Table of contents

Section editors 4
Table of contents 5

Part 1 – Plenaries **52**

1. Measure, predict and act; a paradigm of genetics applied to livestock production now and into the future 53
M.P.L. Calus, D.P. Berry and J.E. Pryce

2. Genetics of quantitative traits in natural populations: lessons from long term studies of wild animals 57
J.M. Pemberton

3. Discoveries and lessons from a genome-wide association study of human height in >5 million individuals 61
L. Yengo on behalf of GIANT Consortium (the height working group)

Part 2 – Young scientist career development **65**

4. History and author analysis of the World Congresses on Genetics Applied to Livestock Production 66
A.L. Van Eenennaam and S. Hermesch

5. What industry needs from an animal breeding graduate 70
T.J. Byrne, P.F. Fennessy and P.R. Amer

6. Young scientist career development: a global discussion on challenges, opportunities and solutions 72
J.E. Newton, M. Gòdia, B. Raymond and M.H.O. Toledo-Alvarado

Part 3 – Education **76**

7. Digital learning in postsecondary education: 30 transformational years 77
J.J. Lindburg

8. A panel discussion: broadening learning by incorporating industry professionals in education 80
J.B. Cole, R.A. Mrode, K.M. Olson and P. Knap

9. Conducting a national beef cattle genetics outreach program in the USA 82
K.D. Bullock, M.L. Spangler, R.L. Weaber, T.N. Rowan, M.M. Rolf, J.E. Decker, D.D. Loy, B.L. Golden, J.J. White and A.L. Van Eenennaam

10. Breeding Lab: a successful industry-academia collaboration to provide MSc consultancy training 86
J. Komen, J.A.M. van Arendonk and D.E. Lont

11. How a group of Merino breeders increased the rate of genetic gain by 134% in five years! 90
T. Granleese, J.H.J. van der Werf and S.J. Martin

12. YouTube applied to the education of genetics and genomics 94
G. Mészáros

13. Creating a good learning and sharing environment for bioinformatics 98
T. Klingström and J.I. Ohlsson

14. European master in animal breeding and genetics (EMABG): A training for research, practical, and transversal skills 102
G. Mészáros, P. Berg, T. Heams, H. Komen, D. Lont, H. Simianer, J. Sölkner, E. Strandberg and J. Tetens

Part 4 – Society – genetic solutions to achieve net zero carbon emission in livestock systems **106**

15. Strategies to mitigate greenhouse gas emissions from pasture-based sheep systems – an EU project consortium view 107
J. Conington, N. Lambe, F. Tortereau, F. McGovern, E. Navajas, I. De Barbieri, G. Ciappesoni, J. Jakobsen, E. Smith, J. Yates, Q. Le Graverand, K. McDermott, G. Steinheim, B. Aspeholen Aby, I. Dønnem, N. McHugh, L. Farrell, C. Marie-Etancelin, P. Johnson and S. Rowe

16. Comparing measurements of product output when defining emissions intensity 111
C.M. Richardson, F. Hely, M. Post, T.T.T. Nguyen, G.J. Nieuwhof and P.R. Amer

17. The genetic progress has effect on greenhouse gas emission intensities from Norwegian pork production 115
E. Gjerlaug Enger, H. Bonesmo, K. Martinsen, I. Andersen-Ranberg, D. Olsen and E. Grindflek

18. An approach to the genetic parameters of methane emission in Latxa dairy sheep 119
C. Pineda-Quiroga, I. Granado-Tajada, E. Ugarte, I. Goiri and A. García-Rodríguez

19. Ameliorating the contribution of livestock to global greenhouse gas production: dream or deliverable? 123
R. Hegarty, J.C. McEwan and S.J. Rowe

20. Genetically more efficient Australian dairy cows and sheep are higher emitters of methane per unit of food 127
B.J. Sepulveda, S.K. Muir, S. Bolormaa, I.M. MacLeod, M.I. Knight, R. Behrendt, L.C. Marett, M.H. Deighton, J.B. Garner, P.J. Moate, W.J. Wales, R.O. Williams, H.D. Daetwyler, B.G. Cocks and J.E. Pryce

21. The role of livestock genetics in addressing national GHG mitigation requirements 131
A.R. Cromie, D.P. Berry, L. Shalloo, T. Kirk and J. Crowley

22. Can genomics cope with a 30% reduction of methane emission from livestock in 10 years? 135
O. González-Recio, J. López-Paredes, A. Saborío-Montero, A. López-García, M. Gutiérrez-Rivas, I. Goiri, R. Atxaerandio, E. Ugarte, N. Charfeddine, J.A. Jiménez-Montero and A. García-Rodríguez

23. Low carbon emissions in future pig production – does a new breeding goal matter? 139
S. Zira, H.F. Olsen and L. Rydhmer

24. Individual animal carbon footprints in a national beef database: AniPrint 1.0 143
J.J. Crowley, L. Shalloo, R.D. Evans, J. Herron, P. Crosson, D.P. Berry, P. Owens and A.R. Cromie

Part 5 – Novel traits: environment and greenhouse gas 147

25. Can ruminal microbial information help improve selection for low-methane emitting dairy cows? 148
L. Zetouni, S. Roques, S.K. Kar, Y. de Haas, D. Schokker and M. Aldridge

26. Phenotypic differences and genetic parameters for methane concentration in BeefxDairy crossbred slaughter calves 152
K. Johansen, M. Kargo, M. Bjerring, P. Løvendahl and A.J. Buitenhuis

27. Genome-wide association study for mid-infrared methane predictions in Walloon dairy cows 156
H. Atashi, H. Wilmot, S. Vanderick, X. Hubin, H. Soyeurt and N. Gengler

28. Genetic parameters for feed efficiency, gas emissions, oxygen consumption and wool traits in Australian Merino 160
C.B. Marques, I. De Barbieri, J. Velazco, E.A. Navajas and G. Ciappesoni

29. Genetic selection of feed efficiency and methane emissions in sheep and cattle in Uruguay: progress and limitations 164
E.A. Navajas, O. Ravagnolo, I. De Barbieri, M.I. Pravia, I. Aguilar, M.O. Lema, B. Vera, P. Peraza, C.B. Marques, J.I. Velazco and G. Ciappesoni

30. Breeding for lowered methane emissions using rumen microbial profiles in sheep 168
T.P. Bilton, R. Jordan, M.K. Hess, S.M. Hickey, N. Amyes, P. Johnson, H. Henry, H. Baird, T. van Stijn, B. Veenvliet, W. Bain, G. Pile, T. Watson, E. Sandoval, J. Peers-Adams, B. Bryson, A.S. Hess, K.G. Dodds, J.C. McEwan and S.J. Rowe

31. Do we estimate dairy cows' methane production precisely enough? 172
M. Pszczola and T. Strabel

32. Heritability of methane emission in Norwegian Red cows based on measures from GreenFeed in commercial herds 176
K.B. Wethal, G.F. Difford, K. Winnberg, E. Norberg and B. Heringstad

33. Heritability and genetic correlations of enteric methane emissions of dairy cows measured by sniffers and GreenFeed 179
A.E. van Breukelen, M.N. Aldridge, R.F. Veerkamp, L. Koning, L.B. Sebek and Y. de Haas

34. Methane emission has low genetic correlations to lamb growth traits in Norwegian White sheep 183
J.H. Jakobsen, T. Blichfeldt, L.-B. Linneflaatten, M.O. Gløersen, L.E. Wallin and J.C. McEwan

35. Life cycle assessment to predict individual environmental impacts: towards selection for sustainable pig production 187
T. Soleimani, S. Hermesch and H. Gilbert

36. Genetic parameters for growth, feed intake and greenhouse gasses emissions in Italian Holstein-Friesian bulls 191
F. Tiezzi, R. Finocchiaro, L. Benzoni, J.B.C.H.M. van Kaam, M. Marusi, R. Bozzi and M. Cassandro

37. Association of genetic resistance to internal nematodes and production traits on feed efficiency and methane emissions in Corriedale lambs 195
E.A. Navajas, G. Ciappesoni, D. Gimeno, J.I. Velazco and I. De Barbieri

38. Rumen microbiota and host gene expression associate to predisposed milk urea concentration in Holsteins 199
H. Honerlagen, H. Reyer, D. Segelke, M. Oster, S. Ponsuksili, N. Trakooljul, B. Kuhla and K. Wimmers

39. Predicting nitrogen use efficiency of individual dairy cows by mid-infrared spectra 203
R. Shi, W. Lou, B. Ducro, A. van der Linden, H.A. Mulder, S.J. Oosting, S. Li and Y. Wang

40. Clearing the air between methane and commercial beef cattle in Ireland 207
C.V. Ryan, S.F. Kirwan, J.J. Crowley, D.C. Purfield, T. Pabiou and R.D. Evans

41. The impact of selection for divergence in methane emissions on alimentary tract measures of eight-month-old sheep 211
K.M. McRae, S.M. Hickey, G.J. Greer, B. Bryson, K.J. Knowler, W.E. Bain, S.N. Elmes, E.A. Young, J. Wing, E. Waller, J.C. McEwan and S.J. Rowe

42. Economic values for climate change responsive traits to develop a sustainable dairy cattle breeding goal in the tropics 215
C.K. Chepsiror, E.D. Ilatsia and T.O. Okeno

43. Phenotypic and genetic trends in American Angus associated with climate variability 219
G. Rovere, B.C.D. Cuyabano, B. Makanjuola, S. Kelly and C. Gondro

44. Genetic variation in resilience to climate effects on beef carcass traits 223
H. Bunning and E. Wall

45. Genetic parameters for rumination time and traits related to sustainable dairy production 227
L.S.F. Lopes, K. Houlahan, L. Alcantara, G.A. Oliveira Jr., D. Tulpan, F. Miglior, F.S. Schenkel and C.F. Baes

46. Genotype by temperature-humidity index interactions on milk production and udder health traits in the Montbeliarde cows 231
A. Vinet, S. Mattalia, R. Vallée, C. Bertrand, P. Bertuzzi, B.C.D. Cuyabano and D. Boichard

Part 6 – Challenges – resource allocation and genetics of feed intake and efficiency 235

47. Modelling multiplicativity in feed efficiency by regression on expected feed intake 236
M.H. Lidauer, E. Negussie, T. Mehtiö, P. Mäntysaari, T. Kokkonen and E.A. Mäntysaari

48. Alternative models to predict residual feed intake in Hereford breed and effects on their breeding values accuracy 240
M.I. Pravia, E.A. Navajas, I. Aguilar and O. Ravagnolo

49. Feed intake can be predicted as quantitative or qualitative traits 244
F. Tortereau, C. Marie-Etancelin, D. Marcon and J.L Weisbecker

50. Prediction of breeding values for feed intake in pigs using individual versus group records along with correlated traits 248
C. Zhang, R.A. Kemp, J.C.M. Dekkers, G.S. Plastow and H. Gao

51. Phenotypic and genetic associations between feed efficiency and FTIR milk-spectra 252
H.O. Toledo-Alvarado, R.J. Tempelman, M. Lopez-Cruz, M.J. VandeHaar, J.E.P. Santos, F. Peñagaricano, P. Khanal and G. de los Campos

52. Genetic relationships between weight loss in early lactation and daily milk production until 305 days in Holstein cows 256
T. Tribout, S. Minéry, R. Vallée, S. Saille, D. Saunier, V. Ducrocq, P. Faverdin and D. Boichard

53. Influence of body condition score genomic index on performance trajectories over the lactation period in Holstein cows 260
R. Lefebvre, P. Faverdin, S. Barbey, J. Jurquet, T. Tribout, D. Boichard and P. Martin

54. Feed efficiency and resource allocation trade-offs: theory, evidence and prospects 264
F. Douhard, R. Rupp and H. Gilbert

55. Mechanistic-based prediction of selection response on resilience and feed efficiency traits in dairy cattle 268
A. Bouquet, M. Slagboom, J. Thomasen, N.C. Friggens, M. Kargo and L. Puillet

56. Towards the characterisation of animal robustness by dynamic energy allocation indicators in fattening pigs 272
G. Lenoir, R. Muñoz-Tamayo, L. Flatres-Grall, I. David and N.C. Friggens

57. Milk metabolite profiles in goats selected for longevity support link between resource allocation and resilience 276
M. Ithurbide, H. Wang, C. Huau, I. Palhière, T. Fassier, J. Pires, T. Larsen, J. Cao, N.C. Friggens and R. Rupp

58. Lifetime feed efficiency and deep phenotypes from scarce feed intake records using the mechanistic LiGAPS-Dairy model 280
A. van der Linden, G.C.B. Schopen, B. Gredler-Grandl, G. de Jong, M. Sol, S. van der Beek and R.F. Veerkamp

59. Genetic analysis of feed efficiency in Atlantic salmon 284
A.K. Sonesson, B. Hatlen, B. Gjerde, G.F. Difford, P. Brunsvik, T.H.E. Meuwissen and A. Norris

60. Validation and genetic analysis of a feed efficiency criterion in French Lacaune ewes 288
C. Machefert, C. Robert-Granié, P. Hassoun, S. Parisot, C. Allain, D. Portes, G. Lagriffoul, J.M Astruc, and H. Larroque

61. Gene co-expression networks contributing to variation in residual feed intake in bovine hepatic tissue 292
K. Keogh, M. McGee and D.A. Kenny

62. Genetics parameters of feed efficiency in dairy goats, under commercial conditions 296
M. Chassier, F. Mosnier, R. Rupp, B. Bluet, A. Bailly-Salins and I. Palhière

63. Genetic analysis of predicted dry matter intake and gross feed efficiency in South African Holstein cows 300
M.A. Madilindi, O.T. Zishiri, B. Dube and C.B. Banga

64. Single-step genomic prediction for metabolic body weight of Nordic Red dairy cattle 304
R.M. Kempe, T. Mehtiö, A.-M. Leino, M. Koivula, T. Pitkänen, R.B. Stephansen, E.A. Mäntysaari, E. Negussie, J. Pösö, U.S. Nielsen, W.F. Fikse, G.P. Aamand and M.H. Lidauer

65. Application of imputed data and single-step GBLUP in the study of residual feed intake trait of Nellore cattle 308
J.A.II.V. Silva, M.H.V. Oliveira, A.M. Castilhos, A.M. Toro-Ospina, H. Srihi and L. Varona

66. Relationship between proxies of energy states and nitrogen use efficiency for Holstein cows in early lactation 312
Y. Chen, C. Grelet, S. Vanderick, H. Hu and N. Gengler

67. Genetic variation exists in nitrogen use efficiency for lactating cows in grass-grazed dairy systems 316
E. Tavernier, I.C. Gormley, L. Delaby, S. McParland, M. O'Donovan and D.P. Berry

68. Study of the causal relationship between the rabbit cecal microbiota and host's growth and feed efficiency 320
M. Piles, M. Mora, J.P. Sánchez, Y. Ramayo-Caldas, O. González-Rodríguez and M. Velasco-Galilea

69. Part of the functional rumen core microbiome is influenced by the bovine host genome and associated with feed efficiency 324
M. Martínez-Álvaro, J. Mattock, Z. Weng, R.J. Dewhurst, M.A. Cleveland, M. Watson and R. Roehe

70. Identifying diversity in cattle performance using Bayesian inference and a model 328
J.F. Ramirez, L. Puillet and N.C. Friggens

71. Feed efficiency of crossbreds of Montbéliarde, Viking Red, and Holstein with Holstein cows fed two alternative diets 332
B.J. Heins, G.M. Pereira and L.B. Hansen

72. Genetic and phenotypic associations among production, feed efficiency and immune traits in indigenous chicken of Kenya 336
S.A. Miyumo, C.B. Wasike, E.D. Ilatsia, J. Bennewitz and M.G.G. Chagunda

73. Novel genetic parameters to improve gRFI in dairy cattle using big data from multiple lactations and countries 340
R.B. Stephansen, P. Martin, B. Gredler-Grandl, C.I.V. Manzanilla Pech, G. Sahana, V. Ducrocq, C. Baes, F. Schenkel, R.F. Veerkamp and J. Lassen

74. Genetic parameters of feeding behaviour traits in parental lines of a mule duck 344
H. Chapuis, M. Lague and H. Gilbert

75. Estimates of genetic parameters for feeding behavior traits and its association with feed efficiency in Holstein cows 348
L. Cavani, W.E. Brown, K.L. Parker Gaddis, R.J. Tempelman, M.J. VandeHaar, H.M. White, F. Peñagaricano and K.A. Weigel

76. Protein efficiency is heritable but not genetically correlated with meat quality in pigs 352
E.O. Ewaoluwagbemiga, G. Bee and C. Kasper

77. Genetic analysis of digestibility traits in pigs measured by near-infrared spectroscopy 356
K.H. Martinsen, E.G. Enger, E. Grindflek, N.K. Afseth, L.T. Mydland, S. Wallen and T.H.E. Meuwissen

Part 7 – Society – contributions animal breeding to animal welfare 360

78. Genetic analysis of number of functional teats, piglet survival, and piglet weight in organic pigs 361
R.M. Zaalberg, T.T. Chu, J. Jensen and T.M. Villumsen

79. Genetic analysis of feeding behaviour and tail lesions 365
K.H. Martinsen, Ø. Nordbø, E.G. Enger, D. Olsen and E. Grindflek

80. Response to selection for social dominance including direct and indirect genetic effects 369
B. Tuliozi, E. Mancin, G. Gomez Proto, R. Mantovani and C. Sartori

81. Empowerment of the Italian small ruminant sector: new traits and tools toward a sustainable management 373
A. Negro, M. Cortellari, A. Bionda, S. Grande, A. Cesarani, A. Carta, N. Macciotta, S. Biffani and P. Crepaldi

82. How can breeding for improved animal welfare meet societal expectations and challenges? 376
A. Wallenbeck

83. Swine inflammation and necrosis syndrome (SINS) and its association with biting behavior after weaning 380
N.L. Leite, E.F. Knol, S. Nuphaus, S. Tsuruta, R. Vogelzang and D. Lourenco

84. Breeding for future social license for beef production 384
S.P. Miller and K.J. Retallick

85. Selection for piglet mortality and litter size in outdoor organic pig production systems 388
T.T. Chu, R.M. Zaalberg, J. Jensen and T.M. Villumsen

86. Heritability of daily activity over time in broilers 393
E.D. Ellen, M. van der Sluis, B. de Klerk, J. Henshall, Y. de Haas, T.B. Rodenburg and P. Bijma

Part 8 – Novel traits: health and well-being **397**

87. Resilience indicators based on individual feed intake from a high-health swine nucleus 398
C.D. Bierman, R.A. Kemp and J.C.M. Dekkers

88. Comparison of milk yield based resilience indicators across dairy cattle breeds 402
G. Bonekamp, M. Poppe, J. ten Napel, C. Kamphuis, Y. de Haas and I. Adriaens

89. Genotype-by-environment interactions for health traits across productivity level or health status of herds in Normande 406
S. Aguerre, A. Vinet and S. Mattalia

90. In search of a new tool for phenotyping tick resistance in cattle 410
O. Matika, S. Foster, N. Githaka, C. Mwendia, H. Brown, K. Watson, A. Djikeng and M. Birkett

91. Lameness in genomic evaluation for foot and claw disorders in Czech Holstein cows 414
L. Zavadilová, E. Kašná and Z. Krupová

92. The lasting effect of udder inflammation on milk lactose content in dairy cows 418
A. Costa, H. Bovenhuis, C. Egger-Danner, B. Fuerst-Waltl and M. Penasa

93. Estimation of genetic parameters for milk-related traits derived from automatic milking systems in Holstein cattle 422
L.S. Gloria, J.P. Boerman, V.B. Pedrosa, S.Y. Chen, M.E. Montes Gonzalez, J.S. Doucette and L.F. Brito

94. Identification of genome regions and promising candidate genes linked to innate immune capacity on young Holstein calves 426
P. Martin, S. Fresco, L. Jouneau, S. Taussat, A. Vinet, R. Lefebvre, D. Descamps, C. Ferret, C. Chottin, V. Pietralunga, T. Pezier, S. Lacroix-Lamandé, M. Boussaha, S. Barbey, V. Denizot, D. Boichard, S. Riffault and F. Laurent

95. Assessment of miRNAs in plasma and leucocytes as potential biomarkers for rumen health in cows fed forage and high-grain diets 430
O.E. Ojo, C. Pacífico, S. Johanns, S. Ricci, R. Rivera-Chacon, A. Sener-Aydemir, E. Castillo-Lopez, N. Reisinger, Q. Zebeli and S. Kreuzer-Redmer

96. Variance component estimation of longitudinal alpha diversity metrics of the ocular microbiome in preweaned beef cattle 434
A.D. Lakamp, A.C. Neujahr, M.M. Hille, J.D. Loy, S.C. Fernando and M.L. Spangler

97. Gene expression patterns observed from the skin of selected cattle breeds infested with *Amblyomma hebraeum* ticks 438
M. Letuka, D. Wragg, A. Bester-van der Merwe, K. Dzama, L.T. Nesengani, O. Matika, B. Dube and N.O. Mapholi

98. Combined effect of genetics and gut microbiota on variations in vaccine response in hens 442
A. Lecoeur, F. Blanc, D. Gourichon, N. Bruneau, T. Burlot, F. Calenge and M.H. Pinard-van der Laan

99. Resilience indicators based on daily milk yield data for genetic selection in dairy cattle 446
M. Poppe, H.A. Mulder, H. Hogeveen, C. Kamphuis, G. Bonekamp, M.L. van Pelt, E. Mullaart and R.F. Veerkamp

100. Genetic evaluation of heat tolerance in Italian Holstein breed 450
R. Finocchiaro, F. Galluzzo, J.B.C.H.M van Kaam, M. Marusi and M. Cassandro

101. Inferring genetic parameters for prenatal heat stress effects on calf diseases and cow productivity 454
T. Yin, K. Halli, S.F. Vanvanhossou, M. Bohlouli and S. König

102. A genetic evaluation for calf health: preliminary analysis 458
C. Lynch, F. S. Schenkel, K. Houlahan, N. van Staaveren, F. Miglior and C.F. Baes

103. Development of a single step genomic evaluation of health traits and relationships with dairy traits in French Holsteins 462
H. Leclerc, A. Barbat, R. Vallée, F. Guillaume, L. Manciaux, J.-B. Davière and M. Philippe

104. Genetic selection for reduced susceptibility to subclinical ketosis using mid-infrared predicted traits 466
A. Köck, L.M. Dale, A. Werner, M. Mayerhofer, F.J. Auer and C. Egger-Danner

105. Heritability of scurs in Wagyu and tropically adapted composite beef cattle 470
G. Moser and M.J. Kelly

106. Genetic parameters for social hierarchy of Nellore cattle using data from electronic feeding system 474
J.P.S. Valente, M. Deniz, K.T. de Sousa, R.C. Canesin, S.F.M. Bonilha, M.E.Z. Mercadante and L.T. Dias

107. Pigs' weighing order stability is favourably linked with tail biting and production: a new proxy for social structure? 478
W. Gorssen, R. Meyermans, S. Janssens and N. Buys

108. Application of machine learning algorithms to develop behavioural and stress phenotypes for sheep 482
H. Keshavarzi, D.L.M. Campbell and C. Lee

109. Heritability of social interactions in dairy cattle 486
L. Rönnegård, I. Hansson and W.F. Fikse

110. Uncertainty about the social network among dairy cows impairs estimation of indirect genetic effects 490
W.F. Fikse, I. Hansson and L. Rönnegård

111. Genetic and phenotypic variation and consistency of cow's preference and circadian use of robotic milking units 493
P. Løvendahl and A.J. Buitenhuis

112. Genetic and environmental influences on maternal calving difficulty in South African Holstein cattle 497
N.E. Mkhize, N.O. Mapholi, B. Dube, M.A. Madilindi, O. Matika and C.B. Banga

113. Genetic evaluation of gestation length in Italian Holstein breed 500
F. Galluzzo, J.B.C.H.M. van Kaam, R. Finocchiaro, V. Ferrari, M. Marusi and M. Cassandro

114. Genetic evaluation of cystic ovarian disease in Czech Holstein cattle 504
E. Kašná, L. Zavadilová and Z. Krupová

115. Entropy of broiler activity: individual variation and consistency 508
M. van der Sluis, L. Asher, T.B. Rodenburg, Y. de Haas, B. de Klerk and E.D. Ellen

116. Laying hens tweet: they also lead and follow – implications for genetic selection against gregarious nesting 512
L. Bécot, N. Bédère, T. Burlot and P. Le Roy

117. Analysis of social behaviors in large groups: simulation and genetic evaluation 516
Z. Wang, H.P. Doekes and P. Bijma

118. Divergent genetic selections for social attractiveness or tolerance toward humans in sheep 520
D. Hazard, E. Delval, S. Douls, C. Durand, G. Bonnafe, D. Foulquié, D. Marcon, C. Allain, S. Parisot and A. Boissy

119. Genetic parameters of novel behaviour traits derived from social network analysis in pigs 524
S. Agha, S. Foister, R. Roehe, S.P. Turner and A. Doeschl-Wilson

120. Genetic parameter estimation of various body temperature and respiration rate indicators in maternal-line pigs under heat stress conditions 528
H. Wen, J.S. Johnson, P.H.F. Freitas, J.M. Maskal, M.K. Byrd, F. Tiezzi, Y. Huang, A.P. Schinckel and L.F. Brito

121. Genetics of body weight and length of Large White piglets and relationship to maternal performance 532
L. Canario, Y. Billon, W. Hébrard and J. Demars

Part 9 – Novel phenotyping tools: machine learning **536**

122. Automated individual walking distance of group-housed broilers: a comparison between ground-truth, RFID, and video 537
J.E. Doornweerd, I. Fodor, G. Kootstra, R.F. Veerkamp, B. de Klerk, M. van der Sluis, A.C. Bouwman and E.D. Ellen

123. Automated processing and phenotype extraction of ovine medical images using deep learning and computer vision 541
J.F. Robson, S.J. Denholm and M. Coffey

124. VTag: automatic pipeline to annotate video data for pig phenomics studies 545
C.J. Chen, G. Morota and H. Cheng

125. Milk spectra selection for equations development to predict milk technological traits 549
M. Frizzarin, I.C. Gormley, A. Casa and S. McParland

126. Using supervised machine learning for honey harvest prediction 553
J. Ramirez-Diaz, A. Manunza, T.A. De Oliveira, T. Bobbo, V. Silva, P. Cozzi, S. Biffani, A. Stella and G. Minozzi

127. Validation of computer vision algorithms for classifying video segments applied to behavioural phenotyping of pigs 557
J.P. Steibel, J. Han, C. Chen, J. Siegford, T. Norton and D. Colbry

128. Automated estimation of pose features in broilers using computer vision 561
I. Fodor, J.E. Doornweerd, B. de Klerk and A.C. Bouwman

129. Predicting carcass cut yields in cattle from digital images using artificial intelligence 565
D. Matthews, T. Pabiou, R.D. Evans, C. Beder and A. Daly

130. Digital phenotyping to improve Atlantic salmon feed efficiency and welfare 569
G.F. Difford, S.K. Lindberg, K. Heia, B. Hatlen, E. Durland, B. Gjerde, R. Alvestad, V. Mota, C. Noble, A. Norris, S. Boison, N.K. Afseth, J.P. Wold and A.K. Sonesson

131. Prediction of roughage intake of dairy cows combining milk mid-infrared spectra and cow variables by deep learning 573
G.T. Gebregiwergis, N.K. Afseth, A. Kidane, E. Prestløkken and T.H.E Meuwissen

132. CFIT – Cattle Feed InTake – a 3D camera based system to measure individual feed intake and predict body weight in commercial farms 577
J. Lassen, J.R. Thomasen and S. Borchersen

133. Video-based analysis of dairy cow behaviour: detection of lying down and standing up 581
I. Adriaens, W. Ouweltjes, I. Hulsegge and C. Kamphuis

134. Image-based cattle conformation prediction using deep learning methods 586
D. Segelke, H. Alkhoder and J. Wabbersen

135. Prediction fat percentage and visceral weight from whole fish images with a multi-input neural network 590
Y. Xue, J.W.M. Bastiaansen and H. Komen

136. A case-control GWAS for the chicken plumage colour using a computer vision approach 594
S. Heo, S. Cho, J. Park, M. Kim, E. Cho, D. Jin, J. Cha, Y.J. Koh and J.H. Lee

137. Machine learning to predict somatic cell count at the subsequent test-day record in the Italian Mediterranean Buffaloes 598
T. Bobbo, R. Matera, G. Pedota, J. Ramirez-Diaz, A. Manunza, A. Stella, A. Cotticelli, G. Neglia and S. Biffani

138. Computer vision systems to advance high-throughput phenotyping in livestock 602
J.R.R. Dorea and G.J.M. Rosa

139. Tracking multiple cows simultaneously in barns using computer vision and deep learning 606
C. Kamphuis, I. Adriaens, W. Ouweltjes and I. Hulsegge

140. A computer vision system for individual tracking of group housed rabbits 610
J.P. Sánchez, I. Muñoz, O. González, M. Pascual, O. Perucho, P. Alsina and M. Piles

141. Clustering of Meishan and Large White sows for activity defined from image analysis, and influence on piglet mortality 614
O. Girardie, M. Bonneau, Y. Billon, J. Bailly, I. David, L. Canario

142. Using machine learning to predict feed intakes of meat sheep from animal traits and ruminal microbiota618
Q. Le Graverand, C. Marie-Etancelin, J.L. Weisbecker, A. Meynadier, D. Marcon and F. Tortereau

143. The magic of predicting shapes from DNA 622
M. Pérez-Enciso and L.M. Zingaretti

Part 10 – Novel phenotyping tools: sensor devices 626

144. Estimates of genetic parameters for milkability traits derived from automatic milking systems in North American Holstein cattle 627
V.B. Pedrosa, J.P. Boerman, L.S. Gloria, S.Y. Chen, M.E.M. Gonzalez, J.S. Doucette and L.F. Brito

145. Classifying the likelihood of conception in dairy cow with milk mid-infrared spectra before the first insemination 631
W. Lou, R. Shi, B. Ducro, A. van der Linden, H.A. Mulder, S.J. Oosting, L. Liu and Y. Wang

146. Use of tracking technology for phenotyping laying hens within cage-free housing 635
C.M. Montalcini, M.B. Petelle, S.G. Gebhardt-Henrich and M.J. Toscano

147. Learning behaviour of dairy cows in automated milking systems: genetic parameters and suggested candidate genes 639
R. Schafberg, F. Rosner, D. Oelschlägel and H.H. Swalve

148. Repeatability estimates of grazing and rumination activity of Merino sheep measured using wearable sensors 643
F. Almasi, M. Khansefid, H. Nguyen, A. Desai, J.E. Pryce and M. Stear

149. Deep data recording for developing resilience traits in Swiss cattle populations: a proof of concept and an application 647
B. Bapst, P. von Rohr and F.R. Seefried

150. Test-day genetic evaluations: a tool to measure herd resilience through monthly milk records 651
S. Mattalia, M. Rocland, S. Aguerre and M. Poppe

151. Genomic selection of postpartum anoestrus recorded with accelerometer collars to improve beef cattle fertility 655
E. Fontanillas, V. Prieur, A. Michenet, G. Auvray and J. Mante

152. Developing precision livestock farming in practice: using sensor time series data for breeding decision support systems 659
J.M.E. Statham, K.L. Burton, I. Adriaens, I. Lora, G. Cozzi, Y. de Haas, C. Kamphuis, L. Vedder, B. Loke and N.C. Friggens

Part 11 – Challenges – genetic control of infectious disease transmission and impact 663

153. Molecular mechanisms involved with influenza A nanovaccine immunogenicity in pigs 664
A.M.G. Ibelli, J.O. Peixoto, L.T. Fernandes, V. Haach, D. Gava, A.P. Bastos, F.N. Fonseca, M A.Z. Morés, M.E. Cantão, R. Schaefer and M.C. Ledur

154. Host variation in susceptibility to lumpy skin disease: gene expression analyses of experimentally infected cows 668
S. Van Borm, T. Klingström, A. Niazi, K. De Clercq, L. Mostin, A. Haegeman and D.J. de Koning

155. Relationship between resistance to a *Pasteurella multocida* experimental infection and production traits in rabbits 672
H. Garreau, F. Lantier, B. Bed'hom, E. Guitton, V. Helies, E. Helloin, C. Herbert, M. Maupin, R. Robert and M. Gunia

156. Quantification of environmental management systems for U.S. Katahdin sheep producers 676
B.C. Arisman, J.M. Burke, J.L.M. Morgan and R.M. Lewis

157. Bias and heritability of the autocorrelation based on longitudinal data used as resilience indicator 680
H.A. Mulder

158. The possibilities of estimating relationships between traits with and without micro-genetic environmental sensitivity 684
M.D. Madsen, J.H.J. van der Werf and S. Clark

159. Selective breeding for survival to *Vibrio harveyi* in European seabass (*Dicentrarchus labrax*) is robust to different feeding environments 688
M. Besson, R. Morvezen, A. Bestin, Y. François, A. Bajek, J. Brunier, T. Morin, M. Vandeputte, M. Dupont-Nivet, M. Izquierdo, D. Barkas and P. Haffray

160. Can we prevent pathogen adaptation when breeding disease resistant livestock? 692
A.D. Hulst, P. Bijma and M.C.M. De Jong

161. Indicators of disease resilience from complete blood count and *in vitro* immunoassays data from young-healthy pigs 696
X. Bai, J. Cheng, F. Fortin, J.C.S. Harding, M.K. Dyck, J.C.M. Dekkers, C.J. Field, C. Rogel-Gaillard, F. Blanc and G.S. Plastow

162. Evidence of naturally occurring genetic variation in host response to challenge with a highly pathogenic PRRSV strain 700
J.R. Dunkelberger, P.K. Mathur, E. Little, D. Hanson, S. Dee and E.F. Knol

163. A quantitative genetic theory for infectious diseases 704
P. Bijma, A.D. Hulst and M.C.M. de Jong

164. Breeding for general disease resistance: a selection experiment in rabbits 708
M. Gunia, J. Ruesche, P. Aymard, E. Gillet, C. Herbert, V. Helies, D. Savietto, R. Robert, L. Warin, H. Gilbert and H. Garreau

165. A single step genetic evaluation including causal candidate SNPs for resistance to paratuberculosis in Holstein cattle 712
M.P. Sanchez, T. Tribout, S. Fritz, R. Guatteo, C. Fourichon, L. Schibler, A. Delafosse and D. Boichard

166. Genetic parameters and QTL mapping for antibody response to paratuberculosis in a natural infected flock of sheep 716
M.G. Usai, S. Casu, T. Sechi, M.G. Cancedda, D. Pintus, S. Salaris, G. Mulas and A. Carta

167. The genetic basis of sex differences in immune responses in wild Soay sheep (*Ovis aries*) 720
E.A. Wimborne, A.M. Sparks, K. Watt, R. Sinclair, J.G. Pilkington, J.M. Pemberton, T.N. McNeilly, D.H. Nussey and S.E. Johnston

168. New tools and insights to enable breeding for reduced disease transmission 724
A. Doeschl-Wilson, G. Marion and C.M. Pooley

169. Transmission experiment in turbot shows high genetic variation in host infectivity affecting disease spread and survival 728
J.C. Prentice, C.M. Pooley, S. Tsairidou, R. Pong Wong, O. Anacleto, M. Saura, R.I. Bailey, G. Marion, B. Villanueva and A.B. Doeschl-Wilson

170. Impact of selection for disease resistance on the spread of infection in a simulated aquaculture population 732
S. García-Ballesteros, J. Fernández, A. Doeschl-Wilson and B. Villanueva

Part 12 – Challenges – across species and breed genomics genetics 736

171. Application of haplotype relationship matrices for genomic prediction in purebred and crossbred cows 737
M. Khansefid, M.H. Ferdosi, M.E. Goddard, M. Haile-Mariam, C. Schrooten, G. de Jong, E. O'Connor, H.D. Daetwyler, J.E. Pryce and I.M. MacLeod

172. *Bos taurus* and *Bos indicus* reduced representation bisulfite sequencing comparison showed high epigenetic variability in *Bos* subspecies 741
E. Capra, B. Lazzari, M. Milanesi, G.dP. Nogueira, J.F. Garcia, P. Ajmone Marsan and A. Stella

173. Evaluating the use of genotype information for the prediction of breed composition in purebred and crossbred cattle 745
C.A. Ryan, D.P. Berry, T. Pabiou and D.C. Purfield

174. Genomic prediction using breed origin of alleles model accounting for probabilities in the assignment of the alleles 749
A. Guillenea, G. Su, M.S. Lund and E. Karaman

175. Making the most of genetic relationships between Iberian dairy sheep breeds: exploring multi-breed genomic evaluation 753
I. Granado-Tajada, C. Pineda-Quiroga, E. Ugarte, M. Serrano, M.A. Jiménez, H. Marina, J.J. Arranz and M. Ramón

176. Online Mendelian Inheritance in Animals (OMIA) – future proofing of a globally used animal genetics knowledgebase 757
I. Tammen, M. Mather, Z. Li, J. Nothman, D.P. Vanichkina and F.W. Nicholas

177. Predicting the purebred-crossbred genetic correlation from phenotype and genotype data of parental lines in pigs 761
P. Duenk, Y.C.J. Wientjes, P. Bijma, M.S. Lopes and M.P.L. Calus

178. Multi-breed genomic predictions from commercial crossbred data 765
B.J Hayes, J. Copley, E. Dodd, E.M. Ross and G. Fordyce

179. Simultaneous mapping of quantitative trait loci in multiple subspecies using hybrid populations 769
C.L. Warburton, R.C. Costilla, B.N. Engle and B.J. Hayes

180. Strategies to find predictive variants that improve multi-breed genomic prediction in dairy cattle 773
I. van den Berg, R. Xiang, M. Khansefid, M.E. Goddard, J.E. Pryce, C.P. Prowse-Wilkins, A.J. Chamberlain and I.M. MacLeod

181. Impact of breed ancestry on the performance of crossbred dairy cattle 777
M.A. Jaafar,B.J. Heins, C. Dechow, C.P. Van Tassell and H.J. Huson

182. DNA pooling is a cost effective method of including commercial crossbred data in selection of purebreds 781
M.N. Aldridge, J. Marjanovic, J.M. Henshall, B. de Klerk, K. Peeters and Y. de Haas

Part 13 – Challenges – understanding and utilizing genetic diversity 785

183. Genetic variability in the individual inbreeding load: genomic prediction for artificial purging 786
L. Varona, D. López-Carbonell, H. Srihi, M. Ramírez, P. Martínez, M. Hermida, J. Altarriba and J. Casellas

184. Inbreeding depression in livestock: comparing trait groups and inbreeding measures 790
H.P. Doekes, P. Bijma and J.J. Windig

185. Global and local genome ancestry reveals signal of Merinization in Noire de Thibar sheep 794
I. Baazaoui, E. Ciani, S. Mastrangelo and S. Bedhiaf-Romdhani

186. Common heterozygosity-rich regions across the genomes of commercial and local goat breeds 798
F. Biscarini, A. Manunza, P. Cozzi and A. Stella

187. Markhor-derived introgression of *PAPSS2* confers high-altitude adaptability in Tibetan goats 802
C. Li, Y. Wu, B. Chen, Y. Cai, J. Guo, P. Kalds, Y. Chen, H. Pausch, J. Han, Y. Jiang and X. Wang

188. Patterns of inbreeding and selection using runs of homozygosity in North American dairy cattle 806
E.A. Lozada-Soto, F. Tiezzi, J.B. Cole, P.M. VanRaden and C. Maltecca

189. Exploring genetic diversity and selection signatures in indigenous African cattle breeds 810
J. Friedrich, R. Bailey, A. Talenti, K. Marshall, J. Prendergast and P. Wiener

190. Understanding and utilizing genetic diversity in Dual-Purpose Blue: genome-wide association for type traits 814
N. Gengler, H. Wilmot, S. Vanderick and H. Atashi

191. Genetic background of productive and adaptive features in the West African indigenous cattle breeds in Benin 818
S.F.U. Vanvanhossou, T. Yin, I.J. Giambra, K. Brügemann, L.H. Dossa and S. König

192. Genetic diversity and population structure of Slovenian local breed Drežnica goat 822
N. Pogorevc, M. Simčič, N. Khayatzadeh, J. Sölkner, B. Berger, D. Bojkovski, M. Zorc, P. Dovč, I. Medugorac and S. Horvat

193. Genetic architecture of a composite beef cattle population 826
E. Hay, S. Toghiani, A.J. Roberts, T. Paim, L.A. Kuehn and H.D. Blackburn

194. Variation in patterns of recombination result in genetic variation in intrachromosomal shuffling in the domestic pig 830
C. Brekke, S.E. Johnston, A.B. Gjuvsland and P. Berg

195. Identification of runs of homozygosity islands and functional analysis for Caqueteño Creole cattle 834
A.M. Toro-Ospina, J.A.II.V. Silva, G.P. Schettini, V.H. Vallejo and E.G. Ortiz

196. Candidate genes related to signatures of selection for body weight and harvest length in American mink 837
D.N. Do, K. Karimi, G. Hu and Y. Miar

197. Maintenance of genetic diversity in subdivided populations using different genomic coancestry matrices 841
E. Morales-González, B. Villanueva, M.Á. Toro and J. Fernández

198. Long-term changes in genetic mean and genic variance and underlying allele frequencies in breeding programmes 845
G.A. de Oliveira Junior, M. Spehar, F.S. Schenkel, C.F. Baes and G. Gorjanc

199. The long-term effects of genomic selection: allele frequency changes and fixation of loci 849
Y.C.J. Wientjes, P. Bijma, J. van den Heuvel, B.J. Zwaan, Z.G. Vitezica and M.P.L. Calus

200. The effect of recombination rate on genomic selection in simulation 853
M. Johnsson, A.M. Johansson, T. Klingström and E. Rius-Vilarrasa

201. Fine-scale study of meiotic recombination in cattle 857
C. Oget-Ebrad, G.C.M. Moreira, L. Karim, W. Coppieters, C. Charlier, M. Georges and T. Druet

202. Sex differences in recombination maps are associated with differential hotspot usage in sheep 861
H. Vassilief, M. Id Bella, D. Hazard, F. Tortereau, T. Faraut, S.E. Johnston and B. Servin

203. Is it possible to differentiate meat products of a local breed from those of its sister breed based on genotypes? 865
H. Wilmot, G. Glorieux, X. Hubin and N. Gengler

Part 14 – Genetic diversity and inbreeding 869

204. Assessing existing admixture in indigenous veld ecotypes and non-descript goat populations of Southern Africa 870
C. Visser and S.F. Lashmar

205. Estimation of sex chromosome inbreeding depression on milk production in cattle 874
I. Curik, H. Vostra-Vydrova, M. Shihabi, J. Sölkner and L. Vostry

206. Assessing genomic diversity and heterozygosity-rich regions of transboundary Nguni cattle of South Africa and eSwatini 878
E. van Marle-Köster, S.F. Lashmar, M. Okpeku, F.C. Muchadeyi, N.O. Mapholi and C. Visser

207. Infographics for management of inbreeding and kinship in small populations 882
M.A. Schoon, M. Neuteboom, S.J. Hiemstra, C. Danchin-Burge, J. Fernández and J.J. Windig

208. Y-chromosomal haplogroups from wild and domestic goats reveal ancient migrations and recent introgressions 886
J.A. Lenstra, VarGoats Consortium, I.J. Nijman, B.D. Rosen, P. Bardou, T. Faraut, T. Cumer, K.G. Daly, Z. Zheng, Y. Cai, H. Asadollahpour, B. Çınar Kul, W.-Y. Zhang, G. E, A. Ayin, M. Bakhtin, V.A. Bâlteanu, D. Barfield, H. Baird, B. Berger, T. Blichfeldt, G. Boink, S.R.A. Bugiwati, Z. Cai, S. Carolan, E. Clark, V. Cubric-Curik, M.I.A. Dagong, T. Dorji, L. Drew, J. Guo, J. Hallsson, S. Horvat, J. Kantanen, F. Kawaguchi, P. Kazymbet, N. Khayatzadeh, N. Kim, M. Kumar Shah, Y. Liao, A. Martínez, J.S. Masangkay, M. Masaoka, R. Mazza, J. McEwan, M. Milanesi, F. Md. Omar, Y. Nomura, N.-A. Ouchene-Khelifi, F. Pereira, G. Sahana, S. Sasazaki, A. Da Silva, M. Simčič, J. Sölkner, A. Sutherland, J. Tigchelaar, H. Zhang, Econogene Consortium, P. Ajmone-Marsan, D.G. Bradley, L. Colli, C. Drögemüller, C. Lei, H. Mannen, F. Pompanon, G. Tosser-Klopp and Y. Jiang

209. Characterization and effect of inbreeding on growth and reproductive traits in Nellore Cattle 890
L.F. Benfica, R.D. do Bem, E.R Carrara, L.F. Brito, D.A. Silva, R. Carvalheiro, J.N.S.G. Cyrillo and M.E.Z. Mercadante

210. Genomic diversity of Czech and Slovak native goat breeds 894
L. Vostry, H. Vostra-Vydrova, J. Rychtarova, B. Hofmanova, N. Moravcikova, R. Kasarda, M. Margetin, I. Drzaic, V. Cubric-Curik, J. Sölkner and I. Curik

211. Population structure of U.S. Holsteins allows for a snapshot of allele frequency changes and family specific SNPs 898
T.J. Lawlor, Y. Steyn, S. Tsuruta, Y. Masuda, D.A.L. Lourenco and I. Misztal

212. Genome-wide evaluation of runs of homozygosity in Indian Sahiwal cattle 902
S.K. Illa, S. Mumtaz, S. Mukherjee, S. Nath and A. Mukherjee

213. Following the hidden footsteps of past human migrations via the goat genome 906
A. Manunza, J. Ramirez Diaz, T. Bobbo, P. Cozzi, B. Lazzari, F. Biscarini, S. Biffani, A.M. Johansson, L. Grøva and A. Stella

214. Are autozygosity estimates from imputed genotypes reliable? 910
M. Ferenčaković, I. Curik, J.F. Garcia, J. Sölkner3 and R. Carvalheiro

215. Genetic diversity and population structure for resistance to mastitis in Braunvieh cattle 914
M.Z. Trujano-Chavez, R. Sánchez-Ramos, P. Pérez-Rodríguez and A. Ruíz-Flores

216. Evaluation of the Istrian cattle population structure by pedigree analysis 919
A. Ivanković, J. Ramljak, G. Šubara, M. Pećina, E. Šuran, Z. Ivkić and M. Konjačić

217. Population dynamics of a long-term selection experiment in chickens divergently selected for high or low body weight 923
S.J. Harrison, P.B. Siegel, C.F. Honaker and R.M. Lewis

218. Genetic management meets genomics 928
J.A. Woolliams and T.H.E. Meuwissen

219. Genetic characterization of the indigenous Sanga cattle of Namibia 932
D.A. Januarie, E.D. Cason and F.W.C. Neser

220. Hedging genetic diversity using a similarity matrix based on Mendelian sampling 936
A.A. Musa and N. Reinsch

221. Genetic basis of sexually divergent early life survival in red deer (*Cervus elaphus*) 940
L. Peters, J.M. Pemberton and S.E. Johnston

222. Changes in genomic inbreeding over half a century in Swedish Red and Swedish Holstein cattle 944
S. Eriksson, E. Strandberg and A.M. Johansson

223. Runs of homozygosity in Nguni and Bonsmara cattle populations 948
P. Soma, B.B. Kooverjee and M.M Scholtz

224. Estimation of old and new inbreeding and their effects on growth traits using pedigree and genomic information 952
P. Sumreddee, A. Ling, S. Toghiani, E.H. Hay, E. Hartono, S.E. Aggrey and R. Rekaya

225. Genome wide characterisation of runs of homozygosity on the main indigenous goat breed of Botswana 956
P.I. Monau, K. Raphaka and S.J. Nsoso

226. Candidate genes for disease, reproduction and meat quality traits in Portuguese native breeds 960
M.V.G.B. Silva, L.L. Verardo, M.A. Machado, J.C.C. Panetto, I. Carolino and N. Carolino

227. Runs of homozygosity harbour genes associated with muscle growth in Pietrain but not with fertility in Large White pigs 964
S.E. Palma-Vera, L. Derežanin, J. Fickel, H. Reyer, N. Reinsch, H. Henne and J. Schön

228. Analysis of runs of homozygosity of cattle living in different climate zones 968
L. Falchi, S. Mastrangelo, A. Cesarani, G. Senczuk, B. Portolano, F. Pilla and N.P.P. Macciotta

229. The genomic inbreeding trend over the last 25 years in three Italian pig breeds 972
G. Schiavo, S. Bovo, A. Ribani, S. Tinarelli, M. Cappelloni, M. Gallo and L. Fontanesi

230. Inbreeding and coancestry trends in Nordic Holstein 976
S. Tenhunen, J.R. Thomasen, L.P. Sørensen, G.P. Aamand, P. Berg and M. Kargo

231. Effect of genomic selection on genetic variability in chromosomal level in the Finnish Ayrshire 980
K. Sarviaho, P. Uimari and K. Martikainen

232. Genomic diversity of two indigenous Croatian goat breeds 984
I. Drzaic, V. Orehovački, L. Vostrý, I. Curik, N. Mikulec and V. Cubric-Curik

233. Consequences on the genome homozygosity of breeding program decisions to improve milk production in Manchega dairy sheep 988
A. Rubio-de Juan, C. Diaz, M.J. Carabaño, M.R. Fernandez-Santos and M. Ramón

234. Heterosis can be explained by thousands of partially recessive, deleterious mutations with very small effects at sites that are conserved across species 992
M.E. Goddard

235. Signatures of selection and runs of homozygosity in the genome of several fancy and meat rabbit breeds 996
M. Ballan, S. Bovo, G. Schiavo, M. Schiavitto, R. Negrini and L. Fontanesi

236. Investigating genetic redundancy as a source of genetic diversity and adaptability in the U.S. Holstein breed 1000
Y. Steyn, T.J. Lawlor, S. Tsuruta, Y. Masuda, A. Legarra, D.A.L. Lourenco and I. Misztal

237. Inbreeding depression and heterosis for live-weight and carcass traits in purebred and crossbred sheep 1004
P. Rafter, N. McHugh, K. McDermott and, D.P. Berry

238. Phylogenetic analysis and nucleotide diversity of 69 cattle breeds including German Black Pied cattle using WGS 1008
G.B. Neumann, P. Korkuć, D. Arends, M.J. Wolf, K. May, S. König and G.A. Brockmann

239. Partitioning of autozygosity in different age-based classes in cattle populations with different demographic histories 1012
T. Druet, L. Flori and M. Gautier

Part 15 – Genetic diversity and inbreeding: genebanking 1016

240. New FAO guidelines for the management of animal genetic resources 1017
P.J. Boettcher, P. Ajmone-Marsan, R. Baumung, J. Boes, L. Colli, C. Ginja, M. Honkatukia, J. Kantanen, G. Leroy and J.A. Lenstra

241. Genebanks for animal genetic resources in Europe: quality management system as a tool to improve their operation 1021
C. Danchin, D. Bojkovski, D.Duclos, M. Neuteboom, M. Schoon, F. Tejerina Ampudia, M. Tixier-Boichard, and S.J. Hiemstra

242. Genetic characterization of endangered indigenous pigs of Angola 1025
P. Sá, D. Santos, A. Leitão, J.M. Cordeiro, L.T. Gama and A.J. Amaral

243. Genetic diversity and inbreeding in US Jersey population and germplasm collection 1029
K. Srikanth, M. Neupane, M.A. Jaafar, C.W. Wolfe, H.J. Huson, C.P. Van Tassell and H.D. Blackburn

244. Development and utilization of the United States gene bank collection 1033
H.D. Blackburn, C.S. Wilson and C.D. Dechow

245. Mapping genetic diversity in European gene banks: preliminary results on chickens for the validation of IMAGE001 array 1037
M. Tixier-Boichard, N. Peynot , D. Duclos, S. Weigend, L. Monteagudo, A. Martinez Martinez, J.V. Delgado, R. Gonzalez Prendes, R. Crooijmans and G. Restoux

246. Conservation of an endangered pig breed using optimum contribution selection 1041
H.M. Nielsen and M. Kargo

247. IDI: an index to assess the usefulness of cryopreserved collections for the management of animal genetic diversity 1045
A. Jacques, D. Duclos, C. Danchin-Burge, M.J. Mercat, M. Tixier-Boichard and G. Restoux

248. Conservation through utilization in German Red and White dual-purpose cattle 1049
M. Slagboom, V. Milkevych, H. Liu, J.R. Thomasen, M. Kargo and C. Schmidtmann

249. Genetic rescue of small populations in the presence of deleterious variation 1053
C. Reimer, S. Weigend, J. Geibel and T. Pook

250. Genebank collections in relation to risk status in livestock species 1057
G. Leroy, H. Blackburn, C. Danchin-Burge, F. Tejerina Ampudia, S.J. Hiemstra, C. Ligda, P. Boettcher and R. Baumung

Part 16 – Challenges – use of whole genome sequence information 1061

251. Pangenomes of haplotype-resolved assemblies enable population-scale genotyping of cattle structural variation 1062
A.S. Leonard and H. Pausch

252. Comparison of methods for building pangenome graphs 1066
D. Crysnanto, A. Leonard and H. Pausch

253. Expanding the genomic toolkit: what does Oxford Nanopore sequencing have to offer? 1070
A. Hess, A. Caulton, R. Clarke, R. Brauning, K. McRae and S. Clarke

254. Successful trio-based reverse genetic screen in an endangered local cattle breed 1074
I.M. Häfliger, F.R. Seefried and C. Drögemüller

255. How does a harsh environment make wild and domestic animals evolve similarly? 1078
G. Romashov, A. Yurchenko, N. Yudin, and D. Larkin

256. Functional and association analyses of sequence data in a region of OAR 20 associated to paratuberculosis in sheep 1082
S. Casu, M.G. Usai, T. Sechi, C. Maestrale, S. Miari, S. Salaris, C. Ligios and A. Carta

257. Discovery of a genetic variant in serum amyloid A that might protect chickens from amyloid arthropathy 1086
C. Falker-Gieske, N.-F. Paul, M. Spourita, K. Gustmann, J. D. Gilthorpe and J. Tetens

258. Genetic background of the porcine immune system using SNP chip data and whole genome sequencing data 1090
C.M. Dauben, C. Große-Brinkhaus, H. Henne, A.K. Appel and E. Tholen

259. Deciphering the origins of Neolithic sheep from northern Iberian Peninsula 1094
M. Serrano, A. Fernández, C. González, J. Martínez-Blanch, M. Moreno-García, M. Rojo-Guerra and J.H. Calvo

260. Prioritisation of variants from whole-genome sequence data for validation of their association with traits of interest 1098
E. Molinero, R.N. Pena, J. Estany and R. Ros-Freixedes

261. Genome-wide association analyses and genomic prediction for pork meat quality traits using whole-genome sequence 1102
M. Heidaritabar, A. Huisman, M.C.A.M. Bink, P. Charagu and G. Plastow

262. A conditional multi-trait sequence GWAS of heifer fertility in tropically adapted beef cattle 1106
M. Forutan, B. Engle, M.E. Goddard and B.J. Hayes

263. Genomic prediction of purebred Merinos from an admixed terminal population using selected sequence variants 1110
N. Moghaddar A.A. Swan, P.M. Gurman, L. Li, and J.H.J. van Der Werf

264. The complete mitochondrial genome of a Peruvian creole cattle (*Bos taurus*) and its phylogenetic analysis 1114
C.I. Arbizu, R.D. Ferro-Mauricio, J.C. Chávez-Galarza, H.V. Vásquez, J.L. Maicelo, C. Poemape, J. Gonzales, C. Quilcate and F-A. Corredor

265. Unravelling the effect of structural variants from whole-genome sequence for depigmentation in Nellore cattle 1118
G. Vargas, H.H.R. Neves, N.A.M. Garzón, L.F.S. Fonseca, G.A. Fernandes Júnior, L.G. Albuquerque and R. Carvalheiro

266. On the advantage of identifying causal genetic variants for genomic prediction 1122
T.H.E. Meuwissen and M.E. Goddard

267. Fuzzy logic as a strategy for combining marker statistics to optimize preselection of high-density and sequence genotype data 1126
A. Ling, E.H. Hay, E. Hartono, S.E. Aggrey and R. Rekaya

268. Genetic evaluations and genomic characteristics for local cattle using genome sequences, 50K and a specific SNP chip 1131
K. May, M.J. Wolf, G.B. Neumann, P. Korkuć, G.A. Brockmann and S. König

269. Genomic prediction using whole-genome sequence data in intensely selected pig lines 1135
R. Ros-Freixedes, M. Johnsson, A. Whalen, C.Y. Chen, B.D. Valente, W.O. Herring, G. Gorjanc and J.M. Hickey

270. Single and multi-breed ssGBLUP using preselected variants from whole-genome sequence data in pigs 1139
S. Jang, R. Ros-Freixedes, J.M. Hickey, C.Y. Chen, W. Herring, I. Misztal and D. Lourenco

271. Application of low-pass sequencing to genomic prediction of egg quality in laying hens 1143
A. Wolc, J. Li, D. Lubritz, J. Arango, J. Fulton, P. Settar, K. Rowland and H. Cheng

Part 17 – Challenges – improving genomic prediction 1147

272. Accuracy of prediction for a genomic evaluation in rotational crossbreeding scheme (Montbéliarde × Holstein × Red Danish) 1148
P. Croiseau, R. Saintilan, A. Baur, I. Croue, V. Ducrocq, J.R. Thomasen, E. Karaman, D. Boichard, H. Leclerc and B.C.D. Cuyabano

273. Genomic evaluation for two-way crossbred performance in cattle 1152
Q. Mei, H. Liu, T. Xiang and O.F. Christensen

274. Improving accuracy of genomic prediction in distant populations by collecting sequence data over generations 1156
M.Y. Nawaz and C. Gondro

275. Comparison of genomic prediction methods for residual feed intake in broilers 1160
Z.X. He, S. Li, W. Li, J.Q. Ding, M.Q. Zheng, Q.H. Li, A.G. Fahey, J. Wen, R.R. Liu and G.P. Zhao

276. Impact of foreign phenotype data on single-step genomic evaluation of test-day protein yields for German Holsteins 1164
H. Alkhoder, Z. Liu, D. Segelke and R. Reents

277. Extend mixed models to multi-layer neural networks for genomic prediction including intermediate omics data 1169
T. Zhao, J. Zeng and H. Cheng

278. The holobiont 'predictome' of immuno competence in pigs 1173
J. Calle-García, Y. Ramayo-Caldas, L.M. Zingaretti, R. Quintanilla, M. Ballester and M. Pérez-Enciso

279. The long and short of Nanopore genomic prediction: the effect of read length on prediction accuracy 1177
H.J. Lamb, L.T. Nguyen, I.A.S. Randhawa, B.J. Hayes and E.M. Ross

280. Accuracy of genomic prediction of dry matter intake in Dutch Holsteins using sequence variants from meta-analyses 1181
B. Gredler-Grandl, B. Raymond, G.C.B. Schopen, P.K. Chitneedi, Z. Cai, C.I.V. Manzanilla-Pech, T. Iso-Touru, D. Fischer, S. Bolormaa, T.S. Chud, F.S. Schenkel, Y. Wang, C. Li, D. Hailemariam, B. Villanueva, A. Fernandez, C. Kuehn, G. Sahana, M.H. Lidauer, J.E. Pryce, O. González-Recio, G. Plastow, C.F. Baes, N. Charfeddine, Y. de Haas, R.F. Veerkamp and A.C. Bouwman

281. Genomic prediction of bull fertility in Italian Brown Swiss cattle 1185
H.A. Pacheco, M. Battagin, A. Rossoni, A. Cecchinato and F. Peñagaricano

282. On the use of SNPs of large effect to improve prediction accuracy in pigs 1189
M.S. Lopes, M. Derks, M. van Son, A.B. Gjuvsland, C.A. Sevillano, E. Grindflek and E.F. Knol

283. Including environmental variables in genomic models for carcass traits in Hanwoo beef cattle 1193
B.O. Makanjuola, G. Rovere, B.C.D. Cuyabano, S.H. Lee and C. Gondro

284. Considering chromosomal trait correlations improves accuracy of genomic prediction 1197
C. Schmidtmann, D. Segelke, J. Bennewitz, J. Tetens and G. Thaller

285. Effects of truncation and false positives in selection of markers for genomic prediction 1201
Z. Loh, J.H.J van der Werf and S. Clark

286. Genomic selection for breeding values under identity disequilibrium 1205
R.J.C. Cantet, B.K. Angarita Barajas, N.S. Forneris and S. Munilla

287. Effect of informative polymorphism on accuracy of genomic prediction and heritability 1209
M.S. Tahir, B.S. Olasege, K. Wockner, W.L.A. Tan, L.R. Porto-Neto and M.R.S. Fortes

288. Long-distance associations generate erosion of genomic breeding values of candidates for selection 1213
D. Boichard, S. Fritz, P. Croiseau, V. Ducrocq, B. Cuyabano and T. Tribout

289. Definition of reliabilities for models with metafounders 1217
M. Bermann, I. Misztal, D. Lourenco, I. Aguilar and A. Legarra

290. A new metric to assess reference populations for genomic selection in Australian beef breeds 1221
K.L. Moore, M.H. Ferdosi, C.G. Girard, S.F. Walkom and D.J. Johnston

291. Decreasing computing cost of categorical data analysis 1225
J. Hidalgo, I. Misztal, S. Tsuruta, M. Bermann, A. Garcia, K. Retallick and D. Lourenco

292. Within and across breed single step genomic prediction for somatic cell count including foreign information 1229
R. Mrode, M.W. Winters and M. Coffey

293. Using convolutional neural networks for image-based genomic prediction in mice 1233
B.C. Perez, A. Savchuk, P. Duenk, M.P.L. Calus and M.C.A.M. Bink

294. Selection for robustness: exploring the value of genomic prediction, reaction norm models and phenotyping strategies 1237
M. Ghaderi-Zefreh, A. Doeschl-Wilson, V. Riggio, O. Matika and R. Pong-Wong

Part 18 – Methods and tools: genomic prediction **1241**

295. Benchmark SNPs selection strategies to achieve optimum prediction in small population 1242
E. Mancin, C. Sartori, B. Tuliozi, G.G. Proto, R. Mantovani

296. Genetic correlations among longevity, fertility, udder health and type traits including or not genomic information 1246
R. Rostellato, L.-H. Maugan and V. Ducrocq

297. Alternative SNP weighting for genomic prediction methods in the presence of causative variants 1250
B.F. Santana, M. Riser and B. Fragomeni

298. Including selected sequence variants in genomic predictions for age at first calving in Nellore cattle 1254
G.S. Campos, D.A. Silva, H.H.R. Neves, D. Lourenco, G.A.F. Júnior, L.F.S. Fonseca, L.G. Albuquerque and R. Carvalheiro

299. Increasing accuracy of single-step evaluations of functional longevity including information from correlated traits 1258
L.-H. Maugan, T. Tribout, R. Rostellato, S. Mattalia and V. Ducrocq

300. Multi-trait genomic estimation of genetic parameters for growth and carcass traits of Duroc pigs 1262
E.C. Akanno, D.M. Thekkoot, C. Zhang, C. Bierman, G. Plastow and R.A. Kemp

301. Accounting for nuclear- and mito-genome in genetic evaluation and breeding of dairy cattle 1266
G.M. Fortuna, B.J. Zumbach, M. Johnsson, I. Pocrnic and G. Gorjanc

302. Using residual regressions to quantify and map signal leakage in genomic prediction 1270
B.D. Valente, G. de los Campos, A. Grueneberg, C.Y. Chen, R. Ros-Freixedes and W.O. Herring

303. Capitalizing on complex annotations in Bayesian genomic prediction for a backcross population of growing pigs 1274
F. Mollandin, H. Gilbert, P. Croiseau and A. Rau

304. Predictive ability of genomic prediction in layers when including CADD scores as genome function information 1278
M.C.A.M. Bink, M.P.L. Calus, M.F.L. Derks, J. Visscher and B.C. Perez

305. Across-sex genomic prediction using pre-selected SNP sets in cattle 1282
B.S. Olasege, M.S. Tahir, L.R. Porto-neto, B.J. Hayes and M.R.S Fortes

306. Genomic prediction with incomplete omics data 1286
E. Karaman, V. Milkeviych, Z. Cai, L. Janss, G. Sahana and M.S. Lund

307. A Bayesian hierarchical model to integrate a mechanistic growth model in genomic prediction 1290
H. Yu, J. van Milgen, E. Knol, R. Fernando and J. Dekkers

308. Mega-scale mixed models for genome-wide prediction with thousands of high-throughput phenotyping traits 1294
J. Qu, D.E. Runcie and H. Cheng

309. Nordic Holstein single-step test day model using metafounders and blending of foreign information 1298
M. Koivula, I. Strandén, G.P. Aamand and E.A. Mäntysaari

310. Effects of missing or wrong pedigree records on Single-Step predictions 1302
E.C.G. Pimentel, C. Edel, R. Emmerling and K.-U. Götz

311. An alternative method to consider a reference population in Single-Step SNP BLUP model without separating genomic terms 1306
T. Osawa, T. Baba, Y. Masuda, T. Kawahara and Y. Goto

312. Accuracy of pedigree and genomic predictions of meat quality in a multi-breed cattle using single and two step model 1310
S. Naderi, R. Evans and D.P. Berry

313. Single-step genomic prediction in small breeds: Finncattle case 1314
A.A. Kudinov, M. Koivula, I. Strandén, G.P. Aamand and E.A. Mäntysaari

314. Challenges to implement an interim genomic prediction for young animals in Wallonia, Belgium 1318
K. Wijnrocx, R.R. Mota, M. Dufrasne and N. Gengler

315. New insights into the computation of the inverse of the numerator relationship matrix for genotyped animals 1322
A. Maiwashe

316. GAPLS – a novel method to genomically rank bulls for daughter reproductive performance 1326
Y. Li, S. Lehnert, L.R. Porto-Neto, R. McCulloch, S. McWilliam, P. Alexandre, J. McDonald, C. Smith and A. Reverter

317. Performance of identity-by-state and identity-by-descent genomic models for meat traits in a cross-pig F2 population 1331
B.K. Angarita, J.P. Steibel, R.J.C. Cantet and N.S. Forneris

318. Modelling missing pedigree with metafounders and validating ssGBLUP evaluation for Uruguayan Holstein dairy cattle 1335
R.D. López-Correa, A. Legarra and I. Aguilar

319. Estimating metafounder relations for Finnish multibreed beef population 1339
M. Taskinen, A.-M. Leino, T.J. Pitkänen and E.A. Mäntysaari

320. A deregression method for a single-step SNP BLUP model using all genotype data 1343
Z. Liu and Y. Masuda

321. Variance component estimation for single-step genomic BLUP for Australian terminal sire sheep 1348
P.M. Gurman, L. Li, A.A. Swan, N. Moghaddar and J.H.J. van der Werf

322. Finetuning hyper-parameters increases the prediction accuracy in single-step genetic evaluation 1352
M. Neshat, Md.M. Momin, B. Truong, J.H.J. van der Werf , S. Lee and S.H. Lee

323. Comparison of single-step and multi-step evaluations for U.S. milk, fat, and protein 1356
R.R. Mota, A. Cesarani and P.M. VanRaden

324. Large-scale multiple-trait single-step marker model implementation 1360
B.L. Harris, R.G. Sherlock and M.A. Nilforooshan

325. An iterative method for deregressed proof in single-step genomic BLUP and its application to a dairy cattle population 1364
Y. Masuda, Z. Liu and P. Sullivan

326. Efficient approximation of reliability for genomic breeding values in large systems 1368
H. Eding

327. Evaluating the suitability of subjectively defined base populations 1372
J. ten Napel, J. Vandenplas, M. Calus, I. Strandén, M. Lidauer and R. Veerkamp

328. Maximum likelihood estimation of metafounder parameters for single and multiple breeds 1376
O.F. Christensen and A. Legarra

329. Exploring the statistical nature of independent chromosome segments 1380
M.K. Hollifield, M. Bermann, D. Lourenco and I. Misztal

330. Including local genomic breed proportions in genomic predictions for crossbred 1384
J.H. Eiríksson, G. Su and O.F. Christensen

331. Investigating the impact of APY core size and definition in single-step GBLUP evaluations 1388
R. Abdollahi-Arpanahi, D. Lourenco and I. Misztal

332. Strategies for choosing core animals in APY and their impact on the accuracy of single-step genomic predictions 1392
N.P.P. Macciotta, C. Dimauro, D. Lino Laurenco, A. Cesarani, L. Degano and D. Vicario

333. Genomic prediction accuracy: how low can we go? 1396
A. Reverter, P.A. Alexandre, Y. Li, B.C. Hine, C.J. Duff, A.B. Ingham and L.R. Porto-Neto

334. Genomic prediction in smallholder tropical dairy herds: modelling milk yield in first and later lactations 1400
E. Negussie, M.H. Lidauer, S. Meseret, A. Tera, E. Tessema, B. Jufar, T. Negera, A. Hassen, G. Gebreyohanes, O.A. Mwai and R. Mrode

335. Genomic prediction of wool shedding in a composite sheep flock using pooled allele frequencies and individual genotypes 1404
N. Vargas Jurado, J.W. Keele, L.A. Kuehn and R.M. Lewis

336. Optimal core definitions for the APY model with an example in large-scale pig dataset 1408
I. Pocrnic, F. Lindgren, D. Tolhurst, W.O. Herring and G. Gorjanc

337. Updating the core animals in the algorithm for proven and young in the American Angus Association national evaluations 1412
A.L.S. Garcia, S. Miller, S. Tsuruta, D. Lourenco, I. Misztal, D. Lu and K. Retallick

338. A critical aspect when using APY inversion with Single-Step GBLUP 1416
C. Edel, E.C.G. Pimentel, R. Emmerling and K.-U. Götz

339. Measures to quantify the accuracy and the erosion of genomic predicted breeding values 1420
B.C.D. Cuyabano, D. Boichard and C. Gondro

340. Model building pipeline to maximize the accuracy of breeding values prediction 1424
J. Jenko and Ø. Nordbø

341. Genomic prediction in multi-breed Irish beef cattle population using a breed origin of alleles model 1428
A. Guillenea, M.S. Lund, R. Evans, V. Boerner and E. Karaman

342. Breed-origin-of-alleles approach using summary statistics for multi-breed genomic prediction in dairy cattle 1432
J.B. Clasen, W.F. Fikse, G. Su and E. Karaman

Part 19 – Methods and tools: software and computing strategies 1436

343. Subsetted orthogonal data augmentation for fast parallel implementation of Bayesian models for whole-genome analyses 1437
L.H. Chen and G.S. Plastow

344. A simulator to evaluate gene editing assisted selection programs 1442
X-J. Yu, B.S. Dagnachew and T.H.E. Meuwissen

345. A database structural improvement for efficient trait variation curation in animal QTLdb and CorrDB 1446
Z-L. Hu, C.A. Park and J.M. Reecy

346. Efficient algorithms to identify duplicated genotypes in large datasets 1450
M.H. Ferdosi, S. Masoodi and M. Khansefid

347. Genotype error correction and the accurate identification of recombination sites 1454
M.M. Hindle and A. Kranis

348. A phasing algorithm targeted at dairy cattle populations having genotyped ancestors with many genotyped offspring 1459
M. Dahl and O.F. Christensen

349. Recent advances and future needs in genotype imputation 1463
P.M. VanRaden, D.J. Null and A.S. Al-Khudhair

350. Imputation of low coverage sequence data by utilization of pre-phased reads and HBimpute 1467
T. Pook and J. Geibel

351. Quantitative trait simulation using MeSCoT software 1471
V. Milkevych, E. Karaman, G. Sahana, L. Janss, Z. Cai and M.S. Lund

352. SIRE 2.0: a novel software tool to estimate host genetic variation in infectious disease transmission 1475
C.M. Pooley, G. Marion and A. Doeschl-Wilson

353. iVPSV: an intuitive visualisation platform for structural variation data 1479
H. Jung, B. Jeon, B. Hayes and E. Ross

354. A variational Bayes method for genomic prediction increases accuracy and computing speed 1482
J. Cheng, H. Cheng, R. Fernando, C. Maltecca, L. Ma, J. Dekkers and J. Jiang

355. Additions to the BGLR R-package: a new function for biobank size data and Bayesian multivariate models 1486
P. Pérez-Rodríguez and G. de los Campos

356. SFSI: a package to solve penalized selection indices and sparse genomic prediction 1490
M. Lopez-Cruz, G. de los Campos, B. Valente, C.Y. Chen, W. Herring and A. Grueneberg

357. INTERGEN: an efficient and flexible tool for large-scale genetic evaluation of complex animal and plant populations 1494
V.S. Junqueira, G.S. Campos and F.F. Cardoso

358. MiXBLUP 3.0 – software for large genomic evaluations in animal breeding programs 1498
J. Vandenplas, R.F. Veerkamp, M.P.L. Calus, M.H. Lidauer, I. Strandén, M. Taskinen, M. Schrauf and J. ten Napel

359. From raw sensor and automated data to genetic evaluation and validation in the cloud 1502
D. Schokker, I.N. Athanasiadis, M. Poppe, J. ten Napel, C. Kamphuis and R.F. Veerkamp

360. Indirect genomic prediction reduces computational costs in large-scale single-step evaluations 1506
I. Strandén, J. ten Napel, R.F. Veerkamp, R. Evans, S. Naderi, E.A. Mäntysaari and J. Vandenplas

361. Accounting for trait-specific genomic and residual polygenic covariances in multivariate single-step genomic evaluation 1510
K. Meyer

362. Avoiding double counting in genomic reliability calculations 1515
H. Ben Zaabza, M. Taskinen, E.A. Mäntysaari, T. Pitkänen, G.P. Aamand and I. Strandén

363. JWAS version 2: leveraging biological information and high-throughput phenotypes into genomic prediction and association 1519
H. Cheng, R. Fernando, D. Garrick, T. Zhao and J. Qu

364. ACCF90GS2: software for fast approximation of reliabilities of estimated breeding values in single-step GBLUP 1523
M. Bermann, D. Lourenco, A. Cesarani and I. Misztal

365. One for all: LMT – the linear models toolbox 1526
V. Boerner

366. Recent updates in the BLUPF90 software suite 1530
D. Lourenco, S. Tsuruta, I. Aguilar, Y. Masuda, M. Bermann, A. Legarra and I. Misztal

367. From data to genomic breeding values with the MiX99 software suite 1534
T.J. Pitkänen, H. Gao, A. Kudinov, M. Taskinen, E.A. Mäntysaari, M.H. Lidauer and I. Strandén

Part 20 – Statistical genetics: GWAS **1538**

368. Haplotypes affecting pulmonary arterial pressure in Angus cattle 1539
D. Lu, A. Garcia, S. Miller and K. Retallick

369. Detection of shared genomic regions between production and health traits in German Holstein cattle 1543
H. Schneider, D. Segelke, J. Tetens, G. Thaller and J. Bennewitz

370. Detecting the presence of genomic imprinting for carcass traits in cattle using imputed high-density genotypes 1547
D. Kenny, R.D. Sleator, C.P. Murphy, R.D. Evans and D.P. Berry

371. Evidence of genetic links between rumen bacteria and milk somatic cell score in Lacaune dairy sheep 1551
G. Martinez Boggio, A. Meynadier, R. Rupp, C. Allain, A.J. Buitenhuis and C. Marie-Etancelin

372. Leveraging GWAS models to map selection on complex traits in massive datasets 1555
T.N. Rowan, R.D. Schnabel and J.E. Decker

373. Fine-mapping young-stock survival QTL on chromosome 6 in Nordic Red Dairy Cattle 1559
Z. Cai, X. Wu, B. Thomsen and G. Sahana

374. Multibreed sequence level genome-wide association study of semen traits in tropical Australian cattle 1563
W.L.A Tan, L.R. Porto-Neto, A. Reverter and M.R.S. Fortes

375. Improved genome-wide associations using a breed-specific 200K SNP chip for German Black Pied (DSN) cattle 1567
P. Korkuć, G.B. Neumann, D. Arends, M.J. Wolf, K. May, S. König and G.A. Brockmann

376. Haplotype-based single-step GWAS for yearling temperament in American Angus 1571
A.C. Araujo, P.L.S. Carneiro, A.B. Alvarenga, H.R. Oliveira, S.P. Miller, K. Retallick and L.F. Brito

377. Genome-wide association analyses for various thermotolerance indicators measured during lactation in maternal-line pigs 1575
P.H.F. Freitas, J.S. Johnson, H. Wen, J.M. Maskal, M.K. Byrd, F. Tiezzi, Y. Huang, A.P. Schinckel and L.F. Brito

378. Investigation of GWAS variants associated with loin depth in commercial pigs 1579
S. Desire, M. Johnsson, R. Ros-Freixedes, C. Chen, W. Herring, G. Gorjanc, R.J. Mellanby, J. Hickey and M. Jungnickel

379. Multivariate GWAS revealed a critical region on chromosome 4 for developmental and feather growth traits in ducks 1583
E. Tarsani, S. Desire, O. Matika, K. McIntosh, A. Rae, A. Kranis and K.A. Watson

380. Investigation of genes associated with maternal weaning weight in South African Bonsmara beef cattle 1586
J.J. Reding, R.R. Van der Westhuizen, D.P. Berry and E. van Marle-Köster

381. Genome-wide genomic and functional association study for workability and calving traits in Holstein cattle 1590
T. Suchocki, B. Kosińska-Selbi, A. Żarnecki, M. Jakimowicz, W. Jagusiak, M. Morek-Kopeć and J. Szyda

382. Genomic region-specific association test identifies new loci for carcass traits in Hanwoo (Korean native cattle) 1594
D.J. Lee, D.H. Lee, J.M. Kang, Y.K. Kim, Y.J. Chung and S.H. Lee

383. Genetic mechanisms underlying feet and legs malformation in Nellore cattle: prioritization of GWAS results 1598
T.L. Silva, C. Gondro, P.A.S. Fonseca, D.A. da Silva, G. Vargas, H.H.R. Neves, I. Carvalho Filho, C.S. Teixeira, L.G. Albuquerque and R. Carvalheiro

384. Genome-wide association studies for milk yield in *Bos taurus* × *Bos indicus* crossbred cattle in India 1602
M. Al Kalaldeh, M. Swaminathan, V. Podtar, S. Jhadav, V. Dhanikachalam, A. Joshi and J.P. Gibson

385. Grouping of highly correlated variables improves performance of genomic evaluations 1606
D. Wittenburg and J. Klosa

386. A Monte-Carlo approximation of the null hypothesis for genome wide association sing the windows variance approach 1610
D. López-Carbonell, M. Ramírez, J. Altarriba, H. Srihi and L. Varona

387. Sequence-based association analyses on X chromosome in six dairy cattle breeds 1614
M.P. Sanchez, C. Escouflaire, A. Baur, C. Hozé, A. Capitan, S. Fritz and D. Boichard

388. Pleiotropic effects on carcass and meat quality traits in crossbred beef cattle 1618
F.M. Rezende, E. Rodriguez, J.D. Leal-Gutiérrez, M.E. Elzo, D.D. Johnson, C. Carr and R.G. Mateescu

389. Sequence-based multi-trait genome-wide association study for linear classification traits in Belgian Blue beef cattle 1622
J.L. Gualdron Duarte, A.S. Gori, G. Costa Monteiro Moreira, M. Georges, C. Charlier and T. Druet

390. Integrating imputed structural variants and tandem repeats in a GWAS for growth and carcass traits in F_2 pig crosses 1626
I. Blaj, J. Tetens, J. Bennewitz, G. Thaller and C. Falker-Gieske

391. Detecting QTL for two lowly correlated traits using multi-trait and meta-analysis approaches in Swiss Large White pigs 1630
A. Nosková, A. Mehrotra, N.K. Kadri, S. Neuenschwander, A. Hofer and H. Pausch

392. A Forward algorithm to identify credible sets in Bayesian variable selection models 1634
G. de los Campos, A. Samaddar, B. Valente, C.-Y. Chen, W. Herring and A. Grueneberg

Part 21 – Statistical genetics: machine learning, deep learning and artificial intelligence 1638

393. Multivariate application of artificial neural networks for genomic prediction 1639
S.O. Peters, K. Kızılkaya, M. Sinecen and M.G. Thomas

394. Comparison of GBLUP and machine learning breeding values for binary disease traits in working dogs 1643
J.A. Thorsrud, K.M. Evans, D.M. Holle, H.J. Huson

395. Predicting the polled genotype of ungenotyped animals using machine learning methods 1647
A.B. Gjuvsland

396. A machine learning approach to classify high and low feed efficient or grower mink 1652
A. Shirzadifar, G. Manafiazar, P. Davoudi, D.N. Do, G. Hu and Y. Miar

397. A machine learning approach for predicting the most and the least feed-efficient groups in beef cattle 1656
A. Shirzadifar, G. Plastow, J. Basarab, Y. Miar, C. Li, C. Fitzsimmons, M. Riazi and G. Manafiazar

398. Combination of SNP markers for discrimination of a target chicken population using machine learning algorithms 1660
E. Cho, S. Cho, M. Kim, T.K. Ediriweera, D. Seo and J.H. Lee

399. LASSO and SVM: an alternative approach to identify associated genome regions for simple and complex traits in cattle 1664
S. Widmer, F.R. Seefried, C. Drögemüller and P. von Rohr

400. Quantifying the functional conservation between human and pig using artificial neural networks 1668
J. Li, T. Zhao, Z. Pan, H. Zhou, L. Fang and H. Cheng

401. Using a U-net architecture to develop an automated ultrasound images analysis method in a rabbit breeding program 1672
C. Herbert, C. Ribas, K. Kashefifard, L. Flatrès-Grall and G. Lenoir

402. Machine learning and genetic improvement of animals and plants: where are we? 1676
D. Gianola, J. Crossa, O. Gonzalez-Recio and G.J.M. Rosa

403. Predicting pig digestibility coefficients with microbial and genomic data using machine learning prediction algorithms 1680
C. Carillier-Jacquin, V. Deru, L. Tusell, A. Bouquet, L. Jacquin and H. Gilbert

404. (Quasi) Multi-task support vector regression for whole-genome prediction of carcass traits in commercial broilers 1684
A.A.C. Alves, A.F.A. Fernandes, V. Breen, R. Hawken and G.J.M. Rosa

405. Genomic prediction of longitudinal body weights in pigs using a neural network 1688
Z. Ni, R.L Fernando, H. Yu, E.F. Knol and J.C.M. Dekkers

406. Compressing microbiota information using an autoencoder to predict growth traits in swine 1692
C. Maltecca, J. Jiang, J. Fix, C. Schwab C. Shull and F. Tiezzi

Part 22 – Society – genetics in the tropics **1696**

407. Providing genetics for the dairy industry in the tropics – the Brazilian Dairy Gir breeding program 1697
J.C.C. Panetto, M.V.G.B. Silva, M.A. Machado, R.S. Verneque, A.R. Fernandes, C.H.C. Machado, M.F. Martins, D.R.L.R. Faza, C.A.V. Borges, H.T. Ventura, M.A. Pereira, J.C. Oliveira, L.A. Glatzl Junior, A.O. Garcia and F.D. Leandro

408. Modelling phenotypic plasticity relative to a temperature humidity index as an indicator of adaptability in beef cattle 1701
W. Shaffer, J.A.H. Moreno, N.M. Bello, R. Weaber, J. Bormann and M. Rolf

409. Differentiated genomic regions in the Afrikaner and Brahman cattle of South Africa reveal parallel adaptive mechanisms 1705
S. Mdyogolo, M.D. MacNeil, F.W.C. Neser, M.M. Scholtz and M.L. Makgahlela

410. Genomic analysis of milk yield and heat tolerance in small holder dairy system of sub-Saharan Africa 1709
C.C. Ekine-Dzivenu, R. Mrode, R.D. Oloo, D. Komwihangilo, E. Lyatuu, G. Msuta, J.M. Ojango and A.M. Okeyo

411. Genetic analysis of traits needed to optimize improvement in beef cow-calf efficiency in Afrikaner cattle1713
M.M. Scholtz, M.D. MacNeil, M.C. Chadyiwa and F.W.C. Neser

412. Genetic diversity of the Cameroon Blackbelly sheep, an indigenous sheep from West Africa 1717
P. Wiener, M. Salavati, A. Djikeng, C.P. Van Tassell, B.D. Rosen, G.L. Spangler, G. Simo, V. Tanya, F. Meutchieye and E.L. Clark

413. Phenotypic characterisation of African chickens raised in semi-scavenging conditions 1721
K.M. Morris, K. Sutton, M. Girma, W. Esatu, B. Solomon, T. Dessie, L. Vervelde, A. Psifidi, O. Hanotte and G. Banos

414. Spatial modelling in genetic evaluation of South African Holstein cattle population 1725
I. Houaga, T.P. Oliveira, I. Pocrnic, E. Lavrenčič, C.B. Banga and G. Gorjanc

415. Testing phenotypes for degree of resilience using fluctuations in milk yield of dairy cows in sub-Saharan Africa 1729
R.D. Oloo, C.C. Ekine-Dzivenu, J.M.K. Ojango, R. Mrode, A.O. Mwai, and M.G.G. Chagunda

416. Egg production and genetic parameters for Tanzanian local chickens 1733
T. Magwaba, E. Mollel, J.R Mushi, M. Walugembe, E.N Amuzu-Aweh, G.H. Chiwanga, N. Chouicha, P.L. Msoffe, T. Kelly, R.A. Gallardo, H. Zhou, A. Wolc, S.J. Lamont, A.P. Muhairwa and J.C.M. Dekkers

417. Expanding the cattle reference graph genome 1737
A. Talenti, J. Powell, D. Wragg, E. Paxton, M. Chepkwony, A. Miyunga, R. Njeru, J.D. Hemmink, A. Fisch, B.R. Ferreira, J.A. Hammond, A.L. Archibald, P. Toye, T. Connelley, L. Morrison and J. Prendergast

418. Genetic structure and diversity of Jersey dairy cattle in Rwanda 1741
O. Opoola, F. Shumbusho, R. Mrode, D. Hambrook, M.G.G. Chagunda, D. Moran and A. Djikeng

419. Estimation of breed admixture levels in Sri Lanka cattle and its relation to performance traits 1745
M. Spoelstra, J. Sölkner, H. Bovenhuis, B. Babigumira, K. Periasamy and C.M.B. Dematawewa

420. Economic values for skin grade, days to market and number of hatchlings in the Australian saltwater crocodile industry 1749
S. Hermesch and S.R. Isberg

421. Exploiting phenotypic plasticity in animal breeding 1753
F.G. Kebede, H. Komen, T. Dessie, O. Hanotte, S. Kemp, C. Pita Barros, R. Crooijmans, M. Derks, S.W. Alemu and J.W.M. Bastiaansen

422. Whole genome sequencing reveals genetic diversity and heat-stress adaptation in Nigerian indigenous chickens 1757
A.A. Gheyas, M. Rachman, O. Bamidele, T. Dessie, J. Smith and O. Hanotte

Part 23 – Challenges – delivering genetic progress in systems around the world **1761**

423. Impact of industry effort to increase dairy heifer genomic testing in Australia 1762
M. Abdelsayed, M.M. Axfordand G.J. Nieuwhof

424. Weekly national dairy evaluations – a Vietnam-Australia collaboration 1766
G.J. Nieuwhof and L.T. Ong

425. The value proposition for using genomics to confirm parentage in Australian dairy systems 1770
J.E. Newton, M.M. Axford, J.E. Pryce, S.L. Bullen and M. Haile-Mariam

426. Changes in genetic trends for dairy cattle in the U.S. since the implementation of genomic selection 1774
F.L. Guinan, G.R. Wiggans, J.W. Dürr, H.D. Norman, J.B. Cole, C.P. Van Tassell, I. Misztal and D. Lourenco

427. Community based breeding programme for low input beef cattle production systems in the arid region of Argentina 1778
S. Munilla, J.M. Tessi and D.O. Maizon

428. A participatory approach to review and update the national breeding objectives for New Zealand dairy cattle 1782
B.F.S. Santos, G.M. Jenkins, J. Kok, K. Stachowicz and P.R. Amer

429. Genetic trends for carcass traits within breeds in a multi-breed evaluation 1787
S.A. Mulhall, R.D. Sleator, R.D. Evans and A.J. Twomey

430. Improving growth performance for dual purpose chickens for challenging conditions in Africa 1791
N. Duijvesteijn, L. Perrault, R. Atikpakpe, N. Garcia Martinez, J. Renckly, T. Arbeau and J.A.M. van Arendonk

431. Genomic selection in the US: where it has been and where it is going? 1795
K.J. Retallick, D. Lu, A. Garcia and S.P. Miller

432. Efficient genetic progress for quantitative traits through genomic selection 1799
S. Tsuruta, D.A.L. Lourenco and I. Misztal

Part 24 – Breeding programs **1803**

433. Strategies to support phenotyping for genomic selection R&D and implementation in beef and sheep industries 1804
R.G. Banks

434. The infrastructure for cattle data at the Swedish university of agricultural sciences, Gigacow 1808
T. Klingström, I. Ohlsson and D.J. de Koning

435. Optimizing sampling strategies for sib test schemes in a broiler breeder program 1812
C.A. de Hollander, V.P. Breen, J. Henshall, F.B. Lopes and M.P.L. Calus

436. Plasticity of breed direct and individual heterosis effects in beef cattle under extensive conditions 1816
G.M. Pyoos-Daniels, M.D. MacNeil, M.M. Scholtz, M.M. Seshoka, H.L. Weepener and F.W.C. Neser

437. Polled Accelerator – a unique application of genomic technologies to address a beef breeding challenge 1820
D.J. Johnston, M.H. Ferdosi, J. Cook and D.B. Savage

438. An approach for the design of breeding programs using genomics 1824
J.C.M. Dekkers, H. Su, L. Kramer and H. Yu

439. Should we breed cows like pigs? A new organisation of dairy cattle breeding 1828
M. Kargo, H.M. Nielsen, S. Østergård, R.D. Kring, M. Slagboom, J.B. Clasen and J.R. Thomasen

Part 25 – Operational breeding programs **1832**

440. Management of undesired alleles at multiple loci for a goat breeding program 1833
J. Raoul, J.M. Elsen, S.T. Rodríguez-Ramilo and I. Palhière

441. Prediction of gametic variance and its use in bovine breeding programs 1837
C. Hozé, A. Baur, S. Fritz and D. Boichard

442. Implementing genomic management of diversity and selection in French dairy goats 1841
I. Palhière, V. Gousseau and J.J. Colleau

443. Partition in long-term contributions of the genetic trend of Basco-Béarnaise dairy sheep 1845
S. Antonios, A. Legarra, J.M. Astruc, S.T. Rodríguez-Ramilo and Z.G. Vitezica

444. Introgression of prolificacy gene in Tunisian Barbarine sheep through marker-assisted selection scheme 1848
E. Arari, I. Baazaoui, N. Letayef, M. Lahmar, M. Hemdène, A. Haile, M. Rekik and S. Bedhiaf-Romdhani

445. Simulation of animal crossbreeding schemes using ADAM software 1852
H. Liu, H.M. Nielsen, M. Kargo, J.R. Thomasen, P. Berg, M. Slagboom, A.C. Sørensen and V. Milkevych

446. A tool for comprehensive implementation of simple and complex breeding programs 1856
B.P. Kinghorn, A.J. Kinghorn and J.L. Baller

447. Beyond scenarios – resource optimization for dairy cattle breeding programs (MoBPSopti) 1860
A. Hassanpour, H. Simianer and T. Pook

448. Predicting the outcome of a selection scheme in maternal traits 1864
A.V. Mäki-Tanila and J. Pietarinen

449. Inbreeding in circular and panmictic mating systems 1868
B. Guldbrandtsen

450. Genomic rotational crossbreeding including advanced optimum contribution selection methods in local dairy cattle breeds 1872
J. Stock, H. Esfandyari, D. Hinrichs, R. Wellmann and J. Bennewitz

451. Allele frequency differences at epistatic QTL explain different genetic trends in number of teats in two pig lines 1876
C.A. Sevillano, B. Harlizius, M.F.L. Derks, M.S. Lopes, M. van Son and E.F. Knol

Part 26 – Developing countries **1880**

452. Phylogenetic analysis of local cattle population in northern province of Sri Lanka 1881
K.G.C.B. Wijebandara, M.S. Kurukulasuriya, P.C.G. Bandaranayake and G.L.L.P. Silva

453. Accounting for heterogeneity of data in implementing genomic selection models applicable to crossbred cattle in India 1885
A. Guintard, L. Bourguignon, G. Restoux and V. Ducrocq

454. Connections among local nomenclature, phenotypes and genetic characteristics of native chickens in Cambodia: a synthesis 1889
P. Menghak and M.G.G. Chagunda

455. Experience in creating a female *Bos taurus* × *Bos indicus* reference population under smallholder system in India 1893
K.G. Bhave, S. Joshi, Y. Gaundare, A. Joshi, T. Shirsath, N. Punde, V. Potdar, V. Ratnakar and M. Swaminathan

456. Learnings and experiences from a community-based goat breeding program in India 1897
A. Schurink, S. Kumar, R. Chakraborty, T. Sawhney, C. Nimbkar and P. Amer

457. Response to index selection for temperate dairy cattle breeds in tropical Sri Lanka 1901
A.M. Samaraweera, J.H.J. van der Werf, V. Boerner and S. Hermesch

458. Challenges on construction and use of female reference populations for genomic selection under Indian smallholder systems 1905
V. Ducrocq, M. Swaminathan and J.P. Gibson

459. Bridging the gap in data from smallholder dairy systems; developing the Africa dairy genetic gains (ADGG) data platform 1909
J.M.K. Ojango, A.M. Okeyo, R. Mrode, E. Chinyere, G. Gebreyohanes, S. Meseret, D. Mogaka, E. Lyatuu, D. Komwihangilo, G. Msuta, S. Kahumbu, J.P. Gibson and S. Kemp

460. Attitudes of Peruvian llama and alpaca farmers towards genetic improvement 1913
M. Wurzinger and G. Gutiérrez

461. Development of a low-density SNP panel for local Ghanaian and Tanzanian chicken ecotypes 1917
M. Walugembe, E.N. Amuzu-Aweh, K.-S. Lim, Y. Wang, N. Chouicha, T. Kelly, A.P. Muhairwa, B.B. Kayang, P.L.M. Msoffe, A. Naazie, H.R. Otsyina, J.S. Mushi, R.A. Gallardo, H. Zhou, S.J. Lamont and J.C.M. Dekkers

462. Combining demographic, production and molecular investigations in genetic improvements: case study in indigenous chicken 1921
G.L.L.P. Silva, M.S. Kurukulasuriya, P.R.M.K. Fernando and C.M.B. Dematawewa

Part 27 – Breeding goals and selection strategies 1925

463. Relative importance of selection objective traits in participatory breeding programs – MultiAtr software 1926
R.N.B. Lobo

464. Validation of Angus HeiferSELECT using historical data 1930
P.A. Alexandre, L.R. Porto-Neto, B. Hine, A. Ingham, M. Samaraweera, C. Duff and A. Reverter

465. Full-scale simulation of the Norwegian red dairy cattle breeding programme to enable testing future breeding directions 1934
A. Ehsani, J. Jenko, H. Storlien, H. Melbo Tajet, I. Pocrnic, J. Obsteter and G. Gorjanc

466. Improving carcase value by incorporating primal weights into beef breeding objectives 1938
N.R. Sarker, B.J. Walmsley and S. Hermesch

467. A method for partitioning trends in genetic mean and variance to understand breeding practices 1942
T.P. Oliveira, J. Obšteter, I. Pocrnic and G. Gorjanc

468. A practical approach to predicting expected response to selection with a new index 1946
X. Zhang, P.R. Amer and C. Quinton

469. Theory and tools that are needed for the design and optimization of breeding programs 1950
P.R. Amer

470. General properties of the optimum selection index 1954
R. Wellmann

471. Advantages of modularisation for industry breeding objective development 1958
C.D. Quinton, P.R. Amer, T.J. Byrne and B.F.S. Santos

472. Enhancement of the terminal carcass production index to incorporate birth weight and lambing ease in Australian sheep 1962
E. Dehnavi and A.A. Swan

473. iGENDEC: a web-based decision support tool for economic index construction 1966
M.L. Spangler, B.L. Golden, S. Newman, L.A. Kuehn, W.M. Snelling, R.M. Thallman and R.L. Weaber

474. Analysis of causal structure of traits involved in sow lactation feed efficiency 1970
M. Mora, I. David, H. Gilbert, G.J.M. Rosa, J.P. Sánchez and M. Piles

Part 28 – Methods and tools: breeding goals 1974

475. Manipulating response to selection on many traits 1975
J.H.J. van der Werf and S.A. Clark

476. Selection for birth weight environmental variability in mice as a model to improve animal welfare in livestock species 1979
J.P. Gutiérrez, N. Formoso-Rafferty, C. Ojeda-Marín, L. El-Ouazizi El-Kahia, K.D. Arias and I. Cervantes

477. Sensitivity Analysis for a new Economic Selection Index for Chilean dairy cattle 1983
J.L. Chuma-Alvarez, H.H. Montaldo, D.A.L. Lourenco, F.J. Ruiz-López, M.E. Olivares and C. Lizana

478. Opportunities for animal genetics to foster the ecological transition of livestock farming systems 1987
D. Savietto, F. Douhard, H. Gilbert, R. Rupp, L. Fortun-Lamothe and A. Ducos

479. Defining animal breeding objectives and strategies within the framework of responsible research and innovation 1991
I. Olesen, A. Kettunen, G.K. Rosendal and H.M. Nielsen

480. On farm specific breeding goals for mating lead to higher genetic gains at herd level 1995
M. Bérodier Gomès, M. Brochard and V. Ducrocq

481. A bio-economic model to estimate the economic value of sow feed intake during lactation 1999
D.M. Thekkoot, R.A Kemp and J.C.M. Dekkers

482. Consequences of using different economic selection index methods on greenhouse gas emissions in beef cattle 2003
B.J. Walmsley

483. Impact of planning horizon length on the relative emphasis of traits in economic breeding goals 2007
H.F. Valasek, B.L. Golden and M.L. Spangler

Part 29 – Society – gene editing: ethics, economics and experiences 2011

484. Effect of alternative synchronisation treatments on the vaginal microbiota of ewes and their impact on pregnancy rate 2012
E.L. Reinoso-Peláez, O. González-Recio, C. González, M. Saura, A. Fernández, A. López-García, A. Saborío-Montero, J.H. Calvo, M. Ramón and M. Serrano

485. Modelling of direct-transfer vitrification of bovine embryos 2016
J. Lamy, A. de Wit, F. Fotinga-Meiring, E. Mullaart, L. Zak, E. Knol, E. Ellen and H. Woelders

486. Fertility analysis in stallions: a 35-year retrospective genetic study in the Argentinean Thoroughbred 2020
A. Karlau, A. Molina, A. Antonini and S. Demyda-Peyrás

487. Bull effects on *in vitro* embryo production quality traits are repeatable and heritable 2024
G. Gebreyesus, J.B. Secher, M.S. Lund, K. Kupisiewicz, M. Ivask and G. Su

488. Five years of optimizing the assisted reproduction protocol for European eel: what worked and what didn't? 2028
A.P. Palstra, P. Jéhannet, L.T.N. Heinsbroek and W. Swinkels

489. Random regressions for modelling semen production traits in HF purebred and crossbred bulls using Bayesian framework 2031
V.B. Ambike, R. Venkataramanan, S.M.K. Karthickeyan, K.G. Tirumurugaan, K.G. Bhave and M. Swaminathan

490. Removing the dopaminergic inhibition with CRISPR-Cas9 to study the progression of sexual maturation in zebrafish 2036
P. Jéhannet, A.A.C. De Wit, S. Brugman, Y. Zhang, J. Bogerd and A.P. Palstra

491. Societal aspects of animal breeding: a bibliometric analysis 2040
M. van der Sluis, K.H. de Greef and G. Bonekamp

492. The need for harmonized, risk-based regulation of gene editing in livestock 2044
A.L. Van Eenennaam and M.L. Mueller

493. Broadening the ethical debate on breeding innovations, public engagement and the role of the Democs game 2048
F.L.B. Meijboom, D.M. Bruce, K. Kramer and A. Bruce

494. Perceptions of genome editing in farm animals by livestock stakeholders 2052
R. Duclos, E. Delanoue, L. Journaux, D. Guéméné, M. Sourdioux and J.P. Bidanel

495. Production of a germline ablated bull using CRISPR/Cas9 to target *NANOS3* in bovine zygotes 2056
M.L. Mueller, B.R. McNabb, J.R. Owen, S.L. Hennig, P.J. Ross and A.L. Van Eenennaam

Part 30 – Challenges – use of multi-omics data **2060**

496. Using allele-specific expression to uncover *cis*-regulation in bovine muscle 2061
J.J. Bruscadin, T.F. Cardoso, W.J.S. Diniz, J. Afonso, M.M. de Souza, J. Petrini, V.H. da Silva, A. Zerlotini, L.L. Coutinho and L.C.A. Regitano

497. Enrichment of causative variants in tissue-specific and shared ATAC-Seq peaks in cattle 2065
C. Yuan, L. Tang, T. Lopdell, C. Oget-Ebrad, G. Costa Monteiro Moreira, J.L. Gualdron, Z. Cheng, M. Salavati, D.C. Wathes, M.A. Crowe, GplusE consortium, W. Coppieters, C. Charlier, T. Druet, M. Georges and H. Takeda

498. Preliminary investigation into the association of members of the rumen biome with production traits in Afrikaner cattle 2069
E.D. Cason, J. Alom, J. Barnard, M. Fair, P.D. Vermeulen and F.W.C. Neser

499. Maternal effect on the metagenomic composition determining the intramuscular fat content in rabbits 2073
A. Zubiri-Gaitán, M. Mora, C. Casto-Rebollo, M.A. Santacreu, A. Blasco, P. Hernández and N. Ibañez-Escriche

500. The gut microbiome profile varies among two maternal rabbit lines with different longevity 2077
I. Biada, N. Ibáñez-Escriche, A. Blasco and M.A. Santacreu

501. Comparing methods to summarize gut microbiota composition in estimating microbiability of host phenotypes in swine 2081
Y. He, C. Maltecca, J. Howard, Y. Huang, K. Gray and F. Tiezzi

502. Organoids as a research tool in animal breeding and nutrition 2085
L.M.G. Verschuren, D. Schokker, S. Verstringe, L. Kruijt, A.A.C. de Wit, E.G.T. van der Valk, S.K. Kar and E.D. Ellen

503. Simulation of host-microbiome evolution throughout a divergent selection experiment 2089
C. Casto-Rebollo, I. Pocrnic, G. Gorjanc and N. Ibáñez-Escriche

504. Rumen bacteria do not provide improved genetic evaluation of dairy traits in sheep 2093
G. Martinez Boggio, O.F. Christensen, A. Legarra, C. Allain, A. Meynadier and C. Marie-Etancelin

505. Phenotypic characterization of organoids derived from pig intestine segments 2097
F. Blanc, M. Mongellaz, F. Pepke, C. Bevilacqua, J. Riviere, M. Vilotte, E. Giuffra and G. Egidy

506. Can microbial data improve prediction of breeding values of efficiency traits in pigs fed conventional or fiber diets? 2101
V. Déru, F. Tiezzi, C. Carillier-Jacquin, B. Blanchet, L. Cauquil, O. Zemb, A. Bouquet, C. Maltecca and H. Gilbert

507. Investigating new technologies for on-site real-time sequencing for any animal scientist 2105
H. Ostrovski, R.P. Savegnago, W. Huang and C. Gondro

508. Impact of the bovine reference genome (ARS-UCD1.2) on functional annotation at genome, transcriptome and methylome level 2109
A. Cánovas, P.A.S. Fonseca, S. McKay and J.F. Medrano

Part 31 – Functional annotation of genomes: causal variants & gene discovery **2113**

509. Detection of genes influenced by environmentally responsive *cis*-regulatory variation in porcine immune cells 2114
E. Murani, F. Hadlich, S. Ponsuksili, and K. Wimmers

510. Insight into the most significant quantitative trait locus for calving traits on BTA18 in Holstein dairy cattle 2117
N. Dachs, M. Upadhyay, E. Hannemann, A. Hauser, S. Krebs, H. Blum, D. Seichter, I. Russ, L.J. Gehrke, G. Thaller and I. Medugorac

511. Finding potentially causal genetic factors for meat tenderness using eQTL study in Hanwoo cattle 2121
Y. Chung, K. Chung, P. Dinh, I. Choi and S. Lee

512. The application of mixed linear models for the estimation of functional effects on bovine stature based on SNP summary 2126
K. Kotlarz, B. Kosinska-Selbi, Z. Cai, G. Sahana and J. Szyda

513. Predicted isoforms of a Brahman cow revealed by full-length transcript sequencing 2130
L.T. Nguyen, Y. Cheng, R. Kuo, B.J. Hayes and E.M. Ross

514. Meta-analysis of genome-wide association studies for litter size in pigs indicates new causal variants 2134
E. Sell-Kubiak, M.F.L. Derks, M.S. Lopes, J. Dobrzański and T. Szwaczkowski

515. Selection signatures analyses revealed genes associated with adaptation in selected goat breeds in Kenya 2138
R.W. Waineina, T.O. Okeno, E.D. Ilatsia and K. Ngeno

516. Investigation of host genetic role in PCV2 infections 2142
H.R. Wijesena, K.M. Sutton, S.D. Kachman and D.C. Ciobanu

517. Olfaction: a critical force driving adaptive evolution in yaks 2147
A. Kour, S.K. Niranjan, S. Jayakumar, M. Pukhrambam and M. Sarkar

518. Functional analysis of selective sweeps to identify phenotypic traits in South African Nguni cattle 2151
A.A. Zwane, K.S. Nxumalo, M.L. Makgahlela, E. Van Marle-Koster and N. Maiwashe

519. Fine-mapping of candidate causal genes for tail length in the Merinolandschaf breed 2154
D.K. Lagler, E. Kunz, K. Eck, D. Seichter, I. Russ, C. Mendel, G. Lühken, M. Upadhyay and I. Međugorac

520. Massive detection of cryptic recessive genetic defects in livestock mining millions of life trajectories 2158
A. Guintard, F. Besnard, M. Cano, C. Hozé, H. Leclerc, M. Boussaha, C. Grohs, A. Barbat, S. Fritz, C. Escouflaire, J. Rivière, C. Péchoux, C. Danchin-Burge, G. Foucras, A. Relun, V. Plassard, M.-A. Arcangioli, S. Mattalia, D. Boichard and A. Capitan

521. A *de novo* missense mutation of COL1A1 causes osteogenesis imperfecta type 2 and premature delivery in Normande Cattle 2162
C. Grohs, J. Corbeau, J. Jourdain, M. Boussaha, V. Plassard, A. Barbat, C. Hamelin, J. Mortier, D. Boichard, R. Guatteo and A. Capitan

522. CRISPR-Cas9 gene editing enables functional evaluation of a host *Synaptogyrin-2* missense variant in PCV2b infection 2166
L.R. Walker, H. Vu and D.C. Ciobanu

523. Sequence-based GWAS meta-analyses for beef production traits 2170
M.P. Sanchez, T. Tribout, N. Kadri, P.K. Chitneedi, S. Maak, C. Hozé, M. Boussaha, P. Croiseau, R. Philippe, M. Spengeler, C. Kühn, Y. Wang, H. Pausch and D. Boichard

524. Deciphering genetic variants from whole genome affecting duodenum, liver and muscle transcriptomes in pigs 2174
D. Crespo-Piazuelo, O. González-Rodríguez, M. Mongellaz, H. Acloque, M.-J. Mercat, M.C.A.M. Bink, A.E. Huisman, Y. Ramayo-Caldas, J.P. Sánchez and M. Ballester

525. Detailed analysis of mortality rates in the female progeny of Holstein bulls allows the discovery of new dominant genetic defects 2178
F. Besnard, H. Leclerc, N. Cesbron, M. Boussaha, C. Grohs, N. Jewell, A. Pinton, H. Barasc, M. Femenia, L. Dorso, B. Strugnell, T. Floyd, C. Danchin, R. Guatteo, X. Hubin, S. Mattalia, D. Boichard and A. Capitan

526. Candidate genes for milk, growth and immune system traits in Brazilian Iberian-derived locally adapted cattle breeds 2182
L.L. Verardo, M.A. Machado, J.C.C. Panetto and M.V.G.B. Silva

527. Copy number variation analysis in Nguni and Bonsmara crossbred cattle 2187
B. Bhika Kooverjee, P. Soma, F.W.C Neser, M.A. van der Nest and M.M Scholtz

528. Resequencing of casein genes in Swedish Red Cattle with varying milk coagulation properties 2191
T.K. Vanhala, F. Lewerentz, L. Buhelt Johansen, C. Sibersen, M. Paulsson, M. Glantz and D.J. de Koning

529. Major histocompatibility complex class II DRB gene Exon-2 of Indian camel breeds show limited genetic diversity 2194
V. Prakash, B. Jyotsana and S. Suthar

530. Transcriptome profile of liver from pigs fed with two different levels of soybean oil revealed the NF-κB1 modulation 2199
S.L. Fanalli, B.P.M. da Silva, F.N. Ciconello, J. Reecy, J. Koltes, D. Koltes, L.C.A. Regitano, J.C.C. Balieiro, L.L. Coutinho, G.B. Mourão, G.C.M. Moreira, V.V. de Almeida, A. Luchiari Filho and A.S.M. Cesar

531. SPP1 gene polymorphisms within Intron-IV and Exon-IV region and their association with milk traits in Gaolao cattle 2203
R.R. Kate, D.S. Kale, J. Singh and D.V. Patil

532. Building *in vitro* tools for livestock genomics: chromosomal variation within the porcine PK15 cell line 2208
M. Johnsson, J.M. Hickey and M.K. Jungnickel

533. Conserved non-coding elements of the bovine genome 2212
N.K. Kadri and H. Pausch

534. A massively parallel reporter assay to screen bovine regulatory variants 2216
M.D. Littlejohn, T.J. Lopdell, A. Trevarton, J. Moody, K.M. Tiplady, K.A. Burborough, C.P. Prowse-Wilkins, A.J. Chamberlain, M. Goddard and R.G. Snell

535. Detection of causative genes for resistance against cardiomyopathy syndrome in Atlantic salmon using omics data 2220
M.L. Aslam, S. Gonen, S.A. Boison, E. Leder, M. Baranski, A. Norris, N. Robinson, S. Koga, T.K.K. Østbye and B. Dagnachew

536. Genetic regulation of ear size in Slovenian and Greek sheep breeds 2224
J. Klawatsch, D. Papachristou, P. Koutsouli, D. Seichter, I. Russ, M. Simčič, I. Bizelis and I. Medugorac

537. Large-scale 'omics fine-mapping identifies expression quantitative trait loci significantly affecting cattle phenotypes 2228
R. Xiang, M.E. Goddard, C.P. Prowse-Wilkins, C.M. Reich, B.A. Mason, J.B. Garner, L.C. Marett, I.M. MacLeod and A.J. Chamberlain

Part 32 – Functional annotation of genomes: structural variation and variants 2232

538. A functional copy number gain at indicine cattle footprint modulates actin-myosin and immune response genes in muscle 2233
V.H. da Silva, J. Afonso, N.S. Morosini, F.C. da Veiga, A.S.M. Cesar, B. Silva-Vignato, G.B. Mourão, A.Z. Neto, L.C.A. Regitano and L.L. Coutinho

539. Functional SNPs and INDELs within regulatory elements associated with mastitis in Holstein cow using -OMICs technologies 2237
V. Asselstine, J.F. Medrano, P. Stothard, F. Miglior, N.A. Karrow, C.F. Baes, F.S. Schenkel and A. Cánovas

540. Allele specific expression as an indication of ploidy in pig IPECJ2 and chicken SL-29 cell lines 2241
J. de Vos, R.P.M.A. Crooijmans, M.F.L. Derks, S.L. Kloet, M.A.M. Groenen and O. Madsen

541. Segregation of the structural variant responds for mastitis resistance in re-sequencing Nordic Holstein animals 2245
Z. Cai and G. Sahana

542. Rare CNVs in the bovine genome are not captured well by 50K density genotyping array SNPs 2249
Y.L. Lee, M. Bosse, W. Coppieters, R.F. Veerkamp, L. Karim, C. Oget-Ebrad, T. Druet, M.A.M. Groenen, M. Georges, A.C. Bouwman and C. Charlier

543. Genome-wide DNA methylation of Gonad in sex-biased zebrafish families 2253
S. Hosseini, N. Trakooljul, M. Hirschfeld, K. Wimmers, J. Tetens, A.R. Sharifi and B. Brenig

544. An approach to study the association between the blood cell methylome with feed efficiency traits 2257
A. López-Catalina, A. Bach, M. Gutiérrez-Rivas, R. Peiró-Pastor and Ó. González-Recio

545. Multi-dimensional functional annotation of bovine genome for the BovReg project 2261
G.C.M. Moreira, S. Dupont, D. Becker, M. Salavati, R. Clark, E.L. Clark, G. Plastow, C. Kühn and C. Charlier on behalf of the BovReg consortium

546. European project AQUA-FAANG: the epigenetic landscape of the Atlantic Salmon; focus on liver tissue2265
M.-O. Baudement, G.B. Gillard, T. Podgorniak, L. Grønvold, S. Lien and M.P. Kent

547. Integration of methylome and transcriptome profiles reveals candidate biomarkers for *S. uberis*-subclinical mastitis 2269
M.Q. Wang, M. Laterrière, P.L. Dudemaine, N. Bissonnette, D. Gagné, X. Zhao, J.P. Roy, M.A. Sirard and E.M. Ibeagha-Awemu

548. eQTL mapping in Brown Swiss bulls to identify variants associated with male fertility 2273
X.M. Mapel, M. Hiltpold, A. Lloret-Villas and H. Pausch

549. Bioinformatics workflow for the detection of eQTL in the cattle genome using Nextflow DSL2 2277
P.K. Chitneedi, F. Hadlich and C. Kuehn

550. Extensive functional genomics information from early developmental time points for pig and chicken 2281
H. Acloque, P.W. Harrison, W. Lakhal, F. Martin, A.L. Archibald, M. Beinat, M. Davey, S. Djebali, S. Foissac, S. Guizard, C. Guyomar, R. Kuo, C. Kurylo, O. Madsen, K. Miedzinska, M. Mongellaz, J. Smith, J. Smith, A. Sokolov, J. de Vos, E. Giuffra and M. Watson

551. Demonstrating the use of a mammalian methylation microarray for epigenome wide association studies in livestock 2285
A. Caulton, K.G. Dodds, K.M. McRae, C. Couldrey, S. Horvath and S.M. Clarke

552. Regulatory QTL and exon expression QTL in the mammary gland of dairy cows 2289
C.P. Prowse-Wilkins, T.J. Lopdell, R. Xiang, C.J. Vander Jagt, M.D. Littlejohn, A.J. Chamberlain and M.E. Goddard

553. H3K27me3 predicted regulation of gene expression linked to calcium quantification in Nelore muscle 2293
J. Afonso, W.J. Shim, M. Boden, N. Palpant, M.R.S. Fortes, W.J.S. Diniz, A.O. Lima, M.I.P. Rocha, T.F. Cardoso, J.J. Bruscadin, C.F. Gromboni, A.R.A. Nogueira, G.B. Mourão, A. Zerlotini, L.L. Coutinho and L.C.A. Regitano

554. Comparative analysis of CAGE-Seq across tissues reveals transcription start sites unique to cattle 2297
M. Salavati, R. Clark, D. Becker, C. Kühn, G. Plastow, G.C.M. Moreira, C. Charlier and E.L. Clark on behalf of the BovReg consortium

555. Transcriptomic characterisation of claw horn disruption lesions in the peripheral blood leucocytes of dairy cattle 2301
X. Dai, D. Xia, B.E. Griffiths, A. Anagnostopoulos, M. Barden, B. Li, M. Coffey, D. Werling, G. Oikonomou, G. Banos, and A. Psifidi

556. Evidences of INFt and ISG gene expression in leukocites of pregnant hair sheep ewes from a thermal stress experiment 2305
J.A. Gómez-Guzmán, J.F. Vázquez-Armijo, A.L. Lara-Rivera, A.M. Sifuentes-Rincón, R. Ramírez-Valverde, R. Nuñez-Domínguez, J.C. Martínez-González, W. Arellano-Vera, G.M. Parra-Bracamonte

557. Identification of differentially expressed transcription factors in Brangus skin infested with *Rhipicephalus australis* 2309
E. Mantilla Valdivieso, L. Nguyen, E. Ross, A. Raza, P. James, B. Hayes, N. Jonsson and A. Tabor

558. Unravelling regulatory variants affecting gene expression in four porcine tissues 2313
M. Gòdia, M.F.L. Derks, B. Harlizius, O. Madsen and M.A.M. Groenen

559. Unravelling the transcriptomic control of growth traits in sheep during prenatal and postnatal development 2317
S.A. Woolley, M. Salavati and E.L. Clark

560. Large-scale cis-eQTL analysis of gene expression in blood of young healthy pigs using PigGTEx 2321
L.M. Kramer, J. Teng, K.S. Lim, Y. Gao, H. Yin, L. Bai, G.E. Liu, Z. Zhang, L. Fang, G.S. Plastow, C.K. Tuggle and J.C.M. Dekkers

561. Unravelling the structural variability in chicken genomes by long-read sequencing 2325
J. Geibel, J. Schauer, A. Weigend, C. Reimer, D.-J. de Koning, H. Simianer and S. Weigend

562. Detection and characterisation of *de novo* structural variants in pigs 2329
M. Steensma, Y.L. Lee, A.C. Bouwman, C. Pita Barros, M.F.L. Derks, M.C.A.M. Bink, B. Harlizius, A.E. Huisman, R.P.M.A. Crooijmans, M.A.M. Groenen, H.A. Mulder and C.M. Rochus

563. Efficient detection of interchromosomal rearrangements in Holstein bulls using large SNP datasets 2333
J. Jourdain, A. Pinton, H. Barasc, A. Barbat, C. Hozé, M. Philippe, D. Boichard and A. Capitan

564. A pan-genome of commercial pig breeds 2337
M.F.L. Derks, A. Boshove, B. Harlizius, E. Sell-Kubiak, M.S. Lopes, E. Grindflek, E. Knol, M.A.M Groenen and A.B. Gjuvsland

Part 33 – Aquaculture 2342

565. Conserved QTL and chromosomal inversions affect resistance to columnaris disease in two rainbow trout populations 2343
F.C.F. Calboli, H. Koskinen, A. Nousianen, C. Fraslin, R.D. Houston and A. Kause

566. Multi-trait genome wide association study in correlated traits: fillet colour and body weight in Atlantic salmon 2347
P. Sae-Lim, S. Boison and M. Baranski

567. Implementation of genomic selection on production and quality traits and linkage disequilibrium in *Crassostrea gigas* 2351
A. Jourdan, P. Boudry, F. Enez, P. Haffray, F. Chenier, E. Vetois, F. Allal, P. Leroy, F. Phocas, J. Bugeon, L. Degremont and R. Morvezen

568. Genetic correlation between IP and cohabitation challenge test model for *Piscirickettsia salmonis* in Atlantic salmon 2355
C. Manosalva, M.L. Pavez, P. Sae-Lim, A. Norris, M. Baranski and S.A. Boison

569. Using 'population-specific haplotypes' to select for resistance to SRS in an admixed population of coho salmon (*Oncorhynchus kisutch*) 2359
T. Moen, J. Ødegård, F. Grammes, T. Knutsen, R. Deerenberg and D. Chichero

570. Potential of imputation for cost-efficient genomic selection for resistance to *Flavobacterium columnare* in Rainbow trout 2363
C. Fraslin, A. Nousiainen, H. Koskinen, A. Kause and R.D. Houston

571. Genomic prediction of complex traits in European sea bass: random cross-validation and leave-one-family-out validation 2367
S. Faggion, D. Bertotto, V. Bonfatti, M. Freguglia, L. Bargelloni and P. Carnier

572. Genetics of parasite attraction in Atlantic salmon: potential for group-level protection against sea lice 2371
J. Ødegård, S. Kjøglum, M. Medina, J.S. Torgersen, S.A. Korsvoll, R. Deerenberg, J.M. Yáñez, D. Cichero, P. Lopez and T. Moen

573. A major QTL affects resistance to viral nervous necrosis in farmed European seabass 2375
R. Mukiibi, D. Robledo, C. Peñaloza, S. Ferraresso, R. Franch, D. Bertotto, M. Freguglia, S. Laureau, F. Pascoli, A. Toffan, C. Tsigenopolous, L. Bargelloni and R. Houston

574. The potential indicator for resilience of Sukamandi strain tilapia grown in brackish water ponds 2379
M.H.F. Aththar, P. Setyawan, I. Imron, B. Gunadi, M. Camara, H. Komen and J.W.M. Bastiaansen

575. Exploiting genomics to infer population structure and genetic variability in wild and farmed seabream and seabass 2383
B. Villanueva, A. Fernández, R. Peiro-Pastor, C. Peñaloza, R.D. Houston, A.K. Sonesson, C.S. Tsigenopoulos, L. Bargelloni, K. Gamsiz, B. Karahan, E.Ö. Gökçek, J. Fernández and M. Saura

576. Comparison of tank and commercial sea-pen family evaluation of Chinook salmon (*Oncorhynchus tshawytscha*) in New Zealand 2387
M.R. Scholtens, K.G. Dodds, S.M. Clarke, S.P. Walker, M.L. Tate, R. Miller, T. Slattery and J.E. Symonds

577. Testing fat content or feeding behaviour as indirect selection criteria for feed efficiency using trout isogenic lines 2391
S. Pouil, T. Kernéis, E. Quillet, D. Lallias, L. Labbé, F. Phocas and M. Dupont-Nivet

578. The possibilities of using electronic sensors in aquaculture breeding 2395
W. Abbink, A. Palstra, W. Agbeti, G. Lembo and J. Komen

579. Genetic parameters and genome-wide association study of resistance to acute hyperthermia in rainbow trout 2399
H. Lagarde, D. Lallias, P. Patrice, M. Prchal, Y. François, J. D'Ambrosio, A. Acin-Perez, F. Cachelou, P. Haffray, M. Dupont-Nivet and F. Phocas

580. QTLs controlling swimming performance and their effect on growth in Nile tilapia (*Oreochromis niloticus*) 2403
X. Yu, S. Bekele Mengistu, H.A. Mulder, A.P. Palstra, J.A.H. Benzie, T. Quoc Trinh, M.A.M. Groenen, H. Komen and H.J. Megens

581. Optimizing genotyping effort in aquaculture breeding programs by pre-selection of candidates 2407
C. Roozeboom, B. Gulzari, H. Komen, M. Camara and J.W.M. Bastiaansen

582. Prediction of production traits by using body features of gilthead seabream (*Sparus aurata*) obtained from digital images 2412
B. Gulzari, A. Mencarelli, C. Roozeboom, H. Komen and J.W.M. Bastiaansen

583. Comparison of genomic selection barramundi breeding schemes for multiple environments with strong G×E 2416
M. Lillehammer, N.A. Robinson, D.B. Jones, C. Massault, S. Loughnan, H.S. Cate, P.J. Harrison, J.M. Strugnell, K.R. Zenger and D.R. Jerry

Part 34 – Avian **2420**

584. Genome-wide association studies of chicken caecal microbiota 2421
X. Dai, A.T. Hinsu, C. Dadousis, R.J. Pandit, M. Crotta, G. Limon, B. Fosso, J. Guitian, F.M. Tomley, P.G. Koringa, C.G. Joshi, D.P. Blake and A. Psifidi

585. Breeding for an optimised gut microbiota composition for the improvement of phosphorus utilisation in Japanese quail 2425
V. Haas, S. Vollmar, A. Camarinha-Silva and J. Bennewitz

586. High-resolution genotyping and analysis of *in silico* predicted proteins for classical MHC genes in Korean native chicken 2429
T.K. Ediriweera, P. Manjula, E. Cho, M. Kim, S. Cho and J.H. Lee

587. Genetic architecture of body weight and carcass traits in Ghanaian local chickens 2433
R.A. Kanlisi, E.N. Amuzu-Aweh, M. Walugembe, A. Naazie, H.R. Otsyina, N. Chouicha, T.R. Kelly, R. Gallardo, J. Dekkers, S. Lamont, H. Zhou and B.B. Kayang

588. Estimating environmental direct-maternal covariance in real data – illustration on broilers 2437
H. Romé, T.T. Chu, D. Marois, C.H. Huang, P. Madsen and J. Jensen

589. Host transcriptome response of meat-type chickens infected with *Eimeria maxima* and reared under heat stress environment 2441
S.E. Aggrey, A.F.A. Ghareeb, A.L. Fuller, M.C. Milfort, J.C. Foutz, G.H. Schneiders, W.S. Habashy, K. Adomako and R. Rekaya

590. Changes in genetic parameters for traits under genomic selection in poultry 2445
J. Richter, J. Hidalgo, V. Breen, R. Hawken, I. Misztal and D. Lourenco

591. Effects of age, line and diet on the occurrence of white striping lesions in broiler breast muscle 2448
L.T. Fernandes, J.O. Peixoto, M.S. Dal Pizzol, A.M.G. Ibelli, M.A.Z. Morés, F.C. Tavernari, A. Coldebella, M.E. Cantão and M.C. Ledur

592. Variation in male autosomal recombination in turkeys (*Meleagris gallopavo)* 2452
C.M. Rochus, B.J. Wood and C.F. Baes

593. Functional annotations of regulatory elements in the chicken genome 2456
Z. Pan, Y. Wang, L. An, Y. Bi, D. Guan, M. Delany, H.H. Cheng and H. Zhou

594. Time-series transcriptome analysis of broilers under *Eimeria tenella* infection reveals host-pathogen interactions 2460
M. Kim, Y. Chung, P. Manjula, D. Seo, S. Cho, E. Cho, T.K. Ediriweera, M. Yu, S. Nam, J.M. Heo and J.H. Lee

595. Genetic diversity of *Eimeria tenella* apical membrane antigen 1 in chickens from KwaZulu-Natal, South Africa 2464
A.J. Fatoba, O.T. Zishiri, D.P. Blake, S.O. Peters, J. Lebepe, S. Mukaratirwa and M.A. Adeleke

596. Chicken quantitative traits follow the omnigenic model 2467
P. Davoodi, A. Ehsani, R. Vaez Torshizi and A.A Masoudi

597. Association of polymorphism of *MAP3K8* with egg production traits of White Muscovy ducks (*Cairina moschata*) 2471
S.F. Bello, H.Xu, S. Zhang, K.D. Aloryi, R.O. Ahmed, A.A. Bahareldin, A.C. Adeola, M.A. Popoola, W. Zhu, D. Zhang, X. Zhang, C. Ji and Q. Nie

598. Genetic markers associated with bone quality in Rhode Island Red laying hens 2475
M. Sallam, H.A. McCormack, R.H. Fleming, P.W. Wilson, B. Andersson, M. Schmutz, C. Benavides, N. Dominguez-Gasca, E. Sanchez-Rodriguez, A.B. Rodriguez-Navarro, I.C. Dunn, D.J. De Koning and M. Johnsson

599. Determining the heritability of premaxillary bone shape and size within two populations of pure line laying hens 2479
S. Struthers, B. Andersson, M. Schmutz, H.A. McCormack, P.W. Wilson, I.C. Dunn, V. Sandilands and J.J. Schoenebeck

600. No G×E on egg qualities and body weight between cage and floor systems, implications for breeding programmes in laying hens 2483
N. Bédère, L. Bécot, T. Burlot and P. Le Roy

601. Growth and laying performance of local chicken breeds and their crosses fed with faba beans 2487
A.R. Sharifi, T. Nolte, S. Jansen, S. Weigend, D. Mörlein, I. Halle, W. Link and H. Simianer

602. Heterosis of egg-laying performance in chickens 2491
A.X. Ni, M.P.L. Calus, H. Bovenhuis, Y.Y. Sun and J.L. Chen

603. *In vitro* effects of probiotic *Bacillus* strains on adaptive immune cells of broiler chicken 2495
F. Larsberg, M. Sprechert, D. Hesse, G. Loh, G.A. Brockmann and S. Kreuzer-Redmer

604. Strain and age effects, as well as genetic parameters for adult traits in ostriches 2499
S.W.P. Cloete, A. Engelbrecht and Z. Brand

Part 35 – Bees and other insects **2503**

605. Economic value and production characteristics of table honey 2504
E.A. Frost, N.C. Chapman, R.G. Banks, S.F. Walkom and S. Hermesch

606. Evaluating the potential for mating control in honey bee breeding in three SE European countries (preliminary results) 2508
A. Uzunov, S. Andonov, B. Dahle, M. Kovačić, J. Prešern, G. Aleksovski, F. Jaman, M. Jovanovska, B. Pavlov, Z. Puškadija, J. Wegener and R. Büchler

607. A model for, and early implementation of, genomic selection in the Australian honey bee population 2512
N.C. Chapman, E.A. Frost and R.G. Banks

608. An over-time distribution map of the main *Apis mellifera* mitochondrial DNA lineage using honey as source of eDNA 2516
V. Taurisano, V.J. Utzeri, A. Ribani and L. Fontanesi

609. Using genomics to predict drone quality: why are there so many 'dud' male honey bees? 2520
G.P. Slater and B.A. Harpur

610. Development of genomic resources in black soldier fly (*Hermetia illucens* L.) via throughput DNA pool sequencing 2524
A.S.L. Donkpegan, A. Guigue, F.X. Boulanger, S. Brard-Fudulea, P. Haffray, M. Sourdioux and R. Rouger

611. The natural history of the black soldier fly, *Hermetia illucens*: insights from complete mitochondrial genome sequences 2528
J. Guilliet, G. Baudouin, N. Pollet and J. Filée

612. Impact of genetic selection in insect populations using different selection designs – a simulation study 2533
R.S.C. Rikkers, J.W.M. Bastiaansen, A.C. Bouwman and E.D. Ellen

613. Genetic parameters of black soldier flies estimated in full sib design 2537
A.C. Bouwman, J.E. Nugroho, D. Wongso, J. van Schelt, B.A. Pannebakker, B.J. Zwaan and E.D. Ellen

614. Towards selective breeding in insects – estimating genetic parameters with individual-level phenotypes and pedigree 2541
L.S. Hansen, S.F. Laursen, S. Bahrndorff, M. Kargo, T.N. Kristensen, G. Sahana, J.G. Sørensen and H.M. Nielsen

615. Genetic improvement program in black soldier fly for increased larval weight in industrial applications 2545
E. Facchini, K. Shrestha, E. van den Boer, P. Junes, G. Sader, K. Peeters and E. Schmitt

616. *Tenebrio molitor* genomic structure among available populations 2549
E. Eleftheriou, B. Vacherie, K. Labadie, C.G. Athanassiou, T. Rigaud, Y. Moret, T. Lefebvre and MA. Madoui

617. Inferring whole-genome tree sequences and population and demographic parameters of the Western honeybee 2552
J. Obšteter, A. Marinč, J. Prešern, D. Wragg and G. Gorjanc

618. Heritability of disease resistance to chronic bee paralysis, chalkbrood and nosemosis in the honeybee (*A.m.carnica*) 2556
A. Hoppe, R. Bernstein, M. Du and K. Bienefeld

619. Genetic analysis of royal jelly production and behaviour traits of honeybees 2560
B. Basso, T. Kistler, T. Gerez and F. Phocas

620. Comparison of heritabilities and estimated breeding values for three honeybee traits using dam and animal models 2564
G.E.L. Petersen, F.S. Hely, P.F. Fennessy and P.K. Dearden

621. Statistics for an accurate genome wide association study on *Varroa* resistance trait in a French honeybee 2568
S.E. Eynard, A. Vignal, Y. Agez, B. Basso, O. Bouchez, T. Bulach, Y. Le Conte, B. Dainat, A. Decourtye, L. Genestout, M. Guichard, F. Guillaume, E. Labarthe, R. Mahla, F. Mondet, M. Neudischko, F. Phocas, Y. Poquet, C. Sann, R.F. Serre, K. Tabet and B. Servin

622. New approach to identify Mendelian inconsistencies between SNP and pedigree information in the honey bee 2572
R. Bernstein, M. Du, A. Hoppe and K. Bienefeld

623. Investigation of parental meiotic contribution in honeybees (*Apis mellifera*) 2576
G.E.L. Petersen, A. Heywood, A.C.L. Walters, P.F. Fennessy and P.K. Dearden

624. SIMplyBee: stochastic simulator of honeybee populations and breeding programmes 2580
L. Strachan, J. Bubnič, J. Obšteter and G. Gorjanc

625. Assessment of uncertainty in direct and maternal genetic parameters estimates for honeybee colony phenotypes 2584
T. Kistler, E.W. Brascamp, B. Basso, P. Bijma and F. Phocas

626. Very local genotype by environment interaction in Austrian honey bees 2588
E.W. Brascamp, M. Rubinigg, R.F. Veerkamp and P. Bijma

Part 36 – Bovine beef 2592

627. Genetic prediction for growth traits in beef cattle using selected variants from imputed low-pass sequence data 2593
C.A. Russell, L.A. Kuehn, W.M. Snelling and M.L. Spangler

628. *Bos indicus* genome percentage effects gene expression profile and differentially expressed genes in Brahman cattle whole blood 2597
E.M. Ross, L.T. Nguyen, B.N. Engle, A.J. Chamberlain, E. Kho and B.J. Hayes

629. Effect of one copy of nt821 mutation in myostatin gene on ultrasound carcass traits in Senepol cattle 2601
G.R.O. Menezes, C.B. Souza, A.L.R. Lima, A. Gondo, F. Siqueira, A.A. Egito, L.N. Silva, J.A. Fernandes Junior and R.A.A. Torres Junior

630. Allelic diversity and effect of the intronic TBX20-191081 marker on temperament in beef cattle 2605
V.M. Del Real-García, A.M. Sifuentes-Rincón, F.A. Paredes-Sánchez, G. Ruíz-de la Cruz, E. Garza-Brenner, G.M. Parra-Bracamonte, H. Bernal-Barragán and F.A. Rodríguez-Almeida

631. Innovative phenotyping strategies exploiting immune response to heat stress conditions 2608
P. Lemal, M. Schroyen and N. Gengler

632. Epistatic interaction networks affecting feed efficiency and methane emission in Nelore cattle 2612
T.F. Cardoso, J.J. Bruscadin, W.J.S. Diniz, P. Banerjee, J. Afonso, J. Petrini, B.G.N. Andrade, J.M. Malheiros, T. Porto, A. Zerlotini, G.B. Mourão, L.L. Coutinho and L.C.A. Regitano

633. Host-genomically influenced ruminal microbial genes are temporally stable during the finishing phase in beef cattle 2616
J. Lima, M. Martínez-Álvaro, J. Mattock, M.D. Auffret, C.A. Duthie, M.A. Cleveland, R.J. Dewhurst, M. Watson and R. Roehe

634. A hypomorphic mutation in the *ATP2A1* gene increases muscle mass yet compromises meat quality of Belgian Blue cattle 2620
T. Rombouts, T. Druet, J.L. Gualdrón Duarte, N. Ahariz, K. Karim, W. Coppieters, S. De Smet, M. Georges and C. Charlier

635. Mitochondrial DNA copy number as a potential genetic indicator of growth and carcass traits in beef cattle 2624
L.P. Sanglard, L.A. Kuehn, W.M. Snelling, and M.L. Spangler

636. Genomic regions in Australian cattle associated with consumer satisfaction of beef 2628
A.M. Lynn, P. McGilchrist, H. Aliloo, J.H.J. van der Werf, R. Polkinghorne and S.A. Clark

637. A genome-wide scan for signatures of selection in Hanwoo and Angus cattle using whole-genome sequence data 2632
H.J. Kim, S. de las Heras-Saldana, S. Clark and J.H.J. van der Werf

638. Genetic analyses reveal the genetic architecture of the thermotolerance – production complex in beef cattle 2636
R.G. Mateescu, F.M. Rezende, K.M. Sarlo Davila, A.N. Nunez Andrade, A. Hernandez, M.A. Elzo and P.A. Oltenacu

639. The effect of allele ancestry on hip height and body weight of tropical beef cattle 2640
L.R. Porto-Neto, S. McWilliam, P.A. Alexandre, M.R.S. Fortes and A. Reverter

640. Mining of producer recorded data; using beef calf and cow live-weight data as a case study 2644
S. Walsh, N. McHugh, R.D. Evans, C. Murphy and D.P. Berry

641. Sexual precocity of purebred Charolais heifers 2648
S. Taussat, A. Vinet, D. Maupetit, D. Dozias, L. Chanteloup, G. Renand and P. Martin

642. Estimation of variance components for female longevity in Australian Angus cattle using random regression models 2652
H. Aliloo and S. Clark

643. Eye muscle area and lean muscle area are genetically different traits in high marbling Wagyu carcasses 2656
R.A. McEwin, M.L. Hebart, R. Tearle, J. Grose and W.S. Pitchford

644. Selection on yearling days to calving improves mature fertility traits in tropically adapted cattle 2660
M.L. Facy, M.L. Hebart, H. Oakey, R.A. McEwin,G.I. Popplewell and W.S. Pitchford

645. Estimation of maternal variance for slaughter traits 2664
A.J. Twomey and T. Pabiou

646. Biological types, direct and maternal heterosis and recombination effects on weaning weight of composite beef cattle 2668
J.B.S. Ferraz, R. Espigolan, F.S. Baldi, J.P. Eler, E.C.M. Oliveira, R. Nuñez-Dominguez and L.T. Gama

647. Breed differences, heterosis and recombination effects for calving interval in a composite beef cattle breed 2672
L.T. Gama, R. Espigolan, F.S. Baldi, J.P. Eler, E.C.M. Oliveira, R. Nuñez-Dominguez and J.B.S. Ferraz

648. Prediction ability for growth and maternal traits using SNP arrays based on different marker density in Nellore cattle 2676
F. Baldi, J.D. Rodríguez, R. Espigolan, R.B. Lôbo, R. López-Correa and I. Aguilar

649. Applying single step genomic evaluation and integrating local with foreign EBVs to increase calving performance 2680
S. Naderi, T. Pabiou and R.D. Evans

650. Understanding the genetics of fertility and temperament in Northern beef cattle using genomic technologies 2684
J.P. Copley, N.J. Corbet, J.M. Allen, A.R. Laing, G. Fordyce, M.R. McGowan, B.M. Burns, R.E. Lyons and B.J. Hayes

651. Genomic prediction with non-additive genetic effects for carcass weight and beef marbling in Japanese Black cattle 2688
K. Inoue, M. Nishio, Y. Inoue, M. Takeda and H. Hirooka

652. Reaction norm models contribute to the investigation of environmental sensitivity for weaning weight in Nellore cattle 2692
I. Carvalho Filho, D.A. da Silva, C.S. Teixeira, T.L. Silva, L.G. Albuquerque and R. Carvalheiro

653. Investigation on inheritance transmission modes using breeding values estimated from genomic or pedigree information 2696
H. Hirooka, M. Nishio, K. Inoue, M. Takeda and Y. Inoue

654. Genetic parameters for fatty acid traits of beef in Australian Angus 2700
C.J. Duff, A.M. Samaraweera, P. McGilchrist and S.A. Clark

655. Integration of beef cattle international estimated breeding values in the Italian evaluation 2704
R. Bonifazi, M.P.L. Calus, J. ten Napel, R.F. Veerkamp, S. Biffani, M. Cassandro, S. Savoia and J. Vandenplas

656. A genomic evaluation of genotype-by-environment interactions for foot scores in American and Australian Angus cattle 2708
A.B. Alvarenga, K. Retallick, A. Garcia, H.R. Oliveira, S.P. Miller, A. Byrne, L.F. Brito

657. Single-step GBLUP evaluation for categorical traits for beef cattle 2712
A. Nazari-Ghadikolaei, S. Eriksson and W.F. Fikse

658. Genetic parameters for mature cow body condition scores and fat and muscle traits in finishing beef cattle 2716
F. Weik, R.E. Hickson, S.T. Morris, D.J. Garrick and J.A. Archer

659. Decision support tools to support a more sustainable beef-on-dairy industry 2720
S.C. Ring, R.D. Evans, J. McCarthy, A. Cromie, and D.P. Berry

Part 37 – Bovine dairy – genetic evaluation methods 2724

660. Breed and heterosis effects for fatty acid composition of milk from dairy cows milked once- and twice-a-day 2725
I. Sanjayaranj, N. López-Villalobos, H.T. Blair, P.W.M. Janssen, S.E. Holroyd and A.K.H. MacGibbon

661. Long term effect of growth in rearing phase on reproduction and production trait in Murrah buffalo 2729
P. Joshi, A. Verma, G.R. Gowane, R. Alex, I.D. Gupta and D. Worku

662. Integrating parent-of-origin effects in random regression models for milk traits 2733
R.E. Jahnel, I. Blunk and N. Reinsch

663. Recombination rate and hotspots in Holstein cattle from Mexico 2737
E.I. Mejía-Melchor, A. García-Ruiz, C. Vásquez-Peláez, H.O. Toledo-Alvarado and F.J. Ruiz-Lopez

664. Longevity in genetic evaluation of Holstein cows in Uruguay 2741
N.F. Silveira, O. Ravagnolo and I. Aguilar

665. Comparison of two models for dairy herd improvement data in Taiwan 2745
Y.H. Lan, K.H. Lin, S.H. Ting, C.L. Su, P.A. Tu and E.C. Lin

666. Comparison of random regression test-day models for production traits of South African Jersey Cattle 2749
M.G. Kinghorn, E.D. Cason, V. Ducrocq and F.W.C. Neser

667. ROH describes the small holder dairy systems with Holstein cattle in Mexico 2753
A. García-Ruiz, J.G. Cortés-Hernández and F.J. Ruiz-López

668. How ssGBLUP became suitable for national dairy cattle evaluations 2757
I. Misztal D. Lourenco, S. Tsuruta, I. Aguilar, Y. Masuda, M. Bermann, A. Cesarani and A. Legarra

669. Options for evaluating multiple breeds in a single-step GBLUP for US dairy population 2761
A. Cesarani, D. Lourenco, P.M. VanRaden, E.L. Nicolazzi, A. Legarra, S. Tsuruta and I. Misztal

670. Integrating MACE breeding values into multiple-trait single step random regression test day evaluations of Aussie Reds 2765
V. Boerner, T. Nguyen and G. Nieuwhof

671. Optimum contribution selection in a dairy cattle population with different relationship matrices 2769
E. Gautason, G. Sahana, B. Guldbrandtsen and P. Berg

672. The rising popularity of embryo transfer in U.S. dairy cattle and implications for national fertility evaluations 2773
A.M. Miles, J.L. Hutchison and P.M. VanRaden

673. Simulating technical, economic and environmental performance of a dairy herd under selection in future climate conditions 2777
J.G. Burns, V. Eory, R. Mrode, G. Simm and E. Wall

Part 38 – Bovine dairy – genome informed breeding 2781

674. Understanding the genetic architecture of claw horn lesions in different lactation stages in Holstein cattle 2782
B. Li, M. Barden, V. Kapsona, E.S. Molano, A. Anagnostopoulos, B.E. Griffiths, C. Bedford, X. Dai, M. Coffey, A. Psifidi, G. Oikonomou and G. Banos

675. Shared response pattern in the mammary transcriptome after intramammary challenge with *E. coli* or *S. aureus* pathogen 2786
D. Becker, A. Heimes, R. Weikard, M. Hoedemaker, M.M. Meyerholz, H.J. Schuberth, W. Petzl, H. Zerbe, M. Schmicke, S. Engelmann and C. Kühn

676. Epistatic interaction between *KIT* and *MITF* causes splotchy face in Hereford × dairy crossbred calves 2790
S. Jivanji, A. Yeates, C. Harland, C. Gray, C. Couldrey, G. Worth, L. McNaughton, T. Fransen, T. Monehan, R. Spelman, D. Garrick and M. Littlejohn

677. Searching for genes involved in heat stress response in lactating cows through transcriptomics 2794
C. Diaz, M. Ramón, C. Gonzalez-Verdejo and M.J. Carabaño

678. Genomic regions exhibiting transmission distortions and copy number variants associated with stillbirth in cattle 2798
A.A.A. Martin, H.R. Oliveira, P.A.S. Fonseca, C.M. Rochus, F. Miglior, S. Id-Lahoucine, A. Cánovas, C.F. Baes and F.S. Schenkel

679. Mating allocations in Nordic Red Dairy Cattle using genomic information 2802
C. Bengtsson, H. Stålhammar, J.R. Thomasen, S. Eriksson, W.F. Fikse and E. Strandberg

680. Genome wide association study of blood cell count measures in Holstein cows 2806
C.J. Siberski-Cooper, J. Chinchilla-Vargas, L.M. Kramer, K.S. Lim, M.S. Mayes and J.E. Koltes

681. Investigation of intestinal atresia in a Jersey sire family 2810
T.R. Carthy, O.M. Keane, J.P. Hanrahan, D. Matthews, J. McEwan, S. Rowe and J. Mee

682. The genomic architecture of feed efficiency over the lactation of dairy cattle 2814
K. Houlahan, F.S. Schenkel, H.R. Oliveira, F. Miglior, G.A. Oliveira Jr., M.J. VandeHaar, K. Weigel, R.J. Tempelman and C.F. Baes

683. Population structure and signatures of selection in Italian Holstein through genome-wide analysis of imputed SNP data 2818
C. Persichilli, M. Marusi, J.T. van Kaam, R. Finocchiaro, G. Senczuk, M. Di Civita, F. Pilla and M. Cassandro

684. Genome-wide association studies for maturity rate in grazing dairy cows 2822
N. Lopez-Villalobos, H.B.P.C. Ariyarathne and R.E. Hickson

685. Selection, validation, and utilization of mitogenome SNP array information in cattle breeding 2826
V. Brajkovic, L. Bradic, K. Turkalj, D. Novosel, S. Ristov, P. Ajmone-Marsan, L. Colli, V. Cubric-Curik, J. Sölkner and I. Curik

686. Genomewide transcriptome profiling of milk derived primary bovine mammary epithelial cells after pathogen challenge 2830
T. Iso-Touru, D. Fischer, M. Kyläniemi, J. Tabell, A. Virta and J. Vilkki

687. Archetypal clustering reveals physiological mechanisms linking milk yield and fertility in dairy cattle 2834
E. Ooi, J.E. Pryce and M.E. Goddard

Part 39 – Bovine dairy – phenotype is king **2838**

688. Candidate genomic regions for forage dry matter intake in Swedish dairy cows using single-step genome-wide association 2839
G.M. Tarekegn, J. Karlsson, C. Kronqvist, K. Holtenius, S. Andonov, B. Berglund and E. Strandberg

689. Stillbirth, dystocia and weaning rates in Australian dairy calves 2843
M.M. Axford, J.E. Pryce, M. Khansefid and M Haile-Mariam

690. The relative importance of linear type traits in determining survival increases as Holstein-Friesian dairy cows age 2847
M. Williams, R.D. Sleator, C.P. Murphy, J. McCarthy and D.P. Berry

691. Genetic parameters of milk composition and fertility traits in cows milked once- or twice-daily in New Zealand 2851
J.M.D.R. Jayawardana, N. Lopez-Villalobos, R.E. Hickson and L.R. McNaughton

692. Identifying phenotypes to enhance stress resilience of dairy cows 2855
T.M. Sullivan, A. Sharma, K. Lamers, C. White, B.A. Mallard, A. Cánovas and N.A. Karrow

693. Estimation of genetic correlations between predicted energy balance and milk fatty acids of Holsteins in Japan 2859
A. Nishiura, O. Sasaki, M. Aihara, Y. Saito, R. Tatebayashi and H. Takeda

694. Associations between milk protein polymorphisms and milk production in Holstein-Friesian cows 2863
D.N. Kelly, F.L. Dunne, R.D. Evans and D.P. Berry

695. Genetic analysis of milking traits in Holstein cows based on automatic milking system data 2867
J. Kawakami, Y. Gotoh, T. Baba, S. Yamaguchi, S. Nakagawa, S. Yamaguchi, T. Oka and T. Kawahara

696. Fertility traits of Mexican Holstein cattle: genetic parameters, correlations and changes in genetic diversity over time 2871
C. Durán-Alvarez, A. García-Ruiz, R.A. Alonso Morales, L.E. Eguiarte , D. Piñero and F.J. Ruiz-López

697. Genetic parameters for residual feed efficiency in three dairy cattle breeds in commercial farms using 3D cameras 2875
C.I.V. Manzanilla-Pech, R.B. Stephansen, T. Andersen and J. Lassen

698. Insemination values to support mating decisions under dairy heifer calf herd size constraints 2879
A. De Vries, N. Bliznyuk, P. Sharma, Y. Han and P. Pinedo

699. Onset of heat stress and development of genomic predictions for heat tolerance in US Holsteins and Jerseys 2883
T.M. McWhorter, M. Sargolzaei, C.G. Sattler, M.D. Utt, S. Tsuruta, I. Misztal and D. Lourenco

700. Detection of genetic variability in cattle infectivity for bovine tuberculosis (bTB) 2887
E. Sánchez-Molano, D. Madenci, S. Tsairidou, M. Winters, A.P. Mitchell, G. Banos and A. Doeschl-Wilson

701. Dairy female fertility traits in seasonal and non-seasonal herds in Ireland 2891
K. Stachowicz, P.R. Amer, M.M. Kelleher, S.C. Ring and R.D. Evans

702. Genetic aspects of age at first calving in Italian Holstein dairy cows 2895
V. Ferrari, F. Galluzzo, R. Finocchiaro, J.B.C.H.M. van Kaam, M. Marusi, M. Penasa and M. Cassandro

Part 40 – Caprine/ovine **2900**

703. Genetic and genomic approaches to ewe's artificial insemination success in the Spanish Assaf and Manchega sheep breeds 2901
M. Serrano, M.A. Jiménez, M. Ramón and O. González-Recio

704. The impact of sire on variation in methane production and dry matter intake in sheep 2905
E. O'Connor, F.M. McGovern, E. Dunne, S.J. Morrison, T.M. Boland and N. McHugh

705. Milk transcriptome analysis to elucidate the impact of prepubertal nutrition in dairy ewes residual feed intake 2909
A. Suárez-Vega, B. Gutiérrez-Gil, G. Hervás, H. Marina, R. Pelayo, P.G. Toral, C. Esteban-Blanco, P. Frutos and J.J. Arranz

706. Inbreeding and effective population size of United States Katahdin sheep 2913
G.M. Becker, J.M. Burke, R.M. Lewis, J.E. Miller, J.L.M. Morgan, B.D. Rosen, C.P. Van Tassell, D.R. Notter and B.M. Murdoch

707. Genetic diversity and population structure of dairy goat populations in Kenya 2917
C.M. Kamidi, R.W. Waineina, C.B. Wasike, D.K. Ngeno and E.D. Ilatsia

708. Resolving the genetic structure of 18 Greek and neighbouring sheep populations 2920
A. Kominakis, E. Tarsani, A. Hager, G. Antonakos, I. Mastranestasis, D. Gkelia and I. Hadjigeorgiou

709. Genetic determinism of quality of lamb leather in Lacaune dairy sheep breed 2924
H. Larroque, E. Dugas, F. Woloszyn, F. Plisson-Petit, J. Gayraud, J.-C. Duchêne, J. Frayssignes, A. Gille, S. Brenot, D. Allain and L. Drouilhet

710. Heritability and genomic analysis of coagulation event in sheep milk 2928
G. Gaspa, A. Cesarani, F. Correddu, M. Congiu, C. Dimauro, A. Pauciullo and N.P.P. Macciotta

711. Genetic parameters across European and North American Alpine goats for two milk production and one udder type traits 2932
M. Teissier, L.F. Brito, F. Schenkel, B. Bapst, G. Bruni, P. Fresi, C. Robert-Granié and H. Larroque

712. Wool colour traits in Gotland sheep and association with a deletion in ASIP 2936
A.M. Johansson

713. Breeding initiatives around reduction of methane emissions in meat sheep – an international review 2940
N.R. Lambe

714. Measuring methane in sheep production systems – phenotypic factors affecting output 2944
F.M. McGovern, E. O'Connor, L. Farrell, E. Dunne, E. Wall and N. McHugh

715. Genetics of methane emissions in a multi-breed sheep population 2948
N. McHugh, E. O'Connor, D.P. Berry, E. Dunne, L. Farrell, P. Rafter, K. McDermott and F.M. McGovern

716. Modelling of productivity, profitability, and greenhouse gas emissions of Irish sheep flocks divergent in genetic merit 2952
L. Farrell, N. McHugh, T. Pabiou, A. Bohan, K. McDermott, L. Shalloo and J. Herron

717. Using milk fatty acids as biomarkers to improve feed conversion ratio in dairy sheep 2956
H. Marina, G. Hervás, R. Pelayo, P.G. Toral, A. Suárez-Vega, B. Gutiérrez-Gil, C. Esteban-Blanco, P. Frutos and J.J. Arranz

718. Six years of genomic selection have increased the genetic gain in French dairy sheep 2960
J.M. Astruc, G. Lagriffoul, A. Legarra and D. Buisson

719. Cross-validation of single-step genetic evaluation in U.S. Katahdin sheep 2964
A.J. McMillan, D.J. Brown, J.M. Burke, J.L. Morgan and R.M. Lewis

720. Partitioning of genetic trends by flock and gender in Istrian sheep breed 2968
M. Spehar, J. Ramljak, V. Poslon and A. Kasap

721. Comparison of GEBV accuracies predicted using the pedigree matrix of female and male potential reference populations 2972
A. Carta, M.G. Usai, S. Casu and S. Salaris

722. Quantification of the effect of incomplete reproduction data on the accuracy of selection 2976
W.J. Olivier

723. Using random regression models to model growth in sheep with irregular data 2980
E. Mutch, M. Coffey, G. Simm and R. Mrode

724. Impact of the order of polynomials in random regression model on the accuracy of genetic evaluation for weight traits 2984
U. Paneru, D.J. Brown, N. Moghaddar and J.H.J. van der Werf

725. Estimation of linkage disequilibrium in Pag and Istrian sheep breed: towards genomic optimum contribution selection 2988
A. Kasap, J. Ramljak and M. Špehar

726. Genome-wide association study for milk composition traits of Canadian Alpine and Saanen goats 2992
E. Massender, H.R. Oliveira, L.F. Brito, L. Maignel, M. Jafarikia, C.F. Baes, B. Sullivan and F.S. Schenkel

727. Evaluating performance of Suffolk, Columbia, and crossbred lambs at birth and weaning 2996
R.M. Lewis, N. Vargas Jurado, D.J. Brown, D.R. Notter and J.B. Taylor

728. Genetic selection for sensory eating quality of lamb using consumer assessments 3000
S.Z.Y. Guy, S.I. Mortimer, L. Pannier, P. McGilchrist, D.J. Brown, D. Pethick and A.A. Swan

729. Genetic characterization and connectedness of dairy goats in Canada, France, Italy and Switzerland 3004
M. Teissier, L.F. Brito, F. Schenkel, G. Bruni, P. Fresi, B. Bapst, C. Robert-Granié and H. Larroque

730. Value of data from ram breeding flocks as an industry reference population for Australian sheep 3008
P. Alexandri, S.F. Walkom, A.A. Swan, J.H.J. van der Werf and D.J. Brown

731. Pairwise principal component analysis of African goat breeds identifies loci involved in meat and/or milk production 3012
S.A. Rahmatalla, D. Arends, G.M. Tarekegn, R. Onzima and G.A. Brockmann

732. Linking genetic merit to phenotypes: a validation of the terminal and replacement Irish sheep breeding objectives 3016

Abstract

Rapid developments in phenotyping and genomic technologies are contributing to lakes of data on animals. Concurrent developments in prediction algorithms are leading to a proliferation of (genomic and phenotypic) predictions on individual animals. Using genetics applied to livestock to reduce the impact of livestock on climate change, while addressing livestock welfare concerns and meeting more sophisticated and diverse nutritional demands of the consumer, are likely to continue to be emerging trends in this and future WCGALP. Being able to measure, predict and act will continue to be the fundamental principles to achieving these objectives. Failure to do so will jeopardise the success of animal breeders into the future, especially if growing numbers of consumers favour entirely plant-based sources of nutrition.

Introduction

Livestock breeding programs can be broadly summarised by the principles of *Measure, Predict* and *Act*. This paper takes a journey through these three components highlighting the advances made, but also the gaps in knowledge. Being able to collapse the deluge of predictions constantly streaming towards producers into actionable information will be one of the greatest challenges to achieving meaningful change. Animal breeders are well versed in not only collapsing vast quantities of data on a whole gamut of traits into a single index value per animal, but also providing the necessary communications/extension and validation of such tools to build trust among stakeholders.

Measure

The breadth of livestock breeding objectives has generally been limited to those traits with data available, either directly or indirectly; health, fertility and growth traits comprised between 12% (1974) and 30% (2006) of the WCGALP papers to-date (Figure 1a). Focussing on those traits may disadvantage traits that are less well recorded (e.g. feed intake, environment), especially in breeds/strains that are less numerous and subsequently have smaller reference populations, which may be exacerbated in a paradigm of market-driven investment in genetic improvement.

The biggest challenge for the current generation of animal breeders is most likely to rapidly address the contribution of livestock to the environment; with livestock being the most significant anthropogenic methane source. Ruminants emit methane as a by-product of rumen fermentation, while poultry are the second largest producer of ammonia, phosphorus, nitrogen, carbon dioxide, and methane, meaning that the challenge spans the main-stream species considered at WCGALP conferences (e.g. de Haas *et al.* 2018, Sell-Kubiak *et al.* 2018). Focusing on the efficient use of feed (especially from sources that cannot be used for human consumption), will likely continue to feature in all animal breeding programs. Feed efficiency was, in fact, a hot topic across species at the 2014 and 2018 WCGALP and continues to be in 2022, with over 5% of papers presented being on the topic (Figure 1b). This rise is likely due to the increased interest in these traits in cattle breeding, while measuring traits associated with feed efficiency has been common in pigs and poultry for a long time. Figure 1b also shows how papers on methane emissions have been

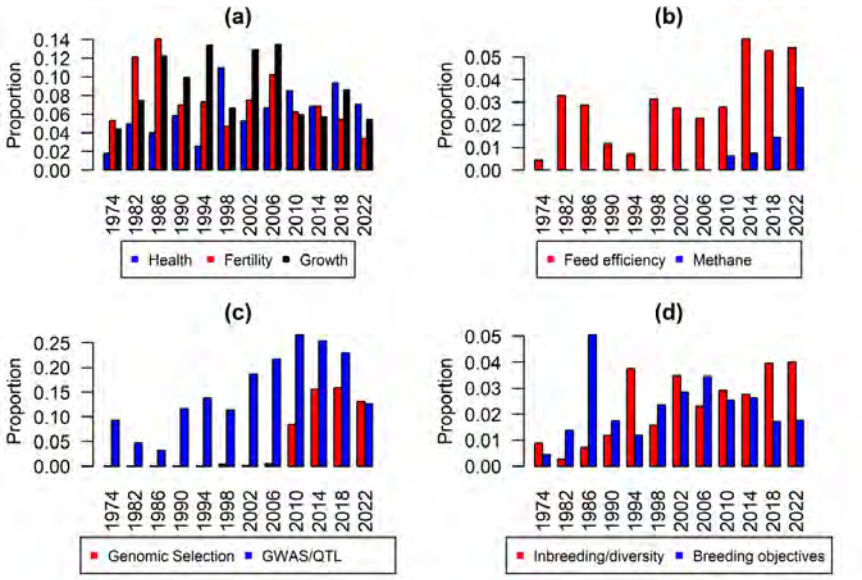

Figure 1. Representation of traits (a & b) and topics (c & d) for each WCGALP year.

increasing exponentially from the 2014 to 2022 WCGALP. The WCGALP2022 sees an increased focus on selecting for a reduction in all pollutants, with ingenious phenotyping strategies and the use of indirect predictors being used as ways to increase the accuracy of genomic prediction anticipated.

Consumers are increasingly demanding high-quality nutritious products. Genetics can be used to select for the best nutritional profile using data from technologies to measure these characteristics. We may see food being tailored to match a person's own requirements. We envisage that animal welfare and sustainability will continue to be important themes. Notable examples are previously observed deterioration in fertility (in dairy cows) and rise of leg weakness (in broiler chickens). Both are, of course, examples of unintended consequences of selection and a warning to animal breeders. To counteract these trends, health and fitness traits have been included in breeding objectives for 20+ years in many cases.

Across many traits discussed, and even ones not thought of yet, it seems very likely that sensors and automated phenotyping will become the primary strategy to collect data for animal breeding purposes and there will be many more high-tech approaches presented at WCGALP2022. For example, CT scanning has been used for non-invasive measurements of (small) carcases for quite a long time, but such precision phenotyping technologies are coming into their own through its combination with genomic technologies (Byrne and Amer 2018). The challenge from this will be processing high volumes of data, data quality control steps and combining it in an informative way with other omics data.

Predict

Genomic selection (GS) has undeniably accelerated the wide-spread use of individual genome-wide information in animal breeding programs, facilitated by the availability of affordable 50k genotyping arrays, all within just one decade. This is supported by the rapidly increasing number of GS papers since WCGALP2006, for the first time being more numerous than GWAS papers at WCGALP in 2022, the latter declining after peaking at WCGALP2010 (Figure 1c). Methodological and technological developments have enabled computational requirements to stay within reasonable limits, despite reference populations

increasing in size exponentially. We expect several reported applications using >50M genotyped animals at WCGALP2026.

Sequencing strategies in the past decade took either the 1000-bulls' genome approach by genotyping key ancestors in the population at high coverage and imputing to other genotyped animals, or a low-pass sequencing approach, genotyping very many animals at (ultra)low coverage followed by imputation taking advantage of high coverage at the haplotype level (Hickey *et al.* 2014). Large scale individual level actual sequence data, including long reads, will be available soon. Unlocking its full potential include routine detection of chromosome anomalies, optimizing selection and mating considering deleterious alleles, and frequent GWAS for all breeding goal traits. We envisage that GWAS results at base pair resolution will become standard output of genomic predictions, which will develop from being a pure *prediction machine* to also be a *discovery machine*. Combining this phenotype-driven discovery with biological information based on increasingly more accurate functional annotation maps, will enable continuous refinement of SNP sets used in genomic prediction (Goddard *et al.* 2018). Finally, other omics data including microbiome, gene expression, and epigenetic profiles, will help by enabling more accurate phenotyping, refining functional annotation maps, and more accurately dissecting phenotypic variances into its underlying components.

Thirty years ago, the idea of 'velo genetics' or germ-line selection was described, with the promise to reduce generations intervals drastically (Georges and Massey 1991). GS indeed has enabled embryo selection in practice. The application of embryo selection based on GS, however, mostly enables to further increase selection intensity, but not to further shorten generation intervals. Genome editing has been a futuristic topic for a long time, but is now part of the available toolbox thanks to CRISPR-CAS. The eventual contribution of gene editing will rely heavily on the ability to identify sufficient numbers of loci that are worthwhile targeting (Simianer *et al.* 2018) coupled with societal acceptance of the technique. With the foreseen *discovery machine* as a 'by-product' of GS, and the increasingly more accurate annotation maps, eventually a list of targets worthwhile pursuing is expected to be available.

Act

The breeding goals of the future will need to explicitly consider three consumer-interest areas of environmental responsibility, animal welfare and nutritive characteristics and product quality (Byrne and Amer 2018). While productivity and feeding the world are still of great importance, ignoring consumer-interests is incredibly risky. Approaches to appropriately weight these features in breeding goals will be important, prompting greater research into the optimal construction of breeding objectives and more so than has been presented to-date (Figure 1d).

Predictions in themselves are merely outputs and must therefore be acted upon to create impact. Whereas artificial intelligence (AI) is being heralded as a disruptive technology to the prediction processes, the field of eXplainable Artificial Intelligence (XAI) could have a role helping comprehend and trust the predictions. Moreover, prescription (i.e. how to deal with predicted outcomes) and, more importantly, the ability to diagnose the root of sub-optimal performance will be crucial in the future as decision support tools. Breeders will have to engage more with the developers of decision support systems to: (1) ensure genetic merit is included as a feature in prediction algorithms; (2) ensure that such support systems diagnoses the root of the sub-optimal performance – such support systems must also be able to detect risk into the future given the current trajectory; and (3) note any remedial measures undertaken for consideration either in data editing or statistical modelling of the resulting genetic evaluation.

While strategies to control inbreeding were popular in the WCGALPs of the 1990s (e.g. optimal contribution selection (Meuwissen 1997); Figure 1d), there is likely to be a resurgence in the future, especially in ways that are easy to implement and utilise genomic information.

Outlook

Breeding is a well proven technology to deliver genetic change; of course, this genetic change has not always been favourable. Whereas the breeding programs of some species has consolidated considerably (e.g. pigs, poultry, aqua), the breeding programs of other species, most notably ruminants, are still largely underpinned by national genetic evaluations. Of strategic importance is data ownership, which is becoming a contentious issue and as yet, has not been unequivocally addressed in ruminant breeding programs. The time is approaching for mega-corporations to realise the power of genetic gain in delivering food security (i.e. power) while also remaining stewards of the environment. Many of these corporations (e.g. Amazon, Google, Facebook) already have the analytical expertise and potential access to data. More importantly they are now part of everybody's (i.e. consumers) home and have strong influential powers through algorithms like recommender systems. While this will jeopardise the *modus operandi* of current ruminant breeding programs, consolidation may lead to new opportunities and exciting challenges. Nevertheless, issues on data ownership and propriety evaluations could impact what is published at future WCGALP.

The biggest challenge faced by livestock production in the near future, is retaining societal acceptance, at least partly by contributing to healthy tailor-made diets and decreasing its environmental footprint. The world is awash with commentary of silver bullets to grand challenges; breeding programs have proven time and time again to deliver on grand challenges but will need to be more vocal. Now is the time to capitalise on the full potential of highly technological and data intensive breeding programs to deliver on carbon neutrality, in close dialogue with its stakeholders and in particular the consumers.

Institute of Evolutionary Biology, University of Edinburgh, EH9 2FL, United Kingdom; j.pemberton@ed.ac.uk

Abstract

From around the 1950s, a number of long term studies of wild animal populations were initiated by researchers interested in the behaviour and ecology of natural populations. These studies focus almost exclusively on vertebrates, and in many cases involve capturing individuals for marking and hence opportunities for tissue sampling. As genetic and genomic techniques have developed, enabling the recovery of pedigrees and now genomic estimates of relationship and inbreeding, these projects have pivoted to more evolutionary topics, especially the genetics of quantitative traits, where statistical techniques developed by livestock breeders have been very influential. I will illustrate some of the advances in the field with examples from long term studies of red deer on the Isle of Rum, and Soay sheep on St Kilda, both in Scotland.

Introduction

Evolutionary biologists and ecologists have long been interested in the relative roles of genetic and environmental factors in determining trait variation and their influence on population and evolutionary dynamics, including the maintenance of genetic variation. Long term studies of individuals commonly involve the tracking of individuals from birth through all breeding attempts, to death, yielding data on individual breeding success, survival and often several fitness-related morphological or physiological traits, and offer a window on these issues. Until the 1990s, the genetics of quantitative traits in *in situ* natural populations was a modest research field, focused mainly on passerine birds, where pairs of individuals feeding chicks at a nest (the 'social parents') were assumed to be the genetic parents and heritabilities were estimated using parent-offspring regression (e.g. Boag and Grant (1978); Van Noordwijk *et al.* (1988)). A key issue was actually determining genetic relationships between individuals, especially paternity: molecular techniques soon showed that extra-pair paternity was common in birds, and behavioural data were likely to be even poorer in predicting paternity in, for example, polygynous species. With the advent of DNA fingerprinting, microsatellites and now SNPs and appropriate inference methods (e.g. Marshall *et al.* (1998); Wang (2004); Huisman (2017)), the recovery of pedigrees is now robust, if still labour-intensive.

Once pedigrees became available, a second breakthrough came from animal breeding: the animal model (Meyer 1991) enabled efficient use of all relationship data to estimate heritabilities and genetic correlations in natural populations (Kruuk 2004). Another major benefit of the animal model approach is that it allows simultaneous estimation of other variance components such as year, spatial and maternal effects (Kruuk and Hadfield 2007). These sources of variation, initially regarded to some degree as nuisances, are important subjects of study in their own right.

Here, I will address four of the several areas in which the field has made progress in recent years – for wider reading see (Charmantier *et al.* 2014). These are: (1) quantifying inbreeding depression; (2) quantifying additive genetic variation; (3) genetic architecture; and (4) evolutionary dynamics of quantitative traits. I will illustrate these topics with examples drawn from two long term studies, of red deer on the Isle of Rum, and of wild Soay sheep on St Kilda. In these projects as many study area individuals as possible are captured at birth for permanent marking and sampling and then followed for the rest of their lives. In the case of the deer, we do not usually handle animals again, so besides reproduction and survival, birth, *post mortem*

skeleton and cast antler measures are the main phenotypic traits available. In the case of the sheep, we attempt to recapture and phenotype as many individuals as possible each summer and so we have a larger array of study traits. In both study populations, all sampled individuals are genotyped on 50K SNP arrays yielding around 38K polymorphic sites in each case.

1. Quantifying inbreeding depression. Close pedigree inbreeding is rare in most wild vertebrate populations, but in both study populations there is extensive low-level inbreeding. Past analyses using (incomplete) pedigrees and microsatellite heterozygosity indicated that there was inbreeding depression in both populations, but its magnitude remained unclear until genomic approaches to estimating individual inbreeding became available. Using a genomic inbreeding coefficient (F_{grm}; Yang *et al.* (2011)) in the deer, we found that inbreeding depresses birth weight, juvenile survival (independently of birth weight), and annual breeding success in both sexes and offspring survival in females (Huisman *et al.* 2016). As a consequence of these effects, inbreeding depression across the lifespan is strong: a female with F_{grm}=0.125 has an average 75% reduction in lifetime breeding success (LBS) compared with an average female with F_{grm}=0. The equivalent figure for males is a 95% reduction in LBS. The same approach found inbreeding depression in several traits in Soay sheep (Bérénos *et al.* 2016). More recently, following imputation of the Soay sheep data to >400K SNPs, we have used a 'runs of homozygosity' approach to quantify inbreeding depression in survival in the Soays and demonstrate that while negative effects are scattered throughout the genome, there are five genome regions with genome-wide significant effects on survival (Stoffel *et al.* 2021a). In further analysis we found that most of the inbreeding depression lies within longer runs, consistent with the idea that the haplotypes forming short runs have been purged of deleterious mutations (Stoffel *et al.* 2021b).

2. Quantifying additive genetic variation for traits. Estimating heritabilities and genetic correlations with precision is a necessary requirement if we are to predict how populations will respond to natural selection. In recent decades many estimates of trait heritabilities have been made in natural populations (Postma 2014). Comparisons between traits enabled us to test the prediction that traits under stronger directional selection would show lower heritabilities (due to attrition of genetic variance by selection). In the deer we did indeed find this pattern: heritabilities are inversely correlated with a trait's association with LBS, our measure of fitness (Kruuk *et al.* 2000). However, this was not for the expected reason: other components of variance (presumably, mainly environmental) increase as one considers ever more integrative traits like components of fitness, and hence the decline in heritability was driven by increasing phenotypic variance, with additive genetic variance showing no consistent pattern.

The genomic era offers the possibility of pedigree-free estimation of heritabilities and genetic correlations using genomic relatedness. In human cohorts selected to be unrelated for GWAS, fitting information from all SNPs underestimates trait heritabilities, for example for height (Yang *et al.* 2010), so it was of interest to know how it performed in natural populations including a wide range of pairwise relatedness and consequently higher linkage disequilibrium. We conducted one of the first comparisons of heritabilities using pedigree versus genomic relatedness in Soay sheep and found that estimates coincided across most traits and age classes (Bérénos *et al.* 2014). The approach offers the potential for wild quantitative genetics to extend into taxa such as invertebrates that cannot be followed so easily in the wild, although note that parentage information will always be required to quantify maternal effects.

3. Genetic architecture. As with livestock and humans, there has been great interest in whether it is possible to locate genes of major effect underlying quantitative traits in the wild, since this would allow detailed studies of selection and response at specific loci. We have carried out a number of GWAS analyses (controlling for relationship) and regional heritability studies across the deer and sheep data, with mixed

results. In Soay sheep, most morphological traits seem to be under highly polygenic control, though two regions contributing to leg length, on chromosomes 16 and 19, are robust and seem likely to have come from a documented introgression event (Bérénos *et al.* 2015). In deer, no regions were found underpinning either neonatal traits (J. Gauzere pers. comm.) or several measures of antlers (Peters *et al.* 2022). On the brighter side, a major locus underpins both the horn polymorphism and horn size in the Soay sheep, and selection analysis using inferred genotypes showed that the polymorphism is maintained by heterozygote advantage (Johnston *et al.* 2013). Using SNP and pedigree data we have also derived individual autosomal recombination rate (ARR) as a trait and shown that it maps to genomic regions containing the genes REC8 and RNF212B, adding to the evidence that these genes control variation in recombination rate in mammals (Johnston *et al.* 2016; Johnston *et al.* 2018).

4. Evolutionary dynamics of quantitative traits. The ultimate aim of most studies of quantitative traits in natural populations is to understand the evolution of traits and the maintenance of genetic variation. Some traits change in the predicted direction: birth date is selected to be earlier in deer and the pedigree breeding values have got earlier over recent years (Bonnet *et al.* 2019). However, and in sharp contrast to animal breeding, a common observation in natural populations is that there is strong directional selection on a heritable trait, but no evidence of phenotypic change in response to selection. This is known as the 'paradox of stasis' and many possible explanations for it have been investigated, including in the deer and sheep. One possibility is that a genetic trend may be masked by an environmental trend affecting a trait by plasticity and in the opposite direction. Such 'cryptic evolution' was suggested to be the case for Soay sheep body size (Wilson *et al.* 2007) which is under positive selection but in the field the mean body sizes are getting smaller. A recent analysis of Soay sheep body weight using genomic prediction finds that the breeding values are indeed increasing (Hunter *et al.* 2022). Another explanation lies in environmental variation causing a phenotypic but not a genetic correlation between a trait and fitness. This appears to be the case for antler size and LBS in deer (Kruuk *et al.* 2002). A third possibility is the potential for constraints arising from antagonistic selection or negative genetic correlations, for example between the sexes or between traits, but in deer at least these do not seem to be very constraining (Morrissey *et al.* 2012; Walling *et al.* 2014). Finally, constraints could also arise via maternal effects, but a recent analysis of deer birth weight, which has a large maternal genetic component, found this too to be unlikely (Gauzere *et al.* submitted).

Conclusions

Advances in genomic and statistical analysis techniques have led to great progress in the study of quantitative traits in the wild (Charmantier *et al.* 2014). A major difference from livestock production is that appreciable plastic effects due to environmental heterogeneity in time and space are to be expected at every turn and must be handled appropriately. Due to relatively small sample sizes and the scarcity of large effect loci, GWAS approaches in natural populations seem likely to yield many flat 'Uppsala' plots for some time to come. Genomic prediction has yet to be widely exploited but holds considerable promise (Ashraf *et al.* 2021).

3. Discoveries and lessons from a genome-wide association study of human height in >5 million individuals

L. Yengo on behalf of GIANT Consortium (the height working group)

Institute for Molecular Bioscience, The University of Queensland, 306 Carmody Road, St Lucia, Brisbane, QLD 4072; Australia; l.yengo@imb.uq.edu.au

Abstract

In this lecture, I will present findings from the largest, to date, genome-wide association study of human height conducted in >5 million individuals of diverse ancestries. This gargantuan effort has led to identify >12,000 independent associations with common SNPs with a frequency >1%. These height-associated variants are clustered within ~7,000 genomic loci enriched for genes which mutations cause abnormal skeletal growth. Across five ancestry and ethnic groups, we found that >90% of the common variants SNP-based heritability is explained by variants within these 7,000 loci, which cumulatively cover ~21% of the human genome. A genetic predictor combining these 12,000 height-associated variants yields a prediction accuracy of R^2~40%, while combining that predictor with the average height of parents reaches an unprecedented accuracy of R^2~54%. Overall, our study proposes a saturated map of genomic loci likely containing most of the genetic variation responsible for the missing heritability of human height.

Introduction

Over the past 15 years, genome-wide association studies (GWAS) have revolutionised our understanding of the genetic architecture of complex traits by allowing the discovery of tens of thousands of genetic variants associated with thousands of traits. GWAS of human height (a classic polygenic trait) had hitherto identified over 3,000 independent SNPs associated with inter-individual differences,[1] explaining about half of the SNP-based heritability.[2] Sample size is the main factor driving GWAS discoveries. However, how large experimental samples need to be before we can account for the totality of the SNP-based heritability has long remained unknown. Here, we perform a GWAS of human height in ~5.4 million individuals with diverse ancestries (Yengo 2022[3]) and show empirically that our sample size is sufficient to map autosomal genomic loci, where genetic variation accounts for 90 to 100% of the SNP-based heritability.

Materials & methods

We analysed data from 5,380,080 individuals whose ancestries were predominantly European (EUR; 76% of total sample), East-Asian (EAS; 8.8%), Admixed Hispanic ethnicity (HIS; 8.5%), African (AFR; 5.5%) and South-Asian (SAS; 1.4%). We tested association at 1.3 million SNPs catalogued in the HapMap 3 project, which includes over 1 million with a minor allele frequency (MAF) larger than 1% in each of the five ancestral groups. We first meta-analysed cohorts within each ancestral group using a fixed effect meta-analysis then strategy, then meta-analysed summary statistics from all 5 groups of cohorts using fixed effect approach. In total we performed 6 meta-analyses: 5 within-ancestral groups and 1 across-ancestral groups. For each meta-analysis, we identified sets of genome-wide significant (GWS) conditionally independent associations using the approximate conditional and joint multiple-SNP analyses,[4] as implemented in GCTA[5].

We defined GWS loci as genomic regions centred around each GWS SNP and including all SNPs within 35 kb on each side of the lead GWS SNP. Overlapping GWS loci were merged so that the number and cumulative length of GWS loci are calculated on non-overlapping GWS loci. To estimate the total variance explained by SNPs within GWS loci, we: (1) partitioned all SNPs from the HapMap 3 panels into two groups (SNPs within those 7,209 loci versus SNPs outside those 7,209 loci); (2) calculated genetic relationship matrices based on these two sets of SNPs; and (3) used these matrices in a GREML analysis to estimate

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_816, © L. Yengo 2022

heritability. The cumulative length of non-overlapping GWS loci is ~647 Mb, i.e. ~21% of the genome assuming a genome length of ~3,000 Mb.

Finally, we used joint SNP effects from our GWAS meta-analysis (re-estimated using GCTA) to calculate a genetic predictor of height from GWS SNPs only.

Results

We identified 9,863, 1,888, 918, 493 and 69 independent genome-wide significant (GWS; $P<5\times10^{-8}$) associations in the EUR, HIS, EAS, AFR and SAS groups, respectively (Table 1). We found a strong genomic co-localisation of associations identified in each population and a correlation of estimated SNP effects >0.64 across all pairs of ancestral groups. Next, we detected 12,111 conditionally independent associations in a multi-ancestry meta-analysis including all study participants. We identified various genomic regions with elevated density of associations. For example, we found on chromosome 15 near the *ACAN* gene a 200 kb-long genomic segments containing 25 independent associations. More generally, high density of associations within 100 kb-long genomic window is associated with the presence of an autosomal gene curated from the Online Mendelian Inheritance in Man (OMIM) database[6], which pathogenic mutations are known to cause syndromes of abnormal skeletal growth (>2.5× enrichment; $P<0.001$).

The 12,111 GWS associations were clustered within 7,209 non-overlapping GWS loci) covering ~21% of the human genome. Using a partitioned GREML analysis we found that >90% of the common variants SNP-based heritability in 5 ancestry groups can be explained by SNPs located within GWS loci. For European ancestries, which constitutes the majority of our discovery sample, that proportion reaches 100% of the SNP-based heritability. Importantly, these observations suggest that although the majority of HapMap3 SNPs within GWS loci are not GWS themselves (only 12,111 out of ~300,000 SNPs; Figure 1), yet-to-be-discovered height-associated variants are most likely located within these GWS loci.

Finally, we used estimated SNP effects from our GWAS meta-analysis at these 12,111 height-associated SNPs to calculate a polygenic score (PGS) of height (Methods). This PGS explains 40% of height variance in European ancestries individuals (76% of our discovery sample; Methods) but shows a reduced accuracy in individuals whose ancestries are more genetically distant to EUR. In particular, the prediction accuracy of the height PGS is only ~10% in individuals with predominantly African ancestries. Note that a 4-fold reduction in prediction accuracy is consistent with previous studies[7,8] and largely explained by linkage disequilibrium and allele frequency differences between European and African ancestries.[8]

Table 1. [Extracted and simplified from Yengo (2022)] Summary of results from within-ancestry and multi-ancestry GWAS meta-analyses. GWS: Genome-wide significant ($P<5\times10^{-8}$). COJO SNPs: near independent GWS SNPs identified using an approximate conditional and Joint analysis implemented in the GCTA software.

Cohort main ancestry or ethnicity	Number of studies	Sample size	Number of GWS COJO SNPs	Number of GWS loci
European	173	4,080,687	9,863	6,386
East-Asian	56	472,730	918	821
Hispanic	11	455,180	1,888	1,599
African	29	293,593	493	436
South Asian	12	77,890	69	66
Multi-ancestry meta-analysis	281	5,314,291*	12,111	7,209

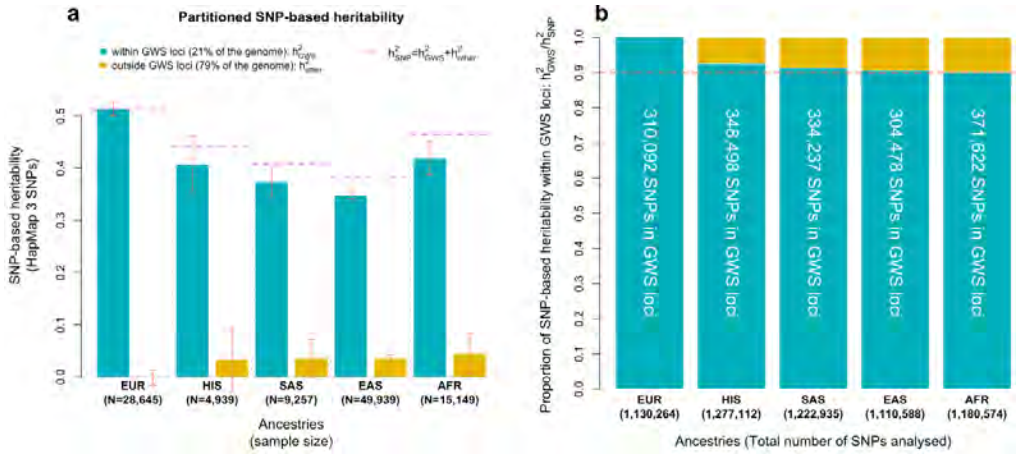

Figure 1. Variance of height explained by HapMap 3 SNP within genome-wide significant (GWS) loci. [Extracted and simplified from Ref.[3]]. Panel a shows stratified SNP-based heritability (h^2_{SNP}) estimates obtained after partitioning the genome into SNPs within 35 kb of a GWS SNP ('GWS loci' label) vs SNPs >35 kb away from any GWS SNP. Analyses were performed in samples of five different ancestry/ethnic groups: European (EUR: meta-analysis of UK Biobank (UKB) + Lifelines study), African (AFR: meta-analysis of UKB + PAGE study), East-Asian (EAS: meta-analysis of UKB + China Kadoorie Biobank), South-Asian (SAS: UKB) and Hispanic group (HIS: PAGE). Panel b shows that >90% of h^2_{SNP} in all ancestries is explained by SNPs within GWS loci identified in this study.

Discussion

In this study, we performed the largest, to date, GWAS of any human trait and thereby identified >12,000 associations explaining >90% of the common variants SNP-based heritability of height. A genetic predictor of height derived from these findings reaches an accuracy of 40% in European ancestry individuals, which rivals that of the average height of parents (i.e. 43%). Interestingly, we showed that these two predictors can be linearly combined to reach an accuracy of 54% and that the optimal weights only depend on the accuracy of the SNP-based predictor, the narrow sense heritability and the spousal correlation for traits, like height, subjected to assortative mating in the population.

By quantifying the relationship between sample sizes and GWAS discoveries, we found that prioritisation of the relevant biological pathways and gene sets is possible at relatively small sample sizes (n<250,000), while identification of variants almost linearly increases with sample size, thereby contributing to increase the density of associations within previously identified loci and reflecting the large allelic heterogeneity for height-associated haplotypes.

Our study has a few limitations, many of which are being currently addressed. The first one is the over-representation of European ancestries in our discovery samples, which limits the transferability of some of our findings to other human populations. Another limitation is that our study focused on common genetic variation (>1%), while our large sample size could, in principle, yield enough power to detect associations involving lower frequency SNPs. However, our large sample is in fact an aggregation of many small studies, which creates a challenge to distinguish true signals from study-specific artefacts.

Altogether, our study reveals that extremely large sample sizes can resolve the missing heritability problem by mapping specific genomic regions likely containing most of the causative genetic variation for complex traits like human height.

Part 2

Young scientist career development

4. History and author analysis of the World Congresses on Genetics Applied to Livestock Production

A.L. Van Eenennaam[1*] and S. Hermesch[2]

[1]Department of Animal Science, University of California, 1 Shields Ave, Davis, CA 95616, USA; [2]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; alvaneenennaam@ucdavis.edu

Abstract

It is almost fifty years since the first World Congress on Genetics Applied to Livestock Production (WCGALP) was convened in Spain in 1974. This paper, targeted for the early-career scientist session, details the history and evolution of WCGALP, and outlines gender composition of the Permanent International Committee, session chairs, plenary and invited speakers, and authors. Data containing 24,351 author records from all WCGALP proceedings, and old programs were used for the analyses. In the early years, there were few women involved in any aspect of WCGALP, however, more recent congresses have featured an increasing proportion of women on WCGALP committees and serving as session chairs. Based on recent data, gender is not playing a determining role in selection of submitted papers for oral presentations. We recommend greater gender diversity on WCGALP committees and encourage early-career scientists to actively participate in WCGALP conferences to further increase the diversity of future congresses.

Introduction

The idea of World Congresses for specialists working in livestock production was hatched in Spain in the 1960s. It started with a World Congress on Animal Feed held in Madrid in 1966 and 1972. Then in 1974 the first World Congress on Genetics Applied to Livestock Production (WCGALP) was held in Madrid. Starting with the second Congress in 1982, also held in Madrid, the event has been held every four years at locations throughout the world, and this Congress in Rotterdam in 2022 is the twelfth.

The governance of the first WCGALP was under the auspices of the local organizing committee, chaired by Carlos Luis de Cuenca, from the University of Madrid. Alan Robertson from the University of Edinburgh joined Carlos Luis de Cuenca in creating a Permanent International Committee (PIC) for WCGALP in 1974, and he was the first President of this committee which has traditionally been primarily responsible for evaluating bids for the location of the next WCGALP. William (Bill) Hill also from the University of Edinburgh, later served as President of this committee for many years. Honorary members of the PIC were Gordon Dickerson and Bill Hill.

The format of WCGALP has varied throughout the years. At the first WCGALP there were six main topics: (1) factorial genetics; (2) cytogenetics; (3) biochemical genetics; (4) quantitative genetics; (5) genetic modelling with laboratory animals; and (6) applied genetics to breeding programs with separate sessions for dairy cattle, beef cattle, sheep, swine/pig and poultry breeding programs. The format at that event included an invited speaker leading off each of these sessions, and invitations to speak were typically made on the recommendation of the local session organizers. Subsequent conferences followed a similar model, some featuring invited plenary speakers, and over time new fields such as transgenic animal research, molecular genetics, and genomics were included as they became established. At WCGALP 2022, the focus of sessions has been shifted to also include addressing a diverse range of societal challenges, relevant for animal breeding, rather than focusing solely on development of new methodologies. This change in topics at Congresses reflects the tremendous developments in the field of genetics and animal breeding in the almost 50 years since the first WCGALP, and moreover profound changes in both society and academia during this time.

Materials & methods

Information about authors of papers presented at WCGALP was obtained from the WCGALP digital archive (http://www.wcgalp.org/). Data contained 24,351 author records detailing the author's name, the year the paper was presented, the title of the paper, and the volume in which the proceedings paper was published. The first name of authors was run through genderize.io (https://genderize.io/), to predict the gender of a person given their name. The gender of plenary speakers prior to 2014, and the members comprising the PIC were manually curated. Further, individuals who were authors on 15 or more WCGALP proceedings papers were examined as a group. If gender was unassigned for authors it was curated manually based on first-hand knowledge, or using the internet-based ISI Web of Science to search for other same-authored papers that provided first names, and/or Google to locate profiles or images of them. Prior to 2014, only initials were available for WCGALP authors, which made it difficult to designate the gender of these authors and gender was assigned unknown. Hence there is less confidence associated with data prior to these two most recent conferences.

Results

For many years both the PIC and the local organising committees (LOC) were comprised predominantly of men. To our knowledge, Helen Newton Turner was the first female invited session speaker in 1974 and member of the PIC, Susanne Hermesch was the first woman to be voted President of this Committee in 2018, and Yvette de Haas was the first female co-leading a LOC in 2022. There has been a continuous increase in the proportion of women on the PIC of WCGALP from 5% in 2010, 15% in 2014, 26% in 2018 and 33% in 2022.

The local organizing committee decides on plenary speakers and session chairs which have both included more women in 2014 and 2018 (Table 1), reflecting an increased awareness of gender balance in key-note presentations or positions. The first invited female plenary speaker was Jenny Marshall Graves in Australia in 1998. The number of proceedings papers increased over time (Table 2), with the exception of conferences in Australasia where there was a decrease, likely due to the travel involved for the majority of European and North American participants to attend these conferences. There has been an increase in the number of authors per paper, mirroring a trend whereby the average number of co-authors per paper published has increased steadily over the past century in all scientific disciplines.

A total of 201 authors had 15 or more papers presented at multiple WCGALP. Jack Dekkers who first presented in 1994 was the most prolific author with 64 papers, closely followed by John Woolliams, who first presented in 1990, with 62. The most prolific female author was Lucia Albuquerque with 35 papers who first presented in 1994. Two authors, Mike Goddard and Moshe Soller, had papers at each of the first 11 WCGALP spanning 1974 to 2018, while Karin Meyer was the female author with the highest WCGALP attendance, participating in conferences from 1982 to 2018. Figure 1 shows the breakdown of the most prolific authors by gender. There was a gender difference ($P<0.005$) in the average number of papers per author in this highly prolific group. For example, of authors in this group that were first-time authors in 2002 and are therefore likely of a similar age, male authors ($\bar{x}=24.2$ (± 1.4), n=35) had on average 5-6 more papers than female authors ($\bar{x}=18.7$ (± 0.8), n=16). Of the 2006 first-time authors, 10 male and one female author had 15 or more papers by 2018, and of the 2010 first-time authors only two male authors had 15 or more papers by 2018.

Encouragingly, of the 2014 first-time authors, a single female author, Daniela Lourenco, had 15 or more papers by the 2018 congress. Approximately one quarter of all the 2014 first-time authors (673 men, 467 women), returned as an author on a paper presented at the 2018 conference, 151 and 136, respectively. Of the 801 papers that were originally submitted to the 2018 New Zealand conference, 59% from male authors

Table 1. The number (N) of plenary speakers, session chairs and invited speakers along with percentage (%) of females for each group where gender of first author was known.

Year	Location	Plenary		Chairs		Invited	
		n	%	n	%	n	%
1974	Madrid, Spain	no plenaries		10	0	67	2
1982	Madrid, Spain	no plenaries		10	0	48	0

2018	Auckland, New Zealand	753	4,055	5.4	2,580	1,187	288	32%

[1] Percentage based on authors with gender known.

and 41% from female authors, around 80 were withdrawn, with an approximately equal number from both genders. Of those papers accepted, 38% were presented in an oral session, irrespective of the gender of the author.

Discussion

The rationale for preparing this paper for the early-career scientist session was our experiences and observations as female scientists both with a PhD awarded in 1997 in a traditionally-male scientific discipline. The dearth of women in the WCGALP congresses initially can possibly be explained by the number of women actively participating in the field over time. Nevertheless, it has generally been observed that the proportion of female speakers differs dramatically by the gender of the organizer, with male-

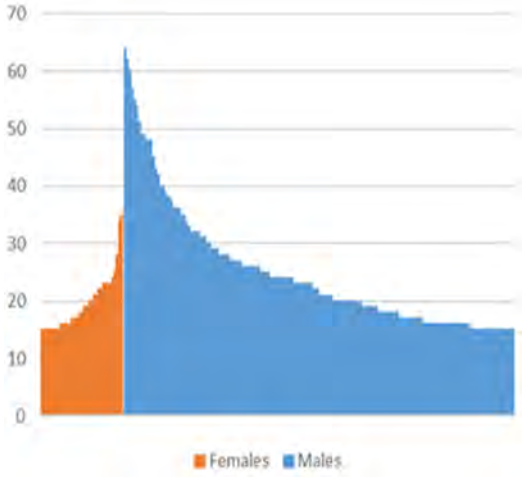

Figure 1. Number of WCGALP proceedings papers sorted by author gender for authors with at least 15 papers.

organized symposia having fewer female speakers than those organized by women, or a mix of genders (Isbell *et al.*, 2012). Further, blinded submissions of abstracts (as to author and institution) was also found to result in more women being chosen as symposium speakers (Newkirk *et al.*, 2005). We recommend improving the involvement of women, early-career scientists, scientists from developing countries and other minorities in key positions involved in the planning and organisation of future WCGALP events to ensure greater diversity of invited speakers. It would also be helpful to ask authors include their ORCID digital identifier when submitting proceedings papers to facilitate analyses such as those presented in this paper in the future.

There are some encouraging trends in the data we analysed. The days of all-male plenary sessions seem to be a thing of the past, and the proportion of female session chairs and invited speakers gradually increased over time. And based on recent data, gender is not playing a role in selection of submitted papers for oral presentations, nor in the observed willingness of conference attendees to attend subsequent conferences. This offers tremendous opportunities for early-career scientists to raise their profile at WCGALP events independent of gender. Inviting speakers is risky for session chairs and organisers, if the speaker is not well known. This naturally decreases the likelihood of unfamiliar scientists to be invited. We encourage all early-career scientists to speak up at WCGALP, to ask questions and to get noticed. We believe that both of these aspects, greater gender diversity of organising committees or chairs and increased courage of early-career scientists to get noticed will lead to greater diversity of session chairs, invited speakers, authors and attendees at future WCGALP conferences.

5. What industry needs from an animal breeding graduate

T.J. Byrne[1*], P.F. Fennessy[2] and P.R. Amer[2]

[1]AbacusBio International Limited, Roslin Innovation Centre, Easter Bush, Midlothian, EH259RG Edinburgh, United Kingdom; [2]AbacusBio Limited P.O. Box 5585, Dunedin, New Zealand; tbyrne@abacusbio.co.uk

Abstract

The historical focus of animal breeding post-graduate qualifications on breeding value estimation methods, and genomic approaches more recently, has resulted in a shortage of people with the necessary skills to design and lead industry breeding programs. While numeracy is important for a complete understanding of animal breeding, prioritisation of mathematical and statistical skills for post-graduate animal breeding training often discourages suitable young people from entering the field. The different incentives and structures of industry and academia also means that career paths in academia and industry are very different and transitioning from one to the other can be challenging. This paper outlines the skills we believe are required for the future, both within an agricultural genetic improvement-based consultancy business, and for our clients.

Introduction

AbacusBio is a consultancy business with approximately 50 people based in New Zealand, the United Kingdom and North America. We have clients across the globe, and a multinational team representing 16 nationalities and many different cultural perspectives. While our consultancy work covers many topics, we have a long history working to support the design and practical function of animal breeding programs. We focus on building long term relationships with our clients and have worked in many different structures and cultures within our client organisations.

In this opinion piece, we outline the key skills we believe are required to build well rounded animal breeders that are capable of leading livestock breeding programs through the next 50 years and beyond.

Key future themes

The divide between academia, government and industry continues to grow. However, all three will be key contributors to the genetic gain achieved over the next 50 years. Academia makes available new ideas and methodologies, and in some cases can be directly responsible for their implementation. For many programs, government is a key source of research funds, but it is also still common for both government regulations and Research and Development Investment to have a significant impact on breeding scheme designs. Industry in this context could be a team working on national infrastructure that supports animal evaluation and genetic improvement, or alternatively a private company competing to survive in a competitive market for gene stocks.

While the potential for introduction of new and disruptive technologies (e.g. historically we have seen BLUP, Genomic Selection, Embryo Transfer, Semen Sexing and Gene Editing) remains, navigation of a number of key tensions will become increasingly important for livestock breeding programs in the future. These tensions relate to the trade-off between short term genetic gain and long-term genetic diversity, the trade-off between genetic change in traits important to society (e.g. environmental and animal welfare influencing traits) and those traits that directly drive farming convenience and competitiveness), and the opportunity to import superior genetic merit from other countries and populations, versus the effort required to directly improve the local population. Moreover, there are financial (e.g. cost-benefit analysis) and operational considerations that span technical and business/organisational spheres.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_5, © T.J. Byrne *et al.* 2022

Successful navigation of these issues will require a new generation of animal breeders, who have a broad range of life experiences, skills, and perspectives.

Training needs

Young professionals need a basic background in quantitative genetics and animal breeding principles, as offered by many undergraduate courses in universities. From here a working knowledge of the principles of mixed model statistical analysis is important, but there needs to be recognition that young professionals are more likely to follow a well-rounded animal breeding career than just crunching large data sets through novel statistical analysis procedures. Principles of trait prioritisation, inbreeding management, breeding scheme design and cost benefit analysis should also be taught in sufficient detail that young professionals can go on to apply these critical tools in their future careers.

Desired attributes

The following attributes are highly desirable when we recruit early career professionals into our business:

- team-work;
- numeracy and literacy;
- enquiring mind;
- willingness to challenge existing ideas and processes, but to do so in a safe and professional way;
- flexibility in approach to team and client needs;
- a desire for constant learning and professional growth;
- recognition of the importance of business principles in the practical application of science.

