# PREFACE

The second edition of the Sterile Insect Technique brings together all updated and relevant information about the sterile insect technique and its application in area-wide integrated pest management programmes. Following the same thematic style used in the first edition, the second edition includes a large amount of new information that has become available since the first edition was published in 2005.

In addition to updating and expanding the original 28 chapters, six new chapters have been added, covering topics that have been developed recently. These chapters discuss managing pathogens in insect mass-rearing, using symbionts and modern molecular technologies in support of the SIT, applying post-factory nutritional, hormonal and semiochemical treatments, applying the SIT to eradicating outbreaks of invasive pests, and using the SIT against mosquito vectors of disease.

In the first edition, each chapter was peer-reviewed, and in the second edition, the new chapters were peer-reviewed. We thank the reviewers for helping to make the book accurate, complete, up-to-date, and generic in content. All chapters in the second edition were thoroughly reviewed and edited by the editors. Uniform Resource Locator (URL) addresses of recent publications have been included in the lists of references, enabling readers using an electronic format to access those publications easily.

Since SIT practitioners tend to operate in the context of only one pest species, it was a challenge for authors to develop and write their chapters from generic and global points of view, stressing the principles of the technology, and including examples from a range of pest species. We are grateful to the many authors, from all over the world, for writing the chapters without financial compensation; authors who are retired, or worked on their own time, deserve special commendation.

In the past 15 years the value of the first edition has been demonstrated over and over again, and it is expected that the second edition will serve the scientific community for many more years.

The Editors
June 2020

# FOREWORD

For several major insect pests, the environment-friendly sterile insect technique (SIT) is being applied as a component of area-wide integrated pest management (AW-IPM) programmes. This technology, using radiation to sterilize insects, was first developed in the USA, and is currently applied on six continents. For almost six decades it has been a major subject for research and development in the Joint FAO/IAEA Programme on Nuclear Techniques in Food and Agriculture, involving both research and the transfer of this technology to Member States so that they can benefit from improved plant, animal and human health, cleaner environments, increased production of plants and animals in agricultural systems, and accelerated economic development. The socio-economic impacts of AW-IPM programmes that integrate the SIT have confirmed the usefulness of this technology.

Numerous publications related to the integration of the SIT in pest management programmes, arising from research, coordinated research projects, field projects, symposia, meetings, and training activities have already provided much information to researchers, pest-control practitioners, programme managers, plant protection and animal health officers, and policy makers. However, by bringing together and presenting in a generic fashion the principles, practice, and global application of the SIT, this book serves as a major reference source for all current and future users of the technology, and also serves as a textbook for academic courses on integrated pest management.

# INTRODUCTORY REMARKS

As evidenced by the successful area-wide insect pest control programmes described in this book, the sterile insect technique (SIT), a component of these programmes, has come of age. The technology has expanded rapidly — additional target species, new rearing techniques, better understanding of genetics and insect behaviour, and especially integration into operational area-wide integrated pest management (AW-IPM) programmes. The SIT has matured; this critical overview of its principles and practice has already greatly facilitated further research, development, and application in the field. The second edition will only accelerate such objectives.

The SIT was among the first biological insect control methods designed for area-wide application. While the SIT gained its reputation in insect eradication programmes, it is essential that the scientific community now recognizes its potential as a part of IPM strategies for the area-wide suppression, containment, prevention and, where advisable, eradication of pest populations.

Insect control methods in the first 70 years of the 20$^{th}$ century were based largely on chemical insecticides; this was especially so after the Second World War with the introduction of synthetic insecticides. The concept of IPM gradually became popular after 1970, and a more selective use of insecticides was emphasized. Attempts to significantly reduce insecticide applications have only gradually become more prominent. Biological control of pest insects, together with the breeding of insect-tolerant or resistant plants, is probably now receiving the major emphasis in IPM programmes. According to an international standard under the International Plant Protection Convention (IPPC), the SIT is now officially considered as one type of biological control, and it is ideally suited for incorporation into AW-IPM programmes.

The scientific underpinning of SIT programmes has broadened as new areas of science have developed, e.g. insect mass-production and quality, geographic information systems and data management systems, genetics and molecular biology, symbionts and pathogens, insect behaviour, aerial release systems for sterile insects, and modelling of AW-IPM. The practical success of a programme incorporating the SIT requires a holistic and multidisciplinary approach, and effective management, since in the last analysis programmes must produce substantial economic benefits. This is clearly evident in the major successes using the SIT against screwworms, fruit flies, and moths.

In spite of documented successes, many colleagues in the scientific community are only partially or inadequately informed on the application and importance of this powerful addition to the biological weapons that can be used against insect pests that are economically important or a threat to human health. The credibility and impact of the technology needs to be described in an objective, comprehensive, and balanced fashion, and in an accessible format. New insect pest problems, new restrictive legislation, as well as older problems such as insecticide resistance and maximum residue levels, require new solutions. There is a real need, and an increasing demand, for information on the SIT so that its potential for addressing some of these problems can be assessed.

The chapters have been written by well-known experts on the SIT and other technologies that are integrated into IPM systems. Worldwide in scope, this book provides an in-depth resource for the whole range of documented scientific information about the SIT. The target audience of the book is the scientific community worldwide. It will assist animal and public health and plant protection practitioners, as well as students, teachers, and researchers, in understanding and applying the SIT. It is anticipated that the book will continue to have a considerable impact on the science and practice of pest control systems.

Research workers new to this field have difficulty accessing the literature — it tends to be widely scattered in multiple publications (some with very limited distribution), in conference proceedings, and in unpublished programme reports. To further the science and application of the SIT, the accumulated knowledge and experience needs to be integrated and synthesized from a generic standpoint. The consolidation of comprehensive information into one volume, with references to the large amount of previous work, is a major resource for the technology. Such a consolidation will facilitate the application of the SIT to those pest problems for which it is appropriate. It will also lay the groundwork for future applications. The present book is uniquely designed to fill this gap. The strengths and weaknesses, and successes and failures, of the SIT have rarely been evaluated openly and fairly from a scientific perspective.

This second edition will help develop further the use of the SIT for pest suppression, and where desirable and feasible, eradication. It will be a gold mine for graduate students who want to learn about the history, accomplishments, problems, and promises of the SIT. As an “autocidal” biological control method, it addresses present-day concerns regarding human health and the environment. There is great potential for significant advances that will make the SIT more effective and economically viable, such as commercializing the different components, developing genetic sexing strains that permit the release of only males, exposing sterile insects to nutritional, hormonal and semiochemical treatments to increase their quality and competitiveness, releasing insects from improved aerial systems, and using modern biotechnology.

It is an honour to have been asked to write these introductory remarks. The developments in this technology are exciting, and I will always remain a part of them.

## SUMMARY

During the 1930s and 1940s the idea of releasing insects of pest species to introduce sterility (sterile insect technique or SIT) into wild populations, and thus control them, was independently conceived in three extremely diverse intellectual environments. The key researchers were A. S. Serebrovskii at Moscow State University, F. L. Vanderplank at a tsetse field research station in rural Tanganyika (now Tanzania), and E. F. Knipling of the United States Department of Agriculture. Serebrovskii's work on chromosomal translocations for pest population suppression could not succeed in view of T. D. Lysenko's opposition to Mendelian genetics and the catastrophic conditions in the USSR during World War II, after which he died. Vanderplank used hybrid sterility to suppress a tsetse population in a large field experiment, but lacked the resources to develop this method further. Knipling and his team exploited H. J. Muller's discovery that ionizing radiation can induce dominant lethal mutations, and after World War II this approach was applied on an area-wide basis to eradicate the New World screwworm *Cochliomyia hominivorax* (Coquerel) in the USA, Mexico, and Central America. Since then very effective programmes integrating the SIT have been mounted against a number of tropical tephritid fruit fly species, some species of tsetse flies *Glossina* spp., the pink bollworm *Pectinophora gossypiella* (Saunders), the codling moth *Cydia pomonella* (L.), the cactus moth *Cactoblastis cactorum* (Berg), the painted apple moth *Teia anartoides* Walker, and the false codling moth *Thaumatotibia leucotreta* (Meyrick). In non-isolated onion fields in the Netherlands, the onion maggot *Delia antiqua* (Meigen) has since 1981 been suppressed by the SIT. In the 1970s there was much research conducted on mosquito SIT, which then went into "eclipse", but has been reviving during the last decade; a number of pilot trials are ongoing or in preparation, in conjunction with the *Wolbachia*-based incompatible insect technique (IIT) against mosquitoes, including *Aedes aegypti* (L.), *Ae. albopictus* (Skuse), *Ae. polynesiensis* Marks, and *Anopheles arabiensis* Patton. Development of the SIT for use against the boll weevil *Anthonomus grandis grandis* Boheman, the horn fly *Haematobia irritans* (L.) (Eschle et al. 1973), and the gypsy moth *Lymantria dispar* (L.) has ended, but it is in progress for two sweetpotato weevil species, *Cylas formicarius* (F.) and *Euscepes postfasciatus* (Fairmaire), the small hive beetle *Aethina tumida* Murray, the brown marmorated stink bug *Halyomorpha halys* Stål (Welsh et al. 2017), the navel orangeworm *Amyelois transitella* (Walker), the African sugarcane borer *Eldana saccharina* Walker, the European grapevine moth *Lobesia botrana* (Denis and Schiffermüller), the carob moth *Ectomyelois ceratoniae* (Zeller), the leafminer *Liriomyza bryoniae* (Kaltenbach) (Walker 2012) and other greenhouse pests, the Old World screwworm *Chrysomya bezziana* (Villeneuve), additional *Glossina* spp., other *Anastrepha* spp. and *Bactrocera* spp. fruit flies, and other pests. New technologies and continuous research support for ongoing programmes, including molecular, microbial and information technology approaches, are resulting in improved methodologies and processes, and thus in enhanced cost-effectiveness for all aspects of SIT application.

## 1. PROLOGUE

When using the sterile insect technique (SIT), it is applied usually as a component of area-wide integrated pest management (AW-IPM) (Hendrichs et al. 2007; Klassen and Vreysen, this volume). The density of the target insect pest population is

initially reduced, eliminating already mated females, with auxiliary control methods (Mangan and Bouyer, this volume). Then the SIT imposes birth control on the population to further reduce its numbers (Klassen and Vreysen, this volume).

The SIT involves rearing large numbers of the target species, exposing them mainly to gamma rays (but increasingly also to X-rays to avoid the transport, security, and regulatory issues related to radioactive sources (Bakri et al., this volume)) to induce sexual sterility (Bakri et al., this volume; Robinson, this volume), and then releasing them into the target population. The released sterile males mate with wild females to prevent them from reproducing (Knipling 1955).

Runner (1916) found that large doses of X-rays applied to the cigarette beetle *Lasioderma serricorne* (F.) rendered it incapable of reproduction. Soon afterwards H. J. Muller (1927) showed that ionizing radiation induced visible mutations in *Drosophila*, and also a much larger number of dominant lethal mutations, which were expressed through a reduction in the hatch of eggs laid by treated females or fathered by treated males. In 1946 he received the Nobel Prize in Physiology or Medicine (Fig. 1); however, only after 1950, when Muller made a special effort to publicize the biological effects of radiation, did economic entomologists become aware that, through gamma or X-ray irradiation, sexual sterility in male insects was quite easily achieved (Bakri et al., this volume).

The fact that chemicals could also produce genetic changes in the same way as radiation was only discovered during the Second World War by Charlotte Auerbach, a German-Jewish zoologist and geneticist, who fled to the UK and had been introduced to mutation research by H. J. Muller. She found in 1941 that mustard gas was mutagenic in *Drosophila*, and also affected fertility (Auerbach et al. 1947). Most of the dominant lethal mutation-producing chemicals are alkylating agents, producing carbonium ions which in living tissues combine with the nucleic acids of cells, causing point mutations and chromosome breakage (LaChance 1967). Nevertheless, the potential of alkylating agents as chemosterilants was not recognized for at least another ten years (Davidson 1974). Then, in view of their low cost compared with radiation sources, much research was done on over 125 pest species of public health and agricultural importance (Knipling 1968; LaBrecque and Smith 1968; Davidson 1974).

The great disadvantage of alkylating agents is that their sterilizing and mutagenic effects extend to higher animals, including humans. Attempts to find safer chemosterilants resulted in the discovery of non-alkylating chemicals. Nevertheless, methods to apply them uniformly were largely impractical for large-scale conditions. Furthermore, the residues on insect bodies, resulting from chemosterilization, can result in their bioaccumulation in natural food chains (Nagel and Peveling, this volume). As a result, their application was largely discontinued in the 1970–80s, although the use of juvenile hormone analogues and other compounds in autosterilization devices in the field, to attract and sterilize individuals that then disseminate these chemosterilants to other individuals of the target population, is being reconsidered (Bouyer and Lefrançois 2014; Baxter 2016).

Nevertheless, besides the means of achieving sterilization in insects, the idea of releasing pest insects to introduce sterility into wild populations, and thus control them, had already been conceived independently in the 1930s and 1940s by A. S. Serebrovskii at Moscow State University, F. L. Vanderplank at a tsetse field

research station in rural Tanganyika (now Tanzania), and E. F. Knipling of the United States Department of Agriculture (USDA) (Fig. 1). However, Serebrovskii and Vanderplank both sought to achieve pest control through the sterility that arises when different species or genetic strains are hybridized (Robinson, this volume).

## 2. SEREBROVSKII AND POSSIBLE USE OF CHROMOSOMAL TRANSLOCATIONS TO CAUSE INHERITED PARTIAL STERILITY

Beginning in 1922, Muller encouraged and assisted Serebrovskii's genetic studies on *Drosophila*. In 1933, Muller became the director of a genetics laboratory, a position created for him by N. I. Vavilov, head of the Lenin All-Union Academy of Agricultural Sciences. Serebrovskii became embroiled in the fierce controversy with T. D. Lysenko about the validity and usefulness of Mendelian genetics in advancing Soviet agriculture (Medvedev 1969), whether genes exist, and whether the Lamarckian concept of inheritance of acquired traits is correct. Lysenko had gained the support of Stalin, and he attempted to force Vavilov, Serebrovskii, Muller, and other geneticists to recant their adherence to Mendelian genetics. In December 1936, exponents of the two trends in Soviet biology confronted each other at a special session of the Lenin All-Union Academy of Agricultural Sciences, and the geneticists vigorously defended their science. Subsequently several prominent geneticists were arrested. Probably Serebrovskii was motivated to develop the concept of using chromosomal translocations for pest population suppression as a means to deflect Lysenko's strident criticism that research in genetics was devoid of promise to benefit Soviet agriculture (Carlson 1981).

Serebrovskii (1940) noted that it was already well known in 1940 that a translocation of segments between two chromosomes caused an abnormal association of four chromosomes during meiosis in heterozygotes, resulting in the formation of gametes with lethal genetic duplications and deficiencies. These abnormalities manifested themselves as partial sterility in the translocation heterozygote. Such partial sterility tended to be passed on from one generation to the next (Curtis 1985; Marec et al., this volume). Those translocations that were viable in the homozygous state had normal meiotic pairing, and were fully fertile. Serebrovskii appreciated that, in such conditions of negative heterosis (or underdominance as it has more recently been called (Davis et al. 2001)), natural selection would favour whichever chromosome type was initially in the majority, with a point of unstable equilibrium, which would be at a frequency of 50% if the viability of the two homozygous karyotypes were equal. At a frequency of 50%, the proportion of heterozygotes, and hence of sterility in the population, would be maximal.

On the basis of Mendelian principles, Serebrovskii worked out: (1) the extent to which sterility would continue to appear in a population in the generations after a single release of translocation homozygotes, (2) ways of enhancing levels of sterility by using several different translocations, and (3) the effects of releasing only males to avoid a temporary increase in the breeding population. A single release into a wild population of strains each with two translocations would cause 93.75% of the embryos to die; correspondingly, three translocations would cause 98.4% of the embryos to die. Years later the alternative possibility was proposed — the deliberate release of a majority of insects with translocations as a means of "driving" into a vector population a gene that would render it harmless to man, e.g. a gene for inability to transmit disease (Curtis 1968, 1985).

Serebrovskii (1940) started practical work on translocations in *Musca domestica* L. and *Calandra granaria* L., but presumably it was impossible to continue it in the

catastrophic conditions in the USSR during World War II. Unlike some other opponents of Lysenko, Serebrovskii was not arrested, but he died of natural causes in 1948. Before his death he expanded his ideas in a book (Serebrovskii 1971), but which could not be published until after the fall from power of N. S. Khruschev and of Lysenko (whom Khruschev also supported).

## 3. VANDERPLANK AND USE OF HYBRID STERILITY TO COMBAT TSETSE FLIES

In the 1930s and 1940s, Vanderplank and his colleagues developed and field-tested an entirely different system of insect control, based on sterility from species crosses and in the hybrids from such crosses. Based on field studies on the *Glossina morsitans* Westwood group of tsetse flies in East Africa, they had discovered the subtle, but unequivocal, differences between *G. morsitans sensu stricto* and *G. swynnertoni* Austen. Laboratory crosses between *G. morsitans* and *G. swynnertoni* were made by Corson (1932), Potts (1944), and Vanderplank (1944, 1947, 1948), but the cross-matings had low fertility. Vanderplank (1947) reported that the genitalia of the hybrids were distinguishable from both parent species, the hybrid males were sterile, and the female hybrids partially sterile. Hybrid sterility in tsetse flies has been studied further by Curtis (1971), and extensively by Gooding (1985, 1993).

Vanderplank (1944) proposed that sterility from crosses could be used for tsetse control, and Jackson (1945) showed that there was random mating between the two species in the field. On this basis, Vanderplank organized the mass-collection of *G. morsitans* pupae and then released the flies in a 26-km$^2$ area occupied only by *G. swynnertoni*. This habitat was separated by at least 19 km from other tsetse populations, and was considered too arid for *G. morsitans* to establish itself permanently.

Vanderplank (1947) briefly described the success of this experiment, noting that the initial effects were as theoretically expected. Surprisingly, he never published the detailed results, but he kindly gave them to C. F. Curtis. After F. L. Vanderplank's death, his son, R. J. R. Vanderplank, gave permission that these remarkable data be published (Table 1). The releases of *G. morsitans* did indeed virtually eliminate the less numerous *G. swynnertoni*, and there was a period in which hybrids could be identified, before they also declined in numbers.

Finally, the predicted decline of *G. morsitans* also occurred, presumably because of its lower tolerance of aridity than that of *G. swynnertoni*. When the density of tsetse flies had been reduced to a low level, local people moved into the area, and apparently completed tsetse eradication by bush clearance. It is unfortunate that the details of this remarkable trial have remained almost unknown for so long, and were not followed up.

*Table 1. Effect of releasing* G. morsitans *pupae into a 26-km²* G. swynnertoni *habitat in Tanzania on the density of these two species and of the interspecific hybrids (*G. morsitans *habitat separated from other tsetse habitats by at least 19 km) (data from F. L. Vanderplank and C. H. N. Jackson, 1944–1946, reproduced with permission)*

| Date | *G. morsitans* released (number) | Average catch of old males (per 5 hours of catching) | | |
|---|---|---|---|---|
| | | *G. morsitans* | *G. swynnertoni* | Hybrids |
| June 1944 | 0 | 0 | 54 | 0 |
| July | 0 | 0 | 69 | 0 |
| August | 27000 | 64 | 50 | 0 |
| September | 25000 | 138 | 25 | 0 |
| October | 26000 | 169 | 16 | 5[1] |
| November | 11000 | 54 | 15 | 7[1] |
| December | 4500 | 39 | 12 | 11[1] |

| November 1945 – March 1946 | No surveys: local inhabitants now grazing cattle in the area | | | |
| April 1946 | 0 | 0.6 | 0.4 | 0.8 |
| After April 1946 | Area given over to local inhabitants who cut down most of the bush | | | |

[1]In this period, not all males were examined under the microscope, so the numbers recorded as hybrids were possibly inaccurate.

## 4. KNIPLING AND USE OF STERILITY INDUCED BY IONIZING RADIATION

### *4.1. New World Screwworm*

The debut of the development and practical application of the SIT occurred in the 1950s in the USA under Knipling's leadership. It culminated in the most successful AW-IPM programme integrating the SIT to date. It was started in 1958 to rid the south-eastern USA of the New World screwworm, a deadly parasite of livestock. During the next 48 years the technique was used to eradicate this pest from the USA, Mexico, and Central America to Panama (Vargas-Terán et al., this volume).

*4.1.1. Early Attempts at Control, and Importance of Correct Identification*

Since ancient times, the tropical and semi-tropical New World screwworm has been a serious enemy of warm-blooded animals, including humans, in an area extending from Argentina to the southern USA. Descendants of European settlers learned to manage their herds and flocks so that the birth of most calves and lambs, as well as castration, branding, and dehorning operations, occurred only during months when screwworms were scarce (Cushing and Parish 1938). Each animal was checked for wounds at least twice per week, and each wound was treated with an insecticidal "smear" (Knipling 1985).

The correct identity of the insect concerned was established in 1858 by French medical doctor and entomologist C. Coquerel who collected larvae in the frontal sinuses of a convict, who later died, in the French penal colony of Cayenne (Devil's Island), off the coast of French Guiana. He published an accurate description of the New World screwworm in the Annals of the Entomological Society of France (Coquerel 1858) where he reported similar human cases with high mortality, describing science as powerless to prevent "these terrible ravages". Coquerel assigned the name *Lucilia hominivorax* Coquerel to this parasite; "hominivorax" literally means "man eater".

North American entomologists were, unfortunately, unaware of Coquerel's paper. Indeed, until 1933, North Americans confused the identity of the New World screwworm with the more abundant scavenger of dead carcasses, *Cochliomyia macellaria* (F.). Due to this inability to recognize that a different species was involved, livestock producers wasted much energy in burying or burning the carcasses of dead animals, and trapping adult flies, in the vain hope of reducing the population of what was believed to be the myiasis-causing screwworm.

E. C. Cushing, under the guidance of W. S. Patton of the Liverpool School of Tropical Medicine, discovered that the genitalia of adult flies that had developed in carrion were different from those of most flies collected from wound-reared specimens, and named the latter species *Cochliomyia americana* (Cushing and Patton 1933). Later this species was found to be the *C. hominivorax* described 75 years earlier by Coquerel (Laake et al. 1936). *C. hominivorax* is now referred to as the New World screwworm, and the scavenger *C. macellaria* (F.) as the secondary screwworm. As soon as the true identity of *C. hominivorax* had been clarified, Knipling and his colleagues made a concerted effort to elucidate its biology and ecology. They concluded that the number of screwworm flies that survives the winter as pupae in the soil was very low, perhaps only 40–80 per $km^2$ (Cushing and Parish 1938; Lindquist 1955; Meyer and Simpson 1995).

