, with F representing the averaged inbreeding coefficient of a certain year, indicated that the inbreeding rate for ILW and ID was lower with F_{ROH1} (with

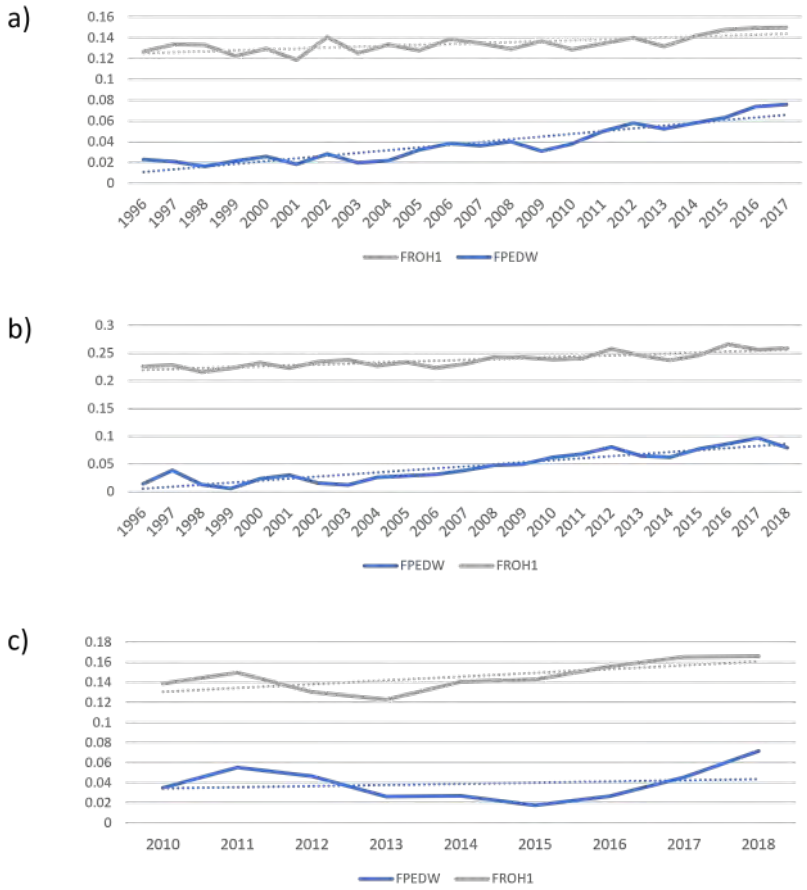

Figure 1. Trends of the F_{PEDW} and F_{ROH1} coefficients over years for the three breeds: (a) Italian Large White; (b) Italian Duroc and (c) Italian Landrace.

an opposite slope of the regression of 0.0002 for ILW and 0.0009 for ID) than with F_{PEDW} (opposite slope of the regression coefficient of 0.00086 for ILW, 0.00169 for ID) and F_{PEDR} (0.00088 ILW and 0.00159 for ID).

Discussion

All breeds had a relatively low level of inbreeding for F_{PEDR}, F_{PEDW}, F_{ROH1}, F_{ROH4}, reflecting a good control of consanguinity during the last decades of the breeding programmes. The low F_{ROH16} indicates scarce occurrence of recent inbreeding events; its relative low correlation with other methods reveals that this parameter is not the proper indicator of inbreeding for these pig breeds. The correlation between F_{PEDR} and F_{PEDW} was high, thus the two methods are comparable for these breeds, probably due to the high proportion of reliable records in the pedigree. The correlation between F_{ROH1} and F_{ROH4} was very high, so the two methods give similar information about the inbreeding level of the animals. The F_{PED} trend over the last 25 years tended to increase for all methods, as expected, but the slope of this trend resulted much more relevant for F_{PED} with respect to the F_{ROH}. This might indicate that there could be an actual overestimation of the inbreeding level for the whole population when using only pedigree information. This means that, in future breeding plans, there could be less limitations in the choice of mating pairs. These results suggest that it could be useful to integrate genomic information aside of traditional inbreeding coefficients in breeding plans defined with optimum contribution selection strategy when the population has a relatively high average inbreeding level. This would make it possible to better control the inbreeding increase over generations.

230. Inbreeding and coancestry trends in Nordic Holstein

S. Tenhunen[2*], J.R. Thomasen[2], L.P. Sørensen[2], G.P. Aamand[3], P. Berg[1,4] and M. Kargo[1]

[1]Aarhus University, Centre for Quantitative Genetics and Genomics, Blichers Alle 20, 8830 Tjele, Denmark; [2]VikingGenetics, Ebeltoftvej 16, 8960 Randers SØ, Denmark; [3]Norwegian University of Life Sciences, NMBU, Universitetstunet 3, 1433 Ås, Norway; [4]Nordic Cattle Genetic Evaluations, Skejby, 8200 Aarhus N, Denmark; saten@vikinggenetics.com

Abstract

Increased rates of inbreeding have been observed in several Holstein populations across the world since genomic selection (GS) was implemented into the breeding programs. The objective of this study was to test whether this is also the case in the Nordic Holstein population using pedigree data. Rates of inbreeding were estimated before, during and after the GS implementation. We could not detect any increase in inbreeding or coancestry rates in Nordic Holstein. Effective population size increased over the studied time periods from 68 to 104, despite fewer sires being used. This might be because more of sires of sons have been used to produce AI bulls compared to the time before implementation of GS.

Introduction

Inbreeding rates have been higher in several Holstein populations around the world after genomic selection (GS) was implemented, compared to before GS (Doekes *et al.*, 2018a; Doublet *et al.*, 2019; Forutan *et al.*, 2018). In theory, GS should decrease loss of genetic diversity (Meuwissen *et al.*, 200; Meuwissen *et al.*, 2016), but in practice the opposite has been observed in several breeds and populations. Loss of genetic diversity due to increasing rate of inbreeding in dairy cattle populations is concerning because it may lead to inbreeding depression, which affects many dairy cattle traits negatively e.g. milk yield, fertility, and udder health traits (Doekes *et al.*, 2019; Makanjuola *et al.*, 2020a), and loss of genetic variation. The Food and Agriculture Organization (FAO) recommends that the increase in inbreeding per generation should not exceed 1% to avoid negative effects of inbreeding depression (FAO, 2013).

Within the Nordic (Denmark, Finland and Sweden) Holstein population, inbreeding trends have not been investigated in recently. The analyses of Sørensen *et al.* (2005) were carried out prior to the introduction of GS in 2011. The Nordic countries have had a common Holstein breeding program since 2010 when the cooperative VikingGenetics (VG) was founded. For this reason, there is a demand for updated research on Nordic Holstein (NH), due to the changes in the breeding program after introduction of GS, to investigate how this has affected the population structure. Thus, the objective of this study is to analyse inbreeding and coancestry trends in the NH population based on pedigree data.

Materials & methods

Pedigree data was supplied by Nordic Cattle Genetic Evaluations. EVA software (Berg *et al.*, 2006) was used to calculate inbreeding coefficient, expected inbreeding coefficient under random mating, alpha (deviation from random mating), coancestry (C), pedigree completeness index (PCI), average generation coefficient (Gencoef), and generation interval (L) (NordGen, 2022). Nordic Holstein females expected to contribute to the next generation of the Holstein breeding population were selected as the base population. Selected females were candidates for VG' Holstein breeding program. They were from milk recording herds and born from January 2016 to November 2018. Only animals with a Nordic Total Merit value >8, Holstein breed percentage >97% and PCI>0.8 were accepted into the base population for pedigree tracing. In total, pedigrees were traced for 372,955 females which reflect approximately 1/3 of the NH female population

R.F. Veerkamp and Y. de Haas (eds)

born in 2016-2018. Pedigrees of the selected base population animals were traced back to the known founders, on average 12.4 generations.

Rates of inbreeding were calculated from the regression of the natural logarithm ln(1-F) on year of birth. Yearly rates of change in inbreeding (ΔF) and coancestry (ΔC) were calculated as $\Delta F/\Delta C = 1 - e^{\beta 1}$ (Pérez-Enciso, 1995), where β1 is the regression slope. Effective population size, Ne, (Falconer and Mackay, 1996) was calculated from ΔF as Ne= 1/2ΔF×L, where L is the generation interval. Expected future effective population size (Exp. Ne) was calculated from ΔC as Ne = 1/2ΔC×L. Animals were allocated to three different groups depending on birth year: before implementation of GS 2007-2010, during the implementation 2011-2014, and after implementation of GS 2015-2018. Calculations of effective population size were done separately for each group.

Results & discussion

The generation interval has decreased in NH after implementation of GS. Before GS, the generation interval was on average 4.9 years, and it has decreased to 3.2 years on average after the implementation (Table 1). Inbreeding and coancestry trends (Figure 1) have been stable in NH across time periods, and we were not able to detect any increase in inbreeding in contrast to what has been seen in some other Holstein populations (Doekes *et al.*, 2018b; Forutan *et al.*, 2018; Makanjuola *et al.*, 2020b). On the contrary, ΔF in NH has remained unchanged (0.0016) from before to after implementation of GS. This was also seen for the ΔC (0.0018). Over the time periods number of starting AI sires has decreased, but in the last time period a wider range of sires of sons has been used compared to earlier periods (Figure 1). These observations agree with the theory of decreasing loss of genetic diversity with genomic selection. Similar results for Nordic animals were seen in the inbreeding survey by World Holstein Friesian Federation (Feddersen, 2020).

The increase in effective population size (Ne) from 68 to 104 across the time periods supports the theory, because even though rates of changes have been the same over the time periods, generation interval has decreased which leads to larger Ne. Expected future effective population size similarly increased over the time periods, but is smaller than the Ne, which might indicate that even though animals are less inbred, they are still related to each other. This might be caused by more intense use of related bulls from same imported sires. This will cause a decrease in inbreeding, but coancestry will increase or remain at the same level. After implementation of GS, sires have been used more equally meaning that all bulls will have offspring in the breeding population even though they might not be used as much in the Holstein production population. GS has made selection of AI sires more reliable, and daughter proven sires has become less competitive; therefore, bulls can be circulated faster in the breeding program. In this study focus was more on the inbreeding trend behind NH females. Studying inbreeding trends behind Nordic AI sires will be beneficial because other studies show that increase in inbreeding is higher for the bulls (Doekes *et al.*, 2018a; Doublet *et al.*, 2019).

Table 1. Yearly rates of change of inbreeding (ΔF) and coancestry (ΔC), generation interval (L), effective population size (Ne) and expected future effective population size (Exp. Ne) in each group of animals before, during and after genomic selection was implemented in NH.

	ΔF	ΔC	L	Ne	Exp. Ne
2007-2010	0.0016	0.0018	4.86	68	59
2011-2014	0.0017	0.0014	4.08	71	88
2015-2018	0.0016	0.0018	3.17	104	87

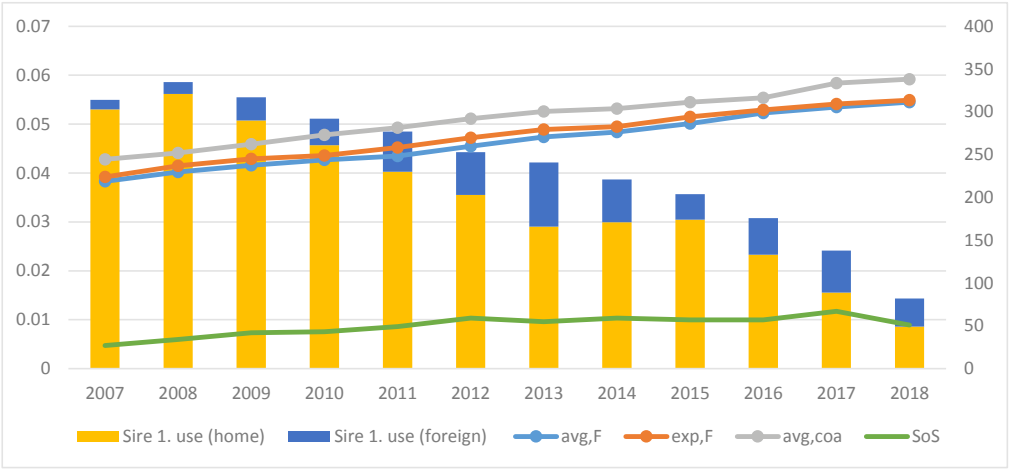

Figure 1. Number of starting Nordic and foreign AI bulls, average inbreeding, expected inbreeding, average coancestry and number of sires of sons (SoS) between years 2007-2018 in NH population.

Considering the effective population size, there has been improvement since the last study on NH from 2005 (Sørensen *et al.*, 2005), where the historical Ne was 49-69 and expected future effective population size was 43-51 across the time periods. Even though Ne for NH has increased, there is reason to monitor the development and improve the breeding scheme to gain higher Ne. Populations with Ne between 50-100 are facing risk of inbreeding depression, and even higher Ne might be needed for long-term (FAO, 2013; Frankham *et al.*, 2014). After the implementation of GS, NH is above the short-term threshold but in the long-term the breed might be in danger of facing issues related to inbreeding depression, when the expected future effective population size is on the threshold for short-term survivability. Therefore, methods for controlling future increase in inbreeding more efficiently need to be developed.

Breeding programs today are based on genomic selection and there has been recommendations that methods to control inbreeding should then be based on genomic information (Sonesson *et al.*, 2012). There has been debate about the best way to manage inbreeding in livestock populations (Meuwissen *et al.*, 2020; Henryon *et al.*, 2019a; Henryon *et al.*, 2019b) and more research on the topic is required. In the future research, inbreeding and coancestry trends should be based on genomic information to investigate whether similar results are seen when studying only genomic tested animals in the breeding population for NH.

231. Effect of genomic selection on genetic variability in chromosomal level in the Finnish Ayrshire

K. Sarviaho*, P. Uimari and K. Martikainen

Department of agricultural sciences, University of Helsinki, P.O. Box 28, 00014, Helsinki, Finland; katri.sarviaho@helsinki.fi

Abstract

This research aimed to study the effect of genomic selection (GS) on median length of runs of homozygosity (ROH) and average genomic inbreeding estimated from the ROHs in the Finnish Ayrshire. The transition from traditional phenotype-based breeding value prediction to genomic-based estimation was assumed to have taken place during 2012-2014. The median length of the ROHs and the average genomic inbreeding varied by chromosomes. In addition, the median length of ROHs and the average genomic inbreeding were generally higher in bulls than in cows. After the introduction of GS, ROHs became longer in the majority of chromosomes. However, the average genomic inbreeding did not follow the trend of ROH length. Those chromosomes, where the median length of ROHs and the average genomic inbreeding increased, included quantitative trait loci associated with a range of traits under selection in the Finnish Ayrshire.

Introduction

Nordic Red dairy population (RDC) constitutes of Finnish Ayrshire cattle (FAY), Swedish Red cattle, and Danish Red cattle (NAV 2021a). They have a joint genetic evaluation by Nordic Cattle Evaluation (NAV) and share a balanced breeding goal: Nordic Total Merit (NTM) (NAV 2021a). Traits included in NTM for RDC are yield, growth, fertility, calving, udder health, general health, claw health, feet and legs, udder, milkability, temperament, longevity, youngstock survival, and saved feed (NAV 2021a). Application of genomic selection (GS) in dairy cattle breeding began in the 2010's (NAV 2021b). Despite its benefits, for example, faster genetic progress, GS could increase average inbreeding, decrease genetic variability, and cause inbreeding depression (e.g. Makanjuola *et al.* 2020). Inbreeding can be measured from runs of homozygosity (ROH) (Purfield *et al.*, 2012). Both selection for and selection against the traits could increase the median length of ROHs and result in increased genomic inbreeding (F_{ROH}) (Kim *et al.*, 2015). This research aimed to study the effect of GS on ROH length and average genomic inbreeding on chromosomal level in FAY (NAV 2021a).

Materials & methods

The genotype data was received from NAV, and the pedigree and breed composition data were obtained from the Finnish Animal Breeding Association. Data included genotypes of 46,914 SNPs (single nucleotide polymorphism) from 24,658 animals that were at least 50% Finnish Ayrshire (FAY). There were 3,228 bulls and 3,856 cows born in 1980-2011, while 1,897 bulls and 15,677 cows were born in 2015-2020. Bulls were genotyped with Illumina BovineSNP50 v1.0 and v2.0 Beadchip, and the majority of the cows were genotyped with Illumina BovineLD v.1 Beadchip, and the genotypes were imputed to 50K with FImpute (Sargolzaei *et al.*, 2014). The genotype data included SNP variants in chromosomes *Bos Taurus* autosomes (BTA) and did not include any missing genotypes.

Traditional phenotype-based breeding value estimation was assumed between 1980-2011, while estimation mainly based on genomic information was assumed from 2015. ROHs were identified using PLINK version 1.90b6.20 (Chang *et al.* 2015, Purcell and Chang 2021) following a method by Meyermans *et al.* (2020). Briefly, no pruning for minor allele frequency, deviations from Hardy-Weinberg equilibrium, or linkage disequilibrium was done. The sliding window was set to 63 SNPs, minimum number of SNPs in ROH

to 63, gap size to 500 Kbp, minimum density to 1 SNP/64 Kbp, and threshold of 0.05. One heterozygous genotype per window was allowed. Estimates of F_{ROH} were calculated as the number of SNPs in ROHs per total number of SNP-variants (Pryce *et al.*, 2014).

Results & discussion

Both the median length of ROHs (Figure 1) and the average F_{ROH} (Figure 2) varied by gender and by chromosomes. In general, ROHs were longer, and the average F_{ROH} was higher in bulls than cows, as was expected, since bulls tend to be highly selected. Additionally, we found the median length of ROHs increasing in the majority of BTAs after the introduction of GS (Figure 1). The median length of ROHs in bulls born between 1980-2011 and between 2015-2020 was 5.44 Mbp and 5.61 Mbp, respectively, and in cows between 1980-2011 and between 2015-2020, 5.36 Mbp and 5.52 Mbp, respectively. However, the average F_{ROH} did not follow the trend of the ROH length (Figure 2). Indeed, the average F_{ROH} in bulls born between 1980-2011 and between 2015-2020 was 0.067 (SD 0.023) and 0.066 (SD 0.023), respectively. Likewise, the average F_{ROH} in cows born between 1980-2011 and between 2015-2020 was 0.065 (SD 0.022) and 0.063 (SD 0.022), respectively. GS and optimization of genetic contributions simultaneously could lengthen the ROHs while the rate of inbreeding is restricted (e.g. Clark *et al.* 2013, Kim *et al.* 2015).

A range of QTLs associated with traits with the biggest weights in NTM, fertility, and yield have been identified in RDC and FAY, which could explain the differences in ROH length found in this study. For example, QTLs associated with fertility traits have been identified in RDC and FAY in BTA01, BTA02, and BTA04 (Höglund *et al.* 2014, Höglund *et al.* 2015, Schulman *et al.* 2011). In addition, in RDC, QTLs associated with fertility have been identified in BTA03, BTA06, BTA07, BTA09, BTA11, BTA13, BTA15, and BTA24 (Höglund *et al.* 2014, Höglund *et al.* 2015). In our study, the median length of ROHs increased

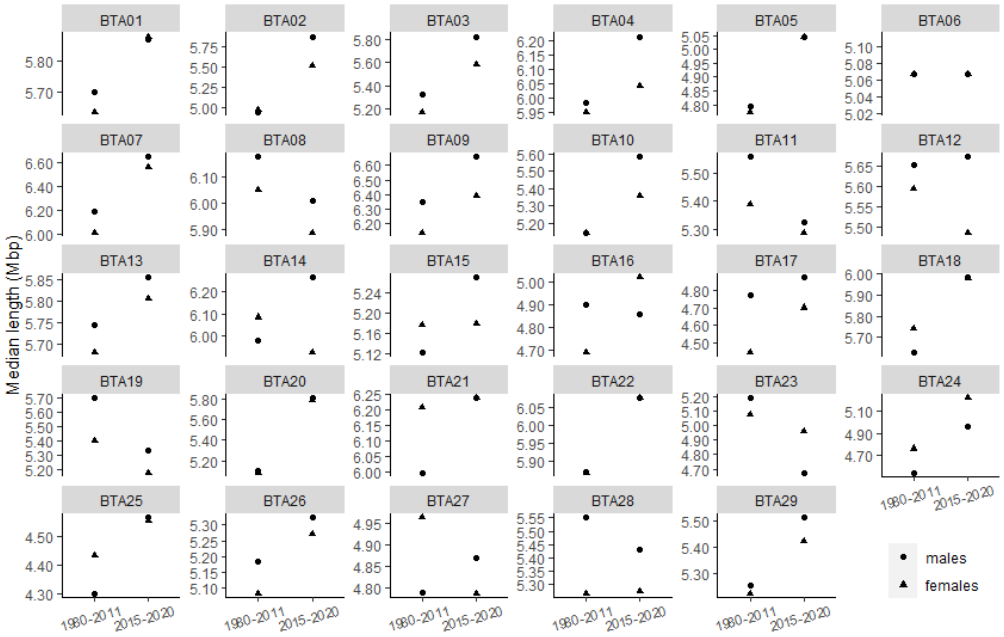

Figure 1. Median length. Median length of ROHs in chromosomes of *Bos Taurus* autosomes (BTA) before and after the introduction of genomic selection by gender.

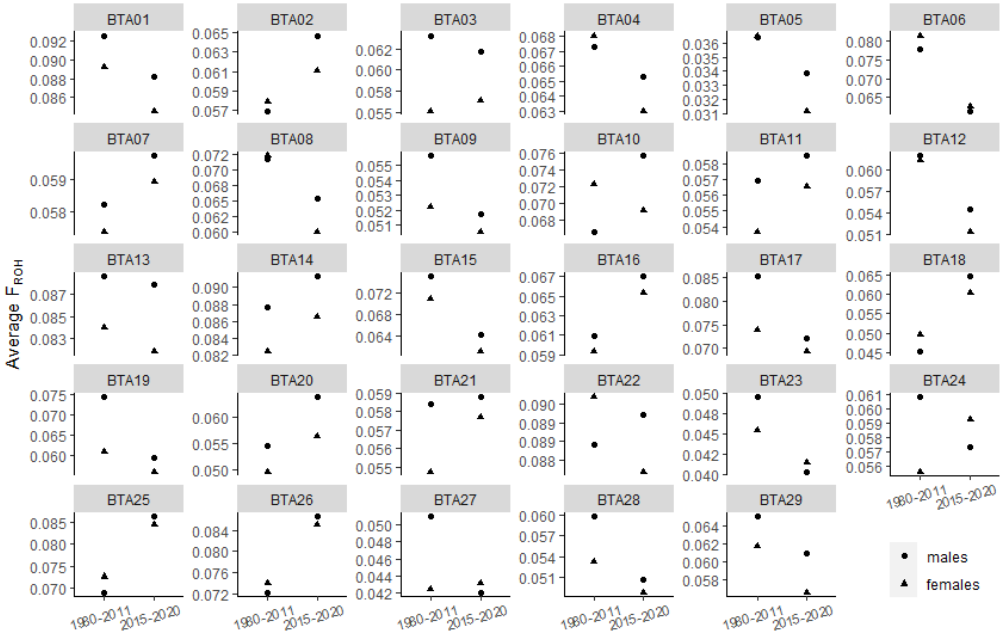

Figure 2. Average F_{ROH}. Average genomic inbreeding F_{ROH} in *Bos Taurus* autosomes (BTA) before and after the introduction of genomic selection by gender.

in all forementioned chromosomes after the introduction of GS. However, in BTA11, the median length decreased, and in BTA15, it increased only in bulls. In comparison, the average F_{ROH} generally decreased with few exceptions. Interestingly, in BTA06, the median length of ROHs was similar before and after the introduction of GS. Additionally, QTLs associated with fertility have been identified in FAY in BTA 20 (Schulman *et al.*, 2011). Both the median length of ROHs and the average F_{ROH} increased in BTA20 after the introduction of GS. In addition, QTLs associated with either fertility or yield traits have been identified in RDC in BTA05 and BTA20 (Höglund *et al.* 2015, Iso-Touru *et al.* 2016, Kadri *et al.* 2015). Again, the median length of ROHs increased in BTA05 after GS was introduced. However, the average F_{ROH} decreased. Finally, QTLs associated with either fertility or yield have been identified in FAY in BTA12 (Kadri *et al.*, 2014). In our study, the median length of ROHs increased only slightly in bulls and decreased in cows after the introduction of GS, while the average F_{ROH} decreased in both bulls and cows.

Conclusions

ROHs became longer after the introduction of genomic selection in majority of the *Bos Taurus* autosomes, where QTLs associated with fertility have been identified. However, no distinct trend in ROH length or average genomic inbreeding was observed in the chromosomes, including QTLs associated with yield traits. In addition, the average genomic inbreeding was similar before and after the introduction of genomic selection and did not follow the trends of ROH length. Further research on potential ROH-islands (e.g. Nothnagel *et al.*, 2010) is needed to assess the effect of genomic selection on genomic variability in the Finnish Ayrshire breed.

Acknowledgements

We are grateful for Suomen Naudanjalostussäätiö for funding our research. The authors thank NAV (Nordic Cattle Genetic Evaluation, Aarhus, Denmark) and Faba (The Finnish Animal Breeding Association, Hollola, Finland) for providing the genotype and pedigree data used in this study.

Abstract

This study used genome-wide SNP data to characterise the Istrian and Croatian Coloured goats genetically. Population structure and conservation status were analysed using 11 Istrian and 33 Croatian Coloured goats and 506 additional animals belonging to 19 European goat breeds. Neighbour-net and admixture results show that the two breeds are unique and retain a great proportion of the ancestral genetic structure. Despite low N_e for Istrian goats, both breeds showed low levels of inbreeding (F_{ROH}~0.05). Considering these results, the Istrian goat is at high risk of extinction and should be carefully monitored.

Introduction

The domestic goat (*Capra hircus*) is one of the first domesticated animals. A relatively small animal with modest requirements and good resistance to harsh environmental conditions, it migrated with humans and colonised Croatian territory around 7,000 years BP (Amills *et al.*, 2017). Since then, goat rearing has been a constant presence in Croatian livestock production, although there have been some difficult times. In 1954, the government banned goat keeping in open areas, which led to a drastic decline in goat populations in Croatia. The indigenous Croatian goats are raised in extensive systems with low production. The Croatian Coloured goat (GCH) has 2261 animals in selection, while the Istrian goat (GCI) has only 14 animals in selection (Croatian Agency for Agriculture and Food, 2021). Local breeds are part of the genetic and socio-cultural heritage of the local community.

For this reason, it is essential to preserve the genetic diversity of the remaining breeds, mostly captured in non-selected autochthonous breeds (Medugorac *et al.*, 2009). To date, there is little knowledge about the genetic structure of indigenous Croatian goat breeds. This study used genome-wide genotype data to analyse the genetic diversity and conservation status of two Croatian indigenous goat breeds, the Istrian goat and the Croatian Coloured goat.

Materials & methods

Sample collection and data genotyping. A total of 11 hair samples from GCI and 34 tissue samples from GCH were genotyped using the Illumina Goat 50K SNP Chip (Illumina INC., San Diego, CA). Quality control was performed using SVS ver 8.9.0 (SNP and Variation Suite, Golden Helix, USA). It included removal of all: (1) loci on the mtDNA, sex chromosome and without position; (2) genotypes with a call rate <90%; (3) individuals with a call rate <95%. We used 506 additional samples downloaded from the Dryad repository (https://doi.org/10.5061/dryad.v8g21pt) representing 19 European goat breeds (VAL – Valdostana, ORO – Orobica, BIO – Bionda dell'Adamello, VSS – Valpassiria, ASP – Aspromontana, ARG – Argentata, GAR – Garganica, DIT – Di Teramo, CCG – Ciociara Grigia, SAR – Sarda, SIT – Saanen, NIC– Nicastrese, CRS – Corse, SFR – Saanen, FSS – Fosses, PTV – Poitevine, PYR – Pyrenean, PVC – Provencale, ARR – Arran, CRP – Carpatian).

Population structure. Population structure was determined using a model-based clustering algorithm computed in ADMIXTURE ver. 1.3.0 software (Alexander and Lange, 2011) for 2-25 populations. Prior to

R.F. Veerkamp and Y. de Haas (eds)

calculation, data was pruned in PLINK 1.9 software (Chang *et al.*, 2015) using the indep-pairwise 50 5 0.03 command. Nei's distances (Nei, 1972) was calculated using the StAMPP package (Pembleton *et al.*, 2013) in R software (R Core Team, 2020) and used to generate the Neighbour-net graph using SplitsTree ver 4.14.2 software (Huson and Bryant, 2006)

Conservation status. Individual genomic inbreeding (F_{ROH}) was assessed using ROH data and then averaged by breed. ROH was determined using SVS software with parameters previously defined in Ferenčaković *et al.* (2013). Effective population size (N_e) analysis was calculated based on LD using GONE (Santiago *et al.*, 2020) and using the molecular co-ancestry method implemented in NeEstimator V2.1 (Do *et al.*, 2014.) with default parameters.

Results & discussion

After quality control, 10 GCI and 33 GCH with 54,216 genotypes remained. The merged Croatian and European dataset consisted of 548 goats and 44,867 genotypes, and after pruning, 19,530 SNP remained.

The genetic relationship between the analysed breeds is represented with the Neighbour-net (Figure 1). Consistent with PCA (result not shown), several clear clusters are revealed in which the breeds form sub-branches. The GCI was clustered with the SIT and SFR, while the GCH was clustered with the CRP goat and is very close to the BIO and VSS. The longest branch formed Ireland ARR goat due to island isolation, similar to the results of Colli *et al.* (2018).

The ADMIXTURE plots showed the results for K=3, K=8 and K=14 (Figure 2). First breed split occurred at K=3, and continued as the K value increased. After calculating CV errors, K=14 was identified as the best-fitting representation. K=14 confirmed clusters that diverged at lower K values and exhibited varying breed admixture degrees. The breeds ARR, DIT, FSS, GAR, ORO, PTV, PVC, PYR, SFR, SIT, SAR, VAL were assigned to separate clusters. Other breeds studied showed a high degree of admixture, as previously described in Nicoloso *et al.* (2015) and Colli *et al.* (2018). GCI showed a common genetic background

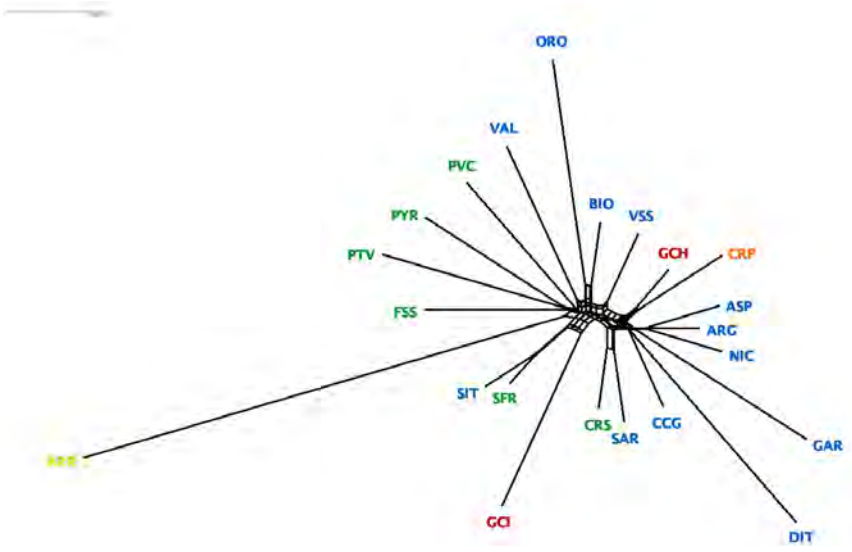

Figure 1. Neighbour-Net graph of Nei's distances between breeds. Each color represents one country: Croatia, Italy, France, Ireland, Romania.

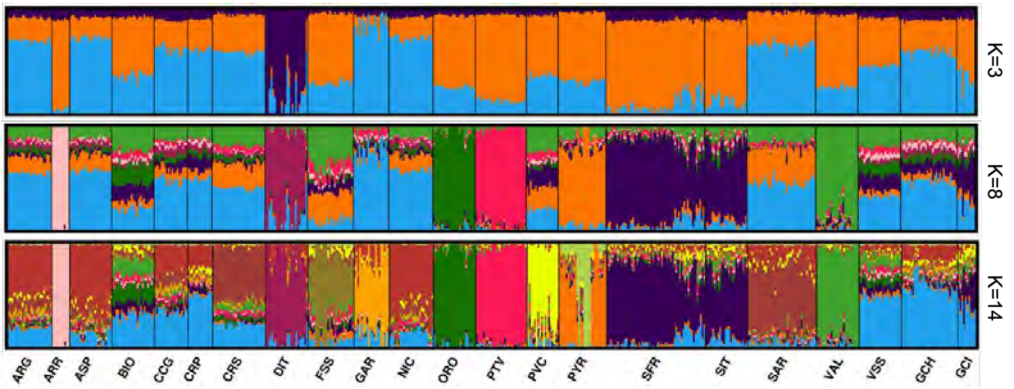

Figure 2. Population structure of 21 selected goat breeds using ADMIXTURE.

of mixed origin similar to BIO and VSS with minor components of ORO, PVC, and Saanen breeds. The admixture pattern of GCH was similar to ARG, ASP, CRP, and NIC with a minor component of SAR. The Croatian goat breeds retained a large part of the historical genetic structure.

The conservation status of Croatian goats was estimated using genomic inbreeding (F_{ROH}) and effective population size (Ne). The distribution of F_{ROH} and estimates of N_e are presented in Table 1. Effective population size was shown for generation 1 (NeEstimator, GONE) and generation 5 (GONE) to be comparable with other authors. GCI had a lower N_e value than the GCH, which was expected due to the smaller population size of the GCI. The results for the GCI should be viewed with caution because the sample size is small. We observed an initial pattern of decreasing N_e in both breeds, but then a small increase in N_e was observed in GCH, probably due to a bottleneck. In general, highly productive breeds (Angora, Boer, Sannen, Alpine) show lower effective population size than local breeds with lower production (Colli *et al.*, 2018). N_e should be at least 100 to ensure that an animal population is viable in the long term in terms of genetic diversity (Meuwissen, 2009), which means that the GCI is at high risk of extinction.

Considering the small N_e it is surprising that the GCI, together with CGH, has a very low genomic inbreeding of 0.06 and 0.04, respectively. The low inbreeding could be explained by high genetic admixture. Similar F_{ROH} values were obtained for native Italian ARG (Bertolini *et al.*, 2018; Cortellari *et al.*, 2021; Mastrangelo *et al.* 2021) SAR, BIO, VSS, NIC (Bertolini *et al.*, 2018, Cortellari *et al.*, 2021) and French CRS (Bertolini *et al.*, 2018) breeds. F_{ROH} values decreased with increasing minimum ROH length, suggesting lack of recent anthropogenic influence. In summary, Croatian goat breeds have great genetic diversity, with a large part of historical admixture resulting from an extensive production system. Decrease in recent inbreeding (F_{ROH}>16Mb) suggest no recent human selection. Caution should be taken when implementing

Table 1. Effective population size and inbreeding coefficients for Croatian goat breeds.

Population	Ne					
	NeEstimator	GONE		F_{ROH}		
		Generation 1	Generation 5	>2 Mb	>8 Mb	>16 Mb
CGI	5.40	27.21	∞	0.06	0.05	0.04
CGH	119.20	477.10	439.27	0.04	0.03	0.02

breeding programmes, especially for the GCI, as the small N_e could seriously affect the overall biological fitness of the breed. This study was supported by ANAGRAMS: IP-2018-01-8708, project No.QK1810253 and Sir je IN: KK.01.1.1.04.0058.

Abstract

Selection focused only on productive traits, which has been the case in small ruminant breeding programs for many years, has resulted in damage to fitness traits. This deterioration could be due, in part, to increased homozygosity in specific genomic regions linked to these traits. With this hypothesis, this study has made use of genomic information from HD chips to characterize ROH regions sheep to explore whether there has been an increase in homozygosity in genome regions associated with traits of economic interest for the breeding program. Results show an increase in homozygosity in regions associated with productive (milk, fat, and protein yields), reproductive (reproductive seasonality), or health traits (clinical mastitis), among others.

Introduction

Breeding programs have been widely used for many years to improve traits of economic interest in various production systems. In some species, gains achieved in traits under selection have been substantial, with yields doubling for many of the traits (Lu Cao *et al.*, 2020). However, due to the complex nature of the relationships between production and functional traits (fertility, health, resilience), which in many cases are antagonistic, the improvement of production levels has resulted in an impairment of functionality (Berry *et al.*, 2014). Possible explanations for this antagonism are the existence of pleiotropic antagonisms or hitchhiking effects and the accumulation of homozygosity in specific regions of the genome (Mastrangelo *et al.*, 2018).

The Manchega sheep breed has been under selection for more than 25 years. The main selection objective has been milk yield, with fat and protein contents and udder shape being included in recent years. The response to selection in milk has resulted in almost doubling the production of this breed, while fertility or udder shape has deteriorated.

Different information can be used to quantify the effects that selection for productive traits may have on other traits. Particularly, the development of genotyping platforms has allowed the availability of individual genome-level information, making it possible to monitor changes in the genome along generations to assess the impact of selection and correlated responses.

This work aimed to make use of genome information to analyze the distribution of homozygosity along the genome and infer if selection for productive traits may have increased homozygosity in regions of the genome associated with functional traits.

Materials & methods

Genomic information from 324 AI rams belonging to the Manchega sheep breeding program was used. This information was provided by AGRAMA breeders association and consisted of SNP data from the

ovine Illumina HD (700K) bead chip. Rams were selected to maximize representativeness of animals in the population. Quality Control (QC) removed samples and variants with missing call rates exceeding 10%, and only autosomes were considered. A total of 540,733 markers and 322 rams remained after QC. Criteria followed to define ROH were the following (Macciotta *et al.* 2021, Signer-Hasler *et al.* 2019, Peripolli and Baldi 2016): only regions greater than 1 Mb and with at least 100 SNPs were considered; the scanning window could contain up to 5 missing calls and 1 heterozygous, must have had at least 50 SNPs per 50 kb on average and if two consecutive SNPs were more than 1000 Kb apart they could not be part of the same ROH. ROH were classified into three groups based on their length: small ranges (from 1 to 2.5 Mb), mid ranges (from 2.5 to 5 Mb), and long ranges (>5 Mb). Distribution of ROHs between animals belonging to different generations was studied to identify ROH regions that have changed throughout the development of the breeding program. The information on the sheep QTL database (https://www.animalgenome.org/cgi-bin/QTLdb/OA/index) was used to have a first approximation of the traits of interest to which these regions of homozygosity could be associated.

Results

Figure 1 shows the number of genotyped animals available in each generation and the coverage of ROH regions per chromosome. In general, the homozygosity observed in this breed was low in agreement with previous estimates carried out in this breed using pedigree information or 50K SNP chips (results provided by the breeders association). ROH regions classified as small range were the most abundant, with abundance decreasing as ROH length increases.

Some interesting regions were identified when examining differences in ROH distribution and abundance among generations. First, two regions of homozygosity conserved in all animals were found on chromosomes OAR2 and OAR10 (Figure 2). In these regions, QTLs associated with production traits such as milk yield, and fat, and protein contents, and morphological traits such as the presence of horns and the testes' weights (Hao Li *et al.*, 2020) have been described. Some genomic regions showing increasing homozygosity over generations were found. These regions contain QTLs associated with milk (OAR3 and OAR16), fat (OAR13, OAR16) and protein (OAR3) yields, milk casein percentage (OAR16), body weight (OAR6), fat density (OAR6), reproductive seasonality (OAR3), clinical mastitis and milk bacterial count (OAR16) (Mateescu and Thonney, 2010; García-Gámez *et al.*, 2012; Banos *et al.*, 2017; Dettori *et al.*, 2017; Hao Li *et al.*, 2020).

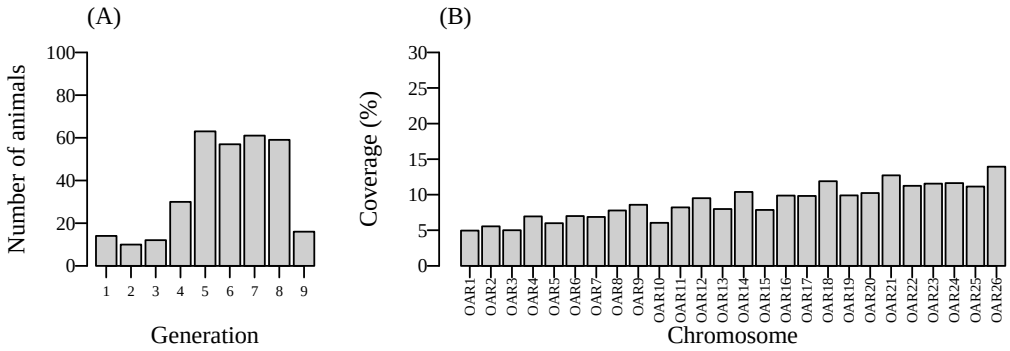

Figure 1. (A) Number of animals genotyped on each generation (from 1990 to 2016). (B) Coverage of ROH regions on the sheep genome.

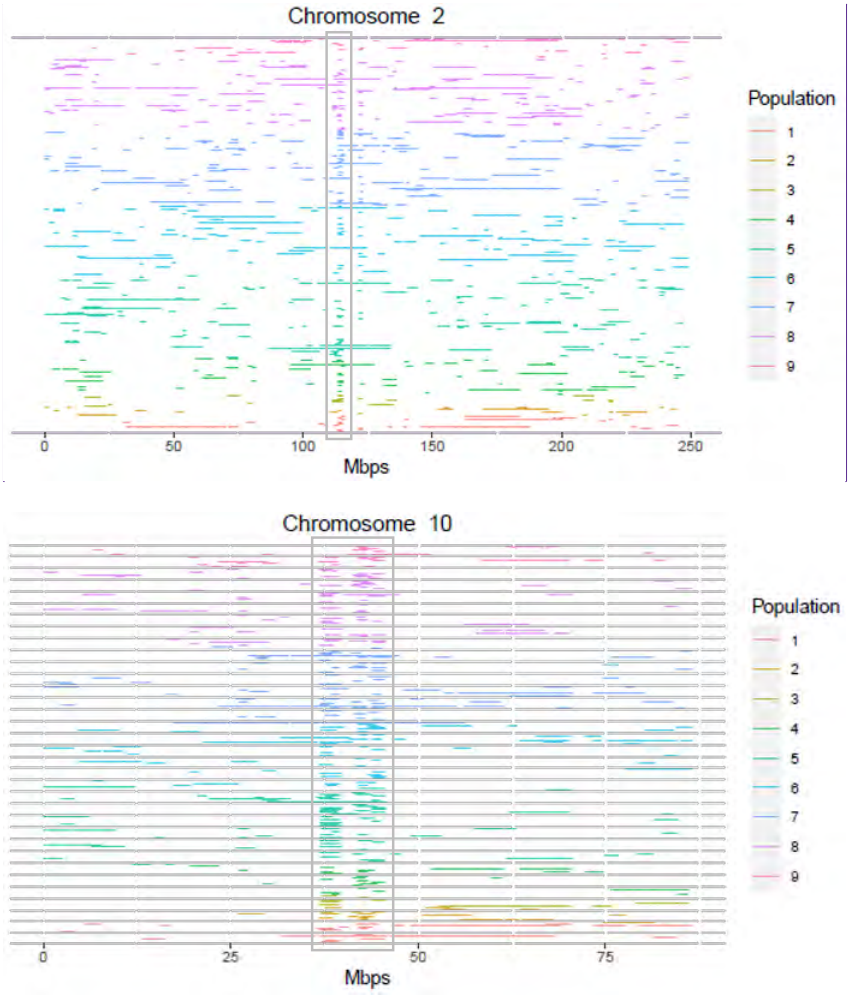

Figure 2. Distribution of ROH regions on chromosomes OAR2 and OAR10 for the 322 animals included in the study. In each graph, rows represent the distribution of ROHs along the chromosome for each ram. Rams belonging to different generations (1-9) are identified by a color scale, being distributed from the oldest (bottom of the graph) to the most recent (top of the graph). A rectangle was used to highlight regions of conserved homozygosity.

Discussion

Characterization of the regions of homozygosity using genomic information from HD SNP chips has allowed the identification of some regions with conserved homozygosity as well as other regions where increased homozygosity has been observed. Most of them were small ranges, something expected since long ROHs have been usually associated with recent inbreeding, and these are usually broken within a few generations as a consequence of recombination (Sumreddee *et al.*, 2021).

The two regions of conserved homozygosity identified on chromosomes OAR2 and OAR10 have been associated with production and morphological QTLs in sheep. More interestingly, some regions have been identified in which homozygosity has increased over generations. In these regions, QTLs associated with traits of productive interest such as fat and protein yields, milk casein percentage, traits such as body size

or body fat density, or fitness traits related to reproductive seasonality or udder health have been described. Thus, selection for increased milk production may have led to increased inbreeding in these regions that would determine the quality of milk production or the greater or lesser susceptibility of animals to mastitis.

In a following work, we will examine the effect that the homozygosity on these regions could have on the characters that have been described in these regions. Thus, we will collect productive, reproductive and health information on these animals and see if there is an effect of inbreeding depression on these traits.

234. Heterosis can be explained by thousands of partially recessive, deleterious mutations with very small effects at sites that are conserved across species

M.E. Goddard

Faculty of Veterinary and Agricultural Science, University of Melbourne and Agriculture Victoria, Bundoora, Victoria, Australia; mike.goddard@agriculture.vic.gov.au

Abstract

A model is proposed to explain heterosis and inbreeding depression. The model assumes the Kacser and Burns model of gene action at thousands of sites which are conserved across species. This implies many polymorphisms with very small effects and partial dominance. This explains 3 surprising features of heterosis – little dominance variance is observed despite dominant gene action; heterosis occurs between populations that have diverged at high N_e; and heterosis is only slightly less than expected from estimates of inbreeding depression.

Introduction

Two fundamental techniques for genetic improvement of animals and plants have been selection and crossbreeding. Crossbreeding benefits from heterosis for which the most parsimonious explanation is directional dominance and differences between breeds in allele frequencies. Directional dominance also explains inbreeding depression. Typically, inbreeding depression and heterosis occur for traits related to fitness such as fertility and many production traits (Doekes *et al.* 2021), but we know very little about the loci responsible. That is, we do not know the number of loci, their effect sizes, the degree of dominance or their allele frequencies. For instance, genome wide association studies (GWAS) have found thousands of markers associated with quantitative traits but most show no significant dominance (Palmer *et al.* 2021).

Three features of inbreeding depression and heterosis seem surprising – there is little or no dominance variance; heterosis occurs even in crosses between subspecies such as *Bos indicus* and *Bos taurus*; and heterosis per degree of inbreeding is only a little less than inbreeding depression per degree of inbreeding (Goddard and Ahmed, 1982). Despite dominance causing inbreeding depression, dominance variance is hard to estimate and many estimates are not significantly different from zero, although this may not be so surprising when the number of loci is large and minor allele frequencies are low (Hill *et al.*, 2008). If populations diverge at moderate effective population size (N_e), selection should prevent deleterious alleles from drifting to high frequency and so there should be little heterosis when the populations are crossed. In reality heterosis is high in wide crosses such as *B. indicus* × *B. taurus* (Goddard and Ahmed 1982, Buning *et al.* 2019). If populations diverged entirely due to drift, the divergence at loci causing heterosis should be the same as at neutral loci. Therefore, we can estimate the inbreeding (%F) that has occurred since two populations diverged using random markers. If this inbreeding coefficient is multiplied by the inbreeding depression per 1%F observed in matings of close relatives we can predict the heterosis expected. Goddard and Ahmed (1982) did this and found the heterosis observed was only slightly less than expected.

The aim of this paper is to present a model that can explain these observations concerning heterosis and inbreeding depression.

Results

Inbreeding depression is explained by variation at conserved sites. Sites in the genome that have been conserved across vertebrates have been identified. Xiang *et al.* (2021) found that homozygosity at conserved sites, but not at other sites, decreased mean trait values in cattle. Yengo *et al.* (2021) found the same result in human traits. Genomic sites conserved across vertebrates must have been subject to very long term, consistent selection. This selection would maintain the most favourable allele and all mutations would decrease fitness.

Kacser and Burns model. This conclusion can be combined with the model of Kacser and Burns (1981) in which a trait that is additively inherited (e.g. concentration of an enzyme =x) affects a quantitative trait or fitness (y) in a curvilinear manner such as y =kx/(1+x) (The Michaelis-Menten equation for enzyme reactions). In this case, y increases as x increases but approaches an asymptote at y=k. Selection will increase x and tend to maintain or conserve alleles that increase x. In this model, mutations which when homozygous reduce x to zero also reduce y to zero but the heterozygote shows dominance. The degree of dominance depends on the value of x in the wild type homozygote. The fitness of heterozygotes for a lethal mutation has been estimated to be approximately 5% below that of the wild type homozygote and this corresponds to a value of x in the wild type homozygote of 19 so that the y = 19k/20 in the homozygote and 9.5k/10.5 in the heterozygote.

Conserved sites are also enriched for additive effects on quantitative traits but they only explain part of the additive variance (e.g. 20% in Xiang *et al.*, 2021). At non-conserved sites that affect quantitative traits, the most favourable allele must vary depending on the background genotype and the environment. For instance, for a trait subject to stabilising selection, the value of a mutation depends on the optimum value of the trait and the current mean. The Kacser and Burns model does not seem to apply to these loci, at least not to their effect on fitness.

Additive and dominance effects. I will assume that the Kacser and Burns model applies only to conserved sites. For small effects on the underlying scale (a_x) the effects on the y scale are

$$a_y = ka_x/(1+x)^2$$

$$d_y = ka_x^2/(1+x)^3 = a_y^2\,(1+x)/k$$

$$d_y/a_y = a_x/(1+x)$$

where x = the mean of x.

The genetic variances and inbreeding depression (D) in y due to one locus are

$$V_a = 2pqa_y^2$$

$$D = 2pqd_y = 2pqa^2\,(1+x)/k = V_a\,(1+x)/k$$

$$V_d = (2pqd_y)^2$$

where p and q=1-p are allele frequencies.

These quantities depend on 3 parameters – the heterozygosity (2pq), the size of the additive effect on x relative to the mean of x ($a_x/(1+x)$) and k/(1+x) which converts from the scale of x to that of y.

Provided V_a is not correlated with (1+x)/k across loci, then $D = V_a (1+x)/k$ holds for the combined effect of all loci.

An example. For a locus that explains 0.0001 of the additive genetic variance in y and has a heterozygosity of 2pq = 0.2, then $k/(1+x) = 0.1\sigma_a$. Then for this locus, $D = 0.0001V_a (1+x)/k = 0.00890\sigma_a$. and d/a = 0.2. If we assume that conserved sites explain 20% of additive genetic variance then there are 2,000 loci contributing to inbreeding depression and combined $D = 1.78\ \sigma_a$. This is approximately the case for milk yield and other traits that show moderate heritability and inbreeding depression. The dominance variance $V_d = 0.0016\ V_a$ or close to zero.

Table 1 gives the results for a range of input assumptions. Reducing the effect size on the underlying x scale, reducing the number of loci, reducing the heterozygosity all reduce the inbreeding depression, while increasing the number of loci increases inbreeding depression.

The conclusion is that commonly observed values of additive and dominance variance and inbreeding depression can be explained by a model with thousands of loci with small effects and partial dominance, and moderate level of heterozygosity.

Slow inbreeding with selection. The inbreeding depression calculated above applies to rapid inbreeding, such as matings between sibs, where selection has little opportunity to act. However, populations of animals diverge more slowly and selection acts to prevent a rise in the frequency of deleterious mutations. For the small effect loci described above the selection coefficients may be $s < 0.001$. At effective population sizes $N_e < 10{,}000$, these loci will drift but at larger N_e selection will prevent their frequency rising greatly. Thus, the small effect mutations at conserved sites will experience drift in breeds with $N_e = 100$ but the wild type allele will be conserved in species with $N_e > 10{,}000$. During rapid inbreeding the inbreeding depression is proportional to heterozygosity (2pq). However, when 2 breeds or populations are crossed the maximum gain in fitness or a trait occurs when there are no homozygotes for the deleterious allele in the F1. This eliminates the loss of fitness caused by homozygosity for these deleterious, partially recessive alleles which is proportional to q^2 where q is the frequency of the deleterious allele. If there is no effective selection and allele frequencies drift randomly then the inbreeding depression and heterosis are equivalent. However, if selection is effective in keeping q small then q^2 is much smaller than 2pq and so heterosis is less than

Table 1. Inbreeding depression (D) in units of genetic standard deviation and dominance variance as functions of the number of conserved loci, the additive variance (Va) per locus, the size of variant effects on the x scale (a/(1+x)), and the heterozygosity (2pq).

No. conserved loci	Va per locus	a/(1+x)[1]	2pq	Inbreeding depression[2]	Vd

[1] Units are the additive genetic standard deviation of y.

[2] Units of genetic standard deviation of y at F=1.

inbreeding depression. In other words, lethal recessive mutations contribute to inbreeding depression and even to heterosis if breeds diverge with very small N_e, but they do not contribute much to heterosis among breeds that diverge slowly at high N_e. Conversely, numerous partially dominant mutations of small effect can contribute to inbreeding depression and to heterosis.

Discussion

The model put forward here of thousands of partially recessive, deleterious mutations of very small effect at genomic sites that are conserved across species can explain 3 surprising features of heterosis, that is, that there is little dominance variance, heterosis occurs even between populations that have diverged at high N_e and heterosis per degree of inbreeding is only a little less than inbreeding depression per degree of inbreeding. I do not imply that this is the only model that can explain the observed facts but only that it is one possibility.

As the number of loci increases while the inbreeding depression is kept constant, the dominance variance declines because inbreeding depression depends on the dominance effect whereas the dominance variance depends on that effect squared (Robertson and Hill 1983). The low dominance variance explains why GWAS seldom find significant dominance effects (just as additive variance explains the power to find additive effects).

Although it is hard to cite published evidence, anecdotal evidence suggests that heterosis occurs even in crosses between species. Farmers in Bhutan deliberately cross Yaks and cattle or Mithun and cattle, and the value of mules is famous. These cases could be due to a completely different mechanism to that discussed here but if they are due to the same mechanism as discussed here it implies that species carry many slightly deleterious, partially recessive alleles segregating at high allele frequency.

Abstract

The European rabbit (*Oryctolagus cuniculus*) is a multi-purpose species raised for meat, fiber, and fur production. It is also considered an important animal model and a companion animal, with many fancy breeds distinguished by several exterior traits. In this study, we analysed SNP array datasets from 16 fancy and meat rabbit breeds using F_{ST} analysis and runs of homozygosity (ROH) analysis. We performed F_{ST} comparisons using the windows-based approach. ROH islands were defined by evaluating the percentile-based threshold of homozygous SNPs frequency. We identified 309 genomic regions that contained putative signatures of selection. ROH islands were detected in a total of 11 autosomes, which covered about 10-20 Mb of the rabbit genome. The putative regions under selection contain genes involved in pigmentation processes and external traits (e.g. *ASIP*, *MC1R*, *TYR*, and *LIPH*). The present study contributes to clarify the genetic architecture and mechanisms that affect phenotypic differences between rabbit breeds.

Introduction

The European rabbit (*Oryctolagus cuniculus*), known simply as rabbit, is a multi-purpose livestock species raised for meat, fiber, and fur production. It is also considered an important animal model and a companion animal. Since its domestication, human-driven artificial directional selection has constituted many breeds and lines. Fancy breeds are mainly distinguished by several exterior traits (e.g. coat colour, hair structure, body size, ear size and position, and structure of the skull), and production breeds that have been constituted by considering performance and production traits. Therefore, this species is characterized by a vast amount of phenotypic diversity linked to economically relevant traits and morphological characteristics. Most of the genetic diversity within this species has been shaped by a combination of several genetic events (e.g. genetic drift, bottleneck, isolation, introgression, migration, crossbreeding) that contributed to define a lot of genetic resources, thus far mostly untapped and uncharacterized.

The rabbit genome has been sequenced and explored (Bertolini *et al.*, 2014; Carneiro *et al.*, 2014) and a high-throughput single nucleotide polymorphism (SNP) genotyping platform is available. This SNP chip has been used in genome wide association studies carried out in several rabbit populations to detect genomic regions affecting economically relevant traits, including production traits such as intramuscular fat and its composition (Sosa-Madrid *et al.*, 2020a, 2020b, Laghouaouta *et al.*, 2020) and reproductive traits, such as litter size (Sosa-Madrid *et al.*, 2020c) and the number of teats (Bovo *et al.*, 2021). Other studies have contributed to explain the variability of external traits, e.g. coat colour, that largely define breed-specific features in most traditional and fancy breeds (Demars *et al.*, 2018; Fontanesi *et al.*, 2006, 2010, 2014a, 2014b; Utzeri *et al.*, 2014).

In this study, we analysed SNP array datasets from a total of 16 fancy and meat rabbit breeds with the aim to identify signatures of selection using F_{ST} analysis. Furthermore, we identified runs of homozygosity (ROH) and we evaluated the occurrence of ROH islands in the genome of some of these breeds to identify putative signatures of selection that might be derived by different selection histories and structures of these rabbit genetic resources.

Materials & methods

Animals and genotyping. Biological specimens (hair roots or buccal swaps) were sampled from a total of 712 rabbits from three meat breeds (Italian White, n. 256; Italian Spotted, n. 93; Italian Silver, n. 20) and 12 fancy breeds (Belgian Hare, n. 24; Burgundy Fawn, n. 6; Champagne d'Argent, n. 19; Checkered Giant, n. 79; Coloured Dwarf, n. 20; Dwarf Lop, n. 20; Ermine, n. 20; Giant Grey, n. 27; Giant White, n. 20; Rex, n. 19; Rhinelander, n. 28; and Thuringian, n. 9) registered to the herd book of the National Rabbit Breeders Association. One commercial meat breed (n. 52) was from another albino meat population. All animals included in this study were selected in order to avoid highly related individuals (no full- or half-sibs). DNA was extracted using the Wizard Genomic DNA Purification kit (Promega Corporation, Madison, WI, USA). Animals were then genotyped using the Affymetrix Axiom OrcunSNP Array (Affymetrix Inc., Santa Clara, CA, USA) which interrogates 199,692 DNA markers. Quality check of the data via the Axiom Analysis Suite and PLINK v.1.9 (Chang *et al.*, 2015) led to discard low-quality samples and DNA markers (call rate <0.90). After filtering, a total of 702 animals and 139,922 SNPs were used in the subsequent analyses.

Data analyses. F_{ST} analyses were performed based on the Hudson estimator as this index is independent of sample size (Bhatia *et al.* 2013). Signatures of selection were computed in 350 kb sliding genome windows, with a step size of 100 kb. In total, 7,951 genome windows were computed after having tested windows of variable sizes as described by Rubin *et al.* (2010). Windows with less than 3 SNPs were discarded from the analyses. Two approaches were used to identify signatures of selection. The first one compared one breed against all others whereas the second one grouped some breeds together according to common features (colour patterns, body size, and use/specialization). Following Rubin *et al.* (2010) putative signatures of selection were identified from genome windows at the extreme lower end of the distributions (99.98th percentile of the distribution). This led to the identification of 14 genome windows for each comparison. We used PLINK v.1.9 (Chang *et al.* 2015) software to call ROH considering the following parameters: (1) the minimum length that constituted the ROH was 1 Mb; (2) a minimum number of 15 consecutive homozygous SNPs to call ROH and a maximum of 2 heterozygous SNPs in the homozygous SNP-windows; (3) the maximum gap between consecutive SNPs was 1000 kb. ROH islands were defined by evaluating the percentile-based threshold of homozygous SNP frequency. First, the proportion of SNPs residing within a ROH was calculated for a given breed by counting the number of times a SNP appeared in a ROH within a given breed divided by the total number of genotyped rabbits of that breed. Then, a percentile threshold of the frequency of a SNP in ROH was calculated. The percentile-based threshold was defined considering the top 1% of SNPs observed in a ROH in each breed. Adjacent SNPs, having a frequency of ROH occurrences over or equal to the identified thresholds, and with a distance ≤1 Mbp between them, constituted ROH islands (Schiavo *et al.* 2021). Genomic regions that displayed signatures of selection from F_{ST} analysis and ROH islands were annotated with the Bedtools v.2.17. (https://bedtools.readthedocs.io/) by retrieving annotated protein-coding genes from the OryCun2.0 NCBI's GFF file (https://www.ncbi.nlm.nih.gov/).

Results

In the pairwise F_{ST} comparison, the averaged F_{ST} values ranged from 0.095 (Italian White vs all) to 0.238 (Ermine *vs* all). In total, 309 unique genome regions that contain signatures of selection were obtained from F_{ST} analysis (single breed approach and group of breeds approach). Several genome regions harbouring coat colour related genes already detected by other studies to affect pigmentation in rabbits or other species were identified. These regions included *TYR* (Burgundy-Fawn, Italian White, Italian Spotted), *OCA2* (Checkered Giant), *MC1R* (Rhinelander), *MITF* (Giant White), and *ASIP* (Giant Grey). Other signatures were highlighted in genes related to: (1) coat structure, such as *LIPH* (Rex); and (2) body size, such as (*COL2A1, LCORL, and GRK5)* in Dwarf Lop breed.

ROH islands were identified in a total of 11 autosomes, which covered about 10-20 Mb of the rabbit genome. Considering overlapping ROH islands between breeds, a total of 22 independent ROH islands were detected. Manhattan plots presenting ROH islands in the four breeds for which more than 50 animals were genotyped are shown in (Figure 1). Several ROH islands contain genes involved in body size, body length, pigmentation process, carcass traits, growth, and reproductive traits as previously determined in humans or in other livestock species such as (*NELL1, TRIB2, NR3C1, TRIB1*, *IFRD1, AOX1, ITGB8, and OCA2*) genes.

Discussion

In this study, different fancy and commercial rabbit breeds were investigated. The methodologies used to perform F_{ST} analysis were able to capture signatures of selection in many genomic regions harbouring genes that were previously identified to affect coat colour (*ASIP*, *TYR,* and *MC1R*), coat structure (*LIPH*), and body size (*LCORL/NCAPG*) in rabbits. Furthermore, signatures of selection were detected in genome windows containing *EDNRB*, *EDNRA*, and *MITF,* that were not reported thus far to affect coat colour in rabbits, despite the role that those genes play in pigmentation. Interestingly, the two independent types of analysis (ROH islands and F_{ST}) pointed out the *OCA2* genome region in Checkered Giant breed. This gene encodes for the homolog of the mouse p (pink-eyed dilution) that is believed to be a melanocyte-specific transporter with an essential role in normal pigmentation. Other studies could be useful including additional breeds and using other statistical approaches will be needed to expand the detection of signatures of selection in rabbit genome.

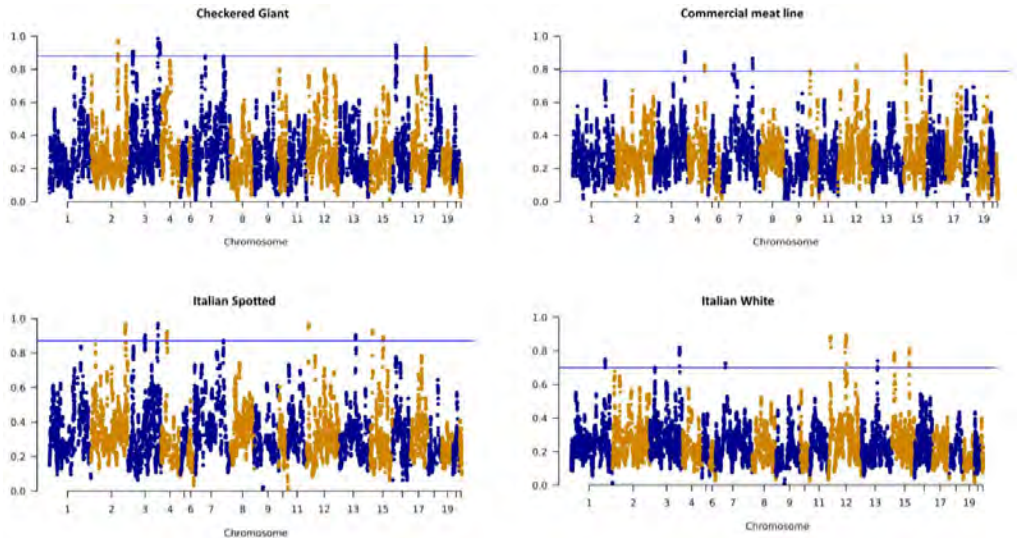

Figure 1. Manhattan plots showing ROH islands in Checkered Giant, commercial meat, Italian Spotted, and Italian White breeds. The blue line indicates the frequency corresponding to the top 1% of the most frequent SNPs in the population.

236. Investigating genetic redundancy as a source of genetic diversity and adaptability in the U.S. Holstein breed

Y. Steyn[1*], T.J. Lawlor[2], S. Tsuruta[1], Y. Masuda[1], A. Legarra[3], D.A.L. Lourenco[1] and I. Misztal[1]

[1]University of Georgia, 425 River Road, Athens, GA 30605, USA; [2]Holstein Association USA Inc., 1 Holstein PI, Brattleboro, VT 05301, USA; [3]INRA, UMR1388 GenPhySE, 31326 Castanet-Tolosam, France; yvette.steyn@uga.edu

Abstract

The continuous increase in inbreeding in the U.S. Holstein is a threat to genetic diversity. Loss of genetic diversity can hinder adaptation to changing environments and consumer demands. K-means clustering on the genomic relationship matrix was used to stratify 20,099 selected candidates into five clusters. These clusters were shown to be different through expected inbreeding within- and across cluster, the fixation index (F_{st}), and genetic correlations for stature between clusters. Expected inbreeding within cluster was mostly higher than across-cluster. The average F_{st} across cluster was 0.03. Genetic correlations ranged from <0.50 to >0.90. Families were formed by tracing pedigrees of each cluster back for 10 generations. Allele frequency changes over generations were evaluated. Polygenic shifts, selective sweeps, hitch-hiking, and epistasis were observed. The Replicate Frequency Spectrum was used to measure genetic redundancy. Results show that sub-populations within the breed have developed differently over time.

Introduction

The U.S. Holstein is generally viewed as a large, homogenous population known for its extensive use of only a few sires. This high level of relatedness among animals is a concern for genetic improvement and overall health of the population. Lack of variation can hinder the ability of populations to adapt to change (Markert *et al.*, 2010), which is a growing concern in the face of climate change and consumer preferences. While trait variation may reduce with selection, genetic variation can still exist. There are two main patterns in which allele frequency (AF) change occurs in a population, namely selective sweeps and polygenic shifts. Genetic hitchhiking can also increase the frequency of markers surrounding the gene of importance simply due to its proximity to the gene. Most traits of economic importance are highly polygenic. These alleles are more likely to undergo small polygenic shifts. Genetic redundancy is a phenomenon where an excess of beneficial variants exists to achieve the same genetic merit (Goldstein and Holsinger, 1992). Thus, different sub-populations may undergo heterogenous changes to converge to the same genotype or phenotype. The objectives of this study were to identify sub-populations within the breed and observe different AF changes over time.

Materials & methods

A total of 20,099 genotyped Holstein animals were used as selected candidates. This includes 3,902 males that were sires of animals born after 2010, with at least 25 progeny, and 16,197 females with measurements in 2013 or 2014. K-means clustering with a built-in R package was applied on the genomic relationship matrix (G) to separate the population into five separate clusters (C1 to C5). Alleles were coded as 0, 1, and 2.

Differences across cluster. Expected inbreeding within or across cluster was calculated based on pedigree information assuming non-zero inbreeding for unknown parents (Aguilar and Misztal, 2008) with the INBUPGf90 package within the BLUPF90 software suite (Misztal *et al.*, 2014). The F_{st} across clusters was calculated as in Bonhomme *et al.* (2010). The genetic correlations across clusters were estimated using stature as trait and an adjusted version of the method by Duenk *et al.* (2020). This correlated the additive breeding value of a cluster using the SNP effects of the same cluster, or when using the SNP effects of another

cluster. Female animals of each cluster were used to estimate SNP effects with the POSTGSF90 package (Misztal *et al.*, 2014) and applied on the males of each cluster. A simple correlation will underestimate the genetic correlation since the accuracy of breeding values is not considered. Therefore, the correlations were multiplied by an adjustment factor using the method by Calo *et al.* (1973). The heritability was considered as a measure of accuracy. Assuming a heritability of 0.45 in all clusters, this adjustment factor is 1/0.45.

Allele frequency changes. Within each cluster, five families were formed (F1 to F5) by tracing pedigrees back for 10 generations (G10 being most recent and G0 earliest). The AF were calculated for each generation within family. Generations overlap and families are connected by shared ancestors, thus animals may appear in more than one generation within a family, or/and in more than 1 family. In G0, 82% of the animals appear in more than one family and 54% are common to all families. The number of shared ancestors decreases over time. By G6, the number of families in common to all is larger than the number of unique animals per family. The total number of unique animals per family is 4,355 (F1), 3,555 (F2), 3,574 (F3). 7,107 (F4), and 4,870 (F5). Specific SNP were identified for visual observation based on previous literature (Ma *et al.*, 2019), the variance of absolute change from G0 to G10 across families, the range between minimum change in a family and maximum change, and the F_{st}. Genetic redundancy was measured using the Replicate Frequency Spectrum (RFS) (Barghi *et al.* 2019). This looks at the number of times the 100 SNP with the greatest change in one family, change by more than 0.30 in each individual family. This reflects non-parallel changes over time.

Results

The inbreeding within each cluster averaged 0.22 for C1, 0.20 for C2, 0.18 for C3, 0.10 for C4, and 0.17 for C5. The average across-cluster inbreeding was 0.11 for C1, 0.11 for C2, 0.12 for C3, 0.10 for C4, and 0.11 for C5. The average F_{st} for markers across clusters was 0.03. The genetic correlations adjusted for heritability are presented in Table 1. The changes in AF over time within each family for the SNP that showed the greatest variance is presented in Figure 1. Table 2 presents the RFS. When the 100 SNP with the greatest change in F1 are observed in each family, 15 SNP change more than 0.30 only in F1, none only in one other family, and 14 in all families. Among the 100 SNP with the greatest change in F2, 15 change more than 0.30 only in F2, none only in one other family, and 16 in all families. Of the 100 SNP with the greatest change in F3, 12 change by more than 0.30 only in F3, none only in one other family, and 13 in all families. When the 100 SNP with the greatest change in F4 are chosen, 3 change by 0.30 only in F4, 3 only in F3, 4 only in F2, and 19 in all. Among the 100 SNP with the greatest change in F5, 18 change by more than 0.30 only in F5, none only in one other family, and 11 in all families. Change was not restricted to be in the same direction in all families.

Table 1. Genetic correlations across clusters, measured as the adjusted correlation between the additive breeding value of animals of each cluster when expressed in the genetic background of each cluster.

Genetic background	Cluster expressed				
	C1	C2	C3	C4	C5
C1	1.00	0.63	0.99	0.76	0.93
C2	0.77	1.00	0.62	0.59	0.51
C3	0.81	0.41	1.00	0.81	0.92
C4	0.80	0.74	0.93	1.00	0.90
C5	0.89	0.45	0.89	0.73	1.00

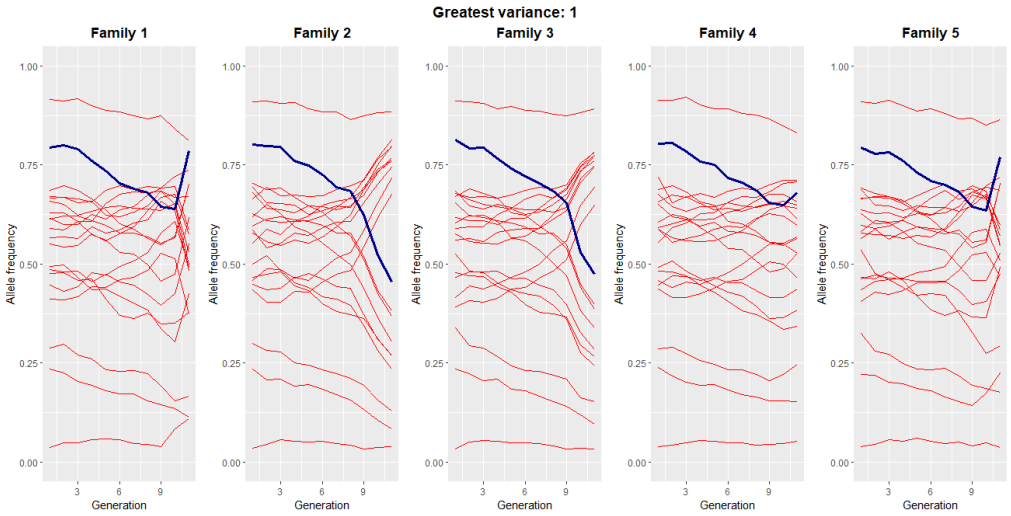

Figure 1. The allele frequency of the SNP that showed the greatest variance in change across families (blue) and the surrounding 20 SNP markers (red) per generation within each family.

Table 2. The Replicate Frequency Spectrum: The number of times the 100 SNP with the greatest change in a specific family (each row), change allele frequency (AF) by more than 0.30 in each family.

Family with top 100 SNP	Number of SNP with AF change >0.30				
	F1	F2	F3	F4	F4
F1	100	45	61	26	59
F2	57	100	68	25	51
F3	60	61	100	31	46
F4	68	67	78	55	60
F5	50	57	57	20	100

Discussion

The generally higher within-cluster inbreeding compared to across-cluster inbreeding, is an indication of genetic differences across clusters. Consistently lower inbreeding occurs for C4, regardless of whether mating was across- or within- cluster. This indicates that, although the clusters are separate from each other, C4 still contains enough variation to allow lower inbreeding. The average F_{st} of 0.03 is higher than what would be expected if no differences exist, and about half of that found between three different dairy breeds in a French study (Flori *et al.*, 2009).

There are two genetic correlations between families – one where the genotype of population 1 is expressed in the genetic background of population 2, and one where population 2 is expressed in the genetic background of population 1. These differ due to the AF in different populations. Although the genetic correlations between some clusters were above 0.85, correlations as low as 0.41 were observed, indicating that clusters show some genetic differences. In general, C2 has the lowest correlations with other clusters.

Some observed SNP showed non-parallel changes across families based on our criteria for selection, indicating genetic redundancy. Figure 1 shows a decrease in AF of the selected SNP (in blue) in F2 and F3

with no change in direction. Relatively small changes in AF are observed in F4, while directional changes in AF occur in F1 and F5. Observed SNP surrounding the selected markers (in red) show signs of potential partial selective sweeps and hitchhiking. Hitchhiking in opposite directions can be achieved when markers are in different phases. Directional changes could be due to a change in selection pressure, or epistasis with a different gene under selection.

The presence of genetic redundancy is further shown with the RFS. Even though many SNP change similarly in all families, there are family-specific SNP that change by more than 0.30 in only one family. While this study shows genetic redundancy, it does not determine whether specific changes were due to selection or drift. Gene-dropping computer simulations could be conducted to identify markers that have changed more than what could be expected under neutral inheritance. Such methods could be applied to identify genes under selection.

Conclusions

The U.S. Holstein breed is a complex mixture of family subgroups with different allelic frequencies and genotypic combinations. The study reveals genetic redundancy that has allowed sub-populations to change differently over time. Genetic redundancy has the ability to continue genetic improvement in the breed without drastically decreasing underlying genetic diversity. The different polygenic shifts in sub-groups avoids the fixation of alleles and the loss of genes that may allow the breed to adapt to climate change and consumer demand.

237. Inbreeding depression and heterosis for live-weight and carcass traits in purebred and crossbred sheep

P. Rafter[1*], N. McHugh[1], K. McDermott[2] and, D.P. Berry[1]

[1]*Animal & Grassland Research and Innovation Centre, Teagasc, Moorepark, Fermoy, Cork, Ireland;*
[2]*Sheep Ireland, Highfield House, Shinagh, Bandon, Cork, Ireland; pierce.rafter@teagasc.ie*

Abstract

Given the importance of inbreeding depression and heterosis, both should be accounted for in breeding and management strategies. The present study quantified the association between eight different pedigree- and genome-based inbreeding and outbreeding metrics with 40-day weight, weaning weight, carcass weight, carcass conformation, and carcass fat in a large multi-breed and crossbred population of sheep. Five of the inbreeding and outbreeding metrics tested were associated with at least one of the traits analysed. Of the five traits analysed, only 40-day weight was not associated with any of the inbreeding or outbreeding metrics used in the present study, although one of the inbreeding metrics for the dam was positively associated with 40-day weight of the lamb.

Introduction

Inbreeding depression is the reduction in progeny performance relative to the parental mean performance which occurs due to the close relationship between the sire and the dam (Falconer and Mackay, 1996). Heterosis (hybrid vigour) can be considered the opposite of inbreeding depression, in that it is an increase in progeny performance relative to the parental mean performance that occurs when the sire and dam originate from different populations (Falconer and Mackay, 1996). The purpose of the present study was to evaluate the association between different estimates of inbreeding and outbreeding with 40-day weight, weaning weight, carcass weight, carcass conformation, and carcass fat of lambs. Both pedigree-based and genome-based measures of inbreeding and outbreeding were considered.

Materials & methods

Genotype and phenotype data. Illumina OvineSNP50 single nucleotide polymorphism (SNP) array (54,241 SNPs) (Illumina Inc. San Diego, CA) genotypes were available for 31,171 sheep with a call rate of >95%. These 31,171 animals consisted of 21,325 crossbred sheep, 3,466 Texel, 2,539 Belclare, 1,511 Charollais, 1,234 Suffolk, and 1,096 Vendeen sheep. Single nucleotide polymorphisms on the Y or MT chromosome, SNPs with a call-rate <95%, SNPs with a GC score <0.55, and SNPs which deviated from Mendelian inheritance in >2% of verified parent-progeny pairs were all excluded. After edits, 47,349 SNPs remained; missing genotypes were imputed using the imputation software suite FindHap v3 (VanRaden *et al.,* 2013).

Five traits were investigated in the present study: 40-day weight (kg), weaning weight (kg), carcass weight (kg), carcass conformation, and carcass fat. Forty-day weight is the live-weight of the lamb measured at approximately 40 days of age while weaning weight is the live-weight of the lamb measured at weaning at approximately 100 days of age (McHugh *et al.*, 2018). Carcass fat cover was graded by processors on a scale of 1 [thin] to 5 [fat] scale. Carcass conformation was also assessed by processors on a 5-point scale where 1 represents poor conformation and 5 represents excellent conformation. Carcass records were retained for crossbred animals which were ≤300 days old at slaughter. After edits, carcass records were available for 5,872 animals while 40-day weight and weaning weight records were each available for 7,196 animals.

Measures of inbreeding and outbreeding. Four different estimates of inbreeding were used: F_{ped} which is the (traditional) pedigree estimate of inbreeding (Wright, 1922), F_{hom} which is a genomic estimate calculated from observed homozygosity (Kardos *et al.*, 2015), F_{ROH} which is the proportion of the genome in a run of homozygosity (ROH) (Kardos *et al.*, 2015), and homozygosity by loci which is a genomic metric that measures the deviation from expected heterozygosity across the genome (Aparicio *et al.*, 2006). Separately, four estimates of outbreeding were also calculated: F_{ROHet} which is the proportion of the genome in a run of heterozygosity (ROHet), observed heterozygosity which is the proportion of heterozygous SNPs in the genome, heterosis which is proportional to the sum of the product of parental breed fractions (VanRaden and Sanders, 2003), and recombination loss which is proportional to the sum of the square of parental breed fractions (VanRaden and Sanders, 2003). For the heterosis and recombination loss calculations, the breed fractions of the sire and the dam were calculated based on the pedigree information.

Runs of homozygosity and ROHet were called in each animal in the population using the R package 'detectRUNs' (Biscarini *et al.*, 2019) using a sliding window approach. The window size for each run was set to 15 SNPs; within each window a maximum of one contradictory genotype was allowed, i.e. for ROH, the contradictory genotype was a heterozygote and for ROHet, the contradictory genotype was a homozygote. The maximum gap between adjacent SNPs within a run was set at 250 kb and the minimum SNP density was one SNP per 100 kb; the minimum number of SNPs per run was five and the minimum length of a run was 1 kb.

Association analyses. The association between each inbreeding and outbreeding statistic with each carcass and live-weight trait was modelled separately for each trait across the entire population using a linear mixed model approach with the software suite ASREML (Gilmour *et al.*, 2015). Pedigree estimates for inbreeding or outbreeding statistics may be biased downwards relative to genomic estimates due to missing pedigree records or violations in the assumption that all founder animals are unrelated. For comparison purposes, the inbreeding and outbreeding statistics were each standardised to have a mean of 0 and a standard deviation of 1. Each of the linear mixed models were solved separately for the five different traits analysed and again separately for each of the eight inbreeding and outbreeding statistics so that overall, 40 different analyses were conducted. Forty-day weight and weaning weight were modelled with a maternal effects model as:

$$y = Xb + Za + Wm + e \quad (1)$$

where y was the vector of phenotypes. The fixed effects were denoted in the model by the matrix b which consisted of, the intercept treated as a continuous variable, the breed category of each animal (which was either crossbred, Texel, Belclare, Charollais, Suffolk, or Vendeen), the inbreeding or outbreeding statistic included in the model which was treated as a continuous variable, the sex of the animal treated as a categorical variable, the age of the animal treated as a continuous variable, an age-by-sex interaction variable, the age of the dam treated as a continuous variable, and the flock-date of each animal was included as a contemporary group in the model. The direct polygenic effect of each animal was denoted by a and was treated as a random effect which was assumed to have the distribution $N(0, \mathbf{A}\sigma^2_g)$, where A was the numerator relationship matrix and σ^2_g was the direct additive genetic variance. The maternal genetic effect, denoted by m, was also treated as a random effect and had the distribution $N(0, \mathbf{A}\sigma^2_m)$ where σ^2_m was the maternal genetic variance. The residual of the model was denoted by e and was treated as a random effect with the distribution $N(0, \mathbf{I}\sigma^2_e)$, where I was the identity matrix and σ^2_e was the residual variance. The matrices X, Z, and W were design matrices for the fixed effects, the direct polygenic random effects, and the maternal genetic effects, respectively. For the analysis of recombination loss and heterosis, purebred animals were not included in the analysis because they have no heterosis or recombination loss.

Each carcass trait was separately modelled using an animal model:

$$y = Xb + Za + e \quad (2)$$

The definitions for variables, y, Z, a, and e were the same as in Equation 1. The fixed effects, denoted by matrix b, were the inbreeding or outbreeding statistic included in the model which was treated as a continuous variable, an age-by-sex interaction variable, and the contemporary group for each animal, which was the flock-by-slaughter date of each animal.

Results & discussion

All full-siblings have, by definition, the same expected pedigree-based estimate of inbreeding because the calculation of the pedigree estimate is based on the pedigree relationship between the sire and the dam (Wright, 1922). Conversely, the genomic estimate of inbreeding between full-siblings can differ because the genomic estimate of inbreeding is calculated per individual based on the observed homozygosity of their genome. In the population used in the present study there were 5,969 full-sibling pairs; the average difference in F_{hom} between full-siblings was 0.0006 (standard deviation of 0.043) and the average difference in F_{ROH} between full-siblings was 0.0005 (standard deviation of 0.015). These results indicate that the genomic inbreeding estimates may have the capacity to detect a truer reflection of inbreeding.

Association analyses. The regression coefficient of each performance trait on each of the eight pedigree and genomic estimates of inbreeding and outbreeding are in Figure 1. Neither homozygosity by loci, heterosis, or F_{ROHet} were associated with any of the traits analysed; additionally, no inbreeding or outbreeding statistic of the lamb itself was associated with 40-day weight. However, while inbreeding or outbreeding statistics relating to the lamb were not associated with 40-day weight (Figure 1), one of the inbreeding

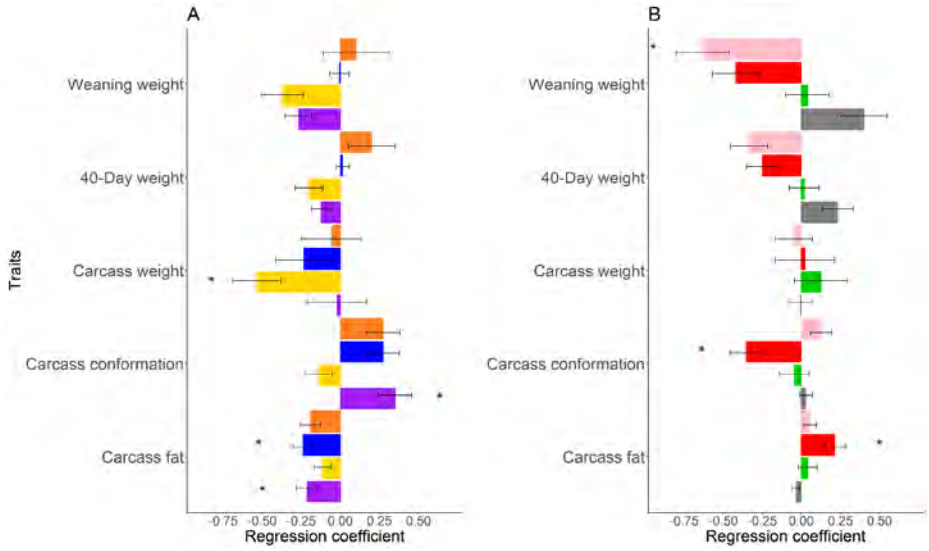

Figure 1. The regression coefficient of (A) inbreeding metrics – F_{hom} (purple), F_{ped} (yellow), F_{ROH} (blue), homozygosity by loci (HL) (orange), and (B) outbreeding metrics -F_{ROHet} (grey), heterosis (Het) (green), observed heterozygosity (OH) (red), and recombination loss (RL) (pink) on carcass fat, carcass conformation, carcass weight, 40-day weight, and weaning weight. The black error bars indicate one standard error. Bars annotated with stars indicate regression coefficients which were different from zero (P<0.001).

metrics (homozygosity by loci) for the dam was positively associated with 40-day weight in the lamb. For weaning weight the strongest association with dam inbreeding (or outbreeding) metrics was also a positive association with homozygosity by loci, although this association was not significant after adjusting for multiple testing. Pre-weaning weight in lambs has a maternal genetic component (Fitzmaurice *et al.*, 2020) which may account for the association between homozygosity of loci in the dam and day-40 weight in the lamb.

Both pedigree-based and genome-based estimates of inbreeding and outbreeding statistics were associated with at least one of the traits analysed. Of the five traits analysed only carcass conformation and carcass fat were both associated with inbreeding and outbreeding metrics (Figure 1). For carcass fat the inbreeding metrics had negative associations whereas the outbreeding metric had a positive association. Conversely, for carcass conformation the inbreeding metric had a positive association and the outbreeding metric had a negative association. These results are consistent with the reported positive genetic correlation between lower carcass fat and higher carcass conformation in sheep (Conington *et al.*, 2001).

Conclusions

Five of the eight estimates of inbreeding and outbreeding were associated with at least one of the live-weight or carcass traits analysed. Therefore, when practicable, pedigree-based and genome-based estimates of inbreeding and outbreeding should be used to account for inbreeding and crossbreeding in sheep populations.

Abstract

Local populations such as the endangered German Black Pied cattle (DSN) are an important genetic resource for the future of livestock breeding. To provide more information on the genome composition of DSN, we performed phylogenetic analysis and calculated genome-wide nucleotide diversity using variants from whole-genome sequencing of 302 DSN, and 1,394 individuals from 68 taurine breeds. Phylogenetic analysis detected four main clusters that could be assigned to their respective geographical origin: Northern Europe, Central Europe, Jersey and Guernsey islands, and an area comprising Eastern Europe, Central Italy, and Asia. DSN showed close relationship to Dutch Friesian Red, Dutch Belted, Holstein, Eastern Flanders White Red, and Kholmogory. Nucleotide diversity was medium in DSN (0.001528) while it was highest in breeds from Asia and Eastern Europe (>0.0017). Nucleotide diversity was particularly high on BTA 23 between 19 and 37 Mb where the bovine major histocompatibility complex and additional immune genes are located.

Introduction

Local indigenous cattle breeds are a crucial source of genetic diversity for livestock breeding, which might be important for future local adaptations. According to the Food and Agriculture Organization of the United Nations (FAO), 84% of all local breeds in Europe are considered at risk (FAO, 2021). This is also the case for the dual-purpose German Black Pied cattle population (DSN, 'Deutsches Schwarzbuntes Niederungsrind'). Its initial breeding in the North Sea region of Germany and the Netherlands dates back to the 18th century. From there, animals were brought by emigrants to North America where they contributed to the breeding program responsible for the generation of the modern high-yielding dairy breed Holstein (Brade and Brade, 2013). Because of its lower milk yield, DSN has been almost entirely replaced by Holstein. Today, only about 2,500 DSN herd book cows remain. The current breeding goal for DSN aims to preserve DSN-typical and beneficial characteristics. For an effective conservation plan, genetic diversity measurements are needed to guarantee an optimised pool of genetic variants that provides sufficient adaptation capacity to changing environments and prevents inbreeding depression (Kristensen *et al.*, 2015). In this study, we compared the genetic relationship of 69 taurine cattle breeds including DSN using phylogenetic analysis and nucleotide diversity (π). Nucleotide diversity has been shown to be a good start point when evaluating the genetic diversity status of a given population (Kardos *et al.*, 2021). It is a region-wide metric used to quantify the degree of polymorphisms within a population.

Methods

Genomic data. Sequence variants were available from whole-genome sequencing data of 302 DSN animals (Neumann *et al.*, 2021). Further sequence variants of 1,394 animals from 68 other *Bos taurus* breeds and 1 Auroch (*Bos primigenius*) were obtained from the 1000 Bull Genomes Project – Run 9 (Hayes and Daetwyler, 2018). The sequence variants were detected based on the ARS-UCD1.2 reference genome. For high data quality, we required a sequencing coverage of at least 8-fold and at least 5 animals per breed. For breeds with >30 animals, 30 animals were randomly selected. For Holstein, 30 animals per country (Germany, Denmark, Netherlands, U.S.) and 30 labelled as 'Holstein Friesian', and not only 'Holstein'

in the 1000 Bull Genomes Project were randomly selected. The sequence variants from 302 sequenced DSN and from the 1000 Bull Genomes Project were merged using BCFtools v1.9. A total of 74,834,092 biallelic variants (68,486,380 SNPs and 6,347,712 indels) occurring in the tranche 99% (from the Variant Recalibration performed by 1000 Bulls Genome Project) with a call rate ≥90% were considered for the analysis.

Phylogenetic analysis. A genome-wide phylogenetic tree was built for all *Bos taurus* autosomes (BTA). The 74,834,092 sequence variants were first pruned removing all variants in high linkage (r^2>0.6) with PLINK v1.9 (Purcell *et al.* 2007) using a windows-size of 50 bp and a step-size of 5 bp. Using the resulting 21,426,106 variants, the Manhattan distance between animals was calculated and the UPGMA algorithm implemented in the biotite library in Python was used for clustering. The tree was rooted using Auroch as an outgroup. The phylogenetic tree was visualized using iTOL v6 (Letunic *et al.* 2019). Branches of the phylogenetic tree represent the position of the majority of animals from each breed.

Genomic diversity. Nucleotide diversity (π) was calculated per windows of 10 kb (π_{window}) for all BTAs using 74,834,092 sequence variants and the package scikit-allel in Python as:

$$\pi_{window} = \frac{\frac{n}{n-1}\sum_{ij} p_i p_j \pi_{ij}}{10\ kb} \quad (1)$$

Where p is the frequency of the respective i^{th} and j^{th} haplotypes, π^{th} is the number of nucleotide differences per site between the i^{th} and j^{th} haplotypes, and n is the number of haplotypes. The average nucleotide diversity per chromosome (π_{chrom}) was calculated as the mean over all windows of the respective chromosomes, and total nucleotide diversity (π_{total}) as the mean across all BTAs.

Results

Phylogenetic analysis. Phylogenetic analysis of 69 cattle identified four main clusters that can be assigned to geographical origins (Figure 1a): Northern Europe (green), Central Europe (violet), Jersey and Guernsey islands (red), and Eastern Europe, Central Italy, and Asia (blue). The cluster of Central Europe comprised breeds from Austria, Switzerland, Southern Germany and France. Those are mainly dual-purpose breeds kept in mountainous areas. However, the majority of the breeds including DSN and Holstein formed a cluster based on their origin in Northern European countries. Jersey and Guernsey cattle formed a separate cluster. The fourth cluster included breeds from Asian, Central Italy, and Eastern European countries. Most breeds showed clear clusters without or with very few misassignments of animals. This was not the case for the Modern Danish Red, Swedish Red, Norwegian Red, Ayrshire Finish, and Modern Angler which showed many misassignments. Regarding DSN, we observed that they clustered closest to Dutch Friesian Red, Dutch Belted, Holstein, Eastern Flanders White Red, and Kholmogory. Those are all breeds originating from Germany, the Netherlands, and Belgium. Kholmogory, a Russian breed, is descendent of animals imported from the Netherlands. Further breeds from the North Sea region, from territories of Germany, the Netherlands, Denmark, Belgium and Scandinavia showed also close relationship to DSN.