In addition to these attributes, we prefer applicants who can demonstrate through previous experience:

- some degree of existing professional network, gained through work experience and or industry internship;
- a background knowledge of one or other farming/ food production system, and the culture of the people working within that system;
- a diversity of experiences gained either through travel, or from having overcome challenging life circumstances;
- a PhD or Masters thesis that demonstrates that a diversity of topics has been addressed, therefore requiring a range of skills to have been mastered to achieve it;
- a demonstrated ability of being able to switch from an academic career to an industry role.

Discussion

While universities provide valuable skills and knowledge, the cultural drivers and performance incentives in academia are very different to those in industry. It is therefore essential that early career professionals seek industry placement opportunities as part of their education. Where possible, combining these experiences with international travel makes for very valuable life experiences that serve people well for the duration of their career.

There is a growing push towards collaboration between universities and industry, as the talent shortage in animal breeding intensifies. With the convergence of plant and animal breeding approaches that is occurring due to genomics, more interchangeability between plant and animal breeding careers can be expected in the future.

Our experience suggests that several structured and unstructured approaches to early career development can build more diverse and valuable talent for the future of animal breeding. The value of mentorship, on-the-job training/internships, and exposure to different career paths cannot be understated.

6. Young scientist career development: a global discussion on challenges, opportunities and solutions

Abstract

Attracting, supporting, and retaining the next generation of young scientists into the field of animal breeding and genetics is important for the future of global livestock systems. The introduction of a Young Scientist Career Development session at the 12th WCGALP provides an invaluable platform to discuss the challenges, but more importantly, opportunities and solutions to foster the development of our next generation of animal breeders. A highlight of this session will be a facilitated panel discussion with Assoc. Prof. Daniela Lourenco (University of Georgia), Prof. Jennie Pryce (Agriculture Victoria Research and LaTrobe University), Prof. John Hickey (Bayer Crop Science) and Prof. Johan van Arendonk (Hendrix Genetics). These challenges will not be solved through a single panel discussion, or conference session. However, providing a platform for the WCGALP community to come together and work collaboratively on solutions to support young scientist career development is an important first step.

Introduction

Livestock industries are of utmost importance in modern society. This positioning has in part been achieved due to advances in the biological sciences – including nutrition, genetics, physiology and disease control. Today, livestock systems globally are facing numerous challenges and the field of animal breeding can play a role in meeting these challenges. Collectively, Animal Scientists, animal breeding companies, universities and governmental institutions need to ensure that the necessary young professionals are attracted and retained to the sector given the type of future leadership and research that the livestock industry requires.

Achieving this requires knowledge of challenges and opportunities that young animal breeders face as well as awareness of what constitutes a desirable career pathway for today's university graduates. The major factors determining the appeal for a particular career that were proposed some years ago (Harwin, 1979) included:

1. vocation/job opportunities;
    a. public sector;
    b. private sector;
    c. self-employed persons;
2. remuneration or earning power;
3. job satisfaction.

A number of other considerations are important to today's early career professionals. This includes job stability, career development, University/company recognition and reputation, work location, work-load and flexibility, parental leave arrangements and alignment between personal and organisational values. The benefits of mentoring, and access to career development for job satisfaction are well documented (Sinha,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_6, © J.E. Newton *et al.* 2022

2020) and are also applicable to the field of animal breeding. Conversely, lack of career stability and long-term or permanent job contracts as well poor work-life balance are key reasons given for early and mid-career animal scientists to leave research positions (Mayberry *et al.* 2021).

Historically, marginalised groups have been underrepresented across STEM disciplines (Wanelik *et al.* 2020) so any conversation about career development should also consider the work still needed in diversity equity and inclusion, including gender equity. While some progress has been made, in part due to initiatives like the Athena Swan Charter (United Kingdom & Ireland) and similar schemes in North America and Australia, there is a long way to go in achieving STEM and animal breeding communities that embody best practice Diversity, Equity and Inclusion. Just 40% of respondents in *Nature's* 2021 salary and job satisfaction survey felt their employers were doing enough to promote diversity (Woolston, 2021). In addition, survey respondents who did not identify as white were more likely to report experiences of discrimination, bullying and harassment in the workplace (Woolston, 2021). Ethnicity and socioeconomic background have also been shown to impact early career progression in STEM (Wanelik *et al.* 2020). In Australia, in 2020 women who graduated with postgraduate STEM qualifications in agricultural and environmental studies earnt $AU 23,000 less than male graduates (Australian Government, 2021). In addition, only ~25% of all agricultural scientists in Australia are women with women also underrepresented in senior leadership roles.

The aim of introducing a Young Scientist Career Development session at the 12th WCGALP in Rotterdam, the Netherlands, 2022 is to provide a platform for a global discussion on the challenges and opportunities for young scientist career development.

Panel discussion

Given the diversity of career pathways in animal breeding available to young scientists, the inaugural Young Scientist Career Development session at the WCGALP 2022 will feature a panel discussion. Panellists will be asked to reflect on both the challenges and opportunities for young scientist career development. During the discussion, panellists will be asked to consider defining moments in their own careers, advice for young scientists, solutions to the challenges faced by young scientists and what they see as the key opportunities for the next generation of animal scientists.

A shortlist of potential panellists was identified by session co-chairs based on a number of criteria including; contribution and profile in the field of animal breeding and genetics, experience across academia, industry and government, diversity in geographical location, gender, experience and research/work focus areas.

Panellists

In this workshop, we will include 4 panellists to discuss their experience in the animal breeding sector, Assoc. Prof. Daniela Lourenco, Prof. Jennie Pryce, Prof. John Hickey and Prof. Johan van Arendonk. Brief biographies are given below.

Assoc. Prof. Daniela Lourenco, Associate Professor, University of Georgia, United States of America.
Assoc. Prof. Daniela Lourenco, is an Associate Professor in Animal Breeding, Genetics, and Genomics at the University of Georgia in the United States. She was born and raised in Brazil, where she earned her MS and PhD degrees in animal breeding and genetics from Maringa State University. She has been working in this field since 2004, and her current interests include the use of genomic information to increase rates of genetic progress, the development of methods for genomic evaluations, and the use of computational algorithms to analyze large data. Her research is focused on genomic selection in beef and dairy cattle, swine, poultry, and fish. Daniela's group has developed and implemented single-step genomic evaluations for several breeding companies and breed associations. She has published over 360 scientific papers and

proceedings, including over 125 refereed journal publications. Daniela has served as advisor or co-advisor for 12 Masters and PhD students, committee member for 18 graduate students at The University of Georgia and 14 at international universities, has received 27 visitors from several countries, and has supervised 9 postdocs. Highly active in all projects developed by the animal breeding group at University of Georgia since 2012, and has been a principal investigator in research projects with budgets up to $500,000.

Prof. Jennie Pryce, Principal Research Scientist, Agriculture Victoria Research and Professor, School of Applied Systems Biology, La Trobe University, Australia. Professor Jennie Pryce is a geneticist who is well known for her work in dairy genetics and genomics. Jennie is principal research scientist for Agriculture Victoria and Professor of animal genetics at La Trobe University. Jennie has dedicated her life to dairy herd improvement and is very passionate about research. She grew up on a dairy farm in Shrewsbury (UK) where at a young age she bred pedigree Holstein dairy cattle under Severnvale Holsteins prefix. Jennie received her BSc (Hons) first class and PhD from The University of Edinburgh (UK). Prior to her work in Australia, she was employed as a dairy geneticist by the Scottish Agricultural College (UK) and as a scientist by the dairy breeding company Livestock Improvement Corporation (New Zealand). In 2008 Jennie made Melbourne her home and started a research position with the Department of Primary Industries (now Agriculture Victoria Research). Jennie now leads the DairyBio animals research program and is responsible for the animals' program. This innovation is critical to the dairy industry – regional Victoria's largest employer and a $1 billion export industry for the state. Jennie is instrumental in development and delivering of successful research, working to build industry groups' understanding and adoption, and led development of tools for direct benefit on farm by most farmers. Her position closely aligns with her main research interests of genetic improvement of traits associated with health, welfare and environmental impact in dairy cows.

In 2016 Jennie was the first non-North American recipient of the prestigious American Dairy Science Association J.L. Lush Award for Animal Breeding and Genetics and in 2019, 2020 and 2021 was named as Australia's top researcher in the field of animal husbandry by research analytics firm League of Scholars; this award is based on number of citations for research papers published in the top 20 journals in each field over the past 5 years.

Prof. John Hickey, Bayer Crop Science, Spain. Prof. John Hickey did his PhD studies in Wageningen University and Research, the Netherlands, on genetic evaluations of multiple breed cattle populations followed by post-doctoral positions in Australia (University of New England) and Mexico (International Maize and Wheat Improvement Centre – CIMMYT). In Australia he developed methods and algorithms, with accompanying genotyping strategies to impute genotype data in livestock populations. This work has subsequently been implemented in some of the largest animal breeding programs globally. In Mexico he researched aspects of genomic selection in plant breeding programs. Subsequently, John held the Chair of Animal Breeding at The Roslin Institute which is part of The Royal Dick School of Veterinary Studies at the University of Edinburgh in the United Kingdom. While at the Roslin Institute, his research group worked on breeding projects in pigs, chickens, cattle, groundnut, forest trees, strawberry, maize, wheat and other species. Software and algorithms developed by John Hickey and colleagues underpin aspects of several of the largest breeding programs globally. Since 2020, John joined Bayer Crop Science as Head of Corn Product Design, based in Barcelona, Spain.

Prof. Johan van Arendonk, Hendrix Genetics, the Netherlands. Prof. Johan van Arendonk received his PhD-degree at Wageningen University in 1985. From 1985 onwards, he worked at the Department of Animal Breeding of the Wageningen University. From 1985 until 2015, he worked in different roles at Wageningen University in the domain of animal breeding and genetics. In 1998, he was promoted to

personal chair and in 2002 he became full professor in Animal Breeding and Genetics In that period, he (co-) supervised around 90 PhD students and (co-)authored 350 papers in scientific journals. The emphasis in his career at Wageningen University changed from doing research himself, to training and coaching the new generation, to building and managing a team of professionals. During the last 5 years at Wageningen, he combined his role as chair of the animal breeding and genetics group with that of Dean of Science, in which he had a university-wide responsibility. In January 2016, he started as Chief Innovation & Technology Officer at Hendrix Genetics a global multi-species animal genetics and technology company. In that role, he contributes to strengthening the research and product development activities for the different species. In April 2020, he joined the executive committee of the company where he is responsible for Research & Development, the company's Sustainability Program and Innovation portfolio.

Conclusions

Given the many challenges young scientists face globally, not just in the field of animal breeding and genetics, the young scientist career development session represents a valuable addition to the WCGALP 12th Conference Program. We are indebted to our panellists for donating their time to participate in this session. The challenges in attracting, retaining and supporting the next generation of animal breeders will not be solved through a single panel discussion, or conference session. However, by creating space for these important discussions we are providing a platform for the whole of the WCGALP community to come together and work collaboratively on solutions to addressing these challenges.

Education

7. Digital learning in postsecondary education: 30 transformational years

J.J. Lindburg

University of Nebraska System, 3835 Holdrege Street, Lincoln, NE 68583, USA; jlindburg@nebraska.edu

Abstract

Digital education has brought sweeping change to postsecondary education since its foundation in the early 1990s. Understanding its origins and complexities; perceptions of faculty and students; and best practices for shaping and supporting the next generation digital learning environment are critical elements for faculty and administrators to consider in positioning our modern universities for post-pandemic success.

Introduction

Digital Education – sometimes also referred to as online learning, distance education, blended learning, hybrid courses, flipped classroom, remote learning, asynchronous delivery, or technology-infused teaching – has its roots in correspondence education, where a century ago institutions would mail packets of learning materials to an individual who would return completed assignments for grading at the end of a term without faculty-to-student or student-to-student engagement. In the 1980s, this model shifted to satellite education, where a faculty member would teach a classroom of students on a physical campus, and their lecture would be broadcast live to room(s) of students in another physical location.

The invention of the internet in 1992 made digital education as we know it today a possibility (Harasim, 2000), and experimental faculty began shaping some of the earliest forms of online course as we know them today on homegrown webpages in the late 1990s and early 2000s. The 21st century began with a 'paradigm shift in attitudes toward online education' (Harsim, 2000), which brought a rapid expansion of courses, programs, and even new postsecondary institutions. In the past two decades, a more modern emergence of digital learning has become a staple of postsecondary education nationally and internationally, in which faculty use a learning management system to deliver course materials, communicate with students, receive assignments, provide feedback, issue grades, and manage general activities of a course. The learning management system has become critical to teaching and learning (Pomerantz *et al.*, 2018), with most institutions running at least one learning management system (Lang and Pirani, 2016), and the rate of overall adoption of learning management systems rivaling only that of cars and cellphones in the United States. Prior to the COVID-19 pandemic, digital education was reaching 6.9 million students in the United States, or 35% of students in the nation (IPEDS, 2018).

Discussion

Broad debates about the efficacy of digital education have long plagued the modality from being fully embraced by all sectors of universities. Faculty argue that engagement is sub-standard, that learning objectives are not effectively met when students study exclusively online, and that the personal and professional development growth capabilities of students are not fully realized when students are learning at a distance. These concerns were further exacerbated by the fact that for-profit institutions dominated the market in the early 2000s, and largely focused on enrollment and marketing tactics rather than rigor, an institution's reputation, faculty credentials and preparedness, or quality of course design. Yet, despite these ongoing debates, students continued to opt into these digital courses and programs that increased their flexibility and access in order to attain a degree. Students' perception of the quality of online learning is also important to consider as they continue to opt into this modality. According to Van Wart *et al.* (2020), factors shaping a student's perception of the quality of online learning include 'their own sense of learning

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_7, © J.J. Lindburg 2022

achievement, satisfaction with the support they receive, technical proficiency of the process, intellectual and emotional stimulation, comfort with the process, and sense of learning community.'

In the past decade, there has been a surge in technology development as related to digital education. Rudimentary webpages and cumbersome, clunky learning management systems gave way to the 'next generation digital learning environment' we see curated and managed carefully at leading institutions. The next generational digital learning environment addresses five dimensions – (1) interoperability and integration; (2) personalization; (3) analytics, advising, and learning assessment; (4) collaboration; and (5) accessibility and universal design (Pomarantz *et al.*, 2018). To support a robust, learner-centric next generation learning environment, three broad considerations must be made: a strong infrastructure to allow for meaningful engagement, humanizing online experiences, and emphasizing access and affordability.

On top of this strategic infrastructure exists tremendous capabilities for innovation and personalized, meaningful engagement at both the peer and faculty-to-student interaction. This engagement in a virtual environment proved to be critical during the COVID-19 pandemic. As the instructional technologies and pedagogical practices that faculty relied on to complete the pivot to remote learning in Spring 2020 not only helped to engage students, but also aided in mitigating student stress. These practices and strategies were not just acts of good teaching, but were acts of compassion during a crisis (Anderson, 2021). As Martin and Bollinger (2018) point out, 'student engagement increases student satisfaction, enhances student motivation to learn, reduces the sense of isolation, and improves student performance in online courses.'

The next generation digital learning environment will be a more humanized space. Humanizing is a teaching strategy that 'removes affective and cognitive barriers from online learning, and provides a pathway towards a more equitable future for higher education that supports the success of all students' (Pacansky-Brock *et al.*, 2020). Some strategies that are at the core of humanizing the online environment include instructor-student relationships, welcoming visuals, warm pre-recorded communications, trust, a 'liquid syllabus,' and a culture of care (Pacansky-Brock *et al.*, 2020). Stock photos of students learning in isolation that are sometimes associated with the digital learner today will give way to a connected, holistic, student-centric experience that engages learners, fosters a sense of community, and accomplishes course objectives.

Finally, the next generation digital learning environment paves the way for true mission-centric commitments to student access and affordability. Efforts like the use of free or reduced-cost digital course materials integrated into the learning management system in lieu of traditional textbooks – commonly referred to as Open Educational Resources – have been accelerated at large institutions like Ohio State University, who has saved students over $20M through this practice. These types of strong commitments to student success and degree attainment by way of innovation within a strategic, well-positioned, interoperable learning management environment will be critical efforts for postsecondary institutions in the future.

As universities continue to shape their digital learning footprint, they must remember that the COVID-19 pandemic exposed the concept of the 'digital divide,' or equal access to technology. The World Economic Forum reports that half of the world's population has no access to the internet, fewer than one in five people in the least developed countries are connected, and that the digital divide impacts women more than men (Broom, 2020). The second element of the digital divide is digital readiness skills. The Pew Research Center reports that just 29% of the population in the United States have high levels of digital skills, with 70 million individuals in the country not prepared for robust online use like we would find in a university digital learning environment (Horrigan, 2016). Even for traditional college-age students, the second layer of the digital divide is staggering in that age is not an accurate predictor of digital readiness but rather education

perpetuates digital literacy skills, meaning that our traditional college students may in fact be digital natives and accustomed to using technology, but not in the capacity needed to be effective in navigating postsecondary digital education (Kirschner and De Bruyckere, 2017).

In conclusion, digital education has brought sweeping change to postsecondary education since its foundation in the early 1990s. Understanding its origins and complexities; perceptions of faculty and students; and best practices for shaping and supporting the next generation digital learning environment are critical elements for faculty and administrators to consider in positioning our modern universities for post-pandemic success.

8. A panel discussion: broadening learning by incorporating industry professionals in education

J.B. Cole[1*], R.A. Mrode[2,3], K.M. Olson[4] and P. Knap[5]

[1]URUS Group LP, 2418 Crossroads Drive, Suite 3600, Madison, WI 53718, USA; [2]International Livestock Research Institute (ILRI), BOX 30709-01001, Nairobi, Kenya; [3]Scotland Rural College, W Mains Rd, Edinburgh EH9 3JG, United Kingdom; [4]ABS Global, 1525 River Road, Deforest, WI 53532, USA; [5]Genus-PIC, Ratsteich 31, 24837 Schleswig, Germany; john.cole@urus.org

Abstract

Educating future animal breeders and geneticists is fundamentally important. During this training, young scholars, both those completing graduate and post-doctoral studies and those establishing their careers, benefit from understanding the range of professional opportunities available, and the skills they require. This includes exposure to the needs of various livestock sectors. Through a panel discussion in the Education session, industry-based experts engaged in developing nation, extensive, and intensive production systems will share their experiences and discuss opportunities to serve a range of livestock industries. In an interactive session, the moderator will present questions to the panel. This will be followed by an open discussion with the audience delving further into the points raised. The goal of the session is to broaden the attendees' understanding, particularly younger scholars, of the skills needed and professional opportunities available to meet the needs of livestock industries globally in animal breeding and genetics.

Introduction

Study of the theory and application of animal breeding and genetics is a centrepiece of graduate and post-doctoral training programmes in animal breeding and genetics. Yet, to fully meet the demands of modern agriculture, exposure to the diverse opportunities available across livestock sectors needs to part of that learning. Including industry-based professionals in the educational process is one way to fill that gap.

As part of the Education session at the WCGALP 2022, through a moderated panel discussion, industry-based experts engaged in developing nation, extensive, and intensive production systems will share their experiences and discuss opportunities to serve a range of livestock industries. In an interactive session, the moderator will present questions to the panel. This will be followed by an open discussion with the audience delving further into the points raised. The goal of the session is to broaden the attendees understanding, particularly younger scholars, of the skills needed and professional opportunities available to meet the needs of livestock industries globally in animal breeding and genetics.

Materials & methods

The session will be led by a moderator, who will present a series of questions to the panel members to consider. This will be followed by an open discussion with attendees, allow them opportunity to seek further insights from the panel members on the points raised, and to share their own experiences.

Panel members and moderator. The panel members were invited due to their recognized expertise in engaging with developing nation, extensive, and intensive production systems.

Dr Raphael Mrode holds a joint position at the International Livestock Research Institute, Nairobi, Kenya and Scotland Rural College, Edinburgh, United Kingdom. He has been lecturing on the Edinburgh University MSc course on Quantitative Genetics and Genome (QGG) since 2005, is a co-teacher at the international course on QGG at ILRI-BeCA, Kenya and has been principal instructor at similar courses in

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_8, © J.B. Cole *et al.* 2022

South Korea, Romania, Turkey, Nigeria, and Kenya in the last 12 years. He is the author of the book, 'Linear models for the Prediction of Breeding Values', which used in many animal breeding courses.

Dr Katie Olson is the Global Director of Dairy Product Development at ABS Global. She is responsible for creation of dairy genetics and germplasm, developmental dairy genetics research, product validation and elements of genetic services. She is on the board of directors for both the Council of Dairy Cattle Breeding, as well as the National Association of Animal Breeders (NAAB), and is a former chair of the board for NAAB.

Dr Pieter Knap studied animal breeding and aquaculture in Wageningen (NL) and has worked in commercial pig breeding since 1981: currently as Genetic Strategy Manager with Genus-PIC (based first in Scotland and now in Germany) and previously with the predecessor of Topigs (NL), and with Norsvin International (NO). From 2002 to 2013 he was also (vice-)president of the commission for pig production of EAAP.

The sessions moderator is Dr John Cole. Dr Cole is the PEAK Sr. VP for Research & Development at URUS Group LP, where he oversees the genetics and reproductive biology research for the largest producer of bovine genetics in the world. He was previously a Research Geneticist (Animals) for the U.S. Department of Agriculture's in-house research arm, the Agricultural Research Service, for 17 years. During his tenure at USDA, he was part of the team that developed genomic selection for U.S. dairy cattle, and his research interests include calving and functional traits and genetic diseases.

Aim and target audience. The aim of the panel discussion is to consider animal breeding education today and in the future, and to identify strengths and challenges in the training process to meet the needs of various industry sectors. It is envisioned that the session will especially attract graduate, post-doctoral and early career scientists. In addition, it is hoped that more experienced scientists will join the discussion to offer their own expertise and experience to the dialog.

Discussion

Although it is imagined that the conversation between the moderator, panel members and attendees will be free flowing, several potential topics for discussion are:

- Incorporating experiential learning, including industry internships, in instruction.
- Including greater focus on globalisation in the content of the animal genetics and genomics curriculum.
- Recruiting diverse and dispersed students (different cultural backgrounds and geographies) into the discipline.
- Integrating industry experts into instruction in animal breeding and genetics.
- Incorporating innovations in pedagogy into the animal breeding and genetics classroom.
- Overcoming the fear of the quantitative aspects of animal breeding and genetics among students.
- Finding the right balance in education between the foundations and current technologies affecting animal genetics and genomics.

The success of the session depends on active engagement among the panel members and attendees. The participation of graduate, post-doctoral, and early career scientists in the discussion will be particularly encouraged.

9. Conducting a national beef cattle genetics outreach program in the USA

Abstract

Reductions in beef genetics Extension specialists and outreach funding in the US has led a group of beef genetics Extension faculty to coordinate their efforts and develop a national Extension program to meet beef producers and Extension educators' needs in beef genetics programming. This effort, collectively called eBEEF, has utilized four platforms to provide these outreach efforts: Beef Improvement Federation, National Beef Cattle Evaluation Consortium, eBEEF.org website and the National Cattlemen's Beef Association education program. Materials provided through eBEEF include the publication of a Sire Selection Manual, major contributions to the Beef Improvement Federation Guidelines for Uniform Beef Improvement Programs, 32 factsheets, 165 videos, over 18 train-the-trainer webinar series, 5 direct producer education webinars, and numerous in person educational programs. This collaboration has proven to be an effective model to provide beef genetics outreach programming to a national audience.

Introduction

The Cooperative Extension Service in the United States was established in 1914 by the Smith–Lever Act and one of its primary functions was to inform farmers and ranchers about current developments in agriculture (https://nifa.usda.gov/cooperative-extension-system). Extension is funded by both federal and state dollars at an amount determined by the population of the state and the level of agriculture in that state. Funding is provided to Land Grant universities in each state and that institution determines what specific areas of agriculture will have an Extension presence in their state. The structure of state Extension systems across the country varies, but in general each county or area within the state has an Extension agent who consults directly with farmers and ranchers with support from state-wide specialists with expertise in specific species/disciplines. State specialists in the area of animal production generally have a PhD, but occasionally will have a Master's degree. The decision of what specialization is needed regarding animal production in each state is typically determined by the Animal Sciences Department and College of Agriculture administration.

Over the past 30 years there has been a decline in the number of specialists in Extension and a more drastic decline in the number of geneticists hired into those roles. Currently in the US there are approximately 10 faculty members with Extension appointments in beef cattle genetics and all have other obligations in research, instruction, and/or administration. The root cause of the decrease in beef Extension geneticists is likely multifaceted including a shortage of trained quantitative geneticists (Green, 2009; Lewis *et al.*, 2014), an increased academic emphasis on nutrition and, within genetics, from quantitative to molecular genetics, a lack of interest from genetics graduates to pursue a career in Extension, and increased competition by

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_9, © K.D. Bullock *et al.* 2022

industry to hire PhD trained geneticists. In addition, funding resources to conduct Extension programming have also decreased, and increasingly those funds have been tied to federally funded integrated projects that include research, teaching and extension components, with research typically receiving the majority (i.e. 2/3) of the funding apportionment.

With the absence of a beef genetics Extension specialist in many states, and no national program to provide educational resources, a group of Extension geneticists teamed together to coordinate efforts to meet the genetics needs of beef producers nationally in an endeavour called eBEEF. This paper will outline how this group coordinated their efforts to provide educational materials and discuss the effectiveness of this effort.

Materials & methods

Currently, there are four primary outlets utilized by eBEEF to provide outreach to a national audience of beef farmers and ranchers: Beef Improvement Federation (BIF), National Beef Cattle Evaluation Consortium (NBCEC), eBEEF.org website, and the National Cattlemen's Beef Association (NCBA) education program.

Beef Improvement Federation. The Beef Improvement Federation was founded in 1968 'to connect science and industry to improve beef cattle genetics' (https://beefimprovement.org). The federation consists of state/provincial beef improvement organizations and beef cattle associations from the US and Canada. This is one of the few organizations that brings together research scientists, Extension, allied industry, and beef cattle producers to collectively pursue improvements in beef cattle selection. The outreach mechanisms of the organization include an annual research symposium and Guidelines for Uniform Beef Improvement Programs (http://guidelines.beefimprovement.org/) available in a wiki format. eBEEF is heavily involved in BIF with four members currently serving on the BIF board of directors, three serving as workgroup chairs for the annual symposium (http://www.bifconference.com), and three serving on the Guidelines for Uniform Beef Improvement Programs Drafting Committee. Consequently, eBEEF members are involved with the program development, and often serve as speakers, for the annual research symposium and have been intimately involved in the development of the guidelines and transitioning them to a wiki format.

National Beef Cattle Evaluation Consortium. Coordination of national beef genetics centric Extension programming originated through the NBCEC Educational Programs (https://www.nbcec.org) (Bullock *et al.*, 2010). Through this federally funded organization, outreach was achieved through several programs including publishing the first two editions of the NBCEC Sire Selection Manual (Bullock *et al.*, 2021), and the Brown Bagger series (2004-2021), which is an annual train-the-trainer online educational program targeted at Extension professionals, breed association representatives and industry educators (Bullock *et al.*, 2010). Additionally, industry thinktanks are hosted comprised of researchers, Extension professionals and beef producers focused on targeted traits for potential inclusion in the national cattle evaluation, and in person educational programs are held at national and regional venues. The federal funding for this organization was terminated in 2012. However, the Brown Bagger series has continued on a no cost basis and other funds were accessed to publish a third edition of the NBCEC Sire Selection Manual (Bullock *et al.* 2021). This 52-page, peer-reviewed manual was written by Extension specialists and outlines basic genetic principles and applications with a target audience of beef cattle seedstock and commercial producers.

eBEEF.org Website. The eBEEF.org website (http://ebeef.org) was initiated in 2015 as a partnership among faculty at 6 U.S. Land Grant universities with the goal of providing beef producers and beef Extension educators/agents with resources related to beef cattle genetics. This also corresponded with a time in which several large U.S. Department of Agriculture integrated grants (e.g. bovine respiratory disease, female fertility, feed efficiency) were nearing an end and a common platform for offering information from these grants to producer clientele was needed. The website contains factsheets (32), videos (165), FAQs (49),

and an e-newsletter (7). The website was initially housed within a website known as eXtension, a national extension effort predicated on the voluntary labor of Extension specialists and educators to create and deliver content through the website. The eBEEF specialists provided content through the Beef Genetics and Genomics Community of Practice. However, eXtension was disbanded in 2020, and the eBEEF website was moved to the University of California – Davis.

National Cattlemen's Beef Association. The NCBA *(*https://www.ncba.org*)* is the national trade organization for beef cattle producers in the U.S. Their contributions to the beef industry include governmental policy, improved marketing, and producer education. eBEEF is heavily involved in NCBA's producer education that pertains to beef cattle genetics. Collaborations include invited presentations at the annual Cattle Industry Convention and NCBA Trade Show's Cattlemen's College, appearances on NCBA's Cattlemen to Cattlemen television program, and presentations on national webinars hosted by NCBA.

Results

Beef Improvement Federation (BIF). The BIF Guidelines for Uniform Beef Improvement Programs officially moved to a wiki format in May 2020. During 2021, the site was viewed by 8,104 users from a worldwide audience. The US was the largest user with 5,315 views, followed by Canada, Australia, and China with 453, 198 and 188, respectively. Excluding the homepage, the pages with the greatest views were the topics of international animal identification letters (1,506 views) and body condition scores (1,445 views).

eBEEF. The numbers of visits to the eBEEF.org site was 5,953, 21,072, 29,767, and 26,612 in 2015, 2016, 2017, and 2018, respectively. Since the migration from eXtension to the site hosted by UC-Davis in 2020 the website has had 9,041 views through December 2021.

There are currently 32 factsheets posted on the website under four categories: Beef Cattle Selection, Use of DNA Information, Simple (single gene) Traits, and New Technologies. Three new factsheets were posted in 2021. As an interesting snapshot of what factsheets have been viewed, in 2017 the factsheet with the most views was 'Color patterns in crossbred beef cattle' with 13,675 views; the second was 'The genetics of horned, polled and scurred cattle' with 8,147; while the third was 'How to get started with DNA testing' with 2,371. These data indicate an appetite for information on simple qualitative traits, and a need for educational material outlying fundamental basics of genetics for those with little familiarity with beef cattle genetics and breeding. The number of views by video was highly variable ranging from over 1000 to as few as 4. The videos range from technical content and long (over 1 hour), to short, concise pieces of 'how to' information, which likely impacts viewership.

Much of the information found on the website of partner organizations (NCBEC, BIF and NCBA) is crosslinked on eBEEF.org and vice versa. For example, the NBCEC Sire Selection Manual is available on both the NBCEC website and eBEEF.org. In addition to distributing the 3rd edition of this manual as a bound paperback book at the 2021 BIF meeting, the manual was made available as a pdf on the websites in April 2021, and as of January 2022 it had been downloaded 774 times between the eBEEF.org and NBCEC.org sites and approximately 1000 hardcopies have been distributed.

National Cattlemen's Beef Association (NCBA). In 2018, the eBEEF team presented a webinar series hosted by NCBA Producer Education that consisted of four sessions: (1) Fake News: EPDs Don't Work; (2) Show me the Money! Are there EPDs for Profit?; (3) The Four S's of Crossbreeding: Simple, Structured, Successful, and Sustainable; and (4) Putting the Tools to Use: Buying Your Next Bull. Over 650 producers participated live and YouTube recordings received over 3,300 views. Survey results rated relevance to beef

producers between 4.3 and 4.5 on a 5-point scale. Participation in eBEEF live presentations at NCBA Cattlemen's Colleges are approximately 800.

Discussion

During a time of reduced funding and a dwindling faculty base of Extension personnel with training in genetics, a team of Extension beef cattle geneticists organized under the name eBEEF provide educational resources to beef producers and Extension educators across the US. The mission of eBEEF is 'to foster a research and outreach community, engage beef cattle producers and ag professionals through trainings and publications, and support research and outreach projects' (https://ebeef.ucdavis.edu/about).

Collaborative efforts of eBEEF resulted in the development of educational materials that were made available across a variety of platforms to a national audience. Moreover, the eBEEF model reduced duplication of effort by the limited number of Extension personnel with genetics training, increased consistency of messaging, and consolidated producer educational material into a single location. Through electronic and limited print publications, train-the-trainer webinars, and direct producer education both virtually and at national venues, eBEEF has established a highly visible, impactful, and cost effective national educational program on beef cattle genetics. Although there have been successes demonstrated through this low-cost model of outreach, avenues for sustained support are needed. As important are mechanisms to ensure that junior faculty receive academic credit for such collaborations, and that well-trained genetics faculty can be recruited into Extension roles. Extension funding sources and personnel to deliver outreach programs in the future remain two primary areas of concern.

10. Breeding Lab: a successful industry-academia collaboration to provide MSc consultancy training

J. Komen[1*], J.A.M. van Arendonk[2] and D.E. Lont[1]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Hendrix Genetics, Spoorstraat 69, 5831 CK Boxmeer, the Netherlands; hans.komen@wur.nl

Abstract

A new course Breeding Lab was developed and introduced, to better prepare students for the diverse job market. The course was set-up by Wageningen University in collaboration with industrial partner Hendrix Genetics. Both organisations played a key role in the course. The academic partner focused on the development and application of skills and competences necessary for solving real life issues in animal breeding and genetics. The industrial partner was responsible for formulating the real-life issue to be addressed, technical supervision of the students and evaluation. The two partners involved in the course and the students found the course as a valuable addition to the curriculum.

Introduction

An important task and challenge of academia is to prepare students for the future job market. Results of the yearly Dutch National Student Questionnaire consistently show students' wish for better preparation for the diverse job market. To respond to this, we recently developed and introduced the course 'Breeding Lab' in close collaboration between industry and academia. This course was offered for first time in 2019-2020 to students of the European Master in Animal Breeding and Genetics (EMABG). The enrolled MSc students worked on a group assignment in an industry setting, allowing them to learn and apply competences relevant for solving real life issues that were difficult to develop on campus.

In this paper, we will explain the set-up and learning outcomes of the breeding lab, and the different educational formats used to achieve the learning outcomes. Subsequently, we will focus on the experiences at both sides: the industry partner, Research & Development team of Hendrix Genetics, and the academic partner, the Animal Breeding and Genomics group of Wageningen University. In the discussion we focus on the experiences of students and give an outlook on expanding the course to accommodate larger numbers of students.

Materials & methods

Breeding Lab: set-up and learning outcomes. The idea of the Breeding Lab was developed over time, following consultation of several R&D directors who expressed the need to have students better prepared for their professional careers in industry, in terms of professional skills and competences. At the same time, results of the Dutch National Student Questionnaire (NSE) showed that students also felt the need to be better prepared for the diversity in the future job market. Combining the two, led to the development of the pilot project 'Breeding Lab' by the Animal Breeding and Genomics group of Wageningen University in 2018. This course was included as an academic consultancy course in the curriculum for the EMABG. Wageningen University is one of the six partners in the EMABG consortium, and one of the two to provide education to first-year students within that master program.

The aim of Breeding Lab is to prepare students for a professional career in industry or (non)governmental organizations. This is achieved by letting students work on an assignment, provided by the industrial partner. The emphasis in the assignment lies on solving a problem in teams and experiencing, learning, and acquiring the professional competences that are needed to successfully operate in an (inter)national,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_10, © J. Komen *et al.* 2022

multidisciplinary team. An important part of the course is devoted to understanding, describing, and reflecting on the competences that are needed to successfully operate in a professional environment:

- sensitive to management structures, politics and governance;
- personal communication skills;
- collaboration and personal effectiveness when working in groups;
- dealing with setbacks, disappointments, and feedback.

The course is scheduled as a combination of a 'group internship' at Hendrix Genetics, and training and exercises related to professional skills. In a period of 4 weeks, groups of students work full-time on an animal genetics-related assignment. This assignment fulfills the following criteria: it should be a commissioned multidisciplinary assignment, concern an authentic case, offer a certain level of complexity, reflect various interests and stakeholders, and it should require an academic (master) level to address the issue.

The learning outcomes: after successful completion of the course students will be able to:

1. Contribute at an academic level to the execution of a multidisciplinary project, both in terms of process and content, related to the discipline of Animal breeding, by gathering, selecting, and analysing information and integrating this into a proposed solution to the assignment given by the commissioner.
2. Report, discuss and defend viewpoints and conclusions in a professional, academic and a collaborative manner before representatives of the commissioner and other stakeholders involved (demonstrate the ability to engage in perspective-taking).
3. Reflect on their personal functioning in and contribution to a professional team.
4. Demonstrate academic competences to execute the team assignment, within the complex (inter) national environment of a professional organisation.
5. Reflect on the work culture of the organisation and its decision-making process.
6. Further analyse the competences that are needed to be successful in a professional environment, as encountered during the assignment, and reflect on these in a self-evaluation.

From an educational point of view, the Breeding Lab can be seen as a 'pressure cooker', due to its short time frame of 4 weeks. It requires students to apply the 'learning by doing' mentality and to have their hands on the assignment from the very first moment. It also requires collaboration and assignment of specific tasks within the teams, and knowing about and respecting each other's strengths and weaknesses.

Professional skills training modules are part of the course, and are given by professionals from the 'Education and Learning Studies' chair group of Wageningen University. The first of the three skills training modules, mostly focusing on intercultural awareness, is planned before the students start the 4-week period. The other two skills training modules are given along the way, and focus on team roles (training 2) and conflict resolution skills (training 3).

Intercultural and collaboration skills are an important part of the course. The target group for the Breeding Lab in its current form, are the first-year MSc students of the European Master in Animal Breeding and Genetics. Given the nature of that programme, this is a highly diverse group of students, representing many different nationalities (Table 1). Hence, intercultural skills, as well as communication and collaboration skills, are an important aspect of the competences to be developed and applied in the course.

Each student team of 4-5 students is assigned to an experienced R&D member from Hendrix Genetics. These experts are indispensable in supervising the content of the assignment. This entails clarifying the content of the assignment, getting the right (company) information at hand, and making sure the students keep heading in the right direction leading to a recommendation or outcome that is useful for the company.

At the same time, the teams get coaching from experienced teachers from Wageningen University, focusing on the group process, personal development of team members and reflection on roles and tasks within the teams.

Results

The course started in academic year 2019-2020 and has run two times, in two consecutive years. The third offering is taking place at the time of writing (January 2022). The composition of the groups in terms of nationalities is given in Table 1.

Experiences from the viewpoint of industry-partner Hendrix Genetics. As Hendrix Genetics, we recognize the importance of introducing students during their training to practices in the industry. That is why we, like colleagues from other breeding organisations, provide guest lectures in course at the university and do offer internships for students. We are very pleased with this new course which gives us the opportunity to introduce a larger group of students to the way of working in a company. The interaction with the students and the results of the assignment help us in finding new or better solutions. Not only the students but also the geneticists involved in the supervision benefit from the interactions during the Breeding Lab.

Experiences from the perspective of Wageningen University. We started the course in 2019-2020 from scratch, with two groups of motivated and very diverse students and in good collaboration with Hendrix Genetics. The course has taught us once again how important students' personal skills are, for a student team to be successful. One of our tasks as coaches is to make students aware of the difference between knowledge-based skills and the personal skills required to be successful in a team. Coaching students on this type of behaviour is sometimes challenging but is also very rewarding. Our goal is to establish an open atmosphere in which students can share their successes as well as their doubts. An important aspect of the Breeding Lab is its international composition. Students are generally unaware of the cultural differences that can lead to different attitudes and types of behaviour (indirect vs direct communication, time management, etc.) during teamwork. At worst, they can lead to counterproductive conflicts and group failure (Meyer, 2010). The first skills training course is therefore fully dedicated to cultural differences and creating understanding. The students, (especially Dutch students), experience this training in many cases as an 'eye opener'.

Table 1. International classroom in Breeding Lab, academic years 2020-2021, 2021-2022, and 2022-2023. Table shows an overview of students' nationalities per edition.

	Year		
Continent	**2019-2020**	**2020-2021**	**2021-2022**
Europe	Dutch (3)	Dutch (1)	Dutch (4)
	Austrian (1)	Irish (1)	German (1)
		Hungarian (1)	
Africa	Nigerian (1)	Ethiopian (1)	Ethiopian (1)
		Ghanaian (1)	
Asia	Bhutanese (1)	Chinese (1)	Mongolian (1)
	Bangladeshi (1)		Indian (1)
			Bhutanese (1)
Latin America	Bolivian (1)	Paraguayan (1)	
		Brazilian (1)	
Total number of students	8	8	9

Due to the pressure cooker nature of the course, we observe quite steep learning curves with our students. We therefore believe that the course is a valuable addition to the MSc programme.

Discussion

We asked for extensive feedback from students of both completed editions 2019-2020 and 2020-2021. Students indicated that they enjoyed a lot working on an assignment with a real company and taking a look into the corporate life of animal breeding. They particularly liked the skills training sessions. The intercultural fingerprint as well as conflict management skills training were equally preferred to each other by the students. This was due to simply interest and experiencing conflicts within the team, respectively. The students generally did experience good group feeling and considered the group size of 4-5 students as adequate in relation to the project. However, some students felt tension within the group and were convinced the skills training, especially regarding conflict management, could have helped them more with such issues.

Quotes from students: 'Great to have complete freedom to determine your own schedule and work on the assignment as a team. A lot of responsibility, a steep learning curve.' and 'I liked the set-up of the course where we had to solve a problem for a company. This was unlike my previous courses, which consisted of lectures and exams.'

One of the objectives of the Breeding Lab was to prepare students better for the job market, e.g. working in a breeding company. The assignments of the Breeding Lab appear to do just that: students work on real life problems, and meet and talk with R&D employees on how they perceive working in a breeding company. Students are generally surprised to find that working in an R&D environment can be equally challenging intellectually, as working in academia (e.g. as PhD student). Many EMABG students continue by doing an internship with Hendrix-Genetics.

As an outlook on future, the Breeding Lab is a clear success as non-EMABG students are also increasingly registering for this course. Students are attracted by the learning-by-doing approach and the high level of independence. The fact that the problems are real life problems that need a solution, rather than pre-cooked exercises makes all the difference for them. The set-up of the course can easily accommodate larger numbers of students. A potential bottleneck is the time that industrial partners can devote to assist/support the students. The current period of 4 weeks might be too short for the partner to get value out of the project.

11. How a group of Merino breeders increased the rate of genetic gain by 134% in five years!

T. Granleese[1*], J.H.J. van der Werf[2] and S.J. Martin[3]

[1]NSW Department of Primary Industries, Grafton NSW 2460, Australia; [2]University of New England, Armidale NSW, 2351, Australia; [3]SheepMetriX Pty Ltd; P.O. Box 1533, Young NSW, 2594, Australia; tom.granleese@dpi.nsw.gov.au

Abstract

The DNA Stimulation Project was a major genetics adoption program in Merino sheep breeding enterprises running from January 2018 to June 2022. Historically, the Australian Merino population have had low rates of genetic gain. This project used a collaborative approach between Meat and Livestock Australia's Donor Company, University of New England, MerinoLink Limited, Merino breeders, scientists, and genetic service providers. A bold project target was set to double the rate of genetic gain by 2022 for the group of 30 breeders who collectively invested over AUD$1.7 million in total and was co-matched by Meat and Livestock Donor Company. The project focussed on working with the project participants to strategically use the genetic and genomic tools currently available. With the ambitious goal being reached a year early (increase of 134% in lifetime of project), the key component to this success was the willingness of project participants to engage and the coaching approach by the project team.

Introduction

On average genetic gain in Australian Merinos has been historically low with very large variations across the industry (Granleese *et al.* 2018). Underlying influences have been caused by a multitude of factors including inaccurate breeding values (Stephen *et al.* 2018) and/or a lack of understanding of selection theory.

The DNA Stimulation Project aimed to build understanding and implementation of genetic selection tools with the project participants. The project focussed on capacity building and working collaboratively at all levels (scientists, genetic service providers, and breeders) across the industry to communicate how to use software tools more effectively for assisting in the design of breeding programs to increase the rate of genetic gain for participants.

During the DNA Stimulation Project, project participants have been faced with significant challenges including unprecedented drought in many parts of Australia and restrictions due to COVID-19. The project team were able to adapt to the challenges and continued to deliver the project requirements.

The aim of the DNA Stimulation Project was to double the annual rate of genetic gain by 2022 (starting 2018) in line with Meat and Livestock Australia's National Livestock Genetic Consortiums aims. This paper outlines methods the project used to almost reach the target of doubling the rate of genetic gain.

Materials & methods

Merino breeders were notified of a project call that would subsidise genomic testing for their seedstock flocks. Given Merino breeders have historically low pedigree recording, this was a vehicle to fast track pedigree collection. The project expectations agreed that in exchange for subsidised genotyping (funding is 58% from the project participants and 42% from the Meat and Livestock Donor Company) that they would form a network to upskill via a series of intense coaching and workshops. Scientists were funded to link to private consulting genetic service providers, the national sheep genetic evaluation group – Sheep Genetics

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_11, © T. Granleese *et al.* 2022

and the Merino breeders. The aim was to create links between all levels of data collection, Australian Sheep Breeding Values (ASBVs) delivery and research and development.

The Project had 30 ram breeders (accounting for 40% of the annual Merino Sheep Genetics database intake of animals) and 15 participating commercial breeders who breed their own rams, 43 commercial breeders who purchased rams and seven private consulting genetic service providers. The project participants were located across New South Wales, Western Australia and Victoria. In total this group represented over 10,000 rams sold annually (contributing to >2.5 million sheep born annually), 15,000 doses of semen sold annually to seedstock and commercial breeders, as well as over one million sheep bred directly by the project participants.

The extension and adoption process include a combination of face-to-face workshops, intensive one-on-one meetings, webinars, phone calls, personal emails, e-newsletters and group email updates. Input into these processes include key personnel within the DNA Project Team, University of New England, Sheep Genetics, Meat and Livestock Australia and participants in the project, including breeders and genetics service providers.

Key tools used with project participants include DNA parentage to capture pedigree, low density genomic tests for pedigree collection and/or genomic selection, ASBVs for selection, MateSel (Kinghorn, 2011) to optimise mating decisions in large breeding programs, Sheep Genetics Ramping Up Genetic Gain report (RUGG) to identify data collection problems, Flock Profile – a genomic only estimation of flock average (Swan *et al.* 2018) for commercial breeders, Ram Team Manager (RamSelect.com.au) for commercial ram buyers to improve their ram teams each year for their breeding objective, Rampower within flock indexes for commercial breeder collecting phenotypes but not pedigree and percentile band tables for context of breeding values.

Each project participant worked through the process of setting and documenting an achievable breeding objective which is revisited each workshop or meeting with the DNA project team. Key questions covered were: – are they on track, what is working well (or not), what can be improved, and how are project participants measuring progress?

To benchmark progress the DNA Stimulation Project used rates of genetic gain were ASBVs generated by Sheep Genetics. The project also used direct workshop feedback to track the effectiveness of the project.

Genetic improvement was benchmarked using a standard breeding objective using Sheep Genetic's Merino Production Plus (MP+) economic index. 'Doubling the rate of genetic gain' was measured by comparing the five-year genetic gain average (2012-2017) compared to the project four-year genetic gain average (2017-2021).

Results

Genetic gain increased by 134% in ram breeders comparing the four-year period of the project to the previous five years prior to the project. Another of the key outcomes of the project with the strategic use of DNA testing technologies was the increased number of ram breeder participants submitting data to Sheep Genetics with full pedigree information. There was an increase in the number of project participants submitting full pedigree from 25 to 70% between January 2018 and January 2022.

At the beginning of the project there were large differences in average genetic merit between the ram breeder participants in the DNA Project, with the lowest average MP+ index 110 (90th percentile) and the highest 167 MP+ index points (1st percentile) at the commencement of the project in 2017. The current MP+ index range between the ram breeders is 138 (70th percentile) to 188 (1st percentile) index points. The diversity in the group facilitated sharing and swapping experiences to allow informal mentoring within the group.

Discussion

The key component to the success of this educational project was providing links between breeders, private genetic service providers and scientists. The interaction between all parties allowed flow of information benefiting all parties and breaking down communication and trust barriers. Furthermore, engaging private genetic service providers who had clients within the project gave extra incentive for them to up-skill. The up skilling of these professionals' results in the multiplier effect with more educated messages and advice being passed on to many of their clients.

Trust within the project was initially built on 'across-the-kitchen table' meetings with ram breeders where they expressed their frustrations with genetic evaluation and barriers that stopped them collecting crucial data for higher quality ASBVs. With this knowledge the team scientist and service provider were able to provide direct feedback as to why not collecting data points was affecting their ASBVs and practical solutions to their problems. Once participants were listened to in a 'safe' and private space, their willingness to change and adopt occurred quickly.

Access to the same genetic service provider as well as scientist at any time in any medium (i.e. email, phone call, text message, Zoom meetings) was another key step in helping breeders upskill and adopt better practice. Further group educational activities held were annual ram breeder workshops where a range of scientific developments, direct feedback, setting S.M.A.R.T. breeding objectives and peer-to-peer learning through social networking and project case studies. Before and after each workshop the project team would get breeders to fill in questionnaires rating their understanding of how ASBVs are calculated and how much they use ASBVs in selection decisions. Prior to the project starting the group average responses and post project average responses are summarised in Table 1. Further into the project as breeders built a depth a pedigree in their flocks they were in a position to use Matesel (Kinghorn 2011) where matings are optimised to maximise genetic and limit future co-ancestry. A series of Matesel workshops were run in the last three years of the project. Either breeders ran their own Matesel at joining or employed their genetics service provider to do this for them which helped accelerate rates of genetic gain given Matesel uses index selection.

The project observed a direct relationship between attending educational activities and rates of genetic gain. Figure 1 demonstrates that the more engaged ram breeder project participants were with the project the higher the rates of genetic gain. This trend validates the intense relationship the breeders have with the

Table 1. Ongoing mean scores at set times throughout project of breeders' knowledge and use of ASBVs throughout the project.

	Understanding of ASBVs	Use of ASBVs in selection decisions
1-Jan-2018	3.6	6.4
1-Jan-2019	6.8	7.5
1-Jan-2020	7.4	8.4
1-Jan-2021	8.3	8.7
1-Jan-2022	8.5	8.9

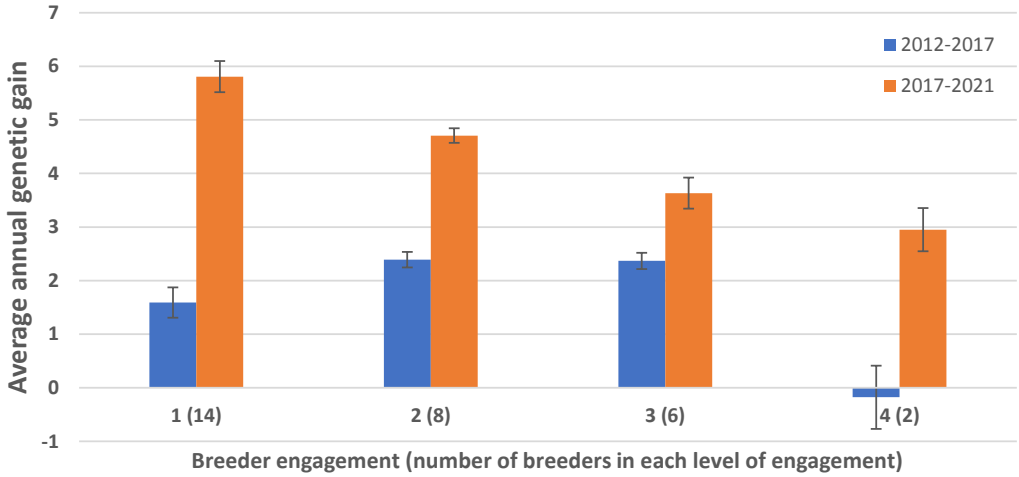

Figure 1. Blue bars represent five-year average annual genetic gain (2012-2017) pre-project and orange bars represent three-year average annual genetic gain (2017-2021) during project for studs grouped by project engagement. 1 – Fully engaged: attends all workshops, calls project leaders, asks for one-on-one meetings; 2 – Engaged: Attends most workshops and/or some extra meetings; 3 – Sometimes engaged: Sporadic attendance to workshops, rarely uses extra opportunities; 4 – Never engaged: Do not turn up to any workshops or extra activities.

project team. A key to keeping breeders engaged was using a co-investment model. Initially the project used the motivation of subsidised genomic testing to 'lure' breeders into the project. With Meat and Livestock Australia offering dollar-for-dollar investment with project partners, the project lead was able to 'skim' small amounts of money off each subsidised test to help fund a genetics service provider's and scientist's time for the life of the project. Furthermore, breeders agreed to pay an annual fee of $2,000 AUD/yr to: (1) help fund workshops and time of staff on the project; and (2) maintain interest and investment in the project after the initial benefit of subsidised genotyping.

Summing up, the DNA Stimulation project was a success in increasing the rate of genetic gain in Merinos. Furthermore, the project had long-lasting implications with the up skilling of genetic service providers and breeders to continue the pursuit of improving breeding objectives and better facilitating clients.

12. YouTube applied to the education of genetics and genomics

G. Mészáros

University of Natural Resources and Life Sciences, Vienna, Gregor-Mendel-Straße 33, 1180 Vienna, Austria;
gabor.meszaros@boku.ac.at

Abstract
Educational videos are a form of asynchronous learning, with their own set of advantages and disadvantages. They are available at any time for students to watch and learn. On the other hand, practical experiences show that the entire duration of videos are not watched. This paper gives practical insight on viewer habits for educational videos, using the 'Genomics Boot Camp' YouTube channel, as an example. Moreover, the aspects of educational video placements on commercial platforms, and their potential innovative use for standard research project dissemination activities are discussed.

Introduction
It is not easy to write this paper. You, as a reader, might say that I write it only to promote my personal brand on a world-wide stage, in front of the most relevant audience there is, for an educational resource focused on genetics and genomics. Certainly, any promotion activities are very useful in this line of work, as you will see in this paper. What you will also see, however, is that in the business of making videos an even more important part is providing a value to people who decide to invest their time into your work.

This paper is to provide my experiences from managing the 'Genomics Boot Camp' YouTube channel, that focuses on teaching theoretical and practical aspects of genomics. I will compare my experiences to the typical classroom setting in face-to-face and online forms, discuss various formats and opportunities such a platform provides, including reach to world-wide audiences across disciplines and the general public. I will also outline how educational videos could be used for classical project dissemination and communication efforts. At the very end of the paper you will find another experimental approach that might be utilized in science communication.

Materials & methods
The paper was based on personal experiences from almost one year of publishing educational video on the YouTube platform. The first public video on the Genomics Boot Camp channel was released on 24 January 2021.

The statistics on viewer counts and engagement were taken from the YouTube analytics application programming interface (API), which retrieves YouTube Analytics data for the channel. The view statistics and visualizations of audience retention were taken from the YouTube Studio. The retention rate was defined as the percentage of viewers still watching at any given time point. The shaded areas in the figures were the average retention rates computed from the most recent videos at the time. At the time of writing of this paper, the channel had 1,700 subscribers, 81 public videos, and 64,600 lifetime views. In the last 90 days there were 30,000 views from 11,800 unique viewers. Overall, numbers related to viewership and audience participation indicate increasing engagement, but the unique viewers are available only for the last 90 days, due to limitations in the YouTube Studio.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_12, © G. Mészáros 2022

Results & discussion

My initial motivation to start this channel was my experience that people need a simple, down to earth explanation on how to deal with single nucleotide polymorphism (SNP) data. This apparent need, at the time, was coming from people involved in livestock research. I kept getting very similar questions and requests from students eager to do their MSc thesis, but also more senior colleagues, who were not closely working in practical genomics before. Soon after launching the channel the audience has broadened, with people from human and plant genetics, genomics, and other fields of biology joining in. Also, the audience broadened from my students and colleagues I knew to the worldwide level.

Videos in teaching and the viewing behaviour. The video lectures and teaching materials are a form of asynchronous learning, which allow learning in different times and locations. Viewers could ask questions, which are regularly answered via the comment section of each video, which are also visible to all future viewers. Such resources were not meant as replacement of traditional learning, but to provide additional resources that students might seek, in form of clarifications or practical tutorials. Similarly, Noetel *et al.* (2021) found that adding video to existing teaching led to strong learning benefits.

The student viewing behaviour of videos is very different from a synchronous, and especially face-to-face classroom setting, where the students sit through entire lectures, typically in length of 1-1.5 hours or more. In asynchronous setting the view durations are shorter. Black (2020) found average view durations between 14 and 25 minutes, for lectures lasting from 46 minutes to 1.5 hour, with relatively longer views for longer videos. There was no optimal length of videos suggested, but generally shorter videos are suggested over longer ones. Still, the creation of, for example, 10-minute videos does not guarantee that students watch it all. In my experience, the average view duration is similar in proportions, regardless of the video length. Using the two examples shown below, the view duration was 2:42 for the video with a below average retention rate (Figure 1, total length: 10:30), and 5:36 for the video with above average retention rate (Figure 2, total length: 10:38). Similar patterns are visible throughout all videos on the channel. Here I must note that average view times were likely influenced by two additional factors. The first one is the large number of users that click away after few seconds in the video, thus greatly decreasing the overall average view duration. The likely reason was that they quickly found that the content of the video was not what they expected and moved on. The second factor could be that the videos are not part of any formal course, thus it is not mandatory for the students to watch them in full. If they had a specific question that was answered within the video, they will likely click away.

Another aspect of learning was the attention span of students during lectures. It is very challenging to measure this behaviour in a classroom setting. Early sources (Hartley *et al.*, 1978) mention an attention span of 10-15 minutes, but Bradbury (2017) contradicts this measure, and suggests waxing and waning attention throughout the lecture, rather than a fixed time period.

Similar behaviour was noticeable, and measurable on the videos related to the retention rate (Figure 1 and 2). In both videos there is a noticeable sharp decline right at the beginning, suggesting viewers clicking away. The exact reason is unknown, possibly due to unintended clicks on the video, or the viewers quickly finding out the content is not what they expect. The retention could be improved by certain techniques, some of which were applied in the video with better retention. Examples of these techniques include a setup of video chapters, which see slight increases in viewership (dashed lines on Figure 2). Regardless of the perceived quality of the video, however, the retention rate seems to decline over time, so viewers do not watch the entire video, from beginning to the end, as one might expect. Similar decline was also shown by Lau *et al.* (2018), which suggest this was a universally applicable viewer behaviour.

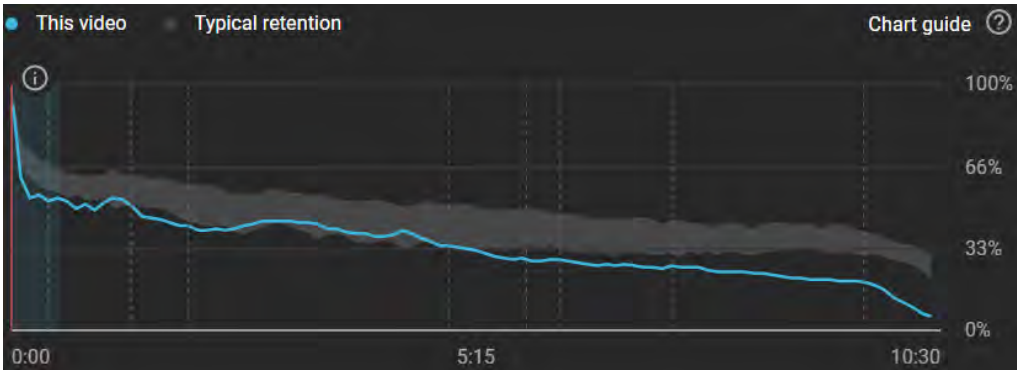

Figure 1. Video with a below average retention rate. Vertical lines indicate video chapters. Views: 6265, Title: 'Genomics in practice – How to start PLINK'.

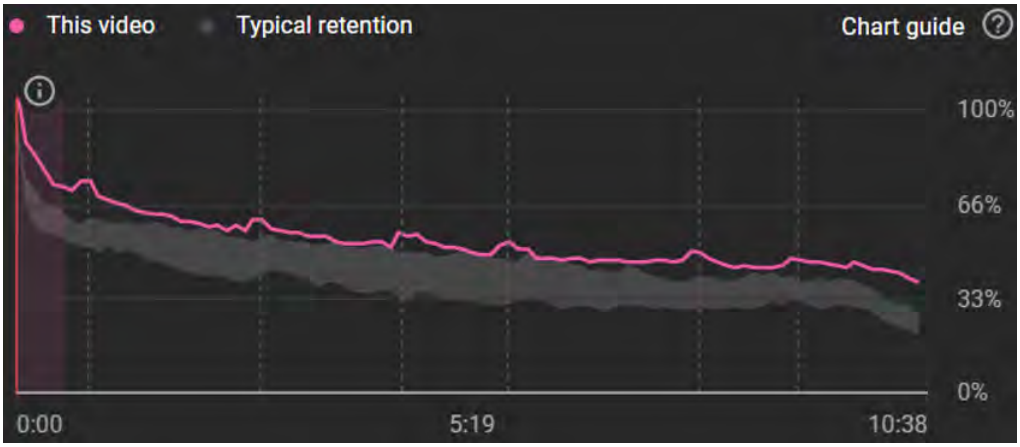

Figure 2. Video with an above average retention rate. Vertical lines indicate video chapters. Views: 274, Title: 'Get organized with your data on your computer'.

Practical considerations. A distinct advantage of video materials on commercial platforms like YouTube is that the setup and maintenance of such platform do not require investment from lecturer's side. YouTube also actively promotes the videos to potentially interested new viewers via so-called 'impressions', i.e. the number of times the video thumbnail was shown to users. From these impressions, only a small percentage actually click (so called 'click through rate'). At the time of writing the monthly impressions are over 120K (ca. 4K daily), which at overall 5% click through rate meant 5.5K views, solely from the results of the algorithm. This is not a lot by any means: large channels have their daily impressions in millions! Still, even these lower numbers are only accumulating, and consistently growing over time in an accelerating manner. According to my experiences related to reaching audiences, this is a distinct advantage of YouTube, compared to other websites. Static websites have stable content, but they need to be discovered, which requires constant and consistent efforts. Other social websites, like Twitter could drive considerable audiences using a similar algorithm, but the promotion of any single message (tweet) is only for a short duration (a few days maximum). Opposing to this, on YouTube a well-done video is continuously suggested for years.

Unconventional use of video lectures. Another way such educational videos could be used is for dissemination activities of standard research project. In my opinion this is currently a largely under-utilized opportunity, with distinct advantages for both the research projects (to reach more people) and the viewers (to learn from experts in the field). Conventionally, dissemination activities rely on sharing results and outcomes of research projects to different audiences, ranging from general public to the wider scientific community. It is perhaps only my impression, but most of the time such reporting goes something like 'We from Project X did a lot of work in Y, so we advanced the science.' This is great. It is shared and reposted mostly by people who were involved, perhaps their colleagues, institutions, and maybe a several other interested people. But I think it could be improved, incorporating the message in an educational video with: 'This is how you do Y. Here are some open access data to do it. And by the way, we are from Project X.' While the first approach provides the information to the community, the second one provides actual value, and a good reason why viewers should engage and share the material, even if they don't really care about Project X. If the topic is of interest, novel or even a very often used standard procedure, wide scale feedback is very likely. Case in point: One of the most viewed videos on the Genomics Boot Camp channel is a tutorial how to do a PCA plot. In all projects, there is a great amount of expertise that could be easily utilized for similar purpose, creating lasting footprints of projects and brands, in the form of videos that people actively search for.

Finally, the promised experimental approach, that might be utilized in science communication, or for other similar purposes. Parallel with the submission of this paper I made an accompanying video with additional commentary. The inspiration for this approach came from the annotated version of Watson and Crick (1953) on the Exploratorium website. Here the annotation gives an entirely new dimension to the paper, providing historical context and supporting information that greatly enhance the pleasure of reading. Similarly, in the case of this paper, you could gain some accompanying information by searching for the 'YouTube applied to the education of genetics and genomics' video. The premiere of this video was set to the beginning of the WCGALP 2022 conference. In general, such annotations or commentaries in audio-visual or written forms could provide context for various audiences. In education, setting the scene, and briefly explaining the relevance of published materials, might similarly improve their understanding by the readers, as opposed to a 'Read this' directive.

For the future a video series on genomics theory basics will be completed, complementing the existing practical tutorial. The overall plan is a continued weekly release of videos that are attractive to learners.

13. Creating a good learning and sharing environment for bioinformatics

T. Klingström* and J.I. Ohlsson

Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Box 7023, 750 07 Uppsala, Sweden; tomas.klingstrom@slu.se

Abstract

Most bioinformatics researchers create their own working environments depending on their training, access to computing resources and what advice they receive from other researchers. This makes the development of training programs difficult as much knowledge and work is locked into each researcher's unique computing environment for data analysis.

Using software container solutions such as Biocontainers and a 'one image per task' coding pattern when developing a workflow, it is easy for an application expert to rewrite workflows for research, training and dissemination of new workflows for analysing data. This paper describes the reasoning behind this approach which is now being tested in a collaboration between livestock researchers in Sweden and South Africa.

Introduction

Advancements in high-throughput technology for genotyping and phenotyping mean that data acquisition, storage, analysis and dissemination is an increasingly large part of the work in agricultural research. In a survey at the Swedish University of Agricultural Sciences, PhD students spend 25% of their time dealing with challenges caused by a lack of training or tools necessary to perform data analysis (Klingström, 2017). Developing and providing the tools and training necessary to work efficiently with data is therefore an important task for the university to improve research efficiency. In the Life Sciences, specialisation in this area falls under the designation of bioinformatics which is a research discipline joining together biology and computer science. Depending on the context the subject of bioinformatics can be viewed from multiple perspectives:

- As a tool supporting the development of knowledge in other fields of the Life Sciences.
- As an independent research subject pushing the boundaries of human knowledge of its own accord.
- As an interface between biology and computer science providing biological inquiries access to high-powered computing resources.

The different perspectives make it difficult to disseminate the wide array of tools available for bioinformatics. Tools for researchers specialising in bioinformatics often prioritise flexibility and control while researchers who only occasionally use bioinformatics require tools prioritising ease of use and high quality training materials. This creates difficulties in sharing bioinformatics workflows between research groups. In the B3Africa project (Klingström *et al.*, 2017), we worked on how to enable interdisciplinary collaborations incorporating all three perspectives to enable researchers to better disseminate bioinformatics tools and apply them to available datasets. One of the key conclusions of the project was that Galaxy (Jalili *et al.*, 2020) is a versatile solution which helps us break down the matter of bioinformatics into three distinct components:

- A single user interface which can be used by researchers with little training to perform bioinformatics research using virtually any open-source bioinformatics tool available.
- A data management platform handling data access, metadata and how data can be accessed from local storage, public repositories or cloud storage.
- Providing users with access to a suitable computing environment with the bioinformatics software necessary to perform the desired data analysis.

A weakness with Galaxy is that the graphical user interface does not provide the flexibility and control desired by most bioinformaticians. This means that any Galaxy server requires dedicated staff scientists who provide training and manage the server to install new tools on behalf of the user. Thus, the efficiency gains from using networked Galaxy resources are reduced or lost as tools are configured for every specialized use, creating an environment with barriers to communication and productivity. This can be avoided by using containerized software in a computing environment shared between the Galaxy server and bioinformaticians using their own preferred workflow management software.

Software containers derive their name from the intermodal shipping container, which is nowadays a ubiquitous component of the international shipping system (Figure 1). Instead of requiring a specifically designed vehicle for each kind of goods transported, vehicles of today are often designed to carry a standardized shipping container. Likewise, software containers ensure that any containerized software has the environment and configuration necessary to function the same on different servers. With modern computers and software, pretty much any laboratory with bioinformaticians can host a data management platform and the software containers to analyse small datasets while access to computing power, data transfer capacity and working memory (RAM) limit the size of datasets which can be processed within a reasonable timeframe. Using software containers, it is thereby possible to fully test a workflow on a subset of data before applying for funding or access to computing power in a shared e-infrastructure for computing, and using the same workflow to analyze larger datasets.

There are a limited number of researchers available for training and the large number of different specialisations within bioinformatics makes it hard for a single university to cover the width of applications for bioinformatics in current-day biology research. The containerized software model makes it easier to document and update your computing environment, and to accommodate workflows and training material developed by other labs. The Galaxy Training Network is a network of researchers who all provide training material which can be used on many different Galaxy servers (Batut *et al.*, 2018). By using software containers on the local server it is possible to keep local computing resources up to date and ensure that researchers can execute the workflows they've learned from the Galaxy Training Network.

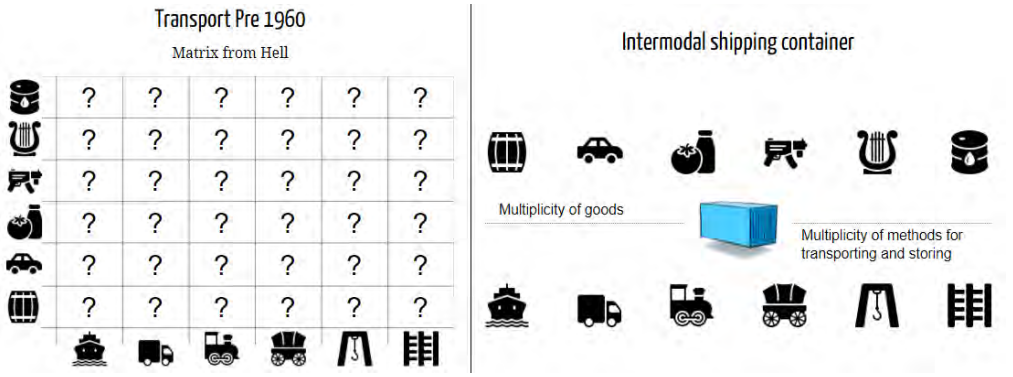

Figure 1. How the intermodal shipping container solved the matching matrix from hell in international shipping. An adaption from 'Docker and Galaxy' by Bérénice Batut and Björn Grüning, licensed under CC BY-ND 4.0.

The Galaxy platform is an excellent learning tool as it enables researchers to quickly start working with different tools and understand the different steps of data processing in a bioinformatics workflow. It is however not popular as an everyday tool for bioinformaticians developing workflows as it is inherently less flexible than scripting and command line tools. There is a plethora of options for bioinformaticians setting up their working environment but workflow managers such as Nextflow (Di Tommaso *et al.*, 2017) are gaining popularity as they provide the flexibility of scripting while improving transparency and reusability of code.

Results

To accommodate these different requirements, we are testing a simple coding pattern to ensure that workflows developed in Nextflow can easily be transformed to run as workflows on Galaxy systems. By using the large repository of Biocontainers (da Veiga Leprevost *et al.*, 2017) which contain container images for a vast number of commonly used bioinformatics tools and a 'one image per task' pattern, it is possible to ensure that workflows developed in Nextflow can also be run on a Galaxy server as both workflow managers can be configured to run Biocontainers on any computing environment that supports Docker or Apptainer (Singularity) containers. The Nextflow scripts can then easily be converted into Galaxy workflows and configured to submit jobs to the same scheduler on a computing cluster, meaning that actual computations will be run using the same software and compute nodes but jobs are defined and initiated by two different workflow management systems with different user requirements. This approach means that developed bioinformatics workflows can be quickly disseminated to other researchers as Galaxy workflows and training material be written as necessary to provide researchers with the knowledge and tools to perform their research.

Developing workflows with Nextflow we use four simple rules for coding (Figure 2).

1. Data is stored on a file storage system. Nextflow is configured so that containers are mounted on the file storage area and can access, modify and store the files used and created by the workflow.
2. Containers are loaded from a registry (usually Biocontainers). Each container contains the software necessary to execute *one task* within the workflow (e.g. quality control, trimming, alignment, etc.).
3. Configuration scripts are set to let the workflow engine take the workflow code, pass the job to the right system and execute the workflow with output being stored on the storage area.
4. All written code is to be commented and committed to the SLU Global Bioinformatics Centre Github. This is where everything is documented so that workflows upon completion of a project can be implemented in Galaxy.

By adhering to these principles bioinformatics research can quickly be turned into reusable workflows which can be adapted and used within the many different projects carried out on different species and breeds of relevance to agricultural researchers.

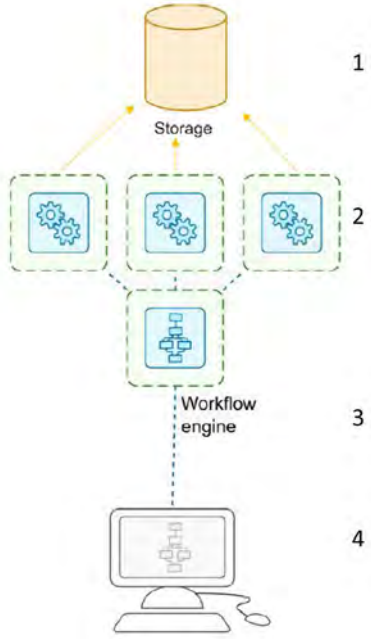

Figure 2. The Nextflow working environment. A workflow consists of an orchestrated and repeatable pattern of operations through which a piece of work is processed from initiation to completion. With the 'one image per task' pattern, a workflow engine like Galaxy or Nextflow mount a succession of software containers on the file storage which each execute the defined set of steps necessary to process the data (Spjuth *et al.*, 2021).

Abstract

The European Master in Animal Breeding and Genetics (EMABG) is an international master program operating on a global scale, with the aim to train experts and future leaders for research and industry. The training and education takes place at six European universities, within four study tracks with carefully designed curricula. One of the central parts of the MSc programme is the integration of teamwork activities and training of transversal skills to increase the employability of the graduates. To achieve this goal several major events are incorporated into the study programme during the entire duration of the two years. Also, strong emphasis is placed on integration of experts from the industry in the form of talks during joint events, internships, and direct work during special courses, as well as the final thesis.

Introduction

The general aim of the livestock sector is to meet the aspirations of the world's population for increased availability of animal products in a sustainable manner, while ensuring food safety, animal welfare, and maintenance of genetic diversity. To meet the challenge of the growing demands for food, livestock production needs to double in the coming thirty years, while halving its environmental impact (FAO, 2017). This implies that livestock production needs to improve efficiency of production, robustness and welfare of animals, and quality of animal products. Genetic improvement programmes help to meet these challenges by selecting animals for increased production with less input, reduced environmental impact per unit of product, and improved animal health and welfare. In the past, typically more than 50% of improvements of livestock productivity were caused by genetic progress through breeding. This illustrates both the need and opportunity for innovations in farm animal genetic improvement. Accordingly, training of young professionals addressing current and future challenges in animal breeding is needed.

European Master in Animal Breeding and Genetics

The European Master in Animal Breeding and Genetics (EMABG) presents a programme that results from intense discussion among six European partner universities. The programme is innovative in that it combines e-learning tools with training that follows the most recent scientific developments, effectively combining the expertise of each partner. It provides a rich learning environment through intense interaction with industry partners and NGOs, and offers flexible and personal learning paths (Figure 1). Summarizing all intakes and editions, a total of 161 students from 54 countries were trained in the program.

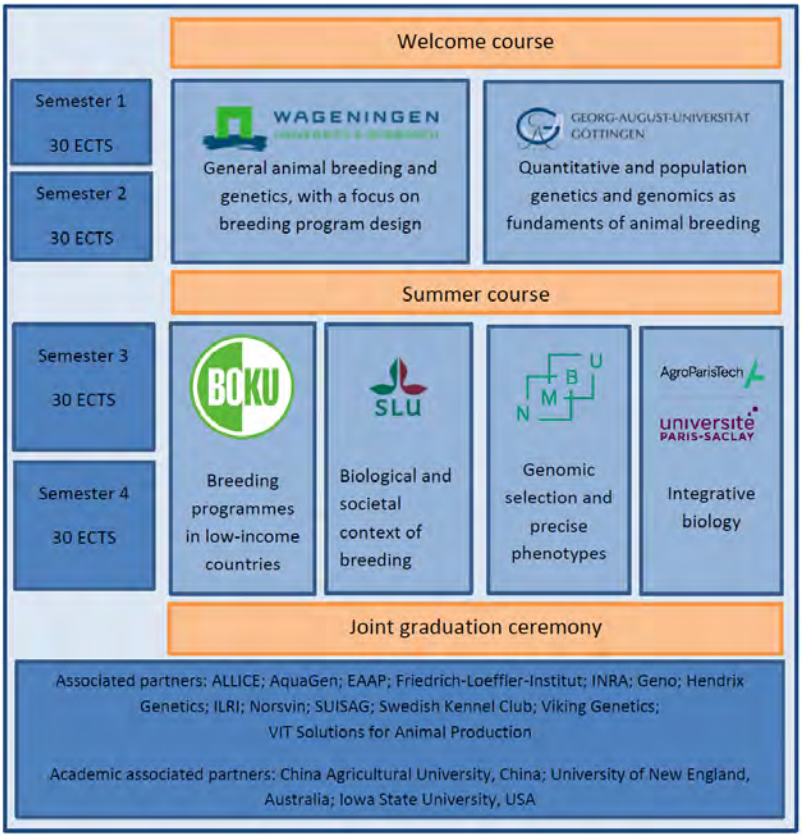

Figure 1. The structure of the EMABG MSc course.

The common vision of the programme is to deliver graduates that are experts in animal breeding and genetics, but with different foci, depending on their chosen study track. This makes them suitable for, e.g. managing breeding programmes in low-income countries, conducting breeding value estimations as required by industry, or responding to societal needs to combat climate change or improving animal welfare through breeding. The ultimate goal is to train a new generation of graduates that are fit to respond to current and future needs of the animal breeding sector in a global context.

The EMABG is a joint master programme that fills a real need for the industry sector and the whole society. It is designed to answer the scientific, practical, and societal challenges of animal breeding and genetics. These challenges can be summarised as follows:

- meet the increased demand for animal and fish products, while preserving or improving product quality and animal welfare, and minimizing the environmental impact;
- preserve natural resources, with special attention to biodiversity;
- make efficient use of novel tools and technologies to reach these goals while maintaining or improving societal acceptance of animal breeding;
- develop sustainable animal breeding programmes that contribute to improved livelihood of farmers and efficient food chains;
- develop sustainable breeding programmes that contribute to improved health and welfare of companion animals, including populations in zoos and nature reserves.

It is a common vision of EMABG partners to meet these challenges by intensive cooperation in the education and training of students, further enhanced by the complementarity among participating universities. Thus, the EMABG was set up to:

- offer quality higher education with a European perspective in the field of animal breeding and genetics, which is attractive to both programme (EU) and partner country nationals;
- enhance the quality of training in animal breeding and genetics and to strengthen attractiveness of the European Higher Education Area;
- contribute to solving societal needs by developing the qualifications of the students so they possess the appropriate skills, are open-minded and internationally experienced.

Joint events for the entire master course. There are three jointly organized courses, and a jointly supervised thesis between first-year and second-year universities (Figure 1). The Welcome course and the Summer course allow for personal interactions between all EMABG students and teaching staff from all partner universities. The teaching activities during the Welcome and Summer courses are covered by lecturers from all partners, associated partners and invited lecturers from academia and industry. The Breeding lab is organized at both WU and UGOE, and involves close collaboration with industry partners in specific group assignments. In addition to these courses, a transversal educational project was set up, where the students expand their knowledge and review various aspects of animal breeding and genetics in the context of the UN Sustainable Development Goals (SDGs).

The Welcome course is the highly successful cornerstone of the EMABG programme (according to regular feedback from students), and the defining element of academic and cultural induction of the students to the European higher education environment. This introductory event was developed to ensure a proper academic orientation of international students. EMABG students are introduced into the academic system in Europe, get the opportunity to establish personal contacts and friendships among each other, and get settled in before the start of the academic year. The students are also introduced to the European and global dimension of farm-animal breeding. During teaching and group work, close attention is paid to cultural differences and to rights and responsibilities of students and teachers in the EMABG. The course includes an intensive skills training part, which introduces students to topics ranging from poster and presentation skills to information literacy and scientific writing. Staff from all six partners participates in this event, which makes it possible to introduce each partner university and discuss the individual learning paths and study track choices of students.

The Breeding lab, is a course that is scheduled in the first and second semester of studies, simultaneously organised by WU and UGOE. Groups of students work on an assignment in close collaboration with associated industry partners. The aim of this course is to familiarize students with the competences and skills that are needed to work in a professional environment. The assignment is solved in interactive group work under the supervision of industry and academic staff from the partner universities. Examples are the design of a breeding programme for a specific environment or market, the definition of a new breeding goal, or the validation of a novel technology for breeding purposes. The aim is to put the knowledge of different elements of animal breeding acquired in the first year into a practical context. This helps the students to identify preferences for the choice of master projects.

The Summer course takes place between the second and third semester, overlapping with the Welcome course. The Summer course, titled 'Contribution of Animal Breeding to Global Food Security', is also offered as part of a summer school within the framework of the Euroleague for Life Sciences (ELLS) network, thus open to a worldwide audience. The content of the summer course is focused on widening the knowledge of students in terms of societal context of animal breeding and its practical relevance, with

participation of industry representatives and other associated partners. This increased networking outside of the academic environment makes it possible for the students to decide on their final preferences on the master thesis topic, including the possibility to collaborate with industry to solve currently relevant problems. The personal interactions also enable the screening of students for potential new hires by the industry, thus increasing the employability of EMABG graduates.

The overlap of the summer course with the Welcome course enables the two student groups to meet in a crucial time point in their studies. In this joint event the summer course students share their experience and give valuable advice to their younger colleagues regarding the habits, expectations, and workplace culture at the first-year universities. Intensifying the connectedness and interpersonal links between students in their mid-studies and those just starting further increases the cohesion of the EMABG programme.

The EMABG student graduation is a one-day event when the students from all second-year universities reunite to present their Master theses, celebrate their success, and receive their EMABG Diploma certificate. Graduates present their MSc theses in a conference-like setting, potentially also including associated partners and industry representatives, family members (online) and other guests. This small conference gives an additional possibility for the students to highlight their professional qualities and connect to potential employers. According to our EMABG alumni survey in 2017, about 40% of the graduates were already employed at the time of their graduation; this increased to over 90% six months after their graduation. The graduation itself is held as a formal ceremony, with the attendance of representatives from all EMABG partner universities, as well as senior officials from the organizing university.

A new element compared to previous iterations of the EMABG programme is the setup of the transversal projects on UN SDGs. This joint student project increases the interactions between the students within and between universities. One of the core elements of the transversal project is the preparatory group work within each university, supervised by each EMABG partner. Within this project the students work on competences that are needed in a professional working (industry) environment. They experience workgroup dynamics and aim-oriented working plan activities. The necessity of these transversal skills was highlighted within our needs analysis survey among potential employers. After course activities at each partner university the students engage in a joint videoconference to present their work and views on components of SDGs. This meeting gives an additional work-related meeting opportunity for the students in mid-semester.

Conclusions

The EMABG is an international master programme aimed at training experts and future leaders for the animal breeding research and industry. This training is being done at six partner universities, along four study tracks that cover various aspects and nuances for the breeding of livestock, fish, and companion animals on the global scale. A strong emphasis is placed on integration of industry experts at various stages of the two years of the MSc, so the students obtain the necessary teamwork, collaboration, and transversal skills. These skills, along with the strong theoretical background and practical computation skills are the foundation of their future success and increased employability.

Abstract

An international project ('Grass To Gas', 2019-2024) to combine expertise and generate new knowledge for the reduction of the potent methane (CH_4) greenhouse gas (GHG) from sheep is underway. Aims are to validate predictors of feed intake, methane emissions and feed efficiency, to investigate the association between feed efficiency and methane emissions measured indoors and outdoors, to explore the opportunity of using genetics and genomics (animal and microbiome) to reduce methane emissions in pasture-based sheep systems and quantify the economic and environmental benefits of more feed-efficient and lower GHG-emitting sheep linked to their microbiome. The potential impact is to deliver applied, sustainable solutions to reduce methane emissions for the international sheep breeding community, by bringing together the latest precision livestock monitoring and molecular technology to identify novel selection targets and potentially candidate genes.

Introduction

International commitments to reduce methane emissions to mitigate the impacts of climate change have been made by over 50 countries through the Paris agreement to limit global temperature rises to less than 1.5 degrees C; the recent Global Methane Pledge is to lower 2020 methane emissions level by 30% by 2030. Effective methane mitigation solutions are urgently needed to reduce CH_4 emissions for sustainable sheep production systems worldwide. In New Zealand, it has been shown that selective breeding can be used to achieve cumulative reductions in CH_4 per animal (Rowe *et al.* 2021), but there is no consensus about how best to implement direct and indirect measurements of CH_4 into breeding programmes internationally.

Materials & methods

Research objectives are designed to explore and validate results emanating from different countries undertaking replicated studies using native or economically important breeds. In the UK where new studies on individual animal feed intake indoors and outdoors are taking place, 250 Texel cross lambs sired by performance-recorded rams that had also been CT scanned as a lamb were monitored post-weaning for 6 weeks using CIEL-funded Biocontrol individual feed intake monitoring equipment in 2021 (and replicated in 2022). Their growth, body composition and rumen volumes (as determined by CT) at the start and finish of the trial (14 and 20 weeks of age on average) were also recorded. Paired lambs (related half- or full-sibs of those monitored indoors) were grazed out of doors on mixed perennial ryegrass swards and growth, body

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_15, © J. Conington *et al.* 2022

composition and grazing offtake measured, which was also replicated in Turkey using 250 Akkaraman sheep. In Norway, the effects of roughage quality (grass silage and freshly cut grass) and sheep breed on enteric CH_4 were investigated. Twenty Norwegian White sheep (NWS) and 20 Old Norwegian spael (ONS) were housed in individual pens and fed *ad libitum* roughage. Feed intake was monitored using the BioControl system. In both experiments, repeated 50-minute CH_4 concentrations were captured in portable accumulation chambers (PAC). Each ewe in the grass silage experiment had 30 PAC measurements, while each ewe in the fresh grass experiment had 21 measurements. Individual animal CH_4 measurements were collected on 454 NWS adult females from 44 breeding flocks from 12 ram circles. Detailed results of these measurements are reported in a separate, related paper (Jakobsen *et al.* WCGALP, 2022).

A validation of the n-alkane technique in Ireland estimated dry matter intake (DMI) of mixed breed sheep grazing perennial ryegrass swards. A total of 242 *in vivo* DMI measurements were obtained. Lin's concordance correlations were used to examine the relationship between the ratio of C_{33} / C_{32} n-alkane when predicting DMI. A series of experiments were carried out using 60 nulliparous ewe lambs whereby to measure CH_4, O_2 and CO_2 levels were measured over 50 minutes using PAC. Data were recorded on multiple days pre- and post-respiration chamber measurements. PAC measurements were subsequently collected on 2,404 animals varying in life-stage, breed, sire line, production type and diet type to quantify genetic variation in methane output within the commercial Irish sheep population.

Feed efficiency and CH_4 emissions have also been measured in Uruguay in 940 Australian Merino, 223 Corriedale, 360 Dohne Merino and 77 Texel lambs, which are part of to the national genetic evaluations, with the objective of investigating phenotypic and genetic associations among these traits, as well as with others relevant for sustainable sheep farming. Individual feed intake is recorded by Intergado® automated feeders during 56-day tests in which lambs are fed *ad libitum* with lucerne haylage. At the end of each test, CH_4 and CO_2 emissions are measured twice using PACs.

In France, male lambs of the Romane breed were measured at 3 months of age for performance, feed intake and feeding behaviour. These lambs emanated from two divergent lines for Residual Feed Intake (RFI) under a concentrate diet. The same measurements were also taken using a mixed diet. A protocol for GHG emissions phenotyping with GreenFeed (C-Lock) was defined. After each feeding period, blood, rumen fluid and faeces were sampled. Metabolomics analyses were undertaken on plasma and rumen fluid, and ruminal microbiota was sequenced for the 16S and 18s rRNA genes with the objective of identifying proxies of feed intake and GHG emissions, by using multivariate analyses (PLS, PLS-DA, Random Forest, SVR). In 2020, rumen volumes of 24 extreme Romane male lambs were CT-scanned to determine body composition and rumen size.

In New Zealand, animals selected divergently for methane emissions have also been measured for rumen microbial composition, milk, meat and wool composition, growth and slaughter traits, faecal egg counts and physiology of the alimentary tract. Part of this program has involved over 1000 female lambs measured for feed efficiency and feed intake traits to estimate relationships between methane emissions, microbial composition and gut related physiology. During this project, the role of New Zealand is to share protocols and data and to supply newly developed rapid sequencing technology of rumen microbes (Hess *et al.*,2020). Details of the feed efficiency programme are described in Johnson *et al.* (2018) and associated PAC measurements in Jonker *et al.* (2018).

Results

For feed intake in the UK after only 1 year of trial work, the Texel-X lambs showed significant between-sire variation in both average daily gain (ADG) and dry matter intake (DMI). At the sire level, initial results did not show a strong relationship between ADG and DMI. Live weight explained 41% of the variation in rumen volume (a potential methane predictor), with considerable variation in live weight adjusted rumen volume (CV 22 and 29% at each scan age), which differed significantly between sires, but was not significantly related to DMI in initial analyses. In the Norwegian grass silage experiment, DMI of early and average cut silage was 2.479 kg and 1.835 kg for NWS, and 1.337 kg and 1.143 kg for ONS, respectively. The difference in DMI was also reflected in enteric CH_4, being 1.65 vs 0.95 grams CH_4/hour for NWS and ONS respectively. When corrected to a mean DMI, ONS still had lower enteric CH_4 compared to NWS, (1.09 vs 1.52 grams CH_4/hr). Similarly, the early cut grass silage resulted in lower CH_4 emissions compared to the average, being 1.28 vs 1.32 grams CH_4/hour. Results from the 4,534 gas measurements of breeding females from 44 NWS flocks revealed mean CH_4 g/hr of 1.37 (s.d 0.28) and heritability CH_4/hr of 0.17 (se 0.04).

When estimating feed intake from grass, using the n-alkane technique in Ireland, the Lin's concordance correlation coefficient and the r-squared calculated between n-alkane estimated DMI using the ratio of C_{33} / C_{32} and measured DMI was 0.59 and 0.79, respectively. Offering animals low and medium herbage mass provided a more accurate estimate of DMI using the n-alkane technique. When investigating the measurement of CH_4 output, the time of day that animals were measured had no effect. For all three gases (CH_4, oxygen and carbon dioxide), the between-day variance (39 to 40%) accounted for a larger proportion of total variance compared to between-animal variance. The correlation between CH_4 production measured in PAC and the respiration chambers was 0.55, similar results were reported in New Zealand (Jonker *et al.*, 2018). When the data edits were applied to the dataset based on the rate of gaseous emissions 44 animals were retained, a higher correlation of 0.66 was estimated.

In determining the most appropriate model for the estimation of residual feed intake (RFI) using Uruguayan data, important fixed effects include pen-trial, average daily gain and metabolic body weight, whilst body composition and fleece growth traits were not significant (P>0.05) (Marques *et al.*, 2021). Amarillo *et al.* (unpublished data) also found the potential of reducing by 7 days the length of the feed efficiency test, without compromising the accuracy of RFI estimates, with R^2 being around 70%. The comparison of high, medium, and low RFI groups of lambs confirmed that more efficient animals are those with lower feed intake at similar performance levels in all breeds. Phenotypic Correlation coefficients in Corriedale, Dohne and Merino were moderate to high between CH_4 emissions and feed intake (0.8 to 64) but weaker with RFI (0.01 to 0.20). No differences in RFI were found between resistant (R) and susceptible (S) Corriedale sheep to internal parasites selected from divergent selection lines (Ferreira *et al.*, 2021). A Principal Component Analysis including body weight, average daily gain and gas emissions measured by PACs indicated the possibility of estimating feed intake, with a precision above 72% in allocating animals to high, medium, and low observed feed intake groups. More detailed results are in Le Graverand *et al.* WCGALP 2022.

In New Zealand, Johnson *et al.* (2018) reported that the most appropriate models to estimate RFI included fitting cohort, average daily gain and metabolic mid-weight (P<0.05) reaching an accuracy of 0.88. It also showed that whilst reduced periods of feed intake data could be used to estimate RFI, to obtain the most accurate average daily gain estimates the full 42d test period was most appropriate. The heritability estimates for CH_4 measured as absolute emissions and CH_4 yield (CH_4/CH_4+ CO_2) were 0.26±0.04 and 0.24±0.03, with the heritability estimate for RFI 0.46±0.13. The phenotypic (r_p) and genetic (r_g) correlation between CH_4 and the weight of the lambs were 0.62±0.03 and 0.84±0.05 respectively for absolute CH_4 emissions and 0.42±0.10 and 0.07±0.05 for methane yield. The phenotypic and genetic correlation between CH_4 and RFI were -0.18±0.12 and 0.08±0.05 respectively for absolute CH_4 emissions and -0.45±0.13 and -0.25±0.04 for

methane yield. There was a negative r_p between RFI and ultrasound fatness at the start of the measurement period (-0.23±0.04), and a positive r_p for RFI and change in fatness across the trial (0.21±0.04).

After three generations of divergent selection (2 s.d.) for RFI in France, more efficient animals (low RFI) ate 10% less concentrate, had shorter daily feeding duration with longer time intervals between feeder visits than less efficient (high RFI) animals. Ruminal microbiota and metabolomics do not yet show any significant difference between efficient and less efficient animals, regardless of the diet, however, more efficient animals have higher relative concentrations of citrate and malate and lower relative concentrations of amino acids in their blood than less efficient animals. Efficient animals also tended to have larger rumens, when expressed in relation to body weight (*P*-value=0.09). The correlation between indoor concentrate intake and indoor forage intake is positive and that with RFI are positive, being 0.22 and 0.25 respectively. In New Zealand, it has been shown that divergent selection for methane is associated with rumen size with high emitters of methane having larger rumens.

Discussion

One of the most successful outcomes for the project is truly independent validation of methods and protocols to monitor complex phenotypes associated with environmental impact. Although a full meta-analysis of data is yet to take place, sharing of methods, protocols and equipment has ensured that studies are comparable. Very similar heritabilities and repeatabilities from the analysis of methane emissions from PACs across different countries and sheep breeds indicate that the same trait is being evaluated and that global comparisons are possible using co-developed or co-validated proxy methods. The roles of feed intake, feed quality, liveweight, body composition and health status in accounting for variations between animals' performance and CH_4 emissions has been central to the investigations so far in this project. The use of PACs in experimental as well as commercial settings has generated data to optimise breeding programmes of the future. Participating countries should consolidate their reference populations locally and internationally to augment the role that genomic selection will have in tackling the problem of GHG emissions from livestock.

Abstract

Various definitions of methane emission traits have been suggested for use within animal breeding programs, including methane production, methane yield, and methane intensity. However, when calculating emissions intensity multiple product output definitions could be used. We compared different definitions of product outputs used to define methane intensity for the purpose of evaluated animal breeding strategies. Three definitions of product outputs were explored: energy corrected milk (ECM), fat and protein corrected milk (FPCM), and protein equivalents (PROT-eq). Emission intensity estimated for each product output definition was 0.57 kg CO_2e/ kg ECM, 0.57 kg CO_2e/kg FPCM and 12.67 kg CO_2e/kg PROT-eq. While ECM and FPCM are primarily used to describe production levels in terms of energy content, PROT-eq consider products in terms of the value to the farmer in economic terms. We therefore recommend that PROT-eq should be used as the primary metric for defining emissions intensity in dairy industries.

Introduction

Multiple definitions of methane emission traits have been suggested for use within animal breeding programs. These definitions include methane production, methane yield, methane intensity and residual methane. In 2016, Australia committed to reduce Greenhouse Gas (GHG) emissions by 26 to 28% of 2005 levels by 2030 (Paris Agreement, 2016). Dairy Australia has set an industry goal of reducing its emission intensity (GHG per unit of product) by 30% by 2030 (Dairy Australia, 2021). Methane emissions intensity is therefore an alternative breeding objective that could be used in the national selection index to balance selection of traits which influence both the emissions and product output associated with traits available for selection simultaneously. This methane definition favours a more net neutral state and is especially efficient for systems where either animal inventories or production levels are capped, as both a reduction in emissions intensity and gross emissions may be achieved (Lahart *et al.*, 2021). While it has been demonstrated that selection for any methane trait may result in progress in all methane traits (Richardson *et al.*, 2021a), one challenge with reaching these emission reductions goals are the various definitions for emissions traits. Previous studies have explored the different methane emissions trait definitions, in particular residual methane production (Richardson *et al.*, 2021b), however, variations of the other methane traits definitions have not been explored. This study builds on our previous research by exploring the impact of alternative ways of quantifying milk output when defining emissions intensity. Methane intensity is defined as the amount of methane per kilogram of product, where the amount of product has been defined under multiple measures including the energy corrected milk (ECM), fat and protein corrected milk (FPCM), or protein equivalents (protein-eq). The aim of this research was to compare the different definitions of product outputs used to define methane intensity for the purpose of evaluated animal breeding strategies with modified weightings on existing traits to reduce GHG emissions.

Materials & methods

Australian dairy cow emissions and product output. The yearly gross methane emissions produced by an average Australian dairy breeding cow was previously estimated by Richardson *et al.* (2021b) using the following equation:

$$E = \sum_{i=1}^{c} n_i F_i \alpha Y_i \quad (1)$$

where E is the total gross methane emitted per breeding cow across c classes (replacement and cow), n_i is the number of animals in a given stock class i per breeding female in the average Australian dairy herd, α is the methane carbon dioxide equivalent coefficient per kg of DMI (0.532 kg CO_2/kg DM), F_i is the amount of feed (in kg DM) per animal of the stock class i, and Y_i is a binary indicator variable that takes a values of 1 or 0 depending on whether the class i is considered in the total definition of methane emissions, respectively. In this case, the animal classes considered were milking cows and replacement heifers as male calves have marginal value in the Australian dairy industry.

Definitions of product outputs. A total of three definitions of product outputs were explored: energy corrected milk (ECM), fat and protein corrected milk (FPCM), and protein equivalents (PROT-eq). These were estimated using the following equations:

$$\text{FPCM} = \text{Milk kg} \times ((0.1226 \times \text{Fat \%}) + (0.0776 \times \text{Protein \%}) + 0.2534) \quad (2)$$

$$\text{ECM} = (\text{Milk kg} \times ((376 \times \text{Fat \%}) + (209 \times \text{Protein \%}) + 948))/3{,}138. \quad (3)$$

$$\text{PROT-eq} = (k_{fat} \times \text{kg Fat}) + (k_{protein} \times \text{kg protein}) + (k_{milk} \times \text{kg milk}) \quad (4)$$

where k_x is defined as the value of each product x expressed as a proportion of the market value of protein. Production parameters in this study were assumed to be representative of the average Australian dairy cow, with an average 305-d production of 6,861.00 kg milk at 4.00% fat, 3.30% protein and 4.80% lactose (DataGene Ltd., 2017).

Calculating k-values for milk and component traits. In-line with previously published studies (Richardson *et al.*, 2021; Zhang *et al.*, 2019), the product classes considered in this study are milk and its components (fat and protein). Similar to the concept that GWP is used to convert methane into CO_2 equivalents (CO_2e), product conversion factors, k_x, convert milk and its component traits into a single output. This allows for multiple product classes to be considered and evaluated, while maintaining a single product class for comparison. The product classes used for comparison in this study are the three definitions of product outputs. The product conversion factors for ECM and FPCM were estimated similarly, where the relative value of each product class was determined by calculating the difference in ECM or FPCM calculated when each product was independently increased by 1 kg. In comparison, PROT-eq conversion factors were based on component values of $6.76, $2.08 and -$0.11, for protein, fat and milk, respectively (Byrne *et al.* 2016). The PROT-eq value for milk volume is constituted by the milk volume percentage of lactose (4.8%) to avoid double counting the value of milk fat and milk protein, when milk volume is increased.

Calculating emissions intensity. Emissions intensity was calculated using the gross emissions per animals as estimated by Richardson *et al.* (2021b), divided by each of the suggested product outputs, and calculated as:

$$EI_i = \frac{E\ (kg\ CO2e)}{P_i\ (kg)} \quad (5)$$

where EI is the emissions intensity value for each of the product output *i* classes (ECM, FPCM, PROT-eq), E is the gross emissions measured in kg CO_2e, and P_i is the total product output for *i* classes.

Results

Product output and the respective emissions intensity for each product output definition are presented in Table 1. Similar product outputs were estimated for ECM and FPCM of 6,869.09 kg and 6,860.18 kg, respectively, whereas the product output expressed in PROT-eq was 306.15 kg. Table 2 presents the implied values of fat and milk relative to protein under alternative milk product output definitions. The change in kg of milk and its components due to a 1 kg increase in ECM or FPCM was 6.66 and 7.76 kg protein, 1.98 and 12.26 kg fat, and 1.00 and 0.99 kg milk. The PROT-eq product conversion factors for milk, fat and protein were -0.0008, 0.31 and 1, respectively.

Discussion

The estimated total product output is highly dependent on the metric of product output chosen, and the resulting emission intensity values are variable and driven by different factors. Thus, choice of different definitions of milk output (i.e. ECM, versus FPCM versus PROT-eq) is likely to lead to quite radically different responses to selection according to the different definition of emissions intensity. The fat and protein corrected milk definition of emissions intensity places a higher weighting on milk fat than on milk protein as a productive output. Use of energy corrected milk for the emissions intensity value is almost identical. These are both ways of correcting milk output based on energy composition of the components, and ignore the fact that protein is typically valued more highly as a milk output than fat, even though it has a lower energy content. There is a wide range in weightings on fat relative to protein across national

Table 1. Product output and methane emissions intensity using ECM, FPCM, PROT-eq.

	Units	Total product	EI[1] (kg CO_2e/kg product)
ECM[2]	kg	6,869.09	0.57
FPCM[2]	kg	6,860.18	0.57
PROT-eq[2]	kg	306.15	12.69

[1] EI is the emission intensity.

[2] ECM is energy corrected milk, FPCM is fat and protein corrected milk, and PROT-eq is protein equivalents.

Table 2. Implied values of fat and milk relative to protein under alternative milk product output definitions.

	Protein (kg)	Fat (kg)	Milk (kg)
ECM	1.00	1.98/6.66 =1.8	1/6.66 = 0.15
FPCM	1.00	12.26/7.76 = 1.58	0.99/7.76 = 0.13
PROT-eq	1.00	0.31	-0.0008

[1] ECM is energy corrected milk, FPCM is fat and protein corrected milk, and PROT-eq is protein equivalents.

selection indexes of different countries. For example, the USA and New Zealand national indexes assume a higher market value for milk fat than for milk protein, while many other national indexes (including Australia) assume a market value for fat which is less than half of the market value of protein.

Defining an emissions intensity breeding objective in terms of ECM or FPCM places a significantly larger and positive value and resulting emphasis on milk compared to PROT-eq. This is in direct conflict with the majority of milk payment systems in Australia which penalise milk volume (Axford *et al.*, 2021).

Conclusions

ECM and FPCM are definitions of product output primarily used to describe production levels in terms of energy content. While PROT-eq on the other hand consider products in terms of the value to the farmer and economics. Therefore, while ECM and FPCM are currently widely used internationally, we recommend that ECM and FPCM should be abandoned as metrics for defining emissions intensity in dairy industries.

17. The genetic progress has effect on greenhouse gas emission intensities from Norwegian pork production

E. Gjerlaug Enger[1*], H. Bonesmo[2], K. Martinsen[1], I. Andersen-Ranberg[1], D. Olsen[1] and E. Grindflek[1]

[1]Norsvin, Storhamargata 44, 2317 Hamar, Norway. [2]Norwegian Institute of Bioeconomy Research (NIBIO), Division of Survey and Statistics, P.O. Box 115, 1431 Ås, Norway; eli.gjerlaug@norsvin.no

Abstract

The environmental sustainability of food production systems, including net greenhouse gas (GHG) emissions, is of increasing importance. The objective for this study was to investigate whether an IPCC methodology-based model could reflect the effects in reduction of GHG emissions from the genetic progress in pork production. Pig production data from 654 Norwegian farms were used in the model and results revealed that the most important traits for GHG emissions were feed conversion rate, weaned piglets per litter and mortality. Estimated genetic gains for 2021 for these traits resulted in an estimated yearly reduction in GHG emissions of 1.4 and 1.9% for Landrace and Duroc, respectively. Further a study of the same farms, based on data from 2014 to 2019 showed that estimated net GHG emissions decreased from 2.49 to 2.34 kg CO_2 equivalents/kg carcass weight, with an average of 1.2% annually over the investigated period.

Introduction

The environmental sustainability of food production systems, including net greenhouse gas (GHG) emissions, is of increasing importance for diet recommendations. Thus, to preserve a proportion of animal-based food in such recommendations, it is necessary to further reduce the net GHG emission intensities from animal husbandry systems. As monogastric animals, pigs have low enteric methane (CH_4) production compared to ruminants. The largest sources of net GHG emissions from pig production systems are manure storage, including nitrous oxide (N_2O) and CH_4, and from the feed production, both N_2O and carbon dioxide (CO_2) are included.

In Norwegian pork production, animal performance is high both in terms of reproduction and growth in addition to low mortality. Following the introduction of genomic selection in the pig breeding program in 2014 (Nordbø *et al.*, 2014), the progress in animal performance has been further increased (Ingris, 2019). Animal health status is high due to the closed national population of animals, which has contributed to the eradication of several swine diseases common in the rest of the world (Grøntvedt *et al.*, 2016). Norwegian pig farms are small, based on family farm units, and the pig production has higher requirements for animal welfare than in most other European countries (Falk and Hofshagen, 2019).

A hybrid sow is often a cross between two maternal breeds; in Norway, this is normally Norsvin Landrace and Topigs Norsvin Z-line (Yorkshire breed). The commonly used sire line is Norsvin Duroc. The aim of this study was to quantify how much the genetic progress contributed to reduction in GHGs, as well as to investigate whether this could be measured in commercial herds.

Materials & methods

The estimates of GHGs include emissions of enteric and manure storage methane (CH_4), direct and indirect nitrous oxide (N_2O) from the pig-barn and manure storage, and emissions from feed production. The emissions from feeds, both domestic and imported, include estimates for direct and indirect N_2O from both manure and synthetic fertilizer, soil carbon change (CO_2), and direct and indirect energy use (CO_2

equivalents (eq.)). In addition, the estimates of GHG emissions intensity encompasses the GHG emissions from the production process and transportation of purchased feeds, and GHG emissions caused by direct energy use in pig-barns. All age classes of the pig's life are included, as well as sow and replacement of gilts. All GHG emissions are expressed as CO_2 eq., to account for the global warming potential of the respective gases given a time horizon of 100 years: CH_4 kg × 25 + N_2O kg × 298 + CO_2 kg × 1 (IPCC, 2007).

The points explain the course of the trial:

1. The IPCC methodology-based model was developed and implemented in a GHG calculator for pig farmers (Bonesmo and Enger, 2021; https://klimasmartlandbruk.no).
2. The GHG calculator was designed to use readily available production parameters from pig farms. The data from commercial farms in this study were obtained from the Norwegian litter recording system (Ingris, Animalia AS).
3. To estimate the effect of the different parameters in the model, a sensitivity test was performed with data from 2019 at 654 Norwegian pig farms. One production parameter at the time were improved with one standard deviation and change in estimated GHG emissions was estimated.
4. The production parameters were ranked based on the effect they had on the estimated GHG emission intensities. The top four are presented in the current paper.
5. Genetic trends for 2021 based on genomic estimated selection values for Norsvin Landrace and Duroc selection candidates for the four parameters were calculated. The effects the four parameters had on GHG emissions were estimated based on data in commercial farms, see point 3.
6. Progress measured in the field from 2014 to 2019 (Ingris, 2014, 2015, 2016, 2017, 2018, 2019) was estimated based on the GHG calculator combined with readily available production parameters from Norwegian pig farms, as described in point 1 and 2. The data used are obtained from a different time period than the data used for genetic gain estimations, described in point 5. However, we have chosen to focus on the reduction in GHG emissions from expected genetic gain in the years to come.

Results

The model enabled estimation of the effects on net GHG emission intensities using available production data from pork production (Table 1).

Of the investigated parameters, the feed conversion ratio (FCR) for finishers had the highest importance. When FCR was improved with one standard deviation, from 2.45 to 2.29 kg feed per kg growth, the reduction in total estimated pork GHG emissions was shown to be of 4.5%. A larger number of parameters were investigated, and the four parameters with largest effect are presented in Table 2, ordered by importance.

Table 1. GHG emissions presented per kg carcass weight (CW), with percentage distribution for Norwegian pig production.

Sources and type of GHG emissions	Estimated GHG emissions, kg CO_2 eq./kg CW	Percentage distribution
Overall	2.33	
Feeds	1.87	80%
Electricity and transport	0.11	5%
Enteric CH_4	0.14	6%
Manure CH_4	0.11	5%
Manure N_2O	0.10	4%

Table 2. Results of the sensitivity test. Changes in estimated GHG emissions are shown for one standard deviation (STD) improvement in key production characteristics.

	Current values, 2019	STD	Estimated GHG emissions intensity, kg CO_2 eq./kg CW	Change in estimated GHG emissions
FCR[1] finisher (kg/kg)	2.45	0.16	2.23	-4.5%
Weaned piglets/sow/year	27.9	3.78	2.28	-2.1%
FCR[1] weaners (kg/kg)	1.54	0.20	2.30	-1.4%
Mortality finishers, %	1.7	1.33	2.30	-1.3%

[1] FCR = feed conversion ratio as kg feed divided on kg growth in live weight, with on overage 9.5 and 9.9 MJ net energy per kg feed for finisher and weaned piglets, respectively.

Estimated genetic gain for parameters from the sensitivity test were based on data from 2021 (Table 3). The corresponding improvements from estimated genetic gain in annual reduced GHG emission intensities (Figure 1) were 1.4 and 1.9% for Landrace and Duroc, respectively. Based on the field data, there was estimated a substantial annual decrease between 2014 and 2019 in the emissions of pork, resulting in 6% lower emissions in 2019 than in 2014 (Figure 2).

Table 3. Estimated genetic gain based on genomic estimated breeding values for selection candidates in Norwegian Norsvin nucleus herds in 2021.

	Dam line (Landrace)	Sire line (Duroc)
FCR[1] finisher (kg/kg)	-0.03	-0.06
Weaned piglets/sow/year	0.96	-
FCR[1] weaners (kg/kg)	-0.01	-0.02
Mortality finishers, %	-0.11	-0.20

[1] FCR: see Table 2.

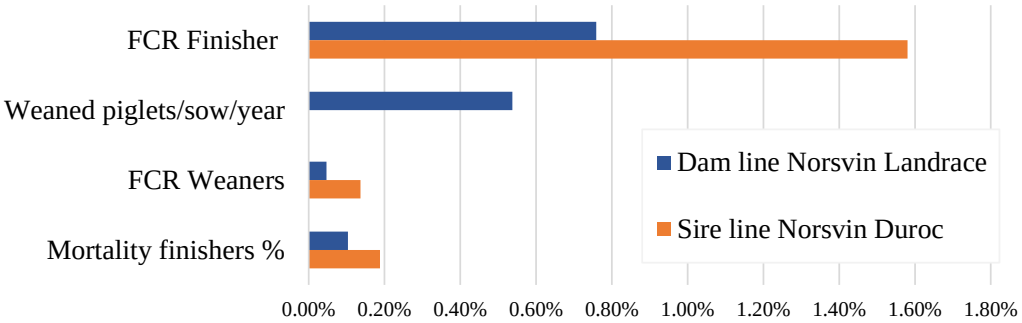

Figure 1. Percentage reduction in GHG emissions for the four most important parameters for GHG emissions in pig production, due to annual genetic gain.

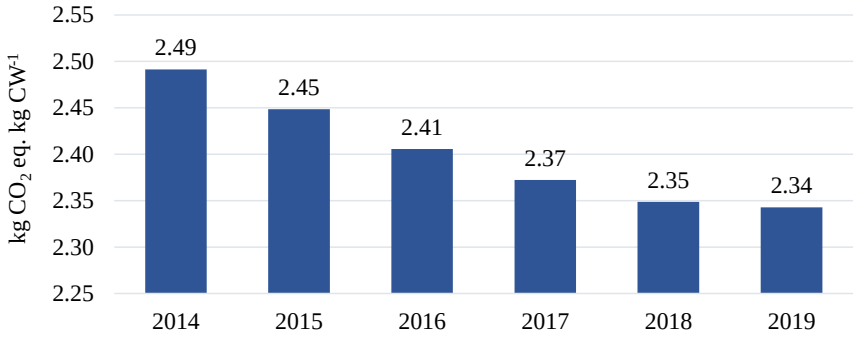

Figure 2. Estimated pork GHG emissions intensity from 632 Norwegian farms.

Discussion

So far, reductions in GHG emissions *per se* has not been included in the breeding programme for Norwegian pigs. However, as direct emissions from animals, *i.e.* enteric methane, is of minor magnitude, it is mainly feed efficiency traits that are of importance. About 80% of the GHG emissions per kg carcass weight comes from feed production (Table 1), and in an average Norwegian pig farm about 75% of the variable costs comes from the feed. It was therefore hypothesized that the genetic progress has led to reduced GHG emissions and that expected improvements will give a cumulative and permanent reduction in GHG emission intensities. In the current study, it was shown a yearly improvement in reduced GHGs of 1.4 and 1.9% for Landrace and Duroc, respectively, based on estimated genetic gain from breeding values. From 2014 to 2019 the average progress measured in the field is 1.2% annually. This encompasses more than genetic progress, there may also be effects from the increase in professionalism of management and feeding. Still, it is no doubt that the effects on net GHG emission intensities from breeding is profound, and the progress in pig genetics therefore contributes to an on-going strengthening of pork as a sustainable source for human food supply. Very few protein-rich foods have as low or lower GHG emissions than those we find for Norwegian-produced pork (Oort and Andrew, 2016; Bonesmo and Enger, 2021).

18. An approach to the genetic parameters of methane emission in Latxa dairy sheep

C. Pineda-Quiroga*, I. Granado-Tajada, E. Ugarte, I. Goiri and A. García-Rodríguez

Animal Production Department, Neiker-BRTA, Campus Agroalimentario de Arkaute, 01080 Vitoria-Gasteiz, Spain; cpineda@neiker.eus

Abstract

Genetic selection is a promising approach to identify and breed lower-methane emitter animals. As a first step, this study aimed at estimating the genetic parameters of methane emission in Latxa breed using an experimental data set. For this, 295 methane concentration measurements were taken on 103 genotyped ewes, using a non-dispersive infrared methane detector. Methane intensity (MeI, g/l of milk) and production (MeP, g/day) were calculated. Results showed the existence of variability for both traits, but they are under low genetic control, with non-significant heritabilities of 0.11±0.13 for MeI and of 0.07±0.10 for MeP. Low repeatability (0.16±0.07 for MeI and 0.07±0.06 for MeP) suggests that the surrounding environment variables are the strongest controlling factors. Indeed, the body weight of ewes and the diet were defined as relevant non-genetic factors influencing emissions. A larger data set is needed in Latxa to properly make inferences.

Introduction

As widely known, there is a significant research effort to find ways to reduce enteric methane emissions produced by ruminants, due to their contribution to global warming. For this, animal breeding could make a valuable contribution to the whole set of methane mitigation strategies, not only because this trait is heritable, but also due to the advantage that results of animal selection are cumulative and last over time (Pickering *et al.*, 2015). Nevertheless, this approach requires time to have a noticeable effect, as selection is carried out over generations (Lassen and Difford, 2020).

Latxa breeding program has been successfully selecting for milk production, composition and udder morphology for the last decades, and the inclusion of new traits to the program scheme in the future is now being studied (Carabaño *et al.*, 2021; Pineda-Quiroga *et al.*, 2021). Before a novel trait, such as methane emission, can be added to any genetic program, a large number of records are needed. Furthermore, complementary information, such as genotyping data, is also valuable when available. Such information is used to appropriately quantify the phenotypic and genetic variability of the trait, as well as to identify non-genetic factors affecting the phenotype. However, obtaining individual methane measurements at the farm level is usually a time-demanding and costly task. In the sheep production context, the huge variety of facilities between breeds and systems represents an additional handicap. For this reason, pilot genetic studies carried out under experimental conditions to shed light about methane emissions in this species are welcome (Piñares-Patiño *et al.*, 2013; Robinson *et al.*, 2020).

In this context, the objective of the present study was to elucidate for the first time the genetic component of the methane emission in Latxa dairy sheep, combining phenotypic and genomic information, under experimental conditions.

Materials & methods

Records of methane emissions from 103 Latxa Cara Negra from Euskadi dairy ewes, from an experimental flock was collected using a portable non-dispersive infrared methane detector (Guardian NG infrared gas monitor; Edinburgh Instruments Ltd., Livingston, UK). Data were collected during different time points,

in which animals were housed indoor and were being fed forage and different concentrates. Briefly, a gas sampling tube was installed in the front of sheeps' nostrils and connected to the gas analyser. Individual methane concentration in the sheeps' breath was continuously measured at 1 s intervals during 10 minutes and stored in a datalogger. Each ewe underwent between two and three measurements (295 in total). Methane intensity (MeI, g/l of milk) and methane production (MeP, g/day) were then calculated.

Molecular information was available for all animals, which had been genotyped using 50K Illumina chip OvineSNP50 (n=28) or Affymetrix Axiom Ovine Genotyping Array (n=75). Markers in common, by chromosome and position between genotyping platforms, were kept before quality control. Monomorphic SNPs, SNPs with a call rate <90, with a minor allele frequency <0.05, and those markers located in the sex chromosomes were filtered out, resulting in a total of 30.074 effective markers for further analysis.

Initial exploratory analyses were undertaken using a general linear model to define the significantly different (P<0.05) and relevant effects to be included in the model for genetic estimations.

For variance component estimations, a genomic restricted expectation maximum likelihood, using the average information (AI) algorithm was carried out by using AIREMLf90 from the blupf90 family programs (Misztal *et al.*, 2002), following the model:

$$y = Xb + Zg + Zp + e \quad (1)$$

where y is the vector of phenotypic records (MeI and MeP), b is the vector of the fixed effects body weight (level 1: 45 to 53 kg, level 2: >53 to 64 kg, level 3: >64 to 95 kg), concentrate supplementation (linseed oil – LO, linseed cake – LC, rapeseed cake – RC, sunflower cake – SC, spent coffee grounds –SCG or without supplementation – CTR) and days in milk production fitted as covariate, with the respective incidence matrix X; g is the vector of direct animal genetic effect with incidence matrix Z, considering the variance/covariance matrix of the SNPs as the relationship matrix G in the mixed model equations, p is the vector of permanent effect with incidence matrix Z_p, and e is the vector of residuals.

Results

As shown in Table 1, the phenotypic values of methane varied depending on the trait used, being lower when it was expressed in function of the milk production (MeI). As regards the genetic components, the heritability showed slightly higher values when methane emission was referred as MeI compared to MeP, because the total variance was lower. The repeatability showed the same tendency as heritability.

Table 1. Phenotypic mean and additive (σ^2u), permanent (σ^2p), residual (σ^2r) variances, heritability (h^2) and repeatability (R) of methane intensity MeI (g/l of milk) and production MeP (g/day).

	MeI (g/l of milk)	MeP (g/day)
Mean ± sd	10.36±5.83	21.28±10.74
σ^2u	2.96	6.52
σ^2p	1.50	0.57
σ^2r	23.01	88.40
h^2 ± se	0.11±0.13	0.07±0.10
R ± se	0.16±0.07	0.07±0.06

Figure 1 shows the influence of non-genetic factors on methane emission. As shown, the emission increased with body weight (~13% for MeI and ~11% for MeP). For concentrate supplementation, LO, LC, RC and SC reduced the emissions in comparison with CTR (~8% for MeI and ~12% for MeP), whereas SCG increased them (~31% for both traits). For days producing milk, a steady increase for both traits was noted, although the slope was double in MeI than in MeP (0.10 vs 0.05).

Discussion

The findings of the present study confirm that methane emission is under moderately low additive genetic control, with the surrounding environment variables being the strongest controlling factor. As expected, Latxa's MeP heritability was low and close to the lowest reported value in the Merino sheep breed (0.10±0.06, Paganoni *et al.*, 2017). It was not possible to make a direct contrast of MeI with other sheep data because, to the best of our knowledge, no results have so far been reported for this. Nevertheless, our value is smaller than the lowest reported for Holstein dairy cows (0.20±0.16, Lassen *et al.*, 2016). These comparisons should be taken cautiously due to the fact that farm conditions, the number of sampled animals, the measurement techniques and the total records taken per individual varied between the studies. On top of that, our results suggest that MeI showed higher genetic variation over the total estimated variance than MeP, although it is evident that a larger set of measurements is needed in Latxa to properly make inferences.

The low repeatability values found in the present study, in line with those from Piñares-Patiño *et al.*, 2011 for methane emission (g/kg of DMI) measured on a hundred animals, might reaffirm that it is necessary to phenotype much more animals. Furthermore, these values may also confirm that other no-genetic effects influence the trait, such as those related to intrinsic factors of the animals' biology and their management on farm, as well as methods of recording (Lassen and Difford, 2020). Indeed, as presented, the body weight

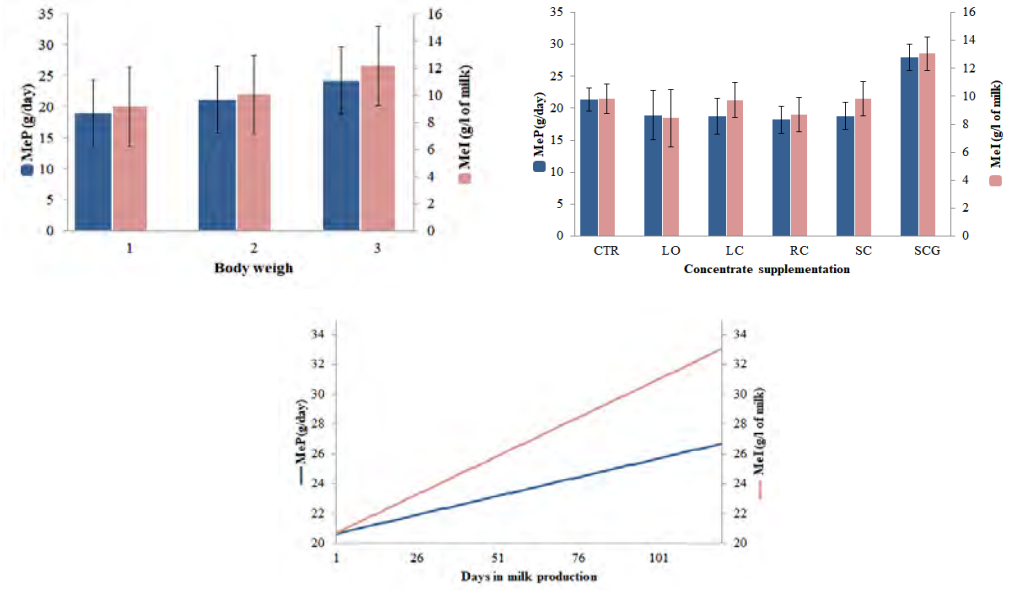

Figure 1. Non-genetic factors affecting the methane emission phenotype. Body weight; level 1: 45 to 53 kg, level 2: >53 to 64 kg, level 3: >64 to 95 kg; Concentrate supplementation – CTR: without supplementation, LO: linseed oil, LC: linseed cake, RC: rapeseed cake, SC: sunflower cake, SCG: spent coffee grounds; days in milk production – from 1 to 120 days.

and the type of concentrate largely influence the methane phenotype. The first factor because the bigger the animal, the larger the rumen capacity and the animals' feed intake, and the second factor because the diet composition alters the bacterial communities (Goiri *et al.*, 2020) and hence the production of methane precursors. Nevertheless, as proposed by Cottle and Conington (2012), it will be probably required to implement a combination of genetic and non-genetic measures to have short-term results, and for a cost-effective reduction in methane production.

All in all, there is potential for adopting genetic selection on methane emissions in ruminants and, in the future, genomic selection. Further investigations involving more phenotyped and genotyped animals, as well as measurements coming from sheep from diverse genetic backgrounds may also be needed.

Abstract

International agreements such as the Paris Agreement, the Global Methane Pledge and alliances such as Race to Zero, engage countries to constrain temperature rise by mitigating greenhouse gas emissions. Nationally Determined Contributions show mitigation ambitions are currently below that needed to reach these targets. While livestock methane need not be stopped completely to reach these targets, mitigation to reverse rising global methane emissions will be required, especially in developed countries. This paper addresses the vision for that mitigation, the sharing of that task across developed and developing nations, and how animal breeding and nutritional or management strategies can contribute. Delivering substantial absolute mitigation as well as reducing emission intensity and improving system efficiency are possible, thereby delivering on many of the Sustainable Development Goals.

Introduction to global greenhouse gases and growing human needs

Mitigation vison. While the nations of the world have committed to binding national targets to lower GHG emissions, progress to meet these targets is slow. Land-based measures (including livestock) have potential to mitigate approximately 10-15 $GtCO_2eq$/yr by 2050, corresponding to about 20-30% of the mitigation needed to achieve the 1.5 °C temperature target (Roe *et al.* 2021). The Nationally Determined Contribution (NDC) declares each nation's highest possible (but non-binding) ambition. (UNFCCC 2021) and possible contribution to the Paris target of 'holding the increase in the global average temperature to well below 2 °C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5 °C above pre-industrial levels' (UNFCCC 2015). Currently, comparison of the target and the likely abatement from countries submitting an NDC shows 'the emissions gap remains large … the new pledges for 2030 reduce projected 2030 emissions by only 7.5%, whereas 30% is needed for 2 °C and 55% is needed for 1.5 °C' (UNEP 2021).

Global methane emissions continue to climb, with livestock CH_4 emissions alone increasing by 10-18 Gg CH_4/yr in 2000-2018. Most (73%) of the increase was due to increased livestock numbers and 27% due to increased emission/animal (Chang *et al.* 2021). Livestock CH_4 emissions are forecast to rise to 140 Gg CH_4 by 2050 under current policies but scope for 10 Mt/year of enteric CH_4 mitigation has been identified by Smith *et al.* (2021). There is no requirement to eliminate livestock methane emission for the Paris agreement temperature targets to be achieved. While net zero for CO_2 is pivotal, modelling of future mitigation pathways anticipates that the 1.5 °C Paris target is possible through zero net CO_2 with only a 38% reduction in livestock CH_4 emissions (Popp *et al.* 2017; Reisinger *et a*l. 2021). This reflects the shorter atmospheric lifetime of methane, meaning the warming due to past CH_4 emission diminishes quicker than it does for CO_2. This is important as it identifies scope for sustaining ruminant livestock as a basis of global food security despite a net zero CO_2 target.

Goals for the developing and developed world. Climate action is only one of the 17 Sustainable Development Goals (SDGs) and other goals may take priority. Developing countries face the greatest human population growth and associated food security threat. The 2020 global population of 7.80 billion people is forecast to rise to 8.6 billion by 2030 and 9.8 billion by 2050. Of the additional 2 billion people

joining humanity between 2020 and 2050, 1.15 billion will be in Africa and 0.65 billion in Asia (UNDESA 2019). Hence, for most of the developing countries, adaptation to climate change outranks mitigation, and cross-cutting actions delivering on numerous SDGs, not just climate are desired.

The developing countries do not have the same obligation for mitigation as the developed countries. Article 4 of the Paris Agreement says 'developed country parties should continue taking the lead by undertaking economy-wide absolute emission reduction targets', while developing countries have their limited capability and need for support recognised. Of the 192 countries submitting NDCs, only 34% included livestock mitigation in their commitments (Rose *et al.* 2021). These authors grouped livestock commitments from all NDC submissions into 6 themes that could achieve mitigation and/or adaptation. These were: animal health, breed management, feed management, herd composition measurement, manure measurement, and silvopastoralism. This is a very loose coalition of strategies, but prospects for each of the leading animal mitigations are assessed below. For brevity and because enteric emissions are the largest livestock GHG source, comments are limited to enteric CH_4.

Direct enteric methane mitigation

Dietary interventions that can specifically inhibit methane production offer direct and readily quantifiable means to mitigate enteric emissions. Feed additives have been extensively reviewed (Smith *et al.* 2021) but a recent broader assessment identified that almost all research has been done using diets in which the additive was mixed in the compete ration. Consequently, after extensive testing and reviewing of methane mitigating feed additives, we are still in a stunningly poor position, with scant knowledge of inhibitor efficacy in grazing systems or which supplement system and frequency will be optimal (Hegarty *et al.* 2021).

Vaccination to harness the animal's immune system is the other direct means of mitigation. Factors affecting immunisation effectiveness in general and relevant to rumen methanogens have recently been reviewed (Baca-González *et al.* 2020) but mitigation results have been sparse since first results were published (Wright *et al.* 2004). A commercial vaccine is considered to be 7-10 years away (Reisinger *et al.* 2021) and despite some demonstrations of efficacy of salivary antibodies in-culture, repeatable mitigation *in vivo* has not been reported.

Animal management and efficiency in the farming system

There are multiple indirect ways of affecting daily methane production, from suppressing rumen protozoa to changing the proportions of starch and of oil in the diet, including breeding genetically modified ryegrass with increased lipid content (Winichayakul *et al.* 2020; Honan *et al.* 2021). Many of these affect fermentation products, feed intake and animal performance, enabling major shifts in livestock enterprise structure. Changes in nutrient supply can change maternal body condition and so reproductive performance, reduce the time to slaughter and the number of replacement females needing to be kept. It is these 'system-based' changes that offer most to the SDGs of developing countries as social, food production and emission outcomes change together. The opportunity to improve efficiency of conversion of feed to animal product (protein) on the global scale was highlighted by Herrero *et al.* (2013) reinforcing the opportunity for improved efficiency to underpin mitigation. Improving feed use efficiency by management or animal breeding not only reduces the emission intensity of product, but also provides farmers the flexibility to maintain production while running less stock, using less land area and so potentially running other enterprises.

Breeding for low methane livestock

The only strategy that has been implemented on a national basis and is applicable across all livestock systems is breeding (Rowe *et al.* 2021). Differences between individual animals in the amount of methane emitted in absolute terms, per unit of production or per unit of feed intake, occur across sheep, beef and dairy cattle. Reported heritabilities for absolute methane emissions (g/day) and methane yield (g CH_4/kg DMI) range from 0.1 to 0.3 (Brito *et al.* 2018). Furthermore, in New Zealand, sheep have been divergently selected for methane yield (g CH_4/kg DMI) for over 3 generations resulting in an average of 12% difference between the lines and up to 25% difference in methane yield amongst young sires. Rowe *et al.* (2019) showed sheep selected for lower methane yield were more profitable than their high emitting counterparts. On this basis, the breeding scheme has been expanded to the NZ national flock.

To date, the inclusion of methane within a selection index has been limited by its unknown economic value and a lack of information on genetic correlations with key production traits. However, the scope for lowering methane by including direct and indirect measures within current breeding goals is emerging. In a large dairy cattle study spanning multiple countries and systems, methane traits corrected for either productivity or intake were moderately correlated and inclusion within the breeding goal resulted in a selection response for lowered methane whilst improving feed efficiency and milk yield (Manzanilla-Pech *et al.* 2021). Authors noted that breeding for increased feed efficiency elicited a favourable correlated response so selection for efficiency could also result in decreased methane production. Conversely Johnson *et al.* (2018) reported an unfavourable correlation between residual feed efficiency and methane in sheep, suggesting that including feed efficiency in the index alone would not reduce methane emissions. De Haas *et al.* (2021) estimated that a putative reduction of 24% in methane intensity (g CH_4/kg milk) could be achieved by 2050 by including feed efficiency in the Dutch national dairy breeding goal. Taken together this is solid evidence that methane emissions can be lowered by breeding when included into an optimised selection index, but it is still unclear what metrics should be used. Rowe *et al.* (2021) described the incorporation of methane breeding values within the New Zealand national sheep breeding scheme giving a rate of genetic change of -0.58% per annum. The selection pressure required for this rate of gain would enable gains in productivity to continue. They showed that even with a lag phase of 6 years, that after 20 years, annual methane production was predicted to have reduced by 7.5% per annum saving a total of 4,490 kt of CO_2e. Whilst this will not meet the current targets set by global governments, it does offer substantial reduction for little input and remains the most cost effective and practical solution proposed to date.

A major issue for progress and uptake is that the value of breeding for lowered methane has yet to be determined. The true cost of emissions at the farm gate will determine the level of trade-offs required with improved production and efficiency. This approach necessitates either explicitly or implicitly placing an economic value on methane emissions that is related to their contribution to global warming. Metrics such as GWP100 and GWP* vary greatly in estimating the impact of methane emissions over the short- and long-term and the associated warming equivalents. Both the method of calculation (Cain *et al.* 2022) and future costs vary over an order of magnitude. It is unlikely therefore that the solution lies in a traditional bioeconomic model, and some form of desired gains index is likely to be preferable.

Although, livestock breeding alone is highly unlikely to deliver substantial mitigation towards Paris Agreement warming targets, it could play a substantial role both in reduction of livestock emissions and in adaptation. This will initially be in developed countries, but breeding is also consistent with SDG priorities of developing nations. Our expectation is that breeding will combine with other dietary and system-based mitigation approaches that are still being prepared for implementation. Together these can deliver decreases in absolute emissions and emission intensity and facilitate more efficient food and fibre production.

Abstract

Both the dairy cattle and sheep industries face the simultaneous challenge of improving feed efficiency and reducing methane emissions. Genomic selection is a valuable tool to reduce residual feed intake (RFI) and reduce methane yield (MeY), which are widely used traits for estimating efficiency and emissions. However, it is important to know how selecting one of these traits would affect the other and this relationship has been contentious in the literature. Here we estimated the genetic correlations between RFI and MeY in 584 Holstein dairy cattle and 445 Australian Maternal Composite ewes using bi-variate genomic best linear unbiased prediction models. In both datasets, negative genetic correlations between RFI and MeY were found, which means that selecting more feed efficient animals would increase the amount of methane emitted per kg of dry matter intake. Diet could play a role in this relationship.

Introduction

Feed is the main production cost for both dairy cattle and sheep production and improving feed efficiency is of economic importance to livestock producers. Residual feed intake (RFI) is an accepted measurement of feed efficiency obtained as the difference between actual and predicted dry matter intake (DMI) required for maintenance, growth, and production. Methane is a greenhouse gas emitted as a by-product of enteric fermentation in ruminants. Reducing methane emissions from dairy cattle and sheep is an important step to achieving the Australian goal of reducing greenhouse gas emissions by 26 to 28% from 2005 levels by 2030. On top of the environmental benefits, reducing methane emissions could increase productivity because methane represents a waste of energy that could be used for production.

Methane yield (MeY) is a methane emission trait calculated as the ratio of methane production (MeP) and dry matter intake (DMI). Both RFI and MeY are time-consuming or expensive to measure traits, making routine recording on commercial farms unviable. For these reasons, and given their socio-economic importance, RFI and MeY are ideal traits to be improved with genomic selection. However, it is necessary to know how selecting one of these traits would affect the other. Our hypothesis was that as methane emissions represent a waste of energy, more efficient sheep and cows were expected to be lower emitters of methane per kg of DMI (MeY).

Materials & methods

Animals. Feed intake and methane emissions were collected on 584 Holstein dairy cattle from 12 herd-year-season (HYS) cohorts between 2013 and 2017 and 445 Australian Maternal Composite ewes between 2013 and 2014. Cows were located at the Ellinbank SmartFarm (Ellinbank, Victoria, Australia), milked twice per day, and were between 55 and 127 (71±26) days in milk (DIM) and across parities 1 to 9. Daily

milk production was recorded in cows, and milk protein and fat were calculated using midinfrared spectroscopy. Energy corrected milk (ECM; kg/d) was calculated with the methodology of Visscher et al. (1994) as follows:

$$ECM = 0.1 \times \text{milk yield (kg)} + 5.2 \times \text{fat (\%)} + 2.6 \times \text{protein (\%)} \quad (1)$$

Ewes were located at the Hamilton SmartFarm (Hamilton, Victoria, Australia), were not in late pregnancy or lactating, and their phenotypes were measured at post-weaning, hogget, and adult age stages.

Phenotypes. Dairy cows were fed *ad libitum* for 3 hours after morning and afternoon milking with alfalfa hay or cubes, after which they were moved to an area without food but with water available *ad libitum*. One feeding bin was allocated per one or two cows. Additionally, cows consumed 6.2±0.25 kg of dry matter per day of crushed wheat in 2 portions at milking. The alfalfa hay and cubes provided to cows contained 8.7 and 10.2 MJ of ME/kg of dry matter (DM), 18.2 and 22.7% crude protein (CP), and 46.3 and 37.3% Neutral detergent fibre (NDF), respectively. The crushed wheat fed to cows had 13.8 and 13.8 MJ of ME/kg of DM, 13.1 and 13.9% CP, and 10.2 and 14.3% NDF, respectively. Ewes were fed *ad libitum* (24 hours per day) with a cereal straw-based pelleted diet for 10-14 days before recording feed intake. The pellets provided to ewes had 9.6±0.58 MJ of ME/kg of DM, 9.8±1.6% CP, 48±3.18% NFD. Ewes were spread across 10 pens, with less than 24 ewes per pen and two automated feeders. Pen number was constant within all experiments, but ewes could be assigned to different pens at different ages. Feed intake was measured between 32 and 37 days in cows and for a total of 53, 42, and 32 days for post-weaning, hogget, and adult ages in ewes, respectively. Ewes were weighed three times a week to calculate the average daily gain (ADG). RFI of cows was estimated by Bolormaa *et al.* (2021) as

$$RFI_{cows} = DMI - (\text{mean} + b_1 \text{ parity} + b_2 \text{ DIM} + b_3 \text{ HYS} + b_4 \text{ poly(age,-2)} + b_5 \text{ diet} + b_6 \text{ ECM} + b_7 \text{ BWT} + b_8 \Delta\text{BWT}), \quad (2)$$

where $b_1 - b_8$ are partial regression coefficients; BWT is mean body weight in the test; ΔBWT daily BWT change. RFI of ewes was calculated as

$$RFI_{ewes} = DMI - (\text{mean} + b_1 \text{ MMWT} + b_2 \text{ ADG} + b_3 \text{ EXP} + b_4 \text{ PEN:EXP} + b_5 \text{ AGE}) \quad (3)$$

where $b_1 - b_5$ are partial regression coefficients; MMWT is the metabolic mid-test weight obtained as the average weight of the animal during the feeding test to the power of 0.75; EXP is the feed intake experiment (n=5); PEN:EXP is the pen nested into the experiment (45 levels), and AGE is the age in days at the start of the experiment. RFI was the residual error of the expression, i.e. additional consumption after accounting for energy sinks, which were maintenance (MMWT) and growth (ADG).

Methane production (MeP; L/d) in cows was measured over 5 days with the sulphur hexafluoride (SF_6) tracer method described by Deighton *et al.* (2014) and averaged to obtain one observation per animal. Methane emissions were measured twice in ewes during each feed intake experiment with the portable accumulation chamber (PAC) technique described by Goopy *et al.* (2011). In the sheep population, the first methane measurement was obtained approximately four weeks after the start of the experiment and the second one approximately ten days later after the first measurement, and MeP (L/d) was estimated. MeY was calculated as MeP divided into DMI for both cattle and sheep.

Genotypes. The dairy cattle animals were genotyped for 54,609 single nucleotide polymorphism (SNP) from the BovineSNP50k v2 BeadChip (Illumina Inc., San Diego, CA). These SNP were mapped to the ARS-UDC1.2 bovine genome sequence assembly. SNP with call rate smaller than 0.9, minor allele frequency smaller than 0.025, and duplicate map positions were removed. After this filter, 36,951 SNP were retained for cattle. Ewes were genotyped with one of three chips – with 12,785, 15,000 or 54,241 SNP – and imputed with FImpute to 46,091 SNPs. Genomic relationship matrices (G) were created with the function Gmatrix of the R package AGHmatrix (Amadeu *et al.* 2016) following the method of Yang *et al.* (2010), and principal component analyses on G were completed. All animals had a genotype call rate greater than 0.9.

Genetic correlations. Genetic correlations between RFI and MeY were obtained with the R package ASReml-R (Butler *et al.* 2009) with bi-variate GBLUP models of the form

$$y = 1\mu + X\beta + Zg + e \quad (4)$$

where y is a vector of phenotypes; μ is the overall mean; β is a vector of fixed effects; g is a vector of random additive genetic effects; X and Z are the incidence matrices for β and g, respectively; and e is a vector of random residuals distributed as $N(0,I\sigma_e^2)$. The distribution of g is $N(0,G\sigma_g^2)$, where G is the genomic relationship matrix calculated from SNP genotypes following Yang *et al.* (2010). The fixed effects in cows were HYS, DIM, age and parity, and in sheep were EXP, PEN:EXP, and AGE.

Results

RFI had means of zero and standard deviations of 1.01 and 0.27 in dairy cows and sheep, respectively (Table 1). MeY means were 19.96±3.61 and 25.08±7.14 for cattle and sheep, respectively. In MeY, the range was wider, and the coefficients of variation and maximum values were lower in dairy cattle than in sheep. The coefficients of variation were 18.09 and 28.48, and maximum values were 32.89 and 54.19 for cattle and sheep, respectively. The coefficient of determination (R^2) of the observed DMI regressed on the predicted DMI in sheep was 0.79. The first two principal components of the G matrices together explained 11 and 12% of the variation in cattle and sheep; 14 and 3 distant animals in cattle and sheep were removed, respectively. The genetic correlations between RFI and MeY were strong and reasonably consistent and were -0.77±0.15 and -0.86±0.13 for dairy cattle and sheep, respectively.

Discussion

The range of phenotypic values of RFI and MeY and the coefficient of variation of MeY show variability in the dairy cattle and sheep populations, which can be used for the genetic improvement of these traits. The percentages of the G matrices explained by the first two principal components showed that population structures in the populations were minor.

Table 1. Descriptive statistics of residual feed intake (RFI) and methane yield (MeY) in dairy cattle and sheep.

Species	Trait	Animals	Mean	SD	Min	Max	CV
Dairy cattle	RFI	584	0.00	1.01	-3.49	4.69	NA
	MeY	424	19.96	3.61	11.11	32.89	18.09
Sheep	RFI	443	0.00	0.27	-1.08	1.05	NA
	MeY	458	25.08	7.14	6.72	54.19	28.47

The results from this study show that the selection of ruminants for improved feed efficiency (i.e. lower RFI), would lead to higher methane emissions per kg of DMI. This is somewhat unexpected, as it was hypothesised that lower RFI (more efficient animals) would have decreased MeY, as methane represents energy that could otherwise be used for production. In accordance with this approach, studies in dairy cattle and sheep fed with lower fibre and higher protein diets than our research found that selecting for low RFI would decrease MeY (Negussie *et al.* 2014; Paganoni *et al.* 2017). In contrast with these studies and with diets with lower protein and higher fibre, we found that MeY was higher for low RFI in dairy cattle and sheep. Similar to our results, heifers with low RFI had higher MeY values under a high-forage diet (Flay *et al.* 2019). Additionally, an inverse relationship between DMI and MeY has been reported in ruminants fed with forage diets (Hammond *et al.* 2013) and RFI as a portion of DMI could be expected as negatively correlated with MeY. The underlying biology of the genetic correlations between RFI and MeY is not clear yet and requires further research to elucidate.

Abstract

Genetic improvement has the potential to mitigate some 1-1.5 MT of GHG from the Irish national cattle herd, over the next 10 years. This represents approximately 25% of the target for the sector, as defined by the Irish government within its National Climate Action Plan. The reductions will come through a combination of current genetic trends, coupled with innovative new approaches such as: (1) increased weighting on female fertility traits in our indexes; (2) selecting directly on new methane EBV's in future indexes; and (3) genotyping the national cattle herd. Given the major climate and environmental challenges that lie ahead, we are fortunate to have such a proven technology at our disposal.

Introduction

Irish agriculture is required to reduce its Greenhouse Gas (GHG) output from agriculture by 4.5-6.5 million ton by 2030; this represents a 21-30% reduction in gross emissions for the sector. Over the next number of months, these commitments will become part of a legally binding National Climate Action Plan, with each sector (e.g. agriculture, transport, construction) then having its own sectoral targets. These requirements are as a result of our country's commitment to global reductions in GHG output, through the United Nations Framework Convention on Climate Change (UNFCCC), the Paris Agreement, and the resultant EU Effort Sharing Decisions and Regulations.

Genetic improvement is well known to be permanent, sustainable, cumulative and highly cost effective with an excellent penetrance rate. As a result, it is a key (and proven!) vehicle to achieve year-on-year cumulative improvement in the profitability and sustainability of livestock (Simm, 2002). More recently, questions have been posed about the potential of genetic selection to address national GHG requirements, in line with the national, EU and global commitments. Indeed, a recently published communication from the European Commission on EU strategy to reduce methane emissions, has identified genetic improvement as a key tool through which member countries can reduce their GHG output nationally. As a result, the Irish government has asked the Irish Cattle Breeding Federation (ICBF), the organisation charged with responsibility for national genetic improvement in cattle in Ireland, to undertake an assessment of the potential role of genetic improvement in addressing our ambitious national GHG mitigation requirements.

The mitigation strategy presented here for cattle is also of global relevance, as other countries signed up to the Paris agreement are similarly being charged with the same effort sharing requirements; some 192 states represent 98% of the total global GHG output. It is therefore anticipated that the strategy proposed here will be of interest to both national and international audiences, as we collectively strive to reduce global GHG outputs from agriculture.

Materials & methods

Scenarios considered. Cattle genetic improvement strategies in Ireland are currently focused on maximizing profitability. This approach is also consistent with ongoing improvement in emissions intensity (EI, CO_2e/kg product) which are highly valued by the consumers of Irish livestock products, many of whom

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_21, © A.R. Cromie *et al.* 2022

are increasingly conscious of the GHG footprint associated with their diet and lifestyle choices. Within the analysis, the impact of current genetic trends on both emissions intensity and on gross emissions (in CO_2e) based on either a fixed level of production or a fixed population size (i.e. increased production) were investigated. This is critical, as traditionally genetic improvement has been viewed to deliver sustainability improvements through an emission intensity perspective, rather than gross emissions, with the latter now being the particular requirement of National and International GHG inventories.

Strategies applied. Various additional breeding strategies were also considered as part of the analysis, in an effort to identify options to yield the greatest GHG mitigation in the future. Each strategy was considered additive; so building on the current level of genetic gain within the National dairy and beef herds and then layering over additional enhancements, based on relevant national data, parameters and assumptions.

The scenarios considered, together with their impact under a fixed national output or a stable national herd size are summarised in Table 1 for the national dairy herd and Table 2 for the national beef herd, respectively.

Table 1. Impact of different strategies for GHG mitigation in the Irish dairy herd (KT CO_2e).

	Description	Fixed output (KT CO_2e)[1]	Stable herd (KT CO_2e)[1]
S1	Current genetic trends for dairy economic breeding index	658	69
S2	Addition of a new carbon sub-index within the EBI, with increased weighting on female fertility traits.	96	108
S3	Addition of direct methane EBVs in the breeding goal at the current economic values for methane.	67	77
S4	Increasing emphasis on new methane EBVs in the breeding goal;30% weighting in the overall index.	85	207
S5	Inclusion of a secondary selection requirement; that only top 40% sires on methane EBV are retained for breeding.	97	101
S6	National herd genotyped, resulting in a 20% increase in accuracy of selection.	200	112
	Total	1,203	674

[1] Based on current dairy cow population of 1.6 m dairy cows producing 8.61 M Tonnes milk.

Table 2. Impact of different strategies for GHG mitigation in the Irish beef herd (KT).

	Description	Fixed output (KT CO_2e)[1]	Stable herd (KT CO_2e)[1]
S1	Current genetic trends for beef replacement index	181	71
S2	Inclusion of methane EBV's in the breeding goal at current economic values for methane.	74	78
S3	Increasing emphasis on new methane EBV's in the breeding goal at a 30% weighting in the overall index.	91	110
S4	National herd genotyped, resulting in a 20% increase in accuracy of selection.	69	52
	Total	415	311

[1] Based on a current beef cow population of 0.9 m cows producing 168 KT Meat.

Modelling outcomes. Geneflow models were utilised where appropriate to quantify the benefits of genetic improvement to the overall GHG mitigation over a 10-year period from 2020 to 2030. When production levels were fixed, emissions mitigation were achieved through both reduced cow numbers and improved emissions intensity. Nonetheless, the mitigation achieved through reduced cow numbers was only counted once in the analysis.

Additional detail on the methodologies applied within the analysis is accessible in the final report and recommendations which were presented to the Irish government and cattle breeding industry in late 2021(Crowley *et al.*, 2021).

Results & discussion

Dairy. Results from Table 1 indicate that, in overall terms, genetic improvement has the potential to offset some 1,203 KT CO_2e (1.203 MT) of GHG under a fixed output scenario and 674 KT of GHG under a fixed population size scenario. Underpinning these potential improvements are the current genetic trends in the Irish national dairy cow breeding index (i.e. EBI), which is increasing at a rate of €10.8/year (or 0.19 genetic standard deviations/year), resulting in a reduction in gross emissions of 5.4 kg CO_2e/cow/year). These reductions are largely being driven by shorter calving interval and greater cow longevity, which are more than balancing out the productivity gains in terms of milk output, resulting in a reduction in gross emissions under a stable herd size scenario of 69 KT by 2030 (-0.7% in overall terms). A shorter calving interval in Ireland enables a greater proportion of the diet to be fulfilled from grazed pasture which has a lower carbon footprint than purchased in feeds and/or silage. The greater cow longevity manifests itself as a reduced requirement for replacement females (with their associated carbon cost) but also a greater proportion of the herd realizing their mature yield potential. Capping milk output would result in further reductions in gross emissions (-41 kg CO_2e/year), meaning that by 2030, cows would be producing the same amount of milk solids, but with 410 less kg CO_2e per lactation. Expressing this in overall terms equates to a reduction in CO_2e at the national level of 658 KT (8% reduction in total farmgate GHG).

Examining the various enhancements (i.e. S2, S3, S4, S5 & S6 in Table 1) indicates that each enhancement has the potential to mitigate additional GHG output, through placing further emphasis on female fertility (S2) and being prepared to select more directly and aggressively on the methane phenotypes within the breeding goal and overall breeding program (S3, S4 & S5). The impact of genomics (in terms of genotyping the national cattle herd and increasing selection accuracy) is also noteworthy (S6), especially when one considers the additional benefits that this strategy would bring from an industry standpoint, i.e. enhanced DNA-based traceability, GHG auditing based herd genetic merit, labor saving for farmers, future R&D, etc.

Beef. Results from Table 2 indicate that, in overall terms, genetic improvement has the potential to offset some 415 KT of GHG under a fixed output scenario and 311 KT of GHG in a scenario where the beef cow herd size is fixed. Fewer scenarios were considered for the beef sector due principally to the lesser use of AI in the national beef breeding program (25% in beef compared to 70% in dairy), which makes rapid implementation of any outcomes much more challenging (albeit it will eventually occur, but with a lag). Nevertheless, when combined with the reductions achieved from the dairy sector (Table 1), results indicate that genetic improvement has the potential to mitigate some 1.6 MT of GHG under a fixed output scenario and almost 1 MT under a stable herd scenario; this is from a total national target reduction of 4.5-6.5 MT.

Again, core to the potential beef improvements are the current genetic trends in the Irish national beef breeding index, the €uro-Star Replacement Index, which is increasing at a rate of €5.6/year (or 0.13 genetic standard deviations/year), resulting in a reduction in gross emissions of 7.5 kg CO_2e/cow/year). These reductions are largely being achieved by a lighter cow, lasting longer, resulting in a reduction in gross

emissions under a stable herd scenario of some 71 KT nationally (-2.1% of total beef farmgate GHG). Under a fixed output scenario (where we have the opportunity to capture increased productivity gains), this reduction increases to some 181 KT (-5.4% of total farmgate GHG). Examining further the various enhancements considered (i.e. S2, S3 & S4 from Table 2), the benefits of each are consistent with those from dairy and, again highlight the benefits of new programs and initiatives focused on methane phenotyping and increased genotyping at the national level.

Looking forward. Since the removal of EU milk quotas in 2015, the size of the Irish national cattle herd has grown steadily, from 6.19 m cattle in 2012 to 6.53 m cattle in 2021 (+5.4%). This, coupled with the continued importance of agriculture to the Irish economy (7.1% of total employment and 10% of total exports in value terms), means that there is little desire to impose strict constraints on output and/or cattle numbers. Instead, government, industry and farmers are now looking for innovative breeding solutions to the GHG (and broader environmental) challenges, through new initiatives such as: (1) national genotyping programs; (2) methane phenotype collection systems; and (3) a preparedness to place more emphasis on female fertility and methane traits in our breeding indexes. The costs of these initiatives will be significant, but as will be the prize; 1 MT CO_2e of potential mitigation and some 25% of our sectoral target at a national level. While many strategies are being routinely touted as the savior to reducing the environmental footprint of especially ruminants, no technology has proven itself time-and-time again to be a reliable, sustainable, cumulative and relatively low cost strategy to address grand challenges. We are fortunate to have such a proven technology at our disposal.

Given that climate change is a global issue, the urgency to cooperate internationally to accelerating genetic gain has never been so important. This must be in the form of more data and knowledge sharing, rather than simply building national and/or company specific solutions. Great strides have already been made at research level (e.g. initiatives such as global DMI, 1000 bulls etc) and international service level (e.g. ICAR, Interbull, Interbeef, etc), but the responsibility to grow this further is now compelling. Can we afford to miss this opportunity? The alternative is a future farming environment dominated by plant based proteins, as opposed to one where climate efficient livestock have the opportunity to interact with plants in the natural eco-systems that is required by both to co-exist, evolve and improve. Surely that is a goal worth aspiring to?!

Abstract

Livestock will face an important challenge within the next decade to cope with the objective of cut by 30% methane emissions, as agreed in the COP26. This study summarises the latest genetic parameter estimates between methane, dry matter intake, microbiota composition, and production and body traits in Spanish dairy cattle. We evaluated the expected genetic progress after including methane into the breeding goal under different scenarios. Under the current trend in the cow population size, it is only possible to achieve the objective if methane is included with a large weight in the selection index and it is accompanied of other strategies. This may generate conflict with dairy producers and balanced strategies must be considered.

Introduction

As many as 104 countries have promised to cut their methane emissions by at least 30% by 2030 at the 26th session of the Conference of the Parties (CoP26) to the United Nations Framework Convention on Climate Change (UNFCCC) summit in Glasgow, United Kingdom. In 2019, methane in the atmosphere reached record levels, around two-and-a-half times above what they were in the pre-industrial era. Methane has a warming potential between 28-34 times that of CO_2 over a 100-year period. Over a 20-year period it is around 84 times as powerful as carbon dioxide per unit of mass. Ruminants are considered one of the most important sources of global methane (CH_4) emissions, producing around 4,623 Mt of CO_2 equivalents (CO_2e) per year, with dairy cattle being responsible for 2,128 Mt of CO_2e per year. Around 40% of total CH_4 comes from enteric fermentation in ruminants (Moss *et al.*, 2000). Eructated CH_4 is not only an important contributor to global warming, but also represents a loss of dietary energy because it is equivalent to between 2 and 12% of net energy intake (de Haas *et al.* 2011, Johnson and Johnson 1995). Levels of methane emissions are linked to the intake capacity of the animal. Consequently, reducing enteric CH_4 emissions in ruminants has become an important area of research, aligned with the commitment to reduce its greenhouse gases emissions by 2030. The short methane lifetime in the atmosphere (10 yrs) offers an interesting opportunity to reduce the global warming contribution from this gas in a shorter period. Decreasing enteric CH_4 from ruminants without altering animal production is desirable both as a strategy to decarbonize the livestock economy and to improve feed conversion efficiency. Selective breeding is an interesting strategy to tackle CH_4 emissions from ruminants. There is great potential in adopting genetic and genomic selection strategies, given that several studies have reported that enteric CH_4 is a heritable trait (Lassen and Løvendahl, 2016; Pszczola *et al.*, 2019). Enteric methane is mainly produced by microorganisms in the rumen during the feed fermentation. Investigating the ruminal microbiota and understanding their role during the methanogenesis will help to develop better breeding strategies. Besides, microbiota composition has also been reported to be heritable (Saborío-Montero *et al.*, 2020).

DOI: 10.3920/978-90-8686-940-4_22, © O. González-Recio *et al.* 2022

The objective of this study is to evaluate the (co)variance parameter estimates between traits related to methane emissions, intake, conformation and production. Then, the genetic changes to reduce methane emissions in the next decade under 3 different selective breeding scenarios were evaluated.

Materials & methods

Data consisted of 11,042 weekly averaged records for dry matter intake (DMI) obtained from 551 dairy cows in 5 farms, as well as 4,624 methane emission measurements using a non-dispersive infrared methane detector installed within the feed bin of the automatic milking system during 14 to 21 days period from 1,501 cows in 14 farms. In addition, ruminal content was extracted from 437 cows with methane phenotypes. Data for milk yield, protein yield, fat yield, fertility, body depth, rump width, chest width and predicted live weight from 11,228 cows were included in the analysis. Heritability and genetic correlations were estimated from bivariate models within a single step framework using AIREML (Misztal *et al.*, 2002).

The large complexity of the ruminal microbiota was aggregated through principal component analysis (PCA), into few principal components (PC) that were used as proxies of the core metagenome. Bivariate animal models were applied using these PC and methane production as phenotypes.

The selection responses under the different scenarios was assessed using selection index theory, including methane production as an additional trait in the breeding goal. We assumed the current selection index (ICO) in the Spanish Holstein population as the benchmark. The other two scenarios included methane with either an economic weight (based on carbon tax) or desired genetic gains (20% reduction in ten years while maintaining positive genetic trends of protein and benefits per cow).

Results

Genetic parameters. Table 1 shows the genetic parameter estimates obtained in this study. The heritability estimates for methane production (0.17±0.05) and methane concentration (0.18±0.04) were moderate, and their genetic correlations with milk yield traits ranged between (-0.05±0.11 and 0.50±0.11). In general, higher genetic correlations were estimated with body capacity traits, ranging from 0.14 to 0.31. The estimated heritability for DMI was moderate (0.16±0.03), with a genetic correlation with milk yield of 0.41 (0.11), and with capacity index of 0.20±0.09. Genetic correlations between methane traits and DMI were positive and ranged from 0.20±0.48 to 0.27±0.43. The heritability estimates for the first PC was >0.30 at all taxonomic levels. The microbiome aggregated variables showed strong genetic correlation with methane traits (0.42±0.19 and 0.83±0.19), and dry matter intake (0.32±0.36).

Table 1. Heritability (diagonal) and genetic correlations (above diagonal) estimates[1] of traits of interest.

Trait	Protein (kg)	Fat (kg)	Milk (kg)	ICAP	DMI	Methane (ppm)	Methane (g/d)	Microbiome (PC1)
Protein (kg)	**0.33**	0.64	0.78	0.29	0.53	0.07	0.13	-0.02
Fat (kg)	0.05	**0.28**	0.87	0.32	0.50	0.30	0.32	0.18
Milk (kg)	0.07	0.08	**0.40**	0.30	0.41	-0.05	0.04	0.04

[1] Standard errors are shown below diagonal.

Expected genetic gain after including methane in the breeding objective. The inclusion of methane in the current ICO would slightly modify the genetic responses, with no relevant change in methane response, which would still increase per cow in future generations. A partial reduction of 20% would only be possible by applying ad-hoc weights for methane in the selection index to achieve such a desired genetic gain (Figure 1). This would come at an expense of a slower genetic progress in milk yield and its components (2 kg of protein per cow), and thus the economic response (5 €/cow/year).

Discussion

The results from our study suggest a correlated response in methane emissions when selecting for more ravenous animals, although these estimates showed large standard errors. These results highlight an important interrelationship between methane production and dry matter intake, with a significant role of the microbiome composition. The core microbiome composition condensed in aggregated PC variables was controlled by the cow genome. The PCA allowed us to condense the huge and fuzzy taxonomical and functional information from the metagenome into a few PC. We selected the PC1 (h^2=0.42±0.05) because it showed the largest association with methane, and separates bacteria from eukaryotes (protozoa and fungi) in the rumen. Protozoa and Fungi provides substrate to methanogenic archaea and their relative abundances represent an important driver of methane emissions (López-Garcia *et al.*, 2022).

Our results suggest that selecting cows that make a more efficient utilization of energy intake is feasible through selection on correlated type traits such as body capacity, stature, and body depth, without compromising high productive performance. Selection for lower methane emissions is expected to have similar results. The inclusion of the microbiome composition may assist on a more efficient selection on lower emissions and higher feed efficiency.

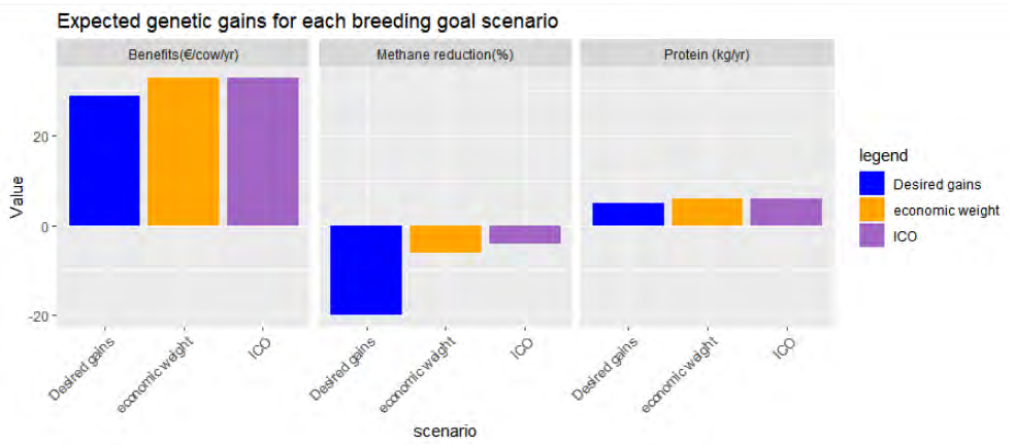

Figure 1. Expected genetic response on benefits, methane emissions, and protein yield according to each selection index scenario (current total merit (ICO) index, economic weight on methane, desired genetic gains) based on the current productive circumstances of Spanish dairy cattle.

Conclusions

The recent Global Methane Pledge aims to limit methane emissions by 30% in 10 years compared with 2020 levels. Selective breeding can contribute to reducing methane emissions from ruminants. Current selection trends will not contribute enough to achieve this goal. Selection indices will need to include methane related traits with weights calculated based on desired genetic gains. This would slow down the genetic gain of other important traits. Even with a slower genetic progress on milk yield traits, selective breeding could achieve a 20% reduction of methane emissions while increasing profitability of dairy cattle.

This study may serve as an example on how selective breeding may be applied to reduce methane emissions in other cattle and small ruminants populations. Selective breeding would contribute in a permanent and cumulative manner to such a reduction. However, other nutritional and technological measurements should be applied complementary to achieve the 30% reduction goal.

Abstract

Breeding goals are based on the market and production expectations and we expect that the market will require pork with lower if not zero carbon emissions in the future. The influence of the breeding goal on the carbon footprint of pork was studied by comparing the carbon footprint of future scenarios (year 2040) with two different breeding goals; one reflecting the current breeding goal and one reflecting a future breeding goal aiming for increased feed efficiency and higher animal welfare. The diets in both scenarios included locally based feed ingredients such as silage and yeast protein, but no soybean. The carbon footprint of the pork production system was 6.5% lower with the alternative breeding goal including increased feed efficiency and better animal welfare, than with the current breeding goal.

Introduction

Pork is a food product with a high nutrient value and the average carbon footprint of pork today in Sweden is 3.3 kg CO_2 per kg pork retail weight (Landquist *et al.* 2020). Although global pork consumption per capita is not anticipated to increase between now and 2050 (Komarek *et al.* 2021), global pork production will increase with population growth. In contrast to ruminants, pigs cannot utilize large amounts of grass in semi-natural pastures but rely on feed crops. Therefore, an increase in pig production may translate to an increase in the amount of feed crops required. Besides feed-food competition, the increase in feed crop production may increase the absolute global warming impacts from pork and the arable land required for pork production. The climate impact of pig production depends on the feedstuffs used and the ability of the pigs to use feed efficiently.

There is an increasing interest in the use of silage from ley crops as an alternative protein source for pigs to reduce the dependency on soybean meal (Friman *et al.* 2021), and ley crops provide lower climate impacts of the following grain crop in the crop sequence through increasing yields and decreasing fertilizer requirements (Martin *et al.* 2020). A recent study indicated no significant difference in slaughter weights for pigs fed grass/clover silage and those fed diets based on soybean meal (Friman *et al.* 2021). Yeast protein produced from the hydrolysis of spruce trees can also be used to replace soybean meal for young pigs (Cruz *et al.* 2020). Yeast is an interesting protein source because it does not directly compete for land with crop production since it can be produced from forest waste, and grass/clover silage produced on annual leys can improve the crop sequence at pig farms.

Since feed production plays a major role in the climate impact of pig production (Landquist *et al.* 2020; Zira *et al.* 2021), individual feed efficiency is an important breeding goal trait. Feed efficiency on a farm level is also influenced by mortality and reproduction traits and these traits are also important for animal welfare. The aim of our simulation was to show the consequences of a breeding goal with high weight on feed efficiency and traits important for animal welfare on the climate impact of a future pig production system.

Materials & methods

The diet was the same in both scenarios and included locally based feed ingredients such as grass/clover silage and yeast protein, but no soybean. The pigs had access to an outdoor veranda, silage and straw for enrichment. We compared the climate impact of pig production after 20 years of selection using a 'standard' breeding goal reflecting current breeding schemes or a new breeding goal.

A breeding program was simulated for a synthetic breed representing all three breeds commonly used in crossbred slaughter pigs ((Yorkshire × Landrace) × sire breed). The selection traits and their economic weights are shown in Table 1. The new breeding goal was based on results from studies aiming for improved sustainability in pig production through improved overall farm feed efficiency (Ottosen *et al.* 2020; Rauw *et al.* 2020; Soleimani and Gilbert, 2021) and improved animal welfare (Wallenbeck *et al.* 2016). The initial economic weights were adjusted in an iterative process, so that none of the traits in the new breeding program got an unfavourable trend (in spite of unfavourable genetic correlations).

A mating ratio of 1:40 was used with 2.5% of the boars and 20% for sows being selected to become parents using Best Linear Unbiased Prediction (BLUP) of breeding values simulated in a program i.e. SelAction (Rutten *et al.* 2002). The genetic evaluation of growth rates, feed efficiency, leg strength, and disease resistance was based on information from own performance of all pigs (i.e. the performance test). The genetic evaluation of meat percentage and meat quality was based on information from elder relatives (since selection candidates were not slaughtered). The genetic evaluation of sow traits (fertility, litter size, piglet survival, shoulder ulcers, and longevity) was also based on information from elder relatives. In the SelAction program, this was handled by simulating recording on a number of half-sibs that gives approximately the same accuracy as recording on elder relatives (400 half-sibs for meat percentage and meat quality, and 100 half-sibs for sow traits).

A population of 70 boars and 1000 sows was simulated in the SelAction program. Rounded values of 'standard' genetic parameters for pigs based on the literature were used as input for the simulation (Table 2). All traits were adjusted so that a higher value is more favourable (e.g. frequency of sows free from shoulder

Table 1. Selection traits, average values, standardised genetic standard deviation and relative economic weights used to calculate genetic change for pigs.

Selection traits	Mean 2020	Genetic stand dev	Current breeding goal		New breeding goal

ulcers instead of frequency of sows with shoulder ulcers). Since genetic correlations vary between pig populations and over time, we carried out a sensitivity analysis with more unfavourable genetic correlations by adding -0.1 to all correlation estimates.

The carbon footprint method was used to estimate greenhouse gas emissions in the two scenarios. The carbon footprint calculation included emissions from feed production, animal housing, enteric fermentation of the pigs and manure management. The system boundary was from cradle to farm gate and the carbon footprint unit was kg carbon dioxide equivalents per kg retail weight pork.

Results

The pigs selected using the new breeding goal had a lower carbon footprint (2.25 kg CO_2 eq/kg pork) than pigs selected with the current breeding goal (2.40 kg CO_2 eq/kg pork) in 2040. The lower carbon footprint for pigs selected using the new breeding goal resulted from a combination of lower piglet mortality, higher growth rate, higher feed efficiency and higher sow longevity (leading to lower sow replacement rate). Using more unfavourable correlations in the simulation had a very small effect on the carbon footprint (2.42 kg CO_2 eq/kg pork with the current breeding goal). The carbon footprint estimated for 2040 was lower than the carbon footprint of pigs with today's genetic capacity (2020) in the same environment, which was 2.74 kg CO_2 eq/kg pork.

Discussion

Breeding is a useful tool in the reduction of the carbon footprint of pork. Twenty years of selection with the current breeding goal reduced the carbon footprint by 12.4%. A new breeding goal, aiming for improved sustainability in pig production through improved overall farm feed efficiency and animal welfare led to 6.5% lower carbon footprint than the current breeding goal, after twenty years of selection. This may seem like a small value but if a country like Sweden, producing an average of 245,000,000 kg of pork per year (FAOSTAT, 2021), would reduce the emissions by 0.15 kg CO_2 eq/kg pork that would equate to savings of 37,000,000 kg CO_2 eq on its carbon budget. It should be noticed that this reduction is possible while at the same time animal welfare is improved. The future breeding goal matters both for climate mitigation and animal welfare.

Abstract

Irish agriculture is required to reduce its GHG output from agriculture by 4.5-6.5 million tons by 2030; this represents a 21-30% reduction in gross emissions for the sector. The Irish Cattle Breeding Federation, responsible there for genetic improvement in dairy, beef and sheep have a unique database on which animal carbon footprints can be estimated and extended to Irish farmers and other relevant third parties. Generating GHG totals at the animal levels allows for differences between animal types, systems, sires and other categories be generated. Additionally, procurement, slaughter age and management style can all be influenced by live animal carbon footprints. To this end, for beef, methods to generate per animal and per kg of product GHG totals (kg CO_2e) were developed and are currently deployed in the ICBF database under a module called AniPrint (current v1.0).

Introduction

Owing to the international concern over the nexus of agriculture and climate change, countries have set internal goals and mandates by which the contribution of agriculture to Greenhouse Gas (GHG) totals must be lowered. Irish agriculture is required to reduce its GHG output from agriculture by 4.5-6.5 million tons by 2030; this represents a 21-30% reduction in gross emissions for the sector. Many efforts are currently occurring and being developed simultaneously, ranging from improved manure storage, to improvements in artificial fertilizers, to measuring animals for enteric methane aiding selection decisions (Ryan *et al.*, WCGALP 2022)

The Irish Cattle Breeding Federation (ICBF) is responsible for genetic improvement of dairy, beef and sheep in Ireland and so have a large database of animal centric production data, pedigrees and genotypes. At the core of ICBFs responsibility to Irish farmers, detailed herd reports, summaries, genetic evaluations and mating allocations are some of the main outputs delivered. In addition to genetic improvement mitigating GHG (Quinton *et al.* 2018, Cromie *et al.*, WCGALP 2022), developing individual animal carbon footprint estimates based on animal data in the ICBF database can prove extremely valuable to analyse across industry differences in GHG per animal type, per production system, per sire, etc. Additionally, as data on carbon footprint values/animal can be available in real time, estimates can influence selection of animals for differing management styles, reproduction, purchase, sale or slaughter; both gross GHG and per unit of product produced. To this end, an initial framework to estimate per animal carbon emissions was drawn up and tested for Irish beef animals and is described herein.

Materials & methods

Energy demand of an animal inevitably drives its carbon footprint. Hence, growth profiles of all animals in the database were generated and subsequently, based on growth rate and animal weight, energy demand for growth and maintenance per day (of life) was calculated using equations set out in Rattray *et al.* (2017). The ICBF database contains liveweight data from many sources, including auction marts, farmer submitted records, progeny test centres and research stations. Carcass weights (Cwt) on all animals slaughtered in

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_24, © J.J. Crowley *et al.* 2022

Irish abattoirs are also collated by ICBF for the purposes of genetic evaluation and were available for this exercise. Figure 1. attempts to capture the concept of the stepwise process.

Predicting liveweights. While initially a random regression model was tested, a multiple regression approach was eventually favoured due to the predictive (rather than explanatory) need in this exercise, plus ease of deployment into a database. In the beef genetic evaluation for growth, ICBF adopt a multi-trait evaluation to utilise the plethora of liveweight data available. While only one growth PTA is published, all animals in the genetic evaluation receive solutions for approx. 8 liveweight traits (liveweight at different ages). It's these PTAs, plus other fixed effects such as animal type (steer, heifer, bull) and interactions with age, that are used as predictors of liveweights at certain key timepoints in an animal's life. Coefficients for these fixed effects were estimated by multiple regression on real liveweight observations. Data after 2005 was retained and almost 7M liveweights on 6.5M animals were available. This table of coefficients is now stored in the database and used when liveweight prediction is required. A current improvement to the current version of this tool is currently testing the usefulness of including the BLUE outputs from the weight evaluations which might give a more refined account of environmental effects.

Key time points. The aforementioned table of coefficients is easily deployable into a database calculation as there are key timepoints in a beef animal's life where we estimate a liveweight, and assume a constant gain between them. These key timepoints correspond to typical management and nutrition changes in the average beef animal's life in Ireland. Table 1. highlights these key timepoints. Once liveweights are estimated at these timepoints, we are able to estimate daily energy demand required (MJME) and subsequently estimate daily DMI (kg) depending on where that energy comes from and its density (MJME/ kg DM; Table 1). Diet types differ for spring and Autumn born animals.

Figure 1. Illustration of stepwise concept of estimating GHG per animal.

Table 1. An example of percentage of diet made up of either grass, silage or concentrate, across growth periods for a spring born animal.

Period	Start age (d)	Grass (%)	Silage (%)	Ration (%)
1	0	0	0	0
2	46	0.33	0	0
3	199	0.46	0	0.13
4	230	0.40	0.40	0.20
5	260	0	0.78	0.22
6	322	0.49	0.51	0
7	351	1	0	0
8	596	0.49	0.51	0
9	626	0	0.83	0.17
10	716	1	0	0
11	991	0.49	0.51	0
12	1,022	0	0.83	0.17
13	1,112	1	0	0

Greenhouse gases. Once daily DMI per animal is estimated, an emission factor (EF; g CH_4/kg DMI) is used to calculate daily enteric CH_4 and is subsequently summed across an animal's life. Different EFs are used for different feed types; 0.22 for grazed grass, 0.25 for silage and 0.13 for concentrate. Manure CH_4 is estimated using a Tier 1 IPCC method (Table 10.14, IPCC 2006) as slurry storage information per farm is absent from the ICBF database. This method attributes an average of 16.4 g CH_4/day or life/animal. Methane is converted to CO_2e (as with all GHG in this tool) using a global warming potential (GWP) of 25.

Using estimated lifetime DMI values per animal, direct and indirect N_2O dung and urine emissions can also be estimated using equations outlined in Ch. 11 of IPCC Guidelines for National Greenhouse Gas Inventories. Essentially these estimates will be a function of dietary N consumed, N retained and N excreted. Finally, N_2O from fertiliser use can also be estimated using equations described in the same IPCC chapter. While the ICBF database does not have data on fertiliser attributable to each animal, an estimated allocation per animal is derived based on an animal's nitrogen stocking rate (kg/ha organic N) and the recommended total N (kg/ha) to apply in consideration for that animal (Teagasc Beef Manual, 2016).

Four sources of GHG have been described as they make up approx. 95% of beef GHG. Currently these GHG is what version 1.0 of this tool is concerned with and additional GHG, e.g. CO_2 from off-farm concentrate production, is being considered for inclusion.

All animals and attribution. The aforementioned methods relate primarily to terminal animals, growing replacement heifers and working stock bulls. The cow, post age of first calving (AFC), will also have a carbon footprint that is attributable to the emissions intensity of the final product. For this framework, and as is common in most LCAs methods, a cow's carbon footprint pre AFC is attributable to her cull cow carcass, with all other lifetime emissions attributable to carcass of her progeny. In this version (1.0) of the framework, we assume a beef cow emits 2,800 kg CO_2e/yr (estimate from Teagasc Beef Research, personal communication). Thus, her AFC, age at slaughter and total number of progeny affect her gross emissions and attribution to emissions intensity. For beef out of the dairy herd (dairy-beef or dairy-dairy animals), a lesser amount of carbon from their dam is attributable to the final carcass (271.6 kg CO_2e) as milk solids are the majority of dairy cow product.

Results

When calculations are implemented, all beef animals in the ICBF database receive a lifetime GHG emissions estimate. This estimate is generated for the animal itself, and for the carcass it produces. Estimates are also available for live animals as a 'live ticker' of an animal's footprint. Table 2. is a sample summary of 2020 slaughtered animals. Additionally, Figure 2 provides an estimate of sources of different GHG by age category of beef-beef animals.

It is noteworthy that there is a large amount of variation within (as dictated by the standard deviations) categories described in Table 2. as well as between them. This highlights that there is potential variance to exploit when selecting for whole system carbon footprint.

Discussion

Initial insights into differences across the Irish beef cattle population from AniPrint 1.0, when it comes to GHG emissions and emissions intensity, has already highlighted avenues for GHG mitigation. Additional assessment of animal GHG totals will be carried out to help identify sires of benefit to the national carbon inventory. Third parties, such as abattoirs, also have interest in this tool in order to identify animals of desired finish characteristics along with a favourable carbon footprint. This may drive change at the farmer level to finish animals at an earlier age and focus on AFC, calving interval and cow longevity in their breeding objective.

Table 2. Summary statistics of gross GHG and emissions intensity by key animal groups; Beef-Beef, dairy-beef or dairy-dairy type animals slaughtered in different age category systems of 2020 slaughtered animals.

Abstract

Greenhouse gas emissions from livestock have been at the centre of a worldwide discussion. To achieve tangible results in mitigation strategies, all tools in the available toolset need to be used. One tool is the rumen microbiome, which are partly under the host genetics' control, and could help explain variation in methane emissions from ruminants. Data on methane emissions and rumen fluid samples were collected from 179 dairy cows from Dutch commercial herds. Genotypes from 70 cows were used to estimate heritability for methane intensity. Our goal was to assess the power of our pipeline, for subsequent application to a bigger dataset, by evaluating the value of adding microbial information to the analysis. Microbial estimates were highly confounded with the effect of farm. Our preliminary results show that our workflow is appropriate and that we will be able to estimate microbiability and heritability when our full dataset becomes available.

Introduction

The Dutch government has agreed on a set of guidelines, named the National Climate Agreement, with the goal to decrease by 2030 greenhouse gases emissions (GHG) by 49% from the 1990 levels. Five different sectors have been targeted, among them agriculture, where a reduction of 3.5 Mton CO_2eq is expected to be achieved. One source of GHG from agriculture is methane emissions from ruminants, which release methane into the atmosphere as a by-product of their digestion. A community of microorganisms produce, amongst other things, CO_2 and H_2 in the rumen while digesting the feed, which in turn are converted to methane and eructed by cattle (Janssen and Kirs, 2008).

Genetic selection is an important tool for breeders, as it brings cumulative and permanent progress for a given trait of interest (Wall *et al.*, 2010). Methane emissions from dairy cattle are known to be partly under genetic control (Difford *et al.*, 2020; Zetouni *et al.*, 2018), which means selecting for cows that emit less methane is possible, and could therefore be used as a tool to help GHG mitigation in livestock. Another feature that seems to be partly under host control is the vast population of microbes, i.e. the microbiome, found in the rumen (Malmuthuge and Guan, 2017; Roehe *et al.*, 2016). Variation in the relative composition of the microbiome, termed microbiability, has been shown to explain 13% of the variation in methane emissions from dairy cattle (Difford *et al.*, 2018). Therefore, microbial information could be used to help shed some light in understanding the genetic factors behind methane variation in cattle. Our goal was to evaluate the power of our sampling strategy and subsequent pipeline in this preliminary dataset, by evaluating to which extent microbial information could explain the variation in methane intensity from dairy cows from Dutch commercial herds. This paper focuses on preliminary data collection as an indicator on how to optimize sampling of a larger dataset for the estimation of methane microbiability and heritability, and in evaluating and developing our chosen methodology. Our study is part of an ongoing project with the aim to collect methane phenotypes, genotypes and rumen fluid samples from 1000 Dutch dairy cows.

Materials & methods

Data collection. Methane phenotypes and rumen samples were collected from 179 Holstein Friesian dairy cows, from 17 commercial herds spread across the Netherlands. Methane emissions were measured non-invasively using the GreenFeed system (C-Lock Inc., Rapid City, SD) depending on farm. Methane

production per cow was expressed in g/day, which was used to estimate methane intensity (MI), defined here as the ratio between methane production and fat and protein corrected milk (FPCM). Genomic information from 70 cows was incorporated into the model to estimate heritability of MI. Cows were genotyped with the Eurogenomics 10K chip and imputation was routinely performed by CRV to 76,438 SNPs. The rumen fluid samples were collected on the last day of the seven-day methane measurement period using the oral stomach tube according to standard operating procedures developed at WUR (Muizelaar *et al.* 2020). The samples were immediately frozen on dry ice and subsequently stored in the freezer. Thereafter, microbial DNA was extracted, followed by library construction of the hypervariable region V4 (from the 16S rRNA gene). Sequencing was performed on an Illumina HiSeq platform at Genotypic Technology Pvt. Ltd. in Bangalore, India. Reads were pre-processed using QIIME2 suite v2020.8 and FAST QC v 0.11.9. The resulting Amplicon Sequence Variants (ASV) were identified using the SILVA v.138 classifier. Cows with less than 20 methane measurements during the measurement period were discarded due to unreliable methane results. The final dataset contained 48,478 ASVs for 179 samples and an average number of reads per sample of 431,476. The ASVs were rarefied to a uniform sampling depth of 81,771 reads, resulting in 42,799 ASVs. Results from the sequencing of individual rumen fluid samples were used as the microbial phenotype of each cow, in order to estimate microbiability.

Variance components estimation and statistical models. In order to test the power of our sampling strategy and chosen methodology when assessing microbial variance in our preliminary dataset, we first estimated microbiability using only the microbial data on all 179 cows – not including genotypes. A microbial relationship matrix was built with the relative abundance of ASVs as described in Ross *et al.* (2013). The relative abundance (RA_{ij}) of ASVs is considered for the elements $X_{ij} = \log(RA_{ij} - \overline{RA_j})$, where i is the rumen sample and j is the taxonomic unit. From that a metagenomic profile (X) is derived, with dimensions $n \times m$ (n is the number of rumen samples; m is the number of ASVs), which are then used to create the microbial relationship matrix, computed as M = XX'/m.

Microbiability was estimated by the following mixed model equation,

$$y = Xb + Zm + Uc + e \quad (1)$$

where y is a vector of the trait observations; X, Z, and U are incidence matrices associated with the vector of fixed effects b of parity (1 to 4+), grazing type (barn pasture or summer barn feeding), season the microbiome sample was taken (fall, spring, summer or winter), soil type (clay, peat or sand), and days in milk, the vector of ASV effects m ~ N(0, Mσ_m^2), the vector of random farm effects caused by a common environment c ~ N(0, Iσ_c^2); and e ~ (0, Iσ_e^2) is a vector of residuals. The terms σ_m^2, σ_c^2, σ_e^2, is for the microbial, farm, and residual variances respectively, and I is an identity matrix. Following Difford *et al.* (2018), microbiability was estimated as the proportion of phenotypic variance associated with differences in the microbiome, calculated as $\hat{m}^2 = \hat{\sigma}_m^2/(\hat{\sigma}_m^2 + \hat{\sigma}_c^2 + \hat{\sigma}_e^2)$. The proportion of variance caused by the common environment effect of farm was estimated as $\hat{c}^2 = \hat{\sigma}_c^2/(\hat{\sigma}_m^2 + \hat{\sigma}_c^2 + \hat{\sigma}_e^2)$.

For estimation of additive genetic variance for MI, a genomic relationship matrix was computed following the second version of the method proposed by VanRaden (2008) and based on the 70 genotypes available. The following mixed model was used,

$$y = Xb + Wg + Uc + e \quad (2)$$

where terms are the same as in (1), with the exception of W, which is an incidence matrix associated with the vector of genotype effects g ~ N(0, G σ_g^2).

In order to determine if microbial information could help refine the heritability for MI, a third model was evaluated, where both the genomic and microbial relationship matrices were fitted and farm was kept as common environmental effect, as follows,

$$y = Xb + Zm + Wg + Uc + e \quad (3)$$

where the terms are as described for (1) and (2). All variance components and model effects were estimated with ASReml 4.1 (Gilmour *et al.*, 2015). Our main objective behind testing three different models was to investigate how well they would perform on our preliminary dataset. With that, we wanted to assess our the sampling strategy, what could be improved in our workflow, and what lessons we could learn for the 1000 samples we aim to collect.

Due to the limited size of our dataset and the nature of our analysis, our expectation was that our estimates would present large standard errors.

Results

Estimates for MI heritability (h^2), microbiability (m^2) and common environmental effect of farm (c^2) for the models tested are shown in Table 1. Microbiability based on microbial information from all 179 (analysis 1_a) was of 0.10±0.13 (m^2 ± SE) and it was not significant. When we moved on to compute m^2 using data from cows with genotypes (analysis 1_b), the estimated value was zero. In analysis 1_a, c^2 was fairly small, 0.06±0.07 (c^2 ± SE); however, once we limited the model to use only data from cows with genotypes, c^2 increased to 0.20±0.19, while m^2 was zero. Heritability for MI, estimated based on 70 genotypes (analysis 2), was 0.06±0.37 (h^2 ± SE) and it was not significant, while c^2 was 0.19±0.19. When fitting both genomic and microbial relationship matrices (analysis 3), estimates for h^2, m^2 and c^2 were the same as the ones obtained for analysis 1_b and 2.

Discussion

There has been a plethora of literature over the past decade showing that there is a genetic component influencing methane production from cattle, regardless of the methane phenotype chosen (de Haas *et al.*, 2017). In this study, we looked at methane intensity. Heritability was low and not significant. High SE were expected due to the limited size of our preliminary dataset. Using methane data from a combined database, where methane was measured with different equipment but where GreenFeed data was present, Manzanilla-Pech *et al.* (2021) obtained a heritability of 0.38 for methane intensity; therefore, we can speculate that our estimates will improve as our dataset grows, and the lessons we have learned by conducting this study will increase the chances of obtaining significant heritability estimates for MI.

In our study, m^2 estimates were highly confounded with c^2. We believe that due to the limited dataset, the models are not able to properly separate the variance explained by the differences in microbiome from

Table 1. Heritability, microbiability and common environmental effect estimates for the different models[1].

Analysis	Group size	h^2 (SE)	m^2 (SE)	c^2 (SE)
1_a	179	NE	0.10 (0.13)	0.06 (0.07)
1_b	70	NE	0 (0.00)	0.20 (0.19)
2	70	0.06 (0.37)	NE	0.20 (0.20)
3	70	0.06 (0.37)	0 (0.00)	0.20 (0.20)

[1] h^2 = heritability for methane intensity; m^2 = microbiability for methane intensity; c^2 = common environmental effect of farm; SE = standard error; NE = not estimable.

the common environmental effect of farm. Data on the 70 cows with genotypes available came from eight different herds, and the number of cows per herd is not evenly distributed. When looking at m^2 based on 179 cows, the model more efficiently separated the microbial effect from the common environmental effect, indicating that data on more animals could help separating both effects.

With the experience of the confounding between farm and microbiome, we propose sampling on fewer farms and sampling as many cows as possible within a farm (here the number of cows per farm was smaller than the number of farms). Due to GreenFeed having a throughput limitation, we will need a method that allows for large scale phenotyping such as the sniffers, but that will mean compromising on the methane trait used. We were also limited by the ratio of cows that had both microbiome and genotype, therefore farms should be selected based on the proportion of animals in the herd already genotyped.

Conclusions

Even though more genotypes are needed in order to obtain significant h^2 estimates for MI, our results have highlighted the importance of modifying our sampling strategy for the next step of our project. The focus will be on data collection from fewer farms, increasing the number of cows per farm, in order to minimize the effect of c^2 on m^2, therefore improving our estimates of microbial effects. With that, we hope to get a deeper look into how the microbiome can be useful in explaining the variance we observe in methane emissions from dairy cows.

26. Phenotypic differences and genetic parameters for methane concentration in BeefxDairy crossbred slaughter calves

K. Johansen[1*], M. Kargo[1], M. Bjerring[2], P. Løvendahl[1] and A.J. Buitenhuis[1]

[1]Aarhus University, Center for Quantitative Genetics and Genomics, Blichers Allé 20, 8830 Tjele, Denmark; [2]Aarhus University, Department of Animal Science, Blichers Allé 20, 8830 Tjele, Denmark; kresten.johansen@qgg.au.dk

Abstract

Genetic selection for reduced methane emission and BeefxDairy crossbreeding are strategies to lower the climate impact of beef. Combined they require knowledge of phenotypes on methane production for BeefxDairy offspring. Slaughter calves sired by Belgian Blue, Charolaise and Angus sires to Holstein dams were compared to purebred Holstein calves. Heritability for methane concentration (CH_4c) were estimated for Belgian blue crosses. Raw phenotypic means showed that CH_4c was lower for calves born after Charolaise and Angus sires compared to Belgian Blue. The heritability of log transformed CH_4c for Belgian blue crosses was estimated to be 0.44 (±0.08), and for log transformed CH_4c adjusted for background CH_4 it was 0.33 (±0.06). This is in line with heritabilities found for log transformed CH_4c in Holstein cows, and will be the basis for further analysis in genetic architecture of methane traits in crossbred slaughter calves.

Introduction

Reducing methane production from the dairy cattle population through genetic selection is seen as one of the ways to reduce the carbon footprint of cattle production. An increasing practice for Danish dairy farmers is insemination of low genetic merit dairy cows with beef semen to increase the value of the slaughter calf and overall income of the farm (Ettema *et al.* 2017). This reduces carbon footprints per kg carcass compared with purebred dairy calves (Mogensen *et al.*, 2015). The beef sires are currently selected on calving ease, youngstock survival and carcass traits (Davis *et al.*, 2020), but new traits could possibly lead to higher efficiency and lower climate impact.

Currently there is a lack of knowledge, whether the sire breed affects methane (CH_4) emission of BeefxDairy offspring, but also if there is variation between sires. Methane concentrations measured relative to CO_2 concentrations in the breath using the sniffer method has a high throughput and has been shown to be heritable in dairy cows (Lassen and Løvendahl, 2016). The aim of this paper is to investigate the distribution of CH_4 concentration in different crosses and estimate the heritability of CH_4 concentration in Belgian Blue (BBL) and Holstein (HOL) crossbred calves.

Materials & methods

Data were collected in the period June 2020 until November 2021. Calves were born on dairy farms in Denmark between July 2019 and June 2021. Six slaughter calf producers purchased these calves at the age of 3-8 weeks, and in these herds the animals were later phenotyped. 2,224 calves were crossbred, either a BBL (n=1,689), Charolaise (CHA) (n=306) or Angus (ANG) bull (n=229) on a Holstein dam. Purebred HOL bull calves (n=429) were also phenotyped, to match the capacity of the system. Calves were raised on a pelleted concentrate ration and offered *ad lib* straw, in five herds. One herd fed total mixed ratio (TMR). Feed intake on pelleted feed and TMR was measured in feed boxes, the feed was weighed as the calf entered and left the feed box. The calf entered the pens between 6 and 10 months of age and stayed in the pen for at least three weeks.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_26, © K. Johansen *et al.* 2022

CO_2 and CH_4 concentrations were measured in feed boxes using the non-invasive infrared gas sensor (Guardian® NG, Edinburgh Instruments Ltd.). Three feed boxes were available for each pen and neighbouring pens shared a Guardian Sensor. The intake air tube for gas measurements were located in front of the calf when it was eating the feed. Feed intake was registered at every visit, whereas gas concentrations was measured in one of the six feed boxes connected to the Guardian Sensor. During visits with gas recording, CO_2 and CH_4 concentrations were registered every other second. Gas concentrations were adjusted for background concentrations and detection of eructations was made using double exponential smoothing (Difford *et al.* 2016). Gas visits where required to contain at least one eructation with methane concentration >500 ppm and be of length longer than 50 seconds. The average CH_4 concentration (ppm) (CH_4c) of the visit was used for estimating genetic parameters. Twice daily the gas sensors were running a reference measurement to measure background gas concentration, which was used to adjust the methane concentration. The adjusted phenotype (CH_4a) was calculated for all visits using the most recent reference measure. To ensure the residuals were normally distributed, both variables were transformed by the natural logarithm (logCH_4c, logCH_4a), to ensure normal distribution for the genetic parameter analysis.

Genetic analysis. Due to sample size, only phenotypes from BBLxHOL calves were used for estimating genetic parameters. For the variance component estimation, using the average information restricted maximum likelihood algorithm (AI-REML), the statistical software DMU was used (Madsen and Jensen, 2008). The univariate model for estimating genetic parameters for logCH_4c and logCH_4a was the following:

$$y= Xb+Z_1a+Z_2pe+e \quad (1)$$

where y is the vector of phenotypic observations, b is the vector of fixed effects (herd-sensor age in weeks, date of the visit, month-year of birth, sex, feed ration, hour of the day), a is the vector of additive genetic effects, pe is the vector of permanent random effects and e is the vector of random residual effect. The incidence matrix, X, assigns observations to fixed effects, Z_1 assigns the observations to random genetic effects and Z_2 assigns the observations to the permanent environmental effect. The distribution of the random effects was: var(a) = $A\sigma_a^2$, where A is the additive genetic relationship matrix and σ_a^2 is the additive genetic variance; var(pe) = $I\sigma_{pe}^2$ where I is an identity matrix and σ_{pe}^2 is the permanent environmental variance; var(e) = $I\sigma_e^2$ where σ_e^2 is the residual variance. Standard error of the estimates was estimated by calculating asymptotic standard errors. The repeatability was calculated as ratio between the sum of additive variance and permanent effect variance, and the phenotypic variance. The heritability was calculated as the ratio between additive variance and phenotypic variance.

Results

The logCH_4 concentration for each cross and herd is shown in Figure 1. Descriptive statistics of visits and methane concentration are presented in Table 1. The number of visits varied between breed groups. The slaughter calf producer contributed with different number of calves due to difference in capacity at sights (farm1=288, farm2=1,583, farm3=62, farm4=71, farm5 =554, farm6=105). The calves represented both sexes (bull=1,620, heifer=1,043). Phenotypic means and standard error of the mean of methane concentration are presented in Table 1.

The genetic parameters were estimated on the 1,689 BBL×HOL calves. The results from the parameter estimation are shown in Table 2. The heritability of the traits are moderate for logCH_4c and logCH_4a, and all significantly different from zero. Repeatability for logCH_4c and logCH_4a is equal to the heritability.

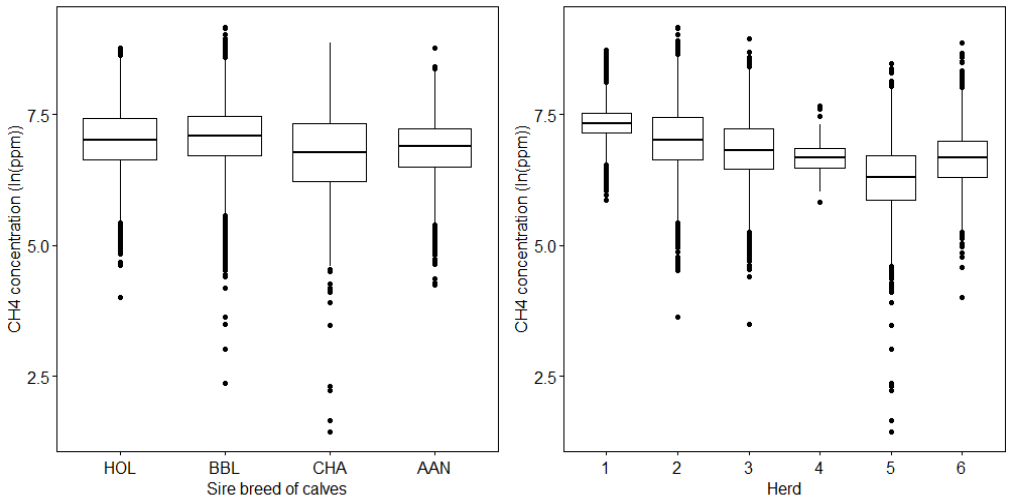

Figure 1. CH_4 concentration (ln transformed) for the breed combinations (left) and between the herds (right).

Table 1. Phenotypic means and standard error of the mean (SEM) for methane visits and traits[1] for each breed group[2] of slaughter calves.

Trait	BBL×HOL	CHA×HOL	ANG×HOL	HOL
Visits per animal (n)	45.4 (1.35)	21.0 (1.89)	23.8 (1.62)	40.0 (2.55)
Visit time (s)	43.8 (0.71)	42.5 (1.55)	49.1 (2.00)	39.7 (1.32)
CH4c (ppm)	1,404 (20.0)	1,066 (41.2)	1,091 (39.3)	1,361 (40.0)
CH4a (ppm)	1,029 (17.8)	729 (33.9)	768 (33.2)	1,076 (35.2)
logCH4c (ln(ppm))	7.09 (0.01)	6.74 (0.04)	6.85 (0.04)	7.05 (0.03)

logCH4a	0.30	0.30 (0.06)

[1] $logCH_4c$ = ln transformed methane concentration, $logCH_4a$ = ln transformed methane concentration adjusted for background.

Discussion

This work is the first step on the road to achieving a methane phenotype for BeefxDairy crossbred calves. The level of CH_4 concentration is higher than what was measured in Danish Holstein cows, when methane was measured in the milking robot (Difford *et al.*, 2020; Manzanilla-Pech *et al.*, 2021). Mean CH_4 concentration CHAxHOL and ANGxHOL was lower compared to BBLxHOL and purebred HOL (Table 1). Variation within groups is large (Figure 1), so conclusions should be made with caution. No difference in CH_4 was seen between herds, and variation was not consistent across herds. This could be due to the use of TMR in one case (Herd 4).

The repeatability was equal to the estimated heritability. This is caused by the estimated permanent environmental effect being zero. This conflicts with other studies in dairy cows, where the repeatability was a lot higher than the heritability (Difford *et al.*, 2020). The standard error in the estimates in this study is however large. Increasing the sample size will provide a lower estimate of the standard error and a higher accuracy.