*4.1.2. Studies on Reared Screwworms in the 1930s, and Conception of the SIT*

*C. hominivorax* was the first obligate insect parasite to be reared on an artificial diet (Melvin and Bushland 1936), and this enabled very large numbers of screwworms to be available for study. Knipling observed the extreme sexual aggressiveness of male screwworms, as well as the refusal of females to mate more than once, and he realized that, if sexual sterility could be induced in males, and if vast numbers could be sterilized and released in the field, then the screwworm population would be suppressed. He also realized that, if releases continued for several successive

generations, and the wild population density decreased, the ratio of the number of sterile males to that of fertile wild males would increase sharply. Provided that the target wild population was isolated, the sterile:fertile ratio would become so great that probably not even a single fertile mating would occur, and thus the wild population would be eradicated (Knipling 1955, 1985). Knipling introduced simple mathematical models to assess the effects of the SIT and the integration with insecticides and other measures on the dynamics of screwworm populations (Barclay, this volume; Klassen and Vreysen, this volume).

The idea of the SIT may well have been triggered in part by the observation of monogamy in female screwworms (Knipling 1955). Thus, initially, there was the widespread belief that the SIT could only be applied to pest species in which the females mated only once. Consequently, there was a certain reluctance to consider the method for pest control of other species. However, Knipling (1959a, b) reconsidered that a monogamous mating system may not always be required, and von Borstel and Knipling (1960) described in detail why, independent of how many times the female mates, it is the competition between normal and lethal sperm that counts. Therefore, as long as irradiated sperm is competitive and can still penetrate eggs, female mating frequency is unimportant for effective SIT application (Bushland 1960; Knipling 1979; Lance and McInnis, this volume; Whitten and Mahon, this volume).

Nevertheless, in the 1930s, mass-rearing was not developed, and no method to induce sexual sterility was known. For a decade, the paramount urgency of World War II prevented Knipling from pursuing this sterile-male concept (Klassen 2003), but R. C. Bushland made a few attempts to induce sterility using chemicals.

### *4.1.3. Sterility Based on Radiation-Induced Dominant Lethal Mutations*

In 1946, after H. J. Muller was awarded the Nobel Prize in Physiology or Medicine for his discovery of induced mutagenesis, he used his prestige to lead a vigorous campaign against the atmospheric testing of atomic weapons. He wrote a popular article in the American Scientist in which he used tombstones as symbols to depict graphically the dead progeny from matings of irradiated *Drosophila* (Muller 1950). A. W. Lindquist recognized that Muller had developed a means of sexually sterilizing insects, and drew Knipling's attention to this paper (Lindquist 1955).

Knipling wrote to Muller, asking if ionizing radiation could be used to induce sexual sterility in the New World screwworm. Upon receiving Muller's confident assurance, Bushland and D. E. Hopkins used the X-Ray Therapy Section of Brooke Army Hospital to conduct the first screwworm irradiations in 1950. They found that, when 6-day-old pupae were exposed to 50 Gy, the adults that emerged appeared to be normal. However, when irradiated males were mated with untreated females, none of the eggs hatched. Females that had been irradiated and mated to untreated males produced almost no eggs, and none hatched. When untreated and irradiated males were caged together with untreated females, the irradiated males competed about equally with untreated males (in accordance with Knipling's model) (Bushland and Hopkins 1953).

*4.1.4. Sanibel Island Field Evaluation Pilot Test*

Sanibel Island (47 km$^2$), 4 km from the Gulf coast of Florida, was selected for a release-recapture experiment (Bushland 1960; Itô et al., this volume) using $^{32}$P-labelled flies. In addition, the ratio of radioactive egg masses to non-radioactive masses was assessed. The release in 1951 of approximately 39 sterile male flies per km$^2$ per week for several weeks resulted in up to 100% sterility of the egg masses in wounded goats, and it greatly reduced the wild population. However, eradication was not achieved, apparently because wild fertile flies were flying to the island from the nearby mainland (Baumhover 2002).

*4.1.5. Curaçao Eradication Trial — Proof of Concept*

In 1954, Knipling was informed that screwworms were causing severe damage to the dairy industry on the island of Curaçao, 65 km from Venezuela, with an area of only 435 km$^2$. For the eradication trial, flies were reared in Orlando, Florida, and irradiated pupae were packaged in paper bags, air freighted to Curaçao, and released by air twice per week. On Sanibel, the release of 39 sterile males per km$^2$ per week had been effective, but on Curaçao this rate caused only 15% sterility of egg masses, and it had little effect on the incidence of myiasis cases due to the presence of thousands of unattended goats and sheep. Since wounds on these animals were not treated, they supported a high screwworm population. The release rate was increased to about 155 sterile males per km$^2$ per week, whereupon egg sterility increased to 69%, and then to 100% by the time two generations had elapsed. Subsequently, only two more fertile egg masses were found, and so sterile-fly releases were continued for another 8 weeks. Evidently eradication had been accomplished within 14 weeks, and the releases were halted after 22 weeks (Baumhover et al. 1955).

*4.1.6. Florida Eradication Programme*

At a meeting of the Florida Livestock Association in 1956, A. H. Baumhover suggested that eradication of the screwworm in Florida might eventually be possible, and he outlined a plan that called for the release of 50 million sterile flies per week. However, Knipling was reluctant to implement immediately a high-risk USD 10-million programme on the mainland — there were too many unknown factors, with problems in mass-rearing and distribution requiring several more years of applied research (which might reduce the eventual cost of the programme by USD 2 million). However, the governor T. L. Collins noted that the agricultural economy of Florida was losing more than USD 20 million per year due to the screwworm, and he pressed for immediate implementation. Nevertheless, to upgrade the rearing and release methodology, a further trial was conducted in 5000 km$^2$ along the Atlantic coast (Baumhover et al. 1959; Graham and Dudley 1959). Meanwhile, in July 1957, the Florida Legislature appropriated USD 3 million to match federal funds for an operational programme.

A mass-rearing facility was constructed at an Air Force Base at Sebring, Florida, with the production capacity of 60 million flies per week, and the programme was scheduled to begin in July 1958 (Scruggs 1975; Meyer and Simpson 1995). However, it was decided to accelerate this schedule following the unusually cold

winter of 1957–1958, which eliminated all screwworms in the south-eastern states, except for the southern one-third of Florida. To contain the surviving screwworm population, the production was rapidly increased in the research facilities at Orlando and Bithlo, from 2 to 14 million sterile flies per week, and by May 1958 sterile flies were being distributed north of the infested area to the border with Georgia using 10 aircraft. The programme also established a quarantine line across central Florida to prevent the shipment of any infested livestock out of southern Florida, and any localized concentrations of screwworm cases in northern Florida were quickly eliminated by treating infested wounds, spraying herds, and releasing large numbers of sterile flies.

The mass-rearing facility at Sebring reached full production in August 1958, and 20 aircraft were used to distribute sterile flies throughout Florida and parts of neighbouring states. The Florida Cooperative Extension Service conducted a public information programme, and trained county agents to educate livestock producers. Field inspectors assisted and trained producers in treating cases and submitting larvae from wounds for identification at eradication headquarters in Sebring. Cases of myiasis in each county were plotted each day. The number of sterile flies released per $km^2$ per week was increased at persistent "hot spots" from about 155 to 1160. The last autochthonous case occurred on 19 February 1959 (Baumhover 2002). All sterile fly releases were terminated in November 1959. The total cost of the programme was USD 11 million, about 50% of the annual losses in Florida (Meadows 1985).

#### *4.1.7. Eradication and Area-Wide Population Management in South-Western USA*

The Florida programme aroused the interest of cattle producers in Texas, the western states, and Mexico. In 1959 the presidents of the USA (D. D. Eisenhower) and Mexico (A. López Mateos) agreed to a feasibility study to eradicate the New World screwworm in Mexico.

The strategy for dealing with the USA south-west was a by-product of the use of the 160-km-wide sterile-fly barrier across Florida, with the release of sterile flies only in the overwintering area, and to let the cold weather destroy the screwworms to the north of this area. Following eradication from that area, sterile flies would be deployed to create a barrier zone along the US-Mexico border to protect against reinvasion (Bushland 1985).

A mass-rearing facility was established at a former air base converted to an insectary, fly sterilization and dispersal centre, near Mission, Texas, and releases began in 1962. By 1964 no screwworms were found in Texas or New Mexico for a period of two or three generations, and USDA officials declared the screwworm eradicated from these states. In 1965, the programme was extended to the Pacific, and in 1966 the entire USA was declared free of screwworms; the federal government took full responsibility to maintain the barrier zone from the Gulf of Mexico to the Pacific. However, no agreement with Mexico to proceed southward had been reached, and the USA remained highly vulnerable to the influx of screwworms from Mexico. At this point in time, the goal of the programme was no longer eradication in the true sense, but had become population containment (Klassen 1989, 2000; Hendrichs, Vreysen et al., this volume).

*4.1.8. Managing Screwworm Population along the US-Mexico Border*

Both US and Mexican cattle producers were anxious to push the screwworm population south to the narrow Isthmus of Tehuantepec, where a barrier of only 220 km would be needed. In 1972 the Mexico-United States Screwworm Eradication Agreement was signed, with the aim of eradicating the screwworm to the north of the Isthmus of Tehuantepec, and to establish a sterile-fly barrier there.

In the meantime, many difficulties arose. Screwworm cases occurred as much as 480 km north of the US-Mexico border. In 1968 almost 10 000 cases were recorded in the USA, and in 1972 such cases rose to 95 000. Knipling (1979) noted that, before the programme began, the maximum flight range of screwworm adults was estimated at 80 km. It was planned that the width of the sterile-fly barrier be twice this figure. However, Hightower et al. (1965) demonstrated that natural fly movement can occur up to at least 290 km, and the pattern of screwworm movement during the spring indicated that dispersal in a single generation was up to 480 km. In addition, Knipling (1979) concluded that the main reasons for the "breakdown" of the containment programme in 1972 were the unusually favourable conditions for winter survival of screwworms, the abandonment by ranchers of traditional animal husbandry practices needed to counter screwworm infestations (including the twice-weekly inspection and treatment of animals), and the explosion of the population of white-tailed deer as a result of almost no screwworm-induced mortality during the previous decade (Nagel and Peveling, this volume).

Critics of the programme postulated changes in the behaviour of the native population through inadvertent genetic selection during mass-rearing, making wild adults prone to avoid matings with the released strain, and the existence of cryptic species in the field (Bush et al. 1976; Richardson et al. 1982). However, no data were generated to support these views (Krafsur 1998; Krafsur and Ouma, this volume), which were strongly rebutted (LaChance et al. 1982). Another important factor was the unwise attempt to reduce sterile fly distribution costs by releasing flies on parallel flight lanes spaced 8 or 16 km apart, and this failed to deliver adequate numbers of sterile flies to all locations where wild virgin females were present (Krafsur 1978; Hofmann 1985).

The Mexico-United States Screwworm Eradication Commission began field operations in Mexico in 1974. A mass-rearing facility, with a capacity of 500 million sterile flies per week, was built at Tuxtla Gutiérrez, Chiapas (south of the Isthmus of Tehuantepec), and it reached full production in January 1977. Nevertheless, as late as 1976, almost 30 000 cases occurred in the USA. Major relief came when fly production at Mission, Texas, was supplemented from the new factory in Mexico (Meyer and Simpson 1995). Subsequently, the need for the Mission facility diminished rapidly, and in 1981 it was closed. The last autochthonous case in the USA occurred in August 1982.

Knipling (1979) stated:

> Had scientists known of the long flight range of the insect, they would not have recommended a sterile fly release programme in the south-west. This would have been unfortunate. By taking this gamble, up to a billion [1000 million] dollars [USD] have been saved. We have learned that despite the long-range movement of the insect, a high degree of pest population suppression can be achieved even against non-isolated populations.

*4.1.9. Programmes in Central America: the Drive to Panama*

By 1984 the Commission had achieved the goal of eradicating the screwworm to Mexico's Isthmus of Tehuantepec (Peneda-Vargas 1985). Nevertheless, at the request of ranchers in southern Mexico and Central America, in 1986 operations were extended to the Yucatán Peninsula and the countries bordering Mexico (Irastorza et al. 1993). Eradication was declared as follows: Mexico 1991, Belize and Guatemala 1994, El Salvador and Honduras 1996, Nicaragua and Costa Rica 1999, and Panama 2006 where since 2004 a permanent sterile-fly barrier is being maintained in the Darien Gap along the border with Colombia (Wyss 2000; Maxwell et al. 2017; Skoda et al. 2017; Vargas-Terán et al., this volume). A smaller mass-rearing facility was constructed in the early 2000s at Pacora, Panama, and the larger facility at Tuxtla Gutiérrez was closed in 2013.

*4.1.10. Screwworm Eradication Programme in North Africa*

In 1988, the New World screwworm was discovered at Tripoli, Libya, where it rapidly spread over 28 000 $km^2$. Many feared that the insect would spread throughout North Africa, the Middle East and southern Europe, and migrate up the Nile River to sub-Saharan Africa, with serious consequences for the African people, livestock, and the already endangered large mammals.

In 1989, the Government of Libya asked the Food and Agriculture Organization of the United Nations (FAO) for assistance in eradicating the screwworm. The operational programme was planned in detail by consultants assembled by the Joint FAO/IAEA Division, and Libya and various donor countries provided the funding (FAO 1992; Vargas-Terán et al., this volume).

The infested area was partially isolated by the Mediterranean Sea, desert to the south, and barren areas with few livestock to the east and west. One hundred teams, each consisting of two individuals equipped with a jeep, inspected all livestock every 21–28 days, applied insecticide to every wound, and sprayed many of the animals. About 80 swormlure-baited wing traps were deployed across the lines of flight of the aircraft from which the sterile screwworms were dropped.

Sterile screwworms were supplied from Mexico — mating studies showed that the factory-strain flies were sexually compatible with the Libyan strain. Some differences in the mitochondrial DNA were observed, but they were not considered to indicate a barrier to applying the SIT (FAO 1992). Each weekly flight from Tuxtla Gutiérrez to Tripoli carried 40 million sterile screwworm pupae. In Tripoli, adult emergence was controlled to allow two early morning releases per week.

The attack on the pest population was planned for the early winter of 1990, since by then cool weather would have greatly reduced the density and the reproductive capacity of this insect. Also, cool weather would synchronize the life stages, and eliminate generation overlap. The number of sterile flies released was quickly increased to the maximum to saturate all suitable niches with sterile males. Thus, from the time that indigenous females emerged from under the soil, they would be in the company of sexually sterile males.

The impact of this strategy was dramatic. Only six instances of wounds infested with screwworm larvae were found in 1991, compared with more than 12 000 cases in 1990. Releases of sterile flies were continued until October 1991, and surveillance of all livestock until June 1992 (Lindquist et al. 1993). Eradication was declared in June 1992 (FAO 1992). As previously in Texas, where critics cast doubt on the effectiveness of the sterile insect technique, claiming that eradication was caused principally by cold winters and hot, dry summers (Richardson 1978; Readshaw 1986, 1987, 1989), there were again voices that affirmed that weather, instead of sterile male releases, had been decisive in screwworm elimination from Libya. These arguments were clearly rebutted, not only for Texas (Krafsur et al. 1986; Krafsur 1987), but also for Libya, where it was shown that all of the conditions for successful screwworm overwintering and dispersal existed in a 15–25-km-wide zone along the Mediterranean coast (Krafsur and Lindquist 1996; Kouba 2004).

#### *4.1.11. Screwworm Programmes in the Caribbean*

By 1975 the screwworm had been eradicated from Puerto Rico and the United States Virgin Islands. In 1999, the Government of Jamaica initiated a programme to eradicate the screwworm that was terminated without reaching eradication (Vreysen et al. 2007; Dyck, Reyes Flores et al., this volume; Vargas-Terán et al., this volume).

No eradication programmes have been initiated on Cuba and Hispaniola, even though they can easily be sources of *C. hominivorax* reintroduction into areas that have been cleared of this pest (Vargas-Terán et al., this volume). This threat has been confirmed by multiple interceptions of screwworm-infested animals at ports of entry, as well as significant outbreaks in Aruba, Curaçao, Mexico, and most recently in Florida, that were efficiently eliminated applying the SIT (Skoda et al. 2018; Vargas-Terán et al., this volume).

### *4.2. Tephritid Fruit Flies*

Currently, the SIT is most widely applied against tephritid fruit flies (Enkerlin, this volume). Already in 1955, immediately after the successful screwworm eradication trial in Curaçao, investigations were initiated by the USDA in Hawaii into the possibility of developing and integrating the SIT to eradicate populations of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), melon fly *Zeugodacus* (*Bactrocera) cucurbitae* (Coquillett), and oriental fruit fly *Bactrocera dorsalis* (Hendel) (Steiner and Christenson 1956; Steiner et al. 1970). Also, prior to 1960, pioneering investigations were underway on the Queensland fruit fly *Bactrocera tryoni* (Froggatt) in Australia, and on the Mexican fruit fly *Anastrepha ludens* (Loew) in Mexico and the USA (Klassen et al. 1994; Enkerlin, this volume). Furthermore, extensive research and development was started in the early 1960s at the FAO/IAEA Laboratory in Seibersdorf, Austria, to develop the SIT for the Mediterranean fruit fly and other fruit fly pests (Klassen et al. 1994).

The first successful use of the SIT against an insect pest, other than the screwworm fly, was the eradication in 1963 of the melon fly from Rota in the Mariana Islands (Steiner et al. 1965). The first large-scale programme, established by Mexico and the USA in the late 1970s, stopped the invasion of the Mediterranean fruit fly from Central America into southern Mexico (Hendrichs et al. 1983). In Japan, the SIT was employed in the 1980s and 1990s to eradicate the melon fly in Okinawa and all of Japan's south-western islands, permitting access for fruits and vegetables produced in these islands to the main markets in the Japanese mainland (Kuba et al. 1996). In Chile, the SIT was used to rid the north of the country of the Mediterranean fruit fly; thus by 1995 the entire country had become a fly-free zone, and a joint programme with Peru operates in northern Chile and southern Peru. Since then Chilean fruits have entered the US market in huge volumes without the need for any quarantine treatment, providing a major benefit to the Chilean economy (Enkerlin, this volume). Argentina also has developed significant SIT Mediterranean fruit fly programmes in several fruit-producing provinces, some of which have succeeded in establishing pest free areas. Mexico has also applied the SIT to get rid of various *Anastrepha* species from northern Mexico (Enkerlin, this volume).

The SIT is increasingly being applied with the objective to reduce losses and pesticide use rather than fruit fly eradication, with suppression programmes ongoing in Brazil, Croatia, Israel, South Africa, Spain and Thailand, and in preparation in Morocco and Vietnam. To prevent Mediterranean fruit fly establishment in the continental USA through infested imported (smuggled) fruit, sterile males are being released preventively in the Los Angeles Basin, Tampa, and Miami. Consequently, there is no longer a need to spray these urban areas with malathion insecticide to suppress and eliminate incipient pest populations each time there are outbreaks.

Several species of tropical fruit flies are extremely destructive pests of fruits and vegetables. Tephritid fruit flies are major economic pests because they have:

- A multivoltine life cycle with an explosive reproductive capacity,
- A polyphagous behaviour with the capacity to exploit a large number of hosts,
- The ability to disperse widely as adults or to be moved in fruit as larvae,
- The ability (adults) to survive several months of inclement weather.

Tropical fruit flies not only cause great losses in fruit and vegetable production, but they also seriously impede international trade because of quarantine regulations designed to avoid cross-border introductions. Consequently, efforts to remove, suppress, or exclude these pests have been made in at least 32 countries (Klassen et al. 1994; Hendrichs 2001; Enkerlin, this volume).

The mating behaviours of tropical fruit flies are very different from the aggressive behaviour of male screwworms, involving complex courtship behaviours with males aggregating in mating arenas or leks, and where receptive females determine mate choice (Hendrichs et al. 2002; Robinson et al. 2002). Thus, special attention in terms of product quality control must be given to the effects of colony-holding conditions, artificial diets, irradiation, and handling procedures on the acceptability to wild females of released sterile males (Cayol 2000; Hendrichs et al. 2002).

*4.2.1. Mexican and Queensland Fruit Flies*

In 1964, the SIT was used to eradicate the Mexican fruit fly from outbreaks in southern California, and as a containment measure to prevent the pest from re-entering California from Baja California Norte in Mexico, and a decade later to exclude the pest from the Rio Grande Valley of Texas. Both SIT containment programmes have continued since then, but the programme on the California-Mexico border was terminated after the Mexican states of Baja California Norte, Baja California Sur, Chihuahua, and Sonora, following successful SIT projects in the 1990s against *A. ludens* and the West Indian fruit fly *Anastrepha obliqua* (Macquart), were converted into fruit fly-free zones from which citrus, stone fruits, apples, and vegetables are now being exported without any postharvest treatment (Reyes F. et al. 2000; Enkerlin, this volume).

Field trials of the SIT against the Queensland fruit fly began in 1962 in New South Wales, Australia. Although the population was suppressed strongly, it could not be eradicated because of long-range immigrants. Since the mid-1990s, an SIT containment programme has tried to protect a "Fruit Fly Exclusion Zone" comprising the "Tri-State" major fruit production area (southern New South Wales, northern Victoria, and eastern South Australia), although the Queensland fruit fly has been increasingly extending its range southward into this free area (Capon et al. 2017). In 1990, use of the SIT resulted in the eradication of this pest from an incipient infestation in 125 $km^2$ at Perth, Western Australia (Fisher 1996). Also, the SIT was used to eradicate the Mediterranean fruit fly in Carnarvon in Western Australia (Fisher et al. 1985), and is now used to eradicate recurrent outbreaks of this pest in South Australia (Smallridge et al. 2002).

*4.2.2. Moscamed*

In 1955, the Mediterranean fruit fly was found in Costa Rica. After the pest had established a small foothold in Nicaragua, and a pilot programme conducted in 1967 (Rhode 1970), an operational programme to contain this pest was initiated to prevent it from invading countries to the north (Rhode et al. 1971). However, very unfortunately, a review team concluded that the Mediterranean fruit fly is not economically important to Central America, and recommended that the programme be terminated (Rhode 1976; Dyck, Reyes Flores et al., this volume). Thus, by 1976 the pest had expanded its range into Honduras, El Salvador, and Guatemala, and by 1979 it already occupied 15 000 $km^2$ in southern Mexico.

In the meantime, to meet this emergency, the Government of Mexico entered into cooperative agreements with Guatemala and the USA to establish the first large-scale fruit fly AW-IPM programme using the SIT. Construction of a rearing facility at Metapa, Mexico, to produce 500 million sterile flies per week, began in 1977 and initiated production in early 1979 (Schwarz et al. 1985). By 1982, pest eradication in the infested area of Mexico was achieved (Hendrichs et al. 1983), and a containment barrier was created through Guatemala (Villaseñor et al. 2000; Enkerlin, this volume). For approximately 40 years, this programme has kept Mexico, the USA, and half of Guatemala free of the Mediterranean fruit fly, allowing Mexico over this period to significantly expand its fruit and vegetable exports, mainly to the USA (Enkerlin et al. 2015, 2017). Mexican horticulture export earnings since 1994 have

tripled to more than USD 9000 million per year (Enkerlin, this volume). In the meantime, the production capacity of the Moscamed programme has increased to over 4000 million sterile males per week, the majority of which are produced at the El Pino facility in Guatemala (Rendón et al. 2004).