Genomic diversity. Total nucleotide diversity (π_{total}) for the 69 investigated breeds ranged between 0.001316 in Väneko and 0.002048 in Buryat (Figure 1a). π_{total} was higher in DSN (0.001541) than in Holstein (0.001505) and 28 other breeds (20 from Northern Europe), but lower than in other European and Asian breeds. The highest π_{total} values were detected in Asian and Eastern European breeds. The other European breeds showed similar π_{total} with a few lower exceptions (<0.0014): Ringamålako (0.001396), Jersey (0.001396), Guernsey (0.001385), Groningen White Headed (0.001345), Traditional Danish Red (0.001339), Scottish Highland (0.001328) and Väneko (0.001316). Regions with particular high nucleotide diversity (π_{window}) in DSN as well as in all other breeds were observed on BTA 4, 10, 12, 15, 29 (Figure 1b),

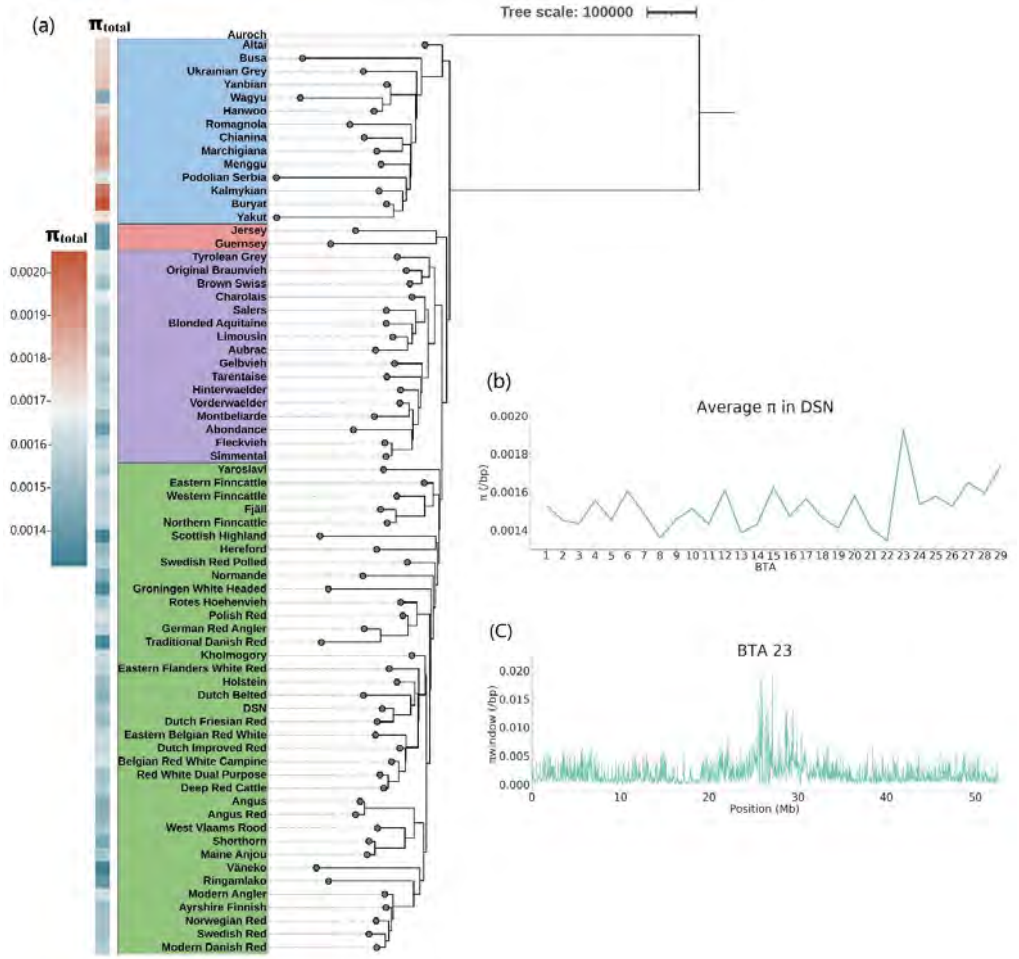

Figure 1: (a) Phylogenetic tree of 69 cattle breeds. Clusters are coloured by their geographical assignment: Central Italy, Eastern European and Asian countries (blue), Jersey and Guernsey (red), Central Europe (violet), Northern European countries (green). Individuals of each breed were collapsed to single clusters (grey spheres). Nucleotide diversity (π_{total}) is listed next to the leaves as gradient (blue=low, red=high). (b) Average nucleotide diversity in DSN per chromosome. (c) Nucleotide diversity in DSN per window on BTA 23.

and in particular on BTA23 between 19 and 37 Mb (Figure 1c), which includes the major histocompatibility complex (MHC) and the bovine leukocyte antigen (BoLA).

Discussion

DSN showed similar nucleotide diversity as the other breeds from the same cluster, indicating a good management of the endangered population. As expected, in DSN and all other breeds, BTA 23 contains a highly polymorphic region where the MHC is located. This high diversity around MHC is also seen in other species (Shiina *et al.*, 2017). Asian and Eastern European breeds showed higher nucleotide diversity (π_{total}) likely due to less intensive breeding programs, genetic bottlenecks, or founder effects in comparison to Central and Northern European breeds (Felius *et al.*, 2014). Further migration of these cattle to Southern, Central and finally Northern Europe are consistent with the clusters in our phylogenetic tree (Felius *et*

al., 2014). The lowest nucleotide diversity of Northern European Red cattle populations was evident in Traditional Danish Red and Groningen White Headed, which resulted from recent inbreeding in the small populations (Schmidtmann *et al.*, 2021). Recently, Schmidtmann *et al.* (2021) have found high levels of admixture between Modern Angler, Ayrshire Finnish, and Norwegian Red, which explains why our clustering between those breeds had many misassignments.

Abstract

Classification of homozygous-by-descent (HBD) segments or ROH in different age-related groups based on their length is useful for several applications. Here we compare the partitioning obtained with our newly developed multiple-HBD classes hidden Markov model (HMM) with an alternative approach consisting of length-based clustering of ROH. When the HMM was applied to simulated data sets, autozygosity was concentrated in the HBD-class associated with the ancestors causing inbreeding. This was however not observed for the ROH-classes corresponding to the expected length of ROH transmitted from these ancestors. On real cattle data, autozygosity was maximized with the HMM in the HBD-class matching the inferred period of reduced N_e. In summary, while ROH-based classifications must be interpreted cautiously, our newly developed multiple HBD-classes HMM seems promising to provide a better picture of the age-based partitioning of individual genomic inbreeding.

Introduction

Inbreeding is common in cattle populations as a consequence of intense selection of elite sires or due to their recent demographic history often characterized by declining effective population sizes or recent bottlenecks. Homozygous-by-descent (HBD) segments, genomic segments inherited twice and through different paths from a common ancestor, are present at high frequency in such inbred populations. HBD segments result in long stretches of homozygous genotypes referred to as run-of-homozygosity (ROH), the length of which being a function of the number of generations to the common ancestor. The distribution of HBD segment lengths is thus informative about the past demographic history of a population and is often summarized, in empirical studies, by grouping observed ROH in several discrete length classes; long/short ROH-classes being considered as resulting from recent/ancient inbreeding. Such classifications are valuable to understand past demographic events from the population, to monitor evolution of inbreeding levels, to infer the mating structure when pedigrees are unknown, to determine how deleterious variants are purged across generations, to compare the effects of recent and ancient inbreeding on phenotypes or even to estimate mutation rates. As an alternative approach, we recently developed an HMM with multiple-HBD classes to partition autozygosity in different age-related HBD classes (Druet and Gautier, 2017). We herein assess the accuracy and robustness of such partitioning of autozygosity based on simulated data sets and genotyping data available for three cattle populations with contrasted recent demographic histories, and compare these classifications with those obtained with ROH-based approaches.

Materials & methods

Classification approaches. The joint identification and classification of HBD segments was first realized with RZooRoH (Bertrand *et al.*, 2019) and a model with 12 HBD classes. In this multiple HBD-classes model, several nested layers of ancestors are successively modelled (Druet and Gautier, 2021). In each layer, the genome is described as a mosaic of HBD and non-HBD segments with an HMM. The length of HBD and non-HBD segments is exponentially distributed with a rate R_c specific to the layer c and related to the number of generations to the common ancestors (approximately $0.5 \times R_c$ generations). The frequency of HBD segments within layer c is defined by a parameter ρ_c, that can be interpreted as the inbreeding

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_239, © T. Druet *et al.* 2022

coefficient accumulated over the generations included in the layer. The non-HBD classes are modelled as a mixture of HBD classes from earlier generations and shorter non-HBD segments. Genotype probabilities in different states (HBD / non-HBD) are obtained from the allele frequencies and the genotyping error rates.

A ROH-based approach was additionally used. The clustering of ROH was carried out with GARLIC (Szpiech *et al.*, 2017) that automatically selects the optimal number of SNPs per window. GARLIC was also ran with 12 classes by selecting ROH boundaries matching HBD-classes. More precisely, the boundary between ROH class c-1 and c corresponded to the ROH-length for which the exponential distributions with rates R_{c-1} and R_c have equal probability.

Simulated data sets. To evaluate the classification approaches, we simulated 500 genomes as mosaics of HBD and non-HBD segments using different values of ρ, corresponding to the inbreeding coefficient *F*. Their length was exponentially distributed with a rate R_c. The genome consisted of 25 chromosomes 100 cM long, and individuals were genotyped for a total of 25,000 SNPs. We subsequently used Argon (Palamara, 2016) to simulate more realistic data under a Wright-Fisher model. In these simulations, bottlenecks occurred 16 or 64 generations ago and effective population size (N_e) dropped to 20 or 50.

Real cattle data sets. Identification and classification of HBD segments or ROH was applied to three cattle data sets with distinct recent demographic history (i.e. decline, severe bottleneck and expansion, respectively): (1) 145 Dutch Holstein (HOL) individuals (Alemu *et al.*, 2021); (2) 18 individuals from the feral cattle population of Amsterdam Island (TAF); and (3) 22 Zebus from Magadascar (ZMA) (Magnier *et al.*, 2021). After quality filtering, the samples were respectively genotyped for 37,675, 23,679 and 531,967 SNPs. Past N_e was first estimated with GONE (Santiago *et al.*, 2020).

Results

The expected length for a HBD segment associated with a common ancestor present G generations ago is L=100/(2G) cM, G is thus often estimated as 100/(2L) for a ROH of length L. However, we observed that classes with L>100/(2L) had larger contributions to autozygosity, more so when simulated inbreeding levels were high (Figure 1). Conversely, with the HMM, the HBD-class with a rate R_c equal to 2G had the main contribution to autozygosity. Similar patterns were observed for simulations with different values of R_c.

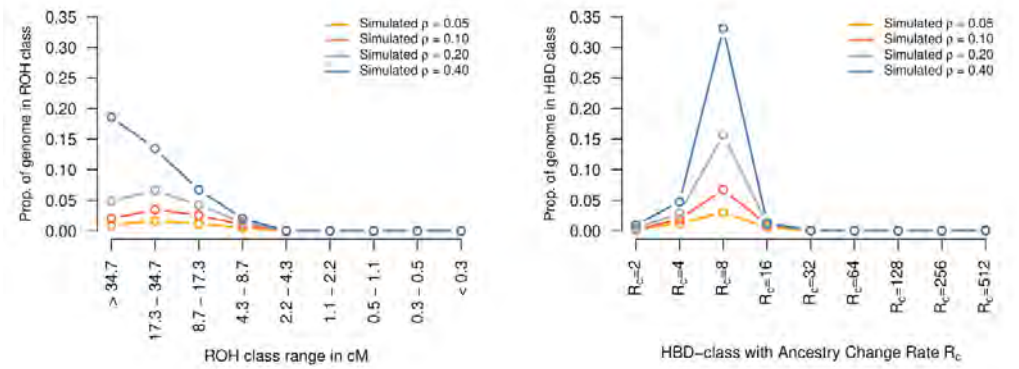

Figure 1. Classification of simulated HBD segments inherited from ancestors living 4 generations in the past (i.e. with an expected length L=12.5 cM) with an ROH approach and with the multiple HBD-classes HMM (expected R_c=8).

The behaviour of the two approaches was confirmed when populations that experienced a bottleneck were simulated under a Wright-Fisher model. With the HMM based approach, the HBD-class with a rate R_c equal to 2G (where G is the timing in generations of the bottleneck), and its neighbours, captured the HBD-segments associated to the bottleneck. On the other hand, with the ROH-based approach, ROH longer than 100/(2G) had the highest contributions to autozygosity, more so when the bottleneck was stronger and inbreeding levels were higher.

This trend was also confirmed when analysing real data on three cattle populations with very different recent histories (HOL, TAF and ZMA) inferred with GONE and which were found consistent with our prior expectations (Figure 2): (1) HOL presented a recent decline with current N_e being equal to 70; (2) TAF experienced a recent and severe bottleneck (17 to 25 generations ago, N_e dropped to 5) in agreement with the historically reported introduction in the Amsterdam island of six founder individuals in 1861 followed by a rapid expansion of the population (up to Ne=1,300); and (3) ZMA is in expansion (100 generations ago, N_e=100 up to a current Ne=3,000). The partitioning with the multiple HBD-classes model closely matches these demographic events (Figure 2). For instance, autozygosity is mainly associated with ancestors living around 16 generations in the past for TAF population, and around 100 generations in ZMA, just before the expansion. In HOL, inbreeding levels were associated to more recent ancestors. The inbreeding levels estimated with GARLIC were highly correlated with those from ZooRoH (0.963, 0.938 and 0.996 for the three populations) although values were lower, indicating that the smaller HBD segments were not captured. By decreasing the minimal ROH size to 20 SNPs with GARLIC, inbreeding levels were closer to those obtained with ZooRoH (although this is a rather small number of SNPs and the optimal values estimated by GARLIC were higher). As for the analyses on simulated data sets, the ROH-based approach associated most of autozygosity to classes with L>100/R_c (R_c is the rate of HBD-classes with the main contribution to autozygosity). Interestingly, for lower inbreeding levels and more recent ancestors, classifications from both approaches were more concordant.

Discussion

In ROH-based approaches, the number of generations to the common ancestor of a given ROH is often estimated as G=100/(2L), based on the expected length of a ROH inherited from an ancestor living G generations ago. ROH are often classified according to their length and G is then estimated independently for each class. In simulations with ancestors present G generations ago, we observed that classes with

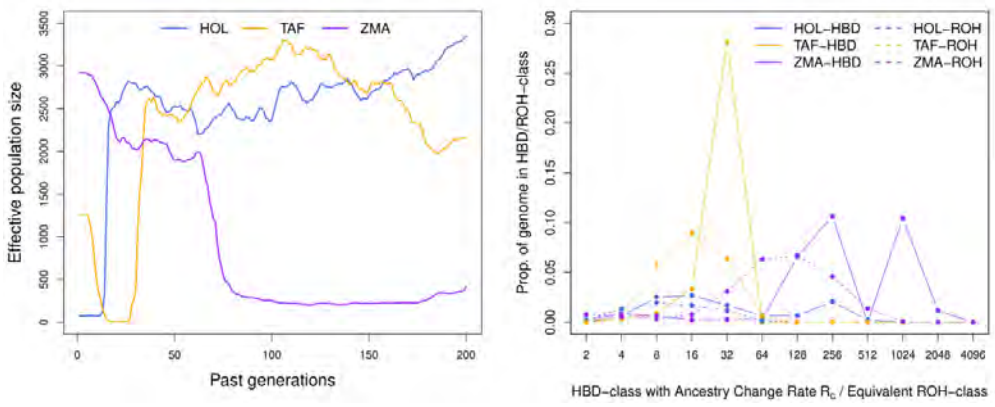

Figure 2. Past effective population size and partitioning in different HBD or ROH-classes for cattle populations with distinct demographic histories.

L>100/2G have larger contributions than classes with smaller ROH, leading to the incorrect interpretation that inbreeding might be associated with more recent ancestors. This result from the fact that ROH inherited from ancestors present G generations ago follow an exponential distribution and their length range spans generally over several classes, with only a subset of these ROH falling into the class centered around L. Such an approach thus fails to account for the possibility that ROH from different classes might come from the same group of founders. A better estimate may be derived by combining information from multiple ROH (from their average length), providing a single ancestor (or multiple ancestors living in the same generation) contributed to the individual inbreeding. The classification varied also as a function of the inbreeding level ρ, possibly because for higher ρ, the probability that two consecutive short and independent ROH appear as one unique long ROH increases, shifting the distribution towards classes with longer segments. Overall, ROH-based classifications should be interpreted very cautiously. By contrast, the HMM allows joint estimation of the parameters of a mixture of exponential distributions that would result in the observed distribution of HBD segment lengths. We are currently evaluating how precisely the age (in terms of generation to the common ancestor) of each HBD segments / ROH can be estimated with different approaches in more realistic demographic histories. For instance, if we want to understand the relationship between HBD class contributions and Ne, we should determine which past generations are captured by each HBD classes. We must also account for the fact that contributions from the most ancient classes might be swept by autozygosity associated with more recent ancestors. However, we showed that the parameters ρ did not require such corrections (Druet and Gautier, 2021).

Abstract

Biotechnology offers powerful tools for the management of livestock genetic diversity. Genomics, bioinformatics, reproductive technologies and tools for cryopreservation of germplasm are particularly important. These biotechnologies have undergone notable advancements in recent years. Developing capacities and sharing expertise are two ways by which the Food and Agriculture Organization of the United Nations (FAO) supports its member nations. For these reasons, FAO has drafted two new guidelines, on: (1) genomic characterization; and (2) cryoconservation. The guidelines update previous versions from the early 2010s by providing information on exploitation of relevant recent biotechnological developments. They were prepared in collaboration with: (1) members of the International Society for Animal Genetics; and (2) partners of the IMAGE research consortium, including NordGen. The guidelines were written by teams of scientific experts and reviewed by FAO Member Nations. Draft versions are already available online and the finalized guidelines will be released during 2022.

Introduction

Animal genetic resources, and their diversity, are an essential part of the biological basis for world food security and contribute to the livelihoods of more than one billion people. Livestock genetic diversity is declining and the capacity to manage animal genetic resources is insufficient in many countries, especially in developing countries (FAO, 2007b and 2015). To establish an intergovernmental policy to address these issues, the Member Nations developed and adopted the Global Plan of Action for Animal Genetic Resources (GPA; FAO, 2007a). The main responsibility for implementing the GPA lies with countries, but international organizations, including FAO, are expected to play important roles, especially with cross-country collaboration. Among the actions and priorities included in the GPA is the development of 'technical standards and protocols for phenotypic and molecular characterization' and 'approaches and technical standards for conservation'. To this end, FAO had previously developed guidelines on molecular genetic characterization (FAO, 2011) and cryoconservation (FAO, 2012) of animal genetic resources, among others.

The last editions of guidelines on molecular genetic characterization and cryoconservation (i.e. gene-banking) were prepared a decade ago. Although much of the content of the two documents has remained perfectly valid, many technological advancements have occurred in the last 10 years, the greater application of which could enhance management of animal genetic resources. Therefore, the objective of this work was to update the FAO guidelines.

Materials & methods

The new guidelines were developed through substantial international cooperation.

Genomic characterization. FAO has a long history of cooperation with the International Society of Animal Genetics (ISAG), including the ISAG/FAO Advisory Group on Animal Genetic Diversity, an ISAG standing committee (ISAG, 2021). Members of this Advisory Group served as authors and reviewers of the previous guidelines on molecular characterization (FAO, 2011). Five current and former members of the Advisory Group served as editors for the new guidelines (and co-authors of this paper). These editors formulated outlines for each chapter, identified and engaged with authors, and oversaw the preparation process. In some cases, the editors also served as authors.

Innovations in cryoconservation. From 2016 to 2020, FAO was a partner in the consortium of the European Union Horizon 2020 research project IMAGE (Innovative Management of Animal Genetic Resources; IMAGE, 2016). The objective of IMAGE was to 'enhance the use of genetic collections and to upgrade animal gene bank management', both in Europe and globally. One deliverable of IMAGE was the review of the existing FAO guidelines on cryoconservation (FAO, 2012) and recommendation of an outline and content for new guidelines. The Nordic Genetic Resource Center (NordGen) was the IMAGE partner responsible for this deliverable, although all partners contributed. NordGen staff were made co-editors of the new guidelines. Authors for each chapter consisted of at least one IMAGE member and (when possible) one author from a non-European country, to ensure global representation and relevance. Scientists from around the world provided case studies.

Preparation. The two guidelines were written over an approximately one-year period starting in the spring of 2020. The content was reviewed by guideline editors, authors, FAO staff, invited experts and public volunteers. Draft versions of the documents were presented to the 11th session of the Intergovernmental Technical Working Group on Animal Genetic Resources for Food and Agriculture (FAO, 2021a) for review by FAO Member Countries in May 2021. In addition, the draft guidelines on genomic characterization were reviewed by seven other members of the ISAG/FAO Advisory Group. In September 2021, the revised versions (FAO, 2021b,c) were presented to the 18th session of the Commission on Genetic Resources for Food and Agriculture, a governing body of FAO.

Results

As previously mentioned, the objective of this work was to update previous guidelines (FAO, 2011 and 2012). Regarding characterization, genomics greatly increases the precision of analyses of genetic variation, relative to earlier tools such as microsatellite markers, and have also opened previously non-existent opportunities for the study of functional variation and population histories, and the management of breeds. For cryoconservation, awareness has increased on the use of *in vitro* collections as sources of variation for *in situ* populations, rather than simply as an 'insurance policy' against breed extinction. The recognition of genomics and gene-banking as complementary tools is highlighted in the guidelines.

Genomic characterization. Table 1 provides the titles of each section of the guidelines on genomic characterization, the main topics of each section. Relative to the previous guidelines (FAO, 2011), the new version provides less information on the basics of genomic diversity studies and much more on genetic tools, methods and applications. Appendices include an extensive glossary, procedures for DNA (blood) sampling, questionnaires for collection of complementary data, description of popular software, and a summary of available DNA chips.

Innovations in cryoconservation. Table 2 has the titles of each section of the guidelines on cryoconservation. Case studies were included as text boxes to demonstrate the real application of the tools and approaches discussed. The guidelines also contain appendices that provide detailed instructions on cryopreservation of the most frequently used types of germplasm and tissues, as well as 'model' agreements for material acquisition and transfer, based on the tools developed by the European Regional Focal Point for Animal Genetic Resources.

Table 1. Title, main topics covered, and authors for each section of the FAO guidelines on genomic characterization animal genetic resources.

Title	Main topics
1. Introduction	Rationale for characterization; history and prospects
2. The basics of genomic diversity studies	Prerequisites and planning for optimal results; choice of DNA technology; complementary data to be collected; key processes undertaken in the field and laboratory; data analysis; translating and disseminating results; international coordination
3. Genomic tools and methods	SNP genotyping; candidate genes vs SNP chips; genotyping by sequencing; preparing a SNP data set; merging existing data sets; quality control; whole-genome sequencing; genotype imputation
4. Applications of genomics	Assessment of genomic variation within and between populations; assessing population structure; reconstructing population history; demographic modelling; mitochondrial DNA; sex chromosomes; selection signatures; genome-wide association studies; applying genomics for sustainable use and conservation of genetic resources
Conclusions and recommendations	Summary of key points from previous sections

Table 2. Titles, main topics covered for each section of the FAO guidelines on innovations in cryoconservation of animal genetic resources.

Title	Main topics
1. Building a gene banking strategy	Role of gene-banking in management of diversity; key issues and challenges; gene-banking objectives; governance; elements of a gene-banking strategy; utilization of stored material; rationalization of collections; multi-country gene-banking
2. Quality management	Quality management systems and benefits for gene banks; key processes; implementation; evaluation and assessment; continual improvement of gene-bank operations
3. Choice of biological material to be preserved	Semen; oocytes and embryos; gonads and gonadal tissues; germ, stem and somatic cells; matching material with national needs for utilization
4. Economics of gene banking	Costs and benefits of gene-banking; cost analysis challenges; cost-effectiveness analysis
5. Developing and using gene bank collections	Analysing genetic variation in a gene bank collection; pedigrees vs genomics; software for bank management; updating collections to account for changes over time
6. Collection and cryopreservation of germ plasm and tissues	Features of long-term cryopreservation; material collection, slow freezing vs vitrification; thawing and utilization; evaluation of quality and viability; semen; embryos and oocytes; gonads and gonadal tissue; germ and somatic cells
7. Sanitary issues	Material collection; testing for freedom of pathogens; processing; storage; distribution; national case studies
8. Databases and documentation	Critical issues for gene-bank data; data management plans; data types; data for internal vs external use; data security and protection; international information systems
9. Legal issues	Legal basis of gene banking; statutes and decision-making bodies; acquiring samples; regulating access; benefit-sharing
10. Capacity building and training	Academic instruction; training for gene-bank staff; public outreach and communication with gene-bank stakeholders

Discussion

Draft versions of the guidelines are already available online (FAO, 2021b,c). The finalized guidelines will be released in 2022. Also in 2022, FAO will organize a series of webinars to raise awareness of the guidelines and disseminate the material to scientists and other stakeholders in FAO Member Nations. Alas, development and dissemination of technical guidelines is merely an initial step in the process of using genomics and cryoconservation to improve the management of animal genetic resources. Ensuring that the knowledge in the guidelines has an impact requires increased political will, investment, and international cooperation.

Abstract

In order to safeguard farm animal genetic diversity for current and future use, reinforcement of national genebank strategies is needed as an important complementary measure next to maintenance and improvement of live breeding populations. A Quality Management System (QMS) is an important tool to integrate the needs of various stakeholders into the genebank strategy, to mitigate risks associated with collections' management and to professionalize the genebank operations and protocols. A peer review system, where genebank staff visit and review other genebanks, was tested and appeared to be an effective tool to enhance the further development of the strategies of individual genebanks, their operations and impact. For instance the peer review was an opportunity to exchange about collection and freezing protocols, advises were given to better organize storage of genetic material and data management, or more general recommendation were done such as suggesting to develop a better communication strategy.

Introduction

The most remarkable advantage of cryoconservation of genetic material in genebanks is its capacity to store reproductive material without deterioration. Providing access to this stored material makes possible a large range of uses aimed at supporting *in vivo* conservation, as a backup in case of genetic or sanitary problems, for developing new lines/breeds, increasing the diversity in the living population, modifying and/or reorienting selection, or for research purposes. The relevance of genebanks is recognized by the FAO Global Plan of Action for Animal Genetic Resources, and by the United Nations in the 2030 Agenda, in relation to SDG 2 (Zero Hunger) and more specifically Indicator 2.5.1: 'number of animal genetic resources (AnGR) for food and agriculture secured in either medium or long term conservation facilities'.

In Europe, recent surveys showed that many countries have established national genebank collections of AnGR as a backup (see Leroy *et al.* 2019, Passemard *et al.* 2018) but still more work needs to be done. Meanwhile, EUGENA (https://eugena-erfp.net/en/), governed by the European Regional Focal Point (ERFP), was established to support *ex situ* conservation.

The development of genebanks in Europe will be overviewed in this article as well as how a QMS and a peer review systems will help further developing them.

State of development of genebanks in Europe

The analysis of SDG indicator 2.5.1 based on FAO online database (https://www.fao.org/dad-is/) shows that the cryopreservation status is known for two thirds of local breeds in Europe. Only 133 local breeds have sufficient material to allow reconstitution in case of extinction (3.5%). This proportion is coherent with findings of Leroy *et al.* (2020), who indicated that most breeds in European countries have either no or insufficient material in genebanks.

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_241, © C. Danchin *et al.* 2022

EUGENA is a network of nationally recognized genebanks for animal genetic resources. It aims to support the *ex situ* conservation and sustainable use of AnGR at European level. Exchange of knowledge and experiences as well as facilitating access to information about genebank collections in Europe are the main objectives of EUGENA. The participation in EUGENA is open to all institutions managing genebanks.

A specific ERFP *Ad Hoc* Action was launched to support the development of EUGENA, to identify candidate EUGENA genebanks, and improve the information about the genebanks in Europe. To do so, a survey was developed to collect information about genebanks in European countries, with questions related to the institution, its objective(s), the livestock species represented in the genebank, the type of biological material stored, and finally any link to communication tools such as a web page or social media channel.

The survey was sent via a large e-mailing to a wide array of stakeholders, including National Coordinators and experts within the ERFP network and the wider European animal breeding and reproduction sector in 34 European countries. A total of 103 answers were received from 26 European countries. Conservation was quoted as the main reason for establishing genebank collections by 58% of the respondents, followed by research (23%) and commercial purposes (18%). The majority of the responding genebanks are holding reproductive material (44 institutions) while 19 of them are specialized in genomic collections; 40 institutions are hosting both type of material. As already found in previous studies (Leroy *et al.* 2019, Passemard *et al.* 2018), cattle is the main species of interest (74 collections) and most collections are holding semen (83 genebanks). Beyond cattle, sheep, goat, pig, horse and chicken are regularly represented in the collections.

The combination of the results of the *Ad Hoc* Action and the study by Passemard *et al.*, 2018 allowed the ERFP network to build up an inventory of 126 different institutions operating as genebanks in the European region. Thus, collaboration and coordination between all these actors involved are needed to foster the *ex situ* conservation activities within EUGENA.

The EU H2020 GenResBridge project (grant # 817580) was a leverage that pushed the ERFP community to formalize an Animal Genetic Resources Strategy for Europe. This Strategy proposes a series of key recommendations with the objective to strengthen the EUGENA network. Recommendations include mapping of all *ex situ* conservation facilities and enlarging the EUGENA network, ensuring breed specific core collections, evaluating sanitary issues connected with stored material and its use, implementing QMS, initiating research on new cryopreservation technologies, and facilitating access to cryopreserved genetic material where possible. Finally, to secure continued funding of the *ex situ* conservation activities, the general public must be informed about the efforts, results and value of the genebanks.

Quality management system (QMS)

Genebanks must ensure high quality conservation by providing secure, long-term storage to guarantee future viability and biosecurity. Dedicated systems for quality management, be they formal or informal, are important tools that can assist genebanks managers to monitor their progress towards their targets and fulfil their mission.

A task performed within the H2020 IMAGE project (grant #677353) was a worldwide survey on QMS (Zomerdijk *et al.*, 2020). An online questionnaire was distributed through the FAO network of national coordinators. Ninety responses were received from 62 countries. It showed that 30% of genebanks have established a QMS, 17% have a formal certification (mainly ISO 9001:2015), 35% have formal cryoconservation goals, and 50% have identified the major risks to their collections. As far as collecting, processing, storage and documentation, 59% of genebanks use Material Transfer Agreements for (part of)

incoming samples, 88% follow specific Standard Operating Procedures for processing and freezing, 49% have a database for monitoring collections. The least compliance was for distribution of outgoing material since only 24% have formal procedures for distribution of the material.

FAO has developed Guidelines with the aim to give technical guidance on the design and establishment of animal genebanks (FAO, 2012), but without any specific reference to QMS. One important conclusion from the EU H2020 IMAGE project was that quality management principles should be better reflected in the FAO Guidelines. Therefore, in the updated version of the guidelines, a whole section is devoted to 'Quality management for improved organization and implementation' (FAO, 2021).

Another output of the H2020 IMAGE project was the design of a self-diagnostic tool to facilitate the uptake of quality management by genebanks which can be downloaded on the project website (https://www.imageh2020.eu/). The IMAGE survey showed that a significant number of European genebanks were interested in developing their QMS, up to the stage of being certified with reference to ISO 9001:2015 for instance. Yet, the development of a QMS is generally viewed as time-consuming and costly, so that few genebanks complete the exercise or hesitate to invest in it. The aim of the self-diagnostic tool is to help a genebank to assess its progress towards a full QMS, so that it can get a precise idea of where to focus its efforts.

Peer reviews to strengthen genebanks and their quality management

The H2020 GenResBridge project gave the opportunity to implement a 'peer review' assessment of genebanks. Peer reviews are based on the principle that genebank experts visit and review other genebanks, genebanks giving full transparency about the strategies, facilities and protocols, and having discussions about these. After each visit a report is written with observations and recommendations, in order to support further development of the genebank strategy and to improve the genebank management. Peer review visits of national livestock genebanks were organised in 2021, involving the French, Dutch and Slovenian National genebanks. After the visits, all reports were published on the ERFP website. Review reports are short and to the point, listing only major observations and associated recommendations.

The overall impression of the genebank review pilot was positive (Bojkovski *et al.*, 2021) and considered as a useful exercise, complementary to internal audits, both for the hosting genebank and its staff, as for the reviewers visiting the other genebank. The complete transparency of the participating genebanks resulted in excellent discussions about strengths and opportunities for improvements. Comparison of the three national livestock genebanks highlighted similarities as well as differences between the genebanks.

Sharing experiences and knowledge was beneficial for all three genebanks and resulted in new ideas and inspiration. These recommendations could be very practical, such as exchanges on collecting or freezing protocols, advises on how to better organize the gene bank, on how much and which material should be stored. QMS traceability documents were also compared. More general recommendations were also given; for instance it was suggested to a genebank to better develop its communication strategy; it was also stressed out the importance of drafting documents linked to the samples that clearly state the ownership of the material. The recommendations listed in the individual reports will help the genebanks to further develop their work and priorities.

The review team with different expertise and background consisted between one and three experts of the other two genebanks. The choice of three relatively different genebanks was very positive; two genebanks with long experiences but very different organizational structures versus one younger genebank; one genebank already with a certified QMS, the second in the process to obtain this and the third not having

this objective for the moment. A rotational system was suggested in case such a review system could be implemented on a larger group of genebanks.

Conclusions

The output of the IMAGE self-diagnostic tool and the peer reviews were both acknowledged of being a valuable experience for genebanks in Europe. A new ERFP *Ad Hoc* action is set to take place in 2022 that will combine both approaches. The expectation is that ten volunteer genebanks could use the tool and be assessed within this year. A cooperative and step by step implementation of a QMS approach is definitely a way forward to secure the gene pools that are conserved in the numerous genebanks from Europe. It is also hoped that this action will encourage genebanks to get involved in EUGENA.

Abstract

It is hypothesized that African pigs derive from Near Eastern pigs that were introduced by land through Egypt, spread to other locations in Africa establishing populations of African indigenous pigs, one of which is called the *Angola Extension*. Angola has been through dramatic social events that have led to a drastic reduction of the population of indigenous pigs, which is currently endangered. These pigs are well adapted to poor diets and harsh environments. Here we used whole-genome-sequencing to explore the genetic diversity of indigenous pigs from Angola and their relationships with worldwide breeds. Results show that these pigs harbour thousands of unique mutations and high levels of heterozygosity. The location of missense mutations suggest the occurrence of adaptation events related with metabolism and tissue remodelling.

Introduction

The history of pigs in sub-Saharan Africa has been poorly studied. The DAD-IS database (FAO) accounts for a large number of African indigenous breeds, most of them with an unknown risk status. Similarly as in Europe, it is hypothesized that African pigs derive from Near Eastern pigs that were introduced by land through Egypt (Blench and MacDonald, 2000). Later during the discovery age, it is known that the Portuguese introduced Iberian pigs along the seacoast in several trading posts. The use of linguist studies focused on the origin of the word pig allowed to identify four regions in which the word pig does not derive from the Portuguese word 'porco' and these have been classified as regions of the distribution of indigenous pigs in Africa. These are called the Ancient Berber, Sennar populations and two West populations, one called the West African Extension and the other the Angola Extension that ranges from Cameroon to Angola (Blench and MacDonald, 2000). Pigs in these regions are mostly bred free ranging with access to a diet poor in protein and are well adapted to the environmental conditions including endemic diseases. The levels of genetic diversity in several African pig populations assessed by microsatellites suggested that these harbour high levels of diversity (Ramírez *et al.*, 2009).

The region of the Angola Extension is still today a remote area where pigs are bred free ranging, whose animals have never been characterized regarding their genetics. In local dialect, pigs are called 'ongulu' or 'olongulu', a word not derived from Portuguese. The country has been through dramatic social events that have led to a drastic reduction of the population of indigenous pigs. The aim of the current study was to investigate the levels of genetic diversity in a population that remains in a remote region near the Angola extension and of its relatedness with worldwide breeds.

Materials & methods

Samples of ear tissue were collected from four local pigs (ANG) at the municipality of Bailundo in Angola near the Angola Extension region. Total DNA was extracted and sequencing libraries with paired 150bp reads expected to achieve 10-fold coverage were generated. Sequencing was performed by outsourcing at Novogene company, using an Illumina NovaSeq 6000 sequencer. Public datasets comprising data from 5 European domestic breeds (5 Iberian, 4 Duroc, 9 Large White, 5 Landrace, 4 Pietrain), and 13 samples from Meishan an Asian domestic breed, plus 13 Asian wild boars and 25 European wild boars (PRJEB9922,

PRJEB1683, PRJNA320525 and PRJNA255085) were included for comparison. Prinseq-lite v.0.20.4 was used to select reads with length of 50-150nt and an average phred score quality higher than 20. After, reads were mapped to Sscrofa11.1 using BWA v.0.7.17 (BWA) (Li and Durbin, 2009). PCR Duplicates were removed using Picard v.2.23.4 (Broad Institute). Variant calling was performed using 'SAMtools Variant Caller' v.1.0.6. BCFtools v.1.10.2 (Li, 2011) was used to select SNPs with minimum read depth of 10 and a minimum number of 3 reads carrying the alternative allele. Variant Effect Predictor (VEP) (McLaren *et al.*, 2016) was used for SNP annotation. SNP summary statistics was estimated using populations module of STACKS (Catchen *et al.*, 2011). David 6.8 (Dennis *et al.*, 2003) was used to assign gene ontology (GO) terms and Revigo (Supek *et al.*, 2011) was used to generate a reduced representation of these.

Results

Raw data generated from ANG pigs, ranged from 95 million to 126 million reads across samples, corresponding to an average size of 108 million reads (Table 1). Read filtering, retained over 99.80% of the reads of which at least 99% were mapped against the reference genome. Read mapping depth ranged from 9.80 to 12.12, similarly to the 78 public datasets analysed. Variant calling identified more than eight million SNPs in autosomes for ANG pigs of which, ~900 thousand are unique to this population in comparison with European and Asian domestic and wild populations. The occurrence of SNPs was on average 1 SNP per 227 kbp. Most identified SNPs were located in intronic regions and have unknown functional significance. Among the exonic SNPs, approximately 21 thousand were annotated as missense, stop-and-start gain and loss.

In order to investigate the impact of missense SNPs in ANG pigs, we have selected the genes that harboured missense SNPs occurring in all the samples. This resulted in the identification of 1,536 genes, for which we were able to retrieve 50 GO terms, further summarized in 9 parental GO terms for biological processes.

GO terms grouped for tissue remodelling were the most frequent, comprising a total of 22 GO terms (Table 2).

Table 1. Summary and mapping statistics of ANG pigs' data and of public datasets.

Sample sets	N[1]	Raw reads	Paired reads	Mapping[1] (%)	Genome coverage[1] (%)	Read depth[2] (x)
ANG	4	108,695,832	108,549,926	99.35	97.91	10.75
PRJEB9922	37	210,848,029	152,596,663	99.21	97.14	11.27
PRJEB1683	37	111,879,123	103,604,188	99.94	80.13	9.29
PRJNA320525	1	211,300,791	192,172,164	97.06	98.11	14.97
PRJNA255085	3	179,282,739	164,017,544	97.90	97.63	12.55

[1] Number of samples.

[2] Values represent mean over samples.

Table 2. Parental GO terms obtained with Revigo's reduced representation of genes with missense SNPs in ANG pigs.

GO ID	Term	Number of child GO terms
GO:0048771	tissue remodelling	22
GO:0051122	hepoxilin biosynthetic process	7
GO:0086073	bundle of His cell-Purkinje myocyte adhesion involved in cell communication	5
GO:1903546	protein localization to photoreceptor outer segment	5
GO:0016139	glycoside catabolic process	4
GO:0060335	positive regulation of interferon-gamma-mediated signalling pathway	4
GO:0008037	cell recognition	1
GO:1904714	regulation of chaperone-mediated autophagy	1
GO:0010659	cardiac muscle cell apoptotic process	1

The observed heterozygosity (Ho) and expected heterozygosity (He) among ANG pigs was 0.78 and 0.41 respectively. The estimated FIS (inbreeding coefficient) was -0.13.

Discussion

In this study, we used whole genome sequencing for the identification of SNPs and characterization of genetic diversity of a local population of indigenous pigs from Angola. The data generated displayed a level of an average depth of 10x and a mapping rate of at least 97.5% similar to previous studies in other pig breeds (Li *et al.*, 2014) and which are within the range of the optimal value for SNP calling in pigs (Jiang *et al.*, 2019). SNP density was 1 SNP per 227 kbp which allows an high power for posterior identification of signatures of selection (Ma *et al.*, 2015). Approximately 900 thousand SNPs are unique to this African population in comparison with European and Asian domestic and wild populations, suggesting the existence of a rich genetic pool. Similarly to other studies in pigs (Groenen *et al.*, 2012; Li *et al.*, 2017) and in other species (Gao *et al.*, 2020; Weldenegodguad *et al.*, 2019) most SNPs were identified in non-coding regions. Among the exonic variants with functional impact these are mostly located in genes with functions related with tissue remodelling. This result is in agreement with the fact that body shape related traits have been a major focus of selection in pig breeds and for which we find 1,631 QTLs in the pig QTL database (Hu *et al.*, 2019). Signatures of selection related to body shape have also been previously reported (Li *et al.*, 2014). In fact, ANG pigs are of smaller stature and are able to survive being fed with leftovers mostly derived from corn and other vegetables, with no access to animal protein (Malungo, 2019). Finally, the levels of observed heterozygosity were higher in comparison with European and Asian pig breeds as previously described by Ramirez *et al.* (2009) in other populations of African pigs (Ramírez *et al.*, 2009). We observed a negative FIS value which indicates an excess of heterozygotes in relation to what was expected under random mating most likely due to the existence of a geographical dispersal of small groups (Parreira *et al.*, 2020) and the possibility of exchange between different regions (Pope, 1992). Thus reinforcing the need to sample in other regions of the country.

This study generated the first whole genome sequencing data of a pig population that is highly threatened. Our results have provided novel insights regarding the genetic value of these pigs. Their genomes harbour unique mutations. The fact that many of the SNPs are located in genes related with tissue remodelling suggests that this population may harbour unique signatures of selection that should be further investigated.

This work was supported by FCT- Fundação para a Ciência e Tecnologia IP (UIDB/00276/2020).

Main St, Reynoldsburg, OH 43068, USA; [4]National Animal Germplasm Program, USDA, 111 South Mason St, Fort Collins, CO 80521, USA; ks786@cornell.edu

Abstract

Genetic diversity is needed to improve health, production traits and for breed conservation. Germplasm collection conserves diversity and enables population reconstruction or corrective mating as needed. The objective of this study was to evaluate genetic diversity in US Jersey cattle and identify animals for germplasm preservation to capture population diversity. Genotype and pedigree information on 36,179 Jersey bulls were obtained from the Council on Dairy Cattle Breeding (CDCB), including the 782 Jersey bulls preserved by the USDA-ARS National Animal Germplasm Program (NAGP). Genetic diversity indices (*Ho*, *He*, *MAF*) were similar in both the groups. Admixture results suggested some differences in the genetic composition between the groups. The pedigree and genomic inbreeding ranged between 7.68 (F_{PED}) and 15.77 (F_{ROH}) for CDCB animals, and between 6.30 (F_{PED}) and 14.43 (F_{ROH}) in the NAGP collected animals. The average correlation between genomic and pedigree inbreeding was 0.63, while between genomic inbreeding estimates was 0.94.

Introduction

Genetic diversity in cattle is associated with improvement of economically important traits, management decisions, and breed conservation. The excessive accumulation of inbreeding or homozygosity leads to genetic diversity loss. Pedigree-based studies have suggested an increased rate of inbreeding and loss of diversity in Canadian Jersey and Holstein cattle (Stachowicz *et al.*, 2011). Melka *et al.* (2012) found lower levels of diversity in Jersey relative to Holstein, and Brown Swiss bull populations and suggested crossbreeding to recover genetic diversity, if diversity within the breeds continues to get worse. The study of genetic diversity promotes understanding of evolution, breed differentiation, and gene pool within the breeds (Doekes *et al.*, 2020 and Huson *et al.*, 2020; Melka *et al.,* 2012). Cryopreservation of recent and historic germplasm is essential to improve management and production of cattle breeds and maintain breed diversity. The USDA-ARS National Animal Germplasm Program (NAGP) collection helps to maintain and dissipate this diversity and reconstruct it in the future if needed (Blackburn *et al.*, 2019). The objective of this study was to evaluate genetic diversity in the US Jersey breed and to identify additional animals for NAGP germplasm collection that would capture and preserve this diversity in cyropreservation. It also aims to assess distant and recent rates of inbreeding in US Jersey cattle.

Materials & methods

Study population. A total of 36,179 genotyped Jersey bulls born between 1950 and 2020 were used in this study. Genotype and pedigree information on these animals were obtained from the national cooperator database maintained by the Council on Dairy Cattle Breeding (CDCB, https://www.uscdcb.com/). This population included 782 NAGP Jersey sires born between 1953 and 2016. Animals were genotyped using 45 different arrays and were imputed to 79,389 markers using Findhap ver 3 (VanRaden *et al.,* 2011). The SNPs used in this study are routinely used in US dairy genomic evaluations. Bulls missing pedigree and phenotype records were excluded, and genotypes for 36,370 (35,675 CDCB and 695 NAGP) animals were used in the study (Table 1).

Table 1. Distribution of samples used in this study.

Decade	CDCB	NAGP	Total
1951-1980	57	29	86
1981-1990	254	110	364
1991-2000	1,352	243	1,595
2001-2010	2,388	212	2,600
2011-2020	28,892	101	28,993
2021-	2,732	0	2,732
Total	35,675	695	36,370

Genetic relationship and diversity estimates. Basic diversity indices such as observed (*Ho*), expected heterozygosity (*He*) and minor allele frequencies (MAF) were calculated using PLINK ver 1.9. Principal component analysis was performed using GCTA ver 1.94. Admixture composition was estimated using a maximum likelihood model implemented in ADMIXTURE ver 1.23 (Alexander *et al.*, 2009).

Inbreeding estimation. Pedigree inbreeding (F_{PED}) was estimated using an additive genomic relationship matrix A using only pedigree information to calculate probabilities that gene pairs are identical by descent. Genomic inbreeding was estimated by two approaches: (1) Genomic relationship matrix (F_{GRM}) G (VanRaden *et al.*, 2008). Both pedigree and F_{GRM} were calculated using inbreed1.f90 and inbreed2.f90 implemented in US dairy evaluations. (2) Runs of homozygosity (F_{ROH}) was determined using a sliding window approach following the criteria suggested by (Doekes *et al.* 2019). Inbreeding coefficient was calculated based on the method proposed by McQuillan *et al.* 2008. ROH length based inbreeding was estimated by classifying the identified ROH segments into different length classes: (1) >16 Mb; (2) 8-16 Mb; (3) 4-8 Mb; (4) 2-4 Mb; and (5) 1-2 Mb.

Results & discussion

Genetic diversity between bulls in the CDCB population and NAGP germplasm collection. The average observed heterozygosity, expected heterozygosity and minor allele frequencies in the two populations were similar (Table 2). Principal component analysis revealed considerable variation in the populations, particularly in recent decades (Figure 1). This result could reflect that most of the sires genotyped are from the recent decades (80% of the genotyped bulls were born from 2011 to 2020). ADMIXTURE results (K=2) suggested differences in composition between the animals in the NAGP collection and the wider population (CDCB), with lower levels of admixture in the NAGP collection (Figure 2a). Inclusion of purebred Holstein data in the analysis (K=3) suggested Holstein introgression for CDCB (8.9%) and NAGP (5.4%).

Table 2. Genetic diversity indices observed in the population and germplasm collection.

Group	*Ho*[1] ± Std	*He*[2] ± Std	MAF[3] ± Std
CDCB	0.37±0.12	0.38±0.13	0.28±0.14
NAGP	0.38±0.11	0.39±0.11	0.29±0.12

[1] Ho – observed heterozygosity.
[2] He – expected heterozygosity.
[3] MAF- minor allele frequency.

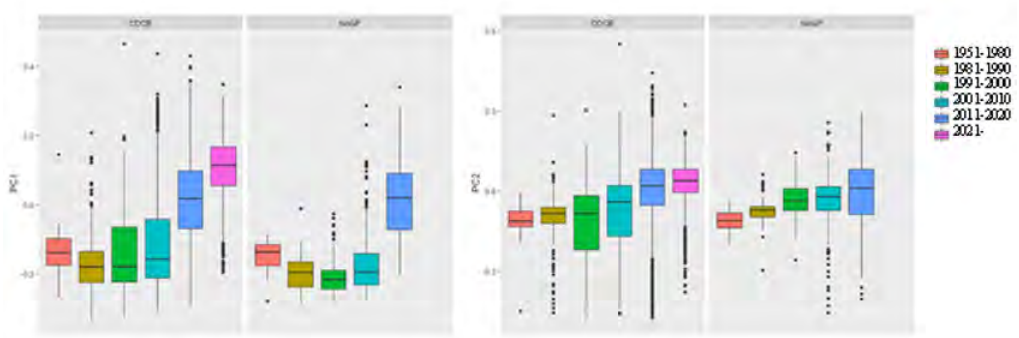

Figure 1. Box plot showing variation captured by Principal components (PC1 and PC2).

Genomic and pedigree inbreeding estimation. The average pedigree inbreeding was 6.3% in the NAGP and 7.68% in the CDCB populations. The genomic inbreeding estimates were 11.12%, 10.16% (F_{GRM}) and 15.77%, 14.43% (F_{ROH}) for CDCB and NAGP collections, respectively. ROH length-based inbreeding ranged between 3.8 and 15.2% for CDCB and 3.94 and 14.43% in NAGP animals (Table 3). The correlation between genomic and pedigree inbreeding ranged between 0.56 to 0.68 with genomic inbreeding estimates ranging between 0.87 to 0.97 (Figure 2b). The average pedigree and genomic inbreeding in NAGP bulls was 10.2 and 6.5 respectively (Table 3). This estimation was similar to previous reports in Jersey (Huson *et al.* 2020). The lack of pedigree completeness, and the random nature of recombination and segregation which pedigree-based measures do not capture, could be a contributing factor for low pedigree inbreeding estimates (Doekes *et al.* 2019). Inbreeding measures based on diagonal elements of the GRM do not distinguish between identity by state (IBS) and identity by descent (IBD) and could lead to inconsistent results (Pryce *et al.* 2014, Villanueva *et al.* 2021). Meuwissen *et al.* 2020, showed that in contrast to classical inbreeding theory, inbreeding measured in terms of drift (F_{DRIFT}) and homozygosity (F_{HOM}) can substantially vary, when inbreeding measures are based on GRM, derived using IBS (F_{GRM}), but not when derived using IBD (F_{ROH}). This could explain the differences in genomic inbreeding measures in this study and based on these reports, F_{ROH} might capture inbreeding more accurately than F_{GRM}. The information generated in this study can be used to improve Jersey diversity, health, and production. It will inform the US Jersey Association of the population status on diversity and inbreeding. Analyses to date suggest the *in situ* population and the NAGP collection have equivalent levels of genetic diversity, but further analysis will better identify gaps in the collection.

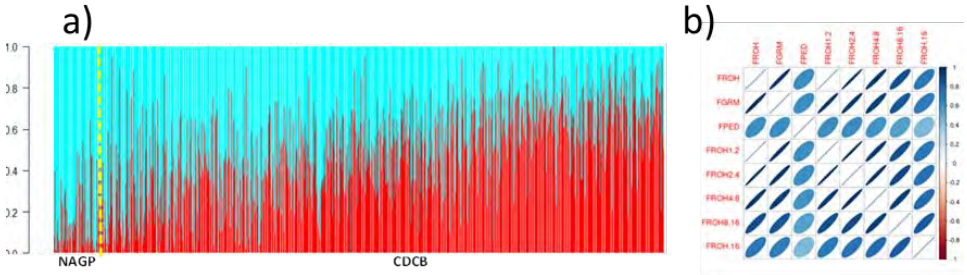

Figure 2. (a) Admixture analysis showing compositional difference between NAGP collection and CDCB population at K=2. (b) Pearson correlation between different inbreeding measures.

Table 3. Comparisons between different inbreeding measures.

Inbreed estimator	CDCB ± SD	NAGP ± SD
F_{PED}	7.68±2.95	6.30±3.16
F_{GRM}	11.12±4.12	10.16±4.15
F_{ROH}	15.77±3.63	14.43±3.73
$F_{ROH\ 1\text{-}2}$	15.23±3.41	14.64±3.02
$F_{ROH\ 2\text{-}4}$	12.56±3.70	12.38±3.83
$F_{ROH\ 4\text{-}8}$	9.34±3.66	9.44±3.73
$F_{ROH\ 8\text{-}16}$	7.16±3.33	7.06±3.41
$F_{ROH\ >16}$	3.80±2.47	3.94±2.59

244. Development and utilization of the United States gene bank collection

H.D. Blackburn[1*], C.S. Wilson[1] and C.D. Dechow[2]

[1]National Animal Germplasm Program United States Department of Agriculture, 1111 South Mason St., Fort Collins, CO 80521, USA; [2]Penn State University, Department of Animal Science, University Park, PA, USA; harvey.blackburn@usda.gov

Abstract

A large and substantial collection genetic resources, exceeding 59,000 animals and over 1.15 million samples, has been acquired by the national gene bank. Approximately 11,000 animals from the collection have been used for reconstituting genetic diversity and genomic studies. As an example, previous research showed *in situ* U.S. Holstein had only two different ancestral Y chromosome linages. It was determined two additional Y Chromosome linages were present in the gene bank and they were reintroduced to the *in situ* population. Reintroducing these two lost Y chromosomes from collection animals representing 1950's genetics illustrated how the collection can be used to address contracting genetic diversity, like limited Y chromosomes. The relatively high PTA measures for net merit and daughter lactation performance suggest gene bank collections may have broader uses than originally thought. Challenges still exist to increase gene bank collection use and to better quantify the diversity captured.

Introduction

For the last 23 years the national genebank has been charged with conserving livestock, aquatic and insect genetic resources important to agriculture (Blackburn, 2018; Blackburn *et al.* 2019). As a result, we have acquired 1.15 million samples from 59,640 animals, representing 191 breeds, 369 subpopulations within those breeds and 44 species. Approximately 50% of the breeds collected have exceeded 50% of the minimum collection targets recommended by FAO (2016). The collection is still being developed with new and existing breeds in the collection or their subpopulations. At this time, it is beneficial to explore how the collection has been used, by whom and some of the results obtained when using the collection.

Materials & methods

The collection has been developed by government, universities and private sector interactions. Program funding facilitates collection development, but the private sector has been highly engaged in donating germplasm samples from various populations. Universities have also contributed to collection development, including the donation of orphan collections developed by retired scientists. From its initiation the collection was designed to encompass all breeds and to serve multiple functions (e.g. research, corrective mating, reconstituting breeds). Therefore, the number of germplasm samples acquired for specific animals can exceed the quantity necessary to reconstitute a population in a worst-case scenario. The Animal-GRIN database contains information on collected samples, e.g. animal identification, phenotypes, genotypes, number and types of samples, geographic locations (https://agrin.ars.usda.gov/main_webpage_dev/ars?language=EN&record_source=US). Sample requests and releases are managed on-line through Animal-GRIN. Upon receipt, requests are reviewed to determine alignment with the program's mission.

For the data presented, Animal-GRIN was queried to determine animal birth year, species, and how the requested animals were to be used. Four sample use categories included: reintroduction (to reintroduce genetic variability or corrective mating), reproductive evaluation (samples used to evaluate sperm quality with live animal matings), genomic evaluation (samples genotyped and used to study genetic diversity or lethal alleles), and regeneration for live animals for research. An example of reintroduction and regeneration

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_244, © H.D. Blackburn *et al.* 2022

for live animal research is given for reintroducing lost Y chromosomes (LYC) into the Holstein breed (Dechow *et al.* 2020). In this example two of the collection's 1950's era bulls were mated to oocytes from current generation cows (ranking in the upper 70th percentile for net merit), resulting in calves from both sexes. The bull calves were raised and placed in a commercial stud and eight daughters remained in the Pennsylvania State University's herd for further study.

Results

To date samples for over 11,000 animals have exited the repository (Figure 1). Most species (cattle, sheep, goats, chickens, pigs, trout, oysters and catfish) in the collection have been used to varying degrees. From 2004 to 2020 a broad range of samples, based upon animal birth year, have been requested and used by stakeholders. There were 10 separate years where samples requested encompassed most birth years, including animals born before 1960. Most of the samples requested were used for molecular genetic studies (92%) by researchers or industry, with 5% being used for reintroduction of genetic variability (480 animals) into *in situ* populations; the remaining two categories accounted for 3% of animals exiting the collection.

Table 1 provides a snapshot of collection use and the results/impacts of those efforts. Industry, universities, and government have used the collection for various purposes. Table 1 also shows that some collection uses have made significant economic contributions to livestock sector. For example, animals from the collection were used in the initial development of genomic breeding values. Breed associations have also used the genotyped animals from the collection to determine if key ancestors were carriers of lethal mutations. Determining the carrier status of these ancestors has led to significant savings in genotyping offspring from sires shown not to carry the mutation.

Genomic predicted transmitting ability (PTA) for founder LYC bulls and their progeny were compared to the national average for net merit and it was determined that progeny from LYC bulls were near breed average (Figure 2) which is contrary to previously thought expectations. Genomic EBV for the LYC daughters averaged 908 kg less than contemporary herd mates; however, the LYC daughters produced 670 and 1,702 kg more milk in first and second parity, respectively (Jewell, 2021).

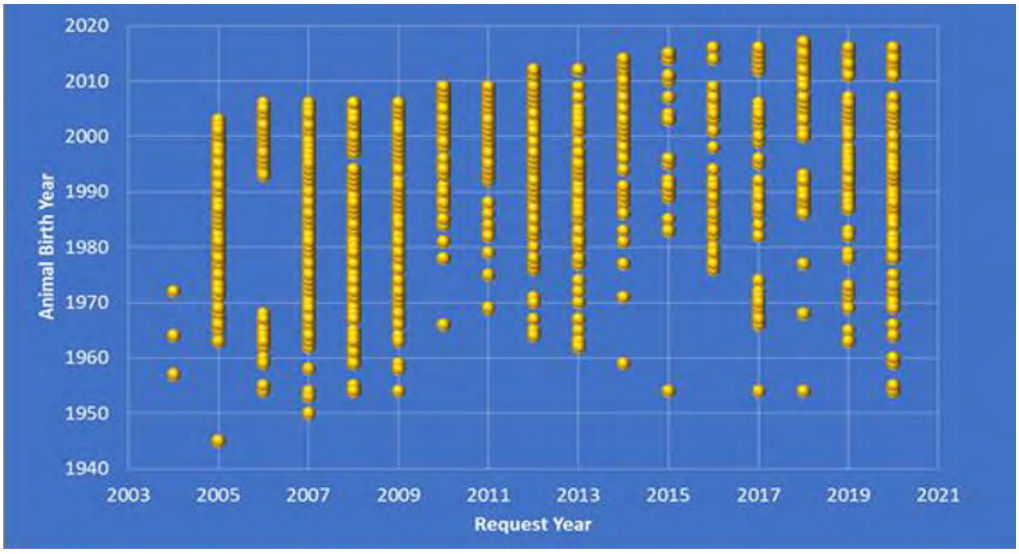

Figure 1. Samples from all species (n=11,000 animals) exiting the gene bank by year requested and animal birth year.

Table 1. Examples and impact of collection use.

Purpose	Breed	User	Results/impact
Develop genomic BV	Holstein Jersey	Research	$400 million/year revenue increase
Identify carriers of lethal genes	Angus, Brangus	Breed Assoc.	Saved breeders >$3 million in genotyping
Reintroduce lost Y chromosomes from 1950 era bulls	Holstein	University & industry	Increased genetic variability, Y chromosome research, progeny semen sold (Dechow *et al.*, 2020)
Reconstituted halothane/napole pig line	Crossbred	University	New research grants, increased university use
Adding genetic variability to rare breeds	Multiple[1]	Industry	Increased genetic variability for stakeholders
Change in allelic frequencies of imported genetics	Meishan	Gov't	Nagoya Protocol – Informed negotiation & policy positions (Blackburn *et al.*, 2014)

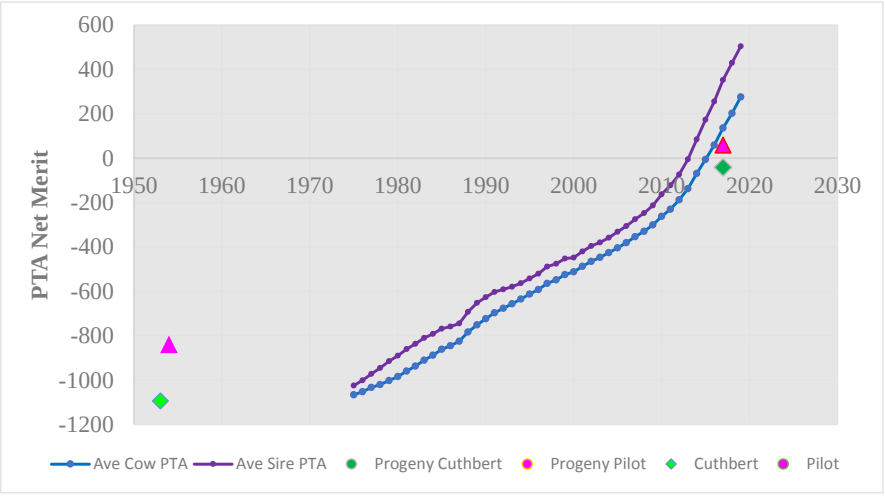

Figure 2. Comparison of 1950 era bulls (Cuthbert and Pilot), progeny of 1950 era bulls to the national average breeding value for net merit (Council of Dairy Cattle Breeding computed PTAs).

Discussion and conclusions

Results indicate that the collection has been widely used and the impact of use has been substantial economically and scientifically. Private breeders of major and minor breeds have used the collection to perform corrective mating for a variety of reasons, including redirecting breeding strategies and adding genetic variation into the *in situ* population.

Reintroduction of two LYC (Table 1) into the Holstein breed is an instructive example of collection use. Figure 2 compares founding sires, their progeny, and the national average PTA for net merit from 1953 to 2019. By mating the bulls to elite cows, the gap between current average bull breeding values and Y-chromosome progeny was substantially narrowed. Bull progeny (born in 2017) PTA were approximately equivalent to breed averages from 2012 to 2014. The lactation performance of LYC daughters was based on a relatively small sample, but substantially exceeded expectations. The LYC project underscores the need to further evaluate collection progeny to determine the extent that current genomic prediction methodology under-estimate phenotypic performance.

In the LYC project it was noted the two 1950 era sires PTA exceeded breed average for milk production by two standard deviations. Blackburn (2019) reported many breeds with animals in the collection exceed the mean BV when compared to other animals of their birth year by an equally large deviation. This finding suggests that while a particular animal may be chronologically older its genetics may be more useful than expected and when mated to above average females the gap between old and new genetics can be narrowed considerably. Generally, we have observed across species that animals in the collection that are outliers for BV may be above breed average for 4 to 6 future generations (8 to 30 years), depending upon selection pressure and generation interval within the breed. This observation has ramifications for how such individual animals might be utilized.

In summary, the collection has been widely used and made substantial contributions supporting its continued growth and development. Future challenges will be to better understand the genetic aspects of the collection, to use the collection effectively in corrective mating programs, and to encourage scientists and industry to increase their use of the collection for any variety of purposes.

Abstract

Gene banks are a component of a national strategy for the preservation of genetic diversity. Gene bank managers need to have a global and comparable picture of the diversity in their collections in order to rationalize them. Facing a diversity of molecular tools is a difficulty. The IMAGE H2020 project aimed at developing a low cost 60k SNP array to facilitate the mapping of diversity in gene banks. The first test of this array was performed for chicken with 204 samples from 18 local breeds and nine experimental lines provided by Germany, France and Spain. The MAF across population was 0.34, showing that this tool is useful over a range of populations. The principal component analysis and the Neighbor-joining tree showed that local breeds did not cluster according to country and were generally homogenous. Comparison with on-farm populations remains to be done to assess the value of the gene bank collections.

Introduction

Genetic diversity is essential for the sustainability of animal breeding. Countries are investing in long term conservation of genetic diversity with the creation of gene banks. FAO promotes this strategy in the Global Plan of Action for Animal Genetic Resources. In Europe, the European Regional Focal Point is gathering national coordinators of animal genetic resources from all countries and includes a permanent working group on ex situ cryoconservation.

Until now, sampling strategies remain national and may vary according to countries, resulting in a variety of situations in terms of species and breeds represented. The ERFP is currently promoting the set up of a European network of Animal Gene Banks (EUGENA) to increase collaboration between national gene banks in Europe. An economic analysis of gene banking was recently performed in the frame of the IMAGE H2020 project (Grant # 677353). Results showed that the cost of preservation of a given number of breeds could be decreased by 20% by a better coordination across European countries (de Oliveira Silva *et al.*, 2018).

Assessing the value of gene bank collections for breeding programmes require data on within-breed diversity as well as between-breeds, since both levels are important for the management of farmed animal species. Whereas pedigree data have been used since a long time to characterize within-breed diversity, for *in situ* populations as well as *ex situ* collections, only molecular data make it possible to map the diversity at all levels within a species.

Mapping diversity has made significant progress thanks to the development of genotyping arrays in all farmed species, whereas whole genome sequencing can provide a deeper analysis of the status of collections. However, sequencing costs are still relatively high for gene bank managers, who generally lack the capacity to analyse such data. Thus, genotyping arrays are still a relevant tool to provide a global description of the

diversity present in gene bank collections and to make comparisons between gene banks as well as between gene bank collections and on farm populations. However, several SNP arrays for chickens coexist, either private (around 60K) or public (around 580K), at a rather high cost (from 90 to 150 € per animal), with a low % of markers shared between the arrays. This is complicated for gene bank managers who need a global and comparable picture of the diversity in their collections. To facilitate a common approach across gene banks, the IMAGE H2020 project has developed a multi-species 60k array, with the aim to provide 10k markers for each of six species, i.e. cattle, sheep, goat, horse, pig and chicken, at a price of 20 US$ per sample maximum for both the array and the genotyping, thus excluding the cost of DNA extraction.

A subset of gene bank collections from different countries was genotyped to validate the IMAGE001 array. In this paper, we show how the first version of IMAGE001 can map diversity of chicken collections from gene banks in Germany, France and Spain.

Table 1. List of chicken populations included into the genotyping test for IMAGE001 array.

Type of population	Breeds	Samples	Country
Experimental lines	Congenic line_LB13 (MHC)	2	France
	Congenic line LB21 (MHC)	2	France
	Congenic line LB4 (MHC)	4	France
	Congenic line_LB19 (MHC)	3	France

Materials & methods

Gene bank samples. A total of 211 chicken DNA samples were provided for 27 breeds from the gene banks of three countries (Table 1). Depending on the breed, the DNA had been extracted from frozen semen or from blood. Quality and concentration were determined with spectrophotometry and at least 1.5 µg of DNA was provided to the IMAGE partner at Wageningen University who was coordinating the test. Sampling represented only local breeds for Germany and Spain, with 10 to 20 animals per breed, whereas experimental lines were also provided by France, with a lower number of animals (2-5) per population (Table 1).

SNP selection. SNP selection was performed based on: (1) overlap with existing arrays with a high allele frequency across populations; (2) location in genes affecting phenotypic traits; (3) mtDNA; (4) Ancestral SNPs as compared to wild species of jungle fowl; (5) MHC region; (6) random genes located into QTL regions. A total of 9,306 SNPs were initially selected to be tested for the chicken, covering 32 autosomes (9,071 markers) and the sex chromosomes (235 markers).

Genotyping. Genotyping was performed on an Affymetrix platform by Eurofins® biotech company.

Analysis. Analysis was performed with *plink* software. The Minor Allele Frequency (MAF) was calculated per chromosome and per breed. Autosomal markers were used to determine the genetic structure with a Principal Component Analysis and a neighbour-joining tree.

Results

Genotyping. Altogether 7,743 autosomal markers passed the calling rate and were included in the analysis. Seven samples did not provide satisfactory results, leading to a total of 204 individual genotypes. The mean MAF per chromosome was above 0.30 for most of the autosomes, exceptions being chr 16 (0.03), chr 25 (0.27), chr 27 (0.20) chr 31 (0.02) and chr 33 (0.04). The overall MAF across all populations was 0.34. At population level, the median MAF was above 0.25 except for three congenic lines (LB4, LB13, LB19), which were less variable.

Principal component analysis. The first four principal components (PC) explained only 16% of the total variance. PC1 explained 7%, populations were scattered across a gradient from Langshan breed to congenic lines, Westfaelische Totleger and Ostfriesische_Moewen breeds. PC2 isolated the Gallina_del_Sobrarbe from other breeds, PC3 isolated the Deutsche Lachshuhn and PC4 isolated the Andalusian.

Neighbor-joining tree. The NJ tree (Figure 1) featured 4 main branches: branch A included only one Spanish breed (Blue Andalusian) and one German breed (Augsburger); branch B included three German breeds (Rheinlander, Westfaelische Totleger and Ostfriesische Moewen) and the four congenic lines which are all of White Leghorn origin; branch C included three German breeds (Krüper, Deutsche Sperber and Bergische Schlotterkamm); branch D included the remaining German breeds, most animals of the Gallina del Sobrarbe, the French local breeds and the experimental lines of a non White Leghorn origin. The divergent lines such as Fat/Lean lines and DPF+/DPF- clustered together.

Discussion

First of all, the high MAF value observed across all populations demonstrates the ability of the array to be used over a large range of populations. The total number of markers was quite reduced and another set of markers will be added to reach the target of 10k markers. Yet, a few chromosomes, (16, 31, 33) are likely to remain underrepresented in the array.

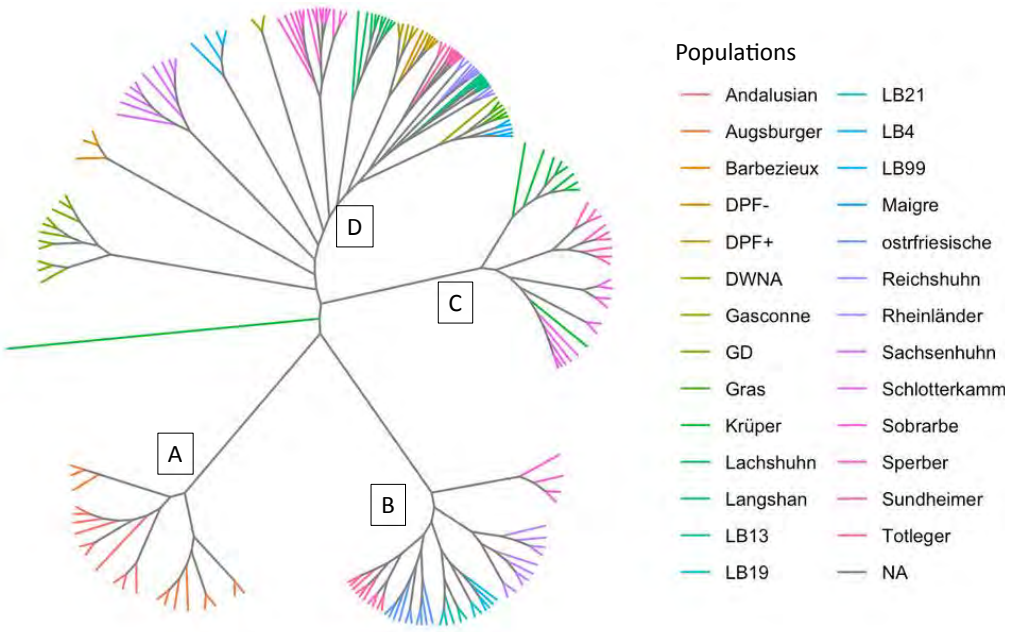

Figure 1. Neighbor-Joining tree of the populations. (A, B, C, D are discussed in the text).

The populations did not particularly cluster according to country, which shows the interest of sharing information across gene banks to assess their complementarity. This finding, however, may result from the unbalanced distribution of breeds according to country in the data set. There was only one branch made up of breeds from a single country (Germany) which is consistent with the fact that these breeds are typical Northwestern European breeds and quite different from Mediterranean breeds such as the White Leghorn. Enlarging the sampling to Northern Europe would make possible to check this hypothesis. More information is needed on the history of the two Spanish breeds to understand their separate clustering pattern in the NJ tree. Besides, the history of breeds from different countries which are located within the same branch of the NJ tree also needs to be further explored.

Each population appeared in a single branch of the NJ tree, with a few exceptions, such as the Gallina del Sobrarbe, for which most animals appeared mainly in branch D but a few were in branch B. Local chicken breeds managed by a breeders'club generally appear to be homogenous, unless the breed is distributed across farmers who do not exchange their animals, thus leading to genetic fragmentation.

In conclusion, using a single SNP array for mapping diversity in gene bank collections is feasible and the next step is to include data from on-farm populations in order to map the diversity within and outside gene banks.

246. Conservation of an endangered pig breed using optimum contribution selection

H.M. Nielsen* and M. Kargo

Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark, hannem.nielsen@qgg.au.dk

Abstract

The present study focuses on optimizing the breeding plan for an endangered Danish Landrace pigs. This original landrace pig breed (DL-1970) was until 1970 used for production of bacon, after which the breed was crossed with other landrace breeds. This study deals with the animals from DL-1970, which originates from the breed before crossing. Seven boars and 46 sows were available for selection. Optimum contribution selection (OCS) was applied to select boars and sows. Average relatedness between male candidates was 0.35, between female candidates 0.45 and between male and female candidates 0.39. Using OCS yielded lower inbreeding levels (0.141) compared to random mating (0.195). Due to the high level of relatedness between the animals and the very small population size it is recommended to use material from the gene bank to increase genetic variation in the future.

Introduction

The DL-1970 is a distinctive feature of Danish agricultural history, as the great export adventure with bacon in the first half of the last century was based on this pig breed. Around 1970, however, the breeding goal for Danish Landrace changed to having increased focus on growth, feed efficiency, fertility and meat quality (Sørensen and Nielsen, 2017). In the 1980s, crossbreeding was also performed between Danish Landrace pigs and landrace pigs from Norway and Finland. Today there are only a few individuals left of the original DL-1970 as it was in 1970 before crossing and change of the breeding goal. Therefore, the breed's existence is currently threatened. If a local breed is lost, a cultural value will be lost (Meuwissen *et al.*, 2009). DL-1970 have a large cultural value in Denmark, since this breed founded the Danish Bacon adventure and most pigs in the current production are founded on this bred. If the breed is to survive and increase in population size, it is important that there are optimal production methods for the breed as well as possible sales opportunities for the finishers. Last but not least, it is important to maintain the genetic variation as large as possible (Meuwissen, 2009). The present study focuses on optimizing the breeding plan for DL-1970 by use of Optimum contribution selection (OCS) for selection of sires and dams.

Materials & methods

Data. The data set included the identity (id) of the animal, id of the sire, id of the dam, sex of the animal and date of birth. There were 1179 individuals in the pedigree with the oldest animal born in 1983 and the youngest born in July 2019. Pedigree completeness (the proportion of known ancestors in each ascending generation, MacCluer *et al.*, 1983) was calculated by tracing the pedigree 8 generations back. Potential breeding candidates were seven boars and 46 sows born from January 2018 until July 2019. Matings were assumed to occur naturally. Thus, for the optimum contribution selection it was assumed that each boar could mate a maximum of 10 sows.

Optimum contribution selection. OCS maximizes the genetic level of the next generation of animals while at the same time restricting rate of future inbreeding by restricting the increase in average co-ancestry (Meuwissen, 1997). We used the EVA software (Berg *et al.*, 2006) to perform OCS. The function to maximize in OCS with overlapping generations was shown in Henryon *et al.* (2015). With full weight on average relationships and minimization of inbreeding, as applied in the current study, the function is:

$$U_t(c) = \frac{\omega}{L^2}(c + Pv)'A(c + Pv) \quad (1)$$

where,

c is a vector with n (total number of animals in the pedigree) genetic contributions to the new cohort, ω is a penalty applied to the average relationship of the current population, L is the generation interval, P is a matrix of size n×k with contributions to each age class of animals in the current generation, k is the number of sex-age classes in the current generation, v is a vector with k expected relative contributions to future age classes, and A is an n×n matrix with additive genetic relationships.

Results

From 1980, pedigree completeness (Figure 1) was low, increasing to around 80% after 2000, when tracing the pedigree back 8 generations.

Figure 2 shows the average inbreeding of the progeny from year 1980 to 2019. The average inbreeding was high, up to 0.33 in year 2002. During the last 5 year period, the average inbreeding was around 0.15 to 0.20.

The average relatedness between male candidates were 0.35, between female candidates 0.45 and between male and female candidates 0.39. By applying OCS for selection of 20 matings, only 3 out of the 7 boars were selected (Table 1). Their contributions varied from 10 to 50%. Thus 2 sires had high contributions, which may be a problem in the future even with the use of OCS. Likewise, OCS selected 20 out of 46 available female candidates. It is clear from Table 1 that the boars selected are those with lowest relationship with the rest of the female populations.

Under random mating, expected average inbreeding was 0.195, whereas expected average inbreeding was 0.141 when applying OCS. In the last year (2017) observed with selection in the dataset, average inbreeding was 0.196. This means that by applying OCS it is possible to reduce average inbreeding in the progeny by around 0.05 compared to the previous year.

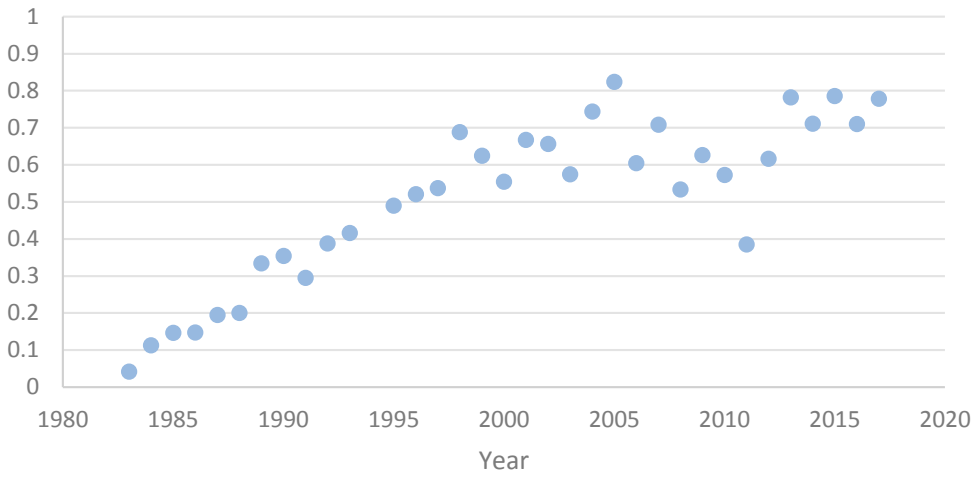

Figure 1. Pedigree completeness index (8 gen) from year 1983 to 2019.

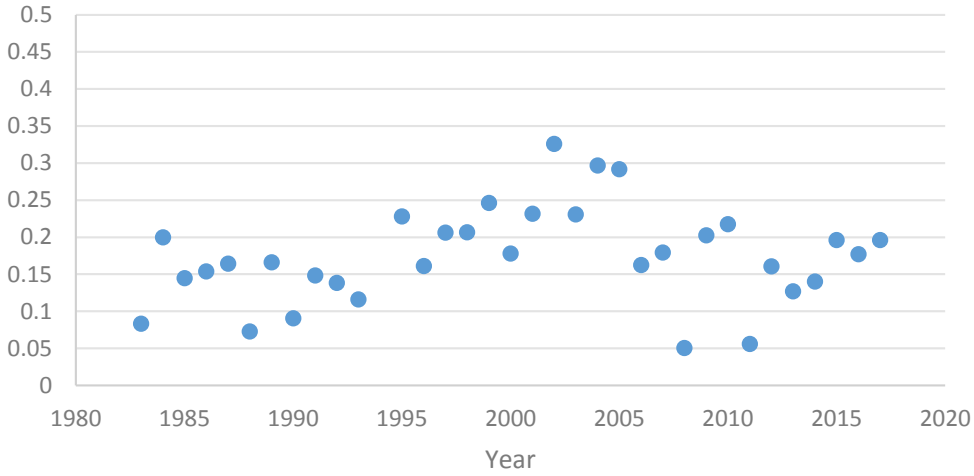

Figure 2. Average inbreeding of progeny over years.

Table 1. No of contributions (matings) for each of the sires and its relationship with the male and female population.

Boar	No of matings	Relationship with males	Relationship with females
1	0	0.405	0.386
2	10	0.424	0.260
3	2	0.439	0.281
4	0	0.484	0.447
5	0	0.507	0.548
6	8	0.424	0.266
7	0	0.530	0.543

Discussion

In the present study we used OCS to optimize the breeding plan for an endangered pig breed.

Using OCS yielded substantial lower inbreeding levels compared to random mating. However, the level of relatedness between the animals is very high, which means that the population is critically endangered.

In addition to using OCS, one option would be to use material from the gene bank (Hulsegge *et al.*, 2019), which contains both semen and embryos. This stock of sperm and embryos in the gene bank was established as a safeguard that can be used if the living population is critically endangered and needs to be able to increase the genetic variation. Freezing of semen and embryos from the breed began as early as in 1996. There is semen from a total of 11 boars produced in 1996, 2001 and in 2017. Seven of the 11 boars are from a previous control line, which has shown to be only distantly related to the current population of DL-1970 (Szekeres *et al.*, 2016). In addition, there are embryos from 16 sows and 13 boars. The living population of Danish Landrace pigs is at present at a size where use of the material in the gene bank is needed. Thus, the next step is to run OCS using semen and embryos from the gene bank.

Abstract

Confronted with the erosion of genetic diversity in domestic animal populations, many countries such as France have created gene banks to limit this loss. However, it is crucial to evaluate the potential of these collections before using them for genetic diversity management. Thus, we propose a new Index of Diversity Impact, IDI, to evaluate and compare the diversity potential of collections. IDI is negative when the use of collections decreases the overall relatedness of the current population and positive when it increases it. IDI was used to evaluate the cryopreserved collections of the French National Cryobank of 14 breeds of three livestock species, pig, sheep and cattle. We obtained significantly negative IDIs for three breeds that differ in terms of collection strategy and population management. The IDI appears to be a relevant tool to help managers and breeders to quickly identify promising collections to be used in future breeding programmes.

Introduction

Genetic diversity is essential for the sustainability of livestock populations by allowing for continuous response to selection and for adaptation to new conditions. However, selection has led to an erosion of genetic diversity over time, which can limit further genetic gain. In addition, for small populations, such as local breeds, the effect of genetic drift is even more important and leads to accelerated depletion of genetic diversity within the breed.

To address this risk, many countries have invested in conserving genetic diversity through the creation of gene banks. These *ex situ* conservation entities have been storing genetic material for several years, including reproductive material such as semen. However, these genetic resources are still underused, even though they could have a potential interest for managing breed diversity. In their study, Leroy *et al.* (2011) showed that the use of frozen semen from cryobanked bulls can be a valid choice for introducing genetic diversity, provided that attention is paid to gene diffusion, or when there is a change in breeding goals. Two other studies showed that the use of cryopreserved semen from ancient bulls could introduce genetic diversity into a local breed under selection (Eynard *et al.*, 2018) but also in an international breed (Doekes *et al.*, 2018).

France is a country with a rich livestock biodiversity, with for instance 47, 57 and 12 French breeds officially recognized in 2015 for cattle, sheep and pigs, respectively, but a majority of local ones are threatened (Verrier *et al.*, 2015). French breeds greatly differ in terms of population size and management programme, with, for example, the Prim'Holstein, first French dairy breed under selection, having nearly 3,400,000 females born in the period 2016-2019 versus the local Tarentaise dairy breed, having only 17,266 females in the same period (Danchin-Burge, 2020). This raises the question of genetic erosion and motivated the creation of the French National Cryobank, FNC, in 1999, in order to preserve the reproductive material from French breeds of domestic animals. Currently, the FNC brings together reproductive resources of 21 species and nearly 8,000 donors with stored material over the last 20 years. However, until today, the use of these available resources to manage the genetic diversity of current populations is very scarce. Thus, this study aims at characterizing the collections of the FNC and evaluating their potential use for the management of breed diversity in future breeding programmes.

CC BY

DOI: 10.3920/978-90-8686-940-4_247, © A. Jacques *et al.* 2022

Materials & methods

Data for individuals in the national cryobank. Donor animal data were obtained from the FNC database (www.cryobanque.org). We focused on three species of livestock that are likely to use frozen semen in their management: cattle, sheep and pig. The national identifier (unique identification in a national pedigree database), the breed and the year of birth of donor animals were recorded.

Breeds, pedigree data and definition of cohorts. A total of 14 breeds were chosen to cover a large range of situations encountered in France, encompassing two pig breeds, the Pietrain (PIE) and the Cul Noir du Limousin (CNL), five sheep breeds, the Dairy Lacaune (LAC), the Manech Tête Noire (MTN), the Manech Tête Rousse (MTR), the Basco-Béarnaise (BAS) and the Mouton Vendéen (VEN), and seven cattle breeds, the Prim'Holstein (HOL), the Montbéliarde (MON), the Abondance (ABO), the Froment du Léon (FRO), the Tarentaise (TAR), the Saosnoise (SAO) and the Maraîchine (MAR). We defined contemporary male and female cohorts, M and F respectively, as individuals with at least one known parent, born between 2018 and 2020 for pigs, between 2017 and 2020 for sheep, and between 2015 and 2020 for cattle, according to the species' generation interval. These contemporary cohorts are assumed to be currently alive and available for breeding. A cohort composed of all the cryopreserved sires present in the FNC for each breed, C, was also defined. For the pig breed (PIE), 13 boars with semen cryopreserved by the breeding companies were added to our study. The pedigrees of all individuals in the three cohorts were extracted from the national database and limited to the 25 last generations. The pedigree quality of the contemporary male and female cohorts were evaluated with the overall equivalent generations as the weighted average of the generation equivalents (EqG) for each year using PEDIG (Boichard, 2002).

Computation of kinship and definition of an index of diversity impact. The calculations of the average kinship between the three cohorts were carried out using the *colleau* module of PEDIG (Colleau, 2002). For each breed, we calculated the average kinship between all the sires present in the cryobank (cohort C) and the contemporary female population (cohort F) ($\overline{\phi_{C-F}}$); and between the contemporary male and female cohorts ($\overline{\phi_{M-F}}$). The average kinship within cohort C between cryobank sires ($\overline{\phi_{C}}$) was also calculated. Then, we defined an Index of Diversity Impact (IDI) for cryobank individuals. This indicator is an estimation of the expected impact of the use of cryobank individuals in random mating with contemporary females on the level of diversity of the next generation under the assumption that only the males in the cryobank would be utilized. It is calculated following the Equation 1.

$$IDI = \left(\overline{\phi_{C-F}} - \overline{\phi_{M-F}}\right) \Big/ \overline{\phi_{M-F}} \quad (1)$$

It is expressed as a percentage of loss (negative) or gain (positive) in mean kinship relative to the current kinship of the population. The confidence intervals (CI) at 95% were defined from the individual IDI of each cryobank individual and applying Equation 2.

$$CI = \left[\overline{IDI} \pm 1,96 \frac{sd(IDI)}{\sqrt{n}}\right] \quad (2)$$

With *sd(IDI)* the standard deviation observed within the cryobank population of *n* donors.

All statistical analyses were conducted using R, version 4.0.2 (R Core Team, 2019).

Results

Composition of the cryobank's collections. For the three species, a total of 84 breeds are represented in the FNC, with 21 breeds for cattle, 15 for pigs and 48 for sheep. This corresponds to 977 bulls, 451 boars and 1,177 rams with frozen semen. The average number of donors per breed is 46.5 for cattle (min=1, max=210,

se=13.4), 30.1 for pig (min=10, max=76, se=4.4) and 24.5 for sheep (min=1, max=302, se=6.4). Donor birth years ranged from 1959 to 2013, 1979 to 2018 and 1974 to 2019 for cattle, pig and sheep respectively. This shows that material from ancient sires was retrieved by the FNC after 1999. The range of birth years of donors varied according to species and breed (Table 1).

Genetic diversity and IDI for the 14 breeds analysed with pedigree data. The number of donors in the cryobank for the 14 selected breeds ranged from 10 bulls in the SAO to 302 rams in the LAC. The size of the contemporary cohorts was very variable according to breed, with the number of females ranging from 534 cows for the FRO to 5,069,731 for the HOL.

The quality of the pedigrees ranged from 3.1 to 19.1 EqG on the female pathway and from 3.1 to 19.3 EqG on the male pathway (Table 1). The mean within-cryobank kinship values ranged from 0.8 to 24.3%. The average kinship values between cryobank sires and contemporary females (cryo-F) ranged from 3.1 to 24.9%, and the average kinship values between contemporary males and females (M-F) ranged from 1.9 to 36.1%. The IDI values varied between -31% for the CNL and 66.5% for the SAO. Three breeds exhibiting different situations have a significantly negative IDI: a local pig breed with quite ancient sires in the cryobank (CNL), a moderately selected sheep breed with a large number of males in the cryobank as compared to contemporary males (VEN), and a highly selected cattle breed (HOL) for which the cryobank favored donors with extreme breeding values and includes old material, thus, increasing the genetic distance with the current population. The 11 remaining breeds have a positive or null IDI.

Discussion

With more than 8,000 donor animals, the FNC needs to know the potential value of its collections for the management of genetic diversity, all the more that ancient sires are represented in the collections and that living populations can suffer from selection and drift. For sheep, the collections include donors born

fairly continuously over time since 1985. For pigs, local breeds have ancient donors whereas breeds under selection have quite recent donors. For cattle, few donors are born after the 2010s following the switch to genomic selection, which considerably shortened the reproductive carrier of males and decreased the quantity of material available for long term storage.

For the breeds studied, the number of donors in the collection is not correlated with the average intra-breed relatedness, which rather depends on the quality of the pedigree of the individuals in collections and the breed management programmes. The IDI reflects the average impact of randomly mating sires in collections with contemporary females relative to expectations for the use of contemporary males only; and makes it possible to rank the usefulness of collections resulting from different sampling strategies. A positive or null IDI reveals a representative collection of the current population, either by the presence of the strongest contributors to the breed (12 AI bulls in collection out of the 13 used in the FRO), or by recent collections likely more related to current females (example of PIE or BAS). However, a positive index does not definitively mean that the use of cryobanked sires is not useful for genetic diversity management, but that on average there will be fewer individuals in the collection that are genetically distant from the current population. In these cases, large confidence intervals suggest that the use of some well-chosen cryobank sires could produce matings with a lower level of relatedness than with contemporary sires, even if the IDI is positive, as for FRO or MON.

In conclusion, the IDI summarizes the impact, on genetic diversity, of using cryopreserved individuals relative to the current level of genetic diversity of the population; it is thus a convenient tool for managers to rapidly screen collections. In our study, IDI values were obtained from pedigree data but could also be calculated from genomic data, especially to be applicable to local breeds without pedigrees. The next step is to analyse options for individual mating plans between cryobank sires and contemporary females.

Abstract

Smaller Red dairy cattle breeds such as German Red and White dual-purpose cattle (RDN) need to be improved genetically to be competitive. One way to achieve this, is by collaboration with a larger mainstream breed such as Red dairy cattle from Denmark, Finland and Sweden (RDC). The aim of this paper was to increase genetic gain in the RDN breeding program by breeding with RDC bulls. Four scenarios with different levels of collaboration between the two breeds were compared in terms of genetic gain, inbreeding, and breed proportions. The results indicate that for 10 years of selection, restricted selection of 20% RDC bulls allows for a double as high proportion of RDN bulls while achieving the same rate of genetic gain as in scenarios with unrestricted selection. However, for a longer time span, the proportion of RDN will likely reduce even more.

Introduction

Red dairy cattle breeds are kept all throughout Europe and can be divided in larger, mainstream breeds such as Red dairy cattle breed from Denmark, Finland and Sweden (RDC), and smaller local breeds such as the German Red and White dual-purpose cattle (RDN) (Schmidtmann, 2021). Conservation of local breeds that are numerically smaller may be achieved by increasing genetic gain in these breeds. Increasing the breed level may be possible by collaboration with a mainstream Red cattle breed such as RDC. Collaboration between these breeds means that RDN will have an increased accuracy of genomic selection due to an increase in the size of the reference population. In addition, there will be more selection candidates, which increases the selection intensity. The RDC breed may also profit from this collaboration, as RDN form a source of genetic diversity. The aim of this paper is to increase genetic gain in the RDN breeding program by breeding with RDC bulls, while keeping the genomic proportion of RDN in RDN bulls as large as possible.

Materials & methods

Four scenarios were simulated with a difference in the origin of bulls selected for breeding with RDN. All breeding bulls that were selected for breeding in the RDN breeding program originated from the RDN breeding program in scenario 'Separate'. In scenarios 'Restricted-20%' and 'Restricted-50%', 20 or 50% of the bulls selected for breeding to the cows in RDN could originate from RDC. All bulls selected for breeding in the RDN breeding program could originate from RDC in scenario 'Unrestricted'. Each scenario was replicated 20 times.

Simulation. A full genomic set-up was simulated in a newer version of stochastic simulation program ADAM (Pedersen *et al.*, 2009) that was updated for multi-breed simulations. Sequence data were available for 38 RDN and 146 RDC. These sequence data were reduced to the SNPs on the Illumina BovineSNP50v3 Beadchip (Illumina Inc., San Diego, USA). The data were split by chromosome and phased. The obtained haplotype data were used as input for the simulations. Simulated time was 30 years, in which the first 20 years were used to build up reference populations and the last 10 years were used to run a genomic

selection scheme with varying numbers of RDC breeding bulls that were selected for breeding with RDN. In the progeny testing scheme (year 1-20), several 1-year-old bulls were genotyped and progeny tested 3 years later. At the end of the progeny testing scheme, the reference population of RDN consisted of 1,200 proven bulls and for RDC this number was 10,000. The genomic selection scheme (year 21-30) included genotyping young males and females every year, as well as multiple ovulation and embryo transfer. Breeding values were estimated using the DMU package (Madsen and Jensen, 2013).

Breeding goals. The simulated breeding goals (BG) included two traits: milk yield and udder health. Heritabilities were based on estimates found in literature of 0.48 and 0.04 (International Bull Evaluation Service, 2012, 2014), and the genetic correlation between milk yield and udder health was -0.32 (Norberg *et al.*, 2009). The BG weights for RDC were set to match the correlation of the milk production index of the Nordic Total Merit index (NTM) with the whole NTM (Sørensen *et al.*, 2018), with a correlation of 0.75 between milk yield and the BG, and a correlation of 0.38 between udder health and the BG. The BG for RDN was set to have more emphasis on health, with a correlation of 0.64 between milk yield and the BG, and a correlation of 0.53 between udder health and the BG.