The heritabilities for CH_4 concentration was estimated with a large standard error, but is in range with CH_4 traits from other studies (Difford *et al.*, 2020; Hayes *et al.*, 2016; Lassen and Løvendahl, 2016, Manzanilla-Pech, 2021). Log transformed CH_4 concentration is used when estimating parameters on CH_4 concentration to meet the requirement of normal distributed residuals (Difford, *et al.*, 2016). Methane concentration can be extrapolated to a daily methane production which has a moderate heritability in lactating HOL cows (Manzanilla-Pech, *et al.* 2021). CHAxHOL and ANGxHOL had a lower phenotypic mean CH_4 concentration compared to BBLxHOL and purebred HOL. The heritability of CH_4 concentration was estimated to be moderate in BBLxHOL crosses. Further work will develop this phenotype further and investigate the genetic architecture of the trait.

Abstract

This study aimed to identify genomic regions associated with two mid infrared-based CH_4 traits [predicted daily CH_4 emission (PME, g/d), and log-transformed predicted CH_4 intensity (LMI)] in Walloon dairy cows. The data consisted of 1,529,282 test-day records from 229,465 cows distributed in 1,530 herds collected from 2006 to 2021. Random regression test-day models were used to estimate variance components. The proportion of genetic variance explained by windows of 50 consecutive SNPs was calculated and regions accounting for at least 1.0% of the total genetic variance were identified. Mean (SD) daily h^2 estimated for PME and LMI were 0.14 (0.05) and 0.24 (0.05), respectively. Two regions on BTA14 (positions 1.86 to 2.12, and 1.48 to 1.68 Mb) were associated with both PME and LMI. A region between 144.38 to 144.46 Mb on BTA1 was associated with PME; and the region between 2.68 and 2.94 Mb on BTA14 was associated with LMI. Results showed potential for genome-enhanced advisory systems to reduce methane emissions.

Introduction

Emissions of greenhouse gases (GHG) have a considerable impact on climate change. Livestock production is a significant contributor to global human-induced GHG emissions in the form of CH_4, N_2O and CO_2 (De Haas *et al.*, 2021). Dairy cattle account for 20% of the global livestock sector's GHG, and over half of this is from enteric CH_4 emissions (Gerber *et al.*, 2013). Although a reduction in CH_4 emission could be achieved by using different CH_4 mitigation strategies like management or feeding (Cottle *et al.*, 2011), a genetic selection of low CH_4 emitting cows can be an effective approach to reduce GHG production from dairy cattle. The genetic variation on CH_4 emission is influenced by many genes with heterogeneous effects (Sypniewski *et al.*, 2021). However, there is currently a gap in the knowledge on the genetic architecture of this new trait (Kandel *et al.*, 2017; Sypniewski *et al.*, 2021). The short-term aim of this study was to estimate the genetic parameters of two MIR-based CH_4 features for the first-parity Walloon dairy cows and to identify their associated genomic regions. The long-term objective is to contribute to genome-enhanced advisory systems to reduce methane emissions.

Materials &methods

Data. Milk samples were collected on first parity cows from 2006 to 2021 by the Walloon Breeding Association (Ciney, Belgium). All milk samples were analysed using Milkoscan FT4000, FT6000, and FT+ (Foss-Electric A/S, Hillerød, Denmark) by the milk laboratory Comité du Lait (Battice, Belgium) to generate the MIR spectral data. Methane emissions (PME, g/d) were predicted from the recorded spectra using the equations developed by Vanlierde *et al.* (2021). To eliminate potential abnormal records, the PME values below the 0.1 percentile and above the 99.9 percentile were deleted (Kandel *et al.*, 2017). Methane emission intensity (PMI, g/ kg of milk) was defined as the ratio of PME divided by the daily milk yield (kg/d) recorded on the same test-day. This PMI was then log-transformed to be normally distributed and called log-transformed CH_4 intensity (LMI). Data were edited to include only cows with known birth date. Records from days in milk (DIM) lower than 5 d and greater than 365 d were eliminated. Age at the first calving (AFC) was restricted to the range of 540 to 1,200 d. Daily milk yield was restricted to the range of 3 to 99 kg. The final dataset consisted of 1,529,282 test-day records on 229,465 cows distributed in 1,530

herds collected from 2006 to 2021. More than 95% of cows included were Holstein. Genotypic data of 730,539 SNPs were available for 7,381 animals. SNPs with minor allele frequency less than 5%, and those that did not pass the Hardy-Weinberg equilibrium were excluded. In total, 565,049 SNPs were kept for genomic analyses.

Variance component estimation. The (co)variance components and genomic breeding values for PME and LMI were estimated based on the integration of the random regression test-day model (RR-TDM) into single-step GBLUP procedure (SS RR-TDM) using the following model:

$$y_{ijklm} = \mu + HTD_i + \sum_{b=0}^{4} AS_j \phi_b(t) + \sum_{b=0}^{2} HY_k \phi_b(t) + \sum_{b=0}^{2} pe_l \phi_b(t) + \sum_{b=0}^{2} a_l \phi_b(t) + e_{ijklm} \quad (1)$$

where y_{ijklm} is the test-day record (PME or LMI) on DIM m of cow l, belonging to i^{th} class of HTD, j^{th} class of AS, and k^{th} class of HY, HTD is the fixed effect of herd-test-day, AS is the fixed effect of age-season of calving defined as following: age at calving class (10 classes) × season of calving (four seasons), $\sum_{b=0}^{4} AS_j \phi_b(t)$ is the fixed regression coefficients of the age-season at calving modelled using Legendre polynomials of order 4, $\sum_{b=0}^{2} HY_k \phi_b(t)$, $\sum_{b=0}^{2} pe_l \phi_b(t)$ and $\sum_{b=0}^{2} a_l \phi_b(t)$ are, respectively, the random regression coefficients of herd-year at calving (HY), permanent environment, and additive effects modelled using Legendre polynomials of order 2, and e_{ijklm} is the residual effect.

The variance components were estimated through the Bayesian Gibbs sampling method using a single chain of 100,000 iterations after a burn-in period of 20,000. The vector of genomic estimated breeding values (GEBV) of the included traits for each animal i, was estimated by multiplying the vector of predicted regression coefficients of the additive genetic effect by the matrix of Legendre orthogonal polynomial covariates; that is, $GEBV_i = T\hat{g}_i$, where $\hat{g}_i$ is the vector of predicted regression coefficients of the additive genetic effect for animal i, and T is a matrix of orthogonal covariates associated with the Legendre orthogonal polynomial functions. The SNP effects were estimated individually for the included traits using the postGSf90 software (Aguilar *et al.*, 2014). The animal effects were decomposed into those for genotyped (a_g) and ungenotyped animals (a_n). The animal effects of genotyped animals are a function of the SNP effects, $a_g = Zu$, where Z is a matrix relating genotypes of each locus and u is a vector of the SNP marker effect. The variance of animal effects was assumed as:

$$Var(\mathbf{a_g}) = Var(\mathbf{Zu}) = \mathbf{ZDZ'}\sigma_u^2 = \mathbf{G}\sigma_a^2 \quad (2)$$

where D is a diagonal matrix of weights for variances of markers (D = I), σ_u^2 is the genetic additive genetic variance captured by each SNP marker when the weighted relationship matrix (G) was built with no weight. The SNP effects were obtained using following equation:

$$\hat{u} = \lambda \mathbf{DZ'}\,\mathbf{G^{-1}}\,\hat{a}_g = \mathbf{DZ'}[\mathbf{ZDZ'}]^{-1}\hat{a}_g \quad (3)$$

where λ was defined by VanRaden (2008) as a normalizing constant, as described below:

$$\lambda = \frac{\sigma_u^2}{\sigma_a^2} = \frac{1}{\sum_{i=1}^{M} 2p_i(1-p_i)} \quad (4)$$

The percentage of genetic variance explained by the i^{th} genomic region was estimated as:

$$\frac{Var(a_i)}{\sigma_a^2} \times 100\% = \frac{Var(\sum_{j=1}^{50} Z_j \hat{u}_j)}{\sigma_a^2} \times 100 \quad (5)$$

where a_i is the genetic value of the i^{th} region that consists of 50 adjacent SNPs, σ_a^2 is the total genetic variance, Zj is the vector of the SNP content of the j^{th} SNP for all individuals, and $\hat{u}_j$ is the marker effect of the j^{th} SNP within the i^{th} region. The results were presented by the proportion of variance explained by each window of 50 adjacent SNPs (with an average size of 165 kb) and windows explaining for at least 1.0% of the total additive genetic variance were identified.

Results

Means (SD) for PME, PMI and LMI were 326.8 (67.65) g/d, 14.97 (5.70) g CH_4/kg of milk yield, and was 2.64 (0.35), respectively. Predicted CH_4 and LMI reached a maximum of 341.6 g/d and 2.83 by DIM 80 and 344, respectively (Figure 1-A). Heritability estimates for PME and LMI were relatively stable across lactation, with a mean h^2 of 0.14 and 0.24, and peak h^2 of 0.21 (DIM 186) and 0.30 (DIM 211), respectively (Figure 1-B, Table 1). Two regions on BTA14 (positions 1.86 to 2.12, and 1.48 to 1.68 Mb) were associated with both PME and LMI. A region between 144.38 to 144.46 Mb on BTA1 was associated with PME; and the region between 2.68 and 2.94 Mb on BTA14 was associated with LMI (Figure 1-C, and 1-D). Functional genes including *LY6D*, *GML*, *CYHR1*, *PPP1R16A*, *ARHGAP39*, *ZNF7*, *OPLAH*, *MAF1*, and *SPATC1* were identified as potential candidate genes for PME and LMI (Assembly UMD3.1).

Table 1. Mean (SD) phenotypic values and heritability estimates for considered milk mid-infrared-based CH_4 features.

	Phenotypic values		Heritability		
Trait	**Mean**	**SD**	**Mean**	**SD**	**range**
PME[1]	326.8	67.65	0.14	0.05	0.06-0.21
LMI[2]	2.64	0.36	0.24	0.05	0.16-0.30

[1] Methane emission (PME, g/d) predicted from the recorded milk MIR spectra.

[2] Log-transformed CH_4 intensity (LMI) based on the ratio of PME divided by the daily milk yield (kg/d).

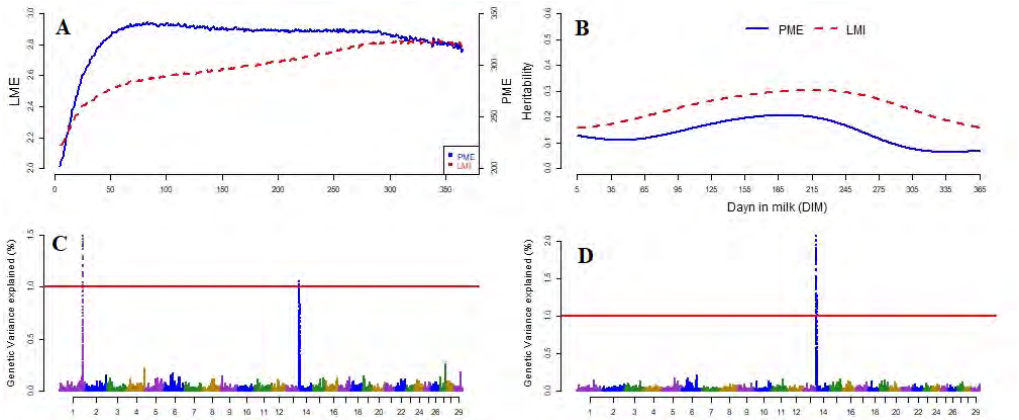

Figure 1. The lactation curves for PME (solid) and LMI (dashed) (A). Heritability estimates for PME (solid) and LMI (dashed) throughout lactation (B). Manhattan plots for PME (C) and LMI (D). The x-axis indicates the BTA number and the y-axis indicates the percentage of additive genetic variance explained by the window of 50 SNPs. The PME is the CH_4 emission (g/d) and the LMI is the log transformed of CH_4 intensity (g CH_4/kg of milk yield).

Discussion

We aimed to estimate genetic parameters and identify genomic regions associated with CH_4 emission in Walloon dairy cows. The mean PME found (326.8 g/d) was in the range reported by previous studies (Pickering *et al.*, 2015; Kandel *et al.*, 2017). Moderate h^2 were estimated for PME and LMI in agreement with the literature (Kandel *et al.*, 2017; Sypniewski *et al.*, 2021). Three genomic regions were found on BTA14 which, when combined, explained 2.10 and 3.35% of the total genetic variance of PME and LMI, respectively. The genomic regions and genes associated with PME and LMI have been previously reported to be associated with milk yield and composition in dairy cows (Bennewitz *et al.*, 2004; Atashi *et al.*, 2020). However, this is the first report on the association between these regions and CH_4 emission in cattle. In conclusion, the moderate h^2 found indicates that the studied traits can be introduced in the breeding programs. Further studies must be conducted to evaluate the relationship of our mid-infrared-based CH_4 traits to direct CH_4 traits and the effect of their inclusion in current breeding objectives. Moreover, large database could be used for genome-enhanced consulting systems to reduce methane emissions.

28. Genetic parameters for feed efficiency, gas emissions, oxygen consumption and wool traits in Australian Merino

C.B. Marques*, I. De Barbieri, J. Velazco, E.A. Navajas and G. Ciappesoni*

Instituto Nacional de Investigación Agropecuaria, INIA Las Brujas, 90100, Rincón del Colorado, Ruta 48 km 10, Canelones, Uruguay; cbalconi@inia.org.uy; gciappesoni@inia.org.uy

Abstract

The purpose of the present study was to estimate genetic parameters of growing globally important traits such as feed intake, residual feed intake, methane, carbon dioxide, oxygen consumption and greasy fleece weight in Uruguay. Data of three Australian Merino generations which integrate the Uruguayan National Genetic Evaluation for sheep were recorded (from 2019 to 2021). Heritabilities and genetic and phenotypic correlations were estimated for 930 animals sired by 19 rams. Results presented suggest that relevant genetic progress can be achieved in all traits (heritabilities between 0.23 and 0.41). Methane emission present moderate to high genetic correlations with the other traits (0.57-0.88). The most efficient animals will tend to consume less feed and emit less methane, without affecting wool production. The genetic correlation between wool production and the other traits were not significantly different from zero. The developing of this work will be the basis for the construction of agroecological breeding objectives.

Introduction

Ruminants emit methane (CH_4) through enteric fermentation in their digestive tract, which represents a loss of 6 to 10% of gross energy intake and is a significant source of anthropogenic CH_4 emissions globally (Schaefer *et al.*, 2016). Sheep emissions and their associations with feed intake and production traits are currently investigated as part of the implementation of greenhouse gas (GHG) mitigation strategies. Genetic selection of efficient and low-emitting animals is promising, as long as these traits are heritable. If a favourable correlation exists between traits such as feed efficiency and CH_4 emissions, a mitigation of CH_4 production could be obtained as a response of selecting for more efficient animals. The purpose of the present study was to estimate genetic parameters for feed efficiency, GHG emissions, oxygen consumption and wool production traits in Australian Merino lambs in Uruguay.

Materials & methods

Data and traits. Data of three Australian Merino generations which integrate the Uruguayan National Genetic Evaluation for sheep were recorded from 2019 to 2021. Information from 930 animals sired by 19 rams was available on the following traits: feed intake (FI), residual reed intake (RFI), CH_4, carbon dioxide (CO_2), oxygen consumption (O_2) and greasy fleece weight (GFW). The 2020 progeny was the first in which several of their dams (27%) or sires (15%) or both parents (4%) had also been recorded for feed intake and gas emissions as lambs in 2019. Descriptive statistics and data structure for ages (at trial and at shearing) and all the traits investigated are presented in Table 1.

Feed efficiency measurements. Three RFI tests were carried out per year (9 in total) where animals were allotted based on sex, birth type and age. After 14 days of acclimatization, each test period had a duration of 42 days, in which animals were allocated to one of five outdoor pens, with five automated feeding systems in each pen, according to body weight, sex and sire. Lambs were fed *ad libitum* with Lucerne haylage. Each pen had two automatic weighing platforms that allowed individual weight control.

Table 1. Descriptive statistics and data structure for ages, residual feed intake (RFI), feed intake (FI), oxygen consumption (O_2), methane (CH_4), carbon dioxide (CO_2) and greasy fleece weight (GFW) traits.

Trait	n	Mean	Standard deviation	Min	Max
Age at trial (days)	930	295.33	45.79	204	378
Age at shearing (days)	930	413.03	8.97	387	432
RFI (kg/dry matter/day)	930	-0.001	0.15	-0.43	1.58
FI (kg/dry matter/day)	930	1.33	0.27	0.67	3.16
CH_4 (g/day)	930	22.43	5.61	8.91	44.66
O_2 (g/day)	930	981.37	191.96	427.33	2,114.66
CO_2 (g/day)	930	1,067.45	234.71	478.18	2,269.63
GFW (kg)	918	4.13	0.73	2.10	6.53

Portable accumulation chamber measurements. Sheep emissions were measured in portable accumulation chambers (PACs) made of polycarbonate sheet with an internal volume of 861.8 l (118.8-cm length × 120.7-cm height × 60.1-cm width), similar to those described by Goopy *et al.* (2011). The CH_4, O_2 and CO_2 concentration measurements were taken after confining the sheep in the PACs for a minimum time of 40 min. Total gas space inside the portable static chamber was estimated by assuming that the volume occupied by the sheep was equal to 1.01 L/kg liveweight (Jonker *et al.*, 2018) and subtracting the liveweight of the sheep from the internal volume of the chamber. Data analysed was the mean value of two measurements collected around day 30 and day 37 in trial. Using an analogous methodology as the described by Goopy *et al.* (2011), a calculation was performed to convert the CH_4, O_2 and CO_2 concentration from PACs to daily measurements.

Statistical analyses. A Bayesian analysis and an assessment of variance and covariance components using GIBBSF90 computer package (Misztal *et al.,* 2002) was performed. The number of iterations after burn-in used for posterior inferences was 300,000 with the model:

$y_{ijklm} = CG_i + BT_j + DA_k + age_l + a_m + e_{ijklm}$ where: y_{ijklm}: m^{th} performance record of animal l, CG_i: fixed effect of the contemporary group i (year-management group-sex-pen-trial, 134 levels), BT_j: fixed effect of birth type j (2 levels), DA_k: fixed effect of dam age k (3 levels), age: age at m measurement of animal l as a co-variable, a_l:random additive genetic effect of animal l (1,962 animals), and e_{ijklm}: random residual.

Results

Heritabilities, genetic and phenotypic correlations estimated are shown in Table 2. Moderate magnitude heritabilities between 0.23 and 0.41 were found for all traits. The three gases presented the lowest values. High genetic correlations were observed between RFI with FI and CH_4, FI with the three gases, and CO_2 with O_2 and CH_4 (range 0.64-0.97). The genetic relationship of RFI with CO_2 and O_2 with CH_4 were moderate (0.50-0.57). In this work, genetic correlations estimated between GFW and feed efficiency and greenhouse traits, as well as between RFI and O_2, were not significantly different from zero.

When analysing the phenotypic results, high correlation values were found between RFI and FI, and between CO_2 and other two gases (0.64-0.93). Phenotypic relationship was moderate between FI and the three gases, and also between O_2 and CH_4 (0.28-0.57). The phenotypic correlations of RFI with CH_4, CO_2 and GFW were not significantly different from zero.

Table 2. Genetic and phenotypic parameters for residual feed intake (RFI), feed intake (FI), oxygen consumption (O_2), methane (CH_4), carbon dioxide (CO_2) and greasy fleece weight (GFW) traits in Australian Merino breed[1].

	RFI	FI	O_2	CH_4	CO_2	GFW

[1] Heritabilities (in bold) on the diagonal, phenotypic and genetic correlations below and above the diagonal, respectively, posterior standard deviation in parenthesis.

In general, genetic correlations were of higher magnitude than phenotypic, except for GFW that also had genetic correlations close to zero with all other traits.

Discussion

To the authors' knowledge, this is the first study that reports genetic parameters for feed efficiency related traits together with gas emissions, oxygen consumption and wool production. The current study presents phenotypic values very similar and at least comparable to several others in literature, such as for FI (François *et al.*, 2002), O_2 (Jonker *et al.*, 2018), CH_4 (Jonker *et al.*, 2018; Pinares-Patiño *et al.*, 2013), CO_2, and GFW (Huisman *et al.*, 2008). In the case of GFW phenotypic parameters, Ciappesoni *et al.* (2010) reported a lower mean for the same breed and country which can be explained by the population structure. The current study used data from recent years of an animal selection nucleus, where a favourable genetic trend for heavier GFW is observed (www.geneticaovina.com.uy).

As genetic improvement by animal selection is possible as long as the selected traits are heritable, the moderate heritabilities presented in this work indicate that promising and faster genetic gains can be achieved in all traits. The heritability values presented for RFI and FI are very similar to those described by François *et al.* (2002), but higher than the heritability values reported by Cammack *et al.* (2005) of 0.11 and 0.25 for RFI and FI, respectively. The limited published literature for heritability of O_2 consumption in sheep is reported as 0.21 (Jonker *et al.,* 2018). In the same study, heritability estimates for CH_4 production and CO_2 were 0.19 and 0.16 for lambs, and 0.20 and 0.27 ewes, respectively. Similar CH_4 heritability estimates were also reported by Pinares-Patiño *et al.* (2013) and Robinson *et al.* (2010). Regarding GFW heritability, our estimate is in agreement with those found by Huisman *et al.* (2008) (0.46), and Ciappesoni *et al.* (2010) (0.45).

A slightly higher value for the genetic correlation between CH_4 and CO_2 of (0.84) and (0.86) was reported by Jonker *et al.* (2018) and Paganoni *et. al*, (2017), respectively. Thus, still in accordance with our high genetic correlation between CH_4 and CO_2.

When evaluating greenhouse gas mitigation strategies, the favourable genetic correlation between RFI efficiency and greenhouse gas emissions is promising in the search for more efficient animals. However, these preliminary data must be taken with caution until more information continues to record, and more precise estimates can be achieved.

Furthermore, GFW correlations were not significantly different from zero, showing that animal selection with emissions mitigation purpose should not impact wool production, which is one of the most important selection objectives in Merino breed. Therefore, the current selection for GFW does not seem to affect the efficiency of the animals or increase emissions. These favourable to zero genetic correlations would make possible to find more animals that face several objectives at the same time: productive, economic, and environmental.

The development of intensive phenotyping systems for traits related to feed intake, efficiency, and greenhouse gas mitigation in association with the estimation of genetic parameters gets on greater significance when is linked to stud-flocks and commercial populations. This will allow the identification of potential trade-off between traits and the implementation of genetic improvement programs for individual traits, or within a more holistic vision such as the agroecological breeding objectives.

Abstract

Residual feed intake (RFI) and methane (CH_4) emissions are potential new selection objectives in beef and sheep breeding programmes to assist reaching greenhouse gas mitigation targets and to support economic, social, and environmental sustainability. Phenotyping platforms in both species are in place in Uruguay, linked with the genetically evaluated populations of main breeds (Hereford, Merino, Corriedale, Dohne and Texel), being the basis of the reference populations for genomic selection. Current progress and main findings are described here. New selection indexes and selection criteria, as residual CH_4, are needed given the potential unfavourable associations between CH_4 and performance. Larger reference populations imply higher genomic prediction accuracies, accurate estimations of genetic correlations among feed intake, RFI, CH_4 and performance and a comprehensive understanding of these associations. On-going rumen metagenomics and metatrascriptomics will also provide information about its value as predictor of genetic merit of these traits.

Introduction

Global concerns regarding mitigation of greenhouse gas (GHG) emissions and efficient use of limiting resources is intensifying, as well as pressures to achieve national targets in the context of international environmental agreements. The identification of alternatives to support sustainable development is particularly relevant for countries whose economy relay on sheep and cattle production, such as Uruguay. The incidence of enteric methane (CH_4) in the total GHG emissions tend to be high in these countries (i.e. 46%, Uruguay) and drastic alternatives, such as reducing national flocks and herds to decrease total CH_4 would have significant unfavourable economic and social implications. Emission intensity (CH_4 per unit of product) is one of the indicators proposed to assess progress of GHG mitigation keeping the balance among environmental, economic, and social sustainability.

Genetic selection can contribute to both components of emission intensity. Uruguay have had breeding programmes in beef cattle and sheep for 30 years, and genetic progress have been reported for individual traits and selection indexes in both species. Although this looks promising in terms of enhancing the contribution of genetic selection to reduce emission intensity, improving production accompanied with higher feed intake may jeopardise the expected progress (Barwick *et al.*, 2019). Feed intake, feed efficiency and GHG emissions are recorded in new phenotyping platforms with the aim of evaluating strategies to incorporate these traits into the national breeding programmes supporting sustainable development (Phocas *et al.*, 2016). Here we describe the research approach carried out in cattle and sheep in Uruguay since 2014, in connection with breeding programmes, results and limitations.

Feed intake and efficiency

Feed efficiency measurements rely on feed intake records (adjusted by dry matter, DMI), which is a difficult-to-measure trait in large number of animals. Commercial availability of automated feed intake recording systems contributed to partially overcome this limitation. Post-weaning feed efficiency tests of Hereford bulls and steers started in 2014 at the Central de Prueba Kiyú of the Hereford Breeders Society of

Uruguay, with the aim of implementing genomic selection of residual feed intake (RFI) (Ravagnolo *et al.*, 2018). Nowadays, the national database includes post-weaning feed efficiency information of 960 pedigree bulls and 560 steers. More recently, RFI at finishing (feedlot) is also evaluated in steers immediately after the postweaning test. A similar initiative is carried out in the main sheep breeds in Uruguay in INIA Experimental Station La Magnolia, with 981 Merino, 300 Corriedale, 367 Dohne and 77 Texel lambs recorded at the end of 2021. These animals belong to Selection Nucleus (Merino), Information Nucleus (Corriedale, Dohne) and Central Progeny Testing (Texel) and are strongly connected with population in the genetic evaluation (performance recorded).

Koch *et al.* (1963) defined RFI as the difference between actual and predicted DMI, based on average daily gain (ADG) and metabolic body weight (MBW). Improving feed efficiency by selecting for RFI is an appealing breeding objective because of the associated increase of farmers net income by reducing feed costs without compromising animal performance. At a production system or national level, improving RFI could also be interpreted as a contribution to optimise the use of limiting resource, such as land in grazing-based systems. The final impact will depend on its genetic variability and covariance with other breeding objectives.

Heritability of RFI and association with production traits

As previously reported in the literature, RFI is a moderately heritable trait in Uruguayan Hereford and Merino breeds, with estimates of 0.25 (Pravia *et al.*, 2022, unpublished) and 0.27 (Marques *et al.*, WCGALP 2022), respectively. The genetic correlations (r_G) of RFI and the traits used for its estimation in Hereford were similar to the phenotypic associations (r_p): positive correlations with DMI (r_P=0.63; r_G=0.40) and very low or zero with ADG (r_G=0.07; r_P=-0.003) and MBW (r_G=-0.12; r_P=-0.001).

Accurate estimations of genetic parameters depend on large databases, principally for genetic correlations, which is challenging for difficult-to-measure traits. Consequently, many of the first studies rely on phenotypic associations and comparisons between animals with extreme values for the traits of interest, particularly when aiming to establish the associations of RFI with other difficult-to-measure traits, such as carcass and meat quality. In agreement with other studies, no significant differences were found in pasture-based finishing performance, carcass quality, meat production and quality between high- and low-RFI steers, based on their post-weaning RFI (Pravia *et al.*, 2018). The analysis of post-weaning RFI and feedlot RFI in 100 Hereford steers indicated that both feed efficiencies were strongly correlated (0.72), whilst AGD and MBW at finishing were independent of post-weaning and feedlot RFI (P>0.05) (Silveira *et al.*, 2022, unpublished data). Although there is evidence indicating that low RFI (high feed efficiency) was associated with lower fatness, we did not find unfavourable phenotypic associations between RFI and fatness measured *in vivo* or post-slaughter, or in terms of genetic correlations (r_P=0.08; r_G=0.01, Pravia *et al.*, 2022, unpublished). This may be explained by the incorporation of subcutaneous fat depth in the multiple regression model used for RFI estimation, as proposed by Basarab *et al.* (2003).

Studies in Corriedale lambs also indicated that RFI tends to be independent of growth, wool production, and genetic resistance to gastrointestinal parasites (Navajas *et al.*, WCGALP 2022, Ferreira *et al.*, 2021), whilst r_P and r_G between RFI and fleece weight in Australian Merino sheep were not significantly different from zero (Marques *et al.*, WCGALP 2022).

Genetics of GHG emissions in beef cattle and sheep

Methane and carbon dioxide (CO_2) emissions are being measured in all lambs with feed intake and efficiency records using Portable Accumulation Chambers (PAC) (Paganoni *et al.*, 2017), leading to a very interesting database that is used to investigate the association between current breeding objectives and

potentially new ones, such as RFI with GHG emissions. Similarly, GreenFeed stations are now installed and recording CH_4 during the feed efficiency tests in Hereford.

The first analysis in Corriedale and Merino lambs showed no-significant phenotypic association between RFI and CH_4 and CO_2 (Navajas *et al.*, WCGALP 2022), although a favourable positive genetic correlation was estimated in Merino which indicates that less efficient lambs are also higher emitters (Marques *et al.*, WCGALP 2022). This is in agreement with other studies in sheep (Paganoni *et al.*, 2017) and beef cattle (Fitzsimons *et al.*, 2013), reinforcing the possibility of using RFI as an indirect selection criterion for reducing GHG emissions. The lack of consistency among studies relies on different factors as discussed by Cantalapiedra-Hijar *et al.* (2018).

A consistent result across studies is the positive association of DMI with RFI, CH_4, as well as with animal productive performance. As mentioned before, several studies indicates that RFI tend to be independent of productive trait (null or low correlation) and moderate to highly correlated with DMI. Associations of similar magnitude have been reported between CH_4 and performance traits, suggesting a potential antagonism that could limit the scope of GHG mitigation strategies. Nonetheless, new CH_4-derived traits such as residual methane emissions and the development of multi-trait selection including DMI and CH_4 are promising alternatives to reduce CH_4 emissions while maintaining animal production (Manzanilla-Pech *et al.*, 2021; Smith *et al.*, 2021).

As DMI is a main driver of animal productivity and CH_4 emissions, disentangling the relationships among these traits is key, and requires considering not only animal genetics but also the role of rumen microbiota. On-going characterization of rumen microbial community and metabolic pathways by metagenomics and metatranscriptomics will contribute to a better understanding of these associations. These analysis in the Uruguayan reference populations will also provide information about its value as predictor of genetic merit.

Improving feed efficiency and methane emission by genetic selection

The complexity of measuring GHG emission and DMI to estimate RFI, clearly indicates the benefits of implementing genomic selection. Because of this, RFI and GHG emissions phenotyping platforms in sheep and beef cattle in Uruguay were designed as the initial reference populations for genomic selection based on national and international research funding. DNA samples are stored at INIA animal DNA bank and have been genotyped mainly with medium density (50k) single nucleotide polymorphism (SNP) panels. An initial binational reference population of 731 Uruguayan Hereford bulls and steers and 1168 Canadian bulls was the basis for the estimation of genomic expected breeding values (GEPD) published since 2017 (Ravagnolo *et al.*, 2018). Research GEPD for RFI and CH_4 have also been estimated in 2021 for Australian Merino, as a first step before incorporating these traits in the breeding programme. Larger reference populations have favourable impact on high accuracies of genomic predictions, which also represent an incentive for breeders to invest in genotyping and RFI and CH_4 phenotyping that accelerates the growth of reference population (Berry *et al.*, 2016). Although the expected benefits of genomic selection are more relevant in difficult-to-measure traits, phenotyping costs and complexity are the main challenges for building the corresponding references populations. Successful implementation and uptake of genomic selection will increase the number of animals in the national genetic evaluation with GEBV for RFI and CH_4, with favourable implications in terms of the applicability of selection indices including these new traits and balancing potential antagonisms between productivity and GHG emissions.

In summary, improving feed efficiency and reducing CH_4 emission by animal selection is achievable as both traits are heritable and phenotyping larger number of animals is now possible, although still costly and limited to experimental research farms or nucleus herds/flocks. Further research is needed for a

more comprehensive understanding of the genetic and phenotypic relationships not only between these groups of traits, but also with productivity in order to optimise genetic progress supporting environmental, economic, and social sustainability. Expanding regional and international collaborations is one of the alternatives to build larger reference population for genomic selection with increased genomic accuracies.

Abstract

Reducing methane emission in ruminant animals via breeding requires estimating methane emissions using indirect or proxy measures, as direct measures are often impractical. Rumen microbial community (RMC) profiles have been shown to be associated with methane emissions and so may be a suitable proxy. Using a dataset of 3,640 sheep across 8 genetically linked flocks, we predicted methane emission from RMC profiles and obtained higher prediction accuracies compared to host genomic prediction. We estimated the correlations between methane traits measured directly using portable accumulation chambers (PAC) and predicted from RMC profiles. Moderate to high genetic correlations (0.66 and 0.77) were obtained, while phenotypic correlations were lower (0.32 and 0.35). These results suggest RMC profiles have potential to be used as a proxy for methane emissions in ruminants and that direct and indirect methane measures could be combined within a breeding scheme.

Introduction

A target of 30% reduction in methane emissions by 2030 has been agreed upon by governments and global organizations to combat climate change. Developing methods for reducing ruminant methane emissions while maintaining productivity is therefore vital for the future of the agricultural industry. This can be achieved through classical breeding practices (Rowe *et al.* 2021), but collecting direct measurements of methane is cumbersome and costly. This necessitates indirect or proxy measures of methane. These vary in applicability according to species and system (Negussie *et al.* 2017). One proxy that has utility across species and system is the collection and sequencing of rumen microbial community (RMC) profiles, which have been shown to be associated with methane emissions (Kittelmann *et al.* 2014; Difford *et al.* 2018). In this study, we assess the feasibility of RMC profiles as a proxy for methane emissions and its potential inclusion in commercial breeding scheme as a predictor of methane emissions.

Materials & methods

Experimental animals and protocols applied in this study were approved by the AgResearch Ruakura (Hamilton, NZ) Animal Ethics committee (approvals 14906, 14907 and 14981).

Animals & phenotypes. Data from 5 industry (n=1,281) and 3 research (n=2,359) genetically linked performance recorded sheep flocks were obtained and consisted of 2,136 ewes and 1,504 rams born between 2014 and 2020 (Table 1). Methane emissions were measured using the PAC protocol described in Jonker *et al.* (2018) for all animals when they were between 3 and 12 months of age, except for the born 2019 ewes in flock 4 which were measured at 18 months of age. Animals were measured in lots of 12. Animal information and methane phenotypes were downloaded from the Sheep Improvement Limited database

(Newman *et al.* 2000). Traits were methane emissions (CH_4 (g/d)) and Carbon Dioxide (CO_2 (g/d)). Scaled CH_4 (g/d) ($ScCH_4$) and the scaled molar $CH_4/(CO_2 + CH_4)$ ratio (ScRatio) traits (scaled by lot mean) were also calculated as described in Jonker *et al.* (2018) to account for variables associated with lot.

Rumen microbial profiles. Rumen samples were collected via stomach intubation immediately after animals were measured through the PAC units and preserved using either TNx2 solution described in Budel *et al.* (2022) (born 2020 animals and all animals in flock 4), or by fast freezing on dry ice and freeze-dried described by Kittelmann *et al.* (2014) and adapted by Hess *et al.* (2020). DNA was extracted using a phenol-chloroform with bead beating protocol (Rius *et al.* 2012) and sequenced using a restricted enzyme-reduced representation sequencing approach using *Pst*I with 384 samples per library as described by Hess *et al.* (2020). Samples were sequenced across multiple flowcells and run on either an Illumina HiSeq2500 or NovaSeq6000. The reference-free pipeline developed by Hess *et al.* (2020) was used to process raw sequence data into tags (unique 65 bp trimmed sequences present in 25% of samples in the training set) to generate individual RMC profiles, which were used to construct a microbial relationship matrix (MRM) by taking the correlation in the cohort adjusted RMC profiles.

Animal genotyping. Animals were genotyped on a variety of nested SNP arrays. SNPs with a call rate of 70% were retained, resulting in 14,923 SNPs in the combined data. A genomic relationship matrix (GRM) was computed in KGD (Dodds *et al.* 2015) using VanRaden method 1 with non-missing SNPs for each matrix entry and assuming missing data is at random.

Statistical models. Data was split into (a) a training set consisting of the 2,262 animals born before 2020 and (b) a validation set consisting of the 1,378 animals born in 2020. Using animals from the training set, univariate mixed models of the form:

$$y_{ijkl} = \mu + aod_j + brr_k + bdev_i + cg_l + a_i + e_{ijkl} \quad (1)$$

$$y_{ijkl} = \mu + aod_j + brr_k + bdev_i + cg_l + m_i + e_{ijkl} \quad (2)$$

$$y_{ijkl} = \mu + aod_j + brr_k + bdev_i + cg_l + a_i + m_i + e_{ijkl} \quad (3)$$

were fitted, where μ is the overall mean, aod_j is the effect of the j^{th} age of dam (1, 2, 3, 4+) group, brr_k is the effect for the k^{th} birth/rear rank (1/1, 2+/1, <3/2, 3+/2, 3+/3+) group, $bdev_i$ is the birth deviation from the flock and birth year mean for animal i, cg_l is the effect for the l^{th} contemporary group based on the

combination of flock, year of birth and sex, y_{ijkl} denotes the PAC methane trait ($ScCH_4$ or ScRatio), $m_i \sim N(0,\sigma_m^2 M)$, $a_i \sim N(0,\sigma_g^2 G)$, $e_{ijkl} \sim N(0,\sigma_e^2 I)$, M denotes the MRM, G denotes the GRM and I is the identity matrix. We refer to the microbial values, m_i, as the 'RMC methane trait' since it provides an estimate of the methane trait y_{ijkl} ($ScCH_4$ or ScRatio) from the RMC profiles. Predictions of the microbial values ($\hat{m}_i$) and the animals direct genomic breeding values ($\hat{a}_i$) were made for the born 2020 animals in the validation set. Prediction accuracies were computed as (a) the correlation between $\hat{m}_i$ or $\hat{a}_i$ and the adjusted phenotype (y_i^*) defined as the residuals from the linear model:

$$y_{ijkl} = \mu + aod_j + brr_k + bdev_i + cg_l + e_{ijkl} \quad (4)$$

fitted using both the training and validation sets, and (b) the accuracy of estimated breeding values (r_{eBV}) or the accuracy of estimated microbial values (r_{eMV}). To assess the heritability and genetic correlation of the PAC and RMC methane traits, a bivariate model of the form:

$$[\hat{m}_i, y_i^*] = \mu + a_i + e_i \quad (5)$$

was fitted using only the animals from the born 2020 validation set. All models were fitted in ASREML v4.2 (Gilmour *et al.* 2015).

Results

Prediction accuracies of the PAC methane traits from the RMC profiles and host genomics are given in Table 2. Higher accuracies were obtained from the RMC profiles for both traits compared to using host genomics. For the combined model (G+M), prediction accuracies were around zero for the host genomics and relatively unchanged for the RMC profiles. The accuracies of the estimated breeding and microbial values were similar across models ranging between 28 and 34%, although the standard errors of r_{eBV} were about twice those of r_{eMV}.

Table 3 gives the genetic parameter estimates from the bivariate analysis using the born 2020 validation animals. Heritability estimates for PAC methane traits were slightly higher than previously reported by Jonker *et al.* (2018) and approximately double the heritability estimates of the RMC methane trait. The genetic correlations between the PAC and RMC methane traits were moderate to high at 0.76 ($ScCH_4$) and 0.66 (ScRatio), while as expected, the phenotypic correlation estimates were lower at around 0.32 (ScCH4) and 0.35 (ScRatio). Given the variation in the data and modest number of animals used in this study, these results show clear potential for the use RMC profiles as a proxy for methane phenotypes.

Table 2. Born 2020 validation animals prediction accuracies for PAC methane traits predicted from RMC profiles (M), host genomics (G) or both combined (G+M).

Trait	Equation	Model	$\rho(\hat{a}_i, y_i^*)$[1]	$\rho(\hat{m}_i, y_i^*)$[1]	r_{eBV}^2	r_{eMV}^2
$ScCH_4$	1	G	0.092		0.32±0.09	
	2	M		0.335		0.31±0.06
	3	G+M	-0.042	0.334	0.30±0.11	0.31±0.06
ScRatio	1	G	0.215		0.34±0.09	
	2	M		0.313		0.28±0.06
	3	G+M	-0.039	0.310	0.34±0.12	0.29±0.06

[1] $\rho(x,y)$ denotes the Pearson correlation between x and y. $\hat{a}_i$ is the predicted breeding value, $\hat{m}_i$ is the predicted microbial value, and y_i^* is the adjusted phenotypes computed in Equation 4 for animal i.
[2] r_{eBV} is the accuracy of the estimated breeding values computed as $(1\text{-}s_i^2/\sigma_g^2)^{0.5}$ and r_{eMV} is the accuracy of the estimated microbial values computed as $(1\text{-}s_i^2/\sigma_m^2)^{0.5}$, where s_i^2 is the prediction error variance.

Table 3. Heritability, genetic correlations and phenotypic variances from bivariate analysis of measured PAC and predicted RMC methane traits using the born 2020 validation animals.

Parameter	$ScCH_4$		ScRatio	
	PAC	RMC	PAC	RMC
Heritability	0.39±0.03	0.19±0.07	0.31±0.05	0.18±0.05
Phenotypic variance	3.01±0.12	0.43±0.02	0.48±0.02	$5.4e^{-2}$±$5.1e^{-3}$
Genetic correlation	0.76±0.14		0.66±0.13	
Phenotypic correlation	0.35±0.03		0.32±0.03	

Discussion

RMC profiling has been shown to be predictive of methane emissions in sheep and cattle, however, direct methane measures of cattle grazing pasture have proven to be extremely difficult and expensive to acquire. These results offer direct evidence that microbial predictors are suitable as a proxy for predicting methane emissions. The method outlined here provides a potential approach to industry implementation, whereby animals will have different information (i.e. pedigree, genotypes, RMC profiles, methane traits) available for genetic evaluations. As shown in this study, implementation could be achieved through a 2-stage analysis, initially converting RMC profiles into predicted methane emissions with a subsequent ssBLUP step.

31. Do we estimate dairy cows' methane production precisely enough?

M. Pszczola* and T. Strabel

Poznan University of Life Sciences, Department of Genetics and Animal Breeding, Wolynska 33, 60-637 Poznan, Poland; marcin.pszczola@puls.edu.pl

Abstract

For sniffers, quantifying methane (CH_4) production relies on milk production, body weight, and the stage of the cow's pregnancy. The relationship between these traits and CH_4 production is assumed to be constant. We assessed the impact of change in the relationships between body weight CH_4 production on selection. Data on 483 (330 genotyped) Polish Holstein-Friesian cows for CH_4 and CO_2 concentrations measured with sniffer and production data were available. We analysed four scenarios in which coefficients relating body weight to CH_4 production varied. Changes in the values of the coefficients had a substantial impact on the daily CH_4 production level, genetic parameters, and possible selection decisions.

Introduction

The sniffer method measures methane (CH_4) concentrations in the air sampled from dairy cows in the feeding bin of automated milking system (AMS), capturing only part of the exhaled or eructated air. Therefore, to quantify the amount of CH_4 produced by a cow, CO_2 production (Madsen *et al.*, 2010) is used. It allows converting CH_4 concentration to production. This conversion requires measuring CH_4 and CO_2 concentrations in the breath of the cows and estimating the daily production of CO_2. The daily CO_2 production is calculated based on converting heat production (HPU) to CO_2 according to Pedersen *et al.* (2008) by employing the formula of Madsen *et al.* (2010). This requires information on cow's milk production, body weight (BW), and stage of pregnancy. Therefore, the final phenotype, i.e. CH_4 production, relies on formula parameters (FP) relating the three mentioned cows' characteristics to heat production (Petersen and Sällvik, 2002). Most studies on methane production use the same values for FP (e.g. Lassen and Løvendahl, 2016; Pszczola *et al.*, 2017; Manzanilla-Pech *et al.*, 2021). However, the FP values may vary depending on the cow's age, production, physiological, or health status of an animal (Petersen and Sällvik, 2002). Using different parameters in FP may result in imprecise CH_4 production estimates and, consequently, impact selection decisions. This study aimed to assess the sensitivity of the CH_4 production to changes in FP related to BW.

Materials & methods

Data were collected at two commercial farms on 483 Polish Holstein-Friesian cows in the following periods: Farm 1: Dec 2, 2014, to Feb 3, 2016, and Jun 1, 2016, to Sep 17, 2016, and on Farm 2: Feb 5, 2016, to Mar 14, 2016. The gas measurements were recorded during milking in an AMS (Lely Astronaut A4; Lely Holding, Maassluis, the Netherlands) using an FTIR analyser (GASMET 4030; Gasmet Technologies Oy, Helsinki, Finland). The remaining data on cows were obtained from the AMS system. We analysed only data collected between 5 and 305 days of lactation. In total, we obtained 34,429 daily records. Cows were fed *ad libitum* with a partial mixed ration (PMR), and additional concentrate was provided in AMS depending on the animal's productivity. A detailed description of the study can be found in Pszczola *et al.* (2017). Out of all the phenotyped cows, 330 were genotyped with the Illumina BovineSNP50 v2.0 BeadChip (Illumina Inc., San Diego, CA, USA); see Pszczola *et al.* (2018) for details.

Predicting daily CH4 production. The daily CH_4 production (expressed in grams) was predicted from the formula presented in Madsen *et al.* (2010) as:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_31, © M. Pszczola and T. Strabel 2022

$$predictedCH_4 = \frac{CH_4}{CO_2} * \frac{c_1 BW^{c_2} + 22MY + 1.6*10^{(-5)} PREG^3}{1000*180*24} * 0.668, \quad (1)$$

Scenarios. We analyzed four scenarios in which FP c_1 and c_2 in formula (1) were modified as follows: (1) *Base scenario* (as in Madsen *et al.*, 2010): c_1=5.6, and c_2=0.75; (2) *scenario C1*: c_1=7.64, and c_2=0.75; (3) *scenario C2*: c_1=5.6, and c_2=0.64; and (4) *scenario C1 & C2*: c_1=7.64, c_2=0.61. For each scenario CH_4 production was estimated.

Variance components estimation. Variance components for CH_4 production were estimated with BLUPF90 suite of programs (Misztal *et al.*, 2002) by combining pedigree and genotype information using the formula:

$$CH_{4_{ijkl}} = LAC_j \times \sum_{n=1}^{4} \beta_n DIM_{kn} + YK_l + \sum_{n=1}^{3} \boldsymbol{a}_{in} DIM_{kn} + \sum_{n=1}^{3} \boldsymbol{pe}_{in} DIM_{kn} + \boldsymbol{e_{ijkl}} \quad (2)$$

Where the $CH_{4_{ikl}}$ was the estimated and adjusted average daily CH_4 output of the i^{th} cow in the j^{th} lactation, the k^{th} day in milk (*DIM*), and the l^{th} year–week of the measurement, where year–week of the measurement (*YK*), where *YK* are farm-specific; β_n are fixed regression coefficients. Lactation (*LAC*) had two levels: 1 and 2+, in which records from up to lactation eight were included. The general lactation curve was modelled using third-order Legendre polynomials and random animal (*a*) and permanent environment (*pe*) effects with second-order Legendre polynomials and *e* is the residual term. The adjustment of $CH_{4_{ikl}}$ made prior to estimating variance components was the pre-correction for diurnal variation and AMS unit followed by averaging observations within one day as described in Pszczola *et al.* (2017). Next to variance components and heritability, we estimated breeding values using ssBLUP procedure (Aguilar *et al.*, 2010) and calculated the 305 breeding values (GEBV). The 305 GEBV were calculated only for genotyped cows with their records.

Results

Modification of the c_1 and c_2 substantially influenced the average daily CH_4 production level and its variation (Table 1). In scenario C1, cows produced, on average, 73 g of CH_4 per day more than in the base scenario and nearly 200 g more than in scenario C2.

Although variance components estimates had similar shapes across lactation for all scenarios (Figure 1), they differed by the levels. The Base scenario yielded intermediate values, while the highest values were obtained for scenario C1 and the lowest for C2.

Heritability of CH_4 production (Figure 2) had a similar pattern for all the scenarios forming a bell-shaped curve with the peak value around mid-lactation and corresponding to Pszczola *et al.* (2017). Although the differences at the beginning and the end of lactation were negligible, the broad range of heritabilities at the peak was obtained, ranging from 0.25 (scenario C1) to 0.35 (scenario C2) (Table 1).

Table 1. Daily methane production (g) and heritability levels across different scenarios.

Scenario[1]	Mean	SD	CV%	h^2
Base	427	83.3	19.5	0.21
C1	500	95.4	19.1	0.20
C2	311	65.4	21.1	0.27
C1 & C2	340	69.0	20.3	0.26

[1] Names of the scenarios indicate the parameter modified in the calculations.

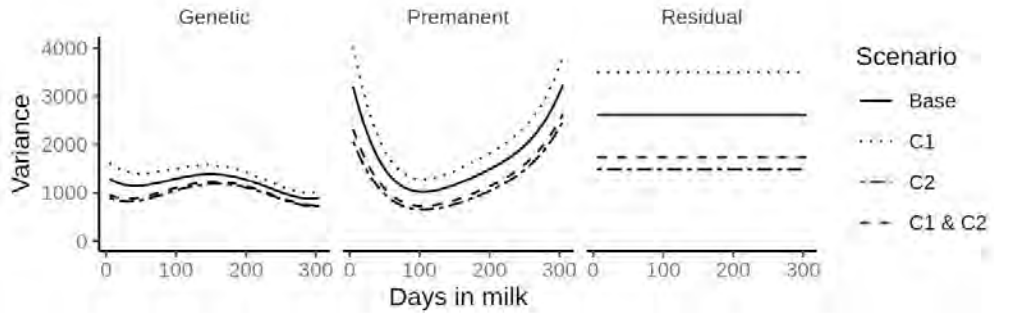

Figure 1. Variance components estimated for daily CH_4 production of dairy cows across days in milk for different parameters used for quantifying CH_4 production across different scenarios.

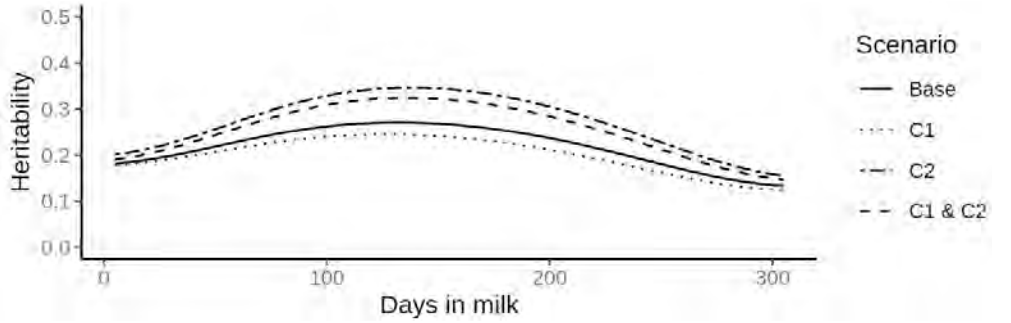

Figure 2. Heritability for daily CH_4 production of dairy cows across days in milk for different parameters used for quantifying CH_4 production across different scenarios.

The substantially different heritabilities had an unavoidable impact on CH_4 GEBV. The correlation between GEBV from the Base and other scenarios are shown in Table 2. The correlation between GEBV for the base scenario C1 scenarios was high (0.996). Whereas the correlation between GEBV for the base scenario and C2 was as low as 0.981, and between C1 & C2 was even lower (0.960) and led to re-ranking of animals which would impact the possible selection decisions. The lists of top 20 cows (lowest GEBV for CH_4 production) for the Base scenario and C1 shared two cows, and between base and C2 or base and C1 & C2 zero cows. For the top 100 cows, these numbers were 39, 34, and 36.

Table 2. Correlations between 305 GEBV for methane production of dairy cows for different parameters used for quantifying CH_4 production across different scenarios.

Scenario[1]	C1	C2	C1 & C2
Base	0.996	0.981	0.989
C1		0.960	0.972
C2			0.999

[1] Names of the scenarios indicate the parameter modified in the calculations.

[2] In the Base scenario, no parameters were modified.

Discussion

Obtaining accurate phenotypes for CH_4 production is challenging. Sniffer methods are promising technology allowing for gathering many observations for a high number of cows. Although sniffers are not exact, they provide phenotypes enabling genetic analyses that give the basis for selection for lower CH_4 production (e.g. Lassen and Løvendahl, 2016; Pszczola *et al.*, 2017; Manzanilla-Pech *et al.*, 2021). We showed that using alternative (to Madsen *et al.*, 2010) FP's for BW have a clear impact on CH_4 production with regard to: (1) assessment of the daily CH_4 production; (2) values of the estimated genetic parameters; and, in consequences, (3) potential selection decisions. Therefore, we suggest that the conversion of the CH_4 concentration to production based on the analysed equation should be employed with care. The parameters, which are sensitive to cow's age, production, physiological, or health status, should be precisely adjusted to analysed individuals to reflect the actual status of the population of interest.

32. Heritability of methane emission in Norwegian Red cows based on measures from GreenFeed in commercial herds

K.B. Wethal[1], G.F. Difford[2], K. Winnberg[2], E. Norberg[2] and B. Heringstad[1,2*]

[1]Geno Breeding and A.I. Association, Storhamargata 44, 2317 Hamar, Norway; [2]Department of Animal and Aquacultural Sciences, Faculty of Biosciences, Norwegian University of Life Sciences, P.O. Box 5003, 1432 Ås, Norway; bjorg.heringstad@nmbu.no

Abstract

The aim of this study was to estimate heritability of methane emissions for Norwegian Red dairy cows. Methane measured by GreenFeed was available from 12 commercial herds. Data was collected from February to October 2021 and the final dataset had a total of 62,057 records from 252 cows. Methane emission from individual visits was analysed. The average methane emission was 441 g/day. A linear animal repeatability model with fixed effects of parity and lactation week, and random effects of herd-testday, animal, and permanent environment was used to estimate variance components. The estimated heritability was 0.22 and repeatability 0.36.

Introduction

International agreements and commitments to reduce greenhouse-gas emissions imply that all sectors have to contribute to meet climate targets. One way to reduce the environmental footprint of dairy production is by breeding for reduced methane (CH_4) emissions. Implementing reduced CH_4 emission in the breeding program would have a direct and long-term environmental impact. Previous studies have reported genetic variation for methane emissions in Holstein dairy cattle (Lassen and Difford, 2020). In order to assess the genetic potential for reduced CH_4 emission in the Norwegian Red population, Geno breeding and A.I. association (www.norwegianred.com) implemented collection of measures of cows CH_4 emissions in commercial dairy herds. So far most genetic research on methane emission has been conducted in small and tightly controlled research herds which cannot encompass the full genetic variation of the population and tend to have multiple dietary treatments which complicate genetic evaluations (Tempelman *et al.*, 2015). For selection to be viable and genetic parameters to be relevant, large scale phenotype collection is needed in the commercial environments in which animals are expected to perform. To this end, Geno has installed GreenFeed (www.c-lockinc.com) equipment for CH_4 recording for individual cows at commercial dairy farms in the mid- and south-eastern part of Norway. The aim of this first initial genetic analyses was to estimate heritability of methane emissions for Norwegian Red dairy cows.

Materials & methods

The GreenFeed unit measure gas fluxes of CH_4 (and other gases) from individual cows. The cows visit the unit voluntary, where they are offered a small amount of concentrate to entice visits. Each cow may have multiple daily visits, but maximum five feedings per day. Each visit results in an estimate of daily CH_4 emission. Only visits of at least 2 minutes with 'good data', defined based on head position or proximity inside the crib, were defined as reliable and retained for further analysis.

Methane emission data was collected from February to October 2021 in 12 herds with loose housing and automatic milking systems (Lely or DeLaval). Additional information on the cows were from the Norwegian Dairy Herd Recording System. Norwegian Red cows that had at least 5 GreenFeed records were included, and data from the period from calving to 350 days in milk were used. The final dataset had a total of 62,057 records (1 record per visit) from 252 cows. The trait analyzed was daily CH_4 emission, gram per day (Each visit results in an estimate of daily CH_4 emission).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_32, © K.B. Wethal *et al.* 2022

A linear animal repeatability model was used to estimate variance components using the DMU software (Madsen and Jensen, 2012). The model included fixed effects of parity (1, 2, 3, and >3) and lactation week (from 1 to 50) and random effects of herd-testday, animal, and permanent environment. The pedigree of cows with data was traced as far back as 6 generations and included a total of 3,791 animals.

Results

The average (standard deviation) methane emission was 441 (114) gram per day. The distribution of the phenotypic records followed an approximate normal distribution (Figure 1).

Methane emissions vary with stage of lactation. Figure 2 shows the solutions for fixed effect of lactation week and illustrates how CH_4 emissions by lactation stage follows the same shape as a lactation curve for milk yield.

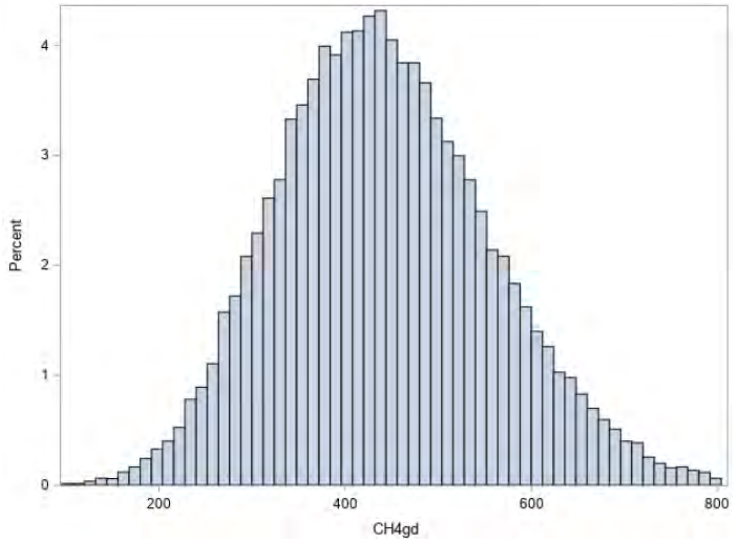

Figure 1. Distribution of phenotypic records of methane emission (CH_4gd) for Norwegian Red cows (1 record per visit at the GreenFeed unit, each visit gives an estimate of daily methane emission).

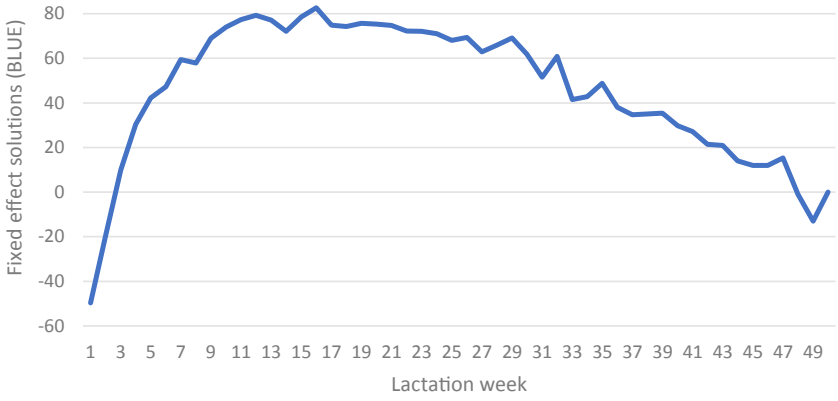

Figure 2. Fixed effect solutions for lactation week, effect on daily methane emission (gram per day) (standard errors were between 7 and 9).

The estimated variance components are given in Table 1. The corresponding heritability of CH_4 emission in Norwegian Red was 0.22 and repeatability 0.36.

Table 1. Estimated variance components with standard error (SE) for daily methane emission.

Variance component	Estimate	SE
Herd-testday	1,024.5	47.4
Additive genetic	2,693.7	1,002.1
Permanent environment	1,670.9	836.9
Residual	6,809.9	39.3

Discussion

Due to challenges related to large scale recording of CH_4 there are so far relatively few estimates of genetic parameters for direct CH_4 emission in dairy cows. This is, as far as we know, the first heritability estimate based on data from GreenFeed in commercial herds, and the first for the Norwegian Red breed. Our heritability estimate agrees well with previous published results, although not directly comparable due to differences in breed and phenotyping method/equipment. A review by Lassen and Difford (2020) showed that heritability estimates of CH_4 emissions measured by 'sniffer' in Holsteins varied from 0.11 to 0.45, with most estimates from 0.21 to 0.27. Our heritability estimate is larger than previous estimates of 0.15 and 0.11 for daily CH_4 emission in 100 Finnish Ayrshires and 409 grazing Italian Holsteins, respectively, both recorded using GreenFeeds in research herds (Wallace *et al.*, 2019). However, it is lower than 0.31±0.15 reported for weekly averaged CH_4 production in 305 Holstein cows from research herds in Canada and Switzerland in a joint evaluation (Manzanilla Pech *et al.*, 2021).

This initial analysis of CH_4 emissions in Norwegian Red cows shows that there is substantial genetic potential for reducing CH_4 emissions from dairy cows by breeding. With GreenFeed units installed in collaborating commercial herds and a system for data collection in place, we will soon have access to larger datasets for further genetic studies of CH_4 emissions. We will estimate genetic correlations between methane production and important traits in the breeding goal. Zetouni *et al.* (2018) found low genetic correlations between methane production and health, fertility and body type traits in Danish Holstein. However, they concluded that further studies based on larger dataset are needed to understand these relationships. Increased knowledge of the genetic relationship between traits related to climate, traditional efficiency traits, including feed efficiency, but also animal welfare and health traits is needed before reduced methane emission can be implemented in Norwegian Reds' future breeding goal.

Acknowledgements

We want to thank the dairy farmers hosting the GreenFeed units and providing data, Geno and Tine for access to data, and the Norwegian Research Council for funding of research project (project 309451).

Abstract

Before methane (CH_4) emission can be mitigated with animal breeding, breath measurements have to be recorded on a large number of cows. Our aim was to estimate heritabilities for, and a genetic correlation between, CH_4 recorded by GreenFeed and sniffers. Repeated records were available for CH_4 production (g/cow/day) by GreenFeed and for CH_4 concentration (ppm) by sniffers. The data included 24,284 GreenFeed daily means from 822 cows, 172,948 sniffer daily means from 1,800 cows, and 1,787 daily means from both devices on the same day from 75 cows. Additionally, records were averaged per week. The datasets were analyzed using bivariate animal models. The results show that CH_4 emissions recorded by either device has a moderate heritability (0.18-0.37). Furthermore, the genetic correlation between weekly mean CH_4 recorded by GreenFeed or by sniffers was high (0.77). This suggest that the measurements can be used in the same genetic evaluations.

Introduction

Before enteric methane (CH_4) emissions of dairy cows can be mitigated through (genomic) selection, breath measurements have to be recorded on thousands of dairy cows to set up a reference population (de Haas *et al.*, 2017). To increase the number of phenotyped cows, it is beneficial if CH_4 records from common recording devices can be used in the same genetic evaluation. For genetics research, CH_4 is commonly recorded by spot-sampling devices called 'sniffers', because of its ability to phenotype a large number of cows cost-effectively (Madsen *et al.*, 2010). The devices use infrared spectroscopy to continuously measure enteric CH_4 and carbon dioxide (CO_2) concentrations (ppm) inside the feed bin of milking robots (AMS). For sniffer recorded CH_4 concentrations, heritabilities have been estimated for the mean CH_4 concentration, which ranged from 0.11 to 0.26 (Lassen and Difford, 2020). Spot-sampling devices that are commonly used in nutritional studies are GreenFeed units (GF). Unlike sniffers, the units record air flux, head position of the cow, wind speed and temperature, from which the CH_4 production in grams/cow/day can be estimated (Hammond *et al.*, 2016). However, this comes at a price and therefore the devices have a ten times higher investment, and also high running costs, which are limiting the number of cows that can be recorded. To date, heritability estimates for GF recorded CH_4 of dairy cows have not been published. Similarly, genetic correlations between CH_4 measured by sniffers and GF are not known yet. In this study, our aim was to: (1) estimate heritabilities for GF recorded CH_4 production; and (2) investigate if sniffer and GF measurements can be combined in genetic evaluations.

Materials & methods

Enteric CH_4 was recorded with GF units (C-lock Inc. Rapid City, SD, US) placed in the barn or in pasture, and by sniffers (WD-WUR v1.0, manufactured by Carltech BV), which were installed in close proximity to the AMS with an air inlet leading from the feed bin of the AMS. The GF units were exchanged between 16 farms and recorded for short periods of time on each farm, ranging from 14 days up to 90 days, between September 2018 and March 2020. Sniffers continuously recorded CH_4 emissions, for at least 64 days and up to 436 days (farm dependent), between March 2019 and September 2020, on 15 farms. A total of six farms were equipped with both devices, of which four farms had records from both devices on the same days. The

GF units, made 161,825 recorded visits on 1,184 cows, which were transformed to CH_4 emissions in g/cow/day (g/day) by C lock-inc. (using the method described by Huhtanen *et al.* (2015)). A detailed description of the general operation procedure of GF units is given by Velazco *et al.* (2017). The sniffers made 470,266 recorded visits on 2,413 cows. Sniffer records were an average of concentration (ppm) measurements taken every ten to thirty-five seconds (varying between devices), and during the second and up to fifth minute of an AMS visit. The recorded cows were of mixed parities and lactation stages. Genotype data, pedigree data, and other phenotypic data (breed composition and calving dates) were made available by the cooperative cattle improvement organization CRV (Arnhem, the Netherlands). In total 1,817 animals were genotyped with 76,438 SNPs.

Data processing. The CH_4 datasets were filtered to only include records for cows up to 305 days in milk, to correctly match the CH_4 records to calving dates and the corresponding parity. Furthermore, cows that were less than 75% Holstein, were removed from the dataset. The pedigree was pruned to only include animals with CH_4 records and their ancestors with the package 'optiSel' in R v3.6.1 (R Core Team, 2019; Wellmann, 2020). The pruned pedigree composed of 41,290 animals, of which 1,800 animals had a sniffer phenotype, 822 animals had a GF phenotype, and 75 animals had both.

The GF and sniffer CH_4 records were averaged and combined in one dataset with daily and in one dataset with weekly means, where records with less than three records per cow per week were discarded for the latter. The dataset with daily means composed of 24,284 GF records from 822 cows and 172,948 sniffer records from 1,800 cows. The combined daily dataset included 1,787 records from both devices on the same day from 75 cows. The dataset with weekly means composed of 4,345 GF records from 724 cows and 31,579 sniffer records from 1,744 cows. The combined weekly dataset included 333 records from both devices in the same week from 73 cows.

Statistical analysis. The pedigree and genotype data were combined in a genetic relationship matrix (H^{-1} matric), following the method of Aguilar *et al.* (2010) and Christensen and Lund (2010) using calc_grm version r1.143 (Calus and Vandenplas, 2016). The H^{-1} matrix comprised all 41,290 pedigreed animals. The CH_4 data was analyzed using animal models, including repeated records, using ASReml 4.2 (Gilmour *et al.*, 2015). Univariate models were used to derive starting values for bivariate models (results not shown). Thereafter, heritabilities, repeatabilities, genetic correlations, and phenotypic correlations were estimated using the following bivariate model:

$$\begin{bmatrix}\mathbf{y}_1\\ \mathbf{y}_2\end{bmatrix} = \begin{bmatrix}\mathbf{X}_1 & 0\\ 0 & \mathbf{X}_2\end{bmatrix}\begin{bmatrix}\mathbf{b}_1\\ \mathbf{b}_2\end{bmatrix} + \begin{bmatrix}\mathbf{Za}_1 & 0\\ 0 & \mathbf{Za}_2\end{bmatrix}\begin{bmatrix}\mathbf{a}_1\\ \mathbf{a}_2\end{bmatrix} + \begin{bmatrix}\mathbf{Zp}_1 & 0\\ 0 & \mathbf{Zp}_2\end{bmatrix}\begin{bmatrix}\mathbf{pe}_1\\ \mathbf{pe}_2\end{bmatrix} + \begin{bmatrix}\mathbf{e}_1\\ \mathbf{e}_2\end{bmatrix} \quad (1)$$

where y_i is a vector with records on trait *i* (GF CH_4 and sniffer CH_4, day/week); b_i is a vector containing fixed effects for trait *i*, which were farm×year×week of the measurement, days in milk, parity (from parity 1 to 4, where 4 is parity four or higher); a_i is a vector containing additive genetic effects for trait *i*; pe_i is a vector containing permanent environmental effects for trait *i*; and e_i is a vector with the residuals for trait *i*; X_i, Za_i and Zp_i are incidence matrices linking the records in y_i to the fixed effects, the additive genetic effects, and the permanent environmental effects, respectively. The additive genetic, permanent environmental and residual effects for all traits were assumed normally distributed with a mean of zero, a genetic variance of σ^2_{ji} for random effect *j* and trait *i*, and a genetic covariance between two traits of σ_{j1j2}:

$$\begin{bmatrix}j_1\\ j_2\end{bmatrix} \sim N\left[\binom{0}{0}, \mathbf{I} \otimes \begin{pmatrix}\sigma^2_{j_1} & \sigma_{j_1 j_2}\\ \sigma_{j_1 j_2} & \sigma^2_{j_2}\end{pmatrix}\right].$$

Results

The mean (±SD) CH_4 emission measured by GF was 436 g/day (±120) per day and 436 g/day (±97) per week. The mean for sniffers was 322 ppm (±251) per day and 325 ppm (±219) per week. The heritability and repeatability were higher for weekly mean CH_4 than for daily mean CH_4, both for CH_4 measured by GF and sniffers (Table 1), due to a reduction of residual variance after averaging per week. The heritabilities and the repeatabilities for GF measured CH_4 and sniffer measured CH_4 were similar.

Phenotypic and genetic correlations between GF and sniffer measured CH_4 were moderately positive, except for the genetic correlation between the weekly mean CH_4 emission measured by GF and sniffer, which was high (0.77±0.14) (Table 2). Both for daily and weekly mean measurements, the genetic correlations were higher than the phenotypic correlations. Furthermore, the genetic correlations between GF and sniffer measured CH_4 increased after averaging emissions to means per week.

Discussion

This study is the first to report heritabilities for CH_4 of dairy cows measured by GF units (g/day), and to report genetic correlations with CH_4 measured by sniffers (ppm). The in this study estimated heritabilities for CH_4 measured by GF or by sniffers were similar (0.19 vs 0.18 and 0.37 vs 0.36, for CH_4 as a mean per day or a mean per week respectively) (Table 1). The heritability and repeatability estimates for CH_4 measured by sniffers were in agreement with previous estimates that have been reported in the literature, where heritability estimates ranged between 0.11±0.02 and 0.26±0.11 (Lassen and Difford, 2020), and repeatability estimates ranged between 0.33 and 0.84 for different trait definitions and sniffer methods (Difford *et al.*, 2016). Similarly, the repeatability estimates for CH_4 measured by GF per day or per week (0.35 and 0.64, respectively) were in agreement with previous estimates for daily CH_4 production (0.47±0.12 (Sorg *et al.*, 2018)), and weekly CH_4 production (0.60 (Coppa *et al.*, 2021)).

The genetic correlation between weekly mean sniffer CH_4 and weekly mean GF CH_4 was high (0.77±0.14). The high genetic correlation shows that the two devices ranked the estimated breeding values of cows similarly from low to high emitting, and that therefore there is promise in using both devices in future genetic evaluations. In practice, the cheaper sniffers can collect CH_4 concentration records on a large number of cows, and the GF can be used to collect records on CH_4 production in gram/day when required for the breeding goal.

Table 1. Heritability (h^2) and repeatability (t) of methane emissions measured by the GreenFeed (g/day) or sniffers (ppm), as a mean per day or per week.

Trait		h^2	t
GreenFeed (g/day)	Day	0.19±0.02	0.35±0.01
	Week	0.37±0.04	0.64±0.01
Sniffer (ppm)	Day	0.18±0.01	0.34±0.01
	Week	0.36±0.02	0.61±0.01

Table 2. Phenotypic (r_p) and genetic (r_a) correlations for methane emissions measured by the GreenFeed (g/day) or sniffers (ppm), as a mean per day or per week.

	r_p	r_a
Day	0.41±0.03	0.53±0.16
Week	0.35±0.07	0.77±0.14

In conclusion, CH_4 by sniffers (ppm) and by GF units (g/day) are both moderately heritable and heritabilities and repeatabilities for the two devices are similar. The high genetic correlation suggests that measurements by sniffers and GF units can be combined in genetic evaluations, by increasing the number of cows with records on CH_4 emissions. However, before enteric CH_4 can be added to genetic evaluations, accurate genetic correlations with other breeding goal traits have to be estimated to ensure favorable changes in CH_4 emission without influencing production, feed efficiency, conformation, fertility, health or behavioral traits.

Funding

This study was part of the Climate Approach project funded by the Dutch ministry for agriculture, nature and food quality (LNV) (project number BO-53-003) and was supported by the TKI Agri & Food project LWV19155, and the partners CRV and FrieslandCampina.

34. Methane emission has low genetic correlations to lamb growth traits in Norwegian White sheep

J.H. Jakobsen[1*], T. Blichfeldt[1], L.-B. Linneflaatten[1], M.O. Gløersen[1], L.E. Wallin[1] and J.C. McEwan[2]

[1]The Norwegian Association of Sheep and Goat Breeders, Box 104, 1431 Ås, Norway; [2]AgResearch Limited, Invermay Agricultural Centre, PB 50034, Mosgiel 9053, New Zealand; jj@nsg.no

Abstract

Selection for reduced methane (CH_4) emission is a mitigation option. Inclusion of liveweight adjusted CH_4 (CH_{4adj}) emissions as a trait in the breeding goal is expected to result in a cumulative and permanent reduction in sheep farms greenhouse gas emission. Fifty-minute CH_4 emissions were measured in portable accumulation chambers on 4,534 Norwegian White ewes from 44 breeding flocks and expressed as grams per hour. Ten years of observations for the lamb growth traits 42-day and 140-day weights were extracted from the database along with the corresponding pedigrees. Heritabilities and direct and maternal genetic correlations were estimated for CH_{4adj} and the lamb growth traits. The heritability for CH_{4adj} was 0.17, and heritabilities for the growth traits were in the range 0.07 to 0.13. The genetic correlation between CH_{4adj} and maternal genetic effect of 42-day weight was 0.32 and significantly different from zero, while other correlations between CH_{4adj} and growth were non-significant.

Introduction

In 2019, the Norwegian agriculture sector made an agreement with the Norwegian government to reduce its cumulated greenhouse gas (GHG) emissions over the 2020 to 2030 period by 11% from 45-million-ton to 40-million-ton (Regjeringen.no, 2021). The main source of GHG emission in lamb meat production comes from enteric methane (CH_4) emission produced as a by-product in the non-aerobic fermentation of feed. Other countries have shown that enteric CH_4 emission is heritable in sheep (Jonker *et al.*, 2018; Pinares-Patiño *et al.*, 2013) and in cattle (e.g. Lassen and Løvendahl, 2016; Pszczola *et al.*, 2017). Breeding is thus a mitigation option (Pickering *et al.*, 2015) and including CH_4 emission as a trait in the breeding goal will result in a cumulative and permanent reduction in the national GHG emission from lamb meat production. The aim of the current study was to investigate the heritability of CH_4 in Norwegian White sheep and compute the genetic correlations to direct and maternal genetic effect of 42-day and 140-day weights.

Materials & methods

Selection of sheep and flocks. Methane measurements in portable accumulation chambers (PAC) were collected on 4,534 Norwegian White sheep ewes that have lambed at least once or were expecting their first lambing. These sheep belong to forty-four (44) breeding flocks from 12 ram circles (Gjerdrem, 1969). Flocks from ram circles were chosen as they circulate rams for natural mating within the ram circle and in addition are required to use artificial insemination. The use of common rams thus results in genetic connectedness between flocks (Kuehn *et al.*, 2008).

Methane emission measurements. CH_4 emission (ppm) was measured in lots of 10 animals at a time. A hand-held Eagle2 instrument was used to capture accumulated 50 min CH_4 emissions following a measurement protocol developed in New Zealand (Jonker *et al.,* 2020). Sheep were either fed fresh grass or grass silage and were required to be off feed for at least one and less than four hours prior to entering the chamber and were in addition weighed prior to measurement. Fifty-minute CH_4 concentration was converted to CH_4 g/hr. Both CH_4 g/hr and ewe weights were scaled, they were divided by the mean of the lot and multiplied by the mean of all observations.

Growth traits in routine genetic evaluation. It is compulsory for the ram circle flocks to weigh lambs at birth and at weaning, while weighing during the main suckling period is voluntary. Weights for the main suckling period are recorded between 15 and 70 days of age and adjusted to a 42-day weight (42-d_{adj}), while weaning weights are recorded between 90 and 180 days of age and adjusted to 140 days (140-d_{adj}). Both 42-d_{adj} and 140-d_{adj} are expressed as weight gain from birth, and 42-d_{adj} thus represents a part of the growth period to weaning. The growth traits 42-d_{adj} and 140-d_{adj} are a part of the portfolio included for the routine genetic evaluations in Norwegian sheep.

Ten years of phenotypes of 42-d_{adj} and 140-d_{adj} were extracted for the 44 ram circle flocks with CH_4 emission measurements. Mean, standard deviation and number of observations of methane emission and weights are listed in Table 1.

Pedigree. Pedigree was extracted from the national sheep recording database and traced as far back as possible on animals with phenotypes. The pedigree included a total of 154,683 animals.

Genetic evaluation model. Data was analysed in a tri-variate animal model using the DMU-software (Madsen and Jensen, 2013).

The model for methane emission was:

$$Y_{ijk} = FL_i + A_j + b_1 \times W_{ijk} + a_{ijk} + e_{ijk} \quad (1)$$

Where Y_{ijk} is scaled CH_4 emission measured on animal k in Flock×Lot i of Age class j. W_{ijk} is scaled weight at measurement, b_1 is regression coefficient on Weight, a_{ijk} is random additive genetic effect of animal k, and e_{ijk} is random residual corresponding to Y_{ijk}.

The model for 42-d and 140-d weight was:

$$Y_{ijkl} = FY_i + ABKW_j + a_{ijk} + m_{ijl} + pe_{ijl} + e_{ijkl} \quad (2)$$

Where Y_{ijkl} is weight observation on lamb k in Flock×Year i and in rearing type $ABKW_j$, a_{ijk} is random additive genetic effect of lamb k, m_{ijl} is random additive genetic effect of the fostering dam l, pe_{ijl} is permanent environment effect of the fostering dam, and e_{ijkl} is random residual corresponding to Y_{ijkl}.

Results

Genetic standard deviations, heritabilities and genetic correlations for CH_{4adj}, 42-d_{adj} and 140-d_{adj} weights are shown in Table 2 along with standard errors. The heritability estimate for liveweight adjusted PAC CH_4 emission is similar to previously published sheep estimates (Goopy *et al.*, 2015; Dominik *et al.*, 2017) and

Table 1. Mean (sd) and number of observations for CH_{4adj}, live weight at measurement ($Weight_{adj}$), 42-day weight (42-d_{adj}), and 140-day weight (140-d_{adj}), above the diagonal is the number of observations with both traits.

	Mean (sd)	CH_{4adj}, g/hr	$Weight_{adj}$, kg	42-d_{adj}	140-d_{adj}
CH_{4adj}, g/hr	1.37 (0.28)	4,534	4,534	3,986	4,253
$Weight_{adj}$, kg	79.70 (9.88)		4,534	3,986	4,253
42-d_{adj}	14.34 (3.31)			91,873	84,496
140-d_{adj}	40.01 (7.69)				93,669

also similar to estimates where either feed intake or its proxies (liveweight, CO_2 emission, O_2 consumption) were used either as covariates or expressed in the denominator of a ratio of methane emission (Pinares-Patiño *et al.*, 2013; Jonker *et al.*, 2018). The only significant correlation between CH_{4adj} and growth traits was the maternal genetic effect of 42-day weight.

Genetic trends for CH_{4adj} and maternal genetic effect of 42-day weight are shown in Figure 1A along with number of ewes with CH_4 observations. Both traits follow the same trend until 2018, where the curve seems to flatten for CH_{4adj}. Most CH_4 observations are from ewes born 2017 through 2020. This may be contributing to the trend change, which in earlier years is largely driven by the maternal genetic correlation with $CH_{4adj.}$

Phenotypic trends for average carcass weight and number of days to slaughter for all 763 ram circle flocks are shown in Figure 1B for the same time period. The figure shows a decreasing trend in number of days to slaughter of one day per year and a simultaneously slight increase in average carcass weight. The increasing trend in methane emission is thus related to an increase in lamb growth during the main suckling period where the rumen only is partly functioning.

Discussion

Based on this study, including liveweight adjusted PAC CH_4 emission into the breeding goal for Norwegian White sheep imply a reduction in the CH_4 conversion factor Ym (% of gross energy intake partitioned into CH_4) Niu *et al.* (2021) and as such also the national emissions, given no additional feed stuffs are grown or imported.

Table 2. Genetic standard deviation (σ_a), heritabilities (in diagonal) and genetic correlations for CH_{4adj}, and direct (dir.) and maternal (mat.) genetic effect of 42-d_{adj} and 140-d_{adj} weights.

	σ_a	CH_{4adj}, g/hr	42-d_{adj} (dir.)	42-d_{adj} (mat.)	140-d_{adj} (dir.)	140-d_{adj} (mat.)
CH_{4adj}, g/hr	0.112	*0.17 (0.04)*				
42-d_{adj} (dir.)	0.897	-0.07 (0.11)	*0.11 (0.01)*			
42-d_{adj} (mat.)	0.776	0.32 (0.09)	-0.19 (0.05)	*0.08 (0.01)*		
140-d_{adj} (dir.)	2.291	0.19 (0.10)	0.71 (0.03)	0.05 (0.05)	*0.13 (0.01)*	
140-d_{adj} (mat.)	1.703	0.11 (0.10)	-0.18 (0.06)	0.82 (0.03)	0.00 (0.06)	*0.07 (0.01)*

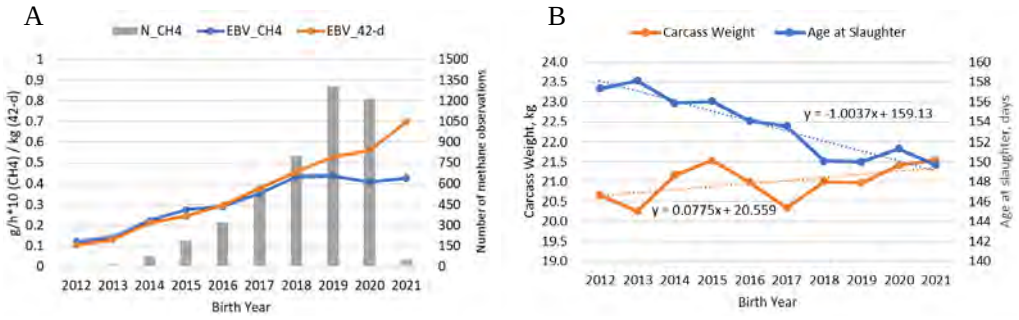

Figure 1. (A) Genetic trends for methane emission (g/hr ×10), maternal genetic effect of 42-day weight, and number of animals with methane measurements by age class. (B) Phenotypic trends for carcass weight and age at slaughter.

However, based on the correlations in Table 2, selection solely for reduced methane emission would result in a decrease in the maternal effect on lamb growth during main suckling period. This antagonistic relation should therefore be handled carefully when including methane emission in the breeding goal via appropriate weighting in the overall selection index.

35. Life cycle assessment to predict individual environmental impacts: towards selection for sustainable pig production

T. Soleimani[1], S. Hermesch[2] and H. Gilbert[1*]

[1]GenPhySE, Université de Toulouse, INRAE, ENVT, 31320 Castanet-Tolosan, France; [2]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; helene.gilbert@inrae.fr

Abstract

A life cycle assessment approach is proposed to quantify four environmental impacts at the individual pig level. The approach was applied to two lines divergently selected for feed efficiency, including simulations of performances with two diets. Significant line differences were obtained with least-cost diets for environmental impacts and profit ($P<0.001$), with a general advantage of the more efficient line. The optimised diets reduced the disadvantages of the less efficient line. Correlations between profit and environmental impact were high for feed efficiency (>0.85), and moderate (<0.45) for growth rate and body composition. Applied to pedigreed populations, this framework will provide genetic parameters of environmental impacts to improve the sustainability of livestock production.

Introduction

The Western pig production systems affect global warming potential (GWP), terrestrial acidification potential (AP), freshwater eutrophication potential (EP), and land occupation (LO) (McAuliffe *et al.*, 2016). However, early attempts to quantify environmental impacts (EI) in pigs essentially focused on nitrogen (N) and phosphorus excretion estimated at the animal level (Shirali *et al.*, 2012; Saintilan *et al.*, 2013). We propose a broader approach to predict the four EI at the individual level via a life cycle assessment model (LCA). It was applied to two pig lines with simulations of two nutritional strategies. Finally, a bio-economic model was used to evaluate the correlations between environmental impacts and profit.

Materials & methods

LCA model. A LCA model of typical pig farms in France was developed with a cradle-to-farm-gate system boundary (Soleimani and Gilbert, 2020) to evaluate GWP (kg CO_2 eq), AP (kg SO_2 eq), EP (kg P eq), and LO (m^2 a crop eq) from individual performance traits (Soleimani and Gilbert, 2021). The functional unit was 1 kg body weight of a pig at the gate. The ReCiPe Midpoint 2016 (H) V1.02 was used, together with the Ecoalim dataset of the AGRIBALYSE® database and the Ecoinvent inventory databases in SimaPro V8.5.4.0 on the MEANS platform, to obtain the impacts of diets and individual pig performance profiles.

Bio-economic model. The bio-economic model was developed from a linear profit model. The model mimicked the LCA model modules and ran from the same individual performances. It included the main costs of feed and water, labour, building and capital, energy, manure disposal, health, maintenance and repair (Soleimani *et al.*, 2021). Prices of diet ingredients (May 2020), energy consumption per kg pig and water to feed ratios were based on French averages. Revenue was from sales of live pigs, computed according to the French price grid from the baseline of a 100 kg carcass with lean meet percentage (LMP) of 56%, corrected for actual carcass weight and composition (July 2020).

Data. Experimental data were collected from the fifth generation of Large White pig lines divergently selected for residual feed intake (RFI, Gilbert *et al.*, 2017)). Fifty seven male pigs from each line (LRFI, more efficient pigs; HRFI, less efficient pigs) had *ad libitum* access to a one phase conventional diet during

growth-finishing. Records for daily feed intake, average daily gain (ADG), feed conversion ratio (FCR) and back fat thickness (BFT) were available.

Diet formulations and performance simulations. Diet formulation was based on wheat, barley, corn, oats, peas, triticale, rapeseed meal, sunflower meal, soybean meal, sunflower oil, and synthetic L_lysine, L_threonine, L_tryptophan and DL_methionine. Compositions were obtained from the INRA-AFZ feed ingredients database (Sauvant *et al.*, 2004).

Individual nutritional requirements profiles were computed from individual performance imported to InraPorc® (Brossard *et al.*, 2014), using a Gamma function. Two diets were formulated within line, covering the average nutritional requirements of the line, to either minimize cost (least-cost diet) or minimize a combination of cost and environmental impacts (optimised diet). This cost and environment multi-objective was a linear function of the sum of the four environmental impacts of the ingredients, considering equal weights for the four EI (EI score), and the sum of the ingredients costs. The relative weights of the environmental and economic objectives was optimized for each line (Soleimani and Gilbert, 2021), using a Pareto-optimal front curve. Next, the individual performances of pigs offered one or the other diet formulated for their line were simulated until slaughter weight (120 kg live weight) with InraPorc®. The resulting fattening traits for each individual were used as input parameters to the LCA and bio-economic models, to compute individual environmental impacts and profit.

Statistical analyses. Analyses were computed in R (R Core Team, 2019). The line differences for performances, environmental impacts and profit were tested with linear models including the fixed effect of the line (lm procedure). To illustrate correlations between variables, principal component analyses (PCA, PCA procedure) were applied to performances, environmental impacts and profit for the full dataset before and after adjusting for line effects.

Results

Diets. Pigs from the LRFI line had higher average requirements than HRFI pigs ($P<0.05$). For instance, digestible lysine was 0.91±0.20 g/MJ net energy in LRFI and 0.86±0.18 in HRFI. As a result, diet compositions differed between lines and formulation objectives: the LRFI least-cost diet contained essentially triticale (55%) and barley (26%), the HRFI least-cost diet contained corn (50%), triticale (17%) and barley (15%), whereas the optimised diets were more diverse (LRFI: corn (38%), triticale (22%), barley (12%); HRFI: barley (36%), corn (17%), triticale (16%), wheat (11%)). Then, as compared to the least-cost diet, the optimized diets had lower EI scores (Table 1), but not all the environmental impacts were reduced. Their prices per MJ of net energy were 1.5 (HRFI) to 4.5% (LRFI) higher.

Table 1. Environmental impacts, environmental score (EI score) and price per unit of net energy of the least-cost (LC) and optimised diets for the low (LRFI) and high residual feed intake (HRFI) lines.

Diet		GWP	AP	EP	LO	EI score	Price
		kg CO_2 eq	g SO_2 eq	g P eq	m^2 a crop eq		0.01€
LRFI	Least-cost	0.541	0.613	0.0526	0.181	0.430	2.01
	Optimised	0.486	0.663	0.0505	0.152	0.394	2.10
HRFI	Least-cost	0.483	0.683	0.0599	0.141	0.399	2.03
	Optimized	0.490	0.643	0.0496	0.163	0.395	2.06

[1] GWP = global warming potential; AP = acidification potential; EP = eutrophication potential; LO = land occupation.

Environmental impacts and profit. As expected, the simulated performances with the two diets were very similar within line (Table 2), and corresponded to known differences between the lines (Gilbert *et al.*, 2017). The environmental impacts of producing 1 kg of body weight with the least-cost diets were lower in the LRFI line than in the HRFI line, by 3.5% for GWP to 12.2% for EP ($P<0.001$), except for LO (-8.7%), as expected from other studies (Monteiro *et al.*, 2021). With optimised diets, these impacts decreased for both lines by 2.2 to 10.6% compared to the least-cost diets, except for AP for LRFI and LO for HRFI. Line differences reduced in simulations with optimised diets, from 2.0% for AP ($P<0.05$) to 8.5% for LO ($P<0.001$)), but LRFI pigs still had reduced impacts compared to HRFI pigs.

Table 2. Mean (standard deviation) and *P*-values of line differences (*P*) for simulated production traits, environmental impacts for 1 kg live weight at the gate, and profit for low and high residual feed intake lines (LRFI, HRFI) fed least-cost or optimised diets.

	Least-cost diets		P^2	Optimised diets		P^2
Trait[1]	LRFI	HRFI		LRFI	HRFI

Profit, €	17.75 (5.56)	14.47 (7.01)	**	16.86 (5.68)	15.58 (5.64)	ns

[1] ADG = average daily gain; FCR = feed conversion ratio; BFT = back fat thickness; GWP = global warming potential; AP = acidification potential; EP = eutrophication potential; LO = land occupation.

[2] *** $P<0.001$; ** $P<0.01$; * $P<0.05$; ns = non-significant.

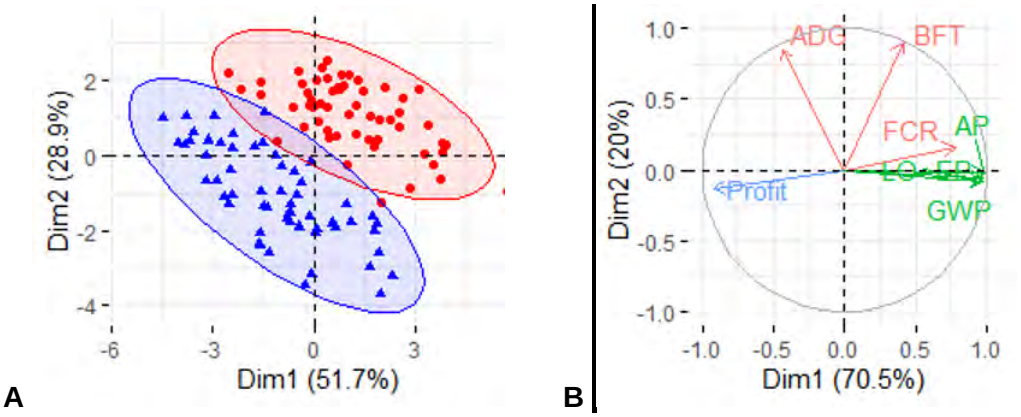

Figure 1. Principal components analyses of the least-cost diets dataset non-adjusted (A, red circles = HRFI pigs, blue triangles = LRFI pigs) and adjusted (B) for line effect.

With the least-cost diet, the LRFI pigs provided on average 3.28€ additional profit per pig, compared to the HRFI pigs ($P<0.01$). With performances and costs simulated with the optimized diets, the profit slightly decreased for the LRFI line (-0.89€/pig), whereas it was increased by 1.11 €/pig in the HRFI line, leading to a reduced and non-significant profit difference between lines with the optimised diets.

The correlations between variables did not differ between diets and Figure 1 only shows results for the least-cost diets. The PCA applied to non-adjusted variables mainly separated lines (Figure 1A.). After adjusting for line effects (Figure 1B.), environmental impacts had strong positive correlations with each other, and high negative correlations with profit (-0.84 to -0.86). FCR had a correlation of -0.76 with profit and ~0.65 with environmental impacts, whereas ADG and BFT had correlations <0.46 in absolute value with these variables.

Discussion

The LCA framework developed considers individual performances. This enables quantifying the main environmental impacts of individual pigs. In divergent lines, we showed how selection and diet formulation strategies result in different environmental impacts, but also that including environmental objectives in diet formulations could reduce the disadvantages of the less efficient line by using different feed ingredients. The proposed LCA framework, applied to large populations, will provide genetic parameters of environmental impacts to be used in breeding objectives, to contribute to the sustainability of livestock production.

Abstract

The objective of this study was to estimate genetic parameters for growth, feed intake and greenhouse gasses emission traits in Italian Holstein, using data collected on young bulls undergoing performance test. The phenotypic information was recorded on 189 bulls, for which genomic information was obtained using SNP chips. Data were analysed using a linear mixed model, which included an additive genetic effect using a genomic relationship matrix. Results show high heritability estimates for growth traits, moderate to high estimates for emission and feed intake traits. Selection for reduced emissions appears possible and reducing methane will also reduce carbon dioxide emissions (genetic correlation of 0.96). Feed intake traits could serve as indicators, because the genetic correlations range between 0.58 and 0.85. Growth traits showed strong positive correlations with emission traits (0.66 to 0.81), selection indices built at reducing emissions should carefully consider these traits as well.

Introduction

Dairy cattle is known to be impactful on greenhouse gasses (GHG) emissions, with its enteric emissions accounting for over ten percent of the emissions from the livestock sector globally (Gerber *et al.*, 2013). Methane emissions are also energetically expensive because of the fermentation process (Appuhamy *et al.*, 2016) but this inefficiency could be reduced by steering the fermentation process, redirecting the energetic resources to reproduction and milk production (Haque, 2018). Methane and carbon dioxide emission have been shown to be heritable, providing the basis for applying genetic selection for their reduction (Pickering *et al.*, 2015; Lassen and Løvendahl, 2016). Such selection could be applied by selecting directly for breath measurements, but also using indirect selection including indicator traits such as feed intake (De Haas *et al.*, 2017).

The objective of this study was to estimate genetic parameters for verifying the feasibility of (direct or indirect) selection for reduced GHG emissions in Italian Holsteins.

Materials & methods

Animals and data. The animals involved in this study were young Italian Holstein bulls undergoing performance test at the Italian National Breeders Association for the Holstein, Brown Swiss and Jersey dairy cattle breeds (ANAFIBJ). Phenotypic data was made available on 189 Holstein bulls between the age of 171 and 541 days. All bulls were genotyped using various SNP chips resulting in 98,586 SNP. Genomic data was edited using the preGSf90 software (Aguilar *et al.*, 2010), removing SNP with call rate below 0.9 and minor allele frequency below 0.05. After editing, 89,625 SNP were available.

The first set of traits included measures of body growth taken using electronic scales and stadiometers operated by qualified personnel. These included body weight (WEI), body condition score (BCS), heart

girth (HG) and height (HEI). The second group of traits included measures of feed intake and feeding behaviour assessed using the Roughage Intake Control system (RIC; Hokofarm Group, Marknesse, the Netherlands). Records were organized as daily measures: number of visits at the feeder per day (NVF), average intake at the feeder (AIF), average time at the feeder (ATF). The third group of traits included measures of greenhouse gasses emission and were obtained using the GreenFeed (C-Lock Inc., Rapid City, SD, USA). Again, the single-visit measures were converted to daily records and included: number of visits (NVG), carbon-dioxide daily emission (CO_2), methane daily emission (CH_4), average airflow (AIR) and average time (ATG). A single dataset was created, containing all the phenotypic information. Individuals showed an average of 4 records for the growth traits, 36 records for the RIC-derived traits, 19 records for the GreenFeed-derived traits. For all records, the age at recording was calculated. In addition, the date of birth of the individual was transformed to numerical values as the difference, in days, from a fixed arbitrary date.

Statistical analysis. Estimates of variance components and genetic parameters were carried out using a linear mixed model that include a genomic relationship matrix constructed using the SNP markers. The model was defined as follows:

$$y = Xb + Z_d d + Z_p p + Z_a a + e \quad (1)$$

where y is the vector containing phenotypic records, X and b are the incidence matrix and vector of solutions for the fixed effects (age at phenotyping, date of birth), Z_d and d are the incidence matrix and vector of solutions for the 'date of recording' uncorrelated random effect, Z_p and p are the incidence matrix and vector of solutions for the animal permanent environmental uncorrelated random effect, Z_a and a are the incidence matrix and vector of solutions for the animal additive genetic random effect (with genomic relationship matrix), e is the vector of random residuals. The model was implemented for single-trait and two-trait analyses in order to obtain estimates of heritability and genetic correlations, using the gibbs2f90 software (Misztal *et al.*, 2002). Estimates of variance components and genetic parameters were obtained as posterior means and their dispersion was obtained as the posterior SD and the 95% confidence intervals. The heritability was expressed as the ratio between the additive genetic variance and the sum of the four variance components.

Results

Descriptive statistics and heritability estimates for the studied traits are reported in Table 1. The growth and condition traits showed the largest estimates, all being above 0.50. While these traits are expected to be highly heritable, the estimates appear larger compared to those found in literature. This could be due to the relatively small sample size. On the other hand, heritability estimates for the RIC-derived traits were lower, ranging from 0.151 (ATF) to NVF (0.299). Heritability estimates for the emission traits were moderate to high, ranging from 0.189 for ATG to 0.530 for CO_2.

Genetic correlation estimates are reported in Table 2. Among the growth traits, correlations were strong for WEI-BCS and BCS-HG, but weak for all the other combinations of traits. Correlations between NVF and AIF was basically null (0.25), the genetic correlation between AIF and ATF was 0.97 (result not shown in table). Correlations among the GreenFeed-derived traits were moderate to strong, especially among CH_4, CO_2 and AIR, which were all above 0.85. NVG was moderately related to the other GreenFeed-derived traits, with correlations below 0.7. The genetic correlation between AIR and ATG was 0.95 (result not shown in table). Genetic correlations between the growth traits and the RIC-derived traits were all positive and strong, approaching unity (0.93 to 0.96). Genetic correlations between the growth traits and the GreenFeed-derived traits were also positive but moderate, with values ranging from 0.66 to 0.86. Similarly, the genetic correlations between the GreenFeed-derived traits and the RIC-derived traits were positive and moderate to strong, with values from 0.58 to 0.90.

Table 1. Descriptive statistics and heritability estimates (posterior means with posterior standard deviation) for the traits analysed.

Trait[1]	Metric	N	Mean	SD	h^2

AIR	**0.85**	**0.86**	**0.76**	**0.79**	**0.87**	**0.64**	**0.89**	**0.85**	**0.90**	

[1] Estimates of the genetic correlations are the posterior mean for the parameter. Values in bold indicate that the value '0' was not included within the confidence intervals, therefore are to be considered significant for $P<0.05$.

[2] WEI: body weight; BCS: body condition score; HG: heart girth; HEI: height; NVF: number of visits at the feeder; AIF: average intake at the feeder; NVG: number of visits at the GreenFeed; CO_2 daily carbon dioxide emissions; CH_4: daily methane emissions; AIR: average airflow at the visit.

Discussion

The estimates show substantial genetic variation for all the studied traits. The CO_2 and CH_4 daily emissions show large heritability with the possibility of selection, therefore reduction of GHG emissions. The estimated values for the heritability of CH_4 and CO_2 are larger than values found in literature (Lassen and Løvendahl, 2016; Brieder *et al.*, 2018), although this could be due to the involvement of growing bulls rather than lactating cows and the limited sample size in the current study. The genetic correlations indicate that there is the possibility to select for less impactful animals. The genetic correlation between CO_2 and

CH_4 emissions is close to unity (0.91), suggesting that selection for one component of the emissions would improve the other as well. Similarly, the AIR shows strong correlations with the GHG emissions, suggesting that this trait could be used as an indicator. Similarly, the NVG could serve as an indicator trait to reduce the emissions, although the achievable genetic progress would be limited due to the moderate genetic correlations (0.7-0.8). In fact, the value of 0.7 was indicated as the minimum acceptable value for achieving a relevant genetic progress in case of multiple-trait genomic predictions by Calus and Veerkamp (2011). Using this same criterion, NVF could reduce GHG emissions better than feed intake (AIF) given the stronger genetic correlations (0.85 vs ~0.60). Unsurprisingly, selection for larger animals will also lead to individuals that consume more feed with all correlations between growth traits and RIC-derived traits being above 0.9. Similarly, selection for larger animals could lead to more GHG emissions, although this relationship seems to be weaker because genetic correlations between growth trait and GHG emissions tend to be equal or smaller than 0.80. In general, selection indices could be built in order to reduce GHG emissions without compromising growth, condition, stature and feed intake. The upcoming research should involve the use of feed efficiency and relative GHG emission, as these components need to be adjusted by the growth and size of the animal.

37. Association of genetic resistance to internal nematodes and production traits on feed efficiency and methane emissions in Corriedale lambs

E.A. Navajas[1], G. Ciappesoni[1*], D. Gimeno[2], J.I. Velazco[1] and I. De Barbieri[1]

[1]Instituto Nacional de Investigación Agropecuaria, INIA Las Brujas, 90100, Rincón del Colorado, Canelones, Uruguay; [2]Secretariado Uruguayo de la Lana, Servando Gomez 2408, 11200, Montevideo, Uruguay; gciappesoni@inia.org.uy

Abstract

Potential trade-off among weaning (WWT) and yearling weights (YWT), greasy fleece weight (GWT) genetic resistance to gastrointestinal nematodes assessed by faecal worm egg account (FEC), residual feed intake (RFI) and methane (CH_4) and carbon dioxide (CO_2) emissions were investigated in 217 Corriedale female lambs. Improving RFI was strongly associated with lower dry matter intake (DMI) and independent of metabolic body weight (MWT) and average daily gain (ADG). Person correlation coefficients were also no significant (P>0.05) with WWT, YWT, GFW and FEC expected progeny differences (EPD). FEC EPD was not correlated with any of the traits investigated here. Both CH_4 and CO_2 were not associated with RFI, although the moderate correlations with DMI. Higher EPD for WWT, YWT and GFW were correlated with higher DMI, CO_2 and CH_4. Optimising higher productivity and environmental sustainability requires further research for a more comprehensive understanding of these associations.

Introduction

Sustainable sheep production requires considering not only traditional production traits but also those associated with resilience and greenhouse gas (GHG) mitigation. Genetic evaluation of Corriedale, as dual-purpose breed, includes body weight and wool production, which are relevant for economic income of commercial production. Improving genetic resistance to gastrointestinal nematodes (GIN), using faecal worm egg count (FEC) as selection criteria, is also included in the breeding programme (Ciappesoni *et al.*, 2014). Given the important losses in pastoral grazing extensive systems due to infestation by GIN, and the difficulties to control it only by grazing management and chemical treatments, genetic selection by FEC may also contribute to economic and environmental sustainability.

Improving feed efficiency and reducing enteric methane (CH_4) and carbon dioxide (CO_2) emissions by genetic selection represents an opportunity for reducing production costs (Tortereau *et al.*, 2020) and contributing to GHG mitigation strategies. Although a minimum detrimental effect on productivity is expected by improving residual feed intake (RFI) (Tortereau *et al.*, 2020) and FEC (Ferreira *et al.*, 2021), potential trade-off between production, efficiency, resilience or immune system, and GHG emissions need to be evaluated. Feed efficiency traits and GHG emissions are being recorded in lambs of the Corriedale Information Nucleus in Uruguay, providing the basis for investigating the associations among current and potentially new breeding objectives towards environmentally sustainable sheep production. The aim of this study was to investigate the association between growth, wool and FEC, based on the expected progeny differences (EPD) for these traits, and feed intake, feed efficiency and GHG emissions.

Materials & methods

Two hundred and seventeen Corriedale female lambs, from three cohorts (2018-2020) sired by 12 rams genetically linked breeding population were studied. The EPDs published in 2021 for weaning weight (WWT-E), body weight as hogget (YWH-E), greasy fleece weight (GFW-E) and FEC (FEC-E), which included animal own records, were provided by the National Sheep Genetic Evaluation System (www.geneticaovina.com.uy)

Feed efficiency and methane phenotypes. 42-day feed efficiency tests were carried out, after 14 days of acclimatisation to feed and facilities. Lambs were allotted to one of five pens according to initial body weight, type of birth and sire, and fed *ad libitum* with Lucerne haylage (22.0% of crude protein, 26.6% of acid detergent fibre, 32.2% of neutral detergent fibre, and 59.0% of dry matter). Average dry matter intake (DMI) and growth rate (ADG) were calculated based on daily feed intake and body weights recorded by automated feed bins and weighing platforms (Intergado®, Belo Horizonte, Brazil), respectively (Ferreira *et al.*, 2020). Portable accumulation chambers (PAC) were used to measure CH_4 and carbon dioxide (CO_2) emissions using protocol described by Paganoni *et al.* (2017). Two estimates per animal were performed in the last weeks of the feed intake test, with one week between them.

Data calculation and analysis. Residual feed intake (RFI, Koch *et al.*, 1963) was estimated as:

$$y = u + MBW + ADG + Test \times Pen + e(RFI)$$

where y = DMI (kg/day), MBW is the metabolic average body weight (kg, covariate), ADG is the average daily gain, previously calculated by linear regression (g/day, covariate), Test is the effect of the test (3 levels), Pen is the effect of the pen (5 levels) and RFI is the residual error.

Phenotypes of DMI, MBW and ADG, as well as CH_4 and CO_2, were adjusted by environmental effect using a lineal model that included Test × Pen as class effects, and age (days) as covariate. The corresponding residuals DMI-A, MBW-A, ADG-A, CH_4-A and CO_2-A were included in the analysis. Given the criteria used to allot animals to pens, adjusting by this factor also implies indirectly adjusting by initial body weight. The associations among traits were assessed by Pearson correlation coefficients based on the data described in Table 1. All analysis were carried out using CORR and GLM procedures in SAS program version 9.4 for Windows (SAS Inst., Cary, NC, USA).

Table 1. Mean, standard deviation (SD), minimum (Min) and maximum (Max) values of EPD for production traits, and feed efficiency and GHG emissions phenotypes of Corriedale female lambs (n=217).

Traits	Mean	SD	Min	Max
Weaning weight EPD (WWT-E, %)	7.80	3.70	-2.53	17.39
Yearling body weight EPD (YWT-E, %)	6.87	3.34	-2.51	15.84
Faecal worm egg count EPD (FEC-E, log FEC)	-0.11	0.10	-0.39	0.21
Greasy fleece weight EPD (GFW-E, %)	1.96	2.94	-5.63	11.82
Residual feed intake (RFI, kg DMI/day)	0.00	0.11	-0.26	0.49
Dry matter intake (DMI, kg/day)	1.21	0.22	0.49	1.80
Metabolic body weight (MWT, kg)	14.20	1.45	9.88	18.30
Average daily gain (ADG, kg/day)	0.17	0.04	0.05	0.27
Methane emissions (CH_4, g/day)	16.41	4.75	6.10	28.48
Carbon dioxide emissions (CO_2, g/day)	826.97	179.06	441.42	1,448.00
Adjusted DMI (DMI-A, kg/day)	0.00	0.15	-0.37	0.53
Adjusted MWT (MWT-A, kg)	0.00	0.77	-2.07	3.52
Adjusted ADG (ADG-A, kg/day)	0.00	0.04	-0.11	0.12
Adjusted CH4 (CH_4-A, g/day)	0.00	2.65	-7.93	7.91
Adjusted CO_2 (CO_2-A, g/day)	0.00	110.96	-319.50	340.64

Results

As expected, RFI was correlated with DMI (r=0.50) and independent of weight and growth. Similar associations were found between RFI and the adjusted traits, although the correlation coefficient with DMI-A was higher than with DMI (r=0.74). The associations among feed efficiency traits and GH emissions are in Table 2. High positive correlations were calculated for DMI and both GHG (~0.60), and the association was weaker for the adjusted phenotypes.

The correlations of growth and weights were also high with unadjusted and adjusted DMI, CH_4 and CO_2 (range 0.30 to 0.74). No significant association (P>0.05) were found between RFI and GHG emissions.

Body weights EPD had positive correlations with most of the traits included in this study. They were medium to high with DMI (0.57), MWT (0.66) and both GHG emissions traits (0.51-0.54). When these traits were adjusted, the correlation magnitude decreased to low-moderate (0.19-0.44) but remained significant (Table 3). The associations of GFW-E were positive and low with MWT and DMI, and negative with ADG. No association were found with between GFW-E and GHG emissions (P>0.05). On the other hand, any of the feed efficiency traits or GHG emissions were significantly correlated with FEC-E. RFI was not significantly associated with any of the EPD considered here.

Discussion

Improving RFI by selection is an alternative to reduce production cost by lowering DMI without compromising animal performance (Tortereau *et al.*, 2020). The lack of statistically significant associations between RFI and genetic merits for growth and wool production is encouraging about the potential benefits of integrating this trait in the Corriedale breeding programme. However, we did not find a reduction in CH_4 emissions in more efficient lambs, as in other studies (i.e. Paganoni *et al.*, 2017). If genetic correlations follow these coefficients among adjusted phenotypes, RFI could not be considered as indirect selection criteria for GHG mitigation.

The positive associations between CH_4 and CO_2 and EPDs for growth and wool production indicate that reducing GHG emissions would imply a decrease of animal performance, and, therefore, of economic incomes derived from meat and wool. When GHG emissions were adjusted, correlation coefficients decreased from moderate-high to low magnitudes similar to those reported by Robinson *et al.* (2014).

One relevant driver of the associations among production, feed efficiency and GHG emission is DMI. Our results confirm DMI is highly correlated with RFI, as was reported at phenotypic and genetic level in the literature (Paganoni *et al.*, 2017; Tortereau *et al.*, 2020). High DMI is also associated with better animal performance, particularly when animals are fed at libitum like in the feed efficiency tests, as well as with CH_4 and CO_2. However, disentangling the biological interrelation among these traits is constrained given DMI remains as very difficult- to-measure trait, with limited available alternative for grazing conditions.

The non-significant correlations of FEC-EPD with feed efficiency traits indicate that improving FEC does not affect feed efficiency, productivity or GHG emissions. These results are in agreement with Ferreira *et al.* (2021), who did not find differences in these traits between lambs from Corriedale divergent FEC selection lines under natural and artificial GIN challenge.

In summary, these preliminary results indicate that improving feed efficiency by RFI would imply maintaining productivity with lower feed costs, with no unfavourable effect on genetic resistance to GIN and independently of GHG emissions. However, the positive correlations of DMI with GHG emissions and productivity implies a trade-off to be considered at the time of including GHG mitigation as new breeding objective, which will be checked by the estimation of the genetic correlations. As phenotyping continues, larger database will enable the estimation of these genetic parameters.

Abstract

The dairy sector has to reduce nitrogen (N) surpluses in the near future. In this context, the cow individual milk urea (MU) concentration has been suggested to reflect N-excretion in breeding strategies. The variability in MU levels is partly affected by ruminal processes attributed to microbes and host gene expression. To investigate the relevance of MU for breeding, we aimed to uncover ruminal mechanisms in cows with predisposed higher compared to lower MU (HMU vs LMU; n=20). Whereas the core microbiota at phylum level remained constant, the abundances of three microbial families differed between HMU and LMU cows. Transcriptome profiling of rumen tissue revealed 28 genes, including *MMP3*, *TNP2* and various genes of immune response that distinguished HMU and LMU cows. Our findings contribute to a deeper knowledge of MU predispositions in Holsteins and attribute to the optimisation of N-usage in conjunction with the reduction of N-emissions from dairy farms.

Introduction

The primary source of N-emissions from dairy cows is displayed by unutilised N, which is ingested by the cow with feed crude protein and excreted via urine, milk and faeces (Abdoun *et al.*, 2006). In this context, the ruminal conversion rate of N into valuable microbial protein, which is the result of rumen microbial growth, considerably contributes to the amount of N-utilisation and N-emissions (Tan *et al.*, 2021). Due to the high phenotypic correlation between milk urea (MU), urinary urea and blood urea concentration (Guliński *et al.*, 2016) the cow individual MU value has been suggested as substitute trait for breeding selection (Beatson *et al.*, 2019; Honerlagen *et al.*, 2021). In regard of successful breeding selection on N-use efficiency and reduced N-excretion from dairy cows, unravelling the molecular biological background of predisposed higher or lower MU concentrations (HMU – LMU) in dairy cows is required. Considering the large impact of ruminal processes on the N-metabolism in lactating ruminants, our study elucidated exclusively differences in the rumen microbial community and corresponding host-specific transcriptional processes between HMU and LMU cows.

Materials & methods

The predisposition for higher or lower MU concentration (HMU – LMU) was determined by deregressed proofs of a breeding value for MU, estimated by vit Verden (Vereinigte Informationssysteme Tierhaltung, Verden, Germany). The subsequent categorisation was further validated by the five recent milk records from each cow (HMU=278.1±15.8 mg/l, LMU 181.54±15.08 mg/l; mean ± SD). Based on this classification, 20 German Holsteins in late lactation were stalled in pairs, comprising one HMU and one LMU cow, treated as previously described (Müller *et al.*, 2021) and slaughtered after two weeks. Samples of rumen villi and rumen fluids (50 ml) were collected from each cow immediately after slaughter, snap frozen (-80 °C) and stored.

Laboratory analyses and sequencing pipelines. Microbial DNA was extracted from rumen fluids, quality checked and used to amplify the V4 hypervariable region of the 16S rRNA gene (Kozich *et al.*, 2013), which was sequenced on HiSeq2500 (Illumina, San Diego, CA). The reads were subsequently

filtered, trimmed, and removed from chimeras within the mothur software (version 1.44.1; Schloss *et al.*, 2009). Sequences were aligned to the Silva reference database (release 138; https://www.arb-silva.de/), aggregated into operational taxonomic units (OTU, sequence identity ≥97%) and annotated according to the Silva database. The count data was rarefied to the sample with the lowest read depth (745,235 reads). Statistical analyses were conducted at phylum (n=19) and family (n=116) levels. Total RNA was isolated from homogenized rumen villus epithelium, purified, qualitatively and quantitatively checked and utilized for mRNA library preparation. Libraries were paired-end sequenced on HiSeq2500. After quality control and filtering, sequences were aligned to the current reference genome (Bos_taurus.ARS-UCD1.2). The number of reads uniquely mapped to each gene were extracted using HTSeq (version 0.12.4).

Statistical analyses of rumen microbiome and transcriptome. Initially the core microbiome of HMU and LMU cows was investigated based on relative abundances at phylum level. Subsequently, DESeq2 was used to identify differentially abundant phyla and families between HMU and LMU cows (Love *et al.*, 2014). Similarly, the transcriptome dataset was analysed for differentially expressed genes (DEG) with DESeq2. The trial of each pair was included in all statistical models as fixed effect accounting for different crude protein levels in the feed rations. DEG were further assigned to their general biological functions using GeneCards (http://www.genecards.org).

Results

Bacteroidota und *Firmicutes* displayed the most dominant phyla in both, HMU and LMU cows by capturing 78.7% of relative abundances in all rumen fluids (43.4 and 35.3%, respectively) (Figure 1). The analysis at family level revealed *Monoglobaceae* ($P<0.01$) and *Ruminococcaceae* ($P=0.01$) being significantly more abundant in LMU compared to HMU cows. Microbes assigned to *Acetobacteraceae* sowed a significantly high relative occurrence in HMU compared to LMU cows ($P=0.04$).

In the filtered transcriptome dataset 28 DEG were identified between HMU and LMU animals. The highest fold changes were revealed for Matrix Metallopeptidase 3 (*MMP3*) and Transition Protein 2 (*TNP2*), with higher transcript abundance in HMU and LMU, respectively (Table 1). Five of the top ten DEG were identified as contributors of immune response and displayed higher expression in LMU cows.

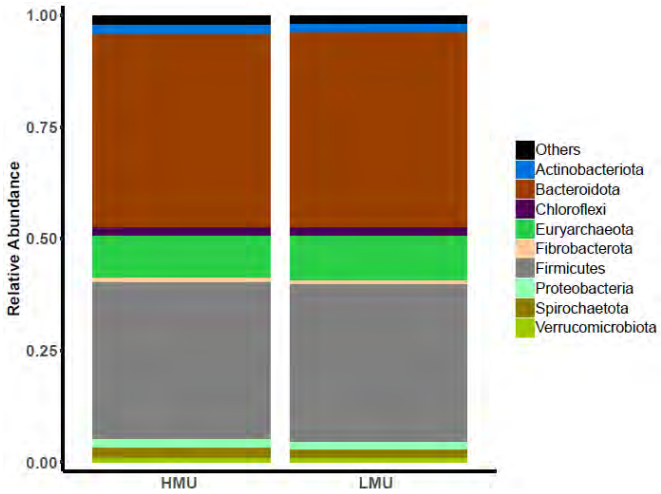

Figure 1. Microbial composition of rumen fluids from HMU and LMU cows at phylum level indicating a similar pattern with dominance of microbes assigned to *Bacteroidota* and *Firmicutes*.

Table 1. Most prominent DEG between HMU and LMU cows.

Discussion

Our study focused on the ruminal characterisation of Holsteins with predisposed higher or lower MU concentration (HMU – LMU). Both, HMU and LMU cows occupied the typical core microbiome of the bovine rumen (Wallace *et al.*, 2019) comprising mainly *Bacteroidota* and *Firmicutes*, which captured 78.7% of total rumen abundances (43.4 and 35.3% respectively). Apparently, MU predisposition was not substantially associated with distinguished rumen flora. However, three significantly differentially abundant families between HMU and LMU cows were identified. Interestingly, the *Ruminococcaceae* family, which displayed higher abundances in LMU cows has already been attributed a fundamental role in amino acidic and protein metabolism in the bovine rumen (Pacífico *et al.*, 2021). In addition, various *Ruminococcaceae* genera displayed higher abundances in goats with high N-efficient phenotypes (Wang *et al.*, 2019). Further analysis of the microbiome at genus level as well as the effect estimation of specific genera on N-utilisation and N-excretion might unravel substantial information of ruminal MU characterisation. The results of DEG analysis elucidated the enhanced expression of immune response genes in LMU cows. Interestingly, Zhang *et al.* reported the activation of immune response pathways in the rumen epithelium of calves with higher N-efficiency (Zhang *et al.*, 2021). Moreover, recent studies identified immune system activities of the host epithelia as key drivers of long- term host – microbial maintenance (Peterson *et al.*, 2007). In this context, the interplay between host gene expression, the microbial community and the rumen environment as well as the different partitioning of nitrogen to body compartments will be further investigated between HMU and LMU cows with regard to divergent N utilisation and N excretion mechanisms.

Abstract

Dairy farming may have negative impacts on the environment, such as ammonia emissions to air and nitrate leaching to water. By selecting more efficient cows, the amount of nitrogen excreted per cow and consequently the adverse environmental impacts will be reduced. The aim of this study was to predict nitrogen use efficiency (NUE) of individual dairy cows using mid-infrared (MIR) spectra of milk. A total of 600 feeding and MIR records of 56 Holstein cows were collected from a farm in Beijing, China. NUE was calculated as the ratio of nitrogen in milk to nitrogen intake. The coefficient of determination of the best model was 0.69, 0.62 and 0.70 for NUE, nitrogen loss and dry mater intake, respectively. The MIR wavenumbers around 981.00 and 1506.93 cm^{-1} and daily milk yield were the most important variables for prediction. These results show potential for large-scale genetic evaluations of nitrogen efficiency.

Introduction

As widely emphasised, nitrogen surpluses at dairy farms have negative impacts on the environment, such as ammonia emission and nitrate leaching to ground and surface water. Meanwhile, the increasing demand for animal products will result in higher production and thus results in more intensive dairy farming with higher total emissions of nitrogen (N) if N losses are not controlled. Therefore, a more efficient, and environmentally friendly production system is needed, in which NUE of dairy cows plays a key role. If efficient cows are selected, the fraction of intake that is not ending up in faeces or urine will be lower, which will contribute to lower N losses to the environment. Generally, this kind of resource allocation trait is difficult to measure individually (Lopez-Villalobos *et al.*, 2018). For instance, it requires assessment of daily feed intake, which is costly. To genetically improve NUE, routinely recording and cost-effective proxies are essential to initiate genetic evaluations. Recently, Grelet *et al.* (2020) obtained reasonable proxies for N related traits such as NUE and nitrogen loss (NL) by including MIR spectra of dairy cows in their prediction models. A maximum coefficient of determination (R^2) of 0.82 was observed in their validations, which indicated the proxies were reasonable for further genetic analysis.

However, these prediction models were only based on records from Holstein cows in early lactation. Individual NUE and NL in other lactation stages have not been predicted yet with MIR data. Literature also indicated that non-informative signals may exist in original MIR data, which will decrease the relation between phenotypes and MIR spectra (Bresolin and Dórea, 2020). Pre-treated MIR data may be beneficial for constructing robust prediction models. Therefore, different pre-processing methods were assessed in the current study. Additionally, it is of interest to quantify the contribution of different input variables. The objectives of this study were (1) to develop the best prediction model of NUE, NL and dry matter intake (DMI) for individual dairy cows in China, (2) to compare different prediction models of these traits, and (3) to investigate the importance of input variables in the prediction.

Materials & methods

A feeding trial was conducted in an experimental farm in Beijing, China between March 2017 and August 2017. A total of 56 Chinese Holstein cows in mid and late lactation stage (154-452 days in milk (DIM)) were offered the same diet during the experimental period in a free-stall design barn. Daily feed intake of

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_39, © R. Shi *et al.* 2022

individual cows was recorded by an automatic system (Roughage Intake Control System, Insentec B.V., Marknesse, the Netherlands). Daily DMI was calculated for each cow based on feed intake and dry matter content of the diet. Each cow was evaluated monthly for body condition scores (BCS) by two technicians. Additionally, the daily milk yield for each cow was recorded by the milking system.

Individual MIR spectra were obtained from Fourier transform spectrometers (Bentley, Chaska, USA) at the Beijing Dairy Cattle Centre. Fat, lactose, milk urea nitrogen (MUN) and total protein of milk samples were estimated from the MIR analysis.

NUE was defined as ratio of total N output in milk to total N intake from feed and NL was defined as total N intake from feed minus total N output in milk (Calsamiglia *et al.*, 2010). Two pre-processing methods were applied to the original MIR data to reduce the influence of noise in the MIR spectra, namely multiplicative scatter correction (MSC) and standard normal variate (SNV). Subsequently, wavenumbers induced by water were omitted, resulting in 215 data points for each record (Grelet *et al.*, 2016). The MIR spectra were then combined with feeding trial data, providing 600 records of 56 cows.

The selected MIR spectra, parity (1 and 2 or more), corresponding daily milk yield, BCS, DIM_g (actual DIM grouped by 5 days) and additional parameters generated by MIR analysis (protein, fat, lactose and MUN) were included for model development. MIR spectra were included in prediction either as original spectra or as result from pre-processing (MSC-spectra or SNV-spectra).

Furthermore, three different algorithms were applied for prediction: partial least squares (PLS), ridge regression (RR), and support vector machine (SVM) regression. Consequently, a total of 48 models were applied for predicting each trait (Table 1).

To validate the models, the dataset was randomly split in test and training sets in a ratio of 1 to 3, and a cow can only be in the test set or in the training set. Prediction models were constructed using the training sets and validated using the test sets. The performance metrics included R^2, root mean square error (RMSE), relative error (RE, calculated as RMSE/mean of the global data), and ratio of standard deviation of the global data to RMSE from the validation (RPD). Besides, the Spearman correlation coefficient (SpearR) between true values and predictions was included to test re-ranking of the best model. Importance of each input variable for the PLS and RR methods was defined as the absolute value of the corresponding regression coefficient.

Table 1. Prediction models for nitrogen use efficiency, nitrogen loss and dry matter intake.

Models	Predictors[1]	Number of input variables	Spectra	Algorithms	Count[2]
Model 1	MIR	215	Original, MSC, SNV	PLS, RR, SVM	9
Model 2	+ Milk yield, parity	217			9
Model 3	+ BCS	218			9
Model 4	+ DIM_g	219			9
Model 5	+ MUN	220			9
Model 6	+ Protein, fat, lactose	8	No MIR		3

[1] For model 2 to 5, the additional predictor of next model is based on previous model, and model 6 includes all additional predictors, except for MIR spectra.
[2] Number of prediction models developed using this set of predictors: 3 algorithms times 3 types of MIR spectra for models 1-5 = 9 models. See main text for abbreviations.

Results

Individual daily NUE was on average 26.4%, with a standard deviation of 8.6%, NL was on average 0.51 kg/day, with a standard deviation of 0.15 kg/day, and DMI was on average 25.15 kg/day, with a standard deviation of 5.95 kg/day.

Model 6 was the least accurate for NL and DMI regardless of the performance metrics (Figure 1). Model 2 generated the best prediction for NUE and DMI, with a relatively high R^2 and RPD, as well as a small RE. Model 1 had a better application to NL, from which the highest R^2 and RPD, as well as lowest RE were obtained. For most models with MIR, the pre-processing step resulted on average in a 12.3% higher R^2 and 8.6% higher RPD, in combination with a 11.2% smaller RE on average.

Model 2 using the SVM method, and model 1 and model 2 using the PLS method were the best models for predicting NUE, NL and DMI, respectively (Table 2). SNV-spectra were included in these models, and the best model for NL only included MIR spectra.

The most important variables were MIR wavenumbers 973.54 to 988.46 cm^{-1}, 1,480.80 to 1,574.07 cm^{-1}, and daily milk yield based on feature score.

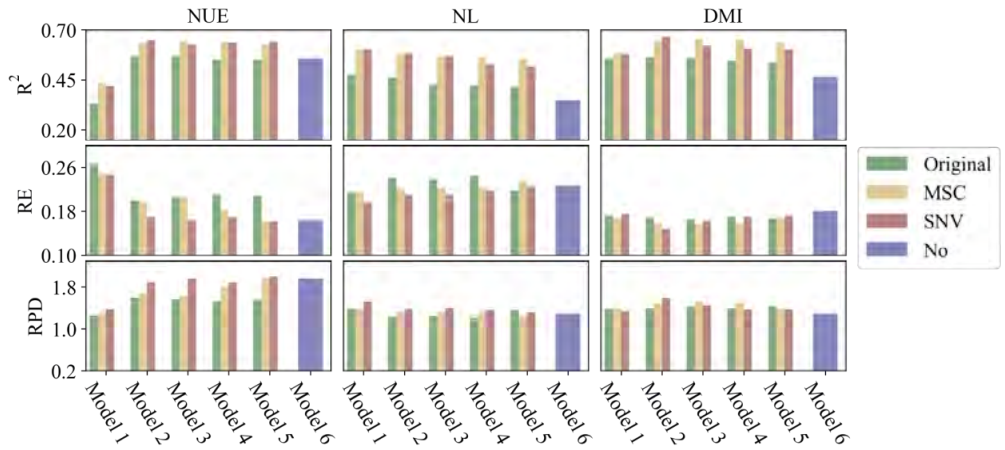

Figure 1. Statistics of different prediction models for nitrogen use efficiency, nitrogen loss and dry matter intake.

Table 2. Performance of best model for each trait[1].

Trait	Model information	R^2	RE	RPD	SpearR
NUE	Model 2, SNV-spectra, SVM	0.69	0.15	2.11	0.84
NL	Model 1, SNV-spectra, PLS	0.62	0.20	1.46	0.79
DMI	Model 2, SNV-spectra, PLS	0.70	0.14	1.70	0.81

[1] See main text for abbreviations.

Discussion

The current study developed accurate prediction models for daily NUE, NL and DMI of individual cows by comparing different prediction algorithms and precorrection methods for MIR data. Furthermore, the contribution of input variables was evaluated. The performance metrics of the best models for these three traits were comparable with those in the study of Grelet *et al.* (2020), which reported a range of R^2 from 0.59 to 0.68, RE from 0.14 to 0.23, and RPD from 1.57 to 2.07. It should be noted that the equations in Grelet *et al.* (2020) were based on three farms in three countries and therefore they might be more robust than prediction equations based on one farm. As long as feeding regimes are very similar on other farms, the prediction equations may facilitate genetic evaluation on a larger data set of MIR spectra. For instance, Chen *et al.* (2021) applied the prediction models of Grelet *et al.* (2020) to a large dataset for genetic evaluation of predicted NUE and NL in early lactation.

In this study, adding MIR spectra in the best models increased the R^2 and RPD by 10 to 30%, as well as reduced the RE by 0.03 to 0.10 compared to using model 6 (Figure 1). Meanwhile, this improvement was more obvious when MIR spectra were pre-treated. These results indicate that MIR includes additional information for better prediction of NUE, NL and DMI. Pre-treated MIR spectra were better than raw MIR spectra for developing accurate prediction models. Milk yield was an important variable in all models because it is highly correlated with N output (phenotypic correlation=0.96). The specific wave range of MIR that was important in prediction comprised C-H, C-N and N-N stretching (Grelet *et al.*, 2015; Xia *et al.*, 2018), which is related to proteins.

The results of current study indicate that the methodology is suitable to exploit MIR data for prediction of NUE, NL and DMI as reflected by a relatively high R^2. The resulting predictions can be applied to improve nutrition and management of dairy herds in China and to perform further genetic evaluations.

Abstract

The focus of this research was to analyse CH_4 data recorded by GreenFeed emission monitoring systems by assessing the repeatability of such phenotypic measures, to estimate genetic parameters and generate estimated breeding values (EBVs) for CH_4 related traits. Additionally, validation of EBVs in this research will aid in establishing a protocol for CH_4 measurement for the generation of national genetic evaluations. In total 979 animals have completed CH_4 recording to date, with 211,136 individual CH_4 observations. The repeatability and heritability of CH_4 increased as the number of the days of methane measurement per animal included in the phenotypic average increased however, EBV validation suggests shorter averaging periods result in better, more consistent EBVs.

Introduction

Measuring CH_4 is a costly exercise, but necessary to incorporate CH_4 traits into national breeding goals with the aim of reducing enteric CH_4 emissions. The GreenFeed emission monitoring (GEM) system estimates daily CH_4 production by measuring gas concentrations and airflow from cattle when they visit a GEM unit (Hammond *et al.*, 2015). While respiration chambers remain the gold standard for CH_4 measurement of livestock, strong correlations (0.81 (S.E.=0.10)) between respiration chambers and the GEM system have been reported (Garnsworthy *et al.*, 2019), suggesting GEM is a suitable lower-cost and scalable alternative to measure CH_4. However, there is large disparity between GEM protocols in existing CH_4 emission measurement studies as CH_4 concentrations (CH_4 gram/day) vary with visit number and duration to the GEM system which has consequences for data comparison across studies (Della Rosa, *et al.*, 2021). The objective of this study therefore was to develop a standardised protocol for routine enteric CH_4 data analysis with the goal of producing national EBVs.

Materials & methods

The data used in the present study were obtained from a pre-existing database managed by the Irish Cattle Breeding Federation (ICBF).

Data. CH_4 and carbon dioxide flux measurements using GreenFeed machines (C-Lock Inc., 2021) were recorded on 979 cattle destined for slaughter between 2018 and 2021 as part of the progeny performance testing in the Gene Ireland Progeny Performance Test Centre (Tully, Co. Kildare, Ireland). Measurements of feed intake, liveweight and ultrasound muscle measurements were also available on all animals. Animals ranged from 368 days to 910 days of age at the time of entry to test centre and were the progeny of AI bulls under evaluation of the Gene Ireland Breeding program. Animals were purchased in groups, referred to as intakes. All 26 intakes of animals were unisex and had an average intake size of 38 animals (S.D.=16.58). The final intake dataset was compromised of 510 steers, and 361 heifers and 90 bulls. On arrival to the test centre all animals underwent acclimatisation periods on both Insentec automatic feed stations for feed intake measurement and GEM machines. Full details of animal recruitment and acclimatisation management are detailed elsewhere by Kelly *et al.* (2019). Dry matter intake (DMI) was recorded as the sum of intake recorded via both the Insentec and GEM systems. To calculate Residual CH_4 (RCH_4) the

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_40, © C.V. Ryan *et al.* 2022

phenotypic relationship between each CH_4 measurement and feed intake at discrete intervals prior to the observation was determined. The resulting correlations with CH_4 were 0.55, 0.55, 0.49, 0.40, 0.31, 0.25, 0.24, 0.36 for the time periods 3, 6, 9, 12, 15, 18, 21, 24 hours respectively. Hence as each time period shows some relationship to CH_4, RCH_4 was estimated using multiple regression incorporating all DMI time periods in MiX99 (Luke, 2017) where RCH_4 is the methane corrected for DMI.

Data edits. From the initial data set of 979 animals, data from visits outside of the defined test period were excluded from all analysis. CH_4 measurements less than zero or in the top or bottom 1% of the data were also removed. For the estimation of genetic parameters, animals with unknown sires were excluded (n=14) and only CH_4 measurements where a minimum of three sires were represented in a given day were included. Animals were also required to have CH_4 records on five individual days. After edits, 712 animals were available for genetic parameter estimation, with 84,091 observations retained.

Trait definitions investigated. Seven phenotypic definitions of CH_4 and RCH_4 were investigated in this analysis. Phenotype 1 was each individual CH_4 observation, phenotypes 2-6 where CH_4 and RCH_4 observations were averaged every 1,5,10,15 and 30 days per animal and phenotype 7 where CH_4 and RCH_4 observations were averaged across the full test period per animal.

Phenotypic analysis. Phenotypic repeatability (for CH_4 only) was estimated for each phenotypic CH_4 averaging period using SAS Proc Mixed procedure, where contemporary group defined as GreenFeed machine, intake group number and day of observation and animal were included as fixed effects.

Genetic analysis. Univariate repeatability animal models in DMU (Madsen, P., and Jensen, J., 2013) were used to estimate variance components. The animal model applied to all seven traits can be described as:

$$y = Xb + Za + Wp + e \quad (1)$$

Where y was the methane trait (CH_4 and RCH_4), b is a vector of fixed class effects (contemporary group, time of day) and fixed regressions (age, breed proportion, general heterosis coefficient), a is the additive genetic effect of the animal, p is the random repeated environmental effect of animal (phenotype 1-6 only), and X, Z and W are the corresponding incidence matrices. Additionally, in phenotype 1, a random animal effect was included to account for within day repeatability per animal. EBVs were estimated using MiX99. Validation was performed by generating EBVs for whole and partial evaluation; partial evaluation excluded the most recent third of animals to enter the test facility, based on test start date. The full evaluation comprised of 961 animals with phenotypes and the validation evaluation had 658 animals. The linear regression method by Macedo, *et al.* (2020) was used to estimate the bias (both level and dispersion) and accuracy of both evaluations.

Results

Phenotypic repeatability of CH4 data. To ensure all animals were represented in each repeat period (Table 1), phenotypic analysis included all animals who were on test for a minimum of 60 days (n=340). Repeatability of CH_4 measure increased as the length of the averaging period increased (Table 1). The average number of visits per animal per day was considerably lower for the young bulls in comparison to the steers and heifers cohorts. However, diet differences between the young bull cohort means the differences in mean CH_4 measurement is not comparable to steer and heifer means.

Table 1. Phenotypic repeatability of CH_4.

	Steers		Heifers		Young bulls	
Number of animals	175		100		65	
Mean CH_4 (SD)	240.23 (84.59)		233.29 (77.74)		158.92 (73.42)	
Average visits per day (SD)	2.59 (1.03)		3.09 (0.70)		0.45 (0.23)	
Repeat period	n[1]	Repeatability	n[1]	Repeatability	n[1]	Repeatability
Within day	31,261	0.16	21,660	0.49	1,417	0.17
1 day period	10,204	0.16	6,649	0.28	725	0.24
5-day period	2,260	0.54	1,503	0.46	345	0.30
10-day period	1,203	0.60	794	0.54	259	0.34
15-day period	827	0.69	573	0.53	214	0.31
30-day period	498	0.62	314	0.49	128	0.45

[1] Number of observations in repeatability analysis.

Heritability estimates of methane traits. Heritability estimates of both CH_4 and RCH_4 increased as the duration of the averaging period increased (Table 2). Standard errors were high due to the limited nature of the dataset, but heritability was deemed significant.

EBV validation. Overall, RCH_4 was more consistent in the dispersion bias than CH_4 across the averaging periods, however the differences are small due to the limited dataset (Table 3). This suggests that RCH_4 may be a more suitable trait for inclusion in the national index.

Table 2. Heritability estimates for methane traits.

		CH_4			RCH_4

Discussion

Methane is an expensive trait to record, and as such data utilisation needs to be maximised. Visit frequency of animals to the GEM system has an impact on the repeatability of phenotypic CH_4 measures and requires careful consideration when utilising CH_4 data. While increasing the length of the averaging period results in higher levels of heritability, EBV validation would suggest that the shorter averaging periods result in a more accurate EBVs due to the increased number of CH_4 measures included in the analysis. Ongoing work on the correct validation approach that correctly accounts for the non-homogenous nature of existing data and limited data size still needs to be completed. While the validation cohort in this analysis were the most recent third of animals, the number of individual CH_4 records excluded was 59.5% of total CH_4 records due to the heterogeneity of records between more recent animals and earlier animals. Other validation cohorts which have a less severe loss of records will be investigated. Further analysis will be required to establish the best trait for inclusion in the national index that is independent of traits in the current breeding objective and fits with industry requirements going forward.

Abstract

Post-slaughter alimentary tract measures were collected from eight-month-old ram lambs during routine culling of sheep divergently selected for methane yield. Measures from 142 and 132 lambs from the high and low methane lines respectively were collected over five years. Low CH_4 animals had lighter reticulo-rumen full, empty and contents weights ($P<0.05$), but tended to have longer rumen papillae ($P=0.06$). Preliminary heritability estimates for reticulo-rumen components and papillae traits were significantly different from zero, ranging from 0.09 to 0.25. Results validate earlier findings that differences in the anatomical characteristics of the alimentary tract are associated with methane emissions and suggest that there is a significant host genetic component, warranting further investigation.

Introduction

Ruminant livestock production systems are under increasing scrutiny due to the release of enteric methane: a potent greenhouse gas associated with climate change. In New Zealand, enteric methane emissions (CH_4) from grazing livestock account for a third of total greenhouse gas emissions (MfE 2020). In ruminants, CH_4 comes primarily from the enteric fermentation process, where through a symbiotic relationship that has evolved over millennia, microbes in the reticulo-rumen break down and ferment plant material, providing energy for the host animal. Despite ruminants providing ~51% of animal protein consumed by humans, the complexity of ruminant digestion is poorly understood. Furthermore, there is little published literature on the plasticity of the alimentary tract despite huge variation across bovinae and ungulates. Research has shown that there is at least partial host genetic control of the symbiotic relationship as methane emissions are heritable and repeatable traits in sheep (Pinares-Patiño *et al.* 2013). Differences in methane production have been associated with variation in the alimentary tract and rumen microbial community structure (Kittelmann *et al.* 2014). Sheep with reduced CH_4 emissions have been shown to have differences in rumen physiology compared to their high emitting counterparts, including smaller rumen surface area and volume (Goopy *et al.* 2014; Bain *et al.* 2014; Lambe *et al.* 2019), and shorter retention times through the alimentary tract (Pinares-Patiño *et al.* 2003; Bond *et al.* 2017). There is also preliminary evidence from CH_4 yield selection lines for differences in lean muscle yield, dressing out percentage, and rumen and reticulum full weights (Elmes *et al.* 2014), as well as feed intake and feeding behaviour (Johnson *et al.* 2018). Breeding for reduced CH_4 emissions in sheep may therefore fundamentally change the morphology of the alimentary tract. Understanding this relationship could be informative for the selection of low methane emitting ruminants and the impact of such selection. The objective of this study was to determine the impact of selecting for divergent CH_4 emissions on anatomical characteristics of the reticulo-rumen.

Materials & methods

The use of animals for this study, including welfare and experimental procedures, was approved by AgResearch's Invermay and Grasslands Animal Ethics committees (Approvals 14907, 14603, 14491, 14370, 14455, 14007).

Animals. Animals were from a flock selected for divergent CH_4 yield (g CH_4 / kg DMI), described fully in (Pinares-Patiño *et al.* 2013). Briefly, 1000 ewes were initially screened from four research progeny test flocks, with 100 ewe lambs retained based on CH_4 yield extremes. Animals were selected using respiration chamber measurements, repeated after 10-14 days (Pinares-Patiño *et al.* 2011). From the above flocks, 96 rams were selected from the born-2009 lambs. The lines were closed in 2012, and all subsequent animals used have been born within the flock, which is currently maintained at 100 ewes per line. Ram lambs that were surplus to breeding requirements were slaughtered between six and nine months of age through either a commercial processing plant or a research abattoir (Table 1).

Measurements. Live weight was recorded for each animal before slaughter. Animals that were processed through a commercial processing plant were slaughtered approximately 24 hours after removal from pasture, whereas those processed through a research abattoir were taken off pasture at least two hours before slaughter. Post-euthanasia, the gastrointestinal tract was removed and the full reticulo-rumen weight was recorded before thorough washing in tap water and re-weighing. Reticulo-rumen contents were estimated by subtracting the empty weight from the full weight. A 2 cm^2 sample was taken from the dorsal area of the rumen atrium, in the centre of the area with profuse papillae (Figure 1), pinned to a corkboard and stored in 10% paraformaldehyde for 10 days before being transferred 70% alcohol.

Table 1. Summary of animals with alimentary tract measures.

Birth year	High CH_4 yield	Low CH_4 yield	Average age (days)	Processing location
2012	37	23	261 (250-270)	Commercial
2013	30	33	255 (239-263)	Commercial
2014	28	29	239 (223-254)	Commercial
2015	30	29	223 (216-233)	Commercial
2017	17	18	274 (250-289)	Research abattoir

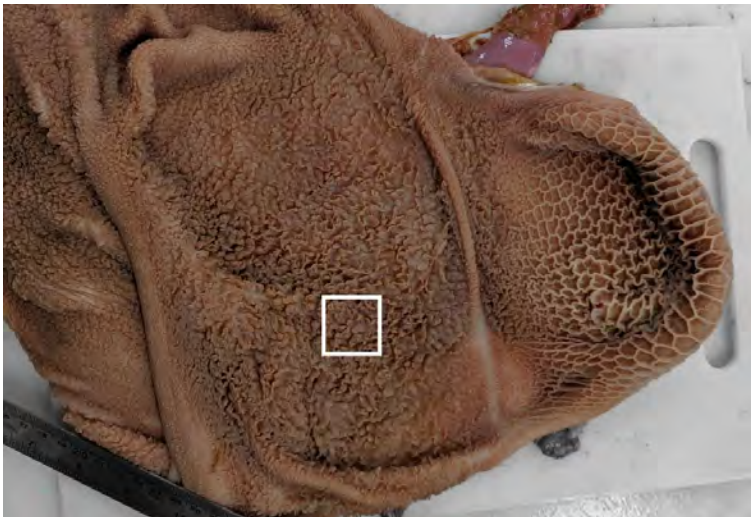

Figure 1. Ovine reticulo-rumen, showing the location for rumen papillae sampling.

Papillae density per cm^2 and length and width of 10 papillae per animal were measured using a dissecting microscope. Papillae length and width were used to estimate surface area (SA) per mm^2 using the following equation (Hill *et al.* 2005):

$$SA=2\times r\times \pi\times L+ \pi\times r^2 \quad (1)$$

where r = radius in mm and L = length in mm.

Statistical analysis. Alimentary tract measures were analysed separately using a standard least-squares model in SAS (SAS Institute Inc., Cary NC, USA) fitting sire as a random effect, selection line (high or low CH_4) and year of birth as fixed effects, and pre-slaughter weight as a covariate. Variance components were estimated using restricted maximum likelihood (REML) procedures fitting a sire model.

Results

The CH_4 selection lines differed in several reticulo-rumen measurements (Table 2). Low CH_4 animals had lighter reticulo-rumen full, empty and contents weights ($P<0.05$), and tended to have longer rumen papillae ($P=0.06$). Using a sire model, preliminary heritability estimates ranged between 0.16 and 0.19 for reticulo-rumen weight measures (Table 2). The heritability for papillae height was 0.25±0.07, however, papillae width was non-significant (0.10±0.06).

Discussion

The finding that low CH_4 emitting sheep have a smaller reticulo-rumen relative to body size is consistent with previous studies (Goopy *et al.* 2014; Bain *et al.* 2014; Bond *et al.* 2017). The mean full reticulo-rumen weight of low CH_4 yield animals was 6% lighter than their high CH_4 counterparts, which is in line with the 10% difference observed by Elmes *et al.* (2014) using a subset of the animals used in this study. Differences in rumen volume as estimated by CT scanning were larger (20%) in the 2009-born selection line ewes (Bain *et al.* 2014), however, that study screened in the phenotypic extremes for methane yield.

The weight of the entire gastrointestinal tract also has important implications for commercial farmers beyond the association with CH_4 emissions. To optimise carcass value, animals are weighed before selection for slaughter as a prediction of carcass weight. Dressing out percentage (carcass weight as a percentage of pre-slaughter weight) can vary, however, with one of the biggest contributing variables being the weight of the gastrointestinal tract ('gut fill') at the time of weighing. Gut fill can be between 10 and 22% of pre-fast live weight (Litherland, Dynes, and Moss 2010). Dressing out percentage was reported to vary in the CH_4

Table 2. Mean ± standard error and heritability of alimentary tract measures from high CH_4 (n=142) and low CH_4 (n=132) yield animals.

Trait	High CH_4	Low CH_4	*P*-value	Diff.[1]	Heritability
Reticulo-rumen full (g)	5,358±82	5,052±83	0.01*	6%	0.19±0.07
Reticulo-rumen empty (g)	988±8	956±8	0.01*	3%	0.16±0.07
Est. rumen contents (g)	4,370±81	4,096±82	0.02*	6%	0.20±0.07
Papillae count (per cm^2)	32±1	31±1	0.61	2%	0.09±0.05
Av. papillae height (mm)	3.69±0.09	3.92±0.09	0.06	-6%	0.25±0.07
Av. papillae width (mm)	1.94±0.04	1.95±0.04	0.85	0%	0.10±0.06
Av. papillae surface area	26.6±1.0	28.5±1.1	0.21	-7%	0.22±0.07

[1] Percentage difference between high and low CH_4 as a proportion of the high.

selection line animals, with low CH_4 animals having lighter reticulo-rumen weights and a higher dressing-out percentage (Elmes *et al.* 2014). Dressing out percentage is heritable (0.25±0.03) in New Zealand lambs (Brito *et al.* 2017), and the genetic relationship between dressing out percentage, CH_4 emissions and alimentary tract measures warrants further investigation.

While estimated in a small number of selection line animals, a significant genetic component was observed to multiple alimentary tract measures, including reticulo-rumen full and empty weights, rumen contents, and rumen papillae length. This finding is consistent with the moderate heritability of reticulo-rumen volume in Texel lambs (h^2=0.45±0.13), as estimated by computed tomography (CT) images (Lambe *et al.* 2022). Together, these results indicate that future research is needed in a larger cohort of animals to estimate accurate genetic parameters for alimentary tract measures, along with their relationship to production traits.

42. Economic values for climate change responsive traits to develop a sustainable dairy cattle breeding goal in the tropics

C.K. Chepsiror[1], E.D. Ilatsia[2] and T.O. Okeno[1,3*]

[1]Animal Breeding & Genomics Group, Department of Animal Science, Egerton University, P.O Box, 536 Egerton, Njoro, Kenya; [2]Dairy Research Institute, Kenya Agricultural Research Organization (KALRO), P.O. Box 25, 20117, Naivasha, Kenya; [3]African Animal Breeding Academy, CoELIB, Centre, 18 Maziwa Road, Egerton University, Njoro, Kenya; tobias.okeno@egerton.ac.ke

Abstract

The objective of this study was to derive economic values for climate change responsive traits for inclusion in a dairy cattle breeding goal in the tropics. Using the Kenyan dairy cattle breeding program as the source of input parameters, a bio-economic model was developed to derive economic values for climate change responsive traits which included feed efficiency (FE), resilience (RE) and adaptability (AD) while economic values for disease resistance (DR) was derived using selection index methodology. Residual feed intake, variance deviations in milk yield, influence of increased temperature-humidity index on milk yield and brucellosis disease resistance were used as indicator traits for FE, RE, AD and DR, respectively. The economic values for FE, RE, AD and DR were; $ -0.14, 0.41, 1.55 and -0.58/cow/year, respectively. These economic values indicate that inclusion of climate change responsive traits in a breeding goal would lead to improved response to selection of dairy cattle in the tropics.

Introduction

Resource poor countries in the tropics are expected to bear the brunt of climate change effects, thus agricultural productivity of livestock systems will be negatively affected. This is because most agricultural activities in the tropics are rain-fed, hence livestock feed resources are expected to reduce as heat waves increase. Dairy cattle production costs are therefore expected to rise as farmers will have to spend more on feeds and cooling systems to manage increasing heat. Fortunately, these challenges could be overcome by breeding for dairy cattle which are adapted to the tropical production conditions as opposed to the current blind importation of genetic materials. This would require development of a robust dairy cattle breeding goal that accounts for both production, reproduction and climate change responsive traits which is currently lacking.

In the tropics, dairy cattle breeding has mainly focused on improvement of production, functional and reproductive traits (Kahi and Nitter, 2004), hence ignoring climate change responsive traits. With the effects of climate change, there is need for a paradigm shift to breed for dairy cattle that are not only productive but are feed efficient, resilient to dynamic environmental changes, adaptable and resistant to diseases. Breeding for such animals require inclusion of traits such as; feed efficiency, resilience, adaptability and disease resistance in the breeding goal. Feed efficiency is the relative ability of cows to turn feed nutrients into milk or milk components. Residual feed intake (RFI) which is the difference between actual feed intake and predicated feed intake on the basis of requirements and body weight maintenance has been used as an indicator for feed efficiency (Hietala *et al.,* 2014). Resilience (RE) is the capacity of the animal to be minimally affected by disturbances (Berghof *et al.,* 2019). Variance of deviations in milk yield provides an indication of the impact of a disturbance. Heat stress is the sum of external forces acting on an animal that causes an increase in body temperature. Temperature-Humidity Index (THI) is an indicator to assess high ambient temperature and humidity. Disease resistance is the ability of the host animal to exert control over a disease. Disease incidences result in high cost of production attributed to veterinary costs, low productivity and loss in products attributed to withdrawal periods when animals are under veterinary care.

DOI: 10.3920/978-90-8686-940-4_42, © C.K. Chepsiror *et al.* 2022

Breeding for disease resistance, especially zoonotic disease such as Brucellosis which causes abortion at the end of gestation period, reduction in milk yield and infertility (Musallam *et al.,* 2019) would be a promising approach towards achieving good health for dairy cows and human consumers. Inclusion of these traits in a breeding goal require estimation of their economic values. Economic value is a unit change in the trait, while keeping all the other traits in the breeding goal constant (Kahi and Nitter, 2004). The objective of the current study was to derive economic values for climate change responsive traits for their inclusion in the breeding goal. Using the Kenyan dairy cattle breeding scheme, bio-economic modeling was used to derive the economic values feed efficiency, resilience and adaptability while selection index methodology was used to derive economic value for disease resistance.

Materials & methods

Procedure. Deterministic simulation approach was used to derive economic values for climate change responsive traits for their inclusion in the breeding goal of dairy cattle in the tropics. The current Kenya dairy cattle breeding goal which account for production, reproduction and milk quality traits was adopted.

Estimation of economic values. The bio-economic model was developed in a python computer program to derive economic values for feed efficiency (FE), resilience (RE) and adaptability (AD). On the other hand economic value for disease resistance (DR) was derived using selection index methodology (Hazel, 1943). All the economic values were in USD. The indicator traits for FE, RE, AD and DR were residual feed intake, variance deviation on milk yield, temperature-humidity index (THI) and brucellosis resistance, respectively. The input parameters on costs were obtained from the current dairy cattle production systems in Kenya. The main sources of revenues included sales of milk, in calf heifers, manure and culled cows and bull calves. The unit prices were adjusted for the current inflation rates. The economic values for FE, RE and AD were computed as:

$$EV = {}^{\Delta P}/_{\Delta T} \tag{1}$$

where, ΔP is change in profit after a unit increase in the trait of interest, while ΔT is marginal change in trait of interest after a unit increase.

Feed efficiency was measured as a function of Residual Feed Intake (RFI) according to Koch *et al.* (1963):

$$Y_i = \beta_0 + \beta_1 ADG + \beta_2 MWT + \varepsilon_i \tag{2}$$

where Y_i is daily feed intake (FI) of animal *i*, β_0 is regression intercept, β_1 *and* β_2 are partial regression coefficients of FI on average daily gain *ADG* and mid-weight *MWT*, ε_i is residual error of FI on animal *i*.

Resilience was measured using variance deviations on the lactation curve of 305-day milk yield according to Berghof *et al.* (2019):

$$\sigma^2 = \frac{x-\mu}{n} \tag{3}$$

where, σ^2 is the variance deviation in 305-day milk yield, $x - \mu$ is the deviation of daily milk yield from the overall mean and n is lactation length in days.

Adaptability was calculated using heat stress as an indicator and temperature-humidity index (THI) as the reference point. The equation by Hahn (1999) was used to calculate THI:

$$THI = 0.81.T + \left(\frac{RH}{100}\right).(T - 14.4) + 46.6 \quad (4)$$

where, T is the mean hourly ambient temperature (°C) and RH is mean hourly relative humidity (%).

The economic value for DR was computed using selection index methodology (Hazel, 1943). This method matches the breeding objective to expected responses in production traits and responses in these traits are maximized relative to overall gains. In the current study economic value for DR was estimated relative to milk yield (MY).

Since dairy farmers in Kenya and others in the tropics are risk averse due to fluctuation in weather conditions, outbreak of diseases and market prices, computation of risk rated economic values are most suitable. The risk rated economic values were computed as described by Kulak *et al.* (2003):

$$\text{REV} = \frac{\mu po\, f(\boldsymbol{g},\boldsymbol{e})}{\boldsymbol{e}\mu pi} - 0.5\ \lambda\ \text{E}\ \{\text{EE}_t - \text{E}\ (\text{EE}_t)^2\} \quad (5)$$

where, E (EE_t) is the expected values of economic efficiencies, λ the Arrow-Pratt coefficient of absolute risk aversion (0.02) and μ_{po} and μ_{pi} are the expected values of output and input prices, respectively, g, the vector of the variables determined by the genotype and e the vector of the variables associated with inputs.

Results

The bio-economic model developed and selection index methodology were able to derive risk rated economic values for climate change responsive traits. The findings indicated that RE and AD had positive economic values of $ 0.14 and $ 1.55/cow/year, respectively. On the other hand, FE and DR had negative corresponding economic values $ -0.14 and $ -0.58 per/cow/year (Table 1).

In this study, accounting for risks in the economic values did not yield errors larger than ±5% for any trait on the basis of evaluation. This indicates that both traditional and risk-rated models can be satisfactorily used to predict profitability and develop selection index criteria applicable in large-scale and smallholder dairy cattle breeding programmes in the tropics.

Discussion

The findings of the current study indicate that inclusion of climate change responsive traits in the current breeding goal would increase response to selection. This could be explained by the fact that the economic values for RE and AD were positive while those for FE and DR were negative (Table 1). The positive economic value for RE and AD indicate that selecting for these traits would result in dairy cattle with better adaptability and potential to produce milk even in the face of environmental fluctuations such as drought and heat stress. This in turn would result in high returns for the dairy farmers in the tropics where productivity of dairy cattle is dependent on weather fluctuations. Positive economic values for RE and AD have also been observed in previous studies of Bergohf *et al.* (2019). The negative economic values for FE

Table 1. Risk-rated economic values in US dollars (USD) for traits in the fixed herd size production system (Arrow Patt coefficient of absolute risk aversion (0.02) /cow/year.

Trait	Economic value
Resilience (RE)	0.14
Adaptability (AD)	1.55
Feed efficiency (FE)	-0.14
Disease resistance (DR)	-0.58

and DR in the current study should be good news to dairy farmers in the tropics. This is because some of the effects of climate change included reduced production of feed resources due to long drought and faster spread of livestock diseases due to migration of nomads with their livestock from one place to another. The negative economic value for FE indicate that selection for FE would result to dairy cattle which can efficiently utilize low quantities local feed resources and convert it to milk. This would reduce the cost of production as feed resources account for over 50% of total dairy cattle production costs in the tropics (Kahi and Nitter, 2004). The negative economic value for FE has also been obtained in the previous studies in the temperate countries Hietala *et al.* (2014). The negative economic value for DR was expected due to negative correlation between DR and MY which it was derived relative to. Similar findings were obtained with mastitis resistance in dairy cattle as reported by Sagwa *et al.* (2019). The negative economic value for DR indicate that selection for resistance to brucellosis would result in cows that are resistance to the disease. This could automatically, reduce production costs attributed to treatment, withdrawal and risk to human health.

Conclusions

Climate change responsive traits; feed efficiency, resilience, adaptability and disease resistance are important traits that should be included in the current dairy cattle breeding goal in the tropics. The positive economic values for resilience and adaptability and negative values for feed efficiency and disease resistance indicate feasibility of including these traits in the current dairy cattle breeding goal in the tropics. This would result in a robust dairy cattle breeding goal with higher returns to both large-scale and smallholder dairy farms in the tropics in the face of climate change.

Abstract

Climate change is expected to not only increase the frequency of extreme weather events, but to also increase the variability of climate conditions within geographical locations. Within the context of climate, livestock genetics research has mostly focused on G×E interactions and on selection for specific environments. This approach, however, does not address the sensitivity of animals to unstable environmental conditions, a likely scenario due to climate change. In this study, we explored the association between the variation in climate variables and the historical trends of growth traits in American Angus beef cattle. Analyses were performed using historical climate data, and phenotypic records of birth, weaning and post-weaning weights from American Angus beef cattle over the last three decades, from herds covering a wide area of the United States of America (USA). Results suggest a greater variation of both phenotypic and genetic trends in regions with high climate variability.

Introduction

One of the most pressing issues that humanity faces is the challenge of feeding a continuously growing population in an environment that is being disrupted by climate change. Due to the current concerns related to climate change there is an immediate need for breeding programs to reduce the environmental footprint of animal production (e.g. methane emission) and at the same time increase the resilience of animals to environmental changes. This is particularly relevant for beef cattle production systems which are largely extensive, and animals are constantly exposed to a broad range of environments (e.g. heat stress, which has a negative effect on commercial traits in beef cattle (Bradford *et al.*, 2016)). In terms of climate, livestock genetic research has mostly focused on estimation of G×E interactions (Fennewald *et al.*, 2018) and on selection for specific environments, viz recent studies that evidenced within-breed genetic diversity associated with different ecoregions in the USA that were defined based on the historical means of several climate variables and topography (Blackburn *et al.*, 2017; Braz *et al.*, 2021; Rowan *et al.*, 2021). However, one of the frequently noted outcomes of climate change is the increasing climate variability and frequency of extreme events (Trenberth *et al.*, 2015; Stott, 2016). It may be the case that subregions within these ecoregions suffer differently the effect of climate variability over the years. The objective of this study was to explore the association between the variability of climate conditions and the historical growth traits trends in American Angus beef cattle.

Materials & methods

Animal performance data. Phenotypic and pedigree information was provided by the American Angus Association. We performed the analysis on phenotypes recorded between 1990 and 2019 from 448 herds, all herds with at least 25 years of records and a minimum of 10 records per year-season (two seasons defined). Birth weight (BW), weaning weight (WW) and post-weaning weight (PWW) were recorded for a total of 1,754,310 Angus cattle.

Climate data. We used historical time-series climate data from 2,334 weather stations spread across the continental USA (Menne *et al.*, 2012). Eight variables[1] based on temperature and precipitation were selected from weather stations with at least 25 years of records between 1990 and 2019. A Principal Component Analysis (PCA) was carried out using the standard deviation and skewedness of each of the eight variables for each station during the period of interest. From this PCA, we used the squared cosine (COS2) of the components to calculate the distance of a given observation (station) from the center of the system. COS2 was then used as a proxy for each station's climate variability (ClimVar). Finally, we classified the weather stations into five ClimVar groups using the values of COS2 as: low [0-0.2], medium-low (0.2-0.4], medium (0.4-0.6], medium-high (0.6-0.8] and high (0.8-1]. Using GPS coordinates, the herds used in this study were associated to each weather station and their corresponding ClimVar group.

Genetic evaluation model. Variance components and estimated breeding values (EBV) were obtained using a single trait model $y = Xb + Za + e$, where y are the phenotype records (of BW, WW or PWW); b are the coefficients of the fixed effects (herd-year-season – 16,047 levels; sex – two levels, male or female; age of the dam at calving – four levels, 2yo, 3-5yo, 6yo, or 7-12yo; for WW and PWW the linear and quadratic effects of the age of the animal was included as well) and X is their design matrix; $a \sim N(0, A\sigma_a^2)$ are the breeding values and Z is their design matrix, with A as the numerator relationship matrix based on the pedigree; $e \sim N(0, I_n\sigma_e^2)$ are n random residuals. A was built tracing three generations back from the animal with records and comprised 2,208,105 animals. The analyses were implemented using airemlf90 which is part of the BLUPF90 family of programs (Misztal *et al.*, 2014).

Results

Figure 1 shows (A) the geographical location of the herds used in the analysis and their ClimVar grouping; and (B) the contribution of the skewness and standard deviation of each of the eight climate variables used to classify the herds into a ClimVar group. We noticed that herds located in the central-north region of the country were closer to locations with higher ClimVar during the analyzed period. These locations mostly correspond to the ecoregion denominated 'high plains' by Braz *et al.* (2021). Approximately 40% of the phenotypic records were from herds classified as medium to high ClimVar. The variables with a higher contribution in the PCA analysis were the standard deviations of the average and maximum temperature (sdTAVG and sdTMAX), and the variables related to precipitation, i.e. the variability of the total amount of precipitation per year (sdPRCP) and the number of days with ≥25.4 mm of rain in the year (sdDP1X). We also observed that the skewness of the average, maximum and minimum temperatures (skTAVG, skTMAX, skTMIN) were relevant, although mostly associated with the second component of the PCA analysis. Figure 2 shows the average phenotypic, genetic, and residual trends by year of birth, for herds located in the five ClimVar groups. We observed a decreasing trend for BW, while WW and PWW showed an increasing trend along the years. These trends are in line with the general emphasis given to selection traits in beef cattle breeding programs. Herds associated with high ClimVar showed a more irregular trend, especially for phenotypes.

A greater difference between the extreme ClimVar groups (low and high) was observed for phenotypic and genetic trends of BW, a rather unexpected result since BW is a phenotype modulated by the maternal environment and should be less directly influenced by changing weather conditions. The residual trends of the herds classified as high ClimVar were distinct for all three traits, however in the three traits residuals were more unstable for herds in the highest ClimVar locations.

[1] Average mean, maximum and minimum temperature in the year, total precipitation per year, number of days with maximum temperature ≥21.1 °C in the year, number of days with maximum temperature ≥32.2 °C in the year, number of days with ≥2.54 millimeters precipitation in the year, number of days with ≥25.4 millimeters precipitation in the year.

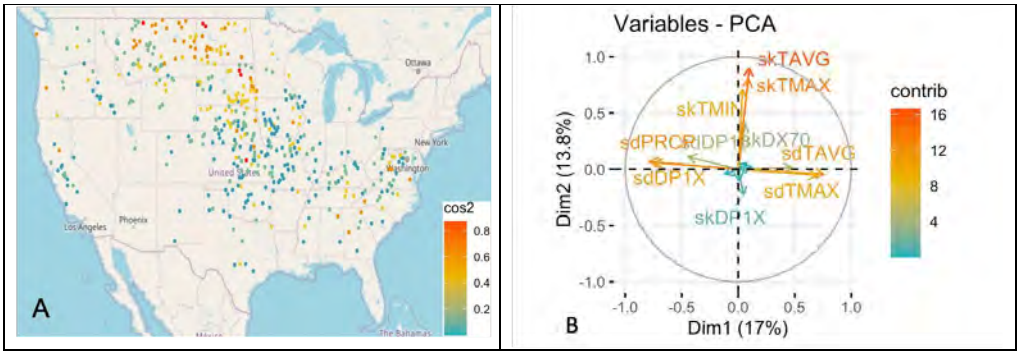

Figure 1. (A) Location of Angus herds classified by cosine square (COS2) distances; (B) contribution of the skewness and standard deviation of each climate variable used to build COS2.

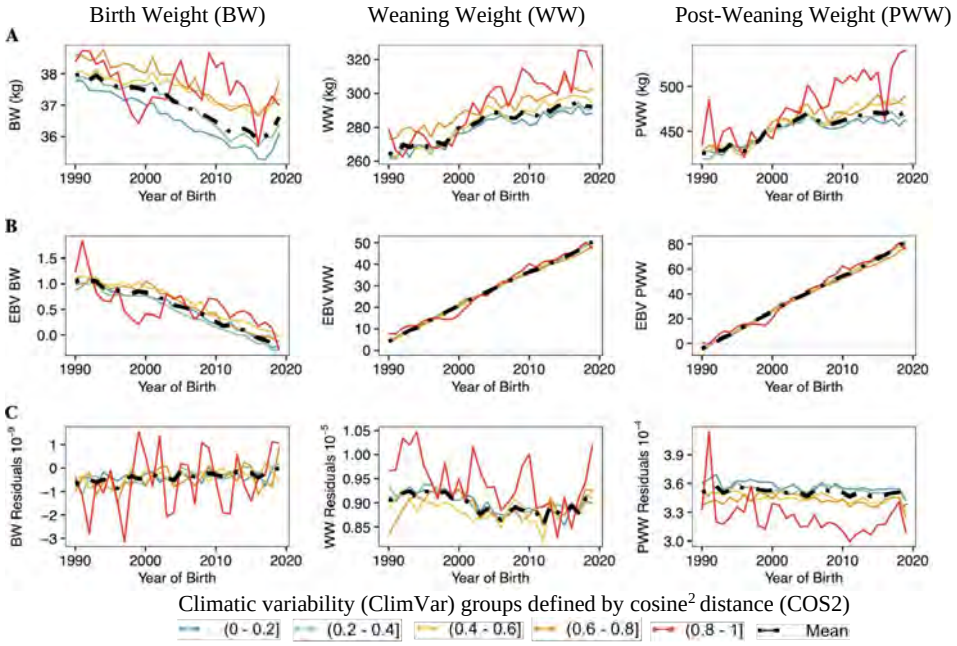

Figure 2. Average (A) phenotypic, (B) genetic, and (C) residual trends by birth year for herds located in the five ClimVar groups, for birth weight (BW), weaning weight (WW) and post-weaning weight (PWW).

Discussion

The USA uses ~45% of its area for agriculture and livestock production (The World Bank, 2021), which spans a large area with very different climate conditions. Previous studies suggested that the information from different ecoregions based on historical climate data averages can be useful for beef cattle production (e.g. Blackburn *et al.*, 2017; Braz *et al.*, 2021). Here, instead of considering these different ecoregions, we considered the climate variability over the last 30 years to geographically distinguish herds by classifying them in five climate variability (ClimVar) groups. High ClimVar was detected in several regions of the USA. Our objective was to examine the trends of Angus beef cattle growth traits in herds with 25 to 30 years of records when the environmental conditions are unstable (i.e. high ClimVar). These trends showed higher

variability across the years when compared to herds in more stable weather conditions, although it should be noted that a smaller number of herds were in these high ClimVar locations. The phenotypic trajectory of the higher ClimVar groups were above the mean trajectory, but it was less obvious for the genetic trends. Then, it is possible that the unstable climate condition biased mostly to beneficial conditions or that the management system adopted effectively neutralized the climate variability. The model used to obtain EBVs included the environmental effect of the contemporary group, however ClimVar groups showed different patterns indicating that more environmental effects could be accounted for in the model. These results reinforce the idea that the inclusion of climate variables and the development of novel methodologies can be of value for traditional genetic and phenotypic prediction models. Additionally, analyses that account for climate variability may be an alternative method to evaluate resilience to environmental changes instead of the use of specific environmental stressors.

44. Genetic variation in resilience to climate effects on beef carcass traits

H. Bunning* and E. Wall

SRUC, Edinburgh, EH9 3JG, United Kingdom; harriet.bunning@sruc.ac.uk

Abstract

Breeding climate resilient cattle is an important strategy to mitigate the effects of climate change. Resilience of beef cattle is less well understood compared to dairy, especially in temperate climates. This study aims to compare resilience to climate, both average weather and extreme weather events, for carcass weight, age at slaughter and carcass growth rate. Linear models were used to analyse these traits in over 1.7 million records from UK abattoirs. Resilience was estimated using regression coefficients for interactions between breed type and weather parameters. Results show variation between breeds for resilience to climate with British breeds showing the greatest resilience. Our results suggest an increase in heat waves by 1 per 100 days of life would reduce cold carcass weights of dairy and continental animals by about 150 g but increase that of British breed animals by about 360 g.

Introduction

Climate change is a challenge facing livestock production globally and mitigation strategies are needed to reduce its impact (Rojas-Downing *et al.*, 2017). The impact of climate change is already seen in tropical climates, but we also expect a significant impact in temperate regions (Wreford and Topp, 2020). Climate resilience is the capacity of the animal to be minimally affected by changes in the climate and there is good evidence of genetic variation for this trait (Doeschl-Wilson *et al.*, 2019).

Between-breed variation in climate resilience has been shown for a range of weather parameters and traits in cattle. Variation in resilience to heat stress is well documented, particularly in the tropics between tropically adapted *Bos indicus* breeds and less adapted *Bos taurus* breeds. For example, extreme heat led to reductions in dry matter intake in taurine Angus cattle, but no significant change in indicine Brahman cattle (Gaughan *et al.*, 2010). In temperate climates, studies have shown variation in the effect of climate on dairy cattle traits, where high producing dairy breeds, particularly Holsteins tend to be less resilience to heat stress than other more robust breeds, such as Simmentals (Gantner *et al.*, 2017) or Jerseys (Bryant *et al.*, 2007).

Climate resilience for beef traits, particularly in temperate systems, is less well understood. This study aims to compare how carcass traits are affected by weather across beef and dairy breeds. For traits expressed repeatedly over time, the effect of weather can be seen within an individual, allowing estimation of individual lifetime resilience by, for example, fitting reaction norm functions (Sánchez-Molano *et al.*, 2019). However, carcass traits are typically measured at the end of life so this is not possible. We also investigate grouping offspring by sire to produce a slope for each sire, which could be used as phenotypes in genetic analysis.

Materials & methods

We analysed data of over 1.7 million slaughter records (2000-2019) from UK abattoir companies (Pritchard *et al.*, 2021). Traits included cold carcass weight (CCW) and age at slaughter (AAS). A measure of daily carcass growth rate was calculated by dividing CCW by AAS (CGR). Breeds were grouped into 3 types: British beef, continental beef and dairy. Other data about animals were extracted to use as factors and covariates in the model. Sex was defined using data from the abattoir as castrated male, female or entire male. We also included age of the dam and the proportion of dairy breed in the dam's pedigree (Pritchard

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_44, © H. Bunning and E. Wall 2022

et al., 2021). We accounted for varying management practices, which might be regionally distributed and linked with weather, by including two contemporary groups in our model: Birth herd-year-season (BHYS) and Finishing (FHYS). Only animals in groups containing more than 4 were included. Location of death (i.e. abattoir) was also included.

We used weather data from the Met Office HadGrid-UK database, a data set of gridded climate variables derived from the network of UK land surface observations (Perry and Hollis, 2004). This was combined with animal locations and dates of stay, allowing the calculation of the average daily maximum temperature (Tmax), minimum temperature (Tmin) and precipitation (Rain) for the lifetime of each animal. Daily weather was also used to define the occurrence of extreme weather events, including heat waves (at least 3 days maximum temperature over threshold of 28, 27, 26 or 25 °C, depending on region), coldwaves (at least 3 days maximum temperature under 0 °C), dry days (less than 0.12 mm rainfall) and wet days (more than 7.65 mm rainfall). The frequency of each extreme weather event for an animal was calculated by dividing by AAS.

Analyses were carried out using linear fixed effect models using AS-REML (Butler *et al.*, 2018) and R. Two models were produced for each trait to assess the resilience of each breed group: (1) to average weather; and (2) to frequency of extreme weather events. Interaction effects between breed group and the weather parameter were fitted. For CCW, AAS was included as a covariate and for AAS, CCW was included as a covariate. We expected interactions between weather to be important so an interaction between Tmax and Tmin and another between Tmin and Rain were included in the average weather models. The generalised model was therefore:

$$\textit{Trait} \sim \textit{weather parameters} \times \textit{breed group} + \textit{other traits} + \text{sex} + \text{breed} + \text{BHYS} + \text{FHYS} + \text{death location} + \text{dam age} + \text{dam \% dairy} \quad (1)$$

To compare the genetic potential for resilience of different sires, we selected Limousin animals with a sire with more than 4 offspring. After edits, the data consisted of 1,945 animals with 237 sires. 94% of records were lost for lack of sire information and small contemporary group sizes. We fitted an interaction between sire and number of heat wave days in our model for CCW. The solutions give an indication of the genetic value for climate resilience of each sire, where sires with values closer to zero can be considered more resilient.

Results

Average weather. CCW increased for animals which experienced higher Tmin and Tmax and lower Rain. For CCW, continental breeds were least affected by changes in Tmin but most affected by changes in Tmax and Rain (Table 1). Animals which experienced higher Tmin and Rain but lower Tmax were younger at slaughter. For AAS, the most affected breed group varied across the different weather parameters. British breeds were the most affected by changes in Tmin, dairy breeds the most affected by Tmax and continental breeds the most affected by Rain. Animals which experienced higher Tmin, lower Tmax and lower Rain tended to have a greater CGR. For this trait, dairy cattle were affected more by changes in all three parameters (Tmin, Tmax and Rain) than the other breed groups.

Extreme weather frequency. CCW tended to be greater for animals which experienced lower extreme weather frequencies, although there were some differences between breed groups (Table 2). An increased frequency of heat waves had negative effects on the CCW of both continental and dairy breeds, but a positive effect in British breeds. Conversely, an increased frequency of extreme dry days had positive effects on both continental and dairy but a negative effect on British breeds. An increased frequency of extreme wet days had negative impacts on CCW of all breed types, but continental and dairy breeds were significantly more affected than British breeds. Animals which experienced more frequent extreme weather tended to be older

	Wet	-0.0225 (0.0025)^{a}	-0.0339 (0.0021)^{b}	-0.0346 (0.0025)^{b}

[1] Values with difference letters within a row are significantly different from one another ($P<0.05$).

at slaughter, although British breeds were less affected by heat waves and wet days, whereas dairy breeds were least affected by dry days. For CGR, increased growth rates were seen when animals experienced lower frequencies of extreme weather across breed types. British breeds were less affected by heat waves and wet days, but more affected by dry days than continental and dairy breeds.

Sire resilience. Results showed that the interaction between sire and number of heat wave days had a significant effect on CCW. The solutions varied between -18.24 (s.e. 14.70) and +12.67 (s.e. 9.01) although the standard errors were large. A sample of slopes for three sires are shown in Figure 1. Here, results suggest that the CCWs of offspring of sires A and B are more affected (although in opposite directions) than sire C. Sire C has a higher genetic value for resilience as the slope is closer to zero.

Discussion

Results show variation between breeds for resilience to climate for CCW, AAS and CGR, both for average weather across the lifetime of the animal and frequency of extreme weather events. We might expect the British breeds to show more resilience as they are thought to be more robust and typically less strongly selected for production traits, which may lead to higher resilience. There is evidence in dairy cattle that

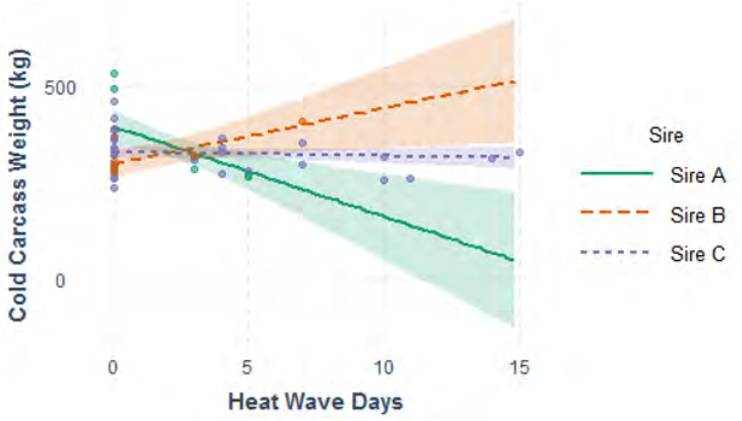

Figure 1. The effect of heat wave days on CCW for offspring of three sires. Solutions for the interaction term are used to produce the slopes of the lines with 95% confidence intervals illustrated by the shaded regions.

animals with lower production levels may be more resilient (Gantner *et al.*, 2017). Our results broadly follow this expectation, with British breeds coefficients being closer to 0. In particular, the positive correlation between heat wave frequency and CCW in British breeds suggests that these breeds may be less affected by heat stress compared to continental and dairy breeds. Results suggest an increase in heat waves by 1 per 100 days of life will reduce CCWs of dairy and continental animals by about 150 g but increase that of British breed animals by about 360 g.

In addition to physiological differences between these breeds, its important to consider that these differences may also reflect varying management strategies. For example, the positive correlation seen between dry day frequency and CCW for dairy and continental breeds (rather than the negative seen for British breeds), may show that dairy animals are less likely to have a forage-based diet, rather than having a genetic resilience. To account for this, we can compare offspring of sires within a breed. Our preliminary results suggest there is variation between the genetic value for resilience of sires. However more offspring per sire may be needed to test if resilience is significantly different between sires within and across breeds.

45. Genetic parameters for rumination time and traits related to sustainable dairy production

L.S.F. Lopes[1*], K. Houlahan[1], L. Alcantara[1], G.A. Oliveira Jr.[1], D. Tulpan[1], F. Miglior[1,2], F.S. Schenkel[1] and C.F. Baes[1,3]

Abstract

Rumination time was assessed as an indicator trait to improve sustainability in dairy cattle. This study contained 6,203 records on 611 mid-first lactation Canadian Holstein cows. Animal models for rumination time and methane emissions, and repeatability animal models for milk yield and dry matter intake were utilized in bivariate analyses to estimate genetic parameters including heritability, genetic and phenotypic correlations between traits. Results showed that rumination time had a moderate heritability (0.41±0.15) and genetic correlations of -0.37 (±0.30) with methane emissions, 0.19 (±0.15) with dry matter intake, and 0.51 (±0.13) with milk yield. These findings provide the basis for future work investigating the use of rumination time as an additional indicator trait for selecting for more sustainable dairy production.

Introduction

As the global population increases, so does the demand for sustainably produced dairy products. One main focus to improve the sustainability of the dairy industry has been to enhance feed efficiency (FE) and reduce methane (CH_4) emissions of dairy cattle (Hailemariam *et al.*, 2020). In addition to global warming concerns, methane emission is also responsible for 2 to 12% of the dietary energy losses in dairy (González-Recio *et al.*, 2020). Since efficient cows eat less while producing the same amount of milk as their counterparts (Houlahan *et al.*, 2021), elevated levels of ruminal CH_4 represent animals of lower sustainability and efficiency. Therefore, improving FE and reducing CH_4 emissions while increasing milk production levels are key for an efficient and sustainable dairy industry worldwide (Richardson *et al.*, 2020). However, it is difficult and expensive to measure phenotypes for FE and CH_4, making it important to study indicator traits. Rumination time (RT) has been suggested as a potential indicator for traits such as CH_4 yield and dry matter intake (DMI) (Schirmann *et al.*, 2009). One advantage of RT is that it can be automatically recorded on a large-scale, in commercial dairy herds, by sensor-based systems (Bikker *et al.*, 2014). However, the use of RT as an indicator trait for FE and CH_4, as well as genetic parameters for RT have not yet been fully explored. Therefore, the objective of this study was to evaluate RT as an indicator trait for efficient dairy cows, by estimating genetic parameters, phenotypic and genetic correlations between RT, DMI, CH_4, and MY in Canadian Holstein cows.

Materials & methods

Data was provided by the Efficient Dairy Genome Project (https://genomedairy.ualberta.ca) and the Resilient Dairy Genome Project (http://www.resilientdairy.ca). Data comprised of 6,203 records for MY (kg), CH_4 (g), DMI (kg), and RT (min) on 611 first lactation Holstein cows between 110 and 210 days in milk from March 2017 to December 2021. Milk samples were taken weekly and analysed by Lactanet Canada (Guelph, ON). Daily CH_4 measurements were obtained using the GreenFeed® System (C-Lock Inc., Rapid City, SD, USA). This system consists of a mobile feeding station that uses airflow, integration of gas concentrations measurements, temperature, humidity, and recognition of muzzle position to allow for the precise measurement of CH_4 (Huhtanen *et al.*, 2015). Daily RT was obtained from Heatime® neck collars, (SCR Hi Tag, Allflex, Netanya, Israel). Sensors in these collars detect and process the sound of rumination and regurgitation every two hours. Finally, daily records for DMI were obtained as described in Seymour *et al.* (2020).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_45, © L.S.F. Lopes *et al.* 2022

Data quality control. Rumination time with fewer than 12 measurements within a day, and total daily RT equal to zero were removed. Traits measured daily (DMI, RT, and CH_4) needed a minimum of two records per week of lactation to be considered for analysis, where the week of lactation was defined using the week of MY test day. Traits were averaged to obtain weekly average measures for DMI, RT, and CH_4. All traits with values greater than three standard deviations from the mean were removed.

Statistical models. Repeatability animal models were fit for MY and DMI, and animal models were fit for CH_4 and RT in bivariate analyses to estimate the genetic parameters. All (co)variance components were estimated using the average information residual maximum likelihood algorithm in the ASREML 4.0 software (Gilmour *et al.*, 2015). Heritabilities were the average of the results of all bivariate combinations for each trait. In general, the models used in this study can be described as:

$$Y_{ijklm} = \mu + CM_i + WOL_j + YS_k\ a_l + pe_l + e_{ijklm}$$

where Y_{ijklm} represents the m^{th} phenotype (for MY and DMI) of the l^{th} animal; μ is the overall mean of the trait; CM_i is the fixed effect of the i^{th} age at calving class months (eight classes); WOL_j is the fixed effect of the j^{th} week of lactation (thirteen levels); YS_k is the fixed effect of the k^{th} year and season of calving class (sixteen classes); a_l is the random additive genetic effect of the l^{th} cow; pe_l is the random permanent environmental effect (for MY and DMI) of the l^{th} cow, and e_{ijklm} is the random residual error term.

Results

Descriptive statistics of the data are presented in Table 1. The observed phenotypic ranges were in line with current literature for first lactation cows at similar lactation stages (Hare *et al.*, 2018; López *et al.*, 2015; Zetouni *et al.*, 2018).

The estimated heritabilities, repeatabilities, phenotypic and genetic correlations for all traits are shown in Table 2. Except for DMI (0.29±0.07), all traits had estimated heritabilities slightly above 0.40, MY and DMI had repeatabilities of 0.79 (±0.01) and 0.55 (±0.02), respectively. In general, RT was genetically positively correlated to MY (0.51±0.13) and DMI (0.19±0.15), while being negatively correlated to CH_4 (-0.37±0.30).

Table 1. Number of records, number of animals with records, average number of weeks with records (Weeks), mean, standard deviation (SD) and coefficient of variation (CV) for milk yield (MY), methane yield (CH_4), dry matter intake (DMI) and rumination time (RT).

Trait	Records	Animals	Weeks	Mean (SD)	Min	Max	CV (%)
MY (kg)	5,734	609	10.69	31.65 (4.63)	17.50	45.50	14.65
CH_4 (g)	409	409	1.00	494.40 (84.02)	263.80	719.30	16.99
DMI (kg)	4,308	446	8.78	20.63 (2.95)	8.13	30.14	14.31
RT (min)	328	328	1.00	445.70 (51.33)	273.60	580.80	11.51

Table 2. Genetic correlation (above diagonal), heritability (diagonal), phenotypic correlation (below diagonal), and repeatability (t) for milk yield (MY), methane yield (CH_4), dry matter intake (DMI), and rumination time (RT).

Trait	MY (SE)	CH_4 (SE)	DMI (SE)	RT (SE)	t (SE)
MY	**0.44 (0.07)**	0.32 (0.12)	0.46 (0.16)	0.51 (0.13)	0.79 (0.01)
CH_4	0.16 (0.06)	**0.43 (0.12)**	0.81 (0.10)	-0.37 (0.30)	NA
DMI	0.31 (0.03)	0.50 (0.05)	**0.29 (0.07)**	0.19 (0.15)	0.55 (0.02)
RT	0.36 (0.06)	-0.10 (0.06)	0.23 (0.07)	**0.41 (0.15)**	NA

However, with the large SE for the genetic correlations, only the correlation with MY was statistically significant.

Discussion

Heritability estimates from this study were in line with those previously reported (Byskov *et al.*, 2017; Moretti *et al.*, 2018). Positive genetic correlations between DMI, MY, and RT, and the negative genetic correlation between CH_4 and RT suggest that selecting for RT could lead to higher milk production and lower emissions for the animals, even if animals of higher intake were obtained in the process. Nonetheless, it is important to note the high standard errors of all genetic correlations, given the dataset size available and the fact that a single herd provided all the data. Previous works (Marino *et al.*, 2021; Zetouni *et al.*, 2018) have shown that RT and CH_4 may not be directly related on a genetic level. However, the significant genetic correlation between MY and RT, and the point estimate between DMI and RT, suggest direct relationships between rumination time, milk production, and a possible relationship between intake and rumination time. Additionally, the moderate negative point estimate for the genetic correlation between RT and CH_4 may indicate a degree of association between RT and CH_4 emission, which would potentially allow for indirect selection for lower emissions. Rumination is a complex trait, mediated by several aspects of the life of the animal, and acquiring more RT data for short and specific periods of the lactation may not be enough to evaluate its relationship with production and efficiency traits since RT may vary according to the stage of lactation (Moretti *et al.*, 2018; Zetouni *et al.*, 2018). Ideally, the evaluation of sensor-based RT as an indicator trait for FE should be carried over for the whole lactation instead. Thus, to consider RT as an indicator trait for FE or CH_4, random regression models for RT over the whole lactation, such as realized for feed efficiency by Houlahan (2021), could be considered. Accounting for other sources of variation over time, and additional data collection for all the involved traits is essential for accurately determining the potential of RT to be used as an indicator trait in sustainable breeding programs.

Conclusions

Rumination time had a moderate heritability and was found genetically associated with MY. No significant relationship between RT, CH4, and DMI was found. A larger dataset is needed to determine whether RT might have the potential to be used in selection programs.

Abstract

This study aimed to estimate the effect of temperature-humidity index (THI) and the magnitude of genotype-by-THI (G×THI) interactions on milk production traits and on somatic cell score in Montbéliarde cows. Test-day records from first and second lactations from 2016 to 2020 were associated with the average THI of the three days before the test-day record. A total of 301,078 test-day records from 39,469 cows in first lactation and 292,648 test-day records from 37,593 cows in second lactation were analyzed. The average THI effect, estimated with an animal mixed model, indicated that the optimal THI was below 55 (i.e. ~12-13 °C). Individual responses to THI were estimated simultaneously with the time-dependent response by random regression models. Regardless of the stage of lactation, genetic correlations along the THI gradient were >0.80 and most of them were >0.90, suggesting that G×THI interactions were weak for production and for udder health traits.

Introduction

Heat stress negatively influences cattle welfare, health and productivity (Lees *et al.*, 2019). To cope with global warming and forecasted increases in temperature and heat waves frequency, identifying high-producing animals tolerant to heat is of capital importance to satisfy the need for animal-sourced foods. Several measures exist to assess heat stress, one of them consists in determining the meteorological conditions that lead to a decrease in performance. The most widespread indicator for heat stress in cattle is a temperature-humidy index (THI) combining the effects of temperature and humidity. The first objective of the present study is to estimate the critical temperature marking the onset of heat stress through the decline in performance and to quantify the amplitude of this decline in the range of THI currently encountered in the French Montbeliarde breeding regions. The second objective is to perform genotype-by-environment studies to find out if there is individual variability in heat tolerance, and therefore if some animals may be better adapted to produce despite warm temperatures.

Materials & methods

Performance and meteorological data. Performances, along with pedigree information, were available for this study from the French national database. Data were selected from first (L1) and second (L2) lactation test-day records of Montbéliarde cows from five French regions (Franche-Comté, Rhône-Alpes, Auvergne, Bretagne and Pays-de-Loire), gathered between August 2016 and December 2020. The phenotypes analyzed were milk yield (MY), fat content (FC), protein content (PC) and somatic cell score (SCS) obtained as a log-transformation of somatic cell concentration ($SCS=\log_2(SCC/100{,}000)+3$). Only animals with known parents and age at calving between 23-42 months and 35-60 months for first and second parity, respectively, were considered. Lactation length was limited to 305 days. Finally, a total of 301,078 test-day performances from 39,469 cows (94,476 animals in pedigree files) in L1 and 292,648 performances from 37,593 cows (98,015 animals in pedigree files) in L2 from herds were randomly selected in the whole population.

Meteorological data were provided by the Safran database from Météo-France. This database contains daily estimated temperature and humidity values on a grid of 9,892 squares of 8×8 km.

Performance and meteorological databases were merged according to the zip code of each farm, and test-day records were associated with the average THI of the three days before the test-day. The daily THI was calculated (1.8×T+32)-(0.55-0.0055×RH)×(1.8×T-26), with T being the 24h-average temperature (Celsius), and RH the 24h-average relative humidity (%).

Estimation of THI effect on phenotypic performances. The model used to estimate the average effect of THI on MY, FC, PC, and SCS was:

$$y = X\beta + Z_1 a + Z_2 p + e \quad (1)$$

where y, β, a, p, and e are the vectors of recorded phenotypes, fixed effects, additive genetic effects, permanent environmental (pe) effects and the residuals of the model, respectively. X, Z_1 and Z_2 are the incidence matrices for β, a and p respectively. For each trait, the fixed effects considered were contemporary group (herd-year combination), days in milk (DIM), age at calving (in months), days carried calf (days from successful insemination until test-day, converted to months), month of calving (12 classes), and THI by classes.

To study the G×THI interactions, the random regression model used was:

$$\mathbf{y} = \mathbf{X\beta} + \sum_{r=0}^{2} \mathbf{Z_r}(d)\, \mathbf{a_r} + \sum_{s=1}^{3} \mathbf{Z_s}(t)\, \mathbf{a_s} + \sum_{m=0}^{2} \mathbf{Z_m}(d)\, \mathbf{p_m} + \sum_{n=1}^{3} \mathbf{Z_n}(t)\, \mathbf{p_n} + \mathbf{e} \quad (2)$$

where y, β, and e are the same as described for model (1). X is the incidence matrices for β. The contemporary group was defined by herd-test-day with at least three cows. The other fixed effects considered were as for model (1) excluding THI. The effect of THI was considered using polynomials along with DIM for the genetic and pe effects. Thus, for the genetic effect, Z_r and Z_s are vectors of covariates of the r^{th} and s^{th} polynomials, respectively, evaluated at DIM d or THI t; a_s and a_r are the genetic random regression coefficients. For the pe effect, the model is the same with Z_m and Z_n, the vectors of the polynomials depending respectively on DIM or THI and p_m and p_n, the pe random regression coefficients. For all traits we used Legendre polynomials of order 3 for THI and order 2 for DIM with an overall mean. The residual variances were considered heterogeneous for the 55 possible combinations of five THI classes and 11 DIM classes. These random regression models allowed to estimate the variances components and individual breeding values (EBV) for all combinations of THI and DIM.

For the analyzes MY, FC, PC, and SCS were considered separately. The pedigree was traced back three generations and trimmed. Variance components and all effects were estimated using the software WOMBAT (Meyer, 2007).

Results & discussion

Effect of THI on performances. The least-squares solutions of each classes of THI are presented in Figure 1. For MY, THI was optimal in the range of 50-55 (i.e. 7 to 13 °C) with both cold and heat stress effects, whereas FC, PC and SCS tended to present only heat stress effect, declining for THI above 35 (i.e. -3 to 2 °C). These results indicate a lower comfort THI than commonly found in high-producing dairy cows (Carabaño *et al.*, 2017). However, the fact that a large part of the studies on high-producing dairy cows concerns cows intensively raised in countries warmer than France may mitigate the effect of high outdoor temperatures due to controlling inside barns, sometimes with cooling systems, and a probable acclimatization to warmer temperatures from a young age. Most of the French Montbeliarde cows are kept outdoor in spring and

summer and thus probably more faced to hot weather events. In terms of phenotypic standard deviations (sd), the decrease in performances due to heat stress was more prominent for FC and PC (respectively 0.8 for FC in all parities, 1.2 and 0.6 phenotypic sd for PC in L1 and L2) than for MY (0.2 and 0.3 phenotypic sd for L1 and L2 respectively) and SCS (<0.2 phenotypic sd for all parities).

Estimation of G×THI interactions. Figure 2 illustrates genetic correlations between all combinations of THI for MY at DIM 150d. These correlations, as well as those for all other traits (Table 1) were very high, mostly higher than 0.9, suggesting that there is no G×THI interactions and therefore few differences between animals in terms of individual response to heat stress.

Even weak, G×THI interactions allow slight variability in individual response to heat stress. An illustration of this variability in tolerance to heat is given in Table 2 presenting the EBV across THI and the corresponding rank for the MY in L2 for the seven sires with at least 500 daughters in the dataset. Although ranking of sires was rather stable and the best sires were always the same, some changes in ranking could be observed. For example, the sire S4 was intermediate at cold and comfort THI but appeared to be one of the least tolerant to high THI (THI=75).

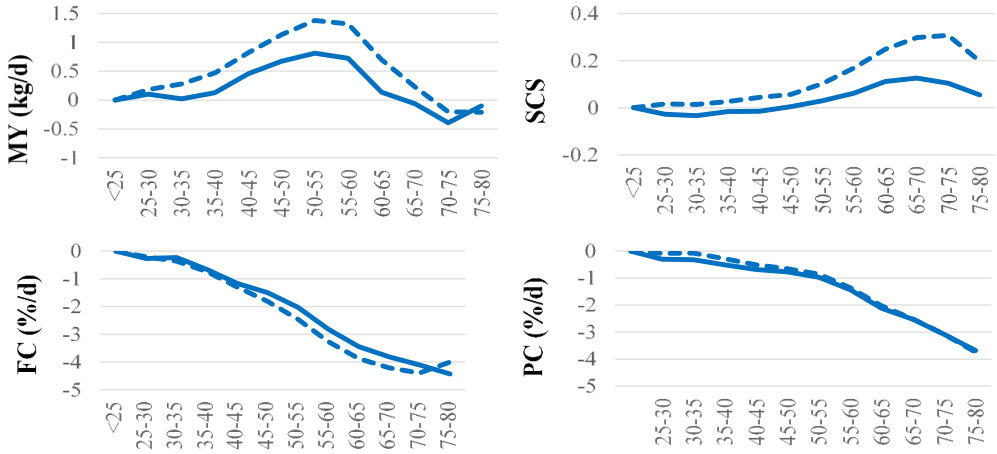

Figure 1. Least-squares solutions for MY, SCS, FC and PC in first (solid line) and second (dotted line) lactation.

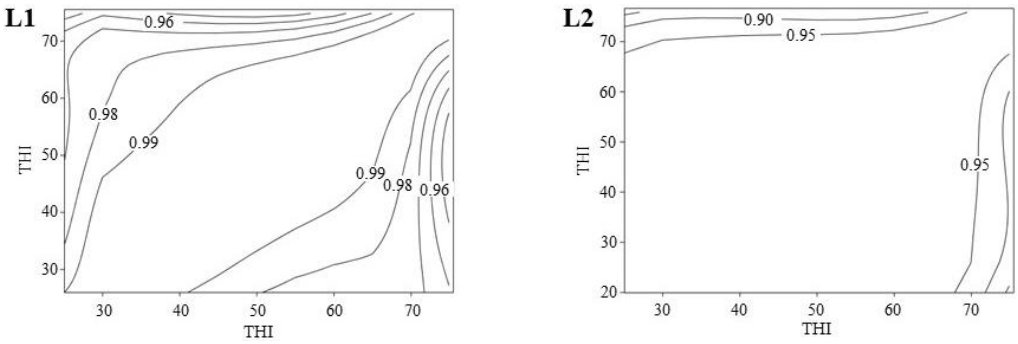

Figure 2. Genetic correlation estimates for MY at DIM 150d in L1 (left) and L2 (right) between all combinations of THI.

Table 1. Genetic correlations from random regression model analyses for MY, FC, PC and SCS between THI=40 and THI=70 at different stages of lactation (60d, 120d and 210d) and lactations rank (L1 or L2).

DIM (d)	MY		FC		PC		SCS	
	L1	L2	L1	L2	L1	L2	L1	L2

S6	-0.63	6	-0.65	6	-0.33	5
S7	-1.14	7	-0.94	7	-1.30	7

[1] EBV: expressed in genetic standard deviation unit, respectively 1.40 kg/d, 1.41 kg/d and 1.24 kg/d for MY in L2 at DIM=150d.