#### *4.2.3. Melon Fly Eradication in the South-Western Islands of Japan*

Between 1919 and 1970, the melon fly gradually invaded most island groups in the south of Japan, including Okinawa. The shipment of fruits and vegetables to markets in mainland Japan was strictly forbidden. Consequently, the Japanese National Government assisted the Prefectural Governments of Kagoshima and Okinawa to conduct two separate programmes to eradicate the melon fly from all of the south-western islands.

A pilot eradication experiment on small Kume Island (60 $km^2$) began in 1972, and eradication was declared in 1978. In 1984, an operational programme was undertaken in the Miyako Islands. The capacity of the rearing facility was 30 million flies per week. Since the wild population was estimated at 34.4 million, male annihilation (using cotton strings impregnated with cuelure and insecticide) was used to reduce it to 5% of its original level. The production of high-quality flies, and supplementary releases in high-density areas, were critically important (Yamagishi et al. 1993; Kakinohana 1994). By 1986 the production capacity had been expanded to almost 200 million sterile flies, and the programme gradually moved from island group to island group until eradication of the melon fly from all of Japan was achieved in 1993 (Kuba et al. 1996; Koyama et al. 2004).

#### *4.2.4. Mediterranean Fruit Fly Genetic Sexing Strains*

In the early 1960s, the Citrus Marketing Board of Israel developed an insecticide-based area-wide programme against the Mediterranean fruit fly that was able to meet the certified quarantine security requirements of fruit importing countries (Cohen and Cohen 1967). Bisexual releases of sterile flies were avoided for this programme because sexually sterile female Mediterranean fruit flies can cause (with their ovipositors) cosmetic damage in some varieties. However, in work with the Australian sheep blow fly *Lucilia cuprina* (Wiedemann), Whitten (1969) found that male and female pupae of a strain, in which the segment of the autosome bearing a gene for black puparium is translocated to the Y chromosome, could be separated mechanically, as all males are brown, and all females black.

This encouraged Rössler (1979) to construct a similar strain of the Mediterranean fruit fly in which male pupae (brown) could be separated from female pupae (white). This special strain was mass-reared and pupae sorted by a seed-sorter at the FAO/IAEA Seibersdorf Laboratory in Austria; it performed well in large-scale tests in Israel (Franz et al., this volume).

Subsequently, this laboratory developed a genetic sexing strain in which a segment of an autosome bearing the dominant wild type allele of a temperature-sensitive lethal (*tsl*) mutant was translocated to the Y chromosome (Franz and Kerremans 1994; Caceres et al. 2004). This enabled the elimination of females at the

egg stage, thereby saving significant costs during mass-rearing, handling, and release, and increasing sterile male production in the same facility.

In addition, this laboratory developed a "filter rearing system" to maintain strain stability in the mass-rearing of such genetic sexing strains (Fisher and Caceres 2000; Franz et al., this volume; Parker, Mamai et al., this volume).

#### *4.2.5. Sterile "Genetic Sexing Strain" Males Alleviate Mediterranean Fruit Fly Crises in California and Florida, USA*

Until 1980, the Mediterranean fruit fly invaded California and Florida at only infrequent intervals. Outbreaks, occurring usually in urban areas, were eliminated mainly by applying malathion-bait sprays. It cost more than USD 100 million to eradicate the infestations in California detected in 1980 and 1982.

In the decade 1987–1997, multiple new infestations were encountered annually in California and Florida. Since each outbreak was addressed independently, this non-area-wide approach often resulted in continuous new satellite infestations, and there was a real threat that the pest would become established. Therefore, in 1994, an area-wide SIT eradication programme was initiated, with twice-weekly releases of sterile Mediterranean fruit flies over the entire Los Angeles Basin. This programme was so successful and cost-effective that, in view of the many introductions, in 1996 a permanent preventive release programme was established over this area (Dowell et al. 2000; Barry et al. 2004). The same preventive approach has also been followed since 1998 in three Florida counties that are at high-risk in terms of introductions.

These preventive release programmes have now been in operation for over 20 years, maintaining the Mediterranean fruit fly-free status of the United States (although this is disputed by Carey et al. 2017, but see rebuttals by McInnis et al. (2017) and Shelly et al. (2017)). Sterile males of the *tsl* sexing strain VIENNA 7 or VIENNA 8, mainly produced by the Moscamed programme in Guatemala, are used for these preventive release programmes. Sexing strains are also used in most Mediterranean fruit fly suppression, containment, or eradication programmes (Caceres et al. 2004; Franz et al., this volume; Augustinos et al. 2017).

#### *4.2.6. Jordan-Israel-Palestine Mediterranean Fruit Fly Programme*

The signing of the Oslo Peace Accord created an opportunity for the international community to assist Middle East countries, notably the Hashemite Kingdom of Jordan, the Palestinian Authority, and Israel, to undertake joint projects that would foster cooperation. An economic analysis of three area-wide programme alternatives was conducted (with the support of the FAO/IAEA) (Enkerlin and Mumford 1997). In the operational programme, initially focused on the Arava/Araba region between Israel and Jordan, the genetic sexing strain VIENNA 7 (Franz et al., this volume) has been used for population suppression rather than eradication (at present, there is no intention to establish disruptive quarantines along a major highway). As a result of this suppression programme, the export of fresh vegetables from the Arava region has reached more than USD 30 million per year (Cayol et al. 2004; Enkerlin, this volume). Initially, the sterile pupae for this programme were shipped from the

Moscamed facility in El Pino, Guatemala, but then BioBee (the largest producer of biological control agents in Israel) constructed a commercial mass-rearing facility, with the goal of expanding suppression to other fruit and vegetable production areas in Israel, West Bank, and Jordan, and to sell sterile flies internationally, for example, to the Mediterranean fruit fly suppression programme in the Neretva Valley in Croatia (Bassi et al. 2007; Bjeliš et al. 2016).

#### *4.2.7. Trend is Suppression, not Eradication, of Fruit Flies*

For technical and economic reasons, including the undesirability of establishing quarantines that interfere with trade, or difficulties in maintaining them effectively, today many fruit fly AW-IPM programmes that integrate the SIT aim to suppress the pest populations (Mumford 2004; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume; Mumford, this volume). Examples of suppression programmes using sterile flies as an additional IPM tool are:

- Mediterranean fruit fly
  - Costa Rica (Reyes et al. 2007)
  - Arava, Israel (Cayol et al. 2004)
  - Hex River Valley, South Africa (Barnes et al. 2004; Venter et al. 2021)
  - San Francisco Valley, Bahia, Brazil (Malavasi et al. 2007)
  - Valencia, Spain (Generalitat Valenciana 2003)
  - Neretva Valley, Croatia (Bjeliš et al. 2016)
  - Souss Valley, Agadir, Morocco (Enkerlin, this volume)
  - Southern Brazil, Brazil (Kovaleski and Mastrangelo 2021)
- Mexican fruit fly
  - Mexico (Orozco-Dávila et al. 2017)
- Oriental fruit fly and *Bactrocera correcta* (Bezzi)
  - Ratchaburi Province, Thailand (Sutantawong et al. 2004).

### *4.3. Onion Maggot*

Since 1981, the SIT has been applied by a private firm (now de Groene Vlieg Bio Control b.v.) in The Netherlands to control the onion maggot *Delia antiqua* (Meigen) on an aggregate area of ca. 10 000 hectares (Loosjes 2000; Everaarts 2016). The flies are reared year-round, and stockpiled in diapause for release during the onion-growing season. Individual farmers contract for the service of population monitoring and releasing the sterile flies independently of their neighbours, many of whom use chemical control (the relevant insecticides were eventually banned by the European Union in the 2000s but the industry lobby managed to get exemptions for the onion crop). As a result of this uncoordinated approach, much efficiency is lost because the sterile flies are not applied on an area-wide basis (protected fields do not form a contiguous block). Some growers in the general area of sterile-fly releases benefit from them, but do not contribute to the programme (free-riders). Nevertheless, the programme has been able to expand to ca. 40% of the onion production area.

### *4.4. Tsetse Flies*

Tsetse flies are confined to sub-Saharan Africa where they transmit the disease trypanosomosis [trypanosomiasis] to humans (sleeping sickness) and livestock (nagana). They are regarded as a major cause of rural poverty because they prevent mixed farming. Crops have to be cultivated manually with hoes because nagana kills draught animals. The surviving cattle produce little milk, and manure is not available to fertilize the worn-out soils. The conquest of sleeping sickness and nagana would be of immense benefit to rural development in sub-Saharan Africa.

Understanding this fundamental role of tsetse at the root of rural poverty, it was E. F. Knipling who in the early 1960s assigned D. A. Dame from the USDA to lead a research effort in Southern Rhodesia (Zimbabwe), in collaboration with the University of Rhodesia, to determine the feasibility of applying the SIT against tsetse flies and to develop mass-rearing technology. Also, the FAO/IAEA, and other institutions from the previous colonial nations, initiated studies to assess the potential of the SIT for tsetse species. Of the over 30 tsetse species, only some (6 or 7) are of economic importance, and since then have been the subject of SIT development (Feldmann et al., this volume).

Tsetse flies are unique among pest insects in being larviparous, i.e. females do not lay eggs but gestate a larva in a uterus (one larva at a time), with a gestation period of about 9 days. Thus, these flies have extraordinarily low rates of reproduction. Therefore, relatively low release rates should be sufficient, compared with those required for highly fertile oviparous pests (Hendrichs, Vreysen et al., this volume). However, rearing tsetse flies is relatively laborious and expensive because adults of both sexes require frequent blood feeding. The development in the 1980s at the FAO/IAEA Laboratory in Seibersdorf, Austria, of an *in vitro* rearing system with membranes and heated abattoir-collected blood (that is previously irradiated to eliminate any microbial contamination) to replace the use of live animals, represented a major breakthrough that enabled the upscaling of mass-rearing (Parker, Mamai et al., this volume).

Table 2 summarizes the SIT trials that have been conducted on tsetse flies. (Data from the trial by Vanderplank are shown above in Table 1.) In a trial on *G. m. morsitans* in 1969 on an island (5 $km^2$) in Lake Kariba, Zimbabwe, pupae collected in the field were chemosterilized in the laboratory, and then returned to the field to permit adult flies to emerge. The sterile flies were fully competitive, but adult flies that were sterilized after emergence and held in captivity suffered an 80% loss in field competitiveness. These studies were followed in 1977–1978 by a larger-scale (195 $km^2$) trial in Tanzania using mass-reared *G. m. morsitans* fed on live animals, which demonstrated full sterile-fly competitiveness following irradiation and release in the pupal stage.

Among the other releases (conducted in the 1970s and 1980s) were several that successfully integrated releasing sterile males with deploying recently developed attractant traps and insecticide-treated targets. Three tsetse species were eradicated simultaneously in 3000 km2 in Burkina Faso (Politzar and Cuisance 1984), and one species in 1500 km2 area in Nigeria (Takken et al. 1986). The technology was successfully applied, but unfortunately the programmes were not conducted area-wide and thus the pest free status of the areas was not sustainable.

*Table 2. Summary of SIT trials with tsetse flies* Glossina *spp.*

| Species, habitat, and location | Method | Outcome and objectives | References |
|---|---|---|---|
| *Glossina swynnertoni*, savannah, north-western Tanzania | Release of *G. morsitans*, which mated with *G. swynnertoni* | 99% suppression in 256 km$^2$, permitted development of the area for agricultural production | Vanderplank 1947, and hitherto unpublished data shown in Table 1 |
| *G. morsitans morsitans,* savannah, Lake Kariba, Zimbabwe | Insecticidal suppression followed by release of chemically sterilized pupae | > 99% suppression on 5-km$^2$ island, feasibility study | Dame and Schmidt 1970; Dame et al. 1981 |
| *G. tachinoides* Westwood, riverine, Chad | Radiation-sterilized, transport from France, ground release sterile ♂ | Feasibility study, sterilization, transport, release | Cuisance and Itard 1973 |
| *G. palpalis gambiensis* Vanderplank, riverine, Burkina Faso | Suppression by aerial insecticide treatment, ground release sterile ♂ | Feasibility study (16 linear km) to control sleeping sickness | Van der Vloedt et al. 1980 |
| *G. palpalis palpalis* Robineau-Desvoidy with *G. tachinoides* as a control, riverine, Lafia, Nigeria | Suppression with traps and targets followed by ground release of radiation-sterilized adults | Eradication of *G. p. palpalis* in 1500 km$^2$ | Takken et al. 1986; Oladunmade et al. 1990 |
| *G. morsitans morsitans*, savannah, Tanzania | Insecticidal suppression followed by ground release of radiation-sterilized pupae | 90% suppression (195 km$^2$), feasibility study | Dame et al. 1975; Williamson et al. 1983 |
| *G. morsitans morsitans,* and *G. pallidipes* Austen, savannah, Lake Kariba, Zimbabwe | Autosterilization of wild flies with pyriproxyfen | Suppression (12 km$^2$), feasibility study | Hargrove and Langley 1990 |
| *G. morsitans submorsitans* Newstead, *G. palpalis gambiensis, G. palpalis palpalis, G. tachinoides*, riverine and savannah, Burkina Faso, Nigeria | Insecticide application and trapping suppression followed by ground release of radiation-sterilized adults | Eradication (3000 km$^2$ - Burkina Faso, 1500 km$^2$ - Nigeria) | Politzar and Cuisance 1984; Takken et al. 1986 |
| *G. austeni* Newstead, bushland and forest, Unguja, Zanzibar, Tanzania | Suppression with insecticide on livestock and attractive devices followed by aerial release of radiation-sterilized adults | Eradication (1650 km$^2$), trypanosomosis transmission ceased | Msangi et al. 2000; Vreysen et al. 2000; Feldmann et al., this volume |
| *G. fuscipes fuscipes* Newstead, forest, Buvuma Islands, Uganda | Autosterilization of wild flies with triflumuron vs. insecticide-impregnated traps | Suppression (5 km$^2$), abandoned because of funding shortfall | Oloo et al. 2000 |

Traps were also used on a small island (12 km$^2$) in Lake Kariba, Zimbabwe, to attract wild flies that were autosterilized by coming into contact with the traps, and then departed (Hargrove and Langley 1990). This, and another failed eradication trial, also in a small island in a Ugandan lake, are almost the only attempts to date to apply the autosterilization principle which avoids or minimizes the need for a rearing facility.

The eradication in 1997 of the tsetse fly *G. austeni* in Unguja Island, Zanzibar, Tanzania, confirmed the feasibility of the area-wide integration of aerial sterile-male releases with other suppression methods to create sustainable tsetse-free areas (Vreysen et al. 2000). This successful programme freed cattle from the burden of nagana, resulting in major socio-economic benefits (Msangi et al. 2000; Feldmann and Jannin 2001; Feldmann et al., this volume). In response, in 2001, the African Heads of State and Government committed their countries to rid Africa of this disease (Feldmann and Jannin 2001). However, the dream to conquer nagana will require many decades of concerted effort. Furthermore, there is a debate about the desirability of using the SIT with other approaches to eradicate populations of major tsetse species from large areas of the African mainland (DFID 2002; Hargrove 2003; Nagel and Peveling, this volume), and the perceived high cost of applying the technique.

Currently ongoing programmes to free selected areas from tsetse are under way against *G. pallidipes* and *G. fuscipes* in the Deme valley in southern Ethiopia, and against *Glossina palpalis gambiensis* in the Niayes area of Senegal (Zerihun 2017; Vreysen et al. 2021; Feldmann et al., this volume).

### *4.5. Mosquitoes*

Mosquito-borne diseases (malaria, dengue, filariasis, yellow fever, chikungunya, Zika) annually cause severe mortality and morbidity. For mosquito SIT, since females bite, blood-feed and may transmit major human pathogens, it is essential that releases of female mosquitoes be reduced to an absolute minimum. Therefore, efficient sexing is needed on a large scale, and genetic sexing systems are the preferred approach (Gilles et al. 2014; Franz et al., this volume). Naturally occurring pupal size difference between males and females, for example in some *Aedes* mosquitoes, are currently exploited for mechanical sexing, although it is difficult to achieve a 100% pure separation under operational conditions and is very labour-intensive when applied on a large scale.

As shown in Table 3 and in Benedict and Robinson (2003), in the 1960s and 1970s there was considerable interest and activity developing the SIT for mosquitoes, and several release trials were conducted, some of them integrating the *Wolbachia*-based incompatible insect technique (IIT), based on the ground-breaking work by Hannes Laven on cytoplasmic incompatibility (CI) (Laven 1958, 1967). The largest-scale trials were conducted in El Salvador and India. Unfortunately, in both countries, political factors in the mid-1970s interrupted further work — civil war in El Salvador, and in India false accusations that the project was intended to collect data on biological warfare (Nature 1975; WHO 1976).

*Table 3. Summary of release trials with sterile or semi-sterile male mosquitoes*

| Target species | Location | Sterilization and sex-separation method | Outcome | References |
|---|---|---|---|---|
| *Anopheles quadrimaculatus* Say | Lakes in Florida, USA | Pupal irradiation, adult release, sex separation by pupal size | Poor competitiveness of colonized males for wild females, which may have been mismatched for sibling species | Weidhaas et al. 1962; Dame et al. 1964 |
| *Culex quinquefasciatus* Say | Okpo, Myanmar | Cytoplasmic incompatibility | Eradication of small village population | Laven 1967 |
| *Anopheles gambiae s.s.* Giles | Pala, Burkina Faso | *An. melas* Theobald x *An. arabiensis* Patton cross yielding sterile hybrid males and few females | Poor competitiveness of hybrid males | Davidson et al. 1970 |
| *Culex quinquefasciatus* | Sea Horse Key, Florida, USA | Chemosterilization with thiotepa | Sterilization of small island population, moderate competitiveness | Patterson et al. 1970 |
| *Culex pipiens* L. | Village near Montpellier, France | Chromosome translocations | Persistent semi-sterility in wild population | Laven 1972; Cousserans and Guille 1974 |
| *Culex quinquefasciatus* | Villages near Delhi, India | Thiotepa sterilization or cytoplasmic incompatibility plus translocations, sex separation by pupal size | 300 000 released per day, 99.8% male, adequate competitiveness in the field for females of wild origin, but high egg sterility not achieved by mass-release due to immigration | Sharma et al. 1972; Singh et al. 1975; Curtis 1976; Grover et al. 1976a; Yasuno et al. 1978; Curtis et al. 1982 |
| *Aedes aegypti* (L.) | Urban areas in or near Delhi, India | Thiotepa sterilization or sex-ratio distorter plus translocations, sex separation by pupal size | Rearing and sex separation as for *Culex quinquefasciatus* above, high competitiveness in the field for females of wild origin | Curtis et al. 1976; Grover et al. 1976b; Ansari et al. 1977; Suguna et al. 1977 |
| *Aedes aegypti* | Mombasa, Kenya | Chromosome translocations | Partial sterility detected in wild population | McDonald et al. 1977 |

*Table 3. Continued*

| Target species | Location | Sterilization and sex-separation method | Outcome | References |
|---|---|---|---|---|
| *Anopheles albimanus* Wiedemann | Lake Apastapeque, El Salvador | Chemosterilization of pupae with bisazir, inaccurate sex separation based on pupal size | 100% sterility induced in wild population, which fell below detection level after 5 months | Lofgren et al. 1974 |
| *Anopheles albimanus* | Pacific coast of El Salvador | Bisazir sterilization, sex separation originally by pupal size + feeding on malathion-treated blood, later by a Y chromosome propoxur-resistance translocation inversion (MACHO strain) | Eventually 1 million MACHO released per day and found competitive, a natural population increase was suppressed, but eradication prevented by immigration in spite of a barrier zone | Seawright et al. 1978; Dame et al. 1981 |
| *Culex tritaeniorhynchus* Giles | Village near Lahore, Pakistan | Pericentric inversion plus translocation, sex separation by temperature-sensitive lethal | Assortative mating — competed for females of colony origin but not for females of wild origin | Baker et al. 1978, 1979 |
| *Anopheles culicifacies* Giles | Village near Lahore, Pakistan | Bisazir sterilization, sex separation by Y chromosome dieldrin translocation | Released males behaved normally in the field but showed subnormal mating competitiveness | Baker et al. 1980, 1981; Reisen et al. 1981 |
| *Culex tarsalis* Coquillett | Kern County, California, USA | Adult irradiation after separation of males by hand | Partial assortative mating — reduced competitiveness for wild females, but supercompetitiveness for colony females | Reisen 1982 |

The work in India showed that two important vector species of culicine mosquitoes could be mass-reared, and the sexes separated (according to pupal size) to ensure that 99.8% of the released mosquitoes were males. Males were chemosterilized in the pupal stage, or by male-linked chromosome translocations combined either with cytoplasmic incompatibility or sex-ratio distortion due to meiotic drive. Field tests showed that the mating competitiveness of the males of both species was acceptable. However, the mass release of *Culex quinquefasciatus* males in villages achieved only limited levels of sterility in eggs laid by wild females. This was attributed to the influx of already-mated females from outside the target release area. A planned mass release of sterile male *Aedes aegypti*, aimed at

the eradication of this urban mosquito from a whole town, was prevented by the political problem mentioned above.

In El Salvador the target was the malaria vector *Anopheles albimanus*. It was multi-resistant to insecticides (partly due to the agricultural use of insecticides), and therefore difficult to control by conventional means. In the initial study, releases during 5 months around Lake Apastapeque were successful in inducing 100% sterility in eggs laid by wild females (Lofgren et al. 1974; Weidhaas 1974). Sex separation in that trial was based on pupal size differentiation; however, it was very imperfect, yielding 15% females among the released males. In a second larger trial, a second separation was added; adults were offered malathion-laced blood through a membrane. This effectively eliminated most of the females, but the males were debilitated from being caged and handled. Therefore, a genetic sexing strain was developed — a chromosome translocation was induced, linking a propoxur-resistance gene to the Y chromosome, and this was combined with a crossover-suppressing chromosome inversion. Propoxur treatment at the egg stage selectively eliminated all but 0.2% of females, thereby allowing a doubling of the male production for release (Seawright et al. 1978). By eliminating the handling losses in the adult stage, the net release was increased from 200 000 males per day to over 1 million, and these males, when released as sterile pupae, were almost fully competitive in the field. Compared with the seasonal upward trend of the untreated population, the releases reduced the target field population by more than 97% (Dame et al. 1981; Benedict and Robinson 2003). However, complete control was thwarted by immigration, and political unrest and war caused the trials to be terminated.