Analysis. The outcome of the simulation was analysed in R statistical software (R Core Team, 2021), for year 26-30 of the simulation. Rate of inbreeding was calculated per generation, both for pedigree-based inbreeding and for IBD-based inbreeding. Rate of genetic gain was calculated per year and per trait in genetic standard deviation (σ_A) units. In addition, genetic gain in the aggregate genotype was calculated by using the BG weights and genetic gain per trait. An ANOVA test followed by Tukey's Honest Significant Differences test was used to find significant differences between scenarios. The percentage of bulls that originated from each breeding program and selected for breeding in the RDN breeding program was calculated per year for year 21-30. The breed proportion based on pedigree data of RDN of bulls selected for breeding in the RDN breeding program was calculated by use of the OptiSel package in R (Wellmann, 2021).

Results

Simulated scenarios showed large differences in rate of genetic gain and inbreeding in the RDN breeding program in years 26-30 (Table 1). Scenario 'Separate' caused the highest rate of inbreeding and the lowest rate of genetic gain. The other three scenarios caused the highest genetic gain in the aggregate genotype, without any significant differences between these scenarios. The rate of inbreeding was the lowest in scenario 'Restricted-20%'.

Table 1. Rate of inbreeding per generation and rate of genetic gain in the RDN breeding program per year for the different scenarios in year 26-30.

	Separate	Restricted-20%	Restricted-50%	Unrestricted
Rate of inbreeding (pedigree)	1.85%^{a}[1]	0.36%^{c}	1.06%^{b}	0.74%^{bc}
Rate of inbreeding (IBD)	2.69%^{a}	0.68%^{c}	1.49%^{b}	1.12%^{bc}
Aggregate genotype (in std. BG)	0.27^{b}	0.45^{a}	0.42^{a}	0.41^{a}
Milk production (in σ_A units)	0.27^{b}	0.43^{a}	0.43^{a}	0.40^{a}
Health (in σ_A units)	0.04^{a}	0.08^{a}	0.04^{a}	0.06^{a}

[1] Subscripts with different letters indicate significant differences between estimates in the same row.

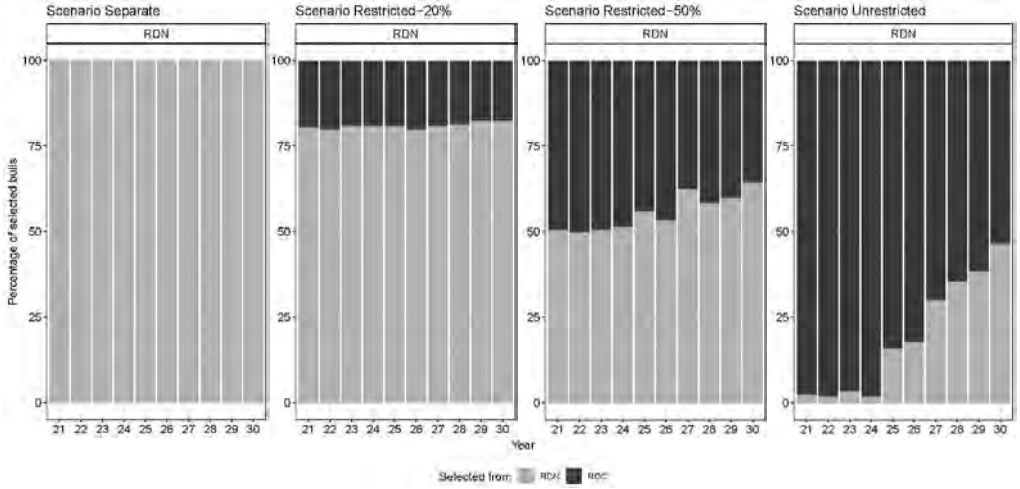

Figure 1. Percentage of selected bulls that are selected for breeding in the RDN breeding program from each breed, per scenario and per year.

The percentage of bulls selected for breeding in the RDN breeding program but originating from the RDC breeding program, or so called 'foreign' bulls was 0% in scenario 'Separate' (Figure 1). Approximately 20% of the selected bulls were foreign in scenario 'Restricted-20%'. The percentage of foreign bulls selected for breeding in the RDN breeding program in scenario 'Unrestricted' and 'Restricted-50%' changed over the years of the simulation. The breed proportion of RDN decreased over the years of the genomic selection scheme for all scenarios except 'Separate' (Table 2). The proportion of RDN genes in year 30 was twice as high in scenario 'Restricted-20%' compared to scenario 'Unrestricted'.

Table 2. Proportion of RDN genes in bulls born in the RDN breeding program and selected for breeding in the RDN breeding program, per year of the simulation.

Year	Separate	Restricted-20%	Restricted-50%	Unrestricted
21	1.00	1.00	1.00	1.00
22	1.00	1.00	1.00	1.00
23	1.00	0.57	0.56	0.50
24	1.00	0.55	0.54	0.75
25	1.00	0.42	0.29	0.27
26	1.00	0.38	0.28	0.26
27	1.00	0.34	0.24	0.18
28	1.00	0.30	0.23	0.16
29	1.00	0.26	0.19	0.12
30	1.00	0.24	0.17	0.12

Discussion

Different scenarios were simulated in this study with the aim of increasing the breed performance in the RDN breeding program by collaborating with the RDC breeding program. In the case of separate breeding programs, the rate of genetic gain in the RDN breeding program was significantly lower compared to the other scenarios. The rate of inbreeding would be too high compared to the rule of thumb of 1% per generation (Oldenbroek and Van der Waaij, 2015). When looking solely at genetic gain and inbreeding (Table 1), scenario 'Restricted-20%' was the best breeding strategy. This scenario caused equal rate of genetic gain in the aggregate genotype and on trait level compared to the other (Un)restricted scenarios, but with a lower rate of inbreeding. This rate of inbreeding was significantly lower in scenario 'Restricted-20%' compared to scenario 'Restricted-50%' because in 'Restricted-50%' some RDN bulls were selected twice due to the set-up of the simulation. In scenario 'Restricted-20%', at least 80% of the bulls that were selected for breeding in the RDN breeding program also originated from the RDN breeding program. However, even in this very restricted scenario, the proportion of RDN genes at the end of the genomic selection scheme dropped to 0.25 (Table 2). The question remains if this proportion is high enough to speak about conservation of the RDN, or that the breeding strategies studied in the current simulation will not lead to the conservation of the RDN genotype. An alternative breeding strategy might be to select bulls based on RDN breed proportions instead of in which breeding program a bull is born. In addition, optimum contribution selection can be used to strengthen the breeding program. This was however beyond the scope of this study.

249. Genetic rescue of small populations in the presence of deleterious variation

C. Reimer[1,2*], S. Weigend[1,2], J. Geibel[2,3] and T. Pook[2,3]

[1]Friedrich-Loeffler-Institut, Institute of Farm Animal Genetics, Höltystraße 10, 31535 Neustadt, Germany; [2]University of Goettingen, Center for Integrated Breeding Research, Carl-Sprengel-Weg 1, 37075 Göttingen, Germany; [3]University of Goettingen, Department of Animal Sciences, Animal Breeding and Genetics Group, Albrecht-Thaer-Weg 3, 37075 Göttingen, Germany; christian.reimer@fli.de

Abstract

Genetic rescue using external breeders or cryo-preserved semen is a reasonable strategy to restore diversity in small breeds. It is also known from natural populations that animals from large populations can convey substantial genetic load when they migrate into small, highly inbred populations, which may compromise the recipient population. We used stochastic simulation to evaluate different scenarios of genetic rescue of two conservation stocks of different sizes and found that introgression of males from larger stocks had a more detrimental effect on the viability of offspring than from smaller stocks, even though both strategies partially restored diversity. Using samples from gene-banks had a comparably negative effect on offspring viability, if the population was substantially larger at the time of cryo-conservation. Our results suggest that careful assessment of genetic load and its consequences is required whenever external animals should be transferred into endangered stocks. As larger breeds have higher genetic load due to less efficient purging, animals from small breeds seem beneficial for genetic rescue.

Introduction

The conservation of genetic diversity is of major concern in many livestock species as commercially less preferred breeds are often decreasing in size, leading to a high degree of inbreeding. It is believed, that such breeds will consequently suffer from inbreeding depression (Charlesworth and Willis, 2009) and might eventually become inviable (Soule, 1987). Deleterious variants seem to play an important role, even though the actual mechanisms are under debate (Charlesworth and Willis, 2009) and their distribution and frequency in livestock might be strongly dependent on population characteristics, demography and breeding practices (Bosse *et al.*, 2019). At the same time, strong recessive deleterious variations are subject to constant selective pressure called purging, which is even more efficient under high levels of inbreeding, leading to viable, though highly inbred, populations (Robinson *et al.*, 2018).

Conservation schemes based either on introgression of animals from related, but numerically larger populations (Kyriazis *et al.*, 2021) or insemination with cryo-preserved semen from gene banks (FAO, 2012) are considered as a reasonable strategy to restore genetic variability and counter inbreeding depression. Albeit, positive effects generally outweigh the negative (Frankham, 2015), outbreeding depression is a concern. Observations from an island grey wolf population, where a male from a much larger population entered a highly inbred insular stock, putatively introducing strongly deleterious variants, resulted in the extinction of the respective population (Kyriazis *et al.*, 2021). This implicates that the aforementioned strategies might not be without risk also in livestock. The aim of this study is to evaluate the effect of animal migration from larger populations and a cryo-conserve into smaller stocks in a livestock setting with specific focus on strong deleterious variations.

DOI: 10.3920/978-90-8686-940-4_249, © C. Reimer *et al.* 2022

Materials & methods

We used stochastic simulation with the R-package MoBPS (Pook *et al.*, 2020) and started with an initial pig population of 1000 pigs with an equal sex ratio. Variants and maps were taken from Ensembl (Howe *et al.*, 2021). First, a quantitative trait with 1000 purely additive QTLs was simulated to mimic a performance trait like 6-month weight. Second, 1000 recessively lethal deleterious variants were randomly placed across the genome. Frequencies of the deleterious variants were sampled from a normal distribution with a mean of 1% and a standard deviation of 0.5%, while setting values below zero to zero. This results in a population with about 88% of all meiosis in the founder population leading to viable offspring.

The simulation was divided into three main stages. S1: Initial 15 generations in a breeding stock of equal sex ratio to generate a viable start population followed by S2: deriving four lines, Large (L), Medium (M), Endangered (E) and Critical (C) and breeding with constant to drastically decreasing size and a sex ratio of 1:2 for 20 generations. Animal numbers were cascaded down sequentially (Table 1). Mild selection for 6-month weight was applied to all stocks in S1 and S2.

In S3, genetic rescue of the 'Endangered' and 'Critical' stock was modelled in scenarios by mating always two males from other stocks or a cryo-conserve, taken from the stock to be rescued ten generations ago, with all females, with the exception of no mating between M and C. After genetic rescue, selection was switched to random mating with constant stock size and sex ratio of 1:2. Proportions of purged deleterious variants, average deleterious allele content per animal, the proportion of offspring being homozygous for at least one lethal allele, and inbreeding rates (calculated based on share of the genome in Identity-by-Descent) were tracked through all generations. All simulations were repeated 500 times. The interested reader is referred to https://github.com/tpook92/MoBPS/ for the R-Script.

Results

The initialisation period S1 in the first 15 generations lead to an average kinship of 3.4% and on average 14.5 deleterious variants per individual, and quickly fixed 60% of the deleterious loci. The decreased population size in S2 led to an average kinship in L, M, E, and C, of 11, 39, 73 and 93%, respectively. Nearly all deleterious variants (>95%) got purged from E, C and M, while L still contained ~12% of the initial deleterious mutations (Figure 1). During S2, in 33% of the simulations C, and in 5% E got extinct.

S3 clearly showed decreased proportions of viable offspring in the first generations after genetic rescue, and decreased inbreeding, when males were taken from other stocks or the cryo-reserve (Figure 2). Consistently across repetitions, males from the largest population or the cryo-reserve had a stronger negative impact than from smaller stocks. In 11 simulations, breeding males from E in C led to extinction of C, likewise in each internal pairing in C and E once each. Inbreeding increase flattened and the benefit was greatest when males were taken from independent stocks rather than the cryo-reserve.

Table 1. Simulated stock sizes in *S2*.

Stock	Generation			
	17	18-21	22-26	27-36
Large	1000	1000	1000	1000
Medium	800	400	200	100
Endangered	700	200	80	36
Critical	300	75	40	15

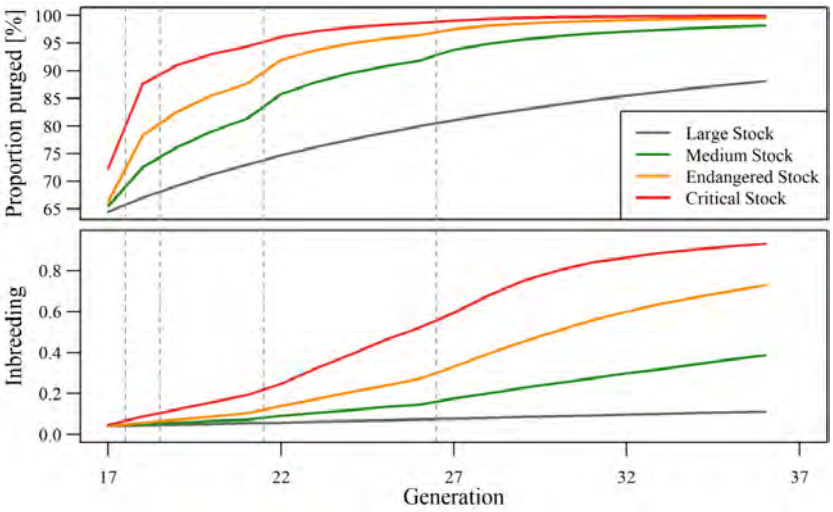

Figure 1. Top: Proportion of purged deleterious loci within a stock in S2, calculated on the basis of the founder generation. Bottom: Development of Inbreeding, calculated as average IBD per genotype.

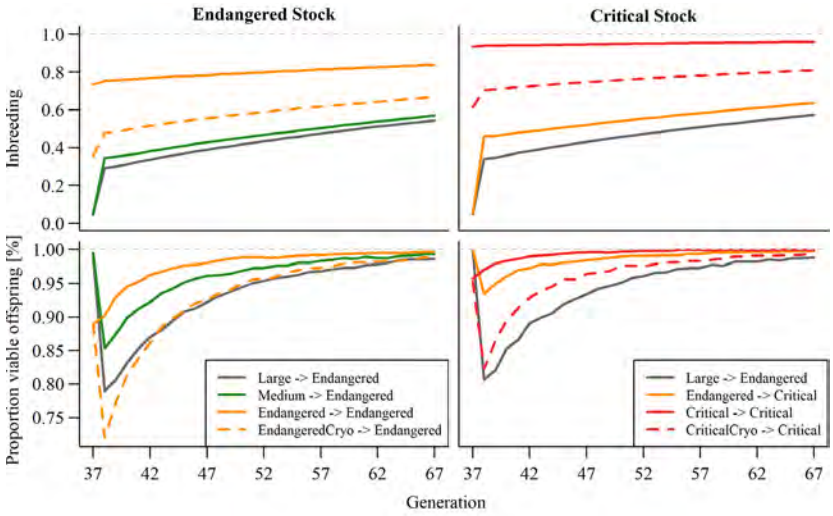

Figure 2. Degree of inbreeding derived from IBD of simulated genotypes and proportion of viable offspring for the genetic rescue scenarios of S3 for the Endangered (n=36) and Critical stock (n=15).

Discussion

Our results give an insight into how inbreeding and strongly deleterious variations interact in a framework of inbred livestock populations when genetic rescue is performed to restore genetic diversity. Strong inbreeding with resulting selection against deleterious variants reduced their number and frequency substantially, but genetic rescue led to decreased offspring viability due to homozygous lethal genotypes in the remaining loci in the short term. Extinction after rescue happened in E and C, but remained a rare event. Compared to the wild population scenario simulated by Kyriazis *et al.*(2021), genetic load in all donor stocks was limited due to fairly efficient purging. The main finding is the effect that introgression

from larger sub-populations was worse compared to usage of similarly endangered stocks, as the first had a substantially higher genetic load. The detrimental effect of using gene-bank semen could be attributed to the larger historical population size at sampling and shows that careful characterisation of deleterious variation is important when using older samples. Simulation seems to be an appropriate tool to assess such effects and has been used before (Wang *et al.*, 1999), but knowledge about the genetic structure of deleterious mutations is paramount to obtain reliable results. We studied strongly lethal variants, which might be purged as demonstrated, but variants with mild effects could become inherent (Charlesworth and Charlesworth, 1987; Hedrick and Kalinowski, 2000) and be more important in long term viability. To better account for the effect of deleterious variation in the context of conservation breeding, novel genomic approaches to assess deleterious variation, such as homozygous haplotype deficiency or sequence guided identification (Derks *et al.*, 2021) might be of high impact when routinely employed.

Abstract

This study investigated national genebanking priorities based on information reported in the Domestic Animal Diversity Information System (DAD-IS) and feedback provided by gene bank managers. Only 3.2% of national breed populations are reported to have enough material collected to allow breed reconstitution in case of extinction. Depending on species, region and demographic risk status, there are substantial differences in quantities of germplasm collected when comparing breeds with a high risk status vs demographically important breeds. Most genebanks have small budgets and use pragmatic approaches for collecting germplasm by partnering with breeding organisations and/or artificial insemination companies. They also work with a variety of breed associations to implement collection strategies to ensure that the breadth of genetic diversity is captured. Future collection growth within countries will be driven by national programs that incorporate stakeholder participation, collection use, the scope of diversity captured; and will depend upon levels of public and private funding.

Introduction

Ex situ conservation by genebanks is an approach that provides insurance against losses of animal genetic resources in the field, caused by breed replacement, genetic erosion and/or emergencies (Smith, 1984; Paiva *et al.*, 2016). Currently, two indicators of the Sustainable Development Goals (namely 2.5.2 and 2.5.1b) consider *in situ* and *ex situ* conservation of animal genetic resources, respectively. Indicator 2.5.2 is defined as the proportion of local breeds (i.e. being reported to exist only in one country) classified as being at risk of extinction. Indicator 2.5.1b considers the number of local breeds stored within a genebank collection with an amount of genetic material (semen, embryos, oocytes, etc.) stored sufficient to reconstitute the breed in case of extinction (FAO, 2012; Leroy *et al.* 2019). Those indicators are based on official data provided by countries to the Domestic Animal Diversity Information System (DAD-IS).

The aim of this study was to assess to what extent genebank collection strategies in livestock consider risks related to genetic diversity, both at species and breed level. To investigate this, DAD-IS data from 197 countries and territories were analysed and augmented with feedback provided by some countries in Europe and North America.

Materials & methods

Data from 15,121 national breed populations belonging to 37 species and species crosses, reported by 197 countries and territories, were extracted from DAD-IS in December 2021. Depending on the information provided, the cryoconservation status of a national breed population can fall into four categories: (1) no information (no information provided on cryomaterial); (2) no material (no material collected, according to the country); (3) not sufficient (material collected, but with an amount insufficient to allow breed reconstitution in case of extinction); and (4) sufficient. Countries can indicate whether they consider the quantities of material stored to be 'sufficient', based on their own conservation objectives and their local

R.F. Veerkamp and Y. de Haas (eds)

capacity in reproductive biotechnologies, as these factors can vary substantially across breeds, species and countries. Otherwise, sufficiency is determined by default, based on internationally agreed criteria considering species, numbers of samples and donors and type of material stored (frozen semen, embyros, oocytes; FAO, 2012).

The cryoconservation status of national breed populations were analysed as the dependent variable in a multinomial logistic regression model (R multinom function) with the following explanatory categorical variables: (1) species (Cattle, Chicken, Goat, Horse, Pig, Rabbit, Sheep, Other avians, Other mammals); (2) region (Africa, Asia, Europe and the Caucasus, Latin America and the Caribbean, Near and Middle East, North America); (3) the breed's geographical classification (Local, Regional transboundary, International transboundary); and (4) the breed's risk classification (Unknown, Not at risk, Vulnerable, Endangered, Critical, Extinct). The risk classification is defined based on demographic thresholds endorsed by the FAO Commission on Genetic Resources for Food and Agriculture (FAO, 2013).

Data from 11 European countries collected through the ERFP (European Regional Focal Point) Ad Hoc Action were used to assess the challenges on developing national strategies for cryoconservation. In addition, five countries from Europe and North America also provided open comments on the question of genetic risk in relation to topics such as the criteria used for selecting breeds sampled for cryoconservation, the amount of material requested, and the sampling strategy at breed level.

Results

On the 15,121 national breed populations reported in DAD-IS, 47.8% are reported without information regarding their cryoconservation status, 43.5% are reported to not have any cryo-material collected, 5.5% are reported to have material collected, but with insufficient amount, and only 3.2% have enough material collected to allow breed reconstitution in case of extinction. Among species, mammals and especially cattle (9.5% of national breed populations with not sufficient and 6.7% with sufficient material), showed larger genebank collections compared to avian species ($P<0.001$). When compared to other regions, Asia, Europe and the Caucasus and North America, showed larger proportions of national breed populations with material stored, either not sufficient (1.4 vs 5.1, 8.2 and 13.4%, respectively) or sufficient (2.2 vs 3.8, 3.2 and 9.2%, respectively) ($P<0.001$). By contrast, cryoconservation status did not vary substantially by geographic status of the breed (local, regional transboundary, or international transboundary breeds) with proportion being 5.9, 4.4 and 5.2% for not sufficient, respectively, and 2.8, 3.1 and 3.6% for sufficient respectively ($P<0.01$). When considering risk status (Figure 1), national breed populations with unknown risk status (i.e. no information provided on their population over the last past years), were the most likely to not have information reported on their cryoconservation status (55.4%) ($P<0.001$). Risk status (population size) seemed to be both a driver (increased need) and an obstacle (greater difficulty in accessing donors) for material collection in small populations. The proportion of national breed populations with material collected was greatest for 'Vulnerable' populations. Among larger (i.e. 'Not at risk') populations, a smaller

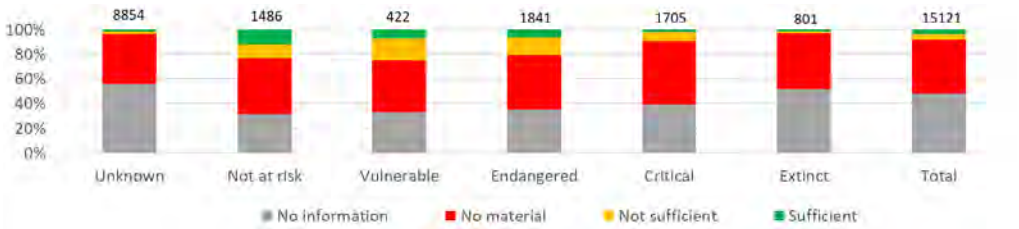

Figure 1. Collection status of national breed populations by risk status.

proportion of breeds had material collected, but the material was sufficient for a greater proportion of these populations, in part due to the economic importance of these populations and the ability to more effectively acquire germplasm. 'Endangered' populations were collected at a rate similar to those 'Not at risk', but the proportion with sufficient material was much less. Practical factors seemed to strongly limit collection of material from 'Critical' populations.

From the ERFP dataset, obstacles related with funding and policy issues were considered as the main drawbacks in development national genebank collections (Table 1). Among them, lack of funding, lack of infrastructures, low interest of breeders' societies and low priorities in governmental policies were ranked as the main ones. Technical issues link to specific species and genetic diversity aspects (low number of males in certain breeds) were ranked as medium obstacles (8.8 and 8.5 on 0-20 scale, respectively). When providing open input, national coordinators indicated that genetic and demographic risk status is only one among many factors for the selection of breeds to be collected. They reported that national genebanks use opportunities to collect material already available in AI centers (i.e. often from mainstream breeds) or through research projects, while trying at the same time to encourage and support breeding associations from local breeds to implement collection strategies. At the breed level, depending on information available (geographic distribution, pedigree and/or genomic information), donor animals are sampled to display a high genetic variability, using for instance optimal contribution selection (the Netherlands) or Ward's Minimum Variance method (USA), but often a more pragmatic approach.

Table 1. Obstacles reported by European countries for the development of ex-situ conservation strategies ranked from 1 (less important) to 20 (most important).[1]

	Obstacles	Rank (s.e.)	Obstacles	Rank (s.e.)	
Funding	**Lack of public funding for *ex situ* conservation**	16.9 (1.1)	Private companies/AI centers not involved	9.5 (1.8)	Organizational
	Unexploited funding opportunities	9.7 (1.5)	Low level of public awareness, in the farmer's community	9 (2.1)	
	No stable funding source	9.4 (2.5)	No integration of *ex situ* and *in situ* conservation activities	8.7 (1.6)	
			Weak structure of breeders associations / poorly developed breeding programs	8.2 (2.6)	
Policies	**Low interest of breeder societies in *ex situ* conservation activities**	12.5 (1.6)	**Lack of infrastructure and technical capacity**	13.3 (1.5)	Technical
	***Ex situ* conservation of animal genetic resources is low priority in governmental policies**	11.5 (2)	Gaps in methods for freezing semen and insufficient fertility in some species	8.8 (2.3)	
	Poor/lack of coordination among actors	10 (2.5)	Extremely small number of males in the population intended to be preserved	8.5 (1.7)	
	Absence of regulations on *ex situ* conservation	8.9 (2.6)	Lack of awareness on EUGENA activities	6.8 (1.9)	
	Bureaucratic burdens in financial planning and agreements	6.6 (1.8)	Lack of capacities at sub-country level	6.7 (2.2)	
	Low coordination among countries in case of transboundary breeds	6.2 (1.9)	Difficulties in the development of new biotechnologies	5.5 (1.3)	
	Legal restrictions in collections on the field or use of old material.	5.5 (1.8)	Problems with storage of duplicate collection	4.5 (1.6)	

[1] In bold the 5 most important obstacles.

Discussion & conclusions

Analysis of DAD-IS data shows that breeds not at risk are well represented in national genebank collections and that breeds at risk on average have limited amounts of genetic material stored in genebanks. Feedback provided by national coordinators indicate that national genebanks take into consideration more than genetic risk based upon a breed's threat level (e.g. socio-economic importance of a breed, or unique phenotypes). Although it is important for any breed and breeding program to develop *ex situ* collections, countries have different priorities and opportunities to support that. In practice, the level of development of genebank collections depends on national priorities, funding, stakeholder participation and the available infrastructure, institutions and capacities. When viewed globally, substantial germplasm collections have been developed in Europe and North America (Paiva *et al.*, 2016) and these resources present interesting research opportunities in the area of genomics and reestablishing lost genotypes (Dechow *et al.*, 2020). But national genetic resource programs must strive to increase the utilization of these collections to the research community and industry, as public and private goods. By increasing utilization of these resources, the genebank raises awareness of the collection's utility, which in turn can justify and facilitate the expansion of the collection.

Challenges – use of whole genome sequence information

251. Pangenomes of haplotype-resolved assemblies enable population-scale genotyping of cattle structural variation

A.S. Leonard* and H. Pausch

Animal Genomics, ETH Zurich, Universitaetstrasse 2, 8006 Zurich, Switzerland; alexander.leonard@usys.ethz.ch

Abstract

Haplotype-resolved, long read assemblies provide access to previously unresolved complex structural variation and enable pangenomic approaches to analyse diversity across multiple cattle breeds. We assess structural variation present in pangenomes integrating 12 HiFi-based haplotype-resolved and 4 older taurine cattle assemblies. Pangenomes produce approximately 15% more structural variants than linear reference-guided calling from sequencing reads and is especially beneficial for detection of variants larger than 50 Kb (238 compared to 75). We leverage population-scale short read data to investigate the prevalence of selected structural variants across multiple breeds. We find good consensus between the read-to-graph alignment approach of minigraph and the k-mer approach of Pangenie. We characterize structural variants within *PRDM9* and at QTL for mammary gland morphology and carcass traits nearby *TBX3* and *ENSBTAT00000082324* that might contribute to complex trait variation.

Introduction

Long read sequencing revolutionised genome assembly, greatly improving the contiguity of assemblies from kilobases to megabases. More recent improvements in the accuracy of long read sequencing, such as Pacific Biosciences HiFi or new Oxford Nanopore Technologies (ONT) chemistry, have further enabled assembly of challenging genomic regions, particularly those that are highly repetitive or share high sequence similarity. While updating reference genomes is beneficial (Aganezov *et al.* 2021), required validation efforts, manual curation, and lifting over existing results limit motivation to do so. As such, reference genomes, including the current Bos taurus reference (ARS-UCD1.2; Rosen *et al.*, 2020), commonly are lacking sequence in these challenging regions, hindering conventional methods like aligning sequencing reads to the reference. On the other hand, *de novo* assembly and pangenome integration allows for newly resolved genomic regions to be accessible to downstream analysis (Crysnanto *et al.* 2021, Leonard *et al.* 2021).

High sequencing and assembling costs are still limiting factors to producing sufficient high quality genomes for conducting population-scale studies at the assembly level. However, there are huge datasets available for many species, both public and private, for individuals either sequenced with short reads or array-genotyped. Recent tools like Pangenie (Ebler *et al.*, 2020) combine these different sources of DNA variation data, determining the spectrum of variation from haplotype-resolved assemblies, and then genotyping that variation across many samples sequenced with short reads. Such approaches are the first step towards understanding complex variation previously inaccessible to genomic analysis at population-scale.

Materials & methods

We used 16 cattle assemblies representing multiple breeds of taurine cattle of which 12 were assembled from HiFi reads (five Brown Swiss [BSW], six Original Braunvieh [OBV], one Piedmontese), three from Pacific Biosciences continuous long reads (one each of Hereford, Angus, and Highland), and one from ONT reads (Simmental [SIM]). A read-based structural variant (SV) panel was constructed with pbsv (Pacific Biosciences), calling on each sample and merging with bcftools (Danecek *et al.* 2021). An assembly-based variant panel was constructed using the assemblies-to-pangenome pipeline of Pangenie. For comparison, both panels were filtered with 'abs(ILEN)≥50' and intersected using bcftools. Graph pangenomes were constructed with minigraph (Li *et al.*, 2020) with the ARS-UCD1.2 reference genome as the backbone.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_251, © A.S. Leonard and H. Pausch 2022

Short paired-end reads (2×150bp) from 49 samples (20 BSW, 20 OBV, 5 SIM, 2 Fleckvieh [FV], and 2 Holstein [HOL]) were aligned with the minigraph short-read preset to estimate the number of reads aligned to each node. Short read sequencing samples were genotyped against the panel with Pangenie using default parameters. The per-sample genotyped vcf files were merged using bcftools. The principal component analysis (PCA) plot was generated with plink2 (Chang *et al.* 2015).

Results

The minigraph pangenome, covering the 29 autosomes, contained 133,725 nodes with an average length of 19.1 Kb. There was approximately 65 Mb of non-reference sequence identified, in line with expectations of a taurus-only bovine pangenome given previous observations (Crysnanto *et al.* 2021). There were 47,324 bubbles across the autosomes, of which 1,554 overlapped with coding sequence annotated in the ARS-UCD1.2 reference genome. Several of these bubbles coincide with previously identified QTL for complex traits: a mammary gland morphology QTL nearby *TBX3* on BTA17 (Pausch *et al.* 2016, Fang and Pausch 2019), a carcass trait QTL nearby *ENSBTAT00000082324* on BTA5 (Fang and Pausch 2019) and insertions in *PRDM9* on BTA1. The structural variation present in the pangenome and population coverage are shown in Figure 1. The small number of assemblies prevent immediate association testing between the bubbles and traits of interest. However, signals of non-reference sequence are clearly visible for some samples, particularly when reads span node-edge-node pairs.

The approximate mapping approach of Minigraph can result in suboptimal pangenomes in complex regions, which interferes with read mapping. In the case of a QTL nearby *ENSBTAT00000082324*, node 5477 effectively contains 342 novel bases followed by 4,006 bases with 98% sequence similarity to node 1,067. This potentially suboptimal graph structure might lead to ambiguous or incorrect alignment of short reads, and erroneously suggest support for the reference or non-reference node.

Alternative VCF-based pangenome models, like that of Pangenie, first require a variant panel. These panels can be created through read-based calling (e.g. pbsv) or assembly-based calling (e.g. minimap2 with paftools.js). Assembly-based calling is more intensive, requiring higher coverage and computational resources to first produce the assemblies and then call variants, but the greater contiguity and correctness allows more accurate calling of large and/or complicated structural variation compared to using reads

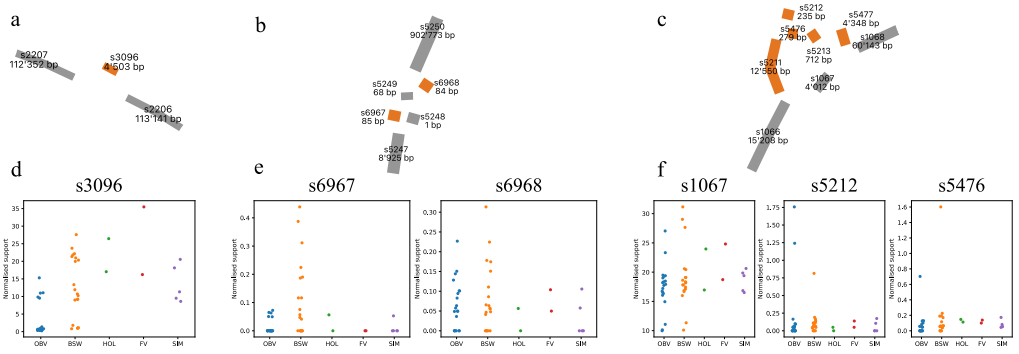

Figure 1. Population-scale short read support for structural variation alleles in minigraph pangenomes. a-c) Bandage plots of pangenome subgraphs for QTL nearby *TBX3*, *PRDM9*, and *ENSBTAT00000082324*. Reference and non-reference nodes are respectively coloured grey and orange. d-f) Short read support per node normalized by sample coverage.

directly. Given the same set of HiFi reads across 6 samples, we find assembly-based calling outperforms read-based calling (Table 1). Over half of the identified SVs are common to both read-based and assembly-based variant calling, but the former yielded a larger number of records, particularly ultra-long variants. Some read-based variants appear as fragmented versions of assembly-called variants, supporting that read-based variants may incorrectly call sufficiently large variation.

After genotyping the 49 samples against the assembly-based panel with Pangenie (containing both small and large variants), we assess the relationship between different input samples. We find good separation in the PCA of the merged sample VCF, shown in Figure 2, indicating the assembly-based variant panel does capture genomic differences across multiple breeds, and this can be leveraged into short read sequencing of much larger cohorts.

There was good consensus between Pangenie and minigraph for the genotyped SVs of interest (Table 2), despite the former using k-mers and variant panels while the latter uses alignment and assemblies directly. The minigraph approach is more suitable to manual inspection, and validates that the more scalable method of Pangenie is sufficiently accurate.

Table 1. Structural variation identified across HiFi cattle samples.

Method	Insertions	Deletions	Mean size (bp)	N>50 kb	N>100 kb
Assembly-based	19,810	12,435	2,252	238	25
Read-based	14,268	11,398	1,894	75	3
Mutual	20,905	13,766	1,079	6	0

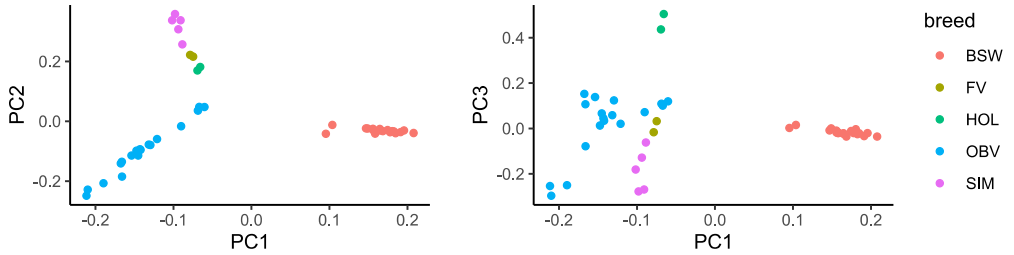

Figure 2. PCA plot for Pangenie genotyped samples. Breed information is not used in the PCA, with colours being assigned manually to breeds.

Table 2. Reference and alternate variant genotyping in minigraph and Pangenie.

Variant	Genotyper	BSW	OBV[1]	FV	HOL	SIM	Consensus
TBX3	minigraph	5/15	15/5	0/2	0/2	0/5	1.0
	Pangenie	5/15	13/5	0/2	0/2	0/5	
ENSBTAT00000082324	minigraph	3/17	9/11	0/2	0/2	0/5	0.96
	Pangenie	2/18	8/10	0/2	0/2	0/5	
PRDM9	minigraph	8/12	15/5	2/0	1/1	4/1	0.82
	Pangenie	10/10	13/5	0/2	0/2	2/3	

[1] Two OBV samples failed with Pangenie.

Simple variants, like an insertion near *TBX3*, are easier to genotype as they appear as large, novel insertions. More complex variants, like the two 84 bp insertions in the coding sequence of *PRDM9,* are more challenging to genotype correctly, as they are repetitive and have high sequence similarity with nearby regions.

Discussion

Population-scale analysis of DNA variation currently still requires cheaper variant detection methods like array-genotyping or short read sequencing over long read *de novo* assembly. Detecting variation through pangenomes and then genotyping additional samples enables analysis in challenging or complex regions that are inaccessible without high quality assemblies. Here we show that different approaches, like that of minigraph+alignment or Pangenie, can effectively genotype variation across large cohorts of short read sequenced samples. Still, repetitive or duplicated regions impair both read alignment and k-mer analysis and may require long read sequence or *de novo* assemblies to confidently assess.

The VCF output of Pangenie can be directly used in conventional downstream analysis, simplifying adoption, but the VCF panel model is substantially weaker than graph pangenome models for representing complex or nested variation. However, it remains unanswered if genotyping variation at the largest (i.e. one allele per variation combination) or at the smallest (i.e. separately assessing a deletion contained inside an insertion) bubble level is more biologically informative. One such example is the carcass trait SV, where a near identical 12.5 Kb insertion is present in four distinct alleles, potentially skewing the analysis when the alleles primarily differ by variation in later nodes. Such questions warrant further investigation as we look to genotype medium-scale short read cohorts and impute into population-scale cohorts.

252. Comparison of methods for building pangenome graphs

D. Crysnanto*, A. Leonard and H. Pausch

Animal Genomics ETH Zurich, Universitätstrasse 2, 8092, Zurich, Switzerland; danang.crysnanto@usys.ethz.ch

Abstract

Graph-based pangenomes could mitigate the bias from the use of a single reference genome. However, the impact of different pangenome integration approaches on the properties of the resulting graph remains unknown. In this study, we compared three methods for building pangenome graphs from multiple genome assemblies. Minigraph performs an approximate mapping of assemblies to a backbone genome to construct the pangenome. In contrast, Cactus and pggb apply reference-free base level alignment to build pangenome graphs. Our results show that pangenome graphs constructed via base-level alignment contain 40% more small variations than the minigraph pangenome. Cactus, pggb, and minigraph uncover an almost identical set of structural variations. However, the breakpoints and allelic paths inferred from minigraph's approximate mapping tend to be less precise than graphs constructed via base-level alignment. Taken together, our study informs on the optimal strategy for building informative pangenome graphs that are now being conducted for many species.

Introduction

It becomes increasingly evident that a single haploid reference genome cannot capture the full species diversity. Pangenomes integrate genomic resources generated from multiple individuals into a more informative reference (Yang *et al.*, 2019). Graph-based structures are commonly used to represent sequence diversity in pangenomes, where distinct alleles form nodes in the graph (Eizenga *et al.*, 2020). More recent approaches construct pangenomes from multiple genome assemblies (Crysnanto *et al.*, 2021; Leonard *et al.*, 2021). However, building multi-assembly graphs can be computationally demanding and the resulting graphs are often convoluted and difficult to interpret. The approximate mapping algorithm implemented in minigraph is one possibility to efficiently construct multi-assembly graphs. Minigraph incorporates large structural changes and requires a single graph backbone, which is typically the reference genome (Li *et al.*, 2020). Recently, Cactus (Armstrong *et al.*, 2020) and pggb (pangenome graph builder) (Garrison, 2021) have been proposed as alternative methods to construct pangenomes through reference-free base-level alignment. However, the properties and differences of graphs resulting from various pangenome approaches are vastly unknown.

Materials & methods

Twelve Bovinae assemblies were used for the graph construction: ARS-UCD1.2 (current reference genome) (Rosen *et al.*, 2020), Angus (Koren *et al.*, 2018), Highland (Rice *et al.*, 2020), Brahman (Koren *et al.*, 2018), Yak (Rice *et al.*, 2020), Simmental (Heaton *et al.*, 2021), Bison (Heaton *et al.*, 2021), Brown Swiss (Leonard *et al.*, 2021), Original Braunvieh (Leonard *et al.*, 2021), Piedmontese (Leonard *et al.*, 2021) and Nellore (Leonard *et al.*, 2021). All assemblies were soft-masked using RepeatMasker. The ARS-UCD1.2 assembly was used as the backbone of the graphs and the order of including the other assemblies was determined based on their mash distance to the backbone (Figure 1a). To limit computational complexity, all analyses are based on bovine chromosome 19.

Three different graph construction methods were applied: minigraph, pggb, and the Cactus Progressive pangenome pipeline. Minigraph extends the minimizer-mapping of minimap2 to a graph that is computationally efficient because it avoids base-level alignment. Cactus and pggb are computationally more demanding because they perform base-level alignment. Pggb consists of three phases: base-level alignment

with *wfmash*, graph induction with *seqwish*, and normalization with *smoothxg*. The pggb pipeline was run with the recommended parameters for a gigabase-sized genome with a repeat content similar to the human genome. The final *.smooth.gfa version of the graph was used for the subsequent analysis. The Cactus pipeline was run with progressive alignment using the guide tree from the mash-based distance. The final HAL alignment was converted into the vg graph format using *hal2vg*. Variations from the different graphs were determined relative to the ARS-UCD1.2 coordinates using snarls decomposition with *vg deconstruct*.

Results

Pggb and Cactus produced pangenomes that contain 5.5 and 5.7 Mb non-reference sequences, respectively, which were mostly found in structural variants longer than 50 bp. They also contained 2.2 (pggb) and 2.5 (Cactus) Mb non-reference bases due to approximately 1.7 million SNPs and Indels smaller than 50 bp. Most of these variants were missing in the minigraph pangenome. 75.58, 69.05 and 64.98% of the bases contained in non-reference nodes larger than 50 bp identified by Cactus, pggb, and minigraph, respectively, were repetitive. A large fraction (>25%) of the repeat elements belonged to L1 elements. Interestingly, 800 kb non-reference sequence of the pggb and Cactus pangenome graphs were satellites. The overall length of large non-reference nodes was smallest in the minigraph pangenome because it did not contain satellites in the non-reference sequences larger than 50 bp. Replacing the ARS-UCD1.2 backbone with more complete assemblies (e.g. Brown Swiss and Original Braunvieh) reduced the amount of non-reference sequences (~2.2 Mb) and slightly increased the proportion of repeat-masked sequences (~66.2%) but still did not recover satellites in the minigraph pangenome.

Pangenomes constructed using Cactus and pggb contained substantially more large variations (4729) than those constructed using minigraph (3027). However, most structural variations were identified by all pangenomes (Figure 1b). Using a 50 bp threshold to accommodate imprecise breakpoint resolution, pggb and Cactus had the lowest and Cactus and minigraph had the highest breakpoint discrepancy. We find that Cactus and pggb had the highest (86.03%), whereas pggb and minigraph had the lowest (82%) intersection of exact paths traversed by the assemblies.

Table 1. Properties of three pangenome graphs constructed for bovine chromosome 19.

Statistics	Unit	Cactus	pggb	minigraph
Total nodes	n	4,838,791	4,469,595	10,419
Node length	bp	69,008,903	68,607,291	65,888,880
Reference nodes	n	3,088,293	2,908,218	6,695
Reference node length	bp	63,274,710	63,061,455	63,449,741
Non- reference nodes	n	1,750,498	1,561,377	3,724
Non-reference node length	bp	5,734,193	5,545,836	2,439,139
Small non-reference node length [1]	bp	2,477,931 (43.21%)	2,204,141 (39.74%)	14,299
Large non-reference nodes length[1]	bp	3,256,262 (56.79%)	3,341,695 (60.26%)	2,424,840
Maximum memory usage	Gb	34.7	31.2	2.6
Average memory usage	Gb	4.8	4.1	1.9
CPU time	h	10.4	78.4	0.21
Wall-clock time (10 threads)	h	1.82	6.16	0.21

[1] small: <50 bp; large: >50bp.

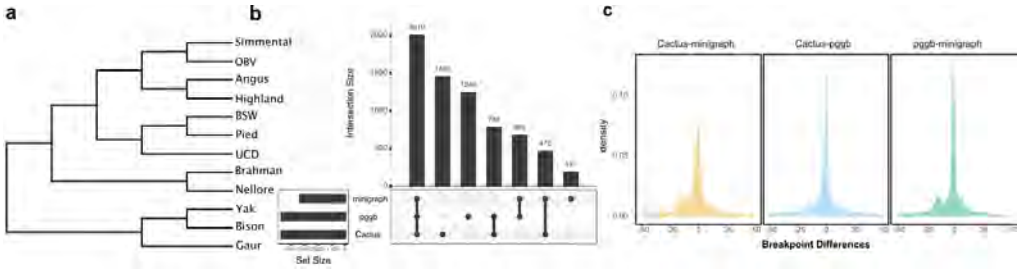

Figure 1 (a) Genetic relationship between 12 assemblies based on the mash distance (b) Overlap of the structural variations discovered among three tools within 50 bp of the breakpoints (c) Density of the differences in breakpoints of the overlapped variations.

Our findings indicate that pggb and Cactus pangenomes more often resolve bubbles with multiple paths that differ only in small variations, whereas these are collapsed into a single allele in minigraph pangenomes (e.g. Figure 2a). Additionally, minigraph pangenomes frequently contain bubbles with suboptimal topology that compromise the re-alignment of assemblies thereby preventing unambiguous assignment of paths (Figure 2b). These findings suggest that the approximate mapping in minigraph as well as the base-level alignment of pggb and Cactus uncover large mutational events quite accurately. However, only the pangenomes built using pggb and Cactus resolve complex bubbles that contain multiple paths that are largely similar.

Discussion

Here we built bovine pangenome graphs from twelve assemblies using either fast approximate mapping or computationally more demanding base-level alignment. We showed that minigraph pangenomes lack 40% of the total variations present in the pggb and Cactus graphs. There was generally good agreement across different pangenomes in terms of large variations. However, breakpoints are less precise and re-alignment of assemblies suffers from suboptimal topology in the minigraph pangenomes likely resulting from collapsed variations due to approximate mapping. We suspect that these limitations hinder the broad and universal applicability of approximate pangenome graphs beyond structural variant detection (Ebert

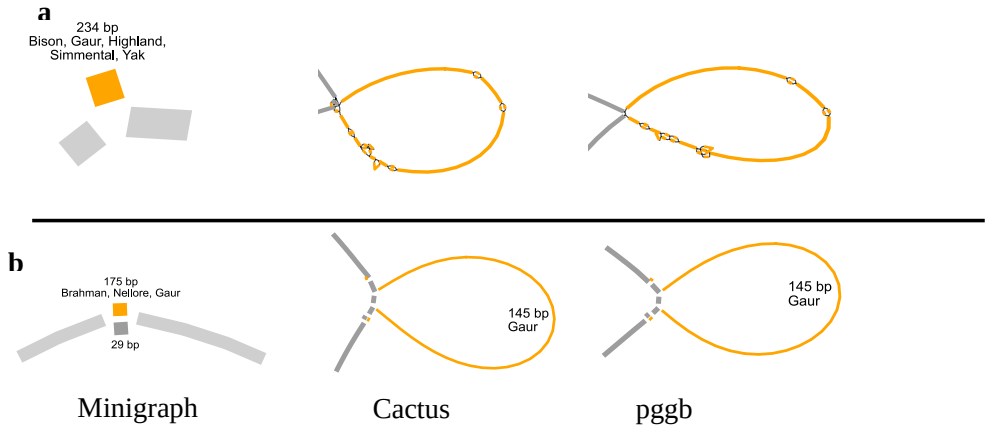

Figure 2. Visualization of allelic variation in three different pangenome graphs. Grey and orange color denote reference and non-reference nodes, respectively.

et al., 2021). A promising pangenome construction pipeline has recently been proposed that exploits the accuracy of full-base level alignment and the computational efficiency of approximate mapping (minigraph-Cactus pipeline) (Armstrong *et al.*, 2020). Our findings suggest that this strategy might increase the general applicability of pangenome graphs.

Abstract

The challenge to provide energy-rich protein to the world while reducing the environmental impact is one of the largest challenges facing the animal industry today. To face this challenge, novel tools need to be adopted for methods to identify animals that perform optimally in their environment. This includes, but is not limited to, utilizing more complex variation, epigenetics, and microbes present within the host. A major hurdle in utilizing these data lies in the development of cost-effective and high-throughput methods for data capture. We argue that Oxford Nanopore Technologies is well-suited to fit this purpose. A computational approach called adaptive sampling couples long-read sequencing with targeted sequencing, affording the potential to capture multiple sources of information specifically and simultaneously in a sequencing run while reducing costs. This paper will discuss the potential benefits currently being explored to integrate this tool into the animal industry.

Sequence-based genotyping fills a niche within animal breeding

Sustainable progress in animal performance can be achieved by estimating and selecting on an individual's genetic merit. Utilizing pedigree allowed for the use of expected relationships based on the probability that two individuals shared alleles because they were identical by decent. This was further expanded to include the use of DNA markers dispersed across the genome, referred to as genomic selection. The use of genotype data has been widely adopted in the animal industry because it captures relationships between individuals at a higher resolution than using expectations from pedigree, resulting in more accurate predictions of an individual's genetic merit. Adoption of genomic information into animal industries has largely been accomplished through the development and use of SNP genotyping arrays; however, other 'minor' livestock species have found success utilizing other low-cost sequence-based platforms, e.g. genotyping-by-sequencing, for genomic analyses.

Expansion into using whole-genome sequence (WGS) has been explored to capture an individual's genetic merit more accurately. In particular, the use of WGS data is expected to increase genomic prediction accuracy in multi-breed genetic evaluations because the causative variant can be captured directly, whereas SNP arrays largely rely on linkage disequilibrium between the marker and the QTL (Moghaddar *et al.*, 2019). Traditional sequencing methods have been limited due to the costs of the technology when considering wide-scale adoption. Instead, a common approach is to build a reference set of animals that have reliable genotype calls from WGS data that are used to impute SNP array genotypes to WGS-level genotypes.

Low-pass sequencing has been developed as a balance between cost and reliability of genotype calls. Using this approach, the animal of interest is sequenced at <1× coverage across the genome, allowing for more accurate genotype calls when imputing the genotype (Snelling *et al.*, 2020). Low-pass sequencing is a cost-competitive alternative to SNP arrays and provides a straightforward approach to impute functional variant genotypes, without the upfront investment and inherent selection biases associated with developing SNP arrays (Matukumalli *et al.*, 2009). However, this approach is still limited by how representative the reference

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_253, © A. Hess *et al.* 2022

animals are of the target population, and a method to capture specific variants more accurately may still be necessary (Snelling *et al.*, 2020).

While genomic analysis using SNPs has been an invaluable tool for more accurately selecting animals with improved performance, moving forward, it is anticipated that our prediction equations will be expanded to include more information than SNPs by expanding to include DNA methylation, metagenomics, and structural variation, among others. The utility of this information will be dependent on the ability of this information to result in sustainable progress in the improvement of livestock species. This will be partially dependent on the ability to capture heritable genetic variation in these datatypes, which can be used for genetic selection purposes. Recently, the theoretical framework for estimating the heritable genetic component for these datasets when combined with traditional SNP information was developed (Christensen *et al.*, 2021). This is promising when considering how to integrate multiple sources of big data (i.e. large in dimensionality and complex). However, the challenge for the industry when considering widespread implementation is to develop tools that will be able to seamlessly capture multiple sources of information in a high-throughput and cost-effective manner.

Oxford Nanopore Technologies (ONT) have the potential to address this need, whereby long reads are produced to aid in accurate capture of more complex variation. Furthermore, they can identify base modifications (such as DNA methylation), making it possible to collect information on epigenetic markers. This technology can also base call sequences in real-time and decide whether to continue to read the sequence through a process called adaptive sampling (Payne *et al.*, 2021a), allowing for an efficient way to capture specific information. Therefore, with further development of this technology, there is potential to utilize ONT to simultaneously collect multiple sources of information on the same animal for genomic selection.

Long reads offer the potential to capture more complex variation

Long read sequencing generates reads that are thousands of base pairs in length, enabling the resolution of complex variation that troubles short read sequencing, such as copy number variation, or large insertions or deletions of sequence in the genome. The ability to accurately capture copy number variation will allow selection on more complex variation, which may improve prediction accuracy, particularly when the trait is under strong control of such a variant (El Hamidi *et al.*, 2018). Copy number variants (CNV) that differ by breed seem to be associated with adaptation. This has been shown in pigs and cattle where CNV regions under differential selection between breed and subspecies, respectively, are associated with disease resistance, heat tolerance, metabolism, muscle development and reproduction (Wang *et al.*, 2015; Hou *et al.*, 2012; Hu *et al.*, 2020; Stafuzza *et al.*, 2019), suggesting the potential of utilizing this information for genomic selection.

A major challenge for selecting on complex variation lies in the ability to accurately genotype the individuals. For example, the polled locus is a major locus that influences the development of horns, which is caused by an insertion in the *RXFP2* gene in sheep. However, to date, prediction accuracy has not improved by imputing the variant using SNP genotypes, presumably because the SNPs were not in high LD with the inserted sequence (Duijvesteijn *et al.*, 2018). The inability to accurately impute complex variation is common across the genome (Rafter *et al.*, 2020), suggesting direct capture of major CNVs would provide an improvement over the use of SNPs. Long-read sequencing can more accurately genotype copy number and complex structural variation by providing longer reads spanning a region of interest. Adaptive sampling (Payne *et al.*, 2021a) provides a means to specifically capture complex variants of interest to be considered when making selection decisions.

Oxford Nanopore machines capture epigenetic modifications

Epigenetics is a modular means for an individual to respond to changes in the environment, which can have an impact on the welfare of the individual. Variation in methylation status has a heritable genetic component, which has been estimated as 0.19 on average for DNA methylation measured at probes with no known SNPs in humans (McRae *et al.*, 2014) and as 0.20 for global DNA methylation rate in sheep (Hazard *et al.*, 2020). Epigenome-wide association studies are being explored for disease outcomes in humans (Rakyan *et al.*, 2011) and more recently in pigs for meat quality traits (Wang *et al.*, 2020). The methylation status at the loci identified in these studies, in addition to already known imprinted loci such as *callipyge* (Cockett *et al.*, 2005), may be utilized to improve the ability to predict individual performance.

Epigenetics can also be used as an indicator of the animal's ability to cope with environmental stressors. The concept of age prediction using epigenetic clocks has recently gained attention in livestock species (Caulton *et al.*, 2022; Hayes *et al.*, 2021). Deviation of chronological age and the age estimated by the epigenetic clock can be used as a predictor of biological age, which in turn could be incorporated into animal selection decisions. More specifically, early selection of animals with a 'reduced biological age' could result in animals with improved longevity through resilience to stressors such as a changing climate (Clarke *et al.*, 2021).

Epigenetic markers captured by long-read ONT sequencing could be used in animal breeding schemes either as a heritable molecular phenotype (e.g. biological age) or used to estimate the epigenomic similarity between individuals to better account for their historic environments (Clarke *et al.*, 2021). There is evidence that the methylation data provided by an ONT machine is more sensitive than the gold-standard bisulfite sequencing (Hayes *et al.*, 2021), but sequencing full genomes for age prediction is still cost prohibitive. Adaptive sequencing (Payne *et al.*, 2021a) may be employed to enrich target regions and reduce costs.

Adaptive sampling can target multiple organisms simultaneously

Metagenomic sequencing has gained attention lately as way to predict individual performance. Rumen microbial community profiles have been associated with environmentally important phenotypes and have been shown to be able to predict individual performance (Hess *et al.*, submitted-a). Microbial abundance has also been shown to have a heritable genetic component (Hess *et al.*, submitted-b), suggesting the ability to make sustained progress by selecting on the abundance of certain microbes. Similarly, capturing a microbial profile at the site of infection could be used to characterize complex polymicrobial diseases, such as pneumonia and mastitis, better which may improve our ability to predict the genetic merit of an individual through the improved definition of the disease afforded by increased resolution of the pathogens responsible for disease.

Adaptive sampling (Payne *et al.*, 2021a) can be used to deplete or enrich specific regions of a genome, or certain species. It has been used to specifically enrich for specific species of interest (Martin *et al.*, 2021), as well as deplete genomic sequence that is expected to be at high prevalence in the sample (e.g. Ong *et al.*, 2022). Therefore, samples can be interrogated to simultaneously screen for microbes of interest, either because they provide a benefit (e.g. reduce the carbon footprint) or a detriment (e.g. cause more severe disease) to the animal.

Towards an integrated approach to data capture

High-throughput, robust, and cost-effective assays need to be developed to successfully investigate, establish, and incorporate multiple datatypes into routine genetic merit predictions. A single platform, such as ONT, that can generate multiple types of desirable information, including complex variation, methylation, and pathogen load, will reduce the cost and turn-around time to the producer. Furthermore, ONT sequencing is also portable, potentially allowing for rapid analyses to be performed on-site. Through

targeted sequencing using adaptive sampling, high-confidence genomic data can be produced for specific targets, with low-depth sequence data being produced outside of the target region. Because background sequencing will still be captured due to the sequencing process, low-depth WGS can be obtained on an individual with higher read support in specific regions of interest, allowing for genomic prediction using the same data. This should provide the sufficient information to make accurate selection decisions (Lamb *et al.*, 2021) while capturing other relevant information that can be used to provide molecular phenotypes or can be used as predictors. The ability to couple adaptive sampling with barcoding (Payne *et al.*, 2021b) has the potential to increase throughput and reduce costs while maximizing the information collected on an individual. However, the throughput that can be achieved and strategies to identify the most suitable candidates for this approach need to be addressed before integration into animal breeding practices.

Abstract

We scanned the genomic data of almost one thousand Evolèner cattle, representing the by far smallest local cattle population of Switzerland, whereof only pedigree records are available. A reverse genetic screen using 94k SNP markers in 585 trios mapped recessive deleterious loci using homozygous haplotype deficiency. We found two haplotypes, EH1 and EH2, with moderate allele frequencies of >0.10. Mining for candidate variants was carried out by linkage analysis of the predicted haplotype status and whole-genome sequencing variant catalogue of seven Evolèner bulls. This led to the detection of two perfectly linked missense variants affecting conserved residues: *GBE1*:p.Arg437Gln for EH1, and *LRRC8A*:p.Ala73Val for EH2. No homozygous animals were observed in >5,100 cattle of various breeds including Evolèner. The presented study showed that very limited data can lead to the identification of candidate variants and thereby help to improve reproduction success in an endangered indigenous breed of cattle.

Introduction

The name of the Evolèner (EV) breed originates from the village called Evolèner in the municipality Val d'Hérens in the Valais; however, genetically the breed evolved from the local Swiss breed Eringer (in French Hérens). EV cattle are characterized by their small body size and by white markings on their foreheads, while their basic coat colour ranges from red to black. The breeds current population is spread across Switzerland and includes 1,175 animals (Dec 31, 2021), of which 823 animals are registered in the herdbook (A. Barenco, personal communication), whereof a proportion of 44% is genotyped. Together with genotypes from previous generations, almost 1000 genotype records were available based on a public SNP array encompassing 150k markers.

Recessive lethal variants had been identified by mapping haplotypes showing significant deviation from the Hardy-Weinberg equilibrium (HWE) in population-wide single nucleotide polymorphism (SNP) array data and subsequent whole-genome sequencing (WGS) data analysis of selected individuals (e.g. Schwarzenbacher *et al.*, 2016; VanRaden *et al.*, 2011). Usually, this approach is applied on large, economically important populations, where the SNP data is generated under the umbrella of genomic selection. Therefore, it is more challenging for smaller populations to identify harmful recessive alleles that impair fertility. Recently, population-wide SNP genotypes have been generated within the framework of a national genetic diversity project aiming at conserving the EV breed. Even though the power for haplotype detection was limited due to the relatively small dataset, the trio-based approach applied allowed the identification of two haplotypes showing significant depletion in homozygosity and the associated candidate causal variants affecting genes important for reproductive success.

Materials & methods

Genotype and pedigree data was provided by the breeding organisation (swissherdbook) and included all genotyped EV cattle born later than 2009 as well as their ancestors. Altogether 964 genotype records were available based on a publicly available SNP array encompassing 150K markers. The genomic positions relate to the latest cattle reference sequence ARS-UCD1.2.

SNP data analysis. As the initial dataset included different batches, genotype data was imputed using Fimpute v3 software (Sargolzaei *et al.*, 2014) with default parameters. SNP data was pruned before imputation on animal and on marker level. Samples were used if the sample call rate was higher than 0.95. Marker were kept in the dataset if each of the following criteria were achieved: minor allele frequency >0.01, call rate per SNP>0.99, and <1% mendelian errors. The final dataset contained 94,345 markers and 964 animals. Imputed genotypes were screened for haplotypes showing a deviation from HWE by depletion of homozygosity in a dataset that includes complete trios (sire, dam and offspring; n=585). Thereby a 50 SNP sliding window approach with overlap within the software snp1101 was applied (Sargolzaei, 2014). Within each region the most significant haplotype that also passed the Bonferroni correction ($P<1.68E^{-4}$) was used for further analysis in WGS data.

WGS data. For each of the selected haplotypes, diplotypes were predicted for the genotyped population to represent an individuals' haplotype status. Aiming at three carrier animals selected per haplotype, five bulls were chosen for whole-genome sequencing. WGS data was prepared for these five samples and additional 196 available samples from other projects as previously described (Häfliger *et al.*, 2021; data published in the European Nucleotide Archive: PRJEB18113). Further genomic information was provided by the international consortium of the 1000 Bull Genomes project run 9, which included 5,116 animals from various breeds (Hayes and Daetwyler, 2019). Finally, the combined WGS dataset encompassed 5,317 genomes, including eight Evolèner cattle.

Variant interpretation. A linkage disequilibrium (LD) approach was performed to identify haplotype-associated variants in WGS data by using plink v1.9 (Purcell *et al.*, 2007). LD (r2) was calculated using the diplotype for each haplotype and WGS-derived protein-changing genotypes for seven EV animals that had both types of genomic information available. For improving the understanding of associated variants, the effects of the amino acid changes were estimated using PROVEAN (Choi *et al.*, 2012) and conservation scores PhyloP and PhastCons (Pollard *et al.*, 2010; Siepel *et al.*, 2005).

Results

With the above described approach two different haplotypes were identified that showed significant deviation from HWE: Evolèner Haplotype 1 (EH1), on chromosome 1 between the positions 29,769,321 and 30,160,645 and Evolèner Haplotype 2 (EH2) on chromosome 11 from 97,965,320 to 99,366,886. EH1 and EH2 were expected to be observed in homozygous state in the analysed dataset in 13 and 16 animals, respectively. The haplotype frequency for EH1 and EH2 in EV was estimated to be >0.1, while a positive or negative trend was not observed over the last 14 year of births. Table 1 provides a summary of the two identified missense variants that show perfect LD ($r^2=1$) with the haplotypes.

Firstly, the EH1-associated variant in *GBE1* shows high conservation scores at DNA level (PhyloP=7.4; PhastCons=1) and the predicted amino acid exchange is most likely deleterious (PROVEAN score=-3.7), as it is situated in the functionally important catalytic domain of the GBE1 enzyme (Figure 1A). Secondly, the EH2-associated genomic variant in *LRRC8A* is not highly conserved across species (PhyloP=0.19;

Table 1. Candidate causal variants for deficiency of homozygotes in Evolèner.

Haplotype	Gene	OMIM	Transcript[1]	Coding DNA change	Predicted protein change
EH1	*GBE1*	607839	NM_001122729.1	c.1310G>A	p.Arg437Gln
EH2	*LRRC8A*	608360	NM_001076807.1	c.218C>T	p.Ala73Val

[1] According to the NCBI Annotation Release 106.

PhastCons=0.002) and is predicted to be neutral (PROVEAN score=-0.49) on protein level, although the residue is located in the first extracellular loop of the LRRC8A protein (Figure 1B).

Both candidate variants were validated in 5,317 individuals with WGS data (Table 2). The EH1-associated *GEB1* variant could only be observed in EV animals, while the EH2-associated LRRC8A variant was observed in EV, as well as in Eringer and Gelbvieh cattle. These results lead to the conclusion that only the EH1-associated variant is breed specific, but both variants could not be observed in homozygous state in more than 5K animals.

Discussion

By applying a reverse genetic approach on a limited number of 595 completely genotyped trios, the SNP data of less than 1000 animals led to the identification of two homozygous deficient haplotypes, and the WGS data of seven animals pinpoint to two candidate causative variants. As far as we know, this is the first successful analysis based on such a limited dataset, concerning a small population for which not any phenotypic information is available. The EH1-related candidate variant in the essential *GBE1* gene, represents a most likely embryonic lethal mutation (Froese *et al.*, 2015). The gene is associated with the recessive, sometimes fatal, glycogen storage disorder type IV known in human, horse, and cat (OMIM: 607839; OMIA: 000420-9796, 000420-9685). Variants in the catalytic domain had been shown to destabilize the enzyme (Froese *et al.*, 2015). The exactly corresponding missense variant in the human *GBE1* gene is reported as rs770819412 and predicted to be likely disease causing; however, no homozygous variant carriers were observed and thereby no phenotype was assigned. These indications support our hypothesis, that we cannot observe

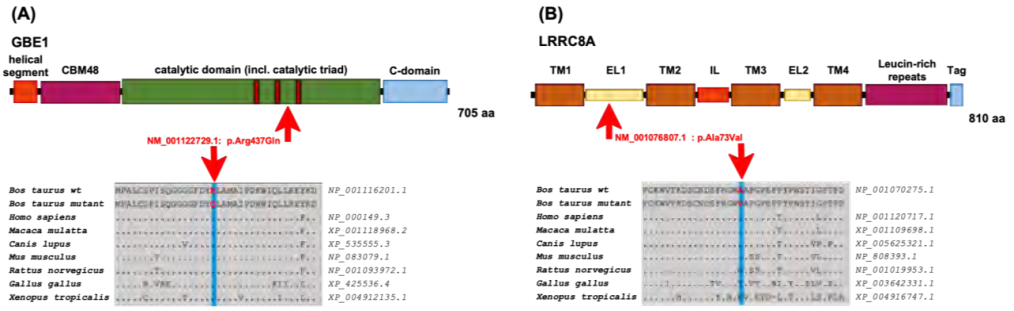

Figure 1. Protein domains and multiple species alignments of the amino acid sequences around the candidate variants. (A) The EH1-related variant in the *GBE1* gene (Froese *et al.*, 2015) and (B) the EH2-related variant in *LRRC8A* (Choi *et al.*, 2021). The abbreviated domains in LRRC8A mean transmembrane domain (TM), extracellular loop (EL), and intracellular loop (IL).

Table 2. Genotype distribution of the candidate variants in all whole-genome sequencing data, including Evolèner cattle.

	WGS data			
Variant	**ref/ref**	**ref/var[1]**	**var/var**	**./.**
EH1 (*GEB1*:c.1310G>A)	5,312	5	0	0
EH2 (*LRRC8A*: c.218C>T)	5,187	10	0	120

[1] Carrier animals of the EH1-associated variant are all of the breed EV; carrier animals of EH2-associated variant are of the breeds EV (4), Eringer (1), Gelbvieh (4), or unknown breed (1).

homozygous individuals or EH1-related cases, due to its embryonic lethal effect. The EH2-related candidate variant in *LRRC8A* gene, represents a likely candidate for a fatal postnatal phenotype. The protein is an essential compound of the volume-regulated anion channel, that maintains cellular homeostasis and is associated with the dominant disorder agammaglobulinemia 5 in human (OMIM: 608360; Choi *et al.*, 2021). In Lrrc8a knockout mice, increased pre- and postnatal mortality, growth retardation and tissue anomalies were observed (Kumar *et al.*, 2014). The extracellular loops were shown to be important oxidation sites during immune responses (Choi *et al.*, 2021). In conclusion, we identified two novel haplotypes and candidate variants potentially affecting fertility in the Evolèner population. Both protein-changing variants affecting candidate genes for developmental defects were never observed homozygous in more than 5,000 animals, and show perfect LD with the deficient homozygous haplotypes. Further steps include validation using farm questionnaires and *in vivo* data. Nevertheless, avoidance of risk matings can be immediately performed due to the ongoing comprehensive genotyping strategy in that population.

Abstract

This study has focused on detecting putative convergently evolved or selected sites in proteins of the northernmost Yakut cattle breed and a set of 12 hibernating, cold adapted, and deep diving mammals. A novel *de novo* assembled, and annotated Yakut cattle genome has been utilised as a reference. Over 8000 orthogroups have been identified and analysed with the *PCOC* software. After an additional filtering, 18 proteins were identified including a previously reported *nebulin related anchoring protein*. Twelve out of the 18 sites were present as SNPs in the 1000 Bull Genomes Project dataset of which five demonstrated high FST (>0.3) between the Yakut and other cattle breeds. Our results imply that convergent evolutionary events are rare between breeds and wild animals, but the same ancestral alleles could be selected in parallel in domestic animal breeds and wild species expressing similar phenotypes.

Introduction

Similar ecological niches lead to similar phenotypes and adaptions in different animals. In a few known cases there are convergent nucleotide changes involved in these adaptations in distinct species. Well-known examples include echolocation in whales and bats in mammals involving the same convergent amino acid mutation in the plestin protein (Liu *et al.*, 2014) and adaptation to different water light conditions in fish involving the same mutation in rhodopsin protein (Hill *et al.*, 2019). Our recent work on the northernmost cattle from Siberia (Yakut cattle) has revealed the phenomenon of convergent nucleotide evolution in breeds of domestic animals and wild species living in similar harsh environments and/or expressing similar phenotypes. We found the same amino acid change in a nebulin related anchoring protein (NRAP) in the northernmost cattle and 16 species of hibernating or entering torpor, cold-adapted, and deep-diving mammals which was absent in all other cattle breeds and other *Bovinae* species from the 1000 Bull Genomes project dataset (Buggiotti *et al.*, 2021). This change was occurred during the last 500-800 years and became nearly fixed in the Yakut cattle population. In the present work we extended the search for nucleotide convergent changes to the whole genome assembly and *de novo* annotated proteins of the Yakut cattle, proteins of 12 hibernating/cold-adapted/deep-diving mammals, and five species not expressing these phenotypes (outgroups). Our results have confirmed amino acid change in the *NRAP* gene and pointed to 17 additional genes with coding variants putatively selected in parallel in the northernmost cattle and wild animals.

Materials & methods

Sequencing the Yakut cattle genome. A Yakut cattle sample have been obtained from Juha Kantanen, Natural Resources Institute Finland (Luke), Finland. DNA was extracted using 100G Qiagen High Molecular DNA Kit. 10X Genomics sequencing has been done at Novogene, Cambridge. Assembly was generated using Supernova assembler on an HPC cluster. The 10x Genomics assembly was then merged with the Oxford Nanopore reads (~1X) using LRScaf (https://github.com/shingocat/lrscaf) to produce a hybrid Yakut cattle assembly. The scaffolds were further assembled into chromosomes using a reference-assisted approach (RagTag; https://github.com/malonge/RagTag) against the reference cattle genome (ARC-UCD1.2). Protein predictions have been done using GeMoMa software (v.1.7; http://www.jstacs.de/index.php/GeMoMa), using taurine cattle, indicine cattle, yak, bison, and buffalo gene annotations.

Species list and protein sequences processing. The following species and phenotypic groups have been used in the analysis: deep diving (*Odobenus rosmarus divergens, Physeter catodon, Eumetopias jubatus, Mirounga leonine),* hibernating (*Myotis brandtii, Marmota marmota marmota, Microcebus murinus, Chrysochloris asiatica),* cold-resistant *(Vulpes lagopus, Rangifer tarandus, Ovis nivicola, Ursus maritimus, Odobenus rosmarus divergens)* and outgroups (*Homo sapiens, Loxodonta africana, Canis lupus familiaris, Pteropus alecto, Bos taurus* (Hereford)). Coding sequences (CDSs) for all species have been downloaded from NCBI RefSeq or predicted with GeMoMa (v. 1.7). From the isoforms of the same protein the longest sequence has been used. The protein sequences have been obtained with PRANK (http://wasabiapp.org/software/prank/) using *-convert -translate* options from gff files. Orthogroups were identified with OrthoFinder (v. 2.5.2; https://github.com/davidemms/OrthoFinder) and additionally filtered to ensure each species had maximum one sequence in each orthogroup and each orthogroup contained ≥3 orthologous sequences, gaps were removed. Nucleotide sequences within each orthogroup were aligned with PRANK (v. 170703).

Detection of convergently evolving amino acid residues. PCOC method looking both at exact same amino acids changes and shifts in amino acid type preferences (Rey *et al.*, 2018) has been applied. For detection of the putative convergent changes between phenotypic groups the detection threshold has been set to 0.8. To identify convergent changes between the Yakut cattle and the ingroup species, all amino acids shared between the Yakut cattle and Hereford reference genome were filtered out.

Results

The hybrid (10X Genomics and Oxford Nanopore) Yakut cattle genome was assembled to N50=15.1 Mbp. A total of 3,805 scaffolds were ordered along 30 cattle chromosomes and the mitochondrial genome. The final Yakut cattle annotation contained 39,412 transcripts. Of these 22,323 were used in the analysis. A total of 8,939 orthogroups each containing one Yakut cattle transcript and the transcripts from at least 14 other mammalian species were generated.

The PCOC algorithm has been applied to the set of 8,939 orthogroups. After filtering for the number of species present in each ingroup and the outgroup, 18 putative convergent events were found in 18 genes. The largest number of putative convergently evolving amino acids with the Yakut cattle have been detected in the deep-diving animals (14), followed by hibernating (2) animals (Figure 1). This analysis did detect the previously found *NRAP* convergent change and identified putative events in 17 additional genes.

Comparison to the 1000 Bull Genomes (Run 9) variant database showed that *NRAP* event is indeed Yakut-cattle specific confirming its convergent formation. Four additional variants had FST>0.3 when Yakut cattle was compared to other taurine breeds, suggesting differences in allele frequencies between Yakut and taurine cattle and a higher frequency in Yakut cattle for the allele present in the deep diving, hibernating or cold adapted animals. This implies no convergent evolution but a parallel selection for the same ancestral amino acids in Yakut cattle and wild animals different from most other cattle breeds. The functional analysis of 18 genes containing convergent and selected in parallel changes revealed two genes previously found under selection in the Siberian human populations (*PLA2G4F* (FST=0.98) and *PAFAH1B2* (FST=0.01) (Hsieh *et al.*, 2017)), a gene involved in resistance to environmental toxicants (*FNBP4* (FST=0.63) (Zhu *et al.*, 2015)), genes involved in controlling the heart function (*NRAP* (FST=1.0) and *POPDC2* (FST=0.3) (Vasilescu *et al.*, 2018)), in regulation of blood pressure and insulin secretion (*SNX19* (FST=0.53) (Yang *et al.*, 2019)), and shortening of long bones (*WDR60* (FST=0.95) (McInerney-Leo *et al.*, 2013)).

Table 1. Genes with the convergently formed or selected in parallel amino acids in the Yakut cattle and deep diving, hibernating, and cold-adapted mammals (FST[3]0.3[1]).

Gene	Function	FST[1]	PCOC[2]
PLA2G4F	Lipid metabolism, cold adaptation	0.98	DD, HB
FNBP4	Resistance to environmental toxicants	0.63	DD
NRAP	Muscle contraction, heart function	1.00	HB
POPDC2	Heart rate	0.30	DD
SNX19	Blood pressure, insulin secretion	0.53	DD
WDR60	Long bone shortening, nervous system	0.95	HB

[1] Against the 1000 Bull Genomes project (Run9), taurine dataset.

[2] DD – deep diving animals, HB – hibernating animals.

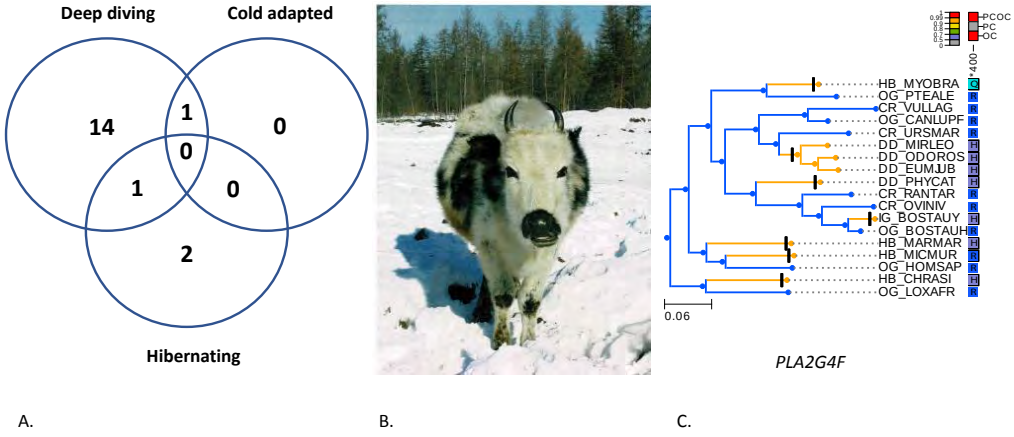

Figure 1. Analysis of convergent evolution and parallel selection in the Yakut cattle and mammalian species. (A) Number of convergently evolved and selected in parallel amino acids shared with three phenotypic groups and the Yakut cattle. (B) An image of the Yakut cattle. (C) Output of the PCOC algorithm for *PLA2G4F*. The histidine amino acid is present in Yakut cattle, deep diving (DD) and hibernating (HB) mammals, but not in Hereford (OG_BOSTAUH) and cold-adapted animals (CR).

Discussion

The aim of this study was to evaluate to what extent convergent nucleotide evolution has shaped the genome of the northernmost cattle from Siberia (Yakut cattle) utilising breed-specific *de novo* genome assembly and *de novo* protein annotations. In agreement with our previous study, we identified a missense mutation in *NRAP* which has occurred independently in Yakut cattle and the cold-adapted, hibernating, and deep-diving mammals (Buggiotti *et al.*, 2021). The current study has, however, pointed to a list of several additional genes which could have convergently evolving amino acid sites in the Yakut cattle and other animals. Five of these genes, however, had no SNPs in the 1000 Bull Genomes Project. Mutations in three of these genes were confirmed in 20 Yakut and other breed individuals aligned against our Yakut cattle assembly while two were transcript alignment artefacts. The fact that FST values for all three confirmed variants were <0.3 suggests that they could have a relatively minor effect on the Yakut cattle as a breed.

Our study has been successful in finding 12 additional mutations which were present in the 1000 Bull Genomes dataset. However, only five of these sites had a substantial difference in the allele frequency between the Yakut cattle and other taurine breeds ($FST^3$0.3). None of the mutations were Yakut-cattle specific, suggesting that these variants were likely selected in parallel in the Yakut cattle and mammals with similar phenotypes rather than occurred independently in the Yakut cattle and other mammals. Importantly, all Yakut cattle alleles were present in other *Bovinae* species (1000 Bull Genomes dataset) implying their likely ancestral origin. Yakut cattle alleles for two genes (*SNX19* and *POPDC2*) were more frequent in non-taurine *Bovinae* species than in cattle breeds.

Our study demonstrates that *de novo* convergent nucleotide evolution in breeds of domestic and wild species could be a rare phenomenon, in line with rare functional convergent nucleotide changes in different species, but the *parallel selection* for alternative ancestral alleles could be more widespread. The use of the population datasets is crucial to distinguish between a true signal and noise. Both the convergently evolving and selected in parallel alleles should be considered when studying the biology of wild animals and livestock breeds and designing the new generations of locally adapted livestock.

Abstract

The aim of this study was to search for mutations influencing immune response of sheep against *Mycobacterium avium* subsp *Paratuberculosis* within a region from 23 to 35 Mb on chromosome 20 previously detected in a nucleus flock of Sarda sheep. Functional annotation and association analysis of polymorphisms identified in the whole genome sequences of 56 animals and imputed into around 3,000 ewes were realized. Accurate imputation led to more precisely localize the quantitative trait locus between 23.77 to 25.83 Mb, in a known 'markers desert' of the OvineSNP50 chip. No significant variants showed functional effects on the genes mapping to this region, most of which belong to the major histocompatibility complex (MHC) II. However, we cannot exclude that such variants may reveal some functional meaning with the evolution of the assembly and the annotation of the sheep genome, especially in this region where accurate mapping of MHC genes is challenging.

Introduction

Paratuberculosis (PTB) is a contagious slowly developing disease, caused by *Mycobacterium avium* subsp. *Paratuberculosis* (MAP) that affects mainly ruminants, with adverse effects on animal welfare and productivity. No treatment exists and the benefits of vaccination are controversial. Genetic variability of susceptibility is documented (Sechi *et al.*, 2011; Küpper *et al.*, 2012) and several quantitative trait loci (QTL) or polymorphisms in candidate genes have been identified, especially in dairy cattle (Sanchez *et al.*, 2020). In sheep, genetic studies are fewer and often based on candidate gene approach or small size experiments (Moioli *et al.*, 2016). Thanks to a genotyped population of around 3,000 ewes with repeated records of serological Elisa tests against MAP antibodies, we were able to detect a genomic region on chromosome (OAR) 20 significantly associated to PTB resistance (Usai *et al.,* this congress). Full genomic sequences of 56 influential animals were available. The aim of this study was to further investigate this region by the functional annotation and association analysis of imputed polymorphisms to search for candidate genes and causative mutations.

Materials & methods

Whole genome sequences (WGS) were available for 56 animals from the experimental population genotyped with the OvineSNP50 chip. Twenty-four animals were resequenced with a coverage of 12X and 32 with a coverage of 30X. WGS data were processed with a pipeline implemented with Snakemake (Köster, 2018), and developed at CRS4 (Center For Advanced Studies, Research and Development in Sardinia https://www.crs4.it/)). The quality control was performed with FastQC (Andrews, 2010). Trimmed reads were aligned, using the BWA (v0.7.15) aligner (Li and Durbin, 2009), to the *Ovis aries* reference genome v4.0 (https://www.ncbi.nlm.nih.gov/assembly/GCF_000298735.2). Joint variant calling was performed using the GATK (v4.0.11.0) software (McKenna *et al.*, 2010). We focused on a large region on OAR20 (from to 23.12 to 35.13 Mb) surrounding the significant peak identified by linkage disequilibrium linkage analysis (Usai *et al.*, this congress). In this region, 217,248 single nucleotide polymorphisms (SNPs) were identified and imputed to the phenotyped ewes with 50k SNP data. The probabilities of carrying the reference allele (R) in the paternal ($P(h^p=R)$) and maternal ($P(h^m=R)$) gametes were predicted. First, gametes of sequenced animals were phased, on the base of the genotype information from sequencing and identity-by-descent

probability (IBD) between gametes at the neighbouring SNP 50k. Then, at each WGS polymorphism of the parental gamete, we inferred the probabilities of carrying R based on the gametic phase of sequenced animals and the IBD between gametes of sequenced animals with the phenotyped ewes (Usai *et al.*, 2019). Accuracy of imputation was assessed by 56 leave-one-out cross validations as the correlation for each left out animal between the allele dosage from imputation (calculated as $P(h^p=R)+P(h^m=R)$) and the allele dosage from sequencing. The association analysis was then ran by regressing the phenotypes on the allele dosage. The analysed phenotype was the status of the animals, defined as 'susceptible' if the animal had at least one positive Elisa test along the recording period. An F-test was performed to calculate the *P*-values of each tested position. Functional annotation of the WGS SNPs surrounding the most significant location was then performed using the NCBI 4.0 sheep genome annotation release 102 and the SnpEff software v4.3.t (Cingolani *et al.*, 2012). Finally, the genes with the most significant SNPs or with SNPs predicted to have HIGH impact or missense effect, annotated by orthology to human genes from the OrthoDB v10 data base, were analysed using the KEGG and gene ontology (GO) biological process terms data bases with the web-based software WebGestalt (Liao *et al.*, 2019).

Results

The accuracy of imputation ranged from 0.843 to 0.984 across animals (0.928 on average) with an average information content across gametes of 0.86±0.02 (from 0 for only 42 SNPs to 0.89). The most significant location ($-\log_{10}$(*P*-value)=20.2) was at 25,253,298 bp, 393 kb from the LDLA peak. We focused on the interval (23.77 to 25.83 Mb), empirically defined by the extreme bounds of genes with SNPs showing $-\log_{10}$(*P*-value)>15, that included 35,506 SNPs. SNPeff provided 167,562 effects: 10 and 77% concerned intergenic and intronic regions. The most significant variants ($-\log_{10}$(*P*-value)>15) were classified as modifier, since they were either intergenic or intronic. In particular, among the 20 most significant positions, 18 were intergenic between ELOVL5 (elongation of very long chain fatty acids protein 5) and LOC101108696 (SLA class II histocompatibility antigen, DQ haplotype D alpha chain-like) genes, one affected the fifth intron of LOC101106976 (glutathione S-transferase A4-like) gene and one was intergenic, between DQA (HLA class II histocompatibility antigen, DQ alpha 2 chain) and LOC101120871 (H-2 class II histocompatibility antigen, E-S beta chain-like). The most highly significant variants mapping within coding regions had only LOW impact on transcripts, being synonymous polymorphisms that affected the genes DQA, DQB (boLa class II histocompatibility antigen, DQB*0101 beta chain) and LOC101109492 (SLA class II histocompatibility antigen, DQ haplotype D alpha chain). Twelve and 383 variants were predicted to have HIGH or MODERATE impact effect on the multiple transcripts of several genes. The twelve HIGH impact variants were identified in stop codons or splice sites of BTNL2 (butyrophilin like 2), PKHD1 (PKHD1 ciliary IPT domain containing fibrocystin/polyductin), LOC101110277 (butyrophilin-like protein 1) and LOC101106976 (glutathione S-transferase A4-like) genes. However, all of them showed low significance ($-\log_{10}$(*P*-value)<5). DQA, BTNL2 and PKHD1 genes also harbour the most significant missense variants ($-\log_{10}$ (*P*-value)>9). Overall, 28 out of 31 protein coding genes in the interval harbour variants that showed HIGH impact, missense effect or high statistical significance.

Functional classification of these genes showed that the top ranked biological functions were all related to immune response processes: GO:0050852: T-cell receptor signaling pathway; GO:0060333: interferon-gamma-mediated signaling pathway; and GO:0019886: antigen processing and presentation of exogenous peptide antigen via MHC class II. Moreover, the top ranked KEGG pathway was Inflammatory bowel disease, a term that includes chronic gastrointestinal inflammatory disorders of humans such as ulcerative colitis and Crohn disease. Thirteen genes enriched this pathway, two of which encode for interleukins (IL17F and IL17A) and 11 for MHC class II molecules (DQA, DQB, LOC101108696, LOC101109220, LOC101109492, LOC101109747, LOC101119856, LOC105603927, OVAR-DRB1, OVAR-DRB3). All these 11 genes also enriched the three most represented GO processes.

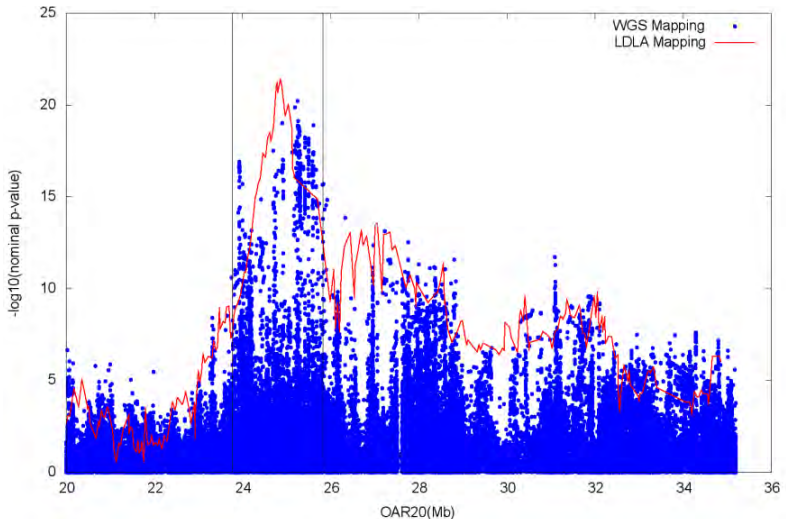

Figure 1. Test statistics profile of the LDLA analysis and Manhattan plot of the association analysis based on WGS data. Vertical grey lines define the interval investigated with the functional annotation.

Discussion

The initially investigated region (23.12-35.13 Mb) partially overlaps the region on bovine chromosome 20 where Sanchez *et al.* (2020) identified several significant SNPs in cattle. However, the candidate gene IER1 suggested by Sanchez *et al.* (2020), mapping between 27255853-27257183bp on OAR20 in Oar4.0 assembly, was far from the most significant position. The peak of the WGS association analysis falls in a known 'SNP desert' in the OvineSNP50 chip (Dicks *et al.*, 2021) where the MHC class IIa genes (DQA, DQB, OVAR-DRB1, OVAR-DRB3) are supposed to occur. Association between MHC alleles and susceptibility to MAP have already been suggested in sheep (Reddacliff *et al.*, 2005) and differential expression of MHC class II genes have been observed in experimentally infected (David *et al.*, 2014) or subclinically affected (Verschoor *et al.*, 2010) cows. MHC II genes are involved in both innate and adaptive immune system. Mutations that modify the expression of these genes or the ability to activate T cells have a systemic effect on the host, causing an inappropriate immune response that could change the course of the infection (Kravitz *et al.*, 2021). Although Gossner *et al.* (2017) did not evidence differential expression of MHCII genes in ileocaecal lymph node of ewes with paucibacillary or multibacillary PTB, Purdie *et al.* (2019) found a differential expression of MHC-II DQ alpha and beta genes in 'resilient' sheep. Combining association analysis with the functional annotation of SNPs within the target region was not able to identify causative mutations in this study. However, it cannot be excluded that highly significant variants located outside coding regions may reveal functional meaning with the evolution of the annotation of the sheep genome.

Abstract

Amyloid arthropathy in chickens is a type of AA amyloidosis with serum amyloid A (SAA) depositions in the knee joints of affected birds. The disease is triggered by bacterial infection, mainly with *Enterococcus faecalis*, and counteracted with the administration of antibiotics. Amyloid arthropathy has a serious impact on animal welfare and the laying hen industry. Brown layers are commonly affected whereas white layers are resistant to the disease. By comparing whole genomes of commercial lines of brown and white egg-laying chickens, we discovered a missense mutation in the SAA gene of white layers, which is predicted to cause an arginine to serine exchange at position 90 in the full-length protein. We cloned and overexpressed this SAA.R90S isoform along with the wild-type SAA in chicken hepatocellular carcinoma (LMH) cells, which will serve as a model system to investigate the influence of SAA-R90S on the molecular pathogenesis of amyloid arthropathy.

Introduction

Amyloid arthropathy is a disease in chickens caused by bacterial infection, in the majority of cases with *Enterococcus faecalis* (Landman *et al.*, 1998). A significant impact on animal welfare, contribution to the overuse of antibiotics, and as a result significant economic losses for the laying hen industry have been reported (Blanco *et al.*, 2016). The main characteristic of amyloid arthropathy is depositions of aggregated serum amyloid A (SAA) in large joints of affected animals (Landman *et al.*, 1998). This is most likely initiated by the release of SAA from the liver in large quantities during an acute phase response to bacterial infection (McAdam and, 1976, Morrow *et al.*, 1981). With white egg-laying chickens being resistant to the disease amyloid arthropathy mostly affects brown layers (Peperkamp *et al.*, 1997). It has been previously reported that no sequence variation in the *SAA* gene exists between the two chicken breeds (Ovelgönne *et al.*, 2001). Noteworthy, in that study, the *SAA* coding sequence of only one animal of each breed was sequenced. With this experimental setup, it is not possible to draw conclusions on the population scale. Consequently, past studies did not pay much attention to sequence variation in the *SAA* gene and rather focused on other aspects of the immune system. High CD8+ T cell counts in synovial tissue and peripheral blood were observed in challenged brown layers. On the contrary, an increase in T cell proliferation and macrophage activity was observed in white layers (Zekarias *et al.*, 2000). The severity of the disease was correlated with elevated levels of IL-1β, IL-6, and TNF-α (Sevimli *et al.*, 2008). Here we describe the discovery of a missense variant in the SAA gene that might confer disease resistance to white egg-laying chickens and present a cellular model system to study the impact of this mutation on the molecular pathogenesis of amyloid arthropathy.

Materials & methods

Variant calling from whole-genome sequencing data. Mapping and variant calling with GATK v. 4 (McKenna *et al.*, 2010) from whole-genome sequences of 25 white and 25 brown layers (BioProject PRJEB30270) were performed as described in our previous study (Falker-Gieske *et al.*, 2020) with genome version GRCg6a. Plink v. 1.9 (Chang *et al.*, 2015) was used to calculate FST values and variant effect prediction was performed with snpEff (Cingolani *et al.*, 2012).

Vector construction. A chicken SAA cDNA was isolated from chicken hepatocellular carcinoma (LMH) cells. Amplification of the cDNA was performed with Phusion High Fidelity DNA Polymerase (Thermo Scientific) with the primers GgSAA-*Nhe*I-F1 CTCATCgctagcATGAGGCTCTGTATCTGCTTCG and GgSAA-*Xho*I-R1: CTCATCctcgagGTATTTGTTAGGAAGTCCTGCGG (restriction sites in lower case letters). The cDNA was cloned into pJET1.2/blunt with the CloneJET PCR Cloning Kit (Thermo Scientific). The Q5 Site-Directed Mutagenesis Kit (NEB) was used to introduce the SAA mutation G270C (rs739601959). The restriction enzymes *Nhe*I and *Xho*I were used to clone the SAA and SAA-G270C cDNAs into pcDNA3.1(-) (Thermo Scientific).