Conclusions

These first results confirm that the increase in temperature and in the frequency of heat peaks expected in next decades will lead to a decrease in milk production and to an increase of udder health problems in Montbéliarde cows raised in France. The selection of animals more heat-tolerant within high-producing cattle is one of the solutions presently studied to limit this decline in performance. Further studies on this topic are needed, especially concerning the reproduction of animals under heat stress. Nevertheless, although we observed only weak G×THI interactions, it seems that it is still possible to identify the animals that are more tolerant to heat stress and therefore, more adapted to global warming.

Challenges – resource allocation and genetics of feed intake and efficiency

47. Modelling multiplicativity in feed efficiency by regression on expected feed intake

M.H. Lidauer[1*], E. Negussie[1], T. Mehtiö[1], P. Mäntysaari[1], T. Kokkonen[2] and E.A. Mäntysaari[1]

Abstract

Factors involved in feed efficiency (FE) have multiplicative effect which should be accounted for in genetic evaluation models. We present the conceptual difference between regression on expected feed intake and residual feed intake applying both models on estimation of variance components using simulated and real FE data. Our results showed, when FE is simulated with multiplicative effects, that applying a residual feed intake model underestimates additive genetic variance. Results of the real data analyses were in line with those of the simulated data, which indicates that the regression on expected feed intake approach may be suitable and is preferred for genetic evaluation of FE in dairy cattle.

Introduction

Presently, FE traits are included into dairy cattle breeding programmes and measuring of feed intake on commercial farms is expected to increase. This will require that models for FE traits can account for the nutritional quality of the different diets. It is known that with same amount of dry matter intake (DMI), a cow's production may drop or raise due to the quality of the feed. Feed quality, for instance digestibility, has a multiplicative effect on production, i.e. the effect is less pronounced at low intake level and more pronounced at high intake level. Furthermore, in situations where intake is measured by its volume (Lassen *et al.*, 2018), metabolizable energy (ME) content per intake unit may change considerably across farms. Cow-specific efficiency factors like the individual metabolic efficiency (Martin *et al.*, 2021) have also a multiplicative effect. However, modelling FE by residual feed intake (RFI) (Koch *et al.*, 1963) offers no ways to account for it. Therefore, we present a modelling approach (Lidauer *et al.*, 2021) that is based on regression on expected feed intake (ReFI). The aim of this study was to describe the conceptual difference between ReFI and RFI and to highlight its implications with simulated and real data.

Materials & methods

For developing simple ReFI and RFI models, we assumed that there are FE records that have been collected repeatedly from cows that performed during different feed years and that the quality of diet differs across feed years.

The regression on expected feed intake approach. Under the assumption that FE factors have a multiplicative effect, it is appropriate to model FE by a random regression model where DMI is regressed on expected DMI (eDMI), which for the assumed FE records could be described as:

$$DMI_{ijk} = \beta_i \times eDMI_{ijk} + \psi_j \times eDMI_{ijk} + \alpha_j \times eDMI_{ijk} + \varepsilon_{ijk} \quad (1)$$

where DMI_{ijk} is a DMI observation k recorded in the year i for the cow j; β_i is the fixed regression coefficient for the feed year i; ψ_j is the random regression coefficient for the permanent environmental effect of cow j [$\psi \sim N(0, I\sigma^2_\psi)$]; α_j is the random regression coefficient for the additive genetic effect of cow j [$\alpha \sim N(0, A\sigma^2_\alpha)$, where A is the relationship matrix]; ε_{ijk} is the random residual [$\varepsilon \sim N(0, I\sigma^2_\varepsilon)$]; and $eDMI_{ijk}$ for record k is calculated based on energy requirements (ER) and realized production. The $eDMI_{ijk}$ covariable can be

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_47, © M.H. Lidauer *et al.* 2022

calculated by applying ER recommendations and an average ME content of the diets, which was assumed to be 11.0 MJ ME / kg DMI. Applying the Finnish ER values (Luke, 2021) results:

$$eDMI_{ijk} = 1.0/11.0\times(5.15\times ECM_{ijk}+0.515\times MBW_{ijk}+28.0\times BW\text{-}loss_{ijk}+34.0\times BW\text{-}gain_{ijk}), \quad (2)$$

where the coefficients represent the expected amount of ME needed to produce 1 kg of energy corrected milk (ECM), maintain 1 $kg^{0.75}$ metabolic body weight (MBW), gain 1 kg of body weight (BW), as well as the ME that becomes available by mobilizing 1 kg body tissue.

The residual feed intake approach. On the contrary, when assuming FE factors have an additive effect, it is reasonable to model RFI observations by a classical repeatability model:

$$RFI_{ijk} = C_i + p_j + a_j + e_{ijk} \quad (3)$$

where a RFI observation for record *k*, $RFI_{ijk} = DMI_{ijk} - eDMI_{ijk}$, is calculated by applying Equation 2; C_i is a fixed contemporary group effect of feed year *i*; p_j is the random permanent environmental effect of cow *j* [$p\sim N(0,I\sigma^2_p)$]; a_j is the random additive genetic effect of cow *j* [$a\sim N(0,A\sigma^2_a)$]; and e_{ijk} is the random residual [$e\sim N(0,I\sigma^2_e)$].

Conceptual difference between the approaches. The conceptual difference between the ReFI and RFI approaches can be demonstrated by assuming four FE records from four cows (A, B, C, D) that have been made in two contemporary groups, and that cows are equally efficient. Further, cow A is the dam of cow C and both have a daily DMI capability of 10 kg, and cow B is the dam of cow D and both have a daily DMI capability of 20 kg. Cows A and B are contemporaries and get a diet with 10% lower digestibility (L), and cows C and D are contemporaries and get a diet with 10% higher digestibility (H) compared to average diet digestibility. Consequently, under the assumption that digestibility has a multiplicative effect, the differences in the diets will cause cows A and C to have proportionally lower and cows B and D to have proportionally higher production. In the ReFI approach the effect of the diet is accounted by the fixed regression (β_i) on eDMI nested within contemporary groups, which results for these four records β_L=1.11 and β_H=0.91. In the RFI approach the effect of the diet is accounted by a fixed contemporary group effect (C_i), which results C_L=1.5 and C_H=-1.5. Then, the ReFI approach will yield no differences among the corrected observations whereas the RFI approach will yield differences within dam-cow pairs as shown in Table 1.

Simulation study. The demonstrated example shows that ReFI would be an appropriate approach if FE factors have a multiplicative effect. On the contrary, RFI would result inappropriate fit, which may cause an underestimation of additive genetic variance. To test this hypothesis, we performed a simulation study

Table 1. Conceptual differences in correcting for the diet effect.

			Regression on expected feed intake		Residual feed intake	
Cow	CG[1]	$eDMI_k$	DMI_k	$DMI_k-\beta_i\times eDMI_i$	$RFI_k=DMI_k-eDMI_k$	RFI_k-C_i
A	L	9.0	10.0	0.0	1.0	-0.5
B	L	18.0	20.0	0.0	2.0	0.5
C	H	11.0	10.0	0.0	-1.0	0.5
D	H	22.0	20.0	0.0	-2.0	-0.5

[1] Contemporary group with low (L) and high (H) digestible diet; eDMI = expected dry matter intake, DMI = dry matter intake; β_i = fixed regression coefficient effect; C_i = fixed contemporary group effect.

where DMI observations were simulated for realized productions that were recorded in FE trials. Therefore, from the Finnish FE research data a suitable data set was extracted that included 5,236 FE records from the lactation period 100£ days in milk £200 of 537 primiparous Nordic Red cattle dairy cows that were recorded during a period of 13 years at three research herds. The pedigree of the cows included 3,540 animals. A record consists of a DMI, ECM, MBW and BW change observation.

In a first step, for each record the eDMI was calculated applying Equation 2. In a second step, for model (1), when fitted to the data set, simulated values were generated for the model effects from normal distributions with standard deviations (SD) of the effects in FE percent units of 10% for the fixed feed year effects, 5% for the permanent environmental effects, and 3% for additive genetic effects. Thus, the fixed regression coefficients β_i were generated with an expectation of 1.0 and a SD of 0.1. The random regression coefficients for the permanent environmental and additive genetic effects were sampled by $\psi \sim N(0, I \times 0.0025)$ and $\alpha \sim N(0, A \times 0.0009)$ where a Cholesky decomposition of A was used for generating α, and the residuals were sampled by $\varepsilon \sim N(0, I \times 1.0)$. The simulated heritability (h^2) was 0.155 and the simulated repeatability (r) was 0.586 and can be calculated as: $h^2=\varphi\sigma^2_\alpha/(\varphi\sigma^2_\psi+\varphi\sigma^2_\alpha+\sigma^2_\varepsilon)$ and $r=(\varphi\sigma^2_\psi+\varphi\sigma^2_\alpha)/(\varphi\sigma^2_\psi+\varphi\sigma^2_\alpha+\sigma^2_e)$ with $\varphi=(d'd)/N$, where d is a vector of size n=5,236 that contains all eDMI covariables. For the used data φ was 416.3. In a final step, simulated effects and model (1) were used to calculated simulated DMI and RFI ($RFI_{ijk} = DMI_{ijk} - eDMI_{ijk}$) observations. Ten independent data replicates were simulated. Each data set was used to estimate the variance components by applying the ReFI model (1) and the RFI model (3).

Estimating variance components from real data. To get an indication of whether the ReFI approach is more appropriate for real data, the originally extracted data was used to estimate variance components by applying the ReFI model (1) and the RFI model (3). The data was recorded at three herds and therefore the feed year classification for the fixed effects in model (1) and (3) was replaced by a herd × feed year classification which comprised 20 classes.

Results

Simulation study. On average, same variance components, heritability, and repeatability as applied for the simulation were obtained (Table 2) when the simulated data sets were analysed with the ReFI model (1). However, when applying the RFI model (3), then this was only the case for the residual variance and the repeatability, but the estimated permanent environmental variance was on average larger and the estimated additive genetic variance was on average smaller compared to those used for the simulation. Thus, this resulted for the RFI model on average 20% lower heritability estimates. Furthermore, the SD of the r and h^2 estimates were larger when the RFI model was applied.

Real data. The estimated variance components when applying the ReFI model were 0.00364±0.00056 and 0.00112±0.00059 for the permanent environmental and additive genetic regression coefficients, respectively, and 1.695±0.03 for the residual effect. Thus, the estimated permanent environmental and additive genetic variation of FE were 6.0 and 3.3%. The estimated heritability and repeatability were 0.13±0.065 and 0.54±0.019. When applying the RFI model estimated variance components were 1.658±0.21, 0.246±0.21 and 1.668±0.04 for the permanent environmental, additive genetic and residual effects, respectively, which resulted a heritability and repeatability of 0.07±0.057 and 0.53±0.018. The estimated β_i fixed regression coefficients by model (1) for the herd × feed year classes had a mean of 1.01 and a SD of 3.9%, and the estimated C_i fixed effects of model (3) had a mean of 0.26 kg and a SD of 0.81 kg.

Table 2. Estimated variance components[1] from ten simulated data sets by two models.

[1] Estimated variance components, repeatability (r) and heritability (h^2) for regression on expect feed intake model (1) and residual feed intake model (3) and mean and standard deviation (SD) of estimates across samples.

Discussion

We elaborated the conceptual difference between the ReFI and RFI approaches. The results of the simulation study indicate that ReFI fits better the data than RFI when FE factors have multiplicative effects. Both models were able to estimate the simulated repeatability. This was most likely because of seasonal calving and therefore having most of the repeated observations nested within same fixed effect classes. Referring to the explanation of the example in Table 2, it can be expected that both models will adjust the feed year effect similarly for average observations but not for observations deviating from the average. For the simulated data this causes reranking of cows within contemporary groups when RFI is applied, which might be the reason that RFI underestimated the additive genetic variance.

The findings from the simulation study were supported by the estimates from the real data analyses. With both models we estimated almost same repeatability for the real data, but the estimated heritability was clearly lower when applying RFI. When studying the fixed effect estimates it showed that for an average observation (eDMI=20.3 kg, RFI=0.35 kg) both models adjusted almost equally for the herd × feed year effect, i.e. the SD of the differences between the effects of both models was only 0.04 kg, whereas for observations with eDMI of 30 kg the SD of the differences increased to 0.37 kg, which caused reranking of cows. If it is valid that more precise ranking of cows will result higher heritability estimates, then this would give an indication that the multiplicative ReFI model was better suitable for the analysed FE data.

48. Alternative models to predict residual feed intake in Hereford breed and effects on their breeding values accuracy

M.I. Pravia*, E.A. Navajas, I. Aguilar and O. Ravagnolo

Instituto Nacional de Investigación Agropecuaria, Las Brujas, Rincón del Colorado, Canelones, Uruguay; mpravia@inia.org.uy

Abstract

Residual feed intake (RFI) is a relevant trait, but expensive to measure so few candidates are phenotyped and have accurate GEBVs. Genetic evaluation corresponds to a single trait evaluation, where RFI are the residual from a lineal regression on feed intake on performance traits during feed-test. This study evaluates two approaches to predict a GEBV for RFI. First combing feed performance traits in a multitrait model to calculate a single measure of RFI using selection index, and 2nd the inclusion of weaning weight (WW) as an indicator trait combined with previous model. The GEBVs for the alternatives proposed were equivalent to conventional RFI. Using WW as a predictor trait on reference animals and candidates could be an inexpensive way to increase the accuracy of GEBVs. It allows to remove possible bias due to preselection of animals that participate on feed test and to extend prediction to more selection candidates.

Introduction

Residual feed intake (RFI) has been included in breeding programs with the aim of reducing feed intake without compromising animal performance. Because it is an expensive and labor-intensive to measure trait, only a small percentage of selection candidates are phenotyped Traditional genetic predictions for the rest of candidates relies on pedigree relationships with animals with records and have low accuracies. Although genomic selection is a promising tool for difficult to measure traits, accuracies depend on reference populations sizes. Using easily recordable predictor traits on both reference animals and candidates without RFI phenotypes could be another inexpensive way to increase accuracy. This approach also allows to remove possible bias due to preselection of animals that participate on feed test and to extend predictions to other selection candidates.

Conventional genetic evaluation of RFI is a two-step process. First, RFI is obtained as the residual from a lineal regression for DMI that includes metabolic liveweight (MWT), average daily gain (ADG), and ultrasound back fat (UBF) measured in feed intake tests. Breeding values are then estimated based on this phenotypic RFI in a genetic univariate model (Ravagnolo *et al.*, 2018). An alternative approach to calculate genetic merit for RFI would be by combining feed intake, growth and backfat in a multi-trait model to calculate a single measure of RFI using selection index theory (Kennedy *et al.*, 1993). Another approach proposed in this work is to use weaning weight (WW) as an indicator trait, which is already available and easily recordable in all animals, combined with DMI, ADG, MWT and UBF in a multi-trait model to calculate RFI using selection index as in previous model. The objective of this work is to analyze and compare the new approaches with the conventional methodology used in the Hereford breed in Uruguay.

Materials & methods

Animals and data. Phenotypic DMI, ADG, MWT and UBF data of 780 Hereford bulls were recorded in 9 postweaning 70-day feed intake tests, using an automated system (Growsafe) for DMI recording and following Beef Improvement Federation guidelines (BIF, 2010). Three generations of pedigree (26,572 animals), as well as genomic information of 5,439 animals imputed to the 50k SNP (BovineSNP50, Illumina San Diego, CA), were included in the analysis.

Methods. Three models were used for the estimation of genomic breeding values (GEBV) for RFI. In Model 1, RFI was first obtained as the residual of the following regression model:

$$DMI = CG + b_1 ADG + b_2 MWT + b_3 UBF + RFI \quad (1)$$

where CG is the feed intake test contemporary group (Test×Pen, n-15), DMI, ADG, MWT and UBF were defined previously, and b_1, b_2 y b_3 the partial regression coefficient of each trait on DMI. Then, GEBV for RFI (RFIg1) were obtained using GBLUP as implemented in BLUPF90 (Misztal *et al.*, 2016).

The genetic model was:

$$Y = Xb + Z_u + e \quad (2)$$

where Y is RFI obtained from (1), X is the incidence matrix for fixed effects (age of the animal in days at start of test as a covariable, age of dam as five class variable), Z is the matrix linking animals to phenotypes, u is the vector of genetic breeding values, and e is the vector of residual effects. It was assumed that $u_{RFI} \sim N(0, H\sigma^2_u)$ and $e \sim N(0, I\sigma^2_e)$, where H is the combination of pedigree-based relationships and differences between pedigree-based and genomic-based relationships (Aguilar *et al.*, 2010).

Model 2 is a 4-multi-trait model which included all traits used for RFI calculation (DMI, ADG, MWT and UBF):

$$\begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{bmatrix} = \begin{bmatrix} X_1\beta_1 \\ X_2\beta_2 \\ X_3\beta_3 \\ X_4\beta_4 \end{bmatrix} + \begin{bmatrix} Z_1u_1 \\ Z_2u_2 \\ Z_3u_3 \\ Z_4u_4 \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \end{bmatrix} \quad (3)$$

where Y_{1-4} are DMI, ADG, MWT, UBF, and X and Z are the incidence matrices previously described. Solutions for GEBV for each trait were obtained, and the estimated breeding value for RFI (RFIg2) was calculated using selection index theory as follows:

$$RFI_{g2} = u_1 - b_2u_2 - b_3u_3 - b_4u_4 \quad (4)$$

where 1-4 are the GEBVs solutions for DMI (u_1), ADG (u_2), MWT (u_3), UBF(u_4) predicted from the model [3], and the RFI index coefficients calculated as:

$$\mathbf{V^{-1}C} = \begin{bmatrix} b_2 \\ b_3 \\ b_4 \end{bmatrix}, \ \mathbf{V} = \begin{bmatrix} \sigma^2_2 & \sigma_{u2u3} & \sigma_{u2u4} \\ \sigma_{u2u3} & \sigma^2_3 & \sigma_{u3u4} \\ \sigma_{u2u4} & \sigma_{u3u4} & \sigma^2_4 \end{bmatrix}, \ \mathbf{C} = \begin{bmatrix} \sigma_{u1u2} \\ \sigma_{u1u3} \\ \sigma_{u1u4} \end{bmatrix} \quad (5)$$

where V are the genetic variances and covariances for ADG (σ_2^2), MWT(σ_3^2), and UBF (σ_4^2), C the genetic covariances between DMI with ADG ($\sigma_{u1,u2}$), with MWT ($\sigma_{u1,u3}$), and with UBF ($\sigma_{u1,u4}$) (Table 1a), which were estimated using AIREML (Misztal *et al.*, 2016)

For Model 3, WW of the 780 animals with DMI, ADG, MWT and UBF data and 4,930 animals presented in their 235-contemporary groups (only with WW) at weaning were included in a 5-multi-trait model to estimate genetic (co)variances. Representation matrix is similarly to model (5). Genetic variances and covariances estimates are presented in Table 1(b). Solutions for the five traits were obtained, but only GEBVs for DMI, ADG, MWT and UBF were combined as in (4) for the estimation of RFIg3.

Table 1. Genetic co-variance components and genetic correlations obtained for 4-trait model used in $RFIg_2$ (a), and 5-trait model used in $RFIg_3$ (b).

a)	DMI (kg)	ADG (kg/d)	MWT (kg)	UBF (mm)	b)	WW (kg)	DMI (kg)	ADG (kg/d)	MWT (kg)	UBF (mm)
					WW	**249.6**	6.65	1.47	72.46	3.24
DMI	**0.36**	0.06	2.67	0.19	DMI	0.54	**0.61**	0.11	4.63	0.24
ADG	0.68	**0.02**	0.35	0.03	ADG	0.57	0.83	**0.03**	0.88	0.04
MWT	0.78	0.44	**32.66**	2.33	MWT	0.66	0.85	0.78	**48.43**	2.22
UBF	0.39	0.23	0.51	**0.64**	UBF	0.40	0.61	0.43	0.62	**0.26**

Additive genetic variance in diagonal, genetic covariances above and genetic correlations below the diagonal.

Accuracy. Individual GEBV accuracies were calculated using prediction error variances (PEV) from the inverse of the mixed model equations, as: $r = \sqrt{1 - PEV/(1+F)\sigma_g^2}$, where σ_g^2 is the genetic variance of RFIg1 ($\sigma_g^2 = 0.08$). For multi-trait analysis, the accuracies for RFI_2 and RFI_3 were calculated using PEV and PEC (prediction error covariances) (Tier and Meyer, 2004).

Bias and re-ranking. Slopes of regression and Spearman rank correlations between the alternative GEBV obtained from the different models were computed to investigate bias and changes in the ranking of animals.

Results & discussion

The high correlation coefficient and the regression slope of 1 between RFIg1 and RFIg2 (Figure 1a) indicated that Models 1 and 2 are equivalent, as described by Kennedy *et al.* (1993). The comparison of GEBVs by Model 1 and Model 3 showed some changes in ranking (Figure 1b), although the correlation between both was high. The regression slope in this case was above one indicating an underestimation of GEBVs when conventional Model 1 is used, which is corrected by Model 3. Based on Pszczola *et al.* (2013), we can assumed that RFIg3 are less biased than RFIg1 due to: (1) it enables the model to more accurately predict the level of the breeding value of an evaluated animal relative to the reference animals because records of own phenotypes for predictor traits on the evaluated animals give information about the Mendelian sampling, and (2) it accounts for differences between the evaluated animals (animals with scarcely trait records) and the reference population where all animals had the predictor trait record.

Higher standard deviations were observed for RFIg2 (0.18) and RFIg3 (0.23), in comparison with RFIg1 (0.17). This should be consequence of the genetic variances components of all traits considered in the multi-trait model. The mean of RFIg2 (0.016), and RFIg3 (0.021) where higher than RFIg1 (0.014), as result of the underestimation of predicted GEBVs mentioned above.

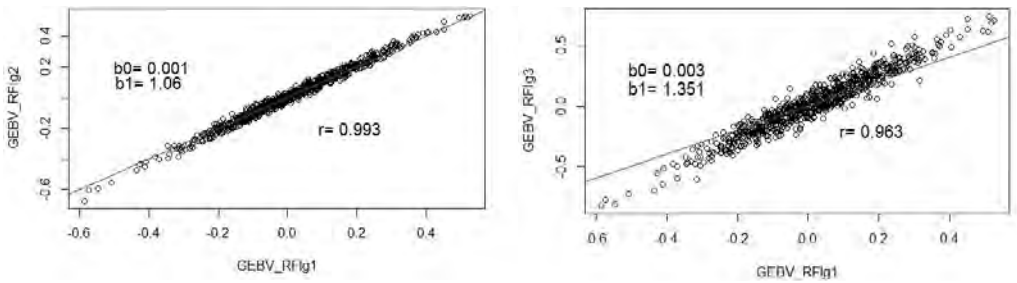

Figure 1. Correlations (r), intercept (b0) and slope of regression (b1) between alternatives GEBVs for RFI for the group of animals with phenotypes. (a) RFIg1 vs RFIg2, (b) RFIg1 vs RFIg3.

A small increase of GEBV accuracy was observed in Figure 2a for RFIg2 in relation with RFIg1, but when WW was considered in the multi-trait analysis (RFIg3, Figure 2b) the mean accuracy improved 39%. The mean accuracies for RFIg1, RFIg2 and RFIg3 for animals with phenotypes were 0.33, 0.36 and 0.46 respectively, meanwhile for contemporary animals without phenotypes nor genotypes the mean accuracies were 0.08, 0.09 and 0.11 for the three approaches, respectively. An improvement in accuracy was expected as WW is highly correlated with DMI and the other traits considered in the calculation of RFIg3.

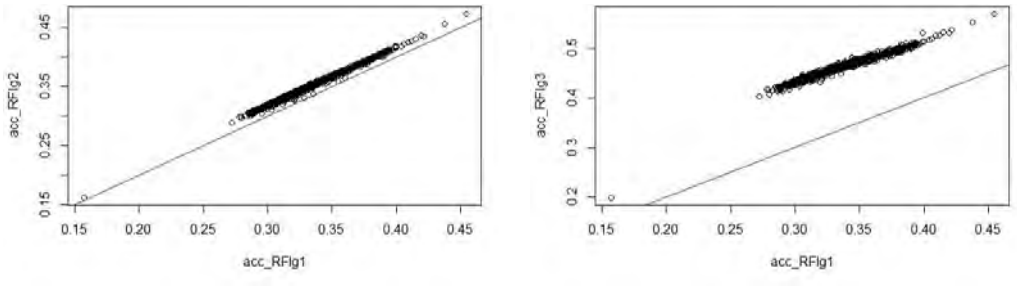

Figure 2. Correlations between accuracy of alternatives GEBVs for RFI for the group of animals with phenotypes. (a) acc_RFIg1 vs acc_RFIg2, (b) acc_RFIg1 vs acc_RFIg3.

Our results show the benefits of considering a multi-trait model including a predictor trait such as WW to predict breeding values for RFI, which were less bias and more accurate than considering a univariate model. This study will be complemented with validations analysis.

49. Feed intake can be predicted as quantitative or qualitative traits

F. Tortereau[1*], C. Marie-Etancelin[1], D. Marcon[2] and J.L Weisbecker[1]

[1]GenPhySE, Université de Toulouse, INRAE, ENVT, 31326 Castanet-Tolosan, France; [2]INRAE, Experimental Unit P3R, 18390 Osmoy, France; flavie.tortereau@inrae.fr

Abstract

Feed intake (FI) of ruminants is of high interest to study feed efficiency, greenhouse gas emissions and health traits. However, FI is a very expensive trait to record. Here, we investigated the genetic correlations between true average daily feed intake (ADFI) considered either as a continuous or categorical trait, and the correlations between simple predictions of FI based on body weights and growth with true ADFI. ADFI is genetically the same trait whether considered as a continuous or categorical trait. RFI calculated from categorical ADFI was genetically the same trait as RFI calculated from true ADFI. However, estimated ADFI from a simple model accounting for zootechnical traits, although positively correlated with true ADFI, led to reduced genetic correlations between categorical traits and ADFI: a maximum of 25% of misclassification of lambs is expected if qualitative predictions of ADFI or RFI have to be considered in future analyses.

Introduction

Feed efficiency (FE) is a key trait to improve in small ruminants, from an environmental to an economic point of view. Different criteria exist to define FE, the more popular being feed conversion ratio (FCR) and residual feed intake (RFI) that are considered the reference/gold standards. However, both require feed intake (FI) to be recorded. Different tools exist to record individual FI, but most of them cannot be used in commercial farms, either because they do not comply with animal management (e.g. individual crates) or because they are too expensive (automatic feeders or individual troughs). Many studies aim at identifying proxies of FI or Average Daily Feed Intake (ADFI, over a given period of time) such as metabolites or microbiota, with models also including feed characteristics. Pittroff and Kothmann (2001) reviewed models of quantitative predictions of FI applied to sheep, and concluded that additional studies and datasets were required. Predicting FI is still a challenge in livestock, as shown by recent studies on the relationships between FI and body weights (Lewis and Emmans, 2020). In physiological studies, animals are commonly grouped based on their ADFI to carry out different analyses, but to our knowledge, no genetic study looked at ADFI as a categorical trait; this could enable the application of other prediction models. The objective of this work is to study the genetic parameters of true and predicted ADFI (over an eight-week period) considered either as a quantitative or categorical trait, as well as RFI.

Materials & methods

Animals and traits. Animals and traits have already been presented in Tortereau *et al.* (2020). Briefly, a total of 951 Romane male lambs were phenotyped under a 100% low-energy concentrate diet for body weights, feed intake and body composition traits during 8 weeks, starting from 3 months of age. Daily feed intake was averaged over the 8-week testing period to estimate the average daily feed intake (ADFI). The individual RFI was estimated as the residual of the multiple linear regression of ADFI on Average Daily Gain (ADG), BackFat Thickness and Muscle Depth at the end of the test to account for production requirements, and on the metabolic BW (mBW) at the end of the test to account for maintenance requirements (proc reg; SAS Institute Inc., Cary, NC, USA).

Definition of alternate ADFI traits and RFI. We defined new traits based either on true ADFI or on estimated ADFI (eADFI). Estimated ADFI was defined based on the coefficients retrieved from the multiple

R.F. Veerkamp and Y. de Haas (eds)

linear regression of ADFI on ADG, mBW and age at the beginning of the test (startAge), on a subset of 465 lambs tested from 2009 to 2012. Then, this equation was applied to all individuals (2009-2016) to calculate eADFI. Mean (m) and standard deviation (sd) of ADFI and eADFI were calculated to define the thresholds between five categories of the new categorical traits ADFI_5 and eADFI_5 (Figure 1).

The average ADFI and eADFI were estimated for each of the five categories, and each lamb was assigned this average as a new trait value (ADFI5 and eADFI5, respectively).

An additional RFI trait (RFI5) was calculated with the same multiple linear regression as presented above applied to ADFI5. To summarize, each lamb had eight traits: ADFI, eADFI, RFI, ADFI_5gr, eADFI_5gr, ADFI5, eADFI5, and RFI5.

Estimation of genetic parameters. Heritabilities and genetic correlations between continuous traits were estimated with univariate and bivariate analyses between each pair of traits under an animal mixed model using the REML methodology implemented in the ASReml software (Gilmour *et al.*, 2009). Genetic correlations involving categorical traits (ADFI_5gr and eADFI_5gr) were estimated with TM software developed by Legarra *et al.* (2011) which handles categorical traits. The fixed effects in the models fitted to each trait were the year (n=8) and the pen (n=7). Body weight at the beginning of the test was included as a covariate for ADFI, but not for RFI.

Results

With the subset of lambs born from 2009 to 2012, we defined the prediction equation of feed intake as eADFI = -550 + 0.90×ADG + 114×mBW – 1.48×startAge (R^2=0.80).

With the full dataset, the phenotypic correlation between ADFI and eADFI was 0.78±0.01. A total of 74% of lambs were classified in the same ADFI and eADFI categories. Among the other 26% of lambs classified in different categories, all individuals but three were assigned to the group just before or just after (Table 1).

The average differences between ADFI and ADFI5 or eADFI5 (average values of ADFI or eADFI) of the category the animal belongs to) were 5.2% (±3.7) and 6.8% (±5.0), with a maximum difference of 14.6 and 30.2%, respectively.

Heritabilities of traits related to ADFI and eADFI ranged from 0.10±0.06 for eADFI5 to 0.33±0.10 for ADFI_5gr (Table 2).

Genetic correlations indicate that ADFI, ADFI_5gr and ADFI5 are genetically the same trait. Similarly, RFI is the same trait whether estimated from true ADFI or from averaged values (RFI5) (Table 2). The genetic correlation between true and estimated ADFI was positive (0.62±0.12). The categorical trait eADFI_5gr and the corresponding continuous trait eADFI5 showed significant positive genetic correlations with ADFI (0.63 and 0.54, respectively).

Figure 1. Definition of ADFI_5gr and eADFI_5gr categorical traits, with m (mean) and sd (standard deviation), for ADFI (m=1,962 g/d; sd=249 g/d) and eADFI (m=1,929 g/d; sd=231 g/d).

Table 1. Distribution of lambs into five ADFI and eADFI categories.

		eADFI_5gr

Table 2. Predicted traits: heritabilities and genetic correlations with true average daily feed intake and true residual feed intake.

	ADFI	ADFI_5gr	ADFI5	RFI5	eADFI	eADFI_5gr	eADFI5
type of trait[1]	cont.	categ.	cont.	cont.	cont.	categ.	cont.
h^2	0.28 (±0.08)	0.33 (±0.10)	0.16 (±0.07)	0.20 (±0.07)	0.22 (±0.08)	0.27 (±0.10)	0.10 (±0.06)
genetic corr. with ADFI		1.00	1.00	0.68 (±0.16)	0.62 (±0.12)	0.63 (±0.16)	0.54 (±0.21)
genetic corr. with RFI	0.78 (±0.08)	not different from 0	0.87 (±0.11)	1.00	not different from 0	not different from 0	not different from 0

[1] Traits are either categorical (categ.) or continuous (cont.).

Discussion

The link between feed intake and body weight, growth and age is well known, and many studies aimed at predicting quantitatively feed intake (Pittroff and Kothmann, 2001). With Romane male lambs, we highlighted that ADFI is genetically the same trait when expressed as a categorical trait (ADFI_5gr) or as average values of feed intake (ADFI5). This makes it possible to consider a wider variety of prediction methods including qualitative prediction methods. Recently, in pigs, machine learning procedures were successfully applied on transcriptomic data to predict either categories of FE (with a 100% success of assignation) or FE values (with R^2=0.80 and RMSE=8%) (Messad *et al.*, 2021). In our study, we highlight that RFI and RFI5 are genetically the same trait despite the 5% difference between ADFI and ADFI5. Moreover, RFI5 was less heritable than RFI (0.20±0.07 vs 0.45±0.08; Tortereau *et al.*, 2020). Additional studies of the impact of feed intake accuracy on RFI estimates and RFI genetic parameters will be of high interest in order to better consider the phenotyping strategies of feed intake.

In our study, we tested different numbers of categories (from two to five based on ADFI and eADFI distributions) and results were similar to the ones we presented with five categories (results not shown). However, the genetic correlation between eADFI_5gr and ADFI is only 0.63, which is significantly different from 1.00: misclassification of a quarter of the individuals would have consequences for the genetic correlation with ADFI.

With a simple estimation of ADFI from age, mBW and ADG, we obtained a new trait, eADFI, significantly correlated with ADFI (Table 2). The distribution of lambs within five classes, eADFI_5gr, was still positively genetically correlated to ADFI. Even if the objective of this paper was not to analyse the prediction accuracy of ADFI from classical zootechnical traits, this result highlights that such a simple prediction might be proposed as a first prediction of ADFI. However, with such a prediction, RFI cannot be calculated given that eADFI represents the maintenance and requirements of ADFI, whereas it might be suitable for prediction

of FCR. Most of the models considered in Pittroff and Kothmann (2001) rely on animal requirements and thus do not consider the residual part of feed intake. New proxies such as transcriptome, metabolites and microbiota have to be considered in order to better predict ADFI and RFI (Cantalapiedra-Hijar *et al.*, 2018). With PLS-DA approaches carried out on ruminal microbiota data only, it was possible to discriminate high vs low efficient animals, and high vs low eating lambs, but with a poor prediction accuracy, particularly for RFI groups (Le Graverand *et al.* 2021). Therefore, future models combining new proxies and zootechnical traits might help in predicting ADFI or RFI in sheep, whether quantitatively or qualitatively.

Abstract

Individual average daily feed intake (ADFI), age at 120 kg (AGE), backfat (FAT), loin muscle depth (LMD), and group feed intake (sumFI) were used to investigate estimated breeding values (EBV) for feed intake (FI) using individual versus group FI data, along with individual data on AGE, FAT, and LMD, which had moderate to high genetic correlations with ADFI. The correlation of FI EBV using only ADFI versus sumFI was <0.25, which increased to 0.78-0.93 when adding data of the correlated traits in 4-trait models. The correlation between FI EBV from the 4-trait model with/without sumFI data was 0.99. The correlation between EBV from the 4-trait model with/without ADFI ranged from 0.79-0.94. Thus, group FI has negligible value when using correlated traits in pedigree-based analyses, while individual ADFI provides benefit, especially for young selection candidates.

Introduction

Feed intake (FI) is an economically important trait for pig production. It is very costly to collect feed intake data on individual pigs compared with other production traits and thus the number of pigs with individual FI data is limited. A more cost-effective way would be to collect feed intake at the group level as pigs are normally housed in groups and fed by a shared feeder. This group data may be valuable in increasing the accuracy of individual feed intake estimated breeding values (EBV) when combined with individual feed intake data. To date, several studies have investigated this approach using simulated data (Olson *et al.*, 2006; Su *et al.*, 2018; Gao *et al.*, 2019; Ma *et al.*, 2021) but very few studies have used real data (Piles and Sánchez, 2019; Gao *et al.*, 2021). The general conclusion from these studies is that group records can be used to obtain EBV for individual animals, and the EBV accuracy can be increased by adding genomic information and individual data on genetically correlated traits. Therefore, the objective of this study was to use previously collected individual feed intake and production trait phenotypes to evaluate the potential of using group feed intake data and correlated traits to enhance prediction of individual feed intake EBV.

Materials & methods

Animals and data collection. A total of 12,021 Duroc nucleus pigs (9,215 males and 2,806 females) tested during 2004-2021 were used for this study. For feed intake, each group started with 22-24 pigs in a single test pen fitted with two electronic feeders (IVOG-feeding-station, Hokofarm Group). Details about animal management and feed intake recording are in Zhang *et al.* (2019). Before 2015, the individual feed intake was recorded from the start of the grow-finish phase (~25 kg), and after 2015 it was recorded from the midpoint (~70 kg), until the average weight within the pen was about 120 kg. Individual average daily feed intake (ADFI) was calculated as the FI in the last 6 weeks of the test period (about midpoint to the end of grow-finish phase) based on linear regression of daily FI on the days on test. Individual body weight was measured around 70 kg and considered as the initial weight. At the end of test, animals were individually weighed and backfat (FAT) and longissimus muscle (LMD) depth were measured by B-mode ultrasound. End test weight was adjusted to 120 kg and used to compute age at 120 kg (AGE). Both FAT and LMD were also adjusted to 120 kg. Group FI (sumFI) was computed as the sum of ADFI of all animals in a pen. Finally,

a total of 742 groups were generated from 12,021 animals. Group sizes ranged from 7 to 24, including 1 to 8 littermates. A pedigree of 18 generations with 16,274 animals, including 905 sires and 3,897 dams, was used to compute the numerator relationship matrix. It is important to note that sumFI was calculated as the sum of the ADFI for all animals in a group. Since ADFI collected on each animal is the only real source of data, ADFI and sumFI are expected to predict the same feed intake breeding value. Thus, any departure from 1 of the correlation between EBV for FI based on ADFI versus sumFI depends on which data is used for prediction.

Statistical methods. Five scenarios were used to obtain FI EBV using ADFI or sumFI, including EBV1: EBV of ADFI from a univariate model using ADFI data; EBV2: EBV of ADFI from a 4-trait model using data on ADFI, AGE, FAT, and LMD; EBV3: EBV of sumFI from a univariate model using sumFI data; EBV4: EBV of sumFI from a 4-trait model using data on sumFI, AGE, FAT, and LMD; EBV5: EBV of ADFI from the same model as EBV2 but with ADFI data being set as missing for all animals. As sumFI was calculated from ADFI, they were assumed to have the same variance components (VCs) as those for ADFI. Therefore, VCs obtained from a univariate analysis of ADFI were used for EBV1 and EBV3, while VCs from the 4-trait model with ADFI, AGE, FAT, and LMD were used for EBV2, EBV4, and EBV5. The model for the individual records was:

$$y = Xb + Z_a a + Z_l l + Z_c c + e \quad (1)$$

where y is the vector of phenotypes for the trait, b is a vector of fixed effects, which represents sex and pen (across off-test dates) and initial body weight as a covariate, a is a vector of random additive genetic effects [$a \sim N(0, A\sigma_a^2)$], where A is the pedigree based relationship matrix and σ_a^2 is the additive genetic variance, l is a vector of litter effects [$l \sim N(0, I\sigma_l^2)$], c is a vector of group effects (combination of off-test date and pen) effects with variance σ_c^2 [$c \sim N(0, I\sigma_c^2)$], where I is an identity matrix and e is a vector of random residuals with variance σ_e^2 [$e \sim N(0, I\sigma_e^2)$], and X, Z_a, Z_l, and Z_c are incidence matrices associating *b,* a, l, and c with y. Following Su *et al.* (2018), the model for sumFI corresponding to the model for individual records was:

$$T(y) = T(Xb + Z_a a + Z_l l + Z_c c + e) \quad (2)$$

where T is an indicator matrix that links individual records to groups. Element (T_{ij}) of T is 1 if the j^{th} animal belongs to the i^{th} group, or 0 otherwise. Matrix T also sums variables for each level of a particular factor within a group. All analyses were performed using the DMU package (Madsen and Jensen, 2013). The correlations of EBVs from different models were compared by sex and for young animals (those completing the test in the last 10 months) and for the remaining called 'old animals' in this study.

Results

Estimates of the genetic correlations between ADFI with AGE, FAT, and LMD were -0.80, 0.20, and -0.49, respectively. Moderate genetic correlations were also found among AGE, FAT, and LMD, with a range of absolute values from 0.25 to 0.42.

Correlations of EBV between different scenarios are presented in Table 1. Based on the univariate models, the correlation of EBV between ADFI (EBV1) and sumFI (EBV3) was less than 0.25. When individual data on AGE, FAT and LMD were included in a 4-trait model, the correlation of EBV based on ADFI (EBV2) versus sumFI (EBV4) increased to 0.78-0.82 for young animals and to 0.93 for old animals. These results indicate that, when using group feed intake records, the individual records on the feed intake correlated traits, such as AGE, FAT and LMD, should be included.

Table 1. Correlations of EBV with or without individual or group feed intake data and data on correlated traits.

			Correlation of EBV[2]								
Sex	Animal[1]	Number	1-3	2-4	5-1	2-5	3-5	4-5	1-2	3-4	4-1
F	old		0.16	0.93	0.68	0.94	0.17	0.99	0.87	0.18	0.67
F	young	595	0.12	0.82	0.42	0.83	0.20	0.99	0.83	0.23	0.42
M	old	8,656	0.24	0.93	0.68	0.93	0.25	0.99	0.88	0.26	0.67
M	young	538	0.09	0.78	0.40	0.79	0.16	0.99	0.85	0.21	0.40

[1] Young includes animals with end of test less than 10 months before the latest end of test date in this data set; the remaining tested animals are referred to as 'old'.

[2] 1-3 means correlation between EBV1 and EBV3, the same for all other comparisons. EBV1: EBV of ADFI from a univariate model using ADFI data; EBV2: EBV of ADFI from a 4-trait model using data on ADFI, AGE, FAT, and LMD; EBV3: EBV of sumFI from a univariate model using sumFI data; EBV4: EBV of sumFI from a 4-trait model using data on sumFI, AGE, FAT, and LMD; EBV5: EBV of ADFI from the same model as EBV2 but with ADFI data being set as missing for all animals.

To further evaluate the value of using group feed intake for individual FI EBV, the ADFI data was set as missing for all animals in the 4-trait model, which means that the EBV of feed intake for individual animals (EBV5) was indirectly predicted using the three correlated traits only. Compared with EBV1, which was based on ADFI only, the correlation between EBV4 and EBV1 was very similar to the correlation between EBV5 and EBV1. Furthermore, the correlation of EBV using the 4-trait model with EBV for sumFI (EBV4) and with EBV without any data on ADFI (EBV5) was 0.99. These results indicate that, if individual data on the correlated traits are already available, adding group feed intake data in the multi-trait model had little impact on FI EBV. When individual data on the correlated traits are available, collecting individual feed intake is beneficial for feed intake EBV, especially for young animals. The correlation between the EBV obtained from the 4-trait model with (EBV2) and without (EBV5) individual feed intake was 0.79 and 0.83 for young males and females, respectively. The correlation of EBV based on ADFI only (EBV1) with EBV based on the 4-trait model without ADFI (EBV5) was even lower, at 0.40 and 0.42 for young males and females, respectively.

Discussion

Our results show that single-trait EBV for feed intake based on group FI records had a very low correlation with single-trait EBV based on individual FI records. When individual data on the correlated traits AGE, FAT, and LMD were added in a multi-trait analysis, the correlation of EBV from group FI records with EBV from individual FI records greatly increased. Therefore, when using group feed intake, these correlated traits should be collected and used to predict EBV for individual FI. Using simulation, Ma *et al.* (2021) also reported that including individual data on a correlated trait (r=0.8) increased the accuracy of EBV for a trait with group records. It is usually assumed that, when using pedigrees, including correlated traits with individual records is a good approach to improve the accuracy of EBV for a trait with group records, as littermates within a group can obtain different EBV resulting from having different phenotypes for the correlated traits (Su *et al.*, 2018; Cooper *et al.*, 2010; Ma *et al.*, 2021). Our results also show that, when individual data on correlated traits are available, adding group feed intake in the multi-trait model had very little value to improve the accuracy of EBV for individual FI. Ma *et al.* (2021) also reported that including group records had little impact on the accuracy of EBV for the trait with group records when individual data of a correlated trait were included in a bivariate model. However, based on our results, adding individual feed intake in the 4-trait model resulted in a substantial change in the FI EBV, especially for young animals.

Several studies have shown that the accuracy of EBV based on group records is greater when group size is smaller and when individuals within a group are more closely related (Olson *et al.*, 2006; Peeters *et al.*, 2013; Su *et al.*, 2018; Ma *et al.*, 2021). For practical reasons, our data consisted of relatively large group sizes, with an average of 16 pigs per group, and a range of 7-24 pigs per group in the final analysis. Relationships within a group were also relatively small, as ~30% of the animals had no littermate within their group and ~30% of the animals had only 1 or 2 littermates. In addition, relationships used in our analyses were based on pedigree, which cannot separate littermates, either across or within groups. Genomic information can distinguish littermates and has the advantage of capturing both Mendelian segregation and genetic links through unknown common ancestors. Both Gao *et al.* (2021) and Ma *et al.* (2021) reported an increase in EBV accuracy from adding genomic information, especially when predicted using the bivariate model. About 60% of the animals in this study have been genotyped and this data will be used in subsequent analyses.

Abstract

Data involving 9,226 records from 483 US Holstein cows were used to study the genetic relationship between feed efficiency, measured as Residual Feed Intake (RFI) and the Fourier transform infrared (FTIR) spectra of milk samples. Estimates of heritabilities, genetic and phenotypic correlations, as well as the accuracy of an indirect selection using spectra were calculated. The prediction accuracy of RFI was also evaluated using different methodologies. Genotypes were used to fit univariate and bivariate (each individual wavenumber and RFI) GBLUP analyses. A genetic relationship between RFI and wavenumbers associated with fat, protein and urea were observed. Notable differences were detected in the patterns of phenotypic versus genetic correlations. The maximum indirect selection accuracy estimated using a particular wavenumber was 0.11. No notable differences in the accuracy of genetic prediction were observed between different methodologies that use the full spectra for RFI prediction, and the accuracies were generally higher (~0.15) than using the individual wavenumbers.

Introduction

Feed efficiency is an economically and environmentally relevant trait; however, measuring it in commercial dairy farms is not feasible. Therefore, there is an increased interest in using milk-spectroscopy to predict and use feed efficiency to improve farming management and genetic programs. Feed efficiency can be measured indirectly through the residual feed intake (RFI) of cows in experimental conditions; these data can be used to calibrate equations to predict RFI from phenotypes recorded in commercial conditions such as milk-spectra. The absorbance of any given Fourier transform infrared (FTIR)-spectra wavelength is a proxy phenotype that is potentially affected by genetic and environmental factors with a given heritability (Bittante and Cecchinato, 2013). Usually, competing prediction methods (e.g. partial least squares, LASSO, Bayesian methods) are compared based on the (phenotypic) correlation between predicted RFI and measured RFI in testing data sets. Such phenotypic correlations are affected by both genetic and environmental effects affecting RFI and the measured traits. From a genetic perspective, the accuracy of indirect selection may be a more appropriate measure of performance. Therefore, the objective of this study was to quantify the genetic prediction accuracy of individual wavelengths and of commonly used prediction models as predictors of genetic merit for RFI.

Materials & methods

Data from several experimental trials conducted at the University of Florida (7,205 records from 311 cows) and Michigan State University (2,021 records from 172 cows) were used in this study. Cows were randomly assigned to individual feeding gates used to evaluate daily feed intake. Cows had *ad libitum* access to their respective diets, which were fed as total mixed ration (TMR). Dry matter intake (DMI) for individual cows was based on the amount of TMR offered minus the amount refused multiplied by the dried matter content of the TMR in a particular week. Data collected each week included the body weights, milk yields and milk composition, and the FTIR spectral data associated with milk samples. All milk samples were analysed using Bentley FTS instruments with 899 spectral points from wavenumber 649 to 3,998 cm^{-1}. Animals were genotyped on various available chips and imputed. The genotypes were edited for quality control and 78,964 SNP were included in the analysis. A better description of the data can be found in Gaddis *et al.* (2021).

RFI calculation. An energy sink model (1) was used to estimate RFI using the net energy for lactation (NE_L) as determined in the NRC (2001). The weekly metabolic body weight (MBW) was calculated as the weekly average $BW^{0.75}$. The weekly body weight changes ΔBW was calculated using a linear regression of actual or projected BW on days from the beginning to the end of a week (Berry and Crowley, 2013). Thus, the model to measure residual feed intake included the fixed effects of parity (primiparous or multiparous) interacting with the specific fifth-order Legendre polynomial regressions on DIM, and linear regressions on NE_L, MBW and the ΔBW. The random effects included the effects of experiment-specific rations and test weeks. The estimated residuals $\hat{\varepsilon}$ from this model were determined to be the weekly RFI.

Prediction accuracy of individual wavelengths. The accuracy of indirect selection of an indicator trait (a wavenumber in our case) is the product of the square-root of the heritability of the indicator trait (h_I^2) times the genetic correlation between the measured trait (wavenumber) and the selection objective (RFI, r_{g_y,g_I}), that is $Acc(g_{y_i}, I_i) = r_{g_y,g_I}\sqrt{h_I^2}$ (Falconer and Mackay 1996), where I stands for each wavenumber. Therefore, we first fitted a sequence of 899 bivariate GBLUP models using RFI and one wavenumber (adjusted by the same effects included in the model to estimate the RFI) as the two traits. From these analyses we estimated h_I^2, r_{g_y,g_I}, and $Acc(g_{y_i}, I_i)$. All the analyses were performed using the Multitrait() function of the BGLR R-package (Pérez and de los Campos, 2014), with genomic relationship matrices derived from genotypes, including the random effects of the animal and the permanent environment.

Genetic prediction accuracy of prediction equations. To evaluate the genetic prediction accuracy that can be achieved when combining information from all the spectrum we calibrated prediction equations for RFI (with the 899 available wavelengths as predictors) using Partial Least Squares (PLS with 10 components) and five Bayesian methods which differed on the prior used. To evaluate accuracy, and following Lopez-Cruz *et al.* (2020), we partitioned the data into a training and a testing set. The testing set was formed by randomly selecting 50 cows and assigning the phenotypes of those cows to the testing set. The remaining data was used for model training. We then calibrated the prediction equations using the training data. We then applied the resulting prediction equations to the milk spectra data of the testing set to obtain a prediction of RFI phenotypes. Finally, we estimated the genetic prediction accuracy of each method by fitting bivariate GBLUP models with RFI and the predicted RFIs as traits, including the random effects of the animal and the permanent environment. To account for uncertainty due to sampling of training and testing sets we conducted 100 random training-testing partitions and applied the procedure above described to each of the partitions; from this, we present results averaged over 100 training-testing partitions.

Results

The estimated heritability for the RFI was 0.17±0.03, while for the spectra the estimated heritabilities (Figure 1a) ranged between 0.12 and 0.30. The maximum heritability was found at wavenumber 2,976 cm^{-1}; in this region, Fat-B [absorbance by the carbonhydrogen stretch (C–H)] is usually filtered (Kaylegian *et al.*, 2006). Genetic and phenotypic correlations varied with spectra region (Figure 1b) with estimated genetic correlations ranging between -0.24 and 0.22. From wavenumber 1,167 to 1,689 cm^{-1}, positive genetic and phenotypic correlations were estimated, this region is associated with the prediction of protein (1,546 cm^{-1}) (Kaylegian *et al.*, 2006), urea (1,469 cm^{-1}), fat (1,460 cm^{-1}) (Hansen, 1998), and acetone (1,238 cm^{-1}) (Hansen, 1999). The maximum value observed for the accuracy of the index was 0.11 at the wavenumber 1,536 cm^{-1}, note that protein is usually filtered from 1,546 cm^{-1} to 1,492 cm^{-1} (Kaylegian *et al.*, 2006).

The heritabilities of predicted phenotypes across different methodologies (Table 1) were similar to the estimated heritability of RFI. No major differences were found between the different methodologies for using milk-spectra in the prediction of RFI (ranging from 0.14 to 0.16). However, the Bayesian methods (A and Lasso) showed a genetic correlation and accuracy slightly higher than the PLS traditional methodology. An important point to note is that the accuracy was higher when using the entire spectrum compared to the analysis of the individual wavelengths.

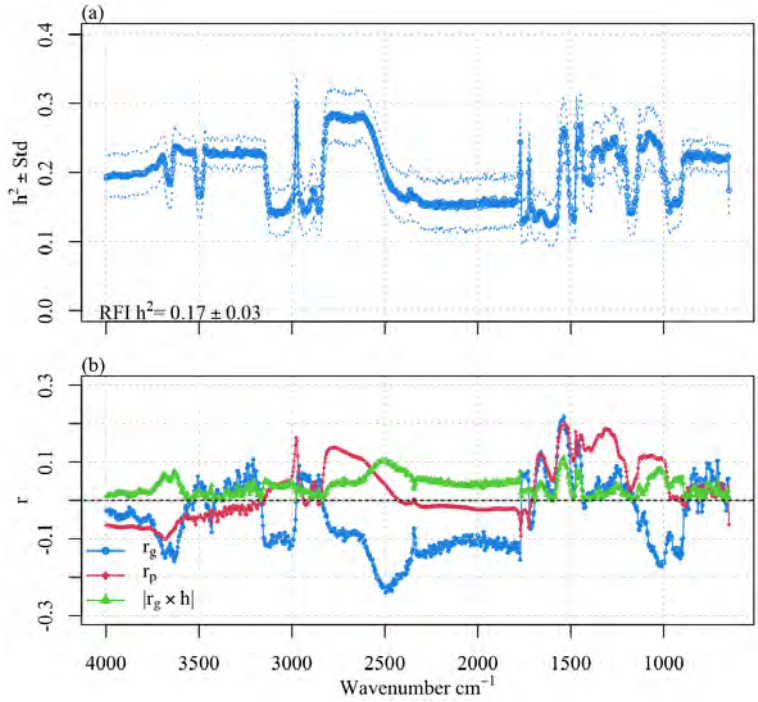

Figure 1. (a) Heritability (h^2) of FTIR wavelengths; (b) Genetic correlation (r_g), phenotypic correlation (r_p), and index accuracy $|r_g \times h|$ between each wavelength and RFI.

Table 1. Heritability (h^2) of predicted Residual Feed Intake, genetic correlation (r_g) and genetic prediction accuracy between predicted and observed RFI using different methodologies.

Method	$H^2 \pm$ Std	$r_g \pm$ Std	Accuracy ± std
PLS	0.15±0.04	0.35±0.19	0.14±0.08
Bayes A	0.16±0.05	0.38±0.19	0.16±0.09
Bayes B	0.19±0.06	0.34±0.20	0.15±0.09
Bayes C	0.18±0.06	0.31±0.20	0.14±0.09
Bayes Lasso	0.16±0.05	0.38±0.19	0.15±0.09
Bayes Ridge Regression	0.16±0.04	0.37±0.19	0.15±0.08

Discussion

The heritabilities for the spectrum were comparable with other studies. Bittante and Cechinato (2013) and Rovere *et al.* (2019) estimated the highest heritabilities from 1,582 to 930 cm^{-1}; whereas we observed several other regions with heritabilities above 0.25 and associated with fat, protein and urea (1,238 to 2,976 cm^{-1}). Regions of the spectra had modest r_g with RFI, this, together with the h^2 of individual wavenumbers, led to individual band accuracies of indirect selection ranging from 0 to 0.1. The wavenumbers most predictive of genetic merit for RFI were located in the fingerprint and in the mid-infrared region (from 3,048 to 1,701 cm^{-1}). When we used all milk-spectra data into prediction equations for RFI we found higher accuracies of indirect selection, with Bayes A achieving the highest accuracy. Since the accuracy of direct selection is $\sqrt{h^2_{RFI}}$, this is a relative efficiency of indirect selection of more than 1/3rd (0.36 using $0.15/\sqrt{0.17}$). This information could be used to derive predictions of RFI at large scale that could be considered as indicator traits for selection to improve feed efficiency.

Abstract

Body mobilization of high-yielding dairy cows is intense after calving and can generate health and fertility troubles. This study aimed to estimate the genetic correlation between body weight loss during the five first weeks of lactation (BWL) and daily milk production (MY24a) in first (L1) and second (L2) lactations Holstein cows. The dataset included 859,020 MY24a and 570,651 body weight (BW) daily phenotypes from 3,989 L1 cows, and 665,361 MY24a and 449,449 BW daily phenotypes from 3,060 L2 cows, recorded in 36 French commercial farms equipped with milking robots including an automatic weighing platform. The genetic parameters of BW and MY24a in L1 and L2 were estimated using a 4-trait random regression model. Genetic correlations between BWL and MY24a ranged from -0.26 to 0.05 in L1, and varied from -0.11 to 0.10 in L2, suggesting that selecting to reduce early body mobilization while maintaining milk production is possible.

Introduction

Dairy cows experience negative energy balance after calving, and mobilize fat and protein reserves to compensate. This mechanism, if excessive, leads to health problems and low fertility and hampers cow longevity and economic profitability. In recent years, a growing proportion of French commercial dairy farms have been equipped with milking robots that record daily milk production and body weight of lactating cows. The objective of the study was to exploit these data to estimate the genetic relationship between early body weight loss, reflecting body mobilization, and daily milk yield, in order to evaluate the possibility of decoupling production and mobilization.

Materials & methods

The data used for this study originated from 36 commercial dairy farms located in Western France. Average herd size was 92 cows [range: 46-189]. These herds are members of the *INNOVAL* DHIS network (http://www.innoval.com).

Data were recorded on 5,372 Holstein cows (4,464 and 3,364 cows in first (L1) and second (L2) lactation, respectively), calved from July 2014 to July 2018. Barns were equipped with Lely milking robots including an automatic weighing platform. At each visit k of a cow in the milking unit, the robot recorded the date and time of the visit, the weight of collected milk ($MILK_{elem,k}$) and the body weight of the cow. In total, more than 4.5 million visits were collected for the 5,372 cows.

For each cow i in lactation j (1 or 2) and each test day t:

- the sum of the $MILK_{elem,i,j,t,k}$ was calculated and standardized into a 24 hours milk yield (MY24) as $MY24(i,j,t)=\Sigma_{k=1,kt}\ (MILK_{elem,i,j,t,k})\times 1440/\Delta_{time}$, where Δ_{time} is the time interval (in minutes) between the last milking of the current day and the last milking of the previous day. Then MY24 was standardized to 4% fat (FC) and 3.3% protein (PC) contents (=MY24a). Daily FC and PC were estimated from monthly measures of each cow with Wilmink's lactation model.

CC BY

DOI: 10.3920/978-90-8686-940-4_52, © T. Tribout *et al.* 2022

- Body weight is affected by change in digestive tract content and therefore by change in feed intake. Feed intake increase in the beginning of the lactation partially hides initial body weight loss. To account for this potential bias, BW was corrected for the change in feed intake between day in milk t and calving (t=0), assuming a 4.5 kg digestive content change per kg dry matter intake change (Faverdin, personal communication):

$$BWci(i,j,t) = BW(i,j,t) - 4.5\times(DMI(i,j,t) - DMI(i,j,0)) \quad (1)$$

where DMI at day in milk t of cow i in lactation j was predicted as:

$$DMI(i,j,t) = \mu(j,t) + \alpha(j,t)\times BW(i,j,t) + \beta(j,t)\times MY24(i,j,t). \quad (2)$$

The prediction equations for $\mu(j,t)$, $\alpha(j,t)$ and $\beta(j,t)$ were previously modelled as second order polynomials on a similar experimental Holstein population for which daily records of BW, MY and DMI were available (Martin *et al.*, 2021).

For each cow and lactation, a 3rd order polynomial was fitted to the lactation MY24a and BWci data, and the outlier phenotypes deviating from prediction by more than 3 standard deviations were discarded.

Pedigree (3 generations) and dates of inseminations of the animals were extracted from the French national database. For each test date of a cow, the corresponding numbers of days in milk (DIM= test date – calving date) and of days carried calf (DCC = test date – date of conception (if necessary) were calculated. The test dates between calving date and successful insemination date were assigned the DCC=0 specific level.

Genetic parameters estimates were obtained using WOMBAT software (Meyer, 2007). Phenotypes in L1 and L2 were considered as different traits. Due to the high number of records it was not possible to directly perform 4-trait random regressions on daily data for MY24a and BWci in L1 and L2. Therefore, a 2-step approach was applied.

Single trait analyses on daily data for BWci and MY24a in L1 and L2. Only data with DIM lower than 305 days and DCC lower than 242 days were considered. Records from animals with unknown parents, older than 3.5 years at first calving, or with less than 30 daily records available were discarded. Herd-test date contemporary groups with less than 4 records were discarded. Numbers of performances and cows after filtering are presented in Table 1.

The model used for single-trait analyses included the fixed effects of herd-test date (HTD), number of milkings per day (1, 2, 3, >3 – only for MY24a) (NMD), DCC as 4-node (DCC 0, 99, 174, 242 days) cubic splines, calving month × DIM interaction as 6-node (DIM 1, 15, 40, 90, 200, 305 days) cubic splines, age at calving (AaC) × DIM interaction as 6-node (DIM 1, 15, 40, 90, 200, 305 days) cubic splines. Five classes of AaC were considered: <25, 25-27, 27-30, 30-33, >33 months of age (moa) in L1, and <37, 37-39, 39-42, 42-45, >45 moa in L2.

Table 1. Numbers of daily phenotypes and cows considered in the single-trait analyses.

	Lactation 1		Lactation 2	
Trait	Daily phenotypes	cows	Daily phenotypes	cows
MY24a	859,020	3,988	665,361	3,060
BWci	570,651	3,439	449,449	2,660

The random permanent environment effect and the additive genetic effect were modeled as second order Legendre polynomials. Finally, the residual variance was considered heterogeneous throughout the lactation period. Seven periods were defined, during which the residual variance was supposed to be constant: DIM 1-7, 8-20, 21-50, 51-100, 101-150, 151-230, and 231-305.

Multi-trait analyses on pre-adjusted weekly means. Daily phenotypes for MY24a and BWci in L1 and L2 were adjusted for DCC, calving month and AaC, as well as NMD for MY24a, and the average performance per week in milk (WM) was calculated for each cow from WM 1 to 44 (wMY24a and wBWci). Cows with less than 9 weekly performances, as well as phenotypes of herd-test week with less than 10 cows were discarded. Numbers of performances and cows remaining after filtering are presented in Table 2.

Then, 4-trait random regression analyses were performed on the weekly averages with models including the fixed effect of herd-test week, the random effects of permanent environment and additive genetic value as second order Legendre polynomials, and a residual whose heterogeneous variance was supposed to be constant on seven periods: WM 1, 2-3, 4-7, 8-13, 14-21, 22-33, and 34-44.

Genetic correlations between early body weight loss and milk production. After adjusting BWci data for environmental effects, the maximum weight loss of cows was achieved on average 31 days after calving in L1 (-33.9 kg) and L2 (-37.3 kg), i.e. in the 5th week of lactation. The genetic variances and covariances between the random regression coefficients of wMY24a and wBWci estimated in the 4-trait analysis were therefore combined together to derive the genetic correlation in L1 and L2 between body weight loss from WM1 to WM5 (BWL=BWci at WM5 – BWci at WM1) and wMY24a across lactation.

Results & discussion

The heritability for wMY24a showed similar trends in L1 and L2, increasing from 0.06 at WM1 to 0.20 at WM12, and then remaining stable. These values are in the low range of the literature for test-day milk yield of Holstein cows (e.g. Druet *et al.*, 2005). BWL showed very small genetic standard deviations compared to BWci (e.g. 5.1 kg for BWL vs 30.2 kg for BWci at DIM 31 in L1). The resulting heritability was low (0.04 in L1 and 0.02 in L2), but consistent with the heritability estimates obtained by Berry *et al.* (2003) for body weight changes from DIM 5 to DIM 60 (0.06) on multiparous Holstein cows.

The genetic correlations (r_g) between wMY24a at adjacent WM were very high, and decreased as the interval increased. However, r_g between early and later lactation (e.g. before WM10 vs after WM15) ranged from 0.3 and 0.8 in L1 and from 0.6 and 0.85 in L2.

The estimates of genetic correlations between BWL and wMY24a along lactations 1 and 2 are presented in Figure 1.

A moderate negative genetic correlation was found on L1 cows between BWL and wMY24a before WM17, being minimum in WM1 (-0.26), and then becoming progressively closer to 0. This suggests that stronger body mobilization in early lactation is genetically associated with higher milk production. This is consistent

Table 2. Numbers of weekly phenotypes and cows considered in the 4-trait analysis.

	Lactation 1		Lactation 2	
Trait	Weekly phenotypes	cows	Weekly phenotypes	cows
wMY24a	122,720	3,728	91,594	2,887
wBWci	102,582	3,253	78,137	2,553

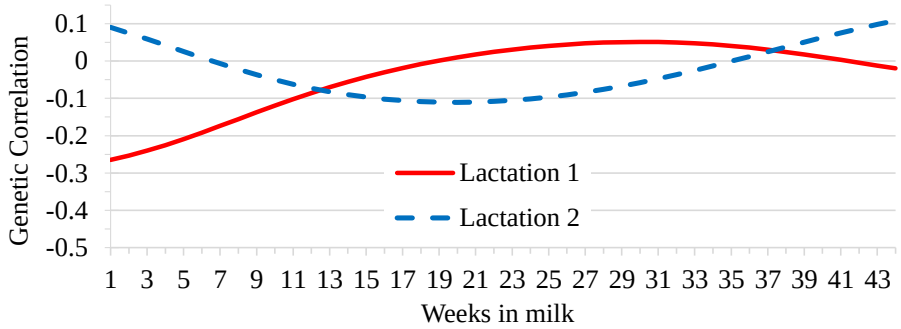

Figure 1. Genetic correlation estimates between body weight loss during the first 5 weeks after calving and adjusted daily milk yield along lactations 1 and 2.

with the results of Berry *et al.* (2003) reporting moderate unfavourable genetic correlations between milk yield and body weight change and body condition score change during the first 2 months of lactation. After ~WM17, BWL and wMY24a appear, however, genetically independent on L1 cows. The genetic correlation between BWL and wMY24a in L2 cows was weaker, declining from 0.1 to -0.1 from WM1 to WM20, and then re-increasing up to 0.1 throughout the second half of lactation.

Milking robots are a valuable source of data. It is unfortunate that we did not have individual daily feed intake of the cows to adjust their BW, leading us to predict it under some assumptions. These predictions seem consistent, even if only approximations. However, keeping this in mind, our results suggest that it is possible to select cows with high milk yield after lactation peak while controlling body mobilization.

Abstract

Body condition score (BCS) is a good estimate of body reserves and could serve as a proxy to prevent some metabolic disorders. Based on 686 lactations from three experimental farms, we investigated to what extent BCS direct genomic values (DGV) from the national evaluation, estimated independently from the phenotypes of this study, reflect profiles of body reserves along lactation, and how it affects body weight, feed intake and milk production. A model including different regressions of BCS DGVs was applied to each trait over the lactation period. Differences in BCS DGV resulted in differences in observed BCS and body weight during the entire lactation. Differences in daily milk production reached 1 kg per day all along lactation. Interestingly, feed intake increased more rapidly with BCS DGV in early lactation but was similar thereafter. The BCS index is a promising tool to limit intense mobilization in early lactation but still needs further investigation.

Introduction

Body reserves are used as an adjustment variable for feed intake during the lactation period. In early lactation, the increase in feed intake is indeed not sufficient to cover the energy requirements for milk production (Banos *et al.*, 2005) and cows therefore enter a negative energy status that leads them to mobilize their body reserves (Friggens *et al.*, 2004). Conversely, later in the lactation, when milk production decreases while intake is still high, cows can recover and build new body reserves. Body condition score (BCS) is a good estimate of the amount of stored fat on the body (Broster and Broster, 1998), despite being based on the human eye which makes it difficult to identify small changes on a short time interval. It has been shown that positive genetic correlations exist between BCS and feed efficiency components such as feed intake and body weight (Manzanilla-Pech *et al.*, 2016). However, if cows with high genetic merit for milk production are reported to mobilize more body reserves than cows with lower genetic merit (Pryce *et al.*, 2001), a too intense mobilization is not favourable as it can lead to metabolic disorders (Weber *et al.*, 2013) and poor fertility. In France, estimated breeding values (EBV) are calculated based on one measure of BCS recorded during the first lactation. In this article, we investigate to what extent this genomic evaluation based on a single phenotypic record per cow may reflect different dynamics of body reserves along the lactation period and how it could be used to limit mobilization in early lactation. We also investigated how differences in BCS evaluation would affect levels and trajectories of other traits such as feed intake or milk production.

Materials & methods

Population resources and feeding management. This experiment was carried out from 2014 to 2020 using Holstein cows from three French experimental farms: 169 Holstein cows from the Le-Pin-Au-Haras INRAE facility, 145 from the Mejusseaume INRAE facility and 121 from the Trinottières experimental farm, representing a total of 686 lactations with parity ranging from 1 to 7. All animals were handled with care in accordance with the French Ministry of Agriculture guidelines for animal research and the applicable European Union guidelines and regulations on animal experiments. Cows were fed individually using an electronic gate feeding system and ear-tag identification. A total mixed ration (TMR) was distributed *ad libitum* (approximately 10% left overs). For Mejusseaume, the TMR was based on maize

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_53, © R. Lefebvre *et al.* 2022

silage and concentrates with an energy value of 0.93 forage unit by kg of dry matter (UFL/kg of DM, 1 UFL equating to 7.12 MJ of net energy for lactation, INRA, 2018). In Trinottières, two TMR were used (one half of the cows for each diet): one based on maize silage and concentrates and the other one including grass silage, with an energy value of 0.96 and 1.00 UFL/kg of DM respectively. Finally, in Le Pin, the TMR was based on maize silage, with grass silage, rapeseed meal, minerals and concentrates, and an energy value of 0.95 UFL/kg of DM.

Phenotyping and trait definition. Cows were milked twice daily and milk yield (MY) was individually recorded at each milking. Body weight (BW) was recorded at each milking using an automatic weighing system. Individual daily feed intake was measured as the difference between distributed and next morning refusals weight (Mejusseaume and Trinottières) or as the sum of intake weighed at each visit of the cow (Le Pin). Dry matter intake (DMI) was calculated daily, based on dry matter content of TMR. Body condition was scored on a 5-point scale with 0.25 steps by the same 2 or 3 trained scorers, monthly or every 2 weeks, depending on the farm. Average BCS of the scorers was used. The study included data from 5-250 days in milk (DIM).

Genotyping and genomic evaluation. All animals were genotyped with the Illumina SNP50k or EuroG10k chip (Illumina Inc., San Diego, CA) from blood samples or ear punches. Genotyping was performed at LABOGENA, Jouy-en-Josas, France. Missing 50k genotypes were imputed with FImpute (Sargolzaei *et al.*, 2014). Direct genomic values (DGV) of experimental animals were obtained by combining their genotypes with the SNP effects estimated by the French national evaluation system. It is worth noting that phenotypes from these three experimental farms are not used in the national evaluation and therefore DGVs used in this study were fully independent of any phenotypic information from the animals. BCS index was expressed in genetic standard deviations, with a zero mean.

Statistical analysis. For each of the four considered traits (MY, DMI, BW and BCS), effect of BCS index (iBC) on trait trajectory over lactation was analysed with a model including: (1) a lactation curve to take DIM into account; and (2) different regressions on BCS index in order to estimate its impact on the trait.

At each day in milk, the following model was applied:

$$y_{it} = \mu + x_i \times f + WIL_t(\text{parity}) + reg_{it}(BC) + \varepsilon_i \quad (1)$$

$$WIL_t(\text{parity}) = a + b \times t + c \times e^{-0.06*t} \quad (2)$$

$$reg_{it}(BC) = \alpha \times iBC + \beta \times iBC \times st + \gamma \times iBC \times st^2 \quad (3)$$

where y_{it} is the performance of animal i at DIM t, μ is the overall mean, f is the vector of fixed effects of farm-date and, for MY and BW, the corresponding DGV as a covariate, x_i is the incidence vector relating cow i to fixed effects, WIL_t(parity) is the intra parity Wilmink model of the lactation curve (primiparous vs multiparous) as described in Equation 2 (Wilmink, 1987) and reg_{it}(BC) is the regression on BCS index as described in Equation 3 with st the standardized DIM ((t-125)/250) and ε_i is the residual.

Analyses were performed with the GLM procedure of the SAS software (SAS institute Inc., 2008).

To illustrate BCS DGV effects, results were averaged by class of DGV values. Five classes were defined as follows: 'BC--' if iBC≤-1; 'BC-' if -1<iBC≤-0.5; 'BC0' if -0.5<iBC<0.5; 'BC+' if 0.5≤iBC<1; 'BC++' if iBC≥1. BC classes included 29, 69, 184, 90 and 63 cows, respectively.

Results

The descriptive statistics regarding MY, DMI, BW and BCS for overall lactations showed no differences in mean DMI, BW and MY between farms. Some slight differences in BCS existed between farms with the highest value for the Trinottières farm (2.7 points), an intermediate value for the Le Pin farm (2.3 points) and the lowest value for the Mejusseaume farm (2.0 points). Trajectories of MY, DMI, BW and BCS are presented in Figure 1. Daily milk rapidly increased by 12 kg between 5 and 50 DIM, then slowly decreased. On the contrary, DMI increased by 8 kg between 5 and 50 DIM but much more slowly than milk. BW decreased by 14 kg during the first two weeks of lactation, and then increased constantly with animals gaining on average 80 kg in total. Regarding BCS, the tendency curve shows a small condition loss of 0.25 points at the beginning of lactation, then a recovery of 0.4 points at the end of lactation.

The effects of BCS index on trait trajectories are presented in Figure 2. Regarding BCS (Figure 2a), positive BC cows always had a greater score than negative BC cows, independent of the stage of lactation. This difference increased along the first 6 months with a 0.4 and 0.8 score difference between extremes in the beginning and mid lactation, respectively. Negative BC cows had a greater milk production (Figure 2b) with barely no difference between extremes at the beginning of lactation, and 1.2 kg per day difference in the middle of lactation. Regarding DMI (Figure 2c), positive BC cows had a greater intake at the beginning of lactation (+1.2 kg a day). After 100 days, we observed no more difference between cows. Negative BC cows were lighter than positive BC cows (Figure 2d) with an increasing difference over lactation from 40 to 65 kg.

Discussion

The small difference observed in the average BCS among the farms is more likely due to slight differences of scale interpretation among the technicians rather than real differences of body reserves, as there was no cross-validation of scores nor common training of technicians. However, these differences were accounted for in the fixed effects of the models.

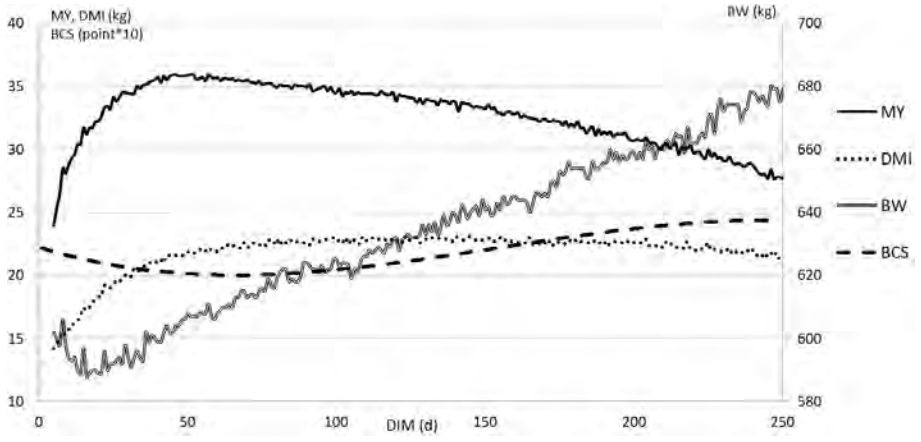

Figure 1. Trajectories of milk yield (MY), dry matter intake (DMI), body condition score ×10 (BCS) and body weight (BW) over days in milk (DIM).

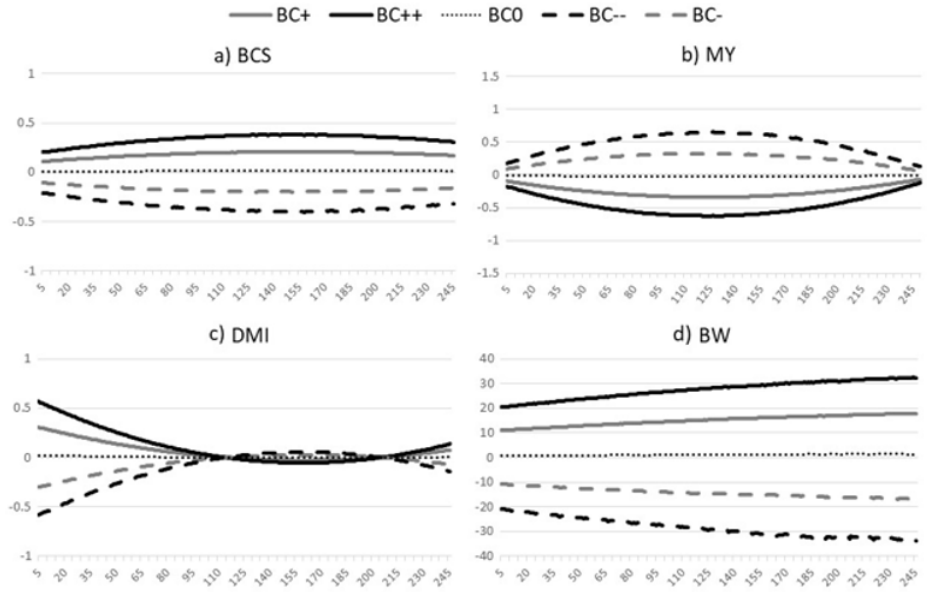

Figure 2. Effect of body condition score (BCS) index on trajectories of (a) BCS (points), (b) milk yield (MY, kg), (c) dry matter intake (DMI, kg) and (d) body weight (BW, kg) from 5 to 250 days in milk.

Observed differences in BCS were in agreement with BCS DGV but a bit lower at the beginning of the lactation. These differences in BCS DGV also translated into moderate differences of BW increasing all along the lactation. Changes of MY per day are minimal (1 l maximum per day between extreme groups) but cumulative. DMI is influenced only in early lactation. Therefore, the BCS index is a promising tool to limit intense mobilization in early lactation but still needs further investigation.

54. Feed efficiency and resource allocation trade-offs: theory, evidence and prospects

F. Douhard*, R. Rupp and H. Gilbert

GenPhySE, Université de Toulouse, INRAE, ENVT, 31326 Castanet-Tolosan, France; frederic.douhard@inrae.fr

Abstract

The resource allocation theory has long been of interest in livestock as a framework to explain the correlated responses to selection for high productivity. Increasing limitations on feed resources and genetic improvement of feed efficiency (FE) should further promote allocation constraints. Yet, predicting those consequences for breeding critically depends upon the possibility to get testable predictions from the current framework. Here we assessed the changes in energy allocation when selecting for FE, and the consequences of those changes on health and reproduction. For this, we used two approaches; a survey of selection experiments among various species and a case study in sheep focusing on a potential trade-off between FE and response to an infectious challenge (parasite infection). Overall, results provide weak evidence for the current allocation framework. We outline several directions to better appraise the consequences of breeding for FE in increasingly challenging environments.

Introduction

Global pressures on feed resources require livestock that consume less feed to produce under controlled conditions but also emphasize the challenge of producing when feed quantity or quality can drop unexpectedly. Although those issues well translate into separate researches on new breeding objectives for FE and for robustness, the links between those two types of traits remain unclear whereas most of their mechanisms should share a common nutritional basis. Moreover, those links may have key implications in terms of trade-offs and genotype-by-environment interactions. A framework representing how nutrition affects multiple traits responses to selection would be thus insightful. For this purpose, the evolutionary theory of resource allocation has become of interest in animal breeding since it provides a simple way to consider the responses to selection according to the feed availability and to the competing demands for nutrient among the different functions of an organism (Beilharz *et al.*, 1993; Rauw, 2009). Yet, this framework only had a limited impact on the study of FE so far. Moreover, some responses to selection for FE have called into question the occurrence of resource allocation trade-offs (Rauw, 2012; Gilbert *et al.*, 2017). Although the resource allocation theory has been introduced in the livestock context since the 90's, its applicability to these conditions remains seldom questioned and tested. The fast-growing body of research on FE thus provides new opportunities to assess the mechanistic bases of resource allocation trade-offs and how they might shape selection responses.

Why should selection for feed efficiency lead to energetic trade-offs?

Recently, we have reconsidered the theoretical background to predict trade-offs, focusing on energy allocation (Douhard *et al.*, 2021). Our framework is based on the classic 'Y model' of a resource acquisition and allocation (Van Noordwijk and De Jong, 1986) applied to animals typically selected under non-limiting resources. For each animal, the daily rate of metabolizable energy intake is split into one part allocated to productivity ('P'; energy retained as new biomass such as muscle, fat, milk, egg or wool plus the associated energy of biosynthesis dissipated as heat), and the other part allocated to activity and self-maintenance. Allocation to maintenance can be approximated by resting metabolic rate (RMR) and is supposed to maximize the chance of survival and future reproduction (Figure 1a). Most undesirable side effects of selection for high productivity are thus thought to stem in the extent to which RMR is reduced in the total energy budget (once its covariation with body size has been accounted for). However, a same selective

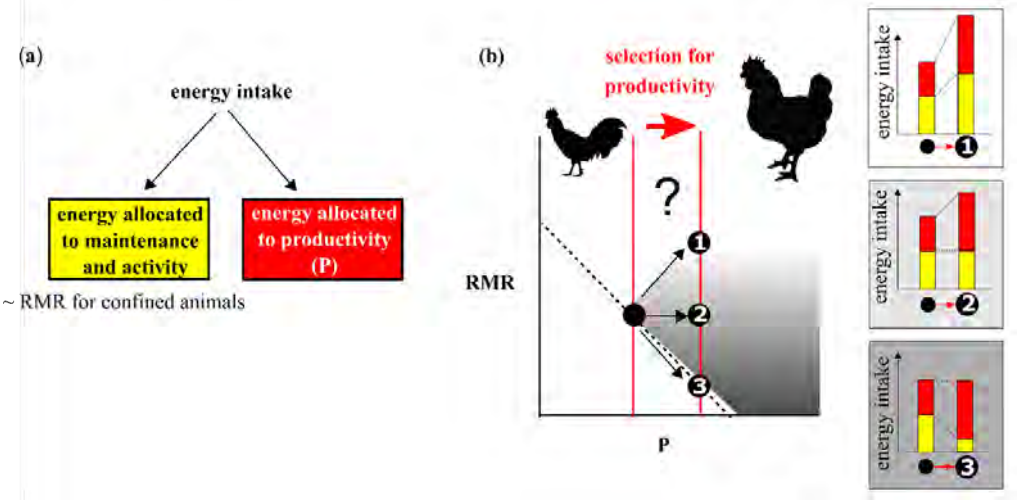

Figure 1. The 'Y model' of energy allocation applied to livestock (a) and the different paths through which increased productivity could translate in terms of changes in energy allocated to productivity or maintenance (b). Maintenance can reasonably be approximated by resting metabolic rate (RMR) for confined animals. Grey shade reflects the trade-off intensity. Adapted from Douhard *et al.* (2021).

increase in productivity could be mediated through different changes in energy allocation depending on the relationships between productivity, maintenance and intake (Figure 1b). A higher rate of biosynthesis could require higher maintenance costs (path no.1 where P and RMR are positively associated) or could be simply fuelled through higher intake (path no.2 where RMR and P are independent). Alternatively, constraints on intake could favour a reduced energy allocation to maintenance (path no.3 where RMR and P are negatively associated). All those cases can lead to an increase in P relatively to energy intake and thus improve FE. However, if an energy allocation trade-off occurs then selection strategies that promote a reduction in RMR should increase the risk of an impaired health or reproduction.

What is the evidence for energy allocation trade-offs?

Review of comparisons between breeds or lines selected in favourable environments. First, to assess the relationships between maintenance, productivity and feed intake in the context of livestock and artificially selected laboratory mammals and birds, we surveyed studies that compared RMR between breeds or lines of contrasting yields when feed intake was not constrained (Figure 2a). Only few studies provided some support for an energy allocation trade-off (path n°3 in Figure 1b), in particular during growth in poultry. In contrast, during reproduction, increased maternal productivity seemed often associated with an increased RMR (path n°1 in Figure 1b). Then, to explore the correlated effects of a reduced RMR on different aspects of health or reproduction, we reviewed selection experiments on FE or RMR (Figure 2b). Indeed, responses to selection for FE or for RMR were consistently and positively related which suggests that selection for FE generally leads to some genetic decrease in RMR (but also in some behavioural activities), even though feed intake is not restricted. Despite this constraint on metabolism, we found little evidence for unfavourable effects on components of health (e.g. oxidative stress, neonatal survival, humoral or cell-mediated immunity) and reproduction (e.g. sperm traits, litter size, milk output).

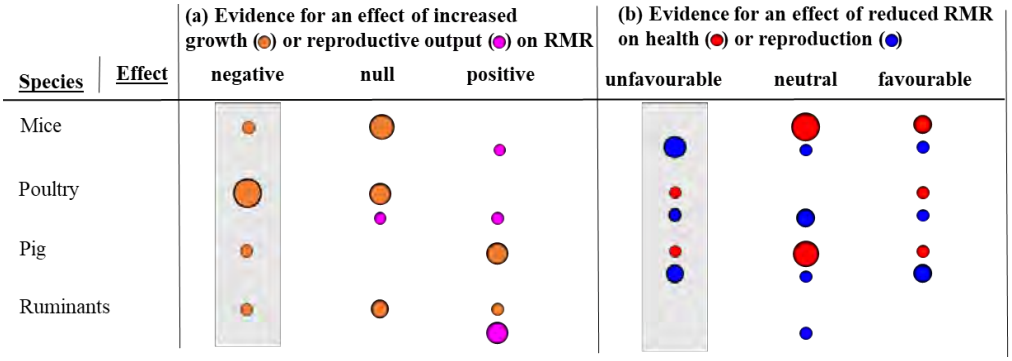

Figure 2. Evidence for association between resting metabolic rate (RMR) and selection for growth or reproductive output when feed intake is not restricted (a), and effects of a genetically reduced RMR on health or reproduction (b). The size of the circle indicates the number of supporting comparisons (1≤n≤5) between selected lines or breeds. In (b) when different components of health or reproduction were investigated within a same pair of lines there were considered as different comparisons. The scenario corresponding to an energy allocation trade-off (path n°3 in Figure 1b) is highlighted in grey.

Case study in sheep selected for response to an infectious challenge or for feed efficiency. To better detect a potential energy allocation trade-off, it may be necessary to go beyond the simple Y model (Figure 1a) notably to focus on a component of maintenance that can be specifically recruited under challenging conditions, e.g. a specific immune response to infection. For this, we studied the potential trade-off between FE and resistance to gastrointestinal parasitism based on an infectious challenge (single-dose infection with *Hæmonchus Contortus*) in growing lambs from Romane meat-sheep (experimental approval D18-174-01). In a first trial, lambs were from lines divergently selected on parasite resistance (resistant (R) vs susceptible (S); Sallé *et al.*, 2021), whereas in another trial they were from lines divergently selected for FE (low Residual Feed Intake (RFI-) vs high (RFI+); Tortereau *et al.*, 2020) from the same flock. Within each trial, direct responses to selection were consistent: fecal worm egg count of was much lower in the R line than in the S line, and FE was better in the RFI- line than in the RFI+ line. Contrary to our expectation, no evidence for a trade-off was found. Between the RFI lines, the difference in FE was maintained during infection, and no difference in parasite resistance was detected. In the R and S lines we even found some evidence for a synergy between FE and parasite resistance. Voluntary feed intake was lower for the R line than for the S line during infection, which also led to a lower RFI. Later on, we re-infected the R and S lines during the first peripartum and tested the effect of a feed restriction (protein). This restriction led to a similar decrease in body weight and condition between lines, with no interaction with parasite resistance.

Limitations and future directions

Based on our findings, the consequences of breeding for FE look much more difficult to predict than one could anticipate from the energy allocation framework alone. First, although the genetic antagonisms observed between productivity and health or fertility are often considered as a result of resource allocation trade-offs, we did not find strong support that those trade-offs can be underpinned by changes in energy allocation. Second, even when energy allocation to maintenance is reduced during selection for FE, the expected unfavourable effects on health or reproduction were far from clear. Lastly, our case study neither indicates that selection for a particular health component (parasite resistance) deteriorates FE during a challenge, nor vice-versa. Overall, we thus confirm a lack of direct or mechanistic support for the energy allocation framework when applied to livestock.

However, there were at least three main limitations when assessing this framework. First, the energy allocation to maintenance remains difficult both to estimate and to interpret. In particular, dissecting the biological basis of FE or RMR does not simply translate into the resource acquisition-allocation framework as various maintenance processes also contribute to feed acquisition or to production. Second, the aspects of energy budgets that fundamentally constrain selection are still very elusive. Third, while the consequences of a reduced allocation to maintenance on fitness-related traits should be considered on the long-term, most studies of FE have focused on reproduction or health traits in young adult animals, which may have led to inadequate measurements to correctly assess the resource allocation framework.

Beyond those limitations, it becomes increasingly clear that resources allocation constraints do not provide a sufficient explanation for the occurrence of trade-offs and that other mechanisms underpinning unfavourable genetic correlations should be considered (e.g. nutrient-sensing signalling). Those considerations should contribute to a more integrative framework to orientate breeding objectives according to the agroecological context.

Abstract

The objective of this study was to present a new methodology to predict selection response on resilience and feed efficiency (FE) in dairy cattle. This approach combines genetic and mechanistic modelling to describe the biological mechanisms underlying these traits. A dairy cattle breeding scheme was simulated considering a non-limiting nutritional environment and two different breeding goals focusing either on milk production or FE. Selection response was predicted within the non-limiting environment but also for a prospective low-input system (LS). Predictions obtained with conventional and mechanistic-based methods were consistent for milk production, body weight and FE within the non-limiting environment. However, genetic trends predicted for fertility were different. Selection response achieved on milk production was much smaller in the LS than in the breeding nucleus due to the increased nutritional constraint. The breeding goal with emphasis on FE enabled a better transfer of genetic gain to the LS environment.

Introduction

Breeding for resilience and feed efficiency (FE) in dairy cattle is difficult because these traits result from a subtle balance between biological functions aiming at maintaining a cow's ability to produce and reproduce. This balance is also highly dependent on the nutritional environment: trade-offs between production and fitness traits are exacerbated when energy intake is limiting (Puillet *et al.*, 2021). With climate change and societal demands for expanding grass-based production systems, nutritional environments might be more uncertain and diverse in the future. When defining novel breeding strategies on resilience and FE, it is critical to anticipate these changes and select cows that can cope with various production systems. This paper describes a new mechanistic-based method (MM) combining genetic and mechanistic modelling to predict selection response on cow milk production and FE traits. This approach can be used within a given breeding environment but also facilitates predicting selection response that would be expected in more challenging environmental scenarios.

Materials & methods

General approach to predict selection response. In this study, we capitalize on the AQAL bioenergetic model to simulate phenotypic trajectories of milk production and FE traits over the lifetime of dairy cows depending on energy available in the environment (Puillet *et al.*, 2016; 2021). This dynamic mechanistic model of a single cow is grounded on the resource acquisition and allocation (AA) theory to describe cows' responses to nutritional challenges. Variability in the response observed at the population level is induced by assuming genetic and phenotypic variance for a set of four input parameters describing energy AA strategies of cows. Acquisition parameters correspond to the maximal intake of a non-reproducing cow (basal acquisition: BasAcq) and the increase of intake during lactation (lactation acquisition: LactAcq) expected in a non-limiting environment. Allocation parameters correspond to the rate of transfer of energy from growth to survival (RTGS) defining the trade-off between structural mass and body reserves, and the allocation to lactation (LactAll) defining the energy investment in milk production. Mean values of these four parameters were determined by a calibration procedure using real data as described by Puillet *et al.* (2021). The effect

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_55, © A. Bouquet *et al.* 2022

of the nutritional environment on the variability of traits was modelled through stochastic simulations. To predict genetic gain, it was assumed that selection on usual production and functional traits changes the mean genetic level of energy acquisition and allocation variables. Thus, updating AA parameters considering this correlated response is a way to simulate new performance datasets mimicking the effects of selection with AQAL. The method comprises three steps. First, datasets with a pedigree structure were simulated with AQAL considering the same AA parameters as Puillet *et al.* (2021) and a non-limiting nutritional environment typical of breeding herds. This environment corresponded to the 'high & stable' (HS) scenario in Puillet *et al.* (2021). Simulated data were used to estimate genetic parameters between simulated traits and AA input traits. Second, the ADAM breeding scheme simulation tool (Pedersen *et al.*, 2009) was used to estimate the correlated selection response expected on AA traits for a given breeding goal and a typical dairy cattle breeding scheme structure. Finally, milk production and FE traits were simulated by updating the AQAL AA input parameters with the correlated selection response to estimate the change in performance due to selection.

Considered traits and genetic parameters. Four traits were analyzed in this study and were estimated for primiparous cows: milk production (MP), body weight at calving (BW), energy conversion efficiency (ECE) and the interval between first mating and conception (IFC). The four AA input traits were assumed to have a heritability of 0.35, a phenotypic coefficient of variation of 10% and to be genetically uncorrelated as assumed by Puillet *et al.* (2021). Genetic parameters were estimated between AA traits and simulated traits using restricted maximum likelihood applied to bivariate linear animal mixed models (Table 1). Genetic correlations were close to 1 between BasAcq and BW, as well as between LactAll and ECE. Hence, we considered these pairs of traits as single traits.

Simulation of breeding scheme. A large-scale breeding nucleus was simulated over a 30-year period with ADAM (Pedersen *et al.*, 2009). It comprised 20,000 females equally distributed in 200 herds and mated with 100 sires each year. True breeding values (TBV) and phenotypes were sampled using genetic parameters in Table 1. Milk production, BW and IFC were recorded on all cows. Genomic selection was simulated using the pseudo-genomic selection approach (Buch *et al.*, 2012). The accuracy of genomic breeding values (GEBV) was estimated using selection index theory to combine information from bull and cow reference populations (Buch *et al.*, 2012). We assumed a reference population of 10,000 bulls with 100 daughters each, 50,000 cows with performance for MP, BW, IFC, and 5,000 cows with ECE phenotypes. The GEBV accuracy of candidates without performance was 0.68 for MP and BW, 0.60 for ECE and 0.58 for IFC. Using simulated traits, pseudo-genomic phenotypes and pedigree, GEBV were predicted using DMU software (Madsen and Jensen, 2013).

Each year, the best 4,000 male and 4,000 female calves were assumed to be genotyped based on parental breeding values. After genotyping, the best 100 1-year old males were selected to be used as sires for one

Table 1. Genetic parameters for acquisition, allocation and simulated traits (heritability on the diagonal, genetic and phenotypic correlations above and below the diagonal).

	BasAcq / BW	LactAcq	RTGS	LactAll / ECE	MP	IFC
BasAcq / BW	**0.35**	0.00	0.00	0.00	0.50	-0.23
LactAcq	0.00	**0.35**	0.00	0.00	0.38	-0.12
RTGS	0.00	0.00	**0.35**	0.00	0.24	-0.64
LactAll / ECE	0.00	0.00	0.00	**0.35**	0.72	0.56
MP	0.52	0.39	0.23	0.73	**0.34**	0.12
IFC	-0.05	-0.02	-0.13	0.11	0.06	**0.01**

year. Within each herd, the best 100 females aged from 1 to 5 years were selected using estimated breeding values. Selection decisions were based on a total merit index. Two breeding goals were defined to reflect a different balance between production and functional traits. In the first breeding goal, called M-FER, equal weight was given to MP and IFC. In the second breeding goal, called EFF-FER, equal weight was given to ECE and IFC. The first 20 years were considered as burn-in period and were discarded. Annual genetic gain was predicted for each trait by regressing mean TBV of selection candidates on their birth year over the last ten years. All presented results were averaged based on 30 replicates.

Genetic gain predictions based on the mechanistic model. Mean values of the four AA parameters were updated considering the correlated selection response expected over a 20-year period. Changes in heritability and phenotypic variance of AA traits due to selection were also estimated as observed in ADAM stochastic simulations. Changes in genetic covariance between AA traits were small (≤0.04 in absolute value) and were ignored. Selection response was estimated for each trait on an annual basis as the change in performance simulated with the initial and updated sets of AA parameters within the non-limiting HS environment.

Selection response that would be expressed in a low nutritional environment following selection in the HS environment was estimated in the same way but simulating datasets with AQAL considering the 'low & stable' (LS) environment in Puillet *et al.* (2021). In this environment, the nutritional constraint was substantial: dry matter intake was on average 14.7% lower than total potential acquisition.

Results & discussion

Correlated selection responses on AA traits predicted for the two breeding goals are presented in Table 2. With the M-FER breeding goal, high genetic gain was achieved on basal acquisition because this trait was positively correlated to MP and IFC. Indeed, when access to feed is non-limiting, increasing feed intake by selection is an option to improve both MP and IFC. Therefore, although a high weight was given to MP, genetic gain on LactAll was only limited. Selecting on the EFF-FER breeding goal led to a more balanced genetic gain on the four AA traits, with a shift in genetic gain from BasAcq to LactAll. In both scenarios, similar positive genetic gain was achieved on RTGS meaning that selection favors cows allocating more energy for body reserves accretion than growing structural mass.

Selection responses predicted for simulated traits are presented in Table 3. With the conventional method, high genetic gain was estimated on MP, BW and IFC for the M-FER breeding goal in the HS environment. Genetic gain on ECE was more limited. With the EFF-FER breeding goal, genetic gain was higher on ECE and more limited on BW and IFC. This was consistent with genetic correlations between AA input traits and simulated traits.

Selection response predictions were consistent across methods and breeding goals within the HS environment for MP, BW and ECE.

Table 2. Mean annual genetic gain[1] (in genetic standard deviation units) estimated for acquisition and allocation traits in the breeding environment for the two breeding goals.

Breeding goal	BasAcq	LactAcq	RTGS	LactAll
M-FER	0.34	0.13	0.20	0.09
EFF-FER	0.22	0.14	0.21	0.23

[1] Standard error of the mean ranged from 0.002 to 0.003 for all predictions.

Table 3. Annual genetic gain (expressed in genetic standard deviation units) predicted for simulated traits with the conventional (CONV) and mechanistic-based (MM) methods in the breeding environment (HS) and the low nutritional scenario (LS).

	CONV prediction – HS		MM prediction – HS		MM prediction – LSI	
	Breeding goal		Breeding goal		Breeding goal	
Trait	M-FER	EFF-FER	M-FER	EFF-FER	M-FER	EFF-FER
MP	0.33	0.38	0.34	0.41	0.15	0.28
BW	0.34	0.22	0.30	0.19	0.23	0.16
ECE	0.09	0.23	0.08	0.22	0.09	0.23
IFC	-0.21	-0.11	-0.01	0.06	0.00	0.06

Indeed, differences in annual genetic gain were lower than 0.04 genetic standard deviation units (σ_g). Differences were larger on IFC. Annual genetic gain was reduced from -0.21 to -0.01 σ_g in the M-FER scenario and from -0.11 to 0.06 σ_g in the EFF-FER scenario, i.e. a zero or even unfavorable trend was predicted on fertility in the M-FER and EFF-FER scenarios with the MM approach.

Genetic gain that would be expressed in the LS environment given selection in the HS environment was estimated with the MM approach (Table 3). In the LS environment, selection response predicted on MP and BW with the M-FER breeding goal was reduced by 56 and 23% relative to the HS environment. The reduction in genetic gain was more limited in the EFF-FER scenario (-32% and -16% for MP and BW). Indeed, increasing basal acquisition by selection in the HS environment led to further increase the nutritional constraint in the LS scenario due to increased maintenance requirements. This also explains the larger reduction in selection response on BW and MP with the M-FER breeding goal due to faster genetic progress on basal acquisition. Hence, a larger proportion of genetic gain was transferred from the high to the low nutritional environment with the EFF-FER breeding goal.

In conclusion, this study showed the feasibility of combining mechanistic and genetic modelling to predict selection response on milk and FE traits in dairy cattle. Predictions were consistent for MP and FE traits within the breeding environment. Compared to the standard approach, the new method also casts light on the AA strategies used to achieve genetic gain. Furthermore, it enabled the estimation of genetic gain that could be transferred to a prospective environment considering both genetic trends and the magnitude of physiological trade-offs on production and functional traits.

Abstract

The objectives of this study were to investigate the possibility of characterising animal robustness by using indicators based on the dynamics of energy allocation of the animal and to determine their genetic parameters. A total of 2,140 pigs, from the Piétrain NN Français line, were raised at the AXIOM boar testing station. This farm was equipped with automatic feeding system, recording individual weight and feed intake at each visit. We used a dynamic linear regression model to characterize the evolution of the allocation factor (α_t) between cumulative net energy available, estimated from feed intake, and cumulative weight gain during fattening period. The variance of α_t, that could be interpreted as an indicator of the response of the animal to perturbations/stress, showed moderate heritability (0.27±0.08). Our perspective is to further decompose the allocation factor into components to better characterise the robustness phenotype.

Introduction

Livestock farming faces new challenges related to climate change and societal concerns, e.g. animal welfare and use of antibiotics. These challenges require having animals able to adapt to these new conditions, which implies an improvement of robustness while maintaining a high level of production. There is no real consensus on the definition of robustness as well as on the ways to phenotype it. Following the definition of robustness adapted to the context of artificial selection of Knap (2005), we have recently proposed robustness scores estimated from phenotypes commonly available on farm (Lenoir *et al.*, 2021). However, these scores had low heritability indicating the need to find other indicators that can be used for genetic improvement. Development of new technologies in livestock production, such as automatic feeding system, allow recording of longitudinal data over a period (weight, feed intake, feeding duration). Several studies have used such data to quantify robustness and resilience indicators based on deviation between potential of production of an individual and its observed production (Nguyen-Ba *et al.*, 2020; Revilla *et al.*, 2022). Definition and modelling of individual potential are challenging issues in these approaches. The first objective of this study was to investigate the possibility of characterising animal robustness by using indicators based on the dynamics of energy allocation of the animal. Our rationale is that these indicators should reflect the ability of an animal to express or adapt its production potential in the face of changes in the environment relative to other animals that have been raised under the same conditions. To identify these indicators, we followed a modelling approach applied on longitudinal measurements of body weight and feed intake of fattening pigs (35 to 110 kg live weight). The second objective was to estimate the genetic determinism of the resulting indicators and to compare them with other robustness traits.

Materials & methods

Animals. Pigs from Piétrain NN Français paternal line, free from halothane-sensitivity, of the Axiom company were used in this study. The animals considered in this study were 2,140 entire males raised from January 2019 to April 2021 at the AXIOM boar testing station and born from two different farms. They entered the boar testing station after weaning and were raised in quarantine rooms and in post-weaning rooms for 7 weeks. Then, animals were transferred to fattening rooms when they were 75.3±3.4 days of age (34.5±6.2 kg BW). They were kept in fattening rooms during 74.8±4.0 days until the individual

candidate test at around 149.7±4.1 days of age (108.8±11.5 kg BW). Fattening rooms were equipped with automatic feeding system (AFS) Nedap pig performance testing feeding station (Nedap N.V.; Groenlo, the Netherlands).

Data. During the fattening period, BW (kg) and feed intake (FI; kg) were recorded each time the animal went into the AFS. Other measurements made during the individual test were: average ultrasonic backfat thickness (BF100) and ultrasonic longissimus dorsi thickness (LD100), both adjusted to 100 kg liveweight. Individual average daily gain (ADG) and daily feed intake (DFI) were calculated. The feed conversion ratio (FCR) was calculated as the ratio between the total FI and the weight gain during the fattening period. A phenotype to characterize the robustness (R2) of the candidates was determined from the visual observation performed during the individual test based on Lenoir *et al.* (2021). The binary trait R2 differentiated animals that were selectable (score 1), from those that were dead or not selectable (score 0). The ABC index developed by Revilla *et al.* (2021) was calculated using weight measured by AFS for each animal alive at the end of the fattening period. The trait ABC was the accumulated difference (area) between a theoretical unperturbed growth curve and the perturbed curve.

After pre-treatment process of data recorded by AFS, the weight (W_t; kg) and the feed intake (F_t; kg) for each fattening day were estimated, where t was time in days since the transfer to fattening room. Then, F_t was converted in net energy intake (EI_t) by using a factor of 9.85 MJ/kg of NE. The net energy available at day t (NEA_t) was the difference between EI_t and the net energy maintenance requirements at day t (MR_t). The value of MR_t was estimated according to Noblet *et al.* (2016), $MR_t = 1.05 \times W_t^{0.6} \times 0.74$.

Modelling growth allocation. We could represent the link between cumulative NEA (CNEA) and cumulative weight gain (CW) by a standard linear regression for each animal (1).

$$CW_t = \alpha\, CNEA_{t-1} + \varepsilon_t, \qquad \varepsilon_t \sim N(0,\sigma^2) \tag{1}$$

Where CW_t is the time series of cumulative weight gain (kg) at day t; $CNEA_{t-1}$ is the cumulative net energy available (MJ) at day t-1; α is an allocation factor of energy to weight gain. We assumed in this study that a perturbation is linked with a change in the allocation of energy available to the growth. Therefore, the relationship between CW and CNEA evolves over time. To characterize this evolution, we used a dynamic linear regression model (Petris *et al.*, 2009) built with two equations: an observation Equation 2, relating cumulated weight gains and cumulated NEA, and a system Equation 3, describing the changes in α_t (unobserved state variable) from day to day according to a stochastic process.

$$CW_t = \alpha_t CNEA_{t-1} + v_t, \qquad v_t \sim N(0,\sigma_v^2) \tag{2}$$

$$\alpha_t = \alpha_{t-1} + w_t, \qquad w_t \sim N(0,\sigma_w^2) \tag{3}$$

The model has been built using the function dlmModReg of the package dlm of R (Petris *et al.*, 2009). It included two unknown parameters (σ_v^2 and σ_w^2) that were estimated by maximum likelihood with the function dlmMLE. The values of α_t were calculated independently for each animal with a Kalman smoother algorithm (function dlmSmooth). For each individual, using the estimated α_t across time, we further calculated two traits: the mean (MA) and the variance (VA).

Genetic parameters estimation. Genetic parameters were estimated using ASReml 3.0 software (Gilmour *et al.*, 2009) using the restricted maximum likelihood method (REML). The fixed effect was the fattening group (33 levels). In addition, two random effects were included in the model: common litter

effect and genetic additive effect of the animal. Traits ABC, MA and VA were standardized on a mean of 0 and a standard deviation of 1. Firstly, variance and covariance components were estimated with a 4-trait linear animal model including traits under selection (ADG, FCR, BF100 and LD100). Secondly, to estimate heritability for each non-selected trait (MA, VA, DFI, ABC and R2) and their genetic correlations with the traits under selection, 5-trait linear animal models including the 4 traits under selection and 1 trait to be estimated were used. R2 was considered as a continuous phenotype. Thirdly, to estimate genetic correlations between MA and VA with the other non-selected traits, 2-trait linear animal models were performed. The pedigree contained 3,944 animals across 24 generations.

Results

For traits ABC, MA and VA, descriptive values are presented in Table 1 (raw values before standardization). For the traits under selection (ADG, FCR, BF100 and LD100) and DFI, heritability estimates were moderate, from 0.31±0.07 to 0.41±0.07, expect for FCR with a lower value (0.15±0.05). Precisions of estimates were quite low, given the sample size. Heritability of MA (0.16±0.05) was similar to those estimated for FCR. For the 3 robustness traits, heritabilities were low for ABC and R2, 0.06±0.03 and 0.08±0.04 respectively, and moderate for VA (0.27±0.08). The trait MA had moderate to high negative genetic correlations with production traits (-0.52 to -0.79). It was positively correlated with DFI (0.28). Genetic correlations between VA and ADG, BF100 and LD100 were not significantly different from 0. The trait VA was moderately correlated with ABC (0.52±0.29) and negatively with FCR and DFI. The three genetic correlations between the traits MA, VA and R2 (ranging from -0.15 to -0.20) were not significantly different from 0. Several estimates of genetic correlations had large standard errors and should be interpreted with caution.

Discussion

The traits MA and FCR were quite similar, with close heritability estimates and a strong and favourable correlation. This correlation looks different from 1, which could imply that the trait MA captures other elements of energy allocation than FCR. The strong and unfavourable genetic correlation with ADG could be related on the way these two traits were estimated. They were measured over an identical period for all individuals but were not standardized between starting and finishing weights (ADG 30-110 kg). Some of the animals tested reached their maturity weight before the end of testing period, which leaded to a drop

Table 1. Descriptive statistics (Mean and *SD*: standard deviation), heritability (h^2 ± standard error) for studied traits and genetic correlations (r^2a ± standard error) of mean of α_t (MA) and variance of α_t (VA) with studied traits.

[2] Estimates from a 5-traits multiple trait model (ADG, FCR, BF100, LD100 and the trait under consideration).

[3] Estimates from a bivariate model (2 traits under consideration).

in feed efficiency. The trait MA described the average allocation of net energy in growth during fattening period. This trait seems to be an interesting way to phenotype feed efficiency but the relationship between evolution of α_t over time and degree of maturity, regardless maintenance requirements, needs further investigation. The trait MA was also unfavourably correlated to the resilience indicator ABC, suggesting that an increase of energy allocation increases the risk of deviation of potential ADG in case of an environmental perturbation. In contrast, VA was favourably correlated with robustness trait and moderately with ABC trait. The trait VA, variation of α_t over testing period, could be interpreted as an indicator of the response of the animal to perturbations/stress. Indeed, more robust animals are less impacted by perturbations, we assumed that these animals would have a 'more stable' α_t and consequently a lower value of VA. Heritability of this trait was higher than the other robustness traits. This makes it possible to consider a selection on the trait VA. A selection to reduce the variance of α_t would have a negative impact on FCR genetic potential, due to the moderate negative correlation with FCR, and no (or slightly positive) effect on the mean of α_t.

These preliminary results show the value of using the dynamic linear regression method in order to estimate time-trends in allocation (α_t) and to define robustness indicators on the basis of energy allocation. Our perspective is to further decompose the allocation factor into components such as degree of maturity, sensitivity to perturbations, etc in order to better characterise the robustness phenotype and propose useful indicators of robustness for genetic selection.

Abstract

The aim of this study was to assess the use of milk metabolites as an indicator of resilience. Hyper-selection based on functional longevity of AI bucks successfully created two groups of goats with different lifespan. Furthermore, the higher body weight of high longevity line goats and lower milk fat:protein ratio during the beginning of the first lactation suggested different resource allocation profiles between lines. Finally, the difference between the two lines of goats in milk metabolites evolutions during an imposed underfeeding challenge supported this hypothesis. These preliminary results support the value of milk metabolites as a promising noninvasive proxy related to resilience in dairy ruminants.

Introduction

Resilience is the ability of a goat to cope with environmental disturbances, such as pathogens or feed restriction. Genetic selection on resilience remains a challenge. Because resilience translates into enhanced functional longevity, we created two lines of Alpine goats using hyper-selected bucks with the most extreme estimated breeding values for functional longevity. Recent literature showed evidence of a relationship between indicators of body fatness dynamics and resilience (Savietto *et al.*, 2015). In the present study, we explored the evolution of metabolic pathways related with lipomobilisation during feed restriction among goats selected for extreme functional longevity. Accordingly, an experiment was carried out in which time-series measurements of 14 milk metabolites were made in dairy goats exposed to an underfeeding challenge during early lactation. The aim of this study was to validate the use of milk metabolites as an indicator of resilience.

Materials & methods

Experiment. Following the method developed by (Palhière *et al.*, 2018), we made a hyper-selection of dairy goats based on the genetic evaluation for functional longevity of 8,787 alpine AI bucks. From 2017 to 2021, two lines of goats were bred in an INRAE experimental farm (Bourges, France; Ethics approval C18-174-01) comprising 212 low longevity line (low_LGV) and 228 high longevity line goats (high_LGV). The following measures were regularly registered by trained technicians: serum immunoglobulin G concentration (IgG) at birth, monthly weight, health treatment, milk production, milk somatic cell scores (SCS), death/culling date.

In 2020, 49 primiparous dairy goats were exposed to a 2-d underfeeding challenge during early lactation (mean days in milk=39, SD=11). The challenge consisted of a 7-d control period (day -7 to 0) with a standard diet composed of forage and concentrate, 2 d of straw only feeding (day 1 and 2), and a 4-d recovery period on the standard diet (day 2 to 6). Prior to the start of each challenge period, the goats received the standard diet from parturition onwards. The goats were milked twice per day. From the beginning of

DOI: 10.3920/978-90-8686-940-4_57, © M. Ithurbide *et al.* 2022

the prechallenge control period until the end of the postchallenge recovery period, concentrations of 14 milk metabolites were measured daily from the morning milking: glucose-6-Phosphate (Glu6P), glucose (Glu), galactose (Gal), beta-hydroxy-butyrate (BOHB), isocitrate (Isoc), glutamate (Glut), NH2, lactate deshydrogenase (LDH), Urea, Cholin, Malate, urate, triacylglycerol (TAG), cholesterol (Chol).

Animals were cared and handled in accordance with the French legislation on animal experimentation and European Convention for the Protection of Vertebrates Used for Experimental and Other Scientific Purposes (European Directive 86/609) under specific authorization number APAFIS#8613-2017012012585646.

Survival analysis and linear models. The R package 'survival' was used to compare lifespan between the two lines. Survival analysis was performed using a Cox model. The model included both fixed covariate (line, year of birth, IgG at birth), and time-dependent covariates: weight, health treatment events (Zhang *et al.* 2018). Moreover, we ran linear regressions using the lm and glm procedures in R in order to compare between the two lines: weight at birth, monthly weight, IgG at birth, first lactation milk yield at DIM 90 and 250 (MY90, MY250), milk fat: protein ratio and SCS.

Functional principal component analysis. We characterized milk metabolite profiles upon challenge using a functional PCA (fPCA) for each milk metabolite (Yao *et al.*, 2005).The daily concentration of each metabolite during the whole challenge period was included in the fPCA. We used the R package 'fdapace'. This performs local linear smoothing on the covariance matrix and then estimates the principal components with conditional expectation method. Each individual milk metabolite curve was then characterized by a PCscore for each component. We chose the number of components as the minimum needed to explain 80% of the variance of the dataset.

Sparse PLS DA. We then used Sparse PLS-Discriminant Analysis (sPLS-DA) to evaluate the ability of milk metabolites to distinguish the longevity lines. This is a linear multivariate model which performs classification tasks and is able to predict the class of new samples (Lê Cao *et al.*, 2011). The method integrated a continuous data matrix comprising the individual PCscores and a categorical outcome variable: the line of the goat (high/low_LGV). sPLS-DA seeks the components that best separate the sample groups, and also selects variables that best discriminate between groups using lasso penalization. We chose the number of components using cross validation on a non-sparse model (comprising all variables) and then tuned the number of variables to select on each component. We assessed the final performance of the model using a 5-fold cross validation.

Results & discussion

Comparison of the two longevity goat lines. Weight and growth during the first year of life were similar in both goat lines. In contrast, the low_LGV goats had a lower weight during the beginning of first lactation than high_LGV goats. The milk fat to protein ratio was also significantly higher in low_LGV goats during first lactation. The overall survival (from birth to death) of high_LGV goats was significantly greater than low_LGV goats (hazard ratio=0.63, CI=0.47;0.86) even after we included treatment, growth, IgG at birth, and year effects, in the model (Figure 1). The line effect was not constant over time: no significant effect was found during the first year of life and the difference emerged after first kidding. This suggests that survival at an early stage of life and during later productive life are under different genetic regulation. These results support the hypothesis that the two lines of goats present different resilience levels and that this may be linked to different resource allocation profiles between lines. The analysis of milk metabolites profiles should contribute to validate this hypothesis.

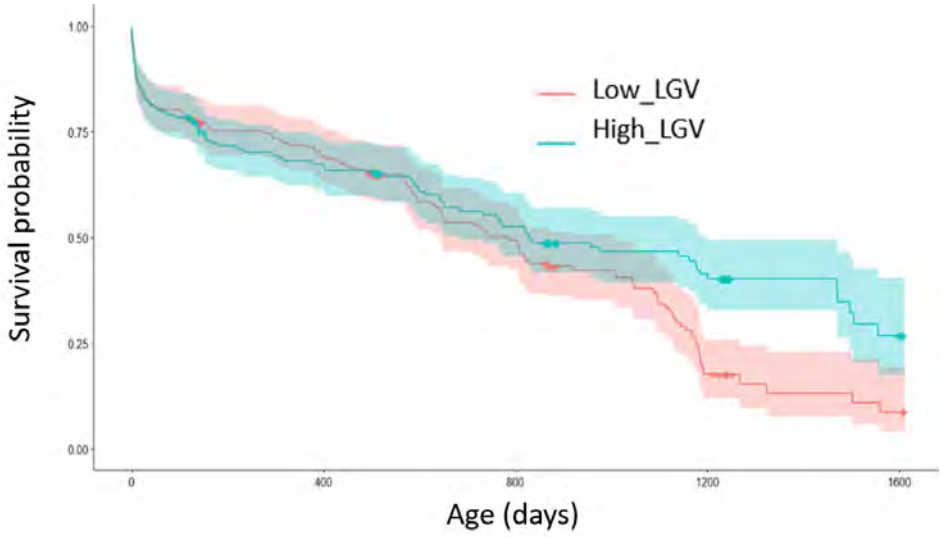

Figure 1. Plot of Kaplan–Meier curve showing survival against time for high longevity line (high_LGV) and low longevity line (low_LGV). Shaded areas represent the 95% confidence intervals calculated by Cox analysis.

Profiling of milk metabolites upon underfeeding challenge. Using functional principal component analysis, between 2 and 4 components were required to explain at least 80% of variation resulting in 50 variables for the Sparse PLS-DA (named Chol1, Chol2 and Chol3 for variables describing cholesterol profiles). Figure 2 details the construction of the fPCA for Glu.

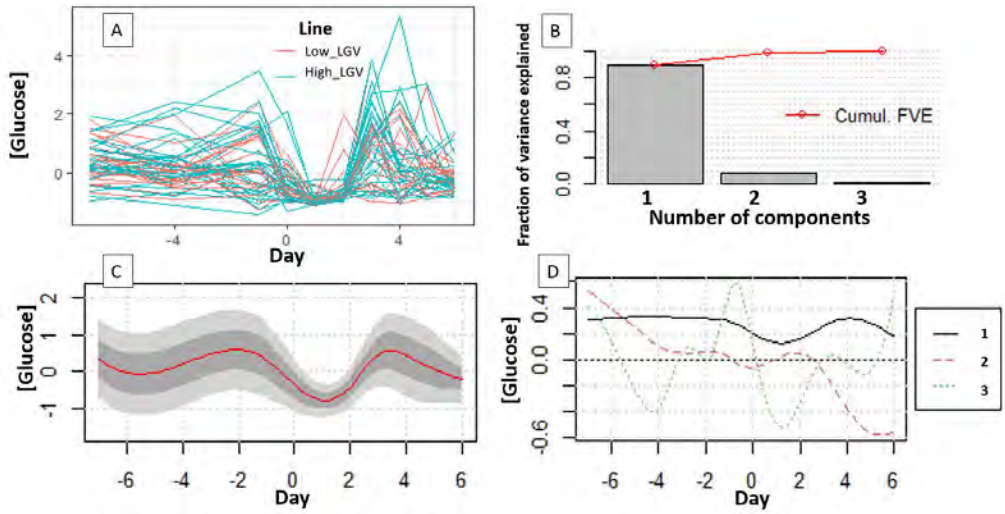

Figure 2. Functional principal component analysis results for one milk metabolite (concentration of milk free glucose) through the underfeeding challenge. (A) Individual raw data, each line represents 1 goat. Colors represent lines. (B) Fraction of variance explained by the first 3 PCA components. (C) Estimation of the mean curve by functional smoothing. (D) Underlying Eigenfunctions.

Discriminating longevity goat lines with milk metabolites. The optimal number of components in the sPLS-DA was 3. The lasso penalization selected 30, 2 and 20 variables for components 1, 2 and 3, respectively. The balanced error rate estimated for the model was 30.2% (respectively 30.0 and 30.3 for low_LGV and high_LGV lines). As shown in Figure 3 the most discriminating parameters between lines were Chol3, Gal2, LDH4, and TAG3. These results indicate that differences in functional longevity, which are seemingly due to differences in resilience, can be detected from milk metabolite responses to a short-term underfeeding challenge. Further, this preliminary analysis suggests that the physiological mechanisms underpinning differences in resilience are related in part to lipid metabolism.

58. Lifetime feed efficiency and deep phenotypes from scarce feed intake records using the mechanistic LiGAPS-Dairy model

Abstract

Ideally, selection for feed efficiency requires deep phenotyping of net efficiency, or lifetime recording of intake and all energy sinks across environments. However, recording of feed intake is scarce. Therefore, net efficiency is often defined as a simplistic linear equation, e.g. RFI. We tested the use of the mechanistic LiGAPS-Dairy model to derive nine deep phenotypes with a dataset for 1,228 dairy cows, combining feed intake, yield and liveweight data, with ration, weather, cow and farm data. Mismatch between data recording and model assumptions made this process time consuming, but allowing for missing parities and further automation should improve this quickly. We managed for 206 cows to estimate the deep phenotypes. Heritability and phenotypic correlations between the nine traits were estimated. When the pipeline is finished, the mechanistic LiGAPS-Dairy model will enable us to derive a more comprehensive breeding goal, more closely resembling net efficiency, whilst utilising scarce records.

Introduction

Extending breeding goals require more and more scarcely recorded data to be included in animal breeding. For example, breeding values for feed efficiency should be based on a full lactation or even a full lifetime of many cows, and across many different environments. However, in practice feed intake has been recorded for limited numbers of cows, during part of their lifetime, and on cows that are mostly kept indoors in intensive feeding systems. Also, feed efficiency is a composite trait containing many elements: energy uses for milk production, gestation, maintenance and growth, all with their own net efficiency (Veerkamp and Emmans, 1995). Ideally, animal breeding should target these net efficiencies (e.g. digestibility or converting net energy to yield) rather than partitioning energy away from essential functions towards production. However, net efficiencies are even more difficult to measure than feed intake, and therefore, often simple approximations, like residual feed intake (RFI), are used. A potential solution to make the step from scarcely recorded traits, with limited data per animal in selective circumstances, towards more plausible breeding goals is to use mechanistic models to standardise or derive new traits that can be used in breeding values estimation.

The mechanistic model LiGAPS-Dairy can assess the performance of cows in different environments and in different farm types and uses recorded phenotypes to simulate the performance of dairy cows over their entire lifetime with a time step of one day. Inputs required for this model are parameters that represent the animals' traits, outside weather temperature, information on feed quality and available feed quantity, and livestock management. The feeding strategy implemented can be precisely set and the model has been evaluated under Dutch conditions (van der Linden *et al.*, 2021).

The model genotype (in contrast to the DNA genotype that animal breeders use) of an animal is included in the LiGAPS-Dairy model as a set of different parameters that represent the individual animal's traits, i.e. traits that otherwise need deep phenotyping. Parameter values of individual cows can be determined by model calibration with measured data for milk production, feed intake and liveweight. Using these deeper

phenotypes, the model simulates milk production, feed intake and liveweight across the lifetime of a cow and therefore allows for new definitions of feed efficiency for dairy cows outside the space where data were recorded, e.g. a full lifetime efficiency or in different environments, on top of selecting for the deeper phenotypes directly. For example, a recent pilot study used data from indoor-housed cows at a commercial farm of CRV (milk production, feed intake and live weight) with input model parameters (feed quality and feed availability, weather conditions and livestock management) to calibrate nine parameters (or deep phenotypes) for 101 individual cows, and simulated feed efficiency of these cows in an outdoor grazing system.

The objective of this study was to get estimates for nine deep phenotypes, and to assess their heritability and correlations. We report on work in progress to expand the LiGAPS-Dairy pipeline on a more complex (more herds and years and different recording strategies) and larger dataset (~1,228 dairy cows).

Materials & methods

A dataset was available on 1,228 cows from Dairy Campus and other experimental farms with weekly records on dry matter intake (DMI), fat- and protein-corrected milk (FPCM) and liveweight (LW) recorded in 3,701 lactations and 605 different experimental treatments between 1991 and 2021. For the weekly records there were at least 25 records for DMI, 9 records for kg of milk and 9 records for LW per cow. A cow should have records for at least 2 lactations (the first lactation often differs from the second or third). All cows in the feed efficiency experiments were housed indoors. Birth and calving dates were used as model input to resemble the life of cows in the experiments.

Weather data were obtained for de Bilt, the Netherlands (52.2°N, 5.2°E) and were assumed to be representative for the locations of the experimental farms. Feed quality was not available for individual experiments. The average feed quality of the diets was used from the study by Zom *et al.* (2012), where the average proportion of concentrates was 37% of the dry matter (DM) intake; Crude protein (CP) of concentrates was 188 g/kg DM, digestible Organic Matter (dOM) was 829 g/kg DM, and CP of roughage was 136 g/kg DM, and dOM was 700 g/kg DM.

The LiGAPS-Dairy model, written in R, was subsequently ran for each individual cow with Azure Databricks on the Microsoft Azure platform with inputs from the cow and farm. The model produced outputs that included FPCM, DMI, and LW. During calibration of the deep phenotypes, the simulated FPCM, LW and DMI were compared with the measured data for individual cows, and the difference was expressed as the root mean squared error (RMSE). The RMSEs for FPCM, DMI, and LW were added up and used as input for a genetic algorithm from the R-package 'GA'. This algorithm selected the combination of the nine deep phenotypes that resulted in the lowest sum of RMSE for each cow by iterating the model.

The deep phenotypes of the LiGAPS-Dairy model resulted in nine newly derived feed efficiency traits, together with DMI, FPCM and LW. Heritabilities and genetic correlations were estimated with ASReml (Gilmour *et al.*, 2015) and the model included only the mean and the additive genetic effect using the pedigree relationship matrix for each animal.

Results

The dataset used at the start is described in Table 1. Since it was the first time that the LiGAPS-Dairy model was used with this large dataset, optimising the model was very time consuming. At the time of writing, missing lactations and cows with parity above 5 created model failures, and needed to be excluded. After this selection, data on nearly all cows tested converged, and we were able to estimate the nine deep phenotypes for a cow in about 50 minutes, a task that could be parallelized by using Databricks. In total,

data on 206 cows converged and a small percentage failed due to mismatches between cow data and model assumptions. Solving these mismatches, and further automation and parallelisation is needed to make this process more efficient, and eventually get data on more animals converged. The summary statistics for the nine deep phenotypes are given in Table 2.

Using the 206 animals available just now, only five of the nine heritability estimates converged, albeit with large standard errors (Table 3). The low number of generations used in GA (n=2) might have reduced accuracy of the phenotypes and therefore the heritably. Phenotypic correlations were large between maintenance requirements and milk efficiency, contrary to what was expected when gross efficiency was used. Also, the correlations between the two milk efficiency traits and two Wood curve parameters were high.

Discussion

We reported research in progress on the development of the LiGAPS-Dairy model to derive nine deep phenotypes for scarcely recorded data on cows. Time needed to fit the sparse data was more than expected, and most effort was, and is, on automation of parallelisation and model adjustments to fit the data.

When efficient data fitting is resolved, in the near future, further steps required are to add more animals for the genetic parameter estimation, and to investigate the model fit per cow. Especially how model fit is affected by the records available for a cow, and the number of generations and base population size assumed in the genetic algorithm. These are likely to improve estimation of the heritability, since minimal

Table 1. Summary statistics of the data used.

# cows	1,228

criteria (two generations and the base population of 40 animals) were used. With a large dataset, the genomic predictions for the nine deep phenotypes can be subsequently used through the mechanistic LiGAPS-Dairy model to derive a more comprehensive feed efficiency breeding goal, more closely than RFI resembling net efficiency or lifetime efficiency, whilst still utilising scarce records for feed intake, FPCM and LW. Furthermore, through this mechanistic model the impact of selection can be estimated in different environments, i.e. indoor versus outdoor systems, or different climates.

Abstract

Families (35) of Atlantic salmon were duplicated in 70 tanks and entered into a feed efficiency trial. Cumulative Feed intake (FI), weight gain (WTGAIN), feed efficiency (FE) and final energy content of the fish (ENERGY), which depends on its lipid content, were recorded at tank level and analysed at the family level using ~55000 SNP markers. To the best of our knowledge, genomic analysis of feed efficiency traits at the family level have not been estimated before, highlighting new possibilities for analysing family level group data with genomics. Results showed medium-high heritability for the four traits. ENERGY, which is a direct effect of body lipid content, was negatively correlated to FE (r=-0.60), showing its potential as a selection criterion for feed efficiency. As expected, the genetic correlation between WTGAIN and FI was extremely high in this dataset, which indicates that gross WTGAIN is a very good predictor of FI.

Introduction

Feed efficiency (g body growth per g feed eaten) is the holy grail in aquaculture production, because of its large economic importance and its relation to resource efficiency. Feed is responsible for 50% of operational costs and 70% of the carbon foot prints are related to feed (Iversen *et al.*, 2020; Winther *et al.*, 2020) in the Norwegian Atlantic salmon production.

Feed intake is difficult to record, especially at individual level, and therefore it is difficult to select directly for feed efficiency in breeding programmes. For selective breeding, feed intake is therefore typically measured at family level (Kolstad *et al.*, 2004), but this is costly and, so far, only small experiments have been performed with low numbers of families and relatively small fish. At individual level, the number of feed pellets eaten can be obtained by X-raying fish after using a feed with X-ray opaque beads (Kause *et al.*, 2006; G.F. Difford, personal communications). Alternatively, protein utilisation efficiency, which is strongly related to FE, can be assessed by measuring isotope retention in the body from feed (Dvergedal *et al.*, 2019). Finally, feed intake of fish in an experimental set up with one fish per aquarium has given promising results in European seabass (Besson *et al.*, 2019), but not in Atlantic salmon (B. Gjerde, personal communications).

Due to the difficulty to measure individual feed intake, feed efficiency has mainly been improved by indirect selection for growth; 62% of the between-tank (family) variation in feed intake was explained by growth and sampling day in Dvergedal *et al.* (2019). With a given feed composition, feed efficiency is proportional to the ratio between energy efficiency and energy in the body. Thus, an alternative route to a more feed efficient fish, avoiding tedious and costly measurements of feed intake, may be via direct selection for both increased growth and decreasing body energy (Kause *et al.*, 2016). In the case of tank level phenotypes, genomic analysis can be used to evaluate genomic differences between families that are linked to phenotypic differences between families.

The aim of this study was to estimate genetic parameters for feed efficiency traits in Atlantic salmon juveniles using family mean records and individual level genomic data.

Materials & methods

Fish. The fish experiment took place at the Nofima Research Station for sustainable aquaculture at Sunndalsøra. Thirty-five full-sib families of MOWIs elite population were split into two duplicated freshwater tanks with 25 individuals per tank, i.e. 1,750 fish in total in 70 tanks that were located in two different rooms with 20 and 50 tanks, respectively. They were grown over 50 days from about 50 g to 110 g average body weight.

Recording. Four relevant traits for feed efficiency were recorded. The mean weight gain (WTGAIN; g) measured on the fish in each of the 70 tanks; Daily feed intake (FI; g) measured at the tank level by means of given feed and feed not eaten on wasted feed collectors; final body energy (ENERGY; kJ/g) measured by bomb calorimetry from a minced pool of all fish per tank; feed efficiency (FE) at the tank level as WTGAIN/FI. The fish were individually genotyped by a customised SNP array of MOWI with 55,735 SNPs.

Genomic analysis. Estimates of (co)variances of the random effects in the applied statistical multitrait SNP effects model was obtained using ASReml software (Butler *et al.*, 2017) with room of the tank as a fixed effect for the four traits FI, WTGAIN, FE and ENERGY. The model was:

$$y_i = H_l + (Z_i \otimes I_4)b + e_i \quad (1)$$

where y_i is a vector of average trait values (over 25 fish) in tank *i* for the traits FI, WTGAIN, FE and ENERGY; e_i is a vector of within-tank residuals for the 4 traits; H_l is the vector of room *l* effects to which tank i belongs; b is a vector of multitrait SNP effects (4 effects per SNP); Z_i is the vector of the average SNP genotypes of the fish in tank *i*, as a deviation from the overall genotype and standardised, i.e. $Z_{ij}=2(q_{ij}-p_j)/s$ where q_{ij},is the frequency of SNP j within tank i, p_j is the overall allele frequency for SNP *j*, and s is the square root of the sum of the heterozygosities ($2p_j(1-p_j)$) of the SNPs. The variance of the trait-effects of SNP *j* is $Var(b_j)=G$, where G is the (4×4) genetic covariance matrix of the traits. Similarly, $Var(e_i) = R$ where R is the (4×4) residual covariance matrix of the traits. Since the trait values are averaged over 25 fish, the actual environmental (co)variances are a factor 25 larger than R, i.e. 25×R.

Results

Figure 1 shows the feed efficiency of the duplicated families; mean was 1.28±0.005. The family mean feed efficiencies range from about 1.1 to 1.4, i.e. a difference of ~30%.

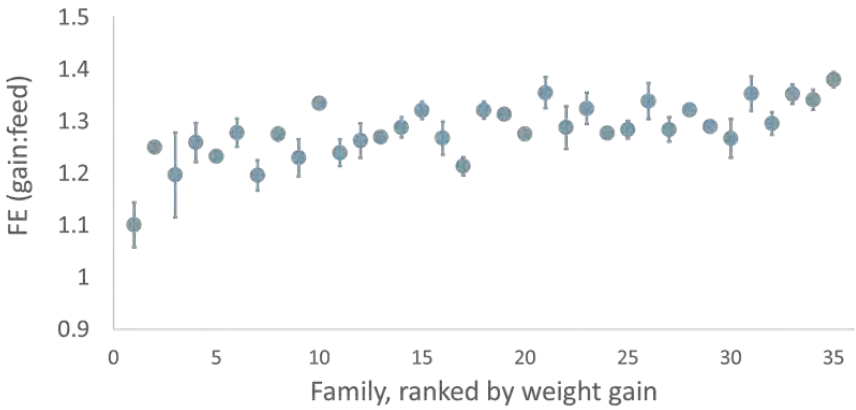

Figure 1. Feed efficiency (FE) of the 35 duplicated families of Atlantic salmon (mean ± s.e).

Table 1. Heritability (diagonal) and genetic (above diagonal) and residual (below diagonal) correlations between FI, WTGAIN, FE and ENERGY in Atlantic salmon.

	FI	WTGAIN	FE	ENERGY
FI	0.35	0.98	0.56	0.09
WTGAIN	0.92	0.42	0.69	-0.24
FE	-0.20	0.20	0.17	-0.60
ENERGY	0.55	0.43	-0.36	0.27

The four studied traits had medium heritability ranging from 0.17 for FE to 0.42 for WTGAIN. The genetic correlation of WTGAIN with FI was very high (0.98) while that with FE (0.69) was much lower. The negative genetic correlation between FE and body ENERGY (-0.60) shows that high FE is accompanied by low fat content.

Discussion

The chosen experimental design of family/tank data proved useful to estimate genetic parameters for the traits when a genomic analysis was used with SNP array data of ~50,000 SNPs. Although genetic parameters are expected to be estimated without bias, the use of tank-means implies that tank-residuals cannot be split into environmental effects of the tank and individual (within tank) environmental effects. This affects the estimates of heritability as shown below. The estimated genetic correlations between the traits were very similar to those obtained from a model with room as a fixed effect, sire and dam as random effects where variance components for sire and dam were assumed to be equal, and with tank as the additional random residual effect, and with the additive genetic numerator relationship matrix added to the sire and dam effects in the mixed model equation. From this sire and dam model, the heritability of the traits cannot be calculated as this requires estimates of the environmental variance within the tanks for each of the traits. The estimated residual (tank) variance from this model accounted for about 3.5% of the estimated total phenotypic variance, i.e. the sum of the estimates of the sire, dam and residual variances.

The heritability of FI, WTGAIN, FE and body ENERGY were moderate, where FE had unfortunately the lowest heritability (0.17). The environmental variances (σ_e^2), which are needed for the denominator in the calculation of heritability, where assumed here to equal $\sigma_e^2=25\times\sigma_r^2$, which assumes that the variance due to tank effects is 0, i.e. environmental effects between the same trait in replicated tanks are uncorrelated. In the presence of tank effects, the environmental effects show an intra-class correlation of t, and the environmental variance is $\sigma_e^2 = \sigma_r^2/[t+(1-t)/25]$, which varies between $25\times\sigma_r^2$ and $1\times\sigma_r^2$, for t=0 to t=1, respectively, where t=1 (no individual environmental variance) is very unrealistic. Hence, we may have used an over-estimate of the environmental variance for the heritability estimation, which implies that the heritability in Table 1 are conservative estimates.

The genetic correlation between WTGAIN and FI was very high (0.98). This shows that gross WTGAIN (not accounted for body composition) is a good predictor of FI and that there is very little room for genetic improvement of residual feed intake, i.e. feed intake not related to WTGAIN, although small improvements of this trait may yield high economic benefits as feed accounts for a large proportion of the total cost. Thus, precise measurements of feed intake is necessary for direct selection for FE. However, the fish used here were only tested at the freshwater stage, and results might differ in seawater-phase fish, which is where most of the growth takes place. Our experimental design may also be applied to larger fish in the seawater-phase fish, but at a much higher cost as larger full-sib family-replicated units (cages) are required.

The medium and thus much lower genetic correlation between WTGAIN and FE (0.69) shows that high growth rate is favourably correlated to FE and that WTGAIN is a relatively good predictor of FE. The negative genetic correlation between FE and body ENERGY (-0.60) shows that high FE is accompanied by low fat content and thus ENERGY and WTGAIN. Together this may provide a very promising indicator trait for genetic selection for improved feed efficiency (as also found by Kause *et al.* 2016), as it is easy to measure compared to feed intake, given that body ENERGY can be reduced without negative effects on consumer preferences.

Acknowledgements

This study was financed by the EU project NewTechAqua- H2020-grant no 862658. We would also like to acknowledge the good work done at MOWI to produce and genotype the fish, and technicians at the Nofima Research Station for sustainable aquaculture at Sunndalsøra for performing the fish experiment in an excellent way.

Abstract

Improving feed efficiency have environmental, economic and social benefits for dairy ewes farming systems. Selection of animals using efficiently their feed resources while maintaining a quality milk production is therefore a major objective for breeders. However, phenotyping feed efficiency remains difficult to achieve on-farm on a large scale. For this purpose, a criterion of lactation feed conversion ratio measurable on commercial farms was proposed. First, accuracy of this criterion was evaluated on experimental data with precise phenotypes including individual intake. This criterion seemed to be, with some recommendations, a good approximation of feed efficiency, with the main limitation of collective feeding. Then, the criterion was applied to 6 test-days from 6,425 lactations of Lacaune ewes from production farms. In these conditions, the estimation of the genetic parameters of this feed efficiency criterion showed a low heritability (0.12±0.02) and a strong genetic correlation with the daily milk yield (0.80±0.03).

Introduction

In addition to its economic importance, improving feed efficiency in dairy sheep could also help to reduce environmental impacts of sheep production and to improve the sustainability of farming systems through food autonomy (Cantalapiedra-hijar *et al.*, 2020). Thus, having animals capable of using their feed as efficiently as possible, of mobilizing their body reserves at key moments of the production cycle, while maintaining a milk production in quantity and quality, as well as all the physiological functions (mating, resistance to diseases) is a strong challenge for the dairy sheep farmers. However, feed efficiency is difficult to phenotype on a large scale in dairy sheep farms. Indeed, for this it is necessary to record individual performances as milk production and its components, body weight (BW), body condition score (BCS) and feed intake (FI). One of the purposes of the European project SMARTER (SMAll RuminanTs breeding for Efficiency and Resilience, 2018-2022) is to evaluate novel phenotypes for feed efficiency, measurable in commercial farms.

The objective of our study was to propose a new criterion to approximate feed conversion ratio (FCR) of lactating ewes in a collective feeding context of commercial farms named lactation feed conversion ratio (LFCR). First, accuracy and reliability of the proposed criterion LFCR were evaluated. For that, using data from Lacaune ewes of La Fage INRAE experimental unit, this criterion was estimated and compared to a 'reference' one calculated with individual performances. Then, phenotypic and genetic analyses were performed in order to evaluate environmental and genetic factors (heritability) that explained variability of this feed efficiency trait as well as to estimate its genetic correlation with daily milk yield (DMY).

Materials & methods

Herds and ewes involved in the European SMARTER project. In France, the monitoring of the zootechnical performances of dairy ewes was carried out on commercial farms during two dairy years: 2019-2020 and 2020-2021. Overall, 8 French Lacaune dairy sheep herds were involved in SMARTER, located in the Roquefort area with around 4,500 ewes phenotyped by year.

Data collected. Phenotypes recorded for each ewe during a dairy year were related to: body reserve dynamics (5 BCS with target physiological stages: 1 month before lambing, end of suckling, 1st test-day (TD), 1 month before and after mating); milk production (milk yield, fat and protein contents on 6 TD after suckling and each month after); quantity and quality of feed offered (collective feed and automatic concentrate feeder (ACF)) at each TD and reproduction traits. After quality control and selection of data of ewes with at least 2 BCS, 2,529 ewes in 2020 and 3,896 in 2021 were retained for the analysis, corresponding to 6,425 lactations, with 1,744 ewes phenotyped over the two dairy years.

Feed efficiency criterion. Classical formula of FCR that divides the milk production by the feed intake does not consider the other requirements. LFCR makes the ratio of lactation requirements and energy inputs used to produce milk from feed and body reserves. BCS_{Δ} represented the variation between two successive BCSs. Energy for maintenance and growth not used for milk was subtracted from the inputs. All variables were first converted to net energy per day (Hassoun and Bocquier, 2007*)*. Lactation requirements were calculated from standardized milk yield (SMY) as proposed by Bocquier *et al.* (1993). Based on SMARTER data, FI represented the estimated average amounts of feed distributed collectively per ewe (pasture, forages and concentrates), plus individual concentrates in the ACF according to the dairy level. For the grazing part, Boissieu *et al.* (2019) proposed an estimation of the ingestion at pasture according to the time of presence per ewe. A parity-dependent reference BW was assigned to all ewes to calculate maintenance and growth requirements. For the growth of the primiparous, a standard average daily gain of 80 g/d was set. LFCR was calculated at each TD. Efficient animals had upper LFCR values.

Validation of the LFCR. Within the framework of the European iSAGE project at the La Fage INRAE experimental unit, Lacaune dairy ewes were individually monitored for their dairy performances (SMY), BW, BCS, and FI (based on weighing of forages and concentrates distributed and refused in individual troughs). All these measures were performed individually once a week (4 times per week for FI) over a period of 4 months during their 2nd and/or 3rd lactation, corresponding to 70 lactations available (46 ewes). LFCR was calculated once at the 2nd TD. BCS_{Δ} represented the variation in BCS between the end of suckling and the 2nd TD. The time step was 20 days. In order to mimic the on-farm SMARTER available data (collective feed, missing data), each variable: SMY, BW, BCS_{Δ} and forage intake, one at a time, was set for all ewes to the mean value of the batch (n=70). The four simplified batch LFCR results were successively compared to the individual LFCR. Statistical parameters as R^2, RMSE and bias were computed with R software to assess reliability of the approximated criterion.

Statistical analysis. In order to determine environmental factors affecting SMARTER feed efficiency results, analyses of variance were performed with the packages car, lme4 and lmer implemented in the R software. First, at each TD, fixed environmental effects were included into a linear model and selected using Fisher's tests. Genetic parameters were estimated with WOMBAT software (Meyer, 2007) using the REML method. A five-generation pedigree was used containing 17,451 animals. For each TD, the single-trait genetic model was:

$$y = Xb + Za + Wp + e \quad (1)$$

where y is LFCR measured at each TD; b the vector of fixed effects: parity (1/2/3/4+), lambing period (start/end) according to parity, litter size (single/multiple), lactation month crossed to TD number (2 groups of lactation months by TD) interacting with dairy year (2020/2021), herd (n=8) interacting with dairy year and herd interacting with mating mode (animal insemination/return/natural breeding); a is the vector of random additive genetic effects ($N(0, \sigma_a^2 A)$); p is a vector for random permanent environmental effects ($N(0, \sigma_p^2 I)$); e is the vector of residual random effects; X, Z and W are incidence matrices. Then merging all

TD data, a multi-trait animal model was retained in order to estimate the genetic correlation between LFCR and DMY. The models used for these two traits were the same as above adding a TD number fixed effect, interactions of all fixed effects with TD number (except lactation month crossed to TD number interacting with dairy year).

Results

Validation of the LFCR. Statistical parameters to assess the reliability of LFCR computed with SMARTER-like phenotypes (Table 1) showed that phenotypes contributing the most to the accuracy of this criterion were: (1) forage intake; (2) SMY; (3) BCS_{Δ} and the less was; (4) BW of the animal.

The absence of individual values for BW has little impact on the accuracy (R^2=0.97). For a small sample, replacing the variation in BCS with the mean value gives a relatively good estimate of feed efficiency (R^2=0.82). The lack of individual values for milk performances or feed intake has more impact and can leads to reclassification of ewes.

Considering these results, calculation of LFCR was carried out for ewes of the SMARTER project with the following principles: (1) Only ewes with complete dairy performances were kept; (2) feed intake was calculated from the feed distributed in the collective feed (with a 10% refusal rate for dry and wet forages) and from the concentrates distributed individually with ACF available in all farms; (3) an imputation of missing body condition scores (at least 2 BCS to register is imposed) was performed per farm using the copyMean method (Genolini and Falissard, 2011); (4) in the absence of BW, a reference value according to parity (in agreement with the technicians and similar to the literature) was applied (Hassoun and Bocquier, 2007).

Genetic parameters. Heritabilities and repeatability of LFCR were calculated at each TD (Table 2). Heritability and repeatability (between the two dairy years) seemed to be lower at the beginning than at the end of lactation.

Table 1. Statistical prediction parameters comparing initial and the four simplified (with a value set to the average of the batch) LFCR results.

	BW (kg)	BCS_{Δ} (over 20 d)	SMY (L/d)	Forage dry matter intake (kg/d)
Average value of the batch (= set value)	76	0.1	2.7	2.5
Standard deviation	8	0.1	0.5	0.4
Minimum	58	-0.4	1.8	1.4
Maximum	96	0.3	3.9	3.6
Coefficient of determination (R^2)	0.97	0.82	0.59	0.37
Root mean square error (RMSE)	0.05	0.11	0.21	0.21
Average bias	0	0.02	-0.03	0.03
Range of individual bias	[-0.26 ; 0.13]	[-0.22 ; 0.39]	[-0.58 ; 0.36]	[-0.24 ; 1.09]

Table 2. Heritabilities and repeatability of LFCR calculated at each test-day.

	TD 1	TD 2	TD 3	TD4	TD 5	TD 6
Heritability ± SE	0.07±0.02	0.11±0.02	0.11±0.02	0.12±0.02	0.12±0.03	0.20±0.03
Repeatability	0.26	0.28	0.28	0.29	0.35	0.40

Combining all TD records, genetic analyses were also performed with a multivariate model for LFCR and DMY. The heritabilities were low for these two traits: 0.12±0.02 for LFCR and 0.20±0.02 for DMY. There was a high genetic correlation of 0.80±0.03 between the two traits. The repeatability of the LFCR was 0.40, and it was 0.53 for DMY.

Discussion

There is a lack of information on the heritability of feed efficiency and its genetic correlation with production traits in dairy ewes. We can compare our results to studies carried out in dairy cows according to the feeding system used. With an estimated FI on pasture Hurley *et al.* (2018) found an heritability for a daily energy conversion efficiency ratio similar to our result (0.11±0.02). With individual daily FI measurements the heritability of a lactation feed conversion ratio was higher (0.25±0.03) and the genetic correlation with SMY was also high (Manafiazar *et al.*, 2016). Close to our results, heritability of daily milk yield of Lacaune ewes is around 0.28 (Barillet and Boichard, 1987). It has been shown that selecting a population on a ratio is difficult to implement because of the difficulty to predict the response to selection of ratio traits (Gunsett, 1984). However, our criterion can be measurable on commercial farms, and reflects an overall feed efficiency of ewe in a collective feeding context.

Acknowledgements

The authors thank the breeders and technicians of the breeding organizations that collected data. This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 772787 (SMARTER). It also benefited from data collected with the financial support of EU project H2020-679302 (iSAGE).

61. Gene co-expression networks contributing to variation in residual feed intake in bovine hepatic tissue

K. Keogh[1*], M. McGee[2] and D.A. Kenny[1]

[1]Animal and Bioscience Research Department, Teagasc, Grange, Dunsany, Co. Meath, Ireland; [2]Livestock Systems Research Department, Teagasc, Grange, Dunsany, Co. Meath, Ireland; kate.a.keogh@teagasc.ie

Abstract

Gene co-expression network analyses were performed on hepatic transcriptome data of two breed types (Charolais (CH) and Holstein-Friesian (HF)), divergent for feed efficiency status through measurement of residual feed intake (RFI). The relationship between co-expressed genes and RFI was further assessed through correlation of co-expression networks with trait data including RFI, average daily gain (ADG) and dry matter intake (DMI). Across both breeds examined, one network of co-expressed genes was positively correlated with DMI (r=0.48, P=0.03), with a tendency also identified between the same network and RFI (r=0.42, P=0.07). Functional annotation of genes within this network revealed enrichment (P<0.05) of pathways related to both amino acid and fatty acid metabolism. Our results suggest a role for these processes in the hepatic tissue of cattle divergent for RFI. Moreover, genes within this network may represent potential biomarkers for the selection of improved feed efficiency in cattle across varying breed types.

Introduction

Provision of feed in beef production systems is a major determinant of overall profitability. For example, feed costs can account for up to 75% of the variable costs associated with beef cattle production (Kenny *et al.*, 2018). Thus, research related to the genomic control and subsequent selection of cattle with improved feed efficiency has received attention in recent years. In particular, RFI, defined as the difference between an animal's actual and predicted feed intake, has become the feed efficiency measure of choice due to its independence of growth and body size (Kenny *et al.*, 2018). Research efforts aimed at uncovering the underlying biology governing RFI in cattle, primarily through global transcriptomic evaluations, have established a role for genes involved in fatty acid metabolism and immune function towards variation in RFI. However, despite these findings, key robust genes or genomic regions contributing to the trait remain to be identified. Of the transcriptomic studies conducted to date few or no genes have been identified as commonly affecting RFI across studies. This is undoubtedly due to the multifaceted nature of the RFI trait as well as the varying experimental parameters employed across different studies, such as breed types, dietary sources and stage of development evaluated, ultimately confounding the subsequent outcome. Moreover, the majority of studies to date have focused on the identification of genes that are differentially expressed between animals divergent for RFI. However, such studies do not allow for an explanation of the interactions between genes governing the expression of a particular trait. The identification of highly co-expressed genes that contribute to the expression of complex traits may offer greater insights into the molecular control of a particular trait. Moreover, examining the relationship between genes through co-expression analyses, also allows for the identification of key hub genes, which are important in regulating the expression of several other genes within a network of co-expressed genes, and which ultimately may hold potential as biomarkers for the selection of a trait of interest. Thus, the objective of the current study was to identify networks of co-expressed genes in the liver tissue of CH and HF steers, divergent for RFI phenotype as well as the component traits of RFI including ADG and DMI. Specifically we sought to identify networks of co-expressed genes that were commonly associated and contributing to the RFI trait across the two contrasting breeds utilised. The liver was chosen as a target tissue as it is a central metabolic organ that has shown to be responsive to variation in RFI in cattle (Kenny *et al.*, 2018).

Materials & methods

Animal model. This experiment was conducted as part of a larger research programme designed to examine the within-animal repeatability of intake, growth and feed efficiency between varying stages of development in CH and HF beef steers (Coyle *et al.*, 2016). In total, 167 steers (90 CH and 77 HF) were used for this study. Following a dietary adaptation period, DMI and growth rates were measured over a 70-day feeding trial, during which all steers were offered the same high concentrate diet consisting of *ad libitum* concentrates plus a restricted allowance of grass silage daily. The residuals of the regression of DMI on ADG, and mid-test metabolic body weight within each breed were used to compute individual RFI coefficients for each steer (GLM procedure of SAS9.3). Residual feed intake was calculated for each animal as the difference between actual and predicted DMI. Within each breed, steers were ranked for high-RFI (feed-inefficient; n=12) and low-RFI (feed-efficient; n=12). Liver tissue samples were collected through percutaneous punch biopsy from all high-RFI and low-RFI steers following completion of the 70-day dietary trial. Tissue samples were washed with sterile DPBS and immediately snap frozen in liquid nitrogen before subsequent storage at -80 °C.

RNAsequencing and co-expression analyses. RNA isolation, cDNA library preparation, RNAsequencing and bioinformatics analysis have been described previously in Higgins *et al.* (2019). The weighted gene co-expression network analysis (WGCNA) software package (Langfelder and Horvath, 2008) was used to derive networks of co-expressed genes from liver transcriptomic data. RNAseq read count data were firstly filtered for lowly expressed genes and then normalised in EdgeR by read counts per million mapped reads, (adjusted for sample library size). Normalised count data were then $Log_2(x+1)$ transformed in R. In order to identify networks of co-expressed genes common across both breeds examined, a WGCNA consensus analysis was undertaken. The consensus analysis was undertaken using the automatic one-step function, blockwise consensus analysis of WGCNA, incorporating unsigned, weighted correlation network construction and module detection. The resultant networks of co-expressed genes, denoted by different colour identifiers, were then correlated with trait data. Specifically the relationship between networks of co-expressed genes and trait data including RFI, ADG and DMI were calculated by Pearson correlation. Networks which were commonly statistically significantly ($P<0.05$) associated with selected trait data across the two breeds evaluated were then selected for further analysis as potentially biologically interesting networks associated with RFI in beef cattle. Pathway analysis was performed on genes from each network identified as significantly correlated with trait data using DAVID gene ontology program. Gene ontology terms were considered significant if the adjusted *P*-value was less than 0.05.

Results

Within each breed, differences in ADG were not apparent ($P>0.05$), however high-RFI steers consumed more feed compared with low-RFI steers across both CH and HF breeds ($P<0.05$). Gene co-expression analysis resulted in the construction of 18 separate networks of co-expressed genes. Within the CH dataset, a number of separate networks were significantly associated with both RFI and DMI. These included the greenyellow network which was negatively associated with RFI (r=-0.44; $P=0.04$). Similarly both DMI and RFI were negatively associated with the tan network (DMI: r=-0.48; $P=0.03$; RFI: r=-0.51; $P=0.02$). Conversely, positive associations were evident within the CH dataset between the pink, blue and yellow networks and both RFI and DMI (pink network: DMI: r=0.59; $P=0.004$; RFI: r=0.47; $P=0.03$; blue network: DMI: r=0.45; $P=0.04$; RFI: r=0.49; $P=0.02$; yellow network: DMI: r=0.52; $P=0.01$; RFI: r=0.54; $P=0.01$). Within the HF dataset only one network (pink network) was associated with the traits evaluated (DMI: r=0.48; $P=0.03$). The pink network also displayed a tendency towards a significant association with RFI for the HF steers (r=0.42; $P=0.07$). Results from the WGCNA consensus analysis indicated significant commonality between CH and HF data for the pink network, which was positively associated with DMI across both breeds (r=0.48; $P=0.03$), whilst a tendency also existed between this network and RFI value

for the consensus analysis (r=0.42; *P*=0.07). Enriched biological pathways for significant networks are presented in Table 1, no pathways were significantly enriched for the greenyellow network.

Discussion

Residual feed intake has become a measure of choice for feed efficiency evaluations in cattle, due to its independence from growth and body size (Kenny *et al.*, 2018). However, despite RFI being a favourable measure of feed efficiency, knowledge of the underlying biology governing the trait remains to be elucidated fully. Studies evaluating the transcriptional control of RFI in cattle have identified biological processes related to fatty acid metabolism and the immune system as contributing to variation in RFI (Keogh *et al.*, 2018). However, despite commonality in biological processes, key genes contributing to RFI have not been identified across studies. This may be due to the use of varying experimental parameters across studies, for example employing different breed types and dietary regimes, which ultimately confound experimental results. Thus, the current study aimed to overcome that limitation through the evaluation of the molecular control of RFI across two varying breed types through gene co-expression analyses. A role for fatty acid metabolism was also evident in the current study through the association between the pink network of co-expressed genes with RFI and DMI across both breed types. Commonality of genes within the pink network across both CH and HF breeds, suggests a potential role for genes within this network towards the RFI trait irrespective of breed. Moreover, specific genes within the pink network were previously implicated towards variation in RFI in cattle, in studies utilising diverse breeds. These included *CYP1A1* and *CES1*, which are involved in fatty acid and lipid metabolism and which were also differentially expressed between high- and low-RFI cattle in the data of Weber *et al.* (2016) and Mukiibi *et al.* (2018). Genes involved in

amino acid processing including the aminopeptidase, *ANPEP* and the transaminase gene *TAT* were also differentially expressed in Higgins *et al.* (2019), Weber *et al.* (2016) and Mukiibi *et al.* (2018). Finally, *AHSG* which encodes a glycoprotein implicated in insulin resistance was differentially expressed in the liver based studies of Chen *et al.* (2011) and Weber *et al.* (2016). Results from this study further implicate biological processes related to fatty acid metabolism towards variation in RFI. Furthermore, genes within the pink network of co-expressed genes warrant further evaluation for their potential role as robust biomarkers for the genomic selection of RFI across varying breed type.

Abstract

The economic importance of genetically improving feed efficiency has been recognized in dairy production. Feed efficiency is a genetically complex trait that can be described as units of product output (e.g. milk yield) per unit of feed input. Previous work showed that feed efficiency is heritable in many species. This study aimed to investigate the heritability for Residual Energy Intake in two breeds of dairy goats (Alpine and Saanen) under commercial conditions. Heritabilities were moderate for both breeds (0.18±0.08 in Alpine and 0.20±0.07 in Saanen).

Introduction

Feeding costs are one of the largest expenditures in dairy production. For reducing their production costs and having a positive impact on environmental sustainability of dairy industry, breeders have increased interest in improving the balance between output (milk production) and input (feed intake). Feed efficiency has been introduced into pig and poultry breeding programmes and begins to be introduced in dairy cattle (Brito *et al*., 2021). In small ruminants (sheep and goat), feed efficiency is poorly documented and need to be evaluated. The European SMARTER (SMAll RuminanTs breeding for Efficiency and Resilience) project aims to develop innovative strategies to improve feed efficiency and farm resilience in small ruminants. This study has been conducted as part of this project and aims to estimate genetic parameters of feed efficiency under commercial conditions, for a large diversity of breeding systems in two breeds of dairy goats (Alpine and Saanen).

Materials & methods

Animals and housing. The experiment was performed in 14 commercial farms and at the Experimental Farm of La Sapinière (INRAE, Bourges), between 2019 and 2021. To date, 1,636 (663 Alpine and 973 Saanen) primiparous dairy goats were phenotyped for feed efficiency. Feed intake was recorded 4 times during the lactation: 2 times at the beginning of the lactation (between 0 and 60 DIM and between 60 and 90 DIM), around the reproduction (between 210 and 260 DIM) and at the end of the lactation (between 240 and 280 DIM). A total of 4,827 records (1,879 and 2,948 for Alpine and Saanen, respectively) were included in the dataset.

Animals were fed with different forages and concentrates, depending on the breeder. At each test day, feed intake was determined by weighing the total ration distributed and that wasted, by trained staff from the milk recording organisms. The forage quantity was measured by weighing all the offered forage, with a scale, at the batch or farm level (not individually). For concentrates, the quantity was measured either individually with automatic feeders or manually in milking parlour, or at the batch level by weighing all the offered concentrates, depending on the farm. Thus, for farms without individual distribution of concentrates, the individual feed intake was the average feed intake of the batch to which the animal belongs (83% of the dataset). For farms with individual distribution of concentrates, the individual feed intake was the average feed intake of the batch to witch the animal belongs for forage plus the individual intake of concentrates

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_62, © M. Chassier *et al.* 2022

(17%). Dry matter intake (DMI) was thus estimated from the information indicated on the concentrate labels and from forage analysis, for each animal and each test day. Energy Intake (EI) was estimated by multiplying DMI and energy concentration. Nutritional feed quality was recorded for each forage and each concentrate and energy content was given by INRAE (Agabriel, 2010). Test day milk recording data (milk yield, fat and protein contents) were also measured, at the same time than the feed intake control.

The chest width (CW) was used as a proxy of the body weight and was measured one time during the lactation (about 150 DIM). No body condition scores were performed.

REI estimation. To estimate feed efficiency, Residual Energy Intake (REI), was estimated as the residual of a linear regression model (1):

$$EI= \beta_0 + \beta_1 \times MY + \beta_2 \times FC + \beta_3 \times PC + \beta_4 \times CW + REI \quad (1)$$

Where, EI is the energy intake (expressed in Unité Fourragère Lait unit (UFL), 1 UFL=1.7 Mcal), β_0 is the intercept, β_1 is the regression coefficient for milk yield (MY), β_2 and β_3 are the regression coefficients of fat and protein contents (FC and PC) and β_4 is the regression coefficient for chest width (CW).

We classified the animals in 3 groups of REI, using standard deviation (sd_REI): inefficient (REI>0.5 × sd_REI), intermediate (-05 × sd_REI≤REI≤0.5 X sd_REI), efficient (REI<-0.5 × sd_REI).

Estimation of genetic parameters. The traits analysed were REI and MY. The genetic parameters were estimated, for each breed separately, using WOMBAT software (Mayer, 2007), with the following animal linear models:

$$Y=Flock + Camp + Htd + PhSt + a_n + perm_p + e \quad (2)$$

$$Y=Age + Camp + Htd + PhSt + a_n + perm_p + e \quad (3)$$

Where, Y is the observation vector for REI (2) or MY (3), Flock is the fixed effect of the flock, Age is the effect of the age at kidding, Camp is the fixed effect of the lactation campaign, Htd is the fixed effect of the herd test day, PhSt is the fixed effect of the physiological stage. The random effects included in the model were the additive genetic effect of the animal (a_n), the permanent environmental effect ($perm_p$) and the residual (e).

Only animals with two or more test day records are kept. The final data set comprised 1,331 and 2,414 test day records of 455 and 785 Alpine and Saanen goats, respectively. Animals were the progeny of 74 and 94 sires and 355 and 576 dams and the pedigree contained 7,484 and 8,652 animals for Alpine and Saanen breeds, respectively.

Results

A general description of the data is presented in Table 1. DMI was on average 2.7 kg with a standard deviation of 310 and 280 g in Alpine and Saanen breed, respectively. EI was on average 2.5 UFL for both breeds, with a moderate variability (CV of 13 and 11%). The residual energy intake (REI) was zero on average by definition. The milk yield was on average 3.40 l in Alpine breed and 3.04 l in Saanen breed with a standard deviation of 940 ml and 770 ml respectively. The mean chest width was 88 cm in the two breeds, with a low variability (CV of 5% for both breeds).

Table 1. Descriptive statistics of REI (residual energy intake), DMI (dry matter intake), energy intake (EI), milk yield (MY) and chest width (CW) per goat breed.

Breed	Trait	n	Min	Mean	Max	Sd[1]	CV[2]
Alpine	REI	1,879	-1.02	0.00	0.71	0.27	11%
	DMI (kg)	1,879	2.01	2.68	3.63	0.31	12%

[1] Standard deviation.

[2] Coefficients of variation.

Dry matter intake was higher in the inefficient group, and lower in the efficient group, with a difference of 0.49 kg of DMI per day in Alpine breed and 0.57 kg in Saanen breed between both groups (Table 2). This difference was explained both by a lower CDMI (concentrates DMI) and a lower FDMI (forage DMI) for the inefficient group. The ratio of milk output to DMI (DMI/MY) is lower for the efficient group. MY (results not shown) is the same in the three groups

Variance components, heritabilities and repeatability of the traits analysed are shown in Table 3. The heritability of test day milk yield was 0.19 and 0.20 in Alpine and Saanen breeds, respectively. Estimated heritabilities for REI, in both breeds, were moderate (0.18 and 0.20), with higher repeatability for Alpine breed (0.31) than Saanen breed (0.12).

Discussion

Feed efficiency is a difficult trait to measure under commercial conditions due to the diversity of feeding systems and the lack of individual feed intake data, due to the expensive cost of automatic feeders for breeders. Our results show that feed efficiency can be estimated, and that a ranking on the REI could be set up to classify goats: efficient *vs* inefficient. The heritability of test day milk yield were around 0.20 in

Table 2. Descriptive statistics of DMI (dry matter intake), energy intake (EI), ratio of milk output to DMI (DMI/MY), concentrates DMI (CDMI) and forage DMI (FDMI) per group of REI and per goat breed.

both Alpine and Saanen breeds. Arnal *et al.* (2019) found higher heritabilities of 0.27 and 0.28 on test day milk yield for the same breeds. The estimated heritability of REI were slightly lower than the feed efficiency heritability reported by Desire *et al.* (2017) in mixed-breed (Saanen, Alpine and Toggenburg) population (around 0.25). In Smarter project, feed efficiency was also investigated in dairy ewes, under commercial farms. Machefert *et al.* (2022) found a lower heritability (0.12) for a feed efficiency conversion ratio, in Lacaune ewes. According to Berry and Crowley (2013), heritability varies between studies depending on the type of model used to estimate feed efficiency (ratio traits or regression/residual traits) and on the type of animal involved (growing and adult animals). Further analysis needs to be conducting before considering a selection on REI in dairy goats.

Acknowledgements

This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 772787 (SMARTER). The authors would like to thank the technical staff of milk recording, FCEL for providing us the data and the breeders involved in the SMARTER project.

Abstract

Genetic parameters were estimated for dry matter intake and gross feed efficiency predicted from milk components in the first three parities of South African Holstein cattle. Test-day data from the South African National Milk Recording Scheme were used to predict dry matter intake (pDMI) from milk yield. Predicted gross feed efficiency (pGFE) was then calculated from pDMI and energy-corrected milk (ECM). Variance components and genetic parameters were estimated by a repeatability animal model using the ASReml program. Heritability estimates ranged from 0.05±0.02 for pGFE in mid lactation to 0.13±0.03 for pDMI in late lactation. Overall estimates of heritability across parities were 0.08±0.02 and 0.13±0.02 for pGFE and pDMI, respectively. Genetic correlations between pDMI and pGFE were moderate and negative in early (-0.42±0.24) and mid lactation (-0.20±0.24), and low and positive in late lactation (0.05±0.17). There was a decrease in genetic correlation between pDMI and pGFE with increase in parity, from 0.26±0.16 to -0.09±0.17. The low heritability estimates for pDMI and pGFE indicate low accuracy of selection for these traits in South African Holstein cattle. This can, however, be improved through multi-trait analyses including both traits and others that are correlated.

Introduction

Feed is a major cost in dairy production; hence, increased feed efficiency is key to achieving sustainable improvements in herd profitability. Better efficiency of feed utilisation is also associated with a reduction of major greenhouse gas emissions and, therefore, may contribute towards mitigating climate change (Connor, 2015). Thus, genetic improvement of feed efficiency could be a solution to increasing environmental sustainability and herd profitability of the dairy industry (Berry *et al.*, 2015).

Genetic selection for feed efficiency is a challenging task that requires the phenotypic measurement of many animals in order to accurately predict the genetic merit of each animal for the trait. Generally, it is costly and difficult to measure dry matter intake (DMI) directly in lactating cows, in order to calculate gross feed efficiency (GFE). This challenge may, however, be overcome through selection on DMI and GFE predicted from routinely measured milk production traits (Zhang *et al.*, 2020; Madilindi *et al.*, 2021). A major prerequisite to the effective use of such predicted traits as selection criteria is that they should exhibit genetic variation. Hence, the primary aim of this study was to estimate genetic (co)variances and related parameters for predicted dry matter intake and gross feed efficiency in South African Holstein cattle. Such parameters could provide the basis for achieving genetic improvement of feed efficiency in this population.

Materials & methods

Data. Data were from 568 herds participating in the South African National Milk Recording Scheme, and were extracted from the Integrated Registration and Genetic Information System of South Africa. The original data set consisted of 1,739,261 test-day records of 140,345 South African Holstein cows that calved

between 2009 and 2019. Only the first three parities were considered, consisting of 440,062 test-day records of 62,695 cows, after data editing.

Prediction of dry matter intake and gross feed efficiency. Firstly, test-day milk yield (kg/day) was used to calculate daily-predicted dry matter intake (pDMI) (kg/day) per cow, based on the simple regression prediction Equation 1, developed by Lindgren *et al.* (2001). Preliminary analysis using South African Holstein data had found this equation to be reliable, as indicated by an R^2 value of 0.76.

$$pDMI\ (kg/day) = 5.7 + 0.43 \times Milk\ (kg/day) \quad (1)$$

Next, energy-corrected milk (ECM) yield (kg/day) per cow was calculated from test-day milk yield (kg/day), protein percent (%), butterfat percent (%) and lactose percent (%), using Equation 2, according to Kirchgeβner (1997).

$$ECM\ (kg/day) = \text{milk yield (kg) x } \frac{(0.39 \text{ x butterfat \%} + 0.24 \text{ x protein \%} + 0.17 \text{ x lactose \%})}{3.17} \quad (2)$$

Predicted gross feed efficiency (pGFE) per cow was subsequently calculated, using Equation 3:

$$pGFE = \frac{\text{ECM (kg/day)}}{\text{pDMI (kg/day)}} \quad (3)$$

Statistical analysis. Variance components, heritability, and repeatability for pDMI and pGFE were estimated by ASReml 3.0 (Gilmour *et al.*, 2009) using a repeatability animal model (Equation 4):

$$y_{jklmn} = \mu + HTD_j + LS_k + P_l + \beta ACC_{jklmn} + a_{jklmn} + p_{jklmn} + e_{jklmn,} \quad (4)$$

where y_{jklmn} is an observation of pDMI or pGFE; μ is the overall mean; HTD_j is the fixed effect of herd-test-day contemporary group; LS_k is the fixed effect of lactation stage (k = early lactation (10-100 days in milk (DIM)), mid lactation (101-200 DIM), and late lactation 201-305 DIM); P_l is the fixed effect of parity (l =1 to 3); ACC_{jklmn} is age of cow at calving; β_{jklmn} is a linear regression coefficient on age of cow at calving; a_{jklmn} is the random animal additive genetic effect with var (a) ~distribution $N(0,A\sigma^2_a)$, where σ^2_a is the additive genetic variance and A is the relationship matrix; p_{jklmn} is the random permanent environmental effect of the animal with distribution $N(0,I\sigma^2_p)$, where σ^2_p is the permanent environmental variance; e_{jklmn} is the random residual effects with distribution $N(0,I\sigma^2_e)$, where σ^2_e is the residual variance and I is an identity matrix.

Bivariate analyses were carried out to estimate genetic correlations between pDMI and pGFE within and across lactation stages as well as parities.

Results

Estimates of heritability and genetic correlations for pDMI and pGFE by stage of lactation are presented in Table 1. Heritabilities ranged from 0.05±0.02 for pGFE in mid lactation to 0.13±0.03 for pDMI in late lactation. The heritability estimates of pDMI tended to increase with stage of lactation. No trend of heritability estimates for pGFE was observed among lactation stages. Genetic correlations between pDMI and pGFE varied from -0.42±0.24 in early to 0.05±0.17 in late lactation.

Table 2 contains estimates of heritability and genetic correlations for pDMI and pGFE within parity. Heritability estimates ranged from 0.07±0.02 for pGFE in both first and third-parity to 0.14±0.03 for pDMI in third-parity. There was a slight increase in heritabilities of pDMI with increase in parity. No trend of heritability estimates for pGFE was observed across parities. Overall estimates across parities

were 0.08±0.02 and 0.13±0.02, respectively, for pGFE and pDMI. Repeatability estimates of 0.26±0.01 and 0.41±0.01 were obtained across lactations, respectively, for pGFE and pDMI. Genetic correlations between pDMI and pGFE varied from -0.09±0.17 in third-parity to 0.26±0.16 in first-parity.

Discussion

Heritabilities for pDMI and pGFE were generally low within lactation stages. The heritability estimates of pDMI slightly increased with stage of lactation, implying that accuracy of selection for this trait may depend on the lactation stage in which selection is applied. Tarekegn *et al.* (2021) similarly reported an increase in heritability estimates for measured daily DMI with lactation week. No trend of heritability estimates for pGFE was observed among lactation stages in the current study. However, a decrease in the heritability estimate for GFE with increase in lactation stage was observed previously by Spurlock *et al.* (2012). These discrepancies may be a reflection of differences in the methods used to measure the traits. The genetic correlations between pDMI and pGFE was inexplicably negative in early and mid-lactations, and positive in late lactation. There were, unfortunately, no estimates available in the literature with which to compare these results. The relatively high genetic correlation in early lactation may assist in increasing accuracy of selection, if the two traits are included in a multi-trait analysis.

Heritability estimates for pDMI and pGFE were low within first-three parities. A slight increase in heritabilities of pDMI with increase in parity was observed. This indicates that accuracy of selection for pDMI may depend on the parity in which selection is applied. Recently, Zhang *et al.* (2020) reported heritability estimates comparable with those obtained in the current study for pDMI in the first-two parities, although the estimate for the first parity was higher than for the second. No trend of heritability estimates for pGFE was observed across parities in our study. Spurlock *et al.* (2012) however reported higher heritability estimates for actual GFE in primiparous (0.47) compared to multiparous (0.43) cows, although their estimates were much larger than those found in the current study. The inconsistency in estimates of heritability for DMI and GFE among studies could be attributable to discrepancies in the measurement/prediction methods as well as stages of lactation during which measurements were taken. Moderate repeatability estimates were obtained across lactations, implying that first lactation records on

Table 2. Heritability estimates (diagonals) and genetic correlations (off diagonals) for daily-predicted dry matter intake and gross feed efficiency within first-three parities in South African Holstein cattle.

	Parity 1		Parity 2		Parity 3	
Traits	**pDMI**	**pGFE**	**pDMI**	**pGFE**	**pDMI**	**pGFE**
pDMI[1]	**0.11±0.03**	0.26±0.16	**0.12±0.03**	0.11±0.16	**0.14±0.03**	-0.09±0.17
pGFE[2]		**0.07±0.02**		**0.10±0.02**		**0.07±0.02**

[1] pDMI[1] = predicted dry matter intake; [2] pGFE = predicted gross feed efficiency.

pDMI can fairly predict pDMI in later lactations. Genetic correlation between pDMI and pGFE decreased with increase in parity in the current study. This may mean that increased accuracy of selection through multiple-trait analysis of the two traits would be more effective with first lactation data. Genome-wide association studies may be warranted to validate these results.

Conclusions

Results of the current study show that there is low genetic variation in DMI and GFE predicted from milk components, which implies low accuracy of selection. Moderate genetic correlations between the traits, however, may be used to increase accuracy of selection in multi-trait analyses. Variation in pDMI appears to slightly vary with parity and stage of lactation; thus, lactation stage-specific and parity-specific selection may be required. Further research may be required to identify genomic regions, and subsequently genes, associated with these predicted feed efficiency traits, for possible marker-assisted selection, which might accelerate genetic improvement.

Abstract

The aim of this study was to predict genomic breeding values for metabolic body weight (MBW) by a single-step model and to compare obtained breeding values to those from a multi-step genomic prediction model and a pedigree-based BLUP model. Data contained over 3 million observations from Danish, Finnish and Swedish Red dairy cattle born in the years 1990 to 2017. The applied multiple-trait animal models included six traits: 1st, 2nd, and 3rd parity MBW, and first parity stature, chest width and body depth. Breeding values from the single-step model were in good agreement with those from the multi-step model (correlations were 0.98-0.99), but BLUP breeding values differed from genomic breeding values slightly for bulls and clearly for cows. The single-step model gave higher validation reliabilities for bulls and cows than the multi-step model. The results support using a single-step approach for the genomic evaluation of MBW.

Introduction

In 2020, Nordic Cattle Genetic Evaluation (NAV) included the Saved Feed Index, which contains the metabolic body weight (MBW) and residual feed intake in the Nordic Total Merit index for the Danish, Finnish, and Swedish Holstein (HOL), Red dairy cattle (RDC) and Jersey populations. MBW is the core trait for the genetic evaluation of maintenance efficiency as the feed requirement for maintenance is assumed to have a linear relationship with MBW. The MBW evaluation (Lidauer *et al.*, 2019) is based on three core traits; MBW in 1st, 2nd, and 3rd parity, and three correlated conformation traits; stature (ST), chest width (CW), and body depth (BD). Currently, genomic breeding values for MBW are predicted by a multiple-step approach but a single-step genomic prediction model (Aguilar *et al.*, 2010; Christensen and Lund, 2010) is expected to improve predictions. The aim of this study was to develop a single-step genomic prediction model for MBW in Nordic RDC. Cross-validation statistics and regression of recent breeding values on earlier breeding values (Legarra and Reverter, 2018) were applied to compare the developed single-step model with the currently used multiple-step model, and with the pedigree-based BLUP model.

Materials & methods

Phenotypic data and pedigree. The data contained all available body weight (BW) and conformation traits observations of Danish, Finnish and Swedish RDC cows born in the years 1990 to 2017. This included BW observations from Finnish cows, which were measured by tape (heart girth), BW observations from Danish cows, which were measured by scale, and first parity conformation observations from cows of all countries. The raw BW observations were pre-processed as explained by Lidauer *et al.* (2019) to obtain for each lactation, that had BW records, one MBW observation ($BW^{0.75}$) with an associated weighting coefficient that accounted for the type and number of the raw BW observations. The first parity conformation observations were taken from the NAV routine conformation evaluation (NAV, 2019) with the following trait definition: ST (linear, cm), CW (linear score from 1 to 9) and BD (linear score from 1 to 9). After editing, the data consisted of 1.28 million MBW observations and 2.94 million conformation observations.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_64, © R.M. Kempe *et al.* 2022

The pedigree of the cows with observations included 2.99 million animals and the base population was described with 182 unknown parent groups (UPG).

Best linear unbiased prediction model. The BLUP model developed for the NAV routine MBW evaluation was the basis for building the single-step genomic predication model. The BLUP model is a multiple-trait animal model with six traits, which are MBW in 1st, 2nd, and 3rd parity, and first parity ST, CW, and BD. The applied heritabilities for these traits were 0.46, 0.51, 0.56, 0.60, 0.18, and 0.26, respectively. A detailed description of the model and the applied variance components is given in Lidauer *et al.* (2019). The correlated information from the conformation traits is important because there is no BW information available from Swedish cows. Moreover, recording of BW by tape is reducing in Finland and measuring BW by scale is slowly becoming more common. Genetic correlations between the three MBW traits and the conformation traits were on average 0.67, 0.55, and 0.49 with ST, CW, and BD, respectively. Furthermore, to improve predictions of Finnish herds the observations from HOL cows were also included to increase contemporary group sizes. The estimated breeding values (EBV) for MBW were used to form for each animal one combined MBW EBV by weighting 1st, 2nd, and 3rd parity EBVs with the weights 0.30, 0.25, and 0.45, respectively, and changing the sign of the index values so that a higher index value refers to a lower MBW.

Marker data. Genotype information from RDC animals only was included for developing the single-step model. Bulls were genotyped using the Illumina Bovine SNP50 Bead Chip (Illumina, San Diego, CA) and the cows using the lower-density EuroG MD chip (http://www.eurogenomics.com/). The unobserved genotypes with the lower-density chip were imputed to the 50K density. After editing there were 46,914 single nucleotide polymorphisms (SNP) markers available for 51,417 animals.

Multi-step genomic prediction model. For building the multi-step genomic prediction model, which was based on SNP-BLUP (msSNPBLUP), all genotyped bulls which had at least 20 daughters and a MBW EBV reliability of at least 0.5 and all genotyped cows that had observations were included. This resulted in 5,554 bulls and 43,276 cows and in total 48,830 genotyped animals. De-regressed proofs (DRP) based on the combined EBV for MBW of 1st, 2nd, and 3rd parity were used as observations for the SNP-BLUP evaluation and each animal's observation was weighted by the animal's effective record contribution (ERC). In addition to marker effects, the SNP-BLUP model included a polygenic effect explaining 10% of the genetic variation.

Single-step genomic prediction model. Relationships between animals in the single-step genomic prediction model (ssGBLUP) were described by the H matrix (Aguilar *et al.*, 2010; Christensen and Lund, 2010) which was implemented as described by Koivula *et al.* (2021). The VanRaden method I (VanRaden, 2008) was used for building the genomic relationship matrix by blending the G matrix with the residual polygenic effect that accounts for 10% of the genetic variation. The QP transformation was applied to account for the UPG. A combined genomic enhanced breeding value (GEBV) for MBW was formed in the same way as the combined EBV for MBW.

Model validation. The ssGBLUP model was validated by forward prediction cross-validation, which was done for all the three models. For the cross-validation, we selected 1,721 cows and 354 bulls that had no own information in the reduced data set. For the evaluation with the reduced data, observations from most recent four years of bulls and their progenies were excluded. The same pedigree and genomic information were used as for the full data set evaluation to obtain breeding values for candidates (BV_c). Thus, in the SNP-BLUP evaluation for the reduced data all candidate animals were included but had no own data. The cross-validation reliability (r^2_{cv}) was calculated as:

$$r^2_{cv} = \text{corr}(DRP, BV_c)^2 / r^2_{DRP} \quad (1)$$

where DRP were calculated separately for both the bull validation candidate, and the cow validation candidate group, to ensure proper calculation of ERC weights used for the de-regression. The second statistic we applied was the regression of full data breeding values on reduced data breeding values (Legarra and Reverter, 2018), which has an expectation of b_1=1.0.

Results

Correlations between ssGBLUP and msSNPBLUP breeding values of genotyped animals were 0.98-0.99, indicating that the models gave almost the same genomic breeding values (Table 1). The correlation between BLUP and ssGBLUP or msSNPBLUP breeding values was 0.97 in bulls and 0.84 to 0.86 in cows, respectively. Thus, BLUP breeding values were slightly different in bulls and clearly different in cows compared with genomic breeding values. The ssGBLUP GEBV had 5 to 12% higher standard deviation compared with msSNPBLUP or BLUP breeding values in cows and 0.2 to 5.5% higher in bulls.

The correlations between candidates' BV_c and their future DRP are presented in Table 2. Correlations were the highest when BV_c were estimated with ssGBLUP for both bulls and cows. This resulted also the highest r^2_{cv} with ssGBLUP being as high as 0.91 for the bull candidates. The r^2_{cv} of BV_c obtained with the msSNPBLUP model was higher than that when using BLUP in candidate bulls, but not in cows. For all three models, r^2_{cv} was higher for bulls compared with cows. Mean DRP reliability was for bulls 0.71 and for cows 0.61.

Table 1. Standard deviation (Std) and correlation between MBW breeding values and those with de-regressed proofs (DRP) for reference population animals.

	Prediction model[1]	Std	Correlations		
			msSNPBLUP	ssGBLUP	DRP
Cows	BLUP	4.11	0.86	0.84	0.88
n=35,075	msSNPBLUP	4.36		0.98	0.75
	ssGBLUP	4.59			0.74
Bulls	BLUP	4.56	0.97	0.97	0.95
n=5,539	msSNPBLUP	4.33		0.99	0.90
	ssGBLUP	4.57			0.91

[1] BLUP = best linear unbiased prediction; msSNPBLUP = multi-step genomic BLUP, ssGBLUP = single-step genomic BLUP.

Table 2. Cross-validation estimates correlation ($r_{(DRP,BVc)}$), validation reliability (r^2_{cv}), regression coefficient (b_1) for the bull and cow candidate groups with different models.

	Prediction model[1]	Cross-validation reliability		Legarra-Reverter	
		$r_{(DRP,BVc)}$	r^2_{cv}	b_1	R_2
Cows	BLUP	0.67	0.74	0.96	0.51
n=1,721	msSNPBLUP	0.65	0.69	1.09	0.70
	ssGBLUP	0.73	0.86	1.05	0.84
Bulls	BLUP	0.74	0.77	0.96	0.56
n=354	msSNPBLUP	0.75	0.80	1.10	0.74
	ssGBLUP	0.81	0.91	1.01	0.85

[1] BLUP = best linear unbiased prediction; msSNPBLUP = multi-step genomic BLUP, ssGBLUP = single-step genomic BLUP.

The b_1 estimates were closer to the expectation for ssGBLUP in candidate bulls than those for the BLUP model and msSNPBLUP model (Table 2). In cows, the *b1* estimate for BLUP was slightly closer to expectation than for the ssGBLUP or msSNPBLUP models. The b_1 estimates for msSNPBLUP were larger than 1.0 indicating that BV_c underpredicted the future breeding values, whereas the b_1 estimates for BLUP were below 1.0 indicating that BV_c overpredicted future breeding values.

Discussion

Breeding values from the single-step model were in good agreement with those from the multi-step model and reasonably different from those of the BLUP model. Correlations between traditional BLUP and genomic models were clearly lower than correlations among genomic models. Also, country-wise (Denmark, Finland, Sweden) investigation of the breeding values confirmed that the single-step model is modelling the data appropriately. The obtained cross-validation reliabilities were higher than those for RDC yield traits ssGBLUP GEBVs (Koivula *et al.* 2018). This can be explained by the high heritability of the MBW traits and ST, and the high genetic correlation between MBW and ST. The reason why we obtained a lower r^2_{cv} value for the msSNPBLUP evaluation compared with the BLUP evaluation for the cow candidate group was unclear and requires further assessments.

The regression of candidates' full data GEBV on candidates reduced data BV_c were close to the expectation when applying ssGBLUP, and therefore ssGBLUP is preferable over msSNPBLUP for obtaining GEBV for candidates. The results of this study support the implementation of ssGBLUP for the genomic evaluation of MBW in Nordic RDC and to develop ssGBLUP also for the Nordic HOL and Jersey MBW evaluation.

Abstract

The availability of genome high density (HD) data provides new opportunities for combined population genomic prediction. An imputation from Nellore animals has been implemented to analyze, the impact of imputed data on heritability estimation (h^2) and breeding values for residual feed intake (RFI), by single-step GBLUP. Data sets of 607 Nellore bulls were used to impute a genotype bank composed of 1,466 Nellore animals, resulting in a dataset of 735,964 SNPs for all animals. The BLUPF90 package was used to perform quality control, resulting in 471,301 SNPs. Analysis to obtain h^2 and breeding values for RFI were performed, using an animal model considering the single-step GBLUP. The BLUPF90 was efficient in processing the imputed file. The higher h^2 of the RFI suggests an influence of the imputed data. The correlation of the breeding values indicates that the use of HD and 56K data result in similar breeding values.

Introduction

Zebu breeds contribute considerably to the agricultural economy (milk and beef) in tropical countries. The Nellore breed (*Bos indicus*) is the main research focus for the beef sector in Brazil and has several genetic improvement programs with private and public coordination.

The scientific advancement and productive research of the taurine beef breeds far surpasses the Zebu breeds. In addition, currently available SNP matrices for genotyping are constructed from dbSNP data, therefore, are biased towards taurine animals limiting genomic studies of indicus breeds (Iqbal *et al.*, 2019). To overcome the taurine preference, some genotyping companies have recently introduced low- and medium-density markers for indicus breeds, but still suffering from verification bias (Boison *et al.*, 2015, Ospina *et al.*, 2021). Additional studies that resemble the entire genome of indicus races from different geographic regions are needed to discover and deposit more indicative SNPs (Choi *et al.*, 2014).

Few studies were performed in Zebu cattle (Stafuzza *et al.*, 2017, Fernandes Junior *et al.*, 2021). The search for alternatives for the imputation implementation data in genomic analysis is essential for its use and, consequently, a reduction in costs.

Several studies have studied residual feed intake (RFI) using genomic data, identifying important regions for selection. However, larger studies at the genome level, mainly in Zebu breeds, are of importance for tropical countries. Research on Nellore breed has increased, but better knowledge of the breed is required to improve traits of economic interest. Thus, studies with Nellore data will contribute for understanding of Zebu breeds genome.

The aim of the study was to implement genotype imputation from Nellore animals, and to analyse by single-step GBLUP the impact of imputed data on the results of h^2, and breeding values for RFI.

Materials & methods

The RFI has been implemented as a selection criterion since 2010 by the Nellore Qualitas Program (group of farms in seven states in Brazil). From 15,000 males produced annually, 120 animals are selected, based on an index (based on breeding values of the traits weight at weaning, post gain weaning, muscle score and scrotal circumference), to participate in a feed efficiency test. At the end of the test, the young bulls, with an average age of 23 months are selected, have the semen collected and the breeders participating in the program use it in a progeny test. RFI is defined as the difference in observed feed consumption minus predicted and is measured in 56 days of testing, after 21 days of adaptation.

Data from 607 Nellore bulls genotyped with HD (~777k) were used to impute a genotype bank composed of other 1,466 Nellore animals from the Nellore Qualitas Program. The imputation was performed using the FImpute v3 software (Sargolzaei *et al.*, 2014), being performed considering a deterministic approach for the haplotypes phase and imputing all the absent genotypes, considering the pedigree information.

Analysis to obtain h^2, GWAS, and breeding values for the RFI trait were performed with the BLUPF90 package (Misztal *et al.*, 2001), using an animal model considering the single-step GBLUP (SSGBLUP, Aguilar *et al.* 2010) method as follows:

$$y = X\beta + Za + e, \quad (1)$$

where y is the vector of RFI; β is a vector with the fixed effects of CG (defined by animals participating in the test in the same year and pen) and age at the beginning of the test as a linear co-variable; a is a vector of additive genetic effects assumed normally distributed N (0, H ⊗ σ_a^2), in which σ_a^2 is the additive genetic variance and H is the pedigree-genomic relationship matrix ⊗ is the Kronecker product and e is a residual vector assumed N (0, I ⊗ σ_e^2), where I is the identity matrix, and σ_e^2 is the residual variance. The X and Z are known as incidence matrices related to fixed and additive genetic effects, respectively.

The H is a matrix that combines pedigree and genomic information, and its inverse (H^{-1}) is given by: $H^{-1} = A^{-1} + \begin{bmatrix} 0 & 0 \\ 0 & G^{-1} - A_{22}^{-1} \end{bmatrix}$, where A^{-1} is the inverse of the pedigree relationship matrix, A_{22}^{-1} represents the inverse of the pedigree relationship matrix for genotyped animals, and G^{-1} is the inverse of the genomic relationship matrix. The pedigree file contained 7,745 animals, generated from animals with phenotypes and up to the fourth generation.

After imputation, and the BLUPF90 family programs were used to perform a new quality control, removing 0 SNPs with a call rate less than 0.90, with MAF less than 0.05 were removed 264,663 SNPs, monomorphic 8,212 SNPs were dropped and there were no animals with a call rate less than 0.90, resulting in 471,301 SNPs of and 2,073 individuals. The correlation between diagonal, all, and off-diagonal elements of G and A were equal to 0.027, 0.766 and 0.821, respectively. From this phase, the estimation of h^2 of the RFI was obtained (AiremlF90 program), the GWAS analyses (results not shown), all SNPs were ranked based on their *P*-values (results not shown) and obtained the genetic values and accuracies of the animals.

Results

The data set with 735,964 SNPs to be imputed had mean MAF equal to 0.566 (minimum of 0.0 and maximum of 1), and after quality control, the file contained 471,301 SNPs, with average MAF equal to 0.539 (minimum of 0.05 and maximum of 0.95).

The RFI h^2 estimate using the imputed data for WGS was equal to 0.29±0.08, a value higher than that obtained with the pedigree alone (0.23±0.07).

The distribution of breeding value for RFI is reported in Figure 1 for three groups (animals genotyped with the HD, 56K and 29K panel) from using only the pedigree file (BV_BLUP), and the pedigree and the imputed data for HD (BV_HD). Low correlation was observed between the breeding values for the lower density panel. The behaviour of all panels of higher density was like those shown (Figure 1) with lower density.

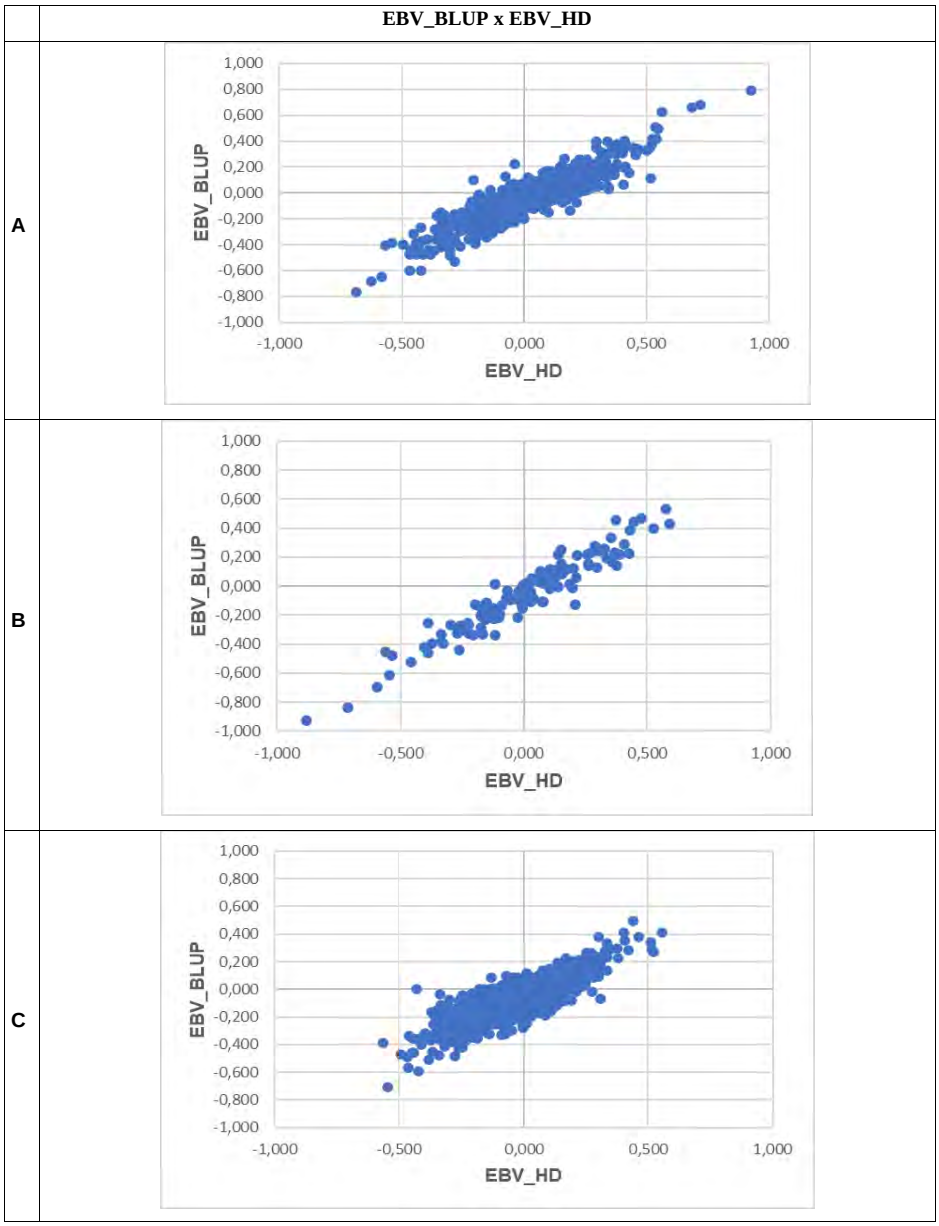

Figure 1. Distribution of expected breeding values for residual feed intake from animals genotyped with the HD (A), 56K (B) and 29K (C) panel from using only the pedigree file (BV_BLUP) and the pedigree and the imputed data for HD (BV_HD).

Discussion

The BLUPF90 package was efficient and fast in processing the imputed file for HD with 471,301 SNPs, and building the H^{-1}, as well as estimating the h^2, GWAS, and breeding values for the RFI trait.

The high MAF mean in the imputed set for WGS indicates that the number of SNPs increased with the high MAF, that is, the number of rare variants decreased.

The h^2 of the RFI higher than that obtained with only the pedigree suggests an influence of the imputed data for HD. Wainschtein *et al.* (2021) suggest that rare variants, in regions with low LD, are important in estimating h^2 for complex traits.

The correlation of the breeding values indicates that the use of HD and 56K data result in similar breeding values (Figure 1). However, the results showing a larger dispersion of EBV from genotyped animals with low-density panel (29K) suggest low quality of imputation.

66. Relationship between proxies of energy states and nitrogen use efficiency for Holstein cows in early lactation

Y. Chen[1*], C. Grelet[2], S. Vanderick[1], H. Hu[1] and N. Gengler[1]

[1]University of Liège, Gembloux Agro-Bio Tech (ULiège-GxABT), Passage des Déportés 2, 5030 Gembloux, Belgium; [2]Walloon Agricultural Research Center (CRA-W), Chaussée de Namur 24, 5030 Gembloux, Belgium; yansen.chen@doct.uliege.be

Abstract

The purposes of this study were to estimate the genetic parameters of the energy status indicator (C18:1 *cis*-9) of Holstein cows in early lactation and its relationship with nitrogen use efficiency (NUE) (predicted NUE and milk urea concentration). After editing, the data included 143,517 records within 5 to 50 days in milk from 52,198 cows, and 3,546 animals in the pedigree with 28,427 SNPs. Two multiple-trait repeatability models were used in this study. In early lactation, the average C18:1 *cis*-9 was gradually decreasing and was highest in May. The heritabilities of C18:1 *cis*-9 for primiparous and multiparous cows were 0.12 and 0.09, respectively. The C18:1 *cis*-9 had positive genetic correlations with predicted NUE (from 0.28 to 0.67), and weak genetic correlations with milk yield, milk urea concentration (from -0.15 to 0.14). This study suggests that breeding for NUE alone may enhance energy troubles in early lactation.

Introduction

Most dairy cows will be in a negative energy balance (NEB) in early lactation due to energy intake that cannot meet the needs of milk production (Churakov *et al.*, 2021). If the dairy cow is in NEB state for too long, the risk of the dairy cow suffering from metabolic diseases (such as ketosis) will increase (Zachut *et al.*, 2020), but it is difficult to directly detect the energy status of dairy cows. Usually, people use indirect prediction of the NEB of dairy cows as an alternative method. Although using milk mid-infrared (MIR) spectra to indirectly predict the NEB of dairy cows is a good method, the coefficient of determination of its prediction model is varying in different studies (from 0.48 to 0.77) (Ho *et al.*, 2019; Smith *et al.*, 2019).