As a result of the increase in the global burden of mosquito-borne diseases, the unsustainability of relying on insecticides for vector control due to increasing insecticide resistance, and the absence of vaccines and efficient, safe and inexpensive drugs to combat malaria, dengue, chikungunya, Zika, and other emerging diseases, the idea of genetic control of mosquitoes is now undergoing a revival (Häcker et al., this volume; Lees et al., this volume).

During the last 15 years considerable progress has been made in developing the SIT as a potential new tool in the arsenal to manage mosquitoes. Recent developments enable efficient mass-rearing and irradiation for male release (Lees et al. 2015; FAO/IAEA 2017b, c, 2018). Equipment and protocols have been developed and validated for efficient mass-rearing, irradiation and release of Aedines and Anophelines. Assessment of male quality is becoming more sophisticated, showing that mosquitoes are not different in their radiation-sensitivity, a common misconception. For example, the radiation doses to sterilize male *Aedes albopictus* (Skuse) and *Aedes aegypti* range between 35–40 Gy and 60–80 Gy, respectively, and have a negligible effect on the biological quality of the mosquito (Bourtzis et al. 2016).

Several institutions and governments are currently evaluating the feasibility of mosquito SIT in various pilot settings and stages of development, including in Brazil, China, Cuba, French Polynesia, Italy, Mauritius, Mexico, Reunion, Singapore, Spain, Sudan, Thailand, and USA (Lees et al., this volume).

Until perfect sexing mechanisms exist, the SIT in combination with *Wolbachia*-induced cytoplasmic incompatibility and pathogen interference is considered the safest solution for *population suppression* (Zhang et al. 2015; Bourtzis et al. 2016;

Bown 2019; Zheng et al. 2019). Being *Wolbachia*-infected, any accidently released females cannot result in population establishment because they are irradiated and therefore sterile**,** but at the same time because of *Wolbachia* they will also be unable to transmit human pathogens. This is not the case with transgenic or only symbiont-based approaches that are also under development (Thomas et al. 2000; Alphey and Andreasen 2002; Itô et al. 2002; Hoffmann et al. 2011; Bourtzis et al. 2014; Carvalho et al. 2015; Häcker et al., this volume), where released females can either vector disease (will result in *population replacement*) or leave an "ecological footprint" (Evans et al. 2019). For such approaches, issues such as stability, sustainability, and biosecurity need to be addressed. Regulatory issues and those relating to intellectual property and the economic cost of application must also be overcome (Bourtzis et al. 2016).

### *4.6. Coleoptera*

#### *4.6.1. Field Cockchafer*

Cockchafers (Scarabaeidae) are important pests of root vegetables. The flight period can be accurately forecast, and is restricted to a few weeks every third year, with males emerging before females. In 1959 and 1962, Horber (1963) conducted two field trials on *Melolontha vulgaris* F. in 30 hectares of agricultural land in Switzerland. He collected adult males in light traps, and gave them a sterilizing dose of 33 Gy. In the two trials, 3109 and 8594 sterile males were released, and the wild populations were reduced by 80% and to eradication, respectively.

Incidentally, in another family of beetles, the SIT is under development for application against the small hive beetle *Aethina tumida* Murray (Coleoptera: Nitidulidae), a serious threat to bee-keeping (Downey et al. 2015).

#### *4.6.2. Sweetpotato Weevils*

Two weevil species are found in Okinawa Prefecture in south-western Japan — sweetpotato weevil *Cylas formicarius* (F.) and West Indian sweetpotato weevil *Euscepes postfasciatus* (Fairmaire) (Yasuda 2000). These are invasive alien pests that threaten agricultural production, and have been designated as plant quarantine pests. Consequently, the transport of fresh sweet potatoes from Okinawa to mainland Japan is prohibited. Currently, both species are the targets of pilot AW-IPM eradication trials integrating the SIT on Kume Island.

Radiation has detrimental effects on these weevils. Digestive obstruction following the collapse of the epithelial tissue of the midgut has been suggested as the cause of the short lifespan of irradiated adults. Nevertheless, mitigation measures, including partial sterility and fractionated-dose irradiation at low temperature, successfully overcame these effects (Kumano et al. 2010, 2012).

From 1994 to 1999, the male annihilation technique (MAT), using synthetic sex pheromone and insecticide in wood fibreboard squares, was applied. The population of *C. formicarius* was suppressed by about 90%, and the plant infestation level dropped from 9.5 to less than 1%. Subsequently, sterile weevils were aerially released, and "hot spots" were treated with additional ground releases (Kohama et

al. 2003). In 2013 *C. formicarius* was declared eradicated from Kume Island (Haraguchi et al. 2014).

Following a successful SIT trial in 1995, and using weevils reared on artificial diet (Shimoji and Miyatake 2002; Shimoji and Yamagishi 2004), an island-wide AW-IPM programme integrating the SIT against *E. postfasciatus* is ongoing on Kume Island.

### *4.7. Lepidoptera*

Throughout the world, lepidopteran larvae cause immense damage to food and forage crops, forests, and stored products. However, there are several problems when applying the SIT against moths (Bakri et al., this volume; Lance and McInnis, this volume; Marec et al., this volume; Simmons et al., this volume):

- Some tolerance to dominant lethal induction by ionizing radiation, because of the holokinetic chromosomes of Lepidoptera,
- Reductions in ability to mate when inducing full sterility,
- Production of eupyrene and apyrene sperm,
- Spermatophore formation,
- Complex sperm transfer.

For species (such as the codling moth) that undergo diapause, the potential exists to mass-rear year-round and stockpile the pupae, and then activate them later in the spring for release in synchrony with the wild population (Parker, Mamai et al., this volume). However, on the whole, the large-scale rearing of moths is more difficult than that of most flies. For these reasons, the development of the SIT against moths has lagged behind work with flies. Nevertheless, the potential to use the SIT against lepidopteran pests appears to be very great (Marec et al., this volume), and its application is increasing (Simmons et al., this volume).

M. D. Proverbs (1962, 1982) in British Columbia, Canada, developed the SIT to suppress the codling moth, an economic pest of apples and pears. He found that very high and debilitating doses of ionizing radiation (about 400 Gy) are required to induce 100% sterility. However, considerably lower and less debilitating doses induce inherited sterility (IS), and the level of sterility of the $F_1$ progeny is greater than that of the irradiated parent (North 1975). Simulation models showed that released males with IS would suppress the wild population to a greater extent than the release of equal numbers of fully sterile males (Marec et al., this volume). In 1994, releases of irradiated codling moths were initiated in the Okanagan Valley of British Columbia, and continue with the objective of permanent area-wide population suppression (Dyck et al. 1993; Bloem and Bloem 2000; Simmons et al., this volume). Overall, codling moth populations have been reduced by 94% relative to pre-programme levels and damage to less than 0.2% of fruit in more than 90% of the orchards in the programme area (Nelson et al. 2021).

Another AW-IPM programme integrating the SIT, which has been implemented as a large-scale operational programme, is for the pink bollworm. Since 1967 sterile moths have been released in 0.4 million hectares of cotton fields in the San Joaquin Valley of California to prevent the establishment of this pest by moths migrating from southern California (Staten et al. 1993; Walters et al. 2000). This programme,

largely funded by growers, has been key to the survival of cotton production in California. More recently, in conjunction with the extensive planting of *Bt*-cotton in the mid-2000s, the programme succeeded in eliminating this pest from south-west USA and northern Mexico (Staten and Walters 2021; Simmons et al., this volume).

The SIT is also being applied for continuous suppression of the false codling moth in citrus orchards in South Africa (Boersma 2021). It has also been applied successfully to eradicate outbreaks of invasive moth pests (Hendrichs, Enkerlin et al., this volume) such as the painted apple moth in New Zealand (Suckling et al. 2007) and the cactus moth in Mexico (Bello-Rivera et al. 2021). Extensive SIT/IS application on the gypsy moth was made in the past (Simmons et al., this volume). Furthermore, it is under development for application against a number of other moth pests (Vreysen et al. 2016; Simmons et al., this volume) including the African sugarcane borer in South Africa (Conlong and Rutherford 2017), the navel orangeworm in California, the European grapevine moth in Chile, and the carob moth in North Africa.

## 5. TRANSBOUNDARY SHIPMENT AND INTERNATIONAL RECOGNITION OF THE SIT

Over the years, the transboundary shipment of sterile insects across borders increased significantly, with cumulative numbers shipped reaching approximately 600 thousand million pupae by 2015 (see Appendix 3 on History of Transboundary Shipments of Sterile Tephritid Fruit Flies in FAO/IAEA 2017a). Also, mass-production of sterile insects has become semi-commercial or fully commercial in several situations (Loosjes 2000; Barnes 2007; Bassi et al. 2007; Everaarts 2016). Consequently, there were increasing demands for guarantees that sterile insects can be safely and legally shipped internationally, as well as for harmonized international regulations to facilitate this trade in order to reduce the need for independent development of national regulations that often hinder insect control programmes. However, even though sterile insects are non-invasive agents that leave no "ecological footprint" because of their sterility (contrary to insecticides or other measures that are toxic or pathogenic, or to most other biological agents whose establishment is irreversible once they are released), they were not formally accepted as biological control agents by the International Plant Protection Convention (IPPC) because they did not fit the IPPC definition of "reproducing" biological control agents (IPPC 1995).

In response to these requests, the FAO/IAEA Division organized a consultant's meeting to quantify transboundary movement of sterile insects and to assess their risks (they were found to be negligible) (see Appendix 4 on Transboundary Shipment of Sterile Insects in FAO/IAEA 2017a). Therefore, at the request of the FAO/IAEA, when the original International Standard for Phytosanitary Measures Number 3 (ISPM 3) was revised by the IPPC in 2005, sterile insects were included in the updated standard (IPPC 2017a). Consequently, as a result of the significant international recognition, positive track record, and innocuous character of the SIT, sterile insects were officially categorized among *beneficial organisms* by the IPPC to which most countries are parties. Furthermore, the terms "sterile insect" and

"sterile insect technique" were formally included in the IPPC Glossary (IPPC 2017b):

> *Sterile insect*: An insect that, as a result of a specific treatment, is unable to reproduce [ISPM 3, IPPC 2017a]
>
> *Sterile insect technique*: Method of pest control using area-wide inundative release of sterile insects to reduce reproduction in a field population of the same species [ISPM 3, IPPC 2017a].

## 6. EPILOGUE

Krafsur (1998) noted that many scientists view the SIT and related genetic methods negatively (Whitten and Mahon, this volume). For example, Hargrove (2003) cast doubt on the potential value of the SIT for tsetse eradication. Especially academic researchers tend to be opposed to programmes they perceive as costly, and would rather see instead more funding of research at universities and research institutions. They are also critical of the scarcity of data clearly linking releases with induced sterility in wild females and population suppression. Krafsur (1998) identified the fundamental problem as follows:

> There is a paucity of published data that relate sterile male releases to population suppression. It would lend much credibility to the efficacy of SIT if sterile mating frequencies were estimated in challenged populations. Numerous models have been constructed that relate sterility and genetic deaths to population density but few were tested with field data. Studies in which target population dynamics are evaluated in terms of sterile mating rates and other covariates are badly needed. In this way, useful mathematical models could be made and tested with actual data.

Nevertheless, in the screwworm programmes, sterile and fertile egg masses were collected routinely in the Sanibel Island, Curaçao, and Florida programmes, and these data were related to target population decline (Baumhover 2002). Vreysen et al. (2000, 2018) described a clear connection between the release of sterile tsetse males and induced sterility in wild females, and between induced sterility and subsequent population decline in the field. Also Rendón et al. (2004) established this relationship on a large scale for the Mediterranean fruit fly.

Regarding lepidopteran pests, North and Snow (1978) confirmed the interaction of released irradiated moths and the wild population by capturing wild females, allowing them to oviposit, dissecting them to determine whether or not the spermatophores were coloured with the dye from the rearing medium, and examining their progeny cytogenetically for chromosomal aberrations. Others have adopted this approach for other species (Simmons et al., this volume; Marec et al., this volume; Vreysen, this volume). All these data confirm the relationship between sterility and pest suppression, yet much remains to be done to further address the paucity of field data identified by Krafsur.

AW-IPM programmes that integrate the SIT serve a very useful role in focusing attention on the need for area-wide strategies in managing major pest problems (Klassen and Vreysen, this volume). They are difficult to manage (Dyck, Reyes Flores et al., this volume), but those that exist have shown that the conventional IPM

programmes tend to be conducted on too small a scale for optimum efficiency, and often employ insecticides in a way that destroys natural enemies.

Progress in developing and implementing the SIT for AW-IPM programmes has been slow in some cases but rapid for others (such as fruit fly pests). The SIT is being or has been practised on an industrial and area-wide scale against the New World screwworm, Mediterranean fruit fly (and other fruit fly species, e.g. *Anastrepha ludens, A. obliqua, Zeugodacus cucurbitae, B. dorsalis, B. tryoni*), pink bollworm, false codling moth and codling moth (Hendrichs 2000; Hendrichs and Robinson 2009). Mass-rearing facilities in several countries produce several thousand million sterile Mediterranean fruit flies per week. Currently, the infrastructure to rear the pink bollworm is being adapted for the production of the navel orangeworm for the suppression of this pest in almond and pistachio orchards in California. The codling moth programme in Canada has weathered major concerns (Myers et al. 1998), and has significantly reduced insecticide use (local pesticide sales indicate a 96% reduction since 1991 in the amount of active ingredient used against the codling moth) (Nelson et al. 2021). The small onion maggot programme releasing sterile flies in The Netherlands survives, even without authority for a mandatory area-wide application, and the citrus production areas in South Africa that are under the false codling moth programme continue to expand. The African Union is attempting to facilitate the integrated use of the SIT to establish tsetse-free zones in selected areas (Feldmann et al., this volume). The SIT has been shown to be valuable in dealing with certain transboundary pest problems, and in eliminating outbreaks of invasive pests (Hendrichs, Enkerlin et al., this volume), as demonstrated again by the recent eradication of a large Mediterranean fruit fly outbreak in the Dominican Republic (Zavala-López et al. 2021).

Programmes continue to receive research support, resulting in improving technologies and thus in enhanced cost-effectiveness for all aspects of the SIT (Abd-Alla et al. 2013; Beier et al. 2014; Bourtzis and Hendrichs 2014; Ready and Feldmann 2014; Vreysen et al. 2014, 2016; Scott et al. 2017). This includes improved colony management, strains and sexing systems (Augustinos et al. 2017; Sánchez-Rosario et al. 2017; Franz et al., this volume), and better mass-rearing, sterilization, shipment, holding and release systems (Bakri et al., this volume; Dowell et al., this volume; Parker, Mamai et al., this volume), a better understanding and management of pathogens and symbionts in mass-rearing (Abd-Alla et al., this volume; Augustinos et al., this volume), post-factory treatments to improve sterile male performance based on the integration of semiochemicals, hormones and symbionts (Pereira et al. 2013; Pereira et al., this volume), and the incorporation of population genetics, GIS, satellite imagery, information technologies and habitat analysis in project planning and implementation (Bouyer et al., this volume).

Finally, the accelerating development and application of modern biotechnology tools are being exploited to develop self-sustaining as well as self-limiting approaches. While the former aim at population replacement strategies using gene drive or *Wolbachia*-based approaches, SIT-based control systems are self-limiting strategies that aim at leaving no “ecological footprint” (Häcker et al., this volume).

Molecular technologies have already been applied to create sterility and sexing strains, and to introduce stable markers for population monitoring purposes (Bourtzis and Hendrichs 2014). Several such strains have undergone an initial

evaluation under mass-rearing scenarios or in open-field trials, although their wider adoption has so far been slow because of low public acceptance of transgenic approaches, and the regulatory requirements and approvals that are required in most countries for their application (Häcker et al., this volume).

*V. A. Dyck, J. Hendrichs and A. S. Robinson (eds.), Sterile Insect Technique. Principles and Practice in Area-Wide Integrated Pest Management. Second Edition.*

SUMMARY

In theory, the sterile insect technique (SIT) is applicable to a wide variety of invertebrate pests. However, in practice, the approach has been applied successfully to only a few major pests. Chapters in this volume address possible reasons for this discrepancy, e.g. Klassen et al., Lance and McInnis, and Hendrichs and Robinson. The shortfall between theory and practice is partly due to the persistence of some common misconceptions, but it is mainly due to one constraint, or a combination of constraints, that are biological, financial, social or political in nature. This chapter's goal is to dispel some major misconceptions, and view the constraints as challenges to overcome, seeing them as opportunities to exploit. Some of the common misconceptions include: (1) released insects retain residual radiation, (2) females must be monogamous, (3) released males must be fully sterile, (4) eradication is the only goal, (5) the SIT is too sophisticated for developing countries, and (6) the SIT is not a component of an area-wide integrated pest management (AW-IPM) strategy. The more obvious constraints are the perceived high costs of the SIT, and the low competitiveness of released sterile males. The perceived high up-front costs of the SIT, their visibility, and the limited private investment (compared with alternative suppression measures) emerge as serious constraints. Area-wide SIT application is management intensive, requiring effective and dedicated management; insufficiently trained, funded or committed managers can negatively affect successful implementation. Failure to appreciate the true nature of genetic approaches, such as the SIT, may pose a significant constraint to the wider adoption of the SIT and other genetically-based methods, e.g. transgenic genetically modified organisms (GMOs). Limited support for the necessary underpinning strategic research also appears to be an important constraint. Hence the case for extensive strategic research in ecology, population dynamics, genetics, and insect behaviour and nutrition is a compelling one. Raising the competitiveness of released sterile males remains the major research objective of the SIT.

## 1. INTRODUCTION: CHALLENGE OF A NOVEL METHOD FOR AREA-WIDE INTEGRATED PEST MANAGEMENT

The 20th century witnessed at least four major advances in methods of suppressing pestiferous invertebrates. The two most ubiquitous of these, synthetic pesticides and biological control, did not require any prior conceptual revolution in scientific thinking for their development and adoption. Both approaches witnessed significant technical innovations, but, conceptually, each was essentially "more of the same". In contrast, the other two important approaches to pest management, autocidal/genetic control (including the sterile insect technique (SIT)) and, more recently, genetically modified organisms (GMOs), have emerged from a totally new worldview as to how each generation passes on the "instructions of life". No language could even come close to explaining these genetic approaches before the 20th century and the influence of Darwin and Mendel. They were simply beyond anticipation (Whitten 1985).

The existence of DNA, and just how these giant molecules might carry the heredity blueprints from one generation to the next as cryptic coded information, was completely outside the thinking of 19$^{th}$ century scientists. Advances in the discipline of genetics — the study of change during an individual's development, and variation between populations over space and time — became the hallmarks of 20$^{th}$ century biology. Not surprisingly, genetics and evolutionary concepts now impinge on many aspects of pest management. They shape our understanding of pesticide resistance and its management (McKenzie 1996), help us determine the specificity and safety of biocontrol agents (Whitten and Hoy 2000), and facilitate the design of novel genetic tactics for pest suppression such as the SIT (Knipling 1955, 1979) and chromosomal rearrangements (Serebrovskii 1940; Curtis 1985; Whitten 1985). They have also enabled researchers to identify toxin-producing, pesticide- and disease-resistant, and

other relevant genes, along with the means to transfer such information to unrelated species, whether crop plants or insects (Häcker et al., this volume).

Unlike biological control or pesticides, both household concepts, an important corollary of the genetics revolution has been a need for the broader community to understand the nature of the hereditary material, and how we can manipulate it, to appreciate the risks and benefits of genetics-based approaches to pest control. Even then, some understanding of ecology and economics is required to put the basket of tactics into a realistic context. In comparison with other pest control tactics, it is difficult for stakeholders, without a basic level of knowledge, to make informed decisions about whether to support or oppose the SIT and transgenic GMOs. Herein lies the biggest constraint to the successful application of the SIT and other genetic means of pest suppression.

It is important that scientists and their institutions enter into meaningful dialogue with the ultimate beneficiaries of genetic approaches to pest control, particularly farmers and communities affected by insect pests and insect-borne diseases, but also the wider public. This is especially true in developing country-generated initiatives; and formal requests for area-wide integrated pest management (AW-IPM) programmes that integrate the SIT are often unrealistic, their implementation is poorly managed (including corruption in some cases), and they lack close interaction with local communities and other stakeholders (Dyck, Regidor Fernández et al., this volume; Dyck, Reyes Flores et al., this volume) (Box 1).

*Box 1. Unsuccessful Attempts to Deploy the SIT and Genetic Control of Mosquito-Borne Disease Vectors in India*

The value of achieving a joint understanding and ownership of genetic control tactics can be illustrated by reference to the unsuccessful attempts of the World Health Organization (WHO) and the Indian Council of Medical Research (ICMR) to develop novel genetic control tactics for three mosquito vectors of disease (malaria, yellow fever and filariasis) in rural India during the 1970s. This ambitious programme evaluated three approaches to genetic control, namely the SIT using either irradiation or chemosterilants, and chromosomal rearrangements (Davidson 1974). Initially, some common ground for this pioneering project was created when the general approach was described to rural communities as family planning for mosquitoes — a concept widely promoted for human population control by the Indira Ghandi Government. Unfortunately, the mosquito programme floundered when journalists, exploiting ignorance and prejudice, persuaded Indian politicians that the project was designed to serve foreign interests and not the national well-being. The programme was abruptly abandoned in 1975, to the chagrin and embarrassment of the WHO and ICMR, to the bewilderment of many, and, undoubtedly, to the lasting detriment for rural communities scourged by mosquito-borne diseases (Nature 1975; WHO 1976; Dyck, Regidor Fernández et al., this volume). There may be some parallels between the attempts for genetic control of mosquito populations in India and those for the eradication of some tsetse *Glossina* populations in Africa. These include the risks of using foreign aid to implement sophisticated technologies not adequately understood by the intended beneficiaries, with the expectation of eliminating a suite of disease vectors on a large area-wide basis covering different political entities and diverse ecologies.

A study on the efficacy, economics and social impact of genetically engineered *Bt*-cotton in China illustrates well the importance of technology users having a reasonable understanding of the available pest control tactics (Pemsl et al. 2003). A similar conclusion can be drawn about the evolution of resistance and its management, whether we are talking about pesticides, GMOs, or the SIT. Not surprisingly, in very few countries is the concept of resistance management understood and effectively

applied (McKenzie 1996). Without doubt, a major challenge for proponents of genetic-based interventions is to secure from participating countries, their communities (especially in rural areas), and relevant stakeholders the prior informed consent, commitment and genuine ownership of the proposed programme (Dyck, Reyes Flores et al., this volume). Otherwise, misconceptions will arise, and serious constraints can emerge unnecessarily.