Cell culture. To create stable cell lines, LMH cells were transfected with pCDNA3.1(-)-GgSAA-WT, pCDNA3.1(-)-GgSAA-G270C, and pCDNA3.1(-) (empty vector). Lipofectamine 2000 (Thermo Scientific) was utilized to introduce plasmid DNA into cells. For that cells were seeded at a density of 6×10^5 cells on a 6-well plate. After 24h the cells were treated with 2.5 µg of DNA with 15 µl of lipofectamine 2000. To select cells that stably expressed the plasmid vector cells were supplemented with 400 µg/ml G418 (Thermo Scientific) 48h post-transfection. The G418 concentration was lowered to 200 µg/ml after two weeks.

Real-time quantitative PCR. For RNA isolation 1×10^6 LMH cells were seeded on T25 flasks. After 48 h cells were processed with the RNeasy Mini Kit and QIAshredder columns (QIAGEN) according to the manual. The QuantiNova Reverse Transcription Kit (QIAGEN) was used to produce cDNA from 1 µg of RNA per sample. qPCR was performed with 10 ng of cDNA with the following primers: SAA forward primer CCATGCTCGTGGCAATTACG, SAA reverse primer CCTGAAGCGGTTGGGATCG, GAPDH forward primer ACTGTCAAGGCTGAGAACGG, and GAPDH reverse primer CATTTGATGTTGCTGGGGTC.

Results

To investigate the genetic basis underlying the difference in the susceptibility to amyloid arthropathy we performed a comparative analysis of 25 white and 25 brown layer genomes (Ni *et al.*, 2017). We calculated Wright's F_{ST} estimate via Weir and Cockerham's method for chromosome 5 since it harbors the *SAA* gene. The average F_{ST} for chromosome 5 was 0.355. We found several fixed variants in the SAA gene with F_{ST} values above 0.8 (Table 1).

Table 1. Fixation indices (F_{ST}) of variants located in the gene encoding chicken serum amyloid A in brown and white egg-laying chickens (values below 0.1 not shown).

Chromosome	Variant ID	Position (bp)	FST	Variant type
5	rs739601959	12686863	0.935	missense variant
5	rs312867488	12687022	0.857	intron variant
5	rs734537979	12687387	0.895	intron variant
5	rs16466917	12687415	0.918	intron variant
5	rs313607895	12687436	0.836	intron variant
5	rs314059120	12687544	0.857	intron variant
5	rs314828146	12687829	0.853	intron variant
5	rs15664672	12687908	0.849	intron variant
5	rs15664674	12687939	0.809	intron variant
5	rs15664676	12687944	0.809	intron variant
5	rs15664678	12687946	0.809	intron variant
5	rs16466918	12687989	0.836	splice acceptor variant
5	rs16466919	12688216	0.794	intron variant

The variant with the highest F_{ST} value (0.935) was the missense variant rs739601959 (GgSAA-G270C) in exon 4 of the *SAA* gene. Variant effect prediction revealed that this variant causes an arginine to serine amino acid exchange at position 90 (SAA.R90S) in the full-length SAA Protein. Although it was classified with a tolerable SIFT score of 0.4 we sought to further investigate this variant. The allele was not present in brown egg-laying chickens whilst 19 white layers were homozygous and three were heterozygous carriers. To create cell lines that stably overexpress SAA we cloned the SAA cDNA from a cDNA library that was prepared from LMH cells. We successfully introduced the GgSAA-G270C mutation by site-directed mutagenesis and sub-cloned both cDNAs into pCDNA-3.1(-) (Figure 1).

A total of seven stable LMH cell lines were generated by lipofection to overexpress the following constructs: pCDNA3.1(-) (LMH-empty-vector), pCDNA3.1(-)-SAA (LMH-SAA.WT pools 1-3) and pCDNA3.1(-)-GgSAA-G270C (LMH-SAA.R90S pools 1-3). Stable SAA expression was validated with qPCR and revealed comparable expression levels between SAA.WT (average $-\Delta Cq=3.64\pm1.15$, n=3) and SAA.R90S cell lines (average $-\Delta Cq=2.51\pm1.18$, n=3), whereas expression in SAA.WT cells was slightly higher.

Discussion

Currently, no other treatment than antibiotics is available to counteract bacteria-induced amyloid arthropathy outbreaks in chicken flocks. Since there is a clear difference between brown and white egg-laying chickens in disease susceptibility the underlying cause for brown layers to contract the disease is most likely genetic. In a comparative whole-genome approach, we discovered a fixed allele in white egg-laying chickens that might confer or contribute to their resistance to amyloid arthropathy. The genetic variant

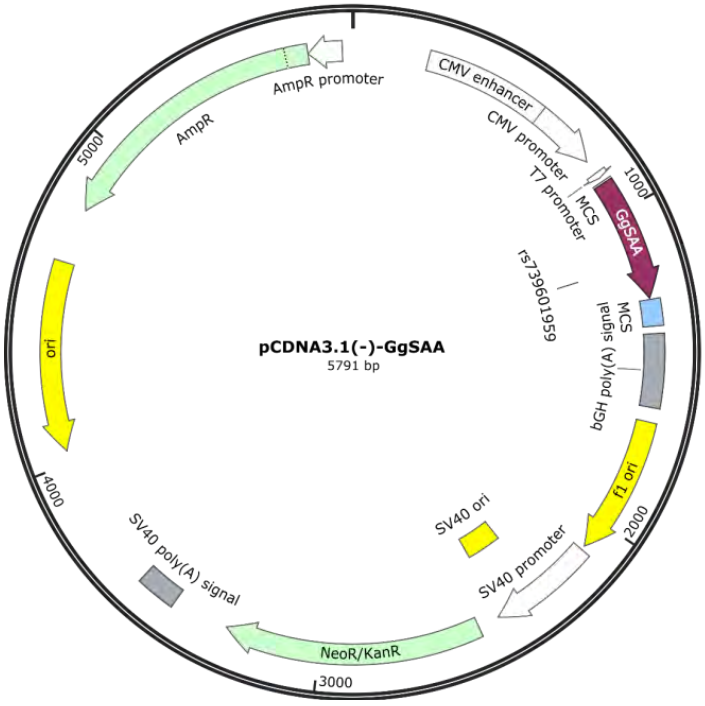

Figure 1. Vector map of the DNA plasmid used for stable overexpression of the wild type and R90S isoforms of serum amyloid A (SAA) in LMH cells. The SAA missense variant rs739601959 was introduced by site directed-mutagenesis.

rs739601959 is located in exon 4 of the SAA gene and leads to arginine to serine mutation at position 90 in the full-length protein. By creating stable chicken liver cell lines overexpressing the SAA.R90S and the wild type isoform we created a basis for the molecular characterization of this missense mutation regarding its potential function in amyloid arthropathy resistance. In humans, several variants have been correlated with lower SAA serum levels (Griffiths *et al.*, 2019). A similar effect might lead to lower SAA serum concentrations in white layers, which would explain the absence of SAA aggregates in their knee joints after challenging them with *E. faecalis* (Peperkamp *et al.*, 1997). Furthermore, variants of SAA1 in humans lead to different levels of SAA protein synthesis in the liver and other organs but also aberrant pathogen responses in the acute phase (reviewed in (De Buck *et al.*, 2016)). The functional characterization of the SAA.R90S isoform is currently ongoing work and involves immunofluorescent staining of cells, intra- and extracellular protein quantification of SAA, aggregation assays of recombinant SAA, and transcriptome analysis by RNA sequencing.

258. Genetic background of the porcine immune system using SNP chip data and whole genome sequencing data

C.M. Dauben[1*], C. Große-Brinkhaus[1], H. Henne[2], A.K. Appel[2] and E. Tholen[1]

[1]Institute of Animal Science, University of Bonn, Endenicher Allee 15, 53115 Bonn, Germany; [2]BHZP GmbH, An der Wassermühle 8, 21368 Dahlenburg-Ellringen, Germany; cdau@itw.uni-bonn.de

Abstract

Over the last years, there is a stronger focus on the porcine immune system in the context of animal welfare and health. Therefore, this study aims to improve the understanding of the genetic architecture of several components of the immune system and immunocompetence of piglets. SNP chip data and whole genome sequencing (WGS) data are combined to deepen the knowledge in a Landrace and Large White population. Animals for re-sequencing experiments were selected using a combined pedigree- and haplotype-based approach to enable the accurate imputation of genotyped animals from both populations to WGS level. Both breeds share the majority of biallelic variants (13.6 million), identified by WGS data. Additionally, 4.5 (Landrace) and 5.0 (Large White) million breed-specific variants were investigated. All these variants will be further used to characterize both populations with a special focus on immune relevant genomic regions and performing Genome-wide association studies with imputed WGS data.

Introduction

The porcine immune system and the implementation of immunocompetence are still a major challenge in pig breeding and production. From the piglets' perspective, immunocompetence is characterised by health and immune traits (e.g. Flori *et al.*, 2011).

A number of studies have shown the genetic foundation of several immune-related traits by estimating moderate to high heritabilities (e.g. Clapperton *et al.*, 2009; Flori *et al.*, 2011; Ponsuksili *et al.*, 2016). Until now, information on 34,342 quantitative trait loci (QTL) is stored in the AnimalQTLdb (Release 46, December 2021, https://www.animalgenome.org/cgi-bin/QTLdb/SS/summary) of which 3,639 are assigned to the immune capacity, 2,900 to blood parameters and 619 to disease susceptibility. A lot of these studies have investigated single nucleotide polymorphism (SNP) chip array-based data. A recent study indicated genomic regions of interest for haematological parameters, cytokines and haptoglobin in a Landrace (LR) and Large White (LW) population under non-challenging conditions (Dauben *et al.*, 2021).

In recent years, technologies in applied genomics have been constantly improved and marker density has increased. Especially the sequencing of a subset of animals and imputation of the population with low marker density to a higher density is a cost-saving and promising strategy to reveal genetic effects in pig breeding populations (e.g. van den Berg *et al.*, 2019).

The aim of this study is to improve the understanding of the genetic architecture of the porcine immune system in LR and LW by investigating health- and immune-related traits in piglets. Therefore, SNP chip data is combined with whole genome sequencing (WGS) data to obtain detailed insights into genomic regions of interest and imputed WGS (iWGS) data is further used in Genome-wide association studies (GWAS).

Materials & methods

Phenotypes and SNP chip data. Phenotypic data was recorded for 24 traits with a link to health and immunity in a total of 535 LR piglets and 461 LW piglets. Four of the traits were excluded from further

analyses due to low expression, resulting in a variation close to zero. Details are given in Dauben *et al.* (2021). Trait complexes and examples for specific traits investigated are listed in Table 1. Piglets were reared on farms of the German breeding organisation BHZP GmbH under high hygienic standards.

Blood and tissue samples were analysed using the PorcineSNP60v2 BeadChip (Illumina, San Diego, CA, USA). Genetic distances led to breed-specific analyses. Breed-specific quality control on autosomes was performed considering the call rate for individuals and markers (95%), minor allele frequency (MAF) (1%) and linkage disequilibrium was estimated in windows of 3 kb.

Genome-wide association studies – SNP chip data. Methods for GWAS using SNP chip data are described in the study of Dauben *et al.* (2021) in detail. In brief, the R-package GenABEL (Aulchenko *et al.*, 2007) with a generalized linear model was used to identify associations between SNP genotypes and phenotypic information on all parameters except for the cytokines, which were analysed with ASReml® (Gilmour *et al.*, 2015). Population stratification was adjusted with the Genomic Control approach (Devlin and Roeder, 1999). Multiple testing was taken into account by correction for a modified false discovery rate (Storey, 2002).

Whole genome sequencing (WGS) data. A subset of 57 (LR: 28, LW: 29) animals was selected for next generation re-sequencing. Selected animals are expected to represent the LR and LW populations with the overall aim of enabling an accurate imputation of SNP chip data to higher density. The selection process followed a combined approach of pedigree and genotype data under the restriction of practical conditions as a follow-up study within the pigFit project (Dauben *et al.*, submitted).

Whole genome DNA sequencing (Illumina HiSeq 4000) was performed in a paired-end approach with a read length of 150 bp. Quality control of raw data was performed using FastQC (https://www.bioinformatics.babraham.ac.uk/projects/fastqc/). Adapter clipping, trimming and quality thresholds were applied using Trimmomatic v.0.39 (Bolger *et al.*, 2014). Alignment to the reference genome *Sscrofa* 11.1 was performed using the Burrows-Wheeler Aligner (BWA, bwa version 0.7.17) (Li and Durbin, 2009), followed by identifying PCR duplications (Picard, https://broadinstitute.github.io/picard) and base quality score recalibration (GATK version v.3.8-1-0) (McKenna *et al.*, 2010). For variant calling, GATK v.3.8-1-0 (McKenna *et al.*, 2010) was used. Variants for further analyses were restricted to biallelic SNPs and variant filtering followed the filtering criteria QD<2.0, MQ<40.0, MQRankSum<-12.5, SOR>3.0 and ReadPosRankSum<-8.0.

Variant statistics and Annotation – WGS data. Handling of vcf files and the calculation of variant statistics, MAF and population parameters was performed with e.g. PLINK v.1.9 (Chang *et al.*, 2015, https://www.cog-genomics.org/plink/1.9/) and VCFtools (Danecek *et al.*, 2011). Annotation was performed using the Ensembl variant effect predictor (VEP version 105) (McLaren *et al.*, 2016).

Table 1. Phenotype measurements related to health and the immune system of piglets.

Complete blood count	Differential blood count [%]	Cytokines [ng/ml]	Acute phase proteins [mg/ml]
e.g.	e.g.	Interferon-γ	Haptoglobin
White blood cells [G/l]	Lymphocytes	Interleukins[1]	
Red blood cells [T/l]	Monocytes	Tumor necrosis factor-α	
Platelets [G/l]	Neutrophils		

[1] Interleukin (IL)-10, IL-12, IL-1β, IL-4, IL-6, IL-8

Imputation and Genome-wide association studies – WGS data. In ongoing steps, imputation of animals with 60k SNP chip data is performed to WGS level. Therefore, only variants on autosomes are used and imputation is performed using FImpute v3 (Sargolzaei *et al.*, 2014). Based on iWGS data, GWAS is going to be performed and results will be compared to that of GWAS using SNP chip data under consideration of the biological function.

Results

Genome-wide association studies – SNP chip data. GWAS on 17 immune relevant traits identified 477 breed-specific SNP markers in 535 LR and 461 LW piglets (Dauben *et al.*, 2021). Three traits did not show any significance. Results revealed highly informative genomic regions and candidate genes across the whole genome. In addition, putative pleiotropic effects were detected on *Sus scrofa* chromosome (SSC) 5, SSC12, SSC15, SSC16 and SSC17. Partly, regions are in accordance with QTL regions that were already published.

Preprocessing, variant calling and variant statistics – WGS data. In total, WGS data of 57 (LR: 28, LW: 29) pigs were available. Alignment was performed against the reference genome *Sscrofa* 11.1 and alignment rate was high (>99%) in both of the breeds. The overall coverage was 12.1 and varied across the chromosomes, but was consistently higher in LR. The highest coverage was observed on SSC16.

After filtering, 13.6 million variants were detected across the LR and LW populations. Additionally, 4.5 million (LR) and 5.0 million (LW) variants were exclusively detected in one of the breeds. In LR, 95.2% of all these variants were located on the porcine autosomes. In LW, this proportion was slightly lower (95.1%). Average distance between the detected variants on autosomes is 128 bp (LR) and 125 bp (LW) with clear chromosomal differences. The average Ts/Tv ratio across the whole genome was 2.33 and 2.32 for biallelic variants in LR and LW, respectively. Further investigations are ongoing.

Imputation and Genome-wide association studies – WGS data. First results indicate high variation of imputation accuracy across and within the chromosomes. In addition, higher-frequency variants (>5%) showed higher imputation accuracies, compared to low-frequency variants (<5%). In next steps, the detailed investigation of imputation results and GWAS on iWGS data will follow.

Discussion

Assuming haematological parameters and cytokines to have an effect as biomarkers of the immune reaction (Fossum, 1998; Ponsuksili *et al.*, 2016), our study has a focus on the underlying genetic background of these trait complexes.

The number of variants identified in this study is on a comparable level to previously reported results in commercial pig populations (e.g. Cai *et al.*, 2020). Investigation of variants is still in progress and detailed statistics will be worked out in further analyses steps. Especially variants within the splice region, stop gained or start and stop lost variants are of particular interest, potentially causing loss-of-function (Derks *et al.*, 2019). These variants will be further analysed in the context of breed-specificity and associations with immune-related parameters.

The LR and LW populations were already investigated regarding significant associations using SNP chip data (Dauben *et al.*, 2021). These analyses revealed highly informative and breed-specific regions, which are of interest with a putative link to immune-related parameters in piglets. In the next step, GWAS on iWGS data is performed to validate and further characterize regions of interest, associated with the porcine immune system. First results from imputation steps revealed regions with highly accurate imputed variants, depending on MAF. As expected from imputation steps using the SNP chip data to validate the composition

of the reference panel (Dauben *et al.*, submitted), the accuracy of some of the low-frequency variants was sufficiently high to be included in association analyses.

Abstract

Domestication events in livestock can be studied by comparing modern DNA with ancient DNA (aDNA) from archaeological faunal remains. Investigating the phylogeny history of sheep remains from the Neolithic Spanish site of Cova de Els Trocs, provides an opportunity to gain some insights about their origins. In this work, aDNA recovered from 15 ovine specimens dated between 6000 to 4000 years BP were sequenced by whole genome sequencing (WGS), and mapped against the *O. aries* modern mitogenome. Complete mitogenomes were restored for 12 ancient samples. Bayesian Inference (BI) and Maximum Likelihood (ML) phylogenetic trees fitting the HKY+G+I model were performed including the mitogenomes of 12 ancient and 74 modern sheep and 4 wild species. All Neolithic samples belong to the mitochondrial haplotype B. Four ancient sheep constituted a clade (89%) with the Viena sheep breed (Karelia), suggesting a complex demographic history of their origins.

Introduction

Archaeological evidence points to the Neolithic as the moment in time of sheep introduction in Europe along the Mediterranean and Danube routes (Zeder 2017). Although mtDNA studies of worldwide sheep breeds have provided some clues about the history of sheep domestication and dispersion, questions such as population colonization, demographic history and patterns of gene flow to Europe, Asia and Africa (Lv *et al.* 2015) are yet unsolved. Current advances in paleo-genetics and aDNA recovering techniques have allowed deepening into the genetic origins and dispersion of sheep breeds by comparing DNA sequences of ancient specimens with those of modern breeds. In this work, aDNA from 15 *Ovis* recovered in the site Cova dels Trocs (6000 to 4000 years BP) were sequenced and mapped against the *O. aries* modern mitogenome. A phylogenetic analysis including complete mitogenomes from 12 Neolithic and 74 modern sheep, and 4 wild species were performed to elucidate the origin of ancient specimens.

Materials & methods

Ovine fossil material, samples processing and DNA extraction and purification. Cova de Els Trocs, situated at above 1,500 m.a.s.l., on the Iberian central Pyrenees, is one of the few sites with a fully documented Neolithic stratigraphic sequence spanning from the 6th to the last third of the 4th millennium cal BC (calibrated years before Christ). In this site, a high number sheep remains have been recovered, revealing the great involvement in herding activities by the human groups from this territory (Tejedor-Rodríguez *et al.* 2021). Fifteen sheep jaws and maxillary from Cova dels Trocs (Huesca Spain), which came from three different occupation phases: 5 from T1 (5800-6100 years BP), 5 from T2 (5500-5800 years BP) and 5 from T3 (3900-4600 years BP years), was the available material. To minimize contamination with modern DNA, two DNA extraction replicates were performed by using new equipment and reagents in two independent laboratories. One of the replicates was used for WGS, while the other one for Sanger sequencing. All steps such as bone/tooth cutting and surface sanding, grinding and solutions preparation, and DNA extraction in sterile conditions, were carried out in separate places and times. Teeth roots were

crushed for 90 seconds at maximum frequency within a ball mill with liquid nitrogen in a mill MM400 (Retsch, Germany). DNA extraction were performed following a modified protocol of Huel (Huel *et al.* 2012). DNA purification was carried out with QIAquick PCR purification kit (Qiagen Inc. USA).

DNA libraries and WGS. Libraries for next-generation sequencing (NGS) were built with the aDNA extracts using the Accel-NGS Methyl-Seq DNA Library Kit and Uniq Dual Indexing kit (Swift Biosciences) following manufacturer's protocol. This kit is specially indicated for sequencing aDNA when retention of fragments containing uracil nucleotides, resulting from damage, is not desired. PrePCR and PostPCR labours were conducted in different spaces to avoid contamination. In order to validate methodology, 4 ancient samples were repeated by using Meyer libraries (Meyer 2010). Sequencing was performed on the Illumina NextSeq 550 platform to obtain between 11 and 62 million 75nt paired-end reads per library.

SANGER sequencing. Twelve overlapping amplicons were amplified, assembling a total length of 4000 bp of the mtDNA after Sanger sequencing (positions 1 to 1,079, and 13,696 to 16,616 of the NC_001941.1 sheep mitochondrial genome). Amplicon sizes varied between 395 and 679 bp. As for WGS, PrePCR and PostPCR were performed in different labs.

Ancient DNA authentication; reads processing, mapping and variant calling. Sample reads were trimmed of adapter sequences and low quality bases by AdapterRemoval v.2.3.1 (Schubert *et al.* 2016) and mapped to the sheep mitochondrial genome (NC_001941.1) using BWA v. 0.7.17 (Li and Durbin 2009). Duplicates were removed with Picard Tools, and the genome coverage was estimated by Samtools v.1.10 (Li 2011). MapDamage 2.0 (Jónsson *et al.* 2013) was used to evaluate fragment lengths and nucleotide misincorporation patterns. Two different algorithms were used to produce the VCF files for mitochondrial positions: bcftools mpileup and GATK UnifiedGenotyper (DePristo *et al.* 2011). All the mutations reported were visually inspected in the Biomatters IGV software v2.3.66 (Robinson *et al.* 2011) to rule out artefacts due to misincorporations in low coverage regions. Finally, Samtools v1.10 was used to create the consensus sequence for all the samples.

Phylogenetic Analysis. Complete mtDNA sequences from Neolithic, modern and wild sheep were aligned using the Clustal Ω program. Evolutionary models were tested with MEGA-X. BI phylogenetic tree was constructed with MrBayes v3.1.2 using the Hasegawa-Kishino-Yano HKY+G+I model, running 4 simultaneous Markov chains for 20 million generations starting from a random tree. Sampling frequency was set to 1/500 discarding as burning the first 25% trees. Bootstrap values for the ML tree were generated with 1000 replicates using MEGA-X.

Results

Twelve of the 15 samples available yielded enough aDNA for sequencing. Table 1 shows average results of aDNA sequencing. MapDamage shows classical patterns of post-mortem damage in Neolithic samples, such as 5' C*T deamination and T missincorporations. However, 3' G*A deamination could not be detected due to the Adaptase technology used in the Accel-NGS Library Kit, which adds a low complexity polynucleotide tail to the 3' end of each fragment. The final mitochondrial fragment length of the Neolithic samples after correction and trimming was 16,616 bp (positions 1 to 16,616 of the sheep mitogenome).

Alignments of nucleotide sequences obtained by Sanger and WGS showed 100% identity, indicating that no contamination occurred in the aDNA extraction and amplification processes. Phylogenetic analysis (Figure 1) assigned the 12 ovine ancient samples to the mitochondrial haplotype B. No clustering was found between the aDNA samples based on their chronology. The distance matrix of Hamming dissimilarity showed that Neolithic sheep from Trocs were very close to Finnsheep, Lacaune, Rasa Aragonesa and Finn-

Dorset breeds. Phylogenetic tree shows that 4 samples from Trocs formed a clade with the Viena sheep breed (Karelia, Russia).

Discussion

Accel-NGS Library Kit is suitable to work with aDNA, however its particular chemistry does not allow detecting in an optimal way the post-mortem damage patterns. However, by using Meyer libraries, both deamination patterns, 5' C$^{\circledast}$T and 3' G$^{\circledast}$A, could be detected. Ancient fragment lengths were longer than the average ~55 bp expected (Skoglund *et al.* 2012), probably due to the good preservation conditions of the Trocs cave. The small distance of all Neolithic samples from Trocs to Finnish breeds suggest a North European origin. Four Neolithic samples constituted a clade with an 89% of posterior probability with the Viena sheep, and ancient breed from Karelia, Russia (Meadows *et al.* 2005). In 2006, Tapio *et al.* found the haplotype A in the old native breeds of Nordic Countries and Russian Karelia, suggesting a previously unrecognized migration of sheep to northern Europe through Russia. This fact could indicate that some of the specimens found in Trocs, could have an origin in sheep populations that migrated to northern Europe, despite they exhibit the B haplotype.

260. Prioritisation of variants from whole-genome sequence data for validation of their association with traits of interest

E. Molinero*, R.N. Pena, J. Estany and R. Ros-Freixedes

Departament de Ciència Animal, University of Lleida, Agrotecnio-CERCA Center, 25198 Lleida, Catalonia, Spain; eduard.molinero@udl.cat

Abstract

Whole-genome sequencing is a powerful tool for identifying genetic variants associated to complex traits. However, the large number of variants in linkage disequilibrium hinders the identification of relevant variants. The aim of this study is to assess if the prioritisation of variants from sequencing data of a reduced number of animals using sequential multi-layer criteria (association analysis, fixation index, predicted variant effect, and gene ontology) is a suitable strategy for identifying variants associated with traits of interest that can later be validated in a larger number of individuals. Using data from 205 pigs, we have designed a custom genotyping array with 240 variants from 193 candidate genes that will be validated in a larger number of pigs (~1000) to quantify the validation rate of this discovery-preselection-validation strategy and define which criteria are the most informative.

Introduction

Whole-genome sequencing is a powerful tool for dissecting the genetics that underlies complex traits because whole-genome sequence data include rare and population-specific variants, including causal variants. The identification of variants associated with complex traits not only contributes to a deeper knowledge of biological and physiological processes, but also has implications for the genetic evaluation of selection candidates. Such variants could increase the accuracy of gene-assisted or genomic predictions, which would in turn increase the rate of genetic gain per unit of investment in the breeding programs (vanRaden *et al.*, 2017), as well as increase the persistence of prediction accuracy across generations and across breeds (Iheshiulor *et al.*, 2016). Nevertheless, due to the large number of variants in linkage disequilibrium, the challenge resides on identifying relevant variants, ideally the causal ones, or representative tag variants. Across livestock species, many variants have been described as associated with a wide range of traits of interest, but in practice few of them have been properly validated and there is still much genetic variance left unexplained. The integration of genomic data with other omics data has been explored as a strategy to enhance the identification of causal variants (Flitman *et al.*, 2021; Mountjoy *et al.*, 2021).

In pigs, we have previously identified and validated two variants in the *LEPR* and *SCD* genes that affect fat content and composition (Ros-Freixedes *et al.*, 2016). With the purpose of identifying additional variants associated with those traits, we designed a strategy based on the sequencing of a small number (205) of pigs for variant discovery, the preselection of a large number (240) of variants according to sequential multi-layer criteria, and then the validation of the preselected variants in a much larger (~1000) number of samples from a referenced biobank. The aim of this study is to assess, using the fat content and composition traits as a model, if this discovery-preselection-validation strategy is suitable for identifying additional variants associated with complex traits and to test which criteria are the most effective.

Materials & methods

Animals and phenotypes. We sequenced 205 Duroc pigs of the same line, born from 123 sires and 188 dams. Pigs were grown in 14 batches from 2002 to 2019 complying with a common data recording and tissue sampling protocol (Ros-Freixedes *et al.*, 2016). The animals were raised from 75 days of age until slaughter at 210 days under similar commercial conditions. All pigs were slaughtered in the same abattoir, where

carcass weight, backfat thickness and loin thickness were recorded using and on-line ultrasound automatic scanner (AutoFOM, SFK-Technology, Denmark). We collected samples of *gluteus medius* muscle. The intramuscular fat content and fatty acid composition were determined by quantitative gas chromatography. Fatty acids were expressed as percentages relative to total fatty acid content. The proportion of individual and total saturated, monounsaturated, and polyunsaturated fatty acids were calculated.

Sequencing and variant discovery. We isolated genomic DNA form the *gluteus medius* muscle for sequencing on NovaSeq 6000 (Illumina, San Diego, CA, USA) in paired-end mode. The average realized sequencing coverage was 7.9x. We mapped the reads to *Sscrofa11.1* reference genome (GenBank accession: GCA_000003025.6) and we called SNPs and indels. We focused the analyses on the variants with call rates above 0.9 and with minor allele frequency equal or greater than 0.20, so that all genotypes were sufficiently represented in the 205 pigs, by using PLINK1.9 (Chang *et al.*, 2015). Although variants in non-coding regions can have regulatory functions (Koufariotis *et al.*, 2018), we focused on variants located in the transcribed region of the genes, defined here to include introns and the 500-bp upstream untranslated region, because it is difficult to predict the effect of variants in non-coding regions based on the DNA sequence alone.

Prioritisation of variants. Using the data of the 205 sequenced pigs, we assessed the association of the variants with carcass backfat thickness and intramuscular fat content and fatty acid composition in *gluteus medius* muscle using GEMMA 0.96 software (Zhou and Stephens, 2012) to fit a univariate linear mixed model accounting for a genomic relationship matrix. Phenotypes were adjusted for fattening batch (14 levels), the *SCD* genotype (3 genotypes), the *LEPR* genotype (3 genotypes), and the slaughter age. The genotypes for *LEPR* and *SCD* were included in the model because of their major impact on the studied traits (Ros-Freixedes *et al.*, 2016). Also, we calculated the fixation index (F_{ST}) for each variant and trait using two subsets of 40 pigs that included, respectively, the individuals with the highest and the lowest phenotypic values of the trait. We selected variants with F_{ST} greater than 0.15. Candidate variants were examined for their predicted variant effect using the Ensembl VEP tool (McLaren *et al.*, 2016). Finally, we identified all genes from the Ensembl database that had been annotated with at least one gene ontology term that is putatively related to the trait or to some underlying biological process. The set of tested variants was sequentially refined based on the association analyses results, F_{ST}, predicted variant effect, and gene ontology.

Results

We called a total of 19,046,451 variants across the 205 pigs, of which 7,379,521 variants passed the filters on minor allele frequency and call rate, and, of these, 3,159,752 were located in the transcribed region of 12,835 annotated genes. This was the set of variants that was refined sequentially based on the association analyses, F_{ST}, predicted variant effect, and gene ontology. Based on gene ontology terms, 875 of these genes (which contained 179,974 of the latter variants) were related to processes potentially involved in body fatness, fatty acid composition or feed intake regulation, among others (here referred to as 'fat-related genes').

As a result of the association analysis (significance threshold of 10^{-6}), we detected 108 associated variants in 16 genes. However, most of these variants were predicted to be intronic or in genes without any gene ontology terms related to our target traits (Table 1). Nonetheless, two of those genes (*EFR3A* and *IL18BP*) were located in quantitative trait loci associated with fat deposition and fatty acid composition that had been previously described. Due to the limited sample size used and the polygenic nature of the traits, we used a less stringent significance threshold as a first step in the prioritisation of the variants. With a significance threshold of 10^{-4} we detected 5,220 variants in 516 genes, of which a small subset were missense variants or variants located in fat-related genes.

Table 1. Number of variants and genes prioritised using the four criteria[1].

Predicted variant effect[2]	Missense variants			Exonic variants			Variants in transcribed region		
P-value[3]	10^{-6}	10^{-5}	10^{-4}	10^{-6}	10^{-5}	10^{-4}	10^{-6}	10^{-5}	10^{-4}
No. of variants in annotated genes	0 (0)	1 (1)	15 (5)	0 (0)	14 (3)	143 (28)	108 (33)	772 (239)	5,220 (1,248)
No. of variants in fat-related genes	0 (0)	0 (0)	1 (0)	0 (0)	0 (0)	15 (3)	0 (0)	9 (7)	129 (39)
No. of annotated genes	0 (0)	1 (1)	12 (5)	0 (0)	10 (2)	82 (20)	16 (14)	91 (52)	516 (191)
No. of fat-related genes	0 (0)	0 (0)	1 (0)	0 (0)	0 (0)	8 (3)	0 (0)	4 (3)	28 (12)

[1] Results from the association analysis are shown in columns for three significance thresholds (*P*-value). Within parentheses, number of significant variants (and genes that contain them) with F_{ST}>0.15. Results by predicted variant effect and gene ontology-based class are shown by columns and rows, respectively.

[2] Exonic variants include variants located in exons and 5'-UTR, 3'-UTR of the gene, while the 'transcribed region' also includes introns and 500 bp upstream the untranslated region.

[3] Significance thresholds used for the association analyses. Number of variants (and genes that contain them) with an association below the specified significance threshold for at least one of the tested traits.

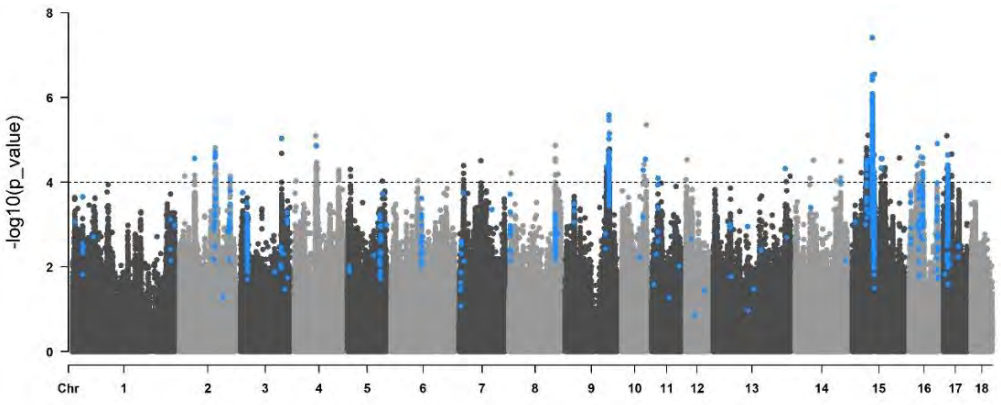

Figure 1. Manhattan plot for the trait with the strongest associations. In grey, the results of the association analysis. In blue, variants with F_{ST}>0.15.

As expected, the F_{ST} mean was close to zero because we calculated it between two subsets from the same population that diverged for a single trait. However, 9,598 variants in 706 genes had F_{ST} values greater than 0.15, of which, 219 variants in 41 genes had gene ontology terms related to our traits of interest. When comparing the results from F_{ST} and the association analysis, we observed that the overlap between both methods was far from complete but that the most relevant signals were captured by both (Figure 1).

Discussion

By sequentially refining a large set of variants from whole-genome sequence data using multiple layers of information (association analysis, F_{ST}, predicted variant effect, and gene ontology), we were able to preselect multiple candidate variants. It has been previously demonstrated that population statistics are efficient criteria for preselecting trait-relevant variants since the F_{ST}-based method, for example, is capable to differentiate weak associations from the spurious ones (Ling *et al.*, 2021). In our case, by using both association analyses and F_{ST} were we able to narrow down not only the candidate variants but also the candidate genes that contained them, particularly when using less stringent significant thresholds for the association analyses. A limitation of our strategy is that due to the limited number of sequenced animals,

we could detect only variants with high minor allele frequency and missed variants with lower minor allele frequency that could have larger effects. We did not consider variants located in non-coding regions, although they can have regulatory functions (Koufariotis *et al.*, 2018). Also, we relied on currently available functional data (like gene ontology), which can be incomplete or inaccurate.

Both *SCD* and *LEPR* appeared as the strongest candidate genes when we did not correct for their effects in the model. This can be interpreted as another evidence of the reliability of this strategy for variants with strong effects. However, the situation is more complex when targeting additional variants with weaker effects. A gene that ranked highly and was preselected using this strategy was *AGPAT5*. We have already validated a missense mutation from this gene in over 1000 animals with an effect on intramuscular fat content and fatty acid composition (Molinero *et al.*, 2021). Using the criteria described here we have designed a custom genotyping array with 240 variants from 193 candidate genes that will be used on ~1000 pigs from our biobank to quantify the validation rate of this whole discovery-preselection-validation strategy and to define which criteria are the most informative.

Abstract

Genome-wide association studies and genomic prediction for several pork carcass and meat quality traits were performed for 1,377 purebreds (PBs) and 954 crossbreds (CBs) using both whole-genome sequence (WGS) and medium-density panels. More associated regions were detected for traits in PBs than in CBs. WGS identified a small number of novel genomic regions in the PBs including three genomic regions for belly bend on chromosomes (SSC) 7, 8 and 13, two for muscle PH (SSC2 and 6), a different region on SSC2 for fresh loin Minolta b*(FMCOL), and one SSC10 for FMCOL Minolta L*. For both within- and between-population predictions, WGS did not improve prediction accuracy compared with a medium-density panel, except for slight improvement for some traits.

Introduction

Pork quality is an economically important trait in the swine industry, and it is one of the main breeding objectives in today's pig breeding programs. Moderate to high heritability of carcass and meat quality traits shows that in addition to the environmental factors, genetic factors control pork meat quality traits (Miar *et al.* 2014). Understanding the complex genetic mechanisms underlying carcass and meat quality traits will support the genetic improvement of these traits. Validated genomic regions can be used in genomic selection schemes to increase selection accuracy and potentially reduce generation interval, particularly in multi-population or across-population genomic evaluations which are applicable in swine breeding programs with crossbreeding schemes to accelerate genetic gain.

Whole-genome sequence (WGS) is expected to improve identification of associated regions (either extending candidate regions or identifying novel regions), because all of the causative single nucleotide polymorphisms (SNPs) are expected to be included. The variance associated with low frequency causative SNPs is expected to be captured using WGS. Our main objectives were therefore to investigate whether the use of WGS will detect novel associated regions in pigs compared with lower density panels. We also investigated how much genomic prediction accuracy is gained with WGS compared to medium-density panels for meat and carcass traits.

Materials & methods

Data. The total number of pigs with both imputed WGS genotypes and phenotypes was 1,377 for purebreds (PBs) and 954 for crossbreds (CBs, three-way cross Duroc-Landrace-Yorkshire). Imputation (using Beagle V5.0) from a medium-density marker panel (50K or 60K) to WGS was based on the sequence from 215 pigs from multiple breeds (Duroc, Large White, Maxter Pietrain). SNPs with the following features were excluded from both imputed WGS and medium-density panels: minor allele frequency <0.01, genotype call rate <0.95, and duplicated or unknown map positions on reference genome (Sus scrofa 11.1). Moreover, imputed genotypes were filtered based on the imputation reliability (cut-off threshold <0.8). After filtering out SNPs with low imputation accuracy, the average imputation accuracy (allelic DR^2 produced by Beagle) was 0.918 for ~10 million SNPs across the autosomes of CBs, and 0.955 for ~9.5 million SNPs of PBs.

CC BY

DOI: 10.3920/978-90-8686-940-4_261, © M. Heidaritabar *et al.* 2022

Meat and carcass quality traits included 15 meat colour traits (Minolta L*, a*, and b* for fat (FCOL)[1], and fresh ham gluteus medius (GMCOL), quadriceps femoris muscle (QFCOL), ham iliopsoas muscle (ICOL), and loin longissimus dorsi muscle (FMCOL)), peak shear force (PSF), fresh loin muscle PH (PH), drip loss (DL), marbling score (MS), and several belly traits. Our analyses were conducted for CBs, PBs, and combined CBs and PBs.

Association analysis. The model used for GWAS was a single marker mixed linear association model implemented in GCTA (Yang *et al.* 2014):

$$y = 1\mu + Zu + g + e \quad (1)$$

where y was the vector of phenotypic records (corrected for significant fixed effects such as sex, slaughter date, birthdate). u was the additive effect of the SNP to be tested for association, Z was a vector containing the SNP genotype coded as 0, 1, and 2. g was a vector of random polygenetic effects, and e was a vector of random residual effects. It was assumed that $g \sim N(0, G\sigma_g^2)$ and $e \sim N(0, I\sigma_e^2)$, where σ_g^2 and σ_e^2 were the genetic and residual variances, respectively. G was the genomic relationship matrix based on genotypes. For all traits, we defined the quantitative trait loci (QTL) regions according to the definition described by van den Berg *et al.* (2019): Firstly, SNPs on each chromosome were ranked based on their -log10 *P*-values. Secondly, starting with the SNPs with the largest -log10 *P*-value, all significant SNPs that exceeded the FDR of 10% and surrounding SNPs within a 0.5 Mb region to the left and right of the SNP were assigned to that particular QTL region.

Genomic prediction. For each population, the youngest pigs formed the validation population, which included 177 for PBs and 111 for CBs. The breeding values of the validation animals were predicted using the results from the oldest animals used as the training population. Accuracy was assessed as the correlation between corrected phenotypes and estimated breeding values divided by the square root of heritability for each trait. Predictions were based on genomic BLUP. Different prediction scenarios were assessed in order to find the optimal genomic selection scenarios to maximize accuracy. Prediction scenarios included: within CBs and within PBs; between-population predictions: (1) prediction of CBs using PBs or combined CBs and PBs; (2) prediction of PBs using CBs or combined CBs and PBs.

Results & discussion

Genome-wide associations. Of the 15 colour traits, we did not detect significant regions for most traits, regardless of panel density. Generally, more associated regions were detected for traits in PBs than in the CBs, and WGS identified only a small number of novel genomic regions in the PBs (Table 1). Moreover, across all datasets (for pork colour traits), we identified more QTL regions with WGS (n=58) compared with medium-density SNP panels (n=22). However, the added value of WGS compared with the medium-density panels was more for detecting extended QTL regions compared with SNP panel arrays, and not for detecting novel QTL regions. For non-colour traits, associated regions were found for PSF (CBs) and PH (both CBs and PBs), and marbling score (PBs). For PSF, PH, and MS, the most pronounced associated region, detected by both panel densities, were on SCC2, SCC15, and SCC1, respectively. When the combined dataset was used for GWAS for pork colour traits, many more QTL regions (11 for medium-density panels and 37 for WGS) were identified for FMCOL Minolta a*, FMCOL Minolta b*, GMCOL Minolta b*, and ICOL Minolta b*, compared with single population GWAS. This suggests that the added value of WGS was more in detecting novel regions compared with medium-density SNP panels when larger

[1] Each of the 5 colors (FCOL, FMCOL, GMCOL, QFCOL, ICOL) has 3 Minolta (L*, a*, b*) values (in total, 15 color traits.)

reference populations are available. This could be because with the larger sample size, the effect of causative mutations on polygenic quantitative traits might be estimated more accurately. Most of the identified QTL regions were also reported in other GWAS studies that used the same colour traits (Zhang *et al.* 2015; Yang *et al.* 2017). The most significant QTL region reported by Zhang *et al.* (2015) was located on SSC15 spanning 133 to 134 Mb which explained 3.51 to 17.06% of genetic variance for PH and some colour traits such as FMCOL Minolta a* (Figure 1). This region is very close to the previously reported gene *PRKAG3* controlling both meat PH and colour in pigs. This region on SCC15 was identified by both densities and the three datasets (CBs, PBs, and combined data). Our results provide additional insights for the genomic regions affecting meat and quality traits. However, overall the use of WGS for GWA studies was relatively disappointing in terms of the identifying new QTL, most likely due to power issues.

Genomic prediction. Simulations showed that if variation from causative variants can be captured with WGS, and exploited in genomic prediction, accuracy may be increased by 2-30% (Druet *et al.* 2014). Nevertheless, in this present study, there was generally no additional gain in prediction accuracy of pig carcass colour traits using WGS over medium-density panels for both within and across population scenarios. Moreover, pre-selection of the variants based on significant variants detected by GWAS did not improve accuracy of the predictions (results not shown).

Within population predictions. For within PB genomic prediction, WGS did not provide more accurate breeding values with the exception of QFCOL Minolta b* (from 0.26 to 0.29) and ICOL Minolta b* (from 0.31 to 0.37). Within CB genomic prediction, the use of WGS did not improve the prediction accuracy with the exceptions of FCOL Minolta b* (increase from 0.10 to 0.12) and QFCOL Minolta L* (from 0.22 to 0.23).

Between population predictions: prediction of CBs. When PBs were used as training for predicting breeding values of CBs, using WGS more accurate breeding values were found for FCOL Minolta a* (from 0.15 to 0.28), ICOL Minolta b* (from 0.49 to 0.54), ICOL Minolta L* (from 0.25 to 0.35). Using combined CBs and PBs as training for CB predictions, the improvement in prediction accuracy was only observed for FCOL Minolta a* (from 0.59 to 0.62), FMCOL Minolta b* (from 0.11 to 0.14), FMCOL Minolta L* (from 0.04 to 0.10), GMCOL Minolta b* (from 0.20 to 0.31), and ICOL Minolta L* (from 0.19 to 0.24).

Between population predictions: prediction of PBs. When CBs or combined CBs and PBs were used as training for PB predictions, WGS did not improve accuracy of predicting breeding values compared with a medium-density panel, except for slight improvement in prediction accuracy for some of the pork colour traits. Possible reasons for the lack of improvement when WGS is used over the medium-density panels include the following: (1) with small number of individuals in the training population, effects of QTL may be estimated with large errors (Druet *et al.* 2014); (2) in the case of within-population, long extension linkage disequilibrium may prevent the precise localization of quantitative trait nucleotides when all sequence variants are fitted simultaneously (van Binsbergen *et al.* 2015); and (3) many different linear combinations of variants may exist and result in equally accurate genomic predictions for the same set of

Table 1. Novel genomic regions detected by WGS in PB pigs.

Trait	Genomic region in Mega base pairs (Mb)
FMCOL Minolta b*	SSC2 (142.79-144.77)
FMCOL Minolta L*	SSC10 (38.12-38.28)
PH	SSC2 (146.65-147.87), SSC6 (168.26-168.33)
Belly bend	SSC7 (111.48-118.67), SSC8 (124.05-124.13), SSC13 (110.97-123.61)

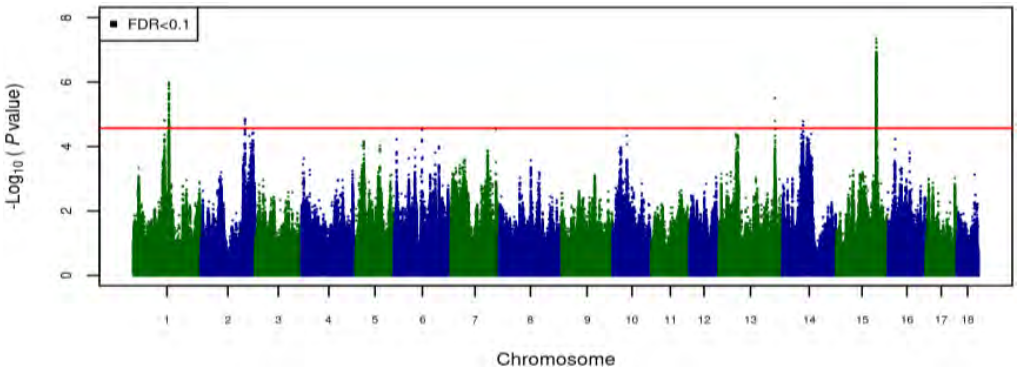

Figure 1. GWAS for FMCOL Minolta a* in combined CBs and PBs. −log10 *P*-values are plotted against genomic position for 18 autosomes. The horizontal red line represents a False Discovery Rate (FDR) of 10%.

phenotypes. Thus, to capture the full advantage of WGS, it is suggested to first preselect markers with a potential causal effect on the trait of interest and use only those preselected variants for prediction.

Conclusions

We conclude that any added value of WGS relative to lower density marker panels for GWAS will likely require larger training populations than those used here. For most pork meat quality traits, WGS hardly improved the accuracy of prediction compared with the medium-density SNP panel. Differences between traits in the effect of panel density and prediction scenario on genomic prediction accuracy can mainly be due to underlying genetic architecture of the traits. For between population predictions, we expect that the results to be specific for the current data set with low relationship between selection candidates and training data (PB and CB populations).

262. A conditional multi-trait sequence GWAS of heifer fertility in tropically adapted beef cattle

M. Forutan[1*], B. Engle[1], M.E. Goddard[2] and B.J. Hayes[1]

[1]Centre for Animal Science, Queensland Alliance for Agriculture and Food Innovation, The University of Queensland, Brisbane, QLD 4072, Australia; [2]Agriculture Victoria, AgriBio, Centre for AgriBioscience, Bundoora, Victoria, Australia; m.forutan@uq.edu.au

Abstract

Reproductive efficiency is major driver of profitability of beef production in northern Australia. Failure of heifers to achieve pregnancy results in a considerable loss to producers and accounts for most of the reproductive costs incurred. Availability of genomic information has provided a noteworthy opportunity to enhance the efficiency of selection, especially for traits such as fertility with low heritability. Here, we used imputed whole genome sequence data and up to 2,119 Brahman heifers in a stepwise conditional multi-trait GWAS (CM-GWAS) to identify pleiotropic putative causal variants and genes associated with fertility traits. We identified multiple genomic regions affecting fertility traits, some previously reported and some novel. Candidate gene findings included the genes *ARHGEF28, RNF150*, *EPHA6*. When we investigated the genes closest to the most significant SNP, they included *CNTNAP4* gene that encodes a member of the neurexin protein family and *PLAG1* gene.

Introduction

Over the past decade, genome-wide association studies (GWAS) have been widely used to identify associations of single-nucleotide polymorphisms (SNPs) with complex traits in livestock, especially in dairy and beef cattle (Visscher *et al.* 2017). Using whole genome sequence data can improve the power of GWAS since the causal variants should be included in the sequence data. However, even using whole genome sequence data, the identification of the causal variants for a complex trait is still difficult. This is due to the small effect size of most causal variants and the linkage disequilibrium (LD) between variants. Consequently, there are too many variants in high LD, any one of which could be the cause of the variation in phenotype. Causal variants are often pleiotropic, i.e. affecting more than one trait, so multi-trait analysis might result in higher power to detect quantitative trait loci (QTL) and greater precision in mapping them (Bolormaa *et al.* 2014).

In this study, the stepwise conditional multi-trait GWAS (CM-GWAS) analysis was performed to identify significant variants and genes associated with four fertility-related traits, including a binary trait (heifer pregnancy status) and three continuously distributed traits including fetal age in weeks, measured via manual palpation at pregnancy diagnosis; heifer age at first calving, defined as the number of days between the birthdate and calving date; and days to calving, defined as the number of days between the date of bull turn out at the beginning of the breeding season and calving date.

Materials & methods

Phenotypic data. For this study, lifetime productivity of a Central Queensland Brahman cow herd was assessed. Born between 1981 and 2015, these cows and heifers were part of a stud herd that has been developed with a heavy emphasis on fertility, where failure to produce a calf was the primary culling criterion. Four fertility-related traits were considered. In these herds, heifer pregnancy status was recorded as a binary trait (1 = successful, 0 = unsuccessful) indicating whether a heifer was able to conceive prior to three years of age. Pregnancy success was determined at time of yearly pregnancy check for all heifers born in 2011 and later. For heifers born prior to 2011, calving records were used to determine pregnancy success. Among those heifers that had both a pregnancy test and calving record available, 6% experienced

DOI: 10.3920/978-90-8686-940-4_262, © M. Forutan *et al.* 2022

pregnancy loss after pregnancy check, making calving success a good approximation in cases where pregnancy check records were unavailable. Fetal age in weeks (hef_wks_preg) was recorded via manual palpation at pregnancy diagnosis for all heifers born in 2011 and later. Age at first calving (AFC) was only available for heifers with a recorded birth date and was calculated as the difference in days between first calving and birth. Days to calving (DTC) is a routinely recorded trait in Australia Brahmans and is defined as the number of days between the date of bull turn out at the beginning of the breeding season and calving date. Heifer days to calving was recorded as the number of days between first calving and bull exposure.

Genotyping and quality control. Heifers were genotyped with the BovineSNP50 BeadChip (Illumina, San Diego, CA). A detailed description of the genotype quality control was given by Hayes *et al.* (2019). Genotypes were imputed up to 728,785 SNPs (Bovine HD array) using the findhap4 software (VanRaden *et al.* 2013), and a panel of 4650 individuals from relevant breeds, including Brahman (300), Droughtmaster (300), Santa Gertrudis (250) and composites (1000) that were genotyped with the Bovine HD array. All genotypes were then imputed to 31,140,417 million whole-genome sequence variants using the 1000 Bull Genomes Run8, TaurIndicus reference (Hayes and Daetwyler 2019), with 600 Holsteins and 400 Simmental animals removed to avoid over-representation of these genomes in the imputation. Eagle (Loh *et al*., 2016) was used for phasing and Minimac3 software (Das *et al*., 2016) for imputation.

Genome-wide association analysis. A linear mixed model was performed using the GCTA software (Yang *et al.* 2011), fitting each sequence variant as a covariate, one at a time, and testing for association with each trait as follows:

$$\boldsymbol{y} = \mathbf{1}_{\boldsymbol{n}}\mu + \boldsymbol{X}\beta + \boldsymbol{Z}g + \boldsymbol{W}_{\boldsymbol{i}}\alpha_i + \boldsymbol{e},$$

where y is the vector of phenotypic values of the animals, 1_n is an n × 1 vector of 1s (n=number of animals with phenotypes), μ is the overall mean, X is an n × x matrix of fixed covariates, β is a length × vector of fixed effects, Z is a design matrix for the random additive genetic effects; g is a vector of random additive genetic effects assumed to be distributed as ~N(0, $G\sigma_g^2$), where G is the genomic relationship matrix (GRM) calculated from high-density genotypes using the GCTA software. W_i is a vector of genotypes for each animal at the i-th variant, α_i is the corresponding variant effect, and e is a random vector of length n as ~ N (0, σ_e^2I), where σ_e^2 represents non-genetic variance due to non-genetic effects assumed to be acting independently on animals. The choice of fixed covariate effect for continuous and binary traits was done using *lm* and *glm* function in R, respectively. For all four traits, year of birth and contemporary group were constantly considered as fixed covariates. Moreover, for trait AFC, calving success defined as 0 and 1, based upon whether they joined at two or three years of age was considered as fixed effect. Also, for trait DTC, the effect of heifer age of joining was fitted as continuous covariate fixed effect. The GRM was generated using variants with minor allele frequency (MAF) higher than 0.01 (609,878 SNPs) in the HD dataset.

We performed a conditional multi-trait meta-analysis (CM-GWAS) according to a previously described approach (Bolormaa *et al.* 2021) using whole genome sequence (WGS) variant effects estimated from four single-trait GWAS to identify pleiotropic variants that affected fertility trait. The multi-trait meta-analysis (M-GWAS) X^2 statistic with 4 degrees of freedom (equal to the number of traits analysed) was calculated as below:

$$X^2 = t_i V^{-1} t_i$$

where t_i is a vector of the signed t-values of the effects of the i-th sequence variants for the 4 traits and V^{-1} is the inverse of the 4 × 4 correlation matrix where the correlation was calculated over all estimated

sequence variants effects (signed t-values) between each pair of traits. The CM-GWAS approach cycles back and forward between the single-trait GWAS for all traits and M-GWAS to re-test variants conditional on jointly fitting the most significant putative causal variants from independent QTL (where we defined significant as $P<5\times10^{-6}$). To determine independent sequence variants, first the most significant M-GWAS variant from each chromosome was selected and added to the list of putative causal variants. If the pairwise LD between this variant and any other significant variant on the same chromosome was greater than 0.1, these other variants are considered as potentially tagging the same causal variant and were not considered as independent QTL for this cycle. Then, from the remaining significant variants in LD, r^2 less than 0.1, the next most significant variant was selected on each chromosome, LD was tested between these and the remaining significant variants and so on, until no more significant variants identified in this cycle.

Results & discussion

There was no indication of inflation of the test statistic due to population structure or other confounding effects for any of the traits (Figure 1B). To be able to identify independent putative causal variants we used the CM-GWAS. We selected only the most significant ('top') variants from each cycle of the CM-GWAS and identified 144 independent putative causal variants across the genome ($P<5\times10^{-8}$). Candidate genes included the genes *ARHGEF28, RNF150*, *EPHA6* located in intronic region of chromosomes 20, 17, and 1, respectively. When we investigated the genes closest to the most significant SNP, they included *CNTNAP4* gene that encodes a member of the neurexin protein family. Members of this family function in the vertebrate nervous system as cell adhesion molecules and receptors. Moreover, we discovered the same mutation as the one Bouwman *et al.* (2018) identified in a very large meta-analysis of height in cattle using imputed sequence data on more than 50k animals in *PLAG1* gene (14: 23300304). In this study, new potential causative mutations affecting fertility traits have been identified that should be incorporated into commercial SNP arrays. This should increase the accuracy of genomic breeding values (GEBV) for these traits, just as a similar approach has increased accuracy of GEBV in sheep and dairy cattle (Moghaddar *et al.* 2019, Xiang *et al.* 2019).

Abstract

The objective of this study was to evaluate genomic prediction accuracy of meat quality traits in purebred Merinos from an admixed terminal sire breed population, including terminal and Merino crosses, using sequence variants selected in the admixed terminal sire breed population. Results showed an increase in genomic prediction accuracy for carcase fat in Merinos compared to using a common 50k genotypes by using significant SNPs selected from the admixed population. This was supported by GWAS results indicating several common significant QTL regions for carcase fat between the two populations. Results for intramuscular fat showed a decrease in prediction accuracy in Merinos by using significant SNPs selected from the admixed population and in line with this GWAS showed fewer significant common QTL regions between the two populations. Results of this study suggest that improvement in the accuracy of across-population genomic prediction by using selected sequence variants varies between traits and depends on the degree of similarity between populations at significant chromosomal regions affecting the trait.

Introduction

Whole genome sequence data covers a large number of genome-wide genetic variants in which a part of them are at or in significant association with quantitative trait loci affecting the genetic variance of a production trait. Literature shows higher prediction accuracy by including selected sequence variants in prediction within population (Van den Berg *et al.* 2016; Moghaddar *et al.* 2019). For some breeds there are limited data recorded for production traits, making it difficult to detect predictive SNPs within breed. However, data from other breeds or admixed populations may be available, and the question is under which conditions these data can be used for SNP selection and genomic prediction. This study aimed to investigate the accuracy of genomic prediction for two meat quality traits in purebred Merinos from an admixed terminal sire breed sheep population (terminals) using selected sequence variants from a genome-wide association study for genomic prediction in terminals.

Materials & methods

Phenotypes for carcase fat (CCFAT) and intramuscular fat (IMF) in Merinos and terminals were extracted from routine genetic evaluation. These data were collected in a mixture of research (Information Nucleus Flocks (Van der Werf *et al.* (2010)) and MLA resource flock) and industry flocks (Sheep Genetics). The number of terminal sheep with both phenotypes and genotypes used in this study was 13,008 and 12,926 for CCFAT and IMF respectively. The number of validation animals (Merino population) were 1,438 and 1,432 for CCFAT and IMF respectively. The Merino population consisted of purebred animals and the terminal population was a multi-breed/admixture of terminal sire breeds including predominantly Poll Dorset, White Suffolks and composite terminals, including crossbreds with maternals and Merinos.

Imputed whole genome sequence data were available from previous studies and were used in this study. Dscription of the genotype imputation is provided in Bolormaa *et al.* (2019). Briefly, research and industry data with different sets of low and moderate density genotypes (12k, 15k, 50k) were imputed to a common 60k genotype set based on a large imputation reference set, then the 60k genotypes were imputed to high-density genotypes (500k: HD) using a 2,266 multi-breed reference set. Subsequently, all animals with HD

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_263, © N. Moghaddar *et al.* 2022

genotypes were imputed to sequence level using 726 multi-breed animals as a reference set. The final set of sequence data covered 36,934,305 variants on 26 autosomes after standard quality control and filtration for variants with low imputation accuracy (r<0.63).

Pre-corrected phenotypes were obtained from Sheep Genetics routine evaluation analyses, which are run separately for Merino, maternal and terminal sire breeds. The pre-corrected phenotypes ($y^* = \hat{u} + res$) used in this analysis were calculated from multi-trait estimated breeding values ($\widehat{u}$) and residual phenotypes adjusted for all effects in the model (*res*). These effects included the fixed effect of contemporary group (flock, year, sex, measurement date and management group), birth and rearing type, age of dam, age at measurement and weight at measurement. In addition to breeding values, the random effects adjusted for included maternal effects, permanent environmental effect for repeated observations of certain traits, and genetic groups.

Genome-wide association analysis was performed on terminals according to the single SNP mixed model regression method based on the following equation $y^* = Xb + Zu + e$ in Gemma V0.96 program (Zhou *et al.* 2014). In this equation y^* refers to the pre-corrected phenotypes, b refers to fixed effect of mean and allele substitution effect of the investigated SNP, u refers to the random additive genetic effect of the animal fitted by genomic relationship matrix (G), and e is the residual effect. G was calculated using 50k genotypes based on the Yang *et al.* 2010 method, and X and Z are incidence matrices relating fixed and random effects to phenotypes. Genomic prediction was performed with GBLUP based on the following equation $y^* = Xb + Zu + e$ implemented in the MTG2 program (Lee *et al.* 2016). In this equation y^* refers to the pre-corrected phenotypes, b refers to animal group (terminal or Merino), u refers to the random additive genetic effect of the animal which were fitted by genomic relationship matrix (G), and e is the residual effect. G was calculated based on Yang *et al.* 2010 using common 50k genotypes, whole genome sequence data, SNPs with non-zero effect and SNPs with non-zero effect pruned for LD, and X and Z are incidence matrices relating fixed and random effects to phenotypes.

Results

Results of genomic prediction are reported in Figure 1. Common 50k genotypes showed an accuracy of 0.35 and 0.32 for CCFAT and IMF, respectively. Whole genome sequence data showed a similar or lower prediction accuracy than the 50k genotypes. The prediction accuracy in cases when SNPs with non-zero effect derived from GWAS on terminals were used, was increasing according to stronger *P*-value threshold in CCFAT and showed a maximum of 0.04 absolute value of increase in accuracy, however, prediction accuracy in IMF was decreasing by using non-zero effect SNPs with stronger *P*-value threshold derived from terminals. LD pruned SNPs in both CCFAT and IMF showed a similar accuracy to unpruned SNPs and the bias of prediction was in line with accuracy and was increasing with more accurate genomic prediction.

Results of GWAS for CCFAT and IMF using imputed whole genome sequence data (Figure 2 and 3) showed more similarity between significant regions in CCFAT between terminals and Merino but showed more different significant regions for IMF between terminals admixed population and Merinos. More notably two highly significant regions for IMF in terminals on OAR18 and OAR2 were not associated with IMF in Merinos.

Discussion

This study investigated the predictability of genomic breeding values of two common meat quality traits, including carcase fat and intramuscular fat, in Merino sheep based on prediction from an admixed terminal sheep population and using selected variants in admixed terminal population. A common set

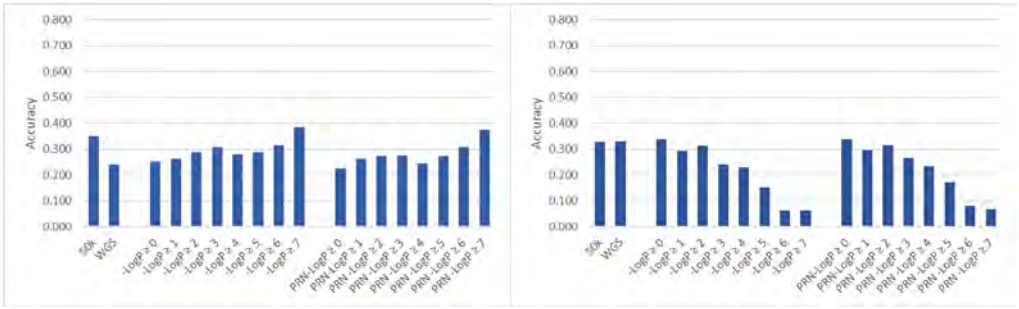

Figure 1. Accuracy of genomic prediction in different scenarios for CCFAT (left) and IMF (right). 50k:50k genotypes, WGS: whole genome sequence, -Log*P*≥0 to -Log*P*≥7 are SNPs filtered based on their *P*-value, PRN: SNPs filtered based on *P*-values and pruned for LD (window size 5,000, sliding window size=100).

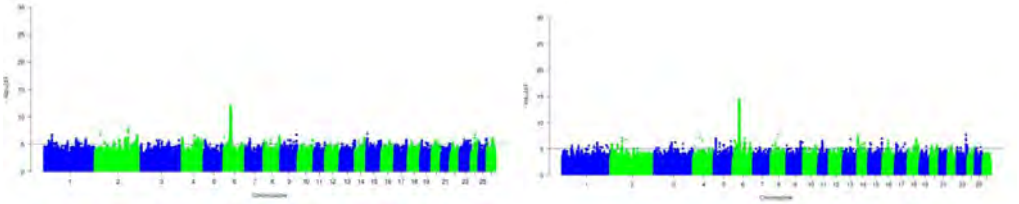

Figure 2. Results of GWAS on CCFAT in terminals (left) and in Merino population (right).

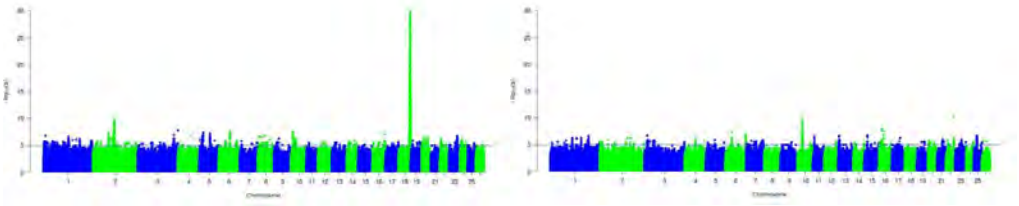

Figure 3. Results of GWAS on IMF in terminals (left) and in Merino population (right).

of 50k SNPs, whole sequence data and non-zero effect sequence variants selected in terminals were used in GBLUP prediction. Whole genome sequence data showed similar or even lower prediction accuracy to 50k which was because of very large number of SNPs provided by sequence data of which the majority are in very low linkage disequilibrium to QTLs. This result was in line with previous findings (Moghaddar *et al.* 2019). Different sets of selected SNPs with non-zero effect according to loose, moderate or stronger cut-off thresholds in terminal population GWAS showed an increasing trend of accuracy in CCFAT but a decreasing trend of accuracy in IMF. This was mainly because of more similar significant QTL regions controlling CCFAT between Merino and terminals which was revealed in GWAS results including highly significant region on OAR6 and different QTL regions affecting IMF between terminals and Merinos, more importantly on OAR 18 and 2 and in general small number of selected SNPs with stringent threshold like –Log *P*-val≥7 fo IMF. Generally low prediction accuracy in this study (less than 0.4) is also because of lower degree of genetic relationship between Merino validation set and terminals as reference set.

Conclusions

This study showed that the genomic prediction accuracy of purebred Merinos from an admixed population is trait specific and depends on the genetic structure of the traits between populations and the degree of similarity between significant chromosomal regions between populations.

Abstract

The population of Peruvian creole cattle (PCC) is decreasing mainly due to the introduction of more productive breeds in recent years. We report the complete mitochondrial genome sequence of a PCC bull for the first time. This genome was 16,339 bp in length with the base composition 31.43% A, 28.64% T, 26.81% C, and 13.12% G. It contained 13 protein-coding genes, 2 ribosomal RNA genes, 22 transfer RNA genes and a control region. Among the 37 genes, 28 were positioned on the H-strand and 9 were positioned on the L-strand. The most frequently used codons were CUA (Leucine), AUA (Isoleucine), AUU (Isoleucine), AUC (Isoleucine) and ACA (Threonine). Maximum likelihood analysis clearly demonstrated that PCC are strongly related to a native African breed, giving insights into the maternal ancestry of PCC. The annotated mitochondrial genome of PCC would serve as an important genetic data set for further breeding work and conservation strategies.

Introduction

The global population of cattle (*Bos taurus* and *Bos indicus*) is around 1.5 billion (McLeod, 2011), making it one of the most common livestock species. The cattle population in Peru is about 5.5 million head (MIDAGRI, 2019) of which 5% are creole cattle (M. Rosenberg, UC del Sur, pers. Comm.). PCC, in difference to other exotic breeds, have developed the ability to survive in environments with food limitations and under climatic factors that heavily affect their performance. Therefore, PCC are the basis for milk and beef production in the Peruvian highlands. In some Peruvian regions, PCC are also used for agricultural purposes and cultural events. In this work, for the first time, we sequenced the complete mitochondrial genome of a Creole bull from Peru.

Materials & methods

Sample collection and DNA extraction. A tail hair sample was collected from a single male specimen from the Andagua district, Castilla province in Arequipa (3,574 masl; -15.499548°, -72.359927°). This individual named as 'Tremendo Cachorro' was considered an 'Arequipa fighting bull' as it possessed exceptional fighting skills and was part of the traditional bullfight activity of Arequipa. We extracted genomic DNA with the Wizard® Genomic DNA Purification Kit (Wisconsin, USA) following the manufacturer's instructions. The quality and quantity of genomic DNA were assessed by agarose gel electrophoresis and NanoDrop One (Thermo Fisher Scientific, USA), respectively. Library preparation and high-throughput sequencing with Illumina HiSeq Sequencing System (Illumina, San Diego, CA) were conducted by Genewiz (New Jersey, USA).

Assembly, annotation and sequence analysis. Pair-end clean reads were obtained by PE 150 library and the Illumina HiSeq 2500 platform. Adapters and low-quality reads were removed using Trim Galore (Martin 2011). We used clean data to assemble the mitochondrial genome using GetOrganelle v1.7.2 pipeline (Jin *et al.* 2020). The annotations of the protein-coding genes (PCGs), transfer RNAs (tRNAs) and rRNA genes from mitogenome were performed using the automatic annotators of mitochondrial genes

online: Geseq (Tillich *et al.* 2017) and MITOS 2 (Donath *et al.* 2019), and curated manually. The tRNA secondary structure was analyzed with tRNAscan-SE 2.0 (Chan *et al.* 2021). The codon usage bias was analyzed using MEGA X (Kumar *et al.* 2018). The circularized drawing of the mitochondrial genome was performed with OGDRAW 1.3.1. (Greiner *et al.* 2019).

Codon usage and tRNA analysis. Codon usage analysis was performed in Molecular Evolutionary Genetics Analysis 11 (MEGA 11) software (https://www.megasoftware.net/). For this purpose, each nucleotide sequence was cured manually, removing the STOP codon and only keeping the codons that synthesize amino acids. Then, 13 nucleotide sequences were concatenated using the Concatenate Sequence Alignment option and we evaluated the Codon Usage using RCSU option in MEGA 11. To predict the secondary structure of each tRNA, we used the tRNAscan-SE website server (http://lowelab.ucsc.edu/tRNAscan-SE/). We analysed the sequences in FASTA format and kept the parameters by default except the Sequence Source that corresponds to Mammalian mitochondrial.

Phylogenetic analysis. To ascertain the genetic relationship of PCC with other *Bos* species, we also included 32 complete mitochondrial genomes from *Bos* species available in GenBank. As outgroup, we used a species of the genus Bison (*Bison bison*) from the same subfamily Bovinae. We used GTR+GAMMA model of evolution to obtain the best-scoring ML tree, and then 1000 nonparametric bootstrap inferences were performed with RAxML v8.2.11 (Stamatakis 2014).

Results

The complete mitochondrial genome of PCC was 16.339 bp in length, which included 13 protein-coding genes, two ribosomal RNA genes, 22 transfer RNA genes and a control region (Figure 1). Most of the genes (28) were encoded within the heavy (H) strand, and 9 genes were positioned on the L-strand. The base composition of this genome was 31.43% A, 28.64% T, 26.81% C, and 13.12% G. The entire mitochondrial genome sequence was submitted to the GenBank database with accession number: OK135155. The associated Bioproject, Biosample, and SRA numbers are PRJNA763011, SAMN21419641, and SRR15883111, respectively. The relative synonymous codon usage (RSCU) analysis showed the highest utilization of CUA, AUA, AUU, AUC and ACA codons among PCGs. Our phylogenetic analysis showed that PCC clustered as expected in a well-supported clade that included *B. taurus* individuals (Figure 2). Interestingly, this PCC was within subclade 1 that contains most African breeds.

Discussion

We sequenced for the first time the complete mitochondrial genome of a Peruvian creole bull using next generation sequencing. The genome size and order was in agreement to previous work on native cattle (Liu *et al.*, 2020). The nucleotide composition of the PCC mitochondrial genome was biased towards adenine and thymine and was in agreement with other studies in *Bos* (Kamalakkannan *et al.*, 2020). This feature is a common characteristic for the bovine mitochondrial genome (Zhou *et al.*, 2019). Similar to other studies in the *Bos* genus, amino acids leucine, threonine, and isoleucine were the most abundant among the protein coding genes (Kamalakkannan *et al.*, 2020). It was possible to recover the three clades that were reported for *Bos* (Kamalakkannan *et al.*, 2020). In addition, our study provided further evidence about the influence of African and European founders. However, more samples from a wider geographic area in Peru, especially form the Andean region, needs to be analysed using both mitochondrial and nuclear DNA to confirm PCC origin. This newly generated sequence would serve for phylogenetic, evolutionary and conservation work for this orphan breed.

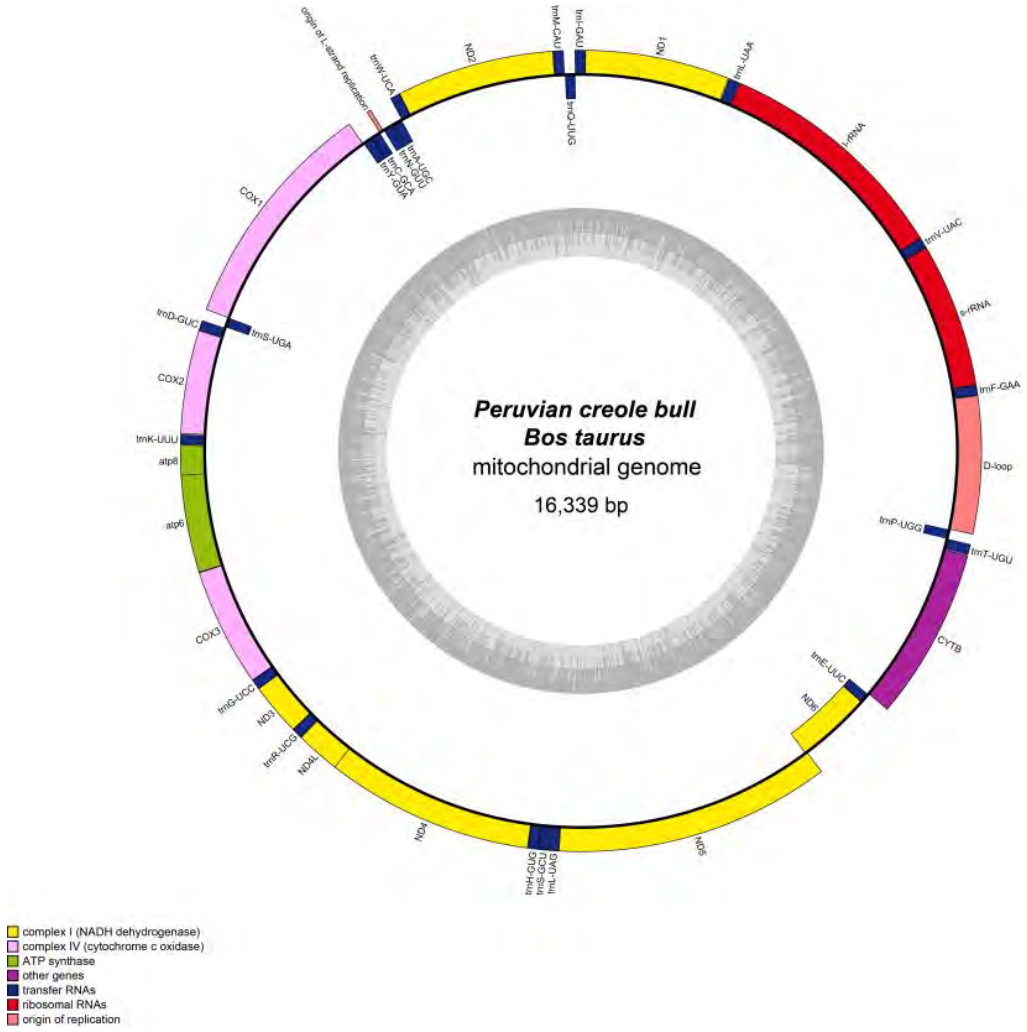

Figure 1. Representative map of the mitochondrial genome of the Peruvian creole cattle. Genes encoded by the heavy strand are shown outside the circle, while those encoded by the light strand are shown inside.

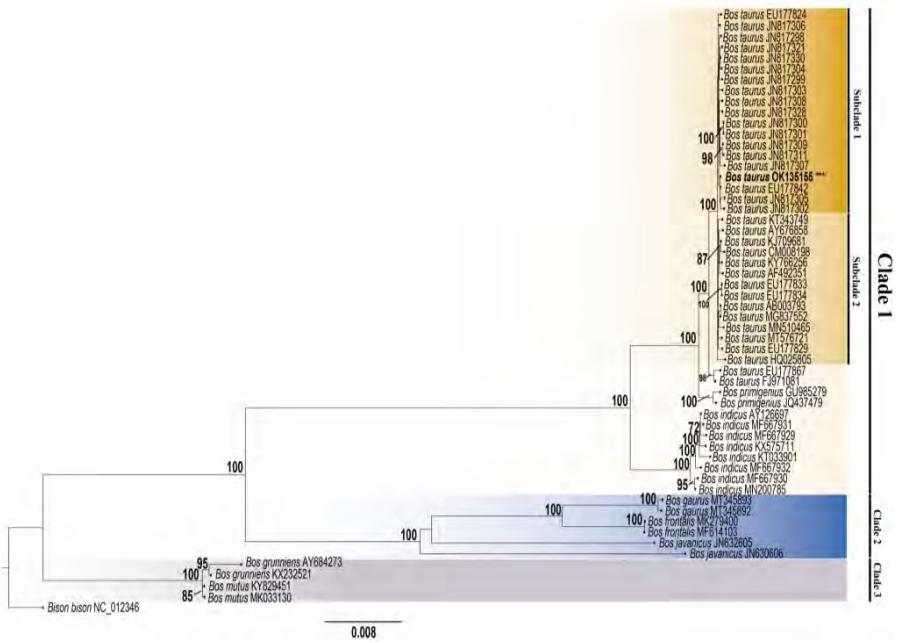

Figure 2. Phylogenetic relationship of *Bos* species inferred from mitochondrial genomic sequences. Maximum likelihood bootstrap support is shown only for branches with <72% support. The *Bison bison* mitochondrial genome sequence was used as an out-group.

Abstract

The aim of this study was to detect structural variants (SVs) associated with skin depigmentation (DP) through genome-wide association study (GWAS), using whole-genome sequence of 81 Nellore sires. Phenotypic and pedigree data from 340,220 animals were used to estimate breeding values from single-trait analysis using a mixed linear animal model. The Parliament2 software was used to identify SVs. After filtering, a total of 46,850 deletions, 15,690 insertions, 7,937 inversions, and 30,446 duplications were identified within genic regions. GWAS for DP revealed 11 significant SVs located on chromosomes 4, 7, 8, 13, 15, 16, 17, 20 and 28; and harbouring 3 candidate genes (*MAML2*, *UMAD1* and *SAMD8*). The main gene identified was *MAML2*, which is involved in human skin pigmentation and is related to the Notch signalling pathway. Our results provide meaningful information about SVs, which may be useful in future assessment of variations associated to skin depigmentation in Nellore cattle.

Introduction

The genetic progress achieved by several breeding programs in Brazil can be credited in large part to the implementation of CEIP (Special Certificate of Identification and Production), a certificate of genetic superiority issued for the top 20-30% animals (young bulls and heifers). The animals eligible to receive the CEIP are evaluated for morphological and functional defects, including skin depigmentation (DP). The combination of dark pigmentation and white hair typical of Nellore cattle is a powerful feature to prevent skin lesions and subsequent complications that can impact the animal's performance. As a type of genetic variation, structural variation (SVs) often refers to structural differences in the genome of complex organisms, including gains and losses of DNA segments and rearrangements, which are inherited and may contribute to a considerable proportion of the differences between individuals for some traits. SVs have been associated with several productive traits and diseases in livestock species. In this regard, many SVs have also been identified and artificially selected in livestock such as a duplication of an allele of the *KIT* gene that results in a white phenotype in cattle, pigs, and sheep (Giuffra *et al.*, 2002; Gutiérrez-Gil *et al.*, 2007). Thus, the aim of this study was to detect structural variants associated with skin depigmentation in Nellore cattle by performing a genome-wide association study using whole-genome sequence data.

Materials & methods

Phenotypes and pedigree data. Phenotypic and pedigree information of 340,220 Nellore animals, collected between 2000 and 2018, were obtained from Alliance Nellore database (www.gensys.com.br). These animals belong to herds that systematically perform evaluations for morphological and functional defects or disorders.

Whole-genome sequencing dataset. A total of 81 influential Nellore sires were sequenced using the Illumina HiSeq X™ Ten and Illumina NovaSeq™ platforms (Illumina Inc., San Diego, USA). Sequencing of all samples was performed using the Illumina sequencing-by-synthesis technology at an overall average

sequence coverage of 14.5×, ranging from 7.8 to 26.3×. The SAMtools program (Li *et al.*, 2009) was used to index the sequences, and the alignment to the ARS-UCD1.2 reference genome was performed using HiSat (Kim *et al.*, 2015).

Variant Calling and Genotyping. Single sample SV discovery (including deletions, insertions, inversions, and duplications) was performed using Parliament2 (Zarate *et al.*, 2020) considering the following combination of callers CNVnator (Abyzov *et al.*, 2011), Lumpy (Layer *et al.*, 2014), Delly (Rausch *et al.*, 2012) and BreakDancer (Fan *et al.*, 2014). The BAM files and associated reference genome file (ARS-UCD1.2) were used to run Parliament2 on each sample via a single Docker image using the DNAnexus platform. A merged VCF file was prepared for each variant calling by merging individual VCF files of the 81 samples using the BCFtools merge function. The output file containing SVs was then transformed to 012 genotypes format using VCFtools (Danecek *et al.*, 2011), where 0 represented the homozygous genotype for the reference allele (no SV), 1 was the heterozygous genotype (heterozygous SV) and 2 was the homozygous genotype for the alternative allele (homozygous SV).

Statistical methods. In preliminary analyses, an additive threshold animal model including a fixed effect of contemporary group (CG) and a linear effect of age at recording as covariate was used to obtain the solutions of mixed model equations using THRGIBBS1F90 software (Misztal, 2014). CG were defined based on the concatenation of season of birth, sex, farm and management group at weaning and yearling, and date of measurement. The GWAS was performed for the 81 sequenced animals using the *fastGWA* (ultra-fast mixed linear model association) option implemented in the GCTA software (Yang *et al.*, 2011), fitting the following linear mixed model:

$$y = \mu + Xb + Zu + e \quad (1)$$

where y is the vector of pseudo-phenotypes (estimated breeding values); μ is the overall mean; X is the incidence matrix of the allele copies (coded as 0, 1, 2); b is the allele substitution effect; Z is the incidence matrix connecting the phenotypes to animals; u is the vector of additive genetic effect; and e is the vector of random residuals. The genomic relationship matrix (GRM) was derived as defined in Yang *et al.* (2010, 2011) based on SVs. According to the Bonferroni correction, the defined GWAS significant threshold was 0.05/N, where N refers to the number of SVs. Significant SVs were investigated for gene annotation using the Genomic Annotation in Livestock por positional candidate Loci (GALLO; http://github.com/pablobio/GALLO) package in R (Version 4.0.0; R Core Team, 2021).

Results & discussion

A total of 146,003 deletions, 52,208 insertions, 84,306 duplications, and 226,036 inversions were identified from the sequence data of the Nellore population, which jointly affect ~2.38 Mb of sequences (Table 1). In general, the number of deletions and inversions detected in each chromosome was greater than the number of duplications and insertions. In addition, the distribution of the SVs detected on each chromosome is quite uniform. Chromosome 1 had the highest density of structural variants, while chromosome 25 had the lowest. The annotation of detected variants was performed to further explore the distribution of SVs in genic regions. Within genic regions there were 46,850 (32.08%), 15,690 (30.05%), 7,937 (3.51%), and 30,446 (36.11%) identified deletions, insertions, inversions, and duplications, respectively. In addition, the number of total genes for deletions, insertions, inversions, and duplications contained in the Ensembl gene database of bovine were 6,483 (37.00%), 5,413 (30.89%), 2,104 (12.01%), and 1,966 (11.22%). The range of the number of deletions, relative to genes distributed on different chromosomes was from 24.23 to 52.87%; for insertions, from 18.30 to 45.97%; for inversions, from 5.08 to 19.4%; and for duplications, from 4.59 to 89.09%. Chromosomes 6, 24, and 28 had the highest number of genes with deletions, insertions, inversions,

and duplications. Single-trait GWAS revealed 11 significant SVs located on chromosomes 4, 7, 8, 13, 15, 16, 17, 20 and 28 (Table 2). A total of three candidate genes (*MAML2*, *UMAD1* and *SAMD8*) were annotated and harbouring three associated chromosomes. The gene protein *MAML2* belongs to the three-member MAML (mastermind-like) family that co-activates Notch receptor-induced transcription. Notch activation regulates skin homeostasis by balancing primarily growth arrest and progressive differentiation processes of keratinocytes, which are associated to skin pigmentation process by accumulating pigmented organelles including melanin (Benito-Martínez *et al.*, 2021). KEGG pathway analysis indicated that the genes with insertions were involved in 3 KEGG pathways (bta04330: Notch signalling pathway; bta04658: Th1 and Th2 cell differentiation; bta05165: Human papillomavirus infection).

Conclusions

In this study, we identified SVs from 81 Nellore sires, including deletions, insertions, inversions, and duplications. The annotation of SVs in different gene families suggests that SVs can be a relevant source of genetic variation for the breed's evolution. The *MAML2* was identified as an important functional candidate gene associated with skin pigmentation, which demonstrate the importance of this gene for the studied trait. The set of SVs reported here could be useful for further studies to investigate the incorporation of SV genotypes into genomic prediction in order to enhance selection and mating decisions aimed to reduce the incidence of skin depigmentation in Nellore.

266. On the advantage of identifying causal genetic variants for genomic prediction

T.H.E. Meuwissen[1*] and M.E. Goddard[2,3]

[1]Norwegian University of Life Sciences, Box 5003, 1432 Ås, Norway; [2]Agriculture Victoria, Bundoora, Australia; [3]Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Parkville, Australia; theo.meuwissen@nmbu.no

Abstract

Genome Wide Association Studies have been successful in identifying Quantitative Trait Locus regions. However, the identification of causal variants (CVs) has proven difficult in many cases. One may hypothesize that knowing the CV would not improve the (genomic) prediction of phenotypes much since otherwise phenotypes would clearly point to the CV. The effect of (not) knowing the CV on local estimated breeding values (LEBV) in 200 kb regions surrounding the CV was estimated for 3 well-known CVs (in ABCG2, DGAT and GHR) in a large whole genome sequence dataset. Knowing the CV improved the accuracy of LEBV for all three CVs: for ABCG2 it was instrumental in pointing to the correct CV; the DGAT-CV was poorly imputed, and knowing the CV would result in improved genotyping; and GHR was poorly predicted by other SNPs in the region. In addition, knowing CVs is important for understanding trait-biology and for targeted gene-editing.

Introduction

Quantitative traits are generally complex in the sense that there are many genes, i.e. causal genetic variants, plus environmental effects that determine the trait phenotype. As an example there are 9,863 independent variants with significant ($P<5\times10^{-8}$) effects on human height (Visscher *et al.*, 2020). If many causal variants affect a trait then most of their effects must be relatively small, but some causal variants may have large effects. The distribution of effects sizes of causal variants can be modelled by a thick-tailed distribution such as a Gamma distribution with shape parameter <1 which includes more large effects than a Normal distribution. (Hayes and Goddard, 2001).

The identification of these causal variants with large effects is the aim of Genome Wide Association Studies (GWAS). GWAS have been successful in identifying many Quantitative Trait Loci (QTL), i.e. small chromosomal regions that explain genetic variance for a quantitative trait. However, identifying the causal variant (CV) within a QTL region is often difficult for a number of reasons:

1. The CV may not be included in the genotype data, even if Whole Genome Sequence (WGS) genotype data are used. For instance, the CV may not be included in the reference set of sequenced animals because it is too rare or hard to call as structural variants often are.
2. GWAS is based on Linkage Disequilibrium (LD), but many variants may be in high LD with the CV making it difficult to distinguish between these variants. If the CV and another non-causal variant (NCV) are in close LD, the NCV may show the higher GWAS signal due to an unfortunate sample of animals entering the GWAS. This problem may be reduced by increasing the sample size, but if the LD between the CV and NCV is 100%, a GWAS study cannot distinguish these two variants (since their genotypes are identical). If the LD is say 90%, a huge data set may be needed to ensure that the CV yields the highest GWAS signal.
3. Large WGS data sets are often obtained by genotype imputation, and genotype imputation errors of the CV genotypes may reduce the association between the CV genotypes and the trait.

DOI: 10.3920/978-90-8686-940-4_266, © T.H.E. Meuwissen and M.E. Goddard 2022

Given that the identification of causal variants is problematic, the question arises whether the identification of the CV is important? From the perspective of understanding the trait biology, a sharp GWAS peak, without identification of the CV, may identify the gene that is affecting the trait, but it will not be able to answer the question what genetic change in (or around) the gene is causing the (positive or negative) trait effect. The latter also prevents studies investigating the mechanism by which the CV affects the trait. In addition, the CVs provide clear targets for gene editing (Jenko *et al.*, 2015).

However, here, we will take the perspective of genomic prediction, i.e. we are only interested in the accuracy of genomic prediction, and whether knowing the CV increases the accuracy of genomic prediction. Instead of performing computer simulations (where the CV is always known), we will address this question using real data and consider 3 known and well-studied CVs affecting milk traits in dairy cattle: the Y581S mutation in ABCG2 on BTA 6 (Cohen-Zinder *et al.*, 2005); the K323A mutation in DGAT1 on BTA 14 (Grisart *et al.*, 2004); and the F2Y mutation in GHR on BTA 20 (Blott *et al.*, 2003).

Materials & methods

Data. The dataset is described in detail in Meuwissen *et al.* (2021). Briefly, it consisted of WGS genotypes and daughter yield deviations (DYD; in case of bulls) or yield deviations (YD; in case of cows) for milk yield of 35,549 Holsteins, Jerseys, and Australian Red bulls and cows. Animals were either directly genotyped with the Illumina 800K BovineHD bead chip (HD), or first genotyped with the Illumina BovineSNP50K chip or a lower density SNP chip, and subsequently imputed to HD. All individuals were imputed to WGS using a reference population of Holstein, Jersey and Australian Red bulls and cows from Run 5 of the 1000 bulls genome project. After filtering out variants with a minor allele frequency (MAF) lower than 0.002 and LD pruning (r^2>0.9), 4,809,520 variants were retained for the analysis. All three mutations (in ABCG2, DGAT1 and GHR) were included in these data.

Comparison of alternatives. All analyses were performed by the BayesGC model (see Meuwissen *et al.*, 2021, for details), which is a Bayesian variable selection model that fits a genomic relationship matrix (GRM) as well as the variable selection term, which selects individual variants from the set of 4,809,520 variants using a Monte Carlo Markov Chain (MCMC) method. The GRM was based on HD SNP genotypes, which did not include the ABCG2, DGAT1, and GHR CVs. The following alternative analyses were compared:

- AV: all 4,809,520 variants were included in the analysis, including the 3 CV (treated the same as all other SNPs);
- AV-CV: the same as AV but excluding the CV (assessing the value of having the CV in the data or not);
- AV+CV: the same as AV except that the 3 CV were assumed known and fitted with a prior probability of 1, i.e. they were always included in the model;
- CV: fits only the three CVs with prior probability 1;
- TOP10: fits 10 SNPs with highest posterior probability in each of the three QTL regions, i.e. a total of 30 SNPs were fitted with prior probability 1.

The TOP10 analysis considers the situation where the QTL region is detected but it is uncertain which of the SNPs is the causal variant. In order to deal with this uncertainty, the model fits 10 top SNPs (the 10 SNPs with the highest posterior probability in a 200 kb region surrounding the CV). Since there are 3 QTL regions, this results in a total of 30 SNPs being fitted. It may be noted that the top-10 of the variates in the DGAT1 region did not contain the DGAT1-CV probably due to the poor imputation accuracy of this SNP (which was variable possibly because it is a 2-SNP mutation which may confuse some software), and possibly also due to other CV in the region affecting the association. In case of ABCG2, the ABCG2-CV ranked number 8 in its 200 kb region, i.e. it was not the most important SNP in the region. The GHR-CV ranked number 1 in its 200 kb region, and was clearly the most important SNP.

The bayesGC model requires a variance assumed for the fitted variants, which was a fraction of 0.0005 of the total genetic variance (Meuwissen *et al.*, 2021) for the AV, AV-CV and AV+CV analyses. For the CV analysis this factor of the genetic variance was assumed 0.01, which assumes that the CV explain a factor of 0.01 of the genetic variance each (and if the actual explained variance is bigger, this would hardly affect the accuracy of prediction). The TOP10 analysis assumes that each SNP explains 1/10 of the variance of the locus, and in order to agree with the CV analysis each SNP was assumed to explain a factor of 0.001 of the genetic variance.

Criteria for comparison. Because the effect of a single CV on the total EBV is often small, and to avoid investigating very small differences in accuracy, we concentrated on the local EBV (LEBV) of each of the 200 kb-regions surrounding the three CVs. As the criterion for comparison of two analyses we used the correlation between the LEBV coming from a part data set to those from the complete data set, following Legarra and Reverter (2018). This criterion estimates the ratio of the accuracies of the part data set to that of the complete data set. Here complete data means more SNPs included in the analysis or more prior information about these SNPs such as which is the CV.