Studies have shown that oleic acid (C18:1 *cis*-9) is a good proxy for identifying NEB in dairy cows (Churakov *et al.*, 2021, Guinguina *et al.*, 2021). When the cow is in NEB, its body fat reserves will be mobilized, leading to an increase in C18:1 *cis*-9 in milk (Zachut *et al.*, 2020). The C18:1 *cis*-9 can be accurately and quickly predicted using MIR. The determination coefficients for cross-validation of its prediction model were 0.95 (Soyeurt *et al.*, 2011), which was confirmed by the study of Grelet *et al.* (2014). The genetic parameters of C18:1 *cis*-9 have been reported but they only focus on the first parity (Bastin *et al.*, 2011; Mehtiö *et al.*, 2020). As the nitrogen use efficiency (NUE) of dairy cows has attracted attention (Chen *et al.*, 2021b) in recent years, we guess that its addition to breeding may increase the NEB of dairy cows. In this study, the new proxy (predicted NUE, PNUE) and traditional proxy (milk urea concentration, MU) of NUE were used as representatives to evaluate their relationships with C18:1 *cis*-9 (Chen *et al.*, 2021a, 2021b). At the same time, this research has added milk yield (MY) as a representative of the main economic traits.

The purposes of this study were to estimate the genetic parameters of C18:1 *cis*-9 in the early lactation of the first five parities of dairy cows and its relationship with PNUE, MU, and MY.

Materials & methods

Data. All data were collected from 2012 to 2019 during the official milk recording in the Walloon Region of Belgium. The MIR analysis of milk samples was performed by MilkoScan FT 6000 and FT+ spectrometers (Foss Electric, Hillerød, Denmark) to provide MIR spectra and milk composition. Edits excluded irregular

DOI: 10.3920/978-90-8686-940-4_66, © Y. Chen1 *et al.* 2022

data for daily MY (<1 and >99 kg) and MU (<2 and >70 mg/dl). The filtering method for C18:1 *cis*-9 (g/dl of milk) and PNUE was the same as Chen *et al.* (2021b). Furthermore, the range of days in milk (DIM) was from 5 to 50, parity within 5, and the ranges of accepted calving age were: from 23 to 37, 35 to 52, 47 to 67, 59 to 83, 71 to 96 months for the first to fifth parity, respectively. After filtering, 134,517 records from 52,198 Holstein cows on 774 farms were used in this study. The pedigree related to the dataset comprised 120,933 animals, and 3,546 (397 bulls) of them had genotypes with 28,427 SNPs. The genotype data were provided by the cattle breeding system in the Walloon Region of Belgium. Besides, each trait was divided into primiparous and multiparous (including second to fifth parity) classes, except the MU (based on the research results of Chen *et al.*, 2021a). Hereafter, C18:1 *cis*-9, PNUE, and MY data were divided following parities and identified as C18:1 *cis*-9_1, PNUE1, MY1, C18:1*cis*-9_2+, PNUE2+, and MY2+. At the same time, based on its trend with DIM (Figure 1), C18:1 *cis*-9 was also divided into 3 traits, C18:1 *cis*-9_1 (first parity), C18:1 *cis*-9_2 (second parity), C18:1 *cis*-9_3+ (from third to fifth parity). All milk MIR spectra were standardized according to Grelet *et al.* (2015). The C18:1 *cis*-9 and PNUE of each cow were predicted by the equations based on the models established by Grelet *et al.* (2014, 2020). The determination coefficients and root mean square errors of cross-validation were 0.95 and 0.06% for C18:1 *cis*-9, and 0.68 and 5.01% for the PNUE model, respectively.

Models. The three-trait and seven-trait repeatability models were used to estimate the variance components for C18:1 *cis*-9 (C18:1 *cis*-9_1, C18:1 *cis*-9_2, and C18:1 *cis*-9_3+) and seven traits (C18:1 *cis*-9_1, PNUE1, MY1, MU, C18:1 *cis*-9_2+, PNUE2+, and MY2+). The models were the same as Chen *et al.* (2021b), expect the number of traits.

Genetic parameters. The variance components, heritability (h^2), and genetic correlations of the three-trait model were estimated by AIREMLF90 (version 1.149). The variance components of the seven-trait model were estimated by Gibbs sampling in THRGIBBS1F90 (version 2.119), and posterior convergence was analyzed by POSTGIBBSF90 (version 3.15). Among them, the posterior means of variances were obtained using 100,000 samples after a burn-in of 20,000 samples. Using the mean of the posterior variance components, the h^2, genetic, and phenotypic correlations were calculated. Approximate standard errors (SE) of parameters were obtained from POSTGIBBSF90 (version 3.15) program.

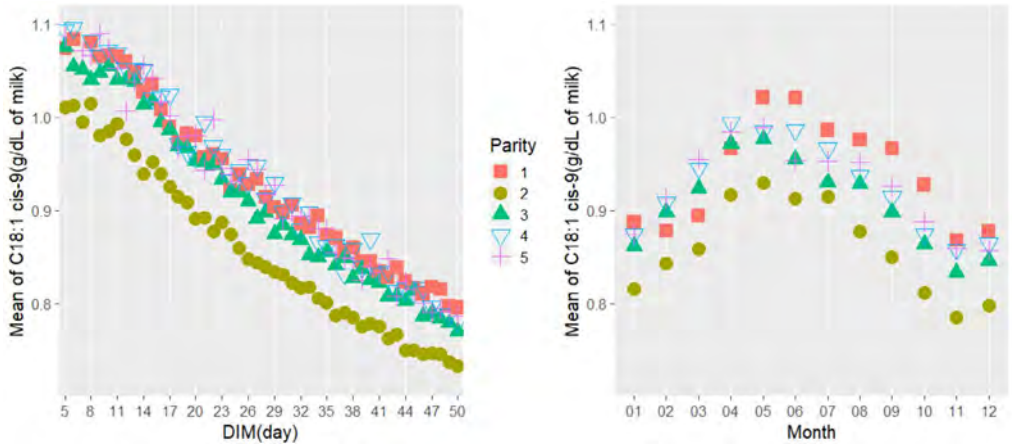

Figure 1. The curves of the mean of C18:1 *cis*-9 (g/dl of milk) with days in milk (DIM) and month for Holstein cows in the first five parties.

Results & discussion

Descriptive phenotype. The average (standard deviation, SD) C18:1 *cis*-9 in primiparous and multiparous cows was 0.92 g/dl (0.25) and 0.89 g/dl (0.24), respectively. This was in line with other studies (Bastin *et al.*, 2011; Mehtiö *et al.*, 2020; Churakov *et al.*, 2021). The trends of the average C18:1 *cis*-9 of dairy cows in early lactation were shown in Figure 1. The average C18:1 *cis*-9 gradually decreased from DIM 5 to 50, ranging from 0.73 (SD: 0.15) to 1.11 (SD: 0.28), which is consistent with the report by Churakov *et al.* (2021). Within the months of the year, the average C18:1 cis-9 ranged from 0.78 (SD: 0.20) to 1.02 (SD: 0.25), and each parity reached its maximum in May, except for the fourth parity. It may be that C18:1 *cis*-9 was very sensitive to heat stress in dairy cows (Hammami *et al.*, 2014), and cows got fresh pasture in May (Frétin *et al.*, 2019).

Heritabilities. In the seven-trait model, the h^2 (SE) of C18:1 *cis*-9 in primiparous and multiparous were 0.12 (0.01) and 0.09 (0.01) (Table 1), which were consistent with our results in the three-trait model (not shown). The h^2 of C18:1 *cis*-9 in this study was similar to the results obtained in the same area of the previous study (Bastin *et al.*, 2011), and was also consistent with the results obtained in the Nordic Red Dairy cattle study in Finland (Mehtiö *et al.*, 2020). Moreover, the h^2 of PNUE and MU were consistent with the results of our previous studies (Chen *et al.*, 2021a, 2021b).

Correlations. The genetic and phenotypic correlations of the seven traits were described in Table 1. From the three-trait model analysis, the genetic correlations of the first and second with third parity+ traits were 0.70 and 0.93, respectively. Then we changed it to two traits, namely primiparous as the first and multiparous as the second one. The genetic correlations between C18:1 *cis*-9 and PNUE were positive (from 0.28 to 0.67), which indicates that increasing NUE in the early lactation may be detrimental to its energy balance. Another reason is that in early lactation, cows both mobilize energy and protein body reserves, so NUE is artificially high. This was similar to the results of Hurley *et al.* (2018) who showed that improving feed efficiency was not conducive to the energy balance of cattle. The C18:1 *cis*-9 had weak genetic correlations with MY and MU, ranging from -0.14 to 0.14, and from -0.15 to 0.03, respectively. The phenotypic correlations between C18:1 *cis*-9 and PNUE were moderately positive in the same parity class (0.33 and 0.34). However, the C18:1 *cis*-9 had low phenotypic correlations with MY and MU, ranging from -0.04 to 0.10.

Table 1. Heritabilities[1] (diagonal, bold), genetic correlations (above the diagonal) and phenotypic correlations (below the diagonal) among the four features[2] for primiparous (n=41,035) and multiparous (n=93,482) Holstein cows in early lactation.

	C18:1 *cis*-9_1	**PNUE1**	**MY1**	**MU**	**C18:1 *cis*-9_2+**	**PNUE2+**	**MY2+**
C18:1 *cis*-9_1	**0.12**	0.67	0.14	0.03	0.67	0.36	0.00
PNUE1	0.33	**0.17**	0.71	0.12	0.28	0.70	0.50
MY1	0.10	0.47	**0.18**	0.01	-0.14	0.51	0.78
MU	0.00	0.03	0.01	**0.12**	-0.15	0.04	-0.02
C18:1 *cis*-9_2+	0.09	0.03	-0.04	0.02	**0.09**	0.48	-0.05
PNUE2+	0.07	0.15	0.13	0.03	0.34	**0.12**	0.74
MY2+	0.02	0.15	0.21	0.03	0.06	0.58	**0.13**

[1] The standard errors of all heritabilities, genetic correlations, and phenotypic correlations are 0.01, less than 0.07, and less than 0.01, respectively.

[2] The four features were divided into seven traits, namely C18:1 *cis*-9 (g/dl of milk) (C18:1 *cis*-9_1), predict nitrogen use efficiency (%) (PNUE1), daily milk yield (kg) (MY1) in primiparous cattle, and milk urea concentration (mg/dl) (MU) in the first five parities, and C18:1 *cis*-9_2+, PNUE2+, MY2+, corresponding to multiparous cattle.

Conclusions

The C18:1 *cis*-9 had low h^2 in the early lactation of the first five parities for Holstein cows. In addition, the C18:1 *cis*-9 had positive genetic correlations with PNUE (unfavorable), and low genetic correlations with MY and MU (favorable). This study suggests that breeding for NUE alone may enhance energy troubles in early lactation.

Abstract

Improving nitrogen efficiency in dairy cattle is of interest to reduce the environmental burden of dairy production. One strategy is to breed cows for improved nitrogen use efficiency and less nitrogen excretion. Two nitrogen efficiency statistics were computed: nitrogen use efficiency (NUE), which was defined as the ratio of the nitrogen in the saleable output relative to nitrogen intake, and nitrogen balance (Nbalance) defined as the difference between the nitrogen intake and the nitrogen output in saleable product. Using a dataset of 2,262 lactations from grazing dairy cows, considerable genetic variability was detected with heritability estimates for NUE and Nbalance of 0.06 (0.02) and 0.13 (0.03), respectively. Nbalance was both strongly phenotypically correlated (r_p=0.98 (0.001)) and strongly genetically correlated (r_g=0.98 (0.01)) with nitrogen intake.

Introduction

Nitrogen excess in grazing dairy systems generally originates either from fertiliser or animal excreta and contributes to eutrophication as well as nitrous oxide pollution. Excreted nitrogen, termed nitrogen loss, can be an economic cost for farms. Improving nitrogen use efficiency (NUE) of the animal can therefore potentially reduce nitrogen excretion, representing both an environmental and economic saving. Nitrogen use efficiency can be defined as a function of nitrogen input and output; nitrogen input is essentially nitrogen intake. Nitrogen output includes both the crude protein (CP) and urea in the milk, as well as nitrogen used for growth and body tissue accretion, along with the nitrogen in the excreted urine and faeces. Milk protein and milk urea nitrogen (MUN) phenotypes are routinely available from milk samples and have been demonstrated to be heritable (Lopez-Villalobos *et al.*, 2018), with MUN having being proposed as an indicator of NUE or nitrogen excretion. Feed intake (and by extension nitrogen intake) is also known to be heritable in dairy cows. No routine measures of nitrogen content of the faeces and urine exist but, within a balanced system, the nitrogen excreted should be a function of what was available less that used in other bodily functions (ignoring differences in the efficiency of nitrogen use for the different bodily functions). The objective of the present study was to quantify the genetic variation in NUE and nitrogen excreted in lactating dairy cows and to estimate its correlation with performance traits.

Materials & methods

Data. A total of 4,979 milk, live-weight and intake measures from 1,324 grazing Irish dairy cows of 4 different breeds (i.e. Holstein-Friesian, Jersey, Norwegian Red, and crosses) were available from experiments conducted between 2008 and 2018 on four Teagasc experimental farms. All the cows were milked twice daily. The chemical composition (protein, fat, casein, lactose, and urea concentration) was computed from mid-infrared analysis of consecutive evening and morning milk samples once weekly. Cow live-weight was recorded every 1 to 3 weeks. Individual grass dry matter intake (GDMI) was recorded using the n-alkane technique as described by Dillon and Stakelum (1989) up to four times per lactation. The measure of GDMI was an average of a 6-d measurement period. Concentrate dry matter intake (CDMI) was also recorded during this measurement period. Grass and concentrate crude protein content were available.

Nitrogen use efficiency. Total nitrogen intake (Nintake) was computed as the sum of (GDMI × CP content of grass) plus (CDMI × CP content of concentrate) all divided by 6.25. The nitrogen output in the milk (Nmilk) was computed as the sum of (milk yield × CP content)/6.38 and (milk yield × MUN content); the weekly mean Nmilk coinciding with the week of GDMI measurement was then calculated. The nitrogen fixed in muscles (Nmuscles) was estimated from fitting a mixed model to individual live-weight records of all cows separately from 20 days after first calving until either culling, the date of sale or date of data extraction; a random regression mixed model with quadratic fixed effects and linear random effect for cow was used. The nitrogen fixed in the conceptus (Nconceptus) was computed using a formula of INRA (2018). The nitrogen mobilised or put into reserve was computed as (33/6.25) × the energy balance (according the French Net Energy system) (INRA, 2018), if it was positive, it was considered as nitrogen put in reserve (Nreserve) and if it was negative, its absolute value was consider as nitrogen mobilised from the reserve (Nmob). The nitrogen fixed in product (Noutput) was defined as the sum of Nmilk, Nmuscles, Nconceptus and Nreserve. The nitrogen available (Navailable) was the sum of Nintake and Nmob. Nitrogen balance (Nbalance) was subsequently calculated as Navailable less Noutput. The NUE was defined as the ratio of Noutput to Navailable. (Co)variance components for all traits were estimated using a series of univariate and bivariate animal models in ASREML (version 4.0), with contemporary group (concatenation of farm, treatment and date of milking), the interaction of stage of lactation (9 classes) with parity, heterosis and recombination loss all considered as fixed effects; a direct additive genetic effect along with a within- and across-parity permanent environmental effect of the cow were all included as random effects with a pedigree relationship matrix used to account for relationships among cows.

Results

Cows, on average, ingested 551 grams of nitrogen per day changing across lactation (Figure 1) using, on average, 23.2% of the Nintake for milk, growth and gestation; cows, therefore, on average, excreted 429 g of nitrogen per day in urine and faeces combined (Table 1). The heritability of the Nbalance was 0.13 (0.03) which is less than for the milk traits while the heritability of NUE was 0.06 (0.02) (Table 1). There was a strong genetic correlation between Nbalance and Nintake (0.98), a moderate to strong genetic correlation of 0.71 between milk yield and Nintake and a correlation of 0.64 between milk yield and Nbalance (Table 2). No genetic correlation existed between MUN and either of the two computed nitrogen efficiency metrics (Table 2).

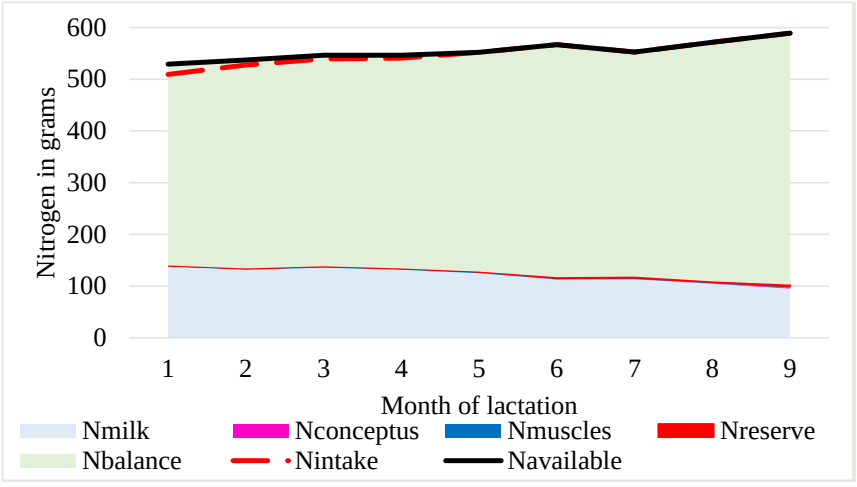

Figure 1. Nitrogen intake and partitioning by month of lactation.

Table 1. Mean, genetic standard deviation (SD), heritability and repeatability with standard errors (SE) of the traits studied.

Trait	Mean	Genetic SD	Heritability (SE)	Repeatability (SE)
Milk yield (kg)	20.2	1.43	0.23(0.04)	0.52 (0.02)
Protein content (%)	3.67	0.16	0.49 (0.05)	0.62 (0.02)
Fat content (%)	4.44	0.39	0.43(0.05)	0.50 (0.02)
MUN (mg/dl)	32.7	2.10	0.20 (0.03)	0.28 (0.02)
Nintake (g)	551	24.05	0.16 (0.04)	0.43 (0.02)
Nbalance (g)	429	17.75	0.13 (0.03)	0.38 (0.02)
NUE (%)	23.2	0.06	0.06 (0.02)	0.25 (0.02)

Table 2. Phenotypic (below) and genetic correlation (above) of the traits studied with their standard errors in parenthesis.

	Milk yield (kg)	Protein content (%)	Fat content (%)	MUN (mg/dl)	Nintake (kg)	Nbalance (kg)	NUE (%)
Milk yield (kg)		-0.58 (0.09)	-0.70 (0.08)	0.10 (0.14)	0.71 (0.10)	0.64 (0.12)	0.49 (0.15)
Protein content (%)	-0.33		0.68 (0.06)	0.10 (0.10)	0.003 (0.12)	-0.03 (0.13)	0.13 (0.18)
Fat content (%)	-0.37	0.47		0.24 (0.11)	-0.08 (0.13)	0.01 (0.13)	-0.45 (0.14)
MUN (mg/dl)	0.03	0.01	0.07		0.24 (0.14)	0.27 (0.15)	-0.07 (0.20)
Nintake (kg)	0.40	0.04	-0.04	0.07		0.98 (0.01)	0.20 (0.23)
Nbalance (kg)	0.23	0.02	0.04	0.06	0.98		-0.01 (0.24)
NUE (%)	0.63	0.05	-0.25	0.04	-0.24	-0.42	

[1] SE range of phenotypic correlation is 0.001-0.02.

Discussion

Almost half of Irish rivers had an unsatisfactory nitrate concentration in 2020 (EPA, 2020). Cows potentially contribute to this since over 70% of the nitrogen ingested by cows is excreted in urine or faeces (Ryan *et al.*, 2011); the mean NUE from the data in the present study was 23.2% so 76.8% of Nintake was excreted by the cows on this study. The relatively high heritability of Nbalance (0.13) means it is more amenable to achieving a higher accuracy of selection thus further improving the potential for genetic gain.

Based on a mean daily Nbalance of 429 g in the present study, a cow is expected to excrete, on average, 131 kg of nitrogen per lactation (i.e. 0.429 N kg/day × 305 day/lactation). Moreover, using the estimated genetic SD of 17.75 g for Nbalance, cows in the top 10% for genetic merit for Nbalance are expected to excrete 9.5 kg less nitrogen per lactation (i.e. 305 days).

No estimates of genetic parameters exist in the scientific literature for either NUE or Nbalance as defined in the present study. Nonetheless, crude protein efficiency, defined as crude protein output in milk divided by the crude protein intake, is commonly used as a nitrogen efficiency indicator. Using a population of 970 American Holstein dairy cows fed in confinement, Vallimont *et al.* (2011) computed a heritability of 0.21(0.06) for this trait while Lopez-Villalobos *et al.* (2018) reported a low heritability of 0.11 (0.08) using 468 New Zealand mixed-breed grazing dairy cows. The present study and the study of Lopez-Villalobos *et al.* (2018) both had low heritability estimates for their nitrogen efficiency approximation, NUE and crude protein efficiency, respectively, which may be linked to the fact that cows were grazing in both studies.

Grazing cow Nintake may be more variable as the grass intake and composition vary during the year, increasing the part of variation explain by the environment, and therefore deflating the heritability.

MUN is commonly used as an indicator of nitrogen efficiency for dairy cows fed in confinement. In the present study, no genetic correlation existed between either Nbalance or NUE with MUN. A positive relationship between MUN and the proportion of nitrogen intake that ended up in milk is often reported but, according to Aizimu *et al.* (2021), this correlation weakens when MUN in high. As grazing cows tend to have a higher MUN than confinement cows, owing to the imbalance between energy and protein intake, and Nmilk is the main part of the Noutput (97% of the Noutput), MUN seemed less sensitive to change of NUE. Thus, MUN does not seem to be a suitable trait to select as a means of trying to reduce the nitrogen excreted by grazing dairy cows.

Conclusions

The results of the present study clearly demonstrate the presence of exploitable genetic variation in several measures of nitrogen intake and efficiency metrics; Nintake seems a good trait to select to reduce Nbalance but Nbalance and Nintake were nonetheless genetically correlated with milk yield implying that genetic selection to reduce nitrogen intake would impact genetic gain for milk yield.

68. Study of the causal relationship between the rabbit cecal microbiota and host's growth and feed efficiency

M. Piles*, M. Mora, J.P. Sánchez, Y. Ramayo-Caldas, O. González-Rodríguez and M. Velasco-Galilea

Institute of Agrifood Research and Technology (IRTA), Animal Breeding and Genetics, Torre Marimon C-59, km 12,1, 08140 Caldes de Montbui, Barcelona, Spain; miriam.piles@irta.cat

Abstract

We proposed a structural equation model to provide a better understanding of how genetic effects directly affect average daily gain on *ad libitum* (ADG_{AL}) and restricted (ADG_R) feeding regimens and how these effects affect those same traits through the microbiota (indirect effects). 138 OTUs (operational taxonomic unit) with structural coefficients statistically different from zero were identified, 104 and 34 had a positive and negative effect, respectively. These OTUs belonged, mostly, to the family *Lachnospiraceae, Ruminococcaeae* and *Clostridiales*. The highest heritability was found for New.Reference369 that belongs to genus *Desulfovibrio* (0.234 (0.091)). This OTU was identified as an important OTU with total negative effect on ADG_R. Members from orders *Bacteroidales* and *Clostridiales* and family *Lachnospiraceae* had a positive and relevant indirect effect on ADG. The contribution of indirect effects to total covariance was greater than 25% for 28 and 17% of the OTUs with a significant effect on ADG_{AL} and ADG_R, respectively.

Introduction

In several studies, the effect of the gut microbiome (M) on phenotypic performance has been studied. The term effect carries a causal meaning but in the case of analysis of the impact of the microbiome on a phenotype, it can be confounded because of the genetic association between the microbiome and the phenotype since both, the relative abundance of microbiota across individuals and the phenotype, can be attributed to host genetic effects. The importance of host genetic effects on growth and feed efficiency (FE) that is exerted through microbiome effects (indirect genetic effects) relative to direct genetic effects is still unknown. Direct and indirect effects could be opposite in sign leading to a null effect of the genotype on the trait if they are of similar magnitude. Structural equation models (SEM) can help to disentangle the complex interplay between the host genome and the microbiome as it allows the decomposition of the total effect on a trait into direct and indirect contributions.

Average daily gain on a restricted feeding (ADG_R) regimen can be considered as a FE trait and used as selection criteria since variation in this trait is directly related to variation in FE because of constant feed intake (FI) (Nguyen *et al.*, 2005; Drouilhet *et al.*, 2016). Both average daily gain on *ad libitum* feeding (ADG_{AL}) and ADG_R are heritable implying that host genetics play an important role in regulating feed utilization and growth (Piles and Sánchez, 2019). On the other hand, it is well known that gut microbiota influences host metabolism (Maltecca *et al.*, 2019) and genome-wide association studies (GWAS) have identified several host genetic variations that affect the gut microbiome composition (Psifidi *et al.*, 2018) and several traits related with growth and feed efficiency (Sánchez *et al.*, 2020). However, it remains unknown whether host genetics affect feed utilization through their ability to promote a favourable and stable microbial community in the gut or whether microbiome and host genetics interact to affect FE and growth.

The objectives of this research are: (1) To identify microbial features with a relevant impact on growth and feed efficiency; and (2) To quantify the relative importance of direct and microbial-mediated genetic effects on total variance and covariances of the same traits.

Materials & methods

Animals and data. Animals came from the Caldes rabbit sire line. At weaning, the animals were randomly assigned to one of the two different feeding regimes: *ad libitum* (AL) or restricted (R) to 75% of the AL feed intake. The individual body weight (BW) was weekly recorded for all animals in both feeding regimes. From BW raw records, individual average daily gain (ADG) was computed as the slope of the within animal regression of all BW measurements on their respective ages in days. This trait was individually computed for each feeding regime, thus obtaining ADG on AL (ADG_{AL}) or R (ADG_{R}). Cecal samples of 425 rabbits of the two feeding regimes were collected. Details about the process of sample processing, DNA extraction and sequencing processes are in Velasco-Galilea *et al.* (2020). After filtering, the OTU (operational taxonomic unit) table contained the sequence counts of 951 OTUs. The analysis was conducted by normalizing the OTU table with the cumulative sum scaling (CSS) method.

Structural equation model. A Bayesian analysis was performed for each combination of both phenotypes (ADG_{AL} and ADG_{R}) and one microbial feature (M, expressed as the relative abundance of a taxon). The SEM for ADG_{AL}, ADG_{R} and the m^{th} microbial feature can be written in the following way:

$$y=\Lambda y+Xb+Z_1l+Z_2c+Z_3u+e \quad (1)$$

Where y is the vector containing the observations for traits ADG_{AL}, ADG_{R} and M (with ADG_{R} as missing value for animals on AL and ADG_{AL} as missing value for animals on R), Λ is a (3×3) matrix with zeros in the diagonal and with structural coefficients (λ) in the off diagonals. Two structural coefficients were considered in this study, $\lambda_{AL\leftarrow M}$ and $\lambda_{R\leftarrow M}$, representing the effect of M on ADG_{AL} and ADG_{R}, respectively; b is the vector of systematic effects with incidence matrix X; this vector included the effects of the factors: the combination of batch and farm (5 levels) and the body weight at weaning (2 levels: big and small); l and c are the vectors of permanent environmental effects of litter (195 levels) and cage (189 levels), respectively; u is the vector of genotypic effects (412 levels) and e the vector of model residuals.

Results

After implementing the SEM, 138 OTUs with structural coefficients statistically different from zero were identified, where 82 OTUs had a statistically significant effect on ADG_{AL} and 80 on ADG_{R}. Of those 138 OTUs, 104 had a positive effect on ADG, where only 14 matched ADG_{AL} and ADG_{R}. Conversely, 34 OTUs had a negative effect on ADG, where 10 matched between the two feeding regimes. However, according to the employed model, neither of the common OTUs had an important effect on the phenotype. The most important OTUs were different for the two feeding regimes, being 860192, a member of genus *Coprobacillus*, the OTU with the most relevant effect on ADG_{AL} (-1.91 g/Normalized OTU count) and New.ReferenceOTU369, taxonomically classified as *Desulfovibrio*, the one with the largest effect on ADG_{R} (-1.93 g/Normalized OTU count), both having a negative effect on ADG. The OTUs with the highest positive effect on this trait belonged to the order *Bacteroidales* (857827) (1.87 g/Normalized OTU count) for ADG_{AL} and to the family *Ruminococcaceae* (New.ReferenceOTU1337) (1.86 g/Normalized OTU count) for ADG_{R}. These structural coefficients indicate the expected change in ADG_{AL} or ADG_{R} when the relative abundance of M increases by 1 unit (in our case in g/ Normalized OTU count).

In general, the estimates of heritabilities for the most important OTUs that affect ADG_{AL} and ADG_{R} were low to medium. Regarding the OTUs that had a meaningful effect on ADG_{AL}, the posterior mean (posterior sd) of heritability ranged from 0.08 (0.05) for New.ReferenceOTU1122 to 0.171 (0.07) for 857827, members of genus *Ruminococcus* and order Bacteroidales, respectively. On the other hand, for OTUs with an important effect on ADG_{R} this parameter ranged from 0.05 (0.03) for a member of genus *Phascolarctobacterium* (New.ReferenceOTU570) to 0.23 (0.09) for New.ReferenceOTU369, which belongs to genus *Desulfovibrio*.

In SEM, variance components correspond to direct effects on ADG_{AL} or ADG_{R}, whereas in MTM they correspond to total effects, i.e. direct plus indirect effects mediated by the microbiota. In general, distributions of total genetic variances and direct genetic variance were slightly different because of the small contributions of the indirect effects. However, for members of order *Clostridiales*, and families *Ruminococcaceae* (New.ReferenceOTU1337) and *Lachnospiraceae* (New.ReferenceOTU381) (Figure 1, panel A) the total indirect effects had an important negative effect on the total genetic variance of ADG_{R} despite the positive value of $\lambda_{R \leftarrow M}$ because of the negative covariance between direct additive genetic effects. The contribution of total indirect effects to total genetic variance was small (less than 10%) for all OTUs.

Regarding associations between ADG_{AL} and ADG_{R} with M, total and direct additive genetic covariance were very similar for members of order *Clostridiales*, OTUs 849147 and New.ReferenceOTU1863, due to the almost null contribution of the indirect effects. Indirect effects of OTU 857827 from order *Bacteroidales* and OTU 825939 taxonomic assigned to order *Clostridiales* had an important positive effect on the covariance with ADG_{AL}, while indirect effects of a member of genus *Desulfovibrio* (New.Reference369) (Figure 1, panel B) and family *Lachnospiraceae* (New.ReferenceOTU381) had an important negative and positive effect on the covariance with ADG_{R}, respectively. The contribution of indirect effects to total genetic covariance was greater than 25% for 28% of the OTUs with a significant effect on ADG_{AL}, and for 17% of the OTUs with a significant effect on ADG_{R}.

Discussion

Feed efficiency and the influence that gut microbiota has on it have been widely studied in the last years in different species like rabbits (Drouilhet *et al.*, 2016), chickens (Wen *et al.*, 2021) and pigs (Bergamaschi *et al.*, 2020). Despite this, the importance of host genetics effects on feed efficiency exerted through microbiome effects is largely unknown. This study provides a better understanding of how genetic effects directly affect ADG_{AL} and ADG_{R} (direct effects) and how these effects affect ADG_{AL} and ADG_{R} through the microbiota (indirect effects). To assess this, a SEM was implemented to determine the causal relationship between the microbiome and the two phenotypes. Knowledge of these effects could help in the design of sustainable approaches to improve growth and feed efficiency in livestock.

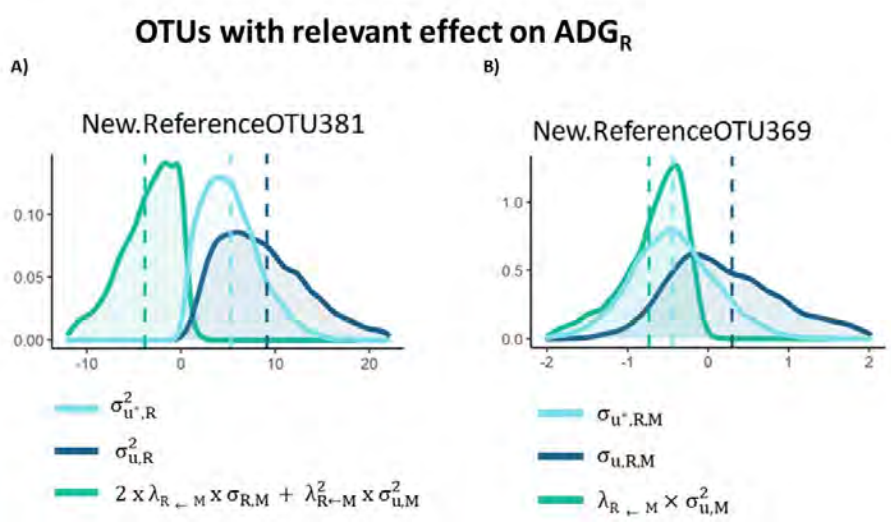

Figure 1. Components of total (light blue) genetic variance (panel A) and covariance (panel B) for ADG_{R}: direct effects (dark blue) and indirect effect (green).

OTUs with an important effect (i.e. structural coefficient) seems to be different for growth and for efficiency. Regarding the contribution of direct and microbial-mediated genetic effects to total genetic variance, only the indirect effects of the family *Ruminococcaceae* (New.Reference1337) and the family *Lachnospiraceae* (New.Reference381, Figure 1 panel A) have a relevant contribution to the total genetic variance of ADG_R. These OTUs had a positive effect on ADG_R but the covariance between M and ADG_R was negative making the contribution of total indirect effects negative.

Concerning the contribution of indirect effects to total genetic covariance between ADG_{AL} and ADG_R with the microbiota, the member from the genus *Desulfovibrio* (New.ReferenceOTU369, Figure 1 panel B) had a negative meaningful effect on ADG_R and the contribution of indirect effects to total covariance is negative and opposite to covariance due to direct effects. This result is in agreement with previous findings in pigs (Bergamaschi *et al.*, 2020; Aliakbari *et al.*, 2021) where members of genus *Desulfovibrio* were identified as being negatively correlated with FE. Members from order *Bacteroidales*, order *Clostridiales* and family *Lachnospiraceae* had a positive and relevant contribution of indirect effect to total covariance with growth and they have been identified in previous studies as members associated with FE in different species (Liu *et al.*, 2021; Velasco-Galilea *et al.*, 2021). For the first time, in this study, the effects that the host genetics exerts on growth and FE (direct effects) and the effects that the host genetics exerts on those traits through the gut microbiota (indirect effects) were evaluated. Knowledge of how direct and indirect effects act on the phenotype is relevant to fully describe the processes of mediation and understand the response in the phenotype if the microbial composition changed.

Abstract

Our research focuses on exploring the possibility of improving feed efficiency in beef through genomic selection of the functional rumen microbiome. Using an environmentally standardized commercial population of 383 crossbred British Blue × Holstein cattle, we demonstrate that the host genome influences microbiome function. A 23% of the 3,594 additive log-ratio transformed microbial gene abundances (*alr*-MGs) identified from whole metagenome sequencing showed significant host genomic effects (heritabilities ranging from 0.15 to 0.66). We also found that 118 of these *alr*-MGs were host-genomically correlated (|0.47| to |0.83|) with feed efficiency. This highlights the strength of correlated host genomic effects of specific microbial processes and feed efficiency and suggests the possibility of improving feed efficiency through a microbiome-driven breeding strategy.

Introduction

Feeding accounts for ~70% of the expenses in commercial beef companies. Any effort to reduce the ratio of feed intake to growth rate will contribute to the economic profit of the industry, but will also help to mitigate the current environmental challenge facing food production systems. Microbial metabolism in the rumen plays a key role in cattle growth performance, as they derive ~70% of their energy and >50% of their aminoacid requirements from microbial fermentation; many microbiome-derived metabolites also act as regulatory signals to the host. The influence of host genetics on the rumen microbiome is now widely recognised, and can likely be explained by genetically influenced host features that favour specific microbial colonisation and their functions in the gut. The main hypothesis of this study is that a substantial part of the host's polygenic control over its feed efficiency is mediated by host-genomic influence on the metabolism of its microbiome, and therefore subjected to genomic selection. In our previous study using an experimental population (Martínez-Álvaro *et al.* 2021), we found that ~18% of the functional core microbiome in the rumen was influenced by the host genome and termed it as host-genomically influenced functional core microbiome (HGFC). In this study, we aim to validate these results by examining the HGFC of a new commercial population of 383 cattle. We also aim to investigate host-genomic correlations between HGFC and feed efficiency, which are critical to obtain animals with more efficient feed fermentation and lower environmental impact by microbiome-driven breeding.

Materials & methods

Animals. Data are from 383 British Blue and Holstein crossbred cattle (230 females and 153 males) balanced along 16 batches reared in Warwickshire (UK) during 2018-2020. At 233±30 days of age, cattle were assessed for feed intake during 35 days using Growsafe (GrowSafe Systems Ltd., Airdrie, Canada) and Integrado (Betim, Brazil) electronic feeding equipment, after a 7-10 day adaptation period. All animals were fed a concentrate-based diet (52.3 g dry matter/kg) and weighed at the beginning (average weight=283±52 kg) and at the end (345±51 kg) of the feeding trial. Their growth rate was calculated as the slope between the weight gain and the days elapsed during the feed intake assessment. Feed efficiency (FCR) was then calculated as the ratio between growth rate (kg/day) and average daily dry matter intake (kg/day).

Genomic and metagenomic data. For host DNA analysis, an ear tissue sample was collected using an Allflex Livestock Intelligence Tissue Sampling Tag (Durham, UK) and stored at -80 °C. Samples were processed and genotyped using the GGP Bovine uLD 35K array (Neogene, Cambridgeshire, UK) and then imputed up to 70K using Eagle (v2.4.1) and Impute (v2). All animals had a call rate>90%. SNPs were filtered (PLINK version 1.09b) for call rates<95%, deviation from Hardy-Weinberg proportions (χ^2 test $P<10^{-8}$), and minor allele frequency<0.05; and 47,206 SNPs remained. For microbial DNA analysis, 5 ml of rumen fluid was collected through an esophageal tube at the end of the feeding trial (at 279±30 days of age), mixed with 10 ml of PBS containing glycerol (87%), and stored at -80 °C. DNA extraction from the rumen samples was performed by bead beating with column filtration, and DNA quality was assessed using Nanodrop ND-1000. DNA Illumina TruSeq libraries were prepared from genomic DNA and sequenced on NovaSeq by Edinburgh Genomics (Edinburgh, UK). Paired-end reads (2 × 150 bp) were generated, resulting in between 15.7 and 58.9 Gigabases per sample. The abundance of 6,963 functional microbial genes (MGs) was determined by comparison with the Kyoto Encyclopedia of Genes and Genomes database (2020-10-04) using KofamScan. To exclude non-core microbiome functions, we used only MGs that were present in >70% of the samples (3,595 MGs). Zero abundances were imputed based on a Bayesian-multiplicative replacement using zCompositions R package. Abundances were then additive log-ratio transformed (3,594 *alr*-MGs) using the abundance of MG NAD+ kinase (*ppnK*) as a reference, selected using the criteria described in Greenacre *et al.* (2021).

Estimation of genomic parameters. Genomic heritabilities (h^2) of FCR and 3,594 *alr*-MG were estimated by fitting 3,595 univariate GBLUP animal models including batch and sex as fixed effects, age as a covariate (for FCR only), and a host genomic effect, assumed to be normally distributed with mean equal to 0 and variance equal to the genomic relationship matrix (VanRaden method 2) multiplied by the genomic variance. Bayesian statistics were used assuming bounded flat priors for all unknowns. Results were based on Markov chain Monte Carlo chains with 1,000,000 iterations (burn-in=200,000, lag=100). The significance of host genomic effects on each *alr*-MG was tested by running models without the host-genomic effect and computing the Deviance Information Criterion difference (DIC_{diff}) between the models, and the Bayes Factor (BF) as the ratio between the means of their posterior likelihood distribution. We accounted for the false discovery rate by setting a BF multitest adjusted threshold to reject the null hypothesis>17.02, as described in Wen *et al.* (2017) assuming an alpha value of 0.01. A joint condition of BF >17.2 and $DIC_{diff} \leq -10$ was required to consider the genomic model more plausible that the model without host-genomic effect. Genomic correlations between FCR and *alr*-MGs (rg_{FCR}) with significant host-genomic effects (n=841) were calculated by fitting 841 bivariate GBLUP animal models, with the same effects as for univariate models and the same assumptions, extended for two traits. To examine their confidence level, we estimated the posterior probability that rg_{FCR} was positive or negative and considered it significant when ≥90%.

Results

In our commercial population, 24% of the phenotypic FCR variation among cattle was explained by host genomic variation (s.e. 13%), and the host-genomic effects on FCR were highly evident ($BF=1.19\times10^{+3}$ and DIC_{diff} = -27.3). Host-genomic effects were significant in ~23% of the functional core microbiome (841/3,594 *alr*-MGs tested), which cumulatively accounts for 6.6% of the total relative abundance in the rumen. The h^2 estimates of this HGFC microbiome, which ranged from 0.15±0.09 to 0.66±0.18 (Figure 1a), indicate that the rumen microbiome is exploitable by genomic selection. These *alr*-MGs are involved in a variety of metabolic functions that could play a key role modulating the nutrient flux available for host growth: e.g. sulfur metabolism (h^2 of *cysU, cysD,* and *cysN* ranged from 0.37±0.16 to 0.46±0.16), synthesis of cysteine, methionine, and arginine (*speE, metN, metC, urea, ureC*) or production of propionate and butyrate (*ACAT*, *alsD*, *cat2*, *pduP*, *lcdA*, *prpF*), all with $h^2 \geq 0.20\pm0.11$. Others could be important

determining microbial fermentation by regulating H_2 intraluminal pressure; e.g. *mtrB*, *mvhD*, *fdhB*, *hdrA2* in methane metabolism presented $h^2 \geq 0.28 \pm 0.13$. Importantly, HGFC also contained *alr*-MGs involved in cell-to-cell microbial communication processes such as quorum sensing (e.g. ABC.PE-*S* and ABC.PE.*P*) and also in genetic processes such as ribosomal biosynthesis (e.g. *RP-L7*, *RP-L2*). Of the 841 *alr*-MGs comprising the HGFC, 118 had rg_{FCR} estimates with $P_0 \geq 90\%$; 48 of them were positive (rg_{FCR} from 0.5 to 0.8), and 70 negative (rg_{FCR} from -0.47 to -0.83) (Figure 1b), suggesting that a part of the HGFC is under common host genomic influence with FCR. Interestingly, the abundance of *mtrB* and *mvhd* in methane metabolism was associated with less efficient animals (rg_{FCR}=0.53 and 0.56, P_0=0.90 and 0.91), whereas the abundance of those involved in the production of aminoacids (*metC, metN, ureA, ureB, speB*) or volatile fatty acids (*ACAT*), sulfur metabolism (*cysD*) or quorum sensing (ABC.PE.*S*) were associated with more efficient hosts (rg_{FCR} -0.54 to -0.73, $P_0 \geq 0.90$).

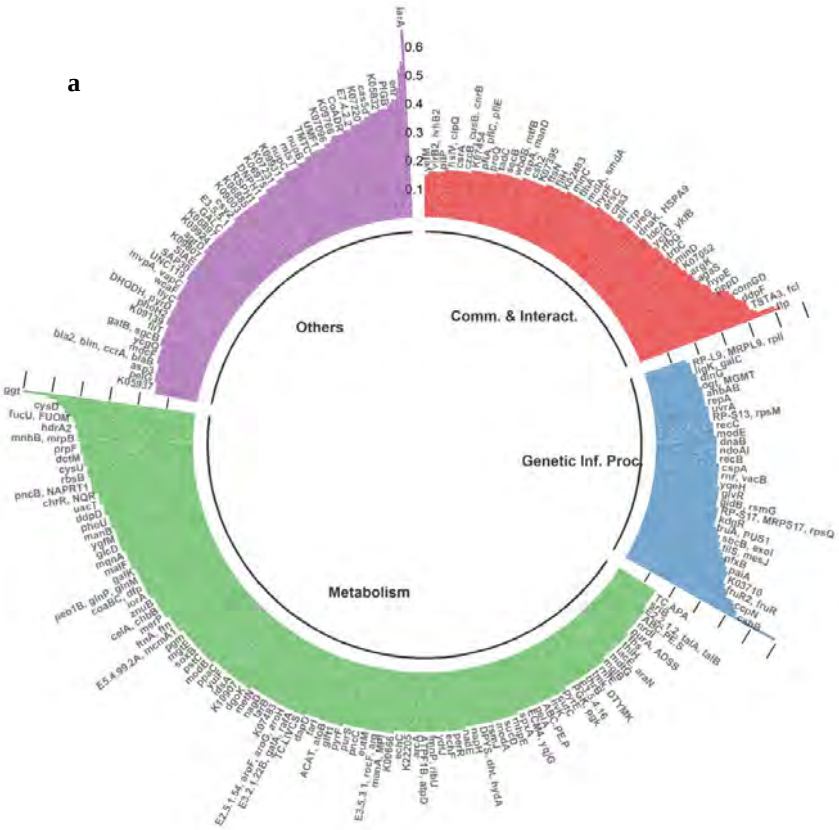

Figure 1. Genomic parameters of additive log-ratio transformed abundances of microbial genes (*alr*-MGs) in the rumen of beef cattle. (a) Heritability estimates of 841 *alr*-MGs with significant host genomic effects based on Bayes Factor>17.2 and Deviance Information Criterion difference≤-10, comprising the host-genomically influenced functional core microbiome (HGFC).

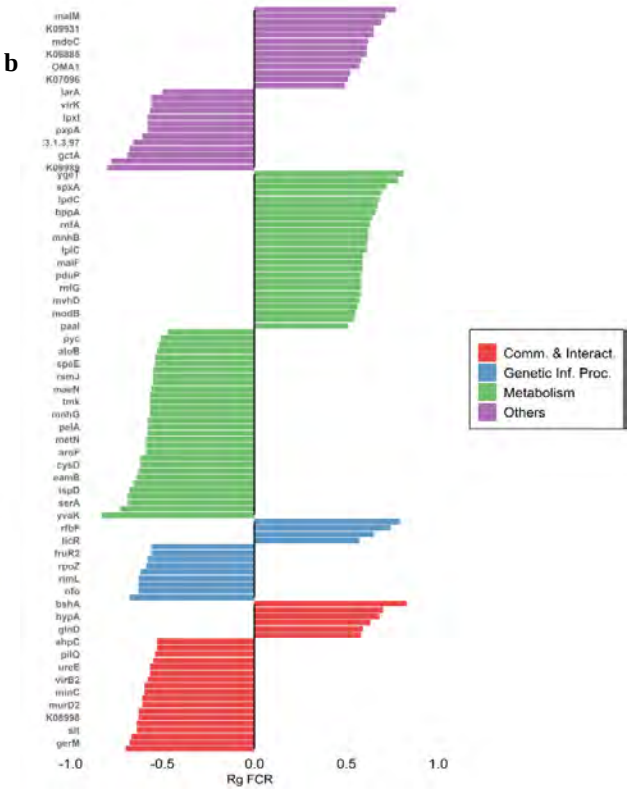

Figure 1. Continued. (b) Genomic correlations between feed efficiency (rg_{FCR}) and 118 *alr*-MGs from the HGFC for which rg_{FCR} was ≥90% likely to be positive or negative. Microbial genes are grouped according to microbial biological processes: Microbial communication and host-microbiome interaction (Comm. & Interact.), Genetic information processes (Genetic Inform. Proc.), Metabolism, and Others.

Discussion

Our study suggests that differences among animals in complex functions of the microbiome are partly (~23%) under the control of the host genome, which is consistent with our previous findings in other experimental populations (~18%), and raises the possibility of exploiting a new source of genetic variation in ruminants. Interestingly, some of the *alr*-MGs with positive rg_{FCR} are involved in methane metabolism (*mtrB and mvhd*), and others with negative rg_{FCR} (*metN*) were estimated to have favourable r_g with methane emissions in a previous study (unpublished data). This suggests that genomic selection on the functional microbiome could be a cost-effective permanent solution to achieve a ruminal balance that optimises fermentation of feed into essential nutrients utilised by the host, while favouring other traits as mitigation of emissions of the greenhouse gas methane.

70. Identifying diversity in cattle performance using Bayesian inference and a model

J.F. Ramirez*, L. Puillet and N.C. Friggens

Université Paris-Saclay, INRAE, AgroParisTech, UMR Modélisation Systémique Appliquée aux Ruminants, 75005 Paris, France; johnfredy.ramirezagudelo@inrae.fr

Abstract

Quantitative description of individual animal performance is a key element of breeding. In addition to measurements of traits associated with productivity, dynamic-mechanistic models can be used for identifying diversity of complex traits like feed efficiency. The objective of this work was to use Bayesian inference to quantify differences in a model's 'genetic-scaling' parameters (related to resource acquisition and resource allocation) within- and between-breeds. We first describe the experimental data processing before calibration, the function used for the error calculation, and the Bayesian algorithm used for parameter inference. Two databases were used as case studies. The results showed that this approach allowed us to identify variations in the genetic-scaling parameters within- and between-breeds. This approach is a useful tool to quantify complex traits for future selection of efficient and resilient animals.

Introduction

In breeding programs, most of the emphasis has been made on traits directly associated with productivity, such as milk yield or daily weight gain. However, the biological mechanisms underlying productivity are difficult to be taken into account for selection. When direct measurements of biological mechanisms are difficult or even impossible, mechanistic models allow estimation of these underlying traits by individual parametrization of a model. Puillet *et al.* (2016) developed a dynamic-mechanistic model (AQAL) to generate genetically-driven trajectories of energy acquisition and allocation in dairy cows lifespan, with four genetic-scaling parameters (GSP). For a given individual, the simulated performance is the result of the combination of a capacity to acquire resources and how these acquired resources are allocated to different life functions. This model was used to evaluate the extent of genotype by environment interaction for feed efficiency traits (Puillet *et al.*, 2021), demonstrating the usefulness of mechanistic modelling in breeding strategies evaluation. In this type of model, Bayesian inference can be used to quantify the uncertainty in the parameter values, because the parameters are treated as random variables with an underlying probability distribution that describes them (Miles and Smith, 2019). This work presents a protocol to use Bayesian inference for within- and between-breeds characterization of resource acquisition and allocation parameters. The protocol presented here aims to provide a comprehensive description for the individualized calibration of AQAL in Python. First, we describe the observed data processing before calibration. Then, we describe the general structure of the calibration process. We illustrate the application of the protocol for two case studies.

Materials & methods

Time-series observations, data handling before calibration. For calibrating AQAL, experimental data is necessary to run the model and to compute the error. The model uses a vector of values to represent the increase in intake per lactation through the cow's lifespan. This vector must be defined by using the relationship among the averages of the maximum values (upper quartile) of milk yield observed in each lactation. The energy value of the diet (GE or ME) is another model input. At least three traits must be used to calculate the differences between simulated and experimental data: milk yield (MY), body weight (BW), and body condition score (BCS, 1-5 scale). MY must be expressed in kilocalories of metabolizable energy (ME) assuming a metabolic efficiency of 0.64, and gross energy content (GE, kcal/kg) of 5,700, 9,200, 3,950 for protein, fat, and lactose.

Formulation of the objective function. In each iteration of the calibration process, the objective function uses the set of parameters generated by the Bayesian algorithm and returns the mismatch between the simulation and the experimental values of MY, BW, and BCS. We used the Mean Absolute Percentage Error (MAPE) to quantify the mismatch because this metric avoids the effect of the trait scales on the average error calculation. One MAPE is calculated for each variable × lactation, then the overall average MAPE was calculated from these individual variable × lactation MAPEs. To minimize the effect of unbalances among the individual errors, the overall error variance was added to the overall MAPE. After calibration, the minimum value of this sum was used to identify the best parameter set for a given individual animal.

Parameter optimization. In the Bayesian approach, the goal of the calibration is to infer the parameter posterior distributions given a set of observations (Miles and Smith, 2019). For parameter generation, we adopt an approximate-inference technique based on Monte Carlo methods, which aims at generating a sequence of random parameters from a Markov chain whose distributions approach the posterior distributions of each parameter. In particular, we have used the delayed rejection adaptive Metropolis (DRAM) algorithm (Haario *et al.*, 2006) implemented for Python in the 'pymcmcstat' library (Miles and Smith, 2019). The adaptive Metropolis (AM) component in DRAM means that each parameter is generated following the distribution calculated with all of the previous states in the chain. The delayed rejection (DR) mechanism is used to stimulate mixing by sampling from a narrower proposed distribution when a parameter sample is rejected (Haario *et al.*, 2006). Information known a priori about the parameter distributions is defined in the prior function; however, the default program behaviour is to use a uniform prior which is a common approach for these types of problems. (Miles and Smith, 2019). The parameters optimized were related to acquisition: *acq_bas_pot*, *acq_bas_lac* (basal and an additional lactation acquisition), and allocation of energy resource: *init_G*, *s2pc_pot*, (growth and lactation allocation).

Case studies. Two databases were used to test our parameters inference procedure. The first database (One-Breed) contains data from 26 Holstein cows. This database reported at least four lactations for all cows. The second database (MEMO, see Friggens *et al.* 2007) contains data from three breeds (18 Holstein, 17 Red Danish, and 19 Jersey cows). This database reported at least three lactations for all cows. Both databases report measures of MY and composition, BW, and BCS. The first and second databases were used to examine within- and between-breed diversity of the four GSP of AQAL, respectively.

Results

Figure 1 shows an example of simulation, using the best set of parameters for a specific cow, and observed data of MY, BW, and BCS. Figure 2 shows an example of the Markov chains for a specific cow. The points in charts of Figure 2 correspond to the accepted parameters values in each iteration. The first half of each chain served to tune the sampler and was discarded (burn-in period). To approximate the posterior distribution for each parameter, parameter sets with low error from the second half of each chain were used. Figure 3 compares the parameter distributions for a specific cow and the breed (One-Breed database). Figure 4 shows the parameter distributions for the three breeds (Holstein, Red Danish, and Jersey) in the MEMO database. The parameters *acq_bas_pot* and *acq_bas_lac* are expressed in kilograms of dry matter, the parameters init_G and s2pc_pot are dimensionless. Table 1 presents the average parameters values and the associated variance.

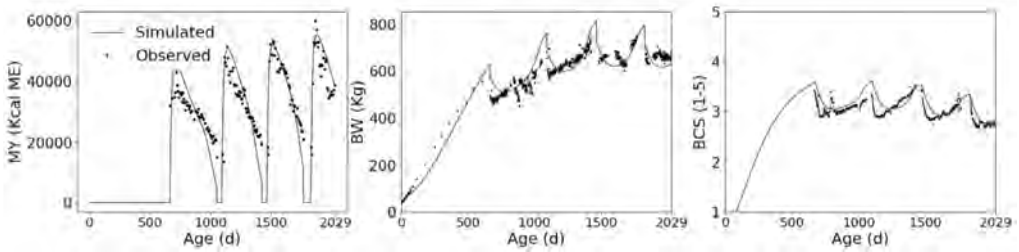

Figure 1. Example of simulation results with the best set of parameters for an individual.

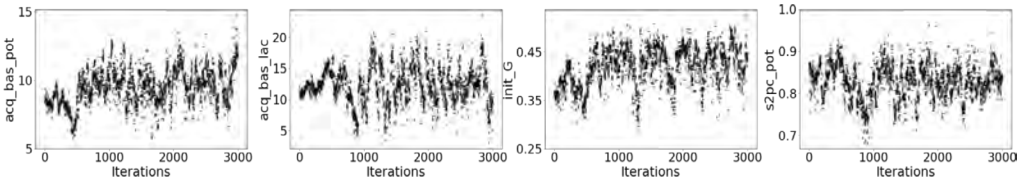

Figure 2. Example of the Markov chains of genetic-scale parameters.

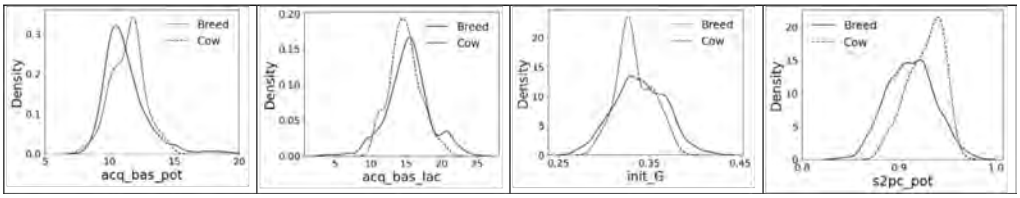

Figure 3. Posterior distributions of the genetic-scale parameters for a breed and an example of one individual of that breed.

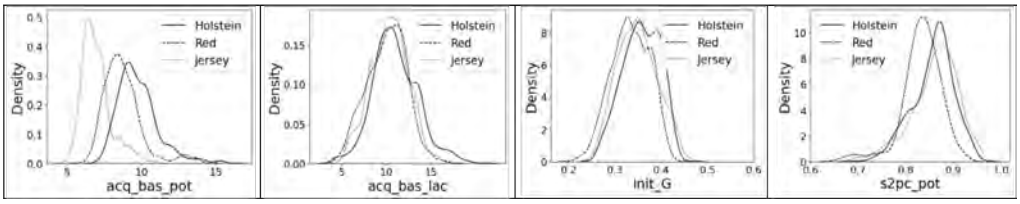

Figure 4. Posterior distributions of the genetic-scale parameters between breeds.

Table 1. Parameter values per database and breed.

Parameters	One-breed	MEMO		
		Holstein	Danish Red	Jersey
	Median (Std)	Median (Std)	Median (Std)	Median (Std)
acq_bas_pot	11.1 (1.3)	9.9 (1.1)	8.8 (1.3)	7.2 (1.3)
acq_bas_lac	16.1 (2.9)	12.0 (2.0)	10.9 (1.4)	10.4 (1.8)
init_G	0.34 (0.025)	0.36 (0.039)	0.33 (0.040)	0.35 (0.037)
s2pc_pot	0.92 (0.022)	0.86 (0.030)	0.84 (0.029)	0.86 (0.042)

acq_bas_pot, *acq_bas_lac:* basal and an additional lactation acquisition (kg of DM).
init_G, *s2pc_pot:* growth and lactation allocation (Dimensionless).

Discussion

We chose to use a Bayesian method for parameter estimation because we expected to explore different local minima within the response surface of the objective function (since the model contains multiple nonlinear functions). In this context, the Bayesian inference used (DRAM) was an efficient method to explore the parameter space, showing the power of the proposed method for this type of task. The results allow us to demonstrate the ability of a dynamic-mechanistic model to identify variations in GSP both within- and between-breeds. This is very interesting for the future identification and selection of efficient and resilient animals because dynamic-mechanistic models (e.g. AQAL) can simulate the consequences of different combinations of acquisition and allocation parameters on animal performance under different nutritional environments (see Puillet *et al.*, 2021).

Abstract

The objective of this study was to compare three-breed rotational crossbred (CB) cows of the Montbéliarde, Viking Red, and Holstein (HO) breeds with HO cows fed two alternative diets for dry matter intake (DMI), fat plus protein production (CFP), body weight (BW), body condition score (BCS), feed efficiency and residual feed intake (RFI) from 46 to 150 days in milk during first lactation. Cows were fed either a traditional total mixed ration (TMR) diet (TRAD) or a higher fibre, lower starch TMR diet (HFLS). The CB cows fed HFLS had less DMI (-12%) compared with the HO cows fed TRAD. For CFP, CB and HO cows were not different when fed TRAD or HFLS. The mean RFI from 46 to 150 days was lower and more desirable for CB cows fed HFLS (-120.0 kg) compared with HO cows fed TRAD (85.3 kg).

Introduction

Feed costs impact the profitability of dairy farms and represent 47% of the total costs of U.S. milk production. In recent years, dairy producers have experienced volatility of cost when purchasing grain for dairy cow diets. Therefore, dairy producers have explored alternative diets for dairy cattle that contain more forage and less concentrate to improve feed efficiency and profitability. Research of crossbred (CB) cows has predominantly focused on production, fertility, and health, but little research has compared CB cows and Holstein (HO) cows for feed efficiency. The dry matter intake (DMI) and feed efficiency of CB and HO cows fed the same TMR have been compared in confinement herds (Heins *et al.*, 2008; Hazel *et al.*, 2013). Shonka-Martin *et al.* (2019) reported 3-breed CB cows of Montbéliarde (MO), Viking Red (VR), and HO breeds had a lower mean RFI compared with HO cows fed a similar TMR during the first 150 days of first lactation. Dairy producers have hypothesized three-breed rotational CB cows of MO, VR, and HO are more feed efficient than HO cows fed a TMR with more fibre and less starch. Currently, a TMR based on corn silage is fed to most cows in confinement herds in the U.S., and dairy producers have explored alternative diets to improve nutrient digestibility, feed efficiency and profitability of cows. Therefore, the objective of this study was to assess the effects of feeding two alternative diets to three-breed rotational CB cows of MO, VR, and HO versus HO cows for DMI, fat plus protein production, body weight, BCS, feed efficiency, and RFI from 46 to 150 days in milk during first lactation.

Materials & methods

Cows were housed at the Dairy Cattle Teaching and Research Facility of the University of Minnesota in St. Paul, USA. Primiparous cows calved from September 2019 to March 2020. In total, 36 cows (17 CB, 19 HO) were unimpaired experimental units with data available from 46 to 150 days in milk.

Collection of feed intake and diets. Cows were assigned to an individual tie stall in a confinement barn for the duration of the study, and the feed mangers were partitioned to provide each cow an exclusive feeding space. The feed delivered and the refusals were electronically recorded with Feed Supervisor (Supervisor Systems, Dresser, WI) software. Diets fed to cows were formulated by a professional nutritionist to meet or exceed dairy NRC requirements. The two diets were formulated to have equivalent net energy content of 1.6 Mcal/kg and CP of 16.8%. Cows were paired by expected calving date and subsequently assigned randomly to a traditional diet (TRAD) or a higher fibre, lower starch diet (HFLS) that were both fed as

DOI: 10.3920/978-90-8686-940-4_71, © B.J. Heins *et al.* 2022

a total mixed ration (TMR). Diets were composed of corn silage, chopped alfalfa hay, corn gluten feed, cottonseed, ground corn, molasses, concentrate supplements and vitamins and minerals

The daily feed intake multiplied by the average monthly dry matter for TRAD and HFLS provided daily DMI for individual cows, and these were smoothed using the mean of seven days (the actual day, the third days before and the third days after). Legendre polynomial random regression function was used to estimate 105-day lactation curves for DMI from 46 to 150 days in milk with four parameters from PROC HPMIXED of SAS. Daily milk production was the sum of the morning and evening milking. Fat, protein, and lactose percentage were from twice monthly Dairy Herd Improvement Association samples (Minnesota DHIA, Buffalo, MN). The BW and body condition score (BCS) were recorded once weekly. The BW was recorded on individual cows with an electronic scale as cows exited the milking parlour during the morning milking. The BCS was recorded by one person throughout the study on a five-point scale with one = thin and five = fat.

Feed efficiency and residual feed intake. The regression coefficients (energy sinks) to estimate RFI of cows were energy expended in milk (MilkE), metabolic BW (MBW) and the energy for BW change (BWCE; Hardie *et al.*, 2015; Shonka-Martin *et al.*, 2019). The MilkE was estimated according to the NRC (2001) as MilkE = 9.29 × fat (kg) + 5.63 × protein (kg) + 3.95 × lactose (kg). Legendre polynomial random regression function was used to estimate 105-day lactation curves for MilkE from 46 to 150 days in milk with three parameters from PROC HPMIXED of SAS. Estimates for daily MilkE were summed from 46 to 150 days in milk to determine total MilkE for each cow. The MBW reflected the maintenance requirements for a cow and was calculated as $BW^{0.75}$ with the mean BW of each cow from 46 to 150 days in milk. The BWCE was estimated as BWCE (Mcal/d) = body weight change (BWC; kg/d) × (2.88 + 1.026 × BCS) × 0.85 (NRC, 2001; Hardie *et al.*, 2015; Shonka-Martin *et al.*, 2019). The BCS was the mean BCS of each cow from 46 to 150 days in milk. The MilkE, MBW, and BWCE were energy sinks in the statistical model to estimate RFI. The RFI was defined as the error term (ε_i) from the regression model:

$$DMI_i = \beta_0 + \beta_1 \times MilkE_i + \beta_2 \times MBW_i + \beta_3 \times BWCE_i + \varepsilon_i \quad (1)$$

where DMI_i is the total DMI from 46 to 150 days in milk for the i^{th} cow; β_0 is the intercept and β_1, β_2, β_3 are the regression coefficients for MilkE, MBW and BWCE from 46 to 150 days in milk, respectively. All CB and HO cows were analysed simultaneously.

Statistical analysis. Independent variables for the statistical analysis of DMI, CFP, BW, BCS, feed efficiency and RFI were the fixed effects of diet (TRAD or HFLS) and breed group (CB or HO) as well as the interaction of diet and breed group. The PROC GLM of SAS was used to conduct the ANOVA and obtain solutions.

Results

The least squares means and standard errors of means from 46 to 150 days in milk of DMI, CFP, BW, BCS, Milk energy, metabolic body weight, body weight change in energy, and RFI are in Table 1. The HO cows fed TRAD (2,592 kg) had more (P<0.05) DMI than HO cows fed HFLS (2,229 kg) and CB cows fed HFLS (2,278 kg). The CB and HO cows that were fed TRAD and HFLS were not different for DMI. The CB and HO cows were not different across diets for CFP. The BW did not differ for CB and HO cows that were fed TRAD. The BCS was higher (P<0.05) for CB cows fed either TRAD or HFLS compared with HO cows fed either TRAD or HFLS. The CB cows were not different for BCS whether fed TRAD or HFLS, and the HO cows were not different for BCS across the two diets.

The CB cows that were fed HFLS (121 kg) had more (P<0.05) MBW compared with HO cows that were fed HFLS (114 kg). The CB cows that were fed either TRAD or HFLS had more (P<0.05) BWCE than HO cows that were fed HFLS. The HO cows fed TRAD had more (P<0.05) BWCE compared with HO cows that were fed HFLS. The RFI was lower (P<0.05) for CB cows that were fed HFLS (-120.0 kg) compared with the HO cows that were fed TRAD (+85.3 kg), and less RFI is favourable.

Discussion

The lower DMI, higher BCS, and similar CFP for CB cows fed HFLS compared with HO cows fed TRAD in this study may suggest improved profitability when cows are fed alternative diets. Perhaps, the CB cows used DMI beyond their needs for production and maintenance for higher BCS. This study only investigated 46 to 150 days in milk of first lactation, and additional research is needed to compare multiple lactations of CB and HO cows across 305 days. Dairy producers initially moved to CB cows to improve health and fertility; however, dairy producers may improve profitability of dairying with CB cows fed higher forage and lower starch diets.

The partial regression coefficients were similar to those of Shonka-Martin *et al.* (2019) who reported coefficients of 0.75, 8.45, and 0.62 for MilkE, MBW, and BWCE respectively for 3-breed rotational CB cows of MO, VR and HO and HO cows that were fed the same diet. The CB cows fed HFLS had lower mean RFI than HO cows fed TRAD but did not differ for MilkE, MBW and BWCE. Furthermore, CB cows fed HFLS consumed less DMI than HO cows fed TRAD. The more favourable RFI for the CB cows fed HFLS met expectations because the CB cows that were fed HFLS had less DMI (-314 kg) and had lower DMI/BW (-0.63) than HO cows that were fed TRAD. Similarly, Shonka-Martin *et al.* (2019) reported three-breed rotational CB cows of MO, VR and HO had a lower mean RFI (-65.5 kg vs +68.8 kg) than HO cows during the first 150 day of first lactation.

In the current study, the CB cows fed HFLS may have had more maintenance requirement for BW; however, CFP and MilkE were not different for the CB and HO cows. The RFI does not consider change in BCS, as well as body measurements (stature, dairy strength, and body depth), fertility and longevity. Therefore,

Table 1. Least square means and their SE for DMI, CFP, BW, BCS, and feed efficiency from 46 to 150 days in milk for primiparous Holstein and 3-breed rotational crossbred cows fed a traditional and a higher fibre lower starch diet.[1,2]

Variable	Traditional				Higher fibre lower starch			
	Holstein		Montbéliarde/Viking Red/ Holstein		Holstein		Montbéliarde/Viking Red/ Holstein	
	LSM	SE	LSM	SE	LSM	SE	LSM	SE
DMI	2,592^{a}	99.2	2,436^{ab}	109.7	2,229^{b}	116.3	2,278^{b}	116.3
CFP	269	7.2	256	7.9	256	8.4	255	8.4
BW	586^{ab}	14.8	576^{ab}	16.3	550^{a}	17.3	600^{b}	17.3
BCS	3.19^{a}	0.1	3.64^{b}	0.1	3.02^{a}	0.1	3.64^{b}	0.1
MilkE	2,808	74.8	2,651	82.7	2,645	87.8	2,610	87.8
MBW	119^{ab}	2.3	117^{ab}	2.5	114^{a}	2.7	121^{b}	2.7
BWCE	342^{a}	24.8	447^{b}	27.4	264^{c}	29.0	377^{ab}	29.0
RFI	85.3^{a}	56.7	0.8^{ab}	62.7	1.8^{ab}	66.5	-120.0^{b}	66.5

[1] Means within a row with different superscripts differ P<0.05.

[2] BWCE = the energy for body weight change; MBW = metabolic body weight; MilkE = milk energy.

RFI may be underestimated in the current study for CB cows compared with HO cows. Dairy producers may feed either TRAD or HFLS to CB cows without loss of CFP. For HO cows, the DMI was less for the cows that were fed HFLS compared with the cows that were fed TRAD. Less RFI for the CB cows fed HFLS compared with the HO cows that were fed TRAD indicated that the CB cows were more feed efficient than HO cows. Genetic selection of feed efficient cows should not be based solely on reducing DMI, but should consider BW, BCS, production, health, fertility, and longevity.

Abstract

This study aimed at determining genetic associations between production traits with feed efficiency and immune traits pre- (eight to 20 weeks) and post (90 days from on-set of lay) maturity in indigenous chicken. Production traits were body-weight at week 12 (BW_{12}) and age at first egg (AFE). Feed efficiency included residual feed intake (RFI) and feed conversion ratio (FCR). Immunity included natural antibodies binding to keyhole limpet hemocyanin (KLH-IgM) and specific antibodies binding to Newcastle disease (NDV-IgG). Heritability estimates in the two periods across traits varied from 0.10 to 0.51. Genetic correlations showed that BW_{12} was negatively correlated with RFI but positively with FCR, KLH-IgM and NDV-IgG in the growing period. Post maturity, AFE was positively correlated with RFI but negatively with FCR, KLH-IgM and NDV-IgG. Results from this study indicate that selection for productivity may have genetic consequences on feed efficiency and immune-competence and this relationship should be considered.

Introduction

Indigenous chicken (IC) play significant roles in nutrition, food security and economic growth in many rural households in most countries in the tropical regions. In Kenya, these chicken are produced under challenging environments (scarce feed resources and high exposure to myriad pathogens) limiting their optimal utilization (Lwelamira *et al.*, 2009). Nevertheless, the Kenyan IC is a highly diverse population with a large plasticity in genomic regions that confer adaptability to scavenging conditions, poor nutrition and tolerance to pathogens (Ngeno *et al.*, 2015). Consequently, efforts are underway to exploit the genetic diversity of IC population to improve their productivity. Selection for production is likely to influence resource partitioning. With resource scarcity, preferential partitioning of resources to specific functions is inevitable. This leads to trade-offs between different functions in the body e.g. high growth rate and low antibody response upon disease challenge (Van der Most *et al.*, 2010). This demonstrates competitive nutrient partitioning between growth and immune functions, and also suggests possible involvement of pleiotropic gene action. Considering IC ability to produce and survive in poor conditions, studies on the impact of improving their growth or egg production on resource use efficiency and immunity are sparse. The current study aimed at estimating genetic and phenotypic correlations among production, feed efficiency and immune traits pre- and post-maturity in indigenous chicken.

Materials & methods

The study was conducted at the poultry research unit of Kenya Agriculture and Livestock Research Organization (NRI-KALRO), Naivasha. The IC population under the chicken breeding program at NRI-KALRO are under continuous selection to develop meat (ML) and egg (EL) lines. The ML is selected for body weight at 12 weeks of age (BW_{12}) while EL is selected based on age at first egg (AFE) (Ilatsia *et al.*, 2017). Five generations of these chicken comprising of a base generation/control line (CL), and four generations of both ML and EL were used. Management of the experimental population followed the standard operating

procedures of the breeding program at NRI-KALRO (Ilatsia *et al.*, 2017). From week eight, the birds were transferred to individual feeding units for individual weight and feed intake data collection. Routine health management involved vaccination against Marek's disease, infectious bursal disease, Newcastle disease, Fowl pox and Fowl Typhoid which are endemic, deworming and disinfection.

Data collection. Data on BW_{12} was recorded while date of hatch and first egg were used to compute AFE in the ML and EL. On both lines, daily feed intake and monthly weight records were collected and used to compute average daily feed intake (ADFI), average daily gain (ADG) and metabolic body weight (MBW), residual feed intake (RFI) and feed conversion ratio (FCR) in the growing period (eight to 20 weeks) (Miyumo *et al.*, 2016). At onset of lay, initial body weight, daily feed intake, egg number and weight recording commenced and continued until day 90, in which final body weight was measured. Using these traits, estimation of ADFI, ADG, MBW, average daily egg mass (EM), RFI and FCR in the laying period was done as described by Yuan *et al.* (2015). To assess antibody traits during the growing and laying periods, birds were blood sampled at 16 and 28 weeks of age, respectively. Natural antibodies (Nabs-IgM isotype) binding to keyhole limpet hemocyanin (KLH) and specific antibodies (IgG isotype) binding to Newcastle disease virus (NDV) were evaluated; KLH antigen was used based on its suitability to test Nabs (Van der Klein *et al.*, 2015) while NDV was considered due to its impact on IC populations (Lwelamira *et al.*, 2009). Antibodies KLH-IgM and NDV-IgG were measured using indirect ELISA (Enzyme-linked Immunosorbent assay). In the growing period, 1,279 records on BW_{12}, 721 records on each of the feed efficiency traits and 1,162 records on each of the antibody traits were available for analyses. In the laying period, 652 records on AFE, 578 records on each of the feed efficiency traits and 652 on each of the antibody traits were used in the analyses.

Statistical analysis. A series of bi-variate mixed animal models were fitted to estimate trait heritabilities as well as genetic and phenotypic correlations among BW_{12}, AFE, RFI, FCR, KLH-IgM and NDV-IgG by restricted maximum likelihood using the WOMBAT software (Meyer, 2007). The model included sex, generation and line as fixed effects and a random animal and a random residual effects. Due to the various combinations of the bi-variate models, the resulting variance components and variance ratios were pooled by weighting each estimate by the inverse of its sampling variance to obtain global estimates.

Results

Genetic parameters on production, feed efficiency and immune traits during the growing and laying periods are presented in Table 1. Heritability estimates across the traits ranged from 0.10 to 0.44 in the growing period and from 0.25 to 0.51 in the laying period. Genetic correlations (r_g) among the traits varied between the two production periods. During the growing period, BW_{12} was negatively (r_g=-0.96) associated with RFI but positively correlated with FCR (r_g=0.29) and KLH-IgM (r_g=0.47) with low association with NDV-IgG (r_g=0.06). There were negative correlations between RFI and FCR (r_g=-0.99), and between KLH-IgM and NDV-IgG (r_g=-0.85). Between efficiency and immunity, RFI was positively correlated with KLH-IgM (r_g=0.92) and NDV-IgG (r_g=0.78). In the laying period, AFE was positively (r_g=0.35) correlated to RFI but negatively associated with FCR (r_g=-0.44) and the immune traits (r_g=-0.12 to -0.39). On the other hand, there were negative correlations between RFI and FCR (r_g=-0.41), and between KLH-IgM and NDV-IgG (r_g=-0.99). Between efficiency and immune measures, RFI was positively correlated to KLH-IgM (0.40) and NDV-IgG (0.50). Genetic correlations of traits between the growing period and laying period are presented in Table 2. Between the two production traits, BW_{12} and AFE were negatively (r_g=-0.88) correlated. For RFI, KLH-IgM and NDV-IgG, the correlations were positive (r_g=0.62 to 0.99) between the two production phases.

Table 1. Estimates of heritability[1] (diagonal), genetic (lower diagonal) and phenotypic (upper diagonal) correlations on production, efficiency and immunity traits.

	Growing period (9 to 20 weeks of age)

[1] ±SE = standard errors.

[2] BW_{12} is body weight at week 12; AFE is age at first egg; RFI is residual feed intake; FCR is feed conversion ratio; KLH-IgM is natural antibody IgM isotype binding to KLH antigen; NDV-IgG is specific antibody IgG isotype binding to NDV antigen.

Table 2. Genetic (r_g) and phenotypic (r_p) correlations on production, efficiency and immunity traits between the growing and laying periods.

Growing period[1]	**Laying period[1]**	**r_g**	**±SE**	**r_p**	**±SE**
BW_{12}	AFE	-0.88	0.38	-0.08	0.05
RFI_1	RFI_2	0.99	0.12	0.04	0.01
FCR_1	FCR_2	0.19	0.18	0.08	0.04
$KLH\text{-}IgM_1$	$KLH\text{-}IgM_2$	0.62	0.21	0.05	0.03
$NDV\text{-}IgG_1$	$NDV\text{-}IgG_2$	0.82	0.17	0.09	0.03

[1] BW_{12}, AFE, RFI, FCR, KLH-IgM and NDV-IgG are as described in Table 1: RFI_1, FCR_1, $KLH\text{-}IgM_1$ and $NDV\text{-}IgG_1$ are traits measured in the growing period; RFI_2, FCR_2, $KLH\text{-}IgM_2$ and $NDV\text{-}IgG_2$ are traits measured in the laying period.

Discussion

Heritability estimates across the traits in both periods (apart from NDV-IgG in the growing period) suggest that adequate additive genetic variance exist, which could be exploited for selection. Genetic associations between production and efficiency traits indicated that genetic improvement for BW_{12} and AFE would be accompanied with lower RFI values (high efficiency) but higher FCR values (low efficiency). Although both are measures of feed efficiency, the disparity in correlation patterns with BW_{12} and AFE could be due to RFI accounting for maintenance function while FCR does not (Yuan *et al.*, 2015). This is further supported by the negative correlations between RFI and FCR in both production periods, indicating that chicken deemed efficient based on RFI would be less efficient when using FCR. This observation, however, contradicts results reported by Yuan *et al.* (2015). Aggrey and Rekaya (2013) found that MBW had more influence on efficiency than production and that MBW was positively and negatively correlated with FCR and RFI, respectively. It is possible that the current population was diverting more resources into maintenance than production and hence, the negative associations between RFI and FCR. Considering

that KLH-IgM has been previously linked to higher survival rates (Sun *et al.*, 2013), the correlations imply that improvement of production traits BW_{12} and AFE may not have negative effects on survivability in IC. On the other hand, selection for BW_{12} and AFE would have little to no influence on adaptive humoral immunity (NDV-IgG). Although RFI reflected the efficiency of feed use into production, its correlations with immune traits suggested inefficiencies such that chicken with higher productivity and immune-competence consumed more feed to support both functions. These observations indicate that an indirect relationship between feed efficiency and immune function may be present (Van der Most *et al.*, 2011). The high and negative association between the two antibody traits in both production periods could be attributed to the different T helper-cell (Th) pathways induced by KLH and NDV (Sun *et al.*, 2013). The observed negative correlation between BW_{12} and AFE implies that selection for high BW_{12} would lead to delayed sexual maturity. This may be undesirable for the egg lines given the negative associations between AFE and egg numbers (Van der Klein *et al.*, 2015). Feed efficiency measured pre- and post-maturity shared a similar genetic background suggesting that efficient chicken in the growing period would likely rank as efficient in the laying period. Similar pattern was also observed in the immune traits such that chicken with higher antibodies pre-maturity maintained their immune-competence post-maturity.

Conclusions

The current study confirms presence of genetic correlations between production traits with feed efficiency and immune traits in the IC population. This indicates that possible consequences on feed efficiency and immune function should be considered when selective breeding for improved productivity in IC is applied.

Abstract

To optimize breeding for feed efficiency, dry matter intake data from 3,967 Holstein cows with 131,234 weekly records from Denmark, France, the Netherlands, and Canada were combined. A random regression model was fitted to 1st and 2nd parity data for dry matter intake, energy corrected milk and body weight. Results showed that genetic residual feed intake is heritable in both parities, with an average heritability of 0.21. Genetic correlations across lactation and parities showed moderate to high estimates between mid and late lactation within parity. Early lactation had low genetic correlation with mid and late lactation. The genetic correlations between parities were around zero at all lactation stages. These findings show the importance of data collection and modelling at all lactation stages and parities.

Introduction

Genetic improvement of feed efficiency (FE) is a hot research topic to increase the environmental and economical sustainability in the dairy cattle industry. However, expensive recording schemes for large-scale feed intake registration and appropriate trait definition for FE in the breeding goal are main limitations to implement effective genetic evaluation of FE. We address the trait definition by studying genetic parameters for genetic residual feed intake (gRFI) and lack of feed intake data by international collaboration. Most evaluation centers use the Feed saved definition (Pryce *et al.*, 2015), where residual feed intake (RFI) is an important part. Residual feed intake is typically seen as an output of phenotypic regression of an animal's feed intake on energy sinks (yield, maintenance, etc.). Kennedy *et al.* (1993) proposed gRFI, assuming that the genetic correlations between feed intake and energy sinks are zero, which is important to avoid double counting in breeding goals. To overcome limited data size, collaboration on feed intake data around the world is crucial to achieve genetic progress for the economical important gRFI trait. Martin *et al.* (2021b) proposed a RFI model that was able to better describe the dynamic nature of the lactation, but this model did not include a genetic part. The aim of this study was to estimate variance components for a dynamic RFI model using time series data from multiple lactations and countries.

Materials & methods

Phenotypes, data editing & pedigree. Data from 870 Danish Holstein cows were collected from 2003-2019, at the Danish Cattle Research Center (DKC; Foulum, Denmark). Feeding data were described by Martin *et al.* (2021b). Data from 329 French Holstein cows were collected from 2014-2020, at the Le Pin and Méjusseaume research herds (Martin *et al.*, 2021a; Lefebvre *et al.* submitted to WCGALP 2022). Data from 1,953 Dutch Holstein cows were collected from 1991-2019, in different research herds at Wageningen University (Heida *et al.*, 2021). The Danish, French and Dutch data were shared as a part of the Gentore project (https://www.gentore.eu). Additionally, data from 815 Canadian Holstein cows were collected from 2015-2020, at the Sunalta, DRTC and Elora research farms (https://genomedairy.ualberta.ca/; http://www.resilientdairy.ca/).

CC BY

DOI: 10.3920/978-90-8686-940-4_73, © R.B. Stephansen *et al.* 2022

The combined dataset consisted of 5,470 lactations and 131,234 weekly records for feed intake. Various editing and plausibility checks were undertaken to ensure high-quality data, and requirements to cohesive lactations with a length of minimum 100 days in milk. All traits had their variance standardized to the average variance across herd, year, parity, and week of lactation. The pedigree obtained from the collaborators was pruned for eight generations. Missing parents were assigned to genetic groups with effects of country, breed, and birth year. Data editing were performed in the SAS software version 9.4.

Statistical analysis. The statistical software DMU (Madsen and Jensen, 2013) was used for variance component estimation, using the AI-REML algorithm. The random regression models were as follows:

$$y_{ijclmnop} = \mu + HYS_i + WOL_j + \beta_1 ACC_c + \beta_2 ACC_c^2 + \sum_{l=0}^{m} a_{cl}\Phi_{cjl} + \sum_{l=0}^{m} pe_{cl}\Phi_{cjl} + EXP_n + YM_o + e_{ijclnop}$$

where y were the phenotype DMI, energy corrected milk (ECM; Sjaunja (1990)) or BW for cow c on week of lactation j (j=1, 2, …, 44), μ were the intercepts, *HYS* were the fixed effects of herd × year × season i (670 levels; season were defined as quarters from date of calving), *WOL* were the fixed effects for week of lactation j, β_1 and β_2 were the regressions on age at calving (*ACC)* and ACC^2 for cow c respectively, a were the random additive effects with the m^{th} order of Legendre polynomials (LP), pe were the random permanent environmental effects with the m^{th} order of LP, *EXP* were the random effects of trial n (376 levels), *YM* were the random effects of year × month defined from the record date o (320 levels) and e were the residuals p (11 levels, one every 4 weeks assuming residual covariance to be 0). It is assumed that var(a) = A⊗m, var(pe) = I⊗m and var(e) = $I\sigma_e^2$ = R, where A is the numerator relationship matrix, ⊗ is the Kronecker product and m is the order of LP fitted for a and pe effects (m was 1st order for DMI and ECM, and 2nd order for BW). To derive genetic and phenotypic output, the notation by Islam *et al.* (2020) and Martin *et al.* (2021b) was followed. The final variance component matrix was made positive definite using the bending method of Schaeffer (2014).

Results

The descriptive statistics show small differences in mean and variance levels between the countries (Table 1).

Genetic RFI is heritable (avg. 1st parity: 0.18, 2nd parity: 0.24) with additive variance ranging between 0.2 and 2.8 in 1st parity and between 0.6 and 3.5 in 2nd parity. The highest levels of additive variance were seen during early and late lactation. The genetic correlations across lactation are presented in Figure 1. For 1st and 2nd parity, gRFI in early lactation was not correlated to gRFI in mid and late lactation. The genetic correlation between gRFI in mid and late lactation was moderate to high. The genetic correlation between 1st and 2 parity was around zero.

Table 1. Descriptive statistics for phenotypes by the different countries.

	Denmark	France	The Netherlands	Canada
No. DMI records	65,793	14,370	52,869	26,741
Avg. DMI (SD)	21.5 (3.7)	21.2 (3.7)	20.7 (3.8)	22.1 (5.0)
Avg. ECM (SD)	34.3 (7.8)	30.4 (6.7)	31.3 (7.2)	35.3 (7.5)
Avg. BW (SD)	653.4 (73.3)	626.4 (71.8)	593.3 (76.8)	667.7 (80.0)
Avg. WOL (SD)	20.7 (12.0)	20.0 (11.7)	17.0 (10.5)	20.8 (11.8)
Avg. Parity (SD)	1.7 (0.8)	1.5 (0.7)	1.6 (0.8)	1.6 (0.7)

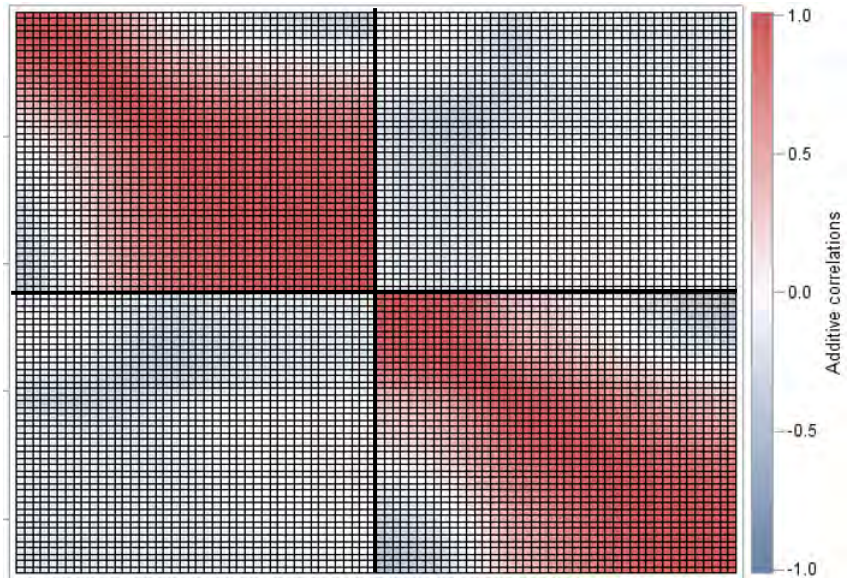

Figure 1. Genetic correlations across lactation in the first two parities. 1st parity is seen in upper left box and 2nd parity in lower right box. The genetic correlations between parities are in the off-diagonal boxes. Each pixel represents one week of lactation, with a total of 88 weeks of lactation when combining 1st and 2nd parity.

Discussion

Within parity, it is expected that gRFI in early lactation is different from the rest of the lactation, because of mobilization not properly accounted for. This was also seen in Li *et al.* (2017) using Danish data from 1st parity Holstein cows.

Absence of correlation between 1st and 2nd parity could be expected in early lactation due to higher mobilization of body reserve in 2nd parity animals compared with 1st parity; however, a higher correlation could be expected between parities in mid and late lactation. This could be an artifact of bending the variance component matrix. These results suggest it is important to register phenotypes for DMI, ECM and BW through the whole lactation and in multiple lactations. This is necessary to achieve the highest possible genetic improvement for feed efficiency. Furthermore, it is important to avoid that selection for gRFI leads to an increased level of metabolic disorders in dairy cattle. The low correlation between early lactation and the rest of the lactation indicates that selection for gRFI possibly leads to an increased degree of mobilization. Future research should focus on ensuring that selection for gRFI do not lead to increased mobilization in dairy cattle. A possibility is to include body condition scores in the gRFI equation, to account for the change in adipose tissue.

Conclusions

We demonstrated that gRFI is heritable and the genetic correlation structure shows that within parity, mid and late lactations are moderately to highly correlated. However, the genetic correlation between parities is around zero at all lactation stages. These results suggest that collection of data in all lactation stages and parities is important for genetic gain in feed efficiency.

Acknowledgements

The research leading to these results has received funding from European Union's Horizon 2020 research and innovation programme – GenTORE – under grant agreement No 727213. 74. Genetic parameters of feeding behaviour traits in parental lines of a mule duck

H. Chapuis[1*], M. Lague[2] and H. Gilbert[1]

[1]GenPhySE, Université de Toulouse INRAE ENVT, 31326 Castanet Tolosan, France; [2]UEPFG INRAE, 1076 route de Haut-Mauco, 40280 Benquet, France; herve.chapuis@inrae.fr

Abstract

Automatic feeders were used to characterize the feeding behaviour traits of two populations of ducks (White Pekin and Muscovy). In addition to feed conversion ratio, six phenotypes were derived at the scale of the day and the meal and genetic parameters were estimated. Feeding rate in the Pekin population was twice as large as in the Muscovy population (19 vs 9 g/min). Feeding traits exhibited moderate (0.38) to high (0.67) heritabilities. A similar pattern of correlations could be observed between these traits in the two populations. Feed conversion ratio did not show any remarkable correlation with feeding traits in the Pekin line, except with daily feed intake, but was negatively correlated with the number of meals and meal feed intake in the Muscovy population (0.68). Further studies will be needed to decipher how these traits can be incorporated in breeding programs without impairing ducks' abilities to produce fatty liver.

Introduction

The mule duck contributes to more than 90% of the production of French fatty liver. It is a sterile hybrid obtained by crossing common duck females (*Anas platyrynchos*) and Muscovy drakes (*Cairina moschata*). Selection to improve fatty liver production is carried out on its parental populations, and only limited knowledge is available about the relationships between parental and crossbred traits. In addition, as recording individual feed intake in both parental populations is still a challenge, feed efficiency remains poor. We set up a design of purebred ducks to investigate detailed feeding traits to improve feed efficiency. We computed feeding behaviour traits using automated feeders (Bley and Bessei, 2008) and estimated genetic parameters for these traits in the parental populations, and their relationships with feed efficiency.

Materials & methods

The present study was conducted in agreement with the 2010/63/EU regulation for use of animals for research purposes. Animals were bred at the INRAE Duck farm (UEPFG, Benquet, France) which has been approved for animal experimentation (C40-037-1).

Birds and housing. Three successive generations of animals were produced in a dam White Pekin (PEK) common duck line and in a sire Muscovy (MUS) line. Electronically tagged animals were reared up to the age of 7 (PEK) or 8 (MUS) weeks in a 96 m^2 pen equipped with 6 automatic feeders similar to those used by Basso *et al.* (2014), including animal weighing at each visit. To facilitate duck management, the area was divided in two parts with a barrier, so each bird had effective *ad libitum* access to 3 feeders. In the PEK line, we reared 273 males and 467 females, while only males (n=460) were studied in the MUS line.

Data acquisition. The date and time at the beginning and end of each visit to the feeder was recorded. Animal weight and feed consumption were recorded for each visit. Feeding behaviour traits were then computed. Daily Feed Intake (DFI) and Daily Feeding Time (DFT) definitions are straightforward. Feeding Rate (FR) was computed as the ratio of feed intake over feeding time for each visit and averaged over the whole period. Following Howie *et al.*'s (2009) method 3 to compute the so-called 'meal criterion', visits were aggregated into meals in order to allow for reliable comparisons of feeding behaviours between the two populations. For each duck, visits were defined as part of a single meal if the interval between visits was

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_74, © H. Chapuis *et al.* 2022

lower than the meal criterion (1,616 s in PEK, 2,113 s in MUS). We therefore recorded the number of meals per day (NM), Meal Duration (MD) and Meal Feed Intake (MFI). Feed efficiency was addressed through computation of feed conversion ratio (FCR), as the ratio of total feed intake over the observed weight gain. Average Daily Gain was also computed. We planned to collect and analyse early feed and growth data over a 5-week span (i.e. 35 days). In order to limit the occurrence of misidentified visits, which were found numerous at early age in the Muscovy population (Cobo *et al.*, 2017), the 35-day control period spanned from Day22 to Day56 in the MUS line, while it started at Day15 and ended at Day49 in the PEK line.

Statistical analysis. The phenotypic comparison of performances between lines was obtained through a linear model accounting for the effects of batch and sex in the PEK line. Then, genetic parameters were estimated using ASRemL (Gilmour *et al.*, 2015), with the model:

$$y = \mu + \beta_{batch} (+ \gamma_{sex}) + u + e \quad (1)$$

where y is the phenotype, μ the general mean, β_{batch} and γ_{sex} are the fixed effects of batch and sex (PEK line only), respectively, u the additive genetic effects, and e the residual effects. In order to normalize the data, DFT and MD were log-transformed prior to analyses. Values more than three standard deviations from the mean were considered as outliers and removed from the analysis. First, univariate analyses were run to compute heritabilities, and next multivariate models were applied with the same effects to obtain correlations.

Results

The least squares means of the linear model applied for phenotypic line comparisons are given in Table 1. MUS ducks spent daily almost twice as much time feeding as PEK ducks, while the amount of feed they consumed was 12% lower. This resulted in a feeding rate more than twice as great for the PEK ducks, as reported in Cobo *et al.* (2017) where only male data were considered. Compared to the MUS line, the number of meals per day was greater and meal duration was roughly 2.5 times shorter in the PEK line (Table 1). FCR was better (i.e. lower) in the Muscovy line. The average daily gain was greater in the MUS line. Yet, it should be remembered that the cut-off points occurred one week earlier in the PEK population.

The genetic parameters are displayed in Table 2. In both lines, feeding traits were highly heritable; most heritabilities were higher than 0.5, such as NM and MFI in both populations. DFT and FR exhibited remarkably high heritability values (~0.6) in the PEK line and around 0.4 in the MUS line.

Table 1. Mean values (least squares means[1] ± standard error) of feeding behaviour traits.

Trait	PEKIN dam line	MUSCOVY sire line	*P* line
Daily feed intake (g/d)	225.00±0.72	200.00±1.16	<0.0001
Daily feeding time (s/d)	811.0±12.1	1,595.0±19.5	<0.0001
Feeding rate (g/min)	18.84±0.15	8.86±0.24	<0.0001
Number of daily meals/d	4.46±0.03	3.54±0.05	<0.0001
Meal feed intake (g)	53.2±0.5	59.1±0.8	<0.0001
Meal duration (s)	191.00±3.98	470.00±6.41	<0.0001
Feed conversion ratio (kg/kg)	3.25±0.01	2.56±0.01	<0.0001
Average daily gain (g/d)	69.1±0.24	79.7±0.38	<0.0001

[1] Least squares means from a linear model including the fixed effect of batch (PEK and MUS) and sex (MUS).

In PEK, DFI was moderately correlated with MFI and FCR (~0.35), while these correlations were much higher in MUS (~0.70). DFI and MD were positively but not significantly correlated in PEK, while the correlation was positive in MUS. In both lines, DFT and FR were strongly and negatively correlated.

Discussion

The lower FCR in the MUS line compared to the PEK line was expected, as Muscovy duck is known to produce a leaner meat than the White Pekin and is popular in France for this very reason. Here we studied only males in the MUS population, which is known to exhibit a larger sexual dimorphism for body weight than the PEK line (Tai and Rouvier, 1998). This may contribute to the difference in FCR observed between lines.

We computed a meal criterion within each batch using Howie *et al.*'s (2009) method 3. This method is based on analyses of the probability for an animal to start feeding given the time since the last visit. This requires finding the nadir of a potentially flat curve, which may be not precisely estimated. For the PEK line, the meal criterion was close to the value of 1,725 seconds found by Howie *et al.* (2009) in another Pekin duck population.

Our genetic parameters for feeding behaviour traits were in good agreement with those obtained on Pekin broilers by Le Mignon *et al.* (2017) and Thiele (2017). With a heritability of 0.33±0.11 for feed intake from Day15 to Day42, Zhang *et al.* (2017) obtained a slightly lower value than ours. Some common features can be noted between our study and that of Le Mignon *et al.* (2017): (1) Strong negative correlations between the number of meals and the meal size, reflecting that an increase in the meal number does not lead to increased feed intake. If the animal has reached satiety, an increase in the number of meals does not respond to an urge to eat more feed but simply illustrates a variability in feeding behaviour; (2) Moderately negative

correlations between number of meals and feeding rate. Birds exhibiting a large FR may swiftly reach satiety and not feel the need to start another feeding sequence; (3) A large and positive, but significantly different from unity, correlation between meal duration and total time spent feeding, emphasizing an exploitable variability of feeding behaviours. As expected, the latter is also strongly negatively correlated with FR. These three points are also common to our two populations, which might suggest some generality about ducks' feeding behaviours.

For feed efficiency, we focused on FCR. Feed efficiency could also be profitably addressed through the fraction of feed intake that is not explained by maintenance and production requirements, *aka* Residual Feed Intake (RFI). Yet, in the case of fatty duck production, attention should be paid to an adequate derivation of RFI, i.e. accounting for body lipid composition, as in Drouilhet *et al.* (2014). With estimates of 0.24 and 0.31, FCR was less heritable in the two Pekin lines studied by Le Mignon *et al.* (2017) than in our study. In the PEK line, our estimates of the correlation between FCR and feeding behaviour traits are in accordance with those obtained by Thiele (2017) and Le Mignon *et al.* (2017): they are of low magnitude (<0.20), except for DFI. Conversely, in the MUS line, FCR exhibited strong correlations with DFI and MFI, which may suggest a larger part of feed allocated to growth compared with the PEK line. In addition, in MUS, the negative correlation between NM and FCR, though not accurately estimated, could indicate that selecting for increased number of meals would improve FCR, which contradicts the literature in which efficient animals generally show less feeding activity.

These first genetic analyses of a large design focusing on feeding characteristics of the parental lines of the mule duck show that feeding traits are heritable in these lines, and some are correlated to feed efficiency. Further studies will be conducted to decipher how these traits can be incorporated in breeding programs without impairing the ducks' abilities to produce fatty liver.

This study was funded by the French interprofessional association for fatty liver production (CIFOG), and INRAE animal genetic division. The authors thank UEPFG technical staff for animal care and data collection.

Abstract

The objective of this study was to estimate genetic parameters for feeding behavior and the genetic correlations with feed efficiency traits in Holstein cows. Data consisted of 75,877 daily feeding behavior records of 1,328 Holstein cows in 31 different experiments conducted from 2009 to 2020. The statistical model included lactation and days in milk as fixed effects, and experiment-treatment, animal, and permanent environment as random effects. Estimates of heritability ranged from 0.09 to 0.23 and repeatability from 0.23 to 0.52 for feeding behavior, with strong genetic correlations between traits. Feeding rate and intake per visit or meal showed positive and strong genetic correlations with residual feed intake, dry matter intake, and metabolic body weight. We conclude that cows that eat at a slower rate may be more feed efficient. Measures of feeding behavior could be useful indicators of dairy cow feed efficiency.

Introduction

Genetic selection is a powerful tool to improve livestock production, given that genetic gains are cumulative and permanent. Genomic technologies allow the inclusion of important economic traits that are difficult to measure into breeding programs. Automated feeders, for example, enable the evaluation of feed efficiency on an individual animal basis. In addition, individual measures of feeding behavior can be assessed using this technology. Interestingly, there is evidence that variation in feeding behavior explains part of the variation observed in residual feed intake (RFI) in dairy cattle (Connor *et al.* 2013; Green *et al.* 2013; Lin *et al.* 2013). Although this is a reliable system, it is too expensive for commercial farms. Therefore, feeding behavior may be used as an indicator trait for feed efficiency, using less expensive wearable sensors or computer vision systems that do not actually measure individual intakes. As such, the objective of this study was to estimate genetic parameters for feeding behavior traits and genetic correlations of feeding behavior with milk energy, metabolic body weight, change in body weight, dry matter intake (DMI), and RFI in US Holstein cows.

Materials & methods

Data consisted of 75,877 feeding behavior records of 1,328 (546 primiparous and 782 multiparous) Holstein cows in 31 experiments from 2009 to 2020 in a freestall facility at University of Wisconsin-Madison with a roughage intake control system (RIC; Hokofarm Group, Marknesse, Netherlands). Cows were provided *ab libitum* access to feed and water, with the diets formulated to meet or exceed nutrient requirements. The RIC system recorded, for each cow, the start and end time of each visit to the feeder and the weight of feed consumed during each visit. Using the feeding behavior variables, we also developed a meal concept. The meal criterion was calculated by fitting a mixture model of the $\log_{10}$ frequency distribution of the intervals between feeder visits (DeVries *et al.* 2003; Horvath and Miller-Cushon 2019). Any interval between feeder visits less than the meal criterion was defined as the same meal. The meal criterion derived from this dataset was 26.4 minutes. Descriptive statistics for daily records of feeding behavior traits and DMI are shown in Table 1. In addition, weekly records of the three energy sinks, namely milk energy, metabolic body weight and change in body weight, and DMI were assessed to calculate weekly RFI values. In addition to phenotypic records, pedigree information for the last three generations was considered in the analyses.

Genetic parameter estimation was performed in bivariate analyses using the following model:

$$y=X\beta+ Z_1b+ Z_2u+Wpe+e,$$

where y is a vector of phenotypic records, β is a vector of fixed effects, b is a vector of random block effects of experiment-treatment (60 levels), u is a vector of random additive genetic effects, pe is a vector of random permanent environmental effects, and e is the vector of random residual effects. Fixed effects included lactation number with 4 levels (1 to 4+) and days in milk with 9 levels (grouped by 19 days). Matrices X, Z_1, Z_2, and W are incidence matrices relating y to β, b, u, and pe, respectively. Estimates were obtained using restricted maximum likelihood method through the AIREMLF90 software (Aguilar *et al.* 2018).

Results

Descriptive statistics for daily records of feeding behavior traits, daily DMI, and their heritability and repeatability estimates are shown in Table 1. Heritability estimates for feeding behavior traits ranged from 0.09 to 0.23, and for dry matter intake was about 0.12. Most traits were highly repeatable across days, with repeatability estimates ranging from 0.23 to 0.52.

Genetic and phenotypic correlations for daily records are depicted in Figure 1. Standard errors (SE) of estimates ranged from 0.01 to 0.10 (data not shown). In general, feeding behavior measures were strongly genetically correlated. Dry matter intake showed positive and strong genetic correlations with feeding rate (0.71 and 0.68), and intake per visit and per meal (0.66 and 0.88).

Genetic and phenotypic correlations between feeding behavior traits and milk energy, metabolic body weight, change in body weight, dry matter intake, and RFI, measured as averages by week, are depicted in Figure 2. The SE of estimates ranged from 0.03 to 0.14 (data not shown). Our results showed that some feeding behavior traits were strongly genetically correlated with RFI, and/or with the traits considered in the equation to calculate RFI. Only body weight change was not significantly associated with feeding behavior.

Table 1. Descriptive statistics and estimates of heritability (h^2) and repeatability (r^2) for daily feeding behavior and feed dry matter (DM) intake in Holstein cows.

Traits	Mean	SD	$h^2 \pm SE$	$r^2 \pm SE$
Number of feeder visits per day	35.7	15.6	0.16±0.03	0.52±0.02
Number of meals per day	7.5	1.75	0.09±0.02	0.23±0.01
Duration of each feeder visit (minutes)	6.8	2.7	0.16±0.03	0.47±0.02
Duration of each meal (minutes)	29.4	8.9	0.14±0.02	0.31±0.01
Total duration of feeder visits per day (minutes)	212.4	55.4	0.16±0.03	0.38±0.02
Intake per visit (kg of DM)	0.9	0.4	0.16±0.03	0.49±0.02
Intake per meal (kg of DM)	3.8	1.1	0.13±0.02	0.28±0.01
Feeding rate per visit (kg of DM per minute)	0.15	0.06	0.11±0.02	0.32±0.02
Feeding rate per meal (kg of DM per minute)	0.14	0.04	0.23±0.03	0.49±0.02
Dry matter intake (kg/d)	21.9	5	0.12±0.02	0.31±0.01

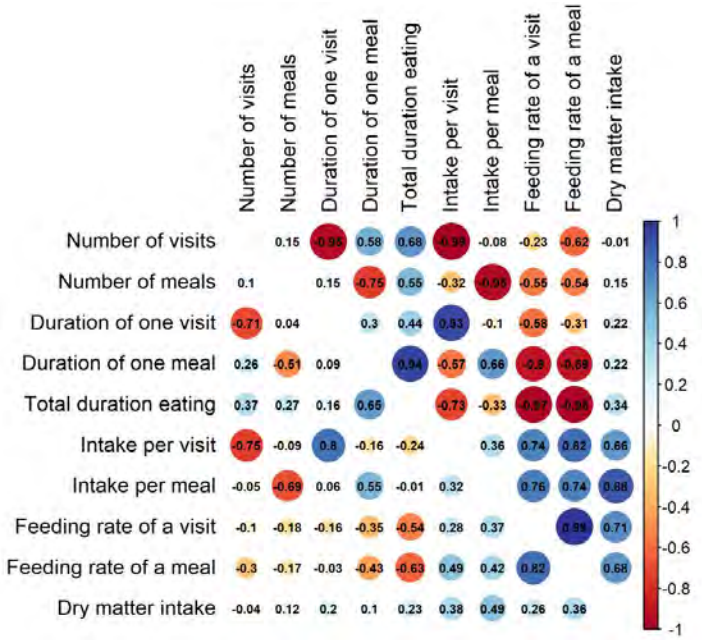

Figure 1. Genetic correlations (above diagonal) and phenotypic correlations (below diagonal) between daily feeding behavior traits and DMI in lactating Holstein cows.

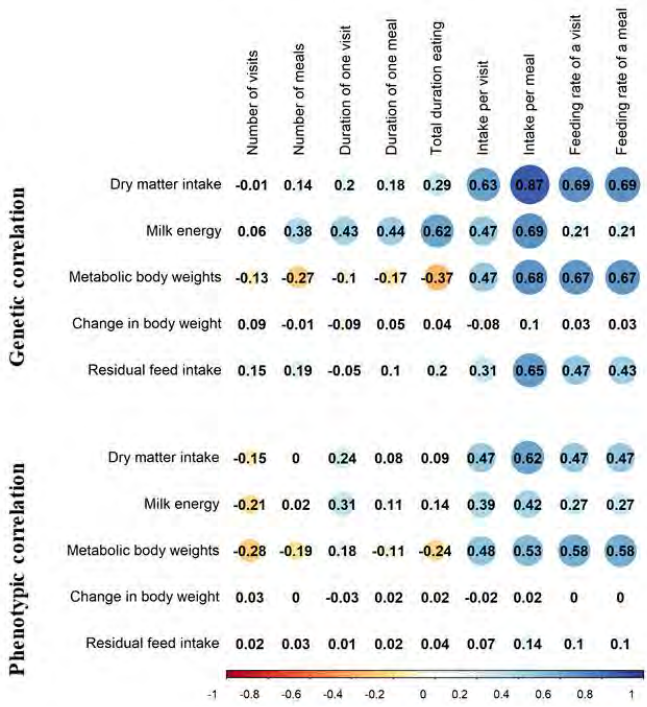

Figure 2. Genetic correlations and phenotypic correlations between weekly averages for feeding behavior and feed efficiency in lactating Holstein cows.

Discussion

Heritability estimates indicated that a significant proportion of phenotypic variance is explained by additive genetic effects, such that feeding behavior could be incorporated into genetic selection schemes. Higher heritability estimates have been reported for feeding behavior in dairy and beef cattle, but those studies used weekly averages (or longer), rather than daily records (Benfica *et al.* 2020.; Lin *et al.* 2013; Olson *et al.* 2020). Genetic correlations among feeding behavior traits showed that, with more visits or more meals per day, cows spend less time at each feeder or meal, with a lower intake per visit or meal. Genetic correlations between feeding rate and RFI (0.47 and 0.43) suggest that selection of animals that eat at a slower rate will also tend to select efficient animals with lower RFI. Feeding rate was strongly associated with DMI and metabolic body weight, both genetically and phenotypically. The same pattern was observed for intake per visit and intake per meal, indicating that cows with greater DMI per visit or meal tend to be less efficient genetically (greater RFI, milk energy, metabolic body weight, and total DMI). Studies reporting genetic correlations between feeding behavior and RFI are limited in lactating dairy cows, though Lin *et al.* (2013) observed a moderate genetic correlation between feeding duration and RFI (0.27) and a negligible correlation between feeding rate and RFI in dairy heifers. Overall, the results of this study suggest that dairy cows with slower feeding rates and smaller intakes per visit or meal are more feed efficient (lower RFI). Therefore, feeding behavior could be implemented into genetic selection programs as indicators of feed efficiency, which would increase selection accuracy for RFI.

76. Protein efficiency is heritable but not genetically correlated with meat quality in pigs

E.O. Ewaoluwagbemiga[1,3*], G. Bee[2] and C. Kasper[1]

[1]Animal GenoPhenomics Group, Agroscope Posieux 1725, Switzerland; [2]Swine Research Unit, Agroscope Posieux 1725, Switzerland; [3]Animal Genomics, ETH Zurich, Zurich, Switzerland; esther.ewaoluwagbemiga@agroscope.admin.ch

Abstract

The improvement of protein efficiency (PE) is an essential component in the development of a sustainable pig production. This study aims to estimate the heritability of PE when dietary protein is reduced, and to estimate its genetic correlations with meat quality and production traits. A total of 682 pigs were used in estimating the heritability of PE, and 512 pigs in estimating genetic correlations. The results from this study showed potential for selective breeding of PE in Large White pigs with a heritability of 0.40. Meat quality, except meat redness, is not expected to be influenced by genetic improvement of PE, as there were no significant genetic correlations between PE and meat quality traits. Favourable relationships exist between PE and feed conversion ratio, and with average daily feed intake, which means that protein-efficient pigs fed under a reduced-protein diet consume less feed and efficiently convert the feed to lean mass.

Introduction

In the past, the focus of animal breeding had been on improving production traits, but today, sustainability concerns are gradually gaining importance. An essential component to consider in the development of sustainable pig production is the reduction of nitrogen excretion in fattening pigs. The inefficient use of dietary protein by the animals results in the excretion of excess nitrogen, thereby contributing to pollution (Notarnicola *et al.*, 2017). Therefore, considering the environmental and ecological impact of pig production, it is essential to improve protein efficiency (PE) in pigs. In addition to nutritional strategies to improve PE, a genetic solution can be sought. Feed conversion ratio (FCR) and residual feed intake (RFI) are used to characterize feed efficiency. Although FCR and RFI are expected to correlate with PE, selection for improved FCR and RFI would likely increase energy efficiency rather than PE (Kasper *et al.*, 2020; Millet *et al.*, 2018) since energy intake is the main factor driving feed intake. Moreover, it has been shown that selecting for improved FCR and RFI with the aim of reducing nutrient excretion may not be as efficient as selecting for the nutrient trait itself (de Verdal *et al.*, 2011). In contrast to FCR and RFI, very few studies have investigated the possibility to improve PE, which may be due to a number of factors such as difficulties in phenotyping animals for this trait and the lack of approved and validated proxies. The heritability of PE reported in the studies of Saintilan *et al.* (2013) and Kasper *et al.* (2020) indicate the potential to select genetically for improved PE in pigs. However, knowledge of genetic correlations of PE with other traits of importance such as meat quality and growth performance traits is important to account for possible trade-offs. The aim of this study was therefore to estimate the heritability for PE and its genetic correlations with meat quality and growth performance traits.

Materials & methods

A total of 682 Swiss Large White pigs were used in this study, which all had *ad libitum* access to feed and water. Once a pig reached a body weight (BW) of ≥20 kg (average ± standard deviation: 22.5±1.6 kg), it was allocated to a pen where it remained until slaughter. The automatic feeder dispensed the grower diet to pigs until an average BW of 63±2 kg, and thereafter a finisher diet until an average BW of 106±5 kg when the pigs were slaughtered. The levels of digestible protein and essential amino acids for the grower and finisher diets were 20% lower than the recommended levels, with the same digestible energy. The automatic feeders

R.F. Veerkamp and Y. de Haas (eds)

(Schauer Maschinenfabrik GmbH & Co. KG, Prambachkirchen, Austria) recorded all daily visits to the feeder and the quantity of feed consumed per visit for each animal.

Protein efficiency. After slaughter, the left carcass including the whole head was scanned with dual-energy X-ray (DXA) absorptiometry to determine lean tissue content, which was used in the following prediction equation to estimate the protein content retained in the carcass (Kasper *et al.*, 2021).

$$\text{Protein content carcass (g)} = -482.745 + 0.23\ (\text{g lean tissue DXA} \times 2) \quad (1)$$

PE of the carcass was calculated as the ratio of protein deposited in the carcass minus the protein content in the carcass at 20 kg BW to the total dietary protein intake. The protein content of the carcass at 20 kg BW was estimated based on data from the experiment of Ruiz-Ascacibar *et al.* (2017).

Other traits in the study. Loin muscle area and backfat thickness were assessed on the left carcass side at the 10th to 12th ribs' level. A picture of the loin muscle was taken and the area was measured. Backfat thickness was measured with a ruler. Intramuscular fat content was determined by the Soxhlet method. A 2 cm thick chop was cut from the loin muscle at the 10th to 12th ribs' level and freed from adhering adipose and connective tissues. After 20 min in the cooling room, CIE Lab-values (lightness, redness and yellowness), were recorded using the Minolta CR-300 colorimeter. Subsequently, the chops were weighed, suspended in sealed plastic bags at 2 °C for 48 h and re-weighed to determine the drip loss. The same chops were then vacuum-sealed and cooked in a water bath at 72 °C for 45 min, then cooled in cold water for 15 min, rinsed to remove coagulated sarcoplasmic protein, dabbed dry and weighed to determine cooking loss. The cooked chops were frozen at -20 °C and shear force was measured on four cores of 13 mm diameter using a Warner Bratzler Shear Force machine.

Statistical Analysis. Bayesian animal models were performed using MCMCglmm (Hadfield 2010) in R. The genetic and common environmental variance components of PE were estimated using a univariate animal model (corrected for the effects of sex, slaughter weight, slaughter age, and farrowing series) and genetic correlations were estimated using bivariate models. Both univariate and bivariate models were performed with a Markov Chain Monte Carlo algorithm, using the model formula

$$y=\mu+Xb+Za+Z_c c+e \quad (2)$$

where y is a vector of observations of PE, b is a vector of fixed effects of farrowing series, sex, slaughter weight and slaughter age. X is an incidence matrix relating records to fixed effects. a is a vector of random additive genetic effects, and Z is the corresponding incidence matrix. c is a vector of random litter effects, and Z_c is the corresponding incidence matrix. Heritability was thereafter computed as the ratio of genetic variance to the phenotypic variance ($h^2 = V_A / V_P$), where phenotypic variance (V_P) is the sum of genetic variance (V_A), litter (common environmental) effect (V_{CE}) and residual variance (V_R). The litter effect was calculated as the ratio of the litter effect to the phenotypic variance ($CE^2 = V_{CE}/V_P$). A non-informative prior with an inverse Wishart distribution for the random effects and normal distribution for the fixed effects were used. The model was run with 2 million iterations, 100,000 burn-in and 1000 thinning intervals.

Results

The posterior distributions of the variance decomposition of PE is presented in Figure 1 (posterior distributions of the respective variance components are shown in the upper part, points representing single estimates are shown together with a box plot, where whiskers represent the 95% credible interval). The PE of the carcass is clearly heritable (h^2=0.40, 95% credible interval = (0.22, 0.59)). The common environment

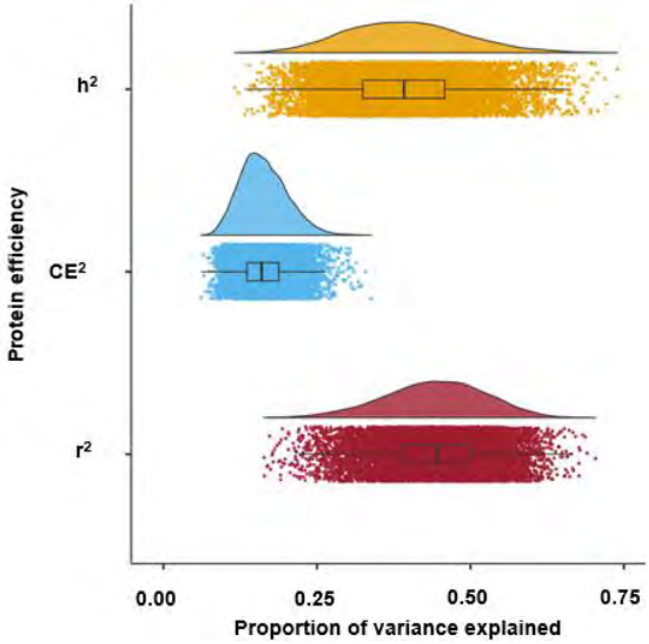

Figure 1. Posterior distributions of heritability (h^2), common environment effect (CE^2) and residual variance (r^2) of protein efficiency of the carcass.

(litter effect) also contributed to the phenotypic variation with a variance of 0.16 (0.09, 0.24), showing that pigs in the same litter performed similarly compared to others in different litters. The genetic correlations between PE and meat quality traits were generally non-significant with wide credible intervals that included zero (Table 1). However, meat redness trait showed a significant negative and moderate genetic correlation. There were high and negative genetic correlations between PE and production traits, with favourable relationships between PE and average daily feed intake and FCR (Table 1).

Table 1. Genetic correlations of protein efficiency with meat quality and production traits.

Group	Trait	r_g [1] [95% credible interval]
Meat quality traits	Loin muscle area	0.06 [-0.44, 0.60]
	Cooking loss	0.04 [-0.34, 0.39]
	Drip loss	0.03 [-0.17, 0.17]
	Shear force	0.05 [-0.20, 0.28]
	Intramuscular fat	-0.07 [-0.29, 0.16]
	Backfat thickness	-0.21 [-0.43, 0.08]
	Meat yellowness	-0.28 [-0.47, 0.03]
	Meat lightness	-0.42 [-0.88, 0.29]
	Meat redness	-0.35 [-0.59, -0.08]
Production traits	Average daily gain	-0.65 [-0.71, -0.58]
	Feed conversion ratio	-0.96 [-0.97, -0.95]
	Average daily feed intake	-0.93 [-0.95, -0-91]

[1] Genetic correlation.

Discussion

In this study, we showed that PE is heritable, and an improvement in PE when dietary protein is reduced is not expected to influence the quality of meat, except for the redness of meat. The favourable genetic correlations between PE and average daily feed intake (ADFI) and feed conversion ratio (FCR) show that protein-efficient pigs are expected to consume less feed and efficiently convert the feed to meat. This suggests that breeding for more protein-efficient, i.e. more sustainable pigs, could lower the cost of production, but special attention should be paid to the genetic correlation with growth rate to actually enable economic pig production. In addition, this could help decrease the competition between humans and livestock for plant-protein sources such as soybean. However, breeding for protein-efficient pigs, under a reduced dietary protein condition, may decrease average daily gain. The heritability estimate here was higher than that reported by Kasper *et al.* (2020), which may be due to higher sample size in the current study or to the experimental design. While all pigs in this study were slaughtered at 100 kg BW, pigs in the study of Kasper *et al.* (2020) were slaughtered between 40-100 kg BW, though differences in slaughter weight were corrected for statistically. A weak but significant effect of litter was observed on PE, in contrast to the study of Kasper *et al.* (2020), where the litter effect estimate was 0.002. This might be also a consequence of the larger sample size. Kasper *et al.* (2020) also reported the same relationship between PE and FCR. Although a strong negative (but favourable) genetic correlation was observed between PE and FCR, selection for FCR does not necessarily equate to selection for PE in terms of selection response. Unravelling this relationship should be the focus of future studies.

Abstract

The aim of this study was to estimate genetic parameters for apparent total tract digestibility of nitrogen (ATTDn) and dry matter (ATTDdm) and to investigate their genetic relationship to other relevant production traits in pigs. Near infrared spectroscopy was used for prediction of nitrogen content in feces. The estimated heritabilities of ATTDdm and ATTDn were 0.22 and 0.20, respectively. The genetic correlations between ATTDdm and ATTDn and feed intake from 40 to 120 kg were -0.5 and -0.65, respectively. No significant genetic correlations were found between any of the digestibility traits and growth and carcass quality traits. The results suggested that the current selection strategy is improving the digestibility of nitrogen and dry matter, but that selection for improved digestibility would reduce the feed consumption from 40 to 120 kg.

Introduction

Protein is a costly nutrient in feed and efficient use of proteins from the feed is therefore important due to global issues such as increasing human population and need for proper nutrition, climate changes, greenhouse gas emissions and profit in pork production.

Less than 1% of the greenhouse gas emissions from Norway is from the pork production. The largest source of emissions from pig production systems is nitrous oxide from manure storage (Bonesmo and Enger 2021). This emission represents a nutrient loss from the animal and by improving nutrient efficiency in pigs, emissions and production efficiency can be improved.

Since 1958, Norsvin Landrace has been bred for improved efficiency (Gjerlaug-Enger *et al.*, 2012). This has led to a reduction in carbon dioxide equivalents per kg carcass weight (kg CO_2-eq./kg CW) from 3.5 to 2.3 kg CO_2-eq./kg CW. This reduction is a result of more weaned piglets, lower mortality, shorter growth period and improved feed efficiency (Bonesmo and Enger 2021). To further improve genetic selection for efficiency to reduce carbon footprint and improved efficiency, nitrogen digestibility can be a trait of interest. However, measuring digestibility on a large-scale can be challenging, as this previously has been measured by using respiratory chambers and total excreta collection. Nirea *et al.* (2018) concluded that near-infrared spectroscopy (NIRS) can be used for prediction of chemical composition in feces and is a cost-effective method for measuring digestibility in large-scale, and Déru *et al.* (2021) showed that additive genetic variation existed for digestibility of different nutrients in Large White pigs measured by NIRS. The aim of this study was therefore to estimate genetic parameters for apparent total tract digestibility (ATTD) of nutrients measured by NIRS.

Materials & methods

The data material for the study was collected at Norsvins boar testing station in Norway. The test period was between 40 to 120 kg live weight of the boars. The data recording was conducted from June 2019 to April 2021 on randomly selected Norsvin Duroc boars, fed *ad libitum* on conventional concentrate containing 9.15 g SID lysine/kg and 9.55 MJ NE/kg.

Fecal sampling. To determine ATTD of nutrients, individual fecal samples were sampled at 120 kg live weight. The samples were stored at -20 °C before processing and chemical analysis. The samples were freeze dried, homogenized and ground (1 mm sieve) prior to chemical analyses and NIRS analyses. In total, fecal samples were collected from 1,895 boars.

Near-infrared spectroscopy. All NIR spectra were acquired using an XDS Rapid Content Analyzer (Foss, Hilleroed, Denmark) over the spectral region of 400-2,500 nm. For all samples, triplicate measurements were obtained. A total of 300 fecal samples were used to make a calibration model for nitrogen content (Kjeldahl-N) in the fecal samples. Partial least squares regression was used for calibration and prediction (cross-validation R^2=0.73, estimation error (RMSECV) = 1.6 g nitrogen/ kg dry matter). Subsequently, this calibration model was used to predict nitrogen contents in the remaining samples. Prior to regression and prediction, all NIR spectra were pre-processed employing 1-order derivatization and subsequent normalisation using the Standard Normal Variate approach (Barnes *et al.,* 1989).

Traits. All animals had individual records of the following traits: feed consumption from 40 to 120 kg (F40120), days from 40 to 120 kg (D40120), loin depth at 100 kg (LDP) and back fat at 100 kg (BF). Apparent total tract digestibility of nitrogen (ATTDn) and apparent total tract digestibility of dry matter (ATTDdm) was calculated by the model described in Maynard and Loosli (1969), using an indigestible marker (acid insoluble ash) occurring naturally in the feed. Descriptive statistics for the traits are shown in Table 1.

Genetic analyses. The traits were analysed using multivariate animal models, and estimation of variance components and genetic correlations were performed using the DMU software package (Madsen and Jensen, 2013).

The following models were used to analyse the different traits.

For ATTDdm and ATTDn:

$$y_{ijklmno} = MOB_i + OP_j + DAY_k + HYS_l + LITT_NO_m + animal_n + pen_o + e_{ijklmno} \quad (1)$$

For F40120, D40120, LDP and BF:

$$y_{ijklm} = MOB_i + HYS_j + LITT_NO_k + animal_l + pen_m + e_{ijklm} \quad (2)$$

Table 1. Descriptive statistics for feed consumption from 40 to 120 kg (F40120), days from 40 to 120 kg (D40120), loin depth at 100 kg (LDP) and back fat at 100 kg (BF). Apparent total tract digestibility of nitrogen (ATTDn) and apparent total tract digestibility of dry matter (ATTDdm).

	n[1]	Mean	SD[1]	Min[1]	Max[1]
ATTDdm (%)	1,895	73.2	4.6	47.2	84.4
ATTDn (%)	1,608	71.3	6.2	31.3	85.6
F40120 (kg)	13,922	171.4	13.7	100.3	274.7
D40120 (days)	14,030	75.4	8.7	50.9	114.8
BF (mm)	9,306	5.7	1.5	2.9	13.0
LDP (mm)	9,526	58.3	4.7	41.2	77.6

[1] Number of animals (n), standard deviation (SD), minimum value (min), and maximum value (max).

The sampler (OP), day of sampling (DAY), herd-year-season born (HYS), birth month (MOB) and dams litter number (LITT_NO) were included as fixed effects, whereas animal and pen were included as random effects. Pedigree information was traced 10 generations back and in total there were 24706 animals in the pedigree.

Results

Estimates of variance components and heritability for ATTDdm and ATTDn are presented in Table 2. Both additive genetic variance components were significantly different from zero. The estimated heritability for ATTDdm was higher than the heritability for ATTDn. The genetic correlation between ATTDdm and ATTDn was estimated to 0.80.

The genetic correlations between ATTDdm and ATTDn to production traits are presented in Table 3. The genetic correlations between the digestibility traits (ATTDdm and ATTDn) and F40120 were -0.50 and -0.65, respectively. The genetic correlations between the ATTDdm and ATTDn and D40120, LDP and BF were not significantly different from zero.

Discussion

This study has shown that genetic variation exists in apparent total tract digestibility traits, when chemical components were predicted by NIRS, and digestibility was estimated based on an internal marker in the feed. Improved digestibility of nutrients will increase the resource utilization of the animal. Selection for changed body composition, such as carcass leanness and reduced backfat has been a strategy to obtain feed efficient animals in pig breeding. Other traits, such as gross feed intake, feed conversion ratio and residual feed intake has also been used (Patience, 2012). Some of these traits might provide selection responses that are related to the allocation of feed resources to different tissues. This has ensured that feed is used for production. However, to improve feed efficiency further, it is important to know how well the intestines utilize the nutrients in the feed. The trait, ATTDn, can therefore further improve the efficiency of the animals, and hence reduce nitrogen loss in the environment, which is becoming an increasing global problem. To predict ATTDdm and ATTDn based on a spot fecal sample as an alternative to total collection method, acid insoluble ash was used as a marker. Brestenský *et al.* (2017) suggested that acid insoluble

ash was a suitable marker to use in digestibility studies for pigs. However, caution must be made with the sampling, to avoid contamination. In the current study, rooting material was held back for three days prior to sampling to avoid the pigs getting acid insoluble ash from other sources than the feed. The method for chemical analysis could influence the level of digestibility estimates, but not the variation. Bastianelli *et al.* (2015) proposed to use direct prediction of digestibility of different nutrients using NIRS. Then, the need for a marker would be minimized, as it is only needed for the fecal samples used for developing the calibration models. The variance components estimated in this study suggested that both digestibility traits are heritable and can be selected for. Few studies have previously carried out genetic analyses of digestibility traits in pigs. However, Déru *et al.* (2021) estimated a heritability for digestibility coefficients for nitrogen to be 0.27. This result is higher than the current study, but on a smaller dataset, different breed and conventional diet. The same study found an even higher heritability for nitrogen digestibility on a high-fibre diet (0.56), due to higher genetic variation. Increasing fibre content in the diet might increase the genetic variation in the trait but could at the same time reduce the digestibility of nutrients (Déru *et al.,* 2021; Zhang *et al.,* 2013). Genetic correlations between the digestibility traits and production traits were identified and suggested that the current selection strategy is improving the digestibility of nitrogen and dry matter. The results are in accordance with Déru *et al.* (2021), which estimated a high negative genetic correlation between nitrogen digestibility and daily feed intake (-0.59) in animals on conventional diet. The current study did not find any significant genetic correlations between ATTDdm, ATTDn and D40120, BF or LDP. This highlights that digestibility traits are heritable, but mainly related to feed intake and general function of the intestines, as opposed to allocation of feed resources to different tissues in the body. However, the results suggested that the current selection strategy is improving the digestibility of nitrogen and dry matter.

Abstract

Organic pig breeding could be improved by including welfare related traits into breeding goals. This study aimed to estimate genetic parameters for traits related to piglet welfare in organic pigs. Data were collected from an organic multiplier farm. Piglets were weighted at birth and at day ten, number of functional teats were counted at birth. For sows number of living and dead piglets were recorded at birth and on day eleven, and for each litter mean litter weight was determined. Pedigree based animal models were used to estimate genetic parameters. For piglet weight, common litter and maternal genetics were included in the model. Heritability estimates was high for number of functional teats and mean litter weight (0.25-0.48), but low for the other traits (<0.10). Piglet mortality and mean litter weight were negatively correlated (-0.55 to -0.72), whereas number teats was positively correlated to number of living piglets (0.40). In conclusion, there is significant genetic variation for traits related to piglet mortality in organic pigs.

Introduction

The organic pig sector in Europe is gradually expanding (Eurostat, 2021). However, few developments have been made in developing organic pig breeding programs and this may have negative consequences on the compliance of the organic principles within organic pig production (IFOAM, 2005). One of the pillars of organic pig farming is improved pig welfare. For example, sows should move freely, and piglets and sows be kept outdoors on pasture with individual huts during the pre-weaning period. On the other hand, these freedoms give rise to welfare issues, such as increased piglet mortality compared to conventional production (Prunier *et al.*, 2014). One reason for this issue could be that organic pig breeding depends on genetic material from conventional breeding populations. This would be reasonable if there are no genotype by environment interactions between organic and conventional pig production systems. Due to the significant differences between the systems, this seems unlikely, especially for traits such as piglet survival. Conventional breeding programs breed for sows that produce larger litters. Large litters are associated with lower average birth weight (Prunier *et al.*, 2014). Smaller piglets struggle with thermoregulation, and often consume less colostrum and, therefore, have lower chances of survival (Milligan *et al.*, 2002; Rangstrup-Christensen *et al.*, 2018). In outdoor organic systems, rapid intervention is not always possible. Consequently, sows and piglets need to be more independent. Sows, for example, need to have enough teats to support her piglets (Rangstrup-Christensen *et al.*, 2018), and piglets should be strong enough to get through the first risky period without intervention from farm personnel (Quiniou *et al.*, 2002). Not much is known about genetic relations between traits related to survival, piglet weight, litter size and number of functional teats for pigs in organic production environments. The aim of this study, therefore, was to evaluate genetic parameters for piglets traits associated to early piglet weight, and number of functional teats, and sow traits associated to piglet survival.

Materials & methods

Data collection. Data were collected from October 2018 through May 2021 at an organic multiplier farm in Denmark (Bovbjerg Økologi A/S). After removing outliers, 13,546 pigs with a record for number of functional teats at birth (NFT) remained. Individual piglet weight was available for 28,345 piglets at birth (W0), and 22,276 piglets at day ten (W10). Litter size traits were piglets alive at birth (A0), alive at

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_78, © R.M. Zaalberg *et al.* 2022

day 11 (A11), dead until day 4 (D4), and dead at day 11 (D11). These litter size traits were available for approximately 1,200 sows with 3,900 litters. Mean litter weight at birth (μLW0) and day 10 (μLW10) was available for approximately 750 sows with 1,800 litters. For piglet weight, 89% of the piglets were Yorkshire × Landrace (YL), and 11% Landrace (LL). For litter size, 6% of the litters was LL, 48% YL and 46% Duroc × YL (DYL). For mean litter weight, 11% of the litters was LL, 88% YL and 1% DYL.

Statistical analyses. Pedigree-based genetic analyses were performed in DMU (Madsen and Jensen, 2013). For estimating variance components, the following univariate linear regression equations were used.

$$NFT = Xb + Za + e \quad (1)$$

$$\text{Piglet weight} = Xb + Za + Z_m a_m + Wc + Sh + e \quad (2)$$

$$\text{Litter size} = Xb + Za + Cpe + Sh + e \quad (3)$$

$$\text{Mean litter weight} = Xb + Za + Cpe + Sh + e \quad (4)$$

Where b is a vector of fixed effects. For NFT, the fixed effect was breed. For piglet weight (W0, W10), the fixed effects were parity of sow, birth group, sex×breed, and a regression on age at the time of recording. For litter size (A0, A11, D4, D11), the fixed effects were litter breed, and parity of sow. For mean litter weight (μLW0, μLW10), the fixed effects were litter breed, parity of sow, birth group, and a regression on average age at the time of recording. Furthermore, a were vector of random additive direct genetic effects, a_m a vector of random maternal additive genetic effects, c a vector of random common litter effects, h a vector of random herd-year-season effects, pe a vector of random permanent environmental effects caused by the sow, and e a vector of residuals. X, Z, Z_m, W, S, and C were design matrices. Random effects were assumed to be independent, and to follow multivariate normal distributions: $a \sim N[0, A\sigma_a^2]$, $a_m \sim N[0, A\sigma_{am}^2]$, $c \sim N[0, I\sigma_c^2]$, $h \sim N[0, I\sigma_h^2]$, $pe \sim N[0, I\sigma_{pe}^2]$, and $e \sim N[0, I\sigma_e^2]$, where A is the relationship matrix, I is an identity matrix, and σ_a^2, σ_{am}^2, σ_c^2, σ_h^2, σ_{pe}^2, and σ_e^2 are the variance components for the random effects. Based on these variance components, heritability was estimated as:

$$h^2 = \sigma_a^2 / (\sigma_a^2 + \sigma_{am}^2 + \sigma_c^2 + \sigma_h^2 + \sigma_{pe}^2 + \sigma_e^2) \quad (5)$$

For estimating genetic correlations, bivariate models were used based on models (1)-(4). Because herd-year-season effects were too small, this random effect was excluded from bivariate models. In addition, for piglet weight only the maternal genetic component was considered.

Results

Means and standard deviations for the nine traits are presented in the top rows of Table 1. In the lower part of Table 1, heritability and correlation estimates for all traits are shown.

Discussion

The results show there is significant genetic variation for the studied traits measured under organic production conditions (Table 1). In addition, heritability estimates for litter traits such as A0 and μLW0 were comparable to those observed in conventional populations (Rydhmer, 2000). This indicates that even in a less controllable environment, such as outdoor, organic production systems, it is still possible to select for higher piglet weight, better piglet survival at sow level, and NFT.

Table 1. At the top, means and standard deviations for nine traits are shown. In the bottom, heritability (diagonal) and genetic correlations (off-diagonal) for three traits recorded in piglets, and seven traits recorded in sows are presented.

[1] Genetic correlation based on maternal genetic component.

[2] NS = not significantly different from 0, because |estimate| <2×SE. For significant parameters, SE ranged from 0.01 to 0.21.

[3] NC = model did not converge.

To increase litter size and reduce piglet mortality, current breeding programs for pigs in Denmark select for number of piglets alive at day 5 (Nielsen *et al.*, 2013; SEGES, 2015). Based on consideration of organic production principles, it would be more suitable to select directly for improved welfare (Nielsen *et al.*, 2011), such as fewer dead piglets. To improve survival among organic piglets, one could select for heavier, and thus, more robust piglets (Milligan *et al.*, 2002; Quiniou *et al.*, 2002). Our results suggest that selection for sows that produce heavier piglets will result in fewer dead piglets, but also, fewer piglets alive at day 11 (Table 1). Also, weighing piglets individually is labour intensive compared to counting piglets for litter size traits. One option would be to develop a breeding goal that includes both number of piglets alive and piglet survival. Yet, it is important that selection for larger litters is accompanied by selection for NFT, to ensure the sow can accommodate her piglets (Rangstrup-Christensen *et al.*, 2018). The heritability and correlation estimates presented in the current study provide a basis for developing a welfare-focused breeding goal for organic pigs. In conclusion, the results of this study show there is significant genetic variation for piglet weight, litter weight, number of dead or living piglets, and number of functional teats for pigs reared in an organic outdoor production system. The genetic parameters found in this study can be used to develop a breeding goal for organic pigs that can be used to select directly for fewer dead piglets, and thus, improved piglet welfare.

79. Genetic analysis of feeding behaviour and tail lesions

K.H. Martinsen[1*], Ø. Nordbø[1], E.G. Enger[1], D. Olsen[1] and E. Grindflek[1]

[1]*Norsvin, Storhamargata 44, 2317, Hamar, Norway; kristine.martinsen@norsvin.no*

Abstract

To improve production efficiency and ensure good animal welfare, novel phenotypes are developed for minimizing damaging behaviour in pigs. The aim of this study was therefore to estimate genetic parameters for two novel feeding behaviour phenotypes and investigate their genetic relationship with other traits recorded at the nucleus boar testing station. The genetic analyses were performed using multivariate animal models. The estimated heritability of interrupter (IntER) and interrupted (IntED) at the feeding station was 0.58 and 0.61, respectively, and the genetic correlation between the traits was 0.89. The genetic correlation between the feeding behaviour traits (IntER and IntED) with tail lesions and feed consumption from 40 to 120 kg live weight was not significantly different from zero. The results suggested that the feeding behaviour traits in this study could be treated as the same trait. However, as the frequency of tail lesions in this study was low, the genetic relationship between feeding behaviour and tail lesions remains unclear.

Introduction

Swine breeding companies strive to develop novel traits for desired pen behaviour to ensure genetic material which is production efficient, have high health status and good animal welfare. This involves minimising antagonistic behaviours such as aggression and tail biting and stimulating positive behaviours such as play and social behaviour. Individual behaviour data is difficult to collect, as it requires continuously recording individual pigs over time, rather than use one single point of observation. Feeding stations with radio frequency identification system (RFID) provide continuous high resolution individual recordings of feeding data. Every time an animal enters the feeding station, weight, feed intake and occupation time are recorded. When such data is aggregated over time, the individual patterns of feeding behaviour become clearly distinguishable, and when combined with pedigree or genomic data, they could be used as a source to find genetic variation in these traits. The feeding station data could be used to measure the feed intake related traits directly on the individual (Cheng *et al.*, 2021; Putz *et al.*, 2019). Alternatively, the timing between subsequent visits of feeding station could be used to improve the interaction matrices in estimation of indirect social genetic effects (Angarita *et al.,* 2021). If an animal is interrupting other animals during feeding, this could affect the feed intake and growth of the pen mates. In this paper, we used the feeding station data to develop novel traits to quantify, on an individual level, interruptions around feeding. These traits were further investigated to identify if the traits were heritable and if there were genetic relationships between these traits, feed consumption, number of visits in the feeding station and tail lesions.

Materials & methods

The data in this study were from purebred Norsvin Landrace boars with feeding data collected at one of the nucleus boar testing stations. In total, 4,281 boars from the period 2018 to 2021, were included in the study.

Feeding data. The feeding data were recorded by feeding stations (FIRE; Osborne Industries Inc., Osborne, KS). Individual amount of feed consumed at each visit and time spent per visit were recorded daily throughout the test period, from 40 to 120 kg live weight. Only one animal can enter the feeding station at the time, but interruptions can occur. Therefore, two traits (events) from feeding stations were generated for this study. These events were when the animal was an interrupter at the feeding station (IntER) and when the animal was interrupted in the feeding station (IntED). In addition, median of daily number of visits through the test period (MVIS) was included in the study. An interruption in the feeding station

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_79, © K.H. Martinsen *et al.* 2022

was defined as the occurrence of two subsequent feed recordings, when the first animal had spent a short period of time in the feeding station (time <2 min), and it was a short time interval (time <1 min) from the animal leaving the feeding station until the next animal entered. The animal leaving the station was defined as IntED and the subsequent animal was defined as IntER. The number of 'interrupted' and 'interrupter' events were summarized per day and averaged over number of days in the test period. Feed consumption from 40 to 120 kg (F40120) was also included in the analyses. Descriptive statistics are presented in Table 1.

Tail biting. Recording of tail lesions (TL) was done throughout the whole test period. The trait was recorded as a binary trait, stating whether the animal had a tail lesion or not. In total, 149 animals (3.5%) in the data set had tail lesions, recorded from 2019 to 2021. Descriptive statistics of the trait is presented in Table 1.

Genetic analyses. The traits were analysed using multivariate animal models, and estimation of variance components and genetic correlations were performed using the DMU software package (Madsen and Jensen, 2013).

The following two models were used to analyse the different traits.

For IntER, IntED, MVIS and F40120:

$$y_{ijklm} = HY_i + MOB_j + PAR_k + animal_l + pen_m + e_{ijklm} \quad (1)$$

For TL:

$$y_{ijk} = YS_res_i + animal_j + pen_k + e_{ijk} \quad (2)$$

Herd-year at birth (HY) *i*, birth month (MOB) *j*, dam's parity number (PAR) *k*, where included as fixed effects in Model 1 and year-season when the animal started the test (YS_res) *i* was included as a fixed effect in Model 2. The effects of animal *l* and pen *m* were included as random effects in Model 1 and animal *j* and pen *k* were included as random effects in Model 2. Litter effect was not significant, as few litter mates were present in the data. Pedigree information was traced 10 generations back and in total there were 12,483 animals included in the pedigree.

Results

Estimates of variance components and heritabilities for feeding behaviour traits and tail lesion are presented in Table 2. Both additive genetic variance components were significantly different from zero. The estimated heritability for the feeding behaviour traits (IntER, IntED and MVIS) were high (>0.5), and the heritability for TL was low (0.05).

Table 1. Descriptive statistics for interrupter (IntER), interrupted (IntED), median daily visits in the feeding station (MVIS), tail lesions (TL) and feed consumption in kg from 40 to 120 kg live weight (F40120).

	n[1]	Mean	SD[1]	Min[1]	Max[1]
IntER	1,926	1.72	0.87	0.34	6.94
IntED	1,926	1.71	1.16	0.11	10.23
MVIS	1,926	9.71	2.92	4	23
TL	4,281	1.03	0.18	1	2
F40120	1,884	171.8	12.1	117.6	239.7

[1] Number of animals (n), standard deviation (SD), minimum value (min), and maximum value (max).

Table 2. Variance components and heritabilities (h^2)[1] for interrupter in feeding station (IntER), interrupted in feeding station (IntED), median of number of visits in the feeding station (MVIS) and tail lesions (TL).

	Additive genetic variance (σ^2_a)	Pen variance (σ^2_g)	Residual variance (σ^2_e)	h^2
IntER	0.27	0.08	0.24	0.53
IntED	0.82	0.02	0.52	0.61
MVIS	6.02	0.02	2.80	0.68
TL	0.0009	0.01	0.018	0.05

[1] $h^2 = (\sigma^2_a) / (\sigma^2_a + \sigma^2_e)$.

The genetic correlations between the traits are presented in Table 3. The genetic correlation between IntER and IntED was 0.89. Similar high genetic correlations were found between IntER and MVIS (0.94) and IntED and MVIS (0.94). The genetic correlations between the feeding behaviour traits and TL and F40120 were low and not significantly different from zero (Table 3).

Discussion

This study has shown that genetic variation existed in feeding behaviour traits recorded in feeding stations and tail lesions in Norsvin Landrace. Other studies have also reported high heritabilities on a wide range of different feeding behaviour traits recorded by feeding stations (Herrera-Cáceres *et al.* 2020; Kavlak *et al.,* 2021). Kavlak *et al.* (2021) reported slightly lower heritabilities for feeding behaviour traits recorded by feeding stations. For number of visits in the feeding station per day, the heritability ranged from 0.26-0.33 depending on age. However, the study included two breeds and crossbred animals in the same analysis and corrected for breed. This might have influenced the results of Kavlak *et al.* (2021). The current study only investigated purebred animals from the same breed. Breuer *et al.* (2005) found significant genetic variation in clinical tail biting in Landrace and estimated a heritability of 0.05 for the trait tail biter. The current study also had information about tail biting animals, but the data material was too small for the analysis. The current study found a heritability of 0.05 for tail lesion in the animal, in accordance with Canario and Flatres-Grall (2018) in a synthetic line (0.06). Scientific studies of tail biting are challenging, as recording of tail biting incidences is difficult. It appears suddenly, is unpredictable and spreads throughout the barn, which makes it difficult to record information pre- or post-outbreak (D'Eath *et al.,* 2014). Using new technology (such as cameras), might make it possible to detect more and a diversity of tail biting incidences, as well as more genetic variation in such traits.

Several studies have tried to investigate potential proxy traits for tail biting, such as pig activity and chewing on objects (Statham *et al.,* 2010: Ursinus *et al.,* 2014). Statham *et al.* (2009) found that activity level in the pen were statistically higher in groups with severe tail biting outbreaks, four days prior to the outbreak. Similarly, Wallenbeck and Keeling (2013) concluded that electronic feeding stations can be

Table 3. Genetic correlations (SE) between feeding behaviour traits, tail lesion (TL), median of number of visits per day (MVIS), and feed consumption from 40 to 120 kg live weight (F40120).

	MVIS	TL	F40120	IntER[1]
IntER[1]	0.94 (0.02)	-0.09 (0.2)	-0.12 (0.13)	-
IntED[2]	0.94 (0.02)	0.05 (0.2)	-0.10 (0.13)	0.89 (0.03)

[2] Interrupted in feeding station.

used for surveillance of tail biting outbreaks in pigs. The current study did not find any significant genetic correlations between the feeding behaviour traits and tail lesions. In this study, 149 animals had recorded a tail lesion (3.5%), and the rest of the animals were assumed healthy. This might underestimate the actual frequency of tail lesions**.** Further, it is reasonable to expect more accurate results if the frequency was higher. In the current study, only information about tail lesions is included. From a biological perspective, a trait like 'tail biter' might be more linked to feeding behaviour traits like IntER, as biting the tail of an animal inside the feeding station is a strategy for getting access to the feeding station. However, such a link was not identified in this study. As the frequency of tail lesions in this study was low, the results should be interpreted with caution. There is a need for more and accurate data to identify the genetic relationship between feeding behaviour and tail lesions. The genetic correlation between MVIS and TL (not shown) was not significantly different from zero, in accordance with the other genetic correlations between feeding behaviour and tail lesions (Table 3). However, the current study revealed high genetic correlations between IntED, IntER and MVIS (Table 3). These results suggested that the feeding behaviour traits in this study were similar, as they describe different quantifications of activity level at the feeding station area. Further, it seemed like IntER or IntED added little additional information to MVIS, which is routinely recorded in the breeding program (Table 3).

80. Response to selection for social dominance including direct and indirect genetic effects

B. Tuliozi*, E. Mancin, G. Gomez Proto, R. Mantovani and C. Sartori

Department of Agronomy, Food, Natural Resources, Animals and Environment, University of Padova, Via dell'Università 16, 35020 Legnaro, Italy; beniamino.tuliozi@unipd.it

Abstract

This study aimed to estimate genetic parameters for social dominance and calculate the response to selection for the direct and indirect component of this trait in an Alpine cattle breed. The outcomes of dyadic interactions occurring in 18 years of ritualized cow contests were analysed using a quantitative model including indirect genetic effects. Response to selection was calculated via a multivariate approach, assigning different weights to direct and indirect components of social dominance. Variances for direct and indirect components were equivalent in magnitude to each other and to their covariance, which exhibited the opposite sign. This caused selection responses to be equal in magnitude but differing in verse whenever selection weights were slightly higher for one component. Our study provides evidence that minimal departures from a balanced selection can strongly select the ability to win (or lose) contests: we argue that this has might have wide-ranging consequences for crucial welfare issues.

Introduction

Social dominance, defined by Strauss and Shizuka (2022) as 'a dyadic social relationship that emerges from sequences of agonistic interactions, where one individual exhibits subordination' is a key aspect of the life of social species. This relationship is the basic component of the social hierarchies that are established within social groups, which in turn can determine resource access and greatly impact individuals' phenotype and welfare. Dominance hierarchies arise in cattle whenever unfamiliar individuals are grouped together, both under intensive rearing systems and in free-ranging conditions (Phillips, 2002). While dominance *per se* is not correlated with increased aggressiveness (Plusquellec and Bouissou, 2001), a consistent selection for dominant individuals can lead to welfare issues, as several key health and life history traits present negative genetic correlations with fighting ability (Sartori *et al.*, 2020). An effective strategy to study the genetic basis of social dominance is to use indirect genetic effects (IGEs), which model the influence of other individuals on the focal's phenotype. Cows of local Alpine breeds of cattle in Switzerland and Italy are employed in ritualized fighting contests that mirror those that happen at summer pastures when herds meet and interact freely. These contests have great importance in local culture and are structured as a series of dyadic agonistic encounters between cows. This setting has given researchers the rare chance to investigate the genetics of social dominance using models including IGE (Sartori and Mantovani, 2013). The response to selection of social dominance has not been yet studied: in this study our aims are thus: (1) assess the variance components for social dominance including IGEs; (2) describe how to calculate the response to selection for direct and indirect components of dominance under different selective conditions. Our results will allow to lay the necessary groundwork for considering social dominance into future welfare decisions.

Materials & methods

Study subjects and data collection. All 12,016 study subjects (23,591 individuals in the pedigree) belonged to the Aosta Chestnut-Black Pied cattle. Information on dominance (42,938 contests) was collected during ritualized cow contests (Batailles des Reines; 20-21 day-long weekly contests per year over 18 years). This local tradition finds its roots centuries ago, as a way of mimicking the same contests for dominance occurring at pasture. Each contest consists of a series of individual confrontations among cows belonging the entire population, where two cows coming from different herds are led to face each other and

are free to interact until one of the two cows shows a submissive posture. Cow interactions are not cruel (most interactions are not physical) and welfare of animals is guaranteed by qualified expert veterinarians monitoring the competitions. Each cow is allowed to compete in multiple contests per year, each including up to seven confrontations per cow. For further details see Sartori and Mantovani (2013).

Modelling social dominance trait. We considered the dyadic interactions as a trait, and to avoid data duplication each interaction was present only once in the dataset, with one individual being randomly chosen as focal while the other was recorded as opponent. Phenotype was 2 for victory and 1 for defeat. Fixed factors retained in the analysis were year, day of tournament, weight category, difference in age and difference in weight between focal and opponent. Under the variance partitioning approach (Bijma, 2010) for IGEs, the genetic model can be written as: $y = X\beta + W_h h + W_D Pe_D + W_C Pe_C + Z_D a_D + Z_C a_C + e$; where y is an N×1 vector including the binary outcomes, β is the vector of fixed effects, h is the vector for the herd of focal, Pe_D is the vector of direct permanent environmental (Pe) components, Pe_C is the vector of Pe effects provided by the opponent, a_D is the vector of direct genetic component, a_C is the vector of the additive indirect effect, and e is the vector of error terms. Moreover, X, W_h, W_D, W_C, Z_D and Z_C are incidence matrices with proper dimensions. With A being the additive relationships matrix, genetic components can be written as C⊗A, with C as a 2×2 matrix including direct and indirect genetic (co)variances, that are σ^2_{aD}, σ^2_{aC} and $2{\cdot}\sigma_{aDC}$. A similar structure can be assumed also for Pe, that is CPe⊗I, including an identity matrix I and a 2×2 matrix for direct and indirect Pe (co)variances σ^2_{PeD}, σ^2_{PeC} and $2{\cdot}\sigma_{PeDC}$. The model was run under a Bayesian approach using the program THRGIBBS1f90 (Misztal 2008). We ran 550,000 Gibbs sampling iterations with a burn-in of 50,000 samples. We computed a direct heritability for social dominance as $h^2_D = \sigma^2_{aD}/\sigma^2_P$, where the total phenotypic variance σ^2_P sums all variance estimates. We also calculated an indirect heritability $h^2_C = \sigma^2_{aC}/\sigma^2_P$, a total heritable variance $h^2_{TOT} = (\sigma^2_{aD}+\sigma^2_{aC}+2\sigma_{aD,C})/\sigma^2_P$, and the genetic correlation between direct and indirect components, $r_{aDC} = \sigma_{aDC}/(\sigma^2_{aD}{\cdot}\sigma^2_{aC})^{0.5}$ (Bijma 2010). The variation of individual estimated direct and indirect breeding values as well as of the estimated total breeding value (written as TBV = DBV+SBV, Bijma 2007) were plotted in a 20 years' time-window (Figure 1).

Predicted response to selection. When selecting for social dominance, typically there is direct selection for the capability to win contests, i.e. being dominant. At the same time, this brings a correlated response on the capability to lose contests, i.e. being subordinate. Direct response to selection for a trait x (R_x; Falconer and Mackay, 1996) is: $R_x = ih_x\sigma_{ax}$ (1), where i is the selection intensity (deviation of selected individuals

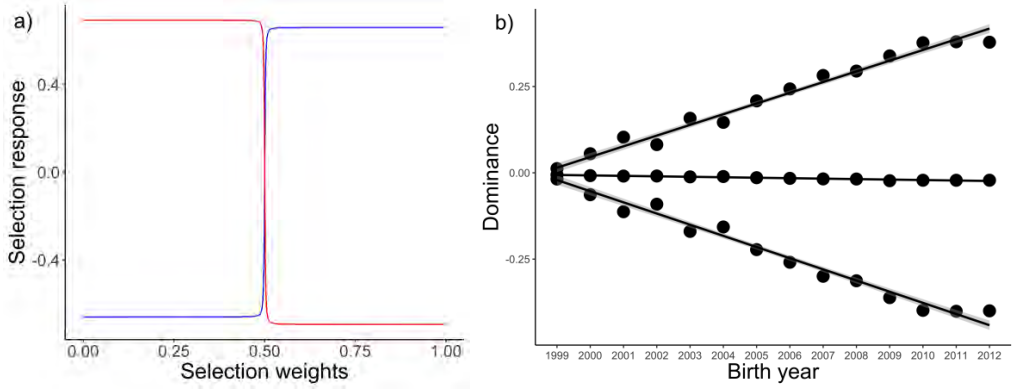

Figure 1. (a) Influence of selection weights of the direct component on selection responses. (b) Genetic trend of direct, indirect, and total estimated breeding values.

from population mean on the phenotypic standard deviation of the trait (σ_{Px}), h is the square root of the narrow-sense heritability of the trait ($h^2_x = \sigma^2_{ax}/\sigma^2_{Px}$), and σ_{ax} is the genetic standard deviation of the trait. The correlated response to selection on a trait y (CR_y; Falconer and Mackay, 1996) is: $CR_y = ih_x r_a \sigma_{ay}$ (2), where r_a is the genetic correlation between traits x and y and σ_{ay} is the genetic standard deviation of the trait y. In social dominance, an individual showing the direct trait 'good at winning' also holds the information 'bad at losing' as indirect effect: we thus expect a genetic correlation between these two components close to -1: r_a = -1, and equal variances but opposite covariances for direct (D) and indirect (C) components (Bijma, 2011): $\sigma^2_{aC} = \sigma^2_{aD}$; $\sigma_{aDC} = -\sigma^2_{aD}$. Empirical evidence has been already provided (e.g. Wilson *et al.*, 2011; Sartori and Mantovani, 2013). Moving from these assumptions and formulas (1) and (2), the direct selection for D is $R_D = ih_D\sigma_{aD}$ and the correlated response on C is $CR_C = ih_D(-1)\sigma_{aD}$, that is: $CR_y = -ih_D\sigma_{aD}$ (3). We therefore expect for the subordinate condition a correlated response to selection that is equal in magnitude but opposite in direction with respect to the direct selection response on the dominant status. Similar relationships may also link the permanent environmental variance of direct and indirect effects when present as in Sartori and Mantovani (2013). We can make similar considerations also moving to a multivariate context and applying the formulas of multivariate response to selection (R; Lande, 1979), here written as in Kause *et al.* (2015): $R = (i/\sigma_i)b'P^{-1}$ (4), where σ_i is the standard deviation of the selection index $\sigma_i = (b'Pb)^{0.5}$, b is the vector of weights for the selection index, being $b = P^{-1}Ga$, P the phenotypic (co)variance matrix and G is genetic (co) variance matrices. Here, the genetic matrix considered is C, and P sums C, CPe and the random residual term. Vector a includes the standardized economic weights of direct and indirect components, obtained as a_0/σ_a, being each a_0 the economic weight assigned to the target component and σ_a the respective square root of the genetic variance (either direct or indirect). We assigned different economic weights varying from 0 to 1 to direct and indirect components, mimicking the possible contexts in which dominance can occur and evolve. Yearly selection rate was calculated by dividing R by the population generation length t=4.32 computed from pedigree.

Results & discussion

Posterior means are reported in Table 1. As expected, σ^2_{PeD} and σ^2_{aD} are close to equal respectively to σ^2_{PeC} and σ^2_{aC}. σ_{PeDC} and σ_{aDC} are also similar in magnitude to their respective components, but with opposite sign; in fact, we found a negative correlation close to -1 between direct and indirect genetic component of dominance. Heritability of both direct and indirect component was in line with previous studies (Sartori and Mantovani 2013), with total heritability close to 0, because of the strong negative covariance (Moore

et al., 2002). Strength of response to selection (R) varied according to the economic weights assigned (Figure 1a): as expected, direct and indirect components showed roughly opposite R, apart when the same economic weight (0.5) was assigned. In this case, both direct and indirect selective pressures are active on both components, constraining R to values close to zero. This mimics a situation in which both being dominant and subordinate status are advantageous for individuals (the selection for indirect component of being dominant is the same to select for being subordinate). It is interesting to note that minimal departures from a balanced selection for direct and indirect components lead to the same R we have when only one component is directly selected, meaning that just scarce selective pressures are able to trigger an empirical selection favouring the ability to dominate, or vice versa. This situation is occurring in Aosta Chestnut-Black Pied cattle: genetic trends (Figure 1b) show a weak but constant divergence of the estimated breeding values of the direct and indirect component and a null variation of the total breeding value, which suggests the occurrence of an active empirical selection for being dominant, as if economic weight higher than 0.5 was assigned to this component. Social dominance itself does not carry a negative connotation for the individuals' welfare: breeds selected for social dominance do not show increased aggressiveness (Plusquellec and Bouissou, 2001). However, the genetic trend hereby reported might underscore a genuine risk for the welfare of the breed due to the worsening of health traits genetically correlated to social dominance, such as somatic cells count (Sartori *et al.*, 2020). Given our evidence in support of the strong selection response for social dominance, both direct and indirect, we argue that an awareness of possible ongoing selective pressures for social dominance at the breed or herd level may help to guarantee an adequate animal welfare by informing management decisions – for example, by choosing breeding individuals showing favourable features for both social dominance and welfare-related traits.

Abstract

This work summarizes the main results of the CHEESR project, a national initiative with the aim of introducing innovative tools for biodiversity conservation and genetic improvements of the Italian small ruminant populations. Pedigrees from 81 breeds and genomic data from 11 case-study breeds have been analyzed. These, together with the collection of new phenotypes, led to the development of welfare- and health-related genomic tools for the first time in Italian sheep and goats. The introduction of these new instruments, which will continue with the SHEEP&GOAT project, will contribute to devise new strategies for sustainable development of the Italian small ruminant sector.

Introduction

Livestock genetic variability has a pivotal role in the ecosystem conservation, the land management, and the mitigation of the effects of climate change (Cao *et al.* 2021). Thanks to its history and variety of environments, climates, and traditions, Italy is characterized by a great biodiversity of all livestock species (Cortellari *et al.* 2021b), with over 80 small ruminant breeds. The scientific research about the Italian biodiversity has been conducted by the *Italian Goat Consortium* for goats (Nicoloso *et al.* 2015; Cortellari *et al.* 2021a; b) and by the Bi.Ov.*Ita Consortium* for sheep (Ciani *et al.* 2014; Mastrangelo *et al.* 2018). The European Agricultural Fund for Rural Development (EAFRD) financed the Italian National Rural Development Plan (PSRN) – sub-measure 10.2 – 'Conservation, Health and Efficiency Empowerment of Small Ruminant' (CHEESR project), managed by the Italian Sheep and Goat Breeders Association (Asso.Na.Pa.). This project aims to introduce in the Italian sheep and goat sector several innovative actions related to: the monitoring and conservation of the biodiversity, the improvement of the breeds with the collection of new phenotypes, and the development of new genetic and genomic breeding values.

The present work summarizes the main results of the CHEESR project, focusing on the application of innovative genomic tools in the Italian small ruminant sector to support biodiversity management and the genetic improvement of the populations under selection, eventually providing information about future developments.

Materials & methods

Genealogic data of 35 goat breeds and 46 sheep breeds were analyzed through *optiSel* R package: pedigree depth and completeness and the main genetic and demographic parameters were estimated. Furthermore, effective population size (Ne) was estimated using Wright's formula, based on the male (M) and female (F) ratio (4MF / M+F), calculated in 2020 for each breed.

The OvineSNP50 and GoatSNP50 bead chips were used to genotype 2,820 sheep of seven breeds (Sarda, Istriana-Carsolina, Comisana, Massese, Delle Langhe, Fabrianese, and Gentile di Puglia) and 3,320 goats of four breeds (Saanen, Camosciata delle Alpi, Garganica, and Nicastrese). Runs of homozygosity (ROH) and the related inbreeding coefficient (F_{ROH}) were analyzed using Plink software. These data were also used, together with phenotypic information collected from 3,680 goats and 766 sheep, to develop new genomic breeding values with the BLUPF90 family softwares. The Single Step Genomic Best Linear Unbiased Prediction (ssGBLUP) method was applied to estimate the variance components of the welfare score (Wel), locomotion score (Loc), body condition score (BCS), and somatic cell score (SC). Wel is composed of 2 traits (chest circumference and BCS) for goats and 4 traits (chest circumference, BCS, presence of abscesses, and *lupìa*) for sheep. Loc is composed of 9 traits for goat and 8 for sheep; these morphological traits and morpho-functional defects are related to limbs, dorsal line and rump, and udder as well as hoof care.

Results

Considering the pedigrees of all the 81 Italian breeds, in median, we could trace up to 2 and 3 full generations and up to 5 and 7 maximum generations for goat and sheep, respectively. The pedigree completeness varied among breeds, with a median percentage of sheep with a complete first generation higher than goats (34 vs 14%). According to the effective population size (N_e), 18% of the breeds appear to be at risk of extinction in the short term (N_e<50).

Pedigree and genomic data for the 11 genotyped breeds are reported in Table 1. The correlation between the pedigree-based (F_{PED}) and the genomic (F_{ROH}) inbreeding coefficients was significant for Sarda, Massese, Comisana, Delle Langhe, Camosciata delle Alpi and Saanen breeds. At species level, the correlation was higher in sheep (r=0.82, *P*<0.0001) than in goats (r=0.28, *P*<0.0001). Differ0ences in the recent inbreeding, derived from long ROH, can depend on the management and structure of the populations.

All the traits presented here (Wel, Loc, BCS, and SC) are not under selection and have been analyzed for the first time in the Italian populations within this project. The results of the two composed scores (Wel and Loc) are reported in Table 2. The great majority of animals do not present welfare-related problems (Wel = 0). Instead, about only one third of the sheep presents the lowest possible Loc score. The heritability of all the analysed traits was calculated. The wide highest probability density (HPD) interval of the estimated h^2 suggests that, increasing the sample size and selecting the most representative animals, there is room for improvement (Table 3).

Table 1. Results of the pedigree and genomic analyses for the genotyped breeds.[1]

Breed	FullGen	MaxGen	N_e	F_{PED}	F_{ROH}	r	% F_{ROH} for ROH>16 Mb
[S]Sarda	9	40	19,169	0.093	0.134	0.80*	19%
[S]Massese	8	28	1,561	0.038	0.078	0.32*	10%
[S]Gentile di Puglia	4	11	1,042	0.008	0.045	0.84	22%
[S]Comisana	8	20	726	0.018	0.051	0.38*	9%

[G]Nicastrese	2	4	684	0.000	0.036	0.00	24%

[1] [S] = sheep; [G] = goat; FullGen = maximum number of fully traced generations; MaxGen = maximum number of generations traced; N_e = effective population size; F_{PED} = mean pedigree-based inbreeding; F_{ROH} = mean genomic inbreeding, r = correlation coefficient between F_{PED} and F_{ROH}; * = *P*<0.0001.

Table 2. Results of welfare and locomotion scores.[1]

Breed	Wel			Loc		
	0	1	2	0	1	2
[S]Comisana (n. 529)	88%	12%	0%	32%	49%	19%
[S]Massese (n. 219)	93%	6%	1%	31%	51%	18%
[G]Camosciata delle Alpi (n. 2662)	97%	3%	0%	87%	10%	3%

[1] [S] = sheep; [G] = goat; Wel = welfare score; Loc = locomotion score; the higher scores are related to animals with more welfare-or-locomotion-related problems.

Table 3. Heritability for the analyzed traits.[1]

Breed	Wel h^2 (HPD)	Loc h^2 (HPD)	BCS h^2 (HPD)	SC h^2 (SD)
[S]Comisana	0.10 (0.006-0.24)	0.09 (0.001-0.24)	0.11 (0.02-0.25)	0.03 (0.01)
[S]Massese	0.13 (0.004-0.34)	0.18 (0.005-0.43)	0.17 (0.004-0.38)	0.05 (0.02)
[G]Saanen				0.09 (0.02)
[G]Camosciata delle Alpi	0.30 (0.003-0.58)	0.13 (0.004-0.28)	0.26 (0.03-0.48)	0.10 (0.02)

[1] [S] = sheep; [G] = goat; Wel = welfare score; Loc = locomotion score; BCS = body condition score; SC = somatic cell score; HPD = high probability density interval; SD = sample standard deviation; h^2 = heritability.

Discussion

Our findings show that the Italian small ruminant populations present a wide variety of situations in terms of pedigree management. Overall, sheep breeds are characterized by a higher pedigree depth, completeness, and effective population size than goats. These parameters are fundamental for the management of the populations, both when pursuing their conservation and genetic improvement, because they can influence the accuracy of inbreeding and parentage estimates. The integration of the genomic tools with the more traditional ones represents an important upgrade that allows to overcome unreliable or incomplete pedigree data. Moreover, the collection of new phenotypes led to the development of breeding values that meet the demands for greater guarantees in terms of animal welfare and health, paving the way for a more sustainable small ruminant sector. Our results show a low variability of Wel and wide high probability density interval (HPD) of the hereditability estimates of Wel, Loc, and BCS. With the aim to develop an accurate welfare breeding evaluation we will review our results and the welfare-related traits collected and analyzed considering the difference between the two species and the diversified management system. All the activities undertaken within the CHEESR project, including the phenotypic and genotypic characterization for the study of biodiversity and the development of genomic breeding values, will continue with the *SHEEP&GOAT* project (supported by EAFRD for the period 2021-2023): through the genotyping of all the Italian small ruminant breeds present in at least three registered farms, this project will help to better portray the situation of the whole sector and will contribute to define national strategies to safeguard the Italian biodiversity.

82. How can breeding for improved animal welfare meet societal expectations and challenges?

A. Wallenbeck

Swedish University of Agricultural Sciences, P.O. Box 7068, 750 07 Uppsala, Sweden; anna.wallenbeck@slu.se

Abstract

Animal production can play an important role in meeting many major societal challenges worldwide. Moreover, expectations from consumers and society on improved welfare in production animals relate to all parts of the production process, including breeding. The welfare of production animals is affected, both positively and negatively, by breeding techniques and by the genetic changes accomplished through breeding. Development of broad breeding goals, including animal welfare traits, taking the preferences of stakeholders in a broad sense into account, would improve the possibilities to meet societal expectations and challenges. A major challenge for future breeding for improved animal welfare meet societal expectations and challenges is to breed animals suitable for unknown future production environments. Examples of breeding options are inclusion of animal welfare-related traits in genomic selection using information from automatic surveillance and development of associative breeding.

Introduction

Public and societal interest in animal welfare is high (Eurobarometer, 2016) and consumer awareness of animal welfare in production animals is increasing (EconWelfare, 2011; Leonardsson, 2011). Animal welfare, i.e. the subjective experience of the individual animal, its biological functioning and its adaptation to its current environment (e.g. Fraser *et al.*, 1997), encompasses a combination of aspects relating to animal health, physiology and behaviour. Expectations from consumers and society on improved welfare in production animals affect all parts of the production process, including breeding. In a growing number of cases, consumer and public opinion are influencing the choice of breeding animals in modern animal production, e.g. the Belgium Blue cattle breed has been banned in Sweden and there are restrictions on the use of fast-growing broiler hybrids in the Netherlands and Norway. Thus, animal production with a high focus on improved welfare is no longer a small niche market for farmers, or for breeding companies.

Animal production, including the aspects of animal welfare and breeding, plays an important role some of the major societal challenges in the world today. Goals set by the United Nations in 2015, in response to the major global societal challenges, include a world without poverty and hunger, and safe from the worst effects of climate change and loss of biodiversity by 2030 (United Nations, 2015). These Sustainable Development Goals (SDGs) have a wide scope and production animals are rarely mentioned, while animal welfare is not mentioned at all. However, mutual benefits from improving animal welfare and achieving the SDGs have been identified, indicating a positive role of improved animal welfare in meeting the SDGs (Keeling *et al.*, 2019; Olmos Antillón *et al.*, 2021).

This paper describes the effects of breeding on the welfare of production animals and examines ways in which future breeding for improved animal welfare can meet societal expectations and challenges.

Breeding for improved animal welfare

Effects of breeding on animal welfare. Animal breeding involves designing a breeding programme, selecting the parents for the next generation and developing techniques related to breeding, such as artificial insemination (AI), embryo transfer (ET), sexing of semen, detailed analyses of DNA information and gene modification. Several of these techniques have consequences for animal welfare, both positive and

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_82, © A. Wallenbeck *et al.* 2022

negative. One example is the strategic use of sexed semen to improve animal welfare by avoiding culling of many young animals (e.g. male offspring with low economic value in egg and dairy production). Another example is the rapid decrease in the spread of diseases when AI was introduced in livestock breeding and mixing of animals from different herds for breeding purposes was no longer necessary. However, AI and ET may include matching of breeds with large size differences, which can result in birthing problems if the offspring is too large for the mother. Moreover, DNA information has been used for many decades for elimination of diseases, and thus improved animal welfare.

The traditional aim of modern breeding programmes for production animals is to increase production efficiency, e.g. more milk, eggs or lean meat growth per animal and/or feed unit. The direct effect has been a remarkable increase in production efficiency (Van der Steen *et al.*, 2005; NAV, 2018), and thus a reduction in the environmental load per unit of product. However, in cases with unfavourable genetic correlations between production and animal welfare-related traits and where animal welfare-related traits are not monitored, it can lead to deterioration in animal welfare.

Towards sustainable breeding – for improved animal welfare, production efficiency and low environmental load. During recent decades, there has been a general trend for broadening breeding goals to include animal welfare-related traits such as health, temperament, survival and longevity. These broader breeding goals have led to improvements in production, resource efficiency and animal welfare simultaneous. For example, there have been improvements in milk yield, udder health, feed efficiency and general health in dairy cows (e.g. NAV, 2018), leg health, feed efficiency and growth rate in pigs (e.g. Aasmundstad *et al.*, 2014) and foot pad dermatitis, feed efficiency and growth in broilers (e.g. Kapell *et al.*, 2012).

Sustainable development of animal production, which includes the animals in the system, needs to consider economic, environmental and social aspects (e.g. Dockes *et al.*, 2011). Increased emphasis on achieving the UN SDGs and increasing consumer and societal interest in animal welfare require the development of long-term sustainable breeding strategies. Sustainable breeding strategies need to consider the requirements of all stakeholders in the food chain, e.g. farmers, retailers and consumers (Gamborg *et al.*, 2005). An important step in the development of breeding goals is to identify traits that are important and which should be included in the breeding evaluation (Boelling *et al.*, 2003).

Decisions on the traits included in modern breeding goals are generally based on expert opinion and what is currently practically and economically feasible. They are more seldom based on farmers' preferences. Although all stakeholder groups are important in the process of developing sustainable breeding strategies, farmers have essential knowledge about how animals are functioning on their farms and they ultimately decide which animals they will use and what genetic material they will purchase. In a study investigating the breeding traits perceived by dairy and pig farmers to affect profitability, environmental load and animal welfare, both pig and dairy farmers considered that all suggested breeding traits have impacts on profitability (Wallenbeck *et al.*, 2013). There were also similarities between pig and dairy farmers regarding traits considered to be related to environmental load and traits related to animal welfare. In the same study, genetic simulations indicated that a breeding goal aiming at decreased environmental impact would lead to genetic improvement in environmental and production traits, while a breeding goal aiming for improved animal welfare would lead to genetic improvement in animal welfare traits without affecting productivity traits (Wallenbeck *et al.*, 2015). Overall, that study showed that it is theoretically possible to design breeding goals which simultaneously improve animal welfare, decrease environmental load and improve production efficiency

Modern breeding is continually developing new approaches, e.g. genomic selection by improved statistical modelling, with the aim of increasing the rate of genetic improvement. Increased genetic change over time can improve the genetic potential for improvements in animal welfare traits as long as these traits are included in the breeding goals or have favourable genetic correlations to traits included in the breeding goals.

Future challenges and ways in which future breeding for improved animal welfare can meet societal expectations and challenges

Breeding for future production environments. Societal expectations and challenges will influence the development of future animal production systems, and thus the context for animal breeding. If evaluation and selection of parents is performed in a production environment diverging from that of commercial production animals, genotype by environment interactions may occur, with a particular phenotypic trait being partly governed by different genes in different environments. One way to take variation in production environments into account is to breed for genetic placidity. A major challenge for animal breeding is to cater for future production environments influenced by e.g. climate change and animal welfare demands.

Including new animal welfare traits. In recent years, housing and management practices aimed at improving animal welfare and methods for automatic surveillance of animal welfare indicators, e.g. methods related to precision livestock farming, have been developed. Examples include processing information derived from video recordings, automatic feeding systems, milking robots and activity monitors, while physiological parameters such as biomarkers are also relevant animal welfare indicators. In parallel, breeding technologies have been developed and improved. There are great possibilities to include animal welfare traits derived from automatic surveillance in both genetic and genomic selection (Brito *et al.*, 2020). Genomic selection, with the opportunity to include a larger number of traits in the selection, has particular potential, as the concept of animal welfare is broad (covering animal health, physiology and behaviour). Thus further development requires a transdisciplinary approach, including e.g. genetics, immunology, physiology, computer science, ethology and animal welfare science.

Another area with great opportunities to improve the genetic potential for animal welfare-related traits is associative breeding focusing on social (or associated) genetic effects, i.e. selecting animals based on their genetic potential to affect their group members (Muir, 2005; Bijma, 2007). Associative breeding is of particular interest in attempts to select against injurious social behaviour. The method is promising for improving production and welfare simultaneously, and captures the entire behavioural profile of the animals as it considers the consequences of their behaviour, not their behaviour as such, in the evaluation (Turner *et al.*, 2018).

83. Swine inflammation and necrosis syndrome (SINS) and its association with biting behavior after weaning

N.L. Leite[1*], E.F. Knol[2], S. Nuphaus[2], S. Tsuruta[1], R. Vogelzang[2] and D. Lourenco[1]

[1]University of Georgia, 425 River Rd, 30602, Athens, USA; [2]Topigs Norsvin, Schoenaker 6, 6641 SZ Beuningen, the Netherlands; nataliagaloro@uga.edu

Abstract

In this study, we estimated genetic (co)variance components of the swine inflammation and necrosis syndrome (SINS), postweaning biting damage (BD), and several production traits in a three-way crossbred population. Additionally, we evaluated the benefits of modeling BD using social interaction models in an F1 gilt population. Our results showed that SINS and BD have substantial genetic variances and are moderately and positively correlated. That suggests that piglets genetically more prone to be born with SINS signs are also more likely to suffer from biting after weaning. Unfavorable correlations between SINS and BD with important production traits, such as backfat thickness and loin depth, require close attention. Modeling BD using social interaction models increased the prediction accuracy of breeding values, reduced bias, and increased the total genetic variation by 2.5 folds, thus highlighting better possibilities for breeding for overall pig welfare.

Introduction

The swine inflammation and necrosis syndrome (SINS) results from a blood flow constraint of capillaries, leading to loss of skin function at the far ends of body parts, such as the tail, ear, and teats. This syndrome can affect up to two-thirds of all newborn piglets, but it can also be observed later in a pig's life. Under such conditions, pigs might suffer from a chronic reduction of their welfare and productivity throughout the growing process (Reiner *et al.*, 2021). Besides the direct effects of SINS, affected animals may be potentially more susceptible to bites after weaning because affected parts of the body, such as the tail and ears, can trigger the suckling and biting behavior of pen mates.

Biting behavior challenges the pig industry in coping with the increasing animal welfare standards. Besides the clear welfare issue, damaged animals might have decreased productivity and be more susceptible to infectious diseases due to open wounds, undoubtedly affecting individual and herd health status. Decreasing biting behavior is needed and might be achieved through improvements in the environment and genetic selection (Schrøder-Petersen *et al.*, 2001).

Biting behavior can be phenotypically expressed as a combination of, for instance, tail, ear, and vulva biting, which are known to result from animal social interaction. Although social interaction is usually taken as a complete environmental effect, animals might behave differently towards their pen mates due to their different genetic backgrounds. The genetic effect of an animal over the phenotype of others in the same group is called the indirect genetic effect, and social interaction models can account for it (Bijma *et al.*, 2007).

Accounting for indirect genetic effects using social interaction models might increase the total genetic variance of a trait and, consequently, improve the rate of genetic gain. Moreover, it could help manage negatively correlated responses in situations where the direct and indirect effects are negatively correlated (Bijma *et al.*, 2007).

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_83, © N.L. Leite *et al.* 2022

Our objectives were to: (1) estimate genetic (co)variance components of the swine inflammation and necrosis syndrome (SINS), postweaning biting damage (BD), and several production traits; (2) evaluate the benefits of modeling BD using social interaction models.

Materials & methods

Genetic relationship between SINS, BD, and production traits. A total of 5,960 three-way crossbred piglets born from 80 sires and 240 dams were evaluated. Piglets presenting any signs of teat, claw, ear, or ear SINS at birth were scored as 2, and piglets with no SINS signs were scored as 1. Information on birth weight (BW), weaning weight (WW), BD (1 or 2), backfat carcass thickness (BF), and loin depth (LOD) were also recorded. Biting damage was recorded on the transferring day from the nursery to the finishing phase (9 weeks of age). The binary codification for BD was chosen because of the low incidence of the trait and the inference problems associated with the evaluation of traits with multiple categories with small variance. Four multiple-trait animal models with combinations of SINS, BD, and an alternative production trait were used to assess trait heritabilities and genetic correlations. Alternative traits were BW (Model A), WW (Model B), BF (Model C), and LOD (Model D). The maternal effect was included only in the BW, WW, and SINS models. Normality was assumed for all traits, and the BLUF90 family of programs was used for further analyses (Misztal *et al.*, 2014).

Modeling BD using social interaction models. A total of 46,340 F1 gilts were scored for BD (1 or 2) at the end of the growing phase (21 weeks of age). Gilts were housed in similar commercial conditions and housed in groups of 10.7±0.7 individuals. Two animal models were used for variance component estimation: an animal model only accounting for direct genetic effects (Model 1) and a second model extended with indirect effects (Model 2), as described as follows:

$$y=X\beta+Z_Da_D+Wc+Fg+e \quad (1)$$

$$y=X\beta+Z_Da_D+Z_Sa_S+Wc+Fg+e \quad (2)$$

where y is the vector of phenotypes, β is the vector of fixed effects of the scorer, line, and age covariate, a_D is the vector of direct genetic effects, a_S is the vector of indirect genetic effects, c is the vector of the common environment of litter, g is the vector of group effects, and e is the vector of residuals; X, Z_D, Z_S, W, and F are incidence matrices for the effects in the vectors β, a_D, a_S, c, and g, respectively.

A forward validation was performed to evaluate the prediction accuracy, bias, and dispersion of both models. The validation set was composed of 14,710 young gilts born from 2020 to 2021 that had classical breeding values (EBV; Model 1) and total EBV (TBV; Model 2) estimated with a complete dataset (including all phenotypic information available) and with a partial dataset (excluding phenotypes of the validation set). TBV were calculated as:

$$TBV = a_D + a_S(N-1) \quad (3)$$

where N is the average number of pen mates in the population.

Both EBV and TBV from partial and complete datasets were later used to calculate prediction accuracy, dispersion, and bias of both models following the Linear Regression (LR) method (Legarra *et al.*, 2018). Phenotypes were assumed to follow a normal distribution, and analyses were performed using the BLUF90 family of programs (Misztal *et al.*, 2014).

Results

Genetic relationship between SINS, BD, and production traits. Estimates of direct heritabilities and genetic correlations in the four multiple-trait models are presented in Table 1. The direct heritability of SINS ranged from 0.15 to 0.24, whereas heritabilities for BD were lower, ranging from 0.05 to 0.06. Direct genetic correlations between SINS and BD were moderate and positive (from 0.19 to 0.50). The direct effect of SINS was negatively correlated with BW (-0.30), WW (-0.40), and LOD (-0.16) but not significantly correlated with BF (0.05). BD was strongly correlated with WW (-0.61), BF (-0.84), and LD (0.76) but not significantly correlated with BW (-0.11).

Modeling BD using social interaction models. BD heritability in Model 1 was low at 0.04, whereas the total heritable variance in Model 2 was about 2.5-fold greater (0.10). The genetic correlation of direct and indirect effects was not significantly different from zero (-0.06). Validation results are shown in Table 2. Model 2 showed a substantial advantage in prediction accuracy (0.29) over Model 1 (0.20), which did not account for indirect genetic effects. Bias was increased for Model 2 compared to Model 1, whereas dispersion was greatly improved by the addition of indirect effects in Model 2.

Discussion

Genetic relationship between SINS, BD, and production traits. The low but significant heritability estimates for SINS and BD indicate that overall welfare improvement through selection is possible in the long term. The intermediate direct genetic correlation between SINS and BD indicates that piglets genetically more prone to be born with SINS signs are also more likely to suffer from biting after weaning. Such correlations can be associated with the triggering aspect of the necrosed skin on the suckling and biting behavior of pen mates after weaning.

Table 1. Direct heritabilities (diagonal) and genetic correlations (off-diagonal) between SINS, BD, and production traits.

Model 1				Model 2			
	SINS	**BD**	**BW**		**SINS**	**BD**	**WW**
SINS	0.21 (0.02)[1]	0.19 (0.08)	-0.30 (0.08)	SINS	0.23 (0.03)	0.23 (0.09)	-0.40 (0.08)
BD		0.05 (0.02)	-0.11 (0.09)	BD		0.05 (0.01)	-0.61 (0.06)
BW			0.07 (0.01)	WW			0.11 (0.02)
Model 3				**Model 4**			
	SINS	**BD**	**BF**		**SINS**	**BD**	**LOD**
SINS	0.24 (0.03)	0.43 (0.07)	0.05 (0.05)	SINS	0.15 (0.02)	0.50 (0.09)	-0.16 (0.07)
BD		0.06 (0.01)	-0.84 (0.04)	BD		0.05 (0.01)	0.76 (0.06)
BF			0.63 (0.07)	LOD			0.42 (0.06)

[1] Estimate standard error.

Table 2. Breeding value prediction accuracy, bias, and dispersion in Models 1 and 2.

	Model 1	**Model 2**
Prediction accuracy	0.20	0.29
Bias	-0.27	-0.55
Dispersion	0.46	0.91

The negative genetic relationship between SINS and early growth traits (i.e. BW and WW) indicates that, at the piglet genetic level, a high incidence of SINS may be associated with low birth and weaning weights. However, there might be a low or no significant association between SINS signs at birth and carcass traits (i.e. BF and LOD), possibly due to the long separation in time scale between such traits.

BD was highly and unfavorably correlated with economic production traits, such as BF and LOD, making efforts for selecting against BD even more critical in pig breeding programs. On the other hand, BD was favorably correlated with WW, indicating that piglets with better genetic potential for growth during the lactation stage might be less genetically prone to be injured by biters during hierarchical rearrangements after weaning.

Modeling BD using social interaction models. Our results underline important genetic components on BD behavior in growing F1 gilts. Modeling indirect genetic effects substantially increased the trait total genetic variance, indicating that the genetic component on the behavior of animals over their pen mates could substantially increase opportunities for genetic improvement against biting behavior. The nonsignificant correlation between direct and indirect effects suggests that neither antagonist nor collaborative behavior among animals exists for BD. Therefore, a selection index for overall BD improvement should consider both direct and indirect effects.

The greater genetic variance obtained through modeling indirect effects with social interaction models combined with the associated higher prediction accuracy and smaller dispersion of breeding values highlights an opportunity for more accurate BD predictions and, therefore, faster genetic improvement.

Overall, enough genetic variation exists for SINS and BD; thus, improving overall welfare through genetic selection is feasible. Selecting animals less genetically prone to developing SINS is also expected to positively affect piglet genetics for heavier weaning weight and reduced BD. The strong and unfavorable genetic correlation between BD and important production traits under selection deserves close attention. Accounting for indirect effects of BD using social interaction models might greatly increase possibilities for faster and more accurate genetic improvement.

84. Breeding for future social license for beef production

S.P. Miller[1,2*] and K.J. Retallick[2]

[1]AGBU, a joint venture of NSW Department of Primary Industries and University of New England, 2351, Armidale, Australia; [2]Angus Genetics Inc., 3201 Frederick Ave., Saint Joseph 64506, USA; steve.miller@une.edu.au

Abstract

Examples from Angus cattle provide evidence of positive genetic trends for production traits and, with increasing frequency, for traits more directly related to welfare outcomes. Genetic improvement programs are optimized when clear market signals linked to the commercial sector are in place. When welfare related traits like foot structure were added to profit driven selection indexes, recording levels increased and the accuracy of the evaluation for these traits improved. It is postulated that effective recording and genetic selection for improved welfare should be of interest to consumers. When faced with an informed choice, consumers should be more attracted to beef products which are sourced from production systems where through selection, welfare issues such as dystocia, lameness and reduced longevity are actively minimized. Beef breeders should be making efforts now to ensure a future 'social license' for their products by preparing for such economic feedback in the future.

Introduction

Beef cattle have been improved considerably through selection, resulting in cattle which better meet consumer demands, generate greater profits for breeders and are more competitive as a protein source. However, a focus on existing breeding objectives may not ensure future success for beef production. Breeding priorities for the future will need to address changing consumer demands.

Consumers are becoming more informed and more critical of their purchases across a range of products, with ethical considerations and environmental impacts being increasingly important. It is expected other papers will address reducing cattle's impact on the environment at this congress. This paper will focus on genetic solutions to improve welfare, enabling what is described as a future 'social license'. The term social license refers to the consumer acceptance of the practises underpinning beef production. Although the concept of a social license to produce beef is a relatively new one, this paper highlights genetic improvement initiatives that are already well established and address aspects of animal welfare. Thoughts are put forward as to how direct consumer pressure in the marketplace could accelerate the adoption, development, and genetic improvement of welfare related traits.

Materials & methods

To illustrate genetic improvement and changes to recording practices over time genetic trends and counts of performance records were acquired from the American Angus Association's as used in the National Cattle Evaluation (American Angus Association 2022).

Results

Recent genetic trends for traits influencing animal welfare, along with selected production traits are presented in Figure 1 as are the changes in trait recording levels.

Discussion

The genetic trends in Figure 1 demonstrate improvement across a range of traits, which has been supported by the levels of phenotype recording, also presented. How these trends relate to improving welfare will be discussed for each trait separately.

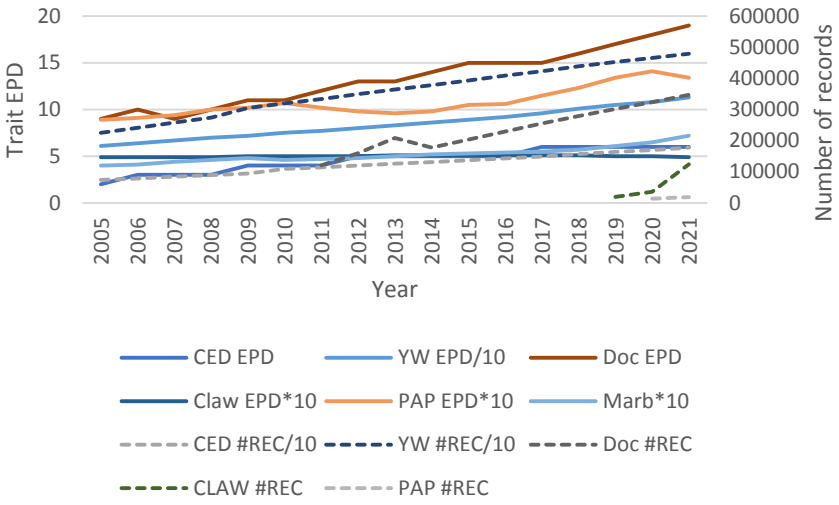

Figure 1. Genetic trends and records available for genetic evaluation for selected traits in American Angus cattle. Traits illustrated are: Calving Ease Direct (CED), Yearling Weight (YW), Docility (Doc), Foot Claw Set (Claw), Pulmonary Arterial Pressure (PAP), Carcass Marbling (Marb). The number of records used in the evaluation from all sources including Canada and Australia, where applicable (#REC).

Calving difficulty. A remarkable thing about the American Angus genetic trends is the continued increase in growth while improving calving ease (reducing dystocia), given the positive genetic correlation between post-weaning gain and birth weight (0.29). Through effective multi-trait selection, aided by the application of economic selection indexes, the Angus breed is now the heaviest breed at a year of age, while also being one of the leading breeds for calving ease as evaluated by the USDA (Kuehn and Thallman 2020). Commercial producers in the USA are conscious of selecting sires that will present very low dystocia rates. There is no doubt dystocia is an animal welfare concern, and it should be recognized that selection for improved calving ease plays a significant role in improving animal well-being.

Docility. The first Docility EPD were presented in 2011 based on 120,770 records and there has been steady improvement in both genetic merit and recording of the trait since. Docility also ranked high in the American Angus survey from 2019 (Santos *et al.*, 2019), but this was also noticeable in interviews involving large processors and feedlots, which indicated that cattle with better temperament were better for their businesses. The docility EPD was added to the maternal component of Angus economic selection indexes ($Values) in 2019. The emphasis has been on improving temperament for the betterment of the farmer, but it should be realized that cattle with better temperament also have better welfare outcomes with *inter alia* less stress and bruising.

Pulmonary arterial pressure (PAP). A disease which affects cattle at higher altitudes in the USA (typically over 1,800 m) is caused by right-heart failure and severe cases lead to death. It is a heritable condition that can be measured with the related trait of Pulmonary Arterial Pressure and significant research has been done on this trait by scientists at Colorado State University (Crawford *et al.*, 2016). Despite the complexity of recording the trait, the PAP measure has been adopted in the region. In 2019, the first EPD were released for PAP, including genomic prediction through the weekly single step evaluation, enabling selection for this difficult trait for breeders across the country. Speaking directly with farmers with affected stock, this disease puts stress on the cattle in their care but also the mental wellbeing of the farmers who need to deal with these losses.

Foot Score. Improving foot structure remains a high priority for breeders as demonstrated by recent survey work (Santos *et al.*, 2019). For this reason, there was much interest in the launch of EPDs for claw set and foot angle in 2018. The evaluation has seen a significant increase in foot score recording since the foot score EPD were incorporated into the economic multiple trait selection indexes ($Values) in 2019. The records contributing to EPDs spiked in 2020 due to a new joint evaluation incorporating records from Angus Australia as described by Alvarenga *et al.* (2022) in a paper submitted to this congress. Cattlemen are searching for 'trouble free' cattle and those with better foot structure will suffer less from lameness and are less likely to be culled. It is clear that improving foot structure is a 'step' towards better animal welfare.

Hair Shedding. Based on work from the University of Missouri (Durbin *et al.*, 2020) a hair shedding research EPD was first released in 2020, based on analyses of 14,396 records and a 2021 re-evaluation involved 22,564 hair shedding phenotypes. The phenotype is based on a simple score (1-5) describing the proportion of winter coat an animal has shed, typically recorded in late spring. This EPD is of most interest to breeders in hotter states, and those in areas that suffer from endophyte infected fescue. With a warming environment, and Angus cattle pushing into hotter regions, such efforts to improve heat tolerance will remain important.

Longevity. Recent research has investigated the potential of a random regression model to estimate breeding values for longevity in Canadian and American Angus but more work is required to further develop a research EPD for release to the membership (Oliveira *et al.*, 2021). In an effort to further improve the data structure to determine longevity, changes have been made to encourage more whole-herd inventory-based reporting from members. Improving longevity will contribute to improved welfare and enhance social license as cows will be less likely to be culled early due to health and structural problems.

Fostering selection for improved animal welfare

Reasons behind breeders' choice to record and select for the traits impacting welfare is likely two-fold. Breeders are also farmers; they naturally want to maintain and improve the health of animals in their care. An example of this not mentioned above is the extensive genotyping Angus breeders have undertaken to reduce the incidence of recessive genetic conditions that result in dead or deformed calves at birth. The other reason for this selection pressure, also pointed out above, is the relationship between these EPDs, $Values and prices for the bulls they sell. By including welfare related traits in the economic selection indexes, which contribute significantly to bull prices, selection of welfare related traits naturally follows.

Proposed here is an additional avenue to put greater economic incentive on animal welfare traits. Afterall, breeding is inevitably about trade-offs. The genetic progress for growth and carcass above is obvious. Any pressure on welfare traits will reduce the progress for these big economic drivers. Welfare traits can become more important economic drivers if more incentives are available in the commercial sector. Work on profit-based selection indexes makes it clear that traits related directly to carcass value, such as marbling in Angus cattle in America, naturally receive significant weighting. If welfare related traits were more directly related to profit in the commercial industry, this would influence selection pressure in the seedstock sector.

To date consumer pressure on production related practices has been evident in other industries, and the objection to caged birds in the laying industry is a good example. Now consumers in developed countries are typically faced with a wide array of choices for eggs, with cage-free, free-range, etc. being predominant options at a premium to cage-laid eggs. This is a typical example of how the marketplace is impacted by welfare concerns, in a straightforward categorical way. The result here being pressure to reduce cage-based production systems.

In beef cattle we could see welfare related traits being addressed in a similar manner. Horns vs polled is a good example, with de-horning becoming an unacceptable practice when there is a genetic alternative available. A breeding program to increase the frequency of polled in the commercial tier is described by Johnston *et al.* (2022) in a paper submitted to this congress. With this economic driver looming, as well as obvious husbandry benefits, the prices of 'polled genetics' in breeds that are introgressing this allele show a significant premium.

The genetic incentive for better welfare should not be restricted to such categorical traits. Consider calving difficulty, where a surgical calving is a greater compromise to welfare than horns disbudded at birth. Like horns, the calving problem could have been avoided in most cases with selection. If consumer pressure can promote differential prices for things like 'cage-free' in hens and perhaps polledness in the future, does it not make sense that this could be extended to all traits impacting welfare? Consider commercial producers purchasing bulls facing the choice between Bull A, which has no genetic description of welfare related traits (as is common in the marketplace now) and Bull B, which is from a seedstock breeder who actively records, and makes EPDs for welfare related traits available to buyers. Should the producer purchasing from supplier B not be rewarded for the due diligence demonstrated to use the tools available to improve animal welfare at the genetic level?

It is argued here that this should be given similar emphasis to moving hens from cages or eliminating horns. If the economic incentive was in the commercial marketplace to reward such selection practices, the increase in recording, selection pressure, and development of new traits could be significant. It has been demonstrated time and again that the greatest incentives for change in cattle breeding always come from the commercial marketplace. Cattle breeders are making good progress in improving welfare related traits now, but if greater direct pull from the commercial sector was present, through demand from consumers, this would improve much faster. It seems such pressure will come and the seedstock sector should be proactive in getting ahead of this demand to ensure a future 'social license' for their products.