Finally, a brief case study of tsetse suppression/eradication in Africa illustrates how misconception and constraint can interplay to influence decision-makers on the feasibility of pest control options surrounding the SIT. Ironically, tsetse fly suppression/eradication, using sterile hybrids (Vanderplank 1947), is often cited as the first convincing field demonstration of autocidal control of an insect pest (Krafsur 1998; Klassen et al., this volume; Robinson, this volume). Yet, subsequent attempts at area-wide eradication of tsetse populations, first with chemicals, and then integrating the SIT, have achieved some success (Vreysen et al. 2000), but have also attracted controversy (Linear 1985; Rogers and Randolph 2002). For example, it is claimed that the pesticide campaign of the Food and Agriculture Organization of the United Nations (FAO), costing about USD 1000 million by 1985, increased rather than reduced the distribution of tsetse (Linear 1985). Important ecological aspects of the debate, such as the role of tsetse in "protecting" vast tracts of natural habitat from occupation by human populations with environmentally damaging cattle ranching, are not directly germane to this discussion. Nevertheless, Nagel and Peveling (this volume) state that new areas are opened up to cultivation as a result of rapidly increasing human population pressure in sub-Saharan Africa, independent of tsetse presence or absence. However, other criticisms levelled by Linear, and partly revived more recently (Rogers and Randolph 2002), at SIT-based tsetse programmes, are more pertinent (Box 2).

## 2. SOME COMMON MISCONCEPTIONS

### *2.1. Are Irradiated Insects Radioactive?*

During the early development of the SIT, chemosterilants were assessed but abandoned, mainly because of concern over the release of sterile insects with residues of non-specific chemosterilants into the environment (Lance and McInnis, this volume; Robinson, this volume). All current and proposed programmes that release sterile insects use Co-60, Cs-137, or X-rays as the irradiation source (Bakri et al., this volume). Is there a similar risk that irradiated insects contain harmful residual radiation?

A study of the irradiation of foodstuffs, where irradiation levels are much higher, dispels this fear. The conclusion of all the studies on irradiated foods for human or animal consumption indicates that there are no levels of residual radiation to give cause for concern. The issue of greater concern was related to the production of biologically active compounds that could be harmful. Again, this concern has been dismissed as insignificant.

Is irradiated food radioactive? The process of irradiating food is regulated and designed to ensure that that is not the case. The radiation sources used to irradiate food

and agricultural products (including insects) are restricted to: gamma rays from the radionuclides Co-60 and Cs-137, and accelerator-generated radiation either as 10 million electron volt (MeV) electrons or 5 MeV X-rays (FAO 2003). Also, it is important to realize that food (non-irradiated), and any natural substance, contain natural radioactivity that can be measurable. Therefore, it is important to put in perspective the issue of possible induced radioactivity in food and natural radioactivity in food. In a document published by the IAEA (2002a), all relevant data generated over the last 40–50 years, and various nuclear mechanisms that can produce radioactivity, were analysed, and it was concluded that:

> . . . the increase in radiation background dose from consumption of food irradiated to an average dose below 60 kGy with gamma rays from Co-60 or Cs-137, with 10 MeV electrons, or with X-rays produced by electron beams, with energy below 5 MeV, is insignificant. It is best characterized as zero.

*Box 2. Can Tsetse Species be Suppressed/Eradicated by the SIT?*

The debate on the potential of the SIT to suppress/eradicate large tsetse populations indicates a mix of misconceptions, and possibly some significant constraints. These include:

- The SIT is highly technological (a misconception driven by inadequate understanding, but to the extent that this is true, the quality of its implementation, which is essential for successful SIT application, can be negatively affected by insufficiently trained or paid managers).
- At least 31 species and subspecies of Glossina are disease vectors, with various mating barriers between taxa. (In fact, most tsetse taxa are not economically important, and are restricted to rain forests, having little contact with humans or domestic animals. In Kenya, for example, elimination of populations of G. pallidipes Austen would eliminate the entire agricultural problem. In Ethiopia, two species are important — G. pallidipes and G. morsitans ssp.).
- The complexity and difficulty of the problem — with 10 million km2, more than 30 countries infested, and multiple taxa — pose immense logistical, financial and coordination problems, especially if eradication is the objective. In fact, only selected populations in priority areas at the edge of tsetse belts are currently being targeted (Feldmann et al., this volume).
- The possibility exists that a neighbouring non-target tsetse species would invade an empty niche following the application of the SIT. This could apply to G. pallidipes and G. morsitans, which are sometimes sympatric.
- Expensive pre-release field studies are required to determine species presence, distribution and abundance (part misconception, and probably an overstated constraint).
- Target tsetse populations are often remote from human population centres (a logistical challenge?).
- Multiple-mating of females, thereby possibly reducing the effective impact of sterile males, is largely a misconception (section 2.3.).
- Sterile tsetse males can act as disease vectors, and the argument of "net benefits" may not suffice (in fact, steps are routinely taken to prevent males from acting as disease vectors (Feldmann et al., this volume; Nagel and Peveling, this volume).
- Pre-release tsetse population reduction measures, e.g. pesticides and trapping, are required (integration with other pest management approaches could be seen as a strength).
- The SIT can be prohibitively slow and costly, and large up-front costs presupposing eradication represent a constraint. However, the low economic returns from animal traction, livestock production and other benefits resulting from eradication are a misconception as shown by the major benefits deriving from the eradication of Glossina austeni Newstead from the island of Unguja in Zanzibar (Feldmann et al., this volume).
- Failure to eradicate could represent a zero return on a substantial investment, although temporary suppression is also the goal of other tactics.
- Technological complexities and poor economics create difficulties in obtaining sponsorship (a constraint).

In recent years the use of irradiation for protecting foodstuffs to meet quarantine and sanitation requirements has become more mainstream without adverse incident (Heather and Hallman 2008). For example, for years all guava exported from Mexico to the USA is irradiated (The Packer 2011), and honeybee hives, infected with bacterial diseases or arthropod pests, are routinely commercially decontaminated with gamma radiation, reducing the need to destroy valuable equipment (Titěra 2009; Queensland Government 2018).

The above facts about food irradiation and related applications can be extended to insect sterilization procedures, since the same sources of irradiation are used (Co-60, Cs-137, electrons or X-rays). Furthermore, insect sterilization for sterile insect releases requires a much lower radiation dose than for food irradiation. In food irradiation, the dose varies from about 100 Gy to 60 kGy, depending on the end objectives. In insect sterilization, the dose is in the range of only 100–300 Gy, depending on the insect and irradiation conditions (Hallman 2000; Bakri et al. 2005; IDIDAS 2018; Bakri et al., this volume). Thus, the induction of radioactivity in insects irradiated for programmes that release sterile insects can also be "best characterized as zero" (Elias and Cohen 1977; Terry and McColl 1992; IAEA 2002a, b).

Given the low levels of irradiation given to insects, the small biomass of the released insects and their wide dispersal, there are no plausible grounds for concern about residual radioactivity, or radiation-induced toxins, in released insects. Conversely, one might argue that the SIT is more environment-friendly than some alternative suppression tactics such as synthetic pesticides or augmentative or classical biological control. Pesticide contamination of foodstuffs, exposure and poisoning of workers, and environmental damage are often very real issues, particularly in developing countries (EJF 2002, 2003). The absence of any collateral damage following directly from the release of radiation-sterilized insects into the environment is indeed one of the strengths of the SIT, compared with chemical control, biocontrol or even GMOs. As with GMOs, concern about the process, and not the product itself, is sometimes the basis for apprehension. It would be very unfortunate if this misconception about the SIT ever became the reason for an otherwise viable AW-IPM programme not being implemented.

### *2.2. In What Sense Are "Sterile Insects" Sterile? Is This a Misnomer or a Misconception?*

In terms of physiology and behaviour, male insects "sterilized" by gamma radiation are not sterile (Robinson, this volume). Indeed, they are expected to generate viable and functional sperm capable of fertilization, to produce a full complement of seminal fluids, and also to enjoy undiminished libido. The population-suppressing impact of released sterile males is realized via radiation-induced dominant lethals that are lethal in the next or subsequent generations. By way of contrast, irradiated females may produce fewer or no eggs, and their behaviour may well differ in other critical ways from normal non-irradiated females. Thus "conventional" sterility is often induced in females, but that is of no consequence in many programmes that release only sterile males.

In species where females multiple-mate and store sperm in spermathecae, it is important that irradiated sperm from sterile males are competitive with non-irradiated sperm in fertilizing eggs. In species where female receptivity is normally terminated after the first mating, again it is important that sterile males induce this behaviour. In species where it is predominantly sperm from the last mating that fertilize egg batches, it is important that sterile males are equally capable of maintaining this outcome.

The above considerations have become important since recent advances in biotechnology and molecular biology have suggested alternative means of sterilizing males (Häcker et al., this volume). For example, the use of gene-silencing techniques (Nowak 2003) to "switch off" a gene essential for sperm development could well induce true sterility. However, unless the male accessory gland product that "switches off" female receptivity is transferred during mating, these techniques would only serve to create a situation where the released males had little or no impact on the target population (Hendrichs and Robinson, this volume).

By way of contrast, Gould and Schliekelman (2004) suggested a range of novel molecular approaches to sterility that cause lethality in the progeny of released males. Such approaches are unlikely to encounter problems in generating the envisaged impacts. However, as stressed by Gould and Schliekelman, it is important that molecular biologists remain in dialogue with field entomologists so that practical outcomes are optimized. These authors noted that closer collaboration existed during the early period of SIT and autocidal programmes than often exists today between laboratory-based researchers and field ecologists, especially with the latter now an "endangered species" in many countries. Burt (2003) discussed some recent advances in molecular biology, with far-reaching and possibly profound implications for genetic engineering or suppression of natural populations. These revolutionary ideas address the potential of removing the need to mass-rear or irradiate insects before releasing engineered individuals into target populations. On the other hand, such self-sustaining approaches have the disadvantage that they aim at leaving an irretrievable "ecological footprint", require regulatory approvals, and often face public opposition to the release of transgenic insects (Häcker et al., this volume). Furthermore, unlike radiation, which is a random physical process, molecular approaches include the likelihood of resistance development (Hendrichs and Robinson, this volume).

### *2.3. Is It Essential That Females Mate Only Once?*

Conceptually and operationally, it is simpler if females of the target species mate only once. Initially, E. F. Knipling thought that monogamy was desirable, but later realized that it was not of central importance (Knipling 1955, 1979; Klassen and Vreysen, this volume; Lance and McInnis, this volume). Actually, monogamy can be a significant constraint where migration introduces inseminated females from outside the sterile-male-release area (Barclay, this volume).

In species where females are monogamous, it is essential that sterilized males evoke the same response as normal males during mating to terminate further receptivity by the inseminated female. The competitiveness of the released male is then measured by the difference between the two ratios — sterilized males to normal males versus field females that have been inseminated by the two classes of males.

Multiple matings complicate the situation, but do not disqualify a pest from being a candidate for the SIT. In the latter case, the issue centres around sperm viability and competitiveness in fertilizing eggs, and the competitiveness of sterile males for second or subsequent matings. However, for tsetse flies *Glossina* spp. (Curtis 1968), females mated first to an irradiated male, and then to a non-irradiated male, were less than 50% fertile, just as the reverse order of mating produced greater than 50% fertility. Curtis also addressed another special problem with a viviparous female containing a mix of dominant lethal and normal sperm — an embryonic death might affect the time of the next ovulation. It turned out that this is only a minor problem, and, in the event of an early embryonic death emptying the uterus, the time before the next ovulation is advanced only from the normal 9 to 7 days.

### *2.4. Should Released Insects Be Fully Sterile?*

There is little doubt that released females should be fully sterile — not so much for ecological or operational reasons, but for good public relations and to avoid potential litigation or compensation claims. Fortunately, for the majority of species of Diptera against which the SIT is deployed, females require a lower dose than males for complete sterilization, although for a few groups of insects this is not true (Bakri et al. 2005). However, where suppression and not eradication is the objective, males need not be as sterile, especially if the higher dose required for complete sterility significantly reduces competitiveness (Toledo et al 2004; Bakri et al., this volume; Lance and McInnis, this volume; Marec et al., this volume; Robinson, this volume). The objective of the SIT, like any genetic control stratagem, is to impart a genetic load to the target population. If that can be imparted more efficiently through the release of fewer but more competitive males, that are not fully sterile, then that must be the favoured strategy.

### *2.5. Does SIT Application Require Isolated Populations or an Area-Wide Approach?*

The SIT, and genetic control methods (as well as pheromone-based mating disruption), are generally sensitive to the effects of immigration, particularly the incursion of females already mated to wild-type males, e.g. studies on compound chromosome strains of *Drosophila* sp. (McKenzie 1976, 1977). In this situation, monogamy can be disadvantageous since an immigrant inseminated female, immune to the abundance of sterile males, can produce fertile offspring (Barclay, this volume). Apparently, the immigration of inseminated females was the cause of only limited success in a large-scale trial on *Culex quinquefasciatus* Say (then known as *C. fatigans* Wiedemann) conducted by the WHO/ICMR in villages in India during the 1970s (Curtis 1976). Immigration was also a negative factor during trials against *Anopheles albimanus* Wiedemann in El Salvador. In one trial an isolated population was eliminated (Lofgren et al. 1974), but in a larger trial immigration reduced the efficacy (Dame et al. 1981), and suppression was achieved only after increasing the release rate of sterile males (Benedict and Robinson 2003).

The negative impact of immigration on the efficacy of the SIT can be countered by applying the technique on an area-wide basis (Hendrichs et al. 2007; Klassen and Vreysen, this volume). For a newly established pest population, such as a recent introduction of an exotic pest, the target area is much less extensive than for an endemic and widespread pest. However, the releases need to extend beyond the target area, taking into account known distribution, habitat suitability, and the pest's dispersal capacity (Barclay et al. 2011).

There would be very few situations where it would be appropriate for a single beneficiary, e.g. owner of a single orchard or farm, to use the SIT independently (Klassen and Vreysen, this volume). Area-wide approaches require organization, coordination, and importantly, financial backing. To provide those resources, the imposition of a levy on stakeholders/producers may be considered (Dyck, Reyes Flores et al., this volume). However, in many situations, some individuals would prefer not to contribute to area-wide control, either because of a perceived loss of independence or a preference for alternative measures (Krafsur 1998). Often the actual or potential beneficiaries of the SIT are farmers, a group that traditionally is independent-minded; and it is inevitable that some would robustly resist making mandatory payments.

It is self-evident that populations of organisms on "islands", either physical (surrounded by water or mountains) or ecological (a patchy distribution of suitable habitat), are isolated to varying degrees from gene flow (Krafsur and Ouma, this volume). The "island" concept might include urban mosquito populations (where the target species is absent in the surrounding countryside) as a form of ecological island population; their suppression or eradication would benefit many people (Curtis 1976). Such situations present attractive targets. Isolation ensures that the method is at its most economical. However, while long-distance dispersal of the target pest is a disadvantage in any programme releasing sterile insects, imposing an area-wide approach and "barrier zones" can, in suppression programmes, accommodate certain levels of immigration (Hendrichs, Vreysen et al., this volume). If barrier zones are "reasonable", and the costs and benefits remain favourable, physical barriers to gene flow have not proved to be absolutely necessary.

In terms of an area-wide approach to release strategies and impact, an interesting contrast can be made between biological control and the SIT (Hendrichs, Enkerlin et al., this volume). Box 3 illustrates the enormous regenerative powers of some insect species when colonizing a vacant niche.

### *2.6. Is Eradication the Only Objective When Using the SIT?*

The term "eradication" may be interpreted in a variety of ways. For example, for the World Health Organization, it necessitates the removal of every last individual of a species on the earth (Heymann 2006). Range-wide species extinctions are a natural, indeed inevitable, consequence of the evolutionary process (Wilson 1992). Mankind has been responsible for many accidental, but few deliberate, "eradications".

On the other hand, eradication at the population level, such as presented by Newsom (1978), is commonly used in plant protection:

> Eradication is the destruction of every individual of a species from an area surrounded by naturally occurring or man-made barriers sufficiently effective to prevent reinvasion of the area except through the intervention of man.

Newsom (1978) argued (with some cause given the containment mode of the programme at the Mexico-USA border at the time) that eradication of the New World screwworm *Cochliomyia hominivorax* (Coquerel) in the USA using the SIT had been an "abysmal failure". However, there should be little argument now, using Newsom's own definition, that populations of the New World screwworm have indeed been eradicated, not only from the USA, but also from Mexico, and all of Central America (Hendrichs, Enkerlin et al., this volume; Hendrichs, Vreysen et al., this volume; Vargas-Terán et al., this volume).

*Box 3. Comparison between the SIT and Classical Biological Control for Area-Wide Control of a Pest*

Both pest management tactics require an area-wide impact to be practical, but operationally, the procedures to achieve this outcome can be quite different. For example, in August 1996 the South African tephritid bitou bush seed fly *Mesoclanis polana* (Munro) was released at two sites, some 300 km apart, along the eastern seaboard of Australia to control seed production by the invasive weed, bitou bush *Chrysanthemoides monilifera rotundata* (L.) (Edwards et al. 1999, 2009). In total, 124 adults of mixed sexes were liberated (67 at one release site, 57 at another). By October 1998, the species had occupied virtually the entire range of bitou bush, a distance of over 1200 km (Edwards et al. 1999), establishing vast populations in the process. Thus, within 2 years, these two miniscule founding populations displayed exceptional rates of dispersal, located and colonized scattered and quite isolated pockets of bitou bush, and in the process traversed vast stretches, even cities like Brisbane, that contain no host plants. In May 2004, a survey of six sites, along 700 km of the New South Wales coastline, revealed that 98% of all flowerheads were attacked by *M. polana*, with a mean of 12 eggs laid in each (P. B. Edwards, personal communication). It would be a sobering thought to contemplate the effort and efficacy of rearing and releasing sufficient sterile males of *M. polana* along the eastern coastline of Australia to reverse the phenomenal outcome achieved by the bitou bush seed fly following its release. Yet, we have no reason to doubt a similar or even greater dispersal and reproductive capacity of an invading pestiferous tephritid such as the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) which, unlike the bitou bush seed fly, is polyphagous with an enormous host range. One is a beneficial insect, the other a pest, but only because of the economic status bestowed by their hosts.

Where repeated immigration of fertile females occurs, either natural or human-made, eradication may need to be followed by preventive releases in areas of high risk of pest incursions (Hendrichs, Vreysen et al., this volume). The recurrent invasions of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) into California represent such a situation (Krafsur 1998). The preventive release for 25 years of sterile flies over the Los Angeles basin, where most incursions occur, has avoided the establishment of the Mediterranean fruit fly in the face of repeated human-assisted incursions (Dowell et al. 2000). Although Carey et al. (2017) claim that there are established Mediterranean fruit fly populations at "undetectable levels" in California, the validity of the concept that populations with a high reproductive rate can remain undetectable for years under favourable host and climatic conditions has not been accepted by trading partners, and has been challenged by McInnis et al. (2017) and Shelly et al. (2017). Thus, in such situations, the SIT is an effective preventive, rather than an eradication, tool to maintain the pest free status (Dowell et al. 2000; Hendrichs, Enkerlin et al., this volume).

A final example of accommodating the objectives of an AW-IPM programme integrating the SIT, by recognizing immigration, is the pink bollworm *Pectinophora gossypiella* (Saunders). The cotton-growing areas of the San Joaquin Valley, California, were protected for decades from infestation by the pink bollworm through the implementation of an AW-IPM programme in which the SIT was a key component in containing the pest. The SIT also played a key role in the subsequent eradication of the pink bollworm from the USA and northern Mexico (in combination with growing transgenic cotton and the use of pheromones for mating disruption) (Staten and Walters 2021).

The eradication of an established population of a pest species is a challenging objective. Even deciding whether or not to attempt eradication is not a simple matter. Myers et al. (2002) stated that:

> . . . evaluation of the ecological and economic costs and benefits of removing an exotic species is difficult, and often the benefits are exaggerated and the costs are understated.

Nevertheless, there is no doubt that, in the case of incipient outbreaks of invading non-native pests, eradication is the most cost-effective alternative when compared with allowing the permanent establishment of a new pest that will have to be suppressed continuously. Furthermore, in view of its inverse density-dependence, the SIT has been shown to be particularly suited to eliminate invasive pest populations in an environment-friendly way (Hendrichs, Enkerlin et al., this volume).

While the SIT does become more effective as the target population dwindles and the ratio of sterile to fertile males increases, this positive attribute of the SIT should not condemn it to be exclusively an eradication option. Krafsur (1998) noted:

> . . . because SIT can lead to eradication, anything less may come to be judged a failure.

In this sense, the necessity of using the SIT only for eradication is clearly a misconception.

Frequently, other strategic options, such as containment, prevention and suppression, rather than eradication, are the objective of applying the SIT (Hendrichs, Vreysen et al., this volume). The objective of suppression, instead of eradication, is often necessitated by the undesirability of establishing quarantines, the lack of isolation resulting in unacceptable levels of immigration, as well as other factors. In this common situation, the integration of the SIT into AW-IPM programmes, such as those for several moths and fruit flies, demonstrates that the SIT can be an important component of such suppression programmes (Hendrichs, Vreysen et al., this volume).

### *2.7. Is the SIT a Stand-Alone Technology or Part of an Area-Wide IPM Strategy?*

The SIT is not a stand-alone technology, and thus it has to be integrated in various degrees with other control tactics (Simmons et al., this volume; Mangan and Bouyer, this volume). Even in the North American New World screwworm regional eradication programme, there has been some integration with other suppression measures, such as dressing infested wounds with larvicides, mobilizing ranchers to report cases of infestation, as well as cultural and quarantine activities (Klassen et al., this volume; Vargas-Terán et al., this volume). In contrast, all the various fruit fly

programmes that release sterile flies range from area-wide suppression to eradication; the SIT for fruit flies is integrated with baits, lures, and cultural practices (Enkerlin, this volume; Klassen et al., this volume; Mangan and Bouyer, this volume).

One impressive example of integrating the SIT into AW-IPM, where the goal is sustained suppression, is the Okanagan-Kootenay Sterile Insect Release (OKSIR) Program (codling moth *Cydia pomonella* (L.)) in British Colombia, Canada; it uses a "knowledge-based" approach (Simmons et al., this volume). This programme requires the cooperation of commercial fruit growers and property owners. The programme is funded through local taxation; it obtains 60% of its funding from property owners in the community and 40% from commercial growers (OKSIR 2018; Seymour 2018; Nelson et al. 2021). At various times the OKSIR has applied the following tactics (*Bt* sprays were deemed to be ineffective):

- Various tree-husbandry practices and field hygiene
- Legal authority to enter orchards and residential properties to inspect for infestation and issue control orders for fruit stripping and tree removal
- Initial chemical sprays to suppress a high pest population
- Initial sex pheromone mating disruption in some orchards
- Sex pheromone traps used for monitoring (about one trap per hectare)
- Twice-weekly sterile moth releases
- End-of-season banding of host trees (to trap mature larvae) in some orchards; later the strips are removed and destroyed).

Although eradication was the initial objective, no quarantines were implemented, and thus this is no longer deemed practical as a short-term solution. Instead, a sustainable programme has evolved, which has successfully implemented the revised objective to:

> . . . substantially reduce the amount of toxic pesticides currently used to control [suppress] codling moth, and that means a more competitive fruit industry and healthier local environment for everyone.