Results

The accuracy of AV-CV versus AV shows it is only in the case of GHR important to include the CV in the BayesGC analysis (Table 1). The latter is presumably because the surrounding SNPs did not fully pick-up the GHR-CV effect and the accuracy of AV-CV LEBV is reduced by ~27%. The AV versus AV+CV comparison shows that in the case of GHR, the AV model fitted the GHR-CV with a high posterior probability anyway, so giving it a prior probability of 1 hardly affected the LEBV. For DGAT, probably most of the LEBV was due to the effect of other SNPs and fitting the DGAT-CV with a prior probability of 1 did not change this much. However, the ABCG2-CV was somewhat important to the LEBV of its region and giving it a prior probability of 1 did improve the accuracy of the LEBV. The TOP10 versus AV(+CV) comparisons show that fitting only the top-10 SNPs in a region is not sufficient in the case of ABCG2 and GHR. Other SNPs also seem to contribute significantly. In the case of DGAT, the top-10 SNPs could predict the LEBV of the entire region. The TOP10 versus CV comparison shows that the top10 SNPs could generally not predict the effect of the CV. The CV versus AV(+CV) comparisons show that the CV alone often does not explain all genetic variation that could be explained in the region. For the DGAT-CV this may be expected due to its imputation inaccuracy. The GHR-CV is an exception to this result where fitting its effect alone yielded virtually the same LEBV as fitting all SNPs in the region.

Table 1. Ratio of accuracies of LEBV for the alternative analyses.

Data		Ratio of accuracies:		
Partial	**Complete**	**ABCG2**	**DGAT**	**GHR**
AV-CV	AV	0.993	0.999	0.726
AV	AV+CV	0.805	0.9996	0.998
TOP10	AV	0.852	0.998	0.781
TOP10	AV+CV	0.758	0.998	0.754
TOP10	CV	0.154	0.531	0.730
CV	AV	0.094	0.551	0.996
CV	AV+CV	0.662	0.547	0.999

Discussion

The results showed that for some CVs a higher prediction accuracy was achieved when the genotype data included the CV whereas for others the surrounding SNPs were able to pick-up its effect. Knowing the CV (giving it a prior probability of 1 in the analysis) improved prediction accuracy for some CV, especially if the analysis had insufficient power to identify the CV. Generally, including all SNPs next to the CV in the analysis seemed to increase accuracy. Fitting the top-10 SNPs in a QTL region seemed generally to result in a reduced prediction accuracy compared to fitting all SNPs.

Albeit, for different reasons, the results indicate that for all three cases prediction accuracies would be improved by knowing the CVs: for the ABCG2-CV prediction accuracy increased because the variable selection analysis did not clearly identify this SNP as the CV; for the DGAT-CV the imputation accuracy was a limiting factor and knowing the importance of this CV would ensure that it would be amongst the set of genotyped SNPs; and without prior knowledge on the GHR-CV it may have been excluded from the analyses by any of the data quality control filters, but Table 1 shows that all analyses excluding the GHR-CV yield markedly reduced prediction accuracies. Thus, it seems important to identify the CVs, from a perspective of: (1) understanding the biology of phenotypes; (2) identifying targets for genome editing; and, as shown here, (3) to improve accuracies of genomic predictions.

Abstract

Marker preselection based on criteria such as *P*-values, F_{ST} scores, and biological information has been proposed as a strategy to increase the functional relevance of preselected markers and reduce overparameterization and multicollinearity when using high-density and sequence genotype data in genomic evaluations. However, marker preselection based on a single criterion has largely failed to benefit predictions in both simulated and real data, and at worst has resulted in less accurate predictions when the trait of interest is lowly heritable with a complex genetic architecture (e.g. health and fertility traits). When multiple preselection criteria are available on markers, consolidating these criteria into a single composite score for preselection has the potential to increase the sensitivity to correctly detect relevant markers and benefit predictions. In this study, we investigate a fuzzy logic approach as a strategy for combining the criteria of *P*-values and F_{ST} scores for preselection of relevant markers in high-density (1.3 million biallelic markers) genomic data.

Introduction

The affordability and accessibility of high-density and sequence data has increased in recent years to allow practical use in genomic evaluations. It was initially expected that genomic prediction accuracy would benefit from such data by increasing capture of genetic variation (Meuwissen and Goddard, 2010), but practical results show little to no advantage relative to low- and moderate-density single nucleotide polymorphism (SNP) panels (Van Binsbergen *et al.*, 2015). This failure is likely due to a combination of excessive multicollinearity between SNP predictors and overparameterization of the association model.

SNP marker preselection may have the potential to improve the quality of genomic predictions by reducing multicollinearity and overparameterization and increasing the biological relevance of markers in the model. Several published studies evaluated single preselection criteria, including *P*-values (Veerkamp *et al.*, 2016), estimated marker effects (Ober *et al.*, 2012), F_{ST} scores (Chang *et al.*, 2018), and annotation missense status (Frischknecht *et al.*, 2018). In each of these studies, prediction accuracies outcompeted genome-wide SNP panels only when one or a few variants had a large contribution to the genetic variance of the trait of interest for both simulated and real data.

The limited success of single-criteria preselection to improve prediction accuracies is likely to be explained by the limited sensitivity of any single criteria to distinguish between relevant and non-relevant markers. All criteria will be subject to false positives and the impact of such markers on predictions is unlikely to be null. Ling *et al.* (2021) showed that while SNP preselection by estimated effect results in less false positives and more genetic variance explained than F_{ST} preselection, the false positives selected by estimated effect have a greater negative impact on predictions and can ultimately offset the benefit from capturing more genetic variance. Based on these observations, it is reasonable to hypothesize that a composite score combining these two preselection criteria may harness the benefits of both to ultimately yield higher accurate genomic predictions. Xiang *et al.* (2019) proposed a composite score for ranking variants from sequence data based on association and biological criteria and found that when preselected variants were combined with a

genome-wide 630k SNP panel, differences in genomic prediction accuracies between high- and low-ranking variants were statistically significant for several economically important milk traits in Holstein.

Fuzzy logic models are a computationally efficient and flexible tool for decision making based on multiple criteria. They have been successfully implemented in a variety of engineering applications, such as self-driving vehicles and automatic rice cookers. In this simulation study, we evaluate the potential of a Sugeno fuzzy logic model to combine *P*-values and F_{ST} scores into a composite score for SNP preselection for use in genomic prediction.

Materials & methods

A simulation was conducted using QMSim (Sargolzaei and Schenkel, 2009). The simulated genome consisted of 29 chromosomes of 100 cM each, modeled after the autosomal cattle genome, and 1.3 million evenly-distributed SNP markers. 5,000 QTL were randomly distributed across 14 of 29 chromosomes. The simulated trait had a moderate heritability of 0.3. Training and validation populations consisted of 5k and 1k individuals from generations 1 to 5 and 6, respectively.

P-values were calculated as described in Aguilar *et al.* (2019) using the BLUPF90 suite of programs (Misztal *et al.*, 2018). SNP effects ($\hat{a}$) were calculated jointly from single-step GBLUP (ssGBLUP) solutions,

$$\hat{\boldsymbol{a}} = \frac{1}{2\sum_{i=1}^{m} p_i q_i} \boldsymbol{Z}'\boldsymbol{G}^{-1}\hat{\boldsymbol{u}}$$

where Z' is the transpose of the $n \times m$ matrix of genotypes, G^{-1} is the inverse of the genomic relationship matrix, $\hat{\boldsymbol{u}}$ is the vector of solutions of genotyped individuals from a ssGBLUP model

F_{ST} scores were calculated as in Chang *et al.* (2018). The two subpopulations were formed by taking 5% of individuals from each of the tails of the phenotype distribution, and then calculating as follows,

$$F_{ST} = \frac{H_T - H_S}{H_T}$$

where $H_T = 2 \cdot p_T \cdot q_T$, $H_S = \frac{H_{S1} \cdot n_{S1} + H_{S2} \cdot n_{S2}}{n_{S1} + n_{S2}}$ and $H_{Si} = 2 \cdot p_{Si} \cdot q_{Si}$,

where p_T and q_T are major and minor allele frequencies, respectively, in the total population; p_{Si} and q_{Si} are major and minor allele frequencies, respectively, in the i^{th} subpopulation; and n_{Si} is the number of individuals in the i^{th} subpopulation.

The Sugeno fuzzy logic model involves sorting the n inputs into c_i categories with fuzzy boundaries and incomplete membership in multiple classes as illustrated in Figure 1. Logic AND/OR rules are constructed around combinations of these categories across inputs. Given n inputs, there will be a maximum number of rules equal to $\prod_{i=1}^{n} c_i$. For each of m rules, a linear combination of the input criterion (x) is constructed, $y = b'x$, where b is a vector of parameters decided by the practitioner.

A given set of inputs is evaluated across all rules and then the contribution of each rule (y_j) to the final fuzzy output is weighted (w_j) by either the minimum (AND logic rule) or maximum (OR logic rule) of the class memberships across inputs, $y_{fin} = \frac{\sum_{j=1}^{m} w_j y_j}{\sum_{j=1}^{m} w_j}$.

Preselected marker sets were evaluated using a ssGBLUP model with BLUPF90 (Misztal *et al.* 2018) and genomic prediction quality measured by the Pearson correlation between true (u) and estimated ($\hat{u}$) breeding values.

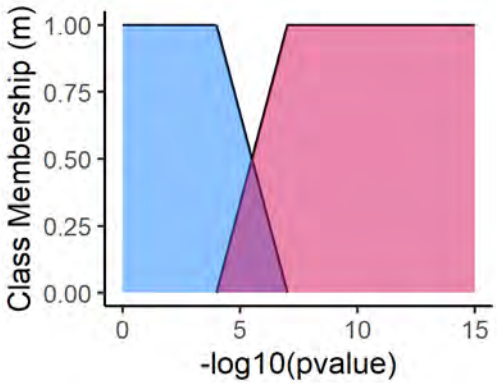

Figure 1. A fuzzy input criteria with 2 classes. The input value and class membership fall on the horizontal and vertical axes, respectively.

Results

For the present study, 2 criteria ($-\log_{10}$(*P*-value) and F_{ST} scores) with 3 classes each were implemented in a Sugeno fuzzy model. A heatmap of the fuzzy output is shown in Figure 2. The highest fuzzy score is yielded when both *P*-value and F_{ST} score take a high value. The lowest score is yielded when *P*-value is high and F_{ST} is low, illustrating the flexibility of the fuzzy approach.

For panels of 20k SNPs and smaller, fuzzy preselection yielded higher prediction accuracies than either $-\log_{10}$(*P*-value) or F_{ST} preselection individually, as shown in Figure 3. These gains were up to 6.3 and 1.9% higher than $-\log_{10}$(*P*-value) and F_{ST} preselection, respectively. For larger panels, both F_{ST} and fuzzy score preselection yielded similar accuracies while outperforming $-\log_{10}$(*P*-value) preselection by 1.5-2.2%.

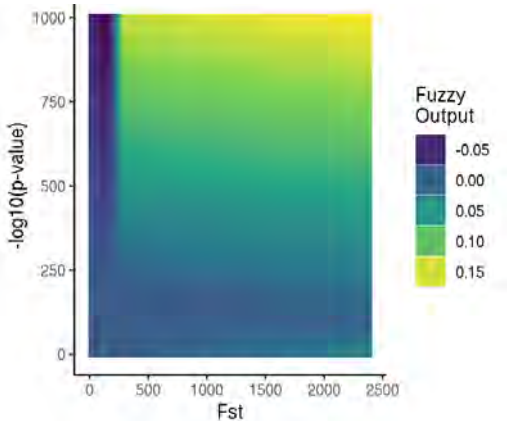

Figure 2. Heatmap of the Sugeno fuzzy model output for scaled values of $-\log_{10}$(*P*-value) and F_{ST} scores.

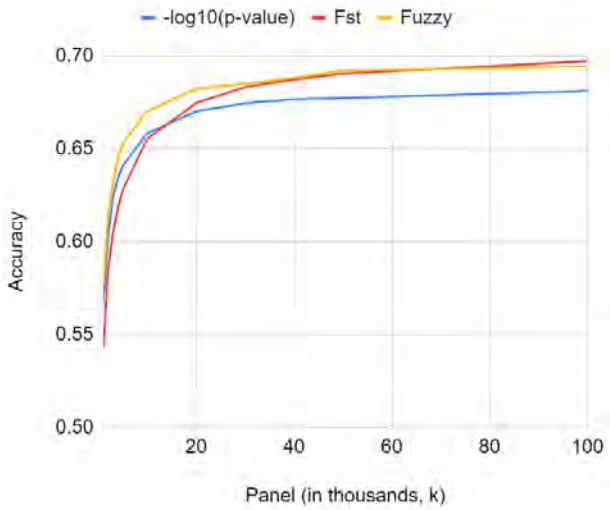

Figure 3. Trend of accuracy for -$\log_{10}$(*P*-value), F_{ST}, and fuzzy score preselection across panels of 1k to 100k SNPs.

Fuzzy preselection correctly distinguished more SNPs linked with QTL than -$\log_{10}$(*P*-value) or F_{ST} preselection for SNP panels of 40k and smaller as shown in Figure 4. Despite capturing more QTL-linked markers than fuzzy or F_{ST} score preselection for SNP panels of 50k and larger, -$\log_{10}$(*P*-value) preselection yielded lower accuracies than either of the other preselection criteria.

Discussion

The inferior accuracy of -$\log_{10}$(*P*-value) preselection relative to F_{ST} and fuzzy score preselection, despite capturing more QTL-linked markers, can be explained by the accumulation of SNP with large spurious associations. Estimated SNP effects and other statistics derived from it, including *P*-values, are highly

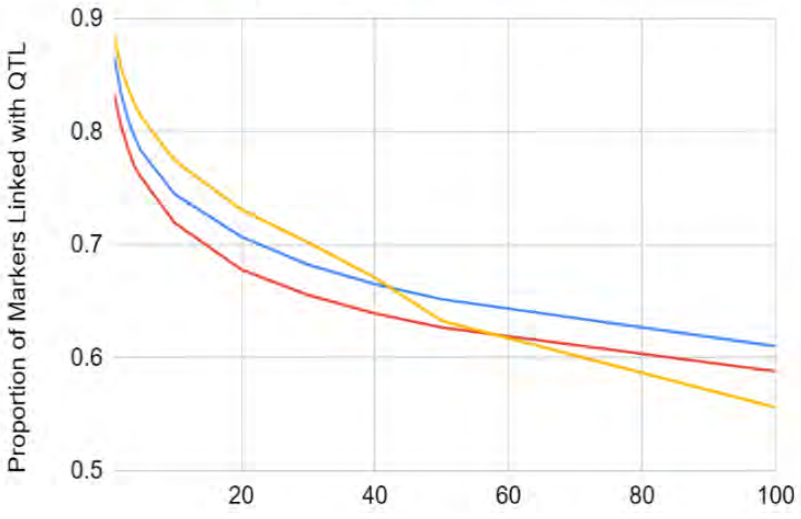

Figure 4. The proportion of preselected markers linked with QTL for -$\log_{10}$(*P*-value), F_{ST}, and fuzzy score preselection across panels of 1k to 100k SNPs.

sensitive to relevant markers, but also have a tendency to select markers with a large spurious association when a single dataset is used for both SNP discovery and model training, a phenomenon known as the Winner's Curse or Beavis effect (Xu, 2003). Ling *et al.* (2021) showed that accumulation of SNPs with large spurious associations could detract from the benefits of capturing more genetic variation and result in lower accuracies of genomic predictions.

Fuzzy score preselection yielded both higher prediction accuracies and sensitivity to detect truly relevant QTL for smaller preselected panels, and this may be due to the fuzzy model capturing the sensitivity of *P*-values to detect truly relevant QTL while identifying and excluding some of the most spuriously associated unlinked markers through contrast of *P*-values with F_{ST} scores. Ultimately, the strengths of both criteria are combined and their weaknesses balanced out.

Fuzzy preselection did not yield higher accuracies than F_{ST} scores for larger panels or outperform use of all markers. It should be noted we used only two criteria to calculate the fuzzy scores due to simulation constraints. In real data, additional prioritization criteria may be available, including prior information on variant-trait associations, gene expression data, and predicted mutation effect. Inclusion of additional criteria into the fuzzy approach has the potential to further increase capture of relevant markers and identification and exclusion of false positives, which may further improve genomic prediction accuracy.

Abstract

This study compares the performance of the Illumina BovineSNP50 BeadChip (50K chip) with sequence data and a novel designed breed-augmented customized 200K SNP chip (200K chip) in the small local dual-purpose breed German Black Pied cattle (DSN). On such genomic databases, we applied genome-wide association analyses and estimated genetic parameters and breeding values for milk production, health indicator and calving traits. Accuracies of estimated breeding values were calculated using a cross-validation approach. We identified significant SNP marker associations and candidate genes with the specifically designed 200K chip, which were not detected with the commercial 50K chip. The annotated genes (e.g. *MGST1* for 305-day lactation milk yield) were confirmed based on whole-genome-sequence data, indicating breed-specific genomic mechanisms. Heritabilities and accuracies of genomic breeding values increased slightly by using the novel specifically designed 200K SNP chip compared with the 50K SNP chip.

Introduction

Marker density affects the power of genome-wide association studies (GWAS) and genomic estimated breeding value (GEBV) accuracy. The Illumina BovineSNP50 BeadChip with ~54.000 markers (hereafter referred to as 50K chip) is commonly used for GWAS and genetic evaluations in various cattle breeds worldwide. The 50K chip is designed on a reference panel of large commercial populations like Holstein Frisian [HF] and Simmental. The chip works particularly well in breeds closely related to these reference population (Matukumalli *et al.*, 2009). The German Black Pied cattle breed (DSN, German: Deutsches Schwarzbuntes Niederungsrind) is an endangered local dual-purpose breed with a small population size of ~2,500 cattle and considered as the founder breed of HF. However, only ~37,000 markers of the 50K chip are informative in DSN after filtering, which coincides with observations in other small cattle breeds (e.g. Hozé *et al.*, 2013). Moreover, the well described *DGAT1*gene with major effects on milk production traits in HF is one example for genes which are not associated with milk production traits in DSN in GWAS (Korkuć *et al.*, 2021), although DSN and HF are closely genetically related. Hence, we designed a customized 200K SNP chip for DSN including breed-specific variants (Neumann *et al.*, 2021). We hypothesize that a denser breed-specific SNP chip is helpful in GWAS to identify DSN-specific variants for a variety of traits. Wu *et al.* (2015) showed an increased power to detect significant associations with increasing marker density for mastitis in Danish Holsteins when comparing 50K, 777K and whole-genome sequence (WGS) data.

The objective of this study was to compare three marker densities (50K, 200K and WGS) in GWAS for milk production, health indicator and calving traits in DSN. Furthermore, we compared the accuracies of genomic breeding values obtained using different SNP chip arrays.

Materials & methods

Phenotypes. We considered first-parity DSN cows from six herds. In total, 2,020 records were available for 305-day milk yield (M305), fat yield (F305) and protein yield (P305), 1,638 records for test-day fat-to-

R.F. Veerkamp and Y. de Haas (eds)

protein ratio (FPR) and somatic cell score (SCS; log-transformed somatic cell count) as health indicators, and 2,606 records for calving ease (CE) and stillbirth incidence (SB). For FPR and SCS, we focused on the challenging early lactation period and included the first test-day record between 5 and 40 days in milk (DIM). The breed (DSN) percentage was larger than 90% for all cows according to an algorithm to clearly differentiate between DSN and HF (Jaeger *et al.*, 2018).

SNP chip design and imputation of genotypes. The customized DSN-augmented 200K SNP chip (Axiom® myDesign™ TG Array; hereafter referred as 200K chip) was designed as described by Neumann *et al.* (2021). Variants for the chip were selected from 20,587,181 sequence variants (SVs) detected from WGS of 304 DSN cattle. The chip contains DSN unique variants, variants associated with important traits of interest in DSN (e.g. disease resistance, milk yield, fertility), variants with low, high or moderate impact on the transcripts, DSN informative variants from the 50K chip as well as 175,537 SNPs and 8,618 indels corresponding to 103,801 haplotype blocks in DSN. In total, 300 DSN cattle were genotyped with the novel designed 200K chip and provided a reference panel for the imputation of 1,797 DSN 50K chip genotypes into 200K genotypes. The filtered WGS data included 16,175,216 SVs of 304 DSN and served as a reference panel for the imputation of 1,797 DSN 200K genotypes to WGS level. The imputation and filtering of SVs were performed in BEAGLE (Browning *et al.*, 2018). Quality control of the three marker densities (50K, 200K and WGS) was performed in PLINK (Purcell *et al.*, 2007). Depending on the trait category, the final number of markers after filtering were ~37,000 SNPs for 50K, ~125,000 for 200K and ~11,600,000 SVs for WGS.

Genome-wide associations and genetic parameter estimations. For the GWAS, we applied a single marker linear mixed model using the 'leaving one chromosome out' option in GCTA (Yang *et al.*, 2011) for all three marker densities (50K, 200K, WGS). The statistical model in matrix notation was:

$$y = X\beta + Zu + Ss + e \quad (1)$$

where y = vector of observations for M305, F305, P305, FPR, SCS, CE and SB; β = vector of fixed effects (herd-calving year-calving season and a linear regression on DIM and age at first calving for M305, F305 and P305; herd, test-day year-season and a linear regression on age at first calving for FPR; herd, test-day year-season, a linear regression on DIM and on fat percentage for SCS; herd-calving year-calving season and sex of calf for CE and SB); u = vector of polygenic effects with $u \sim N(0, G\sigma^2_u)$, with G denoting the genomic relationship matrix (VanRaden, 2008), and σ^2_u the polygenic variance; s = vector for marker effects; e = vector of random residuals; and X, Z, and S were incidence matrices for β, u, and s, respectively. We calculated an adjusted Bonferroni-corrected genome-wide significance threshold (*p*Bonf) with $P=0.05/n_{eff}$ with n_{eff} = effective number of independent SNPs/SVs. In addition, we considered a suggestive significance threshold *p*Sug with $p = 1/n_{eff}$. The -indep-pairwise option in PLINK (Purcell *et al.*, 2007) was used to calculate n_{eff} by excluding one SV of a SV pair in LD $r^2>0.5$ in a window size of 5000 SVs, which was shifted in an interval of 500 SVs. SNP effect correlations were calculated genome-wide and chromosome-wide for each trait for all overlapping SNPs/SVs between the three marker densities. Furthermore, model (1) was applied to estimate genetic parameters for all traits with all three marker densities using restricted maximum likelihood (REML) with the --reml function in GCTA.

Gene annotation. Potential candidate genes were queried and assigned to the associated SNPs/SVs using the current gene annotations from ENSEMBL (release 104). A gene was considered as a candidate gene if at least one SNP/SV with $P<p$Sug was located in the respective gene and/or within 150 kb up- and downstream. Physiological functions of candidate genes were studied in the ENSEMBL and KEGG databases.

Genomic breeding value estimation. Breeding values were estimated in two consecutive runs: (1) 50K chip vs 200K chip using 1,900 DSN; and (2) 200K chip vs 10 random selected 200K out of WGS data (random200K) using 1,980 DSN. Phenotypic data for M305 and F305 were pre-corrected for fixed effects according to model (1) in R. Afterwards, we applied an animal model for genomic breeding value estimations using pre-corrected phenotypes (residuals) in BLUPF90 (Misztal *et al.*, 2002). The statistical model was:

$$y = \mu + g + e \quad (2)$$

where y = vector for residuals for M305 and F305; μ = overall mean; g = vector of additive genetic effects with $\sim N(0, G\sigma^2_g)$, with G denoting the genomic relationship matrix (VanRaden, 2008), and σ^2_g the genomic variance; e = residual effects with $\sim N(0, \sigma^2_e)$, and σ^2_e residual variance. For cross-validation, we divided the dataset in a validation set (20% of cows) and training set (80% of cows). We selected the cows randomly in a procedure with 10 replicates using replacements. The accuracy was calculated for each of the 10 replicates as the correlation between the direct GEBV and residuals. Afterwards, the mean accuracy was calculated based on the 10 replicates for M305 and F305 for 50K, 200K and random200K.

Results

The numbers of associated SNPs/SVs and genes for the three marker densities per trait are given in Table 1. For M305, F305 and P305, we identified 23 SNPs with 50K, 84 SNPs with 200K and 950 SVs with WGS with $P<p$Bonf/pSug. For M305, 14.8% (4/27) of genes (*KLF3*, *LIMCH1, NSUN7, RALGAPA2*) overlapped for 50K and 200K. The genes with the largest number of SNPs/SVs located in a gene for M305 were *MGST1* (BTA5), *ADGRL3* (BTA6) and *GNAL* (BTA24), exclusively detected with 200K and WGS, but not with 50K (Figure 1).

For SCS, we identified 62 SVs with WGS but no SNP reached pSug for the 50K and 200K chips. For the calving traits CE and SB, we identified 11 genes with 50K and 23 genes with 200K. Among them, seven common genes were annotated with both SNP chips. Genome-wide and chromosome-wide SNP effect correlations between 50K and 200K were ≥0.99 (P≤0.001) for all traits, and ranged from 0.62 to 0.81 (P≤0.001) between WGS with 50K and 200K. The estimated heritabilities were quite similar for the three marker densities (Table 1).

Table 1. Number of associated markers (SNPs/SVs) and identified genes (G) in the GWAS and heritabilities (h^2) with standard error (SE) for the three marker densities.[1]

	50K		200K		WGS	
Trait	**No. SNPs/G**	**h^2**	**No. SNPs/G**	**h^2**	**No. SVs/G**	**h^2**

[1] M305/F305/P305 = 305-day lactation yield for milk, fat and protein; FPR = fat-to-protein ratio; SCS = somatic cell score; CE = calving ease; SB = stillbirth.

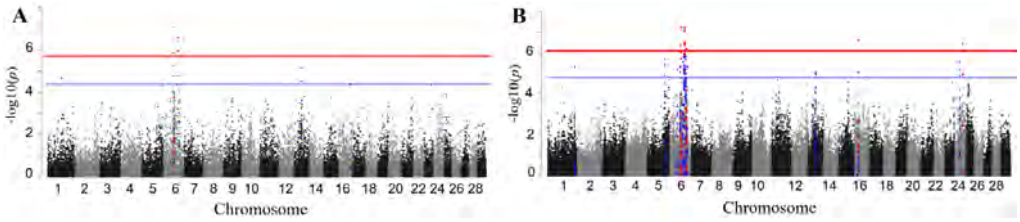

Figure 1. Manhattan-plots for 305-day lactation milk yield (M305); (A) 50K Illumina BeadChip and (B) novel designed DSN 200K SNP chip; markers above *p*Bonf (red line) are highlighted in red; markers above *p*Sug (blue line) are highlighted in blue; markers in a distance of 125 kb up- and downstream of associated markers are highlighted, too.

For GEBV run (1) the mean accuracy was 0.46 for M305 and 0.36 for F305 with the 50K chip, and 0.47 and 0.37 with the 200K chip, respectively. When comparing the 200K chip with random200K in run (2), mean accuracy was 0.46 for M305 and 0.34 for F305 with the 200K chip, and ranged from 0.446 to 0.450 for M305 and from 0.320 to 0.336 for the 10 random200K.

Discussion

Similar heritabilities and GEBV accuracies for different marker densities and traits showed a limited advantage when using the customized 200K chip compared to the 50K chip in genetic evaluations for the endangered DSN breed. Similarly, Erbe *et al.* (2012) indicated a small increase in genomic prediction accuracies of 0.01 in HF and 0.03 in Jerseys when using imputed high-density SNP panels compared to the Illumina 50K. However, since DSN and HF are closely genetically related, a breed-specific SNP chip might be more advantageous for small breeds that are distantly related with the large commercial cattle populations HF, Simmental and Brown Swiss. In agreement with the results by Wu *et al.* (2015), the power to detect candidate genes was improved when using the specifically designed 200K chip and WGS data compared to 50K. This might be due to stronger linkage disequilibrium between markers and quantitative trait nucleotides (QTN) for higher marker densities. SNP effect correlations were close to one between 50K and 200K, but moderate to high between WGS with both SNP chips. Hence, WGS is suitable to detect breed-specific variants affecting traits of interest in small-sized endangered cattle breeds, which can be integrated into genomic prediction models to improve prediction accuracies.

Abstract

We used a large pig dataset to assess the utility of whole-genome sequence data for genomic prediction. We imputed genotypes of 32.8 million variants for 396,100 individuals from seven commercial pig lines (17,224 to 104,661 per line). We used BayesR to perform genomic prediction for 8 real traits and 9 simulated traits with different genetic architectures. Sequence data improved prediction accuracy relative to the marker array, provided that the training set was sufficiently large and especially for traits with high heritability and low number of quantitative trait nucleotides. The most robust results were obtained when variants with statistically significant associations to the trait were preselected and added to the marker array, which yielded average improvements of prediction accuracy of 2.5 and 4.2 percentage points in within-line and multi-line scenarios, respectively, with training sets of around 80k individuals. More robust improvements could be achieved with larger training sets and optimised pipelines.

Introduction

Whole-genome sequence data (WGS) could improve genomic prediction accuracy and its persistence across generations and breeds because it is assumed to contain the causal variants. Early simulations indicated that using causal mutations from such data could increase prediction accuracy by up to 30% if causal variants with low minor allele frequency were captured (Druet *et al.*, 2014). Results with real data have been mixed so far, comprising either no relevant improvement of prediction accuracy compared to marker array data or small, and often non-robust, improvements (e.g. Zhang *et al.*, 2018; Song *et al.*, 2019). One of the strategies to exploit WGS that has been more successful to date consists in augmenting the available marker arrays with preselected variants from WGS based on their association with the trait of interest. In some cases, this strategy improved prediction accuracy by up to 9% (Al Kalaldeh *et al.*, 2019) or 11% (Lopez *et al.*, 2021). Thus, large data sets that capture most of the genome diversity in a population must be assembled so that the allele substitution effects are estimated with high accuracy for millions of variants. We generated WGS for 396,100 pigs from seven different intensely selected lines from diverse genetic backgrounds and with different numerical size. The objectives of this study were to use this dataset to assess the utility of WGS for genomic prediction compared to commercial marker array data and to identify scenarios in which WGS may become beneficial.

Materials & methods

Populations and sequencing strategy. We performed whole-genome re-sequencing of 6,931 individuals from seven commercial pig lines (Genus PIC, Hendersonville, TN) with a median individual coverage of 1.5×. Approximately 1.5% (0.9 to 2.1% in each line) of the pigs in each line were sequenced. Most pigs in each line were also genotyped with commercial marker arrays (GeneSeek, Lincoln, NE, USA).

Genotype imputation. Genotypes were jointly called, phased, and imputed for a total of 483,353 pedigree-related individuals using the 'hybrid peeling' method implemented in AlphaPeel (Whalen *et al.*, 2018), which used all marker array and WGS that was available. Imputation was performed separately for each line using its complete multi-generational pedigree, which encompassed from 21,129 to 122,753 individuals. Individuals with low predicted imputation accuracy were removed before further analyses according to Ros-Freixedes *et al.* (2020). A total of 396,100 individuals remained, from 17,224 to 104,661 individuals for each line, with an average predicted imputation accuracy (individual-wise dosage correlation) of 0.97 (median: 0.98). We also excluded from the analyses variants with a minor allele frequency lower than 0.023, because their average predicted imputation accuracy (variant-wise dosage correlation) was lower than 0.90. After imputation, 32.8 million variants (14.5 to 19.9 million within each line) remained for downstream analyses, of which 9.9 million segregated across all seven lines.

Traits. We analysed data of 8 traits: average daily gain (ADG), backfat thickness (BFT), loin depth (LD), average daily feed intake (ADFI), feed conversion ratio (FCR), total number of piglets born, litter weight at weaning, and return to oestrus 7 days after weaning. Most pigs with records were born during the 2008-2020 period. Deregressed breeding values (dEBV) were used. To assist in the interpretation of results, we also created 9 simulated traits with different numbers of quantitative trait nucleotides (QTN; 100, 1000 or 10,000 QTN; sampled randomly across the called variants) and heritability levels (h^2; 0.10, 0.25 or 0.50).

Genomic prediction. For each line, we defined a testing set as the full-sib families from the last generation of the pedigree. The training set was defined as all those individuals that had a pedigree coefficient of relationship lower than 0.5 with any individual of the testing set. This design was chosen to mimic a realistic situation in which breeding companies evaluate the selection candidates available in the selection nucleus at the given time. We tested genomic prediction using variants from the marker array (referred to as 'Chip'; ~40k variants) or for sets of preselected variants from the WGS of a similar size: (1) LDTags: tag variants retained after pruning based on linkage disequilibrium; (2) Top40k: 40k variants preselected based on genome-wide single-marker regression analyses in the training sets (variants with the lowest *P*-value in each consecutive non-overlapping 55-kb windows along the genome); (3) ChipPlusSign: significant variants with ($P \leq 10^{-6}$; only the lowest *P*-value within each 55-kb window; average per trait: 309, range: 23 to 1,083) were preselected and added to Chip; (4) Functional: variants that were annotated as loss-of-function or missense; and (5) Rand40k: 40k variants chosen randomly. Genomic prediction was performed by fitting a univariate mixed model with BayesR (Erbe *et al.*, 2012). Prediction accuracy was calculated in the testing set as the correlation between the genomic estimated breeding value and the dEBV. Additionally, we considered multi-line (ML) training sets that were conformed by merging the training sets of each line and by performing all analyses adding the line as an effect.

Results

The performance of each set of predictor variants was not robust and differed for each trait and line, sometimes leading to no improvements or losses of prediction accuracy. The most robust results were obtained for ChipPlusSign (Figure 1). The size of the training set was one of the main factors that determined the capacity of variants from the WGS to improve prediction accuracy compared to Chip. The simulation results suggested that genetic architecture of the traits also conditioned the utility of WGS for improving prediction accuracy compared to Chip, as greater improvements were achieved for traits with high heritability and low number of QTN (Figure 2). However, for empirical polygenic traits, average improvements of prediction accuracy of up to 2.5 percentage points were observed with training sets of around 80k individuals. In the most successful scenarios, at least around 200 significant variants were added to Chip. With multi-line training sets, average improvements of prediction accuracy with ML-ChipPlusSign were of up to 4.2 percentage points (not shown). Preselecting an entirely new set of predictor variants from

WGS in Top40k proved more challenging than ChipPlusSign and did not perform much differently from just taking random variants from these windows, as in Rand40k. Selection based on functional variants and, more severely, LDTags reduced prediction accuracy in many cases.

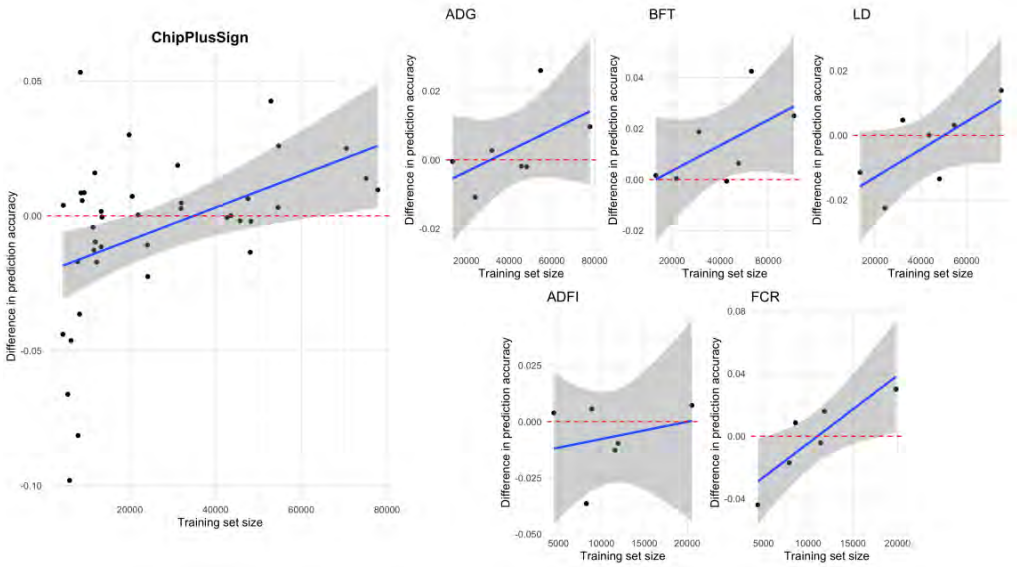

Figure 1. Genomic prediction accuracy with ChipPlusSign for the empirical traits. The difference of prediction accuracy between ChipPlusSign and Chip is shown, for all traits and lines (left) or by trait (right).

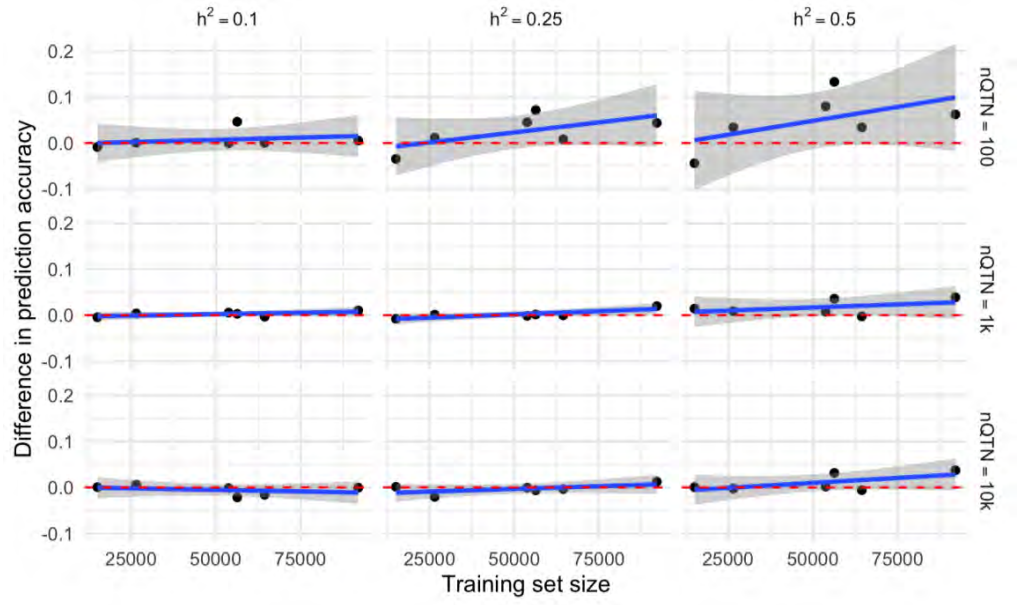

Figure 2. Genomic prediction accuracy with ChipPlusSign for the simulated traits. The difference of prediction accuracy between ChipPlusSign and Chip is shown.

Discussion

Our results evidenced the potential for WGS to improve genomic prediction accuracy in intensely selected pig lines, provided that the training sets are large enough. Improvements achieved so far were modest. On one hand, these limited improvements indicated that the strategies that we tested were likely suboptimal. On the other hand, the positive trend for the largest training sets indicated that we might have not reached the critical mass of data that is needed to leverage the potential of WGS, especially in scenarios where genomic prediction with marker arrays is already yielding high accuracy.

The modest performance of ChipPlusSign is also a consequence of the difficulty for fine-mapping causal variants through genome-wide association studies with WGS. Even though WGS allows the detection of a very large number of associations, problems such as false positives or *P*-value inflation also become more severe in a way that added noise might offset the added information. Therefore, WGS performed better with simple genetic architectures (i.e. traits with low number of QTN). This is consistent with expectations and simulation results (Clark *et al.*, 2011).

Multi-line training sets could be particularly beneficial for the use of WGS because they allow a larger training set with low relationship degree between the individuals. Previous simulations suggested that WGS might be the most beneficial with multi-breed reference panels (Iheshiulor *et al.*, 2016), especially for numerically small populations.

Abstract

Whole-genome sequence data harbor causative variants that may not be present in regular SNP chips. We investigated the impact of using preselected variants from sequence data in single-breed (SB) and multi-breed (MB) ssGBLUP. For SB, three terminal pig breeds were evaluated for five traits. These three terminal breeds were combined for the MB analyses. The number of animals sequenced or imputed to sequence ranged from 42k to 105k, depending on the breed. We examined three genotype sets, namely, regular SNP chip, top markers in each 40k genomic window, and significant SNP based on GWAS combined with the chip. Maximum gains of 0.03 and 0.01 in accuracy were observed for SB and MB with selected sequence variants. The benefits of using sequence data for SB and MB predictions are limited even when information on many sequenced or imputed animals is available.

Introduction

Whole-genome sequence (WGS) data harbor millions of variants, possibly including causative variants that primarily affect the traits of interest. As WGS data are becoming available for many farm animal species, there is a question on whether this information can help increase the accuracy of genomic predictions (GP) beyond that already achieved with SNP chips. Certainly, sequencing the entire population is still unfeasible; therefore, the most efficient approach is to sequence important animals and impute the sequence to other genotyped animals (Ros-Freixedes *et al.*, 2020). Not all variants might be causative or in high linkage-disequilibrium (LD) with the causative ones; thus, using the entire WGS data would not benefit GP (Van Binsbergen *et al.*, 2015). Hence, genome-wide association studies (GWAS) can help identify the variants statistically associated with traits of interest or the variants with large effect sizes. The use of selected sequence variants showed marginal or no increase in prediction accuracy in several populations (VanRaden *et al.*, 2017; Fragomeni *et al.*, 2019); however, the number of individuals initially sequenced was usually small, and the imputation applied to less than 30k animals. Having larger reference populations with WGS could help increase GP accuracy, as well as combining breeds with smaller reference sizes (Song *et al.*, 2019). In this study, we investigated the impact of using preselected variants from imputed WGS (IWGS) on up to 105k animals in SB and almost 207k in MB genomic evaluations.

Materials & methods

Data. Datasets were provided by Genus PIC (Hendersonville, TN). We investigated average daily feed intake (ADFI), average daily gain (ADG), backfat (BF), ADG recorded in crossbred animals (ADGX), and BF recorded in crossbred animals (BFX) in three terminal pig breeds (B1, B2, and B3). A two-trait model was considered for ADFI and ADG (ADFI model), whereas a four-trait model was used for ADG, BF, ADGX, and BFX (GROWTH model). The total number of records and animals in the pedigree are in Table 1. The number of genotyped animals for B1, B2, B3, and MB was 60,474, 41,573, 104,661, and 206,684, respectively. Different SNP panels were used for SB and MB evaluations, which were termed Chip1 and Chip2, respectively. Chip1 was based on the GGP-Porcine HD BeadChip (GeneSeek, Lincoln, NE) and

Table 1. Number of records and animals in the pedigree.

Breed	ADFI	ADG	BF	ADGX	BFX	Number of animals in pedigree
B1	35k	0.36M	0.34M	150k	149k	1.13M
B2	40k	0.30M	0.30M	158k	156k	0.84M
B3	64k	0.94M	0.86M	299k	247k	3.14M
MB	140k	1.60M	1.50M	578k	525k	5.28M

Chip2 was a MB imputed panel. After quality control, 35,786, 40,311, and 43,032 SNP remained for B1, B2, and B3 in SB, whereas 41,303 SNP remained in MB. For a fair comparison of SB and MB, we also used Chip2 for SB (Chip2SB), where 37,909, 42,897, 44,022 SNP remained for B1, B2, and B3.

Imputation. Genotypes were jointly called, phased, and imputed using the 'hybrid peeling' method implemented in AlphaPeel (Whalen *et al.*, 2018). This method used all marker array data available across the pedigrees and sequence data of 731, 760, and 1,856 pigs in B1, B2, and B3, respectively. Imputation was performed separately for each breed. Individuals with low predicted imputation accuracy were removed as described by Ros-Freixedes *et al.* (2020). A total of 60,474, 41,573, and 104,661 individuals with IWGS remained in each breed. These individuals were expected to have an average dosage correlation of 0.97 based on the imputation accuracy of 284 pigs that had both WGS (high coverage) and marker array data. Variants with a minor allele frequency lower than 0.023 were removed because their estimated dosage correlations were lower than 0.90 (Ros-Freixedes *et al.*, 2020).

Preselection of variants. Two preselected variant sets (Top40k and TopSign) were created from the IWGS data. Single-trait GWAS was carried out to identify the variants through Fast-LMM software (Lippert *et al.*, 2011). A total of 53,760, 37,147, and 92,012 animals were used for GWAS in B1, B2, and B3, respectively. For the MB, all animals were used in the GWAS, and a fixed breed effect was included in the model to account for breed differences. Top40k was constructed by selecting top markers in each 40k genomic window of IWGS. TopSign only included significant variants and was integrated into the chip data (ChipSign) for genomic predictions. We combined the selected variants for each trait in the ADFI and GROWTH models because the variants were prospected from single-trait GWAS. After quality control, from 78,714 to 80,899 SNP were used in Top40k and 36,305 to 44,734 in ChipSign for SB, depending on the breed and model. In the MB analyses, 51,297 and 49,738 SNP were retained in Top40k and 62,906 and 59,756 SNP in ChipSign, depending on the model.

Genomic predictions. Variance components were estimated for each breed separately in the SB scenario without using genomic information. Likewise, variance components from the MB scenario were estimated using MB data. All fixed effects in the model were made breed-specific in the MB analyses. For genomic predictions, we used ssGBLUP as implemented in the BLUPF90 family of programs (Misztal *et al.*, 2014). Predictive ability was calculated as the correlation between deregressed EBV (DEBV) and GEBV for the validation animals. The number of validation animals varied from 3,720 to 11,308, depending on the breed and model.

Results

Predictive abilities of both SB and MB evaluations are presented in Table 2. Using preselected variants for SB improved predictive ability up to 0.01 for ChipSign and 0.03 for Top40k compared to Chip1. However, when Top40k was used for MB, there was even a decrease of -0.05 (ADFI in B2) in predictive ability compared to Chip2. ChipSign showed a maximum of 0.01 gain and a -0.01 decrease. Comparisons between Top40k for SB and MB showed greater predictive ability when the top markers in each genomic window of

[1] ADFI = average daily feed intake; ADG = average daily gain; BF = backfat thickness; ADGX = average daily gain crossbreds; BFX: backfat thickness crossbreds.

40k SNP were selected based on SB GWAS. Differences in predictive ability became larger in breeds with less genotyped or sequenced/imputed animals. Moreover, Chip2SB outperformed Chip2 in most of the cases, indicating no benefits of MB genomic prediction.

Discussions

Our study is the first to report the predictive ability of ssGBLUP for large pig populations with IWGS data. Most of the studies have used less than 30k sequenced/imputed animals. We used up to 105k for SB and up to 207k animals for MB evaluations. Current results showed that the advantages of using preselected variants from IWGS highly depend on the trait, breed, and model (SB or MB) used for GWAS. For example, ADGX of B2 and B3 showed some improvement in predictive ability (16 and 8%) in SB when using Top40k, but for the same trait, B1 reported no gains. In contrast, predictive ability for MB was the same or decreased with Top40k, compared to Chip2, possibly meaning that those variants preselected based on MB GWAS are not as informative as the ones identified in the SB GWAS. This raises a question about the amount of information that has been used for selecting variants. Looking at the dimensionality of the genomic information can help to assess the number of genotyped animals needed to maximize the percentage of discoveries in GWAS (Jang *et al.*, 2021). According to Jang *et al.* (2021), populations with smaller effective size (Ne=20) require more data to capture causative variants, whereas for large populations (Ne=200), using the number of genotyped animals equal to that of the largest eigenvalues explaining 98% of the variance of the genomic relationship matrix suffices. Still, only a small proportion of the causative variants can be discovered if those genotyped animals do not have lots of progeny records.

Regarding MB evaluations, breeds with fewer genotyped animals (B1 and B2) observed a decrease in predictive ability when the models involved the top markers in each genomic window of 40k SNP. This might be because those Top40k SNP selected from MB GWAS could be related to causative variants in the largest breed (B3) but not in the small ones (B1 and B2). Larger breeds can easily overwhelm GWAS and GP

results when combined with smaller breeds. Using preselected variants from IWGS slightly improved the prediction accuracy when selected from SB GWAS and used for SB predictions. However, no benefits were observed in MB. Overall, the benefits of using sequence information for SB and MB genomic predictions may still be limited even when information on many sequenced or imputed animals is available.

Abstract

Accuracy of genomic prediction was compared in two layer lines using medium density SNP chip and low-pass sequencing. Three thousand individuals representing two lines were sequenced for the project. Thirty-four genomic regions were identified as genome-wide significant across 11 egg quality traits and their genotypes were added to the chip. Multi-trait single-step animal model was used for genomic prediction. A slight increase in accuracy for some of the traits was obtained by adding the significant SNPs to those present on the chip. Fitting all sequence SNPs had no advantage for predictive ability over chip despite explaining 15% more of phenotypic variance in the Genome Wide Association Study. Further optimization of the utilization of sequence data and cost reduction are required to make low-pass sequence competitive to medium density SNP chips for genomic prediction.

Introduction

Genomic selection has been applied to poultry breeding for a decade providing benefits of increased accuracy of estimated breeding values and shortening of generation intervals. With the reduction in cost, implementation evolved from a combination of low- and high-density panels to population specific medium density panels (50-60,000 SNPs). With the development in sequencing technology the costs of obtaining whole genome sequences were greatly reduced. Low pass sequencing interrogates all genomic locations in contrast to chip genotyping which only considers those SNPs included on the chip. Low pass sequencing comes at a lower cost than standard sequencing but also at a lower accuracy of genotype calls than standard sequencing. Rubinacci *et al.* (2021) notes that the accuracy of genotype calls from low pass sequencing can be recovered by combining the genotype calling with imputation similar to the methodology used to combine information from low- and high-density chips. If relevant reference populations are used accurate genotype calls can be obtained with 1× sequences.

Some studies suggest that low-pass sequencing can improve genome wide association studies relative to chip data (Li *et al.*, 2021). Until now no studies using large scale sequencing were reported in the literature for laying chickens, therefore we investigated the impact of using whole genome sequence data and adding SNPs identified as significant in a Genome Wide Association Study (GWAS) to the 54k chip for genomic prediction.

Materials & methods

Data. One hundred males from 8 major lines were selected for sequencing at 4× coverage and combined with 124 samples from publicly available sequences to provide reference for genotype calling for low-pass (1×) sequenced individuals. Genotypes for 32 million SNPs were called. Vcf files were provided by Gencove with SNPs called using their proprietary algorithm. One generation of breeding males and two generations of breeding females were sequenced at 1× coverage for a total of 3,025 sequenced individuals, including 1,540 individuals from one White Leghorn (WL) line and 1,485 individuals from one Rhode Island Red line (RIR). Genotypes of males were used in single-step genomic prediction (they are sires of hens with phenotypes) but not in GWAS (they don't have own phenotypes). After quality control with minor allele

frequency >1%, 8.6 million markers were left in RIR and 7.6 million markers in WL line. Phenotypes are available for all of the sequenced females with more than 30,000 and 40,000 additional phenotyped relatives for RIR and WL line, respectively. Phenotypes used for the analyses include several egg quality traits such as shell strength, egg weight, yolk weight, albumen height and shell colour measured at different ages.

Validation of SNP calls. Accuracy of 1× genotype calls was validated by comparison to Axiom 54k SNP chip genotypes on the same individuals using absolute value of correlation for genotypes called as 0,1,2 and percentage of identical calls, and as percentage of identical calls for animals sequenced in duplicates.

GWAS. GWAS was performed using a mixed model in Genome Wide Complex Trait Analysis software (GCTA; Yang *et al.*, 2011) for WL and RIR lines separately. The following statistical model was used in the GWAS:

$$y_i = \mu + b\, x_i + g_i + e_i$$

where y_i is the phenotype adjusted by station and hatch effect for individual i; μ is the overall mean; b is the additive effect (covariate) of the candidate SNP to be tested for association; x_i is the SNP genotype indicator of the candidate SNP for individual i coded as 0, 1 or 2; g_i is the random polygenic effect for individual i based on the relationship matrix computed from genotypes and e_i is the residual. No obvious population stratification was observed based on the principle component analysis for both lines, thus it was not considered in the GWAS. The SNPs with *P*-value<0.00001 were added to the SNP panel for genomic prediction.

Genomic prediction. 212 females from WL line and 228 from RIR line had phenotypes removed when conducting the GWAS and genomic prediction for the purpose of validation. The data were analysed per line with AIREMLF90 software using chip data, sequence data or chip combined with significant SNPs from the sequence for the construction of H matrix.

A series of multi-trait animal models fitting fixed effects of hatch within generation, station processing the eggs, age of birds and random effects of animal and permanent environment were applied for genomic prediction. Variance components were estimated with pedigree and only BLUP was performed using H matrix in order to reduce computational requirements.

Accuracy was measured as correlation between the phenotype adjusted for fixed effects and predicted genomic breeding value divided by square root of heritability.

Results

Accuracy of genotyping with low-pass sequencing. Sequence was evaluated on 386 samples by comparing those genotypes to respective allele calls from 54k Axiom SNP Chip (currently a gold standard). Median correlation of the genotypes was 0.97 (SNPs with lower MAF tended to have lower correlation) with 98.4% calls being identical. For 96 test samples sequenced in duplicates, concordance of genotype calls around 98% was obtained compared to >99.5% for duplicates on chip.

Genomic prediction. Based on mixed model in GCTA software using only hens that had both phenotypic and sequence records sequence data explained on average 15% more variance than SNP chip. Across the egg quality traits 43 genomic regions were identified as significant at genome wide level.

In the first step, genomic prediction was performed using SNP chip genotypes. Based on the GWAS results, 7,063 and 7,216 SNPs were added to those present on the chip to conduct another set of genomic prediction. Slight improvement in accuracy was achieved for some of the traits (Table 1). The prediction accuracy based on 54k chip data was close to that based on low-pass sequencing, despite many more SNPs considered with sequencing data.

Discussion

Previous studies (Rubinachi *et al.* 2021, Kim *et al.* 2021, Li *et al.* 2021) used subsampling of high coverage sequence data to evaluate accuracy of low pass sequencing and showed that with exception of low frequency variants accurate calls can be obtained when genotype calling is combined with imputation. We used real samples that were genotyped and sequenced in duplicates under different IDs to validate low-pas sequencing and showed that the quality of information from low-pass sequence is slightly lower than from SNP chip but acceptable for GWAS and genomic prediction.

Mixed results were obtained by using sequence data for genomic prediction with several studies reporting very limited benefits (VanRaden *et al.*, 2016; Heidaritabar *et al.*, 2016). Yang *et al.* (2010) showed that the genetic variance does not depend on the number of SNPs when correcting for incomplete LD between SNPs, which explains why the genomic prediction based on SNP chip and sequencing data were similar.

Some increases in accuracy were observed when SNPs were weighted differentially based on their annotation (McLeod *et al.*, 2016) or smaller panel was designed by combining sequence based GWAS with annotation (Xiang *et al.*, 2021). Therefore, the next step will be to employ differential weighting of SNPs and other computational strategies.

Conclusions

Similar or slightly higher accuracy can be obtained in chicken using low pass (1×) sequence data compared to a medium density SNP chip however further optimization is needed to extract more information from the sequence data.

Challenges – improving genomic prediction

272. Accuracy of prediction for a genomic evaluation in rotational crossbreeding scheme (Montbéliarde × Holstein × Red Danish)

Abstract

In recent years, crossbreeding strategy has grown in dairy cattle farms at an international level. Breeders are interested in keeping crossbred cows in their herd both to combine the strengths of the pure breeds, compensate for their weaknesses and benefit from heterosis. However genetic tools are still lacking to manage these crossbred animals. In this study, we evaluate the performances of a genomic evaluation adapted for rotational crossbreeding schemes with real data. This genomic evaluation was applied to a population that includes pure-breed animals from Holstein, Montbéliarde, and Red Danish breeds, as well as crossbreds between these three breeds. The genomic evaluation approach was based on the estimation of breed specific SNP specific according to the Breed of Origin of the Alleles.

Introduction

Crossbreeding strategy in dairy cattle breeding schemes has significantly grown over the past years, and this trend may be reinforced in the future to face challenges linked to agroecology or to new constraints induced by climate change. Indeed, this strategy is particularly suitable to combine the strengths of the pure-breeds and to compensate for their weaknesses, being an efficient way for breeders to obtain more adaptable and robust animals, resulting in a more sustainable breeding system. Crossbreeding is also relevant to decrease inbreeding or, equivalently, generate heterosis.

Genomic evaluation in pure breed is common, it is developing in terminal crossbreeding, but only a few countries routinely evaluate crossbred animals in continuous crossbreeding programs. For most countries, breeders engaged in a crossbreeding process have information limited to purebred bulls and the raw performances of their crossbred females to manage their selection and mating. In this context, the literature dedicated to continuous crossbreeding relates, for the most part, to simulated data (Van Raden *et al.*, 2021; Eiriksson *et al.*, 2021; Karaman *et al.*, 2021) and rarely to applications on real data (Sevillano *et al.*, 2017).

In this study, we propose an application of genomic evaluation for continuous crossbreeding programs, through a SNP-BLUP based on Breed Origin of Alleles (BOA). This approach estimates specific SNP effect depending on its breed of origin. The rationale for this approach is that linkage disequilibrium between SNP and the causal mutation differs according to the breed; additionally, QTL effects may be breed dependent.

The data used in this analysis consisted of the first steps of a three-way crossbreeding scheme including Montbéliarde (Mo), Holstein (Ho) and Red Danish (RD) breeds. This data set was augmented by purebred data to ensure accurate estimation of within breed SNP effects. The procedure included several steps: imputation and phasing at the 50K level of all the animals; identification of BOA of each allele of crossbred animals; genomic evaluation on five production traits, including a cross-validation procedure. Accuracy of prediction and slope of regression were calculated.

Materials & methods

Genotypes. The data used in this study originated from France and Nordic Countries (NAV). They consisted of 5,238 genotypes of crossbred animals, and 20,000, 22,265, and 6,866 genotypes of pure Mo, Ho, and RD animals, respectively. 53,498 autosomal SNP markers were retained from the Illumina 50K chips used routinely in France for genomic selection. Imputation was carried out into two steps. In the first step, genotypes of purebreds were imputed with FImpute (Sargolzaei *et al.*, 2014) with the pipeline used in the routine French national evaluation system and in the second step, these imputed genotypes were treated as known genotypes. In the second step, the crossbred genotypes were imputed with FImpute software using the purebred Ho, Mo, and RD as a reference, and without using any pedigree information.

BOA of alleles. The frequency (f) of each haplotype of n consecutive SNPs was estimated by counting within each pure breed. BOA i was selected if:

$$\frac{f_i}{\sum_{j=1}^{nbreed} f_j}$$

was higher than a given threshold (0.9). The whole genome was scanned by a sliding window moving one SNP at a time. The initial value of n was set to 16 (leading to 65,536 theoretical haplotypic combinations). When a haplotype origin remained undetermined, the process was iterated after n was divided by 2. Undetermined origins surrounded by identical breed origins were assigned to this breed. When n=1, the small proportion of finally remaining undetermined origins were allocated according to allelic frequencies. This procedure was implemented in the in-house BreedOrigin fortran software and applied to a target population of 5,238 crossbred animals. The results were compared to expected breed proportions based on pedigree.

Crossbreeding parameters. Fractions of heterosis (H) and recombination losses (R) were calculated for each crossbred animal from proportions of breed origins of their parents based on pedigree. Values of the H and R coefficients were calculated as in Dechow *et al.* (2007) using the following formulae:

$$H = 1 - \sum_{i=1}^{nb_{breed}} s_i d_i \text{ and } R = 1 - \sum_{i=1}^{nb_breed} \frac{(s_i^2 + d_i^2)}{2}$$

where s_i and d_i are the proportions of sire and dam genes from breed i, respectively. Heterosis and recombination losses were then estimated by regressing on H and R.

Phenotypes. The genomic evaluation was a two-step procedure. In a first step, a polygenic model was used to estimate all non-genetic effects (herd-year, age-year and year-month of calving), heterosis and recombination losses (as regression coefficients) and heterogeneous variances, as in Dezetter *et al.* (2015). Unknown parent groups accounted for breed of origin, and breed composition of crossbreds was accounted for by the pedigree. Yield deviations (YD) produced by this model correspond to performances adjusted for fixed and non-genetic random effects. Five production traits were analysed: lactation milk yield, protein yield, protein content, fat yield, and fat content. Two batches of evaluations were performed, the first one accounting for heterosis and recombination losses, and the second one ignoring them.

Crossbreed genomic evaluation accounting for BOA. To account for crossbred animals in a genomic evaluation model, we proposed an extension of the SNP-BLUP model where a SNP effect β_i is estimated for each breed as described in the following model:

$$y_i = \sum_{b=1}^{nb_breed} (p_{i,b}\mu_b) + \sum_{b=1}^{nb_breed} \left(\sum_{j=1}^{nb_SNP} (\beta_{i,j,b} X_{i,j,b}) \right) + e_i \quad (1)$$

where y_i is the YD of the animal i, μ is a vector of means defined within each breed, $p_{i,b}$ is the proportion of breed b in the genome of individual i, estimated with the BOA approach. $X_{i,j,b}$ is the allele content of SNP j that originates from the breed b for animal i, centered for the allelic frequency of the SNP in breed b:

$$X_{i,j,b} = \left(k_{i,j,b} - n_{i,j,b} f_{j,b}\right) \quad (2)$$

where $k_{i,j,b}$ and $n_{i,j,b}$ are the number of '2' alleles and the total number of alleles of the SNP j that originates from breed b for the animal i, respectively; $f_{j,b}$ is the frequency of allele '2' of the SNP j in breed b.

To assess the performance of the genomic evaluation, the data set was divided into a training dataset with both genotypes and phenotypic records used to estimate SNP effects according to their BOA, and a validation data set for which predicted breeding values were computed using the effects obtained with the training dataset and then compared to the observed phenotypes. The validation population consisted of 2,000 crossbred cows without progeny.

Results

Breed of origin of alleles. Results for breed composition based on pedigree information and BOA methodology are presented in Table 1. For genotyped crossbred animals, 94% of the alleles were assigned to a breed. 48% of markers were from Ho origin, 34% from RD origin and 13.6% from Mo origin. In comparison, based on pedigree information, the corresponding origins were 56.3, 29.8 and 11.8% respectively. Correlation between breed compositions for both methodologies ranged from 0.95 for the RD breed to 0.99 for the Mo breed.

Across breed genomic evaluation accounting for BOA. Correlations between YD and genomic breeding values and associated slope of regression are presented in Table 2. On the training population, all the correlations are around 0.80 for lactation milk yield, fat yield, and protein yield and around 0.90 for fat content and protein content. Adjusting for Heterosis weakly affected these correlations. The associated slopes of regression were slightly higher than 1 for all the traits. In the validation population, without

Table 1. Results of determination of Breed of Origin based on genomic or Pedigree information.

Breed of Origin	Breed composition with BOA		Breed composition based on pedigree		Correlation
	Mean	Sd	Mean	Sd	
Montbéliarde (Mo)	13.60%	20.00%	11.80%	19.20%	0.99
Holstein (Ho)	48.00%	19.40%	56.30%	20.20%	0.97
Red Danish (RD)	34.00%	17.80%	29.80%	17.80%	0.95

Table 2. Correlations and slopes of regression of the YD, adjusted or not for Heterosis for 5 production traits, on the estimated genomic breeding values, in the training and validation population.

Traits	Performance without heterosis effect				Performance adjusted for heterosis effect			
	Training population		Validation population		Training population		Validation population	
	Corr	Slope	Corr	Slope	Corr	Slope	Corr	Slope
Milk yield	0.85	1.11	0.38	1.62	0.84	1.12	0.39	1.66
Fat yield	0.81	1.16	0.37	1.58	0.80	1.19	0.38	1.64
Protein yield	0.80	1.18	0.34	1.63	0.78	1.20	0.35	1.69
Fat content	0.93	1.11	0.63	1.47	0.93	1.11	0.63	1.47
Protein content	0.94	1.08	0.59	1.50	1.00	1.08	0.59	1.50

integration of the Heterosis effect, correlations ranged from 0.34 for protein yield to 0.63 for fat content trait. The gain of correlation obtained after adjusting for Heterosis was marginal (+1 point for lactation milk yield, fat yield, and protein yield). Regarding the slopes of regression, they were overestimated both with and without adjustment of the performances for Heterosis (between 1.47 and 1.69).

Discussion

In this study, we propose an application on real data of a genomic evaluation in a rotational crossbreeding scheme based on a SNP-BLUP model accounting for BOA.

This approach required to impute and phase genotyping data of crossbred animals in order to predict BOAs for these animals. These steps were tested and an average error rate of about 1.5% for the predicted BOA was observed (data not shown). To complete this information, we compare in this study the breed composition of crossbred animals measured using the pedigree information of the animals and estimated from the genotyped animals. The very strong correlations obtained between these two approaches are completely consistent with previous tests (Table 1).

Finally, the genomic evaluations carried out have shown an honourable accuracy of prediction of around 0.30 for traits with a heritability of 0.3 and around 0.60 for traits with a heritability of 0.50 (Table 2). The adjustment of the performances for Heterosis did not impact the accuracy of the prediction of the breeding values.

Abstract

Dairy cattle production systems are mostly based on using purebreds, but recently crossbreeding has received increased interest. For genetic evaluation including crossbreds, ideally, models accounting for breed specific effects should perform better compared with simple models. A novel single-step best linear unbiased prediction method provides an opportunity to combine purebred and crossbred information when breed specific effects are accounted for. In this study, we applied this single-step method to evaluate two-way crossbred performance for average daily gain in crossbred beef on dairy. Results showed that the single-step method, which accounted for breed specific effects, had a higher predictive ability. We conclude that this method is useful in the genetic evaluation for crossbred performance in cattle production system.

Introduction

Crossbreeding is common practice in many livestock production systems, in particular for pigs and poultry. For dairy and beef cattle, the production systems are mostly based on using purebreds, but recently crossbreeding between dairy breed cows and beef breed bulls has received increased interest for a number of reasons (Berry 2021). In particular, the use of x-sorted dairy semen and herd specific strategies for the necessary number of replacement heifers has provided the option that some dairy cows in a herd can be inseminated with beef semen, and furthermore, meat production from crosses between dairy cows and beef bulls has lower environmental footprint than meat production from beef cattle.

Genomic selection (Meuwissen *et al.* 2001) is another potentially important factor to make the cattle meat production more efficient and with reduced environmental impact. Genomic evaluation in cattle has primarily been done within pure breeds, but ideally for crossbreeding with dairy cows, genomic breeding values on beef bulls should be estimated for such crossbred performance based on phenotypic records on crossbreds. Genomic models that split genomic effect of crossbreds into breed specific terms and account for the breed of origin of alleles (BOA) should in principle perform better than simpler models that do not take BOA into account, but this has not always been seen (Sevillano *et al.* 2017).

Commonly in genomic evaluation, for many reasons, not all relevant individuals are genotyped. For this purpose, so-called single-step genomic best linear unbiased prediction (ssGBLUP) was introduced (Legarra *et al.* 2014). Xiang *et al.* (2016) investigated an extension of ssGBLUP for crossbred performance in a terminal two-breed crossbreeding system for pigs, and concluded that models using marker genotypes of crossbreds improved accuracies of prediction for crossbred performances (Xiang *et al.* 2016). The approach investigated in that paper was based on BOA and so-called breed specific partial relationship matrices that combine genomic and pedigree-based relationships (Christensen *et al.* 2014).

The objective of this paper is to investigate predictive performance of a ssGBLUP model based on BOA compared to the usual ssGBLUP model that did not account for BOA for crossbred beef on dairy cattle.

Materials & methods

Data. All data sets were provided by SEGES cattle. In this study, 2,329 two-way crossbred calves with purebred Belgian Blue beef (BBL) sires and purebred Holstein dairy (HOL) dams were on test for 1 month. These calves had an average age of 210±36 days in the beginning of test, and 245±32 days in the end of test. During this period, feed intake was recorded for each animal, and body weight of each animal was recorded at both start and end of test period. Average daily gain (ADG) of each animal within this period was calculated as the increase in body weight divided by number of days between the two recordings. After data editing, 1,749 crossbred calves with ADG were retained.

Pedigree for crossbred animals was traced back three generations, and there were 13,612 animals in the pedigree. Among these animals, 36 BBL and 138 HOL were genotyped with either EuroG 10k Bead Chip or EuroG MD Bead Chip, and 1,137 crossbreds were genotyped with EuroG MD Bead Chip. In purebred animals, imputation from EuroG 10k Bead Chip to EuroG MD Bead Chip was done with software Beagle 5.2 (Browning and Browning 2007). Quality controls of genomic data with software Plink were as follows: it was first confirmed that no individuals had call-rate less than 90%; following that, SNPs with call-rate less than 90% were removed; SNPs with a minor allele frequency less than 0.05 were removed; SNPs deviating strongly from Hardy Weinberg equilibrium within breed (P<10-7) were also removed (Purcell *et al.* 2007). After quality control, 1,311 individuals and 45,288 SNPs were retained. The retained genotype data was phased with software Beagle 5.2 (Browning and Browning 2007).

Allele tracing. The detection of BOA in crossbred animals is necessary for constructing breed specific partial relationship matrix. In this study, for detecting BOA we used the recently developed AllOr algorithm (Eiríksson *et al.* 2021), which is based on the comparison of haplotypes in overlapping windows.

Statistical Model. Two ssGBLUP models for genomic prediction were evaluated. The first model is the usual ssGBLUP model (M_1):

$$y= Xb+Zu+e \quad (1)$$

where y is a vector of phenotypic records for ADG; Xb refers to the fixed effects including herd-year-season, sex, and covariate of body weight at start test; u is a vector of random additive genetic effects for each animal, and Z is the corresponding incidence matrix; e is a vector of random residual effects. The random effects follow normal distributions of $u\sim N(0,H\sigma_a^2)$, and $e\sim N(0,I\sigma_e^2)$, where H is the combined pedigree-based and marker-based relationship matrix, which can be constructed as previously reported (Legarra *et al.* 2014); I is the identity matrix; σ_a^2 is the additive genetic variance; σ_e^2 is the residual variance.

The second model is the partial ssGBLUP model (M_2):

$$y= Xb+Z_Au_A+Z_Bu_B+e \quad (2)$$

where y, Xb, and e are as in Equation 1; u_A is a vector of random additive genetic effects from BBL, u_B is a vector of random additive genetic effects from HOL; Z_A and Z_B are the corresponding incidence matrices. The random effects follow normal distributions of $u_A\sim N(0,H_A\sigma_A^2)$, and $u_B\sim N(0,H_B\sigma_B^2)$, where H_A and H_B are combined pedigree-based and marker-based breed specific partial relationship matrices, which can be constructed as previously reported (Christensen *et al.* 2014); σ_A^2 and σ_B^2 were additive genetic variances for crossbred performances of BBL and HOL, respectively. The above analyses were carried out using restricted maximum likelihood (REML) algorithm and best linear unbiased prediction (BLUP) in the software DMU (Madsen and Jensen 2013).

In order to reveal the differences in predictive abilities between models M_1 and M_2, data were split into a training dataset and a validation dataset by a cut-off date of October 20, 2020. The numbers of animals in the training and validation datasets were 1,399 and 350, respectively. Predictive abilities were calculated as the correlation between predicted total genetic values (g) and the corrected phenotypes (Y_c) in the validation dataset. Vector Y_c was calculated based on model M_1 with full dataset. In model M_1, g was equal to the additive genetic effects (g= u); in model M_2, g was equal to the sum of additive genetic effects from BBL and HOL (g= u_{A+} u_B). Furthermore, dispersion bias of genomic predictions for each model was assessed as the regression coefficient of Y_c on g, with an expected result of 1.

Results

Variance component estimation. Estimates of variance components and heritabilities are shown in Table 1. In model M_2, the additive genetic variances from BBL (σ_A^2) and HOL (σ_B^2) were equal to 0.011 and 0.013, and the additive genetic variance of crossbred animals was equal to 0.012 (half of the sum of σ_A^2 and σ_B^2), which was a little bit higher than in model M_1. The heritability in models M_1 and M_2 was 0.105 and 0.122, respectively.

Predictive abilities. Predictive abilities of models M_1 and M_2 are shown in Table 2. The Pearson correlation coefficients between the corrected phenotypes and total genetic values of crossbred animals in model M_2 was 0.059, being a little bit higher than in model M_1 where it was 0.052. In terms of regression coefficients of corrected phenotypes on the total genetic values, model M_1 deviated more from 1 compared with model M_2.

Discussion

In this study, the estimated heritability of ADG was low to moderate, which was a little bit lower than previously reported (Freetly *et al.* 2020). One potential reason could be that ADG in this study was calculated in a shorter time period compared to previous studies. Furthermore, Ahlberg *et al.* (2018) pointed out that during different periods, the correlations for each shortened test duration was different. In addition, the smaller dataset could also be another possible reason.

Results of predictive abilities indicated that partial ssGBLUP model accounting for breed-specific effects performs better than the usual ssGBLUP model in terms of accuracy and dispersion bias. This phenomenon

Table 1. Estimates of variance components and heritabilities in different models.[1]

Model	σ_a^2	σ_A^2	σ_B^2	σ_e^2	h_a^2	h_{AB}^{2*}
M_1	0.010			0.088	0.105	
M_2		0.011	0.013	0.086		0.122

[1] h_{AB}^2 = heritabilities of crossbred animals ($0.5(\sigma_A^2+\sigma_B^2)/[0.5(\sigma_A^2+\sigma_B^2)+\sigma_e^2]$).

Table 2. Predictive abilities for crossbred animals in the validation dataset in different models.

Model	$r(Y_c, g)$[1]	$b(Y_c, g)$[2]
M_1	0.052	0.733
M_2	0.059	0.774

[2] $b(Y_c, g)$ = Regression coefficients of Y_c on g.

has also been observed in other species (Xiang *et al.* 2016). The result presented here only focused on the prediction of total genetic values in crossbreds. In future study, we plan to investigate accuracy of estimated breeding value of BBL sires for crossbred performance when mated to a Holstein cow.

274. Improving accuracy of genomic prediction in distant populations by collecting sequence data over generations

M.Y. Nawaz[1,2*] and C. Gondro[1,2]

[1]Genetics and Genome Sciences Program, Michigan State University, East Lansing, MI 48823, USA; [2]Department of Animal Science, Michigan State University, East Lansing, MI 48823, USA; nawazmuh@msu.edu

Abstract

In this study we tested the hypothesis that accuracy of genomic prediction in distant populations can be significantly improved by having the actual QTLs in the SNP panels used for genomic evaluations. Three different simulation scenarios were created for within breed, crossbred and across-breed genomic prediction of Angus, Hereford and Brahman cattle with three sets of SNP panels consisting of only *SNP*, only *QTL*, or *SNP* and *QTL*. We found that when QTL were part of the SNP panel, the decline in prediction accuracy over generations was lower and the accumulation of data over generations led to higher accuracy gains compared to using only non-causal SNPs, especially for crossbred and across breed prediction. A wider adoption of sequence data for genomic prediction still seems a valid proposition to increase the accuracy of genomic prediction in cattle, especially for distantly related animals.

Introduction

Genomic prediction based on single nucleotide polymorphism (SNP) panels is highly dependent on the linkage (LD) between SNP markers and true QTLs regulating the trait. Due to recombination, the linkage between SNPs and QTLs decays across generations and, similarly, animals from different parts of the world or from different breeds also diverge in their genetic composition and LD patterns between markers (De Roos *et al.*, 2008). This results in reduced prediction accuracy across generations (Muir, 2007), across countries (Saatchi *et al.*, 2013) and across breeds as demonstrated by various studies in cattle (Hayes *et al.*, 2009; Kachman *et al.*, 2013; Mason *et al.*, 2012). It was predicted that whole genome sequence (WGS) information would increase the accuracy of prediction (Meuwissen and Goddard, 2010) as it would include most of the variants segregating in a population. Yet, cattle studies to date have reported minimal gain in prediction accuracy using WGS information when compared to medium and high density SNP genotyping panels (Calus *et al.*, 2016; Van Binsbergen *et al.*, 2015). These results were attributed to the high LD observed in cattle populations and an inability to accurately estimate SNP effects due to small sample sizes with millions of SNP markers. The objectives of this study were to: (1) quantify the decay in prediction accuracy as the genetic distances between the reference and test population increased over generations in beef cattle; (2) analyze the effect on prediction accuracy over generations if the true QTLs are part of the SNP panel; and (3) demonstrate the impact of accumulating cross-generational genomic information in the reference population.

Materials & methods

Medium density genotypes (50k) of 7,500 animals from Angus, Hereford and Brahman cattle were used as the base population for the simulation study. These genotypes were phased and imputed separately for each breed using the software *eagle*, converted to *vcf* format with *shapeit* and then into a numerical matrix with the R package *splitstackshape* (R version 4.0.2). The three datasets were subset down to 29,632 SNPs that were common across the three breeds. Matings were simulated using the forward simulator R package *epinetR*. First, a moderately heritable phenotype (h^2=0.4) regulated by 100 QTL was simulated under an additive model using the Angus cattle as a baseline. The SNP effects were extracted and used to create baselines for the Hereford and Brahman cattle. Crossbred F1 genotypes were then simulated using

the same software with equal contributions from the combinations of parental breeds. Once we had the baseline populations, we simulated matings under selection for 20 generations for each of the purebred and crossbred base populations. For this step we used the *runSim* function in *epinetR* with the following parameters: *truncSire*=0.3 (top 30% of males in the population with highest phenotypic value were selected during each generation), *truncDam*=0.8 (top 80% of females in the population with highest phenotypic value were selected during each generation), *breedSire*=50 (maximum number of offspring per sire). These parameters were chosen to represent reasonably well the current structure of the beef industry. Three different scenarios were created to evaluate genomic prediction: within a breed, in crossbreds and across breeds; and each was tested for three different SNP panels, namely SNP (all SNPs except the *causal* ones), QTL (only *causal* SNPs), and all SNP&QTL. For every scenario, we evaluated genomic prediction accuracy trends in two ways: (1) by increasing the number of generations between training and testing population; (2) by accumulating training populations backward from the testing population. Genomic prediction was performed by genomic best linear unbiased prediction methodology (GBLUP) using a genomic relationship matrix (G) to account for genomic relationships between animals (VanRaden, 2008).

Results

In all idealized scenarios where only the true QTLs were used for prediction, the accuracy was high, close to the theoretical limit of 0.63 and largely constant over generations (dotted lines in Figure 1A,1B,1C,1D,1E,1F). Results from *SNP* and *SNP and QTL* model were as follows.

Within breed and crossbred prediction. For genomic prediction of purebreds and crosses, accuracy of prediction was highest when the reference population was one generation apart from the test population. As the distance between reference and test population increased, the accuracy of prediction decreased for the first 10 generations until it hit a baseline level (Figure 1A,1C). When causal QTLs were included in the SNP set, the prediction accuracy was consistently higher, and the prediction accuracy decay was lower over generations in comparison to using only the SNPs. As expected, accuracies were higher in within breed predictions as compared to crossbred prediction.

Across breed prediction. Accuracy was low but constant over generations (Figure 1E). However, when the reference populations were accumulated over generations, we saw an increase in prediction accuracy for the first 2-3 generations (Figure 1F). From then on, the accuracy of prediction did not increase considerably for *SNP* model even though the size of reference population consistently increased due to addition of more generations. If causal QTL were included in the SNP set, the accuracy of prediction continued to increase with the addition of more generations in the reference dataset. Not surprisingly, the taurine breeds predicted each other better as compared to predicting Brahman or when using Brahman to predict the taurine breeds. This was true in scenarios which used only SNPs or both SNPs and QTLs were in the model. However, using only QTLs to predict the other breeds, Angus reference population performed the worst. Its prediction accuracy was even lower than Hereford predicting Brahman cattle and vice versa, which were genetically distant from each other. This result shows that even if we knew the true QTL, their effects may still not be accurately estimated in a reference population that is highly inbred.

Discussion

In this study our simulations demonstrated that if the actual QTLs are part of the SNP panel: (1) the prediction accuracy improved; (2) the decay in prediction accuracy over generations was smaller; and (3) the advantage of collecting genotype data over generations was higher. There was clear evidence that the prediction accuracy increased when the actual QTLs were part of the SNP data. The same is true for the value of accumulating genotypes over generations which is significantly higher when the QTLs are genotyped, although the gains are less pronounced in within breed predictions. This result has important implications

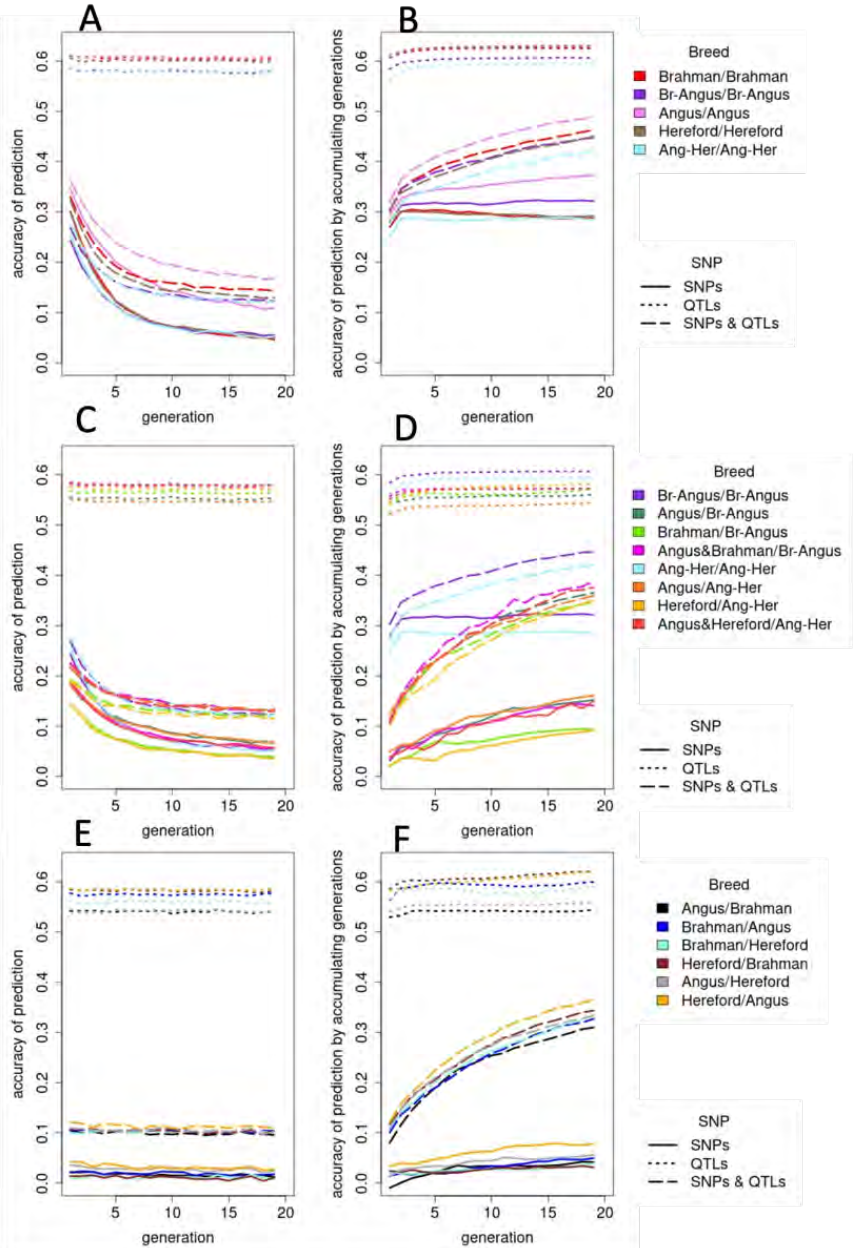

Figure 1. Accuracy of genomic prediction as a function of genetic distance in terms of number of generations between reference and test populations, and against cumulative generations backwards from the reference population in within breed (A,B), crossbred (C,D), and across breed (E,F) predictions.

for breeding companies and breed organizations that have been collecting genotype information for more than a decade now which could be imputed up to WGS to improve prediction accuracy – a strategy that could be especially relevant for across breed or multibreed evaluation programs since our results demonstrated that the benefit of including QTLs was more evident when there was a larger genetic distance between the

reference and target population. The three SNP sets used in this study serve as a proxy for three models. Firstly, SNPs without the QTLs represent widely used SNP chip data which does not include most of the causal QTLs for traits. The SNP and QTL panel represents whole genome sequence data which in principle should include most of the causal variants and other correlated SNPs. Here we should note that a limitation of this study is that it did not address the n << p problem which is frequently discussed when it comes down to the practical use of WGS data for cattle breeding – how well these results hold at the full sequence level with 20-40 million variants needs further studies. Finally, the QTL only panel represents an ideal situation where we can identify and utilize only those SNPs that are directly involved in a phenotype. Such exact SNP panels are still elusive and would require studies based on huge sample sizes at the WGS level. Nonetheless, some studies have already shown the benefits of selecting highly predictive features to increase prediction in distant populations (Raymond *et al.*, 2018; van den Berg *et al.*, 2016; Wientjes *et al.,* 2015). In summary, wider adoption of WGS for genomic prediction still seems a valid proposition to increase the accuracy of genomic prediction in cattle, especially for distantly related animals.

Abstract

Residual feed intake (RFI) is a measure of feed efficiency of animals. Previous studies have identified SNPs associated with RFI. The objective of this study was to compare the GBLUP model with GA-BLUP model included previously identified associated SNPs. The nine RFI-associated SNPs were obtained from the GWAS study on a discovery population, as preselection information. These models were analysed using ASREML software using a 5-fold cross-validation method on a validation population. With the genetic architecture (GA) matrix involved, which was conducted with the nine RFI-associated SNPs, the prediction accuracy of RFI was improved compared to the original GBLUP model. The prediction accuracy increased by 2% in GA-BLUP model with ω is 0.981 compare to GBLUP model. In conclusion, the GA-BLUP with the nine associated SNPs and an optimal ω can improve prediction accuracy for a specific trait compared to GBLUP.

Introduction

Genomic selection (GS) is a genetic improvement tool that utilises marker-assisted selection to predict the genetic merit of animal and is a genetic improvement tool used in animal breeding (Meuwissen *et al.* 2001). The best linear unbiased prediction (BLUP) is a general model in genetic and genomic selection used to estimate breeding values (Henderson 1975). A new method is named BLUP-given genetic architecture (GA, GA-BLUP). GA-BLUP is constructed using a trait-specific covariance matrix (T) by a weighted sum of the GA matrix and realized genomic relationship matrix (G) (VanRaden 2008; Zhang *et al.* 2015). The GA matrix was made by the nine pre-selection SNPs, which resulted from GWAS and fine mapping. A recent study showed that the GA-BLUP method that involved a machine learning method to combine prediction accuracy with computing efficiency(Yin *et al.* 2020).The GA-BLUP method could result in higher prediction accuracy of breeding values with the optimal parameter, weight (ω), applied. However, the optimal weight when combining GA matrix and G matrix needs to be determined.

As a critical factor representing feed efficiency, residual feed intake (RFI) is the difference between actual and expected feed intake, predicting by body weight and body weight gain (Henderson 1975). The advantage of RFI compared to other feed efficiency traits such as average daily gain is that you can select to decrease feed intake without connection to body weight and growth rate (Hoque *et al.* 2007; Crowley *et al.* 2010; Begli *et al.* 2016; Shirali *et al.* 2018). It is necessary to introduce the RFI-associated SNPs to genomic prediction and establish new approaches that result estimated breeding values with higher accuracy. In this study, two separate populations were used for GWAS discovery and GS validation, respectively. RFI-associated SNPs from the discovery population were used as the pre-selection information to build the GA matrix. The ω between the GA matrix and the G matrix was also tested and calculated based on the components explained variance.

Materials & methods

In total, 989 chickens were obtained from the fast-growing white-feathered pure line B. Line B is a synthetic line produced by Foshan Gaoming Xinguang Agricultural and Animal Industrials Co., Ltd. (Foshan, China), and it has been selected for high body weight and growth rate traits for seven generations. All individuals were housed in individual cages (length × width × height: 30×25×45 cm). The total feed intake for each broiler was the total feed consumption during the test period between 28 to 40 days of age, which was then used to calculate the average daily feed intake (ADFI). The individual body weight gain was calculated on the basis of body weight at 28 d (BW28) and (BW42), and was then used to derive the ADG. RFI was the difference between the observed and predicted ADFI. The predicted ADFI was calculated as formula (1).

$$ADFI = \mu + \beta_1 MWT + \beta_2 ADG + e \quad (1)$$

where μ represents the intercept, MWT represents the metabolic body weight at mid-test. ADG represents the average daily gain, β_1 and β_2 represent partial regression coefficients, and e represents the residual. The estimated e was taken as the measure of RFI.

Genotyping. The genotyping was described in detail in previous studies (Li *et al.* 2020; Li *et al.* 2021). The GWAS discovery population is the reference group at that generation, which contained 273 females and 244 males. The GS validation population was the candidate group including 472 males. A GWAS was performed for the RFI trait using a univariate linear mixed model (LMM) implemented in GEMMA version 0.98.1 software (https://github.com/genetics-statistics/GEMMA/releases) (Zhou and Stephens 2012). Gender was used as a covariate in LMM model. Nine RFI associated-SNPs were selected based on the reference group.

Genomic prediction. This study compared genomic prediction accuracy between GBLUP(2) and GA-GBLUP(3).

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Zg} + \mathbf{e}; \quad \mathrm{Var}\begin{bmatrix}\mathbf{g}\\ \mathbf{e}\end{bmatrix} = \begin{bmatrix}\mathbf{G}\sigma_g^2 & 0\\ 0 & \mathbf{I}\sigma_e^2\end{bmatrix} \quad (2)$$

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Zg} + \mathbf{Z}'g' + \mathbf{e}; \quad \mathrm{Var}\begin{bmatrix}\mathbf{g}\\ \mathbf{e}\end{bmatrix} = \begin{bmatrix}\mathbf{G}_{total}\sigma_g^2 & 0\\ 0 & \mathbf{I}\sigma_e^2\end{bmatrix} \quad (3)$$

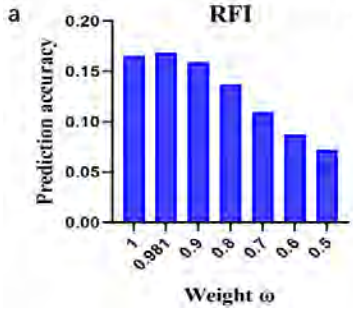
where b is the vector of fixed factor, g is the vector of random direct additive genetic effects, g' is the vector of discovered SNPs effects, e is the vector of random residual effects, and X Z and Z' are induced matrices. σ_g^2 and σ_e^2 are the additive genetic and residual error variances. Gtotal means the weighted sum of G and GA matrices, and G_total=ωG+(1-ω)GA, in which ω is the weight. The ω is calculated by the formula ω=(σ_g^2) / ($\sigma_g^2 + \sigma_{gSNP}^2$), where σ_g^2 and σ_{gSNP}^2 are the variance of 55K array and associated SNPs from GWAS, respectively.

The accuracies of the two different methods and the 5-fold cross-validation (CV) method were both conducted by the ASRmel v4.1 software package (Gilmour 2019). The 5-fold cross-validation method was replicated ten times to get the mean accuracies. For each fold, the same nine SNPs were for GA-BLUP.

Results

The comparison of the prediction accuracies is presented in Figure 1. Compared to the traditional GBLUP model, the prediction accuracy improved by 2% through the GA-BLUP model. The higher prediction accuracy could be explained by inclusion of the SNP information from the GWAS (Lourenco *et al.* 2015).

a



b

Weight ω	Prediction accuracy	Improvement [a]
1	0.165	
0.981	0.169	1.9%
0.9	0.159	-3.9%
0.8	0.137	-17.2%
0.7	0.109	-34.0%
0.6	0.087	-47.3%
0.5	0.072	-56.3%

[a] Improvement is compared the prediction accuracy with the weight equals to 1.

Discussion

This is the first time the poultry RFI was used to conduct GA-BLUP, and it showed improved prediction accuracy, which agreed with many previous studies (Gao *et al.* 2015; Zhang *et al.* 2015; Ni *et al.* 2017; Morgante *et al.* 2018). However, only 2% was found in this study. One possible reason could be the low-density SNP chip was used for GBLUP and few SNPs for conducting GA-BLUP. Another possible reason could be RFI is a low to moderate heritable trait which could cause the low prediction accuracy. A previous study reported that the different traits and the different number of SNPs used for GA could lead to 1-70% of prediction accuracy increase (Romé *et al.* 2021). In conclusion, RFI is a trait in which GA-BULP could increase the prediction accuracy with the SNPs from the GWAS for RFI

Another critical parameter is the ω in the processing of combining GA with the G matrix. In Holstein cow data set, GA in GBLUP showed an improved prediction accuracy compared to GBLUP with the ω range from 0.2 to 0.9% (Zhang *et al.* 2015). Even though the different population sizes could affect the optimal ω, the prediction accuracy increased then decreased with the increasing ω (Zhang *et al.* 2015; Liu *et al.* 2019). The prediction accuracy trend agreed with our result, which indicated that the optimal ω could cause an enormous prediction improvement. However, testing the most optimal ω could waste much time. Thus, a method to calculate the ω is needed. In this method, the genetic matrix's ω was calculated by the RFI variance component explained by G and GA matrix, and it showed a similar result with previous studies (Zhang *et al.* 2015; Ye *et al.* 2020). The calculated ω using the variance component was 0.981, which provided the highest accuracy in RFI. This result indicated that our ω calculation method was valid and efficient.

276. Impact of foreign phenotype data on single-step genomic evaluation of test-day protein yields for German Holsteins

H. Alkhoder*, Z. Liu, D. Segelke and R. Reents

IT solutions for animal production (vit), Heinrich-Schroeder-Weg 1, 27283 Verden, Germany;
hatem.alkhoder@vit.de

Abstract

Foreign phenotype data of bulls integrated in single-step evaluation may have an impact on genomic prediction. We set up three scenarios regarding the selection of integrated bulls from MACE evaluation: all bulls with daughters in any country (ALL), daughter-proven bulls with genotype data available (REF), and daughter-proven bulls linked to national cows or genotyped animals (LNK). For protein yield, GEBV correlation of validation bulls between the truncated and full evaluations differed little among the scenarios. However, regression coefficient of GEBV of the full on the truncated evaluation increased from 0.91 for scenario REF to 0.92 for LNK and to 0.96 for ALL. Scenarios REF and LNK resulted in higher GEBV mean and variance for young genomic bulls than scenario ALL. Results suggest that using MACE data of all bulls for national single-step evaluation leads to a lower inflation of genomic prediction.