85. Selection for piglet mortality and litter size in outdoor organic pig production systems

T.T. Chu[1,2*], R.M. Zaalberg[1], J. Jensen[1] and T.M. Villumsen[1]

[1]Aarhus University, Center for Quantitative Genetics and Genomics, 8830 Tjele, Denmark; [2]Vietnam National University of Agriculture, Faculty of Animal Science, Vietnam; chu.thinh@qgg.au.dk

Abstract

This study evaluated breeding goals for increasing litter size of sows 11 days after farrowing (LS11) in organic production systems while aiming to reduce piglet mortality (Mort11). Investigated breeding goals included LS11 only, or Mort11 and total number of piglets born (TNB) combined. Response to selection, expressed as LS11, was derived using selection index theory. We found that selection based on breeding goal of LS11 only, or using equal economic weights for TNB and Mort11 would increase LS11, but at the costs of increasing piglet mortality. By defining LS11 as two traits of TNB and Mort11, selection could reduce piglet mortality through possibility of altering economic weights for the traits in breeding goals, and through exploiting heritability differences of TNB and Mort11 in selection. By increasing economic weight for Mort11, breeding program for organic pig production could achieve zero genetic change in Mort11 while still gaining more TNB.

Introduction

In non-organic Danish pig production, litter size of sows has increased almost linearly from 2003 to 2019 (Nielsen *et al.*, 2013; Hansen, 2020). In the same period, mortality rate of piglets decreased steadily until 2016, but showed an increasing trend after 2016 (Hansen, 2020). This increase in piglet mortality could be due to a non-linear effect of litter size on mortality traits. However, trait definition in the breeding goal used in some breeding programs could be a problem as well. For example, using litter size at day 5 after farrowing, commonly known as LS5, for selection (Nielsen *et al.*, 2013) might be suboptimal for reducing the mortality of piglets, because this approach assumes the trait total number born per litter (TNB) and mortality traits have the same genetic background. We hypothesized that by decomposing litter size into TNB and a mortality trait, the number of piglets alive can be improved.

Mortality of piglets reduces animal welfare and generates economic losses. Both are major concerns in organic as well as non-organic production systems. However, the welfare concern of piglet mortality is particularly important for the organic system, because consumers and society have high animal welfare requirements and expectations for organic systems (Font-i-Furnols *et al.*, 2019). The use of a trait such as LS5 in selection might increase the number of piglets alive at day 5 after farrowing, but at the cost of an overall increased number of dead piglets. From a welfare point of view, this is not desirable. The trait LS5 is commonly used in the Danish conventional system. In the organic system, number of piglets alive at 11 days after farrowing (LS11) may be more suitable, because of management practices.

The aim of this study was to evaluate breeding goals for increasing number of piglets alive from sows in outdoor organic pig production systems. The specific objectives were to: (1) estimate genetic parameters for sow traits of TNB, number of piglets dead at 0-11 days of piglet age (Mort11) and LS11; (2) evaluate effect of different economic weights for TNB and Mort11 in breeding goals; (3) assess the use of LS11 *versus* TNB and Mort11 in the breeding goals; (4) develop a breeding goal for increasing LS11 without an increase in Mort11.

Materials & methods

Data were collected from the largest organic nucleus and multiplier pig farm in Denmark. Mort11 and TNB were recorded from 3,977 litters of 1,219 sows. The phenotypes of TNB were total number of piglets born per litter of sows. The phenotypes of Mort11 were number of dead piglets per litter that included stillborn piglets and piglets that died from farrowing to 11 days of age. The phenotypes of LS11 were: LS11 = TNB – Mort11. This study considered records of litter size after 11 days of farrowing only, because piglet mortality during this period accounted for the majority (80%) of pre-weaning piglet mortality in the outdoor organic pig production (Chu *et al.*, 2021). In addition, recording of Mort11 was easier and more accurate compared to mortality records at a later period in the outdoor system. Phenotyping of piglet mortality in the Danish outdoor piglet production system is challenging after removing hut fenders, allowing piglets to move freely throughout the field.

For estimation of variance components, pedigree-based linear BLUP models were used. The statistical model for TNB and Mort11 included three fixed effects (breed of the litter, parity of the sow and herd-year-season), two random effects (direct genetic effects of the sow and permanent environment effects caused by sow), and residual term. Bivariate models for TNB and Mort11 were run using the average information restricted maximum likelihood estimation method (DMUAI) in the DMU package (Madsen and Jensen, 2013). Genetic parameters of LS11 were not estimated, but derived from TNB and Mort11. This is because the genetic parameters derived and estimated are mathematically equivalent. We did not want to introduce estimation problem to the comparison of breeding goals for LS11 *versus* TNB and Mort11. In addition, in our preliminary analysis, the use of genetic parameters of LS11 that were either estimated or derived led to the same conclusions for this study.

Phenotypic variance (σ^2_{pLS11}) of LS11 was derived from phenotypic variance estimates of TNB σ^2_{pTNB} and Mort11 $\sigma^2_{pMort11}$:

$$\sigma^2_{p_{LS11}} = \sigma^2_{p_{TNB}} + \sigma^2_{p_{Mort11}} - 2\sigma_{p_{TNB},p_{Mort11}} \quad (1)$$

Other variances and covariances were derived in similar ways.

Responses to selection expressed as LS11 were derived using selection index theory. Investigated breeding goals (H_1 and H_2) were:

$$H_1 = v_{TNB} \times \text{TNB} + v_{Mort11} \times \text{Mort11} \quad (2)$$

$$H_2 = v_{LS11} \times \text{LS11} \quad (3)$$

where v_{TNB}, v_{Mort11} and v_{LS11} are economic weights of trait TNB, Mort11, and LS11, respectively; v_{LS11} =1.

The selection indexes (I_1, I_2) corresponding to H1 and H2 were:

$$I_1 = b_{TNB}\overline{TNB} + b_{Mort11}\overline{Mort11} \quad (4)$$

$$I_2 = b_{LS11}\overline{LS11} \quad (5)$$

where $\overline{TNB}$, $\overline{Mort11}$, and $\overline{LS11}$ are the mean of TNB, Mort11 and LS, respectively with assumption that sows had on average 2 litters (2 repeated records) at the time of selection; b_{TNB}, b_{Mort11} and b_{LS11} are selection indexes.

Expected response to selection and additive genetic change (S_{g_i}) for trait j in the breeding goal were calculated using formula as described in Gibson and Dekkers, (2003). For breeding goal H_2, (S_{g_i} of TNB and Mort11 were derived from correlated response of LS11.

Desired gain indexes were derived as described by Brascamp (1984), so that that the genetic change of Mort11 was zero. After that, economic weight for H_1 in the case of desired gain were derived.

Results & discussion

The mean of TNB per litter was 15.2 with the standard deviation of 4.0. The mean of Mort11 per litter was 2.3 with the standard deviation of 2.4. Overall piglet mortality rate from pre-farrowing to 11 days of piglet age was 15%. This value was lower than the mortality rate reported in Denmark for organic herds (~27% (Rangstrup-Christensen *et al.*, 2018)) and non-organic herds (~20% (Hansen, 2020)). The lower observed mortality level was likely due to the high level of management on the study farm.

Figure 1 shows the data on dead piglets collected for this study, of which about 62% were stillborn piglets and piglets that died before 1 day of age. It was difficult to distinguish between stillborn and dead at 0 or 1 day of age as herdsman might not be present at the day of birth delivery. About 10 to 11 days of piglet age, hut fenders were removed. At this time, uncounted dead piglets were recorded, thus we could see a slightly higher piglet death compared to day 5 to 8.

Heritability and genetic variances of TNB were higher than those of Mort11 although these differences were not statistically significant (Table 1). Genetic correlation between TNB and Mort11 was positive. In other words, the larger litter size of sows, the more piglets died. Parameters of LS11 were derived from estimates of bivariate models of TNB and Mort11. Genetic correlation between LS11 and TNB were highly positive. The genetic correlation between LS11 and Mort11 was also positive, but at low level.

Response to selection in units of LS11 was highest when the breeding goal of selection included TNB and Mort11 traits with an equal economic weight (Table 2). However, the potential gain in LS11 for this breeding goal came from increasing additive genetics of TNB, while at the same time piglet mortality increased. These differences in potential genetic changes for TNB and Mort11 could be explained by the difference in genetic variation, and the positive correlation between the two traits (Table 1).

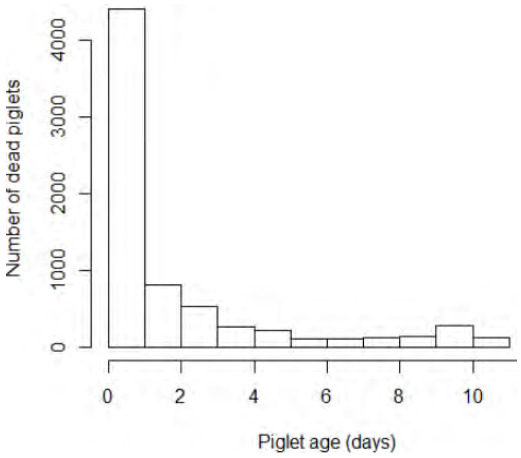

Figure 1. Histogram of piglet mortality from 0 to 11 days of piglet age.

Table 1. Genetic parameters for TNB, Mort11 and LS11: heritability (diagonal), genetic correlations (below diagonal) and phenotypic correlation (above diagonal).[1]

Trait	TNB	Mort11	LS11	Phenotypic variance
TNB	0.09	0.45	0.80	13.45
Mort11	0.66	0.06	-0.18	4.99
LS11	0.87	0.20	0.06	11.08

[1] Standard errors of heritability estimates were ~0.02.

By altering the breeding goal and focusing on Mort11 only, piglet mortality could decrease (Table 2). However, TNB and as well as LS11 decreased, which might not be acceptable from an economic perspective. Therefore, we used a desired gain breeding goal to achieve zero genetic change in Mort11, which might be more acceptable to society and organic consumers (Font-i-Furnols *et al.*, 2019). With the desired gain indexes, more economic weight was put on Mort11. LS11 increased, although the increase in response to selection was lower compared to the scenario using equal economic weights for Mort11 and TNB.

A breeding goal that only consisted of LS11 led to lower response to selection compared to the scenario that included TNB and Mort11 with equal economic weight in the breeding goal. The two breeding goals were equivalent in economic weights for component traits. However, the higher response to selection of the breeding goal using TNB and Mort11 was due to the possibility of having different selection indexes (b_{TNB} and b_{Mort11}) for the two traits. In other words, differences in heritability of the two traits were taken into account. In contrast, the use of LS11 only would assume equal index for TNB and Mort11 (=b_{LS11}).

Conclusions

Selection based on breeding goal of LS11 only, or using equal economic index weights for TNB and Mort11 would increase number of piglets alive at 11 days after farrowing for sows, but at the costs of increasing the number of dead piglets slightly.

By defining number of piglets alive for sows as two traits of TNB and Mort11, selection could reduce piglet mortality through the flexibility of altering economic index weights for the traits in breeding goals, and through utilizing differences in heritability of TNB and Mort11.

By increasing the economic index weight for Mort11, breeding program for organic pig production could achieve zero genetic change in piglet mortality until day 11 while still gaining more TNB.

Table 2. Response to selection expressed in LS11 based on different breeding goals.

Breeding goal[1]	v_{TNB}	v_{Mort11}	v_{LS11}	S_{gTNB}	$S_{gMort11}$	LS11
H_1 [a]	1	-1	-	0.572	0.149	0.424

Abstract

Individual activity is related to the health, welfare and performance of broilers. In previous work using a radio frequency identification system, we were able to collect individual activity data over time, and activity was found to be heritable. The aim of the current study was to estimate genetic parameters for activity while taking into account the effect of age. Therefore, two repeated measurement models were fitted. The model with an intercept and slope for genetic and permanent environmental effect, and a heterogeneous residual variance, yielded the best goodness-of-fit. First results showed that daily heritability varied between 7 and 30%. The heritability was lowest at the start and at the end of the production life. This study shows potential for selection on activity in broilers. Furthermore, this study shows that activity patterns (in time) can be changed, as both the intercept and slope of activity are heritable.

Introduction

Activity levels of broilers are related to their health, welfare and performance (Bokkers *et al.*, 2007; Van Hertem *et al.*, 2018; van der Sluis *et al.*, 2019, 2021). Therefore, individual activity levels appear to have potential to serve as a proxy for other traits in broiler breeding programmes. However, before implementation of activity as a proxy in breeding programmes, it is important to gain insight into the heritability of activity. Several studies have examined this topic. For example, it has been reported that the heritability of activity (recorded as the number of observations during which an animal was moving) at 16 days old, in a cross between two broiler lines that were divergently selected on digestive efficiency, was low (0.09±0.07) and not significantly different from zero (Mignon-Grasteau *et al.*, 2017). In another study, the average activity from hatching until approximately 35 days old was found to be heritable (0.31±0.11; Ellen *et al.*, submitted).

Studies on the heritability of activity have, however, been limited due to the labour required for personal observations, complicating for example the study of changes in heritability with age. To genetically improve activity in broilers, it is, however, important to take into account changing activity levels and variation due to age. In addition, previous research showed that activity decreases with age, suggesting that heritability might change over time. Therefore, research is needed to investigate the heritability pattern of activity. In this study, we examine the heritability of activity in broilers based on individual records of daily activity levels, recorded using a radio frequency identification (RFID) tracking system, over time. We compare two repeated measurements models that take into account heterogeneous variance and an effect of time to estimate genetic parameters for activity. The results of this study contribute to an improved understanding of the genetic variation of daily activity in broilers.

Materials & methods

Animals, housing and pedigree. Data on a total of 387 purebred male broilers were used for the analysis, collected across five consecutive production batches. The broilers were housed on a farm in the Netherlands, in a pen with a size of 4.7 m^2. Food and water were provided *ad libitum*, and wood shavings were provided as bedding.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_86, © E.D. Ellen *et al.* 2022

Nearly the same sires (31 in total) and dams (96 in total) were used in each batch, but with different numbers of offspring. Each sire was mated with approximately 3 dams, and each dam contributed on average 3.7 male offspring. Approximately six generations of pedigree were included in the calculation of the relationship matrix.

Activity recording. All broilers were tracked continuously with an RFID tracking system, using leg tags on the broilers and an RFID antenna grid underneath the pen floor (see van der Sluis *et al.* (2020) for details on the activity tracking). Approximate distances moved during the main light period from 07.00-23.00 were calculated for each day and bird, using the recorded tag positions during this period. The recorded distance was then divided by the recording duration between 07.00 and 23.00 for that specific day, to obtain an average distance moved per hour for each day. This allowed for comparisons between days and batches, even when data were missing for part of a day due to for example weighing of the birds.

Data analysis. For each day and bird, activity was recorded, resulting in 12,232 activity records. R software version 4.1.0 (R Core Team, 2021) was used for an initial analysis and to decide which fixed effects to include in the full model to estimate genetic parameters. The initial model included a fixed effect for batch, day, and the interaction between batch and day. The ASReml software package (Gilmour *et al.*, 2015) was used to estimate genetic parameters for daily activity. Two models were compared using the Likelihood-ratio test (Wald, 1943):

$$y = Xb + Za + Ze_p + e \quad (1)$$

$$y = Xb + Za_0 + Za1.xt + Ze_{p0} + Zep1.xt + e \quad (2)$$

where y is a vector of daily activities, b is a vector of fixed effects, with incidence matrix X linking observations to the fixed effects, a is a vector of breeding values, with incidence matrix Z linking records to individuals, e_p is a vector of permanent environmental effects of individuals to account for repeated measurements, and e is a vector of random residuals, allowing for a different variance for each day. For Model 2, both a genetic and a permanent environmental effect are fitted as an intercept, and as a function of time, where $x_t = 36–Day$ (Day ranging from 1 to 35). We used $x_t = 36–Day$, rather than $x_t = Day$, because an initial analysis showed that the variance decreased over the growing period.

The genetic variance as a function of time is, $\sigma^2_{A_t} = \sigma^2_{A_0} + x_t^2\,\sigma^2_{A_1}$, where t is Day (1-35), $\sigma^2_{A_0}$ is the genetic variance in the intercept, and $\sigma^2_{A_1}$ is the genetic variance in the slope. The variance due to the permanent environmental effect, as a function of time, is $\sigma^2_{P_{e_t}} = \sigma^2_{P_{e_0}} + x_t^2\,\sigma^2_{P_{e_1}}$. We assumed that effects on intercept and slope were independent, to avoid overfitting the data, which contained only 387 individuals. The phenotypic variance as a function of time is $\sigma^2_{P_t} = \sigma^2_{A_t} + \sigma^2_{P_{e_t}} + \sigma^2_{e_t}$, where $\sigma^2_{e_t}$ is the residual variance for a specific day. The heritability for each day is $h^2_t = \sigma^2_{A_t}/\sigma^2_{P_t}$.

Results

Figure 1 shows the average daily activity per batch. As expected, activity decreased with age. Furthermore, differences in activity levels were found between the different batches. Table 1 shows the comparison of the different genetic models. Statistical comparison showed that the model with an intercept and slope for both the genetic and permanent environmental effect yielded the best goodness-of-fit. Figure 2 shows the heritability for each day, which ranged from 0.07 to 0.30.

[1] LR is two times the difference in log likelihood between the complex and less-complex model.

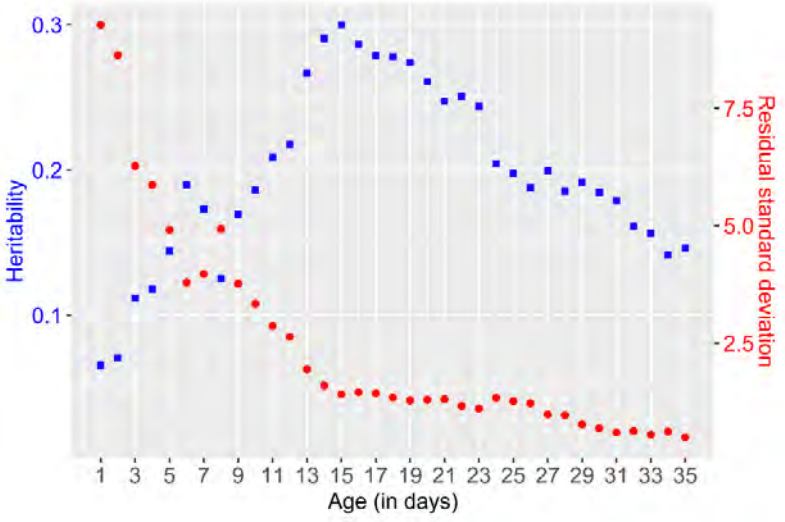

Figure 2. Heritability and residual standard deviation (2nd y-axis) over time.

Discussion

In this study, we found that a repeated measurements model with an intercept and slope for both the genetic and permanent environmental effects, and a heterogeneous residual variance, yielded the best fit. Daily activity is heritable, and heritability changes over time. Despite the limited number of individuals in our data and the presence of up to four random effects in the model, all analyses showed good convergence, and all estimated genetic parameters were significantly different from zero. This is, at least in part, due to the large number of records per individual (35 here), illustrating the power of longitudinal sensor data for genetic analysis.

In our previous study (Ellen *et al.*, *submitted*), we estimated genetic parameters for overall broiler activity and showed that this trait is heritable. However, the activity level changes considerably over time, and so does the variation in activity per day (Figure 1). Furthermore, when repeated observations are available (such as daily activity records), it could be of added value to consider a model that can handle these kind of longitudinal data, to better pick up on changes over time, instead of summarizing across periods and running separate analyses. In this study, a repeated measurements model with a genetic and a permanent environmental effect as a linear function of time was therefore implemented. However, activity is not necessarily fully linear (see Figure 1). In other studies dealing with longitudinal data, random regression models with non-linear terms have also been implemented. Future research could focus on finding the most appropriate model to take into account the effect of time, potentially also as a non-linear function, for daily activity levels in broilers.

In this study, the heritability of daily activity varied between 0.07 and 0.30. Overall, the estimated heritability was lowest at the start and at the end of the production life. At 15 days of age the highest heritability was found. Moreover, differences between animals in their activity patterns over time were observed. This highlights the value of repeated activity recordings, as single-age records might miss important nuances to the (heritability of) activity in broilers. Therefore, future research could focus on investigating the relation between the intercept and slope and the possibilities of changing the activity pattern of a broiler in relation to their health and performance. Furthermore, detailed interpretation of the results and how to implement these results in a broiler breeding program is needed.

Novel traits: health and well-being

87. Resilience indicators based on individual feed intake from a high-health swine nucleus

C.D. Bierman[1*], R.A. Kemp[1] and J.C.M. Dekkers[2]

[1]Genesus Inc, P.O. Box 278, ROHOYO, Oakville, MB, Canada; [2]Iowa State University, Ames, IA 50011, USA; cbierman@genesus.com

Abstract

Resilience to disease holds economic value in swine production, yet placing selection emphasis directly on selection candidates is difficult due to the requirement of high health nucleus herds. New traits derived from individual feeding behavior have been previously found to correlate favorably with disease resilience, which we parallel with stress resilience here. The foundation data for these novel traits are commonly recorded within nucleus herds' individual feed intake (FI) recording systems. Parameter estimates within a higher stress and lower stress dataset identified differences in heritability between the two scenarios. Resilience FI traits are heritable inside a high health nucleus environment and tend to have higher heritability under more stressful conditions. Genetic correlations between FI resilience and production traits range in magnitude and favorability dependent on stress condition. Optimal selection should emphasize relationships between resilience and production traits within expected stress scenarios for desired trait gains.

Introduction

Improving profitability for swine producers is the main breeding goal focus. Mortality and morbidity negatively impact profitability (Boyd 2012) but are difficult to directly include in breeding programs. Higher resilience to stressors implies reduced mortality and morbidity and resilience traits could contribute to genetic improvement in morbidity and survival, leading to increased profitability.

Feed intake has received significant focus in terminal sire programs. Appetite drives growth rate and is linked to robustness (Ocepek *et al.* 2019). Stressors such as disease negatively impact feed intake and subsequent growth (Nguyen-Ba *et al.* 2020). Feed intake behavior under a disease challenge has been investigated, resulting in novel FI resilience phenotypes that are heritable and genetically correlated with production and mortality outcomes under such stress (Cheng *et al.* 2020, Putz *et al.* 2019), suggesting they are plausible indicator traits of disease resilience.

Genetic selection for disease resilience in nucleus farms poses challenges due to their high health status. However, non-disease stressors such as temperature and humidity, movement, and social interactions can also affect feeding behaviors (Pearce *et al.* 2014). As individual FI is commonly measured, data to derive the FI resilience phenotypes of Putz *et al.* (2019) and Cheng *et al.* (2020) are available. Harlizius *et al.* (2020) reported FI resilience phenotypes from nucleus boars correlated favorably with survival of their progeny in a multi-pathogen disease challenge. Under the premise that any stress elicits variation in FI and feeding behavior, a parallel interpretation to the results for FI resilience traits reported under disease challenge (stress) can be made for non-disease stress-induced scenarios, which would allow selection of nucleus candidates. Therefore, the objectives of this study were to determine if heritable variation in FI resilience traits exist within a high health setting and to identify whether stress characterized by climatic variation impacts genetic parameter estimates.

Materials & methods

Data. Automatic recording of daily FI was acquired on Duroc animals using Insentec IVOG® feeders (Marknesse, Netherlands). Animals were grouped by sex in pens of 24 pigs and 0.80 m^2 per pig. Pigs started

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_87, © C.D. Bierman *et al.* 2022

test at an average of 82.9 kg and concluded at 117.4 kg (sex-averaged weights). Quality control of daily FI standardized the intake timeline to 42 days prior to test conclusion. Missing daily records from the filter process were allowed to remain missing. Traditional phenotypes included average daily feed intake (ADFI) and growth rate adjusted to 120 kg (Age120). Novel FI resilience traits from Putz *et al.* (2019) included variation in daily FI (VAR_{FI}), variation in daily FI duration (VAR_{Dur}), and the proportion of off-feed days (OFF_{FI}) and duration of off-feed (OFF_{Dur}) events. The month the animal concluded test was combined into higher and lower stress categories based on the previous 5-year average monthly temperature for the farm's location in southwest Manitoba, Canada. This partitioning provided a seasonality effect designed to separate phenotypes into stress categories based on climatic conditions. Although barn temperature and ventilation are electronically controlled, humidity and hot/cold microenvironments are difficult to overcome during climatic extremes, resulting in different stress levels.

Analysis. After quality control, resilience FI phenotypes were computed from 3,580,517 daily FI records from 7,498 animals tested from 2016 to 2021. Variance components were estimated using the Echidna software (Gilmour, 2021) based on the following animal model:

$$y_{ijklm} = age_{ijklm} + Sex_i + cg_j + animal_{ijklm} + litter_{ijkl} + e_{ijklm} \qquad (1)$$

where y_{ijklm} is the trait phenotype; age_{ijklm} is a covariate of age at test conclusion; Sex_i and CG_j are fixed effects of sex and contemporary group, respectively; $litter_{ijkl}$ is the random litter effect ~ $N(0, I\sigma^2_l)$, where σ^2_l is the litter variance; $animal_{ijklm}$ is the random animal genetic effect ~ $N(0,A\sigma^2_k)$, where A is the numerator relationship matrix, and σ^2_k is the additive genetic (co)-variance; e_{ijklm} is the residual effect ~ $N(0, I\sigma^2_e)$, where σ^2_e is the residual variance. Mean heritability estimates (minimum of 6 per trait) were obtained from eight multivariate models. Bivariate models including FI resilience traits with either Age120 or ADFI were used to estimate genetic correlations.

Results

Definition of the stress categories resulted in 7 months of higher stress and 5 months of lower stress (Table 1). The range in average high and low temps for the higher stress category was 25 to 26 and -22 to -9 °C, respectively. The range in average high and low temperatures for the lower stress category was 9 to 24 and -4 to 12 °C, respectively. Assessment of mean FI resilience traits between the two stress categories suggests that the data were successfully partitioned in terms of level of stress (Table 1). Higher means for the FI resilience traits for both sexes for the higher stress category suggest less resilience during the stressful timeframe.

Table 1. Trait means (standard deviations) by gender under different stress categories.

	High stress		Low stress	
	Female	Male	Female	Male
n	1559	2858	1149	1932
ADFI (kg)	3.11 (0.60)	2.91 (0.69)	3.01 (0.65)	2.97 (0.56)
Age120 (days)	169.4 (11.9)	159.0 (9.9)	168.2 (11.9)	158.1 (9.7)
OFF_{dur}	0.05 (0.07)	0.07 (0.10)	0.04 (0.09)	0.05 (0.08)
OFF_{FI}	0.05 (0.07)	0.06 (0.08)	0.05 (0.09)	0.04 (0.07)
VAR_{FI} (kg)	0.93 (0.27)	0.82 (0.28)	0.83 (0.28)	0.77 (0.25)
VAR_{dur} (min)	16.5 (6.1)	14.2 (5.1)	14.3 (5.7)	13.4 (4.9)

[1] OFF trait unit = proportion.

Genetic variances were higher for all traits under the high stress category (13 to 225%) while changes in residual variances were variable (Table 2). Estimates of heritability for OFF_{dur} and OFF_{FI} were low in the low stress category and moderate in the high stress category whereas VAR_{FI} and VAR_{dur} were moderate and similar in both stress categories.

The estimate of genetic correlation (r_g) between ADFI and Age120 was high and negative as expected and unaffected by stress category (Table 3). In addition, estimates of r_g between OFF traits and ADFI were moderate to high, and stronger under higher stress than under lower stress. Although not as high, estimates of r_g between OFF traits and Age120 were also higher under high stress. Estimates of r_g of the VAR traits with ADFI and Age120 were less consistent when comparing stress categories within traits; with a high SE, $r_g(VAR_{FI} : ADFI)$ was zero under high stress, while $r_g(VAR_{FI} : Age120)$ was twice as large in the low stress than the high stress category. Again with a high SE, estimates of $r_g(VAR_{dur}$ with ADFI and Age120 were stronger under high stress.

Discussion

Individuals with high values for the FI resilience traits are expected to be less resilient, as their daily intakes fluctuate more and they have more off-feed days. These traits have been shown to be genetic indicator traits for resilience through their genetic correlations with mortality, treatment rates, and growth under a severe health challenge (Cheng *et al.*, 2020; Putz *et al.*, 2019). Here we report estimates of h^2 for these same traits in a high-health environment for two stress categories defined by the expected level of climatic stress. Estimates of h^2 for FI resilience traits in the low stress category were higher in this population than the h^2 estimates under disease stress reported by Cheng *et al.* (2020). This is encouraging, as it suggests genetic

Table 2. Estimates of heritability and SE for performance and feed intake resilience traits under different stress categories.[1]

	High stress				Low stress			
	σ^2_g	σ^2_e	Heritability	SE	σ^2_g	σ^2_e	Heritability	SE
ADFI	0.179	0.106	0.46	0.04	0.104	0.156	0.35	0.05
Age120	52.3	50.5	0.42	0.04	46.0	49.8	0.40	0.05
OFF_{dur}	0.002	0.005	0.25	0.04	0.001	0.004	0.18	0.04
OFF_{FI}	0.002	0.002	0.31	0.04	0.001	0.003	0.22	0.04
VAR_{FI}	0.025	0.030	0.33	0.04	0.018	0.027	0.31	0.04
VAR_{dur}	13.0	6.6	0.50	0.04	11.5	7.2	0.50	0.04

[1] σ^2_g = genetic variation; σ^2_e = residual variation.

Table 3. Estimates of genetic correlations (SE) between feed intake resilience traits and performance under different stress categories.

	ADFI		Age120	
	Higher stress	Lower stress	Higher stress	Lower stress
ADFI	-	-	-0.80 (0.05)	-0.82 (0.06)
OFF_{dur}	-0.87 (0.05)	-0.66 (0.09)	0.19 (0.16)	-0.07 (0.18)
OFF_{FI}	-0.95 (0.02)	-0.82 (0.07)	0.70 (0.12)	0.28 (0.18)
VAR_{FI}	0.00 (0.15)	0.49 (0.16)	-0.33 (0.13)	-0.65 (0.14)
VAR_{dur}	-0.22 (0.11)	-0.12 (0.16)	-0.39 (0.12)	-0.36 (0.16)

variation in these traits is expressed even without the severe stress of disease challenges. Furthermore, h^2 estimates were generally higher under the high stress category, with the largest differences for OFF phenotypes, where h^2 increased by 54-64%. The dataset spanned 5 years, limiting potential noise from short term farm management influence outside of any contemporary group effect.

High negative r_g between OFF traits and ADFI corroborate results from Cheng *et al.* (2020). Although r_g(OFF : ADFI) was 16-30% more negative in the high stress category, inclusion of OFF traits collected during low stress could also benefit genetic improvement. Putz *et al.* (2019) reported low correlations between ADFI and the VAR traits, which is also duplicated here under the high stress category. The specific estimate of 0.49 for $r_g(VAR_{FI} : ADFI)$ in the low stress category suggests that when pigs are not undergoing climatic stress, targeting lower ADFI genetically reflects selection for lower variation in daily feed intake, which suggests higher stress resilience. This estimate should be investigated further, as this correlation was zero in the high stress category. Estimates of r_g(OFF : Age120) were generally low and favorable, while r_g(VAR : Age120) were moderately unfavorable. The latter estimates require further study, as they disagree with previous reports (Putz *et al.* 2019) and would reduce selection response for growth rate.

In conclusion, FI resilience traits are heritable in a high health setting during times of both high and low stress. Placing selection emphasis on data from different stress characterizations should be driven by genetic correlations, as resilience may already be emphasized indirectly. Selection on OFF traits may not be as beneficial when collected during the high compared to low stress category. The opposite may be true for VAR traits, for which r_g with ADFI and Age120 were neither high nor consistently favorable. Assuming the r_g with resilience holds true, and that stress levels on pig farms may not be consistent over time, genetic improvement of resilience may benefit from continual inclusion of FI resilience traits in the breeding goal.

Abstract

Resilience is increasingly recognized as an important trait for dairy cattle to improve their functioning and welfare. The log transformed variance (LnVar) and autocorrelation (r_{auto}) of daily milk yield deviations from an expected lactation curve have been studied as potential resilience indicators, so far only using data of Holstein Friesian cattle. The aim of this research was to compare the resilience indicators between different breeds present at Dutch dairy farms and to estimate the effect of crossbreeding on these indicators. Significant differences in LnVar and r_{auto} were found across twelve breeds, with the breed effects on LnVar different from the effects on r_{auto}. We estimated negligible heterosis effects for r_{auto} and LnVar. This study suggests that different breeds respond differently to environmental disturbances and that different breeds might have different levels or types of resilience.

Introduction

Recent local and global developments of the dairy farming industry, such as up-scaling of farm size, have created a demand for healthy and easy-to-manage cows (Elgersma *et al.*, 2018). At the same time, future aspirations towards more circular and agroecological dairy farming, might lead to more environmental challenges for animals due to variable feed quality or exposure to weather extremes. To improve animal functioning and welfare, a more resilient cow is desired (Berghof *et al.*, 2019). A resilient cow is minimally affected by a disturbance or rapidly returns to its former state upon exposure (Colditz and Hine, 2016; Berghof *et al.*, 2019).

Increasing cow resilience through genetic selection requires large-scale quantification of this trait (Berghof *et al.*, 2019). Scheffer *et al.* (2018) proposed to quantify resilience using automatically recorded high-frequency data of traits that are affected by disturbances. For dairy cows, such trait could be milk yield. Milk production drops when cows perceive a disturbance or when they have a disease (Elgersma *et al.*, 2018). In the past, fluctuations in daily milk yield (DMY) have been proposed to create indicators for resilience of individual cows (Colditz and Hine, 2016; Elgersma *et al.*, 2018; Poppe *et al.*, 2020; Adriaens *et al.*, 2020). Poppe *et al.* (2020) calculated resilience indicators from the deviations of DMY records from an expected lactation curve. In the data set of Poppe *et al.* (2020), consisting of purebred Holstein Friesian (HF) cows only, a low variance and autocorrelation were shown to indicate a high level of resilience.

Health, fertility, longevity and production level differ between breeds. For example, Bieber *et al.* (2019) showed that local breeds from Sweden, Austria, Switzerland and Poland tended to live longer, have a better health and fertility, but produced less than the commercial breeds HF or Brown Swiss. They described the local breeds to be more robust and therefore more suitable for locally adapted organic or agroecological dairy production systems. However, large scale analyses of resilience traits based on DMY of non-HF breeds have not been performed. In this study, we compared the resilience indicators proposed by Poppe *et al.* (2020) across breeds and estimated the effect of crossbreeding on these indicators.

Materials & methods

The dataset consisted of 2,763,357,043 milk yield records from farms with an automatic or conventional milking system provided by breeding company CRV (Arnhem, the Netherlands). These records included animal ID, milk yield and the date and start and end time of the milking of in total 1,528,030 dairy cows. Additionally, pedigree data of each animal were available. Data editing steps and calculation of resilience indicators were similar to Poppe *et al.* (2020). In the current study, purebred animals (at least 87.5% of one breed) and crossbred animals (50% HF and 50% of another breed) were selected. The resilience indicators were calculated only for first parities of cows that were milked by an automatic milking system and whose age at first calving was more than 640 days. For these animals, DMY was calculated. All DMY records made after 350 days in milk were removed from the dataset. Animals that had their first DMY record later than 14 days after calving, that had less than 50 DMY records or that had more than 5% missing records per lactation were removed from the dataset.

Calculation of resilience indicators. The resilience indicators used in this study were based on deviations of DMY records from an expected lactation curve that corrects for the lactation shape in absence of disturbances. For the calculation of this expected lactation curve, a polynomial quantile regression (Equation 1) was fitted on the DMY records of each cow:

$$DMY_t = \beta_0 + \beta_1 t + \beta_2 t^2 + \beta_3 t^3 + \beta_4 t^4 + \varepsilon \quad (1)$$

where DMY_T was the observed DMY on lactation day t and ε was a random error term.

Next, variance and autocorrelation were calculated from the daily deviations of DMY from the expected lactation curve. The variance of those deviations had a right-skewed distribution. To create a normally distributed variable a log-transformation was applied to the variance trait (LnVar). The autocorrelation was calculated with a time lag of 1 day (r_{auto}).

Statistical analysis. Breed and heterosis effects on average daily milk yield (ADMY) and on the resilience indicators LnVar and r_{auto} were estimated using linear regression models. For ADMY and autocorrelation the following model was used:

$$y = \mu + FLV + MON + BS + ZRB + NRB + MRY + BBL + JER + G + FH + AYS + cross + \varepsilon \quad (2)$$

Where y was the observed ADMY or r_{auto}, the HF breed was taken as intercept, the other fixed effects represent the individual breed proportions, with respectively FLV as Fleckvieh, *MON* as Montbéliarde, *BS* as Brown Swiss, *ZRB* as Swedish Red, *NRB* as Norwegian Red, *MRY* as Meuse-Rhine-Yssel, *BBL* as Belgium Blue, *JER* as Jersey, *G* as Groninger Whiteheaded, *FH* as Dutch Friesian and *AYS* the proportion of Ayrshire. *cross* was the fixed effect of an animal being a cross (1) or purebred (0) cow to estimate the heterosis effect, and ε was a random error term. Additional to the fixed effects of Equation 2, the model for LnVar included the ADMY as a covariate to correct for the scale effect of milk yield level across breeds. This was done based on the knowledge that an increase in the mean of a trait typically leads to a (proportional) increase of its variance (Falconer and Mackey, 1996).

Results

The final dataset included 450,642 pure and crossbred animals of twelve different breeds (Table 1). The breeds Meuse-Rhine-Yssel, Jersey and Dutch Friesian were mostly present as purebreds, while other breeds were more frequently used for crossbreeding. The individual fixed breed effects showed that ADMY of

all breeds was significantly lower than that of the Holstein Friesian. The heterosis effect on ADMY was significant and was estimated at +0.9 kg.

The r_{auto} differed slightly between breeds (Figure 1). The r_{auto} of Fleckvieh, Montbéliarde, Brown Swiss, Belgium Blue and Jersey was significantly lower than HF, suggesting that their recovery rates are higher. In contrast, Swedish and Norwegian Red and Dutch Friesian had a significantly higher r_{auto} than HF, suggesting that their recovery rate was lower. The heterosis effect on r_{auto} was estimated at -0.007, which is negligible compared to the breed effects.

The LnVar increased with 0.021 per kg ADMY. Breed effects of Montbéliarde and Swedish Red showed a significantly higher LnVar than HF (Figure 2), which is associated with a more variable milk yield. Fleckvieh, Norwegian Red, Jersey, Dutch Friesian and especially the Groninger Whiteheaded and Meuse-Rhine-Yssel breeds showed a significant lower LnVar than HF, suggesting that those breeds have a more stable milk yield in presence of common disturbances. The heterosis effect was estimated at +0.028, which is negligible.

Discussion

The aim of this study was to compare breeds present at Dutch dairy farms for the resilience indicators LnVar and r_{auto}. Differences in LnVar and r_{auto} were found across breeds, demonstrating cattle breeds differ in milk yield variability and recovery rate. This suggests that the level and type of resilience varies between breeds. Some breeds score better for LnVar and others score better for r_{auto}, this suggests that different breeds respond differently to environmental disturbances.

Table 1. Number of pure- and crossbreds and the breed effects on the average daily milk yield (ADMY) for the breeds in the final dataset.

Breed[1]	HF	MRY	FLE	JER	MON	FH	BS	G	ZRB	NRB	BB	AYS
Purebreds	426,335	1,818	1,010	757	663	282	137	33				
Crossbreds		879	7,338	411	3,456	62	3,133	149	2,196	1,470	472	41
ADMY (kg)	27.2	20.0	22.1	17.9	22.8	20.9	21.5	13.6	20.0	23.3	20.6	19.4

[1] HF = Holstein Friesian, MRY = Meuse-Rhine-Yssel, FLE = Fleckvieh, JER = Jersey, MON = Montbéliarde, FH = Dutch Friesian, BS = Brown Swiss, G = Groninger Whiteheaded, ZRB = Swedish Red, NRB = Norwegian Red, BB = Belgium Blue, AYS = Ayrshire.

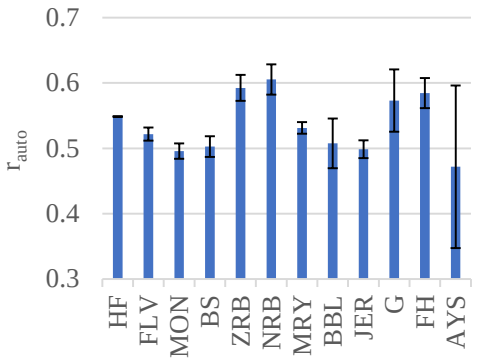

Figure 1. Breed effects on the r_{auto}. Error bars represent the 95% confidence interval.

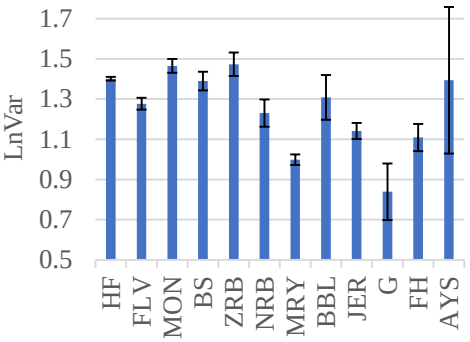

Figure 2. Breed effects on the LnVar, using daily milk yield as covariate. Error bars represent the 95% confidence interval.

In this study, heterosis effects for the resilience indicators were negligible. That was against our expectations because heterosis effects are strongest for health and functional traits (Sørensen *et al.*, 2008). Still, crossbreeding could improve LnVar and r_{auto} of the offspring because some breeds score better than HF. The effect of ADMY as a covariate in the model of LnVar was of considerable strength, taking into account the difference in ADMY between breeds. This is largely explained by a statistical effect, but there might be underlying biological reasons too (Poppe *et al.* 2021). More research is needed to understand that relationship better.

There is no proof in this study that breeds with more favourable LnVar and r_{auto} are indeed more resilient because we have no information on the environmental challenges or on an animal's vulnerabilities that are causing drops in milk yield. The type of production system that the animals are kept in, and thus the type or level of environmental challenges, might be different for the different breeds. In addition, different breeds might be specifically more susceptible to different health issues. So, drops in milk yield might be caused more by mastitis in one breed but more by claw problems in the other. Further research is needed to explore this.

This study suggests that different breeds respond differently to environmental challenges and that different breeds might have different levels or types of resilience (Friggens *et al.*, 2021). This study, however, involved only two resilience indicators, that were both based on milk yield. For a deeper understanding of the resilience of different cattle breeds, more indicators derived from fluctuations in DMY and/or more sources of information, such as animal activity, could be explored (Adriaens *et al.* 2020).

89. Genotype-by-environment interactions for health traits across productivity level or health status of herds in Normande

S. Aguerre[1,2*], A. Vinet[2] and S. Mattalia[1,2]

[1]Institut de l'Elevage, UMT eBIS, Domaine de Vilvert, 78350 Jouy-en-Josas, France; [2]Université Paris Saclay, INRAE, AgroParisTech, GABI, Domaine de Vilvert, 78350 Jouy-en-Josas, France; sophie.aguerre@idele.fr

Abstract

Genotype-by-environment (G×E) interactions for somatic cell score (SCS) and clinical mastitis (CM) were investigated in first lactation Normande cows. Milk and SCS herd-year effects estimated in the French national evaluation were used as environment descriptors of productivity level and health environment of the herds, respectively. Variance and covariance components were estimated using bivariate and reaction norm models. For SCS, heritability estimates ranged from 0.17 to 0.23 according to productivity level. Genetic correlations higher than 0.9 were estimated between groups, showing no G×E interaction for this trait with both models. For CM, the estimates of heritability ranged from to 0.01 to 0.07. Genetic correlations between and 0.3 and 0.99 were estimated across productivity levels and health environments, indicating G×E interactions for this trait.

Introduction

G×E interactions are currently ignored in the national genetic evaluation in dairy cattle in France. But the question arises as to whether these interactions should be taken into account due to the diversity of environments and herd management practices. In a previous study, Huquet *et al.* (2012) investigated G×E interactions for production traits in French dairy cattle. No re-ranking was observed but they found a significant scaling effect for milk yield, with a higher genetic variance in the herds with more intensive management practices.

The aim of this paper was to investigate the magnitude of G×E interactions on SCS and CM in Normande cattle breed. Very diverse definitions of the herd environment have been used in the literature. In this study, herd environment description was based on herd-year effects estimated in the French genetic evaluations of milk production and SCS. The former is assumed to be a descriptor of the productivity level of a given herd, while the latter describes its sanitary status, regardless to its genetic level or the age of the animals.

Materials & methods

Description of the dataset. Data were obtained from the French national database. First parity phenotypes of Normande cows recorded between 2015 and 2020 were included in the analyses. Phenotypes were lactation somatic cell scores (SCS) and clinical mastitis events (CM). Lactation SCS was computed as a weighted average of the test-day SCS ($SCS=\log_2(\text{Somatic Cell Count}/100{,}000)+3$) adjusted for days in milk. CM phenotype was a binary variable set to 1 when at least one clinical mastitis event was recorded during the first 150 days of lactation, and 0 otherwise. Milk and SCS herd-year effects, reflecting productivity level and sanitary status of the herds, respectively, were used as descriptors of the environment. These estimates were obtained as a by-product of the French national genetic evaluation of milk yield and SCS performed in October 2020.

Data analysis. Only cows having completed their entire lactation within the same herd have been included in the analyses to ensure the phenotype was expressed in the right environment. Herds with less than 15 cows, thus with limited accuracy of herd-year effects, were discarded.

The environment description was based on the deciles of the herd-year effect distribution. Two methods were investigated to estimate variance and covariance components for SCS and CM. First, a bivariate analysis was performed, in which the herds with extreme levels of productivity or sanitary status were selected. Then, performances were analysed with a reaction norm model, using the herd-year effects to describe the environment. SCS performances were analysed in relation to the productivity level only. For CM, two separate analyses were performed for the productivity level and the sanitary status, respectively.

For the bivariate analysis, herds randomly selected in the deciles 2-3 and deciles 7-8 defined two groups with contrasted situations. Bivariate models included the fixed effects of herd-year, age at first calving, month of calving, the breeding value as a random effect, and the residual. Performances from 43,111 cows (100,111 animals in the pedigree file) for SCS and 43,182 cows (99,883 animals in the pedigree file) and 48,690 cows (112,810 animals in the pedigree file) for CM with milk and SCS herd-year effect respectively were included.

For reaction norm models, herds were randomly selected in each decile. The average herd-year effects for each decile were used as regression variable. Reaction norm models included Legendre polynomials of order 2 for both traits:

$$y = X\beta + \Sigma_{r=0}^{2} Z_r(t)\, g_{ir} + e \quad (1)$$

Performances from 44,504 cows (85,541 animals in pedigree file) for SCS and 39,161 cows (75,681 animals in pedigree file) and 38,748 cows (74,896 animals in pedigree file) were included for CM with milk and SCS herd-year effect respectively.

For both methods, pedigree information was traced back on three generations. The analyses were performed using Wombat software (Meyer, 2007).

Results

With bivariate models, heritabilities of 0.17 and 0.20 (±0.02) were estimated for SCS in low and high levels of productivity groups respectively (Table 1). No G×E interaction was found for SCS, with a genetic correlation of 0.99 (±0.02) between the two groups. For CM, heritabilities between 0.01 (±0.006) and 0.03 (±0.008) were estimated (Table 1). Genetic correlations between low and high productivity level groups as well as between good and poor health environment groups were 0.7 (±0.2) indicating the existence of G×E interactions.

Table 1. Descriptive statistics, heritability and genetic correlation estimates for SCS and CM in herds with low and high productivity level and in herds with good and poor health environments with bivariate models.

Trait	Herd-Year effect	Group	Mean (std)	Frequency (%)	H^2	r_g
SCS	Milk	Low	3.15 (1.32)		0.17±0.02	0.99±0.02
		High	2.99 (1.33)		0.20±0.02	
CM	Milk	Low		8.94	0.014±0.006	0.70±0.20
		High		10.38	0.025±0.008	
	SCS	Good		10.04	0.020±0.007	0.70±0.20
		Poor		9.46	0.025±0.007	

With reaction norm models, heritabilities of SCS along the milk herd-year effects ranged from 0.18 to 0.23 (Table 2). Genetic correlations between SCS at different milk herd-year effects were all higher than 0.9 (s.e. ranging from 0.003 between close groups to 0.52 between the most distant groups), indicating no G×E interaction for this trait. Heritabilities of CM along milk herd-year effects were low, ranging from 0.02 to 0.06 (Table 2). Similar values were obtained for the heritabilities of CM along SCS herd-year effects (0.01 to 0.07).

Genetic correlations between CM at different milk herd-year effects ranged from 0.44 between groups with the most distant herd-year effects to 0.99 between groups with the closest herd-year effects (Figure 1a). The same trend could be observed for genetic correlations between CM along the SCS herd-year effects with values between 0.3 and 0.99 (Figure 1b). However, the sampling errors were quite high and the estimates were not significantly different from 0 when using SCS herd-year effects as environment descriptor.

Discussion

Our estimates for SCS and CM heritabilities were consistent with the literature (Boichard and Rupp, 1999; Govignon-Gion *et al*., 2016).

Regarding G×E interactions, the analyses with bivariate and reaction norm models gave similar results. Both models supported the existence of G×E interactions for CM, but not for SCS. Our results are in

Table 2. Descriptive statistics and heritability estimates for SCS and CM according to productivity level and health environment with reaction norm model.

Trait	Herd-Year effect		Deciles									
			1	2	3	4	5	6	7	8	9	10
SCS	Milk	Mean	3.42	3.20	3.24	3.16	3.11	3.06	3.04	3.01	3.00	2.95
		std	1.33	1.32	1.34	1.34	1.32	1.36	1.31	1.32	1.32	1.36
		h^2	*0.20*	*0.19*	*0.19*	*0.19*	*0.20*	*0.20*	*0.21*	*0.21*	*0.22*	*0.23*

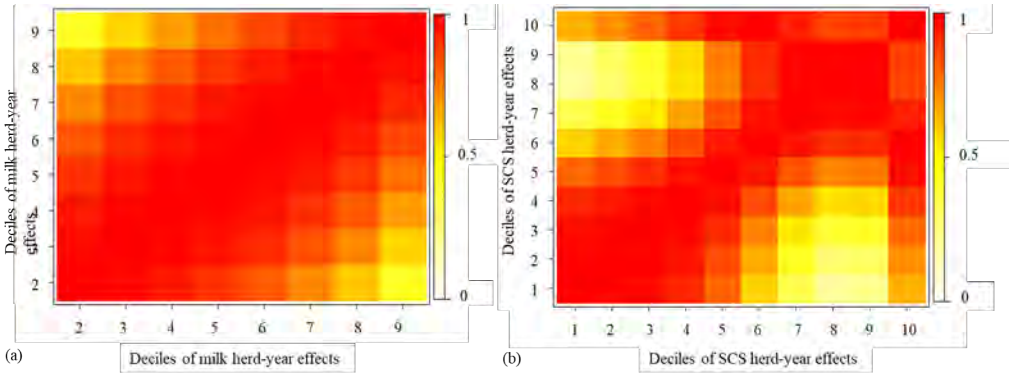

Figure 1. Heatmaps of the genetic correlations between clinical mastitis at different milk herd-year effects (a) and SCS herd-year effects (b).

agreement with previous studies reporting genetic correlations between 0.8 and 1 for SCS at the lactation level across environments (Carlén *et al.*, 2005). However, studies on test-day level are more informative and tend to show the existence of G×E for SCS in early lactation related to a higher incidence of mastitis in early stages of lactation (Calus *et al.*, 2006). Similarly to Carlén *et al.* (2005), our bivariate analysis suggested the existence of G×E interactions for mastitis in different SCS environments. Differences in heritability could not be explained by phenotypic differences between deciles as the average frequencies of CM were similar for all deciles (Table 2).

The use of milk and SCS herd-year effects is an original approach to describe the environment in G×E interactions studies. They represent good estimates of the overall productivity level and health status of the herds and they are easily accessible since they are computed as part of the national genetic evaluations. The use of SCS herd-year effects was particularly interesting since few indicators on the health status of herds are available, these data being difficult to collect routinely. Proxies could be used as shown by Calus *et al.* (2006) who combined bulk milk SCC as an indicator of hygienic conditions to days in milk in their G×E analyses; and Carlén *et al.* (2005) who used herd-year average of somatic cell count and mastitis. Our results indicate that SCS herd-year effects are another useful proxy for health environment.

Different breeding strategies could be considered to take into account G×E interactions in the breeding programs. A guideline was provided by Mulder *et al.* (2006) who showed that it was optimal to have environment-specific breeding programs if the genetic correlation between environments was lower than 0.61.

Conclusions

This study showed that milk and SCS herd-year effects are useful proxies for the productivity level and health environment of the herds. We report the existence of G×E interaction for clinical mastitis in first lactation Normande cows. Taking these interactions into account in breeding programs would allow to adapt breeding strategies to various environments.

Abstract

Ticks and tick borne diseases cause significant loss in livestock production with about 80% world's cattle at risk. The cost of chemical control is high and there is an ever increasing tick resistance to chemicals. Genetic selection as alternative long term control strategy is constrained by laborious phenotyping using tick counts or scores. This study explores the use of host volatile semiochemicals that may be attractants or repellents to ticks as a novel phenotype with potential to be used as a proxy in selection programmes. About a 100 young cattle composed of *Bos indicus* and *Bos taurus* were artificially infested with 2,500 *R. decoloratus* larvae with daily female ticks (4.5 mm) counts taken from day 20 post infection. Volatile compounds we sampled before and after tick infestation. We identified three pre-infestation volatile compounds that were associated with tick resistance (P-value<0.01) and one post infestation (P-value<0.05) using 6 day repeated measure analysis. The high correlation coefficients (r=0.66) between repeated records with all volatile compounds support the potential predictive value for volatile compounds in selective breeding programmes for tick resistance in cattle.

Introduction

Ticks and tick borne diseases cause significant loss of production with at risk about 80% of the world's cattle. Economic losses from ticks and tick-borne diseases have been estimated to range from US$20-30 billion annually (Lew-Tabor and Rodriguez Valle, 2016). Host resistance to ticks has been reported as moderately to highly heritable (Burrow and Henshall, 2014) which translates into a long term, low-cost intervention and requires no extra labour or resources (Frisch, 1999). Although host resistance to ticks can be considered as one of the most economical tick control strategies, improvements in host resistance have been largely neglected (Frisch, 1999). The main reason is that the gold standard tick phenotyping methodology involves tick counts which are laborious, time-consuming and require skilled animal technicians as well as expensive infrastructure to constrain animals. A simpler, cost-effective method of identifying individual animal variation in resistance to ticks (phenotyping) under research, commercial and smallholder production systems is urgently needed to enable improvements in host resistance to ticks. In the past, knowledge of different tick pheromones, allomones and kairomones has been used to develop novel tick control products by incorporating tick pheromones and small amounts of pesticide to attract and kill ticks on their hosts or in vegetation (Latha, 2012). Ticks like other haematophagous arthropods use host olfactory and visual cues known as volatile semiochemicals, which generally regarded as attractants, but also can be repellents in some cases (Logan and Birkett, 2007). In order to use the semiochemicals as proxies for tick resistance, we need to quantify within animal variation of different semiochemicals and how they relate to tick loads. In this study, we investigate within animal variation in tick burdens between *Bos taurus* and *Bos indicus* cattle using artificial tick infestation and quantifying differences in volatile semiochemical production. Evidence for a correlated response between volatile semiochemical and tick loads could underpin a development of a new low-cost and rapid tool for phenotyping cattle for resistance to ticks, with potential use for selection and animal breeding in both commercial and smallholder cattle production systems.

Materials & methods

Animals, ticks and tick infestation. The study animals composed of 24 males and 28 females East African Zebu cattle (*B. indicus*) aged 12 to 18 months purchased from local farmers in Western Kenya were transported to the study site at ILRI, Nairobi, Kenya and male *B. taurus* (45 Holstein-Friesian and 9 Ayrshire) steers from ILRI farm. Cattle were artificial infested with 2,500 Rhipicephalus (Boophilus) Decoloratus (*R. decoloratus*) larvae, with daily counts of female ticks (4.5 mm) conducted over a 6-day period from day 20 post infestation.

Volatile compounds sampling and gas chromatography (GC) analysis. Each animal was held in a crush and volatile organic compounds (VOCs) were collected using air entrainment using the anterior groin of an animal by a hand-held air sampling pump. The funnel was held gently against the skin to ensure a seal around the funnel perimeter. Collections were carried out for 5 minutes. Two samples were collected per animal, i.e. prior to, and 21-23 days after, tick infestation.

VOCs were analysed by high resolution gas chromatography-flame ionization detector (GC-FID) analysis. Nine VOCs (isoamyl acetate, (*E*)-2-heptenal, benzaldehyde, 6-methyl-5-hepten-2-one, hexanal, decane, (*RS*)-limonene, undecane and tridecane) were selected as candidates for investigation based on previous reports as non-host semiochemicals for ticks.

Statistical analysis. Volatile organic compound data were analyzed separately as nine pre- infection values (BI), nine post infection (AI) values and nine differences (diff) between the pre and post infection values resulting in 27 volatile compound traits. The tick counts were treated as six daily counts modelled as repeated measures or each daily count as separate trait and total or average. The distribution of raw tick counts and volatile compounds were mostly skewed; hence they were transformed to approximate normality using log10 (x + 1) with a constant added to allow for the zero counts in our data. Data were subsequently analysed in SAS software (SAS, 2012) for repeated measure analysis modelling the six days tick count effects in the model. The final model fitted for the repeat measure analyses included effects of day, group, body weight and volatile compounds. The fixed effect of 'group' was created by combining the effects of sex (Male or Female) and breed (Zebu or Taurus) to give a group effect for male Zebu, female Zebu and male Taurus animals.

Single trait analysis fitted individual daily tick counts, tick totals or averages analysed using GLM (SAS, 2020) using general linear models but removing the effects of day in the models. The models explored both breed and sex as fixed effects or group, plus the covariates already mentioned above.

Trait ~ breed +sex (or group) + body weight + volatile compounds

Where trait was individual daily log transformed tick counts, log transformed tick totals or log transformed tick averages.

The correlation between transformed tick counts and volatile organic compounds was explored using Pearson correlation coefficients using SAS (2012).

Results

There was wide variation between pre- infection values (BI, CV% ranging from 18.4 to 59.4) and post infection (AI, CV% ranging from 8.2 to 65.2) across sexes and breeds. The CV% was generally higher for BI in female Zebu than Males, except for volatiles BI-(*E*)-2-heptenal/benzaldehyde) and BI-(*E*)-2-heptenal. The CV% of log transformed tick counts ranged from 31.1 to 84.0.

The repeat measure analysis before infestation identified three volatile compounds (BI-(*E*)-2-heptenal, BI-6-methyl-5-hepten-2-one and BI-hexyl acetate) that were significantly (*P*-value<0.05) associated with low tick counts suggesting that they could be used as predictive indicators of tick resistance. All fixed and covariate effects of day, group, body weight and volatile compounds significantly ($P<0.05$) accounted for other variations in the model. Results for after infection tick counts for repeat analysis identified a single volatile compound (AItrans-2-heptenal/benzaldehyde) that was significant ($P<0.05$) on volatile compounds.

There were three volatile compound differences (Diff(AI-BI): (*E*)-2-heptenal/benzaldehyde, 6-methyl-5-hepten-2-one, hexyl acetate)) that were significantly ($P<0.05$) associated with tick counts whilst two of the compounds (6-methyl-5-hepten-2-one and hexyl acetate) were previously identified as significantly associated with tick counts in the BI results.

Five single day tick count and volatile compound combinations were identified in the GLM analysis as significant ($P<0.05$) where isoamyl acetate (TickD25 by AI-isoamyl acetate) and limonene (TickD25 by AI-limonene) had not been previously observed in the repeat measure analysis. Two other volatile compounds ((*E*)-2-heptenal/benzaldehyde and 6-methyl-5-hepten-2-one) were observed in the previous analyses with *P*-values ranging from <0.015 to 0.045. These volatile compounds represent potential proxies for use in predicting tick resistance without counting ticks on the animals. The volatile compound (lnBI6-methyl-5-hepten-2-one) was significantly ($P<0.05$) associated with tick counts during the first 3 days of sampling and also for tick count totals and tick average.

The high correlation coefficients, r=0.66 and r=0.73 respectively for models including repeated records or mean tick counts with all volatile compounds support the potential predictive value for volatile compounds in selective breeding programmes for tick resistance in cattle.

Discussion

The within breed natural differential attractiveness of individual animals to disease-transmitting cattle flies was found to be partly due to differences in volatile semiochemicals emitted by the host (Birkett *et al.*, 2004). Other studies (Jensen *et al.*, 2004) reported a genetic basis to host resistance to cattle flies. High correlation between volatile semiochemical production and tick resistance in cattle could underpin the development of a new low cost tool for phenotyping cattle for selection and breeding for tick resistance in livestock breeding programmes.

The work to develop new anti-tick vaccines are ongoing (Guerrero *et al.*, 2014, Lew-Tabor and Rodriguez Valle, 2016), but new vaccines are highly unlikely to confer total protection against ticks. It has been postulated (Frisch, 1999), that the best method of reducing the impacts of these stressors to improve productivity and animal welfare is to breed cattle that are well-adapted to the different types of stress, and work in concert with other management interventions.

We identified volatile compounds with some naturally found in naïve animals, if this is can be replicated in other studies, it would allow sampling of animals irrespective of the tick infestation status. Results for post infestation compound can be taken to show host responses to an ongoing tick challenge. In sub-Saharan Africa, ticks and tick borne diseases are a major constraint, example of livestock tick-borne diseases reported in Kenya include theileriosis, babesiosis, anaplasmosis and ehrlichiosis, which reflect the diversity of the transmitting tick vectors (Mwamuye *et al.*, 2017).

This search for potential new volatile-based resistance phenotype has the potential to simultaneously improve cattle resistance to both ticks and biting flies. The new phenotype would enhance predictive power across breeds and countries to enhance existing efforts already being undertaken in this regards (Cardoso *et al.* 2021). Our current method will need further refinement to satisfy the requirements of a simple, cost-effective phenotype available for use in large cattle herds as a replacement for the laborious tick counts.

Abstract

Genetic parameters and genomic breeding values for three groups of foot and claw disorders (CD): infectious diseases (ID), claw horn lesions (CHL) and overall claw disorder (OCD) were estimated. Lameness (L) represented the indicator trait for CD. L figured in the two-trait or multi-trait model with ID, CHL or OCD to increase the accuracy of genomic breeding values. Data from 189,893 lactations of 57,711 Holstein cows were recorded on 74 farms in the Czech Republic from 2017 to 2021. The linear animal model and single-step genomic prediction were employed. Genetic correlations between L and ID were 0.27; CHL 0.60; OCD 0.67. An increase in the accuracy of the breeding value appeared in the two-trait model compared to the single trait model. Due to the multi-trait model, the increase in accuracy was no longer as significant as the two-trait model. Paper was supported by the projects MZERO0718 and QK1910320.

Introduction

Foot and claw diseases/disorders are among the main reasons for the deterioration of dairy cows' welfare, production, and reproductive system (Heringstad *et al.* 2018). Welfare problems arise because of claw lesions that are usually long-term and painful (Van der Waaij *et al.* 2005). Other fundamental consequences manifest in the production and reproductive system of the cow (Charfeddine and Pérez-Cabal 2017). The heritability of foot and claw disorders has been verified in several dairy cattle breeds (Chapinal *et al.* 2013). The painful disorder often manifests as lameness (L), e.g. impaired locomotion of variable severity and deviation from normal gait or posture (Greenough 2007). Linear mixed models are often employed to estimate genetic parameters for claw disorders, e.g. especially when the genetic correlation with other traits is estimated (Chapinal *et al.* 2013). The objectives of this study were to use lameness as the second trait in the genomic evaluation of claw health traits in Czech Holstein cattle by a genomic two-trait model for increasing the accuracy of the genomic prediction.

Materials & methods

Cases of foot and claw diseases/disorders (CD) from 189,893 lactations of 57,711 Holstein cows were recorded on 74 farms in the Czech Republic from 2017 to 2021. Records of CD were gathered by farmers and registered voluntarily in the national cattle health monitoring system 'The Diary of Diseases and Medication' (Kasna *et al.* 2017). This recording system was implemented in August 2018 after a one-year trial period in the Czech Republic. It consists of farmers' online health recording form and a simplified key of diagnoses based on ICAR recommendations. Holstein Cattle Breeders Association of the Czech Republic and the Czech and Moravian Breeding Corporation provided health and genomic data. Three groups of CD were defined: infectious diseases (ID), including digital and interdigital dermatitis; interdigital phlegmon and heel horn erosion; claw horn lesions (CHL), including ulcers, white line disease, horn fissures, and double sole; and overall claw diseases (OCD) comprising all the recorded diseases/disorders. Monitoring also included lameness (L). For analyses, foot and claw diseases/disorders and lameness were defined as 0/1 occurrence per lactation.

Description of model equation. The following linear animal model was used to estimate genetic parameters and genomic breeding values for foot and claw disease/disorder traits and L traits:

DOI: 10.3920/978-90-8686-940-4_91, © L. Zavadilová *et al.* 2022

$$y_{ijklm} = parity_agegroup_i + herd_j + year_season_k + PE_l + A_m + e_{ijklm}, \quad (1)$$

where y_{ijklm} is the analysed trait: ID, CHL, OCD, L 0/1 occurrence per lactation; $parity_agegroup_i$ is the effect of parity combined with age at calving class (15 levels: first, second, third, fourth, and five and higher parity; 3 classes of age at calving per parity); $herd_j$ is the effect of herd j (up to 74 levels); $year_season_k$ is the combined effect of calving year k (4 levels) and $season_l$ is the effect of calving season (4 levels: January–March, April–June, July–September, and October–December); PE_l is the random permanent environmental effect on cow traits across parity; A_m is the random additive genetic effect of $animal_m$, and e_{ijklm} is the random residual effect. For the prediction of genomic breeding values, a single-step procedure was applied (Aguilar *et al.* 2010, Christensen and Lund, 2010) with 7,337 genomic animals: 5,215 bulls and 2,122 cows with CD phenotype; a total number of effective SNPs used in the calculation of G matrix was 38,084; effective animals 7,105. The relative breeding values in % (RBV) were calculated using a reference level derived from sires born in 2010 (mean=100%) and SD=12. Higher relative breeding values mean a favourable value for foot and claw disorders, i.e. higher resistance to them. The predictions of breeding values by single-trait model for ID, CHL and OCD; by two-trait model for ID and L, CHL and L, OCD and L, and by multi-trait model for ID, CHL, OCD and L. Lameness was considered as an indicator trait included in the two-trait or multi-trait model prediction for an increase of the accuracy. The basic editing and preparation of datasets, processing of results and basic statistical evaluation were carried out by the SAS 9.4 programme (SAS. 2016). Program package BLUPF90 (Misztal *et al.* 2018) was used to estimate genetic parameters and genomic breeding values. The number of animals in particular models and lactation incidence rate (LIR) in % are presented in Table 1. The datasets for two-trait and multi-trait models were combined according to cows and parity from datasets used for single-trait analyses.

Results

As shown in Table 2, there was a sound increase in the accuracy of the breeding values for all the listed animal categories for the two-trait model compared to the single trait model, which included the particular CD trait and L. When the multi-trait model was employed, the increase in accuracy was no longer as high as for the two-trait model. Notably, for CHL, the accuracy of the breeding values decreased. According to particular traits, the genetic trends for bulls and cows were very similar when compared between single-trait and two-trait models. However, genetic trends based on the multi-trait model differ considerably from previous models, especially for CHL, as is shown in Figure 1. The differences between genetic trends by different models for other traits were less noticeable for ID and OCD than for CHL. The proportion of individual diseases to ID (in lactations) was 52% dermatitis digitalis, 8% dermatitis interdigitalis, 35%

Table 1. Number of animals for different traits models.

Trait[1]	Model	LIR in %	No. of farms	No. of animals in the pedigree
ID	Single	15.12	39	84,644
CHL	Single	15.10	25	56,510
OCD	Single	19.42	51	102,874
L	Single	8.38	43	84,597
ID, L	Two	See single	68	126,176
CHL, L	Two	See single	60	70,730
CHL, L	Two	See single	60	109,277
OCD, L	Two	See single	74	137,202
ID,CHL,OCD,L	Multi	See single	74	137,448

[1] ID = infectious diseases; CHL = claw horn lesions; OCD = overall claw diseases; L = lameness.

interdigital phlegmon and 4% heel horn erosion; around 10% of all ID lactations combined two diseases. CHL was constituted mainly by ulcers (92%). For OCD, the proportion of lactation with both infectious disease and horn lesion was 29%. The heritabilities of traits were ID 0.067; CHL 0.055; OCD 0.056; L 0.026. Based on the two-trait models, the genetic correlation between ID and L was 0.27; CHL and L 0.60 and between OCD and L 0.67.

Discussion

The genetic evaluation is employed for improving foot and claw health of Holstein cows in the Czech Republic using three groups of CD traits: ID, CHL, and OCD. This procedure appears appropriate because foot and claw health traits are usually grouped according to aetiology and pathogenesis (Greenough, 2007) to represent the most frequent disorders and achieve adequate records for genetic evaluation. The other monitored trait is lameness, but it does not enter the genomic evaluation. Because the amount of data for CD data is not optimal, we also try to use L data in the genetic evaluation of CD traits. We proved true what Bicalho *et al.* (2007), and Weber *et al.* (2013) found that L is highly correlated with CD, as we also found especially for CHL and OCD. Heritabilities of all analysed traits were low as usual in the literature (Van

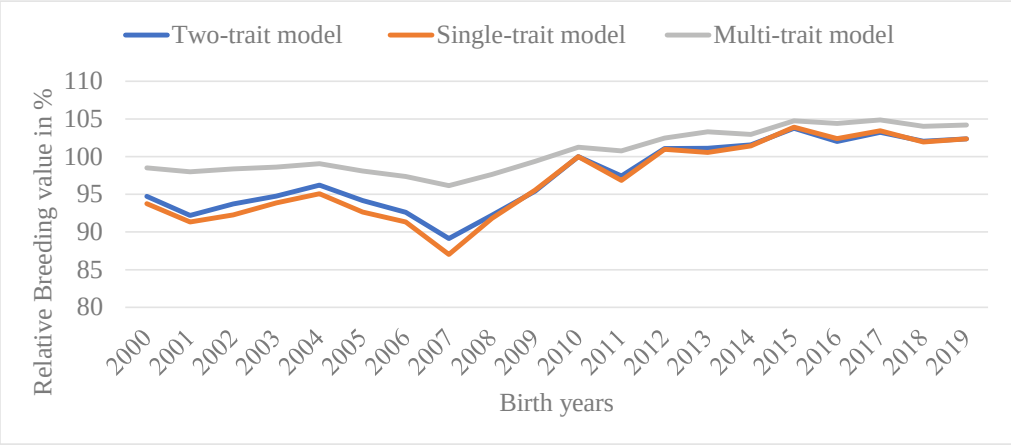

Figure 1. Genetic trends in claw horn lesions for bulls.

der Waaij *et al.* 2005; Weber *et al.* 2013; Heringstadt *et al.* 2018). The presented analysis displayed the very positive impact of the two or multi-trait model on GEBV accuracy. Increasing the amount of information due to the employment of lameness in two-trait model analysis led to an increase in accuracy compared to single-trait genomic prediction. However, we prefer using a two-trait model over a multi-trait model because it has led to a higher increase in accuracy while not expressively altering genetic trends for the particular CD trait.

Sustainable Agricultural Systems, University of Natural Resources and Life Sciences, Vienna, Gregor Mendel-Str. 33, 1180 Vienna, Austria; angela.costa@unipd.it

Abstract

Milk lactose content (LC) reduces with parity in dairy cattle and shows an inverse relation with somatic cell count. The aim of this study was to investigate if the lifetime decrease in LC is due to cumulative number of experienced udder inflammations. For this purpose, milk test-day data of Austrian Fleckvieh cows were available together with records of acute (AM) and chronic mastitis (CM) cases. In addition, inflammations were also defined by using high test-day somatic cell count: ≥200,000 (SCC_{200}) or ≥400,000 cells/ml (SCC_{400}). Inflammation events were calculated for each test-day using data collected across the cows' lifespan, i.e. across all available lactations. The effect of cumulative inflammations on LC was highly significant, with LC being the highest when 0 mastitis events were experienced and significantly different from LC estimated for test-day records linked to ≥1 event. Findings demonstrate that the lifetime LC decrease can be seen as a mammary memory indicator and represents the combined result of physiological aging and past inflammations.

Introduction

A negative correlation between milk lactose content (LC) and somatic cell count (SCC) has been observed in several studies, but only in recent years some attempts have been made to explore why and how LC changes when mastitis occurs. Both the genetic and the phenotypic correlations between LC and SCC and between LC and mastitis confirm the opposite trend of these features. A progressive drop in average milk LC is observed during productive life of cows, i.e. across parities. Costa *et al.* (2020) suggested that LC decreases with parity for two main reasons: physiological aging and cumulative effect of inflammation events. In both cases, the alveolar permeability is subjected to damage and impairment of its functionality, which lead to a loss of lactose from the alveolar lumen (milk) to blood and finally to urine. The reduction in alveolar LC causes an alteration of the osmotic equilibrium, which is compensated by sodium and potassium. In this study, we explored the role of cumulative mastitis events on milk LC using cows' test-day (TD) records and validated health data.

Materials & methods

Data. Data used in the present study included milk and health records of cows born between 1997 and 2017 reared in Austrian farms under validated health data recording system (Egger-Danner *et al.* 2012) located in Styria and Lower Austria. Only Fleckvieh cows with information available from parity 1 were retained and the maximum parity was set at 10. In addition, only TD records from 5 to 500 days in milk were considered and ≥3 cows/farm and ≥3 TD/lactation were required. After editing, date of first calving was within a window from 1 January 2011 to 29 February 2020. This guaranteed the presence of reliable health records and allowed the completion of those lactations started in spring 2020. Finally, 432,839 TD from 53,099 lactations and 18,404 cows located on 566 farms were left. Both acute (AM) and chronic mastitis (CM) events were available. The cumulative number of mastitis events were assigned to each TD of a cow starting from the first available TD in parity 1 onwards, i.e. across lifespan, regardless of the distance

between the diagnosis date and the date of TD. Mastitis events were defined using diagnosed AM, AM+CM or based on high SCC. In particular, TD SCC ≥200,000 (SCC_{200}) or TD SCC ≥400,000 cells/ml (SCC_{400}) were used as threshold. The TD records were classified as reported in Table 1 according to cumulative AM events, i.e. 0, 1, and 2, with the latter including TD records with 2 or more AM. For the sum of cumulative AM+CM, 4 classes were defined, i.e. from 0 (no diagnoses) to 3 (≥3 diagnoses). Furthermore, 5 classes of SCC_{200} and 5 classes of SCC_{400} were created based on the number of TD with 'high' SCC. Specifically, the classes 0, 1, 2, 3, and 4 included 0, 1, 2, 3, and ≥4 'high' TD SCC, respectively. Counting of mastitis events did not stop at each lactation, so that for each TD all events recorded previously in life were considered (Figure 1). Seasons of calving were defined as: Mar-May, Jun-Aug, Sep-Nov, and Dec-Feb.

Effect of mastitis. The following mixed model was used in SAS software v. 9.4 (PROC HPMIXED) to estimate LC with increasing number of experienced inflammations, i.e. including the fixed effect of AM, AM+CM, SCC_{200}, or SCC_{400} separately in four analyses:

$$y_{ilklmn} = u + PO_i + LS_j + ME_k + (PO \times LS)_{ij} + (LS \times ME)_{jk} + YS_l + FC_m + DF_n + e_{ilklmn} \quad (1)$$

where y_{ijklmn} is the milk LC at the given TD, u is the overall intercept of the model, PO_i is the fixed effect of the i^{th} parity (i = 1 to 6, with parities from 6 to 10 grouped together), LS_j is the fixed effect of the j^{th} lactation stage (l = 1 to 7, each class being 50 days wide, except for the last class which included TD from 305 to 500 days in milk), ME_k is the fixed effect of the k^{th} cumulative mastitis event (Table 1), YS_l is the fixed temporal effect of the l^{th} year-season of calving (l = 1 to 43), and FC_m, DF_n, and e_{ilklmn} are the random effects of the m^{th} cow, the n^{th} herd, and the residual, respectively. Random effects were assumed to be independent and normally distributed.

Table 1. Distribution of test-day records across classes of fixed effects.

Fixed effect	Cumulated traits	Frequency (%)				
		0	1	2	3	4
AM	n. past acute mastitis	88.01	8.01	3.98	-	-
AM+CM	n. past acute plus chronic mastitis	84.68	9.41	4.07	1.84	-
SCC_{200}	n. past test-day somatic cell count ≥200,000	51.39	13.74	10.2	5.79	18.88
SCC_{400}	n. past test-day somatic cell count ≥400,000	69.42	12.86	7.51	3.49	6.72

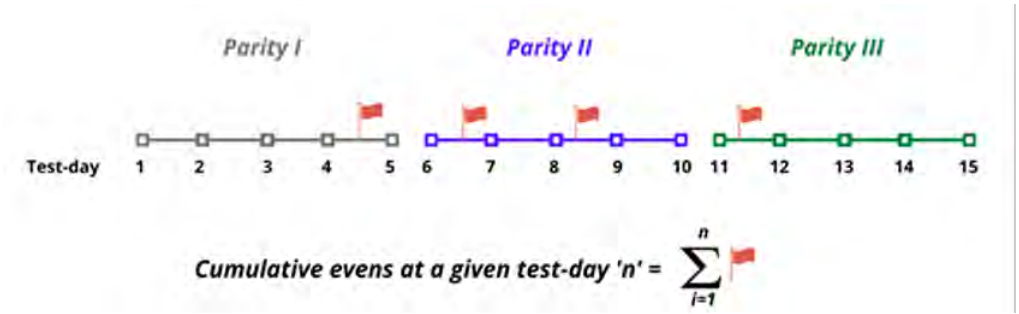

Figure 1. Example of mastitis events calculation for a given test-day record along a cow's lifespan.

Results

Milk LC averaged 4.79% and varied from 3.00 to 5.63%. Each TD was assigned to the cumulative number of mastitis events defined as previously described. The binary events AM and CM were mainly recorded in early and late lactation, respectively, while high SCC values were observed throughout the whole lactation (Figure 2).

All fixed effects in model (1), including the number of mastitis events, were highly significant in all analyses ($P<0.001$). The highest level of LC was observed in class 0 and this estimate was significantly different than those of other classes (Table 2). In addition, the gap between class 0 and class 1 was wider when fixed effect of mastitis was based on SCC_{200} and SCC_{400}.

The lifetime decline in LC is thus due to both parity and past inflammations, and this is particularly evident when looking at the estimates of SCC_{200} or SCC_{400}. In fact, the LC decrease was less noticeable if the effect was either AM or AM+CM. The F-value of fixed effect of parity ranged from 3,104.09 to 5,438.63, while the F-value of mastitis event was 29.87, 18.46, 1,392.03, and 998.99 for AM, AM+CM, SCC_{200} and SCC_{400}, respectively.

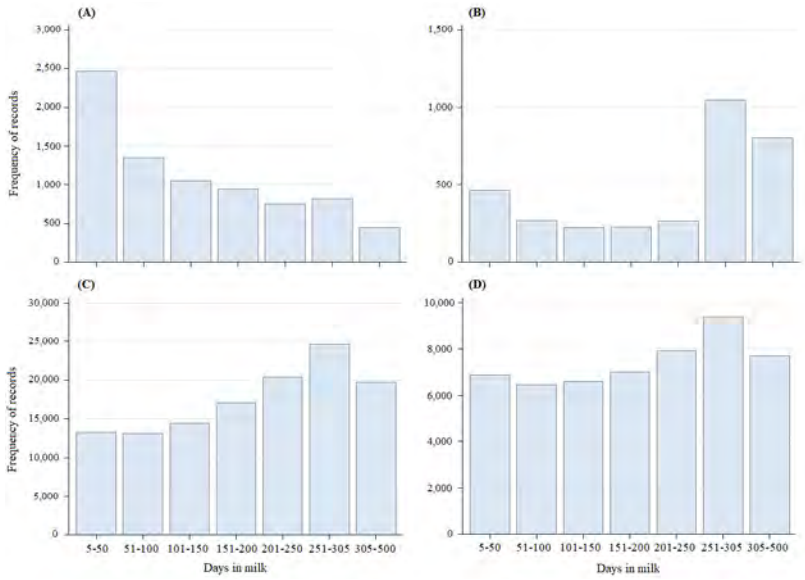

Figure 2. Distribution of mastitis events identified using acute (A) and chronic (B) diagnoses and milk TD SCC ≥200,000 (C) and ≥400,000 cells/ml (D) across days in milk.

Table 2. Least squares means[1] of lactose (%) for cumulative number of mastitis events.

Fixed effect[2]	Class 0	Class 1	Class 2	Class 3	Class 4
AM	4.725 [a]	4.717 [b]	4.714 [b]	-	-
AM+CM	4.724 [a]	4.719 [b]	4.719 [b]	4.712 [c]	-
SCC_{200}	4.763 [a]	4.730 [b]	4.715 [c]	4.705 [d]	4.686 [e]
SCC_{400}	4.746 [a]	4.710 [b]	4.699 [c]	4.687 [d]	4.678 [e]

[1] Superscript letters within row indicate significantly different estimates ($P<0.05$).

[2] Cumulative number of past acute mastitis (AM), acute plus chronic mastitis (AM+CM), and test-day somatic cell count ≥200,000 (SCC_{200}) and ≥400,000 cells/ml (SCC_{400}).

Discussion

Costa *et al.* (2020) opened the debate on the LC reduction across parities in dairy cows and suggested that the drop in LC may be used as a marker of mammary memory. A larger drop in LC within the productive life indicates that the cow faced up more infections, i.e. inflammations. Findings suggest that there is a lasting effect of udder inflammation on the alveolar structure and epithelium, that is detectable through changes in LC. The effect of parity (e.g. tissue aging plus milking mechanical stress) was separated from the effect of cumulative inflammations and, particularly when considering the results of SCC_{200} or SCC_{400}, the hypothesis that the lifetime LC reduction is due to both aging and cumulative udder inflammations was confirmed. Accurate identification of mastitis is challenging, particularly in presence of binary records. On the other hand, identification of mastitis based on milk SCC may led to false positive cases. Thus, in the present study the use of AM and AM+CM may plausibly have led to less glaring findings compared to continuous SCC data. It frequently happens that cows may not be sampled for official TD milk analyses if one or more diagnosis of mastitis is recorded during the lactation. For instance, farmers could opt for culling or for an earlier drying off. In the Austrian system specifically, when AM or CM is recorded it means that a treatment was administered to the lactating cow, speeding up the recovery and likely reducing the potential damage due to inflammation process. Conversely, using milk SCC for identification of inflammations seems a less restrictive approach, allowing detection of LC change after the event(s) in those cows with: (1) considerable number of cumulated high SCC TD; and (2) likely no or few official recorded mastitis diagnoses. The distribution of the different mastitis events within lactation (Figure 2) supports the idea that binary health traits have a different connotation compared to SCC quantitative data. Understanding if there is interaction between parity and cumulative event on LC sounds interesting, even if a small number of TD is expected to be associated with multiple inflammation events in parity 1, inevitably leading to distorted results. Vice versa, it is plausible that very old cows, e.g. in parity >5, have a limited number of TD linked to 0 past inflammations. In conclusion, this study demonstrates that the lifetime change in LC can be considered a mammary memory indicator, representing the combined result of aging and mastitis events in Fleckvieh cows.

Abstract

We estimated genomic-based genetic parameters for daily milk yield (MY), milk electrical conductivity (EC), and somatic cell score (SCS) from automatic milking systems (AMS) in North American Holstein cattle. Random regression models (RRM) enable the estimation of genetic parameters for each lactation day as well as the genetic correlation coefficients among MY, SCS, and EC. The data contained records of 4,118 cows genotyped with 72,820 SNP. The heritabilities and genetic correlations for MY, SCS, and EC and were estimated fitting third-order Legendre orthogonal polynomial. The daily heritability estimates ranged from 0.07-0.28 for MY, 0.03-0.08 for SCS, and 0.39-0.50 for EC. The genetic correlation among MY and other traits had high variation, whereas the genetic correlations between SCS and EC were moderate and positive. These results contribute to a better understanding of the genetic variability of longitudinal traits derived from AMS and can be used when refining dairy cattle selection indexes.

Introduction

Automatic milking systems (AMS; also known as milking robots) are becoming more common in dairy farms around the world due to the improvements in cow welfare, increased productivity, and reduced labor (Samoré *et al.*, 2011). AMS also generates a large amount of data, including phenotypes for production, behavior, health, and milk quality traits (Barkema *et al.*, 2015). AMS provide longitudinal measurements of indicators such as milk electrical conductivity. In addition, the availability of repeated records enable the use of random regression models (RRM) to estimate genetic parameters for each lactation day. RRM provide robust genetic modelling of time-specific effects for longitudinal traits, with key advantages compared to other statistical models, such as: (1) prediction of genetic parameters and genetic correlation among traits for the times-series within the range of data collection (Oliveira *et al.*, 2019); (2) less computational demand; and (3) not assuming that all records represent the same trait.

Electrical conductivity (EC) measures the ability of a solution to conduct an electric current between two electrodes, and it is measured in milliSiemens (mS). AMS are equipped with sensors for measuring EC, which is significantly correlated with somatic cell score (SCS) – an indirect measure of mastitis (Martin *et al.*, 2018). Data from AMS have been used to estimate genetic parameters for milk yield traits (e.g. Dechow *et al.*, 2020), which are highly genetic correlated with traits derived from conventional milking systems (Mulder *et al.*, 2004). Due to their already existing importance for breeding programs, AMS-based data has been collected for evaluating animal health traits such as EC (Romero *et al.*, 2017). In this context, the present study aimed to estimate genetic parameters for daily milk yield, EC, and SCS derived from AMS in North American Holstein cattle.

Materials & methods

Dataset. The data was recorded using 36 Lely AMS between 2017 to 2021 and contained 1,752,713 milking records of 4,118 genotyped Holstein cows from a commercial dairy farm located in Plymouth, IN, USA.

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_93, © L.S. Gloria *et al.* 2022

The traits evaluated are total milk yield per milking (MY, kg/day); EC (mS/cm), which was averaged across quarters; and somatic cell count (SCC, cells/ml) measured from the average across quarters. SCC was log-transformed to SCS using the formula (Piwczyński *et al.*, 2021):

$$SCS = log_2\left(\frac{SCC}{10{,}000}\right) + 3 \quad (1)$$

Genetic analyses. The descriptive statistics of the data was done using the R software (R Core Team, v 4.1.2), after eliminating records deviating 3.5 SD from the mean as potential outliers. Genotype imputation was performed using the FImpute software (Sargolzaei *et al.*, 2014) to converge all SNP panels available into a common set of 72,820 SNPs. Additionally, we performed the quality control (QC) analysis to remove the individuals and SNPs with call rate lower than 0.90, minor allele frequency (MAF) lower than 0.05, and extreme deviation from Hardy-Weinberg equilibrium ($P<10^{-8}$) using the BLUPF90 family programs (Misztal *et al.*, 2018). After QC 57,600 SNPs and 4,118 animals remained for further analyses.

Variance components and genomic-based genetic parameters for each trait were estimated using the AIREMLF90 software (Misztal *et al.*, 2018). RRM was used to describe the covariance structure of the data as a function of days in milk (DIM) (de Boor, 1980; Kirkpatrick *et al.*, 1990; Meyer, 2005). In matrix notation, the model equation can be defined as:

$$y_{ijkl} = YS_k + LN_l + \sum_{m=1}^{m} PM_m \emptyset_m(t_{ij}) + \sum_{m=1}^{m} a_{im} \emptyset_m(t_{ij}) + e_{ijkl}\,, \quad (2)$$

where y_{ijkl} is the predicted AMS traits of i^{th} animal on DIM j within year-season and lactation number, YS and LN are the fixed effects of year-season and lactation number, respectively; PM_m and a_{im} are the m random regression coefficients that describes the permanent environment and the additive genetic effect for the i^{th} animal; t_{ij} is the time of data collection (DIM j); $\emptyset_m(t_{ij})$ is a regression function according to DIM j using third-order Legendre orthogonal polynomial (LP). The residual effect (e_{ijkl}) was assumed to be homogeneous throughout lactation and the random effects were assumed to be normally distributed with zero mean.

Results

Heritabilities for MY, SCS, and EC are shown in Figure 1, in which the standard errors ranged from 0.02 to 0.07. The heritability for daily MY was lower (approximately 0.06) up to DIM 60 and then increased up to 0.28 at 305 DIM. The heritability for SCS increased from 0.02 to 0.08. The heritability for EC was moderate to high (0.39 to 0.50) with a low standard deviation (≈0.02) across DIM estimates. This indicates that EC is highly heritable throughout the entire lactation.

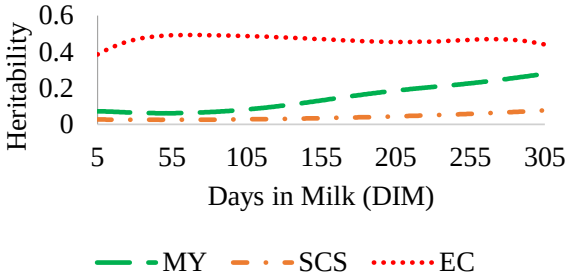

Figure 1. Daily heritability estimates of milk yield, somatic cell score, and milk electrical conductivity in North American Holstein cows. MY = Milk yield, kg; SCS = Somatic cell score, log2; EC = Milk electrical conductivity in mS/cm

Genetic correlations. The genomic-based genetic correlations among MY, EC, and SCS are presented in Figure 2, showing high variation among MY and the other studied traits. These correlation curves presented similar shape compared to a phenotypic lactation curve, increasing at the beginning until achieving a peak [MY and EC (0.42), MY and SCS (0.39)], and then decreasing until a minimum value [MY and EC (-0.32), MY and SCS (-0.42)]. On the other hand, the genetic correlations between SCS and EC are moderate and positive ranging from 0.23 to 0.42.

Discussion

The use of RRM enabled the estimation of time-dependent variance components, in which all three traits were shown to be heritable throughout lactation. However, a differential pattern on their genetic relationship across time was observed. The heritability for MY had a nonlinear relationship along the lactation, which is in agreement with previous reports such as for French Holstein cows milked by AMS (Tribout *et al.*, 2018). These authors using different methods and polynomials to model the random effects obtained heritability values ranging from 0.02 to 0.26 for MY, which are similar to those found in our study on North American Holstein cattle. In addition, a MY heritability of 0.11 was reported in US Holsteins milked using AMS (Dechow et. al., 2020). The heritability for SCS is in the lower range of the literature for Holstein cattle, but it is still heritable throughout the lactation. SCS has been used as an indirect measure of mastitis (Norberg *et al.*, 2004) and commonly used in dairy cattle breeding programs. EC has also been used for evaluating mastitis in dairy herds over the last decade. The use of EC as a selection trait is not new, Schukken *et al.* (1997) was the first to suggest EC as an indicator trait in a breeding program, and with increased use of AMS during this period there is a unique opportunity to closely monitor the mastitis status of dairy cows and incrementing the existing selection indexes for improved udder health. Previous studies have also observed that EC is moderately to highly heritable in other cattle populations (e.g. Piwczyński *et al.*, 2021).

Genetic improvement towards improving mammary gland health in dairy cattle is very important from both economical and animal welfare point of view. Previous studies have reported high variation and unfavorable genetic correlations between MY and SCS (Piwczyński *et al.*, 2021; Samoré *et al.*, 2011). According to Norberg *et al.* (2004), there are significantly differences for healthy, sub-clinically infected, and clinically-infected cows, as demonstrated by the means of EC (mS/cm) obtained by Norberg *et al.* (2004): 5.3 (±0.03), 5.75 (±0.04) and 6.73 (±0.06), respectively. The large amount of information generated through AMS combined with genomic information provide a great opportunity for selecting animals towards improved udder health, which will consequently contribute from both an economical and animal welfare perspective to the long-term sustainability of dairy farms.

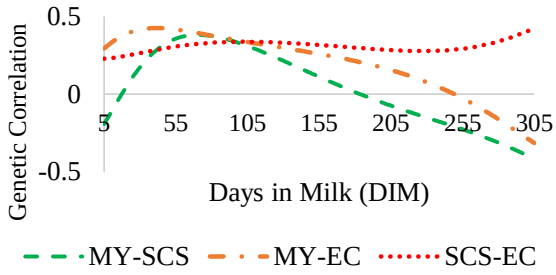

Figure 2. MY = Milk yield, kg; SCS = Somatic cell score, log2; EC = Electrical conductivity in milk, mS/cm

Abstract

In order to investigate the genomic control of innate immune response, the concentration levels of 14 cytokines produced naturally or in response to whole blood stimulation with three pattern recognition receptors agonists were determined in 623 Holstein calves enrolled in the Healthycalf project. The effect of the immunostimulants and the relationship among the cytokines produced were observed through a principal components analysis, and 50K GWAS were performed on all cytokine × condition traits. Results showed that most cytokines are oriented together following the first component that explained 70% of the variability and partially discriminated the agonistic conditions. Additionally, 40 genome regions were found in association with at least one trait with some regions being largely shared between conditions and cytokines. Seven positional candidate genes were considered as especially interesting due to their functional link to innate immune response reported from the literature.

Introduction

In most national breeding programs, the included health traits relate to adult animal health. However, calf health is also a major economical and welfare burden. In France, depending on the breed, between 10 and 20% of the dairy calves die before six months of age (Leclerc *et al.*, 2016). If a large part of deaths occurs in the first 48h and can be related to calving, a considerable and variable part happens between 48h and 2 months of age with a detrimental influence of diarrheas (Jegou *et al.*, 2006). A better knowledge of the mechanisms and genetic determinism of calves' innate immune response could help reducing the prevalence of diarrheas and respiratory symptoms and possible subsequent deaths. In this study, we aim to identify genome regions and candidate genes associated with innate immune response through the concentration level of various cytokines.

Materials & methods

Between 2018 and 2021, a large immune monitoring study was performed on Holstein calves from various commercial farms and one experimental farm (https://doi.org/10.15454/1.5483257052131956E12) all located in the Brittany and Normandy regions of France. A total of 623 calves were sampled at 1-2 weeks of age by veterinarians or qualified technicians. The authors would like to especially acknowledge H. Chapuy, C. Cazals, K. Toukmidine and C. Mechin for this work. Blood samples from the jugular vein were collected in four monovette syringes (Sarstedt, Marnay, France) containing heparin and pre-filled with pattern recognition receptors-agonists (LPS, NOD2L, R848) or a non-stimulated condition with vehicle only. Samples were incubated at 38.5 °C for 24 h and plasma recovered stored at -20 °C for further cytokine determination. An additional sample of blood or cartilage (when twin births) was taken for genotyping. This study is part of the Healthycalf project that was funded by Apis-Gene (https://www.apis-gene.com/).

Determination of cytokine concentrations. Concentrations of 15 cytokines/chemokines (IFN-γ, IL-1α et IL-1β, IL-1RA, IL-2, IL-4, IL-6, IL-8, IL-10, IL-17a, IP-10, CCL2, CCL3, CCL4 and TNFα) were measured in plasma samples with a custom bovine MILLIPLEX® MAP assay (SPRCUS706, Merck Millipore). Data were recorded on a MAGPIX® using xPONENT® software (Luminex). This system allows the quantification of a large number of samples and of 15 cytokines concomitantly. The wide assay range generally allows for accurate measurement of the 15 cytokines at a given plasma dilution (1/10). When a concentration was out of range (below or above), we assigned the minimum/maximum threshold for this cytokine. For IL-8, more than half the samples were out of range and therefore this cytokine was discarded from the analyses. For the other cytokines, the proportion of assigned samples varied from 1 to 22%.

Genotyping and quality controls. All animals were genotyped using the EuroGMD SNPchip designed for EuroGenomics (Illumina Inc., San Diego, CA, USA). DNA extraction and genotyping were performed at LABOGENA (www.labogena.fr, Jouy-en-Josas, France). The following quality controls were applied: an individual call rate higher than 95%, a SNP call rate higher than 90%, a minor allele frequency higher than 2% and genotype frequencies in Hardy-Weinberg equilibrium with $P>10^{-4}$. A total of 573 animals and 46, 910 SNP from the 29 autosomes passed the quality controls.

Statistical analysis. In order to visualize the effect of the condition (LPS, NOD2L, R848 or non-stimulated) and the relationships among the 14 cytokines, a principal component analysis (PCA) was performed using the miXOmics package of the R Software (Rohart *et al.*, 2017).

Genome-wide association study. Single-trait association analyses were performed on 64 traits, corresponding to the 14 cytokines × 4 conditions, plus 8 traits corresponding to the coordinates of each sample under each condition on the two first components of the PCA analysis. The following mixed linear model was used with the mlma option of GCTA software:

$$y= 1\mu + xb + u + e \quad (1)$$

where y is the vector of phenotypes; μ is the overall mean; b is the additive fixed effect of the SNP to be tested for association; x is the vector of predicted allele assays ranging from 0 to 2; $u \sim N(0,G\sigma_u^2)$ is the vector of random polygenic effects (with G being the genomic relationship matrix and σ_u^2 being the estimated polygenic variance based on the null model) and $e \sim N(0,I\sigma_e^2)$ is the vector of random residual effects (with I being the identity matrix and σ_e^2 the residual variance). In a first intend, SNP with –logP>5 were selected, this threshold being on the range of the chromosome-wide threshold of significance under a Bonferroni correction of α=5%.

Results

The results for the PCA are reported in Figure 1. The first axis accounts for more than 70% of the variability while the second axis explains only 10%. Most of the cytokine concentrations are correlated following the first component, which is also able to discriminate the different conditions, reflecting the overall intensity of immune reaction depending on the agonist. The second axis discriminates some specific cytokines (CCL2 and CCL4 versus IP10 and IFNγ) but to a lower extent. No structure is observed depending on the farm, the year or the calf sex (results not shown).

Considering the GWAS results for the 64 traits, a total of 145 SNP reached the threshold, corresponding to 40 different chromosomic regions. From these regions, 18 are detected associated with one trait only while six regions are shared between two traits, four between three traits, two between four traits and 10 regions, presented in Table 1, are shared between at least six traits. The same region was frequently

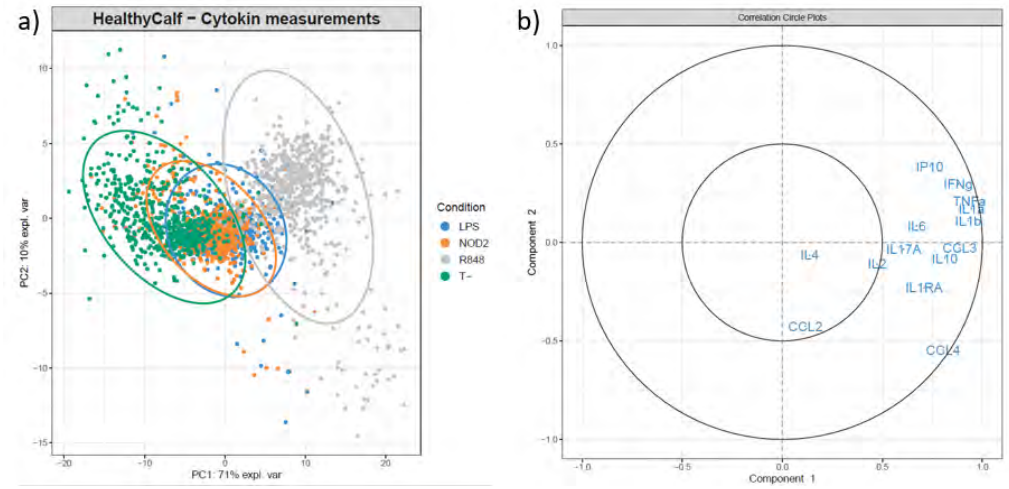

Figure 1. Principal component analysis results with (a) the plot of all samples colorized by condition and (b) the correlation circle plot among the cytokines.

Table 1. Details of the 10 regions identified by the GWAS associated with at least 6 different traits.

Chromosome	SNPmax Position (mb)	Minor allele frequency	Associated cytokines (with number of associated conditions)
2	36.0	0.13	IL1RA (4), IL6 (2)
2	72.7	0.12	IFNγ (1), IL1α(1), IL1RA (3), IL6 (3), TNFα (1)
3	70.4	0.09	IL1RA (4), IL6 (3), TNFα (1)
7	85.4	0.16	IL1α (1), IL1RA (4), IL6 (2), TNFα (1)
8	82.2	0.11	IL1RA (4), IL6 (2)
12	51.9	0.14	IL1RA (3), IL6 (3)
17	66.1	0.08	IFNγ (1), IL10 (1), IL1RA (4), IL6 (3), TNFα (1)
19	31.8	0.03	IL1RA (2), IL2 (2), IL6 (2), TNFα (1)
19	54.5	0.32	CCL4 (2), IFNγ (2), IL10 (2), IL1α (3), IL1β (3), IL1RA (2), IL2 (1), IL4 (4), PC1_LPS, TNFα (3)
24	12.5	0.24	IL17A (1), IL1α (1), IL1b (2), IL4 (1), PC1_LPS, TNFα (1)

associated with more than one condition of the same cytokine but different cytokines also shared some regions. The cytokines sharing the highest number of regions were the ones highly correlated with the first axis of the PCA, while cytokines like CCL2 were mostly associated with regions specific to them. It is however interesting to note that the number of regions associated with the PC traits was small (only five regions overall the eight traits).

Discussion

These results show that the mechanisms of innate immune response are complex with a genomic control that is partially shared between some cytokines but mostly specific for others and also with possible variations depending on the agonist. Among the numerous regions found associated with the traits here, some contain genes that have already been linked with immunity processes and are especially interesting candidate genes: LYAR (Yang *et al.*, 2019) and OTOP1 (Wang *et al.*, 2014), both located in a region of chromosome 6 associated with CCL4; SLC46A2 (Paik *et al.*, 2017), located in a region associated with

IL6 on chromosome 8; SEC14L (Li *et al.*, 2013) found in the largely shared region of chromosome 19; CXCL17 (Lee *et al.*, 2013) on chromosome 18 in a region associated with IL6; OTULIN (Fiil *et al.*, 2013) on chromosome 20 associated with IL4 and finally TREX1, on chromosome 22 associated with IL1β (Yan *et al.*, 2010). The next step will be to confront these cytokine profiles with the clinical status of the animals to determine if there is a link between the cytokine profile observed and the health status of the animals allowing the identification of predictive markers of sensitivity/resistance to diseases in young calves.

Abstract

MicroRNAs are a class of small non-coding RNAs, which regulate post-transcriptional gene expression, and could serve as biomarkers for several biological conditions. Sub-acute ruminal acidosis (SARA), a metabolic disorder characterized by low ruminal pH and the accumulation of volatile fatty acids, is linked to feeding of starch-rich diets. To evaluate the suitability of miRNAs as potential biomarkers in cattle for the diagnosis of SARA, a comprehensive identification of miRNA profiles in plasma and leucocytes was conducted by next generation sequencing technologies. Four dry Holstein cows were fed a control diet of 100% forage and subsequently transitioned to a 65% high-grain diet. In plasma and leucocytes, 520 and 730 miRNAs were found, respectively. Bta-miR-2285u, bta-miR-30b-3p and bta-miR-12034 were differentially expressed between diets, and therefore chosen as potential SARA biomarker candidates and further analysed by RT-qPCR in more cows. Bta-miR-2285 and bta-miR-30-3p could be confirmed as biomarker candidates for rumen health.

Introduction and background

MicroRNAs (miRNAs) are small (≈22 nucleotides long) non-coding RNAs which are crucial regulators of gene expression. These short transcripts limit protein translation through a process referred to as 'gene silencing', where miRNA binds to mRNA molecules and either transiently blocks translation of proteins, or degrades the bound mRNA (Duchaine and Fabian, 2019). Biofluids and other biological matrices, such as plasma, saliva, or faeces are common targets for biomarker profiling as they are obtained through minimally invasive techniques, and contain biologically important molecules which may be predictive of disease outcomes (Tesfaye *et al.*, 2016). Shaughnessy and colleagues reported that specific miRNAs had shown to be differentially expressed in faecal samples of colorectal cancer cases relative to those from healthy human controls (Shaughnessy *et al.*, 2020). MiRNAs are conserved between different species and target most of the protein-coding genes that are involved in various developmental and biological processes (Sun *et al.*, 2019). MicroRNAs in bovine are suggested to play important roles in diverse molecular functions and biological processes which includes rumen development, adipogenesis, mammary gland and ovary development, immunity, and infection. They can also serve as biomarker for production traits (e.g. milk yield and quality), and could be used for early diagnosis of pregnancy (Sun *et al.*, 2019). MicroRNA biomarkers are referred to as the especially produced or enriched miRNAs in a particular tissue under a specific biological condition. Ioannidis and Donadeu reported and identified the miR-802 in cattle, a circulating miRNA shown to regulate insulin sensitivity and lipid metabolism, that could also potentially serve as a specific biomarker of liver function, a key parameter in the context of post-partum negative energy balance in dairy cows (Ioannidis and Donadeu, 2018). The discovery of novel biomarkers in association with specific production traits and disease conditions in cattle is of significant agricultural importance.

The current definition and ruminal pH threshold for SARA varies among studies. However, SARA usually occurs when ruminal pH remains in the range of 5.2 and 6 for a longer period. In this study, SARA was defined as pH disturbances below a threshold of ruminal pH<5.8 for 320 min/d. Despite being reportedly

associated with a systemic inflammation of different organs and tissues in dairy cows, there is no typical clinical sign of illness in SARA-affected cows (Abdela, 2016). Thus, biomarkers are pressingly needed to identify cows that are at a greater risk of developing SARA. Therefore, the main aim of this study was to comprehensively identify miRNA profiles in plasma and leucocytes to evaluate miRNAs as biomarkers in cattle exposed to SARA due to high-grain feeding during a prolonged period.

Materials & methods

Blood samples were collected in EDTA-coated tubes (Becton Dickinson, USA) from the jugular vein of four ruminal-cannulated Holstein cows, average age of 11.3±2.29 years, with a weight of 909.75±98.17 kg. Cows were fed a diet of 100% forage and were transitioned after one week of adaptation to a 65% high-grain diet, which was fed for a total of 4 weeks. The animals were held at the research and training farm of the University of Veterinary Medicine Vienna in Kremesberg, Austria. The trial was approved by the ethical committee, with the protocol number BMBWF-68.205/0033-V/3b/2019. Cell-free plasma and leucocytes were obtained using a two-step centrifugation protocol. Total RNA was isolated using the NucleoSpin miRNA Kit (Machery-Nagel) following the manufacturers protocol with few modifications.

Small RNA libraries were prepared from blood plasma and blood leucocytes using the NEXTflex Small RNA-Seq Kit (Bioo Scientific). A 50 bp single end sequencing approach was performed on an Illumina NovaSeq 6000 platform by the company CeGat (Tübingen, Germany). Read processing and pre-filtering was conducted in sRNAbench and R software 4.0.2. Normalised reads count (reads per million mapped, RPMM) obtained from sRNAbench were filtered (>10 reads) in R using the *tidyr* (version 1.1.4) package. Reads with an average PHRED score below 20 were discarded and all miRNAs that had less than 10 total read counts across the studies samples within each cow were filtered out. Bioinformatics and differential expression analysis was carried out using DESeq2 (version 4.1) (Love *et al.*, 2014). Differentially expressed (DE) miRNAs were considered if false discovery rate (FDR)≤0.05 and a |log2 (fold change) | ≥1. TargetScan (McGeary *et al.*, 2019) and miRBase (Griffiths-Jones, 2006) were used to predict DE miRNA target genes. The filtered and sorted data were further analysed using Venny 2.1 (Oliveros, J.C, 2007-15) for identification of unique and shared miRNAs across animals and diets. The four cows plus one additional cow was tested for RT-qPCR to confirm the accuracy of the sequencing results. Furthermore, a later time point of the experiment, week 4, was included. Quantification of miRNA was done by a poly-A-technique according to the manufacturer's protocol (miRNA 1st-Strand cDNA Synthesis Kit, Agilent Technologies). Therefore, 1 µg of total RNA was polyadenylated for 30 min at 37 °C terminated by 95 °C for 5 min in a total volume of 10 µl. In a second step, 10 µl of the elongated miRNA was reverse transcribed using the AffinityScript RT and the Universal Reverse Primer (3.125 µM) in 20 µl volume. MiRNA-specific primers were designed and validated. RT-qPCR assays were performed using the miRNA QPCR Master Mix (Agilent) on a ViiA7 instrument (Life technologies). MiR-107 and miR-103 served as reference miRNAs to normalize for RNA content. Relative expression was calculated using the ddCT-method. Relative values were calculated relative to the mean expression of the forage-based diet.

Results & discussion

In total, 520 miRNAs were discovered in plasma, with 360 miRNAs (Figure 1a) shared between forage (week1) and high grain (week2), while 730 miRNAs were identified in leucocytes, with 650 miRNAs (Figure 1b) shared between weeks 1 and 2 in all cows. When the cows were fed the high-grain diet, 63 miRNAs were identified in plasma, and they are solely expressed when cows are fed a high grain diet, resulting in higher circulating miRNAs. A total of 730 miRNAs were found in leucocytes, with 650 miRNAs shared between weeks 1 and 2. 17 miRNAs were only expressed when the forage-based diet (week 1) was fed, while 34 miRNAs were only expressed during high-grain feeding (week 2).

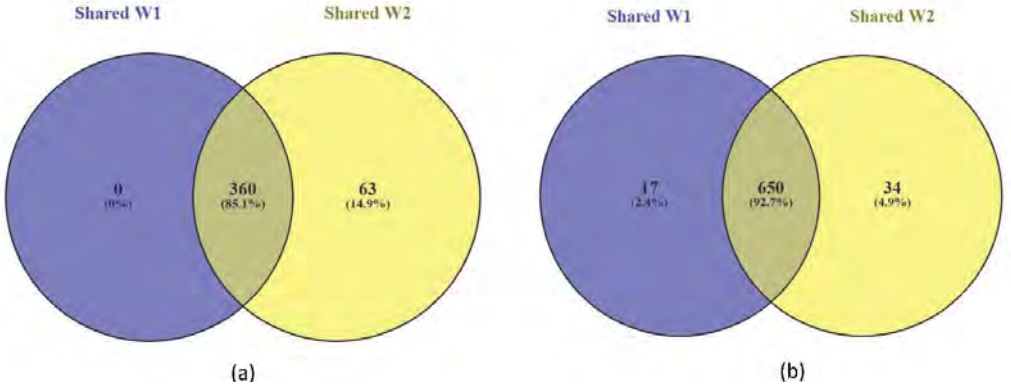

Figure 1. A schematic diagram of shared miRNAs in (a) plasma and (b) leucocytes between forage and high-grain diet.

Twelve miRNAs were differentially expressed in plasma samples (forage vs high-grain diet), from which 10 miRNAs were found to be up-regulated and 2 miRNAs were down-regulated. A total of 25 miRNAs were differentially expressed in leucocytes (forage vs high-grain diet). From these, 5 miRNAs were upregulated, and 20 miRNAs were found to be downregulated. The miRNAs bta-miR-2285u, bta-miR-30b-3p and bta-miR-12034 were chosen for further analyses. RT-qPCR validation included a further sampling time point at week 4, where the cows were already fed high grain for three weeks. These candidate miRNAs obtained from plasma were selected with respect to the total read counts of the filtered and sorted miRNAs in all the cows fed on a high grain diet (n=63), as well as the differentially expressed miRNAs (n=12) in terms of their read count in increasing order and log2 fold change. A Kruskal-Walli's test showed a strong influence (P=0.035) of the high-grain diet on the expression of miR-2285u (Figure 2A). Bta-miR-2285, a huge class of miRNAs, is believed to be rumen specific (Sun *et al.*, 2019). Hence miR-2285-u could be a promising circulating-miRNA candidate biomarker for rumen health. Furthermore, we found a higher expression of miR-30b-3p on week 2 (P=0.098), compared to the forage feeding at week 1 (Figure 2B). The same direction of effect was detected within the next generation sequencing data. On week four, after three weeks of high-grain feeding, the expression level was again at the level of forage feeding. Nevertheless, bta-miR-30b-3p has the potential to be a good candidate to detect short-term imbalances due to high-grain diet. Our result goes in line with the study of Muroya and colleagues, who identified bta-miR-30b-3p to be highly expressed in plasma of cattle fed a high-grain diet compared to grazing cattle (Muroya *et al.*, 2016). In the case of bta-miR-12034 we could not confirm a regulation by feeding high-grain diets through qPCR (Figure 2C).

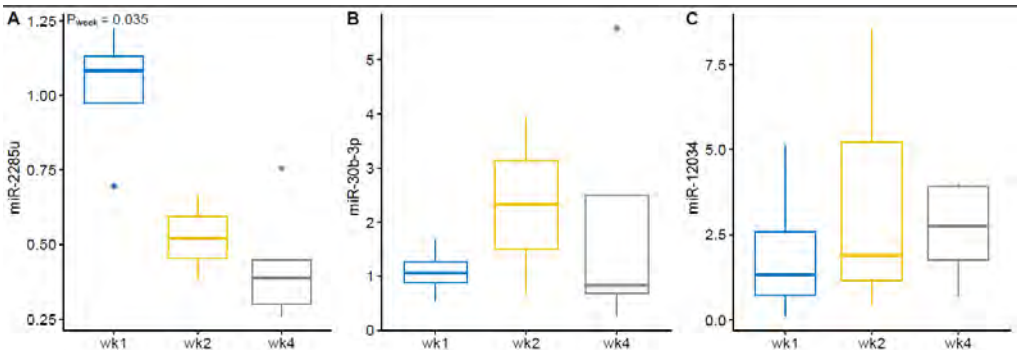

Figure 2. Relative miRNA expression of selected bovine miRNAs (A: miR-2285u, B: miR-30b-3p, C: miR-12034) by RT-qPCR in blood plasma of cows (n=5) at sampling time point week 1, when cows were feed a forage based diet and at sampling time points week 2 and week 4, when cows were fed a high-grain diet with 65% concentrate.

Conclusions

Our findings show that dietary modifications affect the release and expression of miRNAs in systemic circulation, potentially modulating post-transcriptional gene expression in SARA-affected cattle. MicroRNAs bta-miR-2285 and bta-miR-30-3p appear to be good candidates to serve as biomarker for rumen health and will be further analyzed.

96. Variance component estimation of longitudinal alpha diversity metrics of the ocular microbiome in preweaned beef cattle

A.D. Lakamp*, A.C. Neujahr, M.M. Hille, J.D. Loy, S.C. Fernando and M.L. Spangler

University of Nebraska-Lincoln, 3940 Fair St, Lincoln, NE, USA; alakamp2@unl.edu

Abstract

The objective of this study was to examine the relationship between host genetics and four alpha diversity measures of the ocular microbiome in beef cattle. Ocular microbiome samples were taken from 223 preweaned calves at four time points (T1-T4). The average age at T1 and T4 were 65 and 204 days, respectively. The alpha diversity metrics used were observed diversity, the Chao1 index, the Simpson index, and the Shannon index. Variance components were estimated for each diversity metric at each time point using univariate ssGBLUP animal models. Heritability estimates for observed and Chao1 were moderate at T1 (0.35 and 0.36, respectively), high at T2 (0.58 and 0.68, respectively), zero for T3, and increased at T4 (0.45 and 0.55, respectively). Heritability estimates for the Simpson and Shannon indexes were moderate at T1 (0.42 and 0.50, respectively), low to moderate at T2 (0.14 and 0.30, respectively), and zero at T3 and T4.

Introduction

In beef cattle, the composition and diversity of the ocular microbiome are of interest due to their possible relationship with infectious bovine keratoconjunctivitis (IBK), commonly known as bovine pinkeye. Previous research has focused on the effect host genetics on the incidence of IBK infection (Snowder *et al.*, 2005); however, to our knowledge, the relationship between host genetics and ocular microbiome composition and diversity has not been previously investigated. Nonetheless, several studies have demonstrated the abundance of several ruminal taxa to be heritable (Li *et al.*, 2019; Sasson *et al.*, 2017; Wallace *et al.*, 2019). Moreover, the alpha diversity of ruminal bacteria and archaea is also heritable (Li *et al.*, 2019). Therefore, it is possible host genetics also affect the diversity and composition of the ocular microbiome.

The objective of this study was to estimate the degree to which different alpha diversity metrics of the ocular microbiome were heritable in preweaned beef calves.

Materials & methods

Animals, study design, and phenotypes. Data used for the current study was previously described by Bartenslager *et al.* (2021). Briefly, a group preweaned beef calves (n=223) comprised of varying percentages of Angus, Simmental, Red Angus, Hereford, and Gelbvieh from a single herd-year-season of birth were used. Animals were randomly administered one of three IBK vaccine treatments. The corneal and conjunctival surfaces were sampled using an eye swab in each calf at four time points (T1-T4). The first swab was prior to vaccination (day 0) when the average calf age was 65±15 days. Swabs at T2 and T3 corresponded to day 21 (vaccination booster) and 41, respectively, post initial swab collection. The final swab was taken on day 139 when the average calf age was 204±15 days.

Each ocular microbiome sample was subjected to DNA extraction and amplification of the V4 region of the 16S rRNA gene using barcoded primers. This was followed by sequencing of the V4 region on the Illumina MiSeq platform using 250 bp paired-end sequencing strategy (Kozich *et al.*, 2013). Data analysis was performed after quality filtering using the DADA2 pipeline (Callahan *et al.*, 2016) and the phyloseq package v1.26.1 (McMurdie and Holmes, 2013) in R software. This method resulted in groups of microbes collectively known as amplicon sequence variants (ASVs). Finally, ASV taxonomy was assigned using the SILVA reference alignment v138.

The alpha diversity metrics selected as phenotypes for the current study were observed diversity, the Chao1 diversity index (Chao and Chiu, 2016), the Simpson index of diversity (Simpson, 1949), and the Shannon diversity index (Shannon, 1948). The diversity indexes can be interpreted as follows; observed diversity is the number of different ASVs identified in the sample, Chao1 estimate is the diversity estimate after accounting for rare species in the sample. For both observed and Chao1 a higher value represents greater diversity. In the case of Shannon and Simpson indexes, both richness (number of species present) and abundance (number of individuals per species) are considered. Given Shannon diversity is based on measuring uncertainty, a low diversity will result in a low uncertainty value, and therefore, as diversity increases the Shannon index would increase. However, the Simpson index uses the mean proportional abundance information of each species. Therefore, as the number of species increases the proportional abundance for a given species decreases. As such, as diversity increases the Simpson index would decrease. Thus, 1-Simpson index was used as the diversity measurement which would increase with increased diversity, and in this sense, would be similar in interpretation as the other indexes used.

Data were edited to remove animals with different vaccination treatments on day 0 and day 21. Additionally, not all animals had observations for all time points (n=211, 211, 187, and 189, for T1-T4, respectively). In total, 223 animals had observations for at least one time point.

Statistical analysis. A pairwise Wilcoxon rank sum test was performed to determine the statistical significance differences between time points within each metric using R software (R Core Team, 2021).

A four-generation pedigree was constructed for all 223 animals. This resulted in a pedigree of 1158 unique animals. Genotypes were imputed to a common 50K platform by the American Simmental Association and were available for 434 of the animals in the pedigree, including 170 of the animals with phenotypes. Genotypic filtering removed any SNP with a call rate less than 0.90 and a minor allele frequency less than 0.05. In total, 42,897 SNP remained for analysis.

Variance components were estimated using univariate animal models in the BLUPF90 suite of programs (Mitszal *et al.*, 2002). A single-step GBLUP framework (Aguilar *et al.*, 2010) was used to enable using phenotypes from animals with and without genotypes available. Fixed effects included sex, IBK vaccination treatment, and linear covariates of calf age at the time of sampling, individual and dam breed fraction (derived from pedigree), and individual and maternal heterosis. Random effects included a direct additive genetic component and a residual.

Results

The average value of each metric at each time point is detailed in Table 1. In general, alpha diversity decreased from T1 to T2 and then increased such that alpha diversity at T4 was similar to that at T1.

Heritability estimates (Table 2) varied depending on metric and time point. The observed diversity and the Chao1 index followed a similar pattern. At T1, estimates for both traits were moderate. At T2 heritability estimates for both traits increased and were high. As alpha diversity decreased at T3, so did the additive genetic. Thus, the heritability estimates were zero. However, at T4 heritability estimates increased to levels similar to T1 and T2.

Heritability estimates for the Simpson and Shannon indexes at T1 were moderate to high. Both traits exhibited a decrease in additive genetic variance at T2 where heritability estimates were low to moderate. Similar to the observed and Chao1, the heritability estimates at T3 for the Simpson and Shannon indexes were zero. In contrast to the observed and Chao1, heritability estimates at T4 for the Simpson and Shannon indexes remained near zero.

Table 1. Average measurements for the alpha diversity metrics of observed diversity, Chao1 index, Simpson index, Shannon index for the ocular microbiome of preweaned calves at different ages.

	Average measurement[1] (standard deviation)			
Avg. calf age (in days)	**Observed diversity**	**Chao1 index**	**Simpson index**	**Shannon index**
65	158.0 (124)[a]	143.7 (97)[a]	0.5898 (0.22)[a]	1.917 (1.2)[a]
86	27.01 (31)[b]	28.29 (31)[b]	0.3276 (0.15)[b]	0.7415 (0.40)[b]
106	65.50 (48)[c]	63.99 (43)[c]	0.4502 (0.16)[c]	1.140 (0.58)[c]

[1] The greater the measurement, the greater the alpha diversity.

[2] Different superscript letters within a column indicate significantly different means determined by Wilcoxon rank sum test.

Table 2. Heritability estimates (standard error) for the alpha diversity metrics of observed diversity, Chao1 index, Simpson index, Shannon index for the ocular microbiome of preweaned calves at different ages.

	Heritability estimate (standard error)			
No. animals	**Observed diversity**	**Chao1 index**	**Simpson index**	**Shannon index**
211	0.36 (0.23)	0.35 (0.22)	0.50 (0.21)	0.42 (0.22)
211	0.58 (0.25)	0.68 (0.25)	0.14 (0.19)	0.30 (0.21)
187	0.0 (0.0)	0.0 (0.0)	0.0 (0.0)	0.0 (0.0)
189	0.45 (0.27)	0.55 (0.28)	0.0 (0.0)	0.05 (0.20)

Discussion

In the current study, each ocular sampling can be considered as a perturbation that altered the microbiome of the eye. Bartenslager *et al.* (2021) suggested that the decrease in alpha diversity from T1 to T3 was related to the perturbation caused by the ocular swabbing conducted during sampling. Further, the authors suggested that the increase in diversity from T2 to pre-perturbation levels at T4 was evidence that the ocular microbiome was slowly re-establishing when allowed to recover without perturbation.

Heritability estimates of observed diversity and the Chao1 index followed a very similar pattern across time points. This is because Chao1 is a nonparametric estimation of species richness and was intended to achieve the same goal as observed diversity but be more sensitive to rare species (Chao and Chiu, 2016). However, as described above, both the Simpson index of diversity and the Shannon index include both richness and abundance. This resulted in the two measurements, and their corresponding heritability estimates, to behave similarly.

In general, all metrics were moderately to highly heritable at T1. This indicates that at a young age, the alpha diversity of the ocular microbiome may be partially influenced by host genetics. At T2, heritability estimates of the metrics which focus on richness (observed and Chao1) increased, while those that included relative abundance (Simpson and Shannon) began to decrease. This increased heritability with decreased diversity suggests that the dominant bacterial species present during this time period may be under host genetic control. Heritability estimates at T3, post-vaccination booster, were zero across all alpha diversity metrics suggesting that the perturbation may have resulted in allochthonous microbes from the environment to colonize the eye with overdominance of some bacterial species. Despite alpha diversity increasing at T4 to levels similar to that of T1, only observed diversity and the Chao1 index showed increased heritability. This may be because over time autochthonous microbes may have increased in abundance and outcompeted the allochthonous microbial species present in the ocular microbiome establishing microbial species that

were more under host genetic control. However, the reason for the absence of increased heritability in the Simpson and Shannon indexes at T4 may be because although similar microbes were identified at T4, the abundance of these microbes may have been different compared to T1.

Host genetics does appear to influence the alpha diversity of the ocular microbiome in young beef calves. Additional cohorts are being sampled and will add to the current study. Further investigations will include estimating genetic correlations between alpha diversity metrics within a time point and between time points within a diversity metric and estimating the heritability of different microbial taxa (genus, family phylum) within the bovine ocular microbiome.

Abstract

This study aimed to identify genes that mediate immune responses in tick-tolerant Nguni, tick-susceptible Angus, and F2 Nguni X Angus population, infested with *Amblyomma hebraeum* ticks. Skin biopsy samples were collected prior and at post-infestation. RNA was isolated from the skin biopsies and sequenced on the Illumina HiSeq2500 Illumina sequencer. Overall, 139 significantly differentially expressed genes were identified in the current study. Calcium signalling pathway was the most enriched pathway linked to Five genes (PHKG1, PHKA1, CAMK21, NOS2, HRC). NOS2 gene was highly (significantly, $P>0.05$) expressed in the susceptible group before tick infestation and highly expressed in resistant group after tick infestation. Similar pattern was observed with HRC gene. HRC gene has been previously reported to play a role in regulating immune response against infections. This research reports differential gene expression following tick bites, thus providing preliminary data concerning the underlying mechanisms associated with the immune response.

Introduction

Ticks and tick-borne diseases (TTBDs) are a global problem and considered as one of the major challenges to livestock health and performance (Jongejan and Uilenberg 2004). The infestation of cattle by ticks can lead to weight loss, infertility, damage to hides and even death (Mapholi *et al.* 2016). *Amblyomma hebraeum* are native and common in Southern Africa, commonly known as the bont tick (Mapholi *et al.* 2016). The tick diseases are a major impediment to improvement of livestock industry particularly in Africa, due to a large number of tick species present and the variety of associated diseases (Walker 2003). Numerous tick control strategies have been employed including the application of acaricides. However, development of resistance to chemicals by ticks limit the effectiveness of this control strategy. This has created rising demands for different approaches that can alleviate the negative effects of ticks on livestock production thereby enhancing the livestock industries' contribution to the world's economy (Mapholi *et al.* 2014) (Porto Neto *et al.* 2011). Understanding the pattern of gene expression associated with tick resistance and susceptibility will create an opportunity to develop genomic selection programs for tick resistance as a complementary approach that is sustainable in the long term (Piper *et al.* 2008). Furthermore, genomic selection for host resistance may be an alternative for tick control. The current study identified genes that mediate immune responses to cattle infested with *Amblyomma hebraeum* ticks. This approach provides tools that will allow selection towards host resistance.

Materials & methods

Study design. This study was carried out at the Agricultural research council (ARC), South Africa. Ethical approval for the present study was obtained from the ARC- Institute's ethics committee. A total of 18 cattle (Nguni, Angus and F2 progeny from Nguni-Angus cross) were selected for the current study. Pathogen

R.F. Veerkamp and Y. de Haas (eds)

free *Amblyomma hebraeum* larvae, were used in the artificial infestation of the animals for a period of 10 days. Cotton-stoppered vials containing tick larvae (100 larvae per animal) were placed into the calico bags secured to the shaven area on the animal's back. On the 11th day, the number of engorged ticks and the number of ticks that did not survive were counted. The animals were categorized as: high (1-15 ticks), moderate (16-45) and low (46-100) according to the yield of engorged ticks at the end of the artificial infestation period (Mapholi *et al.* 2016).

Skin biopsy and RNA sample collection and sequencing. Skin biopsy samples were collected before infestation and 72 hours post-infestation. RNA was isolated from the skin biopsies following Trizol reagent (Invitrogen) manufacturer's instructions and sequenced on the Illumina HiSeq2500 Illumina sequencer. Analyses were conducted in R using DeSeq2 to identify differentially expressed genes between resistant and susceptible animals. FASTQC v11.9 was used to assess the quality of the raw reads. The reads were aligned to the reference genome *Bos taurus* ARS-UCD1.2 using STAR v2.7.3a. Functional Analysis was performed using DAVID v6.8 (Database for Annotation Visualisation and Integrated Discovery).

A total of 576,676,968 reads were observed from 32 samples after trimming. A principal components analysis (PCA) plot generated using the qqplot package of DESeq2 was used to visualize similarities and variations between pre and post infestation samples (Figure 1). DESeq2 was employed to identify differentially expressed genes (DEGs) by comparing the skin biopsy samples at different time points.

Results & discussion

The overall tick count indicated a considerable variation in the number of ticks fed in animal within a period of 10 days after tick infestation. The overall mean tick count observed amongst all the animals was 33. The Angus group was a low tick resistance group and had an average tick count of 118. The high resistant group had the lowest number of engorged ticks with average tick count of 2. There are several factors that can affect the likelihood of a tick feeding successfully on a host. The breed effect, age of the host and the age of the ticks, a study by Jones and the team (Jones *et al.* 2015) reported that feeding success increases with the host age and decreases with tick age. The study further highlighted that prior exposure of hosts to ticks stimulates immunological responses that deter tick feeding (Jones *et al.* 2015), and that a non-defensive physiological change such as anaemia in the host can reduce blood feeding.

A total of 22,147 differentially expressed genes were detected. At the corrected *P*-value (P_{adj}<0.05), the number of genes that were significantly differentially expressed was 159. Functional enrichment analysis was performed for the identified 159 genes using DAVID Bioinformatics Resources 6.8. The analysis successfully assigned 138 genes to *B. taurus*. The remaining 21 genes were unassigned and therefore excluded from further analysis.

A total of 62 out of 138 genes (45%) were assigned to 23 KEGG pathways. The most enriched pathway was the Calcium signalling pathway.

This pathway revealed 10 genes (NCX, ROC, MCU, SERCA, HRC, TnC, MLCK, PHK, CAMK and NOS2). The 10 genes were compared to the list of 138 differentially expressed genes and only 5 genes namely, PHKG1, PHKA1, CAMK2A, NOS2 and HRC could be linked to the calcium signalling pathway. The five genes were used to create boxplots to compare the pattern across the study groups (Figure 2).

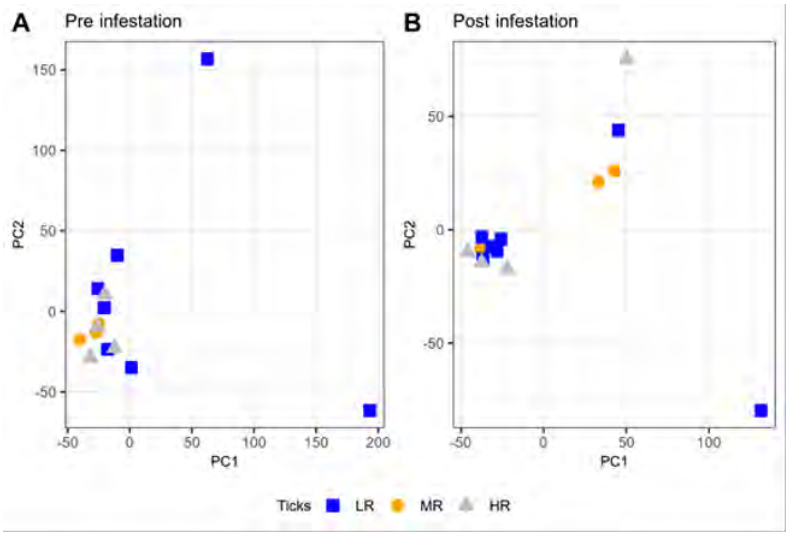

Figure 1. PCA plot depicting the effect of time on gene expression variation. The blue squares (LR=Low Resistant) on this plot refer to the tick susceptible groups, which is the Angus group and the LR group. The yellow circles refer to the moderate resistant group (MR=Moderate Resistant). The grey triangles (HR= High Resistant) refer to the tick tolerant groups, which is the Nguni and HR groups.

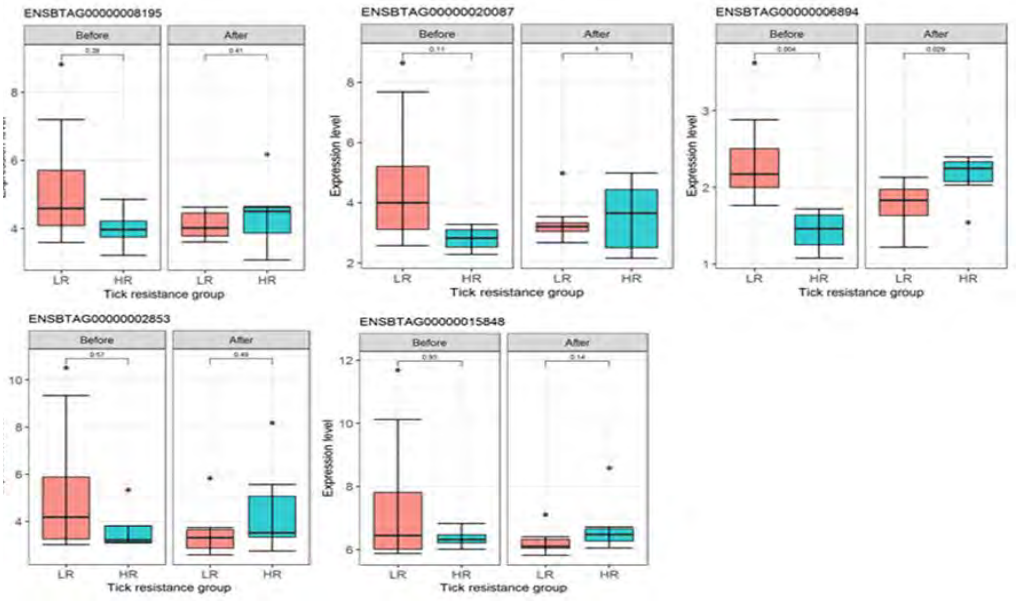

Figure 2. Boxplots showing before and after infestation gene expression comparisons of two groups (LR= Low Resistant, and HR= High Resistant) for the following genes: PHKG1 (ENSBTAG00000008195), PHKA1 (ENSBTAG00000015848), CAMK2A (ENSBTAG00000020087), NOS2 (ENSBTAG00000006894), and HRC (ENSBTAG00000002853). Expression level indicates variance stabilized read counts on a log2 scale. The numbers at the top indicate the significance levels. The *P*-values were obtained using the two sample Wilcoxon test. The bar represents the mean ± SD.

To overcome the challenge of sample size, the tick susceptible groups (LR and Angus) were combined into one group (LR group) and the tick resistant groups (HR and Nguni) were combined into HR group. Interestingly, the genes that were identified by the current study and their involvement in the Calcium (Ca^{2+}) pathway, were not previously reported in previous studies of a similar nature. For instance, (Moré *et al.* 2019) and (Otto *et al.* 2019) reported similar genes that are involved in biological processes that are relevant to various immune system functions.

Conclusions

The current study offered evidence that the Ca^{2+} signalling pathway maybe implicated in host resistance during the first 10 days of tick attachment. Most importantly, this research reports differential gene expression in the skin following tick bites, thus providing preliminary data concerning the underlying mechanisms associated with the immune response.

Abstract

Genetic variabilities cause variations in the efficiency of most vaccines. Variations in gut microbiota composition may be also implied. We studied 4 experimental or commercial lines of laying hens. A strong disruption of the gut microbiota was induced by a cocktail of antibiotics given at two different times. Vaccine response was monitored by hemagglutination inhibition assays and the composition of the cecal microbiota was assessed by the analysis of amplified 16S rRNA gene sequences. The vaccine response level differed according to the line after vaccination. The effect of antibiotics on the vaccine response varied according to the line, with different dynamics over time. Finally, antibiotics intake impacted the composition of the caecal microbiota at the end of the experiment for each line. This experiment confirms the effect of both gut microbiota and genetic lineage on the level of vaccine response.

Introduction

Vaccination is the most effective strategy for preventing infectious diseases. However, most vaccines vary in their efficacy. Host genetic variabilities and variations in gut microbiota composition are two of the likely drivers of this variation in efficacy (Ciabattini *et al.*, 2019; Zimmerman *et al.*, 2018). We have demonstrated the role of host genetics in vaccine response variation by successfully performing genetic selection of White Leghorn laying hens for a stronger vaccine response against Newcastle disease virus (NDV) (Pinard-van der Laan, 2002): a 'ND3 line' has been selected for high response for more than 25 years now, while keeping an unselected control 'TEM' line. Furthermore, the gut microbiota, in hens as in all farm animals, interacts closely with host immunity (Broom *et al.*, 2018), so it is hypothesized to have an effect on the vaccine response as well. This role is less documented, but a few studies demonstrate its influence (Valdez *et al.*, 2014; Borey *et al.*, 2021).

The objective of the present study was to investigate the effect of both genetic background and caecal microbiota on vaccine response. We used 4 laying hen lines: the 2 experimental lines ND3 and TEM and 2 commercial lines from the Novogen breeding company, one Rhode Island line (RIR) and one White Leghorn line (LEG). To study the impact of the microbiota, we modified its composition via the ingestion of an antibiotic cocktail.

Materials & methods

Animals. A total of 204 animals were used (ND3=48, TEM=48, RIR=48 and LEG=60). All animals hatched together at the PEAT unit (Nouzilly) and were then distributed in 3 groups for each line: 1. Group WA: 24 individuals vaccinated and not treated with antibiotics, 2. Group A1: 12 animals vaccinated and treated with antibiotics from D1 to D3, 3. Group A19: 12 animals vaccinated and treated with antibiotics the three days before NDV vaccination. In addition, a control group of 12 animals of the TEM line was neither vaccinated nor treated (Group CTR). The animals were raised in cages of 12 hens and killed at D42 by electronarcosis and cervical dislocation. The animals were weighed before their vaccination (D22) and before their sacrifice (D42). Blood samples were taken at D36, D40 and D42 to measure the vaccination

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_98, © A. Lecoeur *et al.* 2022

response. Caecal contents and spleen were collected post-mortem from each animal. Animals were raised and sacrificed according to French regulations (APAFIS#29749-2021021018217492 authorization).

Caecal microbiota. The gut microbiota was disrupted by a cocktail of 3 antibiotics (Amoxicillin, Streptomycin and Metronidazole) of different families with different methods of action. Caecal contents collected at D42 were frozen immediately in liquid nitrogen. DNAs from these samples were extracted by the @bridge platform (INRAE Jouy-en-Josas). Sequencing was performed by an Illumina Miseq 2×250 bp sequencer, using amplicons of the V3-V4 region of the 16S rRNA gene obtained with the primers Forward: ACGGRAGGCAGCAG and Reverse: TACCAGGGTATCTAATCCT. Raw sequences were analysed using the R package Dada2. The ASV table obtained was analysed with the phyloseq and Deseq2 packages to assess the global diversity of the caecal microbiotas collected and individual taxonomic compositions.

Vaccination and immunity. Animals were vaccinated at 5 weeks (D22) against NDV by ocular injection and vaccine response was measured by hemagglutination inhibition test.

Results

Weight gain. Antibiotics treatment caused neither excess mortality nor health problems. All lines differed significantly from each other for their weight (data not shown). The RIR line showed a faster growth than the three other lines (times 2.6 vs 2.3). The effect of antibiotics ingestion differed according to the line: For the RIR line, the A1 group tended to grow more than A19 (P_{adj}<0.1). For the TEM line, the A19 group had a faster growth than A1, WA and CTR.

Vaccine response. ND3 showed the highest response (Figure 1). The TEM line showed an intermediate level of response, while the two commercial lines had lower levels of response than the two experimental lines, and similar to each other. This ranking of lines was similar for the three time points considered (D36, D40 and D42). We observed an effect of antibiotics intake on the vaccine response, varying according to the line: For the RIR line, no significant difference between the 3 groups was observed, probably due to a high variability of the A1 group. For the LEG line, group A19 showed a weaker vaccine response than the other two groups. This difference between groups, which was slight at D36, increased over time with a peak in vaccine response 3 weeks after injection. The response levels of the ND3 and TEM lines were stable between groups. The variability of the response was very low and decreased with time.

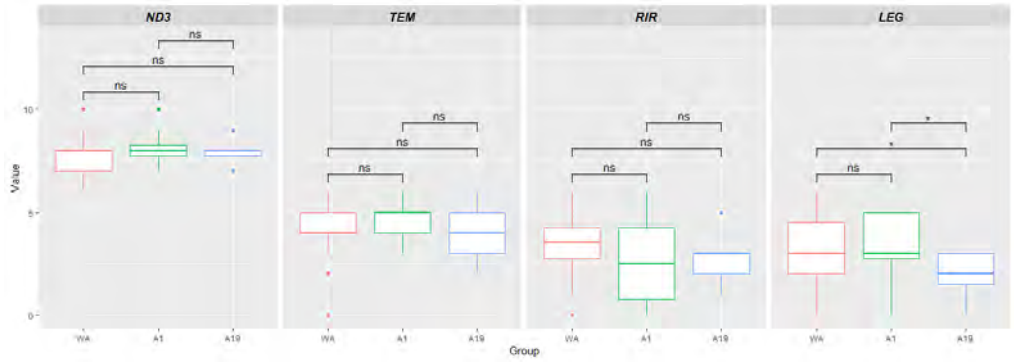

Figure 1. vaccine response levels of the four genetic lines studied (RIR, LEG, ND3 and TEMP) in three different animal groups: WA (without antibiotics), A1 (antibiotics received from day 1), A19 (antibiotics received from day 19, just before vaccination).

Caecal microbiota. We obtained 12.37 million raw sequences, with an average of 49,700 sequences per sample. At the output of Dada2, the taxonomy table of the 204 individuals contained 5,854,649 sequences, with an average of 28,283 sequences per sample, and 9,609 ASV (Amplicon Sequence Variant - significance) in total. Six individuals with too few sequences were eliminated from the analyses (<8,500 sequences). The dataset was normalized to 15,928 sequences per individual. The caecal microbiota of the 4 lines was largely dominated by the Phylum *Firmicutes* (between 95 and 99% of the sequences), followed by *Bacteroidota* (0.1-3.3%), *Actinobacteriota* (0.19-0.38%), *Proteobacteria* (0.1-0.43%). We also observed some sequences of the phylum *Desulfobacterota*. The most represented family was *Ruminococcaceae* (46-66%), followed by *Lachnospiraceae* (8-14%), *Oscillospiraceae* (4.5-7%), *Rikenellaceae* (0.1-3.3%). The analysis of different alpha diversity criteria (Richness, Chao1, Shannon and Simpson) describing the microbiota of the four lineages revealed the existence of differences in microbiota structure between lines. The Shannon and Simpson indices showed significant differences between lines (data not shown). We also compared lines and groups for 4 indices describing the beta-diversity of microbiotas: Bray-Curtis, Jaccard, Unifrac and Weighted Unifrac. They were higher in the RIR line compared to the ND3 and LEG lines, and lower in the ND3 line compared to the RIR and TEM lines. We observed for the 4 indices a line effect, a group effect and a significant line × group interaction.

Discussion

We compared the vaccine response levels of four experimental or commercial laying hen lines treated or not with a cocktail of antibiotics. The animals studied were raised at the same time under identical conditions in the same room after hatching in the same hatchery. Therefore, phenotypic differences between animal groups cannot be attributed to differences in the breeding environment.

By comparing groups of animals treated vs non–treated with antibiotics, we first observed that the antibiotics ingestion led to a microbiota disruption in the hen lines (Figure 2). This effect was different according to the time at which the antibiotics were given (Figure 2). When comparing the different lines for their caecal microbiota composition, we observed global differences in two alpha diversity indices and

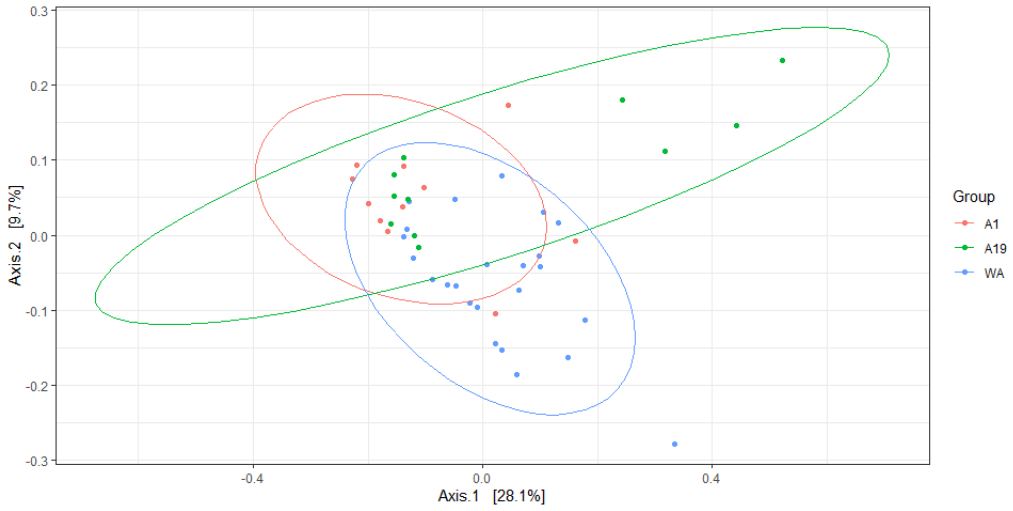

Figure 2. NMDS representation of the bray-curtis distances of the individual caecal microbiota composition in the three treatment groups of the RIR line: WA (without antibiotics), A1 (antibiotics from day 1), A19 (antibiotics from day 19, before vaccination).

in beta-diversity indices, which means that microbiota compositions vary according to the line. The role of host genetics in shaping the caecal microbiota in the chicken has already been demonstrated (i.e. Borey *et al.*, 2020). However, microbiotas of the 4 lines are altered in a similar way by antibiotics ingestion (data not shown). We thus showed that our model of microbiota perturbation is effective for all the lines studied and can be used for further studies.

In parallel, we observed that the 4 genetic lines displayed contrasted vaccine response levels and dynamics over time, with the ND3 line logically displaying the highest vaccine response, and ND3 and TEM displaying the more stable vaccine response (Figure 1). The latter lines have been selected for the stability of their vaccine response, which could explain that a disruption of this characteristic is more difficult. After antibiotics ingestion, the vaccine response was affected differently according to the line (Figure 1). The vaccine response of the LEG line was the most affected by the antibiotics ingestion.

In conclusion, this study allowed us to validate our model of microbiota disruption by antibiotic treatment. The latter induced a relatively long-lasting disturbance of the microbiota without generating any health problem, at least during the 6 weeks of our experiment. This first application of our model allowed us to confirm that host genetic variability partly controls the level and dynamics of the vaccine response. Antibiotics ingestion impacted the vaccine response and the caecal microbiota composition. However, the role of the caecal microbiota in the vaccine response perturbation induced by the antibiotics ingestion, although likely, remains uncertain at this stage and needs further exploration.

Abstract

Dairy cows face many kinds of environmental challenges throughout their life, such as pathogens, sudden changes in feed quality, or heat waves. Resilient cows are cows that can cope well with such challenges – they are minimally affected and recover quickly. Having resilient cows is beneficial for both the cows themselves and farmers. We investigated if newly developed traits, based on daily milk yield can be used to genetically select for improved resilience. Cows change their milk yield in response to challenges. The hypothesis was, therefore, that daily patterns in milk yield can indicate resilience. Breeding for low variability in milk yield and for low autocorrelation, i.e. dependency between day-to-day deviations in milk yield, can help to improve resilience. Genetic improvement of resilience will likely improve welfare and profitability of cows, and improve job satisfaction of farmers.

Introduction

Resilience is the ability of animals to be minimally affected by, and to quickly recover from environmental disturbances, such as pathogens, extreme weather, or changes in feed quality (Colditz and Hine, 2016; Berghof *et al.*, 2019). Resilience is important for the welfare of animals and work pleasure of farmers, especially given the expected increase of disturbances in the future (Boichard and Brochard, 2012; Elgersma *et al.*, 2018).

There are several ways to improve resilience of animals, and one of them is through genetic selection (Colditz and Hine, 2016; Berghof *et al.*, 2019). However, as resilience is a broad concept, it is difficult to quantify and thus difficult to identify which animals are genetically most resilient. Therefore, indicator traits are needed to improve resilience.

Nowadays, many sensor and other automated data are available on animals (Rutten *et al.*, 2013), and these data may contain information about resilience. Many traits recorded by sensors and automated systems are sensitive to disturbances. Hence, the fluctuation patterns in such longitudinal traits are expected to contain information about resilience (Scheffer *et al.*, 2018; Berghof *et al.*, 2019). Two traits based on longitudinal data have been proposed as indicators of resilience: the variance and lag-1 autocorrelation (Scheffer *et al.*, 2018). Variance indicates the variability of a trait, and thus the sensitivity of the animal to disturbances. Autocorrelation indicates the dependency of subsequent records on each other, and thus at what rate the animal recovers from disturbances.

In this paper we summarize results on the resilience indicators variance and autocorrelation of daily milk yield. We focus on the heritability and genetic correlations with other resilience-related traits, the associations with economic performance and we discuss its usefulness for selection.

Materials & methods

Data. The original data set contained 1,782,373,113 milk yield records on 1,120,550 cows, obtained during single milk visits to automatic milking systems (AMS) and conventional milking systems. Only records from AMS were selected and single milk visit records were converted to daily records. Only cows were selected that were registered in the herd-book and that were more than 87.5% Holstein Friesian. The milk yield data were corrected for lactation curve shape by fitting a polynomial quantile regression curve for each cow. The residuals from the fitted curves contained information about short-term fluctuations that are informative about resilience. These residuals were used to calculate the resilience indicators for each cow in lactation 1: variance (LnVar; 198,725 cows) and autocorrelation (r_{auto}, 198,580 cows).

Analyses. We estimated genetic parameters for the resilience indicators using mixed animal models in ASReml (Gilmour *et al.*, 2015). We estimated genetic correlations with traits that are currently in routine genetic evaluation using the multiple across country evaluation (MACE) procedure (Schaeffer, 1994; Klei and Weigel, 1998; Interbull, 2017). We estimated genetic correlations with several traits describing milk yield response to real-life disturbances at herd level using sire-maternal grandsire models in ASReml (Gilmour *et al.*, 2015). Real-life disturbances at herd level were selected based on days where mean milk yield of all cows in a herd suddenly declined, probably due to a disturbance. The traits describing response to the disturbances at herd level were the total yield loss during the temporary decline in milk yield (kg) and the time that the temporary decline lasted (days).

In addition to genetic analyses, we analysed the phenotypic association between the resilience indicators and lifetime gross margin. We performed an analysis of covariance based on records of 1,337 cows from 21 herds, with mean milk yield in lactation 1 as a covariate. Lifetime gross margin of each cow was calculated as the difference between all lifetime revenues (milk, calves, slaughter) and lifetime costs (feed, calving, rearing, insemination, treatment, destruction).

Results

All results are presented in Table 1. Both LnVar and r_{auto} were heritable, with LnVar having a higher heritability (0.21) than r_{auto} (0.09). Both had a positive genetic correlation with mean milk yield and negative genetic correlations with udder health, ketosis, and longevity, with the strongest correlation always for LnVar. These correlations indicate that cows with low LnVar or r_{auto} (good resilience) had low milk yield, good udder health and few ketosis cases, and high longevity, genetically. LnVar had a strong genetic correlation with total yield loss upon real-life herd disturbances (0.90), which means that cows with low LnVar had only a small decline in milk yield upon disturbances. The r_{auto} had no genetic correlation with yield loss upon herd disturbances, but was strongly genetically correlated with the time until milk yield recovered again. This means that cows with low r_{auto} had quick recovery upon real-life disturbances at herd level. The r_{auto} did not have a significant association with lifetime gross margin. However, LnVar did have a significant association with lifetime gross margin, which means that cows with low LnVar in first lactation had generated more profit at the end of life than cows with the same milk yield but with high LnVar.

Discussion

Low LnVar and r_{auto} were expected to be indicators of good resilience based on the assumption that resilient cows have milk yield that does not fluctuate much around its expected value, and if it deviates, recovers quickly (Scheffer *et al.*, 2018; Berghof *et al.*, 2019). Both resilience indicators were heritable, which means that they can be changed using genetic selection. The favourable genetic correlations with health traits, longevity (Poppe *et al.*, 2020; 2021a), and response in milk yield to real-life disturbances at herd level (Poppe *et al.*, 2021b) confirm that selection for these traits will result in improved resilience.

Table 1. Genetic variance (VarA) and heritability (h^2) of resilience indicators, genetic correlations (r_g) with other traits (SE between brackets), and regression coefficients explaining relation with lifetime gross margin.

		Resilience indicator[1]	
		LnVar	**r_{auto}**
Genetic parameters	VarA	0.056 (0.002)	0.003 (0.000)
	h^2	0.21 (0.01)	0.09 (0.01)
r_g with other traits[2]	AMY (kg)	0.79 (0.02)	0.16 (0.04)
	UH[3]	-0.32	-0.21
	KET[3]	-0.48	-0.15
	LON[3]	-0.16	-0.02
	Yield loss (kg)	0.90 (0.05)	-0.01 (0.13)
	Yield loss length (d)	-0.00 (0.29)	0.97 (0.35)
Association with lifetime gross margin	Regression coefficient	-427.98	404.77
	P-value	0.01	0.41

[1] LnVar = natural log-transformed variance of deviations from expected milk yield; r_{auto} = lag-1 autocorrelation of deviations from expected milk yield.
[2] AMY = average daily milk yield; UH = udder health; KET = ketosis; LON = longevity; yield loss = total yield loss upon real-life disturbances at herd level; yield loss length = time until yield is recovered upon real-life disturbances at herd level.
[3] Genetic correlations are estimated with Multiple Across Country Evaluation procedure, which does not give standard errors.

The strong genetic correlations with traits quantifying response to real-life disturbances at herd level confirm that the resilience indicators contain information about the severity of response to disturbances and recovery rate. The current breeding goal does not include response and recovery to disturbances yet, but only incidence of disease for example (CRV, 2020). Therefore, the resilience indicators contain new and relevant information, and resilience could be considered as an additional trait in the breeding goal.

The favourable association between LnVar and lifetime gross margin also suggests that LnVar has economic importance. However, some of the traits used to calculate lifetime gross margin are also included in the current breeding goal, such as milk yield, longevity, and fertility. To avoid double counting in the breeding goal, the marginal economic value, or effect of LnVar partial on these traits should be established first. Moreover, resilience is expected to have an additional non-economic value through its association with animal welfare. Hence, alternative methods are needed to determine the weight in the breeding goal, such as desired gains (Nielsen *et al.*, 2005), choice experiments with farmers (Nielsen *et al.*, 2011), or more research into associations with labour costs (Berghof *et al.*, 2019). Once the weight of resilience in the breeding goal is determined, an index of LnVar and r_{auto} can be used to genetically improve resilience.

Funding

This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project 16022) and the Breed4Food partners Cobb Europe, CRV, Hendrix Genetics and Topigs Norsvin. Additional financial support was provided by the European Union's Horizon 2020 research and innovation program (GenTORE) under grant agreement No. 727213.

100. Genetic evaluation of heat tolerance in Italian Holstein breed

R. Finocchiaro[1*], F. Galluzzo[1], J.B.C.H.M van Kaam[1], M. Marusi[1] and M. Cassandro[1,2]

[1]Associazione Nazionale Allevatori della Razza Frisona, Bruna e Jersey Italiana (ANAFIBJ), Via Bergamo 192, 26100 Cremona (CR), Italy; [2]Department of Agronomy, Food, Natural resources, Animals and Environment (DAFNAE), University of Padova, Viale dell'Università 16, 35020 Legnaro (PD), Italy; raffaellafinocchiaro@anafi.it

Abstract

Heat stress (HS) on dairy cows is triggered by a combination of high ambient temperature and high relative humidity: this phenomenon leads to physiological disorders that have a negative impact on the animal's wellbeing and productive and reproductive performances. The objective of this study was to identify the starting point of HS on milk production, measured on the temperature-humidity index (THI) scale, to define the heritability of the tolerance to HS based on milk production and to estimate breeding values for this trait in the Italian Holstein population. A single-trait repeatability linear animal model was used and the heritability was found to be 0.16. In conclusion, the possibility to select for heat tolerance (HT) based on milk production was confirmed. Further analyses will be performed to assess the possibility of selection for HT based on other productive and functional traits and to define its optimum weight in a selection index.

Introduction

High ambient temperature combined with high relative humidity negatively affects both productive (Bernabucci *et al.*, 2014) and reproductive (Ravagnolo and Misztal, 2002) performance of dairy cows, resulting in a negative impact on herd profitability: this phenomenon is regarded as HS. Not all animals are affected the same way by HS. In Holstein cattle, tolerance to HS was found to be moderately heritable (Aguilar *et al.*, 2009; Bernabucci *et al.*, 2014), meaning that a selection for this trait is feasible. As the majority of the Italian Holstein population lives in areas characterized by hot and humid summer, a genetic evaluation for HT may be beneficial. The aim of our study was to investigate if heat stress results in different effects on Italian Holstein performance due to genetic differences in heat tolerance.

Materials & methods

Data and data editing. Data came from the Italian National Breeders Association (AIA) and consisted, after editing, of 41,063,377 test-day milk production records of 2,591,002 Holstein cows. Heat tolerance was modelled by using data from weather stations. Daily maximum temperature and relative humidity were collected from 1994 till now. Weather measurements (777,980 daily records) were collected from 137 stations distributed across the national territory. Geographical coordinates and altitudes from all weather stations and from the communities of the farms were available. Distances between weather stations and farms were computed. Milk test day records were linked with the nearest weather stations within 80 km. Weather stations more than 500 m above or below the farm were omitted. Weather estimates for the farm were computed for the geometric center of the chosen weather stations as a weighted average accounting for the distance from the farm. The average distance between the geometric center of the chosen nearby weather stations and the farms was 13.5 km.

Holstein test-day records for milk production from the first three parities were included in this study. Records were from cows registered between 2004 and 2021. Cows were required to have, within parity, at least 3 test-days and the first one within 60 days from calving and test-days between 5 and 305 DIM. Cows were also required to have the first parity recorded. First parity cows were required to have an age at parity of minimum 22 months, second parities greater or equal than 34 months and later parity ones between

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_100, © R. Finocchiaro *et al.* 2022

48 and 76 months. Moreover, in order to effectively compare the contemporaries for herd-year-season of recording (HYSR), groups with less than 30 observations were excluded from the analysis. The pedigree went back to four generations.

Because longer periods of heat stress might have a more severe effect than shorter periods, the average weather measurements of 2, 4, 5, 7, 10 and 14 days before test-day recording were considered.

The temperature-humidity index (THI) has been calculated as proposed by Kelly and Bond (1971) by combining maximum temperature, in degrees Celsius, and average relative humidity (as percentage) with the following expression:

$$THI = T_{max} - [0.55\ x\ (1 - RH)]\ x\ (T_{max} - 14.4) \quad (1)$$

where T_{max} is the maximum daily temperature in °C and RH is the average daily relative humidity.

The THI threshold value (THI_{thr}), above which milk yield declines, was identified visually after the computation of least square means of the fixed effect THI class. A function of THI, f(THI), was then created as in Equation 2:

$$f(THI) = \begin{cases} 0 & if\ THI \leq THI_{thr} \\ THI - THI_{thr} & if\ THI > THI_{thr} \end{cases} \quad (2)$$

The visual inspection showed that the threshold value of THI from which milk production starts to decline is ≥24 (Celsius like scale), and this value was defined as THI_{thr}. In addition, the average of 7 days before test-day recording has been found to be the most effective period for modelling the decline in milk production.

Statistical model. The selected model was a single trait repeatability linear animal model. Fixed effects were identified with SAS PROC GLM (SAS Institute Inc., Cary, NC, 2017): only the ones which resulted statistically significant (P<0.05) were retained. The effect of HS on production is modeled as a random regression.

The defined model is described in Equation 3:

$$Y_{ijklmno} = HYSR_i + YS_j + STPY_k + a_{general_l} + a_{heat_l}[f(THI_m)] + PE_{general_n} + PE_{heat_n}[f(THI_m)] + e_{ijklmno} \quad (3)$$

with Y_{ijklmn} is the measurement of daily milk production (kg/d), $HYSR_i$ is the fixed effect herd-year-season of recording i; YS_j is the fixed effect of year-season of calving j, $STPY_k$ is the fixed effect of stage of lactation-parity-year of calving class k. Regarding random effects, $a_{general_l}$ is the general additive genetic effect of cow l, a_{heat_l} is the additive genetic effect of HT for cow l, $PE_{general_n}$ as the general permanent environmental effect of cow l based on repeated measures both within and across lactations, PE_{heat_n} as the permanent environmental effect of HT for cow l and $e_{ijklmno}$ as the residuals. Parities were defined as first, second and later parities while seasons as December to February, March to May, June to August and September to November.

Estimation of genetic parameters. Variance components estimation was performed with the Gibbs sampler THRGIBBS1F90 (Misztal *et al.*, 2002). Three analyses were performed on three samples of 200 herds each and a minimum of 30,000 cows each (average number of test-day records per sample: 817,481) randomly extracted from the full dataset, with 500,000 iterations, a burn-in of 50,000 and a thinning rate of 10. Post-Gibbs analysis was performed using the software POSTGIBBSF90 (Misztal *et al.*, 2002) using

the remaining 45,000 samples. Convergence was assessed by visual inspection. Heat tolerance heritability based on milk production was calculated as described in Equation 4:

$$h^2 = \frac{\sigma^2_{a_{general}} + \sigma^2_{a_{heat}} + 2\sigma_{a_{general}}\sigma_{a_{heat}}}{\sigma^2_{a_{general}} + \sigma^2_{a_{heat}} + 2\sigma_{a_{general}}\sigma_{a_{heat}} + \sigma^2_{pe_{general}} + \sigma^2_{pe_{heat}} + 2\sigma_{pe_{general}}\sigma_{pe_{heat}} + \sigma^2_e} \quad (4)$$

with $\sigma^2_{a_{general}}$ as the general additive genetic effect variance, $\sigma^2_{a_{heat}}$ as the additive genetic effect variance for HT, $\sigma_{a_{general}}\sigma_{a_{heat}}$ as the covariance between the two, $\sigma^2_{pe_{general}}$ as the general permanent environmental effect variance, $\sigma^2_{pe_{heat}}$ as the permanent environmental effect variance for HT, $\sigma_{pe_{general}}\sigma_{pe_{heat}}$ as the covariance between the two and σ^2_e as the residual variance.

Breeding value estimation. Heat tolerance breeding values (BVs) for daily milk production were estimated with MiX99 (Lidauer *et al.*, 2019) and expressed on a scale with mean of 100 and standard deviation of 5: values higher than the mean refer to individuals that transmit a higher tolerance to HS.

Results

Estimation of genetic parameters. Posterior means and standard deviations for variance components and heritability were computed for the three samples. The mean heritability of the samples' posterior means was 0.16 (standard deviation=0.006), confirming the feasibility of a selection for HT. As expected, the genetic correlation between the general additive genetic variance and the HT genetic variance was negative, -0.45 (0.048), meaning that high producing cows tend to be more susceptible to HS.

Genetic trend. The genetic trend for HT by year of birth of bulls is represented in Figure 1. The figure shows a strong decreasing trend in the early '90s, a plateau and finally an important increase in the last 20 years. This trend reflects the introduction of new breeding objectives in the Italian selection index, which progressively shifted some weight from production to functionality, therefore the positive trend can be explained by the negative genetic correlation found between milk production and HT.

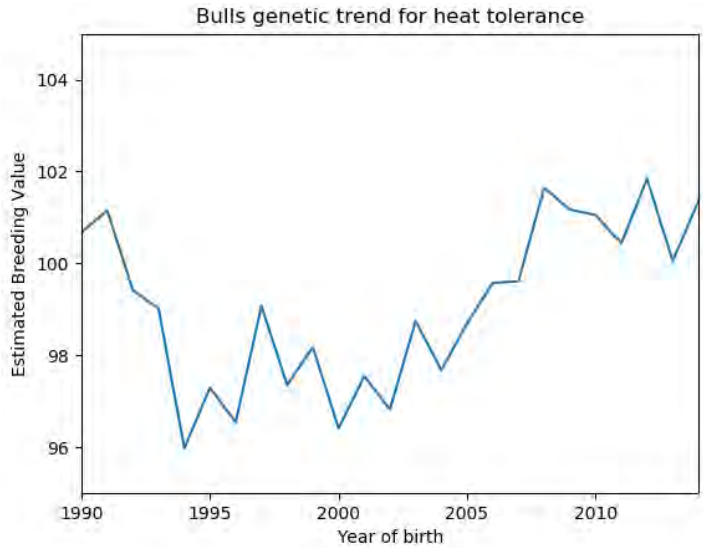

Figure 1. Genetic trend of heat tolerance by year of birth.

Conclusions

The feasibility of a selection for HT based on milk production was confirmed by the moderate heritability found for this trait, 0.16 (0.006). The negative genetic correlation between HT and milk production was also confirmed (-0.45), meaning that HT should not be used as a selection criterion by itself: economic analyses will be performed to define the optimum weight for this trait in a selection index. The use of the Italian selection index (PFT) has already selected, indirectly, for more heat tolerant bulls, it is clear that the availability of a direct index would allow a better selection for more heat tolerant individuals.

101. Inferring genetic parameters for prenatal heat stress effects on calf diseases and cow productivity

T. Yin*, K. Halli, S.F. Vanvanhossou, M. Bohlouli and S. König

Institute of Animal Breeding and Genetics, Justus-Liebig-University Gießen, Ludwigstr. 21B, 35390 Gießen, Germany; tong.yin@agrar.uni-giessen.de

Abstract

The aim of this study was to infer genetic and genomic effects of heat stress (HS) during late gestation of dams on disease occurrences and productivity of ~20,000 genotyped calves and cows, respectively, from an across-generation perspective. The climatic descriptor was the temperature-humidity index (THI) during the last week of pregnancy. For diseases, climatic sensitivity was studied via random regression coefficients nested within maternal genetic effects on prenatal THI alterations. For production traits, a genomic interaction model with THI≥60 indicating prenatal HS, was applied. Maternal heritablities for pneumonia increased from 0.03 to 0.10 with increasing THI from 60 to 74, but was largest for diarrhea at THI 60 (0.07). Genotype by HS interaction variances for production traits explained maximal 3.79% of the total variances. The novel modelling strategies enabled the assessment of maternal climatic sensitivity and the estimation of variances caused by HS.

Introduction

As a heat sensitive breed, Holstein cattle showed variations in phenotypic performances and breeding values under heat stress (HS) conditions. For example, protein yield significantly decreased at THI 68 (Gernand *et al.*, 2019). Genetically, random regression models were applied to infer genetic (co)variance components along a continuous climatic descriptor, i.e. the temperature-humidity index (THI; Bohlouli *et al.*, 2019). Such modelling approach was also used to detect possible genotype × environment interactions (G×E; Bohlouli *et al.*, 2019). Most of the genetic studies focused on immediate responses to HS, i.e. considering THI at the measuring day, or the average THI shortly before the measuring day. Phenotypically, HS during late gestation in dams, termed as prenatal HS, significantly impaired growth, immune competence and functional traits in offspring (Tao and Dahl, 2013). Monteiro *et al.* (2016) studied long-term effects prenatal HS on female fertility and performance traits recorded in offspring and identified most detrimental impact of HS from the last 6 weeks of gestation. Genetically, Halli *et al.* (2021) and Kipp *et al.* (2021) identified alterations of genetic variances for primary traits and G×E in young dual-purpose cattle and in first lactating dairy cows in response to prenatal THI.

In this regard, the aim of this study was to apply alternative modelling strategies and additionally considering genomic data to infer the effects of prenatal HS on genetic parameters for calf diseases and for test-day and lactation production traits in German Holstein cattle. Solutions for genetic effects were used in ongoing genome wide association studies (GWAS). Suggestively associated SNPs from GWAS were considered in gene annotations.

Materials & methods

Calf diseases and cow production traits were recorded in 53 large-scale co-operator herds located in two federal states located from the north-eastern part of Germany.

Dataset for calf diseases. The calf diseases pneumonia (PNEU) and diarrhea (DIAR) were diagnosed by veterinarians or herd producers based on the official hierarchical health diagnosis key from the International Committee for Animal Recording (Stock *et al.*, 2013). For PNEU, we focused on the period

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_101, © T. Yin *et al.* 2022

from 0 to 180 d after birth for female calves. DIAR mostly occurs in a short period after birth (0 to 30 days of age). Hence, both sexes were considered for DIAR. For each of the calf diseases, at least one entry within the respective period implied a score = 1 (diseased calve); otherwise, a score = 0 (healthy calve) was assigned. The pedigree file included 338,158 animals. Among them, 19,247 Holstein cattle were genotyped with the *Illumina BovineSNP50 v2 BeadChip* or the *Illumina Bovine Eurogenomics 10K low-density chip*. The number of genotyped calves with phenotypes was 12,728 for PNEU and 10,170 for DIAR. After quality control, 41,135 SNPs were considered for ongoing analyses.

Dataset for cow production traits. Test-day records from the first official test-day after calving (5 to 35 days in milk) included milk yield (TMY), fat percentage (TFP), fat yield (TFY), protein percentage (TPP), protein yield (TPY) and somatic cell score (TSCS). First lactation records were considered for milk yield (LMY), fat percentage (LFP), fat yield (LFY), protein percentage (LPP) and protein yield (LPY). The lactation lengths for lactation records varied from 275 to 305 days in milk. In total, 41,139 SNPs from 14,188 genotyped cows were used for the ongoing genomic analyses. All genotyped cows had milk production records.

Meteorological data. Pairwise distances (in km) were calculated between weather stations and cowherds. According to the minimal distances, we allocated 33 weather stations to the 53 herds. Hourly THI were calculated considering hourly temperature (T) and relative humidity (RH) as follows (NRC, 1971):

$$THI = [1.8 \times T + 32] - [0.55 - 0.0055 \times RH] \times [1.8 \times T - 26].$$

Afterwards, we calculated the prenatal THI for the week before birth (0-7 d) by averaging hourly THI. For calf diseases, all THI values <60 were set to 60 to eliminate the impact of possible cold load. The average THI for the week before calving was scaled using -1+2((THI-60)/(74-60)), where 60 = minimum THI value and 74 = maximum THI value. The scaled THI were used in the analyses for calf diseases. For cow production traits, a dummy variable with values of either 0 (THI<60) or 1 (THI≥60) was used to indicate prenatal HS. We focused on different strategies to consider THI, because data structures and applied models were not the same for the two trait categories.

Statistical models. For calf diseases, an animal model with maternal effects considering prenatal THI in the week before birth, was applied. The statistical in matrix notation was:

$$y = Xb + Qd + Wm + Sp_m + e \quad (1)$$

where y = vector of records for PNEU or DIAR; b = vector of fixed effects including herd, birth year, birth month, gestation length classes, lactation-calving-age classes for dams, sex-birth type and regressions on scaled THI nested within birth year; d = vector of direct additive-genetic effects; m = vector of maternal genetic effects for random intercepts and slopes on scaled THI; p_m = vector of maternal permanent environmental effects for random intercepts and slopes on scaled THI; e = vector of random residual effects.

For cow production traits, a genomic interaction model (Yao *et al.*, 2017) considering interactions between genotype and prenatal HS was defined:

$$y = Xb + Zg + Wg_{hs} + e \quad (2)$$

where y = vector of observations for test-day or lactation records; b = vector of fixed effects including herd, calving year, calving month, age at first calving classes, lactation-calving-age classes for dams, classes for days in milk (for the test-day traits), lactation length classes (for lactation traits) and a dummy variable

indicating the presence of HS during the week before calving; g = vector of additive genomic effects; g_{hs} = vector of genotype by HS interaction effects for cows with prenatal HS; e = vector of random residuals. The variances of g and g_{hs} were defined as common genomic and interaction variance, respectively. The common genomic variance consistently existed for all cows regardless of prenatal HS. The interaction variance represented the variance due to prenatal HS. Proportions of the common genomic and the interaction variance in relation to the phenotypic variance were defined as common heritability (h_c^2) and interaction heritability (h_i^2), respectively. Additionally, a genomic animal model without interaction effects was applied to identify changes of the heritabilities due to genotype by HS interactions. Gibbs sampling and AIREML algorithms as implemented in the software packages THRGIBBS1f90 and AIREMLf90 (Misztal *et al.*, 2002) were used to estimate variance components for calf diseases and cow production traits, respectively.

Results

Direct heritabilities for PNEU were quite stable with 0.10 at THI 60 to 0.08 at THI 74. For DIAR, the direct heritabilities ranged from 0.16 to 0.17. Maternal heritabilities for PNEU increased from 0.03 to 0.10 along the THI gradient. Oppositely, the maternal heritability for DIAR was slightly larger at THI 60 (0.07) than under prenatal HS conditions. The genetic correlations between maternal effects at THI 60 with the remaining THI values for both calf diseases decreased with increasing THI distances (Figure 1). The smallest correlations of 0.42 for DIAR and 0.26 for PNEU were estimated between the most distant prenatal THI values.

From model 2, h_c^2 were 0.13 for TMY, 0.19 for TFP, 0.15 for TFY, 0.24 for TPP, 0.10 for TPY, and 0.08 for TSCS (Figure 2). For lactation milk production traits, h_c^2 were 0.37 for LMY, 0.72 for LFP, 0.35 for LFY, 0.70 for LPP, and 0.28 for LPY. In general, common genomic heritabilities for milk production traits were identical to genomic heritabilities estimated from the alternative model without G×E interaction effects (results not shown). Among all traits, TPP displayed the largest heritability due to genotype by HS interactions (3.79%). For TFP, TFY, TPY, TSCS, LFP, and LPY, h_i^2 were <1%.

Discussion

Increases in direct heritabilities for cow diseases (Kipp *et al.*, 2021) and milk yield (Bohlouli *et al.*, 2019) along prenatal and prompt THI, respectively, indicate pronounced genetic differentiation in challenging environments. Compared to cow traits, genetic effects of calf diseases comprise direct and maternal genetic effects. Consequently, we focused on the effects of prenatal THI on maternal genetic effects. For PNEU, larger maternal genetic variations were identified in dams exposed to extreme prenatal HS. Oppositely,

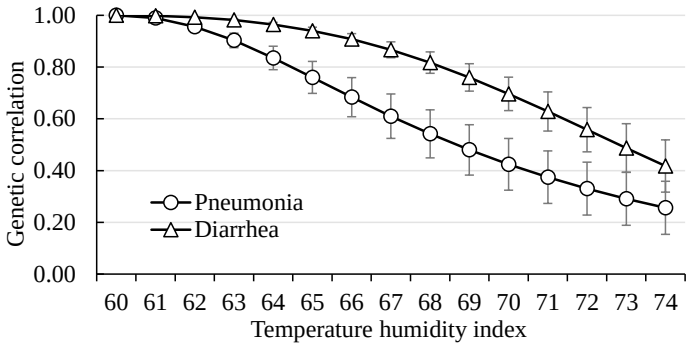

Figure 1. Posterior means for genetic correlations with respective posterior standard deviations between maternal effects at THI 60 and at the remaining THI.

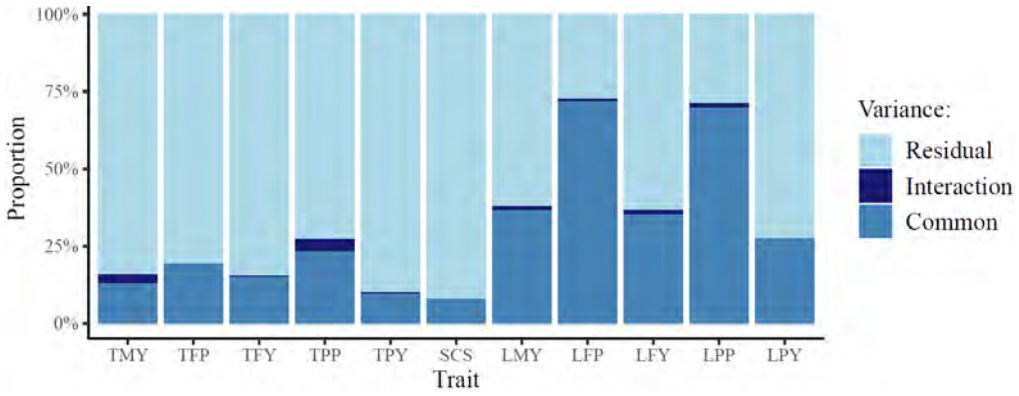

Figure 2. Proportions of common genomic, interaction and residual variances in relation to the total variance for test-day and lactation production traits.

DIAR displayed larger maternal genetic variances under comfort conditions. Hence, responses of maternal genetic effects on prenatal THI alterations are trait-specific. Genetic correlations smaller than 0.80 for calf diseases recorded at THI 60 with corresponding diseases at THI 74 suggest obvious time-lagged G×E for maternal genetic effects. Time-lagged G×E for direct genetic effects due to HS in late pregnancy were reported by Kipp *et al.* (2021) for primary and functional traits in lactating cows. For cow production traits, the ranking of sires according to estimated breeding values under comfort and prenatal HS conditions was almost the same. In analogy, identical heritabilities were estimated for production traits from the model with or without genotype by HS interactions. Additionally, for all traits, the interaction variances only explained small proportions of the total phenotypic variances (up to 3.79%). Similarly, Kipp *et al.* (2021) confirmed the absence of time-lagged G×E for milk production traits, using a random regression sire model. In contrast, ratios of environment-specific genomic variances to overall variances for feed efficiency traits (Yao *et al.*, 2017) were larger than h_i^2 from this study. Consequently, the effect of prenatal HS during late pregnancy is smaller than the prompt herd effect due to geographical impact across latitudes. Nevertheless, effects of HS on direct and maternal genetic (co)variance components of traits in offspring are first indications for epigenetic mechanisms, suggestion ongoing molecular genetic studies in this regard.

Abstract

Growing consumer awareness means that the dairy industry needs to take proactive steps to improve animal health. Limited work has been conducted for improving Canadian calf health through genetics, and therefore, this study aimed to understand the current impact of calf health diseases on Canadian farms and to estimate genetic parameters for calf health traits. Calf health data comprised of 76,405 Canadian Holstein calf disease records for respiratory problems and diarrhea, collected on 1,890 Canadian dairy herds from 2009 to 2020. Incidence rates for respiratory problems were similar to values previously reported in literature, whereas diarrhea incidence rates were lower. Heritabilities of 0.01 and 0.04 were estimated for diarrhea and respiratory problems, respectively, which were lower than estimates reported in the literature. To maximise estimates stricter herd inclusion protocols, incorporating genomic information and splitting the traits by time of occurrence need to be investigated.

Introduction

Emerging issues in dairy, related to animal welfare and social acceptability mean that the dairy industry must take proactive steps to improve animal health. Calf-hood diseases have a major impact on the economic viability of cattle operations, due to costs of treatment and long-term effects on performance (Svensson and Hultgren 2008; Mohd Nor *et al.* 2013). In the literature incidence rates for diarrhea range from 23 to 44%, while producers reported treating roughly 12% of pre-weaned calves for respiratory diseases (USDA 2010, 2018; Urie *et al.* 2018; Haagan *et al.* 2021). Though incidence reports are not available in Canada, diarrhea and respiratory diseases account for 53 and 21% of pre-weaned calf mortality in Canada, respectively (Murray 2011). Therefore, efforts to improve dairy calf health are vital.

From a genetic perspective, efforts aimed at breeding for increased disease resilience offer opportunities. Reported heritability estimates for respiratory disease and diarrhea range between 4 to 10% (Henderson *et al.* 2011; McCorquodale *et al.* 2013; Haagan *et al.* 2021), indicating the potential for genetic selection. In Canada, research has looked at improving overall cow health through initiatives such as Immunity+ provided by Semex, but this is proprietary, and no strategy for including calf health traits within national evaluations has been proposed. Therefore, the objective of this study was to understand the current impact of calf health diseases on Canadian farms and to estimate genetic parameters for calf health traits using existing data available. This work will provide the foundations for the inclusion of calf health traits within national Canadian genetic evaluations. Specifically, these results can be used to identify gaps in data collection methods which should be addressed in future developments for successful implementation of a national calf health selection strategy.

Materials & methods

Data. Calf health data recorded by dairy producers through management software was provided by Lactanet Canada (Guelph, Ontario). It comprised 76,405 Holstein calf disease records for respiratory problems and diarrhea, collected on 1,890 Canadian dairy herds from 2009 to 2020. All other calves present on the farm in a given year without a disease record were assumed to be healthy. To be considered in the analysis, records must have occurred within the first six months of the calf's life and each herd required a minimum

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_102, © C. Lynch *et al.* 2022

annual disease incidence rate of at least 1%. This was calculated using the number of disease events in a herd per year over the total number of heifer calves raised on that farm in a given year. Additionally, herds had to have consecutive calf health records for years leading to and including 2020, or a minimum of three consecutive years of data available if there were no 2020 records. These metrics provided insight to which herds were consistently collecting calf disease information. A total of 62,168 records were used in the analysis after data validation and cleaning (Table 1).

Models. Univariate threshold animal models with a probit link function were used for both traits. A Bayesian approach based on the Gibbs sampling algorithm using the Markov chain Monte Carlo method with 1,000,000 iterations, 100,000 burn-in and 50 thinning interval was used for the analysis. Convergence of all chains was achieved, based on the Heidelberger and Welch, and Geweke convergence diagnostic tests. The general form of the model used was defined as:

$$l = Xb + Za + e \quad (1)$$

where l is a vector of underlying liabilities corresponding to the binary observation (0= healthy, 1= diseased), b is a vector of systematic fixed effects of year born-month born and herd, a is a vector of random additive genetic effects, e is a vector of random residuals and, X and Z are corresponding incidence matrices.

Results

Incidence rates for each disease by year are presented in Table 2. The median incidence rate for each year was always lower than the mean for both traits. This was due to a number of herds with high incidence rates inflating the mean value. Given this, the median value should be seen as a better representation of the true average. For diarrhea, median incidence rate in herds ranged from 5 to 10% with the highest incidence rate

Table 1. Final datasets of calf health records.

Trait	Diseased	Healthy	Total records (herds)
Diarrhea	18,887	101,857	120,744 (425)
Respiratory problems	43,281	212,502	255,783 (664)

Table 2. Descriptive statistics of diseases incidence rates in herds across years.

Year	Diarrhea			Respiratory problems		
	Mean %	Median %	Herds	Mean %	Median%	Herds
2009	10	5	54	16	8	133
2010	12	7	68	13	8	154
2011	12	8	86	15	10	187
2012	12	7	93	16	9	205
2013	11	7	98	16	10	230
2014	13	8	93	15	10	245
2015	13	8	107	16	10	253
2016	11	7	85	13	9	228
2017	11	6	98	14	10	260
2018	12	8	128	16	11	327
2019	13	8	166	17	12	355
2020	16	10	145	16	11	323

seen in 2020. There was also a considerable increase in the number of herds collecting calf health data with this number rising from 54 herds in 2009 to 145 in 2020. For respiratory problems, median incidence rate in herds ranged from 8 to 12%, with the highest incidence rate seen in 2019. Again, there was a considerable increase in the number of herds collecting calf health data with this number rising from 133 herds in 2009 to 323 in 2020.

Variance components for each trait are presented in Table 3. Heritabilities were originally estimated on the liability scale and converted to the observed scale. Heritabilities of 0.01 and 0.04 were estimated for diarrhea and respiratory problems, respectively.

Discussion

Reported incidence rates for respiratory problems were similar to the mean incidence rates previously reported in the literature, while for diarrhea values were lower (USDA 2010, 2018; Urie *et al.* 2018; Haagan *et al.* 2021). These differences may be due to several reasons, including quality of data collection and management practices. However, it is evident that consistent levels of calf disease were observed across years, indicating that there is an opportunity to reduce incidence rates and improve farm efficiency.

Heritabilities estimates for diarrhea and respiratory problems within this study were lower than estimates reported in the literature (Henderson *et al.* 2011; Mahmoud *et al.* 2017; Haagan *et al.* 2021). These differences could be attributed to several reasons including the lack of detailed information on individual calves, such as, birth weights and colostrum intake, which are directly related to the occurrence of respiratory problems and diarrhea (Henderson *et al.* 2011; Mahmoud *et al.* 2017). Another challenge is the uncertainty surrounding recording practices on farms. Farms without strict recording practices may have had sick animals that were assumed healthy in the current study, impacting model performance. Haagen *et al.* (2021) reported heritability estimates of 0.10 and 0.08 for respiratory problems and scours, respectively, with a similar lack of direct calf information as found in this study. The main difference was the use of genomic data for the estimation of genetic parameters. Furthermore, Vukasinovic *et al.* (2018) found higher estimates for respiratory problems by splitting the trait by age of occurrence, with heritabilities of 0.10 between 0 to 3d of age, 0.06 at 4 to 14d of age, and 0.05 at 15 to 50d of age, all above the estimate of 0.04 between day 0-365 of age. Given this, methods such as stricter herd inclusion protocols, incorporating genomic information, and looking at traits at specific times needs to be investigated with the current data to try to maximise model performance and improve parameter estimates.

Conclusions

Growing consumer awareness means that the dairy industry needs to take proactive steps to improve animal health. In Canada, research has looked at improving overall cow health through initiatives such as Immunity+ provided by Semex, but no strategy for including calf health traits within national evaluations

Table 3. Variance components of disease traits in Canadian dairy calves.

Parameters[1]	Diarrhea	Respiratory problems
Residual variance	1.00	1.00
Genetic variance (HPD)	0.02 (0.01-0.02)	0.05 (0.04-0.05)
Liability scale h^2 (HPD)	0.02 (0.01-0.02)	0.05 (0.04-0.05)
Observed scale h^2	0.01	0.04

[1] HPD = highest probability density.

has been proposed. This study determined the current impact of calf health diseases on Canadian farms and provided initial estimates of genetic parameters for respiratory problems and diarrhea in Canadian dairy calves and, although the estimates were lower than those seen in other studies, they provide the foundations for future work. To improve estimates stricter herd inclusion protocols, incorporation of genomic information and splitting the traits by time of occurrence need to be investigated.

Abstract

Selecting for better health has become of primary importance for the dairy industry. In France, where no national database exists for health traits (except mastitis), a collaborative project has been implemented to explore and evaluate farmer health records. Around 10% of herds record health events accurately. Genetic parameters of 4 disorders have been studied here: Displaced Abomasum (DA), Milk Fever (MF), Metritis (MET) and Retained Placenta (RP). Heritabili-ties are low (1-2%), but health traits have moderate genetic correlations with some dairy traits (0.15-0.45). Based on EBV obtained with ssGBLUP for the four health traits, the daughters' incidence of best EBV bulls versus worst bulls is reduced by a factor of 2 minimum.

Introduction

Health traits are of increasing importance for dairy farmers, both for economic reasons (treat-ments' cost/production loss), for working time and for animal well-being. Since 2000, French laws require breeders to record all treatments in a diary. The pathology causing a treatment may also be recorded. Rapidly, a growing number of breeders started recording using one of the available IT application (software, web, etc.), thus making disease data available to their support organisations. In 2015, a collaborative regional project named 'GénoSanté' was initiated by the *Evolution* Breeding Company, together with milk recording and herd support organisations (DHI) of Western France, breeding companies and R&D organisations. The aim of this project was to improve animal health through new tools both for management and selection (Leclerc *et al.*, 2019), adding extra-value to information recorded by farmers in health management diaries. In 2015, a study on a subset of IT application showed that 15% of herds recorded health events exhaustively (Bourrigan *et al.*, 2015) and suggested that these data could help to develop references for management tools and genetic evaluations. The objectives were: (1) to validate the feasibility of using breeders recorded health data for gene-tic purpose; (2) to estimate genetic relationships between some available health traits of interest and other dairy traits; (3) to develop a Single Step Genetic Evaluation of those health traits.

Materials & methods

The health database. 742,973 multi-breed health events (mastitis discarded), corresponding to 178 treatments reasons, collected by farmers from 2008 to 2021 in 16,619 herds were available. Due to lack of supervision in the data acquisition system, the consistency of data was checked by cross-referencing all the data available for those animals with the national genetic databases. Six different categories of animals were established: calves less than 1 month old, calves from 1 to 6 months old, heifers over 6 months old, pregnant heifers, cows, and males. A list of possible diseases was defined for each category. For instance, calving pathologies such as uterine prolapse are only possible for the 'cow' category. Inconsistent data (2.1%) and uncategorized data (3.9%) were discarded. Data from herds with less than 20 lactations per year were excluded (5.6%), as well as data from collective treatments that did not allow to assess individual sensitivity (22.9%). Among health disorders, four traits were selected: Displaced Abomasum (DA), Milk Fever (MF), Metritis (MET) and Retained Placenta (RP). Lameness and ketosis

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_103, © H. Leclerc *et al.* 2022

disorders recorded in herd diaries were not studied here, genetic evaluations for ketosis (through milk MIR spectra of Acetone and Beta-Hydroxybuty-rate (BHB)) and lameness (from claw lesions) being already available (Leclerc *et al*., 2019).

Completeness at herd level. To ensure that data available are from reliable herds, a minimum of 3 different health disorders and health events recorded for at least 15% of the lactating cows per year were required to consider the health status of the herd as complete for that year, regardless of breeds. A minimum of 5 consecutive years of completeness was required to select a herd, to ensure this period covers the cow productive lifespan and to have a dataset quality suitable for the estimation of genetic parameters.

Traits' definition. Health disorders were defined as binary traits (0=no case / 1=at least one case) based on whether or not the cow had at least one disease case recorded during the lactation period (0-60 days after calving for DA, 0-7 d for MF, 0-150 for MET, 0-14 d for RP). MET and RP periods are similar to those used in Canada (Koeck *et al.*, 2012). Breeders are more or less sensitive to certain diseases, so only herds with at least one case recorded in the considered year, the previous or the following one have contemporaries' cows considered as 'no case' (617 herds considered for DA, 756 for MF, 767 for MET and 845 for RP).

Information from the national database was added for other traits on 409,031 lactations (parity 1 to 5) from 2006 to 2021 (Table 1): Milk production traits, recorded between 7 and 40 days in milk (DIM) (kg of milk, Fat%, Pro%, SCS, acetone and BHB estimated from MIR spectra on milk sample ($100\times\log_2([\text{acetone or BHB}]+1)$); number of insemination (#INS), interval between calving and first insemination (ICFINS), interval between calving and last insemination (ICLINS), and number of mastitis cases in the lactation (#MAS).

Analysis. This study, focused on Holsteins' data from the exhaustive herds, was split into 3 parts: (1) variance components estimation within the 4 health traits (herd diaries database); (2) estimation of genetic correlations between the 4 health traits, and acetone/BHB (Milk database), udder health, fertility and production traits (national database); (3) genomic evaluation of the 4 health traits by SSGBLUP.

Pedigree and genotyped animals. Animal pedigree was built by tracing the pedigree of the 167,498 cows with data on 5 generations (339,406 animals). A total 23,132 animals genotyped (or imputed) on the Illumina Bovine SNP50 BeadChip were used for ssGBLUP.

Model. Bivariate and Multivariate linear animal models, with repeated observations across lactations, were fitted by a REML using Wombat software (Meyer, 2007). Multivariate analysis were performed among the 4 health traits, and bivariate for other traits combinations.

Table 1. Summary statistics of analyzed traits.

Trait	N°	#Lact	Mean	Std	Trait	N°	#Lact	Mean	Std
DA (0/1)	a	193,650	0.011	0.102	#MAS	c	409,031	0.44	0.85
MF (0/1)	a	257,482	0.018	0.134	Milk (kg)	b	351,492	32.71	8.26
MET (0/1)	a	215,837	0.063	0.243	Fat%	b	351,492	4.08	0.71

$$y= X\beta+Za+Zp+e \quad (1)$$

where y is the vector of observations for the traits; β the vector of fixed effects consisting of a herd×year (a,b,c), calving age×parity (a,b,c), calving month×year (a,b), length of dry period×parity (a,b), parity×DIM (a) [a,b,c as described in Table 1]; a ($\sim N(0,A\sigma^2_g)$) and p ($\sim N(0,I\sigma^2_{pe})$) the vectors of additive genetic and permanent environment, X & Z the incidence matrices.

A SingleStep genetic evaluation using HSSGBLUP software (Tribout *et al.*, 2020) using uni-variate model similar to variance component estimation was performed on the 4 health traits.

Results

Around 2/3 of health data remained after data edits. It was used to qualify the completeness of 10,019 herds and 8.6% of herds (867) have fulfilled the 5 consecutive years of completeness.

The disease frequencies of the 4 health traits were low, from 1.1% for DA to 6.3% for MET (Table 1). MF frequency were highly dependent of parity (close to 0 in 1st and 2nd up to 9% in 5th). Heritability estimates of the 4 health traits in linear model were between 1 and 2% (Table 2). MET genetic correlations were high with RP (0.64) to moderate with DA (0.31).

Genetic correlations between health traits and other dairy traits are shown in Table 3 (for production traits (dark grey cells), a negative correlation means a favourable relationship). DA and MF have favourable correlations with ketosis (Acetone & BHB) and fertility traits. MET, and RP to a lesser extent, have positive genetic correlations with #INS and ICLINS. Acetone and BHB have moderate favourable correlations with SCS and Pro% and unfavourable with Fat%.

Genomic EBV for 4 health traits have been estimated in an univariate ssGBLUP. Based on 636-779 bulls with at least 20 daughters, in comparison with the 25% worst bulls, the 25% best ones have on average an incidence divided by 2 (MET=8.6% vs 4.2% / RP=8.9% vs 3.9% / MF=3.1% vs 1.3%) to more than 10 (DA=2.2% vs 0.2). The female genetic trend (Figure 1) show a favourable evolution of the genetic level for DA, MET and RP since 2008.

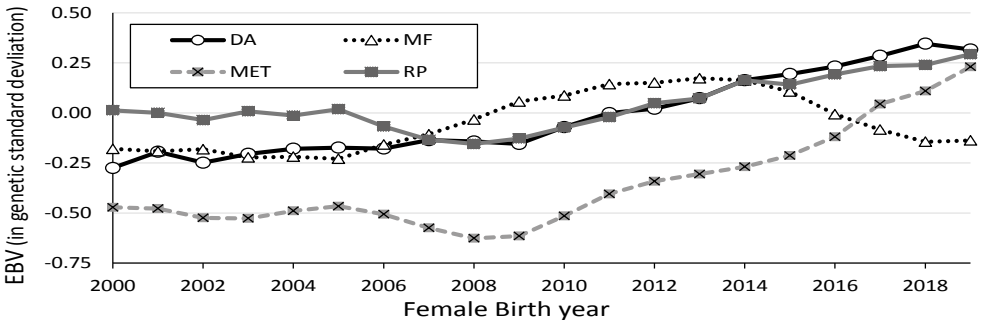

Figure 1. Female genetic trends for DA, MF, MET and RP.

Discussion

Farmer-observed health events recorded in diaries can be used to develop genetic evaluation, even if the number of farms is very limited. At the end, 8.6% of herds value 41% of consistent data (a 3 years completeness period would value 18% of herds – 56% of data). This could be improved by focusing DHI effort to increase participation. Highlighting the benefits of disease recording for herd management and genetic evaluations is essential.

Linear model was preferred to threshold model due to practical consideration on multivariate model and ssGBLUP software although the latter is generally recommended with binary traits, such as health traits. Heritability estimates for the 4 health traits (1-2%) were, slightly lower than in Koeck *et al.* (2012), but consistent with the review of Pryce *et al.* (2016). High genetic correlations between some of the 4 health traits (MET-RP and DA-MET) are consistent to the ones on Canadian study (Koeck *et al.*, 2012) with lower standard errors. Moderate but favour-able correlations between the 4 health traits and functional/other health traits give a promising situation that could, if the latter group of traits are used as predictors, increase the reliabilities of EBV for health traits. The favourable genetic trends observed for DA, MET and RP since 2008 could be an indirect effect of the inclusion of functional traits in Total Merit Index.

104. Genetic selection for reduced susceptibility to subclinical ketosis using mid-infrared predicted traits

A. Köck[1*], L.M. Dale[2], A. Werner[2], M. Mayerhofer[1], F.J. Auer[3] and C. Egger-Danner[1]

[1]ZuchtData EDV-Dienstleistungen GmbH, Dresdner Str. 89, 1200 Vienna, Austria; [2]Regional State Association for Performance and Quality Inspection in Animal Breeding of Baden Württemberg, Heinrich-Baumann-Str. 1-3, 70190 Stuttgart, Germany; [3]LKV-Austria, Dresdner Str. 89, 1200 Vienna, Austria; koeck@zuchtdata.at

Abstract

The objective of this study was to evaluate the value of milk mid-infrared (MIR) predicted traits in breeding programs in reducing the incidence of subclinical ketosis. Data from 670 cows on 49 farms were collected from September 2020 to March 2021. A handheld electronic device (WellionVet BELUA, MED TRUST Handels GmbH, Marz, Austria) for the detection of subclinical ketosis (β-hydroxybutyrate-concentration >1.2 mmol/l) was used on all cows at milk recording in early lactation. In addition to fat-to-protein ratio, data from newly developed MIR traits (KetoMIR, β-hydroxybutyrate, acetone) were available at each milk recording. Heritabilities for all traits were high, ranging from 0.16 (acetone) to 0.30 (KetoMIR). Genetic correlations between β-hydroxybutyrate results gained by the handheld device and traits predicted by MIR ranged from 0.60 to 0.73. The moderate to high genetic correlations between MIR-predicted traits and subclinical ketosis suggest that consideration of these traits would reduce subclinical ketosis.

Introduction

In Austria, the frequency of clinical ketosis is very low (1.2%) (ZuchtData 2020). Subclinical ketosis occurs much more frequently. Data from a previous project showed a frequency of subclinical ketosis of around 14% (ZAR 2016). Since affected cows usually show no signs of disease at all, detection is very difficult. For the diagnosis of subclinical ketosis, various tests for the measurement of ketone bodies in blood, milk or urine are available to the farmer. Khol *et al.* (2019) investigated a handheld electronic device for the detection of subclinical ketosis (β-hydroxybutyrate-concentration (BHB)>1.2 mmol/l), in capillary blood and venous whole blood in cows (WellionVet BELUA, MED TRUST Handels GmbH, Marz, Austria). Altogether, 98% of all the samples were correctly classified as subclinical ketosis or non-subclinical ketosis by the handheld device in capillary blood (sensitivity 0.96, specificity 0.98) and 97.4% in venous whole blood (sensitivity 0.889, specificity 0.991), respectively. This rapid test has high accuracy but means additional work. Therefore, when detecting subclinical ketosis, the milk components from the milk performance recording provide valuable practical information that does not require any additional work. Milk analysis using mid-infrared spectroscopy (MIR) is a fast and inexpensive way of examining milk samples on a large scale for fat, protein, lactose and urea. The classical detection method of subclinical ketosis within routine performance recording is a fat-protein ratio>1.5 at the beginning of lactation. Recently, MIR equations for milk components with low concentrations such as BHB and acetone were developed. Detection of these components is done by indirect links with global milk composition, as MIR technology cannot directly detect components below 100 ppm (<0.1 g/l) (Dardenne *et al.* 2015). A new indicator trait for ketosis, KetoMIR, was developed by LKV Baden-Württemberg (Dale *et al.* 2018, Werner *et al.* 2019). The new concept of KetoMIR is to offer a ketosis risk index via milk samples that is more accurate than the fat-protein ratio. The objective of this study was to evaluate the value of fat-protein-ratio and these newly developed MIR traits (KetoMIR, BHB-MIR, Acetone-MIR) for genetic selection for reduced susceptibility to subclinical ketosis. Cows with subclinical ketosis were identified by using the handheld electronic device. Heritabilities and genetic correlations were estimated for all traits.