From 1991 to 2016 there was an estimated 96% sustainable reduction in insecticides used against the codling moth in the target areas (Nelson et al. 2021). Two important take-home messages emerge from the Canadian codling moth OKSIR Program: informed stakeholders are not hampered by misconceptions, and constraints are viewed as challenges to be met and overcome.

### *2.8. Could Eradication Have Deleterious/Unanticipated Consequences?*

Eradication of a pest population, through whatever means, could conceivably have unexpected consequences. If the species is exotic to the area, and the incursion is small, eliminating the invasive population will re-establish the original situation. However, at the other end of the scale, eradication of a widespread indigenous species, such as a tsetse or screwworm species, may lead to undesirable impacts that need to be considered (Nagel and Peveling, this volume). Myers et al. (2000) provided examples of "secondary" consequences of eradication, following the eradication of exotics from islands, such as the removal of vertebrates, rats, and rabbits. These authors point out that reversing the changes to native communities following the eradication of exotics

is not a trivial undertaking, and requires a sophisticated ecological understanding. In general, however, the negative externalities of the SIT are less than those of most alternative pest suppression tactics, especially pesticides (Nagel and Peveling, this volume).

## 3. SOME CONSTRAINTS ON THE SIT

### *3.1. Changing Contextual Framework for the SIT*

In spite of the successes of significant AW-IPM programmes integrating the SIT against various moth and fruit fly species (Simmons et al., this volume; Enkerlin, this volume), the successful eradication of the New World screwworm in North and Central America (Vargas-Terán et al., this volume) remains a primary model, in terms of its size, economic importance and durability, for most SIT endeavours. Nevertheless, several changed economic and social circumstances, especially over the past 40 years, suggest that even this highly successful programme would encounter difficulties if it were launched today. Changing social, economic, and political circumstances have probably reduced the feasibility of implementing similar-sized programmes elsewhere in the world. In recent times, perhaps of greater relevance as successful SIT models, are the bi-national USA-Mexico pink bollworm programme, and the on-going Mediterranean fruit fly AW-IPM programmes in Latin America.

The successful North American screwworm programme has been characterized as having a pragmatic and opportunistic "can do" approach. For example, it adapted a "mothballed" hangar at a well-sited but unused air force base in southern Texas. This facility did not demand the construction and safety standards currently required of a similar facility. Today, in most countries, occupational health and safety issues, and general worker conditions, are more stringent, and remuneration is more substantial, than in the 1960s. Public liability, insurance premiums, and tendencies to litigate have increased enormously in the past 40 years. Such factors mean that the initial outlay costs for constructing and operating a mass-rearing facility are now much higher. Nevertheless, a facility to rear the New World screwworm has been built in Panama, and several fruit fly rearing facilities are being constructed.

The decline in primary-producer contribution to the gross domestic product (GDP) of many developed nations (now often less than 3%, according to the World Bank) has reduced the political influence of farmers (Europe, Japan, and the USA remain exceptions to this trend). This decline, together with a greater emphasis on the "user-pays principle", aggravates the situation. In cases where pest eradication is the principal objective, reinvasions due to the increased global movement of people, livestock and materials, and threats of bio-terrorism, all serve to reduce the prospects of a sound economic return on the not-insignificant initial outlay. Also, as mentioned earlier, large up-front costs, and the need for stringent quarantine measures that can interfere with trade and the movement of goods, may be serious disincentives to invest in the SIT for eradication of large, established populations. However, this is not the case for the application of the SIT to eliminate outbreaks of invasive pests (Kean et al. 2018; Hendrichs, Enkerlin et al., this volume).

A general decline in financial support for relevant research and development (R and D), compared with that available to the US screwworm programme during the 1960s and earlier (Krafsur 1998), linked to some of the factors listed above, will often mean that less is known about future target populations.

The construction of multi-purpose mass-rearing facilities could lessen the impact of some of the above negativities, and provide significant economies (Fisher 2002). However, in turn, such centralized facilities create new problems, such as increased complexity in management and greater technical challenges relating to the competitiveness of released males. The logistics of material supplies for mass-rearing, and transport of sterile insects to release sites, are also likely to represent greater challenges. Certainly many of the above considerations would impact on risk-adverse decision-makers in Australia, New Zealand and Canada, and probably the European Union, regarding the wisdom of conducting area-wide eradication programmes based on the SIT (Vargas-Terán et al., this volume).

Realistically, if an area-wide campaign were to cover transboundary populations in diverse countries in a region like South-East Asia or Africa, the political, logistical, and ecological challenges would be significant. Such considerations have meant that, in Australia (for area-wide eradication of an existing pest such as the Australian sheep blow fly *Lucilia cuprina* (Wiedemann), or pre-emptive construction of a mass-rearing capacity to cope with an intrusion of the Old World screwworm *Chrysomya bezziana* (Villeneuve) (Vargas-Terán et al., this volume)), the SIT is effectively not on the agenda, in spite of policies to the contrary. Nevertheless, the SIT continues to be used as a rational approach to suppress several fruit fly related problems in Australia and elsewhere (Fisher 1996; Meats et al. 2003; SITplus Partnership 2018).

Compared with most other pest management tactics, the SIT is uniquely affected by another constraint — limited independent and robust experimental field data to evaluate the short- and long-term impact of released sterile insects on population dynamics. Information is often inadequate on key issues such as competitiveness, dispersal rates, and density dependence (Itô et al., this volume); however, data obtained on the Mediterranean fruit fly in Guatemala provide insight into pest population suppression and competitiveness in large-scale field programmes (Rendón et al. 2000, 2004). As Krafsur (1998) noted, many experimental SIT trials have striven to isolate and reduce a target population. A combination of suppression measures are often integrated to achieve this outcome (Mangan and Bouyer, this volume; Nagel and Peveling, this volume). Thus, frequently, according to Krafsur (1998):

> . . . the effects of sterile male challenge are confounded by other treatments.

In this sense, AW-IPM programmes that integrate the SIT, even highly successful ones like the New World screwworm programme in North America, are usually not designed to test hypotheses, but to achieve specific operational outcomes. While this strategy is understandable, it has a serious downside — sometimes little is learned from SIT successes (and failures) that could be applied to other pests.

In spite of the limitations imposed by changes in attitude and resources in the world, the SIT flourishes for species for which the technology is well established, such as the New World screwworm, and various moth and fruit fly pests.

Some encouraging new developments include a revival of interest in the application of the SIT for *Aedes* spp. and *Anopheles* spp. mosquitoes (Touré et al. 2004; Bourtzis et al. 2016; Lees et al., this volume), and in addition two species of tsetse, *Glossina austeni* Newstead and *Glossina palpalis gambiensis* Vanderplank, have been added to the list of targets against which the SIT has been successfully applied (Vreysen et al. 2000, 2021). Also significant is the exploration of opportunities for commercially viable sterile insect production facilities (FAO/IAEA 2008) that hopefully will serve as examples and, in time, provide alternatives to government-funded and government-controlled programmes.

### *3.2. Is the SIT Too Expensive, or Does It Fail the "User-Pays" Principle?*

When control options in AW-IPM programmes are being assessed, whether to suppress or eradicate an existing pest population or deal with an incursion, the question of cost is often foremost. The cost of SIT strategies generally will include the following: expense for monitoring and some other form of control to reduce an initial high target population, and cost of purchasing and releasing the sterile insects. In many programmes, the cost of providing and releasing sterile insects comprises a high proportion of the costs. However, model inputs show that other costs may outweigh the cost of sterile insects (Mumford, this volume). For example, in the case of an eradication programme, proof of pest free status required by a trade partner may drive up trapping costs significantly.

In cases where a reliable and economic supply of sterile insects does not exist, the "deal breaker" need not be just the total cost of the sterile insects, but the substantial upfront investment needed to construct and equip a new production facility. The start-up time for establishing a colony and reaching sufficiently high production is also a factor. However, the risk can be somewhat spread at each step in the SIT-development pathway by collecting evidence to assess the merits of further investment so that it becomes an incremental process: if progress is not promising, withdrawal is possible along the way (FAO/IAEA 2008). For example, at first, small pilot projects are carried out to assess the feasibility of the approach and to validate the technology. Moreover, when planning a mass-rearing facility, this can follow a modular design as described by Tween (1987), where construction of new rearing modules around a central core only proceeds if the demand for sterile flies gradually expands.

Increasingly, the SIT has been used in suppression or seasonal control programmes in a manner similar to pesticides, e.g. codling moth management in Canada, Mediterranean fruit fly in Croatia or Israel, false codling moth *Thaumatotibia leucotreta* (Meyrick) in South Africa, and onion maggot *Delia antiqua* (Meigen) in The Netherlands. The onion maggot control programme is the only example of an ongoing long-term (over 30 years) suppression programme where growers pay a private company to monitor as well as produce and apply the sterile insects. This programme faced the challenge of those who would turn to the SIT only when other options had failed, and therefore the population of the pest was too high to achieve good results using the SIT (Loosjes 2000). Also, due to rotation of crops and some "free-riders", there is no coordination among growers or area-wide approach, and thus no accumulated benefit to the users of the SIT, only a season's benefit. Furthermore,

early support from the Dutch government, in recognition of the enterprise as an environmental business, was terminated due to a change in policy. The loss of this funding eliminated any recognition of public benefits from the reduced use of pesticides, and also caused some users to wonder if the pull-out of the government reflected on the overall product or concept. In spite of these setbacks, the private supply of sterile onion maggots has been maintained, the surface treated has gradually increased to an aggregate area of ca. 10 000 hectares (40% of the onion production), and the programme continues to be successful (Everaarts 2016).

Several large-scale eradication programmes have been cost-effective. Without doubt, successful programmes such as the North and Central American screwworm programmes have proved to be enormous economic successes (Vargas-Terán et al., this volume). The same applies to the Mediterranean fruit fly containment programme that, for 40 years, has maintained Belize, Mexico, USA and ca. half of Guatemala free of this pest, with annual USD multi-thousand-million [multi-billion] benefits to the respective horticultural industries (Enkerlin et al. 2017). These successes have served to ensure a serious evaluation of other potential programmes. However, the problem of cost is more complex than just raising the substantial resources to construct and operate a mass-rearing facility, and conduct the release and monitoring activities. The risk of an eradication venture failing, with no return on investment, can daunt all but the hardiest of optimists. However, a suppression strategy can represent a viable fall-back position, as shown by the Canadian codling moth programme, and some other moth and fruit fly programmes.

One must keep in mind, in any case, that since the SIT does not entail any intellectual property rights (IPR) at this stage, there is little incentive for private enterprise to participate, other than as a "hired hand". Profits must come from the sale of services and sterile flies, as there is little scope for sale of assets of such a company compared with other types of businesses (Barnes 2007; FAO/IAEA 2008). However, in the case of long-term suppression, preventive or containment programmes, that continuously require sterile insects, the financial risk to private investors would be lower than in eradication programmes, where the demand terminates as soon as eradication has been achieved (FAO/IAEA 2008; Simmons et al., this volume; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume).

It can be concluded, in terms of cost-effectiveness, that area-wide application of the SIT is not too expensive when all benefits are quantified, and beneficiaries better understand the technology and participate in the programme (Kruger 2021). In an increasingly "user-pays world", it is equally important to convince those who will capture the benefits to contribute resources in proportion to their benefits. Nevertheless, the most vexatious financial issue is ensuring that all those who capture the benefits pay equitably (Mankad et al. 2021). In suppression programmes, the beneficiaries often contribute to programme costs, e.g. the codling moth OKSIR Program in Canada, where growers and property owners cover all of them (Nelson et al. 2021; Simmons et al., this volume), or the Mediterranean fruit fly programmes in Latin America and South Africa where they pay part of them (Dyck, Reyes Flores et al., this volume; Enkerlin, this volume).

The actual public benefits have usually not been well-measured to date, with some exceptions such as the evaluation in Madeira of indirect impacts on reduction of pesticide use, preservation of cultural heritage, and support of tourism (IAEA 2005).

Unintentional subsidies by government for the production of sterile insects used in third-party programmes will certainly discourage private investment in the sterile insect production sector (Bassi et al. 2007; FAO/IAEA 2008). This could lead to further use of government funds for the SIT, even in those cases where stakeholders are willing to pay their fair share of programme costs.

Much more problematic is the task of identifying the appropriate financial resources, and securing the necessary budget, for programmes that have wider benefits or where the beneficiaries could not afford the cost. For eradication programmes, often the only realistic source is probably the public purse — governments in developed countries, and support from international aid agencies in less-developed countries (Dyck, Reyes Flores et al., this volume). Even when the identity of beneficiaries is clear, if the benefits are not sufficiently appreciated, users are unlikely to pay. For example, in Australia, various attempts to develop a genetic control programme for the Australian sheep blow fly (Foster et al. 1993; Krafsur 1998; Klassen and Vreysen, this volume), either on the mainland or the island of Tasmania, were abandoned, either because the cost was deemed to be too high (Waterhouse 1962), or because it was difficult to obtain the necessary financial backing (King et al. 1992).

In conclusion, AW-IPM programmes that release sterile insects are often susceptible to the "user-pays principle", but many cases fall outside this approach. It will be just as important to establish the "public good" in privately funded programmes, and obtain partial support for that benefit in the future, as in the past it has been to identify and engage private beneficiaries in government-led programmes.

### *3.3. Adverse Population, Ecological, and Behavioural Parameters*

The suppression effects of flooding a natural insect population with sterile males depend on a suite of factors. Difficulty in adequately satisfying some of these could amount to a serious constraint in successfully applying the SIT to a particular pest. However, articulating such issues can sometimes transform a constraint into a challenge, and ultimately into an opportunity. Constraints and complementary opportunities can include:

- Large size of the natural target population versus methods of suppressing numbers before releases by other means (e.g. pesticides, mating disruption, sanitation and other cultural interventions), or simply exploiting seasonal fluctuations (Mangan and Bouyer, this volume)
- Migration from non-target populations versus choice of target area to maximize effective immigration barriers (Itô et al., this volume; Hendrichs, Vreysen et al., this volume)
- Low competitiveness of released insects (due to initial laboratory colonization, artificial diets, radiation and shipment damage, artificial colony management conditions over many generations, especially for adults and mature larval stages which may normally enjoy solitary conditions in the field) versus emphasis on quality control (and more natural colony holding, diet and rearing conditions), strain selection or regular injection of new genetic field material into mass-reared colonies, improving sterile male performance, and using probiotics and symbionts (Liedo et al. 2007; Pereira et al. 2013; Sánchez-Rosario et al. 2017; Augustinos et

al., this volume; Bakri et al., this volume; Lance and McInnis, this volume; Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume)

- Adverse impact of released females (sting damage from some fruit flies or biting behaviour of blood-feeding pests, or animal or plant disease-transmitting vectors) (Lees et al., this volume; Nagel and Peveling, this volume) versus genetic means of removing females, preferably early in the life cycle (Franz et al., this volume)
- Frequency-dependent factors affecting competitiveness (i.e. ratio of released to field males) versus release ratios that minimize this effect (Vreysen, this volume)
- Increased ability of field females to discriminate against released males versus exploration of colony management and mass-rearing conditions that mitigate this selection (Miyatake 1996, 1998), and regular strain replacement to minimize risk of discrimination (Hoffmann and Ross 2018; Lance and McInnis, this volume).

It is one thing to identify constraints and the complementary opportunities, but to turn these to our advantage requires long-term research. As noted by Krafsur (1998) and Gould and Schliekelman (2004), conditions for the necessary underpinning strategic research, both in terms of resources, expertise, and collaboration, were more ideal during the 1960s and 1970s. Resources and creative ideas are abundant in molecular genetics (Burt 2003; Häcker et al., this volume), but unless these are linked to field-oriented research in ecology and behaviour, the advantages are unlikely to be captured (Gould and Schliekelman 2004; Itô et al., this volume).

### *3.4. Mating Barriers — Serious Constraint on Programmes that Release Sterile Insects?*

For the SIT to work, sterile males must be competitive with the field males of the target population(s) of a pest in seeking mates. If we are dealing with a group of distinct species, or even subspecies with limited interbreeding, it is clear that each taxon will have to be tackled separately for progress to be made. This is especially true if the species in the complex are ecologically equivalent, and where a neighbouring taxon can be expected to occupy the vacated niche (Box 2). If the pestiferous species, perhaps vectoring the same disease, is already coexisting, then there is little to be gained by targeting one taxon with the SIT. In such cases, the specificity of the SIT could be a disadvantage.

The above constraint applies equally to cryptic species, where the situation could be more insidious if the mating barriers are undetected because the relevant biological knowledge is simply unavailable. Even supposedly well-known entities such as major malaria vectors, e.g. *Anopheles gambiae s.l.* Giles (White 1974), were found to harbour morphologically indistinguishable, but genetically distinct, species with important consequences for insecticidal suppression programmes (Paterson 1963). Conversely, raising taxa that are not genetically isolated to species status could unnecessarily discourage SIT practitioners (Hendrichs et al. 2015). To avoid both types of problem, it would be prudent to conduct the definitive test — determine if sterile males compete effectively with field males in the target populations (Parker, Vreysen et al., this volume). In his hybridization experiments, Vanderplank (1947) confirmed that this was the case in his pioneering work on autocidal control of tsetse

(Klassen et al., this volume). Below several situations are described where this critical behavioural test was conducted, demonstrating that the SIT should, and did, work.

Based on morphological, cytological, and allozyme differences, Richardson et al. (1982) postulated that the New World screwworm in Mexico and the USA consisted of a number of sympatric, and generally non-interbreeding, populations. The existence of these "gamodemes" was hotly debated (LaChance et al. 1982), and the subsequent eradication of the pest from these regions argues strongly against the Richardson scenario. The question has been rendered irrelevant, now that all screwworm populations north of the Panama-Colombian border have been eliminated (Vargas-Terán et al., this volume). However, what is relevant is that the Richardson analysis could have been used to stop the successful expansion of the screwworm programme, and thereby denying farmers in North and Central America the enormous economic benefits that the SIT actually provided.

Equally important has been the direct-mating test in northern Africa, following the introduction of the New World screwworm into Libya in the late 1980s). Taylor et al. (1991) examined the "reproductive compatibility" of Libyan flies and the mass-reared strain. They also examined genetic variability (chromosome morphology, homolog pairing and m-DNA restriction-site analyses) of populations from Libya, the mass-reared strain, and extant Central American, Mexican, and Caribbean populations. Their analyses indicated that mating barriers should not prevent the eradication of the Libyan populations using "Mexican" sterile flies. Indeed, the successful programme proved to be one of the landmark achievements of the SIT (FAO 1992; Lindquist et al. 1992; Krafsur and Lindquist 1996).

A second example of research being conducted to ensure better mating and genetic compatibility (Feldmann and Ready 2014; Parker, Vreysen et al., this volume), and thus success of the SIT, is provided by the Old World screwworm. Given that the species is found over a large geographical range, possible incursions of this fly might be refractory to the SIT when using a colony established from a distant population. In response, samples of screwworms from southern Africa, the Middle East, and South-East Asia were subjected to various analyses — allozyme (Strong and Mahon 1991), cytological (Bedo et al. 1994), cuticular hydrocarbons (Brown et al. 1998), and laboratory hybridization tests (Mahon 2002a; J. P. Spradbery, unpublished data). No indication of discontinuities, that might indicate the presence of sibling species, was found. Subsequently, analyses of mitochondrial DNA (Hall et al. 2001) resulted in a similar conclusion. However, with the increased resolution of the technology employed, these authors detected the existence of two mitochondrial "races", one in sub-Saharan Africa and the other extending from the Persian Gulf to South-East Asia (Feldmann and Ready 2014). Thus, if the SIT were to be implemented in Australia, it would be prudent to establish a colony from either the introduced flies or the source population.

The absence of mating barriers could reasonably be assumed where the evidence suggests recent movements of an insect species around the globe, including the Australian sheep blow fly, Mediterranean fruit fly (Cayol 2000), the oriental fruit fly *Bactrocera dorsalis* (Hendel) (Hendrichs et al. 2015), and the codling moth (Taret et al. 2010).

### *3.5. Evolution of Resistance to the SIT?*

Insects have shown a remarkable propensity to evolve resistance to chemical challenges used by man in efforts to suppress them. Some species, such as the house fly *Musca domestica* L., certain mosquitoes and whiteflies, are recidivists in that they have evolved resistance to a wide range of insecticides. With this background, it is not surprising that the question is sometimes asked, "Can insects evolve resistance to the SIT?"

Certainly, a species could "escape" if it was able to adopt asexuality. Perhaps only those species that had a pre-existing mix of sexual and asexual modes of reproduction could respond rapidly enough to make use of this mechanism. A sexual species would more likely be driven to extinction before the drastic genetic changes necessary for this process could occur.

A possible caveat to the belief, that an asexual response from an SIT-targeted population represents only a minor threat, is if the cytoplasmic symbiont *Wolbachia* sp. is already present in the species, and plays a role in the determination of sex and the sex ratio. *Wolbachia* is a rickettsia-like bacterium that is found in up to 76% of arthropod species (O'Neill et al. 1997). The presence of these organisms produces a wide range of effects, including conversion of genetic males into functional females, male-killing, cytoplasmic incompatibility, thelytoky, and also may have effects on viability (Bourtzis 2008). Since the effects of an infection with these cytoplasmically-inherited organisms can be so comprehensive, e.g. thelytoky in hymenopteran species (parthenogenesis where the population consists only of females), the implementation of a programme releasing sterile insects could cause the conversion of an apparently sexual species into an asexual one through the elimination of the uninfected, i.e. the sexual, portion of the population.

The dramatic effects of *Wolbachia* vary between groups of species, with perhaps conversion to thelytoky being an extreme effect. Thus, while consideration should be given to the possibility of a programme being thwarted by the effects of *Wolbachia* or similar symbionts, existing programmes have not encountered such problems. More often, *Wolbachia*-induced cytoplasmic incompatibility is being applied as a tool for vector population suppression in a self-limiting way, analogous to the SIT (known as the incompatible insect technique (IIT)) (Lees et al. 2015). However, female removal is critical for such *Wolbachia*-based IIT strategies to be sustainable, but existing mechanical separation is labour-intensive and does not result in the required complete elimination of females, and is therefore not practical for application on a large scale. On the other hand, combining the SIT and the IIT against vectors such as mosquitoes, where male-only releases are an absolute prerequisite, assures that any accidentally released females are sterile, while simultaneously benefitting from the pathogen interference properties of *Wolbachia*, thus avoiding any possibilities of disease transmission by such females (Bourtzis et al. 2016). Alternatively, *Wolbachia* can be used in a self-sustaining way as a means of "driving" desirable genotypes into populations, although such a population replacement is irreversible (Turelli and Hoffman 1999; Bourtzis et al. 2016; Robinson, this volume).