Introduction

For the international dairy breed Holstein, national single-step genomic evaluation (Misztal *et al.* 2009) usually integrates foreign phenotype data, such as bull MACE EBV, to enhance the accuracy of genomic prediction. Daughter-proven bulls born before the implementation of genomic selection were genotyped incompletely or selectively in most countries. Because those genotyped bulls with daughters tend to be genetically superior to un-genotyped bulls of the same age, including only those old, genotyped bulls may bias the genomic prediction of young animals. The aim of this study was to investigate the impact of foreign phenotype data of bulls on national single-step genomic prediction in German Holsteins.

Materials & methods

For test-day protein yields in first three lactations, a multiple-lactation random regression test-day model has been applied in German Holsteins (Liu *et al.* 2004). Because a single-step SNP BLUP (ssSNPBLUP) model by Liu *et al.* (2014) was shown to be efficient (Vandenplas *et al.* 2021), the ssSNPBLUP model was chosen for routine single-step evaluation for German Holsteins (Alkhoder *et al.* 2022). The test-day data of national cows were jointly evaluated with deregressed MACE breeding values of foreign bulls together with effective daughter contribution of the bulls as weights. Genetic covariances between the national and MACE traits were derived using the genetic (co)variances of random regression coefficients (Liu *et al.* 2004). To avoid double counting the contribution of national daughters to those bulls, both deregressed EBV and effective daughter contribution of the bulls were adjusted for the national daughters. Genotype and the phenotype data were obtained from the official German evaluation in April 2021. There were 949,636 genotyped Holstein animals available. A total of 242,121,126 test-day records from 12,432,940 cows were jointly evaluated with 138,770 bulls with daughters outside Germany. Pedigree file for the genotyped or phenotyped animals contained e.g. 20 generations of ancestors for the youngest genotyped candidates born in 2021. The total number of animals in the pedigree file was 20,461,400. The number of unknown parent groups was 177, defined according to country origin, selection paths and birth year of the animals. The assumed proportion of genetic variance not explained by the SNP markers was 30% for the protein yield.

Scenarios of selecting bulls from MACE evaluation. Three scenarios regarding the selection of integrated bulls from MACE evaluation were considered: all bulls with daughters in any country (ALL), daughter-proven bulls with genotype data available (REF), and daughter-proven bulls linked to national cows or genotyped animals (LNK). Figure 1 shows the number of Holstein bulls with daughters evaluated in the April 2021 MACE evaluation of protein yield that were selected for the three scenarios. Prior to the implementation of genomic selection in 2009, less than 20% bulls were genotyped. The reference bulls REF had higher genetic level, i.e. MACE EBV, than the linked bulls LNK and much higher than the bulls ALL for the trait protein yield (data not shown here).

Genomic validation by data truncation. To simulate a forward prediction in four years, test-day data of national cows from the last four years were removed. The integrated MACE bulls born in last four years were deleted. In addition, national daughters of all the deleted bulls were removed to ensure no daughters of the deleted bulls were present in the truncated phenotype data set. Validation bulls were defined as genotyped Holstein bulls with daughters in at least 10 herds in Germany. There were 1,665 validation bulls born in 2013 through 2016. In the truncated phenotype data, there were 10,903,891 national cows with a total of 222,634,210 test-day records and 128,504 bulls for the scenario ALL.

A single-step SNP BLUP model for genomic evaluation. Identical fixed and random effects were used for the single-step evaluation as for the conventional test-day model evaluation (Liu *et al.* 2004). The software MiX99 (Strandén and Lidauer 1999) that was used for the single-step evaluation implemented the ssSNPBLUP model in a special way (Mäntysaari *et al.* 2018, unpublished data). The total number of equations or effects was 338,616,497 for the full data set under scenario ALL. Memory usage was about 347 Gb and solving the equations took about 1.63 minutes per round of iteration on a Linux server using 17 cores. Pre-defined convergence criteria were met within 3000 rounds for all the scenarios.

Three groups of genotyped animals were selected to compare the scenarios: genotyped AI bulls owned by German AI studs, genotyped male candidates without own daughters and genotyped females with or without own phenotype records. We focused on their genetic trends, GEBV variances and correlations between the truncated and full evaluations. Because the genotyped AI bulls had the highest selection intensity among the three groups, we are only showing the genomic evaluation results for a total of 12,249 genotyped German Holstein AI bulls born between 1998 and 2020.

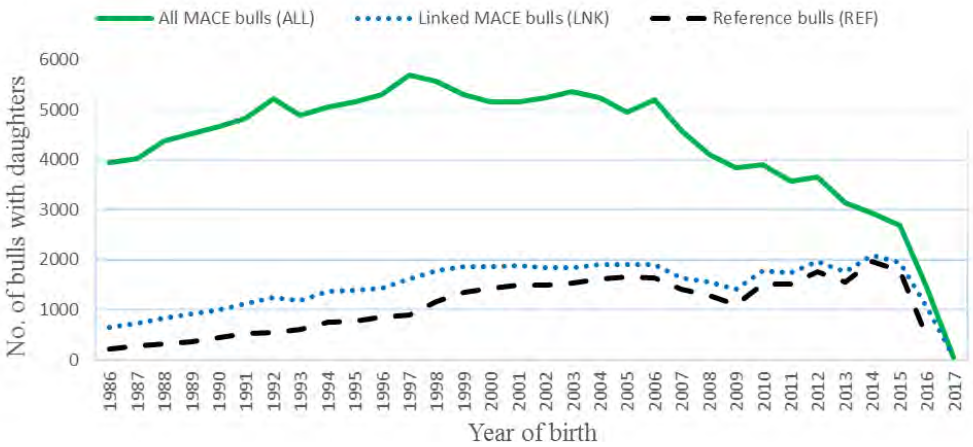

Figure 1. Number of Holstein bulls selected for the three scenarios (trait: protein yield).

Results & discussion

For either the full or truncated data set SNP effect estimates had a correlation higher than 0.99 between any two of the scenarios. Regression of the SNP effects of scenario ALL on either scenario REF or LNK was nearly 1 for all the cases. The three scenarios resulted in almost identical SNP effect estimates.

Genomic validation based on the validation bulls. The LR regression method (Legarra and Reverter 2018) was applied to GEBV of the validation bulls from the full and truncated data sets. Table 1 shows the genomic validation results according to the LR regression. The GEBV correlations of the validation bulls, shown in R^2 values, did not differ among the three scenarios. However, significant differences in the regression coefficient b_1 were observed among the scenarios. The regression coefficients indicate that selecting only genotyped bulls (scenario REF) led to the highest inflation in GEBV of the validation bulls among the three scenarios, whereas the smallest overestimation of candidate GEBV was found when all bulls evaluated in MACE (scenario ALL) were integrated into the national single-step evaluation. This finding may be explained by the fact that the genotyped bulls born before the introduction of genomic selection had higher genetic merits than those non-genotyped bulls in the same years. Additionally, the scenario ALL had the smallest b_0 value among all the scenarios.

GEBV correlations between the full and truncated evaluations. Figure 2 shows GEBV correlations for the genotyped German AI bulls between the full and truncated evaluation. It is clearly seen that using all bulls from MACE resulted in highest GEBV correlation between the full and truncated evaluations among the three scenarios.

Table 1. Regression of validation bulls' GEBV from the full on the truncated evaluation.

GEBV of protein yield (kg)	b_0	b_1	R^2
All MACE bulls (ALL)	0.47	0.96	0.71
Linked MACE bulls (LNK)	1.99	0.92	0.71
Reference bulls (REF)	2.13	0.91	0.70

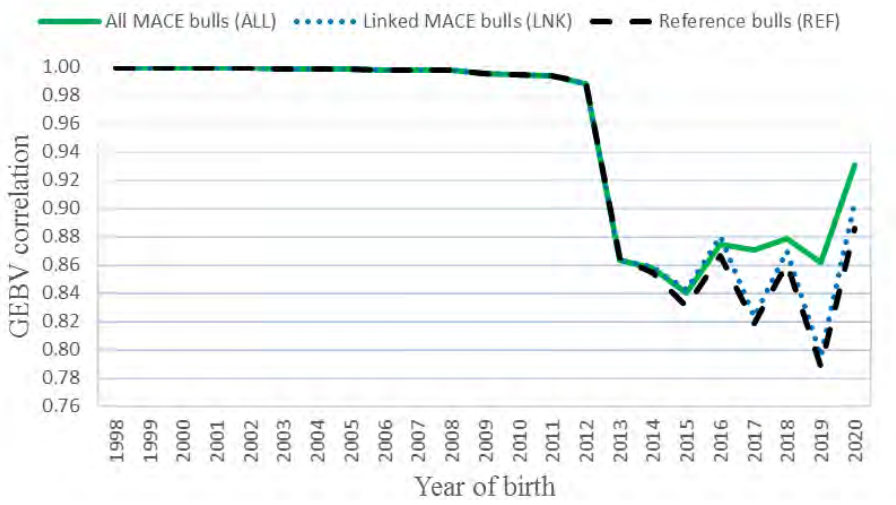

Figure 2. GEBV correlations between the full and truncated evaluations for the AI bulls.

Genetic trends in the genotyped German AI bulls. Genetic trend of scenario ALL, expressed in units of genetic standard deviation, is shown in Figure 3 as solid green line against the secondary Y axis. Genetic trend differences to scenario ALL are shown for scenario LNK in dotted blue line (LNK-ALL) and for scenario REF in dashed black line (REF-ALL). When only the reference bulls were used, an overestimation of GEBV for young AI bulls were evident. The trend difference of scenario LNK to ALL was small for the full data set, but a larger overestimation for the young AI bulls was shown in the truncated data set (unpublished data).

Besides the differences in genetic trends between the scenarios, we saw also slightly higher GEBV variances in young AI bulls, particularly for the truncated data set. Additionally, we calculated regression slopes of GEBV from the full on the truncated evaluation for the AI bulls by birth year. We found clearly lower regression slopes in young AI bulls for the scenario REF or LNK than scenario ALL, suggesting GEBV of young AI bulls were more inflated in the two scenarios REF and LNK.

In comparison to the genotyped AI bulls, genotyped female animals showed smaller GEBV differences between the scenarios. Like the genotyped AI bulls, the male candidates without own data had similar GEBV differences between the scenarios.

Our genomic validation showed a larger inflation, in terms of the regression slope, for scenario REF or LNK than scenario ALL, though the GEBV correlation between the full and truncated evaluation did not differ between the scenarios. For the young, genotyped animals, particularly for the AI bulls, scenarios REF or LNK resulted in a larger bias in genomic prediction.

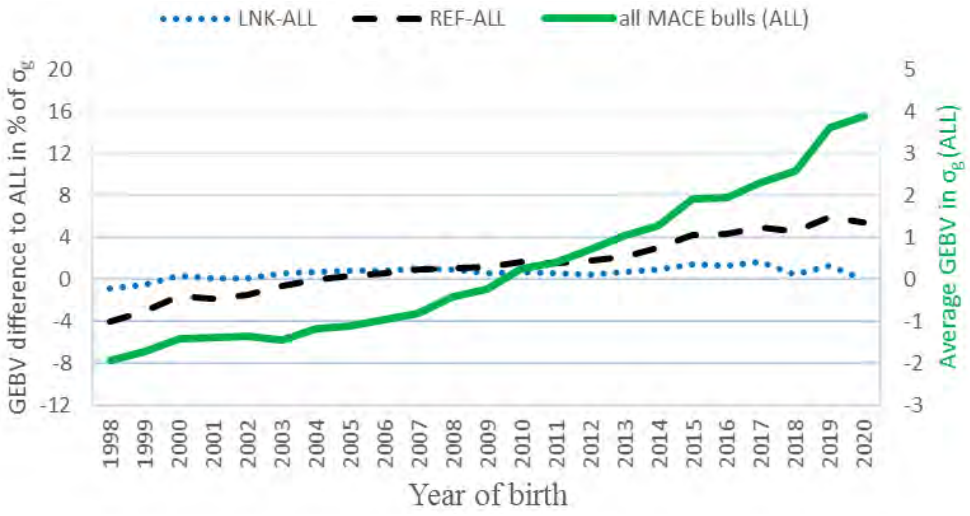

Figure 3. Genetic trends of protein yield in the genotyped AI bulls.

277. Extend mixed models to multi-layer neural networks for genomic prediction including intermediate omics data

T. Zhao[1,2], J. Zeng[3] and H. Cheng[1*]

[1]Department of Animal Science, University of California Davis, 95616, Davis, USA; [2]Integrative Genetics and Genomics Graduate Group, University of California Davis, 95616, Davis, USA; [3]Institute for Molecular Bioscience, The University of Queensland, 4072, Brisbane, Australia; qtlcheng@ucdavis.edu

Abstract

With the growing amount and diversity of intermediate omics data complementary to genomics (e.g. gene expression), there is a need to develop methods to incorporate intermediate omics data into conventional genomic evaluation. We developed a new method named NN-LMM to model the multiple layers of regulation from genotypes to intermediate omics features, then to phenotypes, by extending conventional linear mixed models ('LMM') to multi-layer neural networks ('NN'). NN-LMM incorporates intermediate omics features by adding middle layers between genotypes and phenotypes. Linear mixed models (e.g. GBLUP, Bayesian Alphabet) can be used to sample marker effects or genetic values on intermediate omics features, and activation functions in neural networks can capture the nonlinear relationships between intermediate omics features and phenotypes. NN-LMM had significantly better prediction performance than the recently proposed single-step approach. Moreover, NN-LMM can handle various patterns of missing omics measures. NN-LMM has been implemented in an open-source package called 'JWAS'.

Introduction

The advances in high-throughput sequencing technology provide growing amount and diversity of multi-omics data complementary to genomics. The effects of genotypes on phenotypes can be mediated by multiple layers of omics features through mechanisms such as regulatory cascades from epigenome, to transcriptome, and to proteome (Ritchie *et al.*, 2015; Wu *et al.*, 2018). This multi-layer regulation works as a unified system to connect genome variations to the trait, and the relationships between different layers can be complex with interactions and nonlinear relationships (Kitano, 2002). A system of two linear models has been developed recently for genomic evaluation (Christensen *et al.*, 2021; Weishaar *et al.*, 2020), where one linear model describes how genotypes affect gene expression levels, and another describes how gene expression levels affect phenotypes. This system of two linear models was further extended for incomplete omics data based on single-step approach (Christensen *et al.*, 2021).

We developed a new method named NN-LMM (Zhao *et al.*, 2021a; Zhao *et al.*, 2021b) to model the multiple layers of regulation from genotypes to intermediate omics features, then to phenotypes, by extending conventional linear mixed models ('LMM') to multi-layer artificial neural networks ('NN'). NN-LMM incorporates intermediate omics features by adding middle layers between genotypes and phenotypes. Linear mixed models can be used to sample marker effects or genetic values on intermediate omics features, and nonlinear activation functions in neural networks are used to approximate the nonlinear relationships between intermediate omics features and phenotypes. Compared to other methods, NN-LMM allows various patterns of missing omics data, for example, individuals can have different missing omics features, and the assumption of nonlinearity between intermediate omics features and phenotypes may be more biologically realistic.

Materials & methods

The framework of NN-LMM incorporating intermediate omics data such as gene expression levels is shown in Figure 1(a). Genotypes affect the gene expression levels, then gene expression levels regulate the phenotypes. Linear mixed models can be applied to sample marker effects or genetic values on gene expression levels, and the non-linear activation function in neural networks will be used to capture the complex nonlinear relationships between gene expression levels and phenotypes. For an individual, the gene expression levels of the first two genes are 0.9 and 0.1, respectively, and the gene expression of the last gene is missing to be sampled. Individuals can have different missing gene expression levels. A detailed framework of NN-LMM is shown in Figure 1(b), and Markov chain Monte Carlo (MCMC) approaches are used to infer unknowns.

From middle layer (intermediate omics features) to output layer (phenotypes): non-linear activation function. Given all intermediate omics features, the phenotype of individual *i* is modeled as:

$$y_i = \mu^{(1)} + \sum_{j=1}^{l_1} w_j^{(1)} g\left(z_{i,j}\right) + e_i$$

where y_i is the phenotype, $\mu^{(1)}$ is the overall mean with flat prior, $z_{i,j}$ is the j-th intermediate omics feature, $g(.)$ is the activation function in neural networks, $w_j^{(1)}$ is the effect of $g(z_{i,j})$ on y_i with a normal prior, and e_i is the random residual with normal prior.

From input layer (genotypes) to middle layer (intermediate omics features): mixed models. Given all intermediate omics features, for individual *i*, the relationship between the j-th intermediate omics feature and genotypes can be written as a single-trait mixed model (e.g. Bayesian Alphabet) as:

$$z_{i,j} = \mu_j^{(0)} + \sum_{m=1}^{l_0} x_{i,m} w_{j,m}^{(0)} + \epsilon_{i,j}$$

where $z_{i,j}$ is the j-th intermediate omics feature, $\mu_j^{(0)}$ is its overall mean with flat prior, $x_{i,m}$ is the genotype covariate at locus m (coded as 0, 1, 2), $w_{j,m}^{(0)}$ is the marker effects of locus m on j-th intermediate omics feature, which can be sampled by various linear mixed models, ϵ_{ij} is the random residual with normal prior.

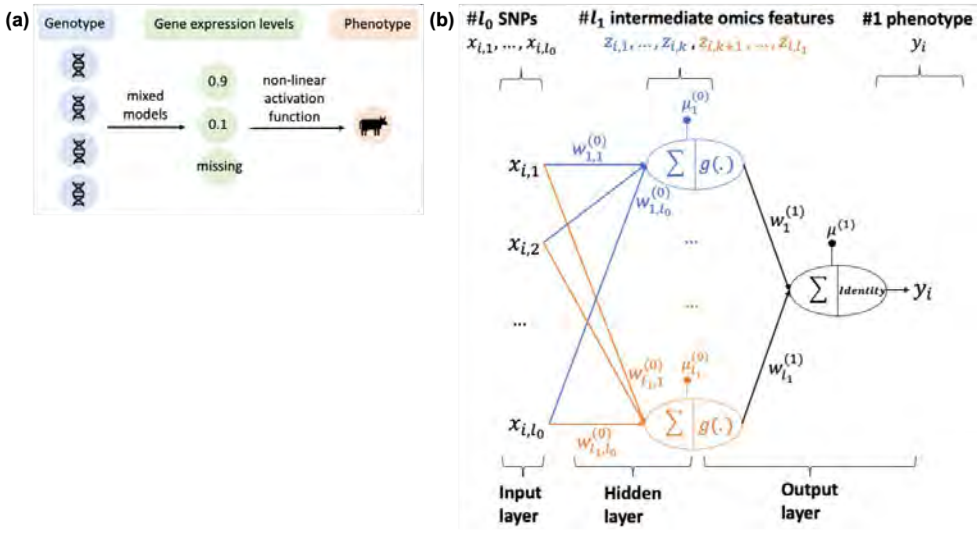

Figure 1. The framework of NN-LMM incorporating intermediate omics data.

Sample missing omics data by Hamiltonian Monte Carlo. Each missing omics feature of individual *i* will be treated as an unobserved intermediate trait to be sampled by Hamiltonian Monte Carlo (HMC) from its full conditional distributions. The introduction to the concepts underlying HMC can be found in Betancourt (2018).

Data analysis. To compare the prediction performance of NN-LMM to the single-step approach in Christensen *et al.* (2021), a linear activation function was used in NN-LMM. GBLUP was used to sample genetic values on intermediate omics features (i.e. NN-GBLUP). Simulated data from Christensen *et al.* (2021) were used. Note that in Christensen *et al.* (2021), a polygenic effect whose covariance matrix is defined by the pedigree or/and genotypes is also included in Equation 1. This part is ignored here for simplicity, and was subtracted from the simulated phenotypes. Two patterns of missing omics data were considered: missing omics pattern: (1): all omics data are completely missing for some individuals; missing omics pattern; (2) for each omics feature, some random individuals have no omics data. The single-step approach only works in the scenario (1), while NN-LMM allows both scenarios. Different proportions of missing omics data in the training dataset were considered, where 0% denotes the scenario where all omics features are measured on all individuals. 20 replicates were used for each scenario. We randomly sampled 5% individuals from the simulated data in Christensen *et al.* (2021) to have a subset of 1,055 individuals. The genotypic data consisted of 15,000 SNP markers observed for all individuals, and the intermediate omics data consisted of 1,200 omics features. The heritability of each omics feature was 0.61, and the heritability of the phenotypic trait was 0.337. More details about the simulation process are in Christensen *et al.* (2021).

We also simulated nonlinear relationships between intermediate omics features and phenotypes, where the logistic non-linear transformation was applied to the omics data as in Equation 1. In this case, the same heritability and variance components were applied.

Results

When all omics features were measured on all individuals, NN-GBLUP had similar prediction accuracies as the system of two mixed model equations in Christensen *et al.* (2021) (correlation r=0.999). When some omics data were missing, NN-LMM had equivalent or better prediction performance, as shown in Figure 2. Overall, the prediction accuracy decreased when the proportion of missing omics data increased. For missing omics pattern (1), when a small proportion of individuals had no omics data, NN-GBLUP (red solid line) had similar prediction performance as the single-step approach in Christensen *et al.* (2021) (blue solid line). However, when a large proportion of individuals had no omics data (e.g. >80%), NN-GBLUP had significantly higher prediction accuracies (pairwise t-test P-value<0.005). When >90% individuals had no omics data, the single-step approach performed even worse than the baseline (black dashed line), which was a conventional GBLUP model where no omics data were used. For missing omics pattern (2), when some random individuals had no omics measures for each omics feature, the prediction accuracy of NN-GBLUP (red dashed line) decreased with larger proportion of missing omics data, and eventually close to the baseline, whereas the single-step approach did not work for this scenario.

When the underlying relationships between omics features and phenotype was nonlinear, results verified that using the nonlinear sigmoid activation function in NN-LMM was significantly better than using the linear activation function.

Discussion

To sample marker effects on omics features, a naive multi-threaded parallelism has been implemented to employ multiple single-trait mixed models in parallel at each MCMC iteration. Parallel computing strategies such as those in Zhao *et al.* (2020) will be further studied.

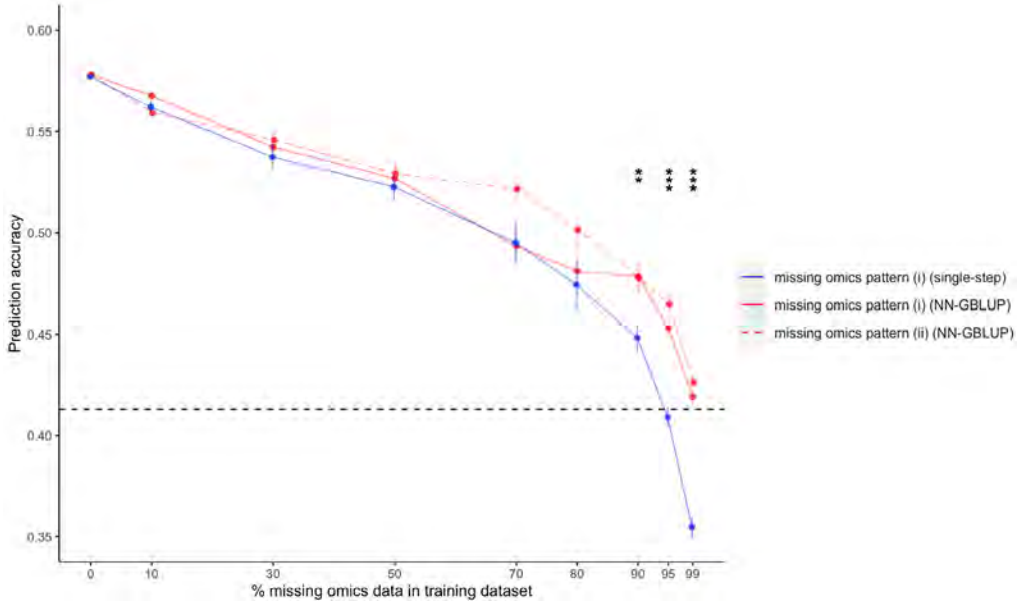

Figure 2. Prediction accuracies of NN-GBLUP with the linear activation function and the single-step approach in Christensen *et al.* (2021). The missing omics pattern (1): all omics features were not measured on some individuals, and missing omics pattern (2): for each omics feature, some random individuals had no omics measures. The horizontal black dashed linear is the conventional GBLUP model used as the baseline. Each dot represents the mean of prediction accuracies from 20 replications with its standard error. The asterisk symbol indicated a significantly better performance of NN-GBLUP.

Abstract

The objective of this work was to assess the ability of holobiont data (i.e. host's genotype and microbiota) to predict six immunity traits in 400 pigs. We propose the term 'predictome' to mean a systematic study of as many predictive methods as possible. With this spirit, we compare REML, Bayes C and Bayesian reproducing kernel Hilbert space (RKHS) regression with a wide range of priors. We assessed the performance of the models by partitioning the data into three disjoint sets. In total, we run 273 analyses per trait. We find that there does not exist a systematically best prediction method, although our results favor slightly Bayes C. By default, microbiota abundances should not be clustered. An holobiont model performs better than models using only genotype or microbiota data, i.e. use all data at your disposal.

Introduction

The role of gut microbiota composition in complex traits is well documented and it is currently a topic of utmost interest (Camarinha-Silva *et al.*, 2017; Difford *et al.*, 2018; Zhang *et al.*, 2020). However, there exist relatively little evidence on the actual advantage of combining genotype and microbial information for predictive purposes. Moreover, there is a plethora of statistical methods for prediction (Gianola, 2013), but we lack a systematic review on their actual behavior in real holobiont data. In this work, we perform a comprehensive holobiont prediction analysis for important traits related to the immune system in pigs. We call this analysis the 'predictome' to signify a comprehensive set of predictive tools and their performance.

Materials & methods

Data. We used genotype, phenotype and microbiota data fully described in Ballester *et al.* (2020), Ramayo-Caldas *et al.* (2021), except that here we included additional 16S sequence. Very briefly, data were available from 400 pigs for six immunocompetence traits: immunoglobulins IgM (IGM) and IgG (IGG), two acute-phase proteins, C-reactive protein (CRP) and haptoglobin (HP), gamma-delta T cells (GAMMADELTA) and lymphocyte phagocytic capacity (PHAGO_LYMPH). Data were corrected for fixed effects as described (Ballester *et al.*, 2020) and scaled. After quality control, 41,131 SNPs were retained from the original Porcine 70k GGP Porcine HD Array (Illumina).

Faecal 16S paired-end sequences were processed with QIIME2 (Bolyen *et al.*, 2019). Amplicon Sequence Variants (ASVs) were assigned using *DADA2* R package (Callahan *et al.*, 2016). ASVs present in less than three samples and representing less than 0.001% of the total counts were discarded. Several quality control measures were applied to ensure that 16S reads from both sequencing batches could be merged, e.g. both resulted in same Euclidean distances between samples and number of ASVs were congruent. The average number of reads per sample was over 136,000 and 2,945 ASVs were retained. We studied the effect in the prediction of clustering by phylogeny at the genus level and by abundance vs using individual ASV abundances. MEGA package and NJ algorithm was used for genus clustering, and *hclust* R package for abundance clustering. In either approach, 232 clusters of ASVs were obtained.

Statistical analyses. We applied a wide range of models and algorithms to characterize the predictive ability for immunocompetence in pigs. Prediction was measured as the correlation between predicted and observed phenotype averaged over three partitions, each containing ~20% of different records. Three models were compared: a holobiont model that includes genotype (X) and abundance data (B), a genetic model fitting only genotypes and a microbiota model with abundance data only. For B, the ASVs were fitted individually or grouped by phylogeny or by abundance.

We considered three statistical methods: REML, Bayesian RKHS regression (equivalent to GBLUP), and Bayes C. REML was run using ASREML and Bayesian methods, using BGLR (Pérez and de los Campos 2014). In RKHS, a pseudo flat prior and the default mildly informative prior were compared. In Bayes C, the following prior probabilities of a variable entering the model were compared P=0.01, 0.001 and 0.0001 for X and P=0.1, 0.01 and 0.001 for B. Combinations of all models, algorithms, priors and clustering approaches were run for each partition and phenotype. In total, 273 analyses per phenotype were run.

Results

Frequentist or Bayes? Bayes C or GBLUP? Performance in prediction is an objective, pragmatic, and easy way of contrasting statistical approaches. Figure 1 shows that REML is not necessarily worse than Bayesian methods, except in lymphocyte phagocytic capacity. The method chosen was not too important except in some phenotypes like PHAGO_LYMPH, where a Bayes C modelling for both X and B outperformed other options, or haptoglobin where GBLUP methods prevailed.

Is it worth using holobiont data? In a recent simulation study (Pérez-Enciso *et al.* 2021), we argued that using an holobiont model could significantly increase predictive accuracy, provided both X and B contribute to phenotypic variance, and that a holobiont model was the best default option. Our results (Figure 2) confirm this conjecture, and we observed that B can improve prediction by a sizable margin, e.g. for HP. For CRP and PHAGO_LYMPH, the combined model X+B increased correlation by ~25% compared to models without B.

Figure 1. Predictive accuracy of the holobiont model by statistical method and trait across priors and ASV clustering. For each analysis combination, the first term (REML, RKHS, BayesC) refers to the algorithm modelling the genotype (X) and the second to the algorithm modeling the microbiota (B). For instance, RKHS.BayesC means genotype modeled as RKHS and abundances as Bayes C.

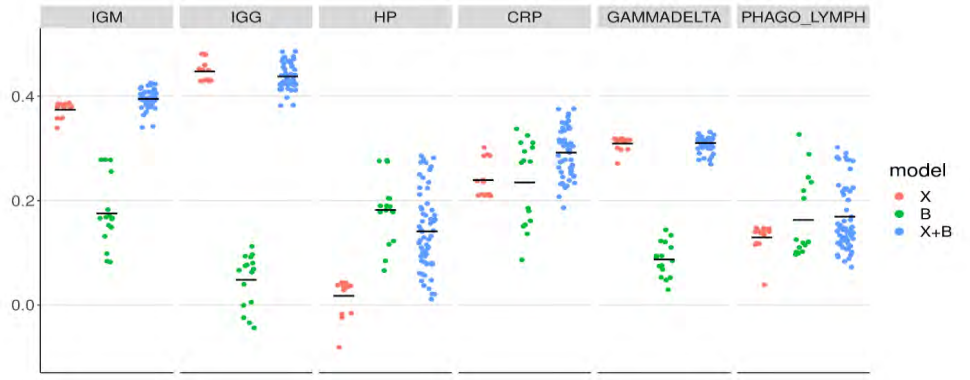

Figure 2. Correlation between predicted and observed phenotypes with genotype (X), microbiota (B) and holobiont (X+B) models. Each dot represents one analysis with different algorithm, prior and microbiota clustering combinations. The horizontal black line is the mean.

Should microbial abundances be grouped? Microbial abundances display highly leptokurtic distributions that require careful quality control, filtering and transformation steps. An option to minimize risks is to group them. Is that useful for predictive purposes? Again, there is not a single best option, although clustering worsens performance for most traits (Figure 3). Clustering by abundance yielded a 50% increase in HP prediction correlation, and clustering by phylogeny increased CRP results by 15%.

Discussion

The term 'hologenome' (Zilber-Rosenberg and Rosenberg 2008) was coined to describe the joint action of the genome and of the microbiota on a phenotype. We confirm that microbiota data can improve prediction, sometimes by a large margin, in important phenotypes related to immunocompetence. Here we systematically explored the optimal statistical approaches for prediction, what we have called 'predictome'. In all, we can conclude the following:

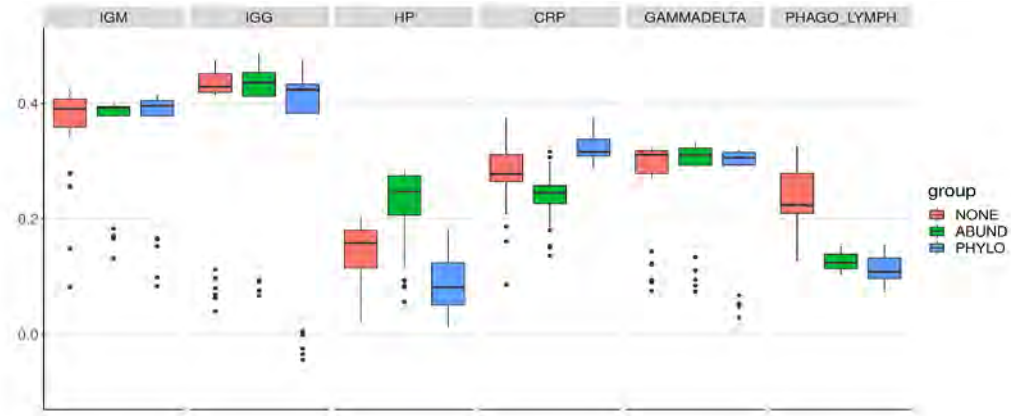

Figure 3. Microbiota clustering effect on prediction. 'NONE': no clustering; 'PHYLO': clustering at the genus level; 'ABUND': clustering by abundance.

1. There does not exist a systematically best prediction method, although our results favor Bayes C. Don't feel culprit though if you choose REML or Bayesian methods.
2. A holobiont model tends to perform better than either genotype or microbiota only models, i.e. use all data at your disposal.
3. By default, we recommend not clustering microbial abundances, despite their highly extreme distributions.

The explosion of statistical methods for holobiont based prediction has neither a clear 'winner' nor a clear 'loser'.

Abstract

On-farm genomic selection using Oxford Nanopore Technologies' portable DNA sequencer is a potential method to accelerate genetic gain in extensive agricultural enterprises. Oxford Nanopore sequencing provides a number of potential benefits including no theoretical read length limit. Here we investigate the effect of read length on the accuracy of genomic prediction from Oxford Nanopore data by creating a range of different read length distributions with average read lengths ranging between 2,569 bp and 110 bp. Read length was found to have limited effect on the accuracy of genomic prediction for the tested range. However, average read lengths below 500 bp demonstrated a significant increase in unmapped reads and reduced sequencing coverage. Importantly, this means to maximise data recovery from Nanopore flowcells, on-farm DNA libraries should have average read lengths greater than 500 bp. This finding will inform the requirements of the on-farm molecular sample preparation, such as DNA extraction and library preparation.

Introduction

Oxford Nanopore Technologies' (ONT) MinION is a third-generation sequencing platform that uses a biological nanopore to interpret DNA sequences. The disruption in ionic current caused by nucleotides passing through the nanopore is interpreted using software to produce a sequence read (Jain *et al.* 2016). This method has two major benefits: firstly, data can be interpreted in real-time and secondly, there is no theoretical limit to the length of sequence reads (Jain *et al.* 2016). Instead, read length is determined by the type of biological sample used and the level of shearing during DNA extraction and library preparation. Methods which subject the DNA to increased levels of mechanical shearing result in more fragmented DNA libraries and shorter average read lengths. Generally, rapid DNA extraction protocols result in more fragmented DNA libraries as a result of the techniques used to speed up bottlenecks.

Long read lengths are able to map with greater specificity to reference genomes and therefore more accurately characterise complex genomic regions. We investigated the effect of read length on genomic prediction accuracy in cattle from ONT sequence data.

Materials & methods

Simulating read distributions. Sixteen Droughtmaster heifers were sequenced from tail hair on the MinION sequencing platform as described in (Lamb *et al.* 2021). The sequence data was sampled down to 0.5x sequencing coverage for each animal. All of the sequencing reads in each of the subsequent fastq files were then cut into halves, quarters and eighths, to create a range of read lengths for each sample. Each read length replicate was then assigned a read length group based on average read length: 0-499 bp, 500-999 bp, 1000-1,499 bp, 1,500-1,999 bp and >2,000 bp. A fifth distribution was also created to replicate the effect of Nanopore adaptive sampling. Nanopore adaptive sampling is a sequence enrichment method that uses software to enrich defined genomic regions. A by-product of this technique is the creation of a number of short ~450 bp read fragments, corresponding to non-target regions (Oxford Nanopore Technologies 2020). To simulate enrichment of 20% of the bovine genome, 80% of reads were fragmented into 450 bp read

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_279, © H.J. Lamb *et al.* 2022

fragments, while the remainder of reads were left whole. This produced a final read distribution referred to as the adaptive distribution and a total of 80 unique samples (each of the 16 samples having five different read length distributions).

Genotyping and imputation. The reads from each simulated distribution were aligned to the ARS-UCD v1.2 *Bos taurus* reference genome (Rosen *et al.* 2020) using Minimap2 v1.2 (Li 2018). Genotypes for the Bovine HD chip were imputed using QUILT v1.01 (Davies *et al.* 2021) and a reference panel of ~1,200 animals which represented a subset of animals from the 1000 bull genomes project (Hayes and Daetwyler 2019).

Estimating breeding values. Genomic estimated breeding values (GEBVs) for four traits: body weight (BW), hip height (HH), body condition score (BCS) and corpus luteum score (CL score) were then calculated using marker effects estimated in Hayes *et al.* (2019), as described in *Lamb et al. (2021).*

Read length linear models. Correlations between the Nanopore GEBVs and SNP array GEBVs were then calculated as well as prediction bias, the regression of SNP array GEBV ~ Nanopore GEBV using

$$\hat{g} \sim \hat{a} + e \quad (1)$$

Where $\hat{g}$ was a vector of SNP array GEBVs and $\hat{a}$ a vector of Nanopore GEBVs. Linear models were used to evaluate the effect of read length on GEBV accuracy. Read length was modelled as a continuous covariate using:

$$y \sim x + e \quad (2)$$

Where x was a vector of average read length values as a random effect and y was a vector of residuals from the regression of SNP array GEBV on Nanopore GEBV.

Results

The average read length for each sample ranged between 3,065 bp and 185 bp and the average read length for the adaptive distribution was 812 bp. The correlations between SNP array GEBV and Nanopore GEBV were between 0.92-0.99, 0.82-0.99, 0.95-0.99 and 0.90-0.99 for BW, HH, CL score and BCS respectively (Figure 1).

The prediction bias ranged between 0.77-1.04 for the adaptive read length distribution 1.03-1.13 for the smallest read length bin and 1.05-1.19 for the largest read length bin (Table 1). The largest prediction bias was seen in the adaptive (overprediction of BCS) and 1500-1999 read length distributions (underprediction of BW).

Read length had no effect (P>0.05) on the regression of SNP array GEBV ~ Nanopore GEBV when fitted as a continuous covariate nor as a categorical covariate using the six distributions. Read length did however have a significant effect (P<0.05) on the fraction of reads unmapped and the sequencing coverage (Figure 2). Average read lengths less than 500 bp had more unmapped reads and less sequencing coverage than larger average read lengths. Despite a similar fraction of unmapped reads, the adaptive distribution had far less mapped bases than the 0-499 bp distribution. This was caused by a larger average read length amongst the unmapped reads in the adaptive distribution than the 0-499 bp distribution. Despite the decrease in effective sequencing coverage, and no actual enrichment in the adaptive samples, no decrease in GEBV accuracy was observed.

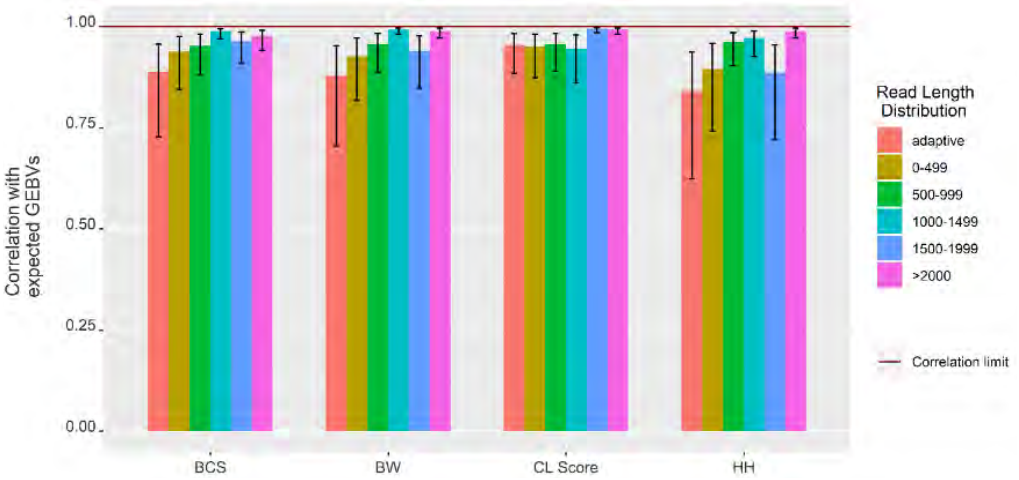

Figure 1. Corelations between SNP array GEBVs and Nanopore GEBVs for each of the 4 traits and the six different read length distributions.

Table 1. Prediction bias for each trait across the read length distributions.

Read length distribution	Body weight	Hip height	CL score	Body condition score
Adaptive	0.88	0.77	0.91	1.04
0-499	1.13	1.03	1.05	1.03
500-999	1.07	0.95	1.15	1.03
1000-1,499	1.09	1.05	0.91	1.04
1,500-1,999	1.21	0.97	0.87	1.13
>2,000	1.06	1.19	1.03	1.12

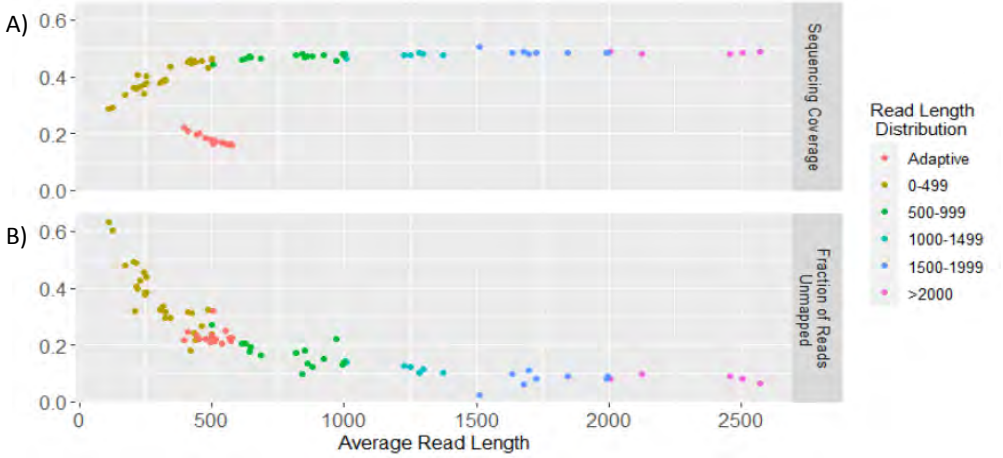

Figure 2. (A) Sequencing coverage plotted against the average read length for each analysis. (B) Fraction of reads unmapped plotted against average read length for each analysis.

Discussion

Despite average read lengths less than 500 bp having an effect on sequencing coverage, there was no effect on correlation or prediction bias. This suggests that despite losing data to unmapped reads, QUILT is still able to accurately impute genotypes from sequencing coverages as low as 0.2×.

Although 0.2× sequencing coverage was sufficient here for accurate genomic prediction, the decrease in sequencing coverage for average read lengths less than 500 bp will have implications when minimising per sample costs. For example, where samples are sequenced to 0.2× sequencing coverage, average read lengths less than 500 bp max cause the effective sequencing coverage to drop below the level required for accurate genomic prediction using QUILT. Therefore, the average read length for genomic prediction should be greater than 500 bp. This is shorter than average read lengths reported by a number of field sequencing studies with (Maestri *et al.* 2019) and without PCR amplification (Goordial *et al.* 2017).

A contributing factor to these results is that the positions of the bovine HD SNPs used in this study are primarily located in genomic regions with low complexity. This means even short read lengths (<500 bp) are able to map accurately for imputation from a large reference panel. If SNP effects in complex genomic regions are to be used in the future, longer read lengths may be required.

Overall, these results indicate that average read lengths greater than 500 bp from ONT sequencing will be sufficient for the purpose of calculating GEBVs. In the context of on-farm genomic predictions this means that little consideration towards read length will be required during DNA extraction and library preparation. Therefore, turnaround time can be prioritised without losing prediction accuracy from fragmented DNA.

Abstract

We evaluated the accuracy of biology informed genomic prediction for dry matter intake in 2,162 Dutch Holstein cows. Sequence variants were selected from meta-analyses including GWAS summary statistics for QTL and metabolomic QTL in several dairy and crossbred beef populations. Selected variants were prioritized in GBLUP models in a five-fold cross-validation. The accuracies were compared to genomic prediction based on routine 50k genotype data. The average accuracy for the 50k scenario was 0.683. Adding selected sequence variants in the GBLUP model did not improve the accuracies for dry matter intake. Next steps will include testing Bayesian variable selection methods to prioritize variants in genomic prediction for dry matter intake.

Introduction

Feed intake is an important trait, but large scale recording schemes on individual animals are costly and hamper implementations of genetic evaluations for dry matter intake (DMI). High prediction accuracies are difficult to achieve for traits like DMI, because the size of the reference population is often limited. Raymond *et al.* (2018) have shown a way to increase accuracy of genomic prediction (GP) in a multibreed evaluation when prioritising sequence variants from a meta-GWAS separate from the routine array genotypes. Additionally, functional information to pinpoint QTL regions may improve predictions. Metabolites in blood plasma represent intermediate phenotypes between the genome and transcriptome and final expressed phenotypes. Here, we evaluate the accuracy of biology informed GP for DMI in Dutch Holstein cows by prioritising variants from various meta-GWAS analyses.

Materials & methods

Meta-GWAS for QTL. To increase power of QTL detection for DMI, a meta-GWAS based on local GWAS results of eight populations was carried out using the METAL software package (Willer *et al.*, 2010). Local GWAS results for imputed sequence variants were available for five different Holstein populations in

Australia (584 cows), Canada (588 cows), Denmark (495 cows), Germany (140 cows) and Spain (561 cows), one Finnish Red population from Finland (366 cows) and two crossbred beef populations in Germany (253 bulls of a Charolais × Holstein cross) and Canada (7,552 heifers and steers of Angus, Charolais, Kinsella Composite and crossbred animals thereof). Phenotypes used in the local GWAS were either de-regressed breeding values (DRBV) or raw phenotypes for DMI corrected for fixed effects across lactation. Variant effects and standard errors of the effect from the local GWAS were standardized based on the genetic standard deviation for DMI for each population. Variants with an imputation accuracy r^2<0.6, a minor allele frequency (MAF)<0.001 or an effect size >5 standard deviations apart from the mean were not considered in the meta-analysis. Three different meta-GWAS were carried out: a meta-analysis including all populations (ALL), Holstein populations only (HOL) and beef populations only (BEEF). The total number of sequence variants considered were 30,216,688, 19,647,876 and 27,839,929 for ALL, HOL and BEEF, respectively.

Meta-GWAS for mQTL. GWAS summary statistics of imputed sequence variants from three cattle populations (Holstein, Charolais × Holstein, mixed beef breed composite) were available for segregating blood plasma metabolomic QTL. Metabolites considered were amino acids, short and long-chain fatty acids and compounds from energy and protein metabolism functions. The METAL software package (Willer *et al.*, 2010) was used for the meta-analysis. Variant effects were standardized by the genetic standard deviation of plasma metabolite concentration. Variants with MAF<0.01 and/or imputation r^2<0.6 were discarded. The number of animals contributing to the meta-GWAS varied across metabolites between 241 and 1,103. The number of variants considered across metabolites were between 14,343,591 and 19,467,841.

SNP selection scenarios. To filter out non-causal and select independently associated variants from the QTL meta-analysis, a forward selection of variants based on the conditional and joint effect method (COJO) described in Yang *et al.* (2012) was conducted. Variants were selected using the following COJO model parameters: conditional and joint *P*-value threshold to declare a genome-wide significant variant of *P*=5e-3 (scencarios ALL3, HOL3, BEEF3) or *P*=5e-5 (scenarios ALL5, HOL5, BEEF5), collinearity between selected markers of 0.9 and window size of 10 Mb. *P*-value significance thresholds were chosen to achieve a reasonable number of selected variants for GP. The mQTL meta-GWAS resulted in 20,426 trait associated SNPs with $P<10^{-6}$ for 27 metabolites. Of those, all variants segregating in the target population for GP (see below) were used in the mQTL scenario. For the base scenario (50k) variants available on the Illumina Bovine snp50 v3 beadchip (Illumina Inc., San Diego, CA, USA) were selected from the imputed sequence genotypes of the target population for GP. The number of selected variants per scenario is shown in Table 1. Selected variants were used to derive the genomic relationship matrices (GRM) for estimation of heritability and genomic breeding values (GEBV) for DMI.

Genomic prediction. An independent data-set of 2,162 Dutch Holstein cows imputed to sequence, and with DRBV

for DMI with reliability ≥0.30 were used in GP models. For the base scenario (50k) and all scenarios where only one GRM was fitted the following model was run in the mtg2 software (Lee, 2016):

$$y = 1\mu + Wg + e \quad (1)$$

where y is a vector of DRBV for DMI for the reference set (missing for the validation set), 1μ is the overall mean, g is a vector of additive genetic effects for all cows, W is a design matrix linking g to DRBV in y and e is a vector containing residuals. g and e are assumed to be normally distributed with $g = N(0, GRM\sigma_g^2)$ and $e = N(0, I\sigma_e^2)$.

Table 1. Number of variants to build the GRM and estimated heritability of DRBV in all scenarios (average across 5 cross-validations).

Scenario	Number of variants	Heritability	SE
50k	37,179	0.849	0.024
ALL3	1,810	0.456	0.032
ALL5	166	0.142	0.026
HOL3	1,834	0.442	0.032
HOL5	63	0.086	0.026
BEEF3	1,746	0.473	0.032
BEEF5	321	0.240	0.030
mQTL	17,056	0.675	0.034
50k + ALL3	37,179 + 1,810	0.796[1] + 0.060[1]	0.037 + 0.030
50k + ALL5	37,179 + 166	0.853 + <0.001	0.025 + 0.007
50k + HOL3	37,179 + 1,834	0.825 + 0.026	0.034 + 0.026
50k + HOL5	37,179 + 63	0.849 + <0.001	0.025 + 0.005
50k + BEEF3	37,179 + 1,746	0.854 + 0.004	0.036 + 0.028
50k + BEEF5	37,179 + 321	0.858 + <0.001	0.026 + 0.012
50k + mQTL	37,179 + 17,056	0.844 + 0.008	0.025 + 0.008

[1] The first and second number represent the heritability estimates for 50k and the respective sequence variant set, respectively.

For scenarios with two different GRM (50k variants and selected sequence variants) the following model was used:

$$y = 1\mu + W_1 g_1 + W_2 g_2 + e \quad (2)$$

where subscripts 1 and 2 represent the first (base 50k) and second (selected sequence variants) GRM fitted, respectively, W_1 and W_2 are identical design matrices linking DRBV to the two genetic effects g_1 and g_2. As above, g and e are assumed to be normally distributed.

A five-fold cross validation was carried out. 400 of the 2,162 cows were randomly selected five times as validation and the remainder (1,762 cows) comprised the reference set. Accuracy of GP was measured as the correlation between the GEBV and DRBV in the validation set. The prediction bias was assessed by regressing DRBV of the validation cows on their GEBV.

Results

The heritability estimated in this study is based on DRBV and can therefore be interpreted as the explained genetic variance of DRBV. The estimates shown in Table 1 are similar between the 50k and all scenarios fitting two GRMs. When using selected sequence variants only, heritability ranged between 0.086 (HOL5) and 0.675 (mQTL).

The accuracy of GP for all scenarios is presented in Table 2. All scenarios fitting two GRMs resulted in similar accuracy as in the 50k scenario only. When using selected variants only, the highest accuracy was observed when using variants from the beef meta-GWAS (BEEF3) and using all populations (ALL3). GEBV were overestimated in all scenarios fitting two GRMs. GEBVs in ALL5 and HOL5 were least biased.

Table 2. Accuracy and slope of the regression of DRBV on GEBV for all genomic prediction scenarios (average across 5 cross-validations).

Scenario	Accuracy	SE	Slope
50k	0.683	0.027	0.909
ALL3 only	0.557	0.035	0.957
ALL5 only	0.363	0.043	1.014
HOL3 only	0.549	0.035	0.973
HOL5 only	0.204	0.048	0.992
BEEF3 only	0.568	0.034	0.983
BEEF5 only	0.469	0.039	1.068
mQTL only	0.475	0.039	0.914
50k + ALL3	0.686	0.027	0.936
50k + ALL5	0.682	0.027	0.932
50k + HOL3	0.683	0.027	0.933
50k + HOL5	0.683	0.028	0.932
50k + BEEF3	0.653	0.029	0.935
50k + BEEF5	0.682	0.027	0.932
50k + mQTL	0.682	0.027	0.931

Discussion

We present accuracies of GEBV for DMI for different sequence variant selection scenarios. No clear advantage in accuracy could be found when adding relevant sequence variants in GBLUP models fitting two GRMs. Reasons may be related to the genetic architecture of the trait DMI in Holstein. Furthermore, variants selected in the different scenarios have generally a very low MAF and imputation errors and linkage disequilibrium can influence the result of GP. Here, we used GBLUP for estimation of GEBV. Bayesian variable selection methods may potentially result in higher accuracy. Further studies will be undertaken in the near future testing Bayesian variable selection methods in a larger Dutch Holstein population and across dairy and beef breeds with DMI phenotypes.

Abstract

Bull fertility has been recognized as an important factor influencing reproductive success in dairy cattle. The objective of this study was to assess the feasibility of predicting bull fertility in Italian Brown Swiss cattle using genomic data. Dataset consisted of 1,102 Italian Brown Swiss bulls with sire conception rate records and 480k single nucleotide polymorphisms (SNP). The analyses included linear and Gaussian kernel-based models fitting either all SNP or also including markers with large effect. Predictive performance was evaluated using five-fold cross-validation. The entire SNP set exhibited predictive correlations around 0.19. Interestingly, the inclusion of two major non-additive markers as fixed effects achieved predictive correlations around 0.32. Therefore, the inclusion of markers with large effect markedly improved the prediction of bull fertility. Our findings have the potential to help the dairy industry to improve Brown Swiss sire fertility through accurate genome-guided decisions.

Introduction

Improving reproductive performance remains one of the most important goals for the dairy industry. Service sire has been recognized as an important factor affecting herd fertility. Recent studies have shown that the reduced ability of low-fertility bulls to establish pregnancy is multifactorial, including not only the fertilization process but also early embryo development (Ortega *et al.* 2018). Interestingly, there are substantial differences in sire conception rate (SCR) between high- and low-fertility bulls, with 10-20% conception rate differences between extreme bulls (Rezende *et al.* 2018; Pacheco *et al.* 2021). Therefore, it is clear that bull fertility should be considered in breeding schemes aimed to improve reproductive efficiency.

There is growing evidence that dairy bull fertility is influenced by genetic factors. Indeed, our team has identified individual genes and gene-sets strongly associated with SCR in both Holstein and Jersey bulls. We have also reported promising results for predicting SCR values using genomic data in these two breeds. However, to the best of our knowledge, no study to date has explored the feasibility of predicting service sire fertility in Brown Swiss cattle using genomic data. Therefore, our first objective was to assess the prediction of bull fertility in the Italian Brown Swiss cattle population using 480k SNP markers spanning the entire genome. Our second objective was to evaluate the potential benefits of incorporating markers with large effect into the genomic prediction models.

Materials & methods

Phenotypic and genotypic data. Phenotypic data consisted in sire conception rate (SCR) records from a total of 1,102 Italian Brown Swiss bulls. Sire conception rate records were calculated using cow field data, considering factors related to the bull under evaluation and factors (nuisance variables) associated with the cow that receives the unit of semen (Pacheco *et al.* 2021). Sire conception rate values ranged from -22.3 to 9.9%, and the number of breedings ranged from 50 to 8,110. Genotype data for 481,839 single nucleotide polymorphism (SNP) markers located in autosomal chromosomes were available for all the 1,102 Brown Swiss bulls with SCR records, kindly provided by the Italian Brown Breeders' Association (Anarb; Italy).

Whole genome scan. The relevance of non-additive effects, namely dominance, recessive and overdominance effects, on service sire fertility was evaluated on a genome-wide scale using a two-step approach. In the first step, the following model was fitted, y = Xb + Zu + e, where y is the vector of SCR records, b is the vector of fixed effects, u is the vector of random animal effects, and e is the vector of random residual effects. The random effects were assumed to follow a multivariate normal distribution with $u \sim N(0, G\sigma_u^2)$ and $e \sim N(0, I\sigma_e^2)$, where σ_u^2 and σ_e^2 are the animal additive genetic and residual variances respectively; G is the genomic relationship matrix, and I an identity matrix. In the second step, the following model was fitted for every SNP, $y = X\beta + X_{SNP}\beta_{SNP} + \epsilon$, where X_{SNP} is the design matrix for the genetic marker under study and β_{SNP} is the regression coefficient or SNP effect. Every SNP genotype was coded using single numeric variables as (0, 1, 1), (0, 0, 1) and (0, 1, 0) for testing dominance, recessive and overdominance effects, respectively. All these analyses were performed using the R package MixABEL (Aulchenko *et al.* 2007).

Genomic prediction. The predictive power of either the entire SNP dataset or the alternative model, which includes markers with large effect as fixed effects, was evaluated using reproducing kernel Hilbert spaces (RKHS) regression models (Morota and Gianola 2014). The analyses were implemented under the kernel-based regression model, y = Xb + Kα + e, where y is the vector of phenotypic records (SCR values); b is the vector of fixed effects including a general intercept (μ); X is the design matrix relating fixed effects to SCR records; K is an $n \times n$ kernel matrix indexed by the SNP genotype matrix; α is the vector of RKHS regression coefficients and *e* is the is the error term. Kernel-based genomic prediction models were fitted using either linear or Gaussian reproducing kernels (K). The linear (K_L) kernel is equivalent to the well-known additive genomic relationship matrix. On the other hand, the Gaussian (K_G) kernel can capture nonadditive effects that might be important for phenotypic prediction of bull fertility. The models were implemented in a Bayesian framework using Gibbs sampling. All the analyses were performed using the R package Bayesian Generalized Linear Regression (Perez and de los Campos 2014). The predictive ability of the different kernel models was assessed by five-fold cross-validation with 10 repetitions. The ability to predict yet-to-be observed SCR values was assessed using the Pearson product-moment correlation coefficient (CORR) and the mean squared error of prediction (MSEP).

Results

Whole genome scan. Figure 1 shows the results of the whole-genome single-marker scan under the recessive model. Two genomic regions, located on BTA6 and BTA26, showed marked recessive effects on SCR (Figure 1B). Figure 1B shows the distribution of SCR values for the two SNP loci with marked recessive effects, rs133071278 and rs41601831. Notably, these box plots demonstrate that the BB genotypes have lower SCR values than genotypes AA and AB. No region showed pure dominance or overdominance effects.

Genomic prediction. Figure 2 shows the predictive performance of the linear kernel-based regression models fitting the entire set of SNP markers, 'Base', or the models that include the two significant recessive markers as fixed effects, 'Base + Recessive Markers'. Note that the 'Base' model (GBLUP model) exhibited an average correlation between observed and predicted SCR values of 0.197, and MSEP equal to 22.03. The 'Base + Recessive Markers' model delivered predictive correlation around 0.322 and MSEP around 20.3. Gaussian kernel models did not outperform linear kernel models in terms of predictive performance (data not shown).

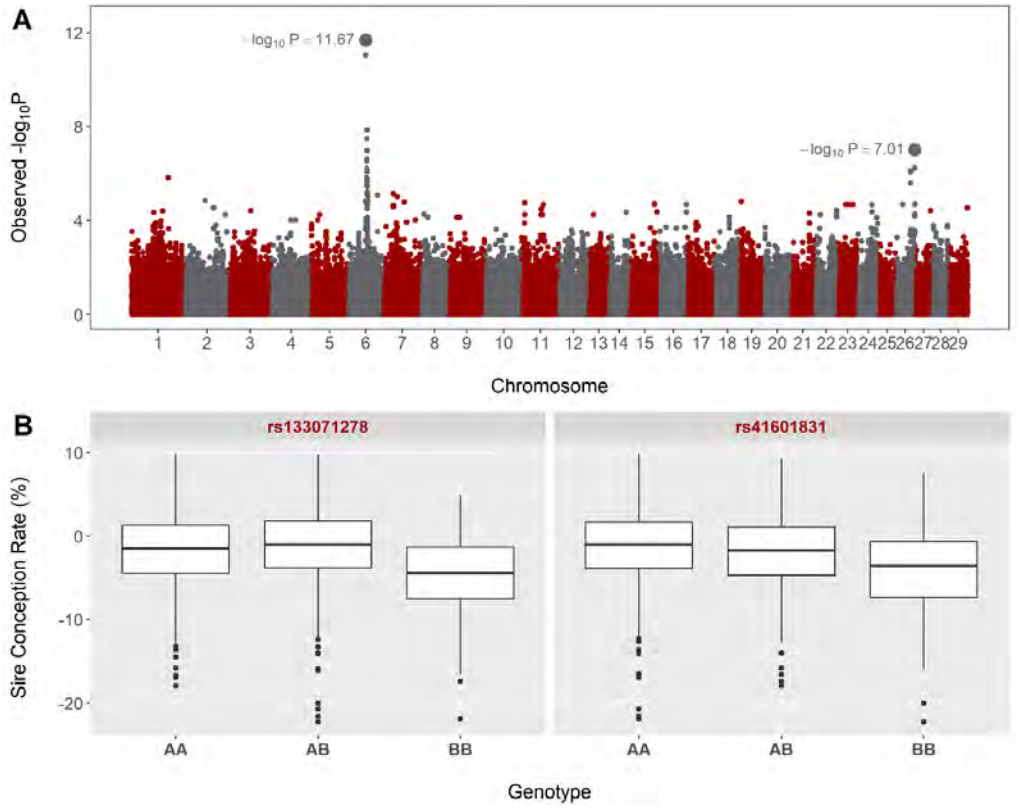

Figure 1. Whole-genome scan for recessive effects on Sire Conception Rate. (A) Manhattan plot showing the SNP significance across the bovine genome for recessive effects on Sire Conception Rate. (B) Boxplots showing the observed differences in Sire Conception Rate for each genotype of the two significant recessive markers.

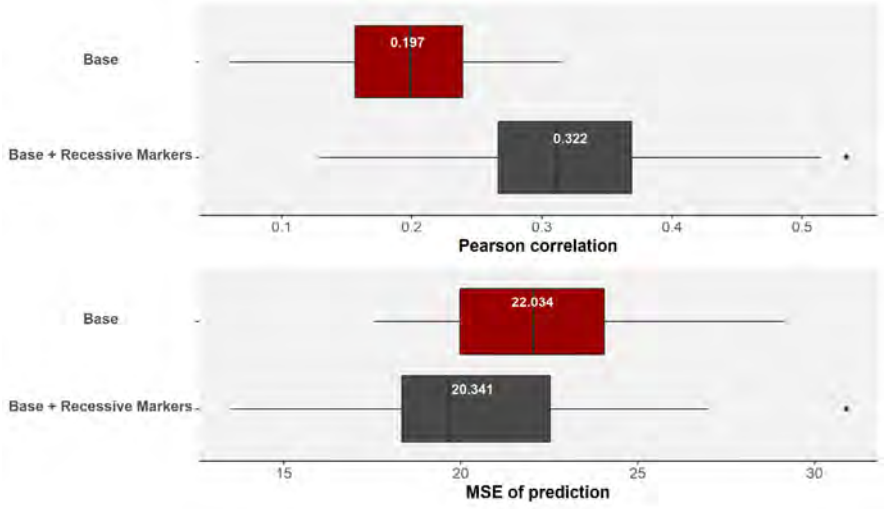

Figure 2. Predicting ability of alternative whole-genome predictive models. Predictive correlation (top) and mean squared error of prediction (bottom) evaluated for each model.

Discussion

The relevance of non-additive effects on Italian Brown Swiss bull fertility was evaluated, and two major genomic regions with large recessive effects were identified. Genomic prediction models including either linear or Gaussian kernels fitting either all SNP or including markers with large effect were evaluated. Notably, model predictive performance was largely improved by including the two markers with large recessive effect as fixed effects, representing an increase in predictive correlation of about 63%. The use of genomic prediction models that include markers with large effect is a promising alternative to the standard approach. Overall, our findings may help to improve reproductive performance of dairy herds through accurate genome-guided decisions on bull fertility.

Abstract

The aim of this study was to develop a strategy for selecting SNPs that could receive higher weight than other SNPs in a GBLUP approach due to their expected association with important pig phenotypes. In addition, we aimed to investigate if such a strategy yields improved prediction accuracy compared to a traditional GBLUP approach. Four prediction accuracy scenarios were evaluated using three production traits in two pig populations. Our results show that adding extra weight to SNPs that are expected to be (close to) causal variants in the G matrix increases the prediction accuracy of genomic prediction. The advantage of weighted G matrix compared to a traditional one is not very large, but the added value is consistent.

Introduction

The first practical use of genomic information in animal prediction models was the application of marker-assisted selection (MAS) where markers of large effect were identified in linkage-based studies using microsatellite markers and then applied in selection. The true benefits of genomics, however, became more pronounced only after the development of dense single nucleotide polymorphism (SNP) panels. With SNPs, the association studies moved from linkage-based to genome-wide association studies (GWAS), and MAS was replaced by genomic selection (Meuwissen *et al.*, 2001), which consists of the estimation of genomic breeding values using a large number of SNPs spread across the whole genome. With GWAS, the power to detect new QTL has increased and SNPs tightly-linked to the causal variants have been identified (van Son *et al.*, 2019). However, GWAS findings have not been extensively exploited for selection purposes as the focus has been mainly on genomic selection. Different methods for genomic selection have been developed, including the extensive Bayesian alphabet (Habier *et al.*, 2011) which allows to put more emphasis on SNPs with large effects. For practical application, however, the most used method in pig breeding is the so-called 'single-step' genomic evaluation (Misztal *et al.*, 2009), which can be considered as an extension of the genomic BLUP (GBLUP) assuming that all SNPs contribute equally to the trait (infinitesimal model). Nevertheless, it has been shown that a finite number of genes control quantitative traits (Hayes and Goddard, 2001) and an approach to give different weights to SNPs when building a genomic relationship (G) matrix has been proposed (Zhang *et al.*, 2014). Therefore, further improvement of traditional genomic prediction models could be achieved by weighting SNPs differently in the G matrix if they are, for example, significant in GWAS (Zhang *et al.*, 2014) or are expected to be a causal variant identified using a porcine Combined Annotation Dependent-Depletion (pCADD) tool (Derks *et al.*, 2021). The aim of this study was to develop a strategy for selecting SNPs that could receive higher weight than other SNPs in the G matrix due to their expected association with important pig phenotypes. In addition, we aimed to investigate if such a strategy yields improved prediction accuracy compared to a traditional GBLUP approach.

Materials & methods

GWAS. Our first step was to perform a GWAS using all traits available in the Topigs Norsvin breeding program. In total, we evaluated 113 traits using five pig populations: Large White, Landrace, Pietrain, Duroc and a Synthetic line. The single-SNP GWAS was ran within population using a single-trait linear animal model in GCTA (Yang *et al.*, 2011). The response variables for most traits were pre-corrected phenotypes for all non-genetic effects using all data available in the routine genetic evaluation of Topigs Norsvin using MiXBLUP (ten Napel *et al.*, 2017). For binary traits, maternal and indirect genetic effects and traits that are an index (e.g. selection index), the response variables were breeding values with a reliability greater than 0.50. Breeding values and reliability estimates were also extracted from the routine evaluation of Topigs Norsvin using MiXBLUP (ten Napel *et al.*, 2017). The number of animals per trait and per line ranged from ~1,300 to ~40,000. Significant association was declared when the SNP presented a *P*-value $<1.0\times10^{-10}$. All significant SNPs located within 5 Mb from another significant SNP were considered to belong to the same QTL region and only the most significant SNP of each QTL region was selected for the further steps.

pCADD. The second step was to select whole-genome sequence variants based on pCADD scores as described in Derks *et al.* (2021). The pCADD score estimates a probability of having a functional (deleterious) impact for each variant. This probability is based on a machine-learning procedure comparing sequence data across species and including annotation data of known functional elements. The score is trait-independent but depends on the quality of the annotation in the region of interest. We selected variants based on their high pCADD score across different annotations as well as variants that are underlying known QTL regions (Derks *et al.*, 2021).

Genotypes. Animals used in the GWAS were genotyped using Illumina Neogen medium-density SNP chips (50K or 80K) (Lincoln, NE, USA). Part of these animals (most influential boars) were also genotyped using the Affymetrix 660K high-density SNP chip (Santa Clara, CA, USA). All animals had their genotypes imputed towards the medium density chip using Fimpute v3 (Sargolzaei *et al.*, 2014) before performing the GWAS. In addition, ~2,000 SNPs were selected from the GWAS and pCADD analyses (2K set) and placed in an Illumina Neogen custom 25K SNP chip together with ~23,000 SNPs (23K set) from the 50K chip that were segregating across all Topigs Norsvin populations or were present on X or Y chromosome. After genotyping over 100,000 animals across all populations with the 25K SNP chip, another round of imputation was performed towards a panel of SNPs that combines all SNPs from the 50K and 25K SNP chips. This new imputed dataset was used for the validation step. Quality control was performed at each level of imputation as described in van Son *et al.* (2019).

Validation. We selected significant SNPs from the GWAS for 113 traits in five populations as well as SNPs based on high pCADD scores which are trait independent. The reason for this is that our final goal is to have a set of SNPs that can be used in multi-trait and multi-population scheme. However, for the validation in this study, we evaluated only the traits backfat (BF) at the end of the test period (~120 kg), average daily gain (DG) and feed intake (FI) during the test period (~25-120 kg) from two populations (Large White and Landrace). From each population we selected the youngest 6,000 animals that had pre-corrected phenotypes for all three traits. The 1000 (very) youngest animals from each population, all genotyped with the 25K SNP chip, were taken as our validation set. The remaining 5,000 animals, genotyped with both 25K and 50K, were taken as our reference (training) set. Four prediction accuracy scenarios were evaluated: 1. 23K, which used a standard G matrix using the same SNPs as the routine genetic evaluation (23K set); 2. 2K, which uses a standard G matrix using only the GWAS and pCADD SNPs (2K set); 3. 25K, which uses a standard G matrix built from a combined set with SNPs from the 23K and 2K sets; 4. w25K, which uses a weighted G matrix using the same SNPs as the 25K scenario. Accuracy of prediction of each scenario was assessed as the correlation between the pre-corrected phenotype and estimated breeding values of the

1000 validation animals from each population. The G matrices of all scenarios were built using calc_grm (Calus and Vandenplas, 2016). To define the weights used in the w25K scenario, we assumed that the 2K set and the 23K set of SNPs can explain the same amount of variance. Therefore, the sum of the weights of the 2K set was equal to the sum of the weights of the 23K set, which means that each 2K SNP has about 20 times heavier weight than the 23K SNPs in the G matrix. We applied the same weights for each SNP independently of the evaluated trait and population. In a standard G matrix, all SNPs have the same weight. Different levels of weights were evaluated (e.g. the sum of the weights of all 2K set was half of the sum of the weights of the 23K set), but the results were similar to those obtained with equal weights and will therefore not be presented.

Results

We selected 260 significant SNPs from the GWAS and 876 with high pCADD scores. The GWAS SNPs explained up to 16% of the phenotypic and 40% of the genetic variance of the evaluated traits. After including them in the custom 25K SNP chip, we obtained 220 GWAS and 784 pCADD SNPs working properly and segregating in both the Large White and the Landrace populations. Therefore, the final 2K set was composed of 1,004 SNPs, while the final 23K set was composed of 21,117 autosomal SNPs also segregating in both populations. The highest prediction accuracies were observed for scenario w25K, except for FI in the Landrace population (Table 1). However, the relative increase in prediction accuracy of the w25K scenario compared to the traditional 23K was not that high, ranging from 0.5 to 4%.

Discussion

Our results show that selecting SNPs that are expected to be (close to) causal variants, including these SNPs in a custom SNP chip and weighting them heavier than standard SNPs in the G matrix might be beneficial to increase the prediction accuracy in the evaluated populations. Although the advantage of w25K scenario compared to the traditional one (23K) is not very large, the added value is consistent. A similar situation has been shown by Khansefid *et al.* (2020) who showed that a custom panel enriched with, or close to, causal mutations yield higher prediction accuracy than their traditional scenario. It is also interesting to observe that using only 1,004 SNP selected from the GWAS or based on pCADD scores (2K scenario), we already obtain high accuracies that are not too far from those obtained with more than 21,000 SNPs (23K scenario). Further, this is a work in progress, and we expect to improve it by investigating other strategies for selecting causal variants and improving the strategy of weighting the SNPs in the G matrix. For practical reasons, we will be looking for strategies that allow improvements in a multi-trait and multi-population scheme. However, working within trait and within population, the added value of a weighted G matrix might be larger due to the differences in allele frequency and linkage disequilibrium across populations.

Table 1. Accuracies of prediction.

Population	Trait	Scenarios[1]			
		23K	2K	25K	w25K
Large White	Backfat	0.474	0.387	0.481	**0.492**
	Average daily gain	0.330	0.228	0.334	**0.340**
	Average feed intake	0.470	0.371	0.474	**0.480**
Landrace	Backfat	0.453	0.412	0.460	**0.473**
	Average daily gain	0.440	0.386	0.444	**0.452**
	Average feed intake	0.522	0.423	**0.525**	0.524

[1] Scenarios: 23K= standard G matrix used in the routine genetic evaluation; 2K= standard G matrix using only the GWAS and pCADD SNPs; 25K= standard G matrix using a combined set with SNPs from 23K and 2K; w25K= weighted G matrix using a combined set with SNPs from 23K and 2K. Numbers in **bold** indicate the highest accuracy of each line.

283. Including environmental variables in genomic models for carcass traits in Hanwoo beef cattle

B.O. Makanjuola[1*], G. Rovere[1], B.C.D. Cuyabano[2], S.H. Lee[3] and C. Gondro[1]

[1]Department of Animal Science, Michigan State University, 474 S Shaw Ln, East Lansing, MI 48824, USA; [2]French National Institute for Agriculture, Food and Environment (INRAE), Génétique Animale et Biologie Intégrative (GABI), 78350 Jouy-en-Josas, France; [3]Division of Animal and Dairy Science, Chungnam National University, Daejeon 305764, Korea; makanjuo@msu.edu

Abstract

The objective of this study was to account for environmental variables to model non-genetic random effects for carcass traits in Hanwoo beef cattle. This model was compared to the traditional model that uses farms as an independent component to model non-genetic random effects. Heritability estimates for all carcass traits in our study ranged from 0.33 to 0.39 when using independent farm effects, whereas with the use of environmental variables, estimated heritabilities dropped and ranged from 0.11 to 0.31. In addition, prediction accuracy increased from a range of 0.39 to 0.45 to a range of 0.50 to 0.58 for all traits when modelling farm effects with environmental variables. This result suggests that environmental variables explain a considerable amount of the observed phenotypic variance, and that not accounting for such environmental variation could upwardly bias heritability estimates. Furthermore, an improvement in the model prediction accuracy was observed when accounting for environmental variables.

Introduction

The impact of climate change resulting from increasing fluctuations in environmental variables and rising temperatures is a major concern for livestock production. Adverse effects of rising temperatures are observed in the form of reduced productivity, performance, growth, and development of animals exposed to such challenging environments (Collier and Gebremedhin, 2015). Traditionally, environmental effects are accounted for by fitting the herd as an effect in genetic evaluation models. With this model, it is traditionally assumed that different herds are completely independent from each other with no similarities. However, herds in closer proximity could be more similar in terms of climatic and geographic factors when compared to more geographically distant herds. Therefore, accounting for relationships of environmental variables between production sites in genetic evaluation models could improve the estimates of genetic components in economically important traits. Improvement in the genetic evaluation of smallholder breeding programs using spatial relationships between herds has already been reported (Selle *et al.,* 2020). In addition, Cuyabano *et al.* (2021) recently showed that using GPS coordinates to create relationships between herds led to an increase in the reliability of the predicted genomic breeding values for carcass traits in beef cattle, when compared to fitting herd effects as independent. Nowadays, public weather stations regularly collect environmental variables and the data is easily accessible for general use. This source of information has been shown to be more accurate than on-farm weather information (Freitas *et al.,* 2006) and can be used to develop a relationship structure between herds based on their weather conditions. Furthermore, temperature-humidity index (THI) as environmental descriptor has been successful in modelling genotype-by-environment interactions with reaction norms (Chen *et al.,* 2021). This present study aimed to: (1) use environmental variables obtained from public weather stations to create a climate relationship matrix between herds; (2) evaluate the impact on estimated variance components by modelling herd effects through the climate relationship structure and (3) assess prediction accuracy for the predicted genomic breeding values.

Materials & methods

Animal and phenotypic data. Data from a total of 4,168 Korean Hanwoo beef cattle was used in this study. There were 3,810 steers and 358 bulls born in 2014 and 2015, all slaughtered in 2017. For this study, four carcass traits were analysed: carcass weight (CWT), backfat thickness (BFT), eye muscle area (EMA) and marbling score (MS). Measurements were taken 24h after refrigeration following slaughter. For BFT and EMA, records were measured at the 12-13th rib junction in millimeters and squared centimeters, respectively. MS was measured visually by a trained evaluator on an ordinal scale that ranged for 1 to 9. The 4,168 animals were raised on a total of 124 finishing farms, which were spread across South Korea.

Genotypes and weather data. All animals used in this study were genotyped with the 50K Illumina (San Diego, CA, USA) Bovine SNP50V2BeadChip array. Quality control measures were performed to retain only SNP present on the autosomal chromosomes with a call rate >90% and minor allele frequency >1%. After quality control, a total of 43,749 SNP genotypes were retained for further analyses. Weather information was available from 78 public weather stations that were close to the farms. To each farm, weather information from the nearest weather station was assigned. The distances between the farms and the weather stations ranged from 0 to 30 km with approximately 45% of the farms sharing the same location as the weather station. The environmental variables used for this study were monthly averages of the maximum temperature (T_{max}) and of the relative humidity (RH_{min}), spanning from 2013 to 2018. Temperature and relative humidity were then combined into THI using the following formula (NRC, 1971):

$$THI = (1.8T_{max} + 32) - [(0.55 - 0.0055RH_{min}) \times (1.8T_{max} - 26)] \quad (1)$$

THI was considered a suitable environmental variable to use because a previous study already reported that THI influences the modulation of the genetic components of these traits in Hanwoo (Chung *et al.,* 2020).

Genomic evaluation. Genetic parameters were estimated for all traits using both of the following linear mixed models:

$$y = Xb + Zg + Wfarm + e, \quad (2)$$

$$y = Xb + Zg + Wst + e, \quad (3)$$

where y is a vector of phenotypic records for CWT, BFT, EMA and MS; b is a vector of fixed effects that included the effects of sex, age at slaughter, herd size and slaughter date; g is a vector of random additive genetic effects; farm is a vector of non-genetic and independent random effects of farm; st is a vector of non-genetic and correlated random effects of farm; e is a vector of random residuals. X, Z and W are incidence matrices that link respectively the fixed effects, random additive genetic effects and non-genetic random farm effects to the phenotypes. The assumptions posed to the random effects were: $g \sim N(0, G\sigma_g^2)$, $farm \sim N(0, I\sigma_{farm}^2)$ and $st \sim N(0, E\sigma_{st}^2)$. σ_g^2 is the additive genetic variance; σ_{farm}^2 and σ_{st}^2 are the non-genetic variance of the herd effect assuming the farms as independent and correlated, respectively. G is the genomic relationship matrix (VanRaden, 2008), I is an identity matrix, and E is the covariance matrix of the farms using the closest weather station information. E was created using the standardized differences between THI values of the farms. First, a matrix D was calculated using the differences between THI values, and the matrix was then scaled by dividing the values by the maximum absolute THI difference, to ensure that the elements of the matrix ranged within the [-1,1] interval (i.e. $D^* = D / \max\{|D_{ij}|: i,j = 1, \ldots, st\}$. Finally, the covariance matrix E was rescaled to have a diagonal of ones and defined as $E_{ij} = 1 - D_{ij}$ with values ranging from $-1 \leq E_{ij} \leq 1$. With this parameterization, stations that are more similar to each other have values closer

to one and the more dissimilar stations will have values closer to minus one. All variance components estimation and genomic predictions were performed using WOMBAT software (Meyer, 2007).

Model predictive accuracy. The predictive accuracy of the different models in predicting the genomic breeding values was performed using a 5-fold cross validation. To evaluate accuracy, the whole data was randomly divided into five subsets of approximately equal size. For each fold of the cross validation, four out of the five subsets (i.e. 80% of data) were assigned as the training set and the remaining subset (i.e. 20% of the data) was used as the testing set. Replication of the 5-fold cross validation procedure was performed 20 times and resulted in a total of 100 estimates. Prediction accuracy in the testing set was calculated as the Pearson correlation between predicted genomic breeding values of the test group and observed phenotypes adjusted for fixed effects ($r = cor(\hat{g}_{test}, y_{test} - X_{test}\hat{b})$).

Results

Table 1 presents a summary of the phenotypic records, with descriptive statistics for each trait.

The proportions of variance explained by each random effect using the two different models for each trait are presented in Table 2, along with the prediction accuracy of the predicted genomic breeding values. Heritability estimates for BFT, EMA, CWT and MS were 0.34, 0.35, 0.39 and 0.38, respectively, when fitting the farm as independent effects. These estimates are in line with other studies that used similar models with heritability estimates that ranged from 0.33 to 0.42 (Chung *et al.,* 2020; Cuyabano *et al.,* 2021). Conversely, using the THI to model the farm effects as correlated resulted in a drop in heritability estimates to 0.31, 0.11, 0.29 and 0.18 for BFT, EMA, CWT and MS, respectively. To the best of our knowledge, no study has reported using a covariance matrix created from THI values from public weather stations. Nevertheless, our results are in accordance with those from a study that used GPS coordinates to create a covariance matrix between farms (Cuyabano *et al.,* 2021). These results suggest that environmental variables and geographic location explain a substantial proportion of the phenotypic variation observed. Prediction accuracies obtained were 0.39, 0.40, 0.45 and 0.40 for BFT, EMA, CWT and MS, respectively, when farm was fitted as an independent effect, and increased to 0.50, 0.54, 0.58 and 0.56 for BFT, EMA, CWT and MS, respectively, when fitting farms with a covariance matrix based on environmental variables, described in this study by the THI.

Discussion

Our study compared modelling herd effects considering farms as correlated or independent. A similar study has already been performed for Hanwoo beef cattle, using GPS coordinates to build correlation between farms (Cuyabano *et al.,* 2021). We innovate with our study by using environmental information from public weather stations, in the form of THI, to build this correlation between farms. Our results showed that a considerable proportion of the phenotypic variation can be explained by correlated environment, in agreement to what was reported by Cuyabano *et al.* (2021), and that this leads to a reduction in the

Table 1. Descriptive statistics of analysed traits including the number of records (N), mean, standard deviation, minimum and maximum of the observations.

Trait	N	Mean	Standard deviation	Minimum	Maximum
BFT	4,168	14.33	5.09	2	47
EMA	4,168	96.74	12.05	34	155
CWT	4,168	442.02	54.95	159	682
MS	4,168	6.44	1.76	1	9

Table 2. Estimates of variance proportions explained by additive genetics (h^2), non-genetic effects of farm or weather station ($(farm/st)^2$) and residual (e^2) and predictive accuracy (r) with their respective standard errors (se).

Trait	Model	$h^2 \pm se$	$(farm/st)^2 \pm se$	$e^2 \pm se$	r
BFT (mm)	g + farm	0.34±0.03	0.03±0.01	0.63±0.03	0.39
	g + st	0.31±0.04	0.13±0.08	0.57±0.06	0.50
EMA (cm^2)	g + farm	0.35±0.03	0.07±.02	0.58±0.03	0.40
	g + st	0.11±0.03	0.69±0.08	0.19±0.05	0.54
CWT (kg)	g + farm	0.39±0.03	0.04±0.01	0.58±.03	0.45
	g + st	0.29±0.05	0.29±0.12	0.43±0.07	0.58
MS	g + farm	0.38±0.03	0.05±.01	0.57±0.03	0.40
	g + st	0.18±0.02	0.54±0.01	0.27±0.01	0.56

additive genetic variance, and consequently to lower heritability estimates. This finding may suggest that not accounting for environmental variation could be upwardly biasing heritability estimates. Additionally, the highest prediction accuracy for all traits was obtained when using the model that accounted for the THI covariances between farms. Such improvement was not observed by Cuyabano *et al.* (2021), suggesting that actual weather information may be more accurate to estimate the random effects than GPS coordinates. Further research is warranted to demonstrate that environmental variables can be used to improve models in another independent population.

Abstract

Genetic correlations at chromosomal level between milk and fat yield in dairy cattle were calculated from SNP effects. The results revealed positive genetic correlations for all chromosomes (r_g=0.327-0.792) except for *Bos taurus* autosome (BTA) 14, where genetic correlation between traits was negative (r_g=-0.794). Two bivariate GBLUP models were fitted – one (Model A) with a single genomic relationship matrix and the other (Model B) with two distinct genomic relationship matrices, one constructed from SNPs of all chromosomes except BTA14 and one constructed only from SNPs on BTA14, where major gene *DGAT1* is located. Accuracy of genomic prediction was evaluated by fivefold cross-validation. Model B showed on average higher relative accuracy of 3.56% for milk yield and 3.67% for fat yield compared to Model A. The presented approach accounts for chromosomal differences in genetic correlations between traits, thereby improving accuracy of genomic prediction.

Introduction

Genetic correlation indicates average similarity between two traits emerging from a shared genetic basis. Patterns of genetic sharing can differ across the genome. Local genetic correlations, i.e. correlations between two traits in particular genomic regions, may differ from a genome-wide estimate. Knowledge about such local genetic correlations can improve the accuracy of genomic prediction. The first objective of this study was to calculate local genetic correlations between traits at chromosomal level. The second aim was to predict genomic breeding values using a bivariate setting and taking into account information on differences in chromosomal genetic correlations between traits. The predictability of this approach was evaluated by cross-validation.

Materials & methods

Data. Genotypes (45,613 SNPs) of 103,496 cows with phenotypic information for traits 305d-milk yield (MKG) and 305d-fat yield (FKG) in 1st lactation recorded between 2015 and 2020 were available. SNPs were excluded from further analysis when they had a call rate lower than 90%, a minor allele frequency lower than 1% or they deviated from Hardy-Weinberg equilibrium at a threshold $P<10^{-5}$. After quality control, 43,665 SNPs remained. For MKG and FKG, SNP effects from routine genetic evaluation were provided by Vereinigte Informationssysteme Tierhaltung (vit), Verden, Germany.

Chromosomal additive genetic (co)variances. For each animal and the two traits MKG and FKG, chromosomal breeding values (CEBV) were calculated as the sum of individual SNP effects on each chromosome. Chromosomal additive genetic variance ($\sigma^2_{g_{CEBV}}$) was calculated as the variance of CEBV across all animals using $\sigma^2_{g_{CEBV}} = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2$, where n is the number of animals, x_i is the CEBV of each animal for trait i and $\bar{x}$ is the average CEBV of each chromosome across all animals.

Chromosomal additive genetic covariance between traits was calculated using:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_284, © C. Schmidtmann *et al.* 2022

$cov(CEBV_{MKG}, CEBV_{FKG}) = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})$,

where n is the number of animals, x_i and y_i are CEBV of each animal for MKG and FKG, respectively. $\bar{x}$ and $\bar{y}$ are the average CEBV of each chromosome across all animals for MKG and FKG.

Chromosomal genetic correlations. The genetic correlation (r_g) at chromosomal level was calculated as $r_{g_{MKG,FKG}} = cov(CEBV_{MKG}, CEBV_{FKG})/ (\sigma_{CEBV_{MKG}} * \sigma_{CEBV_{FKG}})$, where $cov(CEBV_{MKG}, CEBV_{FKG})$ is the covariance between CEBV of MKG and FKG and $\sigma_{CEBV_{MKG}}$ and $\sigma_{CEBV_{FKG}}$ are the standard deviations of CEBV.

Estimation of breeding values. Two bivariate GBLUP animal models were used to estimate genomic breeding values (EBV) for 5,000 animals. Model A was $y = 1_n\mu + Zg_A + e$, where y is a vector of phenotypes MKG and FKG that were adjusted for fixed effects herd-year-season and age of 1st calving. 1_n is a vector of ones, μ is the overall mean, Z is a design matrix for the random genetic effect, g_A is a vector of additive genetic effects, and e is a vector of random residual terms. g_A was assumed to follow $g_A \sim N(0,\mathbf{G}\sigma^2_{gA})$, where G is a genomic relationship matrix (GRM) calculated from all SNPs (n=43,665). Model B included two random genetic terms and was $y = 1_n\mu + Zg_{B1} + Zg_{B2} + e$. The first random genetic effect g_{B1} was distributed $g_{B1} \sim N(0,\mathbf{G}\sigma^2_{gB1})$, where G is a GRM built from SNPs on all chromosomes except of those on BTA14 (n=42,141). The second random genetic effect g_{B2} followed $g_{B2} \sim N(0,\mathbf{G}\sigma^2_{gB2})$, where G is a GRM built only from SNPs on BTA14 (n=1,524). All GRMs were constructed according to VanRaden (2008). Values of variance components for variance-covariance-matrices of genetic effects were determined from (co) variances of computed CEBVs:

$$\sigma^2_{gA} = \begin{pmatrix} 358288 & 3711 \\ 3711 & 334 \end{pmatrix}, \sigma^2_{gB1} = \begin{pmatrix} 280901 & 5666 \\ 5666 & 256 \end{pmatrix} \text{ and } \sigma^2_{gB2} = \begin{pmatrix} 77387 & -1955 \\ -1955 & 78 \end{pmatrix}$$

Mixed models were solved in R (R Core Team, 2021) using the package *sommer* (Covarrubias-Pazaran, 2016).

Cross-validation. Fivefold cross-validation with ten replicates was performed. Prediction accuracy ($r_{(pheno, EBV)}$) was defined as correlation between adjusted phenotypes and estimated breeding values in the validation set. Additionally, mean squared error (MSE) was computed as the average squared deviation of estimated breeding value from the adjusted phenotype over all individuals.

Results

Correlation of SNP effects. The global correlation between MKG and FKG over all chromosomes was positive (r_g=0.623); however, genetic correlations at chromosomal level differed (Figure 1). Weakest and strongest positive correlation was found for BTA20 and BTA9, respectively (r_{gBTA20}=0.327, r_{gBTA9}=0.792). BTA14 showed a strong negative correlation between MKG and FKG (r_{gBTA14}=-0.794). Single weak correlations between chromosomes are shown on the off-diagonals.

Estimated breeding values. For Model A, the average correlation between breeding values (EBV) of MKG and FKG was r_{EBV}=0.407. For Model B, two EBV per trait and animal were estimated (Table 1). A moderate positive correlation was found between $EBV1_{MKG}$ and $EBV1_{FKG}$ (r_{EBV}=0.654), the correlation between $EBV2_{MKG}$ and $EBV2_{FKG}$ was negative (r_{EBV}=-0.531). Weak positive correlations were observed between $EBV1_{MKG}$ and $EBV2_{MKG}$ (r_{EBV}=0.127) and between $EBV1_{FKG}$ and $EBV2_{FKG}$ (r_{EBV}=0.051).

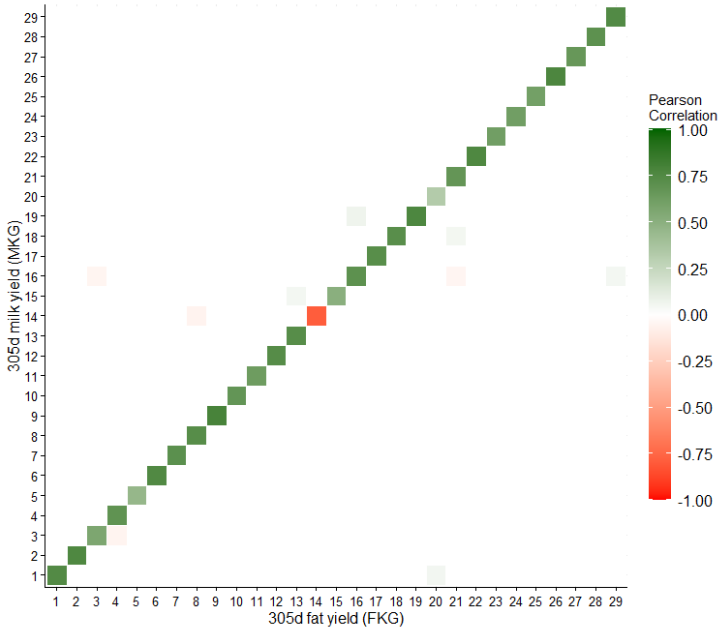

Figure 1. Correlations between chromosomal breeding values for 305d milk yield and 305d fat yield. Values between -0.05 and 0.05 are displayed in white.

Table 1. Correlations (r_{EBV}) between breeding values (EBV1: all chromosomes except BTA14; EBV2: BTA14) for milk yield (MKG) and fat yield (FKG) from Model B.

	$EBV2_{MKG}$	$EBV1_{FKG}$	$EBV2_{FKG}$
$EBV1_{MKG}$	0.127	0.654	0.015
$EBV2_{MKG}$		0.042	-0.531
$EBV1_{FKG}$			0.051

Cross-validation. For both traits, correlations between adjusted phenotypes and EBV in the validation set were higher for Model B (MKG: $r_{(pheno, EBV)}$=0.524, FKG: $r_{(pheno, EBV)}$=0.450) compared to Model A (MKG: $r_{(pheno, EBV)}$=0.506, FKG: $r_{(pheno, EBV)}$=0.434). The results revealed a relative increase in accuracy of 3.56% for MKG and 3.67% for FKG when using Model B. Moreover, the average MSE of Model B (MKG: MSE=1,584.9 kg, FKG: MSE=1.951 kg) was lower for animals in the validation set and for both traits compared to Model A (MKG: MSE=1,619.7 kg, FKG: MSE=1.979 kg).