Materials & methods

Data. This project involved 49 farms with metabolic problems from September 2020 to March 2021. Data collection was carried out by the regional milk recording organisations. As part of the study, capillary blood was analyzed for BHB concentration in all cows during milk recording in early lactation (1st and 2nd test day after calving) using a handheld device (WellionVet BELUA, MED TRUST Handels GmbH, Marz, Austria). In addition, feeding behaviour (1=does not eat, 2 = eats reduced, 3 = eats normal) and metabolism (ketosis prevention, ketosis treatment, milk fever prevention, milk fever treatment) were recorded.

Traits. For the analyses, BHB measurements from the handheld device were divided into 3 classes (1 = BHB≤1.2 mmol/l (healthy), 2 = BHB=1.3-2.9 mmol/l (subclinical ketosis), 3 = BHB≥3.0 mmol/l (clinical ketosis)). KetoMIR was defined as a three-class index (1 = low ketosis risk, 2 = medium ketosis risk, 3 = high ketosis risk). BHB-MIR, Aceton-MIR and fat-protein-ratio were considered as continuous traits. All traits were available on each test-day.

Data edits. Analyses were carried out for Fleckvieh cows from all parities. In total 504 records from 323 Fleckvieh cows were available for analyses. A summary of statistics of the analyzed data set is given in Table 1. An animal pedigree file was generated by tracing the pedigree of cows 5 generations back, ending up with 3,523 animals.

Model. Data were analyzed with univariate and bivariate linear animal models using the average information-restricted maximum likelihood (AI-REML) procedure in the DMU package (Madsen and Jensen, 2008). The following model was applied to all traits:

$$y = X\beta + Z_h h + Z_{pe} pe + Z_a a + e \quad (1)$$

where y is a vector of observations; β is a vector of systematic effects, including fixed effects of month of recording, parity and lactation stage; h is a vector of random herd effects; pe is a vector of random permanent environmental effects; a is a vector of random animal additive genetic effects; e is a vector of random residuals; and X, Z_h, Z_{pe}, and Z_a are the corresponding incidence matrices. Parity had five classes with 1, 2, 3, 4 and 5+. Lactation stage was defined in classes (1 = ≤20 DIM, 2 = 21-40 DIM, 3 = 41-60 DIM, 4 = 61-80 DIM, 5 = >80 DIM).

Results

Figure 1 shows the percentage of healthy cows (BHB≤1.2 mmol/l), cows with subclinical ketosis (BHB=1.3-2.9 mmol/l) and clinical ketosis (BHB≥3.0 mmol/l) detected by the handheld device.

Table 1. Summary statistics of the analysed traits.

	Number of records	Mean	Minimum	Maximum
BHB – handheld device	504	1.298	1	3
KetoMIR	474	1.227	1	3
BHB-MIR	474	1.025	0.370	3.630
Aceton-MIR	474	0.097	0.020	0.420
Fat-protein-ratio	474	1.352	0.629	2.407

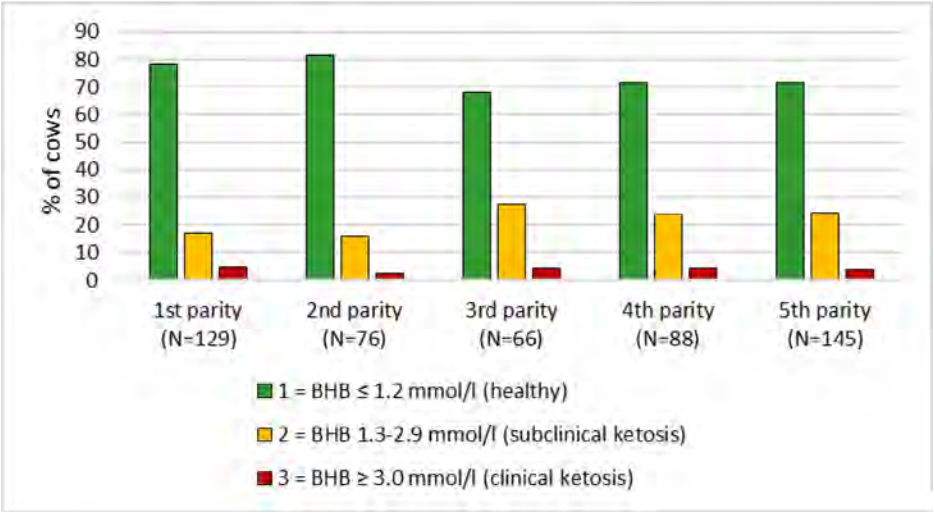

Figure 1. Percentage of healthy cows (BHB≤1.2 mmol/l), cows with subclinical ketosis (BHB=1.3-2.9 mmol/l) and clinical ketosis (BHB≥3.0 mmol/l) detected by the handheld device.

Heritabilities and genetic correlations for the analysed traits are shown in Table 2. Heritabilities for all traits were high, 0.26 for BHB results gained by the handheld device and between 0.16 and 0.30 for MIR predicted traits. The genetic correlations between BHB concentration from the handheld device and the traits predicted by MIR ranged from 0.60 to 0.73.

Discussion

Overall, the heritability estimates found in our study were consistent with previous literature results. Hamann *et al.* (2017) found heritabilities in the range of 0.22 to 0.39 for KetoMIR. Belay *et al.* (2017) reported heritability estimates for predicted blood BHB at different stages of lactation, ranging from 0.250 to 0.365. Benedet *et al.* (2020) found a heritability of 0.21 for BHB-MIR from 5 to 35 DIM. Genetic correlations between BHB results gained by a handheld device and MIR predicted traits could not be found in the literature. However genetic correlations with clinical ketosis from veterinary diagnoses were available. A moderate genetic correlation of 0.47 between predicted blood BHB at first test day and clinical ketosis was reported by Belay *et al.* (2017). Because the standard errors of the estimates in our study were high, the results should be taken with caution. However, the moderate to high genetic correlations between MIR-predicted traits and subclinical ketosis suggest that consideration of these traits would reduce subclinical ketosis.

Table 2. Heritabilities (on diagonal) and genetic correlations (above diagonal) with standard errors in brackets.

	BHB – handheld device	KetoMIR	BHB-MIR	Aceton-MIR	Fat-protein-ratio
BHB – handheld device	0.26	0.61 (0.35)	0.60 (0.32)	0.73 (0.33)	0.60 (0.37)
KetoMIR		0.30	0.48 (0.37)	0.35 (0.39)	0.20 (0.45)

105. Heritability of scurs in Wagyu and tropically adapted composite beef cattle

G. Moser* and M.J. Kelly

Australian Agricultural Company, 76 Skyring Terrace, QLD, 4006, Australia; gmoser@aaco.com.au

Abstract

Breeding genetically hornless cattle provides an alternative to the invasive process of dehorning. Accurate genomic tests for poll status are available but the understanding of scurs genetics remains limited. Scurs status of two breed types was recorded in a large breeding operation in northern Australia (n=1,599). Estimates of SNP-based heritability ranged from 0.26-0.77 depending on breed, sex, and scurs phenotype. Several genome regions were significantly associated with scurs; the largest effects mapped to BTA1 and BTA12. Our findings confirm a complex, highly polygenic genetic architecture underlying scurs, modified by age and sex.

Introduction

Increasing frequency of the polled trait has positive implications for animal welfare, productivity, labour requirements and safety of station staff. The poll genetic test is a highly effective tool to increase the frequency of polled animals, with 99% accuracy in most cattle breeds (Randhawa *et al.*, 2020).

A major limitation of the poll genetic test is that it is not predictive of scurs, which can arise when only one copy of the poll gene is present. Scurs are loosely attached hornlike formations, which are usually smaller than true horns and develop slightly later in life (Grobler *et al.*, 2021). Scurs are not necessarily associated with the same issues as horns, so their removal often constitutes an unnecessary dehorning procedure.

Several studies, albeit with relatively small sample sizes, suggest that scurs are heritable, but genetically complex and affected by poll status, sex and breed (Aldersey *et al.*, 2020; Gehrke *et al.*, 2020; Grobler *et al.*, 2021). In the current study, we have utilised a greater sample size to further our understanding of the genetic architecture of scurs.

Materials & methods

SNPs and genotypes. DNA samples were collected at branding and genotyped with either GeneSeek® Genomic Profiler™ 100K or 50K arrays by Neogen Australasia. A total of 675,476 SNPs remained after imputation to high-density using BEAGLE (Browning and Browning, 2007) and QC. Poll test results are reported as P_cP_c, P_cP_f, P_fP_f for homozygous poll; HP_c, HP_f for heterozygous poll and *HH* for horned, where the specific poll allele is included as a subscript (Celtic (P_c), Friesian (P_f)).

Samples and phenotypes. Phenotypes were recorded for two groups of beef cattle verified by DNA testing as heterozygous polled (total n=1,599), with 10% being Wagyu and 90% Mitchell. Mitchell is a tropically adapted composite breed developed from Brahman, Shorthorn, Charolais, Senepol, Belmont Red and Santa Gertrudis in the 1980s. All cattle were assessed as horned, polled or scurred by station staff during routine handling at branding (2-6 months of age).

Males were excluded from routine dehorning during branding and later reassessed and scored for scurs type between 12 to 16 months of age. Observed phenotypes were scored into five categories using a modified version of the scoring system proposed by Gehrke *et al.* (2020). Polled animals are assigned to category 1 and scurred animals to category 2 to 5 depending on the type and size of scurs (Figure 1). For analysis, the

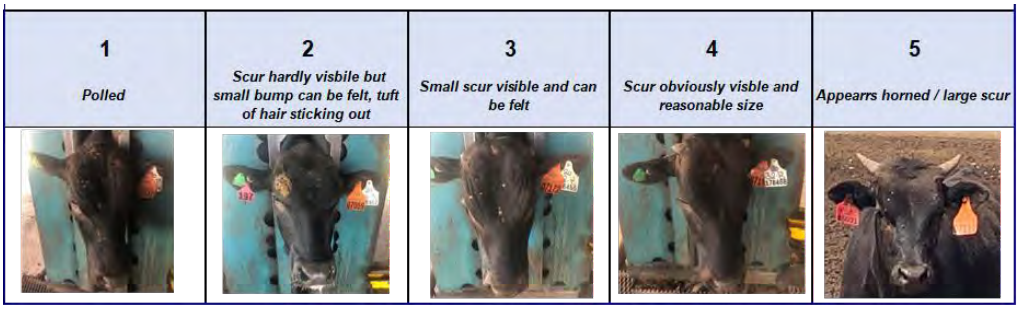

Figure 1. Scoring system for poll phenotype.

coded horn phenotypes were converted into two binary traits. In coding model BC1 only poll animals are counted as cases, in BC2 animals in categories 1 and 2 are combined and categories 3, 4, and 5 make up the controls (Table 1).

Females were assessed once at branding and phenotype recorded as either 'polled' or not Using this routinely collected data, a binary poll/scurs phenotype was constructed for heterozygous animals, with females not recorded polled being classified scurs. Heterozygous animals can only be polled or scurred given the high accuracy of the DNA test. Given manual palpation of the head is generally not performed by station staff at branding, small scurs (Figure 1, score 2) would mostly be recorded as polled, corresponding to coding BC2 for males. This is supported by an observation made in Mitchell males, where 213 bulls recorded as polled at branding presented with scurs as yearlings.

Statistical methods. We estimated genomic heritability and performed association analyses between SNPs and scurs phenotypes. Estimation of SNP based heritability of scurs traits used genome-based restricted maximum likelihood (GREML) implemented in the software WOMBAT (Meyer, 2007). To scan the genome for genetic variants associated with scurs we performed a genome-wide association study (GWAS) in PLINK (Chang *et al.*, 2015), treating BC1 and BC2 as binary phenotypes. To account for the genetic diversity within the Mitchell breed and to correct for population stratification effects in GWAS we fitted genomic breed composition (Boerner and Wittenburg, 2018) as covariates.

Results

The phenotypic variance explained by all SNPs using animals carrying the P_c allele are shown in Table 2. Estimates were moderate to high, and higher for BC2 compared to BC1. All estimates had low precision as shown by the large standard error. In Mitchell, SNPs explained more of the phenotypic variance in males than in females. Using a bivariate GREML we estimated a genetic correlation of 0.64 (0.18) between male and female BC2 phenotypes. Including animals carrying the P_f allele gave very similar results to those shown in Tab 2.

Table 1. Number of HP_c (HP_f in parenthesis) animals for coding BC1 and BC2.

		BC1		BC2	
Breed	**Sex**	**Cases**	**Controls**	**Cases**	**Controls**
Mitchell	Female	-	-	890 (70)	150 (4)
	Male	60 (8)	247 (17)	212 (22)	95 (3)
Wagyu	Male	15 (1)	123 (14)	54 (5)	84 (10)

Table 2. SNP based heritability (standard errors in parenthesis) for coding BC1 and BC2 estimated using HP_c animals.

Breed	Trait	Female	Male	Female + Male
Mitchell	BC1		0.26 (0.17)	
Wagyu			0.33 (0.24)	
Mitchell+Wagyu			0.42 (0.15)	
Mitchell	BC2	0.41 (0.07)	0.77 (0.19)	0.36 (0.06)
Wagyu			0.60 (0.26)	
Mitchell+Wagyu			0.56 (0.14)	0.35 (0.06)

For convenience, we use *P*-value thresholds commonly applied in human studies of 10^{-5} and 5×10^{-8} for suggestive significant and genome-wide significant associations (Visscher *et al.*, 2017). Across analyses, suggestive associations were found on many chromosomes and genome-wide significant peaks were mapped to seven different chromosomes (Figure 2).

Discussion

The presence of scurs was found to be moderately to highly heritable whether coded BC1 or BC2. In contrast to the findings of Gehrke *et al.* (2020), heritability was higher for BC2 compared to BC1. Nevertheless, both studies together strongly suggest that scurs are heritable and can be changed through selection. Gehrke *et al.* (2020) found that the P_f allele suppressed scurs more than the P_c allele. Despite only 10% of animals carrying the P_f allele, we only presented results for P_c animals to avoid potential problems caused

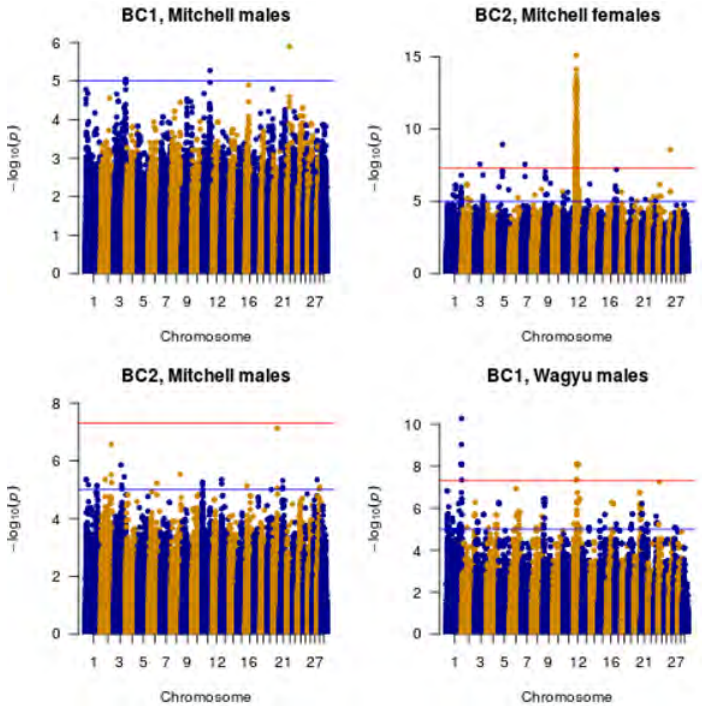

Figure 2. GWAS results for scurs with different phenotype codings. The horizontal lines indicate suggestive ($\alpha=10^{-5}$, blue) and genome-wide ($\alpha=5\times10^{-8}$, red) significance thresholds.

by allelic heterogeneity. Furthermore, confounding between founder breed and poll allele might be present, particularly in Wagyu where a very limited number of poll carriers were used for introgression into the naturally horned Wagyu breed.

The results of the current study do not support regulation of scurs development by a single or a few genes. However, there are several studies that reported putative QTL regions involved in the development of scurs (reviewed in Aldersey *et al.*, 2020; Grobler *et al.*, 2021). A recent study of Holstein-Friesian cattle described three QTL on BTA12 (Gehrke *et al.* 2020). We also found associations in Mitchell females and Wagyu males on BTA12, however, the QTL were mapped to different locations. In addition, two regions distal to the poll locus on BTA1 were detected for both phenotype codings in both breeds and sexes. Although evidence exists supporting a small number of QTL regions, together these QTL regions only explain a small component of the genetic variation in scur presence.

In this study we investigated scurs phenotypes in polled Wagyu and tropical adapted composite males and females. Heritability estimates indicate that reducing the frequency of scurs through selection is feasible. Our findings confirm a complex, highly polygenic genetic architecture underlying poll phenotypes, presumably modified by age, sex and other environmental factors. Several QTLs have been identified, however, our ability to further investigate putative regions is limited by the small sample size of our study.

Abstract

Genetic parameters for traits related to social hierarchy of 970 Nellore young bulls (282±39 days old), from feed event data collected by electronic feeding system, were estimated. Social hierarchy was evaluated from three traits: dominance value (continuous), social rank (binomial), and social hierarchy (three categories). The heritability estimates were moderate (0.23 to 0.29). Genetic correlation (r_g) between social hierarchy, and dry matter intake per visit and time at the feeder per visit were negative (-0.28 to -0.47), while r_g with the number of visits at the feeder were positive (0.21 to 0.34). In general, the r_g between social hierarchy and growth traits were close to zero, suggesting that selection for growth does not affect the social hierarchy. In conclusion, there are genetic effects on the expression of social hierarchy traits. Furthermore, the social hierarchy is genetically related to feeding behaviour, but not to growth traits.

Introduction

The social relationships developed by cattle result in the establishment of social hierarchy within the group (Phillips and Rind, 2002). One of the main functions of social relationships is to regulate access to resources such as food (Bica *et al.*, 2019; de Sousa *et al.*, 2021), water and shade (Deniz *et al.*, 2021).

Understanding the social dynamics of animals is important to establish effective management at the farms and to comprehend how productive traits are affected by animals' behaviour. However, in the genetic field, studies about the social organization of cattle are scarce due to the difficulty to obtain the social behaviour data. Furthermore, most studies use direct visual observation to determine the social hierarchy (Bica *et al.*, 2019; de Sousa *et al.*, 2021; Deniz *et al.*, 2021).

With technology advancement, studies have shown the feasibility of determining the social hierarchy from feed events registered by electronic feeding system (Huzzey *et al.*, 2014; McDonald *et al.*, 2019). A short time interval between the visits of two different animals at the same feeder can be used to establish dominance relationship among animals. This study aimed to estimate genetic parameters for dominance value, social rank, and social hierarchy of Nellore cattle from feed event data collected by electronic feeding system.

Materials & methods

Animals. Data of 970 Nellore young bulls, born from 2012 to 2020, were obtained in 20 feed efficiency tests (282±39 days old at the beginning of the test), conducted at the Beef Cattle Research Center, Institute of Animal Science (IZ), Sertãozinho-SP, Brazil.

Housing. The feed efficiency test lasted 84±12 days. The groups of animals were housed in one of the three collective pens available at the IZ: Pen 1 (1,844 m^2): one common water feeder and five GrowSafe System (Vytelle – Kansas City, Missouri, United States of America) electronic feeder; Pen 2 (3,687 m^2): one common water feeder and 10 GrowSafe System electronic feeder; and Pen 3 (3,020 m^2): four Intergado®

(Contagem, Minas Gerais, Brazil) water electronic feeders and 12 Intergado® electronic feeder. The feeders had physical barriers that allowed access to only one animal at a time. The animals received an electronic ear tag for individual recognition at the feeder. The diet was offered twice a day (8:00 am and 3:00 pm), and the animals had *ad libitum* access to food, water, and mineral salt.

Social hierarchy determination. The method to determine the social hierarchy of the animals in each feed efficiency test group (48±19 animals per group) was based on the replacements that occurred at the electronic feeders (Foris *et al.*, 2019). For the analyses, the feeding event data collected by the electronic troughs during the feed efficiency test were used to estimate one dominance value for each animal. The interval of up to 10 seconds between the exit of one animal and the entry of another animal in the same feeder was considered to determine a replacement since longer intervals can increase the probability of false-positive results (Foris *et al.*, 2019). For each group, two interspersed days per week were selected until the end of the test in order to minimize the number of inconsistencies (De Vries, 1998). On average, 22 test days were used for each group. In addition, only data collected during the periods after feeding were used: three hours in the morning (07:00:00 am to 09:59:59 am) and three hours in the afternoon (02:00:00 pm to 4:59:59 pm). Such periods were selected because the greatest number of replacements between animals occurs following the fresh food delivery (DeVries and Von Keyserlingk, 2005; Val-Laillet *et al.*, 2008). Weeks without information due to technical failures in the electronic feeder were discarded.

The social hierarchy was determined based on the equations proposed by Kondo and Hurnik (1990) from 'socialh' R package (Valente *et al.*, 2021). The dominance value (DV) for each animal was calculated as the sum of all relationships of this animal with each other animal within the group throughout the days. The social rank (SR) [high (1) and low (2)] and the social hierarchy (SH) [subordinate (1), intermediate (2), and dominant (3)] were obtained from the dominance value, as described by Coimbra *et al.* (2012).

Statistical analysis. The heritability estimates of DV, SR and SH were obtained by one-trait analysis, and the genetic correlations estimates were obtained from two-traits analyses with the following traits: average dry matter intake per feeder visit (DMI_v; kg/visit, n=1,003), average time spent at the feeder per visit (TF_v; min/visit, n=1,003), average frequency of visits to the feeder (FF, visits/day, n=1,003), weight at the beginning of the test (BW, kg, n=1,781), average weight throughout the test (AW, kg, n=1,781), weight at the end of test (FW, kg, n=1,781), postweaning weight (PW, kg, n=9,936), and average daily gain (ADG, kg/day, n=1,781). The model can be written in matrix form as follows: $y = X\beta + Z\alpha + e$, where y is the vector of the traits observed; β is the vector of fixed effects [test group (or contemporary group for PW) and the linear effect of animal age at the beginning of the test and the linear and quadratic effects of the dam age as covariates]; α is the vector of direct additive genetic effects; X and Z are incidence matrices for each effect, respectively, and e is the vector of residual effects. It was assumed that $E(y) = X\beta$, $E(a) = 0$, $E(e) = 0$ and $Var(\alpha) = A \otimes S_a$ and $Var(e) = I \otimes S_e$, where S_a is the matrix of genetic (co)variance between social hierarchy, feeding behaviour and growth traits; S_e is the residual (co)variance matrix, A is the pedigree-based relationship matrix (12,228 animals, five generations back), and I is the identity matrix.

The (co)variance components for DV trait were estimated fitting linear models by the AIREML software (Misztal *et al.*, 2021), while the (co)variance components for categorical traits (SR, SH) were estimated fitting threshold models by the THRGIBBS and POSTGIBBS software (Misztal *et al.*, 2021) (500,000 interactions; 50,000 cycles of burn-in; sample every 20 interactions; resulting in 22,500 effective samples).

Results & discussion

Heritability estimates for DV, SR and SH were moderate (Table 1). The values indicate that these traits would respond to direct selection. Despite the relevant presence of the environmental effect on the traits, it is interesting to note the existence of the direct genetic effects on DV, SR and SH which should be considered in the evaluation of animals. Previous studies in the literature presented heritability estimates for dominance value of dairy cows: 0.40 for heifers (Beilharz *et al.*, 1966) and 0.15 for lactating cows (Dickson *et al.*, 1970). These results differ from the present study probably due to the breed and the huge difference between beef and dairy cattle.

Genetic correlation estimates (r_g) between social hierarchy traits (DV, SR and SH), and feeding behaviour traits (DMI_v, TF_v and FF), and growth traits (BW, AW, FW, PW, and ADG) are presented in Table 2. The r_g of DV, SR, SH with DMIv and TFv was negative and moderate, while the r_g with FF was positive. These results suggest that animals at high social positions get access to the feeder more frequently, spend less time, and eat less by feed event when compared to animals at low social positions. On the other hand, selection for growth seems to have no effect on the animal social hierarchy. The r_g between DV, SR, and BW, AW, FW, PW, and ADG indicated a low genetic association among social hierarchy and growth traits. However, the r_g estimates presented high standard deviations or standard errors as a consequence of small number of animals with social hierarchy information, so more studies are necessary to confirm these genetic associations.

Table 1. Estimates of the additive genetic variance (σ_a^2), residual variance ($\sigma_e^2$and heritability (h^2) for dominance value (DV), social rank (SR) and social hierarchy (SH) in Nellore cattle.

Trait	Mean ± SD	σ_a^2	σ_e^2	H
DV	-0.06±9.98	23.08 (7.59)	78.60 (6.97)	0.23 (0.07)
SR[1]	1.48±0.50	0.45 (0.22)	1.02 (0.66)	0.29 (0.10)
SH[1]	1.99±0.68	0.11 (0.04)	0.34 (0.04)	0.25 (0.08)

[1] For SR and SH, σ_a^2, σ_e^2, and h^2 are posterior mean (posterior standard deviation).

Table 2. Genetic correlations between dominance value (DV), social rank (SR) and social hierarchy (SH), with feeding behaviour and growth traits in Nellore cattle.[1]

Trait	Mean ± SD	Genetic correlation		
		DV	SR[2]	SH[2]
DMI_v	0.11±0.04	-0.37 (0.17)	-0.36 (0.17)	-0.28 (0.16)
TF_v	00:01:17±00:00:37	-0.47 (0.16)	-0.44 (0.16)	-0.46 (0.15)
FF	88±24	0.34 (0.18)	0.27 (0.19)	0.21 (0.19)
BW	245±49	0.09 (0.16)	0.03 (0.13)	0.31 (0.13)
AW	290±53	0.07 (0.15)	0.03 (0.13)	0.25 (0.12)
FW	332±59	0.06 (0.15)	0.04 (0.12)	0.20 (0.12)
PW	303±53	-0.08 (0.14)	-0.03 (0.12)	-0.02 (0.12)
ADG	0.00±0.62	-0.03 (0.17)	-0.06 (0.14)	-0.09 (0.14)

[1] DMI_v (kg/visit): dry matter intake per feeder visit; TF_v (min/visit): time spent at the feeder per visit; FF (visits/day): frequency of visits to the feeder; BW (kg): weight at the beginning of the test; AW (kg): average weight throughout the test; FW (kg): weight at the end of the test; and PW (kg): postweaning weight; ADG (kg/day): average daily gain.

[2] For SR and SH, genetic correlations are posterior mean (posterior standard deviation).

Conclusions

As a preliminary study conducted with Nellore cattle, the results indicated the presence of genetic effects on the expression of social hierarchy traits. Social hierarchy is genetically associated with feeding behaviour traits but it is not genetically associated with growth traits. The results found for social hierarchy will help to understand how this trait interferes in the expression of productive traits. In the future, information regarding social hierarchy can probably be included in beef cattle breeding programs.

107. Pigs' weighing order stability is favourably linked with tail biting and production: a new proxy for social structure?

W. Gorssen*, R. Meyermans, S. Janssens and N. Buys

KU Leuven, Department of Biosystems, Center for Animal Breeding and Genetics, Kasteelpark Arenberg 30 - bus 2472, 3001 Leuven, Belgium; wim.gorssen@kuleuven.be

Abstract

In this study, we weighed fattening pigs pen-by-pen every two weeks to study their weighing order as a proxy for social group structure. Hereby, pigs were allowed to choose the order of weighing themselves. We investigated the genetics of the stability of the weighing order and the (genetic) relationship with production and welfare traits. In total, 15,435 recordings from 1,864 crossbred pigs (149 pens) with known pedigree were analysed. Weighing order stability increased over consecutive weight recordings, with correlations for consecutive recordings increasing from r=0.11 to r=0.44. Weighing order stability was lowly heritable (h^2=1.6-5.2%). However, a low weighing order stability was (genetically) correlated with lower average daily gain and lean meat percentage and with more tail/ear biting, lameness and mortality. These results indicate that social structure in fattening pigs can possibly be estimated by weighing order stability, and that a more stable weighing order is favourably correlated with production and welfare traits.

Introduction

Pigs are highly social animals, and hence they form complex relationships. In nature, pigs live in groups based on matriarchal hierarchies, whereas in modern pig farming, pigs from different families are often grouped in pens (Rydhmer and Canario, 2014). Creating new groups of pigs often results in aggression to assess a new social hierarchy, possibly leading to injuries such as ear-biting and tail-biting (Rydhmer and Canario, 2014). Moreover, the emerging fields of social and behavioural genetics have shown that social effects in pigs are heritable (Rydhmer and Canario, 2014; Cheng *et al.*, 2009), and can be exploited in breeding programs to improve overall feed efficiency (Bergsma *et al.*, 2008) or to reduce aggression and biting behaviour (Camerlink *et al.*, 2013). However, we still have little understanding about the importance of social stability and the relation to social behaviour and production traits (Camerlink *et al.*, 2021).

In this study, individual fattening pigs were weighed pen-by-pen and scored every two weeks on a commercial farm. We hypothesize that the weighing order is related to pigs' social behavior, and/or that the stability of these weighing orders is (partly) under genetic control. Moreover, we explored the (genetic) relationship between pigs' weighing order and important traits for pig production.

Materials & methods

Study population and data collection. Data were recorded between July 2020 and July 2021 at a progeny testing farm for the breeding organization 'Vlaamse Piétrain Fokkerij' (Belgium). Pigs were kept in commercial conditions and where housed in seventeen identical compartments of eight pens (4.0×2.5 m) with on average thirteen pigs per pen. Pens were of mixed sex (surgically castrated males and females) and penmates descended from the same Piétrain sire. Pigs were identified with radio frequency identification (RFID) ear tags.

Pigs were weighed individually for the first time nine days after arrival at the fattening farm (average age 83.1±5.6 days; average weight 29.9±6.5 kg). Hereafter, pigs were weighed every two weeks. At the last (eight) recording, pigs had an average age of 172.8 days (SD=7.6) and weight of 104.9 kg (SD=13.4). Pen-by-pen, all individuals were driven to the stable's central hallway, after which pigs were weighed one after

the other. Per pen, the pigs' weighing order was determined based on time of weighing: the first weighed pig of a pen was scored with '1', the second with '2', etc. Moreover, ear swellings (hematomas) and ear biting victims were scored (0=none, 1=left or right, 2=left and right) as well as tail biting victims (0=none, 1=small scratches, 3=bloody and/or infected tail). Mortality (0=alive, 1=dead) and lameness (0=normal, 1=lame) were recorded as well. All recordings were collected by the first author. Lean meat percentage was individually recorded at the slaughterhouse of the Belgian Pork Group using AutoFom III™ (Meer, Belgium). The final dataset consisted of 15,435 recordings from 1,864 pigs (149 pens) originating from 135 Piétrain sires and 266 crossbred dams with known pedigree.

Animal samplings were conducted following the procedures approved by the ethical committee of KU Leuven (P004/2020).

Analysis. Pigs' weighing orders were first rescaled on a pen level from '0' (first) to '100' (last) to account for the number of pigs in each pen (varying from 8 to 15). Hereafter, weighing order stability was estimated by the standard deviation of weighing orders per pig over all eight recordings (SD-order$^{1\text{-}8}$) and over the last five recordings (SD-order$^{4\text{-}8}$), since weighing order seemed to stabilize in general after the first three weighings (Table 1). These standard deviations were used as new phenotypes. For mortality, lameness, hematomas and ear and tail biting victims the maximum observed value over all recordings was retained.

Heritabilities (h^2) and genetic correlations (r_g) were estimated using single or bivariate animal models with average information REML, implemented in airemlf90 and invoked with the R-package breedR (Muñoz and Sanchez, 2019). All models were of the form:

$$y= Xb + Za + Wc + e \quad (1)$$

Where *y* is the vector with phenotypes for the studied trait(s); *b* is the vector containing the fixed effects (sex, 2 levels; parity of dam, 4 levels) and covariates (age last recording); *a* is the vector of additive genetic effects (4,989 levels); *c* is the vector of random environmental effects (17 levels); *e* is the vector of residual effects; *X*, *Z* and *W* are incidence matrices for fixed effects, random animal effects and random permanent environmental effects. The random environmental effect *c* is a combination of farm and date of entrance at farm.

Results

In general, the stability of pigs' weighing order increased over time (Table 1). Spearman correlations of consecutive recordings ranged from r=0.11 to r=0.44. The average correlation of all pairwise combinations for all pens was r=0.21, although large differences were observed between pens from r=-0.05 (low stability) to r=0.50 (high stability). After rescaling, standard deviations of weighing orders were approximately normally distributed (μ=27.0±7.0), ranging between 0.0 and 50.0.

Heritability estimates for weighing order stability were very low: h^2 of SD-order$^{1\text{-}8}$ was estimated at 1.6% (SE=2.4), whereas SD-order$^{4\text{-}8}$ had an estimated h^2 of 5.2% (SE=3.0). However, low to moderate genetic correlations were found (Table 2) between weighing order stability and ear biting scores (r_g=0.22-0.27) and tail biting scores (r_g=0.37-0.40), although standard errors were high (Table 2). Average daily gain and lean meat percentage had low to moderate negative r_g estimates (r=-0.14 to r=-0.41). For mortality and lameness, there was a phenotypic relationship with SD-order$^{4\text{-}8}$ (r=0.15 and r =0.23), but standard errors were too high for these traits to estimate r_g.

Table 1. Pairwise Spearman correlations of pigs' weighing orders over eight recordings. For consecutive weight recordings, the Spearman correlation increases from r=0.11 to r=0.44, indicating the weighing orders of pigs within a pen stabilizes over time.

Order at weighing	2	3	4	5	6	7	8

Mortality	0.09	0.15°	NA	NA

Discussion

This study has shown that the weighing order of a pen of fattening pigs generally stabilizes over time, and that the stability of this weighing order is lowly heritable (h^2=1.6-5.2%). Moreover, the weighing order stability was (genetically) favourably correlated with biting behaviour, lameness, mortality and production traits, although standard errors of genetic correlations were high. These findings suggest that the weighing order stability might have potential to assess social stability and aggression in the pen. Different studies have found an association between social genetics and production, aggression, skin lesions and/or biting behaviour (Rydhmer and Canario, 2014; Bergsma *et al.*, 2008; Camerlink *et al.*, 2013, Angarita *et al.*, 2019). However, where most studies assume that pigs' social hierarchy stabilizes a few weeks after mixing groups, we found considerable differences between pens with regard to the stability of weighing order over time.

We would like to note that the specific weighing setup might be important to interpret (or replicate) these findings. In this study, pigs were weighed individually pen-by-pen and during the weighing process pigs had plenty of space in the central hallway, making it possible for them to (partly) determine the order of weighing, although pigs also interacted with the person performing the weight recordings. This new 'environment' might result in different social rankings than would be observed in the pen or possibly with a different weighing setup. Moreover, it is unclear whether pigs ranked first for weighing order would be

more dominant, as going first could also be an expression of fleeing the group. For future research, it would be interesting to relate the stability of weighing orders with pigs' observed behaviour and social rankings in the pen.

To conclude, our results show a relation between weighing order stability in fattening pigs and increased production and welfare. Since social behaviour is hard (or costly) to phenotype in pigs, the stability of weighing orders might be interesting for future research as a proxy for general social stability.

108. Application of machine learning algorithms to develop behavioural and stress phenotypes for sheep

H. Keshavarzi*, D.L.M. Campbell and C. Lee

Agriculture and Foo, Commonwealth Scientific and Industrial Research Organization (CSIRO), Armidale, NSW, 2350, Australia; hamideh.keshavarzi@csiro.au

Abstract

This study aimed to evaluate the performance of Machine Learning (ML) in relating behavioural phenotypes to stress susceptibility in sheep. Hierarchical clustering was used to categorize 335 sheep for behavioural scores and relate these to cortisol levels in response to an acute stressor (shearing). The individuals were categorized as bold, calm, and fearful based on their behaviour in two behavioural tests, namely the arena and corridor tests. Venn diagrams were applied to plot the common animals between stress and behaviour clusters. Correlation between cortisol and behavioural traits was low (-0.16-0.20); and the Venn diagram did not show a high proportion of common individuals between behaviour and stress clusters. Application of ML is useful to characterise behavioural phenotypes but these were not related to variation shown in the more difficult to measure trait of stress susceptibility in sheep.

Introduction

The development of new technological devices has enabled researchers to collect large datasets on the movement (Keshavarzi *et al.*, 2020), social interactions (Krause *et al.*, 2013), and other behavioural traits such as vocalisations (Blumstein *et al.*, 2011) of individual animals. Challenges such as unknown nonlinear dependencies between variables and failure to meet the assumptions of many classical statistical models have made these datasets complex to analyse and describe (Valletta *et al.*, 2017). However, Machine Learning (ML) methods have been demonstrated to successfully classify samples based on unknown relationships and handle large datasets with missing values (Keshavarzi *et al.*, 2020) which overcomes some of these challenges.

A potential use of ML in animal science is clustering animals based on their behaviour, in which the method puts animals into groups that share common characteristics. This would enable the development of new behavioural phenotypes and these could be related to temperament, personality or resilience, e.g. a response to stress. As variation in behaviour is easier to measure than variation in response to stress, it may be possible to identify proxy behavioural measures for stress. Clustering methods have been widely used in animal behaviour studies to implement various tasks such as classifying species, vocalisations or behaviours or detecting emotional states in animals (Valletta *et al.*, 2017). The relationship between such behaviours with welfare indicators may be detectable with ML.

Previous studies have reported the association between cortisol as a physiological indicator of stress with some behavioural traits such as vocalisation, restraint (Grandin and Shivley, 2015), and fearfulness (Lee *et al.*, 2014). We, therefore, aimed to utilise the ability of ML to reveal the possible relationship between cortisol and behavioural traits in this study using sheep. Further understanding of how behavioural phenotypes relate to a physiological stress response using ML may enable more simple and improved welfare-related phenotypes to be developed.

Materials & methods

Ethical approval of animal experimentation. The protocol and conduct of the study were approved by the Chiswick Armidale Animal Ethics Committee, under the New South Wales Animal Research Act 1985.

Animals and data. A total of 409 Merino × Romney sheep (ewes and wethers) were used in the study. Two weeks after weaning (3 months of age), fit and healthy lambs were individually subjected to behavioural tests (arena, and corridor) as described below.

Arena test. A motivational choice test that measures the conflict between social attraction and fear of a human. Briefly, individual sheep were placed in a 7×3 m outdoor arena for three minutes. The arena was divided into virtual zones. A human stood in front of a pen of four familiar flockmates at one end of the arena. Recorded behaviours included: zone score (quantified the total time spent near to the human and other sheep), the number of zones crossed, and the number of vocalisations.

Corridor test. The corridor test evaluates sheep's reaction to social isolation combined with repeated approaches by a human. The corridor consisted of a 0.6 m wide rectangular circuit (4.2×7.2×1.2 m) with an inner lining of rubber mesh. The circuit was virtually divided into six equal zones. The test consisted of three phases: (1) isolation- sheep left alone in the corridor for 30s; (2) pursuit- human entered the corridor and walked two circuits for 1 min; and (3) confinement- sheep placed into one arm of the corridor with a stationary human standing at one end for 30s. Video recorded behaviours included: the number of zones crossed (phase 1), the zones of the human and the animal, and the time the human could see the animal (phase 2), and zones entered and crossed (phase 3).

Cortisol. At 9 months of age, cortisol response to shearing was extracted by radioimmunoassay from blood samples collected 15 min post-shearing.

The recorded data were limited to animals with all information for all behavioural tests. After editing the data, the final dataset included 335 observations/individuals.

Clustering. Clustering of individuals was performed based on important traits identified from the behavioural tests. The hierarchical clustering algorithm was used to cluster animals into sub-classes. The analysis was implemented in R (R Core Team, 2018) using the function '*hclust*' with the Ward D method. The number of clusters was considered to be k=3. Based on the obtained results from arena and corridor tests (Figure 1), animals were classified as: fearful, bold or calm. Animals were also categorised into high (HC), medium (MC), and low cortisol (LC) based on plasma cortisol concentrations. The common animals between behavioural and stress clusters were then plotted using the package of 'ggVennDiagram' in R. Correlation between variables was also calculated in R (R Core Team, 2018).

Results

Figure 2 presents the number of shared animals between behavioural (fearful, bold, and calm) clusters based on the arena (first row) and corridor (second row) tests and their physiological response to stress (cortisol). All clusters of behavioural tests show overlap with different concentrations of plasma cortisol which indicates that there was no relationship between behaviour and cortisol of sheep in the current study.

Discussion

This study demonstrates the performance of machine learning to understand relationships between stress susceptibility and behaviour in sheep. Individuals were categorised into three groups based on behavioural tests, including fearful, bold, and calm animals. Animals were also grouped into three clusters based on

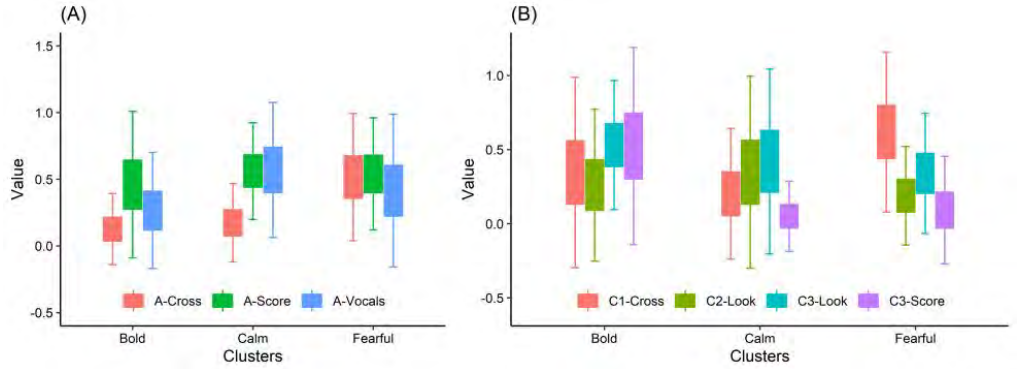

Figure 1. Results of sheep classification using Hierarchical clustering based on selected variables from arena (A) and corridor (B) behavioural tests. Individuals with the same colour belong to the same cluster.

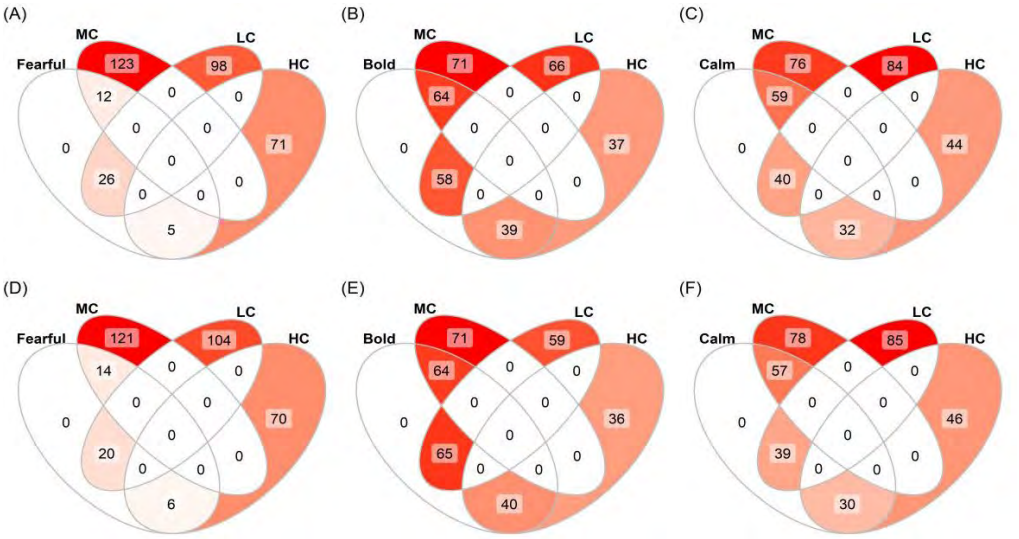

Figure 2. Venn diagram depicting the number of animals in each cluster based on behavioural tests (Arena (first row) and corridor (second row)) vs plasma cortisol, and their overlap. HC, MC, and LC represent high, medium, and low cortisol, respectively.

plasma cortisol responses to stress: high (HC), medium (MC), and low cortisol (LC) concentrations. Venn diagrams were then applied to plot the common animals between stress and behaviour clusters. It was predicted that the behavioural clusters would strongly relate to the stress responses of sheep with a high proportion of shared animals between desired sets (i.e. fearful with HC and bold with LC). This would enable a potential proxy non-invasive behavioural indicator for a more invasive trait (cortisol). However, this was not supported as there was little overlap between the behavioural and stress response clusters. This aligns with the low correlation (-0.16-0.20) between cortisol and behavioural parameters found in the current study. Previous studies have found relationships between physiological measures of stress and behaviour in sheep. For example, high cortisol ewes exhibited fewer bleats (Caroprese *et al.*, 2010) and vocalizations (Diess *et al.*, 2009) and low cortisol responses were associated with reduced fearfulness (Lee

et al., 2014). A possible explanation for the differences in findings may be the different tests and stress measures used. Further studies are needed to determine if other behavioural tests may relate more strongly to physiological stress responses.

Nevertheless, this study demonstrates how the application of ML can be used to gain new insights into the relationship between traits in addition to their potential use to predict (e.g. abortion incidence in dairy cattle (Keshavarzi *et al.*, 2020b)) and cluster individuals into sub-groups based on their behaviour (Teimouri *et al.*, 2018)). This may lead to more accurate behavioural phenotypes for improved welfare in the future.

109. Heritability of social interactions in dairy cattle

L. Rönnegård[1,2*], I. Hansson[1] and W.F. Fikse[3]

[1]Swedish University of Agricultural Sciences, Uppsala, Sweden; [2]Dalarna University, Falun, Sweden; [3]Växa, Uppsala Sweden; lars.ronnegard@slu.se

Abstract

Social interactions in dairy cattle are important to understand since they influence both welfare and disease transmission. We investigated the number of contacts a cow has with other group members closer than 2.5 m. The aim was to quantify how heritable such a trait is and whether cows more related to other cows in the same group have more contacts. Using location data of cows, we quantified the number of contacts between cows and documented in which areas in the barn these interactions occurred. An animal model was fitted using pedigree information from 163 cows in two different milking groups of around 100 cows in each group (group size varied between days). The positions of all cows were recorded once every second to compute the number of contacts. The estimated heritability varied between 0 and 0.20 and was largest in the resting area.

Introduction

Resource-based aggression and sociability are important traits affecting animal welfare for dairy cows. In resource-based aggression, cows approach each other in their competition for resources, such as water or feed (Gibbons *et al.*, 2010; Haskell *et al.*, 2014). Sociability is the willingness to be close to other animals of the same group. Both sociability and resource-based aggression causes cows to be in close proximity to other cows and may be treated as two types of social interactions.

Heritability of social interactions for dairy cows have not been investigated thoroughly. Temperament is a factor that might affect social interactions and is known to be heritable in both beef and dairy cattle (Costilla *et al.*, 2020; Haskell *et al.*, 2014). Nevertheless, there are few, if any, studies on the heritability of social interactions *per se*.

The aim of this study was to estimate the heritability of social interactions in dairy cattle in an indoor environment. To this end, indoor locational data collected every second on all cows over a two-week period were used.

Materials & methods

Data description. Data was collected from a commercial dairy farm in Sweden that housed around 210 lactating dairy cows in a non-insulated free-stall barn. The barn was divided into two milking groups, G1 and G2, where G1 consisted of cows in mid and late lactation and G2 consisted predominately of cows in early and mid-lactation. The pen area was 14×56 m for each group and there were 103 cubicles in G1 and 102 cubicles in G2, with rubber mattresses and sawdust as bedding material. The cows were fed a total mixed ration 12 times a day and had approximately 0.6 m of feed space per cow. The cows were milked twice a day in a milking parlor, and they spent around 1.5 h in the milking parlor during each milking event. Each lactating cow was equipped with a tag mounted on the top of the neck collar connected to a real-time location system (CowView, GEA Farm Technologies, Bönen, Germany) automatically collecting individual positioning data of the cows with one-second fix rate. Raw positioning data were extracted from 16 to 29 October 2020. Individual attribute data such as parity, calving date, and tag-ID were provided by the farm and information about breed, insemination records, pregnancy diagnoses, claw trimming records, and pedigree were extracted from the Swedish official milk recording scheme.

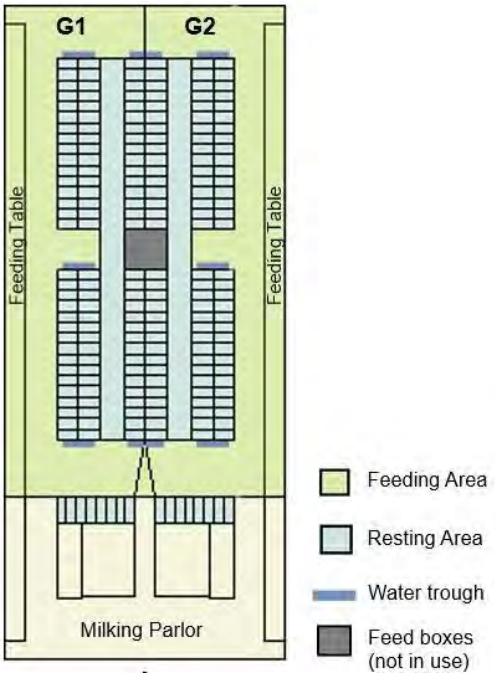

Figure 1. Layout of the barn. Data from two groups were used in the analysis. The late lactating cows (G1) were kept in the half of the barn area depicted by G1 (i.e. the left-hand side), whereas the early lactating cows (G2) were kept in the other half of the barn.

Statistical models. The total duration of contacts for each cow and day was calculated separately for two functional areas in the barn, the feeding area and resting area (Figure 1). The time spent in the two areas were accounted for, as there might be individual variation in time budgets. The response variable was computed as the ratio between total duration of contacts and the time spent in the specific area, and is referred to as the 'average number of contacts'. Cows closer than 2.5 m from each other were defined to be in contact. Contacts that lasted in total less than 10 minutes per day were removed to reduce noise.

Data from the two groups, G1 and G2, were analyzed separately. The response variable was computed for all individuals present on all 14 days using the connections with all individuals present on each day. Both groups were not constant during the study period, and only responses for animals present in the group during the entire period were consider for the subsequent analysis. The number of individuals present in group G1 on all 14 days was 80, and 83 in group G2.

Two linear mixed models with the same explanatory variables were fitted, one for each functional area. Fixed effects were date, parity, lactation stage, breed, pregnancy status, estrus, udder health and claw health, as described in Table 1. Furthermore, level of relatedness was included as a fixed effect nested within breed. The level of relatedness measures how related each cow is with the rest of all the cows in the same group and was computed as the row sums of the additive relationship matrix minus the diagonal element. Random effects were permanent environmental effect and animal effect. The additive relationship matrix was computed, and the model was fitted using the pedigreemm (Vazquez *et al.*, 2010) package in R. Box-Cox transformation was applied to the response variable average number of contacts.

Table 1. Data description of the cows included in the analysis.

Trait	No. of cows in group G1 (n=80)	No. of cows in group G2 (n=83)
Parity		
1	21	23
2	28	22
3	31	38
Lactation stage		
Early (7-49 DIM)	0	17
Mid (50-179 DIM)	16	60
Late (>180 DIM)	64	6

Open	18	47
Udder health		
Low (0-130,000 SCC/ml)	50	58
Mid (130,000-300,000 SCC/ml)	8	11
High (>300,000 SCC/ml)	22	14
Claw Health		
Remark	24	24
No remark	54	58
No information	2	1

Results

The estimated heritabilities were larger in the resting area than the feeding area (Table 2), and the repeatabilities were consistent between groups for each of the two defined areas.

For group G1, in the resting area, the following fixed effects were significant (with $P<0.05$), date and claw health. For group G1, in the feeding area, the following fixed effects were significant: date, breed, pregnancy and lactation stage. For group G2, in the resting area, the following fixed effects were significant (with $P<0.05$), date, pregnancy, estrus and udder health. For group G2, in the feeding area, the following fixed effects were significant, date, parity, lactation stage, and estrus. The fixed effect of level of relatedness was found to be non-significant ($P>0.05$) for both groups and both investigated areas.

Table 2. Estimated heritabilities (h^2) and repeatabilities (r^2) for the two groups in the two different areas. Twice the change in REML likelihood for a model with and without a random animal effect is given as $-2\log LR_{REML}$.

	Group G1			Group G2		
	h^2	r^2	$-2\log LR_{REML}$	h^2	r^2	$-2\log LR_{REML}$
Resting area	0.20	0.47	0.14	0.13	0.50	0.17
Feeding area	0.14	0.35	0.24	0	0.36	0

Discussion

Using a real-time location system, we have computed the number of contacts a cow has with other group members closer than 2.5 m. The estimated heritability for number of contacts varied between 0 to 20% and was found to be largest in the resting area of the investigated commercial free-stall farm. However, for all four models the difference in REML likelihoods (for a model with and without animal effect) were rather low and the estimated heritabilities could not be concluded to be significantly different from 0. Furthermore, we expected cows closely related to other cows in the same group to spend more time together than unrelated individuals. However, the level of relatedness did not have a significant effect on the number of contacts a cow had.

In the current study we constructed social networks to compute the number of contacts each cow had. However, all the information in the social network was not included in the analysis. In terms of social network attributes, we estimated the heritability of social contacts using node attributes (i.e. information on individual cows) as the response variable, whereas an alternative approach is to analyse edge weights (i.e. information on pairs of cows). For instance, suppose there might be a tendency for cows with similar attributes to stay close to each other more often than others, then this is an effect possible to capture in a model with edge weights as response, but not in the model applied in our analysis. In our analysis we focused on whether cows with similar attributes stay close to any cow more often than cows with different attributes. For further information on estimating heritability of social phenotypes in human and wild populations using edge weights, see Radersma (2021).

In our analysis, the social networks were constructed using information on whether a cow was in close proximity to other cows, which does not necessarily capture true social interactions. Also, it would be useful to be able to distinguish between positive and negative social interactions, which is not an obvious task having only positional data. Further investigations are needed on how to define social interactions based on location data.

We do anticipate future studies within this field since social interactions are important to understand for further development of optimal management, welfare, and strategies to counteract disease transmission.

110. Uncertainty about the social network among dairy cows impairs estimation of indirect genetic effects

W.F. Fikse[1*], I. Hansson[2] and L. Rönnegård[2,3]

[1]Växa, Uppsala, Sweden;[2]Swedish University of Agricultural Sciences, Uppsala, Sweden; [3]Dalarna University, Falun, Sweden; freddy.fikse@vxa.se

Abstract

Social interaction among animals living in groups mean that an individual's phenotype can be influenced by conspecifics. One approach for modelling of social genetic effects utilizes intensity of interactions measuring the strength of the interaction. Quantifying the intensity of interactions is not always straightforward, and the aim was to investigate consequences of uncertainty about intensity of interactions. Social networks among 10,000 cows in 100 herds were simulated, and a cow's phenotype was affected by on average five conspecifics. Variance components for social genetic effects were estimated with three different scenarios. Using correct intensities for all conspecifics yielded unbiased estimates. Estimates were still unbiased, but had lower precision, when only one conspecific was included. When intensities were subject to random noise, the variance of the social genetic effect was downwards biased. Hence, estimation of intensity of interactions is of higher priority than identifying all conspecifics for elucidating social genetic effects.

Introduction

Phenotypic performance of animals living in groups is not only affected by their own genetic potential, but also by group mates and their genetic potential. These social effects have been reported to exhibit considerable genetic variation in livestock production species like pigs and poultry (Ellen *et al.*, 2014). Social interactions occur even in dairy cattle (Bouissou *et al.*, 2001), but studies on the genetics of social interactions in dairy cattle are thus far scarce.

The model predominantly used for uncovering social genetic effects assumes that an animals' social genetic effect on its conspecifics is uniform. This model is often applied in the context of animals housed in groups of fixed size and composition. For forest trees, Cappa and Cantet (2008) proposed to consider intensity of competition, in their study quantified as the distance between the focal tree and a neighboring tree. That is, the total additive genetic competition that is exerted over plant i from trees $j_1, j_2, \ldots j_m$ equals $\sum_{j=1}^{m_i} f_{ij}\boldsymbol{a}_{c,j}$, with $a_{c,j}$ being the social genetic effect of tree j, and f_{ij} the intensity of competition (or more neutrally, intensity of interaction) between tree j and i. The intensity can be interpreted as a weighting factor that expresses how intense pairs of individuals interact in relation to all other individuals in the group. Angarita *et al.* (2019) applied this model to group-housed pigs and defined the intensity as the total time of aggressive interactions that took place between the pair of animals over a 9-h period after groups were created.

Social networks in dairy cattle are dynamic (Bouissou *et al.*, 2001), as cows enter and leave the barn in relation to calving and drying off and because the behavior may change over time, for example when time spent feeding alters due to different energy requirements across the lactation (Løvendahl and Munksgaard, 2016). Real-time location systems can provide detailed information about the position of cows in the barn and can be used to determine how long a cow is in the proximity of other cows. Such data can be used to construct network graphs (Chopra *et al.*, 2020), but it remains uncertain whether these accurately reflect the true social network since proximity can occur for reasons other than social interactions.

Data structure has been shown to be of importance for estimating social genetic effects (Cappa and Cantet, 2008). The aim of the present study was to investigate, by simulation, how uncertainty about social networks affects estimation of variance components for social genetic effects in dairy cattle scenario.

Methods

Phenotypes for a conceptional trait were simulated for 10,000 females in 100 herds. Within each herd, half of the females were descendants of 5,000 base population females and were offspring to the other half of the females in the herd. All females were randomly assigned a sire out of 200 unrelated sires, each having 50 female progenies.

For each animal, two genetic traits were simulated: a direct genetic effect and a social genetic effect, assumed to follow a normal distribution, ~ N(0, A $\otimes$ G), where A is the numerator relationship among individuals and G the variance-covariance matrix among traits. The variance of the direct and social genetic effect was 2 and 1, respectively, and the genetic correlation between both traits was set to 0.18.

A social network was generated within each herd. First, the number of conspecifics an animal had interactions with (degree) was generated from a normal distribution (~ N(5,4)). Next, a random social network was generated with the sample_deqseq() function of the igraph package (Sardi and Nepusz, 2006), using the degrees as input. Lastly, for each contact the intensity was sampled from a gamma distribution with parameters 1 (shape) and 2 (rate).

The phenotype for each female was generated as the sum of the direct genetic effect, the product of the intensity and the social genetic effect of all conspecifics the animal had contact with, and a random residual (with variance 2.5). The total heritable variation was about 2.5.

Variance components were estimated using DMU (Madsen *et al.*, 2014) for three different scenarios:

1. Using true intensities for all conspecifics the animal interacted with.
2. Using true intensity for just one (randomly chosen) conspecific the animal interacted with.
3. Using imprecise intensities for all conspecifics the animal interacted with. The imprecise intensities were generated by adding random noise (~ N(0,0.04)) to the true intensities.

The simulation was repeated 25 times and the mean and SD of estimated variance components are presented.

Results

Estimates of variance components were unbiased when true intensity for all conspecifics were included in the analysis (Table 1). When only one conspecific was assumed known, and with the correct intensity, estimates of genetic (co)variances were still unbiased but had lower precision. The social interactions unaccounted for when most conspecifics were presumed unknown caused an overestimation of the residual variance. Using imprecise intensities resulted in an underestimation of the variance of social genetic effects and an overestimation of the residual variance.

Discussion

Constructing a social network of dairy cows in a barn is not an easy task, even with modern technology continuously monitoring dairy cows in a barn. Processing data from real-time locations systems on the position of a cow in the barn and extracting information about the social network requires separating real social interactions from proximity because of other reasons (Chopra *et al.*, 2020). Similar challenges exist if cows are recorded with video. Our results indicate that imprecise information on intensity of interaction results in more problems in variance component estimation than missing information. Studies like these can serve as guidance what to prioritize in constructing social network for elucidating genetics of social interactions.

Table 1. Mean and SD of estimated (ratio of) variance components (vDGE = variance of direct genetic effect, vSGE = variance of social genetic effect, rG = genetic correlation between direct and social genetic effect, vE = residual variance).

	vDGE		vSGE		rG		Ve	
	Mean	**SD**	**Mean**	**SD**	**Mean**	**SD**	**Mean**	**SD**
Simulated	*2.00*		*1.00*		*0.18*		*2.50*	
Scenario 1	1.99	0.12	1.00	0.04	0.18	0.03	2.51	0.10
Scenario 2	2.00	0.15	0.99	0.10	0.18	0.07	4.43	0.16
Scenario 3	1.99	0.12	0.88	0.04	0.18	0.03	2.63	0.10

Scenario 1 = using true intensity for all conspecifics, Scenario 2 = using true intensity for just one conspecific, Scenario 3 = using imprecise intensity for all conspecifics.

The simulated network was a simple, random, symmetric network. Social networks of dairy cows are more complex in practice. Social interactions between cows can be positive or negative, are influenced by familial relationships and familiarity of the cows and can depend on cow attributes like stage of lactation or parity number (Bouissou *et al.*, 2001). Also, the present simulation assumed the degree (number of contacts) to be identically and independent distributed, whereas one can envision that it has a heritable component.

A social network can mathematically be represented as a distance matrix, where each element describes the intensity of the contact between a pair of individuals. This representation relates very well to the model for social genetic effects based on intensity of contacts. This model allows for different number of conspecifics per individual and for non-symmetric networks (where the social interaction effect of individual i on individual j can be different from the effect of individual j on individual i). Extension to consider repeated observations for the trait, for example multiple test-day yields, is easily accomplished. By specifying different intensities for different observations on the same individual, the dynamics of social networks over time can be accommodated for.

Conclusions

Uncertainty in the social network will affect estimation of variance components for a social genetic effects model. Not being able to identify all conspecifics resulted in unbiased estimates, albeit with lower precision. Hence, precise estimation of intensity of interactions is of higher priority than identifying all conspecifics an animal interacts with in constructing social networks for genetic analyses of social effects in dairy cattle.

111. Genetic and phenotypic variation and consistency of cow's preference and circadian use of robotic milking units

P. Løvendahl and A.J. Buitenhuis*

Center for Quantitative Genetics and Genomics, Aarhus University, AU-Foulum, 8830 Tjele, Denmark; bart.buitenhuis@qgg.au.dk

Abstract

Many dairy herds use automatic milking stations (AMS) and in large herds, cows usually have access to two or more AMS, and consequently must make a choice between them whenever they go for milking. For this study, we assume that the degree of using the same milking box is an expression of preference. We used a total of 4,665 cows from a Holstein and a Jersey cohort covering 12 commercial dairy herds in Denmark to estimate heritability, repeatability and individual level correlations between preference choice score (PCS), Time_profile (preference for specific clock hours) and associated milking and behaviour traits. The average PCS was 0.43 (Holstein) and 0.41 (Jersey), respectively. Both PCS and Time_profile had low heritability (0.07/0.11 Holstein, 0.13/0.04 Jersey) and moderate repeatability (0.47/0.40 Holstein and 0.50/0.42 Jersey) and were weakly correlated to each other (Holstein 0.18 and Jersey 0.17) and weakly correlated to milk yield (r_i range 0.0 to -0.10).

Introduction

Dairy cows have been subject to intensive genetic selection for production traits for decades, and many cows are living in housed environments interacting with the confinements of housing, and with various automated installations, including robotic milking machines. In these modern dairy herds cows are making a number of choices every day. For example, at milking cows form an order of entry to milking parlours, and through their use show preference to their favourite side of the milking parlour (Hopster *et al.* 1998). When accessing automated milking stations (AMS, milking robots), they may acquire a routine with preference for a specific one, or be more flexible. If such routines are long lasting, it indicates a degree of consistency, which may have a genetically determined component (Koolhaas and Van Reenen, 1999; Løvendahl *et al.*, 2016). Similarly, cows may develop routines or preferences for being milked at specific hours of the day. The consistency of these routines are sometimes very strong, and the strength of it was shown to be both an acquired feature, but also to include some genetic variation (Løvendahl *et al.*, 2016). However, little evidence is available on how different aspects of behaviour at robotic milking are related, and how these relate to key production traits at the phenotypic and the genetic level. The aim of the present study was to investigate preference consistency, in Holstein and in Jersey cows having access to two, three or four milking boxes, and their use of time of day to be milked, for repeatability over time and for genetic variation, and eventually for correlation to milk yield and time spent in the milking box. The quantitative genetic study was based on records from commercial dairy herds in Denmark.

Materials & methods

Overall design, herds and cows. This investigation was conducted as a cohort study using robotic milking data from 12 Danish dairy herds, having either Jersey or Holstein cows of mixed parities (1-5) between October 2014 and September 2019. There were 2,407 Jersey cows with 28,952 records and 2,258 Holstein cows with 31,290 records. Cows were kept in groups having access to either 2, 3 or 4 milking boxes with free cow traffic, so that cows had a choice at every milking visit. The genetic relationships between cows within each breed was known and traced back 5 generations through the NAV database (NAV, SEGES, Skejby, Denmark). The Hostein pedigree consisted of 20,229 and the Jersey pedigree consisted of 14,543 animals. This study used non-invasive production data and was therefore exempt from animal experimental ethical approval.

Milking data recording. At each milking the time of entry and exit from robot was recorded together with milk yield. From these data the time spent in the milking box (Boxtime, minutes) was calculated. The interval between milkings were expressed as milking frequency (i.e. milkings per 24 h, MilkFreq), because cows have voluntary access to milking boxes and thereby will have variable milking intervals. Milk composition data to calculate the energy corrected milk (ECM) (Sjaunja *et al.* 1990) was measured through the national recording organization RYK (RYK, Skejby, Denmark) at the Eurofins laboratory (Eurofins, Vejen, Denmark).

Milking box preference consistency score calculations. Preference consistency score (PCS) was calculated based on frequency of access's to each of the milking units in a given time period, here chosen at 15 days ('segment'). Cows accessed milking boxes voluntarily so it is assumed that the box being visited most frequently is the preferred one. If all boxes were equally used the frequency of first choice will be equal to 1/number of choices. The PCS is then calculated using:

$$PCS = (Actual_fraction - (1/number\ of\ choices)) / (1 - (1/number\ of\ choices)) \quad (1)$$

Diurnal milking time profile. The time profile of being milked at specific times of the day was here estimated based on frequency of milkings at each hour of the day, condensed in a single number indicating the variation. It was assumed that in case a cow has no hour-preference, the frequency in each hour-bin is equal to all other hour-bins. In contrast, if all or most milkings will fall into one or a few hour-bins, the deviation from equal use of hour-bins will be large. In between these extremes will be a continuum of intermediate cases. The deviation from equal frequency in all hour-bins was quantified using a Chi-square goodness-of-fit approach, and log-transformed to obtain an approximate normal distribution, better suited for analysis of variance.

Statistical models and parameter estimates. Variance-covariance components were estimated within breed across lactation using uni- or bi-variate models in DMU software package (DMU version 6 Release 4.7; Madsen and Jensen, 2008):

$$y = Xb + Z_{pe}a_{pe} + Z_g a_g + Ie \quad (3)$$

where y is the vector of observed traits, b is a vector of fixed effects of herd-year-season, number of AMS units (2, 3 or 4), parity-group (first, second or older=3-5), segment (1-20) by parity interaction. The matrix X contain the design of the fixed effect factors. The random effects are the additive genetic effect of cow (a_g), the permanent (cow) environmental effect across segments (a_{pe}) and the random error effect (e).These have incidence matrices Z_g being the relationship A-matrix and Z_{pe}, being incidence cow within parity. I being the identity matrix and e the random error term. Random (co)variance components were assumed independent following a normal distribution $N(0,\sigma_a^2)$, $N(0,\sigma_{pe}^2)$, and $N(0,\sigma_e^2)$. Genetic parameters were calculated from (co)variance estimates with associated asymptotic standard errors.

Results

The use of available milking boxes differed among cows, because some cows almost entirely used just one box while other cows spread their milkings over all available boxes. This was effectively quantified by the PCS, with values ranging between zero and 1.0, and an overall mean of 0.43 (sd=0.28) and 0.41 (sd=0.27) in Holstein and Jersey cows. This value is clearly larger than zero, where a zero value would indicate even use of all boxes. First parity Jersey cows had the highest PCS followed by first parity Holstein, and lowest values were found in the group of older Jersey cows. The PCS decreased with age in Jersey cows, but remained at similar level for all ages in Holsteins. The Time_profile varied among cows, and high values show that

some cows make most of their milkings during few clock hours, whereas the variation show that other cows spread their milkings over several clock hours. The first parity Jersey cows, and to a lesser degree, the first parity Holstein cows condensed their milking events into fewer clock hours than older cows of both breeds. There was a general trend for the time profile to increase gradually during progression of lactation, and Jersey cows had always a slightly higher Time_profile score than Holsteins. The milking frequency increased during early lactation for young cows of both breeds, and then decreased gradually from about 100 DIM. In contrast, milking frequency decreased throughout lactation in all groups of older cows. The time spent in the milking box increased in early lactation for all breed and age groups, and then declined after reaching a peak at around 50 DIM. Heritability estimates for the behavioural traits and ECM are presented in Table 1.

The genetic and the individual level correlations between PCS and Time_profile (r_i ~ 0.10 to 0.18) showed that cows who more consistently use a given milking box, also tend to have a stronger Time_profile, i.e. be milked more often at the same time of the day. Those cows that are more consistent also have somewhat lower milking frequency (r_i ~ -0.18 to -0.16). However, consistency seem almost unrelated to total daily time spent in the milking box and neither to milk yield. Individual cows who show a stronger Time_profile were also spending less time in the milking box, and may have slightly lower milk yield (r_i ~ -0.10). High milk yield was weakly related to Time_profile and even less to PCS, but positively with higher milking frequency and with more time per day spent in the milking box. Overall, the phenotypic correlations closely resembled the individual level correlations and correlations in the Jersey cows were almost similar to those obtained in Holsteins.

Discussion

Dairy cows entered the milking box on around 3 times per day in this study, and each time they had to wait for a vacant box, either being their favourite one, or another one of at least 2, and often 3 or 4 boxes. There were no obvious reasons for cows to prefer a specific box in general, as the available boxes within a group were used almost equally much, as also found in a previous study (Løvendahl *et al.*, 2016). Assuming a specific cow had a preferred box she would have to wait until it was available, or to choose one of the other boxes. In the waiting area, she could also chase other cows away from the queue to get access to her preferred box. In this context, we interpret higher use of a specific box as preference and measure it over a short period of 15 d. In case only two possible choices are available this is reasonably simple, and a

Table 1. Estimates of heritability and repeatability for milking behaviour consistency traits in Holstein and Jersey cows, across whole lactation.

Trait[1]	Breed	Heritability (h^2±SE)	Repeatability (t±SE)

	Jersey	0.10±0.03	0.68±0.01

[1] PCS: preference consistency score; Time_profile: use of hours at specific time of the day; ECM: Energy Corrected Milk.

'consistency score' can be used (Hopster *et al.* 1998, Løvendahl *et al.* 2016). However, for this study some cows had 2 boxes, others had 3 or 4 boxes to choose between, so in order to adjust for number of choices an adjustment of the consistency score was implemented. This adjusted score, now called a preference consistency score PCS gave values between zero and 1.00 based on how many of the milkings were on the most frequently used box. One should note that the PCS itself resembles a repeatability coefficient, but here used as a response variable.

This study showed that differences between cows in use of specific milking boxes are repeatable and to some degree also heritable. This extends earlier findings from a preliminary study only in Holsteins and only in herds with two milking boxes (Løvendahl *et al.*, 2016), to include many more cows and two breeds, and situations also comprising 3 or 4 milking boxes.

This study was primarily designed to quantify genetic and phenotypic co-variation in milking behavior traits as possible correlated response to selection for production, but not to include these traits in selection programs. Although more than 4,600 cows provided data, genetic correlations had large standard errors, whereas individual level correlations were used as proxies and gave similar results for the two breeds. Obtaining even larger cohorts or using genomic information may help resolve this problem in some future studies.

Abstract

Calving difficulty is an important trait in dairy production, as it affects profitability and animal welfare. Environmental factors and genetic parameters on maternal calving difficulty (MCD) were estimated for South African Holstein cattle using data from the National Milk Recording Scheme. The original data set comprised of calving records of 10,495,603 of cows 192,052, in 14 herds that calved between 1949 and 2018. Environmental effects were tested by the General Linear Models (GLM) procedure of the Statistical Analysis System. Maternal heritability for calving difficulty in the first three lactations was estimated by the ASReml software, using linear animal and repeatability animal models. Sex of calf, parity, herd-year-season and age of dam at calving had significant effects ($P<0.05$) on MCD. Heritability estimates for MCD were low, ranging from 0.04±0.09 in second parity to 0.12±0.10 in third parity. Both estimates of heritability and repeatability of MCD across parities were the same in magnitude (0.04±0.04). Despite the low heritability estimates, these results provide the basis for developing genetic prediction models for MCD in South African Holstein cattle.

Introduction

Calving difficulty (dystocia) is a reproductive trait of outstanding importance in dairy cattle (Abdela and Ahmed, 2016). Along with calf and cow mortality, it results in economic losses due to increased labour and veterinary costs, and other management expenses (Kaya *et al.*, 2015). Difficulties during parturition also affect long-term animal performance through health issues, fertility problems, reduced production, and involuntary culling (Abdela and Ahmed, 2016; Bujko *et al.*, 2018). Dystocia is also a welfare problem, as it causes pain and injury to the cow, which directly leads to poor cow welfare (Abdela and Ahmed, 2016). Furthermore, calving-related infections indirectly affect human health, as they require increased use of antibiotics, which contaminate the cow's milk, leading to possible microbial resistance (Silvestre *et al.*, 2019).

Proper herd management practices may alleviate the effects of dystocia (Newman, 2008); however, several studies have demonstrated that genetic selection for better calving difficulty, is a better option in the long term (Alam *et al.*, 2017). Calving difficulty, along with other functional traits, is becoming increasingly important in dairy cattle breeding objectives worldwide (Egger-Danner *et al.*, 2015).

In South Africa, calving performance traits are currently not included in the national genetic evaluation programme for dairy cattle, and genetic parameter estimates for these traits are not available. Therefore, the primary aim of this study was to estimate environmental and genetic influences on maternal calving difficulty in South African Holstein cattle, in order to develop models for genetic prediction of the trait.

Materials & methods

Data. Data comprised of 14,250 calving records of 8,832 cows from 14 herds participating in the National Milk Recording Scheme, that calved between 2009 and 2018, after editing. Calving difficulty was measured as a binary trait, with animals experiencing a difficult calving being scored 1, and those having a normal calving being scored 0. The pedigree file consisted of 27,091 animals, and was built based on consideration of animals with calving records and going three generations back.

Statistical analysis. Non-genetic effects on MCD were tested by a fixed effects model, using the General Linear Models (GLM) procedure of SAS (SAS Institute, 2012).

The heritability of MCD for each parity was estimated by applying the following model Equation 1, using the ASReml 3.0 software (Gilmour *et al.,* 2015). Only maternal effects of MCD were included in the model:

$$y = Xb + Za + e \quad (1)$$

Where, y is the vector of observations for calving difficulty (0=normal, 1=difficult); b is the vector of fixed effects (herd-year-season and calf sex); a is the vector of random additive genetic effects of the cow; X is the incidence matrix relating observations to fixed effects; Z is the incidence matrix relating observations to random additive genetic effects; e is the vector of random residual effects.

Heritability and repeatability across parities were estimated by the following model Equation 2, using the ASReml 3.0 software (Gilmour *et al.,* 2015):

$$y = Xb + Za + Wpe + e \quad (2)$$

Where y, X, Z, a and e are the same as in Equation 1, b is the vector of fixed effects (herd-year-season, calf sex and parity), pe is a vector of permanent environmental effects and W is an incidence matrix relating observations to permanent environmental effects.

Results & discussion

Incidence of calving difficulty was significantly higher ($P<0.05$) for male (14%) than female (12%) calves (Figure 1A). This is a widely observed fact (Atashi *et al.*, 2012; McHugh *et al.*, 2014) and is attributable to the fact that male calves are generally bigger in size than females, which may put more strain on the dam's birth canal during parturition. First-parity cows had a significantly higher ($P<0.05$) incidence of calving difficulty (16%) than second-parity (11%) and third-parity (11%) cows (Figure 1B). Calving assistance has been mostly found to be higher in first-parity than in later-parity calvings, and calving complications occur more in heifers than in cows (Eaglen *et al.*, 2012; Ghafariania *et al.*, 2014). This may be attributable to poor pelvic development in 2-year-old heifers which often is not fully compensated by a smaller calf (Kebede *et al.*, 2017). Herd-year-season and age of dam at calving also had significant effects ($P<0.05$) on maternal calving difficulty, in agreement with other studies (e.g. Vallée *et al.*, 2013).

Heritability estimates for MCD in the first-three parities are presented in Table 1. Estimates were low, ranging from 0.04±0.09 in second parity to 0.12±0.10 in third parity, with an overall estimate of 0.04±0.04 across the parities. Comparable estimates have been reported in previous studies (Jamrozik and Miller, 2014; Alam *et al.*, 2017) and suggest low accuracy of selection for MCD. However, a study by Vostrý *et al.* (2014) reported higher heritability estimates, ranging from 0.23 to 0.43 in Czech Charolais cattle. Discrepancies in heritability estimates for calving difficulty may be attributable to the manner in which the trait is measured and the statistical models used. In some cases, calving difficulty is scored on a scale of up to 5, unlike the

Figure 1. Incidence of calving difficulty by calf sex (A) and parity (B) in Holstein cows (means (%) of calving difficulty with different superscripts differ significantly at $P<0.05$).

Table 1. Heritability estimates of maternal calving difficulty within and across first-three parities in Holstein cows.

Parity	Heritability ± standard error
1	0.10±0.04
2	0.04±0.09
3	0.12±0.10
All	0.04±0.04

binary measurement used in the current study. Analysis of calving ease with linear models has been found to yield additive genetic variance estimates that are consistently smaller than those obtained with threshold models (Silvestre *et al.*, 2019). A low repeatability estimate of 0.04±0.04 was observed for MCD across the first three parities, which is comparable to those reported in Iranian Holstein cows (Ghiasi *et al.*, 2014). Thus, first parity records may not be used reliably to predict calving performance in later parities.

Conclusions

Sex of calf, parity, herd-year-season and age of dam at calving are significant sources of variation in maternal calving difficulty and, therefore, should be included in models for genetic analysis of MCD. Low heritability estimates suggest poor accuracy of selection on MCD in South African Holstein cows. Further research needs to be conducted, to explore methods of improving accuracy of selection. This may include marker assisted selection or promoting the large-scale recording of calving performance on South African herds, using clear guidelines and standards.

113. Genetic evaluation of gestation length in Italian Holstein breed

F. Galluzzo[1*], J.B.C.H.M. van Kaam[1], R. Finocchiaro[1], V. Ferrari[1,2], M. Marusi[1] and M. Cassandro[1,2]

[1]Associazione Nazionale Allevatori della Razza Frisona, Bruna e Jersey Italiana (ANAFIBJ), Via Bergamo 192, 26100 Cremona (CR), Italy; [2]Department of Agronomy, Food, Natural resources, Animals and Environment (DAFNAE), University of Padova, Viale dell'Università 16, 35020 Legnaro (PD), Italy; ferdinandogalluzzo@anafi.it

Abstract

Gestation length (GL) affects both the cow and the newborn calf. Genetic components of GL are both direct and maternal, meaning that both the calf (direct effect) and the cow (maternal effect) genotypes contribute to determine it. The objective of this study was to define how much of the direct and maternal components is heritable in the Italian Holstein population and to estimate breeding values. A multiple-trait repeatability linear animal model was defined, considering first and later parities as different traits. The heritability of the direct effect was 0.44 (posterior standard deviation: 0.004) for first parities and 0.36 (0.003) for later. The heritability of maternal effect was 0.09 (0.001) for first parities and 0.06 (0.001) for later. In conclusion, the possibility of selecting for GL was confirmed. Further analyses will be performed in order to quantify the economic importance of GL and to identify its relationship with other traits.

Introduction

GL affects both the cow and the newborn calf and the effects come both from the calf's (direct effect) and the cow's (maternal effect) genotypes (Norman *et al.*, 2009, 2011; Eaglen *et al.*, 2013). As nowadays the importance of reducing costs has become crucial in farm management, a deep investigation on the possibility to select for GL and its effects on other economically important traits is needed.

Materials &methods

Data and data editing. Data came from the Italian National Breeders Association (AIA) and consisted of 24,705,045 calvings of Holstein cows. From the original dataset, only calvings from 2004 onwards and with a GL between 260 and 305 days were kept. Furthermore, only animals with both parents known were used. Records from embryo-transfer or multiple births were deleted. Regarding parity, only observations coming from cows with up to 10 calvings were analyzed. Age at parity had to be between 18 and 45 months for primiparous and between 33 and 240 months for multiparous. In order to have an effective comparison between contemporaries for herd-year-season of calving (HYS), groups with less than 20 observations were excluded. The pedigree went up to four generations. Below, in Table 1, the description of the final dataset.

Table 1. Description of the dataset.

Parameter	Value	Parameter	Value
Number of observations (calves)	6,620,306	Observations/HYS[1]	41.90
Number of dams	3,388,361	Male calves – frequency	0.49
Observations/dam	1.95	Female calves – frequency	0.51
Number of herds	6,061	Mean GL[2] male calves – days	279.03 (6.12)
Observations/herd	1,092.28	Mean GL[2] female calves – days	278.05 (5.85)
Frequency parity 1	0.36	Mean GL[2] parity 1 – days	277.71 (5.97)
Frequency parity 2+	0.64	Mean GL[2] parity 2+ – days	278.991 (5.97)
Number of HYS[1]	157,998	Number of records in pedigree	9,389,954

[1] HYS: Herd/Year/Season class.

Statistical model. The genetic evaluation was based on a multiple trait repeatability linear animal model, considering first parities and later parities as different traits. Fixed effects were selected with a stepwise approach using SAS PROC GLM (SAS Institute Inc., Cary, NC, 2017).

The defined model for first parity cows is described in Equation 1:

$$Y_{ijklmn} = HYS_i + SEX_{jk} + AGEC_l + a_m + d_n + e_{ijklmno} \quad (1)$$

with Y_{ijklmn} as the phenotypic observation of GL in days, HYS_i as the fixed effect of HYS i, SEX_{jk} as the fixed effect of sex j of the newborn calf within year of birth k, $AGEC_l$ as the fixed effect of age at calving l, a_m as the random direct additive genetic effect for calf m, d_n as the random maternal additive genetic effect of dam n and $e_{ijklmno}$ as the residuals. Regarding first parity cows, the fixed effect of sex was considered within year of birth because of the increasing use of sexed semen in the last years.

The defined model for later parity cows is described in Equation 2:

$$Y_{ijklmn} = HYS_i + SEX_j + P_k + mpe_l + a_m + d_l + e_{ijklmn} \quad (2)$$

with SEX_j as the fixed effect of SEX j of the newborn calf, P_k as the fixed effect of Parity k (2,3,4,5+), mpe_l as the random maternal permanent environment effect of dam l, a_m as the random direct additive genetic effect for calf m, d_l as the random maternal additive genetic effect of dam l and e_{ijklmn} as the residuals. For later parities, maternal permanent environment was considered because of the presence of across-lactations repeated records.

Estimation of genetic parameters. Variance components estimation was performed with the Gibbs sampler THRGIBBS1F90 (Misztal *et al.*, 2002), which handles linear traits as well as categorical. The analysis was performed on the entire dataset, with 90,000 iterations, a burn-in of 45,000 and a thinning rate of 10. Post-Gibbs analysis was performed using the software POSTGIBBSF90 (Misztal *et al.*, 2002) using the remaining 4,500 samples. Convergence was assessed visually.

For primiparous, the direct and maternal heritabilities were calculated as described in Equation 3 and Equation 4 respectively:

$$h_d^2 = \frac{\sigma_a^2}{\sigma_a^2+\sigma_d^2+\sigma_e^2} \quad (3)$$

$$h_m^2 = \frac{\sigma_d^2}{\sigma_a^2+\sigma_d^2+\sigma_e^2} \quad (4)$$

with h_d^2 as the direct heritability, h_m^2 as the maternal heritability, σ_a^2 as the direct additive genetic effect variance, with σ_d^2 as the maternal additive genetic effect variance and σ_e^2 as the residual variance.

As an animal model with repeated measures, the heritabilities for multiparous were calculated as described in Equation 5 and Equation 6 respectively:

$$h_d^2 = \frac{\sigma_a^2}{\sigma_a^2+\sigma_d^2+\sigma_{mpe}^2+\sigma_e^2} \quad (5)$$

$$h_m^2 = \frac{\sigma_d^2}{\sigma_a^2+\sigma_d^2+\sigma_{mpe}^2+\sigma_e^2} \quad (6)$$

with σ_{mpe}^2 as the maternal permanent environment effect variance and σ_e^2 as the residual variance.

Breeding value estimation. Breeding values (BVs) were estimated with MiX99 (Lidauer *et al.*, 2019) and expressed on a scale with mean of 100 and standard deviation of 5: values higher than the mean refer to individuals that transmit a longer gestation period.

Results

Estimation of genetic parameters. For first parities, post-Gibbs analysis gave a posterior mean (PM) of 0.44 (0.004) for direct heritability and 0.09 (0.001) for the maternal one. For later parities, the PM for direct heritability was equal to 0.36 (0.003) and 0.06 (0.001) for the maternal. The genetic correlation between the direct and maternal GL was equal to -0.50 for first parities and -0.22 for later parities. The genetic correlation between parities was equal to 0.92 for the direct component and 0.85 for the maternal one.

Genetic trend. The genetic trend by bulls' year of birth for direct and maternal effects of GL is represented in Figure 1 and reflects their negative genetic correlation. While direct GL shows a decreasing trend, the maternal one shows a slight increase, especially for first parities over the last 20 years. The decreasing trend of the direct effect may be explained by the negative correlation of direct GL BVs with production traits' BVs (unpublished data): selection for production may have led to such trend.

Conclusions

Heritability estimates, mainly the direct components, confirmed the possibility to select for GL. The genetic correlations between parities showed that first and later parities should be treated as different traits in the genetic evaluation for GL. The genetic correlation between the direct and the maternal components showed, for both traits, the antagonistic relationship between the effect of calf and dam genotypes. The estimation of the genomic breeding values for GL is in progress. Further studies will be led to define how GL relates with other economically important traits, to identify its optimum value and to investigate the possibility to include GL in the genetic evaluation for calving traits.

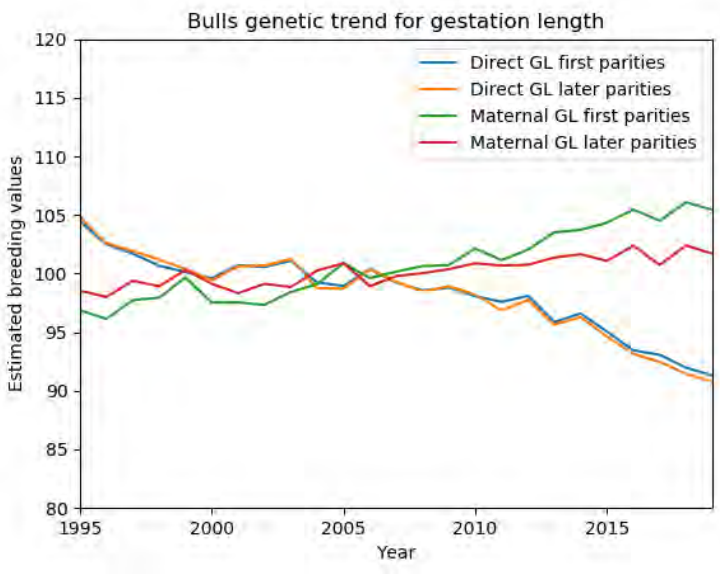

Figure 1. Direct and maternal gestation length (GL) genetic trend by year of birth.

114. Genetic evaluation of cystic ovarian disease in Czech Holstein cattle

E. Kašná*, L. Zavadilová and Z. Krupová

Institute of Animal Science, Přátelství 815, 10400 Prague, the Czech Republic; kasna.eva@vuzv.cz

Abstract

We estimated the genetic parameters and genomic breeding values for cystic ovarian disease (COD) resistance. We used data of 30,729 Holstein cows recorded by Czech farmers between 2017-2021. We conducted pedigree- and genomic-based evaluation. Estimated heritability was small (h^2=0.02). Breeding values were normally distributed. Their reliability increased with added genomic information evaluated with single-step genomic method. This increase was the highest in genotyped cows, where the mean reliability increased threefold. Genetic trends showed gradual improvement of resistance to cystic ovarian disease in Czech Holstein cows. The study was supported by the Ministry of Agriculture of the Czech Republic, project NAZV QK1810253 and institutional support MZE-RO0718.

Introduction

Cystic ovarian disease is economically significant ovarian dysfunction as it increases days open, treating costs and culling due to infertility (Kelton *et al.*, 1998). Its incidence has been reported to vary between 1 and 30% in dairy herds (Kelton *et al.* 1998, Vanholder *et al.* 2006). COD occurs most often during the early postpartum period when there is a transition from the non-cyclic condition (pregnancy) to the establishment of regular cyclicity. It develops when one or more follicles fail to ovulate, they do not regress but maintain growth and steroidogenesis (Vanholder *et al.*, 2006). The primary cause of ovarian cyst development is not clearly established, but the most widely accepted hypothesis is that COD results from a neuroendocrine imbalance involving the hypothalamic-hypophyseal-gonadal axis (Hooijer *et al.* 2001). The possible causes of this imbalance may include stress, herd management, nutritional status, body condition and infectious disease (Silvia *et al.* 2002).

COD is usually defined as the presence of one smooth, rounded structure of more than 20-25 mm in diameter on one or both ovaries persisted for up to 10 days without luteal tissue (Kelton *et al.* 1998). Estimates of COD heritability are usually lower than 0.10 and vary according to the data set and applied method (Jamrozik *et al.* 2021, Koeck *et al.* 2014, Heringstad 2010, Hooijer *et al.* 2001). Studies of genetic correlation showed an unfavourable association between COD and milk production traits (Hooijer *et al.*, 2001, Koeck *et al.* 2014) which indicates that selection on better milk performance would lead to increased COD frequency.

In the Czech Republic, the data on dairy cows' health traits are recorded voluntarily by farmers since July 1, 2017. Data are recorded to the national cattle health database via web application with implemented key of diagnoses based on ICAR recommendations. In 2021, a national genomic evaluation of clinical mastitis was introduced for Czech Holstein cattle (Zavadilová *et al.* 2021). The implementation of genetic-based selection of another health traits, such as reproductive disorders, is actively investigated. The objective of this study was to perform pedigree and genomic-based analysis of COD in Czech Holstein cattle using traditional BLUP and ssGBLUP (single-step genomic BLUP) approaches.

Materials & methods

Data. Data on COD were retrieved from national database of health traits (Czech Moravian Breeding Corporation). COD was scored as 0 (no case) or 1 (at least 1 case) in the period from 30 to 305 days after

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_114, © E. Kašná *et al.* 2022

calving. We included only lactations started between July 1, 2017, and October 31, 2021. Herds with lower than 1% COD incidence were excluded. The data set comprised 47,407 lactations from 30,729 Holstein cows producing in 80 herds.

Pedigree information was retrieved from the national database (Plemdat Ltd.). Genomic data were provided by the Holstein Cattle Breeders Association of the Czech Republic. Animals were genotyped with the Illumina Bovine SNP50 BeadChip (50K, Illumina Inc., San Diego, CA). The genotyped population for the single-step method included 5,394 bulls and 30,095 cows born between 1973 and 2021.

Genetic evaluation model. Single trait animal model was employed for data analysis. The model equation was:

$$y = X\beta + Z_{pe}pe + Z_a a + e, \quad (1)$$

where y is a vector of COD observations (0 – no case, 1 – at least one case in the period from 30 to 305 days after calving); β is a vector of systematic effects (including HYS = fixed effect of herd-year-season with 235 classes; Par = fixed effect of parity of cow with three classes, 1-first, 2-second, 3-third and later); pe is a vector of random cow's permanent environment effect where pe ~ $N(0,I\sigma_{pe}^2)$ with σ_{pe}^2 the permanent environment variance, a = is a vector of random additive genetic effects where a ~ $N(0,H\sigma_a^2)$ with σ_a^2 the additive genetic variance; and e is a vector of random residual errors, where e ~ $N(0,I\sigma_e^2)$, with σ_e^2 the error variance. X, Z_{pe} and Z_a are the corresponding incidence matrices. H is a modified genetic relationship matrix that combines pedigree-based A and genomic-based G relationship matrices. The significance of fixed effects was examined in the preliminary least square analysis (procedure GLM; SAS 9.4.). The variance components estimation was conducted using an AIREML approach; conventional breeding values (EBV) were estimated using the BLUP approach; genomic breeding values (GEBV) were predicted using the ssGBLUP approach, and reliabilities calculated with ACCF90GS program, as implemented in the BLUPF90 family of programs (Misztal *et al.* 2018).

Results

The incidence of COD in Czech Holstein cows was 8.1%. The herd incidence varied between 1.0 and 32.0%. The incidence was lower in primiparous (6.6%) compare to older (8.9%) cows ($P<0.001$). The incidence was higher

Variance components estimation gave phenotype variance $\sigma_p^2=0.069$, and additive genetic variance $\sigma_a^2=0.001$, which led to the heritability $h^2=0.02$. The variance due to permanent environmental effect was twice as high as the additive genetic variance. EBV distribution was close to normal with mean 0.008 and SD 0.012 for EBV and 0.202 for GEBV.

Mean reliabilities of breeding values (Table 1) were higher with the inclusion of genomic information. The highest increase was achieved in genotyped cows whose mean reliability of genomic breeding values increased threefold compare to conventional breeding values. For genomic sires, genomic reliability was 4 p.p. higher. For cows with phenotype, the increase in reliability was only minor.

GEBV were expressed as relative breeding values (RBV) with mean 100 and SD 12, for base bulls born 2010. Genetic trends (Figure 1) based on RBV with reverse sign (higher values mean better resistance to COD) showed gradual improvement in cows since 2012. For bulls, RBV fluctuated and did not show a clear trend.

Table 1. Reliability of breeding values.

		Conventional breeding values			Genomic breeding values		
Sample	**N**	**Mean**	**Min.**	**Max.**	**Mean**	**Min.**	**Max.**
Genomic cows	30,095	0.04	0.00	0.25	0.13	0.00	0.35
Genomic bulls	5,394	0.05	0.00	0.91	0.09	0.00	0.91
Cows with phenotype	30,729	0.08	0.00	0.26	0.08	0.00	0.31

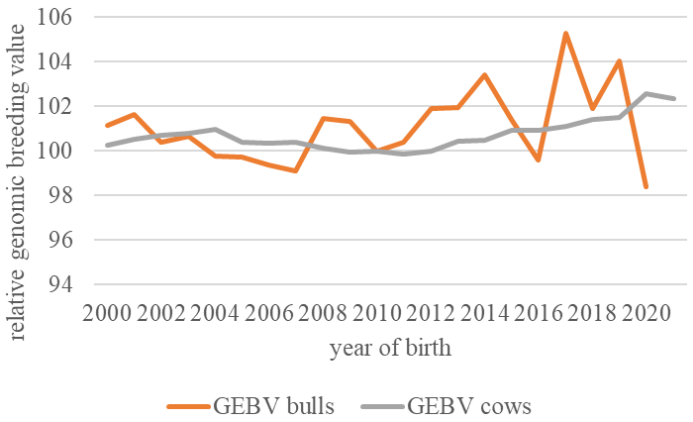

Figure 1. Genetic trend for COD in Czech Holstein bulls and cows.

Discussion

Previous studies of COD resistance (Hooijer *et al.* 2001, Heringstad 2010, Koeck *et al.* 2014, Jamrozik *et al.* 2021) showed, that it has a genetic background and thus could be enhanced by selection. A common problem is the lack of reliable data on COD occurrence. In the Czech Republic, the data are recorded by farmers on voluntarily basis for five consecutive years. Our study conducted on this data showed, that the incidence of COD, its variance components and heritability were comparable with other population studies of Holstein cattle (Vanholder *et al.* 2006, Koeck *et al.* 2014, Jamrozik *et al.* 2021). However, the reliability of EBV estimated with conventional BLUP method was not satisfying because of low heritability and low number of records. One way to increase the reliability of EBV is to incorporate genomic data (Parker Gaddis *et al.* 2014). For that we applied the single-step genomic method, that permits simultaneous utilization of phenotypic, full pedigree and genomic information (Aguilar *et al.* 2010). Genomic information helped to increase the mean reliability of GEBV mainly in the group of genotyped cows that missed phenotype records. In groups with phenotype records (own record, daughters' record) the improvement was lower.

Genetic trends for COD are the result of indirect selection response. Hoojier *et al.* (2001) reported an unfavourable genetic correlation between COD and milk production traits, which implies higher occurrence of COD in cows selected for higher milk production. Jamrozik *et al.* (2021) found unfavourable correlation of COD with length of productive life, protein yield, and several conformation traits (mammary system, rear attachment width, fore attachment), but favourable correlation with fertility and calving performance traits. Some of these traits are also incorporated in the Czech Holstein selection index with weights 28% (protein yield), 15% (fertility), 13% (udder conformation) and 5% (longevity).

Our study showed, that farm-collected health data are useful for routine genomic evaluation and selection of Czech Holstein cattle for better COD resistance.

115. Entropy of broiler activity: individual variation and consistency

M. van der Sluis[1,2*], L. Asher[3], T.B. Rodenburg[1,2], Y. de Haas[1], B. de Klerk[4] and E.D. Ellen[1]

[1]Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; [2]Utrecht University, 3508 TD Utrecht, the Netherlands; [3]Newcastle University, NE1 7RU, Newcastle upon Tyne, United Kingdom; [4]Cobb Europe, 5831 GH Boxmeer, the Netherlands; malou.vandersluis@wur.nl

Abstract

Animal behaviour is complex and comparing average levels of behavioural activities is sometimes insufficient to pick up on behavioural differences between (groups of) animals. Entropy, a measure of the randomness or regularity of time series, might help us to describe aspects of behaviour better. In this study, we determined daily entropy in individual broiler activity levels over time, based on a time series of observed activity per 15 minutes across a day, to assess individual variation and consistency in entropy of activity. Activity data for calculation of entropy were available for 79 broilers for a maximum of 21 days. We observed individual variation in entropy between broilers, but the level of entropy was not very consistent across days. The individual variation in entropy indicates potential for future research to look into whether and how entropy differences relate to other traits in broilers.

Introduction

Animal behaviour is complex and multi-dimensional (Asher *et al.*, 2009) and studies have indicated that mean levels of behaviours are not always sensitive to differences between groups of animals. For example, Dawkins *et al.* (2012) studied broiler flocks using optical flow patterns and observed no correlation between the mean gait score (i.e. walking ability) of the flock and the mean optical flow, but did observe correlations between the mean gait score and the skew and kurtosis of optical flow. This indicates that descriptors of behaviours that capture more than mean behavioural activity levels have potential to provide more insight into (individual) differences in behaviour. One measure that has potential is entropy. Entropy is a measure of the randomness or regularity of time series based on the existence of patterns (Delgado-Bonal and Marshak, 2019) and it has been indicated that entropy can be informative for, or predictive of, human behaviour, health and well-being (e.g. Glenn *et al.* (2006)). Although to a smaller extent, entropy has also been studied, and found to be informative, in non-human animals (e.g. Stamps *et al.* (2013)). In this study, we aimed to describe individual broiler locomotor activity patterns over time and assess individual differences in these patterns, using entropy. Individual differences in entropy have potential to be linked to other traits in broilers and may in the future aid in individual broiler phenotyping.

Materials & methods

Animals and housing. Individual-level broiler activity data were collected for 24 hours per day, from 1 to 33 days old, in a group of 80 birds housed in a pen with a size of 1.8×2.6 m.

Activity tracking. To record the individual broilers' activity levels, we fitted the pen with an earlier-validated RFID activity tracking system (Van der Sluis *et al.*, 2020). This system consisted of tags, that could be fitted to the birds' legs, and a grid of antennas that was placed underneath the floor of the pen. These antennas could register the presence of tags and a log file was stored with information on the tag ID (i.e. bird ID), the time of registration and the antenna (i.e. location) at which the tag was registered. To calculate activity levels, we first determined for every minute whether an antenna switch (i.e. position change) was registered within this minute for this animal. We then calculated the number of minutes in which an antenna switch was registered per 15-minute bin. Subsequently, these values were categorized into four classes based on the quartiles observed in the data. Class one consisted of the observations up to

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_115, © M. van der Sluis *et al.* 2022

and including the largest value observed in the lowest 25% of the data. Class two consisted of observations up to and including the largest value observed in the lowest 50% of the data, that were not already in class one. The upper limit for the third class was the 75% quartile, and the upper limit for the fourth class was the 100% quartile. In this process, we excluded values of zero (those were added as a fifth class), as a large part of the data consisted of zeroes due to low activity levels during the night. As activity is known to decrease with age in broilers (e.g. Weeks *et al.,* 2000), quartiles were determined within each day instead of across the full tracking period (Figure 1). Days on which there were overlapping numbers of antenna switches across the quartiles (e.g. one antenna switch was identified as both the first and second quartile limit) were excluded. This was the case for 28-days-old and older.

Entropy calculation. The resulting classes for the 15-minute bins of activity across each day were used as the underlying time series for the sample entropy (SampEn) calculation. The SampEn values can therefore be interpreted as a measure of regularity in activity within days, with lower values indicating more regularity and higher values indicating more randomness. However, SampEn can only be accurately calculated for days without missing data and therefore days on which the birds were weighed or their leg tags were checked, were excluded. This resulted in 21 days of data available for SampEn calculation, for which the pracma package (Borchers, 2021) was used in R (R Core Team, 2021). A total of 1455 entropy values were available, for a total of 79 individuals.

Statistics. All statistics were performed in R. Descriptive statistics were used to obtain a first overview of individual entropy values over time. To determine whether the individual entropy levels were consistent over time (i.e. the same individuals had relatively high or low entropy values on different days), we calculated Spearman rank correlations between the entropy values on different days, using the Hmisc package (Harrell Jr *et al.*, 2021). Visualisations were made using the ggplot2 (Wickham, 2016) and corrplot (Wei and Simko, 2021) packages. The level of statistical significance was set at 0.05.

Results

The overall mean entropy was 0.96 (SD 0.25), with a range from 0.07 to 1.65. Over time, the median entropy remained similar, but there did appear to be individual differences in entropy, as shown in Figure 2, where quite a large range of entropy values can be seen. The ranking of the entropy values of individual animals over days was not very consistent (Figure 3).

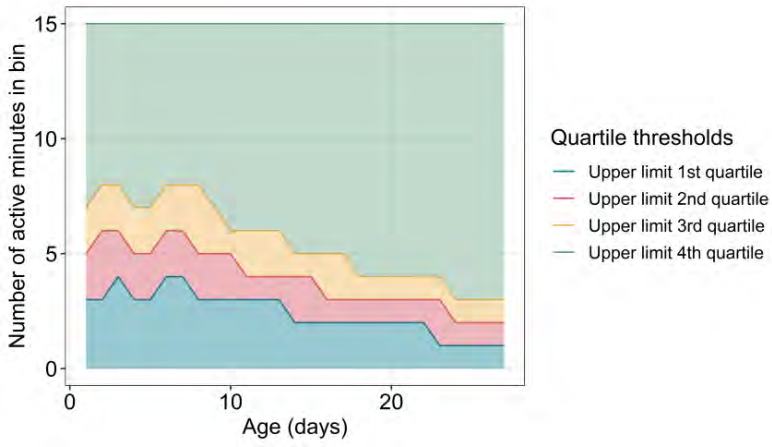

Figure 1. Quartile thresholds over time for number of active minutes per 15-minute bin.

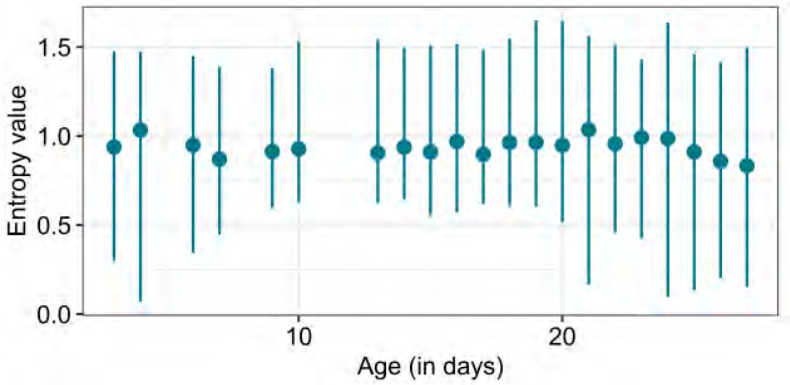

Figure 2. Median entropy values (circles) over time. Bars show the range from the minimum to the maximum observed entropy value for that specific day.

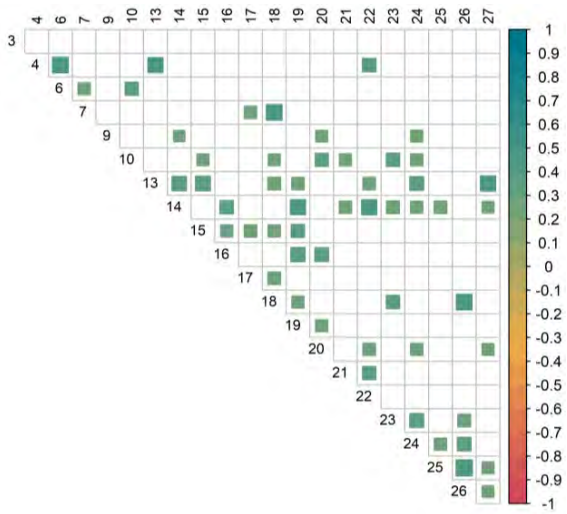

Figure 3. Spearman rank correlations between entropy values of individual animals on different days. On the axes, the day number is shown. Colours and sizes of squares indicate the strength of the correlation. Only correlations with $P<0.05$ are shown, squares associated with non-significant correlations are left empty.

Discussion

In this study, we examined entropy of activity of individual broilers over time and assessed whether there are consistent individual differences in entropy. We observed that the median entropy in activity from 3 to 27 days old was similar, but that there was quite a large range of observed entropy values within a day, suggesting that there are individual differences in entropy. This indicates potential for future research to look into whether and how such entropy differences are related to other traits. Other studies have indicated that differences in entropy can be linked to, for example, animal health. Fasmer and Johansen (2016) observed that spontaneously hypertensive rats displayed a higher complexity of movement time series (that is, a higher entropy) than control rats. However, the lack of strong correlations in entropy values over time observed here suggests that these differences are not consistent. Studies in laying hens have observed quite some consistency in movement patterns for some individuals, when looking at transitions

between five zones in a commercial aviary (Rufener *et al.*, 2018). In this study, however, the activity patterns were simplified considerably by looking at 15-minute bins and five activity categories, and no locations or directions of movement were taken into account. Possibly, if a more detailed overview of activity would have been used as the underlying time series, more consistency in activity or movement patterns would have been observed. On the other hand, the lack of consistency in entropy might be interesting too: perhaps changes in entropy are related to specific traits or environmental conditions of the broilers, but this requires further investigation. Overall, it would be worth exploring different ways of applying entropy to animal behaviour data in the future, to understand how to best capture the behaviour feature of interest and to examine possible relationships with other traits.

Funding

This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project 16022) and the Breed4Food partners Cobb Europe, CRV, Hendrix Genetics and Topigs Norsvin.

116. Laying hens tweet: they also lead and follow – implications for genetic selection against gregarious nesting

L. Bécot[1,2*], N. Bédère[2], T. Burlot[1] and P. Le Roy[2]

[1]NOVOGEN, 5 rue des Compagnons 22960 Plédran, France; [2]PEGASE, INRAE, Institut Agro, 16 Le Clos 35590 Saint-Gilles, France; lorry.becot@inrae.fr

Abstract

Gregarious nesting occurs when a hen chooses a nest already occupied while other nests are vacant, increasing welfare and production problems. This study aims to propose two predictors of gregarious nesting: weighted indegree (WID) and weighted outdegree (WOD), which are the number of times a hen entered an individual nest next to a vacant nest or an occupied nest, respectively. Nesting behaviour was recorded using individual electronic nests for 210 days. Genetic parameters for WID, WOD and nesting behaviour traits were estimated for 1,268 and 1,080 Rhode Island Red and White Leghorn respectively. For both lines, heritability estimates were high for WID (0.40/0.53) and low for WOD (0.12/0.15). Moderate genetic correlations were estimated between WID and WOD (+0.26/-0.35) and strong genetic correlations with some nesting behaviour traits. WID and WOD could help to select against gregarious nesting but the effects for hens using collective nests remain to be evaluated.

Introduction

In the EU, the majority of laying hens are now raised in cage-free systems, such as barn, free-range, and organic (52% in 2020; European Commission, 2021). In these systems, hens lay their eggs in collective nests, allowing them to express natural nesting behaviours (Cronin *et al.*, 2012). Gregarious nesting can occur when a hen chooses a nest already occupied while other nests are vacant (Riber, 2010). This behaviour can lead to mortality with suffocation in the nest and the increase of broken eggs and floor eggs (van den Oever *et al.*, 2021). Selecting hens against gregarious nesting could help to reduce welfare problems and to increase egg production in cage-free systems. However, this behaviour is difficult to record on large scale. Currently, little is known about its genetic background. The development of electronic nests continuously recording the nesting behaviour of hens raised in groups, could make it possible to identify predictors of gregarious nesting (Bécot *et al.*, 2021a). This study aims to propose predictors of gregarious nesting, estimate their heritability and their genetic correlations with nesting behaviour traits.

Materials & methods

Birds. Two laying hens' pure lines – Rhode Island Red (RIR) and White Leghorn (WL) – belonging to the NOVOGEN company (Plédran, France) were mobilised. For RIR, the phenotypes were recorded between 2018 and 2021 on 1,268 hens (three batches) issued from 144 sires and 506 dams. For WL, the phenotypes were recorded between 2019 and 2021 on 1,080 hens (two batches) issued from 100 sires and 372 dams. For both lines, more than 5 generations were used in the pedigree to estimate genetic parameters. For each line and batch, birds were raised in a barn on the floor until 17 weeks of age. Birds were then transferred and raised in another barn until 64 weeks of age. This barn was composed of floor pens (one by line) and was equipped with individual electronic nests overlaid on two rows (about 1 nest for 5 hens). Hens were raised with cocks (about 1 cock for 10 hens).

Recording system. Nesting behaviour was recorded continuously by radio-frequency identification and using individual electronic nests developed by NOVOGEN. Hens were individually recognised when they visited a nest by a transponder tagged on their leg. Thus, the hen's identification, the localisation of the nest visited, the time of entry in the nest, and the time of exit from the nest were recorded for each visit.

Oviposition time was recorded with an egg sensor located behind each nest, allowing us to know if the hen had laid an egg. Data were recorded between 200 and 409 days of age. Thus, 233,127 and 198,760 visits with oviposition were collected for RIR and WL, respectively.

Traits. The recording period was divided into seven 30-days periods. The pairs of hens using a nest for laying at the same time, in nests separated by a horizontal distance of 0 or 1 nest (0 for those at the same horizontal position, on top and bottom row) were selected to calculate predictors of gregarious nesting. This represented on average 2,617 and 3,486 pairs by day for RIR and WL respectively. For each hen of the pairs, the first who was entered in the nests was considered as a leader and the second as a follower. Using this information, two social network traits were calculated by hen as predictors of gregarious nesting: weighted indegree (WID) and weighted outdegree (WOD; Bondy and Murty, 1976). WID was the number of times the hen was the leader. WOD was the number of times the hen was the follower. Finally, hens with at least 15 eggs laid in the nests for a given 30-days period were kept for analyses, as hens with fewer eggs had fewer opportunities to express gregarious nesting. Thus, 8,137 and 7,124 phenotypes respectively associated with 1,268 RIR and 1,080 WL were kept for analyses (Table 1).

Five nesting behaviour traits were then calculated for each of these hens and each 30-days periods. The laying rate in the nests (LRN) was calculated to represent the egg production in the nests. For a given 30-days period, LRN was the egg number laid in the nests divided by 30 and then multiplied by 100. The mean oviposition time (MOT) and the logarithm of the variance of oviposition time (LVOT) were calculated to characterize the laying rhythm, using a procedure described in Bécot *et al.* (2021b). To consider the pre-laying behaviour referring to the nest choice for laying, the mean distance between nests of laying (MDN) was calculated. The distance between nests of laying corresponded to the horizontal distance, in the number of nests, which separated the nests of laying for two consecutive days. To avoid measuring different behaviours, this distance was not calculated for the laying separated by one or more days without laying in the nests. The mean laying duration (MLD) was the mean of the time spent in the nest for visits with oviposition. The time spent in the nest was calculated by the difference between the time of exit from the nest and the time of entry in the nest. The summary statistics of the 7 traits are given in Table 1. All traits were standardized to facilitate the convergence of models.

Model. Genetic parameters and phenotypic correlations were estimated using the restricted maximum likelihood method applied to a multi-trait animal model. The environmental effects of the model included the fixed effect of the hen's hatch date and the random effect of the common environment of the hen.

Table 1. Summary statistics of phenotypic data.[1]

	Rhode Island Red				White Leghorn			
Trait	**Mean**	**Std**	**Min**	**Max**	**Mean**	**Std**	**Min**	**Max**
WID	64.13	40.63	1.00	317.00	92.45	47.73	5.00	425.00
WOD	64.36	24.53	0.00	134.00	92.60	24.76	2.00	137.00
LRN (%)	94.57	7.56	50.00	100.00	92.11	8.33	50.00	100.00
MOT (hh:mm)	02:47	01:23	-00:23[a]	08:12	03:36	01:05	-00:12[a]	07:31
LVOT (sq. h)	-0.62	1.42	-6.28	3.29	-0.15	1.25	-4.14	3.54
MDN (nests)	7.70	4.09	0.12	31.50	10.55	4.64	1.48	33.17
MLD (min)	41.23	18.99	6.54	123.80	58.75	27.99	9.17	193

[1] WID = weighted indegree; WOD = weighted outdegree; LRN = laying rate in the nests; MOT = mean oviposition time; LVOT = logarithm of the variance of oviposition time; MDN = mean distance between nests of laying; MLD = mean laying duration. [a] MOT before the lights were turned on.

Variance and covariance components were estimated for the 7 traits together with REMLF90 (Misztal *et al.*, 2002). The estimated values were used as starting points to estimate standards errors with AIREMLF90 (Misztal *et al.*, 2002).

Results & discussion

Heritability estimates. Heritability estimates for WID and WOD were high (0.40) and low (0.12) for RIR respectively (Table 2). Similar results were found for WL with heritability estimates from 0.53 and 0.15 for WID and WOD respectively (Table 3). To our knowledge, no heritability estimates for these traits were reported in the literature. However, van den Oever *et al.* (2021) observed a different expression of gregarious nesting (considering the number of eggs per nest) between five broiler breeders lines and suggested the influence of genetic background.

Genetic correlations. Moderate genetic correlations, from +0.26 and -0.35, were estimated between WID and WOD for RIR and WL respectively (Table 2 and 3). Counterintuitively, WID and WOD are not genetically opposite and would provide different information linked to gregarious nesting.

For RIR, strong genetic correlations were estimated between WID and the traits MOT (-0.61), LVOT (-0.51) and MLD (+0.78). For WL, strong genetic correlations were estimated between WID and MLD (+0.87). For both lines, these results suggest selecting the leader hens, who have a high breeding value for WID, would increase MLD. This is not desirable as high MLD increases the occupation rate of the nests and therefore the risks for some hens to lay floor eggs (Bécot *et al.*, 2021a).

Table 2. Genetic parameters and phenotypic correlations[a] for Rhode Island Red.[1]

Trait	h^2	r_g / r_p WID	r_g / r_p WOD
WID	0.40 (0.05)	1 / 1	
WOD	0.12 (0.03)	0.26 (0.15) / 0.33	1 / 1
LRN	0.07 (0.02)	0.02 (0.28) / 0.21	0.69 (0.42) / 0.37
MOT	0.48 (0.06)	-0.61 (0.07) / -0.55	-0.13 (0.15) / -0.22
LVOT	0.19 (0.03)	-0.51 (0.10) / -0.34	-0.36 (0.15) / -0.30
MDN	0.19 (0.04)	0.14 (0.14) / 0.15	0.20 (0.19) / 0.11
MLD	0.46 (0.06)	0.78 (0.05) / 0.66	0.02 (0.16) / 0.00

[1] Traits abbreviations are described in Table 1. [a] Heritability estimates (h^2) for all traits. Genetic (r_g) and phenotypic (r_p) correlations between predictors of gregarious nesting (WID and WOD) and nesting behaviour traits. Standard errors are in parenthesis.

Table 3. Genetic parameters and phenotypic correlations[a] for White Leghorn.[1]

Trait	h^2	r_g / r_p WID	r_g / r_p WOD
WID	0.53 (0.06)	1 / 1	
WOD	0.15 (0.04)	-0.35 (0.15) / 0.06	1 / 1
LRN	0.09 (0.03)	-0.18 (0.25) / 0.22	0.36 (0.23) / 0.47
MOT	0.39 (0.06)	-0.33 (0.11) / -0.38	0.43 (0.14) / 0.37
LVOT	0.21 (0.04)	0.02 (0.13) / -0.18	-0.22 (0.16) / -0.31
MDN	0.24 (0.05)	0.14 (0.14) / 0.04	-0.08 (0.18) / -0.05
MLD	0.70 (0.07)	0.87 (0.03) / 0.73	-0.38 (0.14) / -0.11

[1] Traits abbreviations are described in Table 1. [a] Heritability estimates (h^2) for all traits. Genetic (r_g) and phenotypic (r_p) correlations between predictors of gregarious nesting (WID and WOD) and nesting behaviour traits. Standard errors are in parenthesis.

Strong genetic correlations were estimated between WOD and LRN (+0.69; but with a high standard error) for RIR or between WOD and MOT (+0.43) for WL. This suggests selecting the not follower hens, who have a low breeding value for WOD, would decrease LRN and increase MOT for RIR and WL respectively.

For both lines, low genetic correlations, ranging from -0.08 and +0.14, were estimated between MDN and the traits WID and WOD, except between WOD and MDN for RIR (+0.20). Some studies suggest that hens laying eggs in the same nests, i.e. with a low MDN, have a gregarious nesting (Riber, 2010; van den Oever *et al.*, 2021). MDN would be complementary to WID and WOD, each of them capturing a different part of the genetic variance for gregarious nesting.

Selecting the leader and the not follower hens, as well as hens laying their eggs in nests far from each other (high breeding value for MDN), could help to reduce gregarious nesting. However, this behaviour appears complex because it is influenced by multiple factors currently poorly known (Riber, 2012). The strong and unfavourable genetic correlations for WID and WOD with some nesting behaviour traits suggest to be careful before use such traits in breeding programmes. The real response to selection of WID and WOD to reduce gregarious nesting must be evaluated.

Conclusions

This study highlighted that WID and WOD are heritable traits in a RIR and a WL lines. Such traits could be interesting to reduce gregarious nesting by selection. However, strong and unfavourable genetic correlations were estimated with MLD and LRN, according to the trait and the line. Some studies are needed to better understand the potential effects for selection of WID and WOD, especially consequences on gregarious nesting of commercial hens raised with collective nests.

117. Analysis of social behaviors in large groups: simulation and genetic evaluation

Z. Wang*, H.P. Doekes and P. Bijma

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands; zhuoshi.wang@wur.nl

Abstract

Harmful social interactions, such as injurious feather pecking in poultry and tail biting in swine, reduce both animal welfare and efficiency. While these traits are heritable, application of breeding is still limited due to the lack of proper genetic models and precise phenotyping methods for large groups. In the near future, large scale longitudinal data on social interactions will become available thanks to developments in computer vision and artificial intelligence. Here we present models to simulate and analyze such data, which are an extension of the classic social genetic model. Latent traits were defined to represent the tendency of individuals to be engaged in behavioral interactions, distinguishing performer and recipient effects. Binary interaction records were simulated and subsequently analyzed using generalized linear mixed models. Results show that high accuracies of estimated breeding values can be obtained (0.4-0.7), despite the low observed-scale heritability of the binomial trait (0.05-0.2). We conclude that our model can be promising for breeding value estimation for social traits in large groups.

Introduction

Livestock regularly engage in behavioral interactions, and modern group-housing systems may increase the occurrence of harmful social behaviors, such as injurious feather pecking in poultry and tail biting in swine. To reduce the occurrence of harmful social behaviors, management strategies have been proposed (Van Krimpen *et al.*, 2016; De Vries *et al.*, 2004). However, the application of breeding strategies to behavioral traits is still limited.

One challenge of applying breeding strategies is that the social behavior of an individual may depend not only on the effect of the genes of the individual itself (known as the direct genetic effect, DGE), but also on that of its group mates (known as the indirect genetic effect, IGE). In the last two decades, genetic models for social traits have been developed to estimate DGE and IGE (Muir, 2005; Bijma *et al.*, 2007; Ellen *et al.*, 2014). These models assume that each individual has the opportunity to affect the phenotype of each of its pen mates equally. Therefore, these models are particularly useful in small groups, in which animals have ample interactions with all pen mates and the strength of social interaction can be assumed similar between all individuals.

For large groups the assumption of equal interaction does not hold anymore. In recent years, social network analysis has been successfully applied to large animal populations (Krause *et al.*, 2021; Radersma 2021). Social network analysis requires detailed records of the social interactions, including time, physical position, duration, and performer and recipient identity. Recording every interaction event between individuals in a large population used to be time- and labour-demanding, but is gradually becoming feasible due to developments in animal detection and tracking technologies. With these technologies, distinguishing performer and recipient effect is possible. Therefore, the terms performer and recipient effect will be used in the rest of this paper instead of DGE and IGE. It is expected that in the near future these detailed records of social interaction will become available. However, there is still a lack of methods to translate such data into estimates of individual performer effect and recipient effect.

DOI: 10.3920/978-90-8686-940-4_117, © Z. Wang *et al.* 2022

In this study, we: (1) extended the social effect model for genetic analysis of large-scale longitudinal data on animal social behaviors; and (2) evaluated the effect of number of individuals and number of social interactions on accuracy of breeding values (BV) estimated with this model. First, latent traits were defined to represent the tendency of individuals to be engaged in behavioral interactions, distinguishing performer and recipient effects. Second, social interactions with known performer and recipient were simulated under various population settings based on an assumed genetic structure. Last, statistical models were applied to estimate BV of social traits from the simulated records, and to evaluate the accuracies of the EBV.

Materials & methods

Trait definition. For each individual, two latent traits were defined to represent its liability to be engaged in a social interaction as a performer (trait α) or a recipient (trait β). Each trait consisted of two parts: a heritable effect (the BV) and a permanent environmental effect. The latter was used to account for similarity between repeated records on the same individual.

$$P_{\alpha,i} = \mu + A_{\alpha,i} + Ep_{\alpha,i} \quad (1)$$

$$P_{\beta,i} = \mu + A_{\beta,i} + Ep_{\beta,i} \quad (2)$$

where $P_{\alpha,i}$ and $P_{\beta,i}$ were the individual's normally-distributed liability for each trait, $A_{\alpha,i}$ and $A_{\beta,i}$ were the individual's BVs, and $Ep_{\alpha,i}$ and $Ep_{\beta,i}$ were the permanent environmental effects. For the results presented here, we assumed that both traits were independent (genetic correlation of 0) and had the same genetic variance ($\sigma_{A\alpha}^2 = \sigma_{A\beta}^2$), and that the permanent environmental variances were equal to the corresponding genetic variances.

For interaction between individuals i and j (see section 'Simulations' for conditions related to their proximity), the probability of i performing the social interaction towards j is given by:

$$p_{ij} = \text{logistic}(P_{\alpha,i} + P_{\beta,i}) = 1/\ [1+\exp(-P_{\alpha,i} - P_{\beta,i})] \quad (3)$$

Thus, the logistic function was used to rescale $(P_{\alpha,i} + P_{\beta,i})$ from the real number domain of the liability to the probability domain of 0 to 1. Binary interaction records were then generated by sampling a random number from a Bernoulli distribution, where 1 meant the interaction took place, while 0 meant it did not take place.

Simulations. For social interactions to occur, animals need to be in each other's proximity. In this study, we simulated the dynamic physical position of animals through agent-based modelling, using three behaviors that were alternated: eating (at feeders in the pen), resting and walking. Only when animals encountered each other, a 0/1 interaction record was generated as described above. We generated 2000 individuals from 100 sires and 400 dams, and each dam produced 5 offspring. Simulations were run for 20 pens, each with 100 random individuals, and until a total of 10,000 interactions took place in a pen. Given a simulated mean interaction probability of 1% (E(p) = 0.01), this implied a total of ~1,000,000 encounters per pen.

Finding realistic input values. Observed-scale heritabilities for binomial traits related to animal behavior are typically in the range of 0.05 to 0.20. Kjaer and Sørensen (1997), for example, found heritabilities in this range for number of pecks performed, based on an average of ~25 interactions per individual. To find realistic input values for our simulations, we simulated a dataset where individuals performed on average 25 pecks, then estimated the observed-scale heritability with ordinary linear mixed models, and tuned the input value for the genetic variance until observed-scale heritability was either 0.05, 0.1 or 0.2 (Table 1).

Breeding value estimation. To estimate BV for the performer effect (α) and the recipient effect (β), a generalized linear mixed model with a logit link-function and a binomial distribution was fitted in ASReml 4.1 (Gilmour *et al.*, 2015):

$$\text{logit}(p_{ij}) = \mu + Pen_k + A_{\alpha,i} + A_{\beta,i} + Ep_{\alpha,i} + Ep_{\beta,i} \quad (4)$$

where p_{ij} is the probability that i performs a social interaction towards j, Pen_k is a fixed pen effect, A is the BV and Ep is the permanent environment effect.

Results

Table 1 shows the genetic variances (σ_A^2) that correspond to observed scale heritabilities of total number of interactions performed (h_o^2) of 0.02, 0.05 and 0.1. These genetic variances correspond to interaction probabilities of top and bottom ranking individuals ($\pm 2\sigma_A$) that differed by a factor of 1.5 for $h_o^2 = 0.05$, 2.5 for $h_o^2 = 0.10$, and 5.5 for $h_o^2 = 0.20$. Hence, despite the low observed-scale heritability, the genetic differences between individuals in their tendency to engage in social interactions were very large.

To examine the relationship between the number of individuals and the accuracy of EBV, we included 5, 6, …, up to 20 pens in the genetic analysis (thus 500, 600, …, 2,000 individuals). When 500 individuals were included, the GLMM yielded an accuracy of EBV of 0.30, 0.36 and 0.44, given heritabilities of 0.05, 0.10 and 0.2, respectively (Figure 1a). When all the 2,000 individuals were included in the analysis, the accuracies were 0.47, 0.59 and 0.71.

To investigate the effect of the number of interactions on accuracy of EBVs, the GLMM was fitted by including the first 5, 10, 20, 50 or 100 thousand interaction records. Accuracy increased with an increasing number of records because more observations of sibs were included, but benefit was small above 20 thousand records (Figure 1b).

Table 1. Simulated genetic variances (σ_A^2) required to obtain a certain observed-scale heritability (h_o^2), the corresponding m ± $2\sigma_A$ range of expected interaction probabilities, and accuracy of EBV yielded by the ordinary linear mixed model, using data from all 20 pens.

h_0^2	σ_A^2	$\bar{p}(A_a = \mu - 2\sigma_A)$	$\bar{p}(A_a = \mu + 2\sigma_A)$	Accuracy LMM
0.05	0.012	0.008	0.012	0.173
0.1	0.038	0.006	0.015	0.195
0.2	0.170	0.004	0.022	0.241

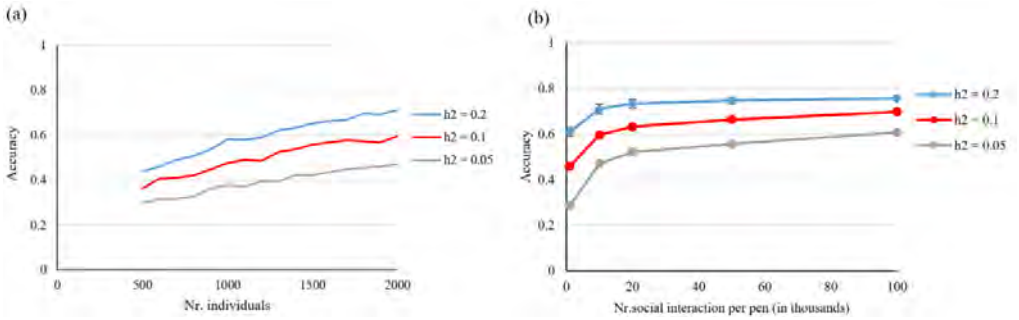

Figure 1. Accuracy of EBV from the GLMM for (a) different numbers of individuals involved and (b) different numbers of observed interactions.

Discussion

Here we developed an individual-based simulation method to generate social interaction events, and a GLMM to estimated breeding values for performer and recipient effect from the resulting data. Results showed that our method yielded a high accuracy of EBV (of 0.47, 0.59 and 0.71 for 2,000 individuals with h_o^2 of 0.05, 0.1 and 0.2, respectively) in comparison to an ordinary LMM (accuracies of 0.17, 0.20 and 0.24), and that genetic differences in the tendency to express a behavior can be large despite a low observed-scale heritability (Table 1).

This simulation shows that, even though the genetic variance (σ_A^2) was the same as the permanent environment variance (σ_{Ep}^2) on the liability scale, the observed-scale heritability can still be very low (e.g. 0.05). This low heritability is due to the random sampling of the event, which introduces extra variance in the observed records.

Our results indicate that the breeding values can be accurately estimated for social interaction traits even if the observed level heritability is very low. Similar results were found when both traits were positively or negatively correlated (results not shown). Note that in these simulations, the maximum information used for BV estimation was own performance, 4 full sibs and 15 half sibs. The accuracy was quite high with this amount of information, and we expect that higher accuracy can be achieved with genomic prediction. This high accuracy can partly be explained by the repeated measures of the trait. In our simulations, one individual could interact with 99 pen mates and was on average engaged in 200 interactions and 20,000 encounters. This means that the breeding value of each individual was expressed 20,000 times. While this may seem a large amount of data, one can easily imagine that an animal performs 10 tail bites or feather pecks a day in total. In that case, our data would correspond to one month of recording, which is shorter than the typical duration of, e.g. the fattening period in pigs or the laying period in laying hens.

In summary, we presented methods to simulate and analyse behavioral data, which distinguishes between performer and recipient effects, and is applicable to large-scale longitudinal data on animals kept in large groups, which will become available in the near future.

Abstract

Including behavioural traits in genetic selection could be an advantageous strategy for improving adaptation and welfare of farm animals to extensive farming systems in an agroecological perspective. The aim of the present study was to investigate in sheep the efficiency of an early selection for social attractiveness or tolerance to humans. Four divergent lines were created according to the reactivity of lambs to social separation or to human presence. Lambs were individually exposed just after weaning to two behavioural tests. The arena test aims at assessing the motivation of the lambs towards conspecifics and the corridor test aims at assessing the reactivity of the lambs to an approaching shepherd. Several behaviours were measured including vocalizations and flight distance from a human used as selection criteria. After two generations of selection, the divergent selection led to highly significant line differences for social attractiveness or tolerance to humans, respectively 1.8 and 1.0 genetic standard deviation between high and low lines. Such divergent selections also affected additional behaviours expressed in the tests.

Introduction

Genetic selection including behavioural traits could be an advantageous strategy for improving robustness and welfare of farm animals in various farming conditions by minimizing unsuitable responses to changes in their social and physical environment, limiting an excessive fear of humans and improving sociability (Mignon-Grasteau *et al.*, 2005). Farm animals are social and gregarious, and relational behaviours are essential for ensuring social cohesion, social facilitation, offspring survival and docility toward humans. Breed differences and genetic variation within breed have been reported in sheep for early social behaviours and found to be heritable, and associated with some QTL, suggesting such behaviours could be selected (Boissy *et al.*, 2005; Beausoleil *et al.*, 2012; Hazard *et al.*, 2014; Cloete *et al.*, 2020). In addition, such early social reactivity of lambs was identified as a robust trait (Hazard *et al.*, 2016). However, up to now, any study has demonstrated the feasibility, efficiency and effects of genetic selection for early reactivity to social separation or towards a human in domestic sheep. Thus, the aim of the present study was to investigate in sheep the efficiency of an early genetic selection for social attractiveness or tolerance to humans using experimental divergent lines.

Materials & methods

Animals and management. The experimental animals were Romane meat sheep, reared at the INRAE experimental farm of La Fage (Saint-Jean Saint-Paul, Causse du Larzac, France) exclusively outdoors under harsh environmental conditions. The flock comprised about 250 reproductive females reared on 280 ha of rangelands. The farming system and management characteristics have been described previously by Gonzalez *et al.* (Gonzalez-Garcia *et al.*, 2014). Ewes lambed for the first time at 2 years of age and all the lambs were born outdoor in the spring.

Behavioural tests and responses. Each year during 7 years, in average 300 female and male lambs were individually exposed just after weaning to two behavioural tests. The arena test (AT) consisted of two successive phases evaluating: (1) reactivity to social isolation (AT1); (2) the motivation of the lamb towards conspecifics in presence of a motionless human (AT2). The arena test pen consisted in an unfamiliar enclosure virtually divided into 7 zones as described in detail by Ligout *et al.* (Ligout *et al.*, 2011). The corridor test (CT) consisted of two successive phases evaluating: (1) reactivity to social isolation (CT1) and; (2) reactivity to an approaching human (CT2). The test pen consisted in a closed, wide rectangular circuit and has been described in detail by Boissy *et al.* (Boissy *et al.*, 2005). Several behaviours were measured: vocalizations (i.e. frequency of high-pitched bleats), locomotion (i.e. number of virtual zones crossed), vigilance posture (i.e. time spent by the animal motionless), the proximity score (i.e. weighting of time spent in virtual zones, a high score indicated a high duration spent close to conspecifics and a human). The mean flight distance (DIST) separating the human and the lamb and the time during which the human saw the lamb (SEEN) were measured in CT2.

Statistical handling. Two synthetic variables were constructed using the first component of each principal component analysis (PCA) (PRINCOMP procedure in the SAS® software). A PCA was performed on vocalizations across the different phases of behavioural tests (AT1, AT2 and CT1) and the resulting synthetic variable (HBLEAT) was used as indicator of the reactivity to social isolation. A PCA was performed on DIST and SEEN variables and the resulting synthetic variable (HUMAPPRO) was used as indicator of the reactivity to an approaching human. For divergent selection, individual estimated breeding values (EBV) were calculated for HBLEAT and HUMAPPRO with univariate analyses under an animal mixed model using the REML methodology implemented in the ASREML software (Gilmour *et al.*, 2009). In order to constitute the divergent lines, extreme animals were chosen as sires (in average 10 sires per generation and line) or dams (in average 70 dams per generation and line) at each generation according to their high or low EBV for HBLEAT or HUMAPPRO while intermediary for HUMAPPRO or HBLEAT, respectively. Selection intensities were in average 10 and 45% for sires and dams, respectively. Two generations of selected animals were produced (in average 270 female and male lambs per generation and line). Linear models (proc GLM, SAS Institute Inc.) were applied to test whether the divergent selections on behavioural traits had a significant effect on the recorded traits considering the adequate fixed effects in the analyses. The linear model used was $y_{ijklm} = \mu + line_i + sex_j + lsr_k + age_l + year_m + e_{ijklm}$; where y_{ijklm} was the behavioural observations of lambs; μ was the overall mean of the population; line, sex, lsr, age and year were the fixed effects of the behavioural line *i*, the sex *j* of the lambs, the litter size born and reared *k*, age *l* of the dam, and year *m* of the experiment, respectively.

Results & discussion

For gregarious species such as sheep, vocalization and locomotion behaviours in response to social separation are interpreted as an active way to re-establish social links (Boissy *et al.*, 2005; Beausoleil *et al.*, 2012). The divergence between low (S-) and high (S+) lines selected on social attractiveness reached 1.8 genetic standard deviation after two generations of selection (Figure 1). The divergence between low (H-) and high (H+) lines selected on tolerance toward humans reached 1.0 genetic standard deviation after two generations of selection. Responses to selection obtained were consistent with those expected considering the heritabilities previously estimated for both traits (h^2=0.5±0.06 for social attractiveness and 0.15±0.04 for tolerance toward humans) and the intensity of selection applied. As expected, the divergent lines for tolerance toward humans were intermediary for social attractiveness compared to S- and S+ lines even if a slight difference was observed between H+ and H- lines for the social criterion (Figure 1). A high difference was observed between S- and S+ lines for tolerance toward humans while no difference was expected between these lines for this criterion. Such difference could be linked to the low positive genetic correlation previously reported between criteria for social attractiveness and tolerance toward humans

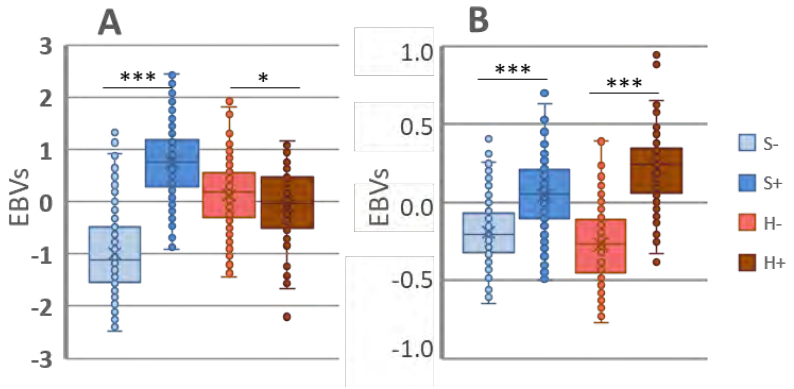

Figure 1. Estimated breeding values for social attractiveness (A) and tolerance toward humans (B) in the four divergent lines after two generations of selection. S- (n=279) and S+ (n=314) lines, low and high social attractiveness, respectively; H- (n=233) and H+ (n=149) lines, low and high tolerance toward humans, respectively. Pairwise comparison between Least Squares Means for line effect: *, and *** for *P*-value<0.05 and 0.001, respectively.

(r_g=0.25±0.11) (Hazard *et al.*, 2016). This difference may also be due to the selection criterion that involved measurement of reactivity to social separation in presence of a human (i.e. vocalizations in AT2). Thus, conflict behaviour between the social motivation toward conspecifics and avoidance of a motionless human included in the selection criterion may thus have resulted in differences between S- and S+ lines for both social attractiveness and tolerance toward humans.

Effects of divergent selections on the different behaviours expressed in response to social separation with or without human presence in arena and corridor tests were also investigated (Table 1). Selection for social attractiveness resulted in a two-fold higher expression of vocalizations in response to social isolation without or with human presence. This selection for social attractiveness also resulted in a higher locomotor activity in response to visual isolation from conspecifics (i.e. AT1 phase) as well as a higher proximity score with conspecifics in presence of a human (i.e. AT2 phase). Thus, selection for social attractiveness based on vocalizations not only affected vocalization behaviour but also locomotor activity in a context

Table 1. Behaviours in the four divergent lines after two generations of selection.

Behaviours	Test	S-[1]	S+	Line[2]	H-	H+	Line
Vocalizations	AT1	8.0	16.2	***	13.6	11.9	***
Vocalisations	AT2	3.0	7.6	***	5.7	5.0	NS
Locomotion	AT1	23.3	27.2	***	26.5	24.0	*
Locomotion	AT2	6.6	7.2	NS	7.2	4.9	**
Vigilance	AT1	18.6	18.2	NS	17.7	19.3	NS
Proximity	AT2	23.9	27.9	*	25.0	29.1	*
Flight distance	CT2	5.5	5.3	*	5.6	5.1	***

[1] S- and S+ lines, low and high reactivity to social separation, respectively; H- and H+ lines, low and high tolerance toward a human, respectively. AT1, arena test 1 (visual social isolation); AT2, arena test 2 (social isolation in presence of a human); CT2, corridor test 2 (reactivity to an approaching human); Vocalizations: frequency; Locomotion: number; Vigilance: duration in sec; Proximity: duration in sec; Flight distance: meter.

[2] Line effect: *, ** and *** for *P*-value<0.05, 0.01 and 0.001, respectively.

specific way. In one hand, more social lambs (S+) increased vocalizations and locomotion behaviours in response to visual separation from conspecifics (i.e. AT1 phase) probably to search actively for them and re-establish social links. On the other hand, when lambs were separated from conspecifics by a grid barrier and a human (i.e. AT2 phase), S+ lambs showed higher levels of vocalizations and proximity while they expressed quite similar level of locomotion compared with S- lambs. This suggested that locomotor activity of S+ lambs was more frequently observed in virtual zones close to conspecifics and the human in the second phase of arena test. As expected, the flight distance of lambs from an approaching human decreased with the selection for tolerance toward humans (Table 1). This selection also resulted in a slight decrease in vocalization and locomotion behaviours in response to social isolation as well as an increase in the proximity score toward conspecifics in presence of a human. We hypothesized that genetic selection for lambs more tolerant toward humans also reduced the overall reactivity to social separation and exposure to humans, may be by reducing overall stress responses.

119. Genetic parameters of novel behaviour traits derived from social network analysis in pigs

S. Agha[1*], S. Foister[2], R. Roehe[2], S.P. Turner[2] and A. Doeschl-Wilson[1]

[1]The Roslin Institute, University of Edinburgh, Easter Bush, Midlothian EH25 9RG, Scotland, United Kingdom; [2]Animal and Veterinary Sciences Department, Scotland's Rural College, West Mains Road, Edinburgh EH9 3JG, Scotland, United Kingdom; sagha@exseed.ed.ac.uk

Abstract

Social network analysis (SNA) has provided novel traits that describe the role of individual pigs in aggression. The objectives were to estimate the genetic parameters for these SNA traits and quantify their genetic association with skin lesions. Pigs were video recorded for 24h post-mixing. The observed fight and bullying behaviour of each animal was used as input for the SNA. Skin lesions were counted on different body parts at 24h (SL24h) and 3wk (SL3wk) post-mixing. A Bayesian approach estimated the genetic parameters of SNA traits and their association with skin lesions. SNA traits were heritable (h^2=0.18 to 0.26) and strongly genetically correlated (rg>0.88). Positive genetic correlations were observed between 3 of the 4 studied SNA centrality traits with anterior SL24h, although they showed negative genetic correlations with anterior SL3wk. This study provides a first step towards potential integration of SNA traits into a multi-trait selection index for improving pigs' welfare.

Introduction

Grouping of unacquainted pigs is a common procedure in commercial farms, but can lead to elevated aggression and injuries (Boumans *et al.* 2018). Genetic selection could help in providing a long-term solution for controlling aggression in pigs (Turner 2011). Skin lesions have been considered as a practical indicator traits for aggression (Wurtz *et al.* 2017). However, they are inadequate for identifying individuals that contribute most to the aggression in a pen. On the other hand, Social Network Analysis (SNA) provides quantitative 'centrality traits' that describe the position of each animal in the social structure (Agha *et al.* 2020). Previous studies have shown strong phenotypic association between SNA centrality traits and skin lesions at the pen level (Foister *et al.* 2018). However, the existence of a genetic component contributing to SNA traits is still unknown. Our objectives were to (1) estimate the genetic parameters for SNA centrality traits, and (2) quantify the genetic association between SNA and skin lesion traits.

Material & methods

The dataset consisted of 1,146 commercial pigs, 698 of them were purebred Yorkshire and 448 were Yorkshire × Landrace. The animals were the progeny of 82 sires and 217 dams. The total number of animals in the two-generation pedigree was 2,427. Animals were distributed into 78 pens, i.e. social groups, each containing 15 animals with the same sex and breed which were formed using 3 animals from each of 5 litters. Fresh skin lesions were counted for each body region 24h (SL24h) and 3 weeks (SL3wk) post-mixing. The body regions were identified as anterior (head, neck, forelegs, and shoulders), central (flanks and back) and posterior (hind legs and rump). The skin lesion records were log transformed ($y= \log_e (x + 1)$) to approach the normal distribution (Full details in Desire *et al.* 2016).

Animals were video recorded for 24h post-mixing. Each animal that initiated or received an aggressive interaction was registered. Aggressive interactions consisted either of fighting or bullying behaviour. Fighting was defined as aggression that lasted at least one second where both pigs engaged in biting, pushing or head knocking the opponent, whereas bullying was defined as when one pig received or delivered aggression with no observable retaliation occurring (Turner *et al.* 2009). All of these aggression

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_119, © S. Agha *et al.* 2022

interactions were entered in the SNA as undirected, allowing for bidirectional initiation of interactions, and unweighted, i.e. the frequency or duration of interactions between a given dyad were not considered. SNA was applied to transform the numerical data of aggressive interactions between animals into graphs, where the animals are displayed in terms of nodes (Farine and Whitehead 2015). The SNA traits for each animal describe its position in the network, i.e. the pen (Table 1). The SNA traits considered in this study were derived from Foister *et al.* (2018) using the 'igraph' package in R (Csárdi *et al.* 2016). All the listed centrality traits showed considerably skewed distributions; therefore, a square root transformation was applied to reduce skewness.

A series of univariate and bivariate analyses were used to estimate the genetic variance components of all transformed SNA and skin lesion traits using the following linear animal model

$$y=Xb + Za + Wc + e$$

where y is the vector of records for the traits, and X, Z and W the incidence matrices of systematic effects, genetic effects and environmental (pen) effects, respectively. Vectors b, a, c and e represent systematic effects (genetic line, sex, batch), additive direct genetic effects, common environmental pen effects and residual error, respectively, whereas body weight at time of mixing was fitted as a covariate. Bayesian analyses were performed using BLUPF90 software (Misztal *et al.* 2018). Heritability and genetic correlations between traits were calculated.

Results

The posterior means of heritability for SNA traits ranged from 0.18 to 0.26. SNA traits were strongly genetically correlated (Table 2).

Positive genetic correlations were observed between all SNA traits and anterior SL24h, except for clustering coefficient, which was weakly negatively correlated with anterior SL24h with HPD95% covering zero (Table 3).

Table 1. The definition of the social network analysis traits considered in this study.

Measures	Interpretation
Degree centrality	The number of animals that a particular animal directly engaged with.
Eigenvector centrality	Takes into consideration both the number of aggressive interactions of the focal individual and the number of aggressive interactions that its social partners have.
Betweenness centrality	Measures the relative importance of the animal in connecting different subgroups directly engaging in aggression.
Clustering coefficient	Quantifies what proportion of an individual's social partners are also connected, and divides this by the possible number of theoretical connections that could have occurred between the social partners.

Table 2. Posterior means of heritability (diagonal) and genetic correlations (off-diagonal) and the 95% highest posterior density intervals (HPD95%) of the SNA traits.

Trait	Degree centrality	Eigenvector centrality	Betweenness centrality	Clustering coefficient
Degree centrality	0.26 (0.11, 0.41)	0.98 (0.96, 1)	0.99 (0.95, 1)	-0.88(-0.99, -0.72)
Eigenvector centrality		0.22 (0.10, 0.36)	0.94 (0.84, 0.99)	-0.95 (-0.99, -0.85)
Betweenness centrality			0.26 (0.11, 0.40)	-0.95 (-0.99, -0.90)
Clustering coefficient				0.18 (0.06, 0.29)

Conversely, estimated genetic correlations between the majority of SNA traits and anterior SL3wk were found to be negative with the HPD95% not including zero, except for clustering coefficient, which was found to be moderately to strongly positively correlated with both anterior and central SL3wk post-mixing (Table 4).

Discussion

To the best of our knowledge, the genetic parameters for SNA traits for aggressive behaviour in pigs and genetic associations to skin lesions have not been previously estimated. The magnitude of the heritability of SNA traits indicates that these traits are partially under genetic regulation and could be utilized for selective breeding. Remarkably, heritability estimates for SNA traits, which partly capture social interactions between group members other than the individual in question, were at similar magnitude as those of dyadic behavioural traits previously estimated from the same dataset (Desire *et al.* 2016) and fall within the range of heritability estimates for skin lesions at 24h post-mixing (Turner *et al.* 2009; Wurtz *et al.* 2017).

Positive genetic correlations between 3 of the 4 SNA centrality traits with anterior SL24h, and their negative genetic correlations with anterior SL3wk suggests that individuals with genetic predisposition for high centrality immediately after mixing would tend to suffer high injuries on the anterior part of the body at this stage but would tend to have lower injuries in the stable group. Except for anterior lesions 24h post-mixing, clustering coefficient was the only trait that was found to be positively genetically correlated with skin lesions at both time points suggesting that using this trait at mixing as selection criterion may not inflict a trade-off for reducing lesions at different time points or different body parts. However, this study only provides a first step towards potential integration of SNA traits into a multi-trait selection index for improving animal welfare by reducing both aggressive interactions as well as resulting injuries. The recent advances in automated capture of animal behaviour would facilitate the application of SNA to derive novel behavioural phenotypes that describe an animal's relative contribution to pen level aggression in commercial pig farms.

Table 3. Posterior means of the genetic correlations and the 95% highest posterior density intervals (HPD95%) of SNA and skin lesions recorded 24h post-mixing.

Trait	Anterior skin lesions 24h (HPD95%)	Central skin lesions 24h (HPD95%)	Posterior skin lesions 24h (HPD95%)
Degree centrality	0.62 (0.34, 0.88)	0.01 (-0.46, 0.44)	-0.02 (-0.60, 0.56)
Eigenvector centrality	0.54 (0.15, 1.00)	-0.19 (-1.00, 0.39)	-0.13 (-1.00, 0.59)
Betweenness centrality	0.46 (-0.01, 0.87)	-0.10 (-0.71, 0.40)	-0.27 (-1.00, 0.41)
Clustering coefficient	-0.14 (-0.56, 0.34)	0.63 (0.08, 1.00)	0.73 (0.24, 1.00)

Table 4. Posterior means of the genetic correlations and the 95% highest posterior density intervals (HPD95%) of SNA skin lesions recorded 3 weeks post-mixing.

Trait	Anterior skin lesions 3wks (HPD95%)	Central skin lesions 3wks (HPD95%)	Posterior skin lesions 3wks (HPD95%)
Degree centrality	-0.37 (-0.66, -0.06)	-0.18 (-0.56, 0.20)	0.06(-0.53, 0.80)
Eigenvector centrality	-0.47 (-0.84, -0.10)	-0.23 (-0.67, 0.19)	-0.17(-0.76, 0.40)
Betweenness centrality	-0.57 (-0.99, -0.24)	-0.49 (-0.87, -0.09)	-0.78 (-1.00, 0.18)
Clustering coefficient	0.68 (0.28, 1.00)	0.62 (0.26, 0.97)	0.40 (-0.22, 0.98)

Conclusions

SNA provides promising new phenotypes to reduce aggression and resulting injuries in pigs through selective breeding. Future studies are needed to determine the response to selection for these traits on pen level aggression and other economically important traits in order to simultaneously improve the performance and welfare of pigs.

Abstract

This study aimed at investigating genetic parameters of six physiological indicators of heat stress (HS) in maternal-line pigs, including automatically-measured vaginal temperature (T_V); ear (T_E), shoulder (T_S), rump (T_R), and tail (T_T) temperature; and respiration rate (RR) under heat stress conditions. T_V had the highest heritability (0.34±0.03) and repeatability (0.57) estimates, whereas the heritability of skin surface temperature (SST) and RR ranged from 0.04±0.01 to 0.08±0.01. The genetic correlations among skin surface temperature (SST) indicators ranged from 0.76 to 0.87, indicating that SST can be measured at any of these locations for genetic selection purposes. T_V is positively correlated with SST and RR. Furthermore, SST and RR are also heritable. Although collecting more repeated records are recommended, they are highly correlated at the genetic level, except for T_E. Thus, T_V, SST, and RR are key indicator traits to be included in swine breeding programs for mitigating the negative effects of heat stress.

Introduction

Heat stress (HS) causes considerable welfare issues and economic losses in worldwide pig production due to a reduction in animal productivity, reproductive performance, and animal health. Currently, heat tolerance (HT) is not included in most swine selection indexes. Continued genetic selection for production and reproduction traits has significantly increased metabolic heat production in sows (Stinn and Xin, 2014; Cabezon *et al.*, 2017), and has likely resulted in greater HS sensitivity due to increased heat gain (McConn *et al.*, 2021). Therefore, there is an urgent need to identify feasible-to-measure and reliable HS indicator traits for including in selection schemes. Genetic selection could enable animals to better adapt to challenging climatic conditions and decrease the negative effects of HS on profitability, animal welfare, and productive efficiency. Physiological indicators, including body temperature, respiration rate, panting score, and pulse rate, might be key indicators of HS in pigs (Gourdine *et al.*, 2017). In this context, the main objectives of this study were to: (1) describe the phenotypic variability of six HS indicators [T_V, SST (ear, shoulder, rump, and tail), RR]; and, (2) estimate variance components and genetic parameters (including heritability and genetic correlations) for these six traits in lactating sows under heat stress conditions.

Materials & methods

Animals and dataset. All the datasets analyzed in this study were collected at a commercial farm in Maple Hill, NC, USA (34.70738, -77.73653). Phenotypic records (T_V, T_E, T_S, T_R, T_T, RR) were collected in 1,645 multiparous (parities 2 to 7) lactating sows (Landrace × Large White cross) from June 5th, 2021 to July 30th, 2021. The T_V of 1,381 lactating sows was measured automatically every 10 minutes using a digital thermometer (iButton model DS1921H, calibrated accuracy ±0.01 °C; resolution=0.125 °C; Dallas Semiconductor, Maxim, Irving, TX, USA). The SST of all sows was measured manually four times a day (8:00, 12:00, 16:00, 20:00) using an infrared temperature gun (Raytek model ST61; accuracy = ±1%; emissivity = 0.98; resolution = 0.10 °C; Raytek Corporation, Fluke Process Instruments, Everett, WA, USA). RR was

collected by counting flank movements for 15 s and multiplying by 4 to calculate breaths per minute (bpm) four times a day (as described in Johnson *et al.*, 2016). The ambient temperature (T_a) and relative humidity (RH) of each room was recorded every five minutes using within-room data loggers (HOBO; Onset ®; Bourne, MA, USA). Dew point (T_{dp}) was calculated by T_a and RH using the Magnus-Tetens equation (Buck, 1981). Outliers were discarded if they deviated by more than 3.5 SD from the mean. A total of 1,639 sows within the studied population were genotyped using the PorcineSNP50K Bead Chip (50,703 SNPs; Illumina, San Diego, CA, USA). SNP markers were kept with a minor allele frequency (MAF) >0.01, SNPs and animals with call rate above 0.90 using the BLUPF90 family software (Misztal *et al.*, 2002). After the quality control, 49,547 SNPs were used for further analyses.

Data analysis. Multi-trait (T_E, T_S, T_R, T_T) and bivariate (T_V and RR with the other five traits) repeatability model analyses were performed using the BLUPF90 family programs (Misztal *et al.*, 2002). The statistical model used can be described as:

$$y = X\beta + Z_a a = Z_{pe} pe + e, \quad (1)$$

where y is the vector of phenotypic records for T_V, SST, and RR; β is a vector of fixed effects, including parity, location, time of measurement, body size, scorer of body size, hair density, scorer of hair density, and T_{dp}; a is the random genetic animal effect and assumed to follow $\mathbf{a} \sim N(0, \mathbf{G}\sigma_a^2)$. The *G* matrix was created based on the method of VanRaden (2008); *pe* is the vector of random permanent environmental effect; X, Z_a, Z_{pe} are the incidence matrices; and e is the residual effect assumed to follow $\mathbf{e} \sim N(0, \mathbf{I}\sigma_e^2)$. The (Co)variances for all traits were estimated using the AIREMLF90 program (Misztal *et al.*, 2002). The heritability, repeatability, and genetic correlations were defined as follows:

$h^2 = \frac{\sigma_a^2}{\sigma_a^2+\sigma_{pe}^2+\sigma_e^2}$, $r_e = \frac{\sigma_a^2+\sigma_{pe}^2}{\sigma_a^2+\sigma_{pe}^2+\sigma_e^2}$, $r_{g_{ij}} = \frac{Cov_{ij}}{\sqrt{Var_i \times Var_j}}$, respectively.

Results

Descriptive statistics from the data available are shown in Table 1. The average ± SD T_V, T_E, T_S, T_R, T_T, and RR were 39.74±0.77, 36.74±1.07, 36.46±1.08, 37.23±0.92, 36.90±0.95, 72.98±28.28, respectively. The average values of SST were remarkably lower than that of T_V. Besides, the high average and maximum T_V and RR indicated that sows are under heat stress conditions. Variance components, heritability, and repeatability estimates for all the traits evaluated are listed in Table 2. The heritability estimates for T_V, T_E, T_S, T_R, T_T, and RR are 0.34±0.03, 0.04±0.01, 0.06±0.01, 0.08±0.01, 0.06±0.01, and 0.17±0.01, respectively. The repeatability estimates for T_V, T_E, T_S, T_R, T_T, and RR are 0.58, 0.09, 0.19, 0.21, 0.18, and 0.19, respectively. T_V had the highest heritability and repeatability estimates. The genetic correlations among all the six traits are shown in Table 3. T_V is moderately and positively correlated with SST (from 0.32 to 0.46) and RR (0.22±0.11). The correlations among SST traits were positive and ranged from 0.75 (T_R with T_T) to 0.84 (T_E with T_S), indicating that SST are genetically similar. Apart from T_E (0.16±0.08), the remaining SST are highly correlated with RR. The genetic relationships between RR and T_S (0.87±0.02) and T_R (0.81±0.01) were positive, while RR had a surprisingly negative correlation with T_T (-0.71±0.01).

Discussion

The presence of genetic variation in the traits evaluated in this study indicates that there are great opportunities for genetic improvement in swine populations. The moderate-to-high heritability estimate of T_V (0.34±0.03) in our study was in agreement with the estimate of 0.32±0.18 under low THI conditions reported by Sarlo *et al.* (2019), who measured T_V every 5 minutes in Brahman–Angus heifers. AI-Kanaan (2016) reported similar heritability estimates (0.018 to 0.035 on different body areas) for SST and high positive genetic correlations among SST (0.688 to 0.937) in cattle. The heritability estimate of RR in our

Trait	Variance components			Heritability	Repeatability
	σ^2_a	σ^2_{pe}	σ^2_e		
T_V	0.07	0.11	0.13	0.34±0.03	0.58
T_E	0.03	0.04	0.70	0.04±0.01	0.09
T_S	0.04	0.10	0.59	0.06±0.01	0.19
T_R	0.03	0.06	0.34	0.08±0.01	0.21
T_T	0.03	0.06	0.43	0.06±0.01	0.18
RR	34.50	70.21	445.53	0.07±0.01	0.19

[1] σ^2_a, σ^2_{pe} and σ^2_e are estimated additive variance, permanent variance and residual variance, respectively; T_V=Vaginal temperature; T_E=Ear temperature; T_S=Shoulder temperature; T_R=Rump temperature; T_T=Tail temperature; RR= Respiration rate.

study is higher than in Holstein (0.04±0.01; Luo *et al.*, 2021) and in a Holstein and German black pied cattle mixed population (0.05±0.04; AI- Kanaan, 2016). However, RR was fitted as a categorical trait in their studies. Low to moderate repeatability estimates of SST and RR implied that their records changed largely within 24 hours. Luo *et al.* (2021) reported similar repeatability of RR (0.14) during heat stress in Holstein cattle. In cattle, genetic correlations between core body temperature and RR were 0.25±0.12 (Gourdine *et al.*, 2016) and 0.26±0.11 (Luo *et al.*, 2021). In general, T_V had the highest heritability and repeatability estimates, and was moderately related to SST and RR. Furthermore, SST and RR are less heritable and repeatable, but highly correlated at the genetic level, except for T_E. The physiological indicators of HS evaluated here can be included in swine breeding programs for reducing the negative effects of HS. Although there is a value in recording all traits, based on the genetic parameters obtained, the automatically-measured T_V appears to be the most recommended indicator trait for selecting for HT in maternal-line pigs.

Table 3. Genetic correlations estimations among six physiological indicators of heat stress in lactating sows.[1]

Trait	T_E	T_S	T_R	T_T	RR

121. Genetics of body weight and length of Large White piglets and relationship to maternal performance

L. Canario[1*], Y. Billon[2], W. Hébrard[2] and J. Demars[1]

[1]UMR1388 GenPhySE, INRAE/INPT ENSAT/INPT ENVT, 31326, Castanet, Tolosan, France; [2]UE GenESI, INRAE, 17700, Surgères, France; laurianne.canario@inrae.fr

Abstract

Body weight and body metrics of newborn piglets reflect their level of development. We studied a Large White population raised in a single experimental herd. Survival and growth performance of 10,101 piglets originating from 689 litters were analysed. In 440 of these litters, 1,320 piglets contrasting for birth weight were recorded for body length and circumference. At piglet level, the estimated direct and maternal heritability values were h^2_d=0.02 and h^2_m=0.13 for birth weight, h^2_d=0.65 and h^2_m=0.21 for the ponderal index and h^2_d=0.23 and h^2_m=0.01 for the ratio of circumference to body length. The genetic correlation between the ponderal index and litter size and gestation length tended to be negative (r_g=-0.38 and -0.35, respectively with SE=0.33).

Introduction

The developmental status of piglets at birth largely determines their survival and growth until weaning. Intrauterine growth retardation results in piglets that are weaker at birth due to the brain-sparing effect, evidenced by a higher brain to organ ratio. Morphometric measurements can be used to measure maturity in addition to body weight, which is only a partial indicator of maturity at birth. A study of head characteristics of newborn pigs showed that developmental delay is influenced by genetics (Matheson *et al.*, 2018). Developmental differences can surface in measurements that combine weight and several lengths on the piglet's body. We worked on objective morphometric measurements, body length and thoracic circumference, obtained by intra-litter sampling. First, analyses at the piglet level allowed to disentangle direct genetic effects from maternal genetic effects. Second, although the metrics data are at piglet level, growth retardation could be considered as a property of the mother, partly due to her uterine capacity and nutritional status at the end of gestation. Genetic relationships of body weight and length, with litter size and gestation length of the sow, and litter growth during lactation were estimated.

Materials & methods

Animals and data. Data were collected from a purebred Large White population raised at the INRAE GenESI experimental farm (https://doi.org/10.15454/1.5572415481185847E12). The project received financial support from the French National Agency for Research (PIPETTE project, ANR-18-CE20-0018). Sows were managed under a batch farrowing system, with three weeks interval. Farrowing was not induced, and interventions including cross-fostering were limited. Piglet death was recorded daily. Each individual piglet, regardless of whether it was stillborn or alive, was weighed within 24h after birth. At the same time, three live-born piglets per litter were measured for body length (crown to rump) and circumference (thorax): the lightest, the one closest to the mean litter weight, and the heaviest of the litter. All piglets were weighed again at 3 wks of age. In this period, their growth depended solely on milk intake. Sows were inseminated with semen from AI Large White boars from the French national scheme, for which variability was maximised after 2018, over the period when morphometric measurements were recorded. Piglets were weaned at 4 weeks of age. Two data sets were constructed. The first data set included individual birth weight (IBW) and weight at weaning (IW3) from which was calculated the individual daily weight gain from birth to 3 weeks, as IWG0-3 = (IW3-IBW)/age at 3 wks (20±3 days). The density index, the body mass index, the ponderal index (PI), and the ratio of circumference to body length (ratioL) were calculated

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_121, © L. Canario *et al.* 2022

from weight and metrics. Litter growth traits, i.e. litter mean birth weight (MBW) and daily weight gain (IWG03) were calculated from individual records. Gestation length was recorded, in full days, as farrowing date minus successful mating date. Prolificacy included the number of piglets born in total (TNB) and that survived until weaning (SURV). The data set contained data on 385 sows with 10,101 piglets born in 689 litters, of which 7,019 were weighed twice and measured at birth. Among sows, 67% had their own weight performance at birth and 3 weeks of age. The data set was augmented with litter records (all traits but morphometrics traits) collected from older and contemporary sows, from end of 2015 to end of 2021. All sows considered were raised in the same housing system, i.e. crate; and with the same management practices. The pedigree file, based on sow pedigree and sire pedigree included 20,666 animals. The second data set included piglet and litter records.

Statistical analysis. All analyses were carried out with the REML procedure of the ASReml software (Gilmour *et al*., 2015). The goodness of fit was used to compare nested models following a chi-square statistics. Models for analyses included the fixed effect of parity (5 levels) and year-month (54 levels). The gender effect (2 levels at birth, 3 levels at 3 wks) was included in all piglet analyses. For piglet traits including IWB, IWG03 and PI, the complete model (possible simplified to reach convergence) was:

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_M\mathbf{a}_M + \mathbf{Vc} + \mathbf{Wl} + \mathbf{e}$$

where y is the vector of observations; X, V and W are known incidence matrices; b is a vector for fixed effects; a_D is a vector of direct additive genetic effects, and a_M is a vector of maternal genetic effects. The model accounted for a covariance between direct and maternal genetic effects, using the variance structure

$$\begin{bmatrix}\mathbf{a}_D\\ \mathbf{a}_M\end{bmatrix} \sim MVN\left(\begin{matrix}\mathbf{0}\\ \mathbf{0}\end{matrix}, \begin{bmatrix}\sigma^2_{A_D} & \sigma_{A_{DM}}\\ \sigma_{A_{DM}} & \sigma^2_{A_M}\end{bmatrix} \otimes \mathbf{A}\right)$$

where A denotes the matrix of additive genetic relationships with $\sigma^2_{A_D}$ and $\sigma^2_{A_M}$ respectively the direct and maternal additive genetic variances and $\sigma_{A_{DM}}$ the co-variance between direct and maternal genetic effects. Next, c is a vector of random permanent environmental effects of the dam, $\mathbf{c} \sim N(0, \mathbf{I}\sigma^2_c)$; l is a vector of random litter effects, $\mathbf{l} \sim N(0, \mathbf{I}\sigma^2_l)$; and e is a vector of residuals, $\mathbf{e} \sim N(0, \mathbf{I}\sigma^2_e)$. Z_D and Z_M are known incidence matrices for the direct and maternal genetic effects. The phenotypic variance was calculated as $\sigma^2_P = \sigma^2_{A_D} + \sigma^2_c + \sigma^2_l + \sigma^2_{A_M} + \sigma^2_e$.

Analyses with a direct-maternal model were applied. Genetic and phenotypic correlations between piglet traits and between a piglet trait and a litter trait (NBT or GEST) were obtained from sets of bivariate analyses. To overcome convergence difficulties, the model could be simplified to a sow model, considering only the random effects of the dam, i.e. genetics and permanent environment.

Results

The distribution of piglet IBW and PI according to IBW of sampled piglets is given in Figure 1. IBW ($\bar{x}$=1.37 kg SD 0.37) and PI ($\bar{x}$=96.35 SD 13.9) were negatively correlated (y=-0.33x+96; R^2=0.0001; n=1,320). Mean TNB was 15.7 (SD 3.4).

The estimates of heritability and variance components for piglet traits are given in Table 1, considering IBW, IWG03, PI and ratio L as traits of both the piglet and the sow. The size of the direct effects and maternal effects on IWG03 was similar. The maternal heritability on IBW was higher than the direct heritability. We found large direct genetic effects on PI that refer to the piglet merit for achieving proper development at birth. Moreover, the maternal heritability was substantial. Applying a two-trait animal model, with piglet as animal and only the permanent environment of the sow, the direct (piglet) heritability was inflated for IBW

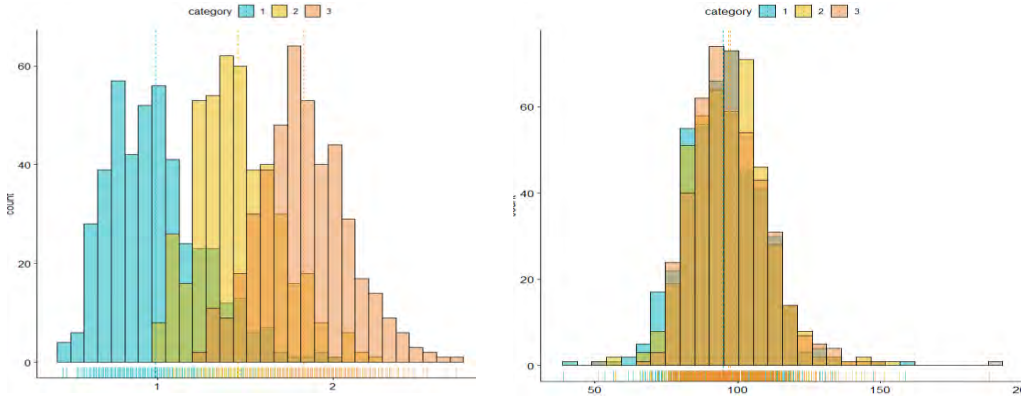

Figure 1. Distribution of piglet IBW (left graph) and PI (right graph) according to within-litter category (1: lightest, 2: mean, 3: heaviest in the litter).

(h^2_d=0.42 SE=0.09) and deflated for PI (h^2_d=0.42 SE=0.09), and the direct genetic correlation between IBW and PI was positive but low (r_g=0.21 SE=0.13; r_p=0.11 SE=0.03).

Since PI depends on sow nutritional state in the end of the gestation phase, next we analysed the piglet measurements as sow traits with an animal model including only direct (sow) effects and sow permanent environment. The estimates of genetic and phenotypic correlations between PI and performance traits are given in Table 2. Similar estimates were obtained with PI adjusted for litter size. At the sow scale, although estimates were not precise, genetic correlations indicate a trend for PI to be correlated negatively with litter size at birth and with gestation length. Sows with higher genetic merit for piglet PI produce smaller litters and have shorter gestation. Since the standard errors of the (co)variances are high, the results need to be confirmed with a larger data set.

Table 1. REML estimates of direct (h^2_d) and maternal (h^2_m) heritabilities and direct-maternal correlation (with SE) for piglet traits.

Estimates[1]	h^2_d	h^2_m	$r_{d,m}$	l^2 (%)	c^2 (%)
IBW	$0.02_{0.09}$	$0.23_{0.05}$	$-0.22_{0.61}$	11.2	1.4
IWG03	$0.12_{0.06}$	$0.12_{0.05}$	$-0.35_{0.28}$	6.7	6.4
PI	$0.65_{0.16}$	$0.21_{0.11}$	$-0.76_{0.01}$	ni[2]	7.8
ratioL	$0.23_{0.17}$	$0.01_{0.11}$	-0.01	13.9	0.5

[1] l^2 and c^2 are respectively the part of phenotypic variance (%) that is explained by litter effects and sow permanent environment effects.
[2] Effect not included in the model.

Table 2. REML estimates of genetic (r_g) and phenotypic correlations (r_p) (with SE) between piglet PI (y_1 h^2_d =0.09 SE 0.05) and litter traits (y_2) from a sow model[1].

PI with	TNB	DGEST	MBW	SURV	$IBW_{(sow)}$
$r_{g\ y1,y2}$	$-0.38_{0.33}$	$-0.33_{0.33}$	$-0.19_{0.33}$	$0.17_{0.41}$	$-0.18_{0.30}$
$r_{p\ y1,y2}$	$-0.05_{0.04}$	$-0.04_{0.03}$	$0.04_{0.04}$	$-0.04_{0.03}$	$0.37_{0.13}$
h^2 of y_2	$0.26_{0.09}$	$0.28_{0.08}$	$0.30_{0.09}$	$0.17_{0.08}$	$0.14_{0.04}$

[1] Models for both traits included the fixed effects of parity and batch, and the random effects of the sow genetics and permanent environment.

Discussion

The heritability for litter size was slightly higher than described in the literature. Heritability estimates for other litter traits were in agreement with previous results (Banville *et al*., 2014; Matheson *et al*., 2018). We investigated new body measures with purposive intra-litter sampling. Although known to be moderately heritable in adult pigs (Johnson and Nugent, 2003), we found a heritability value close to zero for the newborn piglet density index (h^2<0.01) and that of the BMI was not estimable. The sampling limited our ability to estimate the litter effect. Genetic estimates were often of low precision. We obtained the first estimates for PI, a trait of interest that describes whether the newborn piglet was malnourished in utero. This metric is also used in humans for diagnosing fetal growth disorders. The heritabilities for this trait were estimated to be high and a strong genetic antagonism between direct and maternal effects was evidenced. PI is influenced by the genotype of the piglet as well as that of the sow. The genetic correlation with IBW at sow scale was low, which indicate that different genetic determinisms underlie the two traits. Tabuaciri *et al*. (2011) used several lines to create a dataset and averaged the individual records of all piglets in the litter. Their heritability of mean PI was h^2=0.07 (SE=0.08) and the antagonism with MBW was stronger than in the current study (r_g=-0.56; SE=0.61). Moreover, our results tend to indicate that selection for litter size favours the production of piglets with lower PI at birth, in line with the delayed physiological maturity observed in piglets born to modern Large White sows (Canario *et al*., 2007).

Novel phenotyping tools: machine learning

122. Automated individual walking distance of group-housed broilers: a comparison between ground-truth, RFID, and video

J.E. Doornweerd[1*], I. Fodor[1], G. Kootstra[1], R.F. Veerkamp[1], B. de Klerk[2], M. van der Sluis[1], A.C. Bouwman[1] and E.D. Ellen[1]

Abstract

Individual broiler behaviour could serve as a proxy for an individual's health, welfare and performance. However, large-scale individual behaviour recording is difficult. Wearable and remote sensors have both been investigated to record individual broiler behaviour. In this study, we validated the use of automated tracking using video or radio frequency identification (RFID) by comparing the total estimated walking distance to ground-truth annotated from video. By using colour-marked birds we simplified the computer vision task of YOLOv5. The estimated walking distances by video pixel-based closely matched ground-truth pixel-based (≤2 cm difference). Overall, the RFID-system also closely matched ground-truth pixel-based, except for one movement event (75 cm underestimation). Over the entire duration of the trial, RFID and video gave similar animal rankings, but RFID seems more error prone due to missing reads. RFID is suitable to track broilers over time, but video could be more accurate and practical for on-farm application.

Introduction

There is a growing interest in the individual behaviour of broilers (Van der Sluis *et al.*, 2019), as behaviour could serve as a proxy for the individual's health (Hart, 1988), welfare (Van Hertem *et al.*, 2018), and performance (Reiter and Bessei, 2001). However, broilers are often kept in large groups (i.e. thousands of birds), which makes recording individual broiler behaviour difficult, but breeding programs require automated large-scale individual behaviour records.

Several sensors have been investigated to record individual broiler behaviour. Wearable sensors, such as ultra-wideband tracking (UWB; Van der Sluis *et al.*, 2019), radio frequency identification (RFID; Van der Sluis *et al.*, 2020), and accelerometers (Yang *et al.*, 2021) can record individual broiler behaviour. However, these wearable sensors are impractical and expensive, as these sensors either need batteries (UWB, accelerometer) or an extensive network of antennas (RFID). Alternatively, a remote sensor, such as a video camera, could be used. A video camera can observe multiple animals in a group, but it is challenging to automatically identify individual birds. Hence these cameras have been mainly used for flock level observations (Dawkins *et al.*, 2021; Li *et al.*, 2020; Van Hertem *et al.*, 2018). Nevertheless, individual broiler behaviour could be recorded with video cameras with the use of external markers such as colour-marks or RFID.

The aim of this study was to validate the use of automated tracking using video or RFID by comparing the total estimated walking distance to the ground-truth walking distance acquired from manual annotation on the video data. Furthermore, video and RFID were compared over the entire duration of the trial to assess tracking performance over a longer duration. By using colour-marked birds we simplified the computer vision task.

Materials & methods

Animals and housing. The data used in this study were collected in the research of Van der Sluis *et al.* (2020) in collaboration with Cobb Europe. Van der Sluis *et al.* (2020) followed broilers from hatch until 34 days of age. Forty male broilers from two genetic crosses were housed in one pen (1.8×.6 m). At hatch, all birds were fitted with a RFID-tag. Four birds, two from each cross, were marked in four different colours. From 15 days of age, 34 out of 40 birds were equipped with an UWB-tag, because the number of available UWB-tags was limited. In the present study, only data at 18 days of age were used. The birds were kept under standard lighting conditions. Feed and water were provided *ad libitum* (Van der Sluis *et al.*, 2020).

Radio frequency identification system. A passive RFID-system from Dorset Identification (Dorset Identification B.V., Aalten, the Netherlands) was used to track individual broilers. Each broiler was fitted with a high-frequency RFID-tag (13.56 MHz, 15×3.7 mm, <1.0 gram) around its leg. In total, 30 sub-floor high-frequency RFID-antennas (32×41 cm each) covered the entire surface area of the pen. The RFID-system continuously recorded time, RFID-tag, and the antenna that registered the tag (Van der Sluis *et al.*, 2020).

Video. An RGB-camera placed above the pen recorded the birds from 10:44 AM until 12:59 PM at 18 days of age. The two-hour period was recorded in multiple videos of approximately 7 minutes. The video recordings were made with a Zavio B6210 2MP camera (Zavio Inc., Hsinchu City, Taiwan) at 25 frames per second in full-HD.

Frame extraction and annotation. Five-hundred frames were randomly selected from all extracted frames for annotation. The selected frames were randomly divided between two annotators (Annotator A and B). The Computer Vision Annotation Tool (CVAT) (Sekachev *et al.*, 2019) was used for annotation. Three out of the four colour-marked birds were annotated, since the colour of one bird was inconsistent over days. The birds were labelled by bounding boxes, each bird having its own colour-based class (black, lightblue, pink). Inter- and intra-annotator reliability were calculated based on 25 randomly selected frames from the 500 frames, which were annotated twice by both annotators. Reliability was assessed with the intersection over union (IoU), calculated by dividing the area of overlap with the area of the union of the respective bounding boxes. Expressed in median IoU, the inter-annotator reliability was 0.92 (interquartile range [IQR] = 0.08), and the intra-annotator reliability was 0.95 (IQR=0.04) and 0.95 (IQR=0.07) for Annotator A and B, respectively.

Ground-truth. Five one-minute-long snippets were randomly sampled from 5 different seven-minute-long videos at 3 randomly sampled frames per second. The frames were randomly sampled to increase frame differences. From the five one-minute-long snippets, three movement events (5 to 10 seconds), one for each annotated bird, were annotated with bounding boxes for ground-truth.

You Only Look Once (YOLO). YOLOv5 was used to automatically detect the colour-marked birds in the videos (Jocher *et al.*, 2021). A pre-trained YOLOv5s model was trained on 350 randomly selected frames and tested on the remaining 150 frames, with mostly default hyperparameters, except for batch size (lowered to 6). Model performance, reported as mean average precision (mAP@[.5:.95]; value between 0 and 1 in which 1 is perfect), was 0.798 on the train set and 0.812 on test set.

Distance calculations. Animal walking distance was calculated for RFID, video, and ground-truth. The distance moved by the animal was based on the Euclidean distance between the centre points of the recorded antennas in the grid (RFID; Van der Sluis *et al.*, 2020), the centre points coordinates of the detected bounding boxes of YOLOv5s (video) or the centre points coordinates of the annotated bounding

boxes (ground-truth). The Euclidean distance was calibrated using one side of the pen. The animal was assumed to have remained at the last recorded RFID-antenna if no new read was received. The centre point coordinates of the detected and annotated bounding boxes were also translated to RFID-antennas and distances were calculated with the same method as described for the RFID-system (i.e. as RFID).

Results

Walking distance validation. In all movement events, the walking distance recorded by ground-truth pixel-based and video pixel-based agreed within 2 cm (Table 1). Overall, the RFID-system approximated the ground-truth pixel-based and video pixel-based, except for the black-marked broiler where it underestimated the movement with 75 cm. Ground-truth as RFID and video as RFID agreed, RFID reported an antenna switch for the pink-marked broiler and missed switches for the black-marked broiler.

Total walking distance. Overall, the recorded total walking distance substantially differed between RFID and video (Table 2). Compared to video, the RFID-system underreported the total walking distance of the animals. However, both RFID and video gave similar animal rankings, although not when the total walking distance on video was calculated as RFID.

Discussion

The aim of this study was to validate the automated tracking of broilers using video or RFID by comparing the total walking distance to ground-truth from video. Furthermore, video and RFID were compared to assess tracking performance over the entire duration of the trial. This study was the first time we were able to track broilers over time on video with computer vision, and in a setting that allowed us to visually confirm the location of individual broilers

Overall, the estimated walking distances by RFID and video pixel-based closely matched ground-truth pixel-based. However, for the black-marked broiler, RFID deviated with 75 cm compared to ground-truth pixel-based. The RFID-system seems to underestimate the total walking distance of the birds compared to video (Table 2). The RFID-system does not register movement within an antenna and can only register switches between antennas. However, not all antenna switches were registered, something that could be related to the hardware, the software or both. Similar observations were made in Van der Sluis *et al.* (2020).

Table 1. Walking distance (m) per movement event per broiler as recorded by ground-truth, RFID and video.

	Ground-truth		RFID	Video	
Broiler	as RFID	Pixel-based		as RFID	Pixel-based
Black	0.83	1.11	0.36	0.83	1.13
Light blue	0.36	0.34	0.36	0.36	0.35
Pink	0.0	0.48	0.45	0.0	0.48

Table 2. Total walking distance (m) per broiler as recorded by RFID and video.

	RFID	Video	
Broiler		as RFID	Pixel-based
Black	24.10	74.99	59.22
Light blue	24.79	63.68	68.68
Pink	27.85	94.42	80.58

Video pixel-based had a close-match with ground-truth pixel-based (≤2 cm difference, Table 1). Video could potentially overestimate the total walking distance over longer periods of time due to cumulative detection noise, but it could also be due to posture changes while lying and pecking behaviour (Table 2). This potential overestimation could be solved with a minimum movement threshold.

In conclusion, the estimated walking distances by video pixel-based closely matched ground-truth pixel-based (≤2 cm difference). Overall, the RFID-system also closely matched ground-truth pixel-based, except for one movement event (75 cm underestimation). Over the entire duration of the trial, both RFID and video gave similar animal rankings, but RFID seems more error prone due to missing reads. Nevertheless, RFID is suitable to track broilers over time, but video could be more accurate and practical for on-farm application. The study improved the understanding of both sensor systems and can help to develop a system for automated large-scale individual broiler behaviour recording.

Ethical statement

Data were collected under control of Cobb Europe. Cobb Europe complies with Dutch legislation on animal welfare. The Animal Welfare Body of Wageningen Research confirmed that this study was not an animal experiment under the Law on Animal Experiments.

Funding

This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project 16022) and the Breed4Food partners Cobb Europe, CRV, Hendrix Genetics and Topigs Norsvin.

123. Automated processing and phenotype extraction of ovine medical images using deep learning and computer vision

J.F. Robson*, S.J. Denholm and M. Coffey

Scotland's Rural College, Peter Wilson Building, King's Buildings, Edinburgh, Scotland, EH9, United Kingdom; james.robson@sruc.ac.uk

Abstract

In this study, we applied deep neural networks, in the form of a generative adversarial network, to perform image-to-image processing steps needed for ovine phenotype analysis from CT scans of sheep. Key phenotypes such as gigot geometry and tissue distribution were determined using a computer vision pipeline. The results of the image processing using a trained network are strikingly similar (a similarity index of 98%) when used on unseen test images. The combined pipeline was able to process and determine the phenotypes at a speed of 0.11 s per medical image compared to approximately 30 min for manual processing. We hope this pipeline represents the first step towards automated phenotype extraction for ovine genetic breeding programmes.

Introduction

Increase in global food demand has led to livestock breeders seeking to produce breeding lines more able to match economic demand which have genetic advantages to primary traits such as growth speed and reduced feed intake. Recent improvements in genomic technologies such as detection of single nucleotide polymorphisms and whole genome sequencing have allowed unparalleled insight into the driving factors which guide animal phenotypes and successful genomic breeding selection has been able to identify traits which are desirable economically or welfare indicators. As the number and biological complexity of known phenotypes is increasing, there is a call to innovate new ways to detect phenotypes faster and more accurately in addition to detecting and preserving those of potential future relevance.

Machine learning, artificial intelligence and deep learning have been successfully implemented to increase phenotype detection speed and accuracy within many different medical areas including brain cancer and covid detection (Lundervold and Lundervold, 2019). Recently, the same technology has been applied to areas of agricultural science such as detection of bovine tuberculosis status based upon milk spectral data (Denholm *et al.*, 2020).

Similar networks called generative adversarial networks (GANs) can also be trained to translate images, rather than classify or categorise, and have traditionally been used for a variety of image translational tasks including noise removal from low-dose CT, motion artefact correction and produce CT images from MR images (Goodfellow *et al.*, 2020).

By combining GANs with another machine learning technique, computer vision (CV), any images generated by the GAN can then be analysed to extract data of interest in a fully automated way. Computer vison is a research field which aims to extract understanding or context from images and can use both traditional mathematical regression techniques as well as deep learning classification networks. Application of CV can range from simple inspection of food quality and ripeness by counting the number of pixels within images of fruit and vegetables which fall within certain colour hue ranges up to more complex tasks such as identifying road signage or pedestrians to guide automated driving systems (Deva Koresh, 2019). The aim of the present study was to develop a completely automated system for the extraction of phenotypes relevant for breeding programmes.

Materials & methods

Development of the deep learning framework involved an initial manual data collection phase followed by network training, examination of network performance and development of computer vision code to explore phenotypes.

Ovine CT scan collection and tissue calibration. A single cross-sectional 2D images was taken through the top of the leg at the point of the ischium for each lamb using a Somatom Scope (Siemens, located at SRUC CT Unit, Edinburgh) with a slice thickness of 10 mm for a variety of breeds including Beltex, Blue Texel, Charollais, Hampshire Down, Meatlinc, Shropshire, Southdown, Suffolk and Texel as performed previously (Bunger *et al.*, 2011). The images at this stage are referred to as 'raw' images and contain non-subject objects such as scanning cradles. Tissue density windows corresponding to fat, muscle and bone were calculated based upon tissue dissection previously performed (Scholz *et al.*, 2015).

Manual image processing and phenotype analysis. Image objects superfluous for downstream phenotype analysis such as scanning cradles and testes were removed manually using STAR image processing software. Images at this point were then considered as 'ground truth'. From the ground truth images, tissue phenotypes could then be extracted by calculating tissue distribution and geometric phenotypes were measured manually in a 'click and drag' fashion. The total processing time from raw to phenotyped image took approximately 30 min.

Deep neural network (GAN) training and testing. A dataset containing 126 raw and ground truth image pairs of mixed breed ovine CT scans taken between 2019-2020 were used for GAN training. Raw and ground truth image pairs were first split into training (n=101) and validation (n=25) datasets (80 and 20% respectively). Thirty-two previously unseen raw CT scans taken from 2018-2019 and belonging to the breed Charollais were passed through the trained GAN model to produce 'predicted' images.

Calculation of image similarity. Mean squared error (MSE) and structural similarity index (SSI) metrics were used to compare the raw and ground truth images with the resulting predicted images using functions contained within the SciKit Image Python image processing library (Gandhi and Kulkarni, 2013).

Computer vision powered phenotype analysis. Automated phenotype extraction from ground truth and predicted images was performed using a pipeline which incorporated known pixel intensity value thresholding for each component of the carcass. Geometric phenotypes were computed by implementation of area, contour and perimeter functions within the SciKit Image library as part of a custom script (Van der Walt *et al.*, 2014).

Computing hardware and software. All computation was performed on a NVIDIA DGX Station using one TESLA V100 GPU running on CUDA 10.1. The GAN trained in this study is an implementation of AUTOMAP and Pix2Pix which has been optimised for use with paired image datasets (Kaji and Kida, 2019).

Results

The trained model was able to perform the major structural alterations within the image dataset needed to transform the raw CT scans into something which, by eye, strongly resembled the ground truth images as shown below in Figure 1a. Likeness of the raw, ground truth and predicted image sets (n=32) were compared pairwise using MSE and SSI. Both raw vs ground truth and raw vs predicted showed the lowest image similarity values with an average MSE of (58,674±17,766 and 58,008±17,319) and with average SSIs of (0.49±0.025 and 0.48±0.024) respectively indicating a high degree of image dissimilarity. On the other

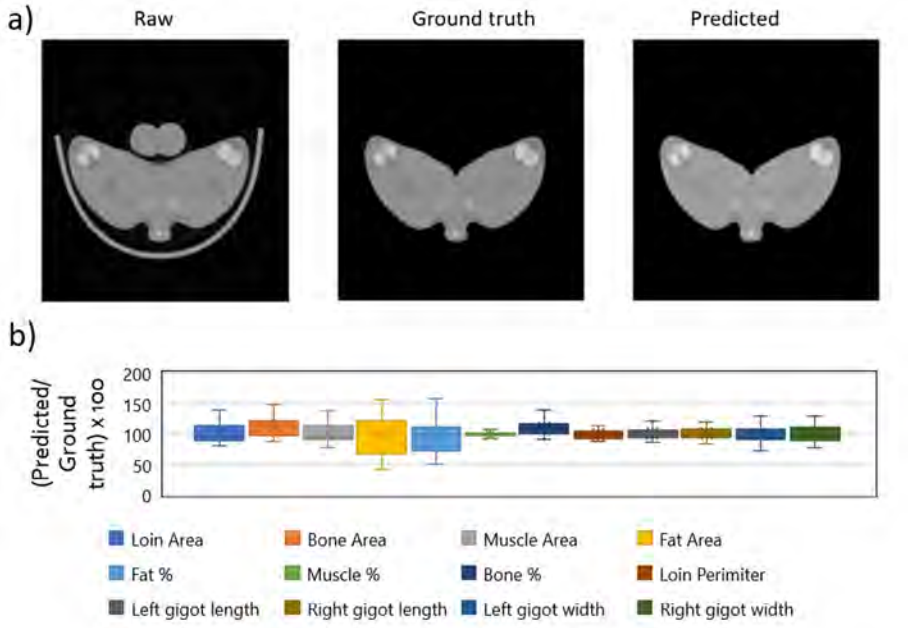

Figure 1. Performance of neural network and computer vision pipeline.

hand, comparing images in the ground truth and predicted datasets showed a much lower average MSE (1,028±1201) and a far higher average SSI of (0.98±0.0035) indicating a far greater similarity and indicated high accuracy of the trained model in mimicking the manual processing of CT scan images.

Phenotypes from both predicted and ground truth datasets were extracted using the computer vision pipeline and compared to determine the suitability of predicted images for phenotype (Figure 1b). Across all phenotypes, the average values were on average 101.44% that of the ground truth value with a standard deviation of 12.90% (n=32). Muscle % was the best performing predicted phenotype with estimated values between 93.67 and 106.65%. On the other hand, calculating fat area was the worst performing predicted phenotype with estimated values between 42.50 and 156.18%.

Discussion

In summary, we believe this research represents the first case of using an automated phenotype detection pipeline on agricultural animal medical images. This was achieved by using a combined GAN-CV pipeline to analyse agricultural medical images in a fully automated fashion. By feeding a paired image dataset into a GAN, we were able to perform the various image processing steps needed to produce a predicted image, containing only the relevant tissues, with accuracies of 98% (SSI) which rivalled that of manual processing and at a fraction of the cost. Phenotypes were then extracted or calculated from these predicted images by applying CV techniques as part of an automated pipeline.

We hope to immediately expand this highly accurate GAN-CV pipeline to process and extract phenotypes from other key CT scan sections such as the 8th thoracic vertebrae and 5th lumbar vertebrae positions. Further on, we hope to develop a pipeline to process a complete set of layered CT images to produce an accurate 3D model from which a multitude of phenotypes can then be extracted, such as spine length and vertebrate number, and detect phenotypes which are best explored in 3D space such as organ

morphology. By continuing this research, we will further expand the automated extraction of phenotypes from agricultural medical imaging data and use the findings to guide genetic and genomic breeding programmes.

124. VTag: automatic pipeline to annotate video data for pig phenomics studies

C.J. Chen[1,2], G. Morota[2] and H. Cheng[1*]

[1]Department of Animal Science, University of California, Davis, CA, USA; [2]Department of Animal and Poultry Sciences, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA; qtlcheng@ucdavis.edu

Abstract

Due to the rising demand of animal products, computer vision (CV) has become a successful practice to automate monitoring important behaviors, including tail biting and lameness, in the pig industry. However, most CV systems are driven by supervised learning algorithms, the robustness of which heavily relies on high-quality hand-annotated data and laborious efforts. Therefore, we derived a software, Virtual Tag (VTag), to facilitate annotating video data for animal phenomics studies. By taking a top-view RGB video as input data, VTag can automatically derive annotations of pig position coordinates by the built-in algorithm. Users are allowed to further fine-tune the annotations through the graphical user interface in VTag and export the results for the training of other CV systems. Along with the coordinate annotations, the individual-level of pig activity is also generated as farming guidance. In sum, VTag can serve as a platform to accelerate pig behavioral studies.

Introduction

Due to the rising demand of animal products, precision agriculture, which aims to massively collect detailed measurements of animal traits, has been an essential practice to maximize the resource efficiency in the pig industry. The poor efficiency can be reflected in pig behaviors or the appearance. For example, pig lameness is an indicator of fractures, skin lesions or trauma, which have negative impact on the body condition and result in severe economic losses. Harmful animal behaviors such as tail-biting (Larsen *et al.*, 2019), aggression (Turner *et al.*, 2006), and excessive mounting (Teixeira and Boyle, 2014) also diminish animal welfare and reduce the production efficiency. Hence, to effectively monitor animal behaviors has become an important topic in the pig industry.

The technology of computer vision (CV), which is inspired by human vision that can intuitively focus on objects of interest and exclude noisy signals, has been used to automate monitoring the pig activity and shown promising results solely based on video information. For example, coupling with unmanned aerial vehicles (UAV), CV is possible to automate cattle counting in real-time with labor costs substantially reduced (Xu *et al.*, 2020), whereas it used to be costly to manage cattle in large-scale pasture lands. In smaller-scale indoor farms, CV systems were also used to detect body cleanness (Li *et al.*, 2019), structure (Liu *et al.*, 2020), positions (Yang *et al.*, 2018; Zhang *et al.*, 2019; Huang *et al.*, 2020), and behaviors (Okura *et al.*, 2019; Fuentes *et al.*, 2020; Ren *et al.*, 2021) for animal productions. However, the robustness of CV systems relies on laborious efforts to obtain a large amount of hand-annotated data, which, for example, store the positions (x-y coordinates) of studied objects from images by manual efforts. In addition, as the uniform annotation format for phenomics studies is not settled, the annotated data are difficult to be shared for community members to validate and extend. Outside precision agriculture, the availability of uniformly formatted and annotated image data has derived revolutionized applications; e.g. in the deep learning domain, annotated image databases, such as ImageNet (Deng *et al.*, 2009) and Cityscapes (Cordts *et al.*, 2016), have been heavily used in benchmarking newly developed models and derived applications for self-driving cars and cancer diagnostics. Current phenomics studies must solely rely on researchers' own resources due to the absence of standard pipeline or software that can generate uniformed annotated images. This limitation has become a significant difficulty for wider deployment of precision farming because of the costly work in generating annotated data.

Therefore, in this paper, we derived a phenomics software, Virtual Tag, to automatically annotate pig positions using images captured by a top-view RGB video. The complete codes and content can be found on github.com/poissonfish/vtag. VTag is developed to meet three major goals:

- Automatically tracking pig positions without requiring training data set.
- Allowing users to annotate video data via a friendly graphical interface.
- Generating uniformed output format that is compatible in other analytical platforms.

Materials & methods

Automatic annotation pipeline. VTag enables tracking pig individuals automatically in two steps: semantic segmentation and instance segmentation. The step of semantic segmentation, which separates objects of interest (i.e. pigs in this study) from the background, uses pig motions to infer their positions. The space area with higher pixel variation across certain time frames indicates stronger observed motion. As the top-view video is expected to only capture group-housed pigs, pig positions should be highly overlapped with the area associated with strong observed motion. After segmenting the object of interest, the next step is to recognize pig identities. This step is also called instance segmentation. VTag extracts imagery or temporal describers, such as skin textures or moving trajectories, from the input video by multi-dimensional convolution operations to identify individual-level features. Then, the describers are used as clustering features in an unsupervised clustering algorithm for VTag to label different pig identities. After the two tracking steps, the annotations of pig position coordinates are generated automatically for the input video data. Through the VTag interface, users have access to the annotation results and is able to make necessary adjustments through the graphical user interface (GUI) of VTag by simple clicking and dragging. Therefore, annotating video data can be both efficient and accurate.

Properties and design of the annotated data. The annotations will be saved in the format of HDF5. This format has multiple merits for the research community: (1) multi-interface support: As much software for phenomics studies were released in R, Python, or GIS plugins, the format is readable in different interfaces for versatile analyses; (2) heterogeneous data integration: phenome annotations are a mixture of images and tabular data; the proposed format is able to store heterogeneous data and provide self-describing metadata for users to manage the collection of data sets; (3) partial data access: Imagery data usually is large in file sizes which imposes a critical burden to computing resources. With the support of partial data access, computers with limited memory are also capable of analyzing annotated phenome data. The output HDF5 has a data hierarchy listed in Table 1.