While an asexual response is considered unlikely, and there are certainly no examples of it, the form of resistance to the SIT more commonly considered (at least to be a possibility) is that females of the target population could evolve behavioural

mechanisms to avoid mating with mass-reared sterile males. The argument for such a possibility has been put forward most strongly by Boesiger (1972), who considered it almost inevitable that, while early releases of sterile males might be highly efficacious, the survivors would be enriched for genotypes capable of avoiding sterile males, and thus selection for this ability (McInnis et al. 1996).

Through genetic divergence, or physiological changes associated with mass-rearing, there should be ample "markers" for field insects to discriminate against mass-reared insects, but the question remains, "Is it likely?" The likely outcome is that in eradication programmes the population will become extinct before resistance has evolved. On the other hand, in suppression or containment programmes, such selection is usually countered by certain levels of immigration of already mated females. Indeed, AW-IPM programmes integrating the SIT have been active for decades against both the Mediterranean fruit fly and the New World screwworm. To date there is no evidence that resistance has developed, and the SIT remains effective for both species (Krafsur 1998). Similarly, the SIT has been deployed against other species as well, and again there is no evidence to suggest the evolution of resistance to the SIT (but note comments by Hendrichs and Robinson, this volume; Lance and McInnis, this volume).

A possible exception is a study on the melon fly *Zeugodacus (Bactrocera) cucurbitae* (Coquillett). Hibino and Iwahashi (1991) examined the mating behaviour of the melon fly using males from a long-term colony, and females from two islands in the Ryukyu Archipelago of Japan. Females from Okinawa Island (where SIT releases had been ongoing for some time) discriminated against mass-reared males, whereas females from Ishigaki Island, not yet exposed to SIT releases, did not. This finding was contrary to an earlier study performed before implementing the SIT, wherein Koyama et al. (1986) found that the mass-reared strain and those from Okinawa mated at random. Hibino and Iwahashi (1991) interpreted this as evidence that Okinawa females had "evolved sexual isolating barriers" to the mass-reared males (note comments by Itô et al., this volume).

Clearly, care should be taken to document any changes in behaviour and mating compatibility during the course of a programme releasing sterile insects. However, perhaps it is more appropriate simply to avoid the problem by maintaining the genotypic variation within the mass-reared colony as similar as possible to that of the target population (Hoffmann and Ross 2018). This can be achieved by "refreshing" the genetic variability within the mass-reared strain, such as the regular replacement of the mass-reared New World screwworm strain with field-derived colonies (Mangan 1992), or the regular infusion of genetic material from the target population into the culture (Parker, Mamai et al., this volume).

Recent advances in our ability to "cryopreserve" the embryos of recently colonized strains of species of economic importance where the SIT is either ongoing or could potentially be employed (Leopold et al. 2001), should facilitate this process. Mahon and Leopold (2002) reviewed the potential uses of this technique within programmes that integrate the SIT, one of which would be to prevent the "deterioration" of colonies through genetic changes brought about by long-term selection in mass-rearing. The suggested procedure is to cryopreserve batches of embryos as soon as a newly established colony becomes sufficiently laboratory adapted to be suitable for mass-rearing. After some generations, the mass-reared colony could be discarded and a

fresh batch of embryos revived to re-establish the colony (Parker, Mamai et al., this volume).

### *3.6. Poor Competitiveness of Released Insects Can Be a Major Constraint*

In this volume, many chapters address aspects of "competitiveness": Bakri et al., Barclay, Hendrichs and Robinson, Itô et al., Klassen et al., Lance and McInnis, Lees et al., Marec et al., Parker, Vreysen et al., Pereira et al., Robinson, and Vreysen.

Competitiveness is an important feature of released insects. Poor competitiveness, when it occurs, contributes to an increased cost of the SIT, and cost is perhaps the major constraint to a more general application of the technique. Superficially, many of the costs of any successful AW-IPM programme that releases sterile insects may appear to be fixed, but the size of the required mass-rearing facility, and the costs of the diet and insect release operations, are all dependent on the competitiveness of the sterile males. Reduced competitiveness inflates the cost if, as occurs often, mass-reared and sterilized insects perform poorly in the field in terms of longevity, flight behaviour or ability to compete for mates. Consequently, the programme must commit to produce and release more insects than would be required if released insects were equal to field (wild) insects in their mating propensity and capability.

Lance and McInnis (this volume) suggest that the competitiveness (as defined by Haisch 1970 and Fried 1971) of Mediterranean fruit fly sterile males may in very extreme cases be less than 1%. This implies that more than 100 sterile males are required to equate to the mating behaviour of a single wild (fertile) male. Clearly, a slight improvement in competitiveness would have a dramatic effect on the costs and benefits of the SIT. Progress in developing semiochemical, nutritional, hormonal and other post-factory treatments to improve sterile male performance has been essential in addressing this major constraint (Pereira et al. 2013).

The low tolerance to fruit damaged by Mediterranean fruit flies, and the relatively low cost of insect production for the SIT, provide positive benefit/cost ratios for this species. However, for other species, this may not be the case. For example, Australian authorities are re-evaluating appropriate preparedness strategies to respond to a potential future incursion of the Old World screwworm (Vargas-Terán et al., this volume). In an SIT trial conducted in Malaysia (Mahon 2002b), the competitiveness of mass-reared and irradiated Old World screwworms was approximately 4%. A re-analysis of a similar trial in Papua New Guinea performed by Spradbery et al. (1989) yielded a similar value (R. J. Mahon, unpublished data). If competitiveness is calculated in this way, the merits of SIT integration could be questioned, but much depends on the programme costs and benefits in relation to alternative tactics that can similarly achieve eradication of the invasive population. Further work must be done to improve competitiveness, thereby ensuring that the costs and benefits of the SIT for this species remain positive (Parker, Vreysen et al., this volume). Unfortunately, increasing the number of sterile insects released (and hence the release:wild ratio) may not be the simple remedy for low competitiveness, especially if there is a negative relationship between the ratio of released:wild males and mating success, as suggested in field trials of sterile tsetse *Glossina palpalis gambiensis* (Rogers and Randolph 1985) and translocation-bearing males of the Australian sheep blow fly (Mahon 1996).

## 4. CONCLUSIONS

The SIT has proved to be a robust and "green and clean" technology, yet the range of species to which it is presently being applied is relatively limited. The outstanding successes of the SIT with the New World screwworm in North and Central America, and in Libya (Vargas-Terán et al., this volume), as well as with the Mediterranean fruit fly and other species of fruit flies and moths in a number of regions of the world (for suppression, eradication, containment, or prevention) (Enkerlin, this volume; Hendrichs, Vreysen et al., this volume), raise questions about why the SIT has fallen short of the high expectations for the technology.

Some misconceptions are partly to blame but, in general, these seem to be more like irritants than real impediments. Two strengths of the SIT are its specificity, and the absence of negative externalities that haunt other pest management tactics such as synthetic pesticides and, to a lesser extent, classical and augmentative biological control. Concern about residual irradiation, or the production of toxic metabolites, is discussed primarily to dismiss this issue as lacking foundation. Other common misconceptions identified include: the need for monogamous females and for released males to be fully sterile; maintaining that eradication is the only possible goal; the SIT is too sophisticated for developing countries; and failure to recognize the SIT as a valuable component of area-wide IPM strategies. In each case, we concede that these warrant analysis, but conclude that each is not an impediment for a successful programme that releases sterile insects.

The identified constraints pose more serious threats to extending the SIT to other insect pests. In particular, we recognize that the SIT and other genetic methods of pest control are knowledge-based technologies. Thus, SIT application is complex and management intensive, requiring dedicated and effective managers to be successful (Vreysen et al. 2007; Dyck, Reyes Flores et al., this volume). Failure of the public to understand the nature of genetic material, and how interventions to disrupt the orderly inheritance or expression of this genetic information can be achieved, can introduce fear of the unknown. Financial considerations rank high on the list of constraints. The need for large upfront expenditure, risk aversion (failure to get any return on a failed eradication campaign), and rigid application of the beneficiary-pays principle in some countries without establishing the "public good" of such programmes, have proved to be serious disincentives for some potential SIT eradication projects that otherwise appeared to be feasible technically.

In the technical arena, the low competitiveness of released males is a serious constraint, especially if not given top priority by managers. Increasingly, detailed quality control manuals are available to assess carefully sterile male behaviour and performance in field cages and the field; also molecular tools and other markers have been developed that allow quantifying sterile and wild sperm presence in females of the target population (Juan-Blasco et al. 2013; FAO/IAEA/USDA 2019; Johnson et al. 2017).

Lack of support for the necessary underpinning strategic research also appears to be an important constraint. Hence, the case for extensive strategic research in ecology, population dynamics, density-dependent regulation, genetics, insect behaviour, and insect nutrition is a compelling one. Raising the competitiveness of released males remains the major research objective for the SIT.

Exciting new developments in molecular biology are being exploited to develop entirely novel genetic tactics, both in support of self-limiting, such as the SIT, as well as self-sustaining approaches that aim at population replacement strategies using gene drives or *Wolbachia* systems (Häcker et al., this volume). Even if the latter do not depend on the release of large numbers of mass-reared and sterilized insects, with all the associated challenges, they have a higher likelihood of resistance development, require regulatory approvals, often face public opposition, and leave an ecological footprint.

SUMMARY

Area-wide integrated pest management (AW-IPM) focuses on the preventive management of pest populations throughout the ecosystem. It seeks to treat all habitats of the pest population in space and time so that none produces migrants to re-establish significant infestations in areas of concern. In contrast, the conventional strategy focuses narrowly on defending the valued entity (crop, livestock, people, buildings, etc.) from direct attack by pests. AW-IPM requires multi-year planning and commitment, coordination among stakeholders, and an organization dedicated exclusively to its implementation, whereas conventional pest management involves minimal forward planning, tends to be reactive, and is implemented independently by individual producers, businesses, or households. AW-IPM tends to integrate advanced technologies, whereas the conventional strategy tends to rely on traditional tactics and tools. The sterile insect technique (SIT) is a species-specific form of birth control imposed to suppress or contain target pest populations, although it is a very powerful tool for "mopping up" sparse and isolated pest populations. On environmental, economic and biological grounds, in many situations the case for the SIT is compelling. While only some area-wide programmes integrate the SIT, deployment as part of an area-wide management system is essential for the SIT to be effective.

## 1. AREA-WIDE INTEGRATED PEST MANAGEMENT STRATEGY

The area-wide concept is a modernizing strategy of providing services efficiently wherever needed. Area-wide management takes advantage of the power of organization and coordination intelligently applied. In older societies, many services were provided on an individual basis by the family, e.g. collecting water and fuel, protection of the family, disposal of waste and sewage, etc., and independently of the activities of the neighbours. These services proved to be rather unreliable, ineffective, and were obtained at great individual expense. Reduced costs, better physical protection, and increased effectiveness were the drivers towards more effective delivery services. As a result, many of these services evolved from an individual to area-wide provision (Hendrichs et al. 2007). Today, many of these services, such as police protection, potable water, garbage and sewage removal, mail service, retailing, ambulance, fire protection, public health, electrical supply, high-speed transport, telephone, and internet services are being provided on an area-wide basis (Lindquist 2001; Hendrichs et al. 2007).

Area-wide approaches to deal with insect pests have ancient roots in coping with locust plagues and vector-borne diseases (Klassen 2000; Faust 2008). By systematic use of quarantines, Venice and Milan in 1347–1350 contained bubonic plague transmitted by the oriental rat flea *Xenopsylla cheopis* (Rothschild), and this approach was gradually adopted throughout Europe.

Area-wide integrated pest management (AW-IPM) came into a degree of prominence in the late 19$^{th}$ and early 20$^{th}$ centuries with the development of classical biological control (1888) (Caltagirone 1981), the use of pest-resistant plants (such as the grafting of all European grapes on phylloxera-resistant American rootstocks in the 1870s) (NAS 1969), campaigns to eradicate the gypsy moth *Lymantria dispar* (L.) in Massachusetts (1890–1901) (Liebhold et al. 2021) and *Boophilus* spp. cattle ticks from the southern USA (1906–1943) (Rutherford 2007), the suppression of yellow fever and malaria vectors in Havana, Cuba (1898) (Lechuga and Castro 2016) and in the Panama Canal Zone (1904) (Stern 2005), and the organization of mosquito-abatement districts, first in West Africa and then in several continents (1900) (AMCA 2004; Foley IV et al. 2021).

The area-wide approach is one of several major strategies for coping with pest problems (Kogan 2000). Various pest management strategies have evolved in response to differences in the challenges presented by various pests (Hendrichs, Vreysen et al., this volume). The strategy for coping locally with a pest problem on an empirical basis gives only temporary alleviation. As methods of control, and guidelines for their use, are developed and refined, they form the basis of the conventional strategy of localized management of only fractions of pest populations. This is the most widely used strategy, and individual producers, businesses and households practice it independently and with no coordination with other stakeholders. However, in response to individual producers or households not being able to adequately meet the challenge of certain very mobile and dangerous pests, the need for total population management or an AW-IPM strategy emerged (Rabb 1972). Mobile pests include not only those that fly long distances, but also those transported passively on wind, water, or animal hosts, or in infested commodities traded locally or internationally.

Edward F. Knipling, the "father" of the sterile insect technique (SIT), was a strong proponent of the area-wide concept to manage many of the major pest problems, independent of the SIT (Klassen 2003). Therefore, area-wide management is often incorrectly associated with the SIT. However, while area-wide management is essential for effectiveness of SIT use, it applies equally to the effective implementation of other control tactics against many other pest insects that are not the target of SIT application. Table 1 lists examples of area-wide programmes not involving the integration of the SIT.

### 1.1. D*efining Area-Wide Integrated Pest Management*

For the purposes of this book, AW-IPM is defined as:

> IPM applied against an entire pest population within a delimited geographic area, with a minimum size large enough or protected by a buffer zone so that natural dispersal of the population occurs only within this area.

The common thread that runs through all AW-IPM programmes is the strong emphasis on the preventive control over space and time of foci of infestation from which recruits emerge to re-establish damaging densities of the pest population in areas of concern.

A few scientists have attempted to define the AW-IPM strategy. Knipling, as cited by Dickerson et al. (2001), stated:

> Area-wide pest management is the systematic reduction of a target key pest(s) to predetermined population levels through the use of uniformly applied control measures over large geographical areas clearly defined by biologically based criteria.

Lindquist (2000) wrote:

> An area-wide insect control programme is a long-term planned campaign against a pest insect population in a relatively large predefined area with the objective of reducing the insect population to a non-economic status.

*Table 1. Examples of area-wide programmes to suppress or eradicate insect pests without integration of the SIT*

| Programme | References |

| Area-wide augmentative biological control of the green peach aphid *Myzus persicae* (Sulzer) on tobacco in China | Yu et al. 2021 |
| Area-wide suppression of invasive *Solenopsis* spp. fire ants using insecticide-baits and self-sustaining biological control agents | Vander Meer et al. 2007; Aubuchon and Vander Meer 2008 |
| Stored-grain insect area-wide integrated pest management based on systematic sampling and decision-support software to guide fumigations | Flinn et al. 2007; Hagstrum et al. 2008 |
| Grape moths *Lobesia botrana* (Denis and Schiffermüller), and *Eupoecilia ambiguella* Hübner, area-wide pest management in Italy based on pheromone mating disruption | Ioriatti et al. 2008 |
| Area-wide application cultural method for the control of western tarnished plant bug *Lygus hesperus* Knight in cotton | Carrière et al. 2006; Abel et al. 2007 |
| Area-wide mosquito abatement or management districts to suppress mosquito populations by integrating physical and biological management, with larviciding, and adulticiding | Fonseca et al. 2013; Foley IV et al. 2021 |
| Cattle fever tick eradication programme operating since 1906, first to eradicate *Rhipicephalus annulatus* (Say) and *Rhipicephalus microplus* (Canestrini) from the USA (1943), and since then to contain incursions along the border with Mexico | George 1989; Rutherford 2007 |
| Area-wide suppression of the Asian citrus psyllid *Diaphorina citri* Kuwayama in Florida based on coordination of insecticide sprays to protect against this vector of devastating citrus greening (huanglongbing) | NAS 2010; Singerman et al. 2017 |
| Navel orangeworm *Amyelois transitella* (Walker) area-wide management in California almonds, pistachios and walnuts through sanitation, mating disruption and integration of selective pesticides and/or biological agents | USDA/ARS 2018 |
| Glassy-winged sharpshooter *Homalodisca vitripennis* (Germar) area-wide management in California based on coordinated insecticide sprays | USDA/APHIS 2015 |

Both of these definitions have considerable merit, and they fit the majority of area-wide programmes. However, slightly different definitions may be needed to describe programmes on the conservation of natural enemies (Schellhorn et al. 2015; Heong et al. 2021), and on classical biological control where the adaptation of the introduced biological agent to all new environments cannot be known in advance of release (Knipling 1992a; Wyckhuys et al. 2021). Also, it may not be possible to clearly define the boundary of the pest population. In a similar vein, Showler (2002) stated:

> Locust swarms can be highly variable, influenced by many factors, including geography, vegetative conditions, land-use patterns, environmental sensitivity, availability of resources and tactics, prevailing winds, insecure areas, and rainfall patterns. Reliance on a single control strategy is therefore unrealistic [Showler 1997]. A more appropriate approach would be to develop specific strategies that will fit with projected scenarios, mostly by harmonizing them with national contingency plans.

### *1.2. Characteristics of Area-Wide Integrated Pest Management*

It is intuitively obvious that the immigration of individuals of a target pest into a managed ecosystem prevents the effective suppression or eradication of a population of that pest. Indeed, the dispersal and migration of pests, usually from small untreated foci into a managed area, have a tremendous impact, and is often underestimated (Byrne 2008). For example, very few codling moths develop in well-managed commercial orchards. Butt et al. (1973) found that the number of codling moths that overwintered in the Wenas Valley of Washington State, USA, dropped by 96% when a few abandoned orchards and neglected non-commercial apple trees were either removed or sprayed with insecticide. This study indicated that most of the moths originated from untreated trees that in aggregate were less than 5% of the host resources of the moth. Similarly, experiences in coping with the pink bollworm *Pectinophora gossypiella* (Saunders) and the boll weevil have shown that the few growers (who do not destroy crop residues immediately after harvest) provide food for these pests to reproduce and to enter diapause (Allen 2008; Staten and Walters 2021). This lapse in field sanitation can be the direct cause of devastating levels of these pests appearing in the following season on neighbouring farms.

Knipling (1972) graphically pointed out the drastic implications of allowing a small fraction of a population of a major pest to reproduce without control (Fig. 1). Knipling showed that more pest individuals would be produced if 1% of the total population was allowed to reproduce without control, while 100% control was applied to 99% of the population, than if only 90% control was imposed uniformly on the total population. Thus Knipling (1972) elaborated the basic principle of total population suppression:

> Uniform suppressive pressure applied against the total population of the pest over a period of generations will achieve greater suppression than a higher level of control on most, but not all, of the population, each generation.

Currently, for the most part, individual producers, who often rely heavily on the use of insecticides, carry out defensively the control of highly mobile and very destructive pests. Although other control technologies are often incorporated into the

producer's IPM system, these technologies are also usually applied by the individual producer independently of other producers. This conventional uncoordinated and localized farm-by-farm or field-by-field strategy provides opportunities for the pest population to build-up and to infest well-managed neighbouring fields. Consequently, on most farms, insect pest populations increase to damaging levels each year, and the farmer is forced to apply broad-spectrum fast-acting insecticides as a rescue treatment. This defeats the primary goal of the IPM system, which is to take maximum advantage of naturally occurring biological control agents (Rohwer and Knipling 1992; Heong et al. 2021). Moreover, the application of insecticides, when an insect pest population reaches the economic threshold, does not prevent the losses that occur before the threshold has been reached. For commodities that are planted on vast areas, such losses are immense. For example, the world production of maize (corn) was roughly 1134 million metric tons in 2017 (World Data Atlas 2017). Avoidance of a loss of only 3% would make available 34 million metric tons, which could be a major factor in alleviating hunger.

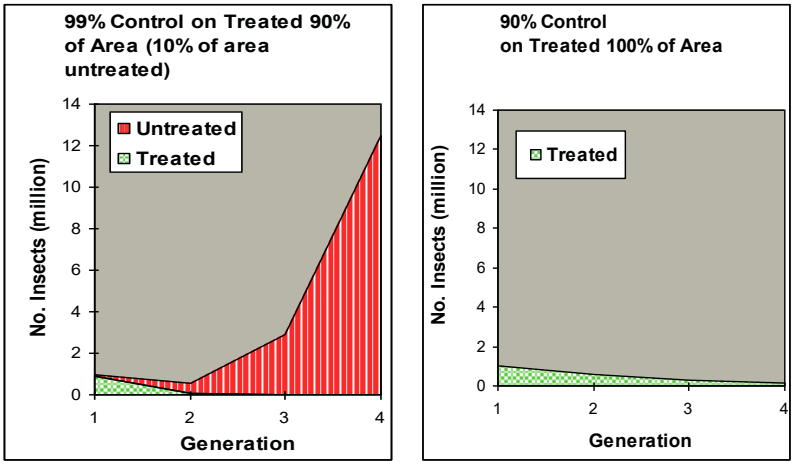

*Figure 1. Results of a model that shows the outcome of neglecting to suppress a small fraction of a pest population in an agroecosystem versus the effect of uniformly suppressing the entire pest population. Left: 10% of the population is untreated, and in four generations it produces a large number of individuals, while the 90% of the population that is treated declines. Right: Entire pest population in the agroecosystem is suppressed uniformly, and its numbers decline from generation to generation. (Figure adapted from Knipling 1972, reproduced with permission.)*

AW-IPM differs from conventional pest management of local pest populations in several important ways (Lindquist 2000; Koul et al. 2008):

1. It focuses on the preventive management of pest populations throughout the ecosystem, while the conventional strategy focuses narrowly on defending a valued entity (crop, livestock, people, buildings, etc.) from direct attack by pests.
2. It requires multi-year planning and commitment, and an organization dedicated exclusively to implementing the strategy; the conventional strategy involves only

minimal forward planning, tends to be reactive, and is implemented independently by individual producers, businesses, or households.
3. It tends to utilize advanced "high-tech" technologies, whereas the conventional strategy tends to rely on traditional "low-tech" tactics and tools that can be reliably implemented by non-specialists (Lindquist 2000, 2001).

Community-based control can be considered as a special case of localized control whereby local communities are responsible not only for the implementation of the control activities but are also involved in their development and management (Vreysen 2001). There have been many examples of community-based control in Africa against tsetse fly populations, and these have shown that these operations can be successful in small areas and when the farmers have access to expertise and initial "seed money" (Dransfield et al. 1991). However, none of these community-based control activities has proven to be sustainable as exemplified by such efforts against the vectors of human sleeping sickness in Ivory Coast (Laveissière et al. 1985) and Uganda (Lancien 1991), or the vectors of nagana in Kenya (Dransfield et al. 1991). The reasons for the unsustainability of this approach are multiple, e.g. lack of scale and central coordination, various sociological factors (e.g. theft of the suppression devices, sustaining the interest of the farmers, willingness to contribute, etc.), inaccessibility of some habitats, and the need to deploy the suppression tools at high densities in some habitats (Vreysen 2006). Despite the quick localized benefits these approaches can bring, they cannot be sustained indefinitely by communities, becoming ineffective in the long run (Vreysen 2001).