Discussion

This study showed that genetic correlations between MKG and FKG differed at chromosomal level. A strong negative correlation was found on BTA14, which deviated from the positive correlations on remaining chromosomes. The major candidate gene diacylglycerol acyltransferase (*DGAT1*) located on BTA14 encodes a protein involved in fat metabolism and is a well-known quantitative trait locus for milk production traits (Grisart *et al.*, 2002, Winter *et al.*, 2002). The unfavorable association between milk and fat yield on BTA14 has been previously described in different studies (Grisart *et al.*, 2004, Thaller *et al.*, 2003). Given the two separate genetic effects in Model B, chromosome-specific (co)variances of traits were modelled more precisely compared to Model A, which included only one genetic effect.

Table 2. Mean of accuracy ($r_{(pheno, EBV)}$) and mean squared error (MSE) from 10 replicates of fivefold cross-validation for animals in training- and validation-set and traits 305d-milk yield (MKG) and 305d-fat yield (FKG), standard errors in parenthesis.

	MKG				FKG			
	$r_{(pheno, EBV)}$		MSE (in kg)		$r_{(pheno, EBV)}$		MSE (in kg)	
	training	validation	training	validation	training	validation	training	validation
Model A	0.846 (0.007)	0.506 (0.025)	194.9 (0.438)	1,619.7 (1.235)	0.834 (0.007)	0.434 (0.032)	0.248 (0.015)	1.979 (0.041)
Model B	0.839 (0.007)	0.524 (0.026)	199.2 (0.339)	1,584.9 (1.241)	0.825 (0.008)	0.450 (0.027)	0.255 (0.012)	1.951 (0.045)
Δ	-0.007	+0.018	+4.3	-34.8	-0.009	+0.016	+0.007	-0.028

Positive correlations were observed between the estimated breeding values EBV1 and EBV2 from Model B for both MKG and FKG, indicating that breeding values are not completely independent. Such correlations can imply existing interchromosomal linkage disequilibrium, possibly induced by directional selection.

The presented approach allows to easily account for differences in genetic architecture of traits at the chromosomal level. Thus, accuracy of genomic prediction improved. The approach will be extended to other pairs of traits including direct health traits of dairy cattle.

Acknowledgements

This study is part of the project 'QTCC: From Quantitative Trait Correlation to Causation in dairy cattle' and was supported by the German Research Foundation, DFG.

285. Effects of truncation and false positives in selection of markers for genomic prediction

Z. Loh*, J.H.J van der Werf and S. Clark

School of Environmental and Rural Science, University of New England, Armidale, 2351, NSW, Australia; zloh@myune.edu.au

Abstract

Association studies are often used to select genetic markers for genomic prediction, requiring truncation with a balance between power and false positives. Using simulation, the aim for this study is to test the effects of truncation on prediction accuracy and particularly the impact of false positives in SNP selection. Bonferroni and Benjamini-Hochberg False Discovery Rate methods were tested. Our study suggested that except for polygenic traits, truncation with a more lenient threshold such as the Benjamini-Hochberg False Discovery Rate increases the genomic prediction accuracy. In an inbred population, false positives could contribute positively to the accuracy especially for a oligogenic trait, although further study would be needed to generalize this result. Our study suggested that for a polygenic trait, all markers should be included in genomic prediction, and if SNP selection were to be applied a lenient threshold for truncation would be desirable.

Introduction

The development of high-density marker panels has allowed genomic prediction of breeding values estimation in livestock. The large number of markers also increased the computational intensity (Brøndum *et al.*, 2015) although most of the markers share no correlation with any causal loci (Moghaddar *et al.*, 2019). Thus, van der Berg *et al.* (2014) suggested that these markers can be truncated and only use selected markers ('top SNPs') using Genome-Wide Association Study (GWAS) with no significant negative impact on prediction accuracy, allowing the prediction to be conducted on smaller set of markers. Results were mixed however; Frischknecht *et al.* (2018) reported reduced accuracy when using top SNPs alone, compared to inclusion of all SNPs, while Chang *et al.* (2018) reported increased accuracy with top SNPs. A study for the possible causes of such mixed results, as well as effects of truncation threshold stringency would be desirable.

An important aspect to be considered in marker selection is the threshold used in GWAS. The most common threshold is from the Bonferroni multiple test correction, which has been criticized for its overly stringent threshold. The Benjamini-Hochberg False Discovery Rate (BH-FDR), was developed as a less stringent threshold, increasing power but also the false positive rate (Huang *et al.*, 2018). Studies on the effects of false positives when using them for genomic prediction are lacking however.

The aim of this study is to test the effects of truncation in marker selection and the associated effects of false positives on the genomic prediction accuracy. Truncation as defined by the Bonferroni and BH-FDR methods were tested.

Method

The experiment was conducted using simulation in R (version 3.6.1) and Python (version 3.9.7).

Simulation of base and parent genotype and phenotype. The base population was simulated by coalescent using the R package AlphaSimR (Gaynor *et al.*, 2021) with the command 'runMacs2' with six chromosomes of one Morgan each. The mutation rate was set at 10^{-5} per individual. To simulate a

population structure commonly found in livestock, the effective population size of the base population was set to 100. Via coalescence, a base population of 6,000 individuals was generated, each with 20,000 SNPs The tested parameters, along with their default and alternative values, are provided in Table 1. When a parameter is tested, default values were used for all other parameters.

The base population is then used to simulate a six-generation selection program. From the base population, an equal number of males and females were sampled randomly to be included in the selection program, with the total number of individuals sampled provided in Table 1. This served as the founder for the selection program. For each breeding pair, two offspring were generated for the next generation. The population size remained unchanged throughout the simulation. The Housworth-Stahl recombination model was used, with chiasma distance following a gamma distribution with shape parameter a=2 and rate parameter b=4. Selection was applied to sires only, with the top 50% of all sires been selected to propagate to the next generation, with each sire mated to two dams. An additive genetic model was assumed with heritability of the trait phenotype set at 0.3. A number of QTL was simulated, with their effect size following a gamma distribution with the parameters provided in Table 1.

Genotypes and phenotypes from the fifth generation after the base, denoted as parent generation, were used as training dataset, and those of sixth generation, denoted as offspring genotype and phenotype respectively, were used as test dataset.

GWAS and determination of top markers. To determine the top SNPs to be used in genomic prediction, genome-wide single SNP regression (GWSSR) of parent phenotypes on genotypes was used. Markers with minor allele frequency less than 0.05 were excluded from GWSSR. The threshold was calculated using either Bonferroni or BH-FDR multiple test correction, with alpha=0.05 for both methods. The number of true and false positive markers for both correction methods was recorded. Two types of false positives were identified: correlated false positives (FPC), defined as false positives in linkage disequilibrium (LD) (r^2>0.1) with at least one QTL, and uncorrelated false positives (FPU) that do not have correlation with any QTL.

Genomic prediction. The parent generation data was used to predict the breeding values of the offspring. Using the parent and offspring genotypes, a genomic relationship matrix (GRM) was built based on the methodology by VanRaden (2008), and based on parental generation phenotypes, the estimated breeding values (EBV) of the offspring were calculated using MTG2 (version 2.22) by Lee and van der Werf (2016). The prediction accuracy was defined as the correlation between the EBV and TBV of the offspring.

To test the effects of truncation method for top SNP, we compared different sets of markers used for genomic prediction. We used the selected top-SNPs and to remove the effect of varying number of markers included in the GRM and to ensure the prediction covered the entire genome, we added null markers uncorrelated with any QTL up to a total of 10k. To test the effects of false positives, two tests were conducted for each correction method, with one that utilized all the positives (AP), and the other with FPU excluded, hence only included true positives, and null, negative and uncorrelated markers were used in place of FPU.

Table 1. Parameters and value tested in this experiment.

Parameter tested	Default values	Alternative values
Parent sample size	2,500	500
QTL effect size distribution	Γ(0.3,1)	Γ(0.8,1)
Number of QTL	100	2,500

As control, additional tests were conducted on 10k randomly chosen markers (RND) and 10k markers including all true QTL (ALQ). This experiment as repeated 50 times for each scenario.

A pairwise t-test was conducted to compare the accuracies from different approaches, and for comparison between accuracies between two parameters, an independent Welch t-test was used. A comparison was deemed significantly different if $-\log_{10}(p)$ exceeded 3.0.

Results

The number of true and false positives from both correction methods are shown in Table 2, and the prediction accuracies are provided in Table 3.

Compared to all other methods, genomic prediction that include all QTL has the highest accuracy. Compared to 'RND', truncation for top SNPs generally was also associated with an increased accuracy. The only exception is for the polygenic trait (i.e. large number of QTL), where truncation was associated with a decreased accuracy.

Compared to the Bonferroni method, the use of BH-FDR for top SNP selection generally yielded significantly increased accuracy in genomic prediction in both all positives and true positives GRMs. This increase was associated with an increased number of positives associated with the trait. Interestingly, for both correction methods, the presence of uncorrelated false positives generally significantly increases the accuracy of prediction, although such increment due to false positives was not as significant when the trait is polygenic however (under Bonferroni correction, $-\log_{10}(p)=3.9$ for polygenic trait, compared to $-\log_{10}(p)=18.8$ for default condition).

Table 2. Number of true (TP), correlated false (FPC) and uncorrelated false (FPU) positives for each correction method and different simulated parameter values.

Parameter values	Bonferroni			BH-FDR		
	TP	FPC	FPU	TP	FPC	FPU
Default values[1]	8.4	39.0	173.5	13.7	65.8	523.3
Parent sample size =500	2.1	9.3	24.5	4.1	20.3	86.0
QTL effect size distribution= Γ(0.8,1)	10.2	39.1	152.1	18.4	79.4	575.4
Number of QTL =2,500	23.0	59.9	42.0	124.9	357.1	323.6

[1] The default values were provided in Table 1.

Table 3. Prediction accuracy from all markers, as well as all and true positives from each correction method under varying simulated parameter values.

Parameter values	All markers		Bonferroni		BH-FDR	
	RND[2]	ALQ	AP	TP	AP	TP
Default values[1]	0.730[a]	0.775[b]	0.771[c]	0.701[d]	0.778[e]	0.694[f]
Parent sample size =500	0.565[a]	0.599[a]	0.569[a]	0.531[b]	0.582[a]	0.531[b]
QTL effect size distribution= Γ(0.8,1)	0.728[a]	0.764[b]	0.755[c]	0.700[d]	0.766[b]	0.697[d]
Number of QTL =2,500	0.742[a]	0.755[a]	0.700[b]	0.697[c]	0.725[d]	0.721[e]

[1] The default values were provided in Table 1.

[2] Abbreviation: randomly chosen markers (RND); all QTL included (ALQ); all positives (AP); true positives (TP).

[3] All methods used 10k markers.

[4] Values with a different superscript with each rows were significantly different.

Discussion

Under default parameter values, truncation for top SNPs was associated with an increased prediction accuracy.

This could be caused by the genetic architecture of the traits. For an oligogenic trait (i.e. small number of QTL), only a small proportion of the markers have a correlation with a QTL, thus fewer markers are predictive. Compared to randomly chosen markers, truncation for top SNPs preferentially selects for markers that are likely associated with the trait variation, thus increasing the accuracy of prediction. This is further facilitated by the large variance explained by the detected QTL, further increasing the accuracy. For polygenic traits, a large portion of the markers have a correlation with QTL. Thus for randomly chosen markers, a large portion of the markers with predictive values would be included, increasing the accuracy, and limited gain is made by selecting them from GWAS. Given that many traits are polygenic, this study revealed the limited applicability of truncation in genomic prediction unless a very large dataset is made available. Between correction methods, the use of BH-FDR as truncation threshold yielded significantly higher accuracy than Bonferroni method. This could be attributed to the more lenient threshold of BH-FDR, which allowed more TP and FPC to be captured, thus increasing the prediction accuracy. This suggested that if truncation is to be applied in genomic prediction, a more lenient threshold might be favourable.

The inclusion of uncorrelated false positives in the selected top markers resulted in an increased accuracy in genomic prediction. One possible explanation for such observation was that these uncorrelated false positives, while not neighbouring to any true QTL, shared similar genotype structure with a QTL. This is evident from the LD structure of training data, where distant blocks of loci that shared relatively high LD with a locus have been observed. This structure can be linked to the high level of inbreeding within the population (Gondro, 2015). While not physically linked to a QTL, these loci might have added weight to the true QTL, increasing the accuracy. If this explanation is true, this supported the argument by Goddard (2009) that high accuracy can be achieved for an inbred population. Further study would be required on testing the generalizability of this observation under varying LD structure, and the role of FPU under these changes.

In conclusion, this study suggested that selection for predictive SNPs improves the prediction accuracy for oligogenic trait, but not for polygenic traits. If truncation was to applied in the genomic prediction, a more lenient threshold such as those proposed by BH-FDR would be desirable. While the inclusion of FPU increases the accuracy of prediction in this study, further study into the generalizability of such observations into other scenarios would be desirable. Further study should also focus on the optimal threshold for truncation given certain genetic architecture.

286. Genomic selection for breeding values under identity disequilibrium

R.J.C. Cantet[1,2*], B.K. Angarita Barajas[2], N.S. Forneris[1,2] and S. Munilla[1,2]

[1]Facultad de Agronomía, Universidad de Buenos Aires, Argentina; [2]Instituto de Investigaciones en Producción Animal (INPA) CONICET, 1417 CABA, Argentina; rcantet@agro.uba.ar

Abstract

We present formulae and properties of the additive recursive model for breeding values called the 'ancestral regression through parents', which combines pedigree and genomic data to account for identity disequilibrium due to differential contributions of the grandparents to the gametes forming the individual. At the end, we present an algorithm to predict breeding values of genotyped animals without own or progeny phenotypes measured.

Introduction

When fitting the 'ancestral regression' (AR) to the genetic evaluation of growth traits of Brangus beef cattle from South American countries, we have found computationally efficient to implement fittting the 'ancestral regression through parents' (PAR): a recursive model for breeding values (BV) that accounts for 'identity disequilibrium' (Weir and Cockerham, 1969) due to differential grandparental contributions to the animal's genome (Veller *et al.*, 2020). We have fitted PAR to a system of almost three million equations and found consistent predictions and accuracies between 2020 and 2021. In this presentation we give a summary of PAR, emphasizing on the properties of the covariance matrix of BV and show how to perform genomic selection.

Methods

Identity disequilibrium and the ancestral regression through parents (PAR). When predicting BV with the 'animal model' (Henderson, 1984), genetic similarity or relatedness between the BV of animals X and Y has been measured by twice the probability of identity by descent (*P*(IBD), Malecot, 1969). That is to say when animals X and Y have equal homologous alleles at site *i* in the genome because they are copies from an allele in a common ancestor to both animals. Weir *et al.* (1980) defined single 'site' (base, allele, gen, chromosome, individual) IBD with the random variables X_i and Y_i that indicate the location of the *i*-th homologous site at the genomes of X and Y, respectively. Thus, $P(\text{IBD}) = P(X_i \equiv Y_i)$ is equal to one when X_i and Y_i are IBD, and it is zero otherwise. However, genome inheritance is in 'segments' (Thompson, 2013) or multiple sites and $P(\text{IBD}) = P(X_1 \equiv Y_1, .., X_n \equiv Y_n)$. Under random mating and gametic equilibrium all sites are independent such that:

$$P\left(X_1 \equiv Y_1, ..., X_j \equiv Y_j, ..., X_N \equiv Y_N\right) = \prod_{j=1}^{N} P\left(X_j \equiv Y_j\right) \approx P\left(X \equiv Y\right) \quad (1.1)$$

The term on the far-right results from the fact that the *P*(IBD) under gametic equilibrium is 'equal at all sites'. In practice, genome inheritance is in 'segments' (Thompson, 2013) and not by single sites. Hence, we have to move to *P*(IBD) for non-independent sites, i.e. we have to consider linkage and linkage disequilibrium. For the *P*(IBD) at two sites, J.B.S. Haldane (Weir and Cockerham, 1969) observed the joint *P*(IBD) is always greater than single site *P*(IBD):

$$P\left(X_1 \equiv Y_1, X_2 \equiv Y_2\right) > P\left(X_1 \equiv Y_1\right) P\left(X_2 \equiv Y_2\right) \quad (1.2)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_286, © R.J.C. Cantet *et al.* 2022

In turn, expression (1.2) allowed Weir and Cockerham (1969) to define 'identity disequilibrium' to the following difference, which is also the variance of IBD for two sites or loci (Weir *et al.*, 1980):

$$P\left(X_1 \equiv Y_1, X_2 \equiv Y_2\right) - P\left(X_1 \equiv Y_1\right) P\left(X_2 \equiv Y_2\right) = P\left(X_1 \equiv Y_1, X_2 \equiv Y_2\right) - P\left(X \equiv Y\right)^2 \tag{1.3}$$

Identity disequilibrium increases with inbreeding and linkage (Weir and Cockerham, 1969). Thus, the P(IBD) = $P(X_1 \equiv Y_1,.., X_n \equiv Y_n)$ at a segment is a 'multivariate binary' random variable that enables us to generalize identity disequilibrium to a large number of sites by means of theorem 5.1 in Esary *et al.* (1967), which can be translated here as that the P(IBD) from n sites is always greater or at least equal to the P(IBD) at n – 1 sites taken together, which in turn is greater than the P(IBD) at n – 2 sites taken together to eventually reach the single locus P(IBD). This is possible because multivariate binary random variables with 'non-negative covariance' among them are 'associated' and thus display 'positive quadrant dependence' when the 'covariance between BV is non-negative'. Under gametic equilibrium this is easy to prove because $\text{cov}(a_X, a_Y) = A_{XY}\sigma_A^2$ and, by definition, both terms are non-negative. The fact that BV are positive quadrant dependent Gaussian variables ensures that animals with larger (smaller) BV than the mean will tend to have progeny with larger (smaller) BV than the mean (Esary *et al.*, 1967; Bølviken, 1982).

We will call IDAR to the identity disequilibrium caused by unequal contributions of the grandparental genomes in the gametes forming the individual. Veller *et al.* (2020) proposed the parameter P_G as a measure of IDAR. This is the fraction of genome of a 'grandsire' in the gamete originated in parent G. The parameter space is $0 \leq P_G \leq 1$, and 'it is identifiable only with genomic information' from dense chips of SNP markers, originated in animals of at least three generations (Cantet *et al.*, 2017). When $P_G = 0$, the genome in the gamete is originated completely from the granddam, whereas $P_G = 1$ means that the genome in the gamete is originated completely from the grandsire. The expected value under gametic equilibrium is $E(P_G) = 0.50$ (Veller *et al.*, 2020) and grandparents contribute genome in equal parts in the gamete of parent G. It can be shown that the parameters of our 'ancestral regression' (Cantet *et al.*, 2017) carry IDAR, and the parametric equivalences are equal to $0.5\,(P_S - 0.5) = \beta_S$ and $0.5\,(P_D - 0.5) = \beta_D$. The equation for the AR (Cantet *et al.*, 2017) is:

$$a_X = 0.5\,a_{*S} + 0.5\,a_{*D} + \beta_S\left(a_{*SS} - a_{*DS}\right) + \beta_D\left(a_{*SD} - a_{*DD}\right) + \phi_{*X} \tag{1.4}$$

Notation is S for sire, D for dam, SS for paternal grandsire, DS for paternal granddam, SD for maternal grandsire and DD for maternal granddam. All BV in (1.4) are in gametic equilibrium (*), whereas the IDAR is contained in the term $\beta_S\,(a_{SS_} - a_{DS}) + \beta_D\,(a_{SD_} - a_{DD})$.

The recursive equation for BV under PAR parallels the 'animal model' but with unequal parental contributions to the 'information' for the BV of X due to IDAR:

$$a_X = \rho_S\,a_S + \rho_D\,a_D + \phi_X \tag{1.5}$$

The parameters ρ_S and ρ_D are the respective path coefficients of a_S and a_D in a_X, with parameter space $0.25 \leq \rho_S, \rho_D \leq 0.75$, and oftentimes ρ_S and ρ_D will have different values. Compared to (1.4), all BV in (1.5) are under IDAR. In other words, whereas in the AR the animal is regressed to the BV of parents and grandparents, in PAR – as in the animal model – the BV is 'regressed' to parental BV that are now under IDAR. The ρ parameters are shown to be the unique solution of the following system of equations:

$$\begin{bmatrix} 1 + F_S - \boldsymbol{\Sigma}_{S,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,S} & \Sigma_{S,D} - \boldsymbol{\Sigma}_{S,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,D} \\ \boldsymbol{\Sigma}_{D,S} - \boldsymbol{\Sigma}_{D,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,S} & 1 + F_D - \boldsymbol{\Sigma}_{D,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,D} \end{bmatrix} \begin{bmatrix} \rho_S \\ \rho_D \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Sigma}_{S,X} - \boldsymbol{\Sigma}_{S,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,X} \\ \boldsymbol{\Sigma}_{D,X} - \boldsymbol{\Sigma}_{D,G}\,\boldsymbol{\Sigma}_G^{-1}\,\boldsymbol{\Sigma}_{G,X} \end{bmatrix} \tag{1.6}$$

The Σ are relatedness coefficients under PAR for the 4 × 4 covariance matrix Σ_G among the four grandparents of X, $\Sigma_{G,S}$, $\Sigma_{G,D}$ and $\Sigma_{G,S}$ are vectors of the PAR coefficients between the grandparents with the sire, the dam and X, respectively, also with PAR coefficients $\Sigma_{S,D}$, $\Sigma_{S,X}$ and $\Sigma_{D,X}$ among them. Following the logic of Wright (1922), the quantity $2\,\rho_S\,\rho_D\,\Sigma_{SD} = F_X$, i.e. the inbreeding coefficient of X under IDAR. Under gametic equilibrium, $\rho_S = \rho_D = 0.5$ and $\Sigma_{SD} = A_{SD}$, $F_X = 0.5\,A_{SD}$. The variance of the residual breeding value (RBV), $\mathrm{Var}(\phi_X)$ is equal to:

$$\mathrm{Var}\left(\phi_X\right) = \left[1 - \rho_S^2\left(1 + F_S\right) - \rho_D^2\left(1 + F_D\right)\right]\sigma_A^2 \tag{1.7}$$

Again, when $\rho_S = \rho_D = 0.5$, $\mathrm{Var}\left(\phi_X\right) = 0.5\left[1 - 0.5\left(F_S + F_D\right)\right]\sigma_A^2$ as in the animal model.

Cox and Grimmett (1984) proved a general central limit theorem for 'associated' random variables under very mild requirements that gives the distribution of BV under PAR: if $\sigma_A^2 > 0$ and $\mathrm{cov}(a_X, a_Y) \rightarrow 0$ when the number of sites grows large, then the BV are asymptotically multivariate normal. Independently, Tallis (1989) used asymptotic theory of 'positive quadrant dependent' random variables to prove that when sites are 'linked' the distribution of BV remains to be multivariate normal.

Under PAR the inverse covariance matrix of BV can be written as A^{-1} (Henderson, 1984) such that $\boldsymbol{\Sigma}^{-1} = \left(\boldsymbol{I} - \boldsymbol{B}'\right)\boldsymbol{D}^{-1}\left(\boldsymbol{I} - \boldsymbol{B}\right)$. All elements in any row of B are equal to zero except for ρ_S and ρ_D in the columns pertaining to the parents of the animal, whereas D is a diagonal matrix whose elements are shown inside the square brackets in (1.7). As the parental path coefficients are all positive, Σ^{-1} has the property that all 'partial correlations' (i.e. the PAR relatedness coefficients) are non-negative (Bølviken, 1982). In addition, the 'number of non-zeroes' in the coefficient matrix of the mixed model equations has the same number in Σ^{-1} as in A^{-1}. It is worth mentioning that Σ^{-1} is calculated by simply modifying the algorithm of Henderson (1984) for A^{-1}, by replacing the 0.5 values in the contributions to A^{-1} by ρ_S or ρ_D, and 0.25 values by the product of ρ_S and ρ_D, or the squared values of these path coefficients. Mixed model equations for a single trait under IDAR following a PAR model for BV then are:

$$\begin{bmatrix} \boldsymbol{X}'\boldsymbol{X} & \boldsymbol{X}'\boldsymbol{Z} \\ \boldsymbol{Z}'\boldsymbol{X} & \boldsymbol{Z}'\boldsymbol{Z} + \boldsymbol{\Sigma}^{-1} \end{bmatrix}\begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{a}} \end{bmatrix} = \begin{bmatrix} \boldsymbol{X}'\boldsymbol{y} \\ \boldsymbol{Z}'\boldsymbol{y} \end{bmatrix} \tag{1.8}$$

It is important to indicate that AR and PAR are not equivalent models in the sense of having the same covariance matrix of the phenotypes (Henderson, 1984).

Covariances between breeding values under PAR. Once the r parameters are estimated, the additive covariance under PAR between the BV of an ancestor (A) and a descendant (X) is calculated by a recursion to the BV of X in the following manner:

$$\Sigma_{A,X} = \rho_{S_X}\,\Sigma_{A,S} + \rho_{D_X}\,\Sigma_{A,D} \tag{2.1}$$

At the same time, when neither individual is an ancestor of each other the covariance under PAR requires expanding the BV of both individuals, and it is equal to:

$$\mathrm{cov}\left(a_X, a_Y\right) = \rho_{S_X}\,\rho_{S_Y}\,\mathrm{cov}\left(a_{S_X},\, a_{S_Y}\right) + \rho_{S_X}\,\rho_{D_Y}\,\mathrm{cov}\left(a_{S_X}, a_{D_Y}\right) + \rho_{D_X}\rho_{S_Y}\,\mathrm{cov}\left(a_{D_X},\, a_{S_Y}\right) + \rho_{D_X}\rho_{D_Y}\,\mathrm{cov}\left(a_{D_X},\, a_{D_Y}\right) \tag{2.2}$$

Specific expressions for the covariance between full-sibs (*FS*), paternal-half-sibs (*PHS*) and maternal half-sibs (*MHS*) are calculated by properly replacing in (2.1) with the appropriate expressions described some lines before. Respective covariances for *FS*, *PHS* and *MHS* are:

$$\text{cov}(FS) = \left[\rho_{S_X}\ \rho_{S_Y}\ (1+F_S) + \left[\rho_{S_X}\ \rho_{D_Y} + \rho_{D_X}\rho_{S_Y}\right]\boldsymbol{\Sigma}_{SD} + \rho_{D_X}\rho_{D_Y}\ (1+F_D)\right]\sigma_A^2 \tag{2.3}$$

$$\text{cov}(PHS) = \left[\rho_{S_X}\ \rho_{S_Y}\ (1+F_S) + \rho_{S_X}\ \rho_{D_Y}\ \boldsymbol{\Sigma}_{S_X D_Y} + \rho_{S_Y}\ \rho_{D_X}\ \boldsymbol{\Sigma}_{S_Y D_X}\right]\sigma_A^2 \tag{2.4}$$

$$\text{cov}(MHS) = \left[\rho_{S_X}\ \rho_{D_Y}\ \boldsymbol{\Sigma}_{S_X D_Y} + \rho_{S_Y}\ \rho_{D_X}\ \boldsymbol{\Sigma}_{S_Y D_X} + \rho_{D_X}\rho_{D_Y}\ (1+F_D)\right]\sigma_A^2 \tag{2.5}$$

Genomic selection for animals without own or progeny phenotypes. Suppose X is an animal with neither phenotype nor progeny, but with genotype. After calculating BLUP(a) under PAR, the breeder can calculate BLUP(a_X) by predicting all terms in the 'parental regression' $a_X = 0.5a_S + 0.5a_D + \phi_X$. For individual X, first calculate the RBV of the i^{th} collateral (c_i = sibs, cousins, uncles, great-uncles, etc) of animal X as $\hat{\phi}_{C_i} = \hat{a}_{C_i} - \rho_{S_{C_i}}\hat{a}_{S_{C_i}} - \rho_{D_{C_i}}\hat{a}_{D_{C_i}}$. Then, using mixed model theory (Henderson, 1984) we write:

$$\text{BLUP}\left(\phi_X\right) = \text{cov}\left(\phi_X, \hat{\boldsymbol{\phi}}_C'\right)\left[\text{Var}\left(\hat{\boldsymbol{\phi}}_C\right)\right]^{-1}\hat{\boldsymbol{\phi}}_C \tag{3.1}$$

Full and half-sibs will be the most informative collaterals of X and relevant covariances are displayed in (2.3)-(2.5). We can show that the covariance between the RBV of X in the 'animal model' with the RBV of collateral c_i under IDAR is $\text{cov}\left(\phi_X, \hat{\phi}_{C_i}'\right) = \boldsymbol{\Sigma}_{X,C_i} - \boldsymbol{A}_{X,C_i}$. Hence, on calling t to the number of collaterals of X, expression (3.1) can be written as:

$$\hat{\phi}_X = \text{BLUP}\left(\phi_X\right) = \sum_{i=1}^{t}\left[\frac{\left(\boldsymbol{\Sigma}_{X,C_i} - \boldsymbol{A}_{X,C_i}\right)}{\text{Var}\left(\phi_{C_i}\right)}\hat{\phi}_{C_i}\right] \tag{3.2}$$

The prediction in (3.2) is written and can be programmed using scalar algebra. Finally, the predictor of a_X for genomic selection purposes is equal to:

$$\text{BLUP}\left(a_X\right) = 0.5\hat{a}_{S_X} + 0.5\hat{a}_{D_X} + \hat{\phi}_X \tag{3.3}$$

Abstract

Early fertility traits are linked with beef cattle profitability, and so they have become target traits for selective breeding. Informative single nucleotide polymorphism (SNP) can potentially increase the accuracy of genomic predictions for target traits. Multi-trait meta-analysis was applied on two reproductive traits measured early in life: pregnancy outcome after the first mating opportunity (PREG1) and rebreeding within the first two mating opportunities (REB) to identify informative SNP associated with these traits. The accuracy of genomic prediction using informative SNP was compared to using the bovine high density (HD) SNP chip in full. Accuracies were calculated in five-fold cross validations, through genomic best linear unbiased prediction (GBLUP) methods. The accuracy of genomic prediction for PREG1 was similar for both SNP sets: 0.18 for the informative SNP set, 0.19 for the HD SNP set. However, the accuracy of genomic prediction for REB was higher when the informative SNP set was used (0.36), in comparison to the HD SNP set (0.19).

Introduction

Genomic selection for puberty-based reproductive traits measured early in life can contribute to increasing cow fertility, and therefore to the profitability of beef farming. Easy to measure puberty-based reproductive traits are heritable, ranging from low to moderate heritability (Cavani *et al.*, 2015; Porto-Neto *et al.*, 2015; Tahir *et al.*, 2021). The heritability of a trait directly impacts the accuracy of its genomic prediction (Goddard, 2009). The use of informative variants in genomic analyses can increase the accuracy of genomic predictions (Sarup *et al.*, 2016; Van den Berg *et al.*, 2016). In this context, investigating the role of informative and non-informative SNP on estimation of the heritability and accuracy of genomic prediction can be insightful for puberty-based reproductive traits. A routine way of identifying informative SNP is to conduct genome-wide association studies (GWAS). However, the number of SNP passing the stringent criteria of significance in a GWAS is usually small for traits with low heritability. An alternative is to use multi-traits meta-analysis which has demonstrated identification of increased number of SNP associated with similar traits in different studies (Bolormaa *et al.*, 2014; Melo *et al.*, 2018).

Keeping in mind the advantage of multi-traits meta-analysis to identify informative SNP, we applied this methodology on two similar puberty-based reproductive traits: pregnancy outcome after first mating opportunity (PREG1) and rebreeding score of first two mating opportunities (REB). The aim was to identify maximum informative SNP and use those in genomic prediction and estimation of heritability of these traits.

Materials & methods

Animals and phenotypes. We selected 5,414 animals for the trait PREG1 and 3,118 animals for the trait REB from Female Fertility Phenobank. Female Fertility Phenobank is a platform that maintains genotype and phenotype database for female beef cattle fertility traits. The selected animals belonged to different breeds and properties from Northern Australia.

Genotypes. The animals belonging to both traits were originally genotypes for 35K and 50K SNP chips. All the animals were imputed to HD SNP level (700K) using the software Eagle and Minimac as procedure described by Tahir *et al.* (2021).

Splitting animals into training and validation groups. To avoid the bias in downstream genomic prediction analysis, the populations of animals from both traits were split into five training and five validation groups (Table 1). Only training groups of both traits were used in estimation of SNP effects and identification of the informative SNP through processes described below.

GWAS. Genome-wide association studies for all training groups of each trait were performed using linear mixed model implemented in software GCTA (Yang *et al.*, 2011).

$$y = X\beta + Z\mu + S\alpha + e$$

where, X is vectors of fixed effects, β is estimates of fixed effects. Z is an incidence matrix of random polygenic effects; μ is the estimate of random polygenic effects ~N(0, G$\sigma\mu^2$) where G is the genomic relationship matrix (GRM) based on all SNP. Residual is represented as 'e' ~N(0, σe^2). S is an incidence matrix of genotypes and α is the estimate of SNP effects. A fixed effect combined for information of property and year of birth was used in the model. Similarly, to correct for breed differences, the top two principal components were also used as covariates.

Multi-trait meta-analysis. The SNP effects and their standard error obtained from GWAS of corresponding training groups of both traits were used to perform multi-trait meta-analysis using SNP & Variation Suite v8.x Golden Helix (Golden Helix).

$$\text{Multi-trait } \chi^2 = t'_i \, V^{-1} \, t_i$$

where, χ^2 is multi-trait test statistics approximately distributed as chi-squared, t_i is a vector 2 × 1 of the $_i$th SNP effects divided by their respective standard errors, t'_i is the transpose vector of t_i, and V^{-1} is an inverse of the 2 × 2 correlation matrix of the correlations between the *t*-values.

From multi-trait meta-analysis, all the SNP associated with both traits, simultaneously (empirical *P*-value<9.0×10^{-5}) were selected and termed as informative SNP sets. The informative SNP were extracted from HD SNP set for all training groups of both traits. This process resulted in formation of five training groups with informative SNP sets.

Genomic prediction. The training groups of both traits were used to estimate GEBVs using informative and HD SNP sets through GBLUP method implemented in software GCTA.

$$y = X\beta + Z\mu + e$$

The GEBVs estimated through equation above were back solved to estimate the GBLUP-SNP effects for the training groups of both SNP sets using the software GCTA.

Accuracy of genomic prediction. The SNP effects from training groups of both traits were used to calculate the GEBVs of the validation sets of both traits. The accuracy of genomic prediction was calculated as:

Accuracy = r = correlation between GEBVs, and phenotypes adjusted for fixed effects.

Multiple GRM model. To account for random polygenic effects in the estimation of heritability of the traits with informative SNP set, the GRM of informative SNP was also modelled along with GRM of non-informative SNPs (HD SNPs minus informative SNPs), simultaneously.

Results

In single trait single training group GWAS, average number of SNP suggestively associated with PREG1 were 51 (empirical *P*-value<0.9×10^{-5}), while in case of REB, this number was 52. All training sets, through multi-trait-meta-analyses of both traits, identified an average of 516 SNPs (empirical *P*-value<0.9×10^{-5}) associated with both traits (Table 1).

The heritability estimated by HD SNP set was 0.17 (S.E 0.02) for PREG1 and 0.21 (S.E 0.03) for REB, while the heritability estimated by the informative SNP set was 0.21 (S.E 0.02) for PREG1 and 0.24 (S.E 0.02) for REB (Table 1). In single GRM models, the heritability explained by informative SNP set was more than the HD SNP set for both traits. In multiple GRM models, the heritability of PREG1 explained by informative SNP set was reduced to 0.19 while the heritability of REB explained by informative SNP set remained same as in single GRM model (Table 2).

For PREG1, informative SNP set produced similar accuracy of genomic prediction (0.18) as did HD SNP set (0.19). For REB, the informative SNP set, however, performed much better with accuracy of genomic prediction of 0.36 in comparison to HD SNP set which produced accuracy of genomic prediction of 0.19.

Discussion

This study aimed to investigate the effect of using informative SNP for the estimation of heritability and accuracy of genomic prediction of puberty-based reproductive traits in female beef cattle. In this study, the heritability estimates of PREG1 and REB by HD SNP set were comparable to the previous studies who reported heritabilities for similar traits such as pregnancy outcome after first fixed-time insemination (0.18)

Table 1. Estimates of heritability and accuracy of genomic prediction for PREG1 and REB using HD and informative SNPs.[1]

Trait	h^2	Accuracy	SNP set	SNPs (n)	Total population (n)	Training population (n)	Validation population (n)
PREG1	0.17	0.19	HD	669,396	5,414	4,331	1,083
PREG1	0.21	0.18	Informative	516	5,414	4,331	1,083
REB	0.21	0.19	HD	662,896	3,118	2,495	623
REB	0.24	0.36	Informative	516	3,118	2,495	623

[1] h^2 = heritability.

Table 2. Heritability estimates by informative SNP sets in multiple GRM model.

Trait	Multiple GRMs	Heritability explained
PREG1	Informative SNP	0.19
	Non-informative SNPs	0
REB	Informative SNP	0.24
	Non-informative SNPs	0

and rebreeding (0.22) (Cavani *et al.*, 2015; Porto-Neto *et al.*, 2015). The results indicate that the estimate of heritability of PREG1 by informative SNP set was slightly inflated which was confirmed by application of multiple GRM model (Table 1, 2). The estimate of better heritability by informative SNP set for REB seems unbiased as the informative SNP set resulted in same heritability in multiple GRM model as in single GRM model. Heritability of the traits impacts the accuracy of genomic prediction (Zhang *et al.*, 2014). In this study, the accuracy of genomic prediction was coherent with the estimates of heritability in case of PREG1 by both informative and HD SNP sets without any noticeable difference between performance of both SNP sets. However, in case of REB, the accuracy of genomic prediction was almost double using informative SNP set in comparison to HD SNP set. This increase in accuracy of genomic prediction of REB is very encouraging when compared to the other reports who reported small to moderate increase in accuracy of genomic prediction of fertility traits using biologically informed polymorphisms (Abdollahi-Arpanahi *et al.*, 2017; Nani *et al.*, 2019). Further exploration of these traits with larger dataset can confirm these findings with more confidence and can present these traits as suitable option to be adopted for genomic selection programmes in beef cattle industry.

Abstract

Most validation studies of genomic evaluation observe inflation, i.e. regression coefficients of the later phenotypes on early predictions smaller than one. In this paper, we show that this is due to non-zero contributions of distant QTLs, especially those located in other chromosomes than the SNPs. These effects result from linkage disequilibrium (here measured with r^2) present in the reference data but eroded in the population of candidates. In six French dairy cattle breeds average r^2 is low across chromosomes but a substantial proportion of SNP pairs show r values higher than 0.05. A simulation study based on real genotypes from the Normande breed shows that 5% of the SNP effect's variance is explained by distant QTL with associations not maintained across generations. A real Holstein example illustrates extensive across chromosomes covariances between effects. It is thus recommended to erode SNP effects to compute unbiased genomic values of candidates to selection.

Introduction

In genomic evaluation, SNP effects are estimated in a reference sample and applied to selection candidates. This method is extensively used to select candidates at an early stage of their life or yet without phenotypic information. The standard interpretation is that a trait depends on QTLs, and those genetic markers in close LD to these QTL are good proxies for them. Implicitly, this assumes that estimated marker effects reflect those of the neighbouring QTL. Under this assumption, associations observed in the reference sample should be very similar in the next generation as short-distance LD erodes slowly due to recombination.

It is, however, well known that genomic evaluation efficiency is highly dependent on the relatively close relationship of the candidates to the reference sample (Habier *et al.*, 2007, 2013; Legarra *et al.*, 2008; Pszczola *et al.*, 2012). Many studies have shown the limited gain in accuracy in multi-breed evaluation (Erbe *et al.*, 2012; Hozé *et al.*, 2014), illustrating that distant reference data are not informative. Other studies have shown decrease in accuracy over generations when the reference sample is not updated (Sonneson *et al.*, 2009; Solberg *et al.*, 2009). Moreover, it has been observed that the absence of the parents in the reference sample directly influences the prediction accuracy of the selection candidates. All these results suggest that SNP effects erode as the distance between candidates and reference sample increases.

Despite these observations, validation studies of genomic evaluations are generally based on the regression of later performances on the early predictions. These studies frequently observe an inflation pattern, i.e. the regression coefficient is systematically below 1, meaning that later performances of the best candidates were below those initially predicted (and later performances, if any, of the worst candidates were above those initially predicted).

An interpretation is that some long-range LD exists, even between chromosomes, and, accordingly, many markers may capture some partial effects of supposedly unlinked QTL. Long-distance LD is much lower than short-distance LD, but the number of variants involved is much higher and their joint effects can explain a substantial proportion of the predicted genomic value. In this paper, we show that markers capture some effects of distant QTL due to long-distance LD. Because this long-range LD dissipates over

generations, the erosion of marker effects must be taken into account to predict the genomic value of the candidates.

Materials & methods

LD across chromosomes was measured in the female reference data of six French dairy cattle breeds (Holstein, Montbeliarde, Normande, Abondance, Tarentaise, Vosgienne). The size of these reference samples varied from 2,617 to 362,363. Vosgienne, Tarentaise, and Abondance are regional mountain breeds, Montbeliarde and Normande are large national populations (18 and 7% of the French dairy herd, respectively) and Holstein (70%) is international. One every 20 SNP was considered, resulting in a sample of ~3 million r^2 values for each breed (vs ~1.2 billion in total).

To study the impact of long-distance LD on SNP effects, we used the Normande population (n=69,220 genotyped cows with records). Only the first five chromosomes (ns=13,608 SNP) were considered. Two hundred (nq=200) additive QTLs were sampled at random among those SNPs with MAF>0.02 over the first four chromosomes whereas chromosome 5 remained empty of QTLs. Additive QTL effects were independently drawn from a normal distribution assuming a heritability of 0.3. Two scenarios were tested: (1) the SNP-BLUP model accounted for the 13,608 SNPs including the QTL, a situation believed to minimize the impact of long-distance LD; (2) the SNP-BLUP model did not include the QTL, a situation in which QTL effects are to be distributed on more markers. The contribution of each QTL to each SNP was estimated as follows. The SNP-BLUP equations can be written as $(M'M + \lambda I)\,\hat{s} = M'y$, with M the (N × ns) matrix of centered and scaled genotypes, s the vector of SNP effects, y the vector of phenotypes adjusted for fixed effects, and $\lambda = \sigma_e^2 / \sigma_s^2$. According to the simulation, the phenotype can be written as $y = Pq + e$, i.e. the sum of nq QTL effects and an error term, with P the (N × nq) matrix of genotypes at the QTL level and q the vector of true QTL effects. Therefore, the equations can be rewritten as $\hat{s} = (M'M + \lambda I)^{-1} M'(Pq + e)$. If c_i is line i (corresponding to SNP i) of $C = (M'M + \lambda I)^{-1}$, the contribution of QTL j to SNP effect i is $c_i M' P_j q_j$. These contributions were squared and summed within each of the 6 following categories of distance between QTL and SNP: (1) the QTL is the SNP; (2) the distance between the QTL and the SNP is less than 5 Mb; (3) this distance is between 5 and 20 Mb; (4) the QTL and the SNP are on the same chromosome but more than 20 Mb apart; (5) the QTL and the SNP are on different chromosomes; category (6) corresponded to the special case of SNPs on chromosome 5 with no QTL. Thirty replicates were simulated.

This way to estimate contributions by accumulating squared effects by individual SNP does not account for the covariances between SNP effects. This method is therefore only an approximation (De los Campos *et al.*, 2015). However, the long-distance covariances have a major impact and reinforce the contribution of distant markers. They are illustrated by the part of DGV variance explained by haplotypes of increasing size. These results were from the French Holstein evaluation for resistance to paratuberculosis (Sanchez *et al.*, 2022, WCGALP).

Results

Table 1 presents different LD statistics across chromosomes in the reference samples of six French dairy cattle breeds. Average r^2 values are small, which at first glance may suggest that across chromosomes effects are negligible. These values decreased when the size of the breed (reference sample, number of females in the breed, or effective size) increased. Note, however, the parameter of interest here is r instead of r^2, as the impact of a QTL on a SNP effect is proportional to r. The proportion of SNP pairs with |r| greater than 5% varied from 1.5 to 33%, depending on the breed. The larger the reference sample, the lower this proportion. Nevertheless, even with a few percentuals, one to several thousand SNP have some correlations to QTLs (assuming that these r distributions are the same between SNP and QTL).

Table 1. Statistics of |r| and r^2 values across the 29 chromosomes in reference samples of six French dairy cattle breeds (selection of 1 every 20 SNP within chromosome).[1]

Breeds	# cows in reference sample	Mean(|r|) *	% |r|>0.03	% |r|>0.05	Mean(r^2)
Vosgienne	2,617	0.0420	54	33	0.0029
Tarentaise	3,788	0.0225	41	18	0.0015
Abondance	7,115	0.0268	35	15	0.0012
Normande	69,220	0.0206	25	7	0.00073
Montbeliarde	185,053	0.0173	18	4	0.00053
Holstein	362,363	0.0148	12	1.5	0.00038

[1] Statistics based on 2,812,741 to 3,231,80 r-values per breed.

Table 2 presents the relative contribution of the 6 classes of QTL-SNP distance, expressed in proportion of the total sum of squared SNP effects. In the model including the causal variants, these variants succeeded to capture the largest part of the genetic variability, leaving little contributions to the nearby markers. Contributions of distant QTLs were nearly zero. In the model without causal variants, more similar to a real situation, the distribution of contributions was spread on more distant markers, even across chromosomes, although the largest part of the variability was still captured by the closest markers. This result was obtained with only five chromosomes and the contribution to distant markers is likely to be even larger with 29 chromosomes, due to the multiplicity of the across chromosomes contributions.

These contributions at long-distance are the consequences of long-distance LD (M'P is a measure of the covariance between SNP and QTL). This basal LD is a function of the effective size Ne and remains more or less constant across generations on average at the genome level. Two opposite forces explain this steady-state LD: (1) The existing long-range LD is reduced by a 0.5 factor at each generation due to segregations; and (2) it is regenerated by drift (and possibly selection) at random. However, this is not true for a given pair of loci and the LD between 2 unlinked loci existing in the reference sample is reduced by a 0.5 factor.

Finally, Table 3 illustrates that the part of the DGV variability explained was very small with individual variants and gradually increased with haplotype size, showing the huge amount of positive covariances between marker effects. Even when entire chromosomes were considered, the sum of the 29 variances represented only 58% of the total, showing that 42% of the total variance originated from inter-chromosomal covariances.

Table 2. Relative contribution of each of the 6 classes of QTL-SNP pairs defined according to their distance. The contribution of a class is the sum of squared effects. Results on 30 replicates.

Classes of QTL-SNP relationship	Relative contribution (%)		# of QTL contributions to SNP
	Model including causal variants	Model without causal variants	
1: QTL=SNP	95.2	0.0	200
2: distance(QTL,SNP) <5 Mb	4.6	73.8	42,660±530
3: 5 Mb < distance <20 Mb	0.1	19.6	112,500±1,500
4: distance(QTL,SNP) >20 Mb	0.02	0.6	410,000±3,700
5: QTL and SNP on different chromosomes	0.02	2.4	1,671,000±4,500
6: SNP on chromosome 5 (without QTL)	0.02	3.5	485,200

Table 3. Proportion of DGV explained by haplotypes of various sizes in French Holstein.[1]

Interval length (# markers)	1 (single markers)	10	100	500	Entire chromosomes	Whole- genome
% variance explained	1	8.5	26	47	58	100
# intervals	53,469	5,360	548	121	29	1

[1] Variances were computed from partial DGV per interval in the evaluated population.

Conclusions

The practical consequences are important. In the overall prediction of candidates, the short distance contributions are rather stable, slightly eroded by recombinations (Dekkers *et al.*, 2021), but the long-distance contributions are divided by 2 at each generation. According to the relative weight of short and long-distance LD, the overall erosion may strongly fluctuate, but it is always important. Assuming this erosion factor per generation (ρ) is known, eroded direct genomic values (DGV) of candidate i can be estimated from the raw DGV of i and of its parents s and d: $DGV_i = 0.5\ (DGV_s + DGV_d) + (1-\rho)^k\ MS_i$, with MS being the Mendelian sampling component and k the number of generations between i and the reference sample on both paternal and maternal pathways. This formula is recursive, as sire's and/or dam's DGV should also be eroded if they do not belong to the reference.

Further investigation is needed to estimate this ρ erosion factor. It of course depends on basic LD in the population (i.e. on Ne and the genome length L). But it also probably depends on the genetic architecture of the traits (number and magnitude of QTL effects) and the model used (SNP-BLUP/GBLUP vs Bayesian models). However, one can anticipate that: (1) inflation factors $(1 - \hat{b})$ frequently observed are between 0.1 and 0.2 and give an idea of the importance of the phenomenon; (2) models including causal variants are more persistent and less subject to erosion; (3) breeding schemes with accelerated generations without updating reference data accumulate more erosion; (4) models including a residual polygenic component present less inflated predictions because they combine two estimates of the MS term, the genomic one which is inflated and a polygenic one which is equal to zero. We believe that accounting for erosion is more rigorous and accurate than adding an arbitrary polygenic effect.

289. Definition of reliabilities for models with metafounders

M. Bermann[1], I. Misztal[1], D. Lourenco[1], I. Aguilar[2] and A. Legarra[3*]

Abstract

For models with several base populations (Unknown Parent Groups or Metafounders), the usual definition of reliability is ill-posed. Here we propose to define reliability based on contrasts with one or several metafounders, leading to a sounder genetic interpretation. In the case of a single metafounder, our definition equals the definition of reliability for the classical animal model. This definition also allows expressing the reliability of contrasts of metafounders, which may be of interest to decide if their setup is estimable with sufficient reliability. All desired quantities can be obtained from elements of the inverse of the MME.

Introduction

Reliabilities (*Rel*) are usually defined as the square of the correlation between estimated and true breeding values (EBV and TBV) on conceptual repeated sampling. When different base populations exist, they are modelled as Unknown Parent Groups (UPG; fixed or random) or Metafounders (MF; random). The total EBV (u) can be seen as a sum of genetic levels of the different base populations plus random deviations. An EBV has a reference point with a value of '0'. In the animal model with neither UPG nor MF, the base population is infinite with a mean breeding value of 0, so the EBVs already refer to this base population. In fixed UPG, EBVs are non-estimable functions and the '0' depends on the particular generalized inverse used for solving. There is thus no meaningful base population the EBVs refer to. In the case of MF, the EBVs refer to an ideal population of maximum heterozygosity, which has a value of 0.

Reliabilities need to refer to a base population, which is the '0' point when using some form of BLUP (Tier *et al.*, 2018). In the case of UPGs, the fact that they are fixed effects means that the reliability cannot be properly defined or computed. For MF, reliabilities obtained referring to the ideal population made little genetic sense as this population doesn't actually exist. We show that a sensible thing to do is to refer reliabilities to one (or several) MF using a contrast. In the case of a single base population, these reliabilities are identical to the classical ones.

On the other hand, UPGs or MFs are essential for correct genetic evaluations when animals lack pedigrees or when crosses of different breeds / populations / countries exist. Some genetic evaluations fit as many as 400 UPGs. In practice, UPG/MF may include few animals with phenotypes; therefore, they may not be accurately estimated, leading to suboptimal selection decisions (Kennedy, 1981). We therefore propose to routinely evaluate reliabilities of contrasts among MF, to ascertain if MF are correctly set up and estimated.

In (with neither UPG nor MF) BLUP and ssGBLUP, 'classical' reliabilities for individual i can be obtained using explicit inverses of the Mixed Model Equations, e.g. $Rel^c = 1 - PEV/(A_{ii}\sigma_u^2)$ using prediction error variance (PEV). However, including UPG or MF in the model leads to practical and conceptual problems. When UPG are fit as fixed effects, the usual equation for reliability does *not* hold, because $Var(\hat{u}) \neq Cov(\hat{u}, u)$ when u includes the UPG (Henderson, 1984). The expression is approximately correct *only* when UPG are estimated with very high precision. This is the case (roughly) when a large number of first-generation offspring from UPG have records, and UPG are not confounded. When UPG are fit as random effects with variance σ^2_{UPG}, the equation holds, but the UPG variance component should be included in the denominator e.g. $Rel_i^c = 1 - PEV/(\sigma^2_{UPG} + A_{ii}\sigma_u^2)$.

On the other hand, MF are a comprehensive solution to model genetic relationships (Γ) between and within different base populations, for instance the increase of overall relationship within a breed over time (Legarra *et al.*, 2015). These are reflected in modified relationships $A^{(\Gamma)}$ and genetic variance $\sigma^2_{u(\Gamma)}$. By construction, MF are deemed to be more adequate than UPG, in particular for ssGBLUP applications. Because MF are random effects, in principle, one could use $1 - PEV^{(\Gamma)}/(A^{(\Gamma)}_{ii}\,\sigma^2_{u(\Gamma)}))$ to obtain reliabilities. However, empirical assessment showed that this equation underestimated reliabilities for proven bulls.

Materials & methods

The reliability from PEV in the MF case computed as $1 - PEV^{(\Gamma)}/(A^{(\Gamma)}_{ii}\,\sigma^2_{u(\Gamma)}$ refers to this ideal population, but we are not interested in this reliability as it has no genetic interpretation or use. It is more meaningful to refer the reliability of the EBV to a single, genetically well-defined population (Tier *et al.*, 2018). This population can simply be one of the MF. In a purebred population with MF modelling missing pedigree, it can simply be the oldest MF. Thus, instead of considering the EBV $\hat{u}_i^{mf}$, we consider the contrast $\hat{u}_i^{mf} - \hat{u}_{mf}^{mf}$. To clarify, we use the super-index *mf* for an EBV modelled with metafounders, whereas subindices refer generally either to individual *i* or to the reference metafounder *mf*.

Reliability of EBV with metafounders. Given the contrast of EBVs, we can define the reliability of the contrast as $Rel_i^{mf} = Rel\left(\hat{u}_i^{mf} - \hat{u}_{mf}^{mf}\right)$. This is equal to:

$$Rel_i^{mf} = Rel\left(\hat{u}_i^{mf} - \hat{u}_{mf}^{mf}\right) = 1 - \frac{Var\left(\left[u_i^{mf} - u_{mf}^{mf}\right] - \left[\hat{u}_i^{mf} - \hat{u}_{mf}^{mf}\right]\right)}{Var\left(\left[u_i^{mf} - u_{mf}^{mf}\right]\right)}$$
$$= 1 - \frac{PEV\left(\hat{u}_i^{mf}\right) + PEV\left(\hat{u}_{mf}^{mf}\right) - 2PEC\left(\hat{u}_i^{mf}, \hat{u}_{mf}^{mf}\right)}{\left(A^{(\Gamma)}_{ii} + A^{(\Gamma)}_{mf,mf} - 2A^{(\Gamma)}_{i,mf}\right)\sigma^2_{u(\Gamma)}}$$

This is the general equation to obtain the reliability of the contrast 'individual – reference MF' $(\hat{u}_i^{mf} - \hat{u}_{mf}^{mf})$ from the inverse of the MME. In the equation, $PEC\left(\hat{u}_i^{mf}, \hat{u}_{mf}^{mf}\right)$ is the prediction error covariance, and $A^{(\Gamma)}_{ij}$ are corresponding relationship coefficients (which in ssGBLUP will be from matrix $H^{(\Gamma)}$. Interestingly, we can define different reliabilities with different metafounders; for instance, in a complex, unbalanced cross, for the same animal, one can potentially define different reliabilities for each origin.

In the particular case of a single metafounder, it can be shown that $Rel_i^{mf} = Rel\left(\hat{u}_i^{mf} - \hat{u}_{mf}^{mf}\right)$ is equal to the classical 'animal model, no UPG' reliability $Rel_i^c = 1 - PEV/(A_{ii}\sigma^2_u)$ where PEV is from the 'classical' animal model, i.e. $Rel_i^{mf} = Rel_i^c$. This is intuitively expected.

Reliability of metafounders' contrasts estimation. Following the same logic, we define a reliability of contrasts of MF estimation, namely

$$Rel^{mf}_{mf(i),mf(j)} = Rel\left(\hat{u}^{mf}_{mf(i)} - \hat{u}^{mf}_{mf(j)}\right)$$
$$= 1 - \frac{PEV\left(\hat{u}^{mf}_{mf(i)}\right) + PEV\left(\hat{u}^{mf}_{mf(j)}\right) - 2PEC\left(\hat{u}^{mf}_{mf(i)}, \hat{u}^{mf}_{mf(j)}\right)}{\left(\Gamma_{i,i} + \Gamma_{j,j} - 2\Gamma_{i,j}\right)\sigma^2_{u-related}}$$

this allows to appraise the quality of MF estimates in a scale from 0 to 1, something very difficult to do with UPG. Indeed, Kennedy (1981) suggested to check the standard error of contrasts of UPG to avoid wrong selection decisions. It is worth noting that the definition of Rel^{mf} above is strictly the same as for animals.

Computing aspects. To obtain reliabilities in 'classical' animal models (neither UPG nor MF), only the PEV from the diagonal of the inverse of the MME are needed, usually from the sparse inverse. In our

proposal, to obtain Rel_i^{mf}, the vector of $PEC\left(\hat{u}_i^{mf}, \hat{u}_{mf}^{mf}\right)$ is needed. This vector can be obtained by solving the equation $(MME)x = y$, where y contains 1 in the position of the reference MF and 0 elsewhere; on the output, x contains PEC of the reference MF versus all the other unknowns in the MME. Because MF are random effects, this vector of PECs (and all PEVs in the procedure) is invariant to the usual lack of full rank of the MME.

Additionally, the relationships of the metafounders with the other individuals can be obtained by solving $\boldsymbol{A}^{(\Gamma)^{-1}}\boldsymbol{x} = \boldsymbol{y}$ where $y = 1$ in the location of the metafounder and 0 otherwise. The solution vector x contains the values of the row of $A^{(\Gamma)}$ corresponding to the reference MF, and hence all $A_{i,mf}^{(\Gamma)}$. A similar procedure can be used for SSGBLUP $H^{(\Gamma)}$, combined with Legarra *et al.* (2020) to obtain $diag(H^{(\Gamma)})$.

Example. The 12-individuals pedigree with 2 MF described in Legarra *et al.* (2015) (Figure 1) was considered, with:

$$h^2 = 0.5\ ,\ \boldsymbol{\Gamma} = \begin{pmatrix} 0.55 & 0.48 \\ 0.48 & 0.77 \end{pmatrix},$$

and one record per individual. The model includes an overall (fixed) mean. We computed Rel^{mf1}, Rel^{mf2} and Rel^{c} (in the last case, ignoring MF in the model).

Results

Numbers from the example are shown in Table 1. It can be seen that Rel_i^{mf} is roughly similar to Rel_i^{c} in this (rather artificial) example. It is interesting to note that the reliability is higher with respect to the MF who is *not* the ancestor of the individual, and this can be explained because the phenotype of an individual contributes both to its EBV and to the EBV of its ancestral MF. It is also of interest to see that the reliability of the contrast of metafounders is not very high.

Discussion

This work provides a rationale for the definition and computation of reliabilities in a model with several founder populations – something that had not been done before. Our proposal should give more meaningful reliabilities in populations with missing pedigrees or crossbreds. In addition, we emphasize that the computations involved are doable for medium-size data sets, and approximations can be used for larger ones. Moreover, the reliability of contrasts among MF may be used to verify whether differences across MF are estimated with enough precision, and therefore to help defining number and definition of MF.

290. A new metric to assess reference populations for genomic selection in Australian beef breeds

K.L. Moore*, M.H. Ferdosi, C.G. Girard, S.F. Walkom and D.J. Johnston

AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; kmoore7@une.edu.au

Abstract

Research has shown that to maximise benefits (i.e. EBV accuracy and spread and decreased generation interval) of genomic selection, reference populations of genotyped and phenotyped animals need to be large, diverse in relationships and closely related to the selection generation. In practice, applying these design principles can be challenging as metrics to aid decision making are often not available. This paper applies a metric that objectively describes reference populations and their impact on accuracy for seven Australian beef populations. All populations for live weight and abattoir carcase had different levels of phenotyping, genotyping and overall size. Carcase traits had the lowest reference population size, and assessment of average relatedness in almost all the breeds showed there were herds that were not currently represented in the reference population. Generally, increasing reference size resulted in increased accuracy, but there were some exceptions. The metrics described in this paper are easy to apply and can assist in the construction of reference populations.

Introduction

Single-step GBLUP has been implemented into Australian BREEDPLAN genetic evaluations (Johnston *et al.* 2018). Reference population data to underpin genomics are generated by a number of projects, and are run by either breed societies or research organisations. Reference population design is critical and impacts the benefit obtained from genomics. The accuracy of genomic selection is directly impacted by reference population size, trait heritability, and effective population size (Goddard and Hayes, 2009), as well as relatedness amongst the reference animals, and relatedness to selection animals (Pszczola *et al.* 2011). As the relationship between the reference and selection population increases, smaller reference population sizes are required to achieve the same level of accuracy (Lee *et al.* 2017). Therefore, multiple design principals need to be balanced when constructing reference populations. Applying these design principals can be challenging for many practical reasons, including that there are limited quantitative metrics and tools available to make informed objective decisions on sire selections for building reference populations. The aim of this study was to develop a metric that describes and assesses reference populations for suitability for genomic selection on a breed, herd or individual level, and to explore the relationship between reference size and the realised accuracy observed in industry datasets from single-step genetic evaluations.

Materials & methods

Seven Australian beef populations represented a wide range of population structures and will be anonymised. Breeds A, B, D and G have established BREEDPLAN single-step genetic evaluations with breed F recently implementing single-step. Breed C and E are yet to implement single-step into their genetic evaluations. All metrics described in this paper were applied to animals born 2010 or later. Live weight and carcase reference populations were considered, with reference animals being those involved in structured projects and also qualifying industry animals. The reference population was defined as animals with both phenotype and genotype available, as well as genotyped but un-phenotyped sires with five or more progeny phenotypes not already included in the reference. For inclusion in the reference population, animals required at least one live weight record (200, 400 or 600 day) for the live weight reference population, and at least one of abattoir

carcase records (carcase weight, P8 rump fat, rib fat, eye muscle area, retail beef yield or intramuscular fat) for the carcase reference population.

Numerator relationship matrices were constructed with unpublished AGBU nrmblock software written by Ferdosi based on algorithms by Aguilar *et al.* (2011) and Sargolzaei *et al.* (2005). For each animal, the average relatedness with all animals and then reference only animals for each trait was calculated based on the off-diagonal elements. To assess how trait specific reference populations represented the wider population, the average relatedness to reference animals (y-axis) was plotted against the average relatedness to all animals (x-axis) (Figure 1). This visual metric was quantified by the regression slope for all animals and for individual herds. If all animals were phenotyped and genotyped the figure (and slope) is a 1:1 line with no deviations. A regression slope close to 1 was considered optimum, <1 under and >1 over-represented in the reference population.

To explore the relationship between reference size and selection accuracy, single trait BLUP approximate accuracies from the BREEDPLAN genetic evaluations were used. The average live weight (200, 400 or 600 day) accuracy for genotyped but un-phenotyped animals was plotted against the reference size for each breed. To control against influencing factors (i.e. different effective population sizes) and considering only the larger reference populations, a series of phenotype knockouts were undertaken for breed B and D 400 day yearling weights. Phenotypes of whole contemporary groups were randomly removed from the analysis to achieve reference sizes between 1000 and 20,000 animals. The accuracy of genotyped but un-phenotyped animals was plotted against the reference size.

Results

Each beef population was different sized with varying levels of phenotyping and genotyping (Table 1). The percentage of genotyped animals were 4, 6, 8, 12, 16, 50 and 80% respectively for Breeds C, F, D, B, A, G and E. Reference sizes were greatest for live weight (3.5 to 68.3% of all animals) and smallest for abattoir carcase (0.0 to 3.7% of all animals) traits where recording tended to be limited to research projects.

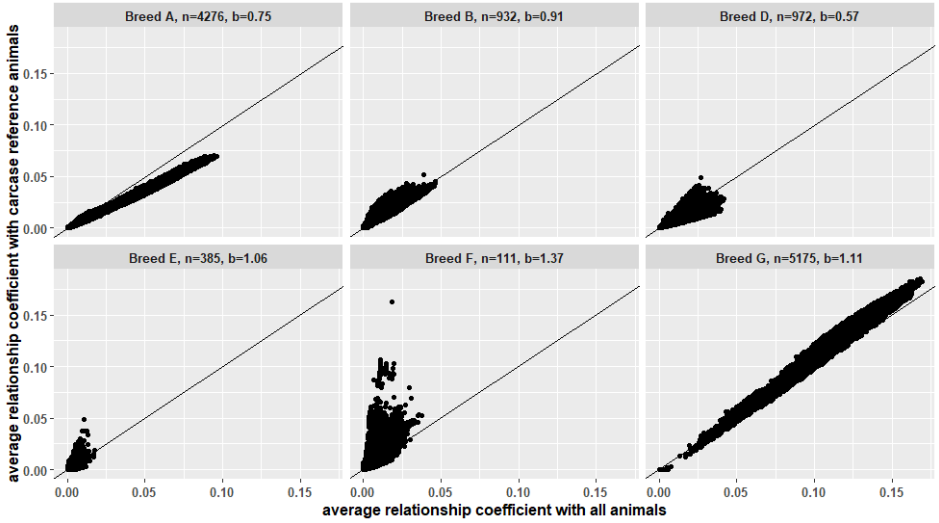

Figure 1. The average relatedness to all animals (x axis) compared with animals in the carcase reference population (y axis) for six Australian beef populations.

Table 1. Description of population and reference size and regression slope from average relationship plots for live weight (LWT) and abattoir carcase (CAR) traits.

[1] GT=genotyped.

[2] All = slope for all animals.

[3] Herds= Minimum slope for an individual genotyped herd.

Slopes were calculated for all animals and individual herds, Table 1 reports the overall slope and the minimum herd slope. Larger reference groups were more representative of the general population. For breed G, the overall slope (1.11) and minimum herd slope (1.03) indicated a relevant reference population for genotyping herds. However, the minimum herd slope for un-genotyped herds (results not shown) were as low as 0.02. Breed D had the lowest slope both on a breed (0.57) and herd level (0.03) and along with Breed C showed the most variation in herd slopes (results not shown).

The size and structure of the reference population both impacted accuracy of genotyped un-phenotyped animals. Figure 2 shows that as reference size increased, EBV accuracy also increased. The trajectory was similar for all breeds, as well as when knock-out results were considered for Breeds B and D. Breed G accuracy was higher than expected given reference size, but Figure 1 showed the breed to have higher average relationship values. Breeds B, E and F all had similar accuracy yet reference sizes ranged from 4,619 to 12,896.

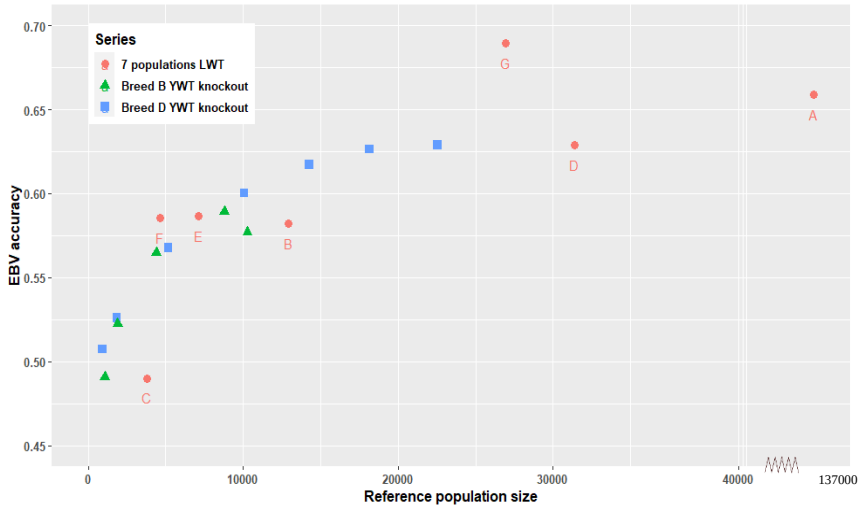

Figure 2. The relationship between reference size and average accuracy of genotyped only animals for live weight (LWT) from seven populations and yearling live weight (YWT) for Breed B and D knockout evaluations.

Discussion

The regression slope metric describes how well reference populations covered the general populat-ion. Larger refer-ence populations generally represent-ed the general population better. This may be more of a reflection on the reference size relative to the wider population size.

Breed B was much closer to 1. Breed D has a much larger population with more herds genotyping but overall fewer animals genotyped. This was also evident with Breed A, who had lower slopes despite having one of the numerically largest carcase reference populations, but when expressed as a proportion of the wider population, the carcase reference was one of the smallest. Results for Breed A show the population to be generally consistent with no herds identified with low slopes. The shape of the average relatedness figure was also informative with the ideal shape being a narrow cloud following the 1:1 line. Breed F had a large number of dots above the line indicating animals already heavily represented in the reference. This plot shape is more likely with a very small reference like we see with Breed F. Herds that genotype benefit from genomic selection due to their linkage to the reference population. The regression slope metric can identify herds with low slopes so that their genetics can either be included into reference data projects or they can use reference animals to build genetic links with their herd and ultimately increase the overall accuracy of genomic selection.

Breed G accuracy was higher compared to other breeds with similar sized reference populations, but Figure 1 shows the breed to have higher average relatedness values. Breeds B, E and F all had similar accuracy despite different reference numbers and proportions. A generally consistent relationship between size and EBV accuracy was observed. Compared to theoretical values (for similar heritability) reported by Goddard and Hayes (2009), the accuracy values we observed from industry datasets were higher when the reference was small (≤2,000) but lower with larger reference populations (≥10,000). For yearling weight, after 10,000 reference animals the observed accuracy tended to plateau rather than continuing to increase as theoretical equations have predicted. Further research is required to understand these differences.

These metrics are an effective and easy way of describing reference populations in the context of the general population and at individual herd level. They provide important information to assist in enhancing the design of the reference population. Breeds can utilise these metrics to identify animals/herds that are not connected to the reference and respond appropriately. These metrics do not consider data quality, so that would need to be considered separately. This simple quantitative metric can help maximise the benefits of the reference population and may be the first objective measurement available to breed societies for managing their reference populations. The next stage of the research will be to investigate the relationship between the relatedness to reference metric with EBV accuracy.

Abstract

Threshold models used in the analysis of binary traits such as calving ease provide solutions in liability scale that are easily transformed into probabilities. However, these models are prone to convergence and computing time issues because of the nonlinear equations involved. Although linear models provide a high correlation to liability solutions and are alternative to overcome the issues above, the lack of a transformation from linear to probability scale may prevent using linear models. We derived formulas for transforming linear solutions to probabilities using conditional expectations and variances. This transformation was evaluated by correlating solutions in probability scale for calving ease obtained using threshold or linear models. The transformation from linear solutions to probabilities was equivalent to its counterpart. The correlation for all animals, sires, or animals with records was 0.99. Combining linear models with the new transformation provided an optimal ranking of animals and reduced computing time by five-fold.

Introduction

The nonlinear equations involved in the threshold models increase complexity and computing time in contrast to linear models (Meijering and Gianola, 1985; Weller, 1988). In the genomics era, convergence issues and increased computing time have become significant challenges. As an illustration, the evaluation for calving ease at the American Angus Association which uses a bivariate threshold-linear model with calving ease (1.8M phenotypes) and birth weight (9.4M phenotypes) takes 5 h for a classic BLUP run and 52 h with genomic information (1.12M genotyped animals). This represents a 10-fold increase in computing time, even when using BLUP solutions as initial values in the genomic evaluation.

Although threshold models are more theoretically appropriate for analyzing binary and categorical traits, several studies reported limited advantages over linear models (Varona *et al.*, 1999; Ramírez-Valverde *et al.*, 2001). For example, using a sire model to analyze dystocia and calf mortality in dairy cattle, Weller *et al.* (1988) reported correlations between solutions from the threshold and linear models ≥0.96, and ranking changes for sires were small contrasting both models. Furthermore, the robustness of linear models to departure from normality increases with progeny group size (number of records), number of categories, and incidence (Meijering and Gianola, 1985). A neat feature of threshold models is that solutions in the liability scale are easily transformed into probabilities so genomic estimated breeding values (GEBV) of animals represent the probability of expressing the category of primary interest. However, such a transformation is not well defined for solutions from linear models. Therefore, formulas were derived for transforming GEBV from linear into probability scale using conditional expectations and variances for direct and maternal effects. The computing time and the correlation between GEBV in probability scale for calving ease obtained using threshold or linear models were evaluated.

Materials & methods

Data. The American Angus Association (St. Joseph, MO 64506, USA) provided the data including 11M animals in the pedigree, 9.2M birth weight phenotypes (BW), and 1.8M calving ease phenotypes (CE) recorded as a binary trait, where 1 = easy calving and 2 = assisted calving. A total of 964,444 animals were genotyped for 54k SNP, of which 39,739 remained after quality control.

Model and computations. Analyses were performed using single-step genomic BLUP (Aguilar *et al.*, 2010) with the algorithm for proven and young (Misztal *et al.*, 2014a), including 22k animals in the core. Two bivariate animal models for CE and BW were implemented: a linear-linear animal model and a threshold-linear animal model:

$$\begin{bmatrix}\mathbf{y}_{ce}\\ \mathbf{y}_{bw}\end{bmatrix}=\begin{bmatrix}\mathbf{X}_{ce} & 0\\ 0 & \mathbf{X}_{bw}\end{bmatrix}\begin{bmatrix}\mathbf{b}_{ce}\\ \mathbf{b}_{bw}\end{bmatrix}+\begin{bmatrix}\mathbf{Z}_{ce} & \mathbf{0}\\ \mathbf{0} & \mathbf{Z}_{bw}\end{bmatrix}\begin{bmatrix}\mathbf{u}_{ce}\\ \mathbf{u}_{bw}\end{bmatrix}+\begin{bmatrix}\mathbf{T}_{ce} & \mathbf{0}\\ \mathbf{0} & \mathbf{T}_{bw}\end{bmatrix}\begin{bmatrix}\mathbf{m}_{ce}\\ \mathbf{m}_{bw}\end{bmatrix}+\begin{bmatrix}\mathbf{W}_{ce} & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{cg}_{ce}\\ \mathbf{0}\end{bmatrix}+\begin{bmatrix}\mathbf{e}_{ce}\\ \mathbf{e}_{bw}\end{bmatrix} \quad (1)$$

in which y, b, u, m, cg, and e are vectors of phenotypes, fixed effects [contemporary group (only for BW), sex, age of dam, and sex × age of dam interaction; the latter two effects only for CE], additive direct genetic effects, additive maternal genetic effects, random contemporary group effects (only for CE), and random residuals; X, Z, T, and W are incidence matrices for b, u, m, and cg, respectively.

In the threshold-linear animal model, it was assumed that the CE phenotype for individual i (y_{ce_i}; i = 1, 2, …, n) is the expression of an underlying continuous random variable, the liability (L_{ce_i}) of individual i. If L_{ce_i} exceeds an unknown fixed threshold (t), the $y_{ce_i} = 2$ (assisted calving), and $y_{ce_i} = 1$ (easy calving) otherwise. We assumed that the liability was normally distributed with mean vector θ and unit variance:

$$L_{ce_i}|\boldsymbol{\theta} \sim N\left(\mathbf{s}_i'\boldsymbol{\theta},1\right) \quad (2)$$

where θ' = (b', u', m', cg') is a vector of fixed and random effects, and $\mathbf{s}_i'$ is a row incidence vector linking θ to the records.

The response of CE was modelled with the following distribution:

$$p(\mathbf{y}_{ce}|\mathbf{L}_{ce}) = \prod_{i=1}^{n}\left[I\left(L_{ce_i} > t\right)I\left(y_{ce_i} = 2\right) + I\left(L_{ce_i} \le t\right)I\left(y_{ce_i} = 1\right)\right] \quad (3)$$

where I is an indicator function that takes the value of 1 if the condition specified is true, otherwise 0. Variance components were estimated using the average information restricted maximum likelihood algorithm (linear-linear model) or the Gibbs sampling methodology (threshold-linear model). All computations were done using the BLUPF90 suite of programs (Misztal *et al.*, 2014b). For both models, direct breeding values were transformed to probabilities assuming independence between direct and maternal breeding values (independent transformation; Equation 4) or conditioning on maternal breeding values (conditional transformation; Equation 5):

$$P_i = 1 - \Phi\left(\frac{u_i - \mu_u}{\sigma_u}\right) \quad (4)$$

$$P_i = 1 - \Phi\left(\frac{u_i - \mu_{u_i|m_i}}{\sigma_{u|m}}\right) \quad (5)$$

where P_i is the probability of easy calving for animal i, Φ is the standard cumulative distribution function, u_i is the breeding value of animal i; u_u is the mean of breeding values; σ_i is the standard deviation of breeding values; $\mu_{u_i|m_i} = \mu_u + \left[\sigma_{u,m}(\sigma_m^2)^{-1}(m_i - \mu_m)\right]$ is the conditional expectation of the direct breeding value given the maternal breeding value, for animal i; $\sigma_{u|m} = [\sigma_u^2 - (\sigma_m^2)^{-1}(\sigma_{u,m})^2]^{0.5}$ is the conditional standard deviation of the direct breeding values given the maternal breeding values. Spearman rank correlations and the genetic trends were used as indicators of the agreement between probabilities from both models.

Results

Computing time for the threshold-linear and the linear-linear models was 145 and 32 hours, respectively. Spearman rank correlation between direct GEBV obtained with threshold or linear models was 0.988 before

and after the transformation to the probability scale assuming independence between direct and maternal breeding values. The correlation was 0.988 before the transformation, and it was marginally improved (0.991) using the conditional transformation. The correlations were the same for all animals in the pedigree, sires, and animals with CE records. Hence, the linear model provided an optimal ranking of all animals, i.e. the ranking was virtually the same as when using threshold models. Furthermore, the transformation of solutions to probabilities in the linear-linear model was equivalent to that in the threshold-linear model. Figure 1a shows the distribution of direct GEBV in liability and linear scales. Figure 1b shows the distributions in the probability scale. The transformation from the linear scale to the probability scale not only yielded an equivalent ranking of animals, but the breeding values were also in the same range and with nearly identical distributions; therefore, genetic trends obtained by both models were equivalent (Figure 1c), and the agreement was improved using the conditional transformation. These results suggest that using linear models does not lead to significant losses in selection response in this population.

Discussion

Misztal *et al.* (1988) estimated that the cost of a threshold model analysis would be 3 to 5× larger than that of a linear model; their results agreed with the current results–computing time in the threshold-linear model was ~5× larger than computing time in the linear-linear model. However, it is essential to highlight that we used the solutions from a non-genomic, threshold-linear analysis as initial values in the genomic threshold-linear analyses to accelerate convergence. Without the latter strategy, differences would be more prominent.

The transformation of GEBV from liability and linear scales to probability scale relies on the standard cumulative distribution function. If the distribution of solutions has an extreme departure from normality, the probabilistic statements based on linear solutions assuming normality can be distorted. In this study, GEBV obtained in the linear scale was normally distributed, leading to a similar distribution of GEBV in the probability scale from both linear and threshold models. Additionally, the conditional variance reduces the dispersion of breeding values improving the agreement between distributions and genetic trends.

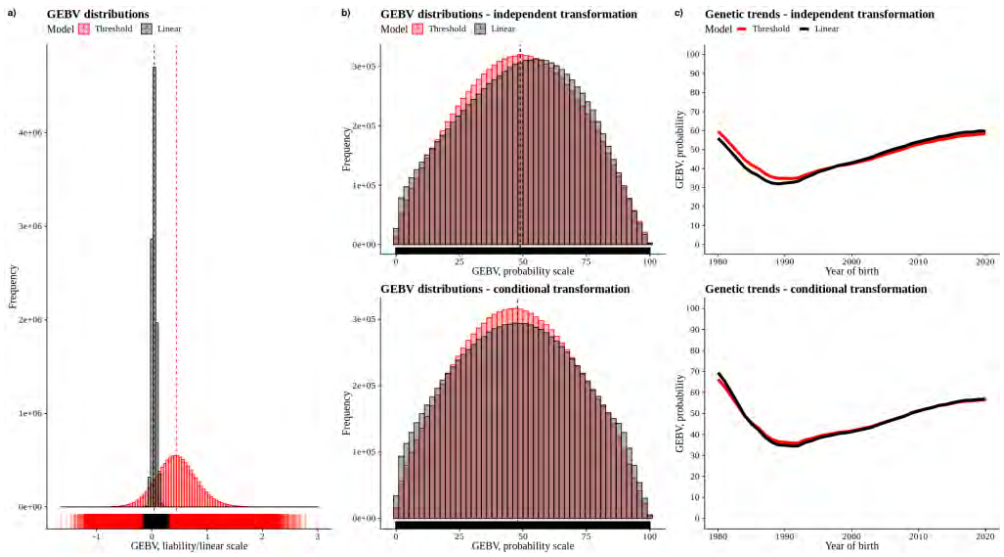

Figure 1. Distributions of direct genomic estimated breeding values (GEBV) and genetic trends in American Angus contrasting linear and threshold models for calving ease.

Robustness of linear models to departure from normality increase with the amount of data (Meijering and Gianola, 1985). In this population, the average progeny number with CE records per sire was 31, and 84% of the heifers had progeny with CE records. In addition, a large amount of BW records (9.2M), which is highly (0.82) correlated with CE, increase the accuracy of GEBV for CE, as also reported by Varona *et al.* (1999) and Ramírez-Valverde *et al.* (2001). These factors lead to a high correlation (0.99) between GEBV for CE obtained from threshold-linear and linear-linear models.

In this study, the correlation between GEBV in probability scale from linear and threshold models was the same despite the number of progeny per sire with CE phenotypes. Such a concordance suggests that large amounts of data in this population provide a similar ranking for all the animals, not only for sires with large progeny group size. The latter contrasts with Meijering and Gianola (1985) and Ramírez-Valverde *et al.* (2001), who, using non-genomic analyses, found higher correlations for sires with larger progeny group size with records for CE. A possible explanation is that genomic information increases the GEBV accuracy for all genotyped animals as every genotyped animal with CE phenotypes influences the direct genomic value of all genotyped animals. In summary, implementing a linear-linear model for the genomic evaluation of calving ease and birth weight, together with the new transformation to the probability scale, represents a feasible alternative to overcome convergence issues and long computing time without harming the genetic progress. The solution presented here may enable large-scale evaluations with multiple categorical or binary traits, which is impractical under the threshold methodology.

292. Within and across breed single step genomic prediction for somatic cell count including foreign information

R. Mrode[1,2*], M.W. Winters[3] and M. Coffey[1]

[1]Scotland Rural College, Edinburgh EH9 3JG, United Kingdom; [2]International Livestock Institute, Box 30709, Nairobi, Kenya; [3]Agriculture and Horticulture Development Board, Stoneleigh Park, Kenilworth, Warwickshire, CV8 2TL, United Kingdom; raphael.mrode@sruc.ac.uk

Abstract

Current UK genetic evaluations for somatic cell count (SCC) are based on an across breed repeatability animal model. Genomic prediction for SCC was investigated using ssGBLUP within the Holstein (HOL) breed only and on an across breed basis. Also, impact of incorporating de-regressed MACE proofs for foreign bulls on accuracy of predictions was investigated. In the within HOL breed analysis, accuracy of bull predictions increased by about 50% to 0.66 with ssGBLUP and by 70% to 0.76 with including foreign information. Results from the across breed evaluations for HOL were similar to results from the within breed analysis. Increases in cow accuracies were low at about 13% with including foreign information. However, there were no increases in accuracies for the other smaller breeds in the across breed evaluations, due may be to the limited number of their bulls in the validation set with genotypes. Evaluations from the various models were highly correlated.

Introduction

Currently in the UK, conventional genetic evaluations for somatic cell count (SCC) are based on an across breed repeatability animal model using up to 5 lactations with unknown parent groups (UPGs) handled by the QP transformations. The de-regressed proofs from this model are subsequently fed into the multi-step SNPBLUP model that incorporates de-regressed MACE proofs from INTERBULL for genotyped foreign bulls. Genotyped cows have not yet been incorporated into the training population for the multi-step genomic SNPBLUP. However, the simultaneous use of pedigree, phenotypic and genomic information for genomic prediction utilizing a single-step approach (ssGBLUP) would allow genotyped cows to be part of the training population and should, in theory, overcome some of the problems of preselection bias associated with the multi-step SNPBLUP. Therefore, this study examines the use of ssGBLUP for genomic prediction of SCC, initially within the Holstein (HOL) breed and then in an across breed setting involving the Ayrshire (AYR), Jersey (JER) and Guernsey (GUE). In addition, it examines the impact of incorporating de-regressed MACE for foreign bulls on the accuracy of genomic prediction.

Materials & methods

The SCC data for the official UK conventional genetic evaluations and MACE from INTERBULL for the August 2021 run and corresponding genotypes for the genomic prediction, were used for these analyses. The summary of the data showing number of cows, records, pedigree and genotypes are in Table 1. SCC was analysed as $\log_e$SCC and the conventional model (AM1) fitted herd-year-season, lactation, age nested within parity, month of calving as fixed effects and random effects of herd-sire interaction, permanent environment and animal. A pedigree of five generations was used in the analysis with a total of 209 UPGs defined by year of birth, breed, country of origin and the four paths of dam of cows and bulls, and sire of bulls and cows. In the ssGBLUP, 79,051 SNPs used were derived by USDA (Al-Khudhair, *et al.*, 2021). Initially, only HOL was analysed (ssGBLUP-HOL1) with the G matrix computed from genotypes of 9,214 and 45,547 UK bulls and cows, with UPG fitted for both A and the pedigree relationship matrix for genotyped animals (A_{22}) (Cesarani, *et al.*, 2021). Thus, the inverse of the H matrix was computed as:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_292, © R. Mrode *et al.* 2022

$$\mathbf{H}^{-1} = \mathbf{A} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & \mathbf{G}^{-1} - \mathbf{A}_{22}^{-1} & -\mathbf{A}_{22}^{-1}Q_2 \\ 0 & -\mathbf{Q}_2'\mathbf{A}_{22}^{-1} & \mathbf{Q}_2'\mathbf{A}_{22}^{-1}\mathbf{Q}_2 \end{bmatrix}$$

Foreign information was included for a total of 31,633 HOL bulls with genotypes and MACE proofs, using two slightly different approaches. For bulls with UK daughters included in their MACE, an adjustment was made to avoid double counting of this domestic information. The procedure described by Guarini *et al.* (2019) was implemented as: $PTA_{adj} = \frac{[(DE_M+k)\times PTA_M]-[(DE_D+k)\times PTA_D]}{(DE_M-DE_D)+k}$ and $Rel_{adj} = \frac{DE_M - DE_D}{(DE_M - DE_D)+k}$; where PTA_M and PTA_D are PTAs from MACE and domestic evaluations respectively;. DE_M and DE_D are corresponding daughter equivalents calculated from their respective reliabilities for PTA_M and PTA_D; and k is a variance ratio computed as $(4\text{-}h^2)/h^2$. The de-regressed PTA_{adj} multiplied by two were used as the response variable in the analysis for these bulls with a weighting of corresponding daughter equivalents (DE) computed from Rel_{adj}. However, for foreign bulls with no domestic information included in MACE, their de-regressed PTAs using a full pedigree and multiplied by two were used in the analysis, weighted by their corresponding DEs computed from MACE reliability. To handle the increased number of genotypes by including foreign information, the inverse of G inverse was computed using the APY approach, with 35,000 random bulls with genotypes used as core animals. The model with foreign information included was termed as ssGBLUP-HOL2.

The ability to predict the future performance of young candidates was used for validation of accuracy of genomic prediction. The validation cows comprised of 282,728 cows with 357,591 SCC records born in 2017 and onwards and their records were set to missing in the validation run. Yield deviations (YD) were computed for validation cows by adjusting their records for all fixed effects in the model. Validation bulls were sires with all their UK daughters born within the validation years for validation cows. The YD of validation cows were further adjusted for half the breeding value of their dams and averaged by sires, to compute estimated daughter yield deviations (DYD) for the validation bulls. The accuracy of predictions was computed as the correlation between (G)EBV and YD or DYD for validation cows or bulls. Regression coefficients of YD or YD on (G)EBV were used to measure the inflation of predictions in validation cows and bulls.

Across breed predictions. The conventional repeatability animal model used for HOL was implemented including other breeds; AYR, JER and GUE and various crossbreeds (AM2). This involved 69,737,471 cows with 17,572,710 SCC records with a pedigree consisting of 9,063,330 animals (Table 1). The same UPG structure was utilized since animals from some of the other breeds were dams of cows in the Holstein evaluation. Similarly, ssGBLUP was implemented for the across breed model (ssGBLUP-ALL1) resulting in the inclusion of an additional 1,583 bulls and 6,402 cows with genotypes from the AYR, JER and GUE in the construction of G_{22}. Moreover, foreign information was included for an additional 10,924 foreign bulls for these breeds with genotypes and MACE proofs as described for the HOL only evaluations. The ssGBLUP with foreign information included was termed ssGBLUP-ALL2. The validation bulls and cows were defined as for the within HOL analysis and comprised of 311,633 cows with 393,492 SCC records born in 2017 and onwards and their records were set to missing in the validation run. Similarly, accuracies and measures of inflation of predictions were computed as described for the within HOL analysis. The heritability of 0.11 was used in all analyses within the HOL breed and in the across breed evaluations. All analyses were carried out using the MiX99 software (Strandén *et al.*, 2017).

Table 1. Summary statistics of number of animals, records and genotypes.

	Evaluations	
	Holstein breed only	Across breed
Cows	6,453,896	6,973,747
Records	16,245,062	17,572,710
Pedigree size	8,420,844	9,063,330
UK bull genotypes	9,214	10,797
Cow genotypes	45,547	51,949
Foreign bull genotypes	31,633	38,130

Results

Accuracies and measures of inflation of predictions. The estimates of correlations between (G) EBVs and DYDs for bulls or YDs for cows in the validation set are shown in Table 2 for HOL from the various models. In the within HOL run, the accuracy of genomic prediction for bulls increased from 0.44 with the AM1 by about 50% to 0.66 with ssGBLUP. However, the inclusion of foreign information increased accuracies by 72% relative to the AM1 to 0.76. The pattern of results for HOL from the across breed evaluations was similar to results from the within breed analysis. In terms of measures of inflation of predictions, the regression coefficients (Table 2) were close to unity apart from the ssGBLUP in the within HOL analysis where there was some under-prediction. The accuracies of genomic prediction were much lower for cows at 0.23 from the AM1 and increased slightly to 0.26 with ssGBLUP and with foreign information included. In general, the regression coefficients were close to unity for cows from all models.

The number of bulls with 50 UK daughters in the validation set for the other breeds were too few to obtain any reliable results. Using only bulls with at least 10 UK daughters resulted in a total of 149 bulls across the three breeds, AYR, JER and GUE in the validation set. The accuracy of predictions using these 149 bulls was 0.43 from AM2 but decreased to 0.42 from ssGBLUP-ALL1 with no foreign information included and further to 0.30 when foreign information was incorporated. The regression coefficients were 1.02 for both AM2, ssGBLUP-ALL1 and lower at 0.84 for ssGBLUP-ALL2. In terms of the accuracies of predictions for cows, the accuracies were in generally similar to those obtained to HOL from the AM2 but ssGBLUP with or without inclusion of foreign information did not result in any increases in accuracies.

Table 2. Estimates of correlations between (G)EBVs and DYDs of bulls and YDs of cows in validations data set and corresponding estimates of regression coefficients of DYDs or YDs on (G)EBVs.[1]

Model	Bulls		Cows	
	Correlation	Regression	Correlation	Regression
AM1	0.44	1.00	0.23	0.95
ssGBLUP-HOL1	0.66	1.20	0.24	1.01
ssGLUP-HOL2	0.76	0.98	0.26	0.99
AM2	0.43	0.98	0.23	0.96
ssGBLUP-ALL1	0.66	1.23	0.24	1.06
ssGBLUP-ALL2	0.77	1.00	0.26	1.00

[1] AM1= Within HOL repeatability animal model; AM2= Across breed repeatability animal model; ssGBLUP-HOL1 and ssGBLUP-HOL2= within HOL ssGBLUP without (1) and with (2) foreign information; ssGBLUP-ALL1 and ssGBLUP-ALL2= Across breed ssGBLUP without (1) and with (2) foreign information.

Genetic trends and correlations among various evaluations. The correlation between (G)EBVs for bulls from the AM1 and ssGBLUP-HOL1 was 0.99, 0.98 between AM1 and ssGBLUP-HOL2 and 0.99 between ssGBLUP-HOL1 and ssGBLUP-HOL2. Corresponding estimates for cow evaluations were all 0.99. The estimates of correlation for bulls and cows for the other breeds in the across breed evaluations followed the same pattern with correlations generally between 0.97 to 0.99. Estimates of genetic trends for HOL from all the models within and across breed evaluations were very similar.

Discussion

Increased accuracy of prediction has been one of the major advantages of genomic prediction and an increase of about 50% in accuracy of predictions for the HOL have been observed with ssGBLUP from the within and across breed evaluations. Cesarani *et al.* (2021) reported similar ranges of increases in reliabilities of bulls implementing ssGBLUP for milk, fat and protein yields in the USA. However, Guarini *et al.* (2019) reported lower increases of about 10 to 19% for milking temperament and speed. However, the largest increase in accuracy for HOL of about 70% resulted in the inclusion of foreign information. Guarini *et al.* (2019) reported similar increases in accuracy of about 90% with inclusion of foreign information for milking temperament and speed. However, the levels and increases in accuracies for cow predictions were low and similar to those reported by Cesarani, *et al.* (2021) for productive traits in USA cows. Similar to the results of Guarini, *et al.* (2019), the inclusion of foreign information generally improved the bias of genomic predictions with regression coefficients being closer to unity. However, there were no improvements in accuracy for both bulls and cows for other breeds in the across breed evaluations with ssGBLUP or inclusion of foreign information. The limited number of bulls with genotypes in the validation set may account for this and this will further be investigated.

However, correlations and estimates of genetic trends showed that evaluations from the various models were consistent.