Results

The graphical interface has three components: the video preview, the playback controller, and the pipeline configuration. The preview (Figure 1a) will show the results of the annotated video for both pig contours and position centroids with a distinct color for each individual. Through the controller panel (Figure 1b), the video will play, pause, go forward or backward one frame by mouse-clicking the corresponding symbols, or pressing the arrows keys and space key on the keyboard. It is also possible to traverse the video to any frame by hovering the cursor on the playback progress bar. Each frame in the progress bar is colored in a gradient scale from yellow to blue, showing the levels of observed interaction between individuals. The

Table 1. Stored attributes of the annotated data.

Attributes	Data type	Description
Phenotypes	Tabular	Three-column data frame: object identity, trait name, phenotype.
Trial date	Text	Datetime format in MM-DD-YYYY or MM-DD-YYYY hh:mm.
Trial location	Text	Geo-Information in CRS, or general description of locations.
Trial scope	Text	Individual, house-grouped, field plots, etc.
DOI	Text	DOI number if it is published data.
Published	Text	Datetime format in MM-DD-YYYY.
Object positions (contour)	Numerical matrix	Four-dimension matrix: time frame by width by height by spectral channel.
Object positions (coordinate)	Tabular data	Three-column data frame: object identity, position coordinate, time frame.
Measurement	Text	RGB colors, near infra-red, depth, thermal, etc.
Measurement (details)	Numerial	One-dimension vector: scanned wavelengths
Studied species	Text	General name or Binomial nomenclature for studied species.

yellow color indicates the strong interaction and short distance between individuals are observed. On the right side of the interface is a panel for configuring the annotated results and outputs (Figure 1c). Several preview items can be adjusted including play speed (frames per second), annotation opacity, and displayed information. The output file paths and annotated attributes are also configurable in this section. In addition to the position coordinates, the outputs will cover several derived information, which includes the activity at specific time frame (Figure 1d), individual level of activity (Figure 1e), cumulated activity at specific time frame (Figure 1f), and spatial hot spots of pig movements (Figure 1g). In sum, VTag provides a friendly platform to annotate video data and generate informative farming guidance. These resources can pace an efficient way for further sophisticated work in behavioral research and animal phenomics studies.

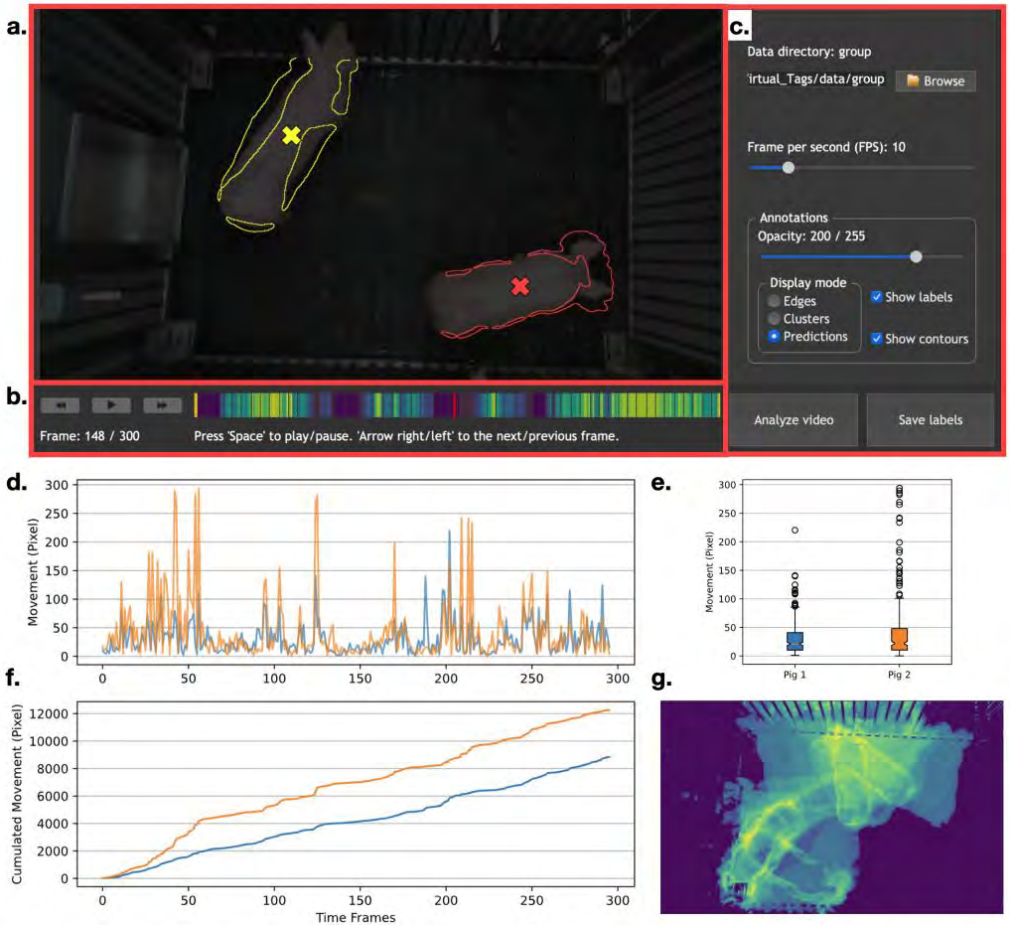

Figure 1. Overview of VTag. 1a-1c: Graphical user interface of VTag. 1d-1f: Individual-level of monitored unit time activity. 1g: Spatial hot spots of pig movement.

125. Milk spectra selection for equations development to predict milk technological traits

M. Frizzarin[1,2], I.C. Gormley[2], A. Casa[2] and S. McParland[1*]

[1]Teagasc, AGRIC, Moorepark, Fermoy P61 P302, Co. Cork, Ireland; [2]School of Mathematics and Statistics, UCD, Ireland; sinead.mcparland@teagasc.ie

Abstract

Using all observations in a dataset to predict a phenotype may be sub-optimal for poorly represented predictands. Here we investigate the use of only observations similar to the predictand to predict milk technological traits using mid infrared spectrometry (MIRS) data. Similarity between observations and the predictand were judged according to: (1) the correlation between the MIR spectrum of the predictand and the other available spectra (the LOCAL approach); (2) the Mahalanobis distance between the predictand spectrum's principal components (PCs) and the other spectra PCs (the local changepoint approach; LCPA). Results are compared to the prediction performance of the traditional approach whereby the entire dataset is used to inform prediction (the global approach). The global approach provided the lowest root mean square error of validation (RMSEV) for 5 traits, while the LCPA had the lowest RMSEV for the remaining trait. When only observations with spectra poorly represented in the dataset were considered, the LCPA had the lowest RMSEV for 2 traits.

Introduction

The use of mid-infrared spectrometry (MIRS) data to predict milk and animal traits is well established (De Marchi *et al.*, 2014). The benchmark statistical method used to relate the spectra to a phenotype is partial least squares regression (PLSR; Wold 2001) whereby, in general, all available data are used in the development of the PLSR prediction equation. However, if the dataset analysed contains observations grouped in clusters or non-linear associations are present between the spectra and the trait of interest, the utilization of all the available observations may present some limits (Lesnoff *et al.*, 2020). These limits can be overcome using statistical approaches such as cluster methods (Franzoi *et al.*, 2018) or local methods (Shenk *et al.*, 1997), both of which use only part of the available observations in a dataset. Cluster methods identify a specific number of clusters in the dataset, and then develop a specific equation for each of these clusters. Local methods group observations in a dataset according to similarity between the predictand (neighbours) and other observations. The same number of neighbours are generally selected for all the observations in a dataset.

The objective of the present paper was to test a new local approach, the local changepoint approach (LCPA), to predict milk technological traits using MIRS data. The novelty of the tested approach is that the selected neighbours were identified in an objective, data driven manner, and the number of neighbours changed for each observation according to its characteristics. The prediction performance of the novel approach was then compared to global PLSR and the local method developed by Shenk *et al.* (1997; LOCAL).

Materials & methods

Data and data editing. Milk samples (n=713) were collected from 622 cows differing in breed, parity, and stage of lactation. Samples were analysed using a MilkoScan FT6000 and the resulting spectra were stored; samples were subsequently assessed to quantify rennet coagulation time (RCT), curd firming time (k20), curd firmness at 30 and 60 minutes (a30 and a60), casein micelle size (CMS), and pH.

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_125, © M. Frizzarin *et al.* 2022

A single observation for each cow was retained, identified as that with the greatest Mahalanobis distance between the principal component scores (PCs) of the observation and the average PCs scores of the entire dataset. Spectra were transformed from transmittance to absorbance, and noise regions were deleted. Outliers for the milk technological traits were identified as those greater than 3 standard deviations from the trait mean. Only observations with values for all the 6 traits were used in the subsequent analyses. The final dataset comprised 348 samples.

Statistical methods. Three approaches to perform prediction were tested; PLSR equations were developed using the statistical software R (R core team, 2020) for all approaches. Neighbours were identified according to: (1) the correlation between the predictand spectrum and the other spectra in the dataset (the LOCAL approach); and (2) the Mahalanobis distance between the predictand spectrum PCs and the other spectra PCs (LCPA). Results were compared to the global approach whereby all samples in the dataset were considered as neighbours.

The LOCAL approach tests different numbers of neighbours and number of PLSR factors, and selects for the final analyses the combination of neighbours and factors which produces the lowest root mean square error (RMSE). These tuning parameters are then used for all the observations in the dataset.

During the LCPA analyses, the PCs of the spectra was calculated with both standardized and unstandardized spectra, and the Mahalanobis distance between the first 4 PCs of the spectra was used to measure the similarity. Then, to identify the optimal set of neighbours, changepoint analysis, which identifies a single or multiple changes in the mean of a vector, was used (Killick *et al.*, 2012). In the context of neighbours' identification, the vector of Mahalanobis distances between the predictand and the other spectra was used after being sorted from the smallest to the largest values. Changepoint analysis identified multiple points where the mean in the similarity vector changed and the first changepoint, which selected at least 20 observations, was used to select neighbours. During the changepoint analysis, the PELT method associated with the SIC and MBIC penalties were tested.

Analyses. During the global PLSR analyses, all samples in the dataset, with the exception of the predictand, were used to identify the optimal number of PLSR factors using leave-one-out (LOO) cross validation (CV). Then, all dataset observations (except the predictand) and the optimal number of factors were used to predict the predictand trait value.

Nine different LOCAL equations were developed. In each equation a different combination of number of neighbours and number of PLSR factors were considered. The number of neighbours used was 25, 50, and 100, and the number of PLSR factors used was 5, 10, and 20.

For the LCPA, neighbours were identified using the changepoint analysis, and were used to define the optimal number of PLSR factors using LOO CV. Then the neighbours and the optimal number of PLSR factors were used to predict the predictand trait values.

Measuring prediction performance. The prediction performance of the different approaches tested was quantified using the RMSEV and the correlation between the true and the predicted trait values (r).

Results

Prediction performance. Table 1 summarizes the RMSEV and r for the different approaches tested. Regardless of the approach employed, pH consistently had the greatest r, while CMS consistently had the lowest r. When comparing the predictions across approaches, the global approach had the lowest RMSEV

for 5 traits (i.e. RCT, a30, a60, CMS, pH), while the LCPA using the MBIC penalty without standardizing the spectra before the PCs calculation had the lowest RMSEV for k20. If only the local approaches are compared, the LCPA had the lowest RMSEV for 4 traits (i.e. RCT, k20, a30, CMS), while the LOCAL approach had the lowest RMSEV compared to LCPA for a60 and pH.

Prediction for spectra at the edge of the principal component space. Prediction performance for the 5% spectra with the greatest Mahalanobis distance between the PCs of the predictand and the average PC scores of the entire dataset was considered. For such outlying samples, the global approach had the lowest RMSEV compared to other approaches for 4 traits (i.e. RCT, a30, a60, and pH), while LCPA had the lowest RMSEV compared to the other approaches for k20 and CMS. The LCPA outperformed the LOCAL approach for all the traits with the exception of pH.

Table 1. Root mean square error of validation (RMSEV) and correlation (r) between the true and predicted trait values obtained from global, LOCAL, and local changepoint approaches to Partial Least Squares Regression Analysis.

	Global		Local		Local changepoint	
Trait	RMSEV	r	RMSEV	r	RMSEV	r
RCT, min	**5.74**	**0.51**	6.29	0.35	6.23	0.44
k20, min	2.55	0.47	2.71	0.42	**2.54**	**0.50**
a30, mm	**12.04**	**0.64**	13.25	0.54	13.01	0.56
a60, mm	**11.12**	**0.46**	11.41	0.38	12.38	0.33
CMS, mm	**24.17**	**0.32**	25.22	0.21	25.16	0.22
pH	**0.060**	**0.77**	0.065	0.73	0.068	0.72

[1] Bold font identifies the lowest RMSEV and highest correlation value for each trait.

[2] Results for the LOCAL and local changepoint approach are those produced from the optimal combination of tuning parameters.

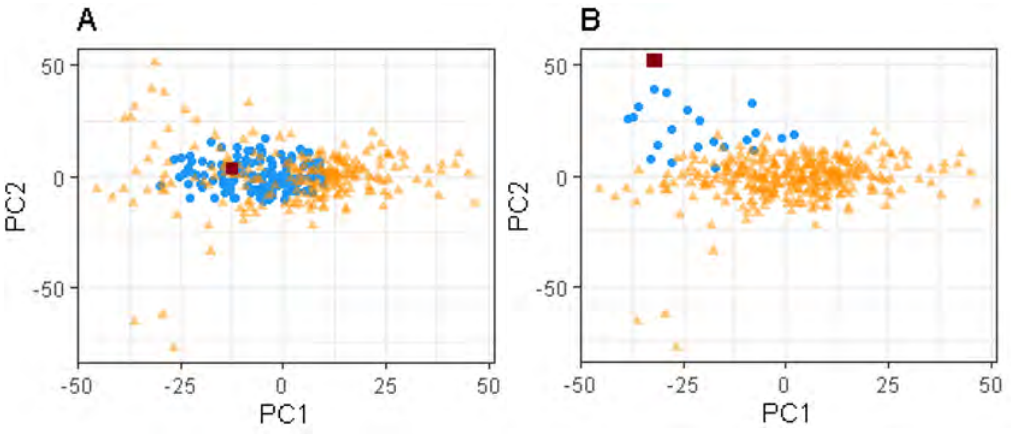

Figure 1. Neighbours selected according to the MBIC penalty after standardising the spectra for a target spectrum (red square) that lies in the centre ((A) n=133, blue dots) and at the edge ((B) n=21, blue dots) of the four-dimensional principal component space. The yellow triangles represent the other spectra not selected as neighbours.

Discussion

The local approaches presented in the literature generally select a fixed number of neighbours for use in prediction, regardless of the characteristics of the predictand. However, the number of samples with similar characteristics to the predictand may differ, particularly when we compare samples at the centre and at the edge of the dataset PCs space. In this study, samples at the centre of the PCs space had a greater number of neighbours identified when compared to samples at the edge of the PCs space (Figure 1). The sample with the greatest number of neighbours (133) was the 25th most central point (Figure 1A), while the sample with the lowest number of neighbours (21) was the fourth farthest point from the centre (Figure 1B). The benefit of varying the number of neighbours according to the characteristics of the spectra can be partly visible looking at the RMSEV when the 5% of observations with the greatest Mahalanobis distance from the centre were analysed.

Local methods have been successfully used to improve prediction analyses when multiple datasets were considered (Lesnoff *et al.*, 2021). However, those datasets comprised samples which originated from different sources and when these datasets were plotted in their first 2 PCs space, clusters were generally evident. The dataset considered in the present paper is composed only of milk samples with no obvious clusters in the PC space. This milk dataset can be thus considered an homogeneous dataset.

The application of local approaches in homogeneous datasets presents some limits, as reported also by Rabenarivo *et al.* (2013) who used local methods to predict soil traits. They reported better prediction results using the global approach compared to the local approach, with few exceptions. The limits of the local approaches when applied to homogeneous datasets can be related to the fact that all the observations in the dataset are similar to each other, and thus are informative during the prediction. In more heterogeneous datasets, the utilization of the local approaches can identify sub-groups and exclude uninformative samples during the predictions.

Conclusions

The local changepoint approach is a data driven and objective method for neighbours' selection, and in the present dataset improved the performance compared to the LOCAL approach. However, compared to the global approach, the local approaches had poorer predictions, probably due to the homogeneity of the dataset. The local approach can be useful for some specific traits, and more in general with heterogeneous datasets.

Abstract

Honeybees are a critical pollinator with a high economic and social impact on farming and natural ecosystems. Suitable climatic and ecological conditions play a crucial role on honey production. Machine learning has created an opportunity for predicted patterns in complex data structures (e.g. non-linear associations). We used 349 honey harvest records (kg) and 1,047 records of temperature, precipitation and atmospheric pressure from 6 apiaries collected between 2016 and 2019. Linear regression, Random Forests and eXtreme Gradient Boosting – XGBoost algorithms were employed to predict total honey harvest (THH). The lowest RMSE in testing set was estimated by XGBoost algorithms. Although the features were likely not enough to adequately capture the total variation of honey harvest the model performed well within its constraints. Using supervised machine learning was possible to predict THH with the error of 8.24 kg. More accurate phenotypes may better serve estimates of breeding values and improve selection outcomes.

Introduction

The *Apis mellifera* species are widely distributed in diverse climates around the world as a result of being potential for honey production. Climatic conditions have a direct influence on inside/outside colony activities like thermoregulation (Stabentheiner *et al.*, 2010), egg laying rate (Abou-Shaara *et al.*, 2017), food storing (Seeley and Visscher, 1985), flight and foraging activity (Haftom Gebremedhn *et al.*, 2014) and honey production (Neupane and Thapa, 2005). One of the biggest challenge's beekeepers face is estimating the effects of extremely low temperatures and high humidity during the winter season, which can lead to a significant reduction in honey harvest. Machine Learning Methods (MLM) have been useful to predicted complex biological data in agriculture (Liakos *et al.*, 2018), in meteorology (Choi *et al.*, 2018) and ecology (Peters *et al.*, 2014). In honeybees, MLM have been used for predicting health traits (Bjerge *et al.*, 2019), behaviour (Blut *et al.*, 2017), genetics (Fathian *et al.*, 2007), queen body mass (Prešern and Smodiš Škerl, 2019) and honey production (Karadas and Kadırhanogullari, 2017). Supervised regression models (SRM) are a group of learning algorithms that allow predicting targets (dependent variables) from a set of variables or features (predictors). The learning process is divided into training and testing steps. In training step, a data sample is taken as input in which features are learned by algorithm and build the learning model, then this model is used to make the prediction at new data during testing step (Nasteski, 2018). The next step is to choose the right metrics to assess its effectiveness. Our objective was to develop a predictive model for honey harvesting that incorporates the climatic conditions of winter prior to harvest. This approach can help beekeepers to identify potential limitations and establish new strategies to adaptively manage beehives in the coming seasons.

Materials & methods

Data sources. We used 349 honey harvest records (kg) from hives distributed in 6 apiaries collected between 2016 and 2019 and located in Lombardy region (Italy). The total honey harvest (THH) is the total weight of honey produced per hives per apiary between spring (March) to summer season (June). The number of hives with honey harvest records by apiary(year) were: Apiary A: 41(2019), Apiary B: 27(2016) and 41(2017), Apiary C: 31(2016), Apiary D: 32(2016) and 16(2017), Apiary E: 100(2018) and 30 (2019) and Apiary E: 31(2016). Geographic coordinates (latitude and longitude) were used to retrieve climatic data from meteorological stations for each apiary. Daily records of the atmospheric pressure (Hpa), temperature (°C) and rainfall (mm) between 2015-2019 for the winter prior to harvest were recovered from of the Copernicus Earth Observation program (https://www.copernicus.eu/it). The variation of temperature, rainfall and atmospheric pressure in the winter prior to honey harvest were 3.87 to 6.53 (°C); 66.10 to 100 mm and 5.23 to 7.00 Hpa (Table 1).

Preprocessing – exploratory analysis and standardization. For exploratory analysis, descriptive statistics (mean, standard deviation, interquartile range) were calculated (Table 2). Distributions, scatter diagrams and Pearson correlations were also estimated to identify outliers and to determine the relationship between climatic variables and THH. Subsequently, the hives with a THH lower than 5 kg were removed. A total of 1,047 observations from winter climatic conditions were included in the models. In addition, we rescaled the quantitative features using the z-score because the use of original scale may put more weight on the variables with a large range (Ahsan *et al.*, 2021).

Supervised machine learning analyses. For predictive analytics, three different SRM were used: Linear regression, Random Forest and eXtreme Gradient Boosting – XGBoost. Consequently, the database was divided into the training and testing set, with a chosen ratio of 70/30. The training set was used to create the initial models that they learned for each algorithm and to adjust the hyperparameters for cross-validation using 4 folds and 10 repetitions using the GridSearch technique that allow selected the best

Table 1. Climatic conditions in the winter prior to the honey harvest.

Apiary	Winter (December to March)	Climatic conditions		
		Temperature (°C)	Rainfall (mm/month)	Pressure (Hpa/month)
A	2018-2019	5.23	66.10	6.43
B	2015-2016	3.87	100.00	5.23
	2017-2018	3.97	85.30	5.23
C – D – F	2015-2016	6.40	90.00	6.93
D	2017-2018	6.53	69.20	7.00
E	2017-2018	4.37	80.90	6.13
	2018-2019	5.23	66.10	6.43

Table 2. Descriptive statistics of quantitative features and THH.

	Mean ± SD	Median	Q1	Q3
THH (kg)[1]	20.83±9.87	19.10	13.70	27.20
Temperature	5.10±3.06	5.09	3.80	6.80
Atmospheric pressure (Hpa)	6.27±0.99	6.30	5.40	7.00
Precipitation (mm)	81.83±23.88	84.30	70.50	103.72

[1] THH = total honey harvest (kg).

combination of hyperparameters. The root mean square error (RMSE) and the coefficient determination (R^2) were employed to measure model performance. RMSE is the most common metric for evaluating linear regression and represent the average magnitude of the error. All analyzes were performed using tidymodels package (Kuhn *et al.* (2020) in R v.4.0.3 (R core team 2020).

Results

Distribution of THH was asymmetric (mean: 20.83; median: 19.10). Correlations close to zero were found between the features and THH, indicating that there is no linear relationship between them. RMSE was used to evaluate the predictive performance of the models. The RMSE mean estimated was ±8.54 kg of THH (Table 3). The RMSE mean variation between training and testing set was close to 7%, this suggests that the algorithms used for the analysis of THH were consistent and that the use of winter season climatic variables are important on the prediction of THH.

In addition, a XGBoost had an optimal hyperparameters configuration that allowed a higher prediction performance. The best model was the eXtreme Gradient Boosting (XGBoost) with the lowest RMSE (8.24 on testing set) and R2 (coefficient determination) value of 0.29.

Discussion

In this study, the lowest RMSE (8.24 kg) was estimated fitting the XGboost algorithm that included apiary, year of harvest, and monthly observations of temperature, precipitation, and atmospheric pressure, which was similar to the value of MAE (mean absolute error; 10.3 kg) found by Campbell *et al.* (2020) using 115 climatic and remotely sensed features, and greater than the RMSE (1.85 kg) obtained by Karadas and Kadırhanogullari (2017) in models that included also the number of full beehives, working period in apiculture during year and control frequency of beehives in summer the results from 85 apiaries. The best algorithm should have the lowest values of RMSE (Ali *et al.*, 2015) and the highest estimation of adjusted R^2 (adj.R^2). In our results the estimation for adj.R^2 was 0.29 on XGboost algorithm, which was considerably smaller than the adj.R^2 reported by Karadas and Kadırhanogullari (2017) using MARS algorithm, nevertheless, our model considered less features and apiaries, and by Sakanovic *et al.* (2019) who included climatic variations such as carbon dioxide, temperature, oxygen levels and humidity present in apiaries using IoT (internet of things) technology. Although the features were likely not enough to adequately capture the total variation of honey harvest, the model performed well within its constraints and suggested an important effect of winter season climatic condition on the honey harvest. Finally, it is feasible to create a more informative algorithm that includes other climatic conditions, human management systems, and ecological and botanical information to find effective independent variables in beekeeping. A more informative algorithm could offer opportunities for the THH prediction and the development of better management and genetic/genomic selection strategies for the apiaries.

Table 3. Root mean square error (RMSE) for the models studied in training and testing.

Supervised regression models	Training set	Testing set
Linear regression	9.66	9.15
Random Forest	8.90	8.25
XGBoost[1]	8.87	8.24

[1] XGBoost = eXtreme gradient boosting algorithm.

Abstract

We compared validations for classification of behavioural interactions between pigs using computer vision and deep learning. We recorded interactions between pigs at a single-space feeder for 6 groups of 10 finishing pigs/group over the course of 6 weeks then compared different strategies to validate findings. Random cross validation is the most common procedure used in similar studies and consists of randomly partitioning video episodes into training and testing. This resulted in the highest classification accuracy (95%). Validation blocked-by-time used videos from early recordings for training and videos recorded three weeks later (same pigs) for testing (accuracy = 86%). Validation blocked-by-feeder used videos from one feeder for training and videos from another feeder (different pigs) for validation. This approach resulted in accuracies of 86 and 77% depending on which feeder was used for training and which feeder was used for validation. These results are worth considering when designing large scale behavioral.

Introduction

Computer vision is being used for automating behavioural phenotyping of pigs, including the detection of feeding and drinking events, interaction of pigs with enrichment objects and aggression between pigs (Chen, Zhu, Steibel, *et al.* 2020; Chen, Zhu, Oczak, *et al.* 2020). In most studies deep learning is used for automatically learning features from images and videos and for classifying them into different behavioural classes. Using this approach, good classifier properties under random cross validation are usually observed. One limitation for the applications of those approaches to large-scale phenotyping is the availability of training data, which typically requires extensive manual annotation of images and video segments. An important question is how to validate the resulting classifiers for large scale application in genetic evaluations involving large number of animals, groups, farms and timepoints. We investigated alternative cross validation schemes for classifying behavioural interactions between pigs at the feeder. The chosen problem has multiple potential application in animal breeding. For instance, detecting social interactions at the feeder can be used to parameterize competition effects in genetic evaluation models (Angarita *et al.* 2021).

Materials & methods

Experimental design. Two pens equipped with single-space automatic feed intake recording systems and digital video cameras were available for this study. Six groups of pigs were rotated through these pens every week for six consecutive weeks. Each group was recorded twice at different stages of the production cycle following the schedule in Table 1.

Table 1. Rotation schedule of social groups (SG) through feeders/pens.

	Week 1	Week 2	Week 3	Week 4	Week 5	Week 6
Feeder 1	SG 1	SG 2	SG 3	SG 1	SG 2	SG 3
Feeder 2	SG 4	SG 5	SG 6	SG 4	SG 5	SG 6

DOI: 10.3920/978-90-8686-940-4_127, © J.P. Steibel *et al.* 2022

Within each week, the first 5 days were for (re) acclimation of pigs to the new pen and the last two days were used for video recording of pig behavior at the feeder during the daylight hours (approximately from 8 AM to 4 PM).

Video recording and labelling. Video was recorded using the RGB module of the Intel® RealSense™ D435 camera. Videos of the feeder region were cropped at a resolution of 982×238 pixels with a target frame rate of 30 frames per second. Video segments containing two pigs at the feeder were segmented into 30 frame units and manually annotated by a trained observer according to the observed interaction at the feeder. After an initial assessment of a limited number of videos, an ethogram was built to classify video segments into five types of interactions between pigs at the feeder: (1) direct head to body contact; (2) indirect/ unintended head to body contact; (3) mounting; (4) levering; and (5) no contact. After further checking and validation, we decided to merge the two head to body categories into a single category of head to body.

Classification algorithm. We used deep learning (DL) and followed previously published work on classification of video episodes for behavioural phenotyping (Li *et al.* 2021). In brief, our algorithm was comprised of two stages (Figure 1). First, a pre-trained convolutional neural network was used for feature extraction. Second, a long short-term memory DL algorithm was trained from scratch for classification of video segments using the features extracted in the previous step.

When training DL models, it is extremely important to carefully chose hyperparamter values including network architecture, optimizer options, etc. (Han *et al.* 2021). For this study we used a combination of previously suggested options and grid search using internal cross validation.

A particular challenge in this case was the imbalance of the behavioural classes. Levering and mounting were clearly less frequent interactions, however, they are particularly important ones as they often lead to immediate replacement of pigs competing for feeding space and are forcible physical interactions between the pigs. Yet, when training DL classifiers, it is important to keep classes balanced. Up sampling or down

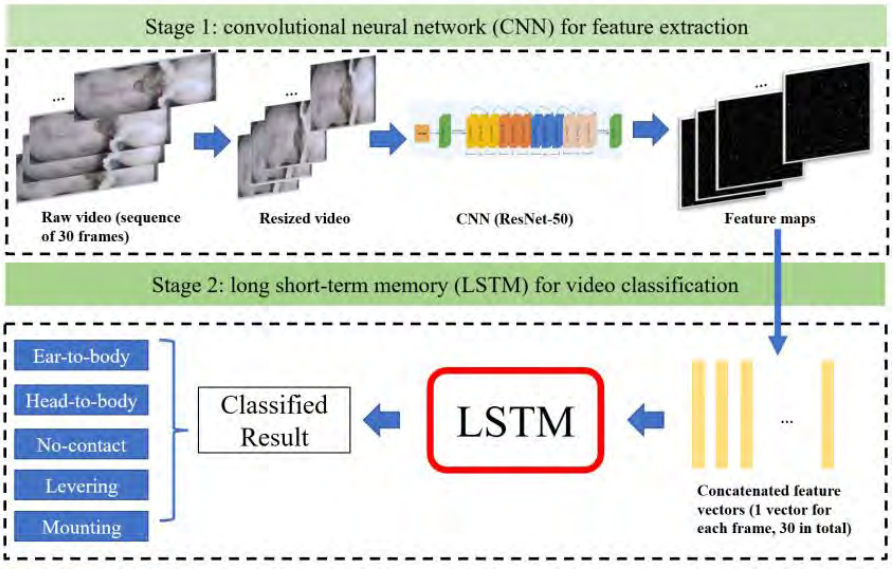

Figure 1. Deep learning pipeline for pig's aggressive behavior detection based on videos.

sampling are commonly used for this purpose. We were able to partially alleviate this problem through up sampling of the least frequent classes through data augmentation by selecting partially overlapping video segments of mounting and levering events. However, the imbalance persisted. Thus, we used a multi-class focal loss function that is specifically recommended for class-imbalanced data (Equation 1).

$$loss_{FL} = -\sum_{i=1}^{C} \alpha(1-y_i)^{\gamma} t_i log(y_i) \quad (1)$$

where C is the number of behavior classes, i is the class index, t_i is an indicator variable of correct/incorrect classification, y_i denotes the probability of behavioural class i (obtained from the last softmax activation function in the last layer), α is the focusing parameter, and γ is the balancing parameter.

The performance of the trained classifiers was assessed under cross validation (next section) using two metrics: class-specific recall (Equation 2) and class-specific precision (Equation 3).

$$recall_i = \frac{Number\ of\ correctly\ classified\ episodes\ for\ class\ i}{Total\ number\ of\ annotated\ episodes\ for\ class\ i} \quad (2)$$

$$precision_i = \frac{Number\ of\ correctly\ classified\ episodes\ for\ class\ i}{Total\ number\ of\ episodes\ predicted\ for\ class\ i} \quad (3)$$

Validation strategies. The structure of our data allowed assessing the properties of classifiers using different validation partitions. Under random cross-validation, five different random training and validation sets were selected. For validation blocking by time, video segments from the first three weeks were used for training and video segments from the last three weeks were used for validation. For the validation blocking by feeder, video segments recorded at one feeder were used for training and video segments recorded at another feeder were used for validation. To facilitate comparison of results, the size of the training set was kept fixed at 7,500 video episodes for all validation schemes and the validation was repeated five times by randomly selecting different test and validation video episodes, subject to the constraints of each validation scheme.

Results

Random cross validation. The performance of the multi-class classification algorithm of video segments under random cross validation was on par with previously published work using binary classification of video episodes for aggression, drinking and feeding. Overall classification accuracy was above 95%, precision ranged between 93% for levering and 97% for head-to-body interactions and recall varied between 85% for levering and 97% for mounting (Figure 2). This is remarkably good performance considering the complexity of multi-class classification with heavy imbalance among classes, as is the case in this example.

Validation blocked-by-time. Overall, using early episodes for training the algorithm to classify video episodes recorded later from the same social groups resulted in a significant loss in performance. Overall classification accuracy was 86±3%. Class-specific precision ranged between 35% (levering) and 97% (head-to-body contact) and recall ranged between 82% (no contact) and 96% (levering). The low precision in detecting levering was due to many head-to-body contact events that were classified as levering.

Validation blocked-by-feeder. When using video episodes from one feeder for training to classify video episodes recorded on another feeder, the performance dropped even further. But most remarkably, the performance differed between the two partitions in this validation strategy. Specifically, using video episodes recorded at feeder 1 (social groups 1, 2, 3) for training to classify video episodes recorded at feeder 2 (social groups 4, 5, 6) resulted in better accuracy (86±1%) compared to using episodes recorded at feeder 2 to classify video episodes recorded at feeder 1 (77±3%). Moreover, the specific pattern of mis-

classifications also differed between the two implementations of this validation. A principal component analysis of features extracted from frames and input into the LSTM classifier revealed that the first two principal components clearly separated video frames according to feeder at which they were taken. However, higher order principal components indicated that variation between frames taken at feeder 2 was less than variation between frames taken at feeder one. This hints at the possibility that training on the most variable set and predicting on the less variable set produces better performance compared to the opposite scenario.

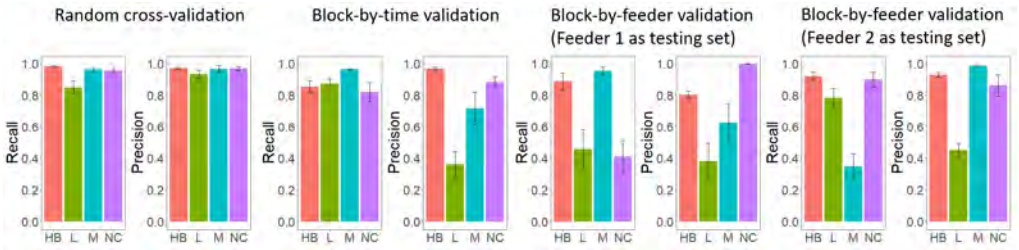

Figure 2. Recall and Precision of video classifiers of behavioral interactions under alternative validation strategies. HB: head to body, L: levering, M: mounting, NC: no contact.

Discussion

Deep learning algorithms combining transfer learning for feature extraction and di-novo training for classification are a very promising tool for video classification using computer vision for animal behavioural phenotyping. However, as these algorithms are developed and tested under realistic production conditions it is important to conduct validations that are commensurate with the intended applications. For instance, for research applications where a large amount of video is collected over time and across social groups for later analysis, random cross validation seems to produce the best results. On the other side, if 'on-the-flight' training is necessary, where videos segments recorded early are annotated and used to train algorithms to classify video segments recorded in later production stages, validation over time gives more realistic results than random cross validation. Validation blocking by time is also worth considering when training computer vision for animal identification algorithms that will be used through the production cycle of each individual. Finally, training classifiers on video recordings of certain groups of animals to be used in videos recorded on different groups will likely require larger training sets and more extensive validation as demonstrated in our study through the blocking-by-feeder scenario.

Abstract

The importance of sensor-based phenotyping is increasing in the broiler industry, aiming at improved animal health and welfare, and lower economic losses. We analysed 11 pose features of 87 individual chickens at three ages (day 14, 21, and 33) using video recordings filmed from behind while the broilers walked through a corridor one by one. A pre-trained deep learning model was trained on a limited number of frames (n=181) to adapt it to a new environment for accurate keypoint detection. Extraction of the three poses of interest (double support, left and right steps) was fully automated. Significant (P<0.05) differences were observed among ages in hock joint angles, shank versus horizontal line angles, normalized drumstick and shank lengths, and hock/knee distance ratio. Recording walking broilers from behind proved to be useful in obtaining relevant pose features in an automated way.

Introduction

Poor leg health is a significant welfare and economic issue in the broiler industry (Knowles *et al.*, 2008). Sensor-based phenotypes collected at large scale can support the improvement of genetic gain of locomotion if incorporated in the breeding strategy. In a study of 51,000 broilers from 176 flocks, 27.6% of the birds showed poor locomotion (defined by gait score ≥3 on a 0-5 scale), and 3.3% were almost unable to walk (gait score ≥4; Knowles *et al.*, 2008). Several approaches have been proposed to monitor locomotion in poultry, including inertial measurement units (Bouwman *et al.*, 2020) and cameras (Aydin, 2017; Caplen *et al.*, 2012). In a study, broilers were filmed from above while walking through a corridor, and broilers with higher (≥3 on a 0-4 scale) gait scores had shorter steps, lower speed, and more pronounced lateral body oscillation (Aydin, 2017). In another study, the pose of standing broilers was compared to their gait using photogrammetry from 21 to 42 days of age (Mendes *et al.*, 2016). The aim of our study was to analyse the pose of individual broilers across ages using video images under semi-practical circumstances.

Materials & methods

Experimental setup and video recording. Individually tagged male broilers (n=109) from the same cross were filmed three times (at 14, 21, and 33 days of age) at a Cobb test facility in the Netherlands. During testing, birds had to walk one by one through a corridor created within their pen with dimensions 3 m (length) × 0.4 m (width). An Intel® RealSense™ Depth Camera D415 (Intel Corp., Santa Clara, CA, USA) camera was placed at the start of the corridor, which recorded the chickens from behind during walking. Some birds were removed from the experimental groups for other purposes or due to mortality, therefore, 87 birds remained for video recording by 33 days of age. The RGB video recordings of the camera were converted to .mp4 format with 12 FPS and 1,280×720 pixels resolution for further analysis using a custom Python code.

Keypoint detection. Eight keypoints (head, neck, left and right knees, hocks, and feet) were detected using a pre-trained broiler pose estimation deep learning model developed in DeepLabCut (Mathis *et al.*, 2018). Details of the pre-trained broiler pose estimation model are described in detail elsewhere (Doornweerd *et al.*, 2021). However, this pre-trained model struggled with accurately detecting the keypoints of the chickens in the new environment (e.g. different illumination, red drinkers above the head of the chickens,

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_128, © I. Fodor *et al.* 2022

other chickens at the end of the corridor). Therefore, video frames of some birds that had been removed from the current setup between day 14 and 33 were used for retraining of this model. Altogether, 181 frames were used for retraining (day 14: five birds, day 21: eight birds), whereas 40 frames (day 14: two birds, day 21: two birds) were used for testing the retrained model, which resulted in a 82/18 train-test split. This model was then used for the analysis of the newly acquired videos, along with a spline filter and dynamic cropping (the latter in day 14 videos only) to reduce noise in the keypoint estimates. Coordinates and likelihoods of the estimated keypoints were used for pose extraction and calculating the features.

Automated pose extraction. Birds that did not walk during the test (n_{D21}=1, n_{D33}=3) were excluded from further analyses. Briefly, the first and last 10% of the frames of each video were discarded. Then, maximum leg lift and feet being on the ground were detected, based on the local maxima and minima in the longitudinal data of keypoint coordinates. Based on these two distinct feet positions, pose proposals were generated for the three specific poses of interest: double support stance, left and right steps with maximum leg lift. Pose proposals were then sorted based on the normalized vertical difference between the left and right feet, using the vertical difference between the highest knee and lowest foot in the given frame for normalization. Frames with double support phase were selected by minimizing the vertical difference between the left and right foot. On the contrary, steps were selected based on maximizing the vertical difference between feet. For each bird-age-pose combination, the three best frames (based on the vertical differences as sorting criteria) were chosen to calculate pose features. The quality of automatically detected poses was checked visually by extracting the respective frames of 10 randomly selected birds from each age.

Pose features. Altogether, 11 features were defined, where the left and right sides of the same attribute counted as two separate features: normalized step height (%), hock joint lateral angles (degrees), medial angle of the shank and the horizontal line (degrees), normalized drumstick length, normalized shank length, and the ratio between the horizontal distance of hocks and that of the knees (Figure 1). The same normalization was performed as with pose proposals described above. Pose features of the three extracted best frames were averaged to represent the given feature of the bird at that specific pose at a given age.

Statistical analysis. Birds alive on day 33 were included in the analyses. Extracted features were analysed in R version 4.0.2 (R Core Team, 2020). Differences by age were tested using a linear mixed model with age as a categorical variable and chicken as a random factor, using the lme4 package in R (Bates *et al.*, 2015). Pairwise post hoc comparison of age groups was performed using Tukey contrasts. The level of significance was set to 0.05.

Results

Based on the visual check of the labelled keypoints using the original pre-trained model, label jumps between the bird of interest and birds in the background were more common at younger ages. However, label jumps between the drinker and the head occurred quite frequently irrespective of age. Further training

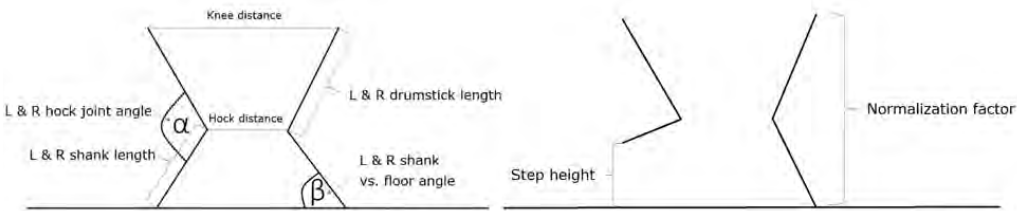

Figure 1. Schematic representation of the analysed features at double support (left) and steps (right).

of the pre-trained broiler pose estimation model substantially reduced the occurrence of these errors. The training and test errors of the final model were 2.11 pixels and 4.02 pixels, respectively, at 100,000 iterations.

The automated pose extraction algorithm correctly identified and selected the relevant poses. Examples of automatically extracted double support stance, left and right steps from day 14 are shown in Figure 2.

Sharper hock joint angles ($P<0.01$) and shank vs horizontal line angles ($P<0.05$) were observed on day 33 than on day 21 (Table 1). Normalized drumstick lengths were shorter ($P<0.0001$), whereas normalized shank lengths were longer ($P<0.05$) on day 21 and 33 than on day 14. The hock/knee distance ratio was larger ($P<0.01$) on day 21 and day 33 compared to day 14. No clear trends were observed regarding step height by age.

Figure 2. Automatically extracted double support stance, left and right steps on day 14 (images cropped and enlarged).

Table 1. Descriptive statistics of pose features by age.

Feature	D14		D21		D33	
	Mean	SD	Mean	SD	Mean	SD
Left hock angle (°)	153.7	7.1	153.6	6.6	150.1	8.2
Right hock angle (°)	154.5	5.8	157.2	5.5	154.0	6.6
Left shank vs horizontal line angle (°)	84.24	4.76	85.38	6.47	82.93	6.65
Right shank vs horizontal line angle (°)	83.06	5.94	83.58	4.55	81.18	6.33
Left drumstick rel. length	0.583	0.048	0.542	0.047	0.535	0.046
Right drumstick rel. length	0.601	0.047	0.564	0.046	0.572	0.037
Left shank rel. length	0.423	0.033	0.443	0.061	0.454	0.051
Right shank rel. length	0.411	0.037	0.449	0.047	0.439	0.040
Hock/knee distance ratio	0.586	0.094	0.625	0.058	0.644	0.066
Left step height (%)	36.47	6.53	39.08	6.79	39.20	8.71
Right step height (%)	39.20	7.08	36.00	7.36	32.08	9.59

Discussion

We demonstrated the usability of recording walking broilers from behind for monitoring certain locomotion features. Further training of a pre-trained pose estimation model with a limited number of frames improved its performance in the new environment. The automated pose extraction algorithm proved to be useful for high-throughput pose extraction. Although, further improvements could be made to this algorithm, because in some instances the double support stance was somewhat asymmetric, and not the highest leg lift was captured during some steps.

In contrast with the photogrammetry method used by Mendes *et al.* (2016), video recordings have the potential to be upscaled to practical circumstances. Using a top view of the chickens, Aydin (2017) calculated features such as speed, step frequency and length, and lateral body oscillation. In our setup, angles, hock-knee distance ratio, and step height were the most informative features, whereas relative drumstick and shank lengths were more heavily influenced by perspective. Further work could focus on the relationship of these video-derived features with gait.

Ethical statement

Data were collected under control of Cobb Europe. Cobb Europe complies with Dutch legislation on animal welfare.

Funding

This study was financially supported by the Dutch Ministry of Economic Affairs (TKI Agri and Food project 16022) and the Breed4Food partners Cobb Europe, CRV, Hendrix Genetics and Topigs Norsvin.

129. Predicting carcass cut yields in cattle from digital images using artificial intelligence

D. Matthews[1*], T. Pabiou[1], R.D. Evans[1], C. Beder[2] and A. Daly[2]

[1]Irish Cattle Breeding Federation, Ballincollig, Co. Cork, Ireland; [2]Munster Technological University, Bishopstown, Cork, Ireland; dmatthews@icbf.com

Abstract

Deep Learning (DL) is a successful tool for many image classification problems but has yet to be applied to carcass images. The aim of this study was to train DL models to predict carcass cut yields and compare predictions to more standard machine learning (ML) methods. Three approaches were undertaken to predict the grouped carcass cut yields of Grilling cuts and Roasting cuts from a large dataset of 54,598 and 69,246 animals respectively. The approaches taken were: (1) animal phenotypic data used as features for a range of ML algorithms; (2) carcass images used to train Convolutional Neural Networks; and (3) carcass dimensions measured directly from the images, combined with associated phenotypic data and used as feature data for ML algorithms. Results showed that DL models can be trained to predict carcass cuts yields but an approach that uses carcass dimensions in ML algorithms performs slightly better in absolute terms.

Introduction

Currently, beef carcasses in the European Union are graded for payment and processing using the EUROP classification grid for conformation and fat. The degree of association between EUROP predicted scores and meat yield of a carcass, both on a total meat yield level or on a carcass cut level, is highly variable (Conroy *et al.*, 2009; Conroy *et al.*, 2010; Drennan *et al.*, 2008; Pabiou *et al.*, 2011) yet meat yield to the processor is the primary driver of a carcass' subsequent economic value. Nonetheless, payments to primary producers, price reporting, and trade to wholesalers are all still based on the EUROP system. It is therefore desirable at an industry level to have mechanisms to predict the actual meat yield of a carcass accurately.

From an animal breeding perspective, EUROP predictions are often used as genetic traits notwithstanding the variable association between EUROP predicted scores and a carcass' economic value. Connolly *et al.* (2019) established the benefit of including breeding values for meat yields in the Irish breeding program. However, meat yields have yet to be included as genetic traits in the Irish breeding program, mainly due to the difficulty in recording meat yields during carcass processing. If accurate meat yield predictions could be calculated these would offer a potential approach for including meat yields in breeding programmes and thus, allow producers to breed for higher yields of more valuable cuts of meat. In this study we have investigated the performance of Deep Learning (DL) to predict grouped carcass cut yields from images and compared the models to machine learning (ML) models using animal data and also using carcass dimensions measured directly from the carcass images.

Materials & methods

Data collection. Data from Irish cattle slaughtered for meat between 2011 to 2018 was available from a range of sources: carcass images and phenotypic data captured at different stages throughout the animal's lifetime were collated along with target variables of meat yields for different processed cuts of the carcass. The yield of specific meat cuts in kilograms were recorded during routine carcass processing in an Irish commercial abattoir. As such, the dataset contained steers, heifers, cows and young bulls. Also, the vast majority of animals were commercial crossbred animals with varying proportions of beef and dairy breeds. The meat cuts recorded and used in this study were the Silverside, Topside, Knuckle, Rump, Striploin, Fillet, and Cube-roll. Only cut data from animals that: (1) had a yield recorded for each of the 7 cuts

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_129, © D. Matthews *et al.* 2022

examined; (2) had a weight within 3 standard deviations of their respective cut mean; (3) matched to an animal record present in the ICBF database; and (4) also matched to a carcass image were included in the study. Similar to Pabiou *et al.* (2011), the meat cuts representing the highest value cuts of the carcass were grouped together into Grilling cuts (combined yield of striploin, fillet and cube-roll) and Roasting cuts (combined yield of silverside, topside, knuckle and rump). The final clean dataset contained 54,598 Grilling yields and 69,246 Roasting yields. Meat yields recorded in the abattoir were matched to animal records in the ICBF database and features deemed informative for this study were extracted. Categorical data was one-hot encoded into multiple features and joined to continuous features which were standardised. Two photographs of the carcasses were taken immediately after slaughter: a standard two-dimensional image (2D) and a structured light image (3D). The video image analysis (VIA) system used across Irish abattoirs is the VBS2000 (E+V GmbH, Germany) and prediction of carcass conformation and carcass fat on the EUROP scale uses proprietary VIA software. In this study, the 2D and 3D images collected in abattoirs are used to train novel models, but the propriety software was not.

Models. To investigate the predictive performance of models created in this study, two distinct datasets were created: a training set and a hold-out test set. The test set was approximately 10% of the total dataset and was chosen randomly. Three different approaches were examined for predicting Grilling and Roasting cuts largely determined by the suitability of the data type to a specific ML algorithm. The 3 approaches were: (1) phenotypic data as input features for a range of ML regression algorithms, (2) carcass images fed into a DL neural network adapted to predict a regression value rather than classification, and (3) measuring 346 carcass dimensions from the carcass image and concatenating these measurements with the phenotypic data available to use as features in a range of ML algorithms.

The Root Mean Squared Error (RMSE) was used as the main determinant of a model's predictive ability. Mean Absolute Error (MAE) and coefficient of determination (R^2) were also calculated as a final measure of accuracy.

Results

Of all ML algorithms tested in Approaches 1 and 3, Gradient Boosting performed the best and therefore those results are presented here. Table 1 presents the predictive performance of optimised models on the hold-out test set. As this test set has never been included in any training or validation set, it allows for a more direct comparison between the different predictive models. For Grilling yield, all models performed very similarly with small RMSE and MAE metrics relative to the Grilling yield mean of 35.1 kg. The difference between the best performing and worst performing models was 0.16 kg RMSE. Approach 1, utilising the phenotypic animal data, had the lowest predictive performance on the test set with a RMSE of 2.94 kg. Predicting Grilling yield directly from digital images used to train a DL model reduced RMSE to 2.84 kg for both '2D' and '3D' images. Including carcass measurements, taken from the digital image, marginally reduced the RMSE further to 2.78 kg giving the highest predictive performance for the Grilling yield overall. Removing the conformation and fat score predicted previously from the digital image by a different process increased the RMSE fractionally to 2.81 kg.

The performance of the models trained to predict Roasting yield were also very similar across approaches with a 0.16 kg RMSE differential between the best performing and worst performing models (Table 1). Approach 1, utilising the phenotypic animal data to predict the Roasting yield resulted in an RMSE of 3.23 kg on the test set which in turn had a mean yield of 78.2 kg. The DL models used in Approach 2 had fractionally worse performance with RMSE values of 3.26 kg for both '2D' and '3D' images respectively. Models produced from Approach 3 had the best predictive performance at an RMSE of 3.19 kg without including conformation and fat scores, and 3.07 kg when including these scores. Overall, from a production

Table 1. Model performance for prediction of Grilling and Roasting yields on hold-out test data. RMSE and MAE are in kilograms.

			Grilling			Roasting

[1] No fat and conformation score.

[2] Including fat and conformation score.

viewpoint there are small differences in performance between models. The significance of this is discussed further below.

Discussion

One of the key results of this study is that there is little difference in the performance of the DL and ML models. From a practical point of view, once the DL models are trained, they are easier to deploy than the ML models. This is because the DL models require the carcass images only, captured in the abattoir within minutes of slaughter. In contrast the ML models require significant more data collection. In Approach 3, carcass measurements were combined with the associated phenotypic data. Matching carcass images to animal phenotypic data adds a layer of complexity and likely removes the possibility of an immediate prediction as nearly always the associated phenotypic data is stored in databases not instantaneously available. Consequently, it may be preferred at a processing level to obtain an immediate cut yield prediction with a slightly reduced predictive performance. In this scenario, our DL models predicting grouped carcass cuts from digital images could offer a mechanism to achieve just that.

A marked improvement in all approaches for predicting Roasting yields compared to predicting Grilling yields was observed in this study. Pabiou *et al.* (2011) also found variation in predictive performance for different areas of the carcass. The EUROP conformation classification places large emphasis on the hindquarters of a carcass. The Roasting cuts are exclusively in this area of the carcass, and it can therefore be postulated that predicted conformation score is more highly correlated to Roasting yield than Grilling yield. However, DL models also had much improved predictive capability for Roasting yield over Grilling yield when trained on the images alone without any predicted conformation score included in the model. The Roasting yield has a larger mean weight than the Grilling yield and makes up a larger proportion of the total carcass. Therefore, many more pixels from the digital image contain direct information on the Roasting yield than the Grilling yield. Conversely, the Grilling cuts have a smaller proportion of image pixels conveying direct information on these cuts. Furthermore, the fillet cut which is one of three Grilling cuts, is located beneath the rump and striploin cuts and therefore is not directly represented in any image pixel. Many successful applications of DL applied to images match the performance of a trained human (Miotto *et al.*, 2018). Fundamentally, these DL applications do not observe visual information beyond the capability of the human eye. Given that little information on Grilling yield is directly available from the image it is our opinion that the DL models presented here are approaching the predictive ability of a trained human grader.

In this study we have used 43,628 and 55,362 training records (in addition to 5,466 and 6,935 validation records) for Grilling and Roasting cuts respectively. Compared to the training set sizes observed in many successful DL models such as those trained on the ImageNet database with ~20 million images (Deng *et al.*

2009), the size here is limited especially considering the similarity between carcass images. We have applied transfer learning to overcome this issue of a smaller dataset, however, a much larger dataset would be an optimum solution. Nonetheless, given the impracticality of obtaining a carcass image training dataset of millions of records with associated meat yields, a more suitable option may be to collect more information from the digital images. This is commonly applied with the current VIA processes for EUROP score prediction and we have also investigated this approach by including carcass measurements in ML models. Including these measurements, as carried out in Approach 3, gave the best overall performance, albeit by a very small margin. However, predicted conformation and fat scores are still necessary features to include in the model to maximise performance. The fact that a reduction in performance does occur, indicates that the current VIA processes effectively capture available information from the carcass images, and therefore demonstrates the potential for the current VIA processes and models to be re-trained on meat yield rather than EUROP classification.

We conclude that DL models applied to meat yield data hold potential and may be more practical to deploy at an abattoir level, but our results suggest that the training datasets need to be significantly larger. In the scenario of more limited datasets, the standard approach of VIA and further image processing to capture important carcass dimensions and contours which flow into predictive ML models, has better predictive ability for carcass meat yields.

Abstract

Recent developments in rapid digital phenotyping methods have resulted in new phenotypes in finfish aquaculture like feed intake, growth, and body fat towards improving the feed efficiency complex. Similarly, digital operational welfare indicators have been newly developed for Atlantic salmon including: the number of lice, the number and severity of wounds, condition of fins and smoltification status. The methods employed across these diverse phenotypes vary in approach but show some similarities. In general, they focus on being high throughput and non-invasive, reducing the fish time out of water by using semi-automated image or vibrational spectroscopy. All phenotypes tested were significantly heritable (0.18-0.61) and correlated to their respective gold standards (0.70-0.98). The added benefit of being either higher throughput, cheaper or less invasive than their gold standard counter parts; means digital phenotyping methods will likely continue to develop to meet the needs of future genetic selection programmes.

Introduction

The Atlantic salmon industry faces challenges to maintain good health and animal welfare, reduce environmental impacts, whilst remaining profitable. The sheer scale of aquaculture operations, as well as the operational and biological limitations of recording fish out of water, has spurred new research into rapid and non-invasive digital phenotyping methods. Genetic selection for improved feed efficiency is one approach that can lead to reductions in feed costs and environmental impact, as more than 50% of operational costs and 70% of the carbon foot print are related to feed (Iversen *et al.*, 2020; Winther *et al.*, 2020). Ensuring individual animal welfare is a moral and legal imperative, however genetic research into animal welfare is still in its infancy due to difficulties obtaining phenotypes.

Both feed efficiency and animal welfare traits are complex phenotypes comprised of numerous subtraits. Feed efficiency requires recording of growth and lipid deposition in different body tissues and, most importantly, feed intake. A standardised set of traits entitled 'operational welfare indicators' was recently established (Noble *et al.*, 2018) including smoltification status (determining readiness for seawater), number of ectoparasites, presence and severity of skin wounds and fin condition. Trained observers score these operational welfare indicators, which entails a rapid assessment of as many as 20 different traits. A conundrum while recording this data is that individual welfare and feed intake should not be compromised by the act of measuring traits themselves. The longer a fish remains out of water while being handled, the higher the chance of harming its welfare and stress induced loss of appetite. We present a number of potential rapid, non-invasive, digital phenotypes in development to address these challenges.

Materials & methods

Different digital phenotyping methods used in the feed efficiency complex or operational welfare indicator suites are described below with an emphasis on the basic principles, number of salmon recorded and their life stages.

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_130, © G.F. Difford *et al.* 2022

The feed efficiency complex. The feed efficiency complex is a group of traits including feed intake, growth and lipid deposition, all of which are now being digitalised to increase the frequency and quality of recordings. Growth of Atlantic salmon can now be continuously and non-invasively measured underwater at sea using diode frames. As fish swim through the frame, they obstruct the infrared light providing the length and depth record of the fish. Weight is then estimated using allometric predictions. Our innovation combines the underwater passive integrated transponder (PIT) readers into the diode frame thereby linking the radio frequency identification of the individual salmon with their growth phenotypes (Difford *et al.*, 2020). To date, more than 5,000 Atlantic salmon have been continuously phenotyped until 2 kg.

The addition of radio opaque markers to pelleted feeds makes it possible to determine the mass of feed consumed by an individual fish using a calibration equation for the relationship between marker numbers and feed mass. Individual fish are then X-rayed and the number of markers (which can be as high as 30-500) must be counted. Since manual counting is time consuming and tedious, we developed semi-automated image analysis together with automated deep learning tools to count the number of markers. Hitherto, more than 1,200 Atlantic salmon have been recorded for feed intake, ranging from 50-1000 gram.

The third component of feed efficiency is body lipid content in whole fish or in the muscle and other tissues at slaughter, resulting in a wide variety of spectroscopic methods. Currently, two non-invasive methods are in use for whole fish, a handheld dielectric spectroscopic method (Distel Fat Meter™) and an online rapid and non-invasive NIR sensor (SmartSensor). Both methods have been recorded simultaneously on 680 post-smolt Atlantic salmon. Three different methods using Raman and NIR sensors on salmon fillets or ground meat have been simultaneously tested on more than 500 Atlantic salmon broodstock (Difford *et al.*, 2021).

Operational welfare indicators. To reduce excessive handling and time during welfare scoring, we developed an imaging system with rapid delivery of fish via conveyor belts. This system makes it possible to image both sides of an anesthetised fish in under 30 seconds. By handling the fish with care and monitoring their recovery post-anaesthesia, none of the measured fish showed impaired welfare. The images undergo image analysis and deep learning methods to determine numerous traits including fish smoltification status, fin morphology, presence of wounds, as well as salmon lice numbers. For genetic evaluations, standardised *in vivo* lice challenge models are used, where large numbers of fish (2,000-3,000) must be counted for lice within a 2-3 day period with between 0-180 lice per fish, before the chalimus lice (<1 mm in length) become motile. To this end, we have digitally recorded more than 1,200 genotyped smolt infected with over 18,000 salmon lice. We have also successfully scored 450 Atlantic salmon during their transformation from fresh- to saltwater, where observable changes in their morphology, including skin and fin colorations were captured. We have successfully recorded more than 2,500 Atlantic salmon parr and post smolts for presence and severity of skin lesions, scale loss, damage to pectoral, dorsal, pelvic and caudal fins for indicators to welfare.

Results & discussion

We present the digital phenotypes, methods, number of recorded salmon, heritability and validation results for each method in Table 1. A variety of digital methods are employed each with different forms of multivariate data captured either as images, vibrational spectra, or sensors in time series. To unlock the phenotyping potential of these diverse data streams, we applied a wide variety of skills in image analysis, machine learning and deep learning. As the data types continue to diversify and the volumes increase, a large proportion of phenomics will be devoted towards data processing, compression and handling.

Table 1. Digital phenotypes, methods, number of fish, heritability estimates and validation in Atlantic salmon.

Phenotypes	Methods	N[1]	h^2	Validation[3]
Feed efficiency complex				
Feed intake	Xray	1,200	0.22	rp=0.85
Length	Infrared Diode frames	5,162	0.22	rg=0.90
Weight	Infrared Diode frames	5,161	0.18	rg=0.84
Lipid (fillet)	NIR spectroscopy	523	0.60	rg=0.93
Lipid (fillet)	Raman spectroscopy	523	0.52	rg=0.98
Lipid (whole)	Dielectric spectroscopy (Distell meter™)	680	0.45	rp=0.87
Lipid (whole)	NIR spectroscopy (SmartSensor)	680	0.61	rp=0.80
Operational welfare indicators				
Skin & fin	Spectral imaging	2,500		rp=0.94
Smoltification	Spectral imaging	450		rp=0.90
Lice count	Spectral imaging	1,200		rp=0.70

[1] N = number of fish.

[2] h^2 = heritability.

[3] Validation using either phenotypic correlations (rp) or genetic correlations (rg).

All new digital phenotyping methods must be compared to the appropriate gold standard methods in order to benchmark the level of their agreement. In a few instances it is possible to have enough phenotypes with both methods to estimate genetic correlations (Table 1). However, in most instances the gold standard is too expensive or invasive and only a small number of fish can be recorded. In such cases, we estimated the phenotypic correlation. In all cases the correlations were above 0.7 and mostly over 0.84. Assessing the costs of recording, the heritability, the gain in throughput over the gold standard method and proportion of variation in the gold standard captured, all contribute to assessing the merit of including digital phenotypes in the breeding goal.

Importantly, this work shows that digital methods can be adapted to meet the needs of fish biology. This is the first instance where individual growth of Atlantic salmon was measured underwater at sea and found to be heritable. The ability to record salmon in their commercial environments opens up the possibility of improving growth, yield, and, ultimately, feed efficiency. Furthermore, the shift from relying on human-scored operational welfare traits to rapid, image-based methods has resulted in larger sample sizes in far shorter time (Figure 1). This not only reduces the welfare burden on the fish being measured but also

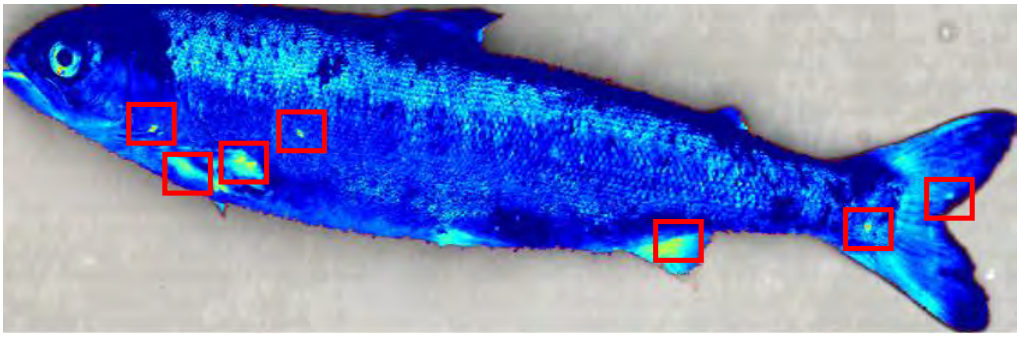

Figure 1. Enhanced image of Atlantic salmon with copepod salmon lice attached (red).

the financial burden of requiring human resources, a costly exercise in Norway. Currently, no studies have reported heritability estimates for welfare traits in Atlantic salmon, and more research is needed to address this.

Method development is not static; rather, improvements are continuous as new technology and digital phenotypes are created, which must then be rigorously validated. For example, significant genomic heritability of feed intake in Atlantic salmon is reported for the first time using digital Xray radiography (Figure 2). Whilst these estimates are from land-based research facilities, the latest developments in portable Xray technology make cage-side imaging of larger fish feasible. Atlantic salmon breeding programmes of the future will likely contain many digital phenotypes in their breeding goals.

Abstract

Combining milk Mid-infrared (MIR) spectra with other cow descriptive and performance variables improves the prediction accuracy of total dry matter intake (TDMI) in dairy cows above using the milk MIR spectra only. However, the improvement in accuracy of prediction depends also on data fusion and prediction methods. Our objective was to evaluate low- and high-level data fusion strategies with partial least square (PLS) and artificial neural networks (ANN). Prediction equations were developed using a total of 384 observations and 4 different models. Predictions were performed using ANN, PLS and multiple linear regression (MLR). MLR was implemented using the variables A (milk yield, concentrate dry matter intake, week of lactation, parity and metabolic body weight). ANN was implemented using variables A, using only milk MIR spectra data or combining milk MIR spectra and variables A. PLS was implemented using variables A or using the milk MIR spectra and variables A. The high-level data fusion method using ANN had the highest out of sample coefficient of determination (R^2) of 0.62. Direct merging of milk MIR spectra data with variables A explained better the TDMI than the milk MIR spectra data using both ANN and PLS prediction methods. Generally, the ANN methods perform better than PLS at low as well as at high level data fusion. Merging both milk MIR spectra data and animal variables at high level fusion enables to exploit better the information in the data. This method has thus a great potential to predict TDMI in commercial dairy farms. However, our finding needs additional evidence using large dataset and external validation.

Introduction

Milk MIR spectra are useful for predicting TDMI in dairy cows (Dórea *et al.* 2018; Lahart *et al.* 2019; Grelet *et al.* 2020). Based on most studies, combining milk MIR spectra data with other cow descriptive and performance variables, such as milk yield, lactation stage, parity, body weight, and feeding behavior, gave better predictions of TDMI than predictions based on milk MIR spectra data alone (Dórea *et al.* 2018; Wallén *et al.* 2018; Lahart *et al.* 2019). Moreover, combining individual cow concentrate intake data with milk MIR spectra improved prediction accuracy of DMI (Wallén *et al.* 2018; Rachah *et al.* 2020). However, the improvement in accuracy of prediction of TDMI depends also on the prediction method. Dórea *et al.* (2018) reported a better performance using artificial neural network (ANN) than partial least squares regression (PLS) to predict TDMI using milk MIR spectra and animal variables in dairy cows. Generally, direct combination of descriptive and performance variables into milk MIR spectral data improves TDMI prediction accuracy, but how well the method would be able to fully exploit this data in both ANN and PLS prediction methods is not known.

To fully utilize the benefits of integrating the milk MIR spectra data and other descriptive and performance variables of cows, different data fusion methods were used in this study in both prediction methods (PLS and ANN). A data fusion method can be used to combine the outputs and complementary data from multiple instruments to generate better inferences than a single method (Biancolillo *et al.* 2014). There are three levels of data fusion: low level, mid-level, and high level (Biancolillo *et al.* 2014; Li *et al.* 2019), and we will investigate the low- and high-level here.

We hypothesized that the high-level data fusion with advanced analytical methods, such as with machine learning gives better prediction accuracy of TDMI than the low-level data fusion with PLS prediction. Therefore, the objective was to evaluate the low (direct merging of milk MIR spectra data with other descriptive and performance variables)- and high-level data fusion strategies. Both PLS and ANN prediction methods were assessed using the low and high data fusion strategies to predict TDMI in dairy cows.

Materials & methods

Data. Data were collected from a feeding experiment of dairy cows at the dairy research farm of the Norwegian University of Life Sciences (Ås, Norway). The experiment lasted for 54 days and used 48 early- and mid-lactation Norwegian red dairy cows. A detailed description of the experiment objective, design, and results are available at Kidane *et al.* (2018). In the experiment period, concentrate dry matter intake (CDMI), Total dry matter intake (TDMI), and milk yield (MY) data were available daily per cow. The daily measurements of MY, TDMI and CDMI of a specific date was merged into weekly averages for each experimental week.

Milk MIR spectra. Each cow was milked twice daily (between 06:15 to 08:15 h=a.m. and 05:00 to 17:00 h=p.m.) using milking machines. During the first two weeks of the experiment, only Monday milk samples were collected. During weeks three to eight, milk samples were collected Monday and Thursday. Morning and evening samples were kept separately and analyzed using a FOSS instrument (MilkoScan 6000; Foss Analytical, Hilleroed, Denmark).

In the Foss MIR spectrum, there are 1,060 data points corresponding to the absorption of infrared light in the 900 to 5,000 cm^{-1} region. In order to predict TDMI, wavelength regions recommended by Wallén *et al.* (2018) were used: between 926 and 1,593, between 1,745 and 3,061, and between 3,781 and 5,149 cm^{-1}.

For each MIR wavelength, the morning and evening measurement averages for week 1 and week 2 were calculated but from weeks 3 to 8, Mondays and Thursdays morning and evening measurements were averaged. In the end, there were 384 records available, that is, one MIR spectrum for each cow each week.

TDMI model development and validation. Prediction equations were developed using 10-fold cross-validation. Three alternative models were considered to predict TDMI of dairy cows. These were, partial least squares regression (PLS), artificial neural network (ANN) or MLR (Multiple linear regression). The models were as follows: Model 1 included MY, CDMI, WL, Parity and $BW^{0.75}$; model 2 included milk MIR spectra data; model 3 included all variables in model 1 and 2. Model 1 was implemented using both MLR and ANN as statistical approaches to predict TDMI. Model 2 and 3 were implemented with both PLS and ANN.

The cross-validation coefficient of determination (R^2) between true and predicted TDMI values and the root mean squared error (RMSE) were used to assess the accuracy and robustness of the models.

Models fitted using ANN were performed using H2O's AutoML (automatic machine learning) in R (LeDell and Poirier 2020). All parameters were left at their default values, except for max_runtime_secs=36,000, nfolds=10 and include_algos=deeplearning. The training data comprised 80% (288) and the test data 20% (96) of the data set. As in the PLS and MLR approaches, R^2 and RMSE were used to assess the accuracy and robustness of the models in the 10-fold cross-validation, full training data set and test data set.

High-level data fusion. In high-level data fusion, the results of model 1 and model 2 were integrated to obtain an ensemble decision and binary linear regression was used to solve the advanced data fusion problem as described by Li *et al.* (2019).

Results

Our results supported our hypothesis that high-level data fusion using ANN had the highest coefficient of determination (R^2=0,62) which means 62% of the variation in the total dry matter intake (TDMI) was explained using the model (Table 1).

Direct merging (low-level data fusion or model 3) of milk MIR spectra with other variables such as MY, CDMI, WL, Parity and $BW^{0.75}$ explained TDMI better than the milk MIR spectra using PLS prediction (Table 2). Multiple linear regression (MLR) using other variables (MY, CDMI, WL, Parity and $BW^{0.75}$) (model 1) explained TDMI better than the milk MIR spectra (model 1) (R^2=0.39 vs R^2= 0.38 in the calibration and R^2=0.37 vs R^2=0.33 in the validation) (Table 2). In case of ANN prediction methods, the low-level data fusion (model 3) had the highest R^2 next to the high-level data fusion method (Table 1).

Discussion

Our results showed that the ANN method is better for prediction of TDMI than the PLS method. This implies that the relationship between the milk MIR spectra and TDMI is not only a linear relationship since the former method capture both the linear and non-linear relationship and other complex relationships (Dórea *et al.* 2018). Our results also showed that adding animal variables to the milk MIR spectra improves

Table 1. Root mean square error (RMSE) and coefficient of determination (R^2) for low -and high-level data fusion obtained from predicting total dry matter intake using milk MIR spectra data and other variables (MY, CDMI, parity and $BW^{0.75}$) and artificial neural networks (ANN).

the prediction accuracy of TDMI especially using ANN. However, it matters how we combine the milk MIR spectra with other cow variables in order to fully exploit the information in the data and improve accuracy of prediction. Instead of directly adding the animal variables to the milk MIR spectra as addition explanatory variables and use it for the prediction of TDMI, merging both milk MIR spectra and animal variables at high-level enables to exploit better the information in the data. Moreover, the animal variables are easy to record and may be already in the dairy farm management system. Thus, merging milk MIR spectra data with animal variables at high-level have great potential to predict TDMI in commercial dairy farm industries and this tool can be practically implemented without additional infrastructure and without extra costs. However, this finding should be verified using a large dataset and external validation.

132. CFIT – Cattle Feed InTake – a 3D camera based system to measure individual feed intake and predict body weight in commercial farms

J. Lassen[1,2*], J.R. Thomasen[1] and S. Borchersen[1]

[1]Viking Genetics, Ebeltoftvej 16, Assentoft, 8960 Randers, Denmark; [2]Center for Quantitative Genetics and Genomics, Aarhus University, Blichers Alle 20, 8830 Tjele, Denmark; jalas@vikinggenetics.com

Abstract

A 3D camera technology to measure feed intake and body weight on individual cows in commercial farms has been developed. The camera based method for feed intake measurements is validated using scale measures in a commercial farm. In this study the squared correlation between camera data and scale measures on daily intake was 0.90. Body weight is predicted based on images of back couvertures and corresponding scale measures in three dairy breeds: Jersey (301 cows), Holstein (398 cows) and Red dairy cows (103 cows). Root mean square error between observed and predicted weight was 23.5, 31.0 and 22.7 kg and the repeatabilites were 0.86, 0.83 and 0.90 for Jersey, Red dairy cattle and Holstein respectively. Several management tools continue to be developed based on the data for the farmers that have the equipment installed and more traits are expected to be developed based on the 3D methodology in the future.

Introduction

Feed intake (FI) is the highest variable cost in the dairy farm. Therefore even marginal improvements in the amount of feed that is used to produce an amount of milk and meat will have a huge effect on the turnover for a farmer. Milk and meat production has been core traits in most breeding systems for several decades, but not until recently feed efficiency has been a trait that has been evaluated. This is not due to lack of value of the trait, but more due to lack of data on the trait at an individual level. Individual FI measures has only been available on cows from research farms, and often only for limited parts of lactation and in few lactations per cow. FI is a main driver for cow health and welfare. Most diseases occur in early lactation so if data is not available in this period it is very difficult to provide information that possibly could prevent diseases from developing. The system is currently installed in 20 dairy herds in Denmark where more than 10,000 cows are providing data.

FI measures historically has been done using scale based measures. These systems are relatively expensive and labour intensive. Therefore they are also impractical for measurements in commercial herds. Over the recent years both 3D cameras, hardware such as graphic cards and algorithms around image analysis has been under drastic improvements. This includes among others artificial intelligence (AI) algorithms such as the convoluted neural network method called MASK-CNN (He *et al.*, 2018). Combining all these developments into a working system is very difficult.

Since 2016 a 3D camera system has been developed to measure individual FI records and make body weight (BW) prediction at an individual cow level. In this paper the methodology as well as the system will be described and discussed.

Materials & methods

System and data description. In order to make individual FI and BW measures 3D cameras was used in a top down position (Microsoft Kinect). Each camera is placed 2.5 meter apart and 4.5 meter from the empty feeding table in order to cover the entire feeding table. Also, in the exit corridor of the milking system an ear tag reader and a 3D camera was placed. Three type of images were recorded from the 3D camera:

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_132, © J. Lassen *et al.* 2022

normal pictures, infrared (IR) pictures and depth pictures. These images were indicating the distance from the camera to the object that can be seen by the camera. When cows left the milking system their electronic ear tag was read and at the same time a 3D picture was taken of the back of the cow. For BW prediction as well as a reference to predict the same cow these pictures were stored and used. The identification was done based on the contours, colour and patterns of the back of the cow, when eating at the feeding table. The MASK-CNN algorithm based on instance segmentation prediction was used for this (He *et al.*, 2018) and this approach was validated in an earlier study (Thomasen *et al.*, 2018; WO 2017/001538). When a cow entered the head to the feeding table the last image of the feeding pile before she put in her head and began eating was stored from virtual boxes defined in the feeding table. When the cow had finalized the meal and took the head out again the first new image of the feeding pile was stored. In the next step the height in each pixel from two stored images were now subtracted from each other and the removed feed was quantified on pixel level. Five variables were stored from each specific visit: the ID of the cow, the placement in the barn, time when the meal was initiated and finalized and the amount of feed eaten. During a visit feed would be allocated to a specific cow from a total of 5 virtual boxes – the virtual box right below the cow as well as the two virtual boxes to the left and the right respectively. If a virtual box was shared during a feeding visit cows would also share the feed taken from this box during the two cow specific visits.

Feed intake trial. FI was measured both with cameras and on a scale in an area of the herd where only one cow could attend the feed. Daily intake was estimated with the camera based FI algorithm as well as with the scale data as the difference between provided feed and residual feed for a day. Six different cows was used in the trial and each cow was measured for 4 days. Correlations between these measures where estimated.

Body weight prediction. Weight data of the cows has been recorded in 6 weeks periods in 4 herds: 2 Jersey (JER), 1 Red Dairy Cow (RDC) and 1 Holstein (HOL) after every milking. Using the partial least square approach (PLS) where the 12 variables that described the most of the variance where chosen to predict BW (SAS software version 9.4). In a 10-fold crossvalidation the root mean square error (RSME) was estimated. Variance components for BW was analysed using the following model:

Weight = mean + herd + week of year + lactation number + week of lactation + animal + residual

Where herd, week of year, lactation number and week of lactation was fixed effects and animal and residual was random effects. The repeatability was estimated as the random animal variance divided by the total variance.

Results

Mean daily FI based on scales in the feeding trial was 55.4 kg of feed and the squared correlation between observed FI from the scales and the predicted FI from the cameras was 0.90. Descriptive statistics from scales as well as RMSE, variance components and repeatabilities for camera based BW in JER, HOL and RDC cows are presented in Table 1.

The mean BW was 678 kg for Holstein, 508 kg for Jersey and 624 kg for RDC. The RMSE were 23.5 kg (4.6% of mean), 31.0 kg (5.38% of mean) and 22.7 kg (3.60% of mean) for JER, HOL and RDC respectively. Repeatabilities were 0.86, 0.83 and 0.90 for JER, HOL and RDC respectively.

Table 1. Breed, mean observed weight, RMSE in kg and in % of mean, animal variance, residual variance, repeatabilities and number of animals used in the study.

Breed	Mean obs weight	STD	RMSE kg/%	Var animal	Var Res	Repeatability	Number of animals
JER	508	48.8	23.5/4.60	950	153	0.86	300
HOL	678	84.2	31/5,38	2,527	512	0.83	398
RDC	624	59.6	22.7/3.60	2,216	233	0.90	101

Discussion

The validation trial of the FI algorithm showed a squared correlation between FI measured from scales and cameras of 0.90. This indicates a strong relationship between the two methods. We are currently not aware of any other studies that have made such a comparison. BW based on 3D image analysis was predicted based on scale measures with RMSE between 22.7 and 31 kg. This is lower or in the same range as other studies (Song *et al.*, 2018). Several parameters can influence these results including camera and scales, information used from images, software and statistical model.

A major priority for developing this system was to obtain data throughout lactation. In relation to genetic analysis several studies have shown that genetic correlation change during lactation between FI, milk yield and BW (Manzanilla-Pech *et al.*, 2014; Li *et al.*, 2017). Estimates for the genetic correlation between FI and milk yield varies from -0.80 in early lactation up to 0.8 in mid and late lactation (Manzanilla-Pech *et al.*, 2014). Selection for improved efficiency in early lactation where FI and BW changes specifically needs to be improved based on records obtained in mid lactation then might lead to even lower FI in early lactation. From a management perspective also FI records and BW are interesting throughout lactation. In early lactation the absolute majority of health problems occurs both related to mastitis, BW changes, reproduction and nutrition. In mid lactation the farmer wants to know which cow are most efficient to optimize culling strategy and in late lactation the FI is interesting in order to optimize strategies in relation to drying off cows. With this system all information will be available for the farmer. Heritability estimates for FI and BW is presented in another abstract in this conference (Manzanilla-Pech *et al.*, 2022). Also the data is used for national prediction of saved feed which consist of a maintenance part and a physiological part described as residual feed intake (NAV 2020; Stephansen *et al.*, 2021). The identification algorithm was validated in an earlier study where more than 6,000 cow visits were annotated and in over 99% of the visits the right ID was predicted (Thomasen *et al.*, 2018; WO 2017/001538). This system opens up for working with phenotypes such as body condition score and lameness.

Conclusions

FI and BW can be predicted based on image analysis using a 3D camera system. The squared correlation between FI measured with scales and cameras was 0.90. Repeatability was between 0.86 and 0.90 for BW.

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands;
ines.adriaens@wur.nl

Abstract

Digital agriculture offers opportunities for improved monitoring and precision phenotyping of farm animals, crucial to achieving a more sustainable livestock production sector. Video-based analysis enables the quantification of animal behaviour in a non-invasive, automated way with few sensors. To unlock its full potential, appropriate computer vision techniques are needed. In this study, we propose an algorithm to detect lying-down and standing-up behaviour in dairy cows based on changes in bounding box properties detected via YOLOv5 and tracked with DeepSORT. We analysed 86 videos with a standing-up or lying-down event. With different criteria applied to the bounding box time series, we could detect up to respectively 92.3 and 80% for standing-up and lying-down events, respectively, with an accuracy of less than 2 seconds. Using bounding box properties as proxy for body shape and location, a general cow detection algorithm can serve multiple behavioural analyses simultaneously, whilst interpretability of the algorithms is maintained.

Introduction

Today's society faces a plethora of challenges to achieve a sustainable, socially accepted, safe and sufficient food production. Digital agriculture and related technological solutions contribute to addressing these challenges, as they allow to monitor and phenotype production entities in an automated and standardized way (Basso and Antle, 2020). In precision livestock farming, both individual animals and groups are monitored via automated sensor technologies, providing farmers, veterinarians, nutritionists and other stakeholders with information on health, fertility and welfare. Besides individual on-animal sensors, more and more also off-animal technologies that allow simultaneous and non-invasive monitoring of multiple animals emerge.

A main challenge in precision livestock farming is the translation of raw and sometimes unstructured sensor data into valuable animal or herd parameters that can be used for decision support. Often, this translation needs dedicated tools for data interpretation, including animal identification, feature extraction, time-series modelling and detection of abnormalities. The development of robust and targeted data-processing pipelines is therefore a crucial step in the digital agricultural transition (Basso and Antle, 2020).

Automated analysis of animal behavior provides new tools for welfare and health monitoring and (precision) phenotyping, as many links between health disturbances and behavior in livestock are known. Traditionally, behavior is observed visually, rendering it a subjective and tedious task with only limited value in commercial farm settings. Automation of behavior assessment allows to use behavioral traits in monitoring and decision support tools for the entire herd with limited observation costs, and is therefore seen as an important focus in current research and development (Rushen *et al.*, 2012).

DOI: 10.3920/978-90-8686-940-4_133, © I. Adriaens *et al.* 2022

In dairy cows, lying behavior changes upon disease such as lameness, mastitis and metabolic problems, and can therefore be used to assess health and welfare status (Dittrich *et al.*, 2019). In the past, on-animal sensors (e.g. 3D accelerometers) have been used for detection of health problems, with varying success. Off-animal sensors such as video cameras have the advantage that a single sensor can be used for: (1) multiple animals simultaneously; and (2) many different behavioral traits, based on spatial as well as temporal features of the individual cows. However, to extract valuable information from the unstructured video footage, targeted data processing is crucial, for example via the use of cow detection, key point identification or pose estimation (Porto *et al.*, 2013).

In this study, we aimed at developing a tool for the detection of 'lying down' (LD) and getting up (GU) events from video footage collected in a freestall barn as leverage for lying behaviour analysis in dairy cows. We started from state-of-the-art cow detection and tracking models, and propose the use of bounding box (bb) properties to predict the LD and GU events.

Materials & methods

Data. Video footage of a freestall barn with synthetic flooring was collected at the research facility 'Dairy Campus' in 2019. Cows were fitted with a 3D accelerometer (IceQube, IceRobotics Inc. Edinburgh, Schotland), from which the timing of GU and LD events was derived. Based on the location of the animals, 1 out of 4 cameras were selected, and the footage surrounding the GU or LD event was isolated to obtain videos of approximately 460 frames (frame rate 15f/s). To collect ground truth information on timing of the GU and LD events, the cows' poses were manually observed and the exact start and end frame were determined and recorded together with the animals' coordinates when lying down. When the target cow was occluded by other cows, videos were removed from the analysis.

Cow detection and tracking. A cow detection model (YOLOv5x) combined with a tracking algorithm (DeepSORT) trained and validated on a separate dataset on the high performance computing infrastructure of WUR (the Netherlands) were applied on each video to obtain bounding box coordinates (x,y), their width (w) and their height (h) for each of the cows (Kamphuis *et al.*, 2022). All further data processing was done in Matlab R2020b (The Mathworks Inc., Natick, MA, USA), and corresponding code can be found on https://git.wur.nl/iadriaens/kb_ddht_ai. Bounding box data of the target cows was gathered using the Euclidian distance of the centre of each bb with the ground truth location of the target cow during lying down (i.e. using either the first (for GU events) or last (for LD events) 50 frames of each clip). When no cow detection had taken place, or when the target cow was not detected in more than 10% of the frames and could not be reidentified, the clip was removed from the analysis. Examples of the bb are shown in Figure 1.

Figure 1. Example of bounding box changes of cow during a getting-up (left panel) and lying-down (right panel) event.

Bounding box properties. The bb coordinates, width and height were smoothed with a third-order Savitsky-Golay filter with window size of 25 frames to correct for noise and instability caused by the YOLOv5 detection algorithm. Next, we calculated the Euclidian distance from the center of the frame (*cntr*), the circumference of the bb (*circ*), and the ratio between width and height (*rwh*) as follows:

$$cntr = \sqrt{(x_{bb} - x_c)^2 + (y_{bb} - y_c)^2} \quad (1)$$

$$circ = 2 * h_{bb} + 2 * w_{bb} \quad (2)$$

$$rwh = \frac{w_{bb}}{h_{bb}} \quad (3)$$

These bb properties (bbp) were standardized with a min-max standardisation as follows:

$$\text{bbp}_{st} = \frac{bbp - \min(bbp)}{\max(bbp) - \min(bbp)} \quad (4)$$

Finally, the ratios between each of the bbp_{st} (e.g. *centr*/*circ*, *circ*/*rwh*) to represent simultaneous change across bbp were computed.

Event detection and statistics. Unique statistical change points, and local and absolute minima and maxima of the bbp_{st}, of the ratios, and of their first and second derivatives were calculated as proxies for sudden change and maximal slopes in the bbp throughout frames. Next, the location of first and last local peaks within the frame time series was compared with the annotated location of the start and end of the GU/LD events and the frame and time distance was calculated. Appropriate bbp for the detection of GU and LD are those consistently close to the target event throughout all videos, independently of the location and orientation of the cow. The detection was considered sufficiently accurate when the detection was within 2 to 5 seconds (i.e. 30-75 frames) of the actual event.

Results

Eighty-four clips were retained for the analysis, from which 45 with a LD event and 39 with a GU event. The results are summarized in Table 1 with the best performing bbp printed in bolt. When both events were considered, the maximal difference in the *circ* and *cntr* showed the best detection accuracy, with an average distance of resp. 1.3 and 2 seconds from the event, and 82.1% of the videos having a distance of less than 2 seconds from the event. Considering only the GU behaviour, the best detection criteria were the maxima of the second derivatives of *cntr* and *circ*, with average distances of respectively 0.7 and 1.7 seconds and 92.3 to 74.4% of the events being detected within 2 seconds of the ground truth. For LD detection, additional to the maximal differences in *cntr* and *circ*, also the ratios between *cntr* and *circ* and the changepoints of these ratios in all three bbp performed well, with up to 80% of the LD events detected within 2 seconds and 86.7% within 5 seconds of the ground truth.

Discussion

This study investigated the possibility to use a cow detection and tracking algorithm to identify lying down and getting up events via changes in bbp time series over frames. The idea relied on the expectation that during lying down, body shape and location remain constant, while during the GU/LD event, they suddenly change. When the detection algorithm works well and draws its bb tightly and accurately around the animal, the defined bbp were expected to link with lying behaviour. In this study, we showed the potential of using bbp for detection of lying down and getting up events with video footage, and demonstrated that the criteria most suitable for detecting LD or GU separately might differ.

Table 1. Time distance and % events detected within 2 to 5 seconds with the different bounding box properties for all (GU+LD), get-up (GU) and lying-down (LD) events.

[6] second derivative of circumference.

In the past, accelerometer sensors have been used to automatically detect lying down or getting up (Ledgerwood *et al.*, 2010), and also in this study, this served as ground truth benchmark. As these sensors are individually attached to the cows, a separate sensor has to be purchased for each animal, which increases costs. Also maintenance (e.g. battery, broken sensors replacements) and the limited number of potential behaviours monitored are drawbacks for this type of technology that are overcome by using cameras. While accelerometers do not require a separate identification step needed for machine vision, these sensors have the disadvantage to not provide spatial information regarding the behaviours monitored.

The advantage of using bbp over e.g. key point based methods, or even over methods that specifically annotate videos for lying animals (Porto *et al.*, 2013) is that it allows a general cow-detection algorithm (for which only bb annotations are needed) to be used as a basis for multiple location and body-shape based behavioural analyses. This limits annotation time and contributes to interpretability and understandability of the methodology, which is an advantage when aiming for e.g. monitoring and decision support. The same bb and tracking could be used for e.g. analysis of feeding behaviour (based on location and orientation of the bb at the feeding rack) or social behaviour (by calculating proximity). The alternative of including the behaviour as input for the (deep learning) video analysis would require many more time consuming and tedious annotation work, with a lower number of potential applications.

Future work can focus on further automatizing the algorithm, testing it on more and longer videos and multiple cows simultaneously. Additionally, a regression model in which several of the bbp time series can be combined potentially further improves detection accuracy.

Video-derived behavioural analysis allows for automated monitoring of multiple animals and multiple traits simultaneously in a cost-effective way using few sensors. In the future, this can contribute to improved monitoring and precision phenotyping, and as such, ultimately leverage a more sustainable dairy sector.

134. Image-based cattle conformation prediction using deep learning methods

D. Segelke*, H. Alkhoder and J. Wabbersen

Vereinigte Informationssysteme Tierhaltung w.V. (vit), Heinrich-Schröder-Weg 1, 27283 Verden, Germany; dierck.segelke@vit.de

Abstract

Automated image-based phenotyping has become more feasible due to the improvement in deep learning methods aiming at identifying regions of interests within an image. To investigate the possibility of using standard deep learning tools to predict the conformation score out of an image, a dataset of 8,950 images obtained from 3,561 different cows was used. Each animal was also scored by a classifier. The conformation traits analysed included: udder depth, rear leg set and rump angle. These showed that automated extraction of relevant regions within an image are possible and the defined regions can be used to predict a classification score for an animal. Image-based (deep learning) heritability scores were 0.35, 0.20 and 0.25 for udder depth, rear leg set and rump angle, respectively. Genetic correlations between both methods were highly positive for all traits.

Introduction

In commercial dairy herds reduced costs of genotyping result in a growing genotyping interest. However, to receive reliable breeding values, accurate phenotyping in large scale has become increasingly important. Due to the high labour costs, the total cost of phenotyping for breeding programs is high. Furthermore, differences between and within classifier scores is another drawback. Improved computer-based image analyses might be the solution to reduce phenotyping costs while obtaining reliable phenotype scores for breeding value estimations. Nye *et al.* (2020) showed that estimating conformational traits in dairy cattle is feasible using a two-step deep learning automated phenotyping and segmentation approach. High heritabilities suggest that more meaningful biological information could be extracted from image data. Manzanilla Pech *et al.* (2021) indicated that reliable genetic parameters for feed efficiency can be derived from 3D camera-based systems. Poppe *et al.* (2019) reported another approach for affordable extraction of large-scale automated conformation traits. They applied their method on cartesian teat coordinates measured by automatic milking systems to record udder conformation traits. The aims of this study were to investigate whether classification scores can be predicted from image data and to estimate genetic parameters from this novel data.

Materials & methods

Data. To collect the images, the vit mobile app for reporting the classification results was extended to support both taking and uploading images of defined body regions. To receive comparable images, the app shows a silhouette of the body region of interest. The classifiers were asked to take up to seven different images per cow, covering all important routine conformational traits. Out of these seven different images per cow, a single image was used for the prediction of one trait. The traits in this study include udder depth (UDE), rump angle (RAN), and rear leg set (RLS). The exact number of images for the studied traits is shown in Table 1. Images were randomly split into four distinct subsets. The splitting process took place at different times for the three traits while new images were still coming in. Hence, there were different numbers and ratios of images in each of the four subsets. Images that were received after the splitting were moved to the cross-validation and test sets. The prediction for each trait relies on two models connected in series, which were trained and validated: One model to find the regions of interest (ROIs) in the image, as depicted in Figure 1 and Figure 2, and a second model to predict the score by using the post-processed

R.F. Veerkamp and Y. de Haas (eds)
CC BY

DOI: 10.3920/978-90-8686-940-4_134, © D. Segelke *et al.* 2022

regions of interest found based on the first model. In Table 1, the subset used for training the ROI detection model is called training set and the subset used for validating this first model is called validation set. The subset called cross-validation set was used to select and tune the second model of the pipeline (i.e. the model that predicts the trait's score). The test set was finally used to evaluate the presented system on images that were never touched before in order to get an unbiased performance estimate. It should be noted that the present system does not estimate a score for all images available in the test set. This is due to several reasons such as: images without cows, images with multiple cows in the centre of the image, images that do not include all necessary ROIs, or failed detection of all necessary ROIs. Besides the image data set, a data set with classification scores on all linear conformation traits on the same cows were available. Classification scores ranged from 1 to 9 and were scored by 15 professional classifiers.

Two-step system. All ROI detection models were trained with the TensorFlow Object Detection API. For UDE, a pre-trained EfficientDet D1 was fine-tuned with the labelled training set in order to detect different morphological regions within an image. The outcome is a list of bounding boxes of the ROIs searched for, as depicted in Figure 1. The list of bounding boxes was then cleaned to only include the ones from the cow in the centre of the image. The second model, which predicts the UDE score, is just a simple formula dividing the distance between udder floor and hock by the distance between hock and buttock, followed by an affine transformation to receive scores from 1 to 9. The divisor of the formula approximately corrects different distances between the camera and the cow that leads to different sizes of the cow in the image.

Table 1. Nb. of cows in different subsets for udder depth, rump angle and rear leg set.

Dataset	Udder depth	Rump angle	Rear leg set
Total	3,302	2,734	2,914
Training	326	282	182
Validation	81	73	30
Cross-validation	1,060	937	1,226
Test	1,835	1,442	1,476
Heritability estimation	1,551	1,170	1,430

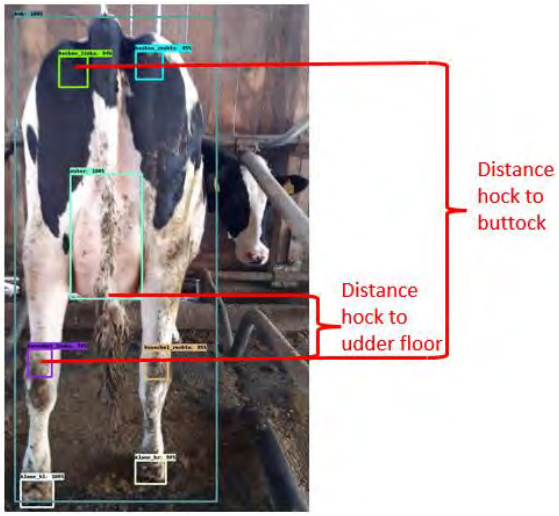

Figure 1. Schematic example of the processing steps for udder depth.

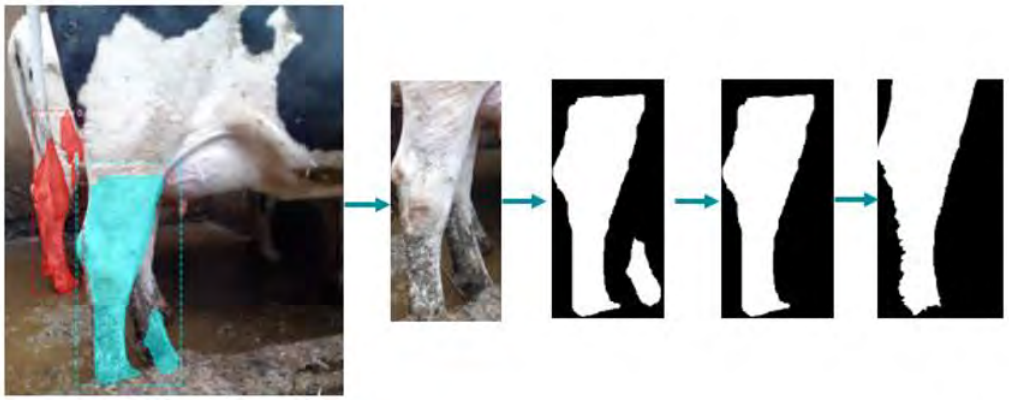

Figure 2. Schematic example of first processing steps for rear leg set.

For RAN, the same pre-trained EfficientDet D1 was fine-tuned to detect pins, tailheads, hooks, and withers. A similar post-processing as for UDE was used. In order to estimate scores, the bounding box information was used to create features such as distances between boxes, and angles between line segments connecting the centres of bounding boxes. These features were used as input for a feedforward neural network (FFNN) to estimate the conformation score. The training of the FFNN was performed by using the scores of the classifiers.

For RLS, a pre-trained Mask R-CNN was fine-tuned to detect hind legs. The outcome of this model is visualized in Figure 2. Mask R-CNN is a model for instance segmentation, meaning that it predicts, in addition to bounding boxes, a pixel mask for every hind leg it detects in the image. This way, the shape of the hind leg of interest is extracted by searching for a centred and large enough hind leg detection in the image, removing small blobs not belonging to the hind leg, and correcting the boundary of the hind leg with a method called GrabCut. The outcome of this post-processing is fed into a convolutional neural network to predict the trait's score.

Statistical models. To investigate whether derived traits from the images have a biological meaning, variance, and covariance components for both scored and image-based traits were estimated by fitting a bivariate animal model based on a restricted maximum likelihood (REML) approach using the software ASReml 4.1. The general model can be described in matrix notation as follows:

$$Y = X\beta + Z\alpha + e \quad (1)$$

where Y was the vector of observations (scored conformation trait, imaged conformation trait); β were the vectors of fixed effects for the analysed traits which were herd, classifier, days in milk, age at first calving and region, α was the direct additive genetic effects; X and Z were the incidence matrices related to the respective effects and e was the vector of random residuals. All animals were scored in 2021, thus a year of classification effect was therefore not considered.

Results

Table 2 shows the heritabilities for the three traits as well as the genetic and phenotypic correlations between the scoring by classifiers and the image-based scoring. Heritabilities from classifier-scoring were higher than the image-based scoring. However, the standard error was in general high and slightly lower

Table 2. Heritabilities (h^2) of udder depth, rump angle, and rear leg set scored by classifiers and image-based scoring and the genetic (r_g) and phenotypic correlation (r_p) with SE in parentheses.

Conformation trait	h^2 class.	h^2 image	r_g	r_p
Udder depth	0.56 (0.11)	0.35 (0.09)	0.95 (0.05)	0.67 (0.02)
Rear leg set	0.31 (0.09)	0.20 (0.08)	0.90 (0.16)	0.48 (0.02)
Rump angle	0.48 (0.13)	0.25 (0.11)	0.86 (0.12)	0.56 (0.02)

for the image-based approach. Genetic correlations between both approaches were high for all three traits meaning that image and classifier-based scoring are genetically the same trait, although the standard error was relatively. Phenotypic correlations between both trait definitions were lower than the genetic correlations ranging between 0,49 and 0,67 with a very small standard error.

Discussion

High genetic correlations suggest that images and deep learning methods can be used to predict the conformation of an animal. Large heritability estimates and standard errors indicate that larger data sets are needed to compare the strengths and weaknesses of both scoring methods. Because field data was used, the dataset contained a relatively large number of different classifiers and herds. The results of this study are based on a relatively low number of observations per classifier and herd, which may reduce the reliability of heritability estimations. In tendency, it could be observed that image-based scoring is less confounded with the classifier and the region of scoring. Furthermore, only one image per region of the cow was used and the trait of interest was not always fully covered by the image. However, these promising results show that routine field data can be used for animal scoring and the deep learning methods can effectively extract region of interests from a large variety of different farms, light conditions and not highly standardised distances between camera and region of interest.

135. Prediction fat percentage and visceral weight from whole fish images with a multi-input neural network

Y. Xue*, J.W.M. Bastiaansen and H. Komen

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands;
yuanxu.xue@wur.nl

Abstract

In aquaculture, high accuracy in trait measurements benefits the genetic progress from a breeding program. Breeding traits like fat percentage and visceral weight are related to feed/cost efficiency of growth and product quality, and important metabolism and health indicators. Problems concentrate on finding the proper methods to accurately measure or predict these traits, as most current approaches are invasive, labour-intensive or may disturb or damage the fish. Interior trait prediction from image analysis would allow a real-time, large-scale and non-invasive alternative for such traits. This study investigates using whole-fish images in combination with exterior traits to improve the prediction of fillet fat percentage and visceral weight. The result of including images as extra input shows improvement on the accuracy of fat percentage prediction. The neural network extracted contour-based features and brings into view several biological indicators that appear to be informative for prediction.

Introduction

In aquaculture, accurate measurements of breeding traits on individuals are essential for the assessment of breeding values and the progress of the breeding program. Modern breeding programs emphasize not only on production traits, but also traits that are important indicators of metabolism and health of the fish, such as fat percentage and visceral weight. However, these two traits are costly to measure for two reasons: the required measurement involves stress challenges and may require sacrificing the fish, risking the loss of a potential breeding candidate; these measurements are invasive and damaging, raising societal and ethical concerns (Seibel, Weirup and Schulz, 2020).

To answer the need for accurate assessment of these traits, researchers and breeders start to include indirect measurements. Popular approaches include fitting prediction models using easy-to-measure exterior traits to approximate the fat percentage and visceral weights (García-Celdrán *et al.*, 2015, Vandeputte *et al.*, 2017). Another approach, image analysis, has received increasing attention in recent years (Prchal *et al.*, 2020). However, image analysis often heavily relies on morphological annotation. This transfer of image data to interpretable numeric value inevitably discards other image features that are potentially informative to prediction. Color pattern, for instance, is difficult to be objectively quantified as a morphological reading. Yet the information is easy to obtain non-invasively and can be valuable to assess the health status of fish (Parolini *et al.*, 2018). Combined with the proper statistical methods, images might offer more than annotated predictors for invasive traits.

This study estimates the accuracy of predicting fat percentage and visceral weight by different models. It aims to elucidate if adding whole-fish image as extra inputs is beneficial to predict these two traits, and if so, how images contribute to the prediction.

Materials & methods

Data was collected on a total of 4766 gilthead seabream (*Sparus aurata*) and kept separated in two groups. Images for these seabreams were taken with a Logitech HD Pro Webcam C920.

Group A. Records of fat percentage and body weights on 3,069 individuals with their corresponding images. Data was modelled for the predictability of body fat percentage based on body weight with and without images.

Group B. Records of visceral weights, fat percentage and body weights on 1,697 individuals with their corresponding images. Data was modelled for the predictability of visceral weight based on body weight, body fat percentage, and with and without images.

For each group, data was divided into training, validation and test sets with a size ratio of 3:1:1. Training and validation sets were used for exploratory data analysis, cross validation and hyperparameter tuning. To avoid information leakage, test set was only used once for the final evaluation of the prediction. Three methods were included for comparison on their prediction performance.

Linear regression (LR). Although the assumed relationship between the variables and the response is simple, linear models are highly robustness with low computing cost. Given its simplicity and robustness, LR is chosen as the benchmark to use body weight for prediction of fat percentage and to use body weight and fat percentage for prediction of visceral weight. LR was combined with 5-fold cross validation to avoid overfitting.

Multilayer perceptron (MLP). Trait prediction sometimes requires more complex model as the relationship between the predictors and response are not always linear. Therefore, this study uses MLP to represent a simplified collection of all complex prediction model like polynomial regression, sinusoidal regression, etc. It is intended to capture the real relationship by going through all possible combinations of mathematical connections between body weight, fat percentage, and visceral weight to use body weight for prediction of fat percentage and to use body weight and fat percentage for prediction of visceral weight. Images are not included as predictors.

MLP is in essence a collection of neurons. Each neuron consists of a value and relates to either an input or an output neuron, or both. Neurons are grouped per layer. The connections between layers form a chain of mathematical functions that continuously manipulate the original input towards a final output. These functions can be as simple as a subtraction or addition or as sophisticated as a derivative. At the end of every round of calculation, these functions will self-update to minimize the difference between the calculated and observed output until the difference reaches the minimum. This is the learning process through which a MLP finally realizes a prediction.

Multi-input neural network (NN). To incorporate images to the prediction, a multi-input NN is applied. It is meant to include all pixel-level information from a whole-fish image, regardless of the biological interpretability of the information, and combine it with other measurement like body weights. A multi-input NN consists of two parts: a convolutional neural network (CNN) and an MLP. CNN scans the images repeatedly using different filters. These filters form different layers like neurons in MLP and translate the value of raw image pixels into imaginal features and concepts. In parallel, the MLP establishes a mathematical relationship between the numeric input from other traits like body weight. The outputs of these two compartments are combined and matched with the response variables. Multi-input NN uses the same 'learning process' as MLP to update all connected layers, until the difference between the observed output and the prediction stabilizes and reaches its minimum.

Feature visualization helps to visualize the learning process by displaying the filtered features from each convolutional layer. Mathematically, these features maximize the information that contributes to the

observed output. According to the human visual comprehension, these features can vary from edges and textures to patterns and parts of the objects.

The predictions were evaluated using two metrics: Mean squared error (MSE) and Pearson correlation coefficient (r). Lower MSE and higher r values imply that a prediction model has better prediction performance.

Results

Table 1 shows the results of prediction fitting three models on both test set. Accuracy of predicting visceral weight is high and similar for all methods (0.87-0.90). Prediction of fat percentage benefits from the image data which increases accuracy from 0.48 to 0.70.

To understand how images facilitate the prediction, the extracted features by each convolutional layer are displayed in Figure 1. Each row contains features obtained from the same layer. Moving to the next row, the layer goes deeper, which means that the features extracted will become more abstract but also more informative to the final prediction. The first row in Figure 1 illustrates that in the beginning layer, multi-input NN extracts different features, like whole-fish contours and contrasts between regions, as informative inputs for fat percentage prediction. Colour might also be considered as an informative feature given the visual inconsistency in the background. Visually dark regions on the fish correspond to locations like patch, eye and fin on the colour image. However, the multi-input NN quickly abandons this information and fixates on outlines and contours, starting from the second row of Figure 1. The final convolutional layer in the last row comprises features mostly highlighted in visually dark colour: the curvature of the dorsal side, together with the upper edge of pectoral fins.

Figure 2 compares the final convolutional features in both groups. Like its performance in group A on fat percentage, multi-input NN applied to visceral weights in group B has a strong preference for the contour.

Table 1. Evaluation of prediction methods on test sets.

	Group A – fat percentage		Group B – visceral weight	
Metrics	**MSE[1]**	**r**	**MSE[2]**	**r**
LR	4.86	0.48	63.26	0.90
MLP	5.26	0.48	75.41	0.89
Multi-Input NN (with images)	2.98	0.70	87.14	0.87

[1] Test set has a mean of 11.52 and a standard deviation of 2.5.

[2] Test set has a mean of 40 and a standard deviation of 18.

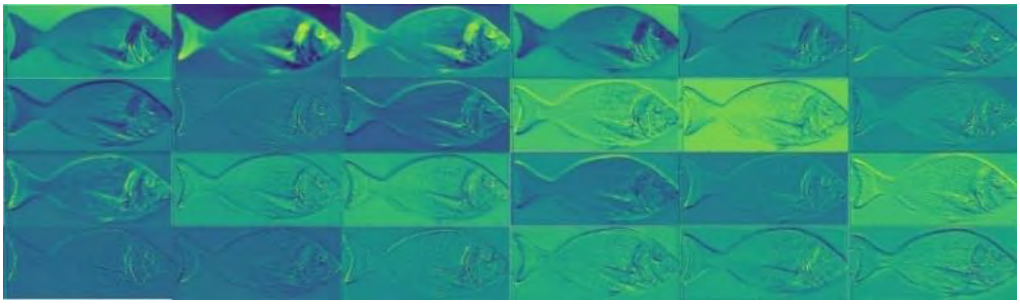

Figure 1. Visualized extracted features by each convolutional layer of the multi-input neural network from Group A, fat percentage.

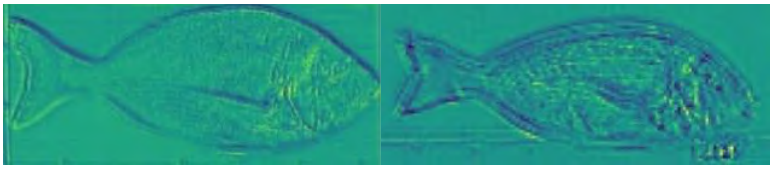

Figure 2. Visualized extracted features from the last convolutional layer of the multi-input neural networks. Left: Group A, fat percentage; Right: Group B, visceral weight.

The right image in Figure 2 shows an overlapping highlighted pattern around the edges, indicating that the contour has been read repetitively for visceral weight prediction. Compared to the result in fat percentage, however, there are additional patterns revealed on the body of the fish, especially around the operculum, dorsal edge and anal fin.

Discussion

For fat percentage prediction, accuracy of LR and MLP are similar. This similarity on accuracy indicates that the non-linear, complex MLP failed to capture more information compared to a linear model for predicting fat percentage. In contrast, multi-input NN uses the images and outperformed both LR and MLP. Features extracted suggest two important factors in predicting fat percentage: contour and pectoral fin. Contour can be interpreted as the size of body area, which is strongly correlated with body weight (Fernandes *et al.*, 2020). However, given the poor performance of LR with only body weight as predictor, the multi-input NN probably uses a different interpretation of the contour. Curvature is hypothesized to be the informative factor in fat percentage prediction. The result of MLP implies that prediction accuracy does not benefit from mathematically complex indicators. Including the images as inputs identifies curvature which is also a rather explicit morphological description. Further work could separate the contour and investigate a proper quantitative description of the curvature and of the location of pectoral fin and test the predictive value of these features. However, without a quantitative description of the contour, images can still improve the fat percentage prediction by the feature extraction of multi-input NN.

For visceral weight prediction, three models yielded similar results, suggesting that neither the complexity of the MLP method nor the information-concentrated image are good additions for visceral weight prediction. Future work may look into replacing body weight by body features detected from images as a fast, non-invasive alternative to assess the visceral weight.

Abstract

There has been a limitation in which ambiguity occurs in classifying qualitative traits such as colour. To solve it, a phenotyping approach of analysing RGB (Red, Green, and Blue) values of chicken plumage colour and assorting it into binary groups is proposed. With a total of 389 animals (100 high-pigmented as a case group and 289 low-pigmented as a control group), a case-control genome-wide association study was performed using F_2 offspring population of a cross between two different pure lines, White Leghorn and Yeonsan Ogye chicken. The result revealed 51 significant markers including 5 candidate genes for eumelanin pigmentation: *PMEL*, *SLC48A1*, *NEUROD4*, *KRT6A*, and *KRT80*. Therefore, this study can give sights to classify diverse phenotypic variance and to investigate genetic mechanisms related to eumelanin pigmentation in chicken plumage.

Introduction

Generally, the plumage colour variation in birds is mainly attributed to the total melanin concentration and the ratio of eumelanin to pheomelanin in the feather. The Eumelanin gives rise to black, brown, or grey colouration, while the pheomelanin makes it appear light red and yellow (McGraw *et al.*, 2005).

Many studies have been conducted to find the genetic basis related to chicken plumage pigmentation, colouration traits have been judged by human eyes (Kinoshita *et al.*, 2014, Yang *et al.*, 2017). A recent attempt has been made to objectively represent diverse colour variations using quantitative values for shank colours in chickens (Jin *et al.*, 2016). However, the method of classifying qualitative traits such as colour has the limitation that the criteria can still be subjective and ambiguous when there is a diverse variance in colour (Yang *et al.*, 2017; Jin *et al.*, 2016). Therefore, this study aimed to identify genes and genetic regions that affect eumelanin pigmentation in chicken plumage using an objective criterion for differentiating the degree of pigmentation.

Materials & methods

Animals. The F_2 cross-bred population was generated between Yeonsan Ogye (YO), a Korean native chicken breed and White Leghorn (WL) chicken. The YO has entirely black external features including plumage in contrast to the WL which has pure white plumage. Reciprocal mating between unrelated individuals, i.e. 1 WL male × 5 YO females were used to produce the F_1 generation. One F_1 male and 10 F_1 females were randomly selected to produce the F_2 generation. The distribution of body plumage colour in F2 population is as follows: all-black (10.0%), black and white barred (12.6%), black with brown-spotted (0.8%), black with white spotted (0.5%), all-white (35.7%), white with brown-spotted (9.5%), white with black-spotted (23.1%), bright grey (5.9%), dark grey (1.8%). In this study, a total of 389 F_2 chickens, which have both phenotypic and genotypic information was used as samples.

Phenotyping. The process of collecting RGB (Red, Green, and Blue) values for classifying the phenotype is as follows: all photographs were acquired using a camera under the same background, lighting, angle, and position of the chickens. To accurately crop the chicken layer in the samples, the background was removed under a Python computing environment. Then, a segmented layer of body feathers excluding hackles, wings, and tail feathers in the sample was cropped out using Adobe Photoshop CC 2021. The RGB values of all pixels in the segmented layers were derived, and the average values were calculated. The distribution in a histogram of average RGB values of total samples was used for setting the criterion for differentiating two phenotypes, one with a high proportion of eumelanin pigmentation (HP) and the other with lower of it (LP).

Genotyping. Genomic DNA was extracted from blood samples collected from the chicken using the Wizard Genomic DNA Purification Kit (Promega, Wisconsin, USA). All DNA samples were genotyped using the Illumina chicken 60K SNP BeadChip.

PLINK v1.9 software (Purcell *et al.*, 2007) was used for the quality control (QC) of genotyping. Only SNPs with a call rate >90% and a minor allele frequency (MAF) >5% were used for subsequent QC steps. Further, SNPs with the *P*-value of deviation from Hardy-Weinberg equilibrium (PHWE) $<1\times10^{-4}$ were removed. Ultimately, 389 individuals and 19,876 SNPs were retained for the association analysis.

Case-control GWAS. To identify loci conferring eumelanin pigmentation in chicken plumage, we performed the case-control GWAS through PLINK v1.9 software with a total of 389 chicken samples, including 289 LP (74.3%) and 100 HP (25.7%). The HP was used as a case group whereas the LP was used as the control group (Table 1). The genome-wide significance level was set based on the Bonferroni correction *P*-value as $0.05/19{,}876 = 2.52E^{-6}$.

Results

The distribution of average RGB values was divided into two: one below 50 and the other above 50 (Figure 1). The samples were divided into the former and the latter group, and the maximum and minimum values of each RGB were derived, which are [45.2, 47.8, 45.4] and [59.6, 65.5, 59.1]. The average of these two values was used as a criterion for dividing the distribution. Therefore, one case less than [52.4, 59.7, 52.3] is classified as group HP, and another exceeding it is classified as group LP.

Table 1. The average RGB values of each image layer represent body feathers excluding hackles, wings, and tail feathers.

Group[2]	HP			LP		
Image layer[1]						
R (Red)	45.2	33.2	8.5	152.9	89.6	91.3
G (Green)	47.8	34.6	8.8	155.3	91.9	90.3
B (Blue)	45.4	32.5	8.6	131.2	80.6	74.5

[2] HP; high-pigmented as a case group and LP; low-pigmented as a control group.

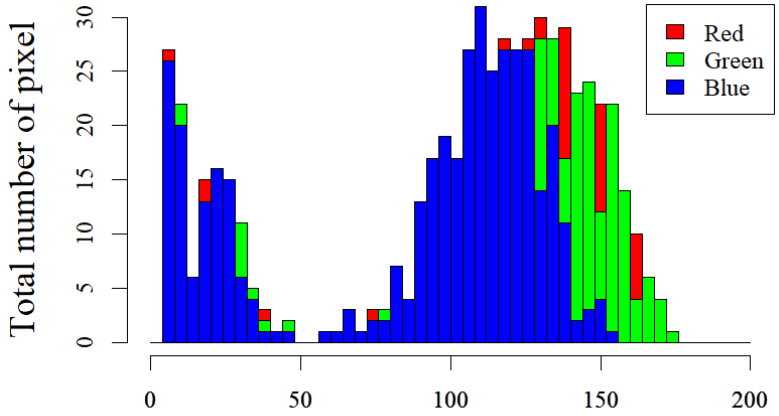

Figure 1. Histogram plot for the distribution of average RGB values of total samples.

We identified a total of 51 SNPs on chromosomes 1, 7, 18, 33 and linkage group E22C19W28_E50C23 (Figure 2). Specifically, the significant region (3.22-7.09 Mb) in chromosome 33 comprises 18 known genes and 5 anonymous genes. We identified the most significant SNP near genes, including *DGKA*, *CDK2*, *RAB5B*, and *PMEL* (P=5.369e^{-56}). Moreover, the GWAS results revealed *SLC48A1* and *NEUROD4*, as well as the keratin genes, *KRT6A* and *KRT80*.

Discussion

Genes involved in eumelanin pigmentation in many studies were reported as follows: the melanocortin 1 receptor (*MC1R*), *NUAK* family kinase 1 (*NUAK1*), sonic hedgehog signalling molecule (*SHH*), and premelanosome protein (*PMEL*) (Dávila *et al.*, 2014, Yang *et al.*, 2017; Kerje *et al.*, 2004). Of these genes, the *PMEL* gene, related to the dominant white allele, is a melanocyte protein responsible for eumelanin deposition and fibril formation in melanosomes (McGlinchey *et al.*, 2009; Kerje *et al.*, 2004). A recent study revealed that the downregulation of *PMEL* may lead to reduced eumelanin synthesis, which may alter eumelanin and pheomelanin content in chicken plumage (Zheng *et al.*, 2020).

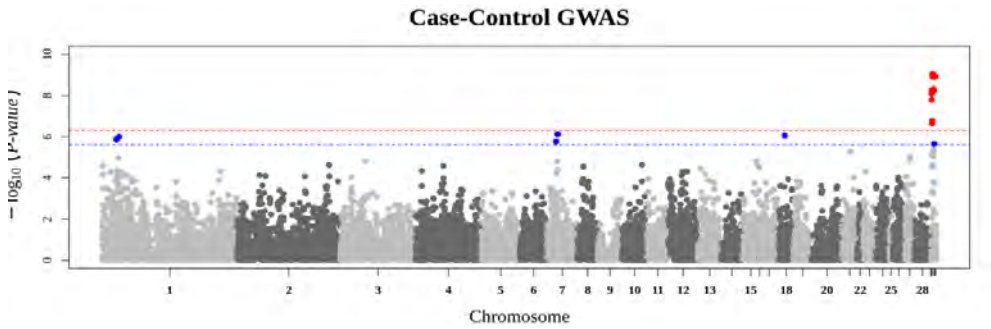

Figure 2. Manhattan plot representing the case-control GWAS result. The red and blue lines indicate Bonferroni corrected significance (α=0.01 and 0.05, respectively).

Other identified genes near the SNPs on chromosome 33 such as *SLC48A1*, *NEUROD4* have not been reported as relevant to eumelanin pigmentation. However, a previous study revealed the *SLC48A1* and *NEUROD4* in ~0.51 Mb region of the E22C19W28_E50C23 linkage group are related to *HOXC8* which is expressed in chicken cranial skin (Wang *et al.*, 2012). The homeobox genes including *HOXC8* turned out to be candidate genes involved in the plumage melanogenesis in black-bone chicken (Yu *et al.*, 2018). Therefore, *SLC48A1* and *NEUROD4* may be candidate genes for eumelanin pigmentation in chicken.

Of the candidate genes, the *KRT6A* and *KRT80* have clues that these are related to feather follicles in chicken. Previous studies found that the *KRT6A* gene, which is responsible for the development of hair follicles in mice, may also influence the development of feather follicles in chicken embryo fibroblasts (Chen *et al.*, 2017; Gu and Coulombe, 2007). In addition to that, *KRT6A* and *KRT80* were included in the results of GWAS for the frizzle feather trait in chickens (Chen *et al.*, 2021).

Previous studies reported that the crested and frizzle and dominant white traits were linked and located on linkage group E22C19W28 (Romanov *et al.*, 2004; Ruyter-Spira *et al.*, 1997). It implies various genes may influence eumelanin pigmentation in chicken feathers. Therefore, this study can be used as genetic clues to reveal the physiological mechanism of plumage pigmentation by indicating five candidate genes: *PMEL*, *SLC48A1*, *NEUROD4*, *KRT6A*, and *KRT80*.

Abstract

Collection of a large amount of data during the routine milk recording procedures makes it possible to train machine learning algorithms for predicting traits of interest. In this study, we applied two different machine learning methods (General Linear Models and Random Forest) to predict the udder health status of Italian Mediterranean Buffaloes at the subsequent monthly test-day record, using milk data collected at the previous test-day. Prediction accuracies of both methods were above 73%. According to different metrics, General Linear Models had the best performance in predicting the udder health classes (high or low somatic cell count, based on a threshold of 200,000 cells/ml). Findings of this study highlight the promising role of machine learning algorithms to improve the surveillance of subclinical mastitis, helping farmers in the preventive identification of animals that would possibly have high somatic cell count the subsequent month. Such information may also be exploited for breeding purposes.

Introduction

Subclinical mastitis, i.e. the inflammatory condition of the mammary gland with no clinical signs, is a costly health issues of the dairy Mediterranean Buffaloes (*Bubalus bubalis*) (Alterisio *et al.*, 2021). Efforts have been made to improve udder health, exploring also novel indicators of mammary gland inflammation based on traditional somatic cell count (scc) (Costa *et al.*, 2021). However, there is still need to improve mastitis detection, management and selection. Collection of a large amount of data in the frame of the routine milk recording procedures and by automatic milking recording systems makes it possible to exploit such information to train machine learning algorithms for predicting specific traits of interest. Machine learning analyses have already been applied in different areas of dairy research to support farmers in decision making (Cockburn, 2020). Previous studies have applied machine learning methods to predict subclinical mastitis in dairy cows, some based on the presence of high scc in milk (Bobbo *et al.*, 2021; Ebrahimi *et al.*, 2019), others based on the presence of mastitis pathogens (Hyde *et al.*, 2020; Sharif *et al.*, 2018). Nevertheless, only few studies reported predictions based on data collected at different time points (Anglart *et al.*, 2020; Bobbo *et al.*, 2021). Following the approach reported by Bobbo *et al.* (2021), in the present study we exploit information collected during the routine milk recording to predict the presence of high or low scc level in milk collected the subsequent month in Italian Mediterranean Buffaloes.

Materials & methods

Data collection and editing. Test-day (TD) records were provided by the Italian Breeders Association (Rome, Italy). Data included information about herd, animals (ID, stage of lactation and parity), daily milk production, milk composition, scc, β-hydroxybutyrate (bhb), electrical conductivity, and milk coagulation properties [rennet coagulation time (r) and curd firmness 30 minutes after rennet addition (a30)]. The dataset was edited to include animals that calved in the years 2019 and 2020, with at least two TD within

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_137, © T. Bobbo *et al.* 2022

lactation, and with less than 360 days in milk (dim). In addition, only consecutive TD records with an interval lower than six weeks were selected. Among milk traits, outliers beyond four standard deviations were considered as missing values and only full records were considered. Average daily milk production (milk_htd) and scc (scc_htd) of contemporary groups, i.e. animals sampled in the same herd and day, were also determined. Finally, the two scc-related traits were log-transformed to somatic cell score (scs and scs_htd). A total of 18 features were considered: parity (from 1 to ≥6), stage of lactation (dim30:12 classes of 30 d each), year and month of calving (ymc: 24 levels), year and month of sampling (yms: 19 levels), daily milk production, fat, protein, casein, lactose, pH, urea, scs, bhb, electrical conductivity (cond), milk_htd, scs_htd, and the two milk coagulation properties. Udder health status at the subsequent TD (outcome) was coded as a binary trait: low (≤200,000 cells/ml) or high (>200,000 cells/ml) scc. After editing, the dataset included 3,939 records of 1,035 buffaloes in six herds. In each record, information of two subsequent TD was provided: 18 features of the previous TD and outcome at the subsequent TD. The prevalence of subclinical mastitis (SCC>200,000 cells/ml) was 41.2%.

Data processing and models building. Machine learning analyses were performed following Bobbo *et al.* (2021). Prediction models were developed to identify the best udder health prediction method [Generalized Linear Models (GLM) or Random Forest (RF)] using information recorded at the previous TD. The dataset was randomly split into two subsets: 80% of the data (3,152 records) to train and test the models, and 20% of the data as a validation set. To automatically select the most predictive features, we applied a recursive feature selection using a 10-fold cross validation (cv) repeated 10 times with RF method. A stratified 10-fold cv repeated 10 times was then applied to train and test the models. The train/test dataset was randomly divided into 10 subsets; prediction models were trained on 9 subsets and tested on the last one. Each 10-fold cv was repeated 10 time, for a total of 100 iterations. Data standardization was performed within cv. Data analysis was performed using Caret v.6.0-86 (Kuhn, 2021) and Tidyverse v. 1.3.1 (Wickham *et al.*, 2019) packages of R software v.4.1.2 (R Core Team, 2021).

Evaluation of methods performance on testing and validation set. Sensitivity, specificity, accuracy, Cohen's kappa value, F1 score and area under the receiver operating characteristic curve (AUC) were used to compare the predictive performance of the models on the testing set. Feature importance based on the prediction model with the greatest accuracy was then assessed. Finally, predictive ability of both models on the validation set were estimated and compared using the same metrics reported above.

Results

Results of the recursive feature selection applied before model training suggested that the most parsimonious model (with the highest accuracy of prediction using the lowest number of features) was the one that included all the features of interest (Figure 1a).

Evaluation of methods performance in predicting udder health classes (low or high scc) on testing and validation sets was based on several metrics (Table 1). Whereas similar results were obtained in the testing set, GLM showed a slightly better performance in the validation set in comparison to RF. Nevertheless, in both methods, accuracy was above 73%, F1 above 78%, and AUC above 80%.

According to considered metrics, GLM was the best method in predicting udder health classes. Feature importance using GLM for predicting udder health status on testing set suggested that scs-derived traits were the most important features, followed by electrical conductivity and milk production (Figure 1b).

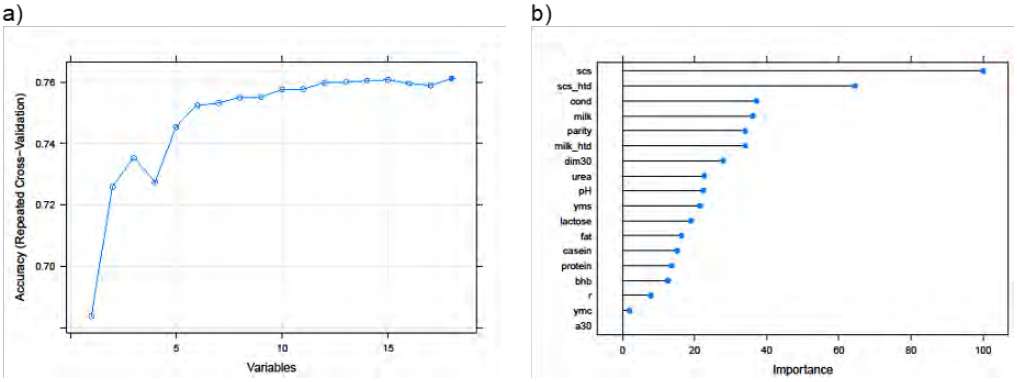

Figure 1. (a) Results of the recursive feature selection incorporating one to 18 features. (b) Plot of the feature importance showing the ranking for the prediction of udder health status in the testing set. Evaluated features, using Generalized Linear Models, are: individual somatic cell score and of contemporary group (scs and scs_htd), electrical conductivity (cond), milk production, parity, milk production of contemporary group (milk_htd), stage of lactation (dim30), urea, pH, year and month of sampling (yms), lactose, fat, casein, protein, β-hydroxybutyrate (bhb), rennet coagulation time (r), year and month of calving (ymc), and curd firmness 30 minutes after rennet addition (a30).

Table 1. Methods performance metrics [Sensitivity (Se), Specificity (Sp), Accuracy (Acc), Kappa value, F1 score, and area under the receiver operating characteristic curve (AUC)] on testing and validation sets.

Method	Testing set						Validation set					
	Se	Sp	Acc	Kappa	F1	AUC	Se	Sp	Acc	Kappa	F1	AUC
GLM[1]	0.84	0.62	0.75	0.47	0.80	0.82	0.84	0.62	0.75	0.47	0.80	0.81
RF[2]	0.83	0.64	0.75	0.47	0.79	0.82	0.81	0.63	0.73	0.44	0.78	0.80

Discussion

In the present study, we applied two different machine learning methods (one linear and one based on decision trees) to predict the udder health status of Italian Mediterranean Buffaloes at the subsequent TD record, using already available milk data collected at the previous TD. The comparison of the performance of the two methods on both testing and external validation sets were based on several metrics. Besides accuracy, which is one of the most used metrics in classification problems, we included also F1 score and AUC, that have the advantage of being independent from outcome rate. Although GLM was the method with the best performance, similar results were obtained using RF. Findings of this study are in accordance with the results of Bobbo *et al.* (2021), who reported linear methods, RF and neural network to be the best methods for predicting the udder health status of Italian Holstein cattle. The scc-traits recorded at the previous TD were expected to be the most important features for making the prediction. The important role of electrical conductivity confirmed results of previous studies (Ebrahimi *et al.*, 2019, Ebrahimie *et al.*, 2018). In conclusion, machine learning methods applied to the large amount of data currently available represent a promising tool to improve the surveillance of subclinical mastitis, helping farmers in the preventive identification of animals that would possibly experience mammary gland issues. Further studies are required for a practical implementation of these methods in the management supporting systems as well as in the use of complex phenotypes in genetic and genomic evaluations.

Abstract

Applications of computer vision are growing in importance in livestock systems due to their ability to generate accurate, real-time, and non-invasive animal-level phenotypes. However, the development of a computer vision system requires sophisticated statistical and computational approaches for efficient data management and appropriate data mining, as it involves large datasets. In this talk, we will discuss some of the challenges, applications, and potentials of computer vision systems in livestock phenomics. The development of computer vision technologies will potentially have a major impact in the livestock industry by providing real-time and accurate phenotypes, which can be used to enhance breeding for novel and hard-to-measure traits, as well as to assist animal research across various disciplines, and to improve management decisions in commercial herds.

Introduction

Computer vision and image analysis have been undergoing a great revolution in the last few years, mainly due to the advent of specific machine learning tools as deep learning. These methods show better performance than classic techniques for many challenging computer vision problems such as natural image segmentation, optical character recognition, and object classification (LeCun *et al.* 2015). Nowadays, computer vision systems using deep learning algorithms show comparable or better accuracy than humans in several visual recognition tasks, including recognizing traffic signs, faces, and handwritten characters. Among the various digital technologies in livestock, computer vision systems are emerging as a powerful solution for high-throughput phenotyping (HTP), which is crucial for the development of optimized farm management decisions and for the genetic improvement on novel traits, namely animal health and behavior traits.

High-throughput phenotyping and genetic improvement of livestock

HTP techniques based on computer vision can be used in animal breeding programs to provide more efficient and accurate phenotype scoring of traits traditionally used in breeding programs. For example, live body weight and average daily gain is nowadays measured at standard ages in beef cattle, such as birth, weaning, 365 and 550 days of age. With the implementation of computer vision, body weight can be estimated daily (even multiple times per day) for each animal, so selection can be applied not only for the traditional standard ages but also for the parameters describing the growth curve shape of each animal. In addition, computer vision tools can be used for scoring novel phenotypes or indicator traits to be used in advanced breeding programs (Silva *et al.*, 2021).

Phenotypes of economic or societal importance that are generally difficult to measure without digital technologies include individual feed consumption and feed efficiency, heat tolerance, mothering ability, aggressive behavior, disease resistance, among many others. Image analysis and computer vision systems (CVS) are extremely promising HTP tools as they do not require attaching sensors to the animals. In addition, camera sensors can be used for multiple animals and be reused across pens and over time, and

image or videos can be used to monitor many traits simultaneously. Some of the most desired applications of CVS for live animals correspond to animal identification, tracking, and monitoring, ultimately identifying changes in their daily behavior (Fernandes *et al.* 2020a).

Computer vision for livestock systems

Image analysis has been applied to various traits in different livestock species. In dairy cattle, for example, is has been explored for lameness classification, body condition score, and behavior monitoring (Fernandes *et al.*, 2020a). However, most of the studies published in the literature used manual feature extraction, such as animal biometric measurements (e.g. distance from the head to the tail, hip height, spine curvature, etc.), and then fit those features using linear models (Gomes *et al.* 2016) or other simple predictive approaches.

Recently, RGB-D sensors have gained attention due to the incorporation of the depth information to the digital color image. The image data from these sensors have been shown to be more informative for animal identification and for body parts recognition (Fernandes *et al.*, 2020a). The main applications have been on identification of animal locomotion and back posture, body condition score, leg angle and udder depth, and body weight (Nasirahmadi, *et al.*, 2017; Wurtz *et al.*, 2019; Fernandes *et al.*, 2020a; Oliveira *et al.*, 2021) of dairy cows. In addition, there are studies showing the applicability of thermal cameras for evaluation of lameness and mastitis (Hovinen *et al.*, 2008; Alsaaod *et al.*, 2015).

Mining large image datasets generated by computer vision systems is one of the most important challenges to deploy efficient systems in livestock operations. For example, the type and amount of feature extracted from 3D images (Fernandes *et al.*, 2019) and modeling approach (Fernandes *et al.*, 2020b) are important factors that may improve prediction quality in image analyses. Fernandes *et al.* (2020b) and Cominotte *et al.* (2020) evaluated the impact of different combinations of image features on the predictive model quality in pigs and cattle. The authors used features related to biometric body measurements (dorsal area and length, projected body volume, height, and width in 11 points across the dorsal area) and body shape discriminator (Fourier descriptors and eccentricity) and found that models including both shape descriptors and body measures presented the best performance.

Reducing data dimensionality in livestock image datasets

Recently, we implemented autoencoders to reduce data dimension from 2D depth images to 1D signals. The signal was built using two concatenated vectors. The first vector is a line crossing the center of the animal body, which represents the body length, and the second vector is a perpendicular line, crossing the center of animal body, and representing body width (Figure 1).

We explored one of the most straightforward autoencoder architectures to extract features from images. A sequence of fully connected layers composes the architecture: in the encoder, the number of nodes decreases at each layer, until we get to the most inner layer – the code, followed by the decoder, composed by a sequence of layers where the number of nodes increases at each layer symmetrically until we get the same data representation as observed in the input. In the model used in our experiments, we defined the hyperparameters as code size of 20; 3 layers in the encoder with 2,000, 2,000 and 500 nodes respectively, 3 layers in the decoder with 500, 2,000, 2,000 nodes respectively and the mean squared error as loss function. When we compared the predictive performance of algorithms trained with biological (BIO) features (i.e. body volume, area, length, width, eccentricity, and others, see Fernandes *et al.*, 2019) extracted through depth images and 20 autoencoder features (AUTO) from 1D signal, we did not observe important differences in R^2 (BIO=0.81, AUTO=0.78), Root mean squared error of prediction (RMSEP (kg), BIO=6.50, AUTO=6.90), and Concordance Correlation Coefficient (CCC, BIO=0.88, AUTO=0.88). However, the size of the dataset dramatically decreased as the input was reduced from approximately 600

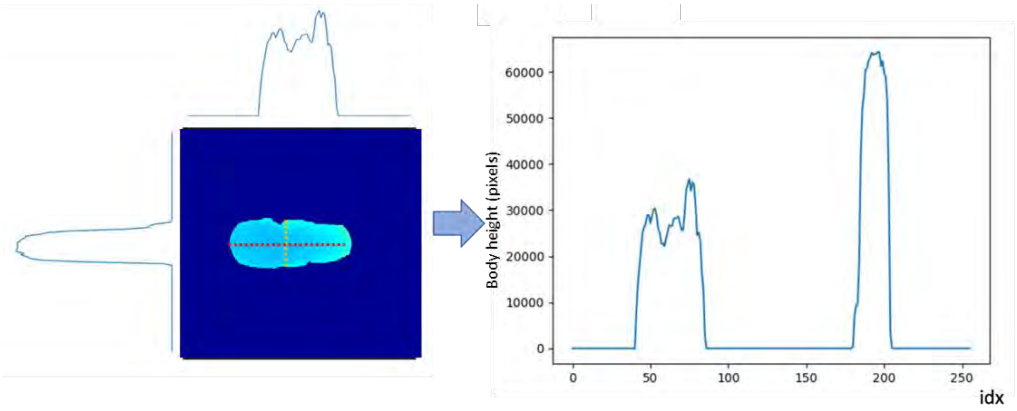

Figure 1. Pre-processing steps: from a calf depth image, vertical and horizontal projections create the 1D signal used for training the autoencoders.

KB (single depth image) to 0.21 KB (single 1D signal). Such example indicates that efficient analytical strategies can be adopted to reduce data dimensionality in large datasets, while keeping satisfactory predictive performance. In livestock farm conditions, where internet speed is generally a critical constraint to implement data collection and analyses in real-time, the development of efficient analytical systems play an important role for large scale deployment of phenotyping technologies, as well as to advance Machine Learning Development and Operations (DevOps or MLOps) in agricultural systems.

To highlight the recent growth and importance of Computer Vision in livestock, four recent review articles (Nasirahmadi, *et al.*, 2017; Wurtz *et al.*, 2019; Fernandes *et al.*, 2020a; Oliveira *et al.*, 2021) explored the potential of computer vision systems for HTP. Wurtz *et al.* (2019) and Nasirahmadi *et al.* (2017) discussed the advances on automated and high-throughput image detection of farm animal behavioral traits, focusing on animal welfare and production. Fernandes *et al.* (2020a) provided an overview of key concepts related to computer vision, image processing, image analyses, and the types of devices and image ranging systems. Fernandes *et al.* (2020a) also provided important key metrics for image-based prediction quality assessment, and a compilation of animal phenotypes used for management purpose (e.g. body condition score, body weight, animal behavior, etc.). An overview on how deep learning has been implemented and how it can be an effective tool to predict animal phenotypes, accelerating the development of predictive modeling for precise management decisions in livestock, was reported by Oliveira *et al.* (2021).

Final considerations

Systematic collection of animal-level phenotypes in large-scale operations is one of the main constraints to advance animal breeding programs and optimal farm management decisions, and HTP technologies are a key factor in this context. Despite all the challenges related to data collection, management, and analyses in livestock systems, the use of HTP technologies, such as computer vision, are crucial to generate cost-effective and reliable precise phenotypes.

139. Tracking multiple cows simultaneously in barns using computer vision and deep learning

C. Kamphuis*, I. Adriaens, W. Ouweltjes and I. Hulsegge

Wageningen University & Research, P.O. Box 338, 6700 AH Wageningen, the Netherlands;
claudia.kamphuis@wur.nl

Abstract

This study investigated the automated tracking of multiple cows simultaneously using computer vision and deep learning. Video clips were collected in 2019 at Dairy Campus, where cows were housed in small groups (n=16). A systematic approach covering the true variability of barn circumstances eventually resulted in the selection of 159 frames that were annotated by drawing bounding boxes around each cow. These frames were used to retrain and test four You Only Look Once version 5 (YOLOv5) models to automatically detect cows. The weights of the best performing YOLOv5 model were used to parametrize the deep learning algorithm DeepSORT to track multiple cows simultaneously. This algorithm was applied to a 10 min timeframe of a randomly selected video clip and evaluated by computing the multi-object tracking accuracy, which was 92.8%. This outcome is a promising and essential step towards automated monitoring of individual behaviour of group-housed cows.

Introduction

Monitoring cow behaviour in research and in practice largely depends on visual observation. In research, experts usually visually observe a limited number of animals, for restricted periods of time and with long time intervals between observations (e.g. Mayo *et al.*, 2019). In practice, farmers visually observe their herd for altered behaviour related to e.g. lameness, with the risk that typically the more severe clinical abnormalities are detected, whereas mild abnormalities often remain unnoticed (Whay *et al.*, 2002). Despite previous efforts to automate continuous monitoring of behaviour, reliable and cost-efficient tools are still lacking. Recent advancements in computer vision and artificial intelligence opens up opportunity to automatically and continuously monitor behaviour of every animal (O'Mahony *et al.*, 2019), in a non-invasive manner and with relatively few sensors.

This study investigated the feasibility of detecting and automatically tracking multiple cows simultaneously with the use of computer vision and deep learning. In doing so, two challenges were addressed: the first was the detection of cows in video footage, and the second was the tracking of all detected cows through time and space. If this detecting and tracking of cows can be done with high accuracy levels, next steps involve the automated identification of cows and quantification of behaviour.

Materials & methods

Data. Data used in this study were collected as part of the Freewalk project (https://www.freewalk.eu/en/freewalk.htm), conducted at the Wageningen research facility Dairy Campus (Leeuwarden, the Netherlands). As part of that project, video footage was collected with four cameras placed in a freestall barn with a synthetic floor and with two cameras in a cubicle barn with a concrete slatted floor. Both barns housed a group of 16 Holstein Friesian cows. All cameras (HikVision DS-2CE16H5T-IT3E) generated footage with 15 frames per second with a resolution of 2,560×1,440 pixels per frame. From the collected video footage, 111 video clips of approximately 60 min each were selected for the current study. This selection included a number of clips recorded in summer (n=16, in July or August) and winter (n=95, in December) of 2019. In systematically selecting the clips we attempted to cover the true variability in barn circumstances in terms of coat patterns of cows, cow behavior (e.g. standing, lying, eating), camera

viewpoints and lighting conditions. The selected video clips were used to first automatically detect cows, and subsequently to automatically track these detected cows.

Automated detection of cows. The automated detection of cows was done with the latest version (version 5) of the unified, real-time object detection algorithm You Only Look Once (YOLO; Redmon *et al.*, 2016; Ultralytics, 2020). The YOLOv5 algorithm is pretrained with the COCO-dataset (Meel, 2021), a dataset including >200K annotated images of which also images of cows. We retrained four YOLOv5 models (YOLOv5s, -m, -l, and -x), each having different configuration and parameter sizes (Ultralytics, 2020). The YOLOv5s is the simplest model, requiring the least computation time; YOLOv5x is the most complex model, requiring the most computation time. Each of the models was retrained with 200 epochs. Retraining the YOLOv5 models was done with frames from the 111 selected video clips. These frames were selected by first dividing each video clip in 10 equal parts (based on the total number of frames in a clip), from which, in a second step,one frame per part was randomly selected. This resulted in 1,110 frames. From these, 159 frames were selected randomly for annotation. Annotation was done by manually drawing a bounding box (BB) around each cow visible in each frame (Figure 1), using a self-designed annotation tool implemented in Matlab 2018a (the Mathworks Inc., Natick, MA, USA). The 159 frames were subsequently divided to a training (n=127), validation (n=16), and test (n=16) dataset. The test dataset was used to assess the performance of the four YOLOv5 models by comparing the annotated (ground truth) and predicted BBs. Performance indicators were precision, recall, two mean average precision (mAP) indicators, and the F1-score. The mAP is a measure that explains how well the predicted and annotated BBs overlap. The first mAP indicator counts a predicted BB as true positive if the overlap between annotated and predicted BB is at least 50% (mAP@.5). The second mAP indicator is the average overlap from a threshold range (with steps of 5%) from 50-95% (mAP@.5;.95). The YOLOv5-model performing best on the test set was selected to be used for tracking the detected cows.

Automated tracking of cows. The weights of the best performing YOLOv5 model were used to parametrize the deep learning-based tracking algorithm DeepSORT (Brostrom, 2007; Wojke *et al.*, 2017). The performance of this DeepSORT tracking algorithm model in detecting and subsequently tracking multiple cows simultaneously was evaluated with one 10 min video clip. This video clip was randomly selected from the available 111 video clips. From this video clip, a 10 min timeframe was manually selected such that different behaviours, e.g. cows walking in or outside the camera view, cows walking around, cows standing up or lying down were present. The performance was evaluated by manually computing the multi-object tracking accuracy (MOTA; Bernardin and Stiefelhagen, 2008): from the 10 min video clip, the first frame of each second was selected resulting in 601 frames. The DeepSORT algorithm assigned BBs to each frame, and for each of the 601 frames, the number of false positive BBs (FP; predicted BB without an

Figure 1. Examples of annotated frames (left free-stall barn; right cubicle barn), with bounding boxes drawn around each cow visible in the frame.

annotated BB), false negative BBs (FN; annotated BB without a predicted BB), and identity switches (IDS; one annotated BB receives multiple predicted BB) were visually assessed. Each error was counted as one error. The MOTA was computed using formula 1

$$MOTA = (1 - ((\Sigma_t FN_t + FP_t + IDS_t) / (\Sigma_t \text{ annotated } BB_t))) \times 100 \quad (1)$$

Results

The subset of 159 randomly selected frames to retrain and test the YOLOv5 models for cow detection included frames from all the 111 video clips, with a maximum of two frames per videoclip. Table 1 summarizes the performance indicators of the four YOLOv5 models when tested on the frames in the test dataset: the four YOLOv5 models largely overlap in performance indicators. The $YOLOv5_m$ model and $YOLOv5_x$ perform similarly, but the first required less computation time. Therefore, the weights of the $YOLOv5_m$ model were used to parametrize the DeepSORT algorithm.

The selected 10 min timeframe to evaluate the parametrized DeepSORT algorithm had a total of 4,874 annotated BBs (cows), in which the number of BBs (cows) per frame varied between seven and nine. The DeepSORT algorithm applied to the 10 min video clip resulted in 32 FP BBs, 283 FN BBs, and 35 IDSs. These numbers resulted in a MOTA of 92.8%.

Discussion

This study retrained YOLOv5 models to detect cows in practical circumstances. This transfer learning approach has the advantage that it requires much less annotation. Moreover, a systematic annotation approach was applied to capture the true variability in practical circumstances. This resulted in good performing YOLOv5 models with just 143 (out of the 159) annotated frames that were used for retraining, comparable to performance results reported by Tassinari *et al.* (2021) who annotated more data (~25K frames) and applied YOLOv3.

The weights of $YOLOv5_m$ were used to parametrize DeepSORT, resulting in a MOTA of 92.8% when applied to 10 min of a single selected video clip. This is a promising high accuracy, but results have to be confirmed with more video clips that cover more variability in practical barn circumstances. The DeepSORT had low numbers of FP BBs and IDSs but the number of FN BBs was relatively high. A closer look into the data revealed that FN BBs often occurred when cows were overlapping each other in the camera view. In these cases, the algorithm often predicted one BB (one cow) instead of two. The FP BBs occurred often when

Table 1. Performance of four YOLOv5 models on the test set (n=16 frames), with YOLOv5s being the simplest model, and YOLOv5x the most complex model.

	YOLOv5			
Performance indicator (%)	**s**	**m**	**l**	**x**
Precision	95.9	95.9	95.7	97.5
Recall	95.1	96.7	91.0	93.5
mAP@.5[1]	97.5	97.1	95.9	98.0
mAP@.5:.95[2]	60.3	65.4	65.9	68.9
F1-score	95.5	96.3	93.3	95.5

[1] Mean average performance using a threshold of 50%: if the overlap between annotated and predicted bounding boxes is >50% the prediction is counted as a true positive prediction (cow detection).

[2] Mean average performance using a threshold of 50-95%: the average true prediction over a range of thresholds (with steps of 5%) running from 50 to 95% overlap between annotated and predicted bounding boxes.

cows had a 'strange' pose, e.g. when the cow was scratching her head with her hindleg. Both issues may be solved by adding more annotated frames with overlapping cows or unique poses to the training data. The IDSs often occurred when a second cow temporarily occluded the view of another cow. In these cases, the algorithm assigned a new identify to the occluded cow once the second cow passed-by completely. Building-in a memory function such that the DeepSORT algorithm remembers the assigned identities from previous images may help to solve this problem. This building in, however, has still to be developed.

The amount of data used in the current study was limited, and the evaluation of tracking cows was done on a single 10 min video clip only. Still, it confirmed the feasibility of detecting and tracking multiple cows simultaneously with a high level of accuracy (92.8%). This provides perspective to automatically continuously monitor individual group-housed cows. The use of BB to track cows, and the change in BB properties during tracking may be useful to detect specific cow behaviour as demonstrated by Adriaens *et al.* (2022).

Abstract

We are developing a computer vision system for tracking growing rabbits' movements, in order to quantify individual variability on physical activity. The system relies on a Deep Convolutional Neural Network for the identification of the animals; and on the Hungarian and the Kalman Filter algorithms for tracking the animals across photograms. When the animals were sparsely distributed a precise identification was achieved with few images (mean Average Precision (mAP)≥0.95). When the rabbits were crowded within a given region, the quality of the identification dropped, but by increasing the size of the training set and by applying data augmentation techniques, we managed to improve the identification accuracy (mAP=0.83). In spite of these improvements, and the fact that good results were observed during some short tracking examples, the overall performance at tracking is still low and further training rounds are needed to properly define the aimed physical activity metrics.

Introduction

Our research group has been working on a line related to the genetic improvement of feed efficiency during fattening, aiming to propose genetic evaluation methods and tools to increase the amount of meat produced per kilo of feed supplied. In this context, we have designed and manufactured a device allowing for the individual registration of feed consumption in rabbit (Sánchez *et al.*, 2018). Information on consumption is essential for the implementation of genetic selection programs for the direct improvement of feed efficiency in group-housed animals.

An important percentage of the resources used by the growing animal is spent on physical activity. In pigs, it has been shown that selection for reducing residual feed intake (the amount of feed consumed above or below the needs of an animal) has led to less active animals (Gilbert *et al.*, 2019). To monitor the movements of the rabbits we have begun the development of a computer vision system using artificial intelligence techniques that will allow to quantify their physical activity. The ultimate goal of our development would be to record this information on physical activity for being considered in the selection processes for feed efficiency we are conducting (Pascual *et al.*, 2021). Once this computer vision system is ready, we also expect to train it for being used in other fields of animal production: behavior studies, interactions between group mates or early detection of pathological outbreaks.

Our purpose with this communication is to inform the animal breeding community about the development of this new computer vision system. We describe the methods that it implements and present some results related to its capacity of individual detection and tracking.

Materials & methods

Algorithms for artificial vision and individualized tracking of rabbits. The first step to achieve an individualized tracking of objects in a video signal is to have a good localization system for each of the objects that we want to track, in our case the rabbits. The problem of locating one or more objects of a certain class (rabbit) in an image is known, in the computer vision context, as instance segmentation. It

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_140, © J.P. Sánchez *et al.* 2022

consists in assigning each pixel of an image to one of the different classes we might have defined, and grouping together the nearby pixels belonging to the same class to define the different objects (instances) of that class in the image. In this way, it is possible to count the items belonging to each class in a single photogram or to track them across photograms. One of the most advanced and efficient tools to perform instance segmentation is the MaskR-CNN library (He *et al.*, 2018), which is based on deep convolutional neural networks (ResNet101). The result of applying MaskR-CNN to an image will be a table with as many rows as objects detected in the image. Each row includes the coordinates of the smallest rectangle that can be defined to cover the pixels corresponding to each detected object and the object class.

To be able to detect the rabbits, it is necessary to train the MaskR-CNN system. This training consists in obtaining the ResNet101 network parameters that allow identifying the rabbits in any image. This is done by cross-validation that consists in providing images in which the rabbits have been manually identified (training set). With this information, the values of the parameters of the ResNet101 network are iteratively adjusted.

Deep layers of the ResNet101 network are useful for the detection of general patterns, common to any type of image: angles, shadows, curvatures, etc. Thus, the coefficients of the deep layers of the ResNet101 network remained equal to the values previously trained within COCO project (Lin *et al.*, 2014), that aimed at detecting all types of common objects. The coefficients from this generalist training project will not only be valid for our specific problem, but will be probably better than those that we could obtain with our images. In COCO project hundreds of thousands of images have been used for training, whereas we will only have several hundred or a few thousand images with the identified rabbits. The outer layers of the ResNet101 network, those in charge of classifying the pixels into the defined classes, are the only ones specifically trained with the rabbit annotated images in the training set.

The detected rabbits were tracked across photograms using a library named Simple Online and Real-Time Tracking (SORT) (Bewley *et al.*, 2016); which implements two algorithms for object tracking: the Hungarian algorithm and the Kalman Filter. This library has been used in a similar project aiming to track pigs (Van der Zande *et al.*, 2021).

Collection of images: training and identification of the rabbits. The training of the ResNet101 network has been carried out using photos taken with a 2D RGB high resolution camera (3,280×2,464 pixels), placed on the ceiling of the barn at about 2 meters above the rabbits. The camera was positioned to record the area corresponding to 4 cages of 75×75 cm each. Each cage housed 6 rabbits.

Each of the images used for training had a size of 1,280×1,280 pixels, covering one single cage. The images for training were collected during 4 production batches, and within each of them, the images were taken on a few days chosen at random from the fattening period (35 to 56 days of rabbit's life). In the first two batches, the images were chosen so that the rabbits could be perfectly distinguished from each other (Figure 1A), while in the last two batches images corresponded to rabbits stacked next to each other, making them difficult to identify (Figure 1B). In addition, with the images from the last production batch, different data augmentation techniques were used, i.e. the images were subject to random twists and distortions, which allows increasing the available information without the need to carry out new manual identifications. For each training, a number of annotated images were reserved to validate the precision of the identifications.

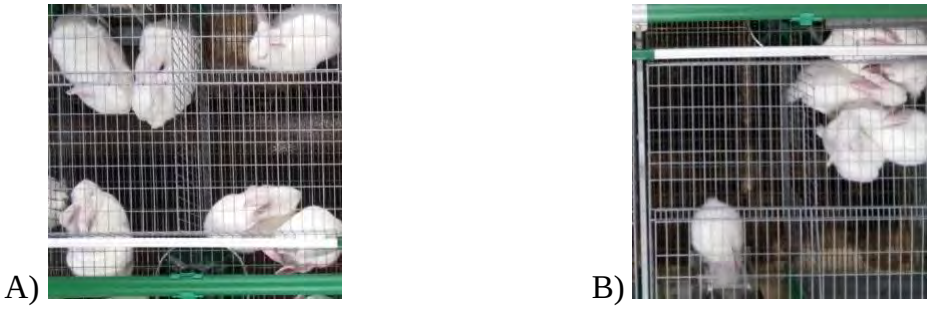

Figure 1. Examples of images: animals are easily differentiated (A) or animals are huddled on top of each other (B).

Results

The identification of the animals with a sparse distribution showed a high accuracy. With only a few training images a high precision of the location of the animals in the validation images was obtained (mean Average Precision (mAP)≥0.95) (Table 1). As expected, the use of images in which some individuals are huddled on top of others makes the identification notoriously difficult. It must be taken into account that in some of the images used it was difficult, even for the human eye, to determine where one individual ended and the next began. However, by increasing the number of training images and by including complex data augmentation procedures significant improvements were achieved.

Regarding tracking rabbits across consecutive photograms we have conducted two assessments. One has been done using standard central processing units (CPUs). The following link shows a video with the tracking results: https://www.youtube.com/watch?v=LVPEWSoh-zk. It can be seen how the identifications assigned in the first frame remain the same (in most of the cases) throughout the entire video, even when an animal passes by (or even over) some other cage mate. The other assessment has been done using one graphics processing unit (GPU). With this alternative system, it is possible to process a single-cage photogram every two seconds, i.e. a real-time processing is feasible. MaskR-CNN library does not support processing multiple cages at the time using a single GPU; thus, our strategy has been to process every cage, eight in total, for ten minutes during approximately 5.5 days; thus, a total of 777 10-minutes tracks were recorded. Figure 2 shows a graphical representation of the movements in three of these 10-minutes tracks. Panels A and B are two examples of good tracking performances; panel C, on the contrary, is an example of poor individual tracking.

Table 1. Performance of different trainings steps of the MaskR-CNN system.

Training set size	Validation set size	# Epochs[1]	# Steps / epochs[1]	Image type[2]	Data augmentation	mAP[3]
50	37	20	25	A	NO	0.95
156	44	20	100	A	NO	0.96
176	24	20	100	B	NO	0.69
331	24	10	50	B	Yes (Vertical)	0.76
331	24	20	100	B	Yes (45°)	0.76
331	24	30	150	B	Yes (Complex)	0.83

[1] At the end of each epoch all the training images would have been processed.

[2] See Figure 1.

[3] mAP=mean Average Precision in the validation set at the end of the training. It can be interpreted as a correlation between the class of the pixels in the annotated image used for validation and the class assigned by the algorithm.

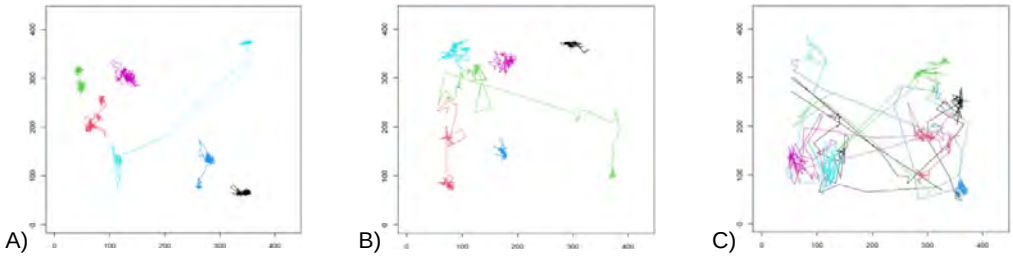

Figure 2. Graphical representation of three cage surfaces with the individual tracks (10 minutes) of the six rabbits in each cage. Each colour represents one animal.

Discussion

The preliminary results we present seem to be promising for achieving our objective, i.e. automatically monitoring individual activity. The key element for achieving such objective would be the real-time processing already accomplished, which would grant keeping animal identifications for long periods. The observed issues on limited accuracy (mAP=0.83) during the identification of the animals can be solved with additional training rounds. Similarly to Van der Zande *et al.* (2021) the performance of our system strongly depends on the quality of the identification of the individuals. Our ambition is to extend this system to growing or finishing pigs. In this species, we expect the animal recognition training to be easier since they do not pile up to each other as frequently as in rabbits (Figure 1 panel B). Another point yet to be solved is the definition of the metrics to quantify individual activity; we could not advance in this regard yet since better individual recognition is needed. Obtaining these metrics on the current tracks would be strongly influenced by the observed misidentifications (Figure 2C).

Abstract

A computer-vision based procedure was developed to predict behaviour of 22 Meishan and 21 Large-White lactating sows kept in individual pens. A neural network analysis allowed detecting 5 postures (standing, sitting, lying ventrally, lying laterally without and with udder exposed) and 2 sow standing activities, i.e. drinking, eating. The accuracy was 31% for sitting and varied from 78 to 96% for the standing and lying postures. Sow behaviour was estimated from 3 days before to 9 days after farrowing. First, cluster analyses were carried out to identify patterns of activities over successive periods: pre-farrowing, the day of farrowing and post-farrowing. Second, a survival analysis was carried out using Cox proportional hazards model to study the influence of sow behaviour on piglet mortality. Piglets born from sows that were less active before farrowing and make more rooling and less changing standing to lying on the day of farrowing had a risk of dying up to 8 and 3 to 7 times higher than other piglets, respectively.

Introduction

More freedom is required for lactating sows. However, it is often reported that loose-housed sows may have higher piglet mortality than sows in crate but conclusions obtained from a few animals varied between studies (Baxter *et al.*, 2012). In addition, the analysis of relationships between sow behaviour and litter mortality is limited to short time periods and a few variables when it depends on human video observations. The recent and successful use of computer vision to analyse animal behaviour allowed addressing this issue with automated phenotyping over extended periods on large numbers of animals. In particular, methods based on convolutional neural networks (CNN) were recently used to estimate the posture and activity of a sow in an individual pen with its piglets around (Yang and Xiao, 2020). The first objective of our study was to use a CNN to predict sow postural activity from video recording. From the data produced, the second objective was to study differences between sows in time-budget activity (accounting for time elapsed from farrowing), and to identify sow behavioural traits related to piglet mortality.

Materials & methods

Animals and measurements. The study included 21 Large-White (LW) and 22 Meishan (MS) primiparous sows that were raised at the INRAE GenESI experimental farm (https://doi.org/10.15454/1.5572415481185847E12) in 5 batches from November 2010 to January 2011. Sows were moved to the farrowing unit about 1 week before farrowing. The pen size was 7.3 m^2 (286×255 cm) and included a creep area with a heat lamp. The concrete floor was covered with a thin layer of straw that was changed every morning. Sows were fed twice daily, at approximately 8am and 4pm and they had free access to water provided from a low-pressure water trough located on the wall opposite to the feeding trough. LW and MS sows were located alternately in adjacent pens. Farrowing was not induced, and interventions to save piglets were highly limited. Piglet death was recorded daily and causes of death were identified distinguishing stillborn piglets, piglets crushed by the sow, piglet that died from starvation and other causes.

Video recording and algorithm. A 2D camera was mounted on the ceiling above each pen to cover the entire surface of the pen. Sows were video recorded continuously 24h a day from 3 days before farrowing, to 9 days after farrowing. An ethogram was defined to analyse sow behaviour. It included six sow postures: sitting (A), standing (S), lying on the belly (LB), lying on the side (L), lying on the side with udder exposed (LU) and kneeling (K); and three sow activities while standing: drinking (D), eating (E) or other (N). From the videos, 8,400 images were selected randomly from all the sows (LW and MS) and the entire recording period. The images were manually labelled according to the ethogram. The location of the sow and piglets were also recorded. These images were used to train a YOLO detector (Redmon *et al.*, 2016), with ResNet50 as a feature extractor. YOLO was trained with 6 object classes, corresponding to the different postures. Thus, it was used to predict animal location and posture at the same time. The sow's centre of gravity was the estimated centre of gravity of the YOLO detection. The distance between sow head and each trough was calculated to detect drinking and eating activities. YOLO was finally used to predict sow posture and activity on 25,830 images, again selected randomly and manually annotated. The accuracy of prediction was 31% for A, 88% for S, 9% for K, 95% for LB, 96% for LU and 78% for L. The K and S postures were then grouped together for further analysis as they were highly confounded. YOLO training and predictions were done using Matlab (R2020b).

Statistical analyses. Sow activity was summarised per day, by % of time spent in each posture over 24h and % of time spent in each activity when the sow is standing. We considered 3 periods: the pre-farrowing period from D-3 to D-1, the farrowing day D0, defined as 24h after the birth of the first piglet, and the post-farrowing period from D1 to D9. A k-means clustering approach was carried out to identified posture and standing activity longitudinal patterns for the 3 periods (Genolini *et al.*, 2015). Obtained clusters represented different patterns of use of postures and standing activity. A survival analysis was carried out to evaluate the influence of sow posture (cluster posture) and standing activity (cluster standing activity; found during clusterisation procedure) on piglet survival. Deaths, stillborn excluded, were considered events. Piglets alive at weaning were censored. Survival time or time until censoring were defined from the farrowing day. First, survival probabilities were calculated by piglet genetic type using the Kaplan-Meier (KM) approach. The Cox proportional hazard model was used for each period to evaluate if cluster posture, cluster standing activity or number of postural changes influenced piglets mortality. In addition to sow clusters or number of postural changes (3 levels: I = below average, M = around average, S = upper average) effects included in each cox models were the piglet genetic type (4 levels), batch (5 levels), litter size (3 levels; defined as the total number of piglets born), and box (3 levels; defined by distance with maternity entrance). All statistical analyses were carried out using R software (version R 4.1.0).

Results

Clusters identified for postures and standing activity in each period are shown in Figure 1 and 2, respectively. Before farrowing (bf), clusters according to posture differed mainly according to the percentage of time spent lying on the side. The two clusters are defined according to the sow breed: A_{bf} included 17 LW sows and B_{bf} 11 MS sows.

At farrowing (af), posture clusters differed mainly according to the time spent lying (3 clusters: A_{af} including 5 LW, B_{af} 6 LW + 2 MS, and C_{af} 8 + 9), and after farrowing (pf) by the time spent lying on the belly (A_{pf} :10+16; B_{pf} :10+1). In the 3 periods under study, the standing activity clusters differed mainly by the percentage of time spent in other activity than drinking and eating.

Two, three and two clusters were obtained, respectively: Aa_{bf} (6+10) and Ba_{bf} (11+1) before farrowing, Aa_{af} (6+5), Ba_{af} (3+4) and Ca_{af} (10+2) at farrowing, and finally Aa_{pf} (19+6) and Ba_{pf} (1+12) after farrowing. Based on KM estimator, piglet survival differed markedly between the 4 piglet genetic types (P<0.0001; Figure 2a).

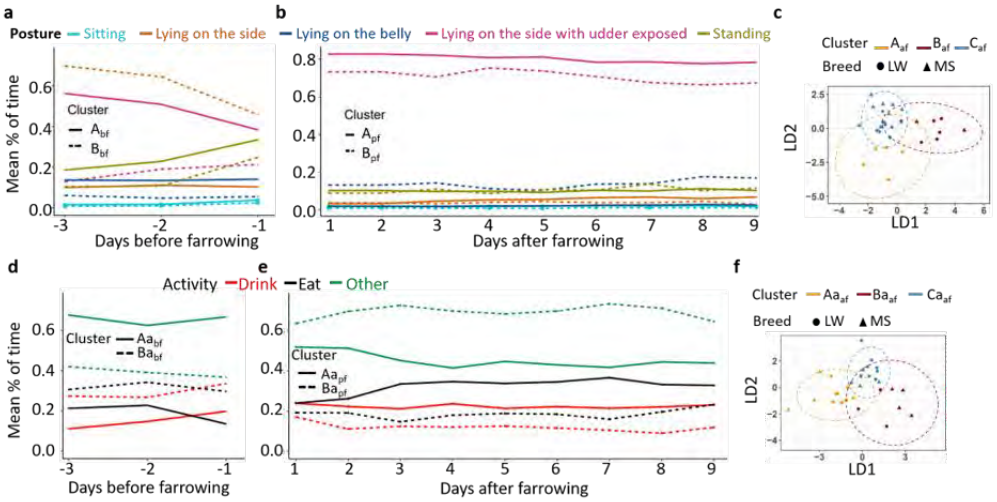

Figure 1. Clusters before farrowing, for sow postures (a) and for sow standing activity (d). Cluster after farrowing, for sow posture (b) and for sow standing activity (e). Cluster at farrowing obtained from discriminant analyses for sow posture (c) and sow standing activity (f).

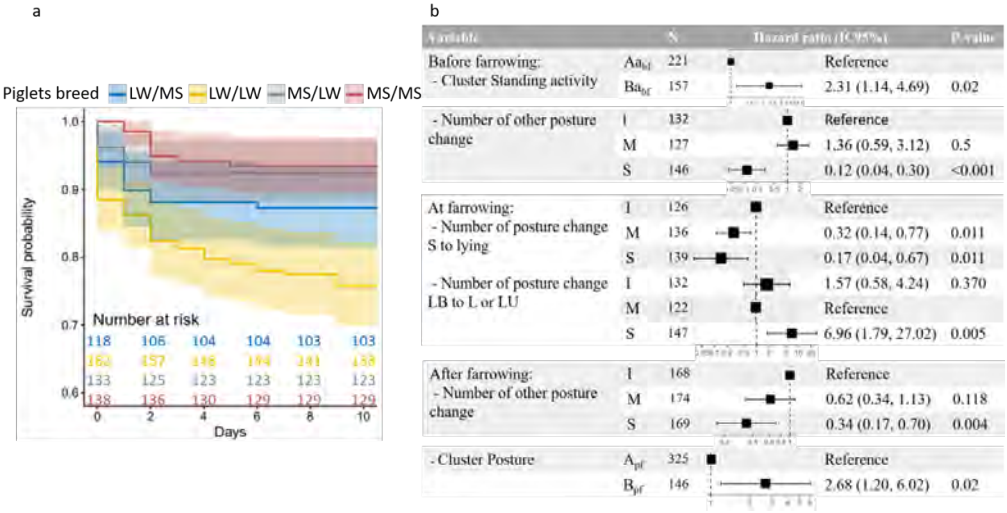

Figure 2. (a) Kaplan-Meier curves of piglet mortality after farrowing in Large White/ Large White (LW/LW), Meishan/Meishan (MS/MS), LW/MS and MS/LW genetic types of piglets; (b) Hazard ratios from the Cox models.

Piglet postnatal mortality was related significantly to sow standing activity before farrowing. Piglets from sows spending more time eating and drinking (in cluster Ba_{bf}) had a 2.3 times greater instantaneous risk of dying than piglets from sows in cluster Aa_{bf} ($P<0.02$). Piglets born from sows calmer before farrowing (I group) had an instantaneous risk of dying 8 times higher than other piglets. Piglets born from sows which made more rooling (change posture LB to L or LU) on the day of farrowing (S group) had an instantaneous risk of dying 7 times greater than other piglets. Conversely, if sow change less standing to lying (I group) on the day of farrowing, the piglets had an instantaneous risk of dying between 3 and 6 times greater

than other piglets (Figure 2b). In early lactation sow posture influenced piglet mortality; piglets from sows spending more time lying ventrally (B_{pf}) had an instantaneous risk of dying 3 times higher than piglets from cluster A_{pf} (P=0.02). Furthermore, piglets with sows performing fewer postural changes (I group) had a 2.5 higher risk of dying than other piglets (Figure 2b).

Discussion

The contrast between the two sow breeds in piglet mortality was confirmed. We studied how much maternal behaviour was involved in such difference. Clusters according to postures pre-farrowing were based solely on sow breed differences. A previous study showed that tethered MS sows spent twice less time lying on the belly before farrowing, and more time rooting especially 24h before farrowing (Meunier-Salaün *et al.*, 1991). In cluster Aa_{bf}, which was composed of 10 MS sows, 64% of standing time was allocated to other activity than eating and drinking. Presumably, it refers to nest-building which is positively correlated to piglet survival (Andersen *et al.*, 2005). All other clusters were a mix of sows from the 2 breeds. At farrowing, the risk of dying was higher in sows that performed more posture changes. Previous studies (e.g. Yun *et al.*, 2019) found that numerous posture changes during the first 24h after farrowing is positively correlated with crushing of piglets by the sow.

To conclude sow pattern of activity over the 3 studied periods influenced the risk of mortality of born alive piglets.

142. Using machine learning to predict feed intakes of meat sheep from animal traits and ruminal microbiota

Q. Le Graverand[1*], C. Marie-Etancelin[1], J.L. Weisbecker[1], A. Meynadier[1], D. Marcon[2] and F. Tortereau[1]

[1]GenPhySE, Université de Toulouse, INRAE, ENVT, 24 Chemin de Borde-Rouge – Auzeville CS 52627, 31326 Castanet-Tolosan, France; [2]INRAE, Experimental Unit P3R, Domaine de la Sapinière, 18390 Osmoy, France; quentin.le-graverand@inrae.fr

Abstract

Animal traits, such as body weights, and rumen microbiota composition have been proposed as feed intake predictors. The present study assessed what are the best predictors out of animal traits, metabarcoding data or a combination of both. Predictions were carried out with sparse Partial Least Squares Regression (sPLSR), Support Vector Regression (SVR) and Random Forest Regression (RFR). With all three approaches, best feed intake predictions were obtained with animal traits only. The generalizability of models to animals of an independent year was assessed: negative (<-0.1) to high (>0.8) correlations between actual and predicted feed intakes were obtained. Finally, estimated breeding values (EBVs) were computed for actual and predicted feed intakes. These EBVs were highly correlated (>0.9) depending on the prediction approach. It mainly varied with proportions of true and predicted feed intakes used during the genetic evaluation.

Introduction

To assess feed efficiency of sheep, expensive feed intake recording is necessary. Thus, most meat sheep breeding companies cannot afford to select for feed efficiency. Predicting feed intake or feed efficiency could be one solution. As reviewed by Pittroff and Kothmann (2001), many sheep feed intake prediction models include live weight. Omics data were also used as predictors, such as 16S data to predict sheep Residual Feed Intake (RFI) with a general linear model (Ellison *et al.*, 2019), or rabbit feed intakes with mixed models and SPLSR (Velasco-Galilea *et al.*, 2021).

We have chosen to focus on the prediction of feed intake since it intervenes in the definition of many complex phenotypes such as feed efficiency or the environmental footprint. Moreover, to our knowledge, there is no comparison between accuracies of feed intake predictions from animal traits or microbiota compositions with a large number of sheep and machine learning.

The first goal of our study is to check whether microbial information improves feed intake predictions with different machine learning approaches. To do so, we compare accuracies of different machine learning approaches (sPLSR, SVR and RFR) applied to several sets of predictors (body weight, body composition traits, and/or ruminal microbiota composition). Then, the second objective is to see if a machine learning model could be generalized to new animals raised a different year. Finally, the last objective is to assess if a genetic selection with machine learning predictions is feasible.

Materials & methods

Animal husbandry and traits. Overall 277 Romane male lambs were reared at the INRAE Experimental Unit P3R between 2018 and 2020. Animals originated from two experimental divergent lines selected for a decreased or increased RFI. Lambs are part of the second generation of selection in 2018 (n=103) and the third generation in 2019 (n=101) or 2020 (n=73). The divergence represented 1.9 genetic standard deviations during the third generation. After weaning, lambs were accustomed to an *ad libitum* diet with low-energy concentrates. When animals were approximately 3 months old, feed intakes were recorded

R.F. Veerkamp and Y. de Haas (eds)

DOI: 10.3920/978-90-8686-940-4_142, © Q. Le Graverand *et al.* 2022

during six weeks. Average Daily Feed Intake (ADFI) was computed as the daily feed intake mean over six weeks. At the beginning and end of the trial period, body weights were recorded, then average daily weight gain and growth capacity (estimated body weight at 145 days old) were calculated. Back ultrasound measurements enabled to estimate the back-fat thickness and muscle depth at the trial end.

Ruminal microbiota composition. At the end of the six-weeks trial, ruminal fluid was collected with a medical gastric tube and DNA was extracted from samples. The V4-V5 region of 16S rRNA gene was amplified and then sequenced at the Genomic and Transcriptomic Platform (INRAE, Toulouse, France). Sequences were processed, cleaned and clustered into Operational Taxonomic Units (OTUs) with FROGS tools and pipeline (Escudié *et al.*, 2018). OTUs were pre-filtered according to their relative abundance: only OTUs representing at least 0.005% of all sequences were kept.

OTUs zero counts were imputed with Bayes-Laplace multiplicative replacement (Martín-Fernández *et al.*, 2015) before applying the Centered LogRatio (CLR) transformation. CLR coordinates were filtered to retain OTUs with less than 90% imputed values each year. Finally, the 496 retained OTUs coordinates were adjusted for the age, the year, the pen and sequencing plate effects with a robust MM linear regression (Maechler *et al.*, 2017).

Machine learning. Three different approaches of machine learning were carried out to predict ADFI: sparse Partial Least Squares (sPLSR, mixOmics R package), support vector (SVR, e1071 R package) and random forest (RFR, randomForest R package) regressions. Different sets of prediction features were considered: animal traits (body weights, growth traits and body composition), or adjusted 16S CLR coordinates. Those feature sets were used separately or were combined together by concatenation for ADFI predictions. Successively, animals of one year were used as a testing set. To avoid a bias, 2018 will not be used as a testing set because 2020 lambs are the progeny of 2018 individuals. Animals of the two remaining years were used as training/validation sets: 10-fold cross-validations repeated 50 times were used to tune the hyperparameters and maximize the coefficient of determination (R^2) between predicted and actual ADFI phenotypes. Models were then fitted without the testing dataset. Next, ADFI of testing set animals were predicted with each predictor set and machine learning model. Pearson correlations between predicted and actual ADFI phenotypes were computed. Within one testing set, significance of differences between machine learning approaches and features sets were tested with Dunn and Clark's z test (Dunn and Clark, 1969). *P*-values were adjusted with Bonferroni's procedure.

Breeding values estimation. Breeding values were estimated with PEST (Groeneveld *et al.*, 1990), considering a feed intake heritability of 0.28 (Tortereau *et al.*, 2020). Two sets of populations were used to estimate breeding values: an entire Romane population named E (born from 2009 to 2020), with 6,419 animals in the pedigree including 1,900 with ADFI records; one subset population named S (2018 to 2020), with 4,102 animals in the pedigree including 277 with records. The model included the fixed effects of year, pen, early life traits (litter size, suckling method), sex and body weight as a covariate. EBVs of actual ADFI and EBVs of predicted phenotypes are estimated. EBVs were only estimated for phenotypic ADFI predicted with accurate strategies (R^2>0.7).

Results

Comparison of different predictors and machine learning approaches for phenotypic ADFI. Table 1 details accuracies of ADFI predictions for the three machine learning models carried out with 16S data, animal traits and a concatenation of both. Considering correlations between actual and predicted ADFI phenotypes, there was no significant difference between sPLSR, SVR and RFR accuracies whatever the testing set or the predictors.

Table 1. Pearson correlations between predicted and actual ADFI phenotypes of testing set animals.

		Testing sets	
Models	**Features**	**2019**	**2020**
sPLSR	16S	-0.116[a]	0.191[a]
	Animal	0.763[b]	0.810[b]
	Animal+16S	0.726[b]	0.818[b]
SVR	16S	-0.040[a]	0.351[a]
	Animal	0.766[b]	0.802[b]
	Animal+16S	0.763[b]	0.817[b]
RFR	16S	0.031[a]	0.312[a]
	Animal	0.777[b]	0.773[b]
	Animal+16S	0.709[b]	0.737[b]

[a,b] Within one testing set, correlations with no common letter significantly differ (adjusted $P<0.05$, Dunn and Clark's z test).

With all testing sets and machine learning techniques, correlations were significantly lower when only 16S data was used as the feature set. Whatever the testing set and the machine learning model, combining animal traits and 16S data together as predictors did not significantly increased correlations.

Relationship between EBVs of predicted and actual ADFI. The quality of predicted ADFI EBVs is presented in Table 2. Within one machine learning approach and regardless of the testing set, correlations between EBVs are significantly higher when a full set of records (E) is used during the genetic evaluation compared to a partial set (S).

In 2020, no significant difference could be found between machine learning approaches. However, when only animal traits were used as 2019 ADFI predictors, sPLSR performed significantly better than SVR, with RFR having intermediate performances. Finally, the combination of animal traits and 16S data as predictors did not significantly improve correlations between actual and predicted ADFI EBVs.

Discussion

Rumen microbiota composition alone lead to poorly accurate ADFI predictions with sPLSR, SVR and RFR, which was also observed with sPLSR carried out with rabbit caecal microbiota compositions (Velasco-Galilea *et al.*, 2018). Predictions made with animal traits reached higher performances, whatever the

Table 2. Pearson correlations between predicted and actual ADFI estimated breeding values of testing set animals.

		Testing sets and populations[1]			
		2019		**2020**	
Models	**Features**	**S**	**E**	**S**	**E**
sPLSR	Animal	0.681[a]	0.868[c]	0.843[a]	0.954[b]
	Animal+16S	0.698[ab]	0.876[cd]	0.852[a]	0.956[b]
SVR	Animal	0.624[b]	0.814[d]	0.848[a]	0.962[b]
	Animal+16S	0.650[ab]	0.817[cd]	0.839[a]	0.956[b]
RFR	Animal	0.731[ab]	0.891[cd]	0.863[a]	0.952[b]
	Animal+16S	0.698[ab]	0.880[cd]	0.848[a]	0.959[b]

[1] Populations differ in the number of records used for EBVs estimation. S: subset population; E: entire population.

[a,b] Within one testing set (2019 or 2020), correlations with no common letter significantly differ (adjusted $P<0.05$, Dunn and Clark's z test).

machine learning model. The integration of animal traits and microbiota compositions did not improve predictions. Therefore, our results do not advocate for the use of metabarcoding data to predict feed intake. However, the microbiota composition could be more relevant when one is trying to predict feed efficiency. Ellison *et al.* (2019) managed to predict RFI of 20 animals with 16S data and achieved a correlation of 0.71 between actual and predicted feed efficiency. In the future, another comparison will be done with RFI to assess the potential of 16S and 18S data predictors and determine the relevance of archaeal, bacterial, fungal and protozoal compositions.

Depending on testing sets and predictors, no consistent difference was found between the three modelling approaches when it comes to predict ADFI and then estimate its EBVs. Only SVR performances seemed to be less stable across testing sets when predicted ADFI EBVs were compared to actual ADFI breeding values.

The moderate or high correlations achieved between EBVs of predicted and actual ADFI suggests that predictions could be used for genetic selection of feed intake. Further research in the phenotyping strategy should be carried out, especially about the ratio between predicted and recorded phenotypes. In the present study only two testing sets were used to assess performances of machine learning predictions. Those testing sets were constituted as independent cohorts, i.e. with animals raised a different year than the training set. When predictors are sensitive to environmental factors, such as microbiota compositions, the presence of contemporaneous animals in both training and testing sets should improve predictions.

Abstract

The generation of realistic images from marker information could be a main contribution of artificial intelligence to genetics. This paper is a proof of concept demonstrating its feasibility, since shapes and colors are heritable. We generated 2D and 3D images and 2D Cucurbitaceae shapes –which harbor the most extreme shape variation in the plant kingdom- assuming they are controlled by a set of QTLs. We use a class of deep models, called encoders, to reproduce the expected shapes given a linear vector of QTL and random SNPs. This novel theoretical framework can have an important impact in breeding, as studies so far focused on determining the genetics of shape related statistics, and not on predicting shape per se.

Introduction

Shape and color patterns of animals and plant fruits are not only aesthetic features; they convey essential information on animal welfare or fruit quality and are critical for consumer appreciation. Animal and fruit shapes are heritable. In fact, heritability of some phenotypes like human face features approaches one. It should be possible then to predict, i.e. to generate, shapes and appearance from DNA sequence. However, research so far show has focused on identifying quantitative trait loci of shape-derived statistics, such as elongation, which often explain only a percentage of observed variability (Monforte *et al.* 2014; Brewer *et al.* 2006). Further, the study of derived shape statistics constrains the type and role of genes to be discovered and does not allow the inference on shape as a whole.

We propose to approach this issue from a holistic, opposite angle. We aim to reproduce expected shapes and textures that would result from a given individual's DNA sequence. This paper is a proof of principle, and we show that this can be accomplished using decoder deep learning algorithms, at least in simplified scenarios. For simplicity, we focus on fruit shapes, although the same principles apply to animal images. Note we focus on generating images and not on predicting quantities, e.g. areas from the images.

Materials & methods

Generating simple 2D and 3D shapes. We generated images of size 64×64 pixels containing ellipses with different height / width ratios and sizes using OpenCV (https://opencv.org/). We assumed that shape and size was controlled by a set of QTLs with an environmental error added, together with a variable number of non-causative SNPs. To do this, a random shape (x / y axis ratio) and size (pixel number) were sampled, noise added to the causal loci, and an ellipse was drawn with these parameters. We employed pymrt library (Metere and Möller 2017) to generate 3D images of 128×128×128 size, where pixels take values 0/1 depending on whether the position is within the ellipsoid or not. To plot 3D images, we used marching cubes algorithm as implemented in scikit learn (Pedregosa *et al.* 2011), via pyplot projection='3d' option.

Cucurbit shapes. Cucurbitacea family displays, probably, the most extreme shape range in the whole plant kingdom, and *Cucurbit melo* is the most variable species within the family, in terms of shape (Paris 2001; Montero-Pau *et al.* 2017). *C. melo* comprises squashes, zucchini, scallop shapes, among others (Figure 1). We developed an algorithm to generate *C. melo* shapes and intermediate, unobserved variants. Starting from Figure 1, we segmented contours using a thresholding algorithm in openCV, next we generated 200 pseudo-landmarks using the algorithm in (Zingaretti *et al.* 2021), followed by a procrustes alignment (https://

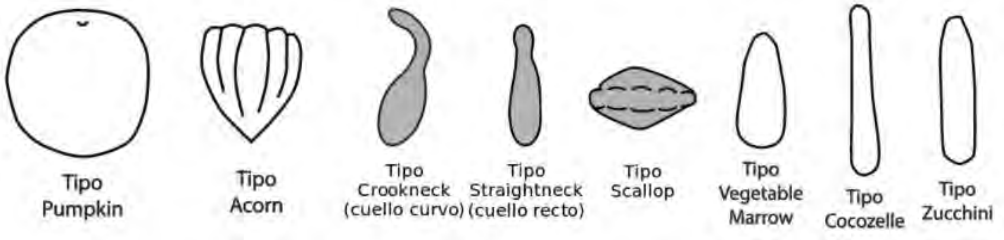

Figure 1. *C. melo* shapes used for simulation. Source: https://es.wikipedia.org/wiki/Cucurbita_pepo, based in Paris *et al.* (2001).

github.com/theochem/procrustes). Following Paris *et al.* (2001), we assumed a hypothetical evolutive path where the ancestral form is a small pumpkin that evolved into acorn → scallop, and a second evolutive path pumpkin → marrow → straightneck → zucchini → cocozelle. The different shapes were determined by a continuous breeding value (20 loci) and therefore intermediate shapes were possible (Figure 2). A random noise to the contour was finally added via an autoregressive process (https://stackoverflow.com/questions/33898665/python-generate-array-of-specific-autocorrelation). Finally, 100 random genotypes were added to the 20 causative loci.

Decoding algorithms. To generate images from linear genotypic data, we used the 'decoder' part from an 'autoencoder'. Very briefly, an autoencoder is an unsupervised deep learning algorithm where the inputs are equal to the outputs (Goodfellow *et al.* 2016). Penalization is employed to avoid overfitting, allowing the algorithm to retrieve repeatable patterns between images. Principal component analysis is equivalent to a linear autoencoder. An autoencoder consists of an 'encoder', which transforms image into a lower dimensional 'latent space' and a decoder that transforms back the vector into a reconstructed image. Since input and output dimensions are the same in an autoencoder, this is unsuited for our needs. However, we can use a decoder architecture and train it for our objective, since in this case input is linear (DNA information) and output is an image. We treated DNA as our latent space. As input, then, the model received non causative SNP and QTL genotypes, the output consisted of the corresponding shapes.

Implementation. About 1000 SNP lists and their corresponding images were generated, which were split into training (n=800), validation (n=100), and testing (n=100) subsets. Predictions presented are for test samples. All analyses were implemented in python 3.9 using keras, tensorflow, open-cv, scikit-learn, PIL libraries, among other packages.

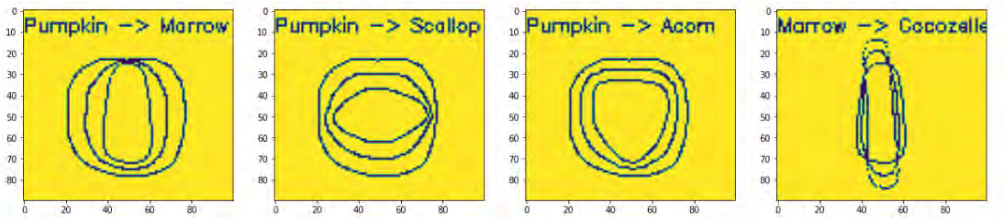

Figure 2. Examples of several pseudo-landmark profiles of *C. melo* shapes from Figure 1 and intermediate simulated shapes that represent hypothetical unobserved evolutive forms.

Results

Predicting 2D and 3D shapes and size. Top row in Figure 3 shows some of the ellipse shapes simulated, whereas the predicted shapes are in the lower row. The algorithm retrieves accurately size, orientation, and shape. Moreover, a similar algorithm using 3D convnet layers also accurately predicts 3D volumes (Figure 4).

Generating and predicting cucurbit shapes. Figure 5 shows a sample of simulated and predicted *C. melo* shapes. The use of a very simple and unoptimized network possibly prevented us from obtaining results as accurate as in the previous case. Yet, the algorithm provides quite reasonable outputs, except in a few cases (sample 999).

Discussion

This work opens new, unprecedented perspectives on the applications of deep learning to Agriculture. Although in simplistic scenarios, we show that it is possible to generate 2D and 3D images out of a linear vector, e.g. from DNA data. Undoubtedly, much work remains to be done. Improved algorithms should be trained with real image and SNP data and much more realistic images could be generated via, e.g. conditional generative adversarial networks or variational autoencoders (Goodfellow *et al.* 2016), but technology is there.

Abstract

This study aimed to estimate genomic-based genetic parameters for milkability traits derived from automatic milking systems (AMS) in Holstein cattle. The traits analysed included average milk flow rate (FR, kg/min), maximum milk flow rate (FRM, kg/min), milking speed (MS, kg/min), and milking time (MT, min). The genetic parameters for FR, FRM, and MT were estimated based on random regression models while a repeatability animal model was used for MS. The daily heritability estimates ranged from 0.45 to 0.56 for FR, 0.47 to 0.58 for FRM, and 0.22 to 0.28 for MT. The heritability for MS was 0.39. The genetic correlation between all traits ranged from -0.85 to 0.96, demonstrating that FR, FRM, and MS are highly genetically correlated but a negative correlation with MT was observed. These results indicated that all traits evaluated can be improved through genetic selection and used when designing breeding schemes to improve milkability in AMS.

Introduction

Automatic milking systems (AMS; also known as milking robots) are revolutionizing the worldwide dairy cattle industry, by improving animal welfare (Jacobs *et al.*, 2012), reducing the need of human involvement in milking practices, and enabling large-scale automatized data collection from farms (Dechow *et al.*, 2020). Another advantage of using AMS is the continuous collection of milking information, including milk yield and other parameters such as milking speed and time (Wethal *et al.*, 2019). Automatic milking systems are equipped with sensors that can measure milk flow rate, milking time, and automatically store a variety of milking related variables. Gathering a large amount of daily phenotypic records enables the derivation of novel phenotypes for the genetic improvement of dairy-associated traits, and result in more accurate genetic parameters and genetic or genomic breeding values (Carlström *et al.*, 2013).

The use of random regression models (RRM) enables the estimation of genetic parameters for individual days of lactation as well as the genetic correlation coefficients between the daily measurements recorded on the same or on different days of lactation (Schaeffer, 2004). Furthermore, the use of RRM as well as individual genomic information in genetic evaluations can result in higher accuracy of estimated breeding values in comparison to other approaches (Oliveira *et al.*, 2019). Thus, the combination of advanced statistical models as RRM with genomic information can enhance the reliability of genetic results for traits with repeated records (longitudinal traits) in dairy cattle.

Evaluating the genetic background of milkability traits is paramount for the design and refinement of selection indexes, especially those focusing on precision dairy systems. To our knowledge, this is the first study using the GBLUP approach to estimate genetic parameters for flow rate and milking time across lactation in dairy cows, especially in North American Holsteins. The use of genomic information to predict genetic parameters can provide more reliable estimates, which are essential for designing or refining selection indexes for implementation in dairy cattle breeding programs. Thus, the main objective of this

work was to estimate heritabilities and genetic correlation for AMS-derived traits in North American Holstein cattle using genomic information.

Materials & methods

Dataset. A total of 1,752,713 daily records of milk flow rate (FR, kg/min), maximum milk flow rate (FRM, kg/min), milking speed (MS, kg/min), and milking time (MT, min) from 4,118 genotyped Holstein cows were collected from 2017 to 2021. The data was recorded by 36 Lely automatic milking systems (AMS) installed on a commercial dairy farm located in Plymouth, IN, USA. FR was calculated directly from the AMS, and MS was estimated by dividing the average daily milk production by the daily milking time. Phenotypic consistence was evaluated using the R software (R Core Team, v 4.1.2), with a threshold of 3.5 SD from the mean to exclude potential outliers. Genotype imputation was performed using the FImpute software (Sargolzaei *et al.*, 2014) to converge all SNP panels available to a common set of 72,820 SNPs for all individuals. Quality control (QC) was performed to remove individuals and SNPs with call rate lower than 0.90, minor allele frequency (MAF) lower than 0.05, and extreme deviation from Hardy-Weinberg equilibrium ($P<10^{-8}$) using the BLUPF90 family programs (Misztal *et al.*, 2014). After the QC, 57,600 SNPs and 4,118 animals remained for further analyses.

Models and parameters estimation. First, two-trait random regression models were used to estimate genetic parameters for FR, FRM, and MT, using a third order Legendre polynomial considering the number of days in milk from 5 to 305 days post-partum. A repeatability model was applied to estimate the heritability for MS. Variance components and genetic parameters were estimated using the AIREMLF90 software (Misztal *et al.*, 2014) and the following statistical model:

$$Y = \mu + YS + L + pe + ak + e;$$

Where μ is the overall mean; YS is the concatenation of year and season (March – May, Jun – Aug, Sep – Nov, Dec – Feb) of calving, fitted as a random effect; L is the fixed effect of the lactation number (1, 2, or 3+); pe and ak are the effects of the random regression coefficients of Legendre orthogonal polynomials for the additive genetic effect and permanent environmental effect, respectively. For MS, the same effects were considered, and DIM was fitted as a linear covariate (fixed effect).

Results

The average (±SD) phenotypic values for FR, FRM, MS, and MT were 1.55±0.54 kg/min, 2.40±0.75 kg/min, 2.16±0.54 kg/min, and 19.14±6.76 min per day, respectively. The heritability estimates for the traits analysed showed low variation throughout the lactation (Figure 1). The daily heritabilities ranged from 0.45 to 0.56 for FR, 0.47 to 0.58 for FRM, and 0.22 to 0.28 for MT. The shape of the heritability curves for FR and FRM was similar, with the highest heritability values around the lactation peak. For MT, the shape of the heritability curve presented a smoother wave, gradually increasing from the first days of lactation. The heritability (S.E.) estimate for MS was 0.39 (0.01) and the repeatability (S.E.) was 0.64 (0.02).

The phenotypic correlations between FR, FRM, MS, and MT ranged from -0.48 to 0.89 (Table 1). Positive and high phenotypic correlations were observed between traits related to milking speed, but on the other hand, the phenotypic correlations of all traits with MS were moderate and negative. The genetic correlation estimates between the milkability traits (Table 1) ranged from -0.85 to 0.96 and followed a similar pattern of the phenotypic correlations. The genetic correlations between milk flow rate traits (FR and FRM) and MS indicate that they are controlled by a similar set of genes. However, MT and the other studied characteristics showed an antagonist genetic correlation.

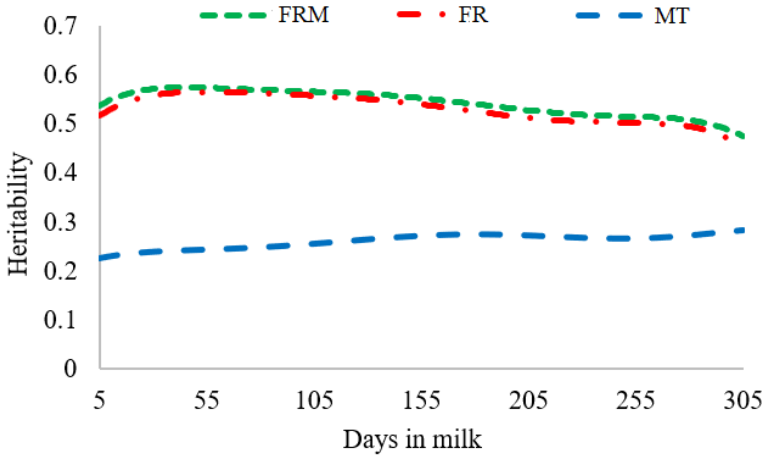

Figure 1. Heritability estimates for milk flow rate (FR), maximum milk flow rate (FRM), and milking time (MT) based on random regression models in North American Holstein cattle.

Discussion

The moderate to high heritabilities observed for FR (0.45-0.56), FRM (0.47-0.58), MS (0.39), and MT (0.22-0.28) indicate that all these traits are heritable and can be improved through genetic or genomic selection. These estimates agree with literature reports for other dairy cattle populations as demonstrated by Carlström *et al.* (2013), Marete *et al.* (2018), Wethal *et al.* (2019), and Dechow *et al.* (2020), with heritabilities ranging from 0.26 to 0.58 for the same traits evaluated in our study. High heritabilities for milkability traits are essential since milking flow/speed is a relevant aspect related to the adaptation of cows to automatic milking systems and can be associated with milking efficiency.

The genetic correlations among FR, FRM, and MS were high and positive, in part because these traits represent similar biological mechanisms related to milking speed. High genetic relationship between FR and FRM was also reported in the literature (0.95±0.01) in a study using different breeds milked in AMS (Edwards *et al.*, 2014). Due to the similar heritabilities and the high genetic correlation between FR and FRM, the use of one of these traits as a selection criterion is sufficient to improve milking flow in North American Holstein cattle. The same concept was observed for the genetic correlation between milking flow traits and MS (Table 1), where high genetic associations were observed. Usually, FR and MS are treated similarly in the literature, often considered as the same trait. However, in our study, these two traits cannot be interpreted as the same since they were measured differently, where FR was calculated directly from

Table 1. Estimates of genetic (above diagonal) and phenotypic (below diagonal) correlations (±S.E.) between milk flow rate (FR), maximum milk flow rate (FRM), milking speed (MS), and milking time (MT) for North American Holstein cattle.

Trait	FR[1]	FRM[2]	MS[3]	MT[4]
FR[1]	-	0.98 (±0.01)	0.95 (±0.02)	-0.75 (±0.02)
FRM[2]	0.89 (±0.01)	-	0.96 (±0.02)	-0.77 (±0.02)
MS[3]	0.85 (±0.01)	0.80 (±0.01)	-	-0.85 (±0.02)
MT[4]	-0.47 (±0.01)	-0.44 (±0.01)	-0.48 (±0.01)	-

the AMS, and MS was calculated by dividing the average daily milk production by the daily milking time. Nevertheless, the high genetic correlation between FR and MS indicates that only one of the measurement methods is necessary to obtain similar genetic progress in the breeding goal. Finally, the negative but moderate genetic correlation observed between the milking flow/speed traits and MT indicates that these traits have a different genetic control, and both should be included in breeding schemes. Genetic selection for FR, FRM, or MS, and MT can directly benefit farmers who seek to improve milking efficiency of herds managed in automatic milking systems. Our research group is actively investigating other novel traits derived from AMS data.