Abstract

Convolutional neural networks (CNN) are well suited image recognition tools for their ability to recognize latent patterns from images. Here, we investigated whether CNN can be used for genomic prediction. We created genomic images from genotype data and used them to predict phenotypes in mice. This approach was compared with traditional GBLUP and gradient boosting machine (GBM) models. For the two traits analysed, CNN was competitive in terms of predictive performance. The resolution of genomic images impacted model performance where, for this dataset, optimum results were obtained with 100×100 pixels. These first results demonstrate the potential of genomic images for genomic prediction using CNNs and merit investigation on adding layers of information to further increase accuracy of prediction.

Introduction

In recent years, machine learning algorithms have appeared as promising tools for genomic prediction. These algorithms do not require prior assumptions about the underlying genetic architecture of traits, being capable of capturing these patterns from training data (Pérez-Enciso and Zingaretti 2019). For these reasons, machine learning algorithms could yield better predictive performance than traditional linear models like GBLUP. Convolutional Neural Networks (CNN; fully connected layers and convolutional/pooling filters) are algorithms that are widely used in image recognition tasks for their ability to identify latent patterns and features from images (Trevisan *et al.* 2020). Visual representations of genotype data as predictors could help to improve performance of CNN models for genomic prediction of complex phenotypes (Galli *et al.* 2021). The objective of this research was to investigate the predictive performance of CNN models using genomic information transformed into images, benchmarked with a parametric linear method and an alternative machine learning method.

This project is part of EuroFAANG (https://eurofaang.eu), a synergy of five Horizon 2020 projects that share the common goal to discover links between genotype to phenotype in farmed animals and meet global Functional Annotation of ANimal Genomes (FAANG) objectives.

Materials & methods

Diversity outbred (do) mouse dataset. The DO mice data comprising 835 animals were obtained from The Jackson Laboratory (Bar Harbor, ME). The animals originated from 6 non-overlapping generations (4, 5, 7, 8, 9 and 11) in which males and females were represented equally. Based on anticipated differences in genetic architecture of traits, we selected circulating cholesterol at 12 weeks (CHOL) and fat percentage at 19 weeks (FATP, Table 1). Prior to the analyses, phenotypes were pre-corrected for fixed effects of generation, sex, cage, and diet. All animals had genotype data available for 50,122 SNP markers.

Genotype data formats. We transformed genotypes from tabular format into a genomic image using the DeepInsight algorithm (Python implementation, available at http://www.alok-ai-lab.com) proposed by Sharma *et al.* (2019). This algorithm applies a similarity measuring technique, here we used t-SNE, to obtain a 'topology graph' based on the similarity between genomic markers. In this resulting graph,

Table 1. Trait abbreviation, number of records, heritability estimate, and anticipated genetic architecture of circulating cholesterol and fat percentage.

Trait	No. records	Heritability	Genetic architecture
CHOL	832	0.29	Evidence of epistasis
FATP	834	0.37	Highly polygenic

each point represents a marker. If two or more markers are strongly related due to linkage disequilibrium patterns, these will be placed at similar coordinates. After that, this graph is transformed into an image, one uniquely per individual, and the genomic marker information, e.g. 0, 1, or 2, is mapped to its corresponding pixel position (Figure 1). At this stage, each pixel in the genomic image may contain information from one or more SNP markers (in case these were collapsed due to high similarity) and colours for each pixel indicate A1A1 (light grey, 0), A1A2 (medium grey, 1) and A2A2 (dark grey, 2) genotypes, or no information (black). We compared three different image resolutions: 50×50 pixels (CNN50), 100×100 pixels (CNN100 and 150×150 pixels (CNN150) (Figure 1).

Genomic best linear unbiased prediction (GBLUP). For its well stablished and wide use in routine genomic prediction, GBLUP was used as a benchmark for comparisons. The implementation of this model was performed using the BGLR package (Perez and de los Campos, 2014).

Gradient boosting machine (GBM). The GBM model is an ensemble learning technique that combines gradient-based optimization and boosting techniques (Friedman, 2001). It applies an iterative process of assembling 'weak learners' and therefore, can be expressed as a linear combination of multiple models. The algorithm is also able to prioritize informative predictors while ignoring uninformative ones. Optimal hyperparameters were defined using a grid search (described in Perez *et al.* 2021) on an inner validation comprised of a random sample of 20% observations from the original training set. Results reported come from the best performing model for each trait analysed. The GBM model was implemented using the h2o.ai R package (Click *et al.* 2016).

Convolutional neural networks (CNN). The input layer for the CNNs consisted of the pixel matrix of the genomic image for an individual. A basic network architecture was proposed (described below) and kept the same for both traits. At trait level, a simple hyperparameter search was performed on an inner validation set (20% of the training set) on one replicate, and the best combination of hyperparameters

Figure 1. Illustration of genomic images for a single individual using resolutions of 50×50 (*left*), 100×100 (*middle*) and 150×150 (*right*) pixels, reshaped to a common format for visual comparison.

(lowest mean squared error) from this one search was used for all other tested resolutions in 10 replicates. For the network architecture chosen, the input data was first passed through three convolutional layers, followed by a maximum pooling layer, a dropout layer, a flattening layer, a dense (i.e. fully connected) layer and finally to the output layer containing one node with the predicted trait value. We used the rectified linear activation unit (ReLU) as the activation function in the hidden layers. To reduce the time and memory requirements, models were trained using a fixed batch size (32) and run for a maximum of 400 epochs. The CNN were implemented in Python 3.6 using Tensorflow 2.0 and Keras libraries (Gulli and Pal, 2017).

Predictive performance. Predictive performance was determined with a forward-prediction validation scheme, in which models were trained using data from older individuals (generations 4,5,7,8 and 9; n=643) and prediction was carried out for younger animals (generation 11; n=192). The predictive performance was evaluated by the correlation between model solutions and pre-corrected phenotypes on validation animals (hereafter termed accuracy). For GBM and CNN, for each trait results were reported for the models that obtained best results in the model-specific grid search analysis previously mentioned.

Results

Predictive accuracies varied from 0.221 (CNN50) to 0.301 (GBM) for CHOL and from 0.285 (CNN50) to 0.352 (GBLUP) for FATP (Figure 2). For the root mean-squared error (RMSE), results varied from 0.78 (GBM) to 0.84 (CNN50) for CHOL and from 0.71 (GBLUP) to 0.76 (CNN50) for FATP. The resolution of the genomic image had an impact on both predictive accuracy and error, with CNN100 showing the best results for both traits. The CNN50 yielded poorest results, while CNN150 performed slightly worse than CNN100.

Discussion

In the present study our current CNN model was slightly outperformed by either GBM or GBLUP for CHOL and FATP, respectively (Figure 2). Nevertheless, our results show the potential of using genomic images for phenotype prediction using CNN models as prediction performance for CNN was better than GBLUP for CHOL and better than GBM for FATP. It must be noted here that for time/computational constraints, the network architecture was kept simple and the hyperparameter tuning for the CNN model was limited to a simple search. A more detailed procedure could help to improve performance of CNN

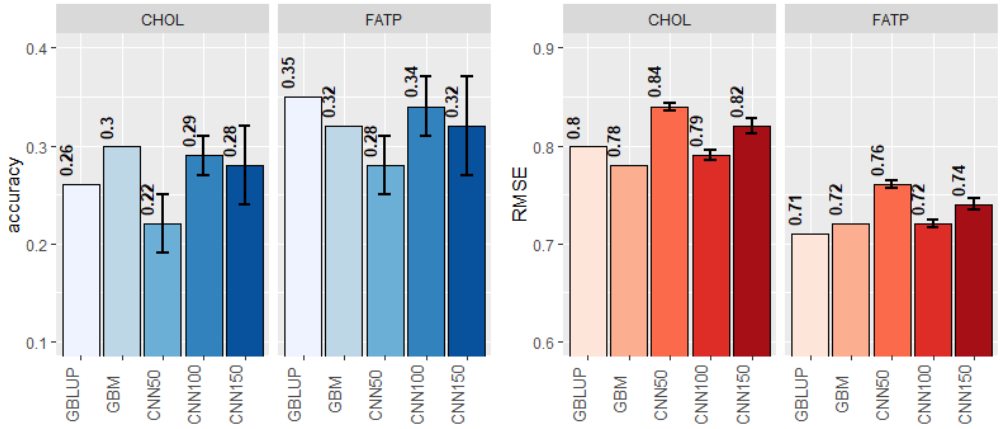

Figure 2. Predictive accuracy & RMSE for GBLUP, GBM and CNN models on genomic images of 50×50 (CNN50), 100×100 (CNN100) and 150×150 (CNN150) pixels.

models. In a case study in maize hybrids, Galli *et al.* (2021) observed superior predictive performance for CNN (using genomic images) over GBLUP (relationship matrix). A common limitation in both studies was the size of datasets (n=904 in Galli *et al.* (2021); n=835 in the present study). Future studies using larger datasets are required to assess performance of genomic prediction using images on routine of breeding programs or other commercial applications.

The resolution of genomic images had major impact on predictive performance. In the present study, the resolution of 100×100 pixels (CNN100) yielded best results and weakening results were found for CNN50 and CNN150. This indicates that there is an optimum image resolution, most likely dependent on the number of SNP genotypes available for prediction and the size and structure of the population studied. For a fixed number of variants, lower resolutions will merge too much information making it harder for the model to capture some patterns in data. Higher resolutions on the other hand can accommodate detailed and complex patterns but will require much bigger training sets to achieve a good predictive performance. These encouraging results and the flexibility of CNN models deserve further investigation to include additional layers of information, such as genome annotations, that can increase accuracy of prediction.

Abstract

Animals with high production potential and simultaneously high resilience to environmental challenges are vital for sustainable livestock production. A simulation study was carried out to: (1) evaluate the influence of genomic data, statistical models, and phenotyping strategies on prediction accuracies for resilience and production potential; and (2) assess the impact of different selection strategies on genetic improvement in these traits. Prediction accuracies were found to be compromised when families were clustered in similar environments or when the environmental challenge level was unknown. Selection on individuals' performance alone could simultaneously improve resilience if performance records of individuals were obtained across a wide range of environments, whereas a narrow range may decrease resilience. Simultaneous genetic improvement in resilience and production potential strongly benefits from the use of genomic evaluations, reaction norm models, and phenotyping in a wide range of environments.

Introduction

Robust animals are highly resilient (i.e. remain productive in challenging conditions) and have a high production potential (Knap and Doeschl-Wilson, 2020). To genetically improve robustness in animals, accurate estimates of breeding values for production potential and resilience are needed. These can be estimated using reaction norm models based on performance records from different environmental conditions. For linear reaction-norms, the estimated breeding value (EBV) for the intercept represents the production potential, and the inverse of the slope represents resilience (Knap and Su, 2008). One of the impediments in improving robustness using such models is that the environmental challenge level is often unknown and that proxies need to be used instead (Knap and Doeschl-Wilson, 2020).

The objectives of this study were: firstly, to evaluate the influence of genomic data, statistical models, and phenotyping strategies on the accuracy of genetic prediction for resilience and production potential. Secondly, to assess the impact of different selection strategies on genetic improvement in these traits. The data are simulated assuming a sheep population, but the results can be generalised to other species.

Materials & methods

Simulation of data. The phenotypes were simulated assuming a linear reaction norm model where the performance is affected by two components: one related to the performance under ideal rearing condition (i.e. no challenge) and another influenced by the ability of the animal to withstand a challenge. Here, these components will be denoted as the production potential and resilience, and both are assumed to be under genetic and environmental control.

Hence, the performance (y) of individual j in environment k with a challenge level X_k is:

$$y_{j,k} = (m_0 + a_{0j} + e_{0j,k}) + X_k\,(m_R + a_{Rj} + e_{Rj,k}) \quad (1)$$

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_294, © M. Ghaderi-Zefreh *et al.* 2022

where m_0 is the mean performance of the population in the absence of any challenge and, m_R is the average reduction of performance due to the challenge level X_k; a_{0j} and a_{Rj} are the breeding values of individual j for production potential and resilience; $e_{0j,k}$ and $e_{Rj,k}$ are the respective random environmental deviations for each trait. Both traits were assumed with a heritability of 0.1, phenotypic variance of 1.0, zero environmental correlation and an antagonistic genetic correlation of -0.5. Values for m_0 and m_R were arbitrary chosen to be 10 and -3, respectively and X values ranged between 0 and 2 (i.e. average performance in best and worst environment differ by six phenotypic deviation).

The true breeding values were sampled by simulating the genome of each individual in the population (see info about population structure below). To assume a sheep species, the genome was distributed on 26 chromosomes, each with 1,500 segregating biallelic loci in linkage disequilibrium (500 QTL affecting both traits, and 1000 in the SNP panel used to calculate the genomic relationship matrix). Linkage disequilibrium was simulated by sampling the base animals using a mutation-drift algorithm (Meuwissen *et al.*, 2001). The offspring' genome was simulated by gene dropping haplotypes following Mendelian inheritance rules, given their parents' genotypes. The environmental deviations (e_0 and e_R) for each individual and environment k were sampled from a normal distribution.

The level of the environmental challenge that an individual was exposed to (X) was simulated by assuming ten farms, each farm being a subset (10%) of the entire range of challenge levels. Once individuals were allocated to a farm, their specific challenge level were sampled within the range of that farm (i.e. all individuals in the same farm have different challenge level), and their phenotype were calculated from Equation 1.

Genetic evaluation. Best linear unbiased predictor (BLUP) or genomic BLUP (GBLUP) (Strandén and Garrick, 2009) assuming the random regression model as in Equation 1 was used to obtain genomic estimated breeding values (GEBV) for both production potential and resilience. If the level of the environmental challenge was assumed to be unknown (i.e. not measured), a reaction norm approach (Knap and Su, 2008) was implemented where the unknown challenge levels are first estimated using the average farm effects. The farm effect is estimated with the same data using a simpler model ignoring the resilience component. The farm effect estimates are rescaled, and all individuals with performance within a farm are assumed to have the same challenge level, equal to the scaled value of the effect of that farm.

Scenarios compared. To assess the factors affecting the GEBV accuracy, a population of half sib families was assumed, where 100 grandsires were mated to 1,100 granddams to produce 100 sires and 1000 dams, which in turn, were mated to produce 1000 offspring. Only the offspring generation were assumed to have performance records. We considered three different scenarios how families were distributed across environmental conditions: random, clustered, and assortative. In the random scenario, offspring of a sire are randomly allocated to different farms. In the clustered scenario, all offspring of a sire are allocated to the same farm. In the assortative scenario, a correlation between genetic merit and environment challenge was assumed, so that offspring of sires with the highest EBV were allocated to farms with the lowest challenge levels. The effect of knowing or not the challenge level was also assessed.

To assess the response to selection for resilience, we assumed a population of 8,100 individuals (2,700 males and 5,400 females) per generation, where the best 270 males and 2,700 females are selected to produce the next generation. Individuals were randomly distributed across the entire range of environments. The genetic evaluation was done via GBLUP implementing the reaction norm model (where the estimated farm effects were used as challenge levels, see genetic evaluation section above). All candidates were genotyped and had one phenotypic record. Thereafter, a selection index was defined as $I = (1 - \alpha) \times \hat{a}_0 + \alpha \times \hat{a}_R$, where

α ($0 \leq \alpha \leq 1$) is the weight given to resilience. The selection scheme was done over 10 discrete generations. We also considered scenarios where performance records were evaluated in a narrow range of environment (i.e. X values between 0 and 1). The results were compared with the case where candidates were evaluated using a conventional genetic model that does not account for the term influenced by the level of environmental challenge.

Results

Impact of genomic information, unknown environmental challenge level and distribution of families across environments on prediction accuracies. As expected, genetic predictions for production potential and resilience were significantly more accurate with GBLUP than with BLUP (70-163 and 79-114%, respectively). Figure 1 shows the effect of unknown challenge level and the distribution of families on the prediction accuracies for production potential and resilience. Both traits have reduced accuracy when the environmental challenge level is unknown. In general, the accuracy of GEBVs for production potential are higher than that of GEBVs for resilience but also more sensitive to the distribution of individuals across environmental conditions. When the individuals were allocated at random across the whole range of available environmental conditions, the accuracy of GEBVs was highest (between 6-75% higher for production potential and 4-17% for resilience).

Response to selection. Figure 2 shows the genetic gain for production potential and resilience after ten generations of selection using different strategies and when the data are obtained in a wide or a narrow range of environmental challenge levels. When the selection index has all the weight on one component only (i.e. α=0 or α=1), a genetic loss for the other component was observed due to the assumed negative genetic correlation. When the information comes from a wide range of environmental conditions, selection based on the conventional model (which ignores the resilience component) yielded genetic gain for both traits, despite their negative genetic correlation (solid circles in Figure 2). However, when the range of environmental conditions were narrowed down, selection ignoring resilience yielded genetic gain for production potential, but resilience deteriorated. Using a selection index based on the GEBVs of the reaction norm analysis, both traits can be improved regardless of the range of environmental conditions where the animals were measured.

The trend of the selection response when varying α depended on the range of environments where the animals were phenotyped. Phenotypes obtained from a narrower range of environmental conditions generally led to higher gain for production potential (except for large index weight on resilience, α>0.84), but reduced genetic gain for resilience. Genetic gain in resilience could only be obtained when the index weight α was sufficiently large (α>0.12 and α>0.42 corresponding to the wide and narrow environmental range, respectively).

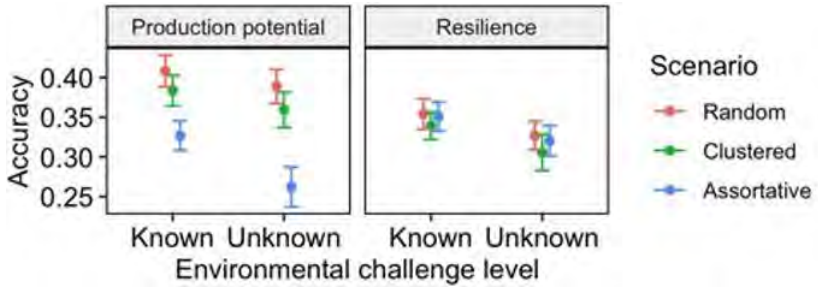

Figure 1. Effect of unknown environmental challenge level and distribution of families across environments on the prediction accuracy of production potential and resilience.

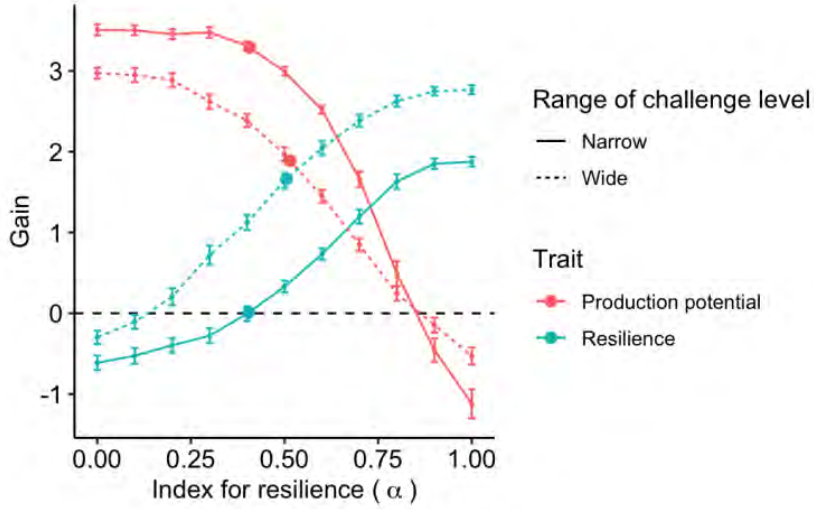

Figure 2. Genetic gain for production potential and resilience after ten generations of selection with different index weight α for resilience (error-bars indicate 95% C.I.). The results for the conventional model, which ignores the resilience component, are shown with solid circles.

Discussion and conclusion

The study showed that genomic prediction is beneficial to improve genetic prediction for production potential and resilience. The GEBV accuracies for both traits are strongly affected by the distribution of phenotyped individuals across environments and knowledge of the challenge level. Whilst the prediction accuracies for resilience was generally lower than for production potential, they were less sensitive to the distribution of phenotypes. Our results on the response to selection show the potential benefits for improving resilience using a random regression/reaction norm model in the evaluation. Conventional genetic evaluations ignoring resilience can improve both resilience and production potential if candidates are evaluated under a wide range of environmental conditions, even when their genetic correlation is negative. However, this is not the case when the performance data come from a narrow range of environmental conditions. This problem can be avoided with the reaction norm model. Hence, reaction norm model and selection index with appropriate weights have great potential for simultaneous improvement of both production potential and resilience.

Methods and tools: genomic prediction

295. Benchmark SNPs selection strategies to achieve optimum prediction in small population

E. Mancin*, C. Sartori, B. Tuliozi, G.G. Proto, R. Mantovani

University of Padova, Department of Agronomy, Food, Natural resources, Animals and Environment – DAFNAE, Viale dell'Universita' 16, 35020 Legnaro (PD), Italy; enrico.mancin@studenti.unipd.it

Abstract

In recent decades, genomic selection has become a routine practice for genetic evaluations of most livestock species and breeds. However, its use is still limited in small local populations. The main reasons are the lower interest to invest in these breeds, and the poor accuracy of their genomic predictions due to the low number of animals. Bayesian variable selection regression models (i.e. Bayes B/C) appear to improve the accuracy of genomic prediction from small populations, but their ability to account for selection remains unclear, especially when using time-series cross validations. In the present work, we evaluated in terms of accuracy and bias the impact of constructing the genomic matrix using only a subset of informative SNPs. Analysis was performed on Rendena cattle, a small local cattle population of North Italy.

Introduction

One of the major challenges of genomic best linear unbiased predictor (GBLUP) is the breeding values estimation in small populations, such as those of local breeds. Indeed, different methods have been exploited to feature single nucleotide polymorphisms (SNPs) selection or assume heterogeneous SNP variance (Gianola *et al.*, 2009; Habier *et al.,* 2013). However, properties linked to the possible bias of SNPs selection were never considered.

For this reason, many studies have 'relaxed' the assumptions of the G matrix by trying to assign different weights to each SNP. However, there are two main drawbacks in this approach: (1) although these methods have greater accuracy, they result in greater dispersion and bias; (2) in a single step GBLUP (ssGBLUP) framework, an excessive SNPs shrinkage can lead to an incompatibility between the genomic and pedigree matrices.

In the present study, we tried an alternative strategy which consists of constructing the G matrix by removing the non-informative SNPs. Indeed, Fragomeni *et al.* (2017) demonstrated that accuracy of GBLUP can substantially improve by removing SNPs close to quantitative trait loci (QTLs), especially in small populations. According to Fragomeni *et al.,* this is due to the shrink effect of those SNPs on QTLs. Since position of QTLs are unknown on real populations, different variable selection approaches to select SNPs for the construction of the G matrix. Then prediction of ssGBLUP using these sets of informative SNPs was benchmarked. Analysis was conducted on Rendena breed. Rendena is small local cattle (~4,000 cows) reared in the North-Eastern Italian Alps and in the adjacent plains. The breed shows appreciable levels of fertility and longevity, and the ability to adapt to marginal areas and graze during summer in high Alpine pastures. Rendena is mainly bred for milk improvement and meat (35%).

Materials & methods

Study subject. We used the performance test database of Rendena cattle, and the target trait was *in vivo* dressing percentage. The study considered 1,691 young bulls with only phenotypic information, 1,739 animals with only genotypic information, and 687 animals with both phenotypic and genotypic information. After quality control (MAF<0.05, LD prune, SNP missing rate <0.1) 85,331 SNPs were used for the analysis.

Statistical analysis. All genetic predictions were computed using BLUPF90 family program (Aguilar *et al.*, 2018). In the present work we compared 'classical' models (pedigree BLUP, Single step Genomic BLUP and Weighted ssGBLUP) with ssGBLUP using only a set selected SNP. Three categories of SNPs selection were performed: randomly even spaced SNPs, based on allele substitution effect, and using variable selection algorithm

Pedigree BLUP (PBLUP). The equation for PBLUP is written as follows:

$$\begin{bmatrix} X'X & X'Z \\ X'X & Z'Z+A^{-1}\frac{\sigma_e^2}{\sigma_a^2} \end{bmatrix} \begin{bmatrix} \hat{\mu} \\ \hat{a} \end{bmatrix} = \begin{bmatrix} X'y \\ Z'y \end{bmatrix} \quad (1)$$

Where y is the vector of phenotypes, X represents the incidence matrix for systematic effects, b is the vector of fixed effects of contemporary group (142 levels) and the parity order of the mother (four classes). Z is the incidence matrix of random genetic additive effects, *a* represents the vector of these effects (EBVs) and e is the random residual. Normal assumption was assumed for random effect. In the Pedigree BLUP model, covariances of random genetic effect were sampled from a distribution $N(0, A\sigma_a^2)$, where A is the Identical by Descendent (IBD) matrix. Variance components were estimated under PBLUP tracing back all generation in the pedigree.

Single step genomic BLUP (ssGBLUP). The equation for ssGBLUP is equal to (1) but A is substituted by H (Auguilar 2010).

$$H^{-1} = A^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & G^{-1} - A_{22}^{-1} \end{bmatrix} \quad (2)$$

where A^{-1} and A_{22}^{-1} represent the inverses of the IBD matrix for all individuals and only genotyped animals, respectively. G is the genomic relationship matrix (VanRaden, 2008)

$$G = \frac{MM'}{2\sum p_i(1-p_i)} \quad (3)$$

where M is a matrix of SNP content centered by twice the current allele frequencies, and p_i is the allele frequency for the i^{th} SNP.

ssGBLUP with selected SNPs. Then ssGBLUP was performed by constructing G using only a set of SNPs. Different selection methods for selecting SNPs were used, as following:

Selection of top SNPs. In this strategy the best 500, 1000, 30,000 SNPs were based on their allele substitution, calculated as (Gualdrón Duarte *et al.,* 2014):

$$\hat{g} = \frac{1}{2\sum pq} M'G^{-1}\hat{a}_{22} \quad (4)$$

Selection of even spaced SNPs. In this strategy 500, 1000 and 30,000 even spaced SNPs were randomly selected.

Selected by Feature selection algorithm.

1. Lasso Regression (LASSO), further information see Tibshirani, 1996, compute with R package (https://cran.r-project.org/web/packages/glmnet/index.html).
2. Recursive Feature elimination using Support vector machine (RFESVM), hand wrote R code following what was reported in Sanz *et al.,* 2018.

3. Extreme Gradient Boost (XGBOOST), further information see Cheng *et al.* 2016 and compute with h20 R environment (https://cran.r-project.org/web/packages/h2o/index.html).
4. Spike-and-Slab LASSO (SSLASSO); for information see Ročková and George, 2018.

The hyperparameter of those models were estimated via cross validation by using young animals as test population (genotyped animals born after 1-1-2015), and mean squared error was used as the parameter to select the best set of hyper parameters

Weighted ssGBLUP (WssGBLUP). In addition, WssGBLUP was also considered, and nonlinear A SNP weight was also performed. For simplicity, only two WssGBLUP predictions were reported: (1) using the best iteration CT=1.105; and (2) best iteration of CT=1.250; all SNPs were also considered in this model. For further details of this strategy see *Fragomeni et al.* (2019).

Cross validations. LR cross validation has been used (Legarra and Reverter, 2018). Two validation cohorts have been considered (young bulls born after 1-1-2013 and young bulls born after 1-1-2016).

Results

Bar plot of Figure 1 reported accuracy measured and dispersion of prediction models. All genomic models had better accuracy than PBLUP. Slight increase of accuracy was observed for nonlinear models with CT=1.105, with highest increase being CT=1.250. Interestingly, no substantial differences were observed for models that used random selection of SNPs. On the other hand, a substantial increase of accuracy of prediction was observed for the SNPs selected based on alleles substitution effects, especially when number of SNPs was low. However, the main goal was to observe the impact that the feature selection algorithm had on ssGBLUP. On these topics the impact of XGBOOST appeared to be marginal for both accuracy and dispersion; lasso regression presented similar performance, although a slight increment in accuracy was observed. RFESVM and SSLASSO presented better accuracy values.

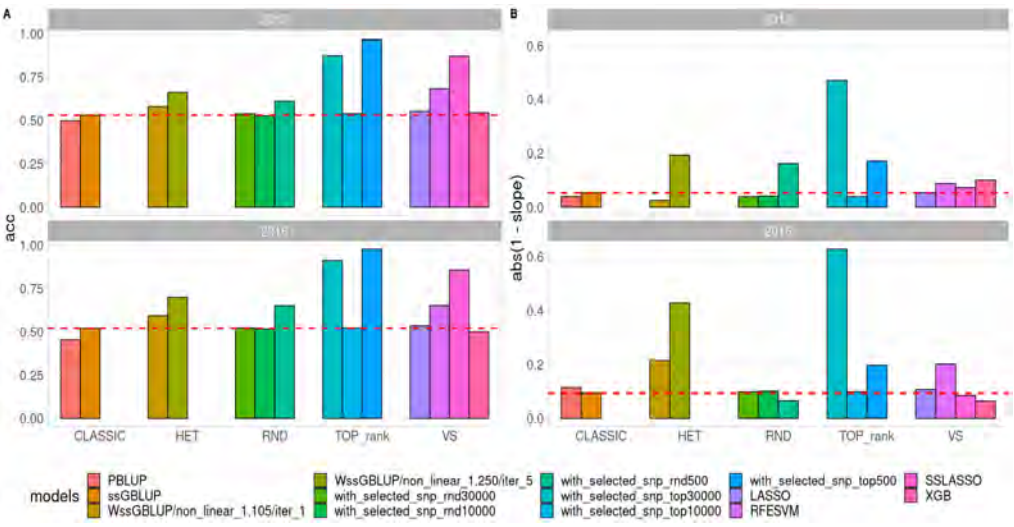

Figure 1. Accuracy (A) and dispersion (B) of prediction using the two-validation datasets from 2013 and 2015.

Discussion

We demonstrated that selection of SNPs based on allele substitution effect (Selection of top SNPs) or WssGBLUP models were not a promising strategy since the increase of accuracy of these models relates to an increase of dispersion. On the other hand, selection of random even spaced SNPs did not affect accuracy and dispersion. However, the variable selection models, especially SSLASSO or LASSO can be considered the best for this trade-off since they increase accuracy of prediction without affecting the dispersion. For that reason, we demonstrated that using ad-hoc algorithms for SNPs selection can be a suitable strategy for small populations. From these studies SSLASSO appears as a better strategy for selecting the most informative SNPs. However, there are still some concerns about: (1) its impact on SNPs selection over the time; (2) its efficacy in multi-traits models.

296. Genetic correlations among longevity, fertility, udder health and type traits including or not genomic information

R. Rostellato*, L.-H. Maugan and V. Ducrocq

Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; roberta.rostellato@inrae.fr

Abstract

The aim of the study was to estimate genetic correlations among functional longevity, conception rate of heifers and of lactating cows, somatic cell score, clinical mastitis, udder depth and udder balance in Montbéliarde breed. Bivariate random regression sire models including a pedigree or a genomic relationship matrix were used to compute (co)variance components. Genetic correlations obtained including genomic information were consistent with those estimated using the pedigree relationship matrix. Conception rate, somatic cell score, clinical mastitis and udder depth showed moderate to high genetic correlations with functional longevity, suggesting that they can be good indirect predictors of the length of productive life when included in a combined genomic evaluation. In addition, the large genetic correlations among the two udder health traits and udder depth indicate that they can improve the prediction of the other traits in a multi-trait single-step model.

Introduction

Functional longevity (FL) is defined as the ability of a cow to avoid being culled for other reasons (e.g. illness or infertility) than low milk production (Ducrocq *et al.*, 1988). Dairy cow's longevity can be expressed as the length of productive life, that is the time between the date of the first calving and the culling or death date. Similarly to other functional traits, FL is increasingly considered in breeding programs because of growing concerns about animal welfare. As reported in Rostellato *et al.* (2021), it is affected by factors that are known to reflect resilience, such as fertility problems and diseases, suggesting that FL can be used as an indicator of long-term resilience.

In French dairy cattle, FL is analysed using a Weibull proportional hazard model. The heritability estimated for the trait using such model is small and accuracy of estimated breeding values (EBVs) of young bulls is low given that the majority of their daughters are censored (Ducrocq and Sölkner, 1998). To overcome those drawbacks and to include EBVs for FL in total merit index, a combined polygenic evaluation was developed (Ducrocq *et al.*, 2001). This methodology consists in an approximate multi-trait animal model, where several genetically correlated traits are included and used as predictors of the other traits. In addition to FL, the traits considered are female fertility, udder health and type traits (GenEval, 2021).

Variance and covariance components used in the current combined polygenic evaluation have been estimated ignoring genomic information. Hence, the objective of the present study was to estimate genetic correlations (r_g) among FL, reproductive, udder health and udder type traits using a pedigree (A) relationship matrix or a genomic (G) relationship matrix.

Materials & methods

Data. The data were extracted from the French bovine national database. The dataset included 1,308,066 Montbéliarde cows, born between 2000 and 2018, from 2,345 sires with a minimum of 30 daughters. The investigated traits were FL, conception rate of heifers (CR_h) and of lactating dairy cows (CR_c), somatic cell score (SCS), clinical mastitis (CM), udder depth (UDE), and udder balance (UDB).

DOI: 10.3920/978-90-8686-940-4_296, © R. Rostellato *et al.* 2022

Sires of cows were genotyped using the BovineSNP50 BeadChip (Illumina Inc., San Diego, CA). Markers exhibiting call rate <0.9 or minor allele frequency <5% and monomorphic single nucleotide polymorphisms (SNPs) were discarded. After quality control, 37,133 SNPs remained.

The sire's pedigree was traced back for 3 generations and it included 5,946 animals.

Estimation of genetic correlations. The investigated traits are described by very different statistical models (e.g. FL is analysed using a survival model). It makes the use of a multiple trait animal model not feasible to compute r_g among traits. Hence, pre-adjusted performances (i.e. phenotypes corrected for all non-genetic effects) adjusted for the dam's EBV and their associated weight were computed for each cow and each of the investigated traits by means of an accurate model as described in GenEval (2021). Then, these corrected records were used as pseudo-phenotypes in a simple and unique model for all traits, whatever the complexity of the original univariate model of analysis, as proposed by Ducrocq *et al.* (2001).

Variance and covariance components were estimated using bivariate random regression sire models. To take into account heterogeneous residual variance for each pre-adjusted performance due to the different amounts of information (weight), the statistical model was as follows:

$$y^{\#}_{i,m} = \upsilon_{i,m} y^{*}_{i,m} = \upsilon_{i,m} \times by_m + \upsilon_{i,m} \times a_{i,m} + \varepsilon_{i,m} \quad (1)$$

where $\upsilon_{i,m}$ is the square root of weight for the trait i and animal m, $y^{*}_{i,m}$ is the pre-adjusted performance corrected for the dam's EBV of trait i and animal m, by_m is the birth year of cow m, $a_{i,m}$ is the additive genetic value of animal m for trait i, and $\varepsilon_{i,m}$ is a residual. The fixed effect of birth year is to take into account changes in genetic due to selection on correlated traits.

Two distinct analyses were carried out in order to estimate (co)variance components using A matrix or G matrix, respectively.

Variance and covariance components were estimated using the average information REML algorithm implemented in AIREMLF90 program (Misztal *et al.*, 2014).

Results

Genetic correlations among the investigated traits including or not genomic information are presented in Table 1.

Comparison of estimates including or not genomic information. Genetic correlations estimated using the A matrix were consistent to those estimated with G matrix. The inclusion of genomic information gave higher r_g among FL, SCS and CM, as well as between the two fertility traits. Only r_g estimated using G matrix are presented and discussed hereinafter.

Genetic correlations between FL and the other investigated traits. Genetic correlations between FL and the two fertility traits were favourable. Conception rate of heifers exhibited a lower r_g compared to CR_c. High and favourable (i.e. lower culling risk when lower SCS or CM) r_g were found between FL and the two udder health traits. Udder depth and UDB exhibited a moderate and favourable r_g with FL (i.e. lower culling risk when shallow and/or balanced udder).

Genetic correlations among fertility, udder health, and udder type traits. Genetic correlation between CR_h and CR_c was moderately positive. Conception rate of heifers did not show significant genetic relationships with udder health and udder type traits. In contrast, conception rate of lactating cows exhibited moderate and favourable r_g with SCS, CM and UDE (higher conception rate when low SCS or CM or UDE). A very high and positive r_g was found between the two udder health traits. Moreover, SCS and CM were positively correlated with UDE. A negative and moderate r_g was estimated between the two udder type traits.

Discussion

Comparison of estimates including or not genomic information. The increase of the magnitude of r_g for FL, fertility and udder health traits when genomic information was taken into account was related to higher genetic covariances with respect to the estimates obtained using A matrix (data not shown). Similar results were also found by Gordo *et al.* (2016).

Genetic correlations between FL and the other investigated traits. In our study, we found that FL is genetically correlated with fertility, udder health, and udder type traits, suggesting that they are good indirect predictors of the length of productive life.

The favourable genetic relationships between FL and conception rate indicates that selection for a better fertility can prolong the length of productive life of dairy cows. In addition, it confirms the major importance of reproductive problems in culling-decision making (Olechnowicz *et al.*, 2016). Functional longevity exhibited a quite large relationship with SCS and CM. It suggests that the risk of being culled increased when the cow is more prone to develop sub-clinical or clinical mastitis. Hence, selective breeding for a better udder health improves the length of productive life and animal welfare. The r_g between FL and UDE indicates that a deep udder is associated with poor longevity, as reported in Larroque and Ducrocq (2001). The favourable genetic relationship between FL and UDB suggests that cows with good udder balance have a lower risk to be culled with respect to animals with poor UDB. It is in agreement with the study of Rostellato *et al.* (2021).

Table 1. Genetic correlations among the investigated traits using a pedigree relationship matrix (above diagonal) or a genomic relationship matrix (below diagonal).[1,2]

	FL	CR_h	CR_c	SCS	CM	UDE	UDB
FL	-	-0.21 (0.03)	-0.42 (0.03)	0.45 (0.02)	0.47 (0.03)	0.44 (0.02)	-0.29 (0.03)
CR_h	-0.20 (0.04)	-	0.34 (0.04)	-0.08 (0.03)	-0.02 (0.05)	-0.02 (0.03)	-0.1 (0.03)
CR_c	-0.43 (0.03)	0.44 (0.04)	-	-0.23 (0.03)	-0.23 (0.04)	-0.24 (0.03)	0.04 (0.03)
SCS	0.50 (0.02)	-0.08 (0.04)	-0.28 (0.03)	-	0.71 (0.02)	0.33 (0.02)	-0.11 (0.02)
CM	0.53 (0.04)	-0.04 (0.05)	-0.26 (0.05)	0.82 (0.02)	-	0.41 (0.03)	-0.08 (0.02)
UDE	0.42 (0.03)	0.08 (0.04)	-0.26 (0.03)	0.33 (0.02)	0.46 (0.04)	-	-0.39 (0.02)
UDB	-0.29 (0.03)	0.06 (0.04)	-0.05 (0.04)	-0.11 (0.03)	-0.09 (0.04)	-0.36 (0.02)	-

[1] FL : functional longevity (low risk to be culled → high risk to be culled), CR_h : conception rate of heifers (poor conception rate → good conception rate), CR_c : conception rate of lactating dairy cows (poor conception rate → good conception rate), SCS : somatic cell score (low somatic cell score → high somatic cell score), CM : clinical mastitis (few clinical mastitis events → several clinical mastitis events), UDE : udder depth (shallow udder → deep udder), UDB : udder balance (poor udder balance → good udder balance).

[2] Sample standard deviation within parentheses.

Genetic correlations among fertility, udder health, and udder type traits. Conception rate of heifers did not show a significant r_g with the investigated traits, except with CR_c. However, its inclusion in a multi-trait genomic evaluation can improve the prediction of conception rate in multiparous cows. A strong positive genetic relationship between the two udder health traits is reported in many other studies (e.g. Rupp and Boichard, 1999; Govignon-Gion *et al.*, 2016), confirming that SCS can be used as an indicator of CM. In addition, the positive r_g with UDE indicates that deep udders are associated with an increase of the number mastitis events and that this type trait can be used as a predictor of mastitis resistance.

Conclusions

Genetic correlations among functional longevity, conception rate, udder health and udder type traits estimated including genomic information were consistent with those obtained using a pedigree relationship matrix. The analysis presented in this study will be extended to other breeds and the results will be used in the development of a combined single-step evaluation in French dairy cattle.

297. Alternative SNP weighting for genomic prediction methods in the presence of causative variants

B.F. Santana[1*], M. Riser[1] and B. Fragomeni[1,2]

[1]University of Connecticut, 17 Manter Rd, 06269, Storrs, USA; [2]Institute for System Genomics, 67 North Eagleville Road, 06269-3003 Storrs, CT 06269-3003; USA; bruna.santana@uconn.edu

Abstract

Commercial implementations of genomic selection usually assume that SNP markers distributed across the genome explain the same proportion of the additive genetic variance, which may be erroneous. Furthermore, the accuracy of selection may be increased by including selected variants from sequence data. The presence of selected variants and alternative SNP weights may enhance accuracy, depending on the method applied to account for this information. This work aimed to study the impacts of weights and inclusions of causative variants in different methods using simulated data and alternative SNP weighting for different genomic selection methods. SNP weights were computed with the termed nonlinear A and quadratic weighting approaches. Accuracies increased with the inclusion of causal variants in the tested scenarios. Gains due to SNP weighting were more prominent in less polygenic scenarios and the nonlinear A approach was superior to the quadratics, however results from nonlinear A were dependent of the equation parameters.

Introduction

The introduction of genomic selection in dairy cattle breeding has led to expressive improvement in progeny transmitting ability's accuracy, especially in young bulls (Mc Hugh *et al.*, 2011). On the other hand, the accuracy of selection may still be increased with the adoption of technologies such as the inclusion of sequence variants (VanRaden *et al.*, 2017). Preceding work in simulated data has shown that accounting for causal variants might improve accuracy to its maximum (>0.99) (Fragomeni *et al.*, 2017). However, researchers were not able to reproduce those findings with real data, and the overall gains in accuracy from including selected variants are modest. Furthermore, depending on the genomic selection method used, the presence of causative variants might bring different results.

Most commercial applications of genomic selection rely on the single-step GBLUP (ssGBLUP) method (Aguilar *et al.*, 2010, Christensen and Lund, 2010). This approach uses phenotypes, genotypes, and pedigrees and allows the inclusion of non-genotyped individuals. Alternative to ssGBLUP, there are methods that rely on the calculation of pseudo-phenotypes and allow only the inclusion of genotyped animals, following the linear predictions with a genomic relationship matrix, proposed by VanRaden (2008), which will be hereby termed GBLUP. The default implementation of ssGBLUP assumes that all SNPs follow the same distribution, which may not be biologically accurate. Modifications on the genomic relationship matrix can be made to assume unequal SNP variances in both GBLUP and ssGBLUP. However, the nuances of weighting strategies are not fully understood and vary with trait, population, and method. For instance, Fragomeni *et al.* (2019) found that weights and causative variants increased accuracy in a GBLUP approach with homogeneous residual, but not with ssGBLUP.

The objective of the current study is to evaluate the impact of alternative SNP weighting in the accuracy of a multi-step method (GBLUP) and ssGBLUP using regular SNP, causal variants, and the combination of both in a single panel. Finally, the effects of weights in different genetic architectures were tested by simulating traits with different numbers of causative quantitative trait nucleotides (QTN).

Materials & methods

The data used were simulated by the package AlphasimR (Gaynor *et al.*, 2020). Three traits with the heritability of 0.3 were assumed, and 100% of the genetic variance was accounted for 100, 1000, or 2,000 quantitative trait nucleotides. The effects of the causative QTNs were sampled from a Gamma distribution with a shape parameter of 0.4 and scaled internally for the simulated genetic variance.

Populations mimicking dairy population characteristics were simulated. Initially, founder genomes were generated by sampling 100k haplotype sequences across 29 diploid chromosomes mimicking the length of the bovine genome. The haplotypes were coded as either zero or one. A total of 10,000 loci sequences were simulated for each chromosome, in which 50k were selected as markers. The founder sample was composed of 5,000 individuals. The same recombination rate for females and males was assumed.

An initial historical population was created over 1000 generations of random mating from the founder population. This process allowed a mutation and drift balance while linkage disequilibrium was established. The breeding population started from a sample of the last generation of the historical population and was carried out for 20 generations. The number of males and females were selected to result in an effective population size of 120. At the end of the simulation process, 440,000 animals were available in the pedigree, wherein 16,800 of those individuals were genotyped.

Genotypes were available for all sires and randomly selected dams sampled from generations 16-19, plus 2,000 animals from generation 20, totaling 16,800 individuals. Phenotypes for animals in generation 20 were not included in the analysis, for they were used for validation. This process mimicked selection for young individuals.

Genomic estimated breeding values (GEBV) were computed using GBLUP and ssGBLUP. For GBLUP three pseudo-phenotypes were included in the analyses, varying from the raw phenotypes, the simulated true breeding value (TBV) with a noise sampled from a N~(0,0.2), and the TBV, termed GBLUP1, GBLUP2, and GBLUP3, respectively. SNP weights were calculated based on SNP effects backsolved from direct genomic value (DGV). The square of the SNP effect was called the quadratic weight aproach, and is similar to what was suggested by Zhang *et al.* (2010) and Wang *et al.* (2013). Additionally, the weights were also computed with the nonlinear A formula as described in VanRaden (2008). Different equation parameters were used on the nonlinear A approach. Accuracy was the correlation between TBV and GEBV for animals in generation 20, and bias was the slope of the regression of TBV on GEBV.

Results

Figure 1 includes the accuracies of prediction for the quadratic weights. This approach returned higher accuracy gain for the less polygenic traits. Additionally, models without causative variants experience losses in accuracy, except for the trait with 100 QTN.

Figure 2 includes the accuracies for the nonlinear A method. The accuracies varied according to the method, trait, and equation parameters. Accuracies either increased or remained stable with nonlinear A weights. However, when large numbers for the constant and limit equation parameters were tested, a drastic decline in the accuracies was observed (results not shown).

Discussion

The inclusion of selected sequence variants in SNP panels increasing prediction accuracy or ability have been reported in previous studies (Moghaddar *et al.*, 2019; VanRaden *et al.*, 2017; Xiang *et al.*, 2021). The correspondent accuracy gain depends on how validation was performed, and how variants were selected.

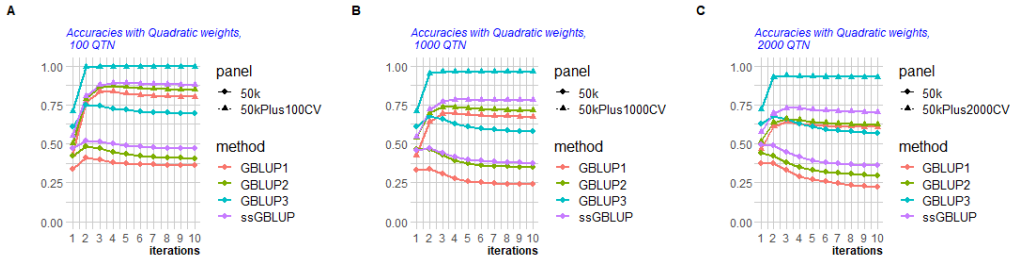

Figure 1. Accuracy of selection with quadratic weights for traits with 100, 1000, and 2,000 simulated QTN (A, B, and C, respectively) The panel included only SNPs (50k) or the inclusion of causative variants (50kplus).

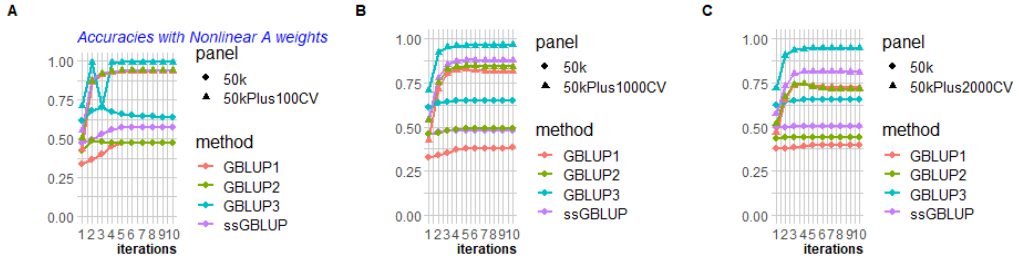

Figure 2. Accuracy of selection with nonlinear A weights for traits with 100, 1000, and 2,000 simulated QTN (A, B, and C, respectively) The panel included only SNPs (50k) or the inclusion of causative variants (50kplus).

Results from real data are still far from achieving what simulations have found, indicating that identifying all variants is a challenge.

Assumptions of non-uniform SNP weights led to expressive gains, especially when causative QTN were included in the panel. For the more polygenic traits, the nonlinear A weighting approach was superior to the quadratic method, in agreement with other authors (Fragomeni *et al.*, 2019; Lopez *et al.*, 2019). When the QTNs were not included in the panel, the quadratic weights reduced accuracy for the more polygenic traits, as expected based on the literature (Fragomeni *et al.*, 2019). However, when extreme values for nonlinear A equation parameters were used, it led to noticeable losses in accuracies, similar from what happens with quadratic weights. For the trait with 100 QTN, the difference between quadratic weights and nonlinear A weights was smaller than the other traits.

Less polygenic traits showing better responses due to the weight implementation is expected, since genes with major effects are more likely to occur in such case. Quadratic weights tend to shrink most of the SNP effects to 0, while increasing others dramatically. For that reason, only the trait affected by a small number of QTNs experienced gains in accuracy with this method. For polygenic traits, extreme shrinkage may remove information from important regions, which results in loss of accuracy.

The ssGBLUP method resulted in lower bias than the GBLUP approach (results now shown), which was expected and has been reported previously (VanRaden *et al.*, 2012). This may have occurred because ssGBLUP takes into consideration all available information simultaneously and also due to high pedigree completeness in this study. Additionally, the use of weights overall increased bias (results not shown), which was also expected (Lee *et al.* 2017, Lourenco *et al.*, 2017).

Finally, the proportional gain from the inclusion of variants and use of weights was higher in GBLUP than in ssGBLUP. Additionally, within GBLUP the method with the raw phenotypes experienced higher proportional gains in accuracy than the model that used the TBV. A possible explanation for those results is that models with less information depend more on the priors and agree with the findings of Fragomeni *et al.* (2019).

The inclusion of causative variants increased the accuracy of selection in all scenarios. The use of weights further increased such gains. The more polygenic traits performed better under more conservative weighting strategies, while the trait with 100 QTN achieved higher accuracy with extreme weight. The use of non-uniform weights may help elucidate features of trait architecture based on the pattern of accuracy variation across scenarios.

Abstract

The objective of this study was to evaluate the gain in accuracy of genomic predictions by adding selected sequence variants to a high-density SNP panel and using weighted or regular single-step GBLUP (ssGBLUP) for age at first calving evaluations in Nellore cattle. Phenotypic records from 224,110 heifers from the Alliance Nellore database and 42,788 genotyped animals were used. All genotyped animals were imputed to whole-genome sequence based on a reference of 151 Nellore sires. A whole-genome association was performed, and 403 sequence variants were selected for inclusion in the high-density SNP panel. Accounting for sequence variants in ssGBLUP did not increase prediction accuracies and only marginally increased accuracy (1%) in weighted ssGBLUP. Our study indicates that genomic selection with ssGBLUP helps to improve prediction accuracy for age at first calving; however, only a marginal gain is observed by including selected sequence variants in the ssGBLUP.

Introduction

Age at first calving (AFC) plays a critical role in identifying heifers that will reach puberty earlier, especially under tropical conditions, and directly affects the herd productivity and profitability of beef cattle. Although genetic progress is slow for reproductive traits such as AFC, genomic information can help increase the prediction accuracy and, consequently, genetic gains. Research interest in whole-genome sequence (WGS) data has increased in the last few years. This data harbors causal mutations, which can be identified and included directly in genomic models without relying on linkage disequilibrium between markers and quantitative trait loci. Pérez-Enciso *et al.* (2015) showed, in a simulation study, that if all causative variants were known, the accuracy of genomic prediction would be perfect (i.e. equal to 1). However, including millions of genome sequence variants into genetic evaluation routines is not advantageous. A practical strategy could be variant selection to identify ones associated with traits of interest (VanRaden *et al.*, 2017).

One suitable method to consider genotyped and ungenotyped animals in genomic evaluation is ssGBLUP (Aguilar *et al.*, 2010). As ssGBLUP is an extension of GBLUP, which in turn is equivalent to SNP-BLUP, SNP effects can be backsolved from ssGBLUP genomic enhanced breeding values (GEBVs), and variance explained by SNPs can be calculated based on those effects. The variance explained by SNPs can then be used as weights in constructing the genomic relationship matrix (G) to account for the fact that SNPs may explain different proportions of variance. This approach may be helpful when causative variants from WGS data are included in the SNP chips used for genomic evaluations (Fragomeni *et al.*, 2017). The main objective of this study was to evaluate the gain in accuracy of genomic predictions using weighted or regular ssGBLUP when adding selected sequence variants to a high-density SNP panel for AFC evaluations.

Materials & methods

Phenotypic, pedigree and genotypic data. AFC records from 224,110 Nellore females belonging to the Aliança Nelore database were used in this study. AFC average was 1,010±133.40 days. Contemporary groups (CG) were formed by heifers born in the same year and season, from the same farm, and raised in the same management group at birth, weaning, and yearling. From 1,348,164 animals in the pedigree data, 42,788 were either genotyped with the Illumina 777k BovineHD bead chip (HD) or a medium-density SNP chip (30k-80k SNPs). In the latter, genotypes were imputed to the HD panel. In addition, 151 influential Nellore sires were sequenced with the Illumina sequencing-by-synthesis technology at an overall average sequence coverage of 14.5× (Fernandes Júnior *et al.*, 2021). A quality control filtering step was implemented according to Fernandes Júnior *et al.* (2021), using the following exclusion criteria: quality by depth <2.0; Fisher Strand test >60.0; root mean square of the mapping quality score <40.0; ranked sum test for the distance of alleles from the end of the reads <-8.0; mapping qualities of reads <-12.5; and SOR >3.0. After this step, we excluded non-biallelic markers and also those with a minor allele frequency lower than 0.01. Marker genotypes with a phred-scaled confidence (a genotype quality score) less than 15 were treated as missing and those SNPs with missing values for more than 40 individuals (26.5% of the total population) were removed from the analyses. A total of 30,394,484 sequence SNPs in autosomal regions remained after quality control. All genotyped individuals were imputed to WGS using those 151 sires as a reference population. After imputation with the software FImpute3 (Sargolzaei *et al.*, 2014), we filtered out variants with minor allele frequencies lower than 0.001 and linkage disequilibrium values (r^2) greater than 0.9 using PLINK 2.0 (Chang *et al.*, 2015). After this step, 4,809,603 SNPs were retained for subsequent analysis.

Whole genome sequence association analyses. A model considering CG as a fixed effect, random additive genetic and residual effects were used to estimate variance components and estimated breeding values (EBVs) with regular BLUP. The EBVs were used to calculate deregressed breeding values as proposed by Garrick *et al.* (2009) and they were used as response variables for the whole-genome association analysis. The software GCTA (Yang *et al.* 2014) was used to estimate SNP effects via linear mixed models with a random polygenic effect based on G. We also performed a principal component analysis and included the first eight principal components as covariates in the model to account for possible population stratification. To prevent SNP double-counting, we utilized the option LOCO (leaving-one-chromosome-out) that excludes the chromosome on which the candidate SNP is located (Yang *et al.* 2014). The significant variants were selected by using a false discovery rate lower than 5% for multiple test correction. The selected variants (SV) not present in the HD panel were included for genomic prediction.

Genomic prediction. The AFC GEBV were computed using ssGBLUP with the same animal model described in the previous subsection. Two scenarios were tested to compute GEBV as follows; (a) using only HD SNPs, and (b) using HD SNPs and selected variants (HD+SV). Furthermore, the ssGBLUP was performed without and with weights iteratively, with G constructed with quadratic or nonlinear A weights. The weighted ssGBLUP was performed only for the scenario considering HD+SV. We chose five iterations for the weighted ssGBLUP as suggested by Fragomeni *et al.* (2019), and results are shown only for the last iteration. The pedigree BLUP was also applied to assess gains in prediction accuracy when using genomic information.

Validation. Validation was performed by the linear regression method proposed by Legarra and Reverter (2018), where young animals had no phenotypes in the reduced dataset (r) and complete records in the whole dataset (w). The prediction accuracy ($\widehat{acc}$), which considers the covariance between the (G)EBV in the whole and reduced datasets, was calculated as follows: $\widehat{acc} = \sqrt{cov[(G)EBV_w, (G)EBV_r]/(1-\bar{F})\sigma_u^2}$, where cov is the sample covariance, $\bar{F}$ is the average inbreeding coefficient of validation animals (i.e. young animals) and σ_u^2 is the additive genetic variance computed with the whole data set. The regression coefficient

(b_1) of (G)EBV$_w$ on (G)EBV$_r$ was used to assess the degree of inflation/deflation of pedigree and genomic predictions. Statistics were calculated for genotyped and non-genotyped young heifers and for genotyped young bulls that were at most two years old.

Results

The heritability for AFC was 0.06±0.004, which is lower than in other studies with Nellore cattle (Mota *et al.*, 2017). Regarding the whole genome association analysis, 403 significant variants were included in the HD SNP panel for genomic prediction. Among those significant variants, 143 are on chromosome BTA23.

The prediction accuracies of GEBV using regular or weighted ssGBLUP are presented in Table 1. In general, the GEBV accuracies ranged from 0.39 to 0.43 between the methods, and b_1 varied from 0.87 to 1.16 across the validation groups (young heifers and young genotyped bulls). The GEBV accuracies from ssGBLUP (weighted or not) outperformed those from BLUP, with an average increase in accuracy of 18% for young heifers and 48% for young genotyped bulls. Including SV in the regular ssGBLUP has not increased prediction accuracies and only marginally increased accuracy (1%) in weighted ssGBLUP with nonlinear A method (HD+SV).

Discussion

Even though AFC has low heritability, our study indicates that genomic selection with ssGBLUP can help to improve prediction accuracy and, therefore, accelerate genetic gains for AFC in this Nellore population. Using SV combined with SNP panels considerably increased prediction accuracy in simulation studies (Fragomeni *et al.*, 2017) when applying weighted ssGBLUP, compared to the regular ssGBLUP. However, we found only a marginal increase (1%) when including SV in weighted ssGBLUP with nonlinearA weights compared to the HD SNP panel. This result is similar to those from Fragomeni *et al.* (2019) for stature in US Holsteins. The authors compared ssGBLUP with and without weights and did not find any gain by including nearly 17,000 significant variants to a medium-density panel. According to Lourenco *et al.* (2020), the amount of information used in ssGBLUP overwhelms any *a priori* assumption on SNP effects, being less sensitive to weighting approaches for large data sets. These authors suggested that an ideal algorithm should assign large variance to causative SNPs while reducing the variance of nearby SNPs. Exploring methods to increase the power of detection of causal variants, as multi-trait meta-analysis or gene expression and genome annotation could help avoid spurious associations. The use of additional biological sources of information (i.e. multi-omics data) could also help to increase the likelihood of identifying mutations that contribute to the variance of complex traits and possibly, increase the prediction accuracies.

Table 1. Accuracy of (G)EBV and regressions coefficients (b_1) of (G)EBV in the whole data set on (G)EBV in the reduced data set when including or excluding selected variants (SV) in single-step GBLUP (ssGBLUP) for young heifers and young genotyped bulls for age at first calving.

Method[1]	Scenario[2]	Young heifers		Young genotyped bulls	
		Accuracy	b_1	Accuracy	b_1
BLUP	Pedigree	0.35	0.87	0.37	0.89
ssGBLUP	HD	0.42	0.88	0.56	0.93
ssGBLUP	HD+SV	0.42	0.88	0.56	0.93
WssGBLUP_quadratic	HD+SV	0.39	0.89	0.51	1.16
WssGBLUP_nonlinearA	HD+SV	0.43	0.87	0.57	0.95

299. Increasing accuracy of single-step evaluations of functional longevity including information from correlated traits

L.-H. Maugan[1*], T. Tribout[1], R. Rostellato[1], S. Mattalia[1,2] and V. Ducrocq[1]

[1]Université Paris Saclay, INRAE, AgroParisTech, GABI, 78350 Jouy-en-Josas, France; [2]Institut de l'Elevage, UMT eBIS, 78350 Jouy-en-Josas, France; laure-helene.maugan@inrae.fr

Abstract

Breeding values for low heritable traits are difficult to estimate. Often, if traits are correlated to each other they should be analysed together in a multivariate genetic evaluation to improve accuracy. However, the correlated traits may not be described by the same model. To overcome the resulting complexity, a 'combined' genetic evaluation consisting of two successive evaluations has been implemented in France, resulting in more accurate breeding values. The aim of this study was to verify that a combined Single-Step evaluation is more accurate than a univariate Single-Step evaluation. To that end, genomic breeding values obtained with univariate and combined Single-Step evaluation were compared for functional longevity and five other correlated traits in 2016 and 2021. The average and the correlation between breeding values in 2021 and 2016 suggested that the combined Single-Step evaluation is more accurate than univariate Single-Step evaluations.

Introduction

Longevity is a complex trait with a low heritability. Genetic evaluation for this trait requires a complex survival model to account for highly nonlinear data and for the existence of censored records, corresponding to cows that are still alive (i.e. only a lower bound of their actual longevity is known). Another level of complexity is added by the fact that we are mostly interested in the functional longevity (FL), i.e. the ability to avoid involuntary culling regardless to the milk production level of a cow. Because of these intricacies, the genetic evaluation of French dairy cows on FL is based on a Weibull sire model (Ducrocq, 2005). Moreover, FL is correlated to other traits such as udder health, fertility and type traits that can be used as predictors. Unfortunately, all these traits are described by very different models, making difficult the development of a multiple trait evaluation of FL and of its predictors using raw performances. This is why a 'combined' genetic evaluation was developed (Ducrocq *et al.*, 2001) including FL and correlated traits. It relies on a two-step approach: first, univariate evaluations (or multivariate evaluations by group of traits described by a same model) are performed. For all traits, records are corrected for all fixed effects (and possibly for the heterogeneity of residual variances). As a result, each recorded animal gets one 'pseudo-record' for each observed trait and an associated weight is calculated. Then a multivariate genetic evaluation is carried out on these weighted pseudo-records, based on a very simple model with only one fixed effect, a year of birth effect, in order to account for selection on correlated traits not accounted for in the first step, and the individual genetic value of each animal (Govignon-Gion *et al.*, 2016). Such combined evaluations have major advantages: as a result, all animals have an estimated breeding value (EBV) on all traits and the construction of a total merit index is straightforward.

In the context of single step evaluations, the combination of Genomic Estimated Breeding Values (GEBVs) from separate genomic evaluations is not optimal. In order to illustrate the benefits of a combined Single-Step (CSS) approach and to evaluate low heritability traits such as FL and its predictors in comparison with several univariate SS (USS) evaluations, performances of six correlated traits were used in the Montbéliarde breed: FL, somatic cell score (SCS), conception rate in heifers (CRH) and lactating cows (CRC), clinical mastitis (CM) and udder depth (UD).

Materials & methods

Data. The number of records available in Montbéliarde since 2002 and included in the analyses is listed in Table 1. Records were obtained from the French bovine national database.

Method. The FL pseudo-records were derived from the Weibull sire model mentioned above (Ducrocq, 2005). For the other traits, pseudo-records were derived from the SS evaluation results, applying the same univariate models as in the corresponding current official evaluations. Two SS evaluations were run: one considering all available performances (recorded from 2002 to mid-2021) and one considering truncated data after deletion of the performances recorded from 2016 to 2021 to mimic a SS evaluation performed on data available in 2016.

The objective was to verify whether the GEBVs obtained for young animals (2016 SS evaluations) predicted more accurately the CSS GEBVs of 2021 (supposedly the most accurate GEBVs), using a CSS instead of a USS. For this purpose, the GEBVs of the 10% best cows estimated using a CSS evaluation and all data available in 2021 were compared to the GEBVs calculated with a USS or a CSS, and using only data available five years before. This group of best cows included 1,972 cows born and genotyped in 2014, having their first performances in 2016 or later.

Model and software. The general Single-Step model equation for the first step of the CSS evaluation can be summarised as:

$$\mathbf{y}_{kj} = \sum_{i=0}^{n} \mathbf{b}_k + \mathbf{a}_j + \mathbf{e}_{kj} \quad (1)$$

with y_{kj} the vector of performances of animal j, b_k the corresponding vector of fixed effects k. For each trait, performances were modelled using the effects used in the current routine evaluation run by GenEval (https://www.geneval.fr/indexations-mutualisees), these models being adapted to each group of traits. a_j is the vector of additive genetic effects of animal j with $a = \{a_j\} \sim N(0, H \otimes G)$, G is the genetic (co)variance matrix between traits (in the case of multivariate evaluation), H is the genetic/genomic relationship matrix between animals, and e_{kj} is the vector of residuals for animal j with $e = \{e_j\} \sim N(0, I \otimes R)$, R being the residual (co)variance matrix between traits (in the case of multivariate evaluation). For UD and CM, phenotypic heterogeneous variances were accounted for using Meuwissen's approach (Meuwissen *et al.*, 1996).

GEBVs for USS_2016 and pseudo-records for each trait are estimated using model (1). These pseudo-records are used in the second step of the CSS evaluation of which the equation is:

$$y_{kj} = \mu_{year} + a_j + e_{kj}, \quad (2)$$

Table 1. Number of records for the investigated traits.[1]

	FL	SCS	CRH	CRC	CM	UD

[2] i.e. ignored in the 2016 analyses.

where y_{kj} are the pseudo-records of animal j for trait k, μ_{year} is the birth year of the animal. The objective of μ_{year} is to adjust the additive genetic effects for potential selection on correlated traits not accounted for in the (univariate) first step. a_j and e_{kj} are the same as in (1) but in a multivariate context.

Unknown parent groups were used in the SS evaluations. They were defined according to the birth year of the animals with unknown parent.

Both Single Step evaluations were performed using the HSSGBLUP software (Tribout *et al.*, 2020).

Results & discussion

Average of GEBVs. In Figure 1, the average GEBVs of the top 10% cows increased between 2016 (CSS or USS) and 2021. This was expected, since the increase in accuracy due to additional information leads to a greater variability of GEBVs in 2021 and thus to higher GEBV means of the best females. Moreover, for CM, CRH and CRC in 2016 the average GEBV for USS is lower than for CSS, which could be explained again by higher accuracies obtained with the CSS. For the other traits, the difference is small. It could be explained for UD and SCS by the fact that the accuracy is not much improved using a combined evaluation, since the heritability of these traits is high enough (SCS: 15%; UD: 38%). For FL, the difference between average GEBVs in USS_2016 and CSS_2016 are about 0.02 while is it about 0 for SCS and UD. The theoretical heritability of FL is about 14.5% but is lower in practice because of censored animals (i.e. still alive) at the time of evaluation (GenEval, 2021).

Correlation between GEBVs. Correlations between GEBVs (Figure 2) are higher with the CSS than with the USS evaluation for all traits. It indicates that in 2016, CSS is more efficient than USS to predict CSS in 2021. These differences are small for the most heritable traits (SCS and UD) but are quite clear for the low heritable traits (CM, FL, CRC and CRH).

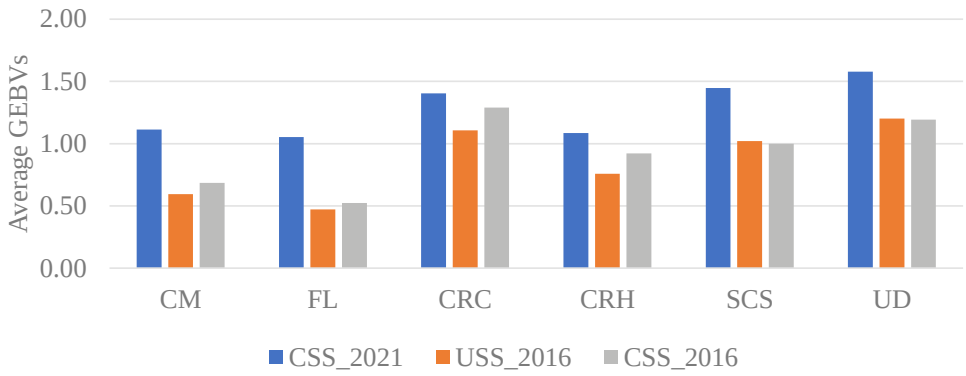

Figure 1. Average GEBVs obtained with the different evaluations for the top 10% cows and for the investigated traits. FL: functional longevity, SCS: milk somatic cell score, CRH: conception rate of heifers, CRC: conception rate of lactating cows, CM: clinical mastitis, UD: udder depth, CSS 2021: combined Single-Step evaluation of 2021, CSS 2016: combined Single-Step evaluation of 2016, USS 2016: univariate Single-Step evaluation of 2016. All results expressed in genetic standard deviation units.

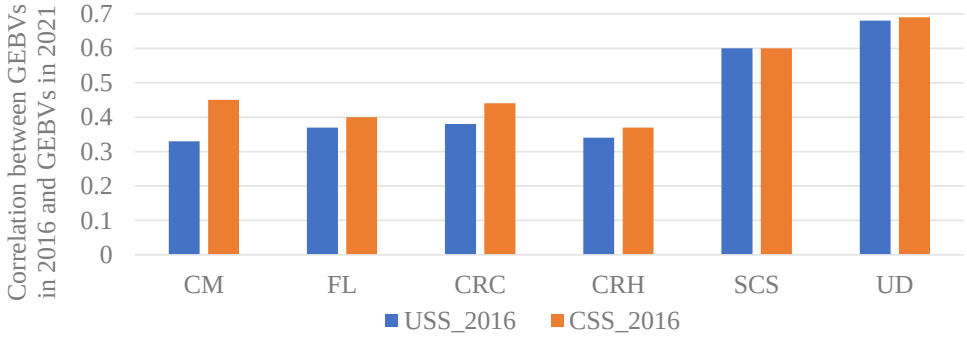

Figure 2. Correlations between GEBVs obtained in 2021 with those obtained in 2016 (USS or CSS) for the top 10% cows and for the investigated traits. FL: functional longevity, SCS: milk somatic cell score, CRH: conception rate of heifers, CRC: conception rate of lactating cows, CM: clinical mastitis, UD: udder depth, CSS 2021: combined Single-Step evaluation of 2021, CSS 2016: combined Single-Step evaluation of 2016, USS 2016: univariate Single-Step evaluation of 2016.

Conclusions

A combined (multivariate) SS evaluation leads to a gain in accuracy for GEBVs for low heritable traits. Even though differences between GEBVs in USS 2016 and CSS 2016 were expected to be higher, the results of this preliminary study are encouraging.

The genetic parameters (particularly genetic correlations) used in our study were estimated a few years ago and did not consider the genomic information on bulls. This could explain why relatively minor differences were found. Therefore, we plan to use updated genetic parameters and to complete the analyses with a study of the GEBV reliability of bulls and cows.

300. Multi-trait genomic estimation of genetic parameters for growth and carcass traits of Duroc pigs

E.C. Akanno[1,2*], D.M. Thekkoot[1], C. Zhang[1], C. Bierman[1], G. Plastow[2] and R.A. Kemp[1]

[1]Genesus Inc., 101 2nd St., Oakville, MB, R0H 0Y0, Canada; [2]Livestock Gentec, University of Alberta, 116 St & 85 Ave, Edmonton, AB, T6G 2R3, Canada; eakanno@genesus.com

Abstract

A total of 10,581 Duroc pigs with genotype, phenotype and pedigree were used to estimate genetic parameters for nine growth and carcass traits utilising pedigree- and genomic-based multi-trait animal models implemented in MTG2 software. Moderate to high heritability that ranged from 0.12±0.01 for average daily feed intake (FI) to 0.50±0.02 for carcass lean (CL) were observed. Genomic-based estimates were slightly larger than the pedigree-based estimates, on average, and had smaller standard errors. Genetic correlations from a genomic-based model were high for the following trait pairs; Ultrasound fat depth (UF) and Intramuscular fat percent (IF) (0.65), FI and Days to 120 kg (-0.63), UF and Carcass fat (CF) (0.97), IF and CF (0.63), CF and FI (0.59), Ultrasound lean depth and CL (0.91), and IF and Marbling score (0.65). Therefore, facilitating improvement in accuracy of genetic parameters by incorporating genomic information is encouraged.

Introduction

Genetic parameters as well as components of total phenotypic variance are essential for the design of pig genetic improvement programs (Akanno *et al.* 2014). Traditionally, genetic parameters are estimated using large, across-generation datasets with reliable pedigrees, however, traits that are difficult to measure such as feed intake and those measured after harvest such as carcass traits may lack sufficient data for accurate estimation. With the growing availability of genomic data, genetic parameter estimation can be improved by incorporating genomic information. In addition, the development of enhanced statistical models, improvement in computing capacity and the likelihood that population parameters may have evolved due to improved rearing conditions and selection may necessitate the re-estimation of genetic parameters from time to time (Wray and Visscher, 2008). The objective of this study was to compare a multi-trait pedigree- and genomic-based estimates of genetic parameters for combined growth and carcass traits in Duroc pigs.

Materials & methods

Data. A total of 10,872 Duroc pigs were genotyped with a custom Affymetrix Axiom® Porcine Genotyping Array (59,400 SNPs). Genotypes were filtered for 95% animal and SNP call rate and <0.02 minor allele frequency resulting in a total of 45,240 SNPs and 10,581 genotyped animals. Animals with missing genotype calls were imputed using FImpute software (Sargolzaei *et al.* 2014). Pedigree records were available on 13,241 individuals, 581 sires and 2,497 dams. Phenotypes were available for days to 120 kg (DA), ultrasound fat depth (UF), ultrasound lean depth (UL), average daily feed intake (FI), intramuscular fat percent (IF), hot carcass weight (HW), carcass fat depth (CF), carcass lean depth (CL) and marbling score (MS). MS was a subjective score from 1 to 6 and evaluated by a single, experienced technician. UF and UL were adjusted to 120 kg while HW was adjusted to 130 kg. The data were edited to remove records with more or less than 4 standard deviations from the mean.

Statistical analyses. Genetic parameters of nine growth and carcass traits were estimated using a multi-trait animal mixed model. The model utilised either a numerator relationship matrix (A) constructed from pedigree, or a genomic relationship matrix (G) constructed from 45,240 SNPs using $\mathbf{WW}'/2\sum p_i(1-p_i)$, where W contains centred genotypes codes and p_i is the minor allele frequency for locus i (VanRaden, 2008). The following mixed effect model in matrix notation (1) implemented in MTG2 version 2.22 (Lee *et al.* 2016) was applied.

$$y = Xb + Z_1l + Z_2a + e \quad (1)$$

where y is the vector of observations for multiple growth and carcass traits, b is the vector of varying fixed effects depending on the trait which includes sex applied to all traits, Improvest® (https://zoetis.cvpservice.com/product/view/1198451) applied to growth traits, ultrasound machine type applied to ultrasound fat and lean depth, and management groups. Management group for growth traits was defined as probe year, probe week, location, and technician while management group for carcass traits was defined as slaughter date and technician, l is the vector related to random litter effects ~N (0, L⊗I), a is the vector related to random direct additive genetic effects of animals ~N (0, G_a⊗A) for pedigree-based model or ~N (0, G_a⊗G) for genomic-based model and e is the vector related to random residuals ~N (0, R⊗I). X is the design matrix that relates the fixed effects to the observation, Z_1 is a design matrix that relates random litter effects to observations, Z_2 is a design matrix that relates random animal genetic effects to observations, L, G_a, and R, are litter, additive genetic and residual (co)variance matrices between traits, respectively, and I is identity matrix.

Different four-trait analyses were initially performed separately for growth and carcass traits and their results were found to be comparable to a nine-trait model that includes all traits. Thereafter, only a nine-trait multi-trait model was applied and reported. Total phenotypic variance (σ_p^2) was calculated $\sigma_p^2 = \sigma_l^2 + \sigma_a^2 + \sigma_e^2$, where the σ_l^2, σ_a^2 and σ_e^2 are the litter variance, additive genetic variance, and residual variance, respectively. Heritability (h^2) was computed as $h^2 = \sigma_a^2 / \sigma_p^2$. Genetic correlations ($r_g$) were estimated as $r_g = \sigma_{a_1 a_2} / \sqrt{\sigma_{a1}^2 \times \sigma_{a2}^2}$, where the σ_{a1}^2 and σ_{a2}^2 are the genetic variance estimates for traits 1 and 2, respectively, and $\sigma_{a_1 a_2}$ is the genetic covariance between two traits.

Results

The descriptive summary and estimates of h^2 from pedigree- and genomic-based models are presented in Table 1. Moderate to high h^2 ranged from 0.12±0.01 (FI) to 0.50±0.02 (CL) across the traits and models. Genomic-based model h^2 were slightly larger for UF, UL, CF, CL, and MS than estimates from a pedigree-based model. Also, the standard error (SE) of h^2 estimates for the genomic-based model were generally smaller than those of pedigree-based model. Traits measured on live animals (UF and UL) had similar h^2 to those measured on carcass (CF and CL) in both the pedigree- and genomic-based models.

Table 1. Number of records (N), mean, standard deviation (SD), heritability (h^2) ± standard error (SE) for pedigree- and genomic-based estimation in Duroc pigs.

Traits	N	Mean	SD	Pedigree h^2±SE	Genomic h^2±SE
Days to 120 kg (d)	10,859	162.27	11	0.16±0.02	0.16±0.01
Ultrasound fat (mm)	10,807	13.98	2.78	0.42±0.03	0.48±0.01
Ultrasound lean (cm^2)	10,840	70.24	5.24	0.43±0.03	0.48±0.01
Intramuscular fat percent	7,778	2.71	0.87	0.28±0.03	0.27±0.02
Average daily feed intake (kg/d)	8,387	2.93	0.62	0.16±0.02	0.12±0.01
Hot carcass weight (kg)	3,377	103.19	3.48	0.22±0.05	0.17±0.03
Carcass fat (mm)	3,395	15.88	3.74	0.44±0.04	0.49±0.02
Carcass lean (cm^2)	3,402	68.63	5.15	0.45±0.05	0.50±0.02
Marbling score	3,402	2.97	1.15	0.25±0.05	0.31±0.03

Table 2 shows the variance components and genetic correlations among the nine traits studied. Genetic variances from the genomic-based model were slightly greater than those from the pedigree-based model for majority of the traits (UF, UL, CF, CL, and MS). Similarly, the genetic covariances from the two models showed similar signs for most of the trait combinations except for a switch in sign between DA and HW. The estimates of genetic correlation from the pedigree- and genomic-based models were similar in magnitude and direction except for a switch in sign for DA and HW. Genomic-based model also had smaller ranges of SE for the (co)variances and genetic correlation than the pedigree-based model (Table 2). The litter and residual (co)variances from the pedigree- and genomic-based models were generally similar. Also, the signs of the covariance estimates from both models were generally the same except for some trait pairs in which the covariance estimates were close to zero.

Discussion

The moderate to high h^2 observed for most of the growth and carcass traits were within the range of estimates (0.10-0.47) reported by MacNeil and Kemp (2015) and Esfandyari *et al.* (2020) utilising a related purebred Duroc population. Genomic-based models gave slightly larger h^2 estimates for UF, UL, CF, CL and MS which corroborates the findings of Esfandyari *et al.* (2020) that compared the difference in estimates for pedigree-based and a single step genomic-based model (ssGBLUP). This is probably because genomic-based models included contribution of causal variants in linkage disequilibrium with SNP markers in the estimation process. Also, utilising the same size of data but including genomic information in the estimation

Table 2. Additive genetic variances on the diagonal, genetic covariance above diagonal and genetic correlation below diagonal for growth and carcass traits[1] in Duroc pigs[2].

[1] DA = Days to 120 kg (d), UF = ultrasound fat (mm), UL = ultrasound lean (cm^2), IF = intramuscular fat percent, FI = average daily feed intake (kg/d), HW = hot carcass weight (kg), CF = carcass fat (mm), CL = carcass lean (cm^2), MS = marbling score.

[2] Genomic-based estimates in brackets.

[3] Standard error for variances in the pedigree-based model ranged from 0.005-2.000 while genomic-based model ranged 0.003-1.360; standard error for covariances in the pedigree-based model ranged from 0.005- 1.132 while genomic-based model ranged from 0.004-0.827; standard error for genetic correlation in the pedigree-based model ranged from 0.005-0.151 while genomic-based model ranged from 0.009-0.103.

process decreased the SE of estimates for all the studied traits, thus, accuracy of estimates is improved for genomic-based model than for pedigree-based model.

The genetic, litter and residual variances and covariances among trait combinations are required for constructing complete variance-(co)variance matrices for joint genetic evaluation of growth and carcass traits. Estimates of the variance components observed in this study are consistent with estimates reported elsewhere (Akanno *et al.* 2014; Esfandyari *et al.* 2020). The high positive genetic correlation observed among traits measured in live animals (UF, UL, and IF) and those measured in carcass (CF, CL, and MS) are expected because of the linear relationship among these traits and has been previously observed (Esfandyari *et al.* 2020). In addition, estimates from the genomic-based model had smaller SE and thus more accurate than those from the pedigree-based model.

Conclusions

Estimation of genetic parameters can be very challenging due to requirements for sophisticated computing techniques and large datasets. It is even reassuring to obtain results that appear similar when applying different models and methods. Therefore, facilitating improvement in accuracy of genetic parameters by incorporating genomic information is encouraged.

Abstract

Studies indicate that mito-genome variation impacts phenotypes in a range of species. In dairy cattle up to 5% of phenotypic variation for milk production has been associated to mito-genome variation. Bearing in mind that milk production is a very energy demanding process that inflicts systemic physiological changes, it is logical to expect that it depends on well-functioning mitochondria. Here we evaluated the impact of accounting for nuclear- and mito-genome variation in genetic evaluation and breeding of dairy cattle with the means of stochastic simulations. Results show that accounting for mito-genome variation can increase the accuracy of estimated breeding values by up to 0.04, particularly in females, and consequently increase genetic gain.

Introduction

Mitochondria are involved in many critical cellular processes via proteins encoded in nuclear-genome and mito-genome. While variation in nuclear-genome is driven by mutations, recombinations and combination of parental genomes, variation in mito-genome is driven by mutations that are inherited from dams to their offspring in haploid form without recombination. Dorji *et al.* (2021) recently reported a high level of variation in mito-genomes across globally important cattle breeds, with most of the variation attributed to within-breed component. Considering the critical role of mitochondria and the observed variation, it is expected that mito-genome variation impacts livestock production. Recent and past studies suggest that mito-genome accounts for up to five percent of phenotypic variation for yield traits in cattle (Boettcher *et al.*, 1996; Gibson *et al.*, 1997; Brajković, 2019). Previous studies have evaluated the impact of accounting for mito-genome variation in genetic evaluation in livestock using pedigree information, while this impact has not yet been evaluated with genomic information. Furthermore, given that mito-genome has a different mode of inheritance than nuclear-genome, we need to revise the definition of a breeding value that accounts for the inheritance of each genome in males and females.

The goal of this study was to evaluate the impact of accounting for nuclear-genome and mito-genome variation in estimating breeding values and using different definitions of breeding values and their estimates in a dairy cattle breeding programme with a stochastic simulation.

Materials & methods

Simulation setting. Dairy cattle breeding scheme was simulated using AlphaSimR R-package (Gaynor *et al.*, 2020). We simulated nuclear-genome and mito-genomo independently. To generate nuclear-genome chromosomal haplotypes, we used the option 'CATTLE' in 'AlphaSimR' with 10 diploid chromosomes (to reduce computation time) with 10^8 base pairs each, mutation rate of 2.5×10^{-8}, recombination rate 1×10^{-8}, and effective population size as in MacLeod *et al.* (2013). We chose 1000 loci per chromosome as SNP markers and another 1000 as QTL. For the mito-genome haplotypes we considered 1 haploid chromosome with 16,202 base pairs, mutation rate of 2.5×10^{-7}, no recombination, and effective population size of 1000 to obtain a level of diversity that matched values found in literature (Brajković, 2019; Xia *et al.*, 2019; Dorji *et al.*, 2021). We chose all polymorphic loci (on average 1084 across 10 replicates) in mito-genome as

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_301, © G.M. Fortuna *et al.* 2022

SNP markers and as QTL at the same time. We also evaluated a setting where only one locus was a QTL. Both simulated haplotypes were randomly sampled giving rise to nuclear-genomes and mito-genomes of founding individuals. The nuclear-genomes were passed between generation with recombination and combining two parental nuclear-genomes, while mito-genomes were passed only from mothers to their progeny without recombination. We defined one polygenic trait with heritability of 0.3, partitioned between nuclear-genome ($\sigma^2_{a_n} = 0.25$) and mito-genome ($\sigma^2_{a_m} = 0.05$) components in the base population with allele substitution effects of the QTL sampled from a Gaussian distribution that gave rise to targeted genetic variances. The trait was expressed only in cows for each lactation and generated as:

$$y_{ij} = \mu_i + a_{n,j} + a_{m,j} + p_j + e_{ij} \quad (1)$$

where y_{ij} is the phenotype of cow j in lactation i, μ_i is the population mean for lactation i, $a_{n,j}$, the value of nuclear-genome for animal j, $a_{m,j}$ the value of mito-genome for animal j, which was the same as for its mother, maternal grand-mother, etc., p_j the permanent environment effect of animal j ~N(0,0.10), and e_{ij} is the environmental effect ~ N(0,0.60).

Genetic evaluation. We analysed the phenotype data using the generative model (1) with pedigree- and genome-based information accounting for the mito-genome or not. In the pedigree-based model we assumed a_n ~ N(0, A0.25) with A being pedigree relationship matrix for nuclear-genome and a_m ~ N(0, I0.05) with I being an identity matrix of dimension equal to the number of different maternal founder lineages. In the genomic-based model we assumed a_n ~ N(0, H_n0.25) with H_n being the 'single-step' joint pedigree and genomic (SNP marker) relationship matrix for nuclear-genome (Aguilar *et al.*, 2010) and a_m ~ N(0, G_m0.05) with G_m being genomic (SNP marker) relationship matrix for mito-genome with dimension equal to the number of distinct mito-genomes, n_m. We calculated it as $G_m = MM^T / k$, where M is an $n_m \times n_s$ matrix of 0 (ancestral allele) and 1 (mutation) for n_m mito-genomes and its n_s polymorphic loci (we assume we know all these loci by sequencing mtDNA within pedigrees), $k = \sum_{l=1}^{n_s} p_l(1 - p_l)$, and p_l is the frequency of mutations. For both models we firstly assumed that p ~ N(0, I0.10) and e ~ N(0, I0.60) during a burn-in phase. Following we estimated the components and used the new estimates as fixed parameters for the remainder of simulation. We fitted the models with the BLUPF90 suite (Misztal *et al.*, 2018).

Breeding value definition. We defined breeding value of individual j in two ways: (1) as nuclear breeding value $a_{n,j}$; or (2) as the sum of nuclear and mitochondrial breeding value, $a_{n,j} + a_{m,j}$. The definition (2) is the correct definition for females because they transmit both nuclear-genome and mito-genome to the next generation. However, males potentially express the effect of mito-genome they inherited from their mother, but they only transmit their nuclear genome to the next generation. Hence, for males, the definition (1) is the correct definition.

Breeding scenarios. We evaluated sixteen scenarios driven by three factors across 10 replicates. The first factor was a breeding scheme: (1) progeny testing-based selection (PT); and (2) genomic selection (GS). The second factor was a modelling and selection scenario: (1) using a model without mito-genome effect and selecting both females and males on their nuclear breeding values (STANDARD); (2) using a model with mito-genome effect and selecting both females and males on their nuclear breeding values (BASELINE); (3) using a model with mito-genome effect and selecting both females and males on their nuclear plus mito breeding values (EXTREME); and (4) using a model with mito-genome effect and selecting females on their nuclear plus mito breeding values and selecting males on their nuclear breeding values (OPTIMAL). The third factor was assuming that all or just one polymorphic locus in mito-genome is a QTL. We evaluated all the scenarios with: (1) accuracy of genetic evaluation (as correlation between true breeding value and

estimated breeding value) in scenarios STANDARD vs BASELINE and (2) genetic gain in nuclear breeding value over 20 years in scenarios STANDARD, BASELINE, EXTREME, and OPTIMAL.

Results

We present the results separately for the following five categories: (1) heifers; (2) 1st lactation cows (cows1); (3) cows with 2 to 5 lactation records (cows2-5); (4) young bulls, males without progeny; and (5) proven bulls, males that have undertaken a progeny test or have been used as sires. For the GS scenarios, the female categories were expanded to show the difference between genotyped and non-genotyped animals. We present only the scenario where all polymorphic loci in mito-genome were QTL (the other scenario was qualitatively the same).

The accuracy of mito breeding values in both PT and GS was close to one for all animal categories (results not shown) which is expected given the lack of recombination. When evaluating the accuracy of the nuclear breeding values (Table 1), accounting for mito-genome variation increased accuracy from 0.01 to 0.04, depending on the animal category. In the PT scenario, the highest increase in accuracy was observed for 'Cows2-5' (+0.04). In the GS scenario, the 'Cows2-5 (not geno.)' was the category showing the best improvement (+0.04), followed by 'Young-bulls (geno.)' (+0.03).

The results presented in Figure 1 show that considering mitochondrial effect when estimating breeding values can increase genetic gain when both males and females are selected on their nuclear breeding values (BASELINE scenarios). When using the OPTIMUM scenario, results are comparable to that observed for the STANDARD scenario. Lastly, the EXTREME scenario seems to induce less gain than all other scenarios in both genomic and progeny-testing settings.

Discussion

Dairy breeders are basing their genetic evaluation and selection solely on nuclear breeding values. Gibson *et al.* (1997), however, defined genetic merit as the sum of nuclear and cytoplasmatic components. Southwood *et al.* (1989) performed a simulation to evaluate estimation of additive maternal and cytoplasmic variance. They found inflated estimates of additive genetic variance when ignoring cytoplasmic variance or both

Table 1. Accuracy of nuclear breeding values for different animal categories in the model with nuclear-genome (Model N) or nuclear-genome and mito-genome (Model N&M) with the pedigree-based model in progeny testing-based selection (PT) or with genomic-based model in genomic selection (GS).

Scenario	Category	Model N	Model N&M	Difference
PT	Heifers	0.47±0.02	0.48±0.01	0.02±0.02
	Cows1	0.61±0.02	0.63±0.01	0.03±0.02
	Cows2-5	0.54±0.04	0.58±0.01	0.04±0.04
	Young bulls	0.37±0.03	0.38±0.03	0.01±0.02
	Proven bulls	0.74±0.01	0.76±0.01	0.02±0.01
GS	Heifers (non-geno.)	0.43±0.01	0.44±0.01	0.01±0.01
	Heifers (geno.)	0.72±0.03	0.75±0.01	0.02±0.02
	Cows1 (non-geno.)	0.58±0.02	0.60±0.00	0.02±0.02
	Cows1 (geno.)	0.76±0.02	0.78±0.01	0.02±0.02

the cytoplasmic and additive maternal effects in the analysis. Our study complemented this past work by extending it with genomic information in estimating breeding values and by clarifying the definition of breeding values in females and males when both nuclear- and mito-genome affect a trait.

Abstract

Prediction accuracy is commonly used to evaluate genomic prediction models, but it can be insufficient to describe how different models perform in terms of capturing (or missing) genetic signals. Here we propose using residual single-marker regression analyses to identify loci harbouring genetic signals that were not captured by a model – we refer to this phenomenon as signal leakage. The proposed approach was applied to average daily gain in pigs. Different prediction models were compared: pedigree-BLUP, ssGBLUP, Bayesian Ridge Regression (BRR) and BayesC. Genomic scans were based on either medium or ultra-high-density SNP panels. Signal leakage was strong and widespread in pedigree-BLUP. Including genomic data in ssGBLUP reduces the extent of signal leakage, but regional peaks of missed signal remain. BayesC performed better than BRR, indicating that over-shrinkage contributes to signal leakage. Residual regressions with ultra-high-density panel suggested that imperfect LD between SNPs and causal variants also contributes to signal leakage.

Introduction

Multiple factors (including the statistical model used, sample size, marker density, etc) can affect the ability of a genomic model to extract genetic signals from phenotypic data. Models' performances are often evaluated based on their ability to predict phenotypic values in testing data. However, because multiple factors can affect prediction accuracy, predictive ability alone can be insufficient metric for characterizing how models behave in terms of capturing genetic signals. For example, shrinkage methods may be better at capturing genetic signals in regions of very high LD and in those where there are multiple variants with small effects, while variable selection methods may be better at capturing signals in regions with large-effect variants. Likewise, increasing marker density with the use of sequence data may be more relevant in some regions than others.

Our research was originally motivated by the goal of identifying regions of the genome holding genetic signals that are missed by a model (hereinafter referred to as signal leakage). To this end, we propose using single-marker regression analysis applied to the residuals of this genetic model. The intuition behind the approach is simple: strong associations between residuals and SNP genotypes are suggestive of possible genetic signals missed by the predictor used to derive the residuals. These residual GWA can be applied to the same SNP panel used to derive predictions and residuals or to a different one. We use different panels and show that signals captured by one panel (e.g. imputed sequence-level SNP data) can be missed by a lower density panel. The residual regression approach can also provide insights into the effect of shrinkage on signal leakage.

Materials & methods

Data sets. A total of 28,156 pigs from a single line with genotypes and phenotype records for average daily gain (ADG) were considered in this study. Phenotypes were pre-corrected for contemporary group and random litter effects. Pedigree information for 42,946 pigs was available for models that use this type of data. This study used a medium density (MD) SNP panel and an ultra-high density (UHD) SNP panel. The MD panel included 41,205 SNPs from a commercial marker array (GeneSeek, Lincoln, NE, USA) after quality control and imputation. The UHD panel was based on sequence-level SNP calling. A subset of the full population was sequenced for different depth levels. Variants called were then imputed for the remaining population that was genotyped for MD panels. Details of this approach are described by Ros Freixedes *et al.* (2020). The UHD panel contained ~18M SNPs after filters.