Indeed, it is the use of organizations dedicated to coordinate and conduct area-wide programmes that provides the opportunities to employ sophisticated technologies and professional management. Computer-based models are utilized in planning and management (Bouyer et al., this volume), and satellite imagery is used to identify localities of alternate hosts that can be treated to reduce the number of migrants that cause the damage in commercial production areas. Area-wide programmes acquire or develop highly sensitive detection systems, use spatial tools such as the global positioning system (GPS), geographic information systems (GIS), and satellite remote sensing (RS), and employ specialised software for data management to ensure efficient implementation of these programmes.

Also, they may implement area-wide approaches to resistance management to prevent or retard the development of resistance to insecticides or the loss of host-plant resistance (Prasad et al. 2009). Computer programmes and real-time environmental data to predict insect populations can be used effectively in an area-wide programme, but usually not on an individual farm basis. Thus, modelling of pest distribution and immigration patterns, analysis of weather to predict increases or decreases of populations, genetic analysis to determine and forecast resistance levels, or to assess the level of isolation of targeted insect pest populations, etc., are utilized in area-wide programmes (Elliott et al. 2008; Bakhoum et al. 2021; Bouyer et al., this volume).

Most insect populations are not distributed uniformly in time and space (Vreysen, this volume). Metapopulation and landscape ecology are approaches that have been used to study or characterize spatially structured insect populations, and the basic concept of these dynamics is the heterogeneity of the environment (Levins 1969; Clark 2010). This heterogeneity results in discrete patches that are suitable or

unsuitable, as well as persistent or unstable, for inhabitation of the pest insect (Elliott et al. 2008). The main difference between the two approaches involves the role of the matrix in the dynamics of the population patches, i.e. uninhabitable but consistent effects on the dynamics of the population in the metapopulation approach versus the matrix having varying effects on the local populations in the landscape ecology approach, which can influence within-patch dynamics (Hanski 1998). These approaches are important predictive modelling tools for a better understanding of the dynamics of the pest populations and, hence, allow for better planning of AW-IPM programmes.

Efficient implementation of AW-IPM requires defining the temporal and spatial scales that must account for the behaviour and longevity of the target pest. The minimum time-unit for analysis is likely to be the generation time of the target insect, whereas the minimal spatial unit should be the average two- or three-dimensional scale that a target insect can disperse within a generation (Elliott et al. 2008), and should be large enough to encompass all normal movement of the average individual insect (Schneider 1989; Barclay et al. 2011).

Finally, area-wide programmes can take advantage of the power and selectivity of specialized methods to manage insect pests that, for the most part, are not effective when used on a farm-by-farm basis. These include the SIT, inundative releases of parasitoids, the use of semiochemicals, mating inhibitors, large-scale trap cropping, treatment of hosts on public lands and in private gardens, etc.

### *1.3. Benefits of Area-Wide Integrated Pest Management*

Suppressing highly mobile pests on an area-wide basis is usually more benign environmentally, more effective, and more profitable, than on a farm-by-farm basis because of economies of scale (Carlson and Wetzstein 1993; Keenan and Burgener 2008). Also, AW-IPM is better at capturing the benefits of mobile natural enemies (Knipling 1992a; Ives and Settle 1997).

Area-wide programmes enable many producers and other stakeholders to pool resources to utilize technologies and expertise that are too expensive for individual producers. These may include mass-rearing facilities, aircraft services, information technologies, and highly trained specialists. In addition, a coordinated area-wide programme can avoid or internalize external costs. External costs (externalities) are the harmful effects arising from pest control operations, which affect parties other than the pest control decision-maker, but for which no compensation is paid to the persons harmed (Reichelderfer et al. 1984). Spray drift onto neighbouring properties frequently provokes disputes. Also, insecticide use to protect agricultural crops has caused resistance to develop in other insects, including vectors of disease. This has been an important factor in the resurgence of malaria.

AW-IPM is more likely to succeed when the number of farmers involved is small and the crops are similar. In addition, the suppression of the pest under the leadership of a third party makes it easier for a heterogeneous group of farmers to collaborate. Farmers who cultivate crops with a high economic value and low-pest tolerance suffer greater losses than farmers who cultivate a crop of lower economic value but with a higher pest tolerance (Yu and Leung 2006). Therefore, it is much

easier to encourage the former to participate in an area-wide programme as compared with the latter (Stonehouse 2007).

AW-IPM provides imperfect public goods, and is prone to free-riding, and therefore most successful programmes depend on government funding, coordination, and management (Hendrichs et al. 2007). However, joint funding by federal/state governments and growers can enhance implementation because growers are stakeholders (Ervin and Frisvold 2016). The contributions of the producers and/or the general public (Halasa et al. 2012; Mumford, this volume) are often obtained by levying taxes, e.g. the codling moth programme in Canada (Nelson et al. 2021), or through contracts between farmers and a private entity, e.g. the false codling moth *Thaumatotibia leucotreta* (Meyrick) programme in South Africa (Boersma 2021). Sometimes, unexpected economic outcomes are obtained, e.g. results from an AW-IPM programme against the Queensland fruit fly *Bactrocera tryoni* (Froggatt) in Australia indicated that returns from tighter roadblocks were greater than returns from increased surveillance or enhanced eradication capacity (Florec et al. 2013).

Benefit/cost analyses have become important and valuable tools to assess the direct and indirect benefits of AW-IPM programmes; they provide consistency, flexibility, objectivity, and comprehensiveness at the decision-making stage (Enkerlin et al. 2007; Quinlan and Larcher-Carvahlo 2007; Mumford, this volume). Direct benefits are easy to assess because they result from increased crop yield and crop quality, increased livestock productivity, and reduced insecticide use and control costs. Indirect benefits are more difficult to quantify because they often relate to reduced environmental or human-health costs (Quinlan and Larcher-Carvahlo 2007; Enkerlin, this volume).

As evidenced by the few examples below, the benefits of properly executed AW-IPM programmes can be enormous:

1. The boll weevil, since its introduction into the USA in the 1890s, has cost the cotton industry more than USD 2300 million in economic losses. As exemplified in Georgia, its eradication provided significant benefits to growers; the average gross crop revenues increased from USD 70 million per year (prior to eradication) to USD 400 million per year (afterwards) (USDA/APHIS 2013).
2. The eradication of the New World screwworm *Cochliomyia hominivorax* (Coquerel) in North and Central America resulted in annual benefits to livestock keepers amounting to USD 1300 million, despite an investment of the same amount to eradicate the pest over 45 years. The eradication of the same pest when it invaded Libya resulted in a benefit/cost ratio of 5:1 for the infested area and 10:1 for the whole of Libya (Vargas-Terán et al., this volume).
3. A recent benefit/cost analysis of the Moscamed containment programme, assuming that the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) is eradicated in Guatemala and the containment barrier is moved to the border with El Salvador and Honduras, indicated a benefit/cost ratio of 140:1 for Belize, 16:1 for Guatemala, and 127:1 for Mexico (Enkerlin et al. 2017).
4. An economic analysis of an AW-IPM programme against the Asian tiger mosquito *Aedes albopictus* (Skuse) in New Jersey, USA (based on adulticiding, larviciding, and resource reduction) indicated that the incremental cost of the programme was USD 41 per person per year. Over a period of 3 years, a benefit/cost ratio of 8.6:1 was obtained, indicating that for every USD spent, the

programme gave adults additional time outdoors worth USD 8 (Shepard et al. 2014).

Finally, economies of scale can be captured in area-wide programmes, although complex trade-offs may be involved. The more mobile the pest, and the more uniform the damage caused by the pest, the larger the area under coordinated management should be (Barclay et al. 2011). The total cost of pest detection, monitoring, and suppression per hectare of crop usually declines as the size of the managed area increases. However, as the project size increases, the per-hectare organizational cost usually increases because of the increased need for coordination and other communication costs. For these reasons, in very large programmes such as the effort to eradicate the boll weevil or the pink bollworm in the USA, the vast area was subdivided into several operational zones (Allen 2008; Staten and Walters 2021). Also, considerable organizational cost savings may be realized in instances where towns, municipalities, or cooperatives already have structures in place for decision-making and communication.

### *1.4. Contingencies Often Dictate Changes in Strategy*

Contingencies often arise that require replacement of one strategy with another (Geier 1970; Hendrichs, Vreysen et al., this volume). For example, at various times during the 45-year campaign to remove the New World screwworm from the USA, Mexico and Central America, different pest management strategies had to be selected. This programme began when an unusual series of frosts, beginning early in December 1957, killed all screwworms in the south-eastern USA north of a line from Tampa to Vero Beach in southern Florida. Sexually sterile flies, from a culture in a research laboratory, were released in a broad band north of this line to contain the pest population. In the summer of 1958, this exclusion or containment strategy was replaced by the strategy of eradication; the sterile flies were derived from a recently constructed mass-rearing facility that was able to produce 50 million sterile flies per week. Eradication was accomplished in 1959; in 1966 the New World screwworm was officially declared eradicated in the USA. However, it was obvious that, unless the insect was removed from northern Mexico, it would reinvade the USA. Nevertheless, the programme to eradicate the screwworm from northern Mexico could not commence immediately because, until 1972, there was no agreement between the Governments of the USA and Mexico. Therefore, in 1966, the programme strategy had to change from eradication to exclusion in the form of a sterile-insect barrier along the entire Mexico-USA border. Sterile flies were released in a zone that was about 130-km wide. Unfortunately, this barrier proved to be too narrow to exclude female screwworms from entering the USA and causing many cases of screwworm myiases (Graham 1985). Finally, operations began in Mexico in 1974. The last screwworm case in the USA occurred in 1982 (Vargas-Terán et al., this volume).

### *1.5. Legal Authority for Area-Wide Integrated Pest Management*

Legal authority to implement area-wide and other regulatory programmes is absolutely essential, but is still evolving (Dyck, Reyes Flores et al., this volume). Without explicit legal authority, the organization implementing an area-wide programme would not be able to conduct operations on private property, nor operate quarantines.

In about 1860 the grape phylloxera *Daktulosphaira vitifoliae* (Fitch) was introduced into France from the USA. Within 25 years of its arrival, this insect had destroyed one million ha of vineyards (fully one-third of the production capacity). To protect the German wine industry, in 1873 the Government of Germany passed the first law that provided for quarantines and regulatory control of agricultural pests (NAS 1969). Other governments quickly followed the example, and in 1881 representatives of many European countries together developed a set of regulations governing the movement of grape-propagating material.

In about 1880 the establishment of the San Jose scale *Quadraspidiotus perniciosus* Comstock in California, its rapid spread on nursery stock throughout the country, and the failure of a programme to eradicate it, caused Canada, Germany, and Austria-Hungary in 1898 to prohibit the importation of American fruit and living plants (Klassen 1989). This crisis in the USA led to the passage in 1905 of federal legislation on quarantine and the regulation of interstate shipments (Plant Quarantine Act) (Womach 2005).

Indeed, now many countries have legislation on: (1) prevention of the introduction of new pests from foreign countries, (2) prevention of the spread of established pests within the country or state, and (3) enforcement of the application of control measures against exotic pests to prevent their introduction and establishment, eradicate their outbreaks, retard their advance or prevent damage by them. In some countries the law allows people, who wish to organize a programme against a pest, to hold a referendum. If the referendum passes by a certain margin (usually 67% in US counties), then all parties at interest must cooperate in the venture (Boll Weevil Eradication Law 1992; Grefenstette et al. 2009; Ervin and Frisvold 2016).

The programme to eradicate the citrus canker disease in Florida was initiated in 2000 but was hampered for 4 years because of insufficient legal authority. This pathogen is carried considerable distances on driving rain, and to achieve eradication the Division of Plant Industry decided to destroy all citrus trees within a radius of 578 m from an infected tree. Homeowners in urban areas, who did not understand the need for such drastic action, felt that their rights were violated by workers who, as part of the eradication programme, entered residential yards and destroyed citrus trees. Thus, the Broward County Circuit Court ruled that programme employees must have a separate court-issued warrant to enter each privately-owned property. The need to apply for tens of thousands of warrants prompted the Florida Department of Agriculture and Consumer Services to appeal this ruling; in 2004 the Florida Supreme Court overturned it. Nevertheless, as a result of all these delays, during which three major hurricanes traversed infected areas, the disease was spread widely, and the mandatory eradication programme had to be abandoned in January 2006 (Centner and Ferreira 2012).

### *1.6. Apathy, Outrage, and Area-Wide Integrated Pest Management*

The strategy of eradication emerged just over a century ago as the brainchild of C. H. Fernald of the University of Massachusetts, USA. Under Fernald's leadership, Massachusetts attempted to eradicate an introduced pest, the gypsy moth, in an 11-year campaign from 1890 to 1901. Initially, the primary eradicant was Paris green, but this insecticide, of only modest efficacy and phytotoxicity, had to be abandoned because of adverse public reaction. Forbush and Fernald (1896) noted:

> Considerable opposition to the use of Paris green for spraying was manifested by many people living in the infested towns. A mass-meeting of opponents of the spraying was held in Medford. One citizen, who attempted to cut the hose attached to one of the spraying tanks, and threatened with violence the employees of the Board who had entered upon his land, was arrested and fined. Others neutralized the effects of the spraying by turning the garden hose upon trees and shrubs that had been sprayed, and washing off the solution. The opposition to the spraying affected the results of the work unfavourably to a considerable extent.

Clearly, apathy by many members of the public had turned into outrage.

If not concerned primarily with the economic dimension of the pest problem, stakeholders tend to be highly concerned with ecological, environmental, social, and human-health implications of area-wide programmes (Rabb 1972; Dreistadt 1983; Scribner 1983; Myers et al. 1998). Therefore, leaders of AW-IPM programmes need to be very sensitive to the perceptions and attitudes of the public toward certain programme operations (Dyck, Regidor Fernández et al., this volume). Often, eradication efforts must be conducted by the ground rules of the urban, rather than rural, setting. In programmes to eradicate outbreaks of the Mediterranean fruit fly in California and Florida, members of the urban public strongly protested against the aerial malathion bait-spray applications (Scribner 1989), even though the same insecticide was used without dissent for mosquito abatement. On the other hand, the same public has usually applauded the release of sexually sterile male flies.

As explained by Sandman (1987), the public is usually apathetic towards technological programmes. However, certain factors inherent in programmes, and in the manner in which they are managed, can precipitate an almost irreversible shift in the public's attitude from apathy to outrage. A sense of outrage can be evoked by involuntary exposure to pesticide residues, imposed levies of fees, quarantines, right of trespass, unfair and inequitable sharing of risks, costs and benefits, temporary loss of control of one's property or field operations, the perception that endangered species may be harmed, etc. Starr (1985) asserted that:

> Public acceptance of risk is more dependent on public confidence in risk management than on the quantitative estimates of risk consequences, probabilities and magnitudes.

He noted that, when a zoo wishes to acquire a tiger, the public does not demand a refined assessment of the risk that the tiger might escape and kill someone. Instead, the public wants assurance that the zookeeper can be trusted to prevent the tiger from escaping, and that, if the tiger should escape, the zoo is fully prepared to implement an emergency plan to meet this contingency. Similarly, the public's confidence in the management of an area-wide programme is of paramount importance.

In each area-wide programme, a special effort must be made to anticipate and identify those factors that may be emotionally upsetting to various stakeholders, and take pre-emptive actions to avoid or mitigate adverse reactions. Public officials must be kept apprised, public education materials produced (FAO/IAEA 2017), fora must be created for effective two-way communication with the public, surrogates of the public must be included in oversight and decision-making processes, and referenda may have to be conducted to secure support and funding for the programme (Batra and Klassen 1987; Klassen 1989; Dyck, Regidor Fernández et al., this volume).

### *1.7. Invasive Pests, Global Trade, and Area-Wide Integrated Pest Management*

The rapid globalization of trade in agricultural products, and increasing tourism, have dramatically increased the spread of invasive harmful organisms (Klassen et al. 2002; Hendrichs, Enkerlin et al., this volume). We have entered an era of an unprecedented level of travel by exotic invasive organisms. Native flora and fauna on islands are sustaining great harm from non-indigenous invasive organisms, and major pests are becoming established with increasing frequency on all continents, except Antarctica.

For about a century many countries relied on the inspection of arriving cargo and passengers at the port of entry as the primary exclusion strategy. However, the volume of arriving cargo is doubling every 5 or 6 years (Zadig 1999), and it is not possible to increase similarly the human and other resources devoted to inspection at ports of entry. Clearly exclusion at the port of entry is no longer sufficient to protect plant resources, even though a number of emerging technologies are likely to facilitate safeguarding activities (Batkin 1999). Thus, to stem the influx of exotic pests into the USA, the National Plant Board asserted that the most important change needed in the US safeguarding system is to shift primary reliance from exclusion at the port of entry to offshore actions, i.e. pest-risk mitigation in the areas of production, certification at the point of origin, and pre-clearance at the port of export (NPB 1999).

An important approach to offshore risk mitigation is the creation of pest free areas. Indeed, countries that export raw agricultural commodities can effectively remove the threat of exotic pests to the importing country by creating and maintaining pest free areas (Rohwer 1992; Malavasi et al. 1994; Dalal et al. 2017; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume). A pest free area is an area in which a specific pest does not occur as demonstrated by scientific evidence and in which, where appropriate, this condition is being officially maintained (FAO 2019). There are two kinds of pest free areas: (1) pest free zones — large geographic areas, including entire countries such as Chile, Japan or New Zealand — that are certified free of tropical fruit flies of economic importance, and (2) pest free production fields or areas that require demonstration of non-host-status or the demonstrated suppression of quarantine pests to non-detectable levels. In addition, there are low-prevalence areas that are established by means of a systems approach through the application of a series of preharvest and postharvest suppression and mitigating measures.

According to Griffin (2000), both the International Plant Protection Convention (IPPC) and the World Trade Organization (WTO) Agreement on Sanitary and Phytosanitary Measures (Devorshak 2007):

> … are structured to accept and encourage area-wide pest management as a tool for promoting safe trade and contributing as much as possible to the complementary goals of food security and economic security for all countries.

The first US-recognized pest free area was established in 1988 in Sonora, Mexico (SARH/DGSV-USDA/APHIS 1990), and since then Mexico has been ridding large additional sections of its territory of all fruit fly species of economic importance (CNCMF 2002). The Mexican states of Baja California, Chihuahua, and Sonora have been freed of all economically important species of fruit flies. Citrus, stone fruits, apples, and vegetables are being exported from these states without any suppression or postharvest treatment. In other parts of Mexico, low-prevalence fruit fly areas are being established by means of a systems approach (Reyes F. et al. 2000; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume). Chile rid the entire country of the invasive Mediterranean fruit fly by 1995 (SAG 1995), and since then large volumes of Chilean fruits have been exported to the USA and other markets without the need for any quarantine treatments. Also, other countries have created fruit fly-free areas (Rendón and Enkerlin 2021; Enkerlin, this volume).

Other examples of successfully preventing the establishment of invasive insect pests are the eradication of outbreaks of the European grapevine moth *L. botrana* in California (Simmons et al. 2021), the red palm weevil *R. ferrugineus* in the Canary Islands (Fajardo et al. 2021), the painted apple moth *Teia anartoides* Walker in New Zealand, and the cactus moth *Cactoblastis cactorum* (Berg) in Mexico (Hendrichs, Enkerlin et al., this volume; Simmons et al., this volume).

An area of low pest prevalence is an area (whether the entire country, part of a country, or all or parts of several countries), identified as such by the competent authorities, in which a specific pest occurs at low levels, and which is subject to effective surveillance, suppression or eradication measures (FAO 2019; Hendrichs, Vreysen et al., this volume). Requirements to establish low-prevalence areas include a sensitive detection programme, suppression of the quarantine-significant pest to non-detectable-levels, strict sanitation and control of the fields, and safeguards to prevent infestation during packing and transit to the port of export (Riherd 1993; Simpson 1993; Malavasi et al. 1994; Riherd et al. 1994).

Florida is able to export grapefruit to Japan by creating pest free grapefruit groves in about 22 counties. Regulatory experts from Japan inspect the entire process of production, packing, and transit. Official protocols for pest free fields can be found in Gomez (1999). Similarly, fruit groves free of the South American cucurbit fruit fly *Anastrepha grandis* (Macquart) have been created in Mossoro, Brazil, and Guayaquil, Ecuador, through demonstration of non-host status under appropriate crop management (Malavasi et al. 1994).

The concept of low prevalence, using bait sprays and the SIT, was pioneered during the early 1960s against the Mexican fruit fly *Anastrepha ludens* (Loew) along the Mexico-USA border (Knipling 1979). Also, in the early 1960s, the Citrus Marketing Board of Israel developed a bait-spray-based area-wide programme

against the Mediterranean fruit fly that has been able to meet the certified quarantine security requirements of fruit-importing countries (Cohen and Cohen 1967).

A significant development has been a preventive approach involving the continuous area-wide release of sexually sterile male Mediterranean fruit flies in the Los Angeles Basin (Dowell et al. 2000; USDA/APHIS 2004; Enkerlin, this volume), and around high-risk ports in southern Florida, to prevent Mediterranean fruit fly establishment resulting from recurrent introductions in ports of entry (USDA/APHIS 1998; Hendrichs, Enkerlin et al., this volume).

### *1.8. Area-Wide Integrated Pest Management – Future Directions*

Despite the fact that AW-IPM programmes are technically complex and managerially challenging (Vreysen et al. 2007), this strategic approach bears great promise for the future. Over the last two decades, interest in this strategy has been mounting, especially considering the substantial benefits obtained when area-wide programmes are properly executed. However, it should be emphasized that these programmes require long-term planning, i.e. from stakeholder commitment to feasibility studies, pilot trials, and pre-operational and operational phases (Vreysen et al. 2007; Bouyer et al. 2020; Vreysen et al. 2021; Vreysen, this volume); they also need close collaboration among researchers, farmers, extension workers, community leaders, local and regional governments, and the general public (Liu and Yan 1998).

AW-IPM is probably most appropriate for high-value crops, key livestock pests, and major human-disease vectors; it is also appropriate for those rural areas where the number of farmers is small, agroecological heterogeneity is low, and only a few key pests need to be addressed (Hendrichs et al. 2007). However, the approach may not be applicable to very mobile or migratory insects or to all animal- or human-disease vectors.

A major obstacle to the successful implementation of AW-IPM is the lack of trained extension workers -- that may lead to even increased insecticide inputs. In Asia, many state-employed extension workers are also involved in marketing insecticides, and their advice to farmers becomes biased against IPM approaches (Koul and Cuperus 2008; Heong et al. 2021). Better education of farmers and the general public will remain key to better implementation of AW-IPM programmes, and also to better understand economic trade-offs among treatment alternatives.

Another major limitation in implementing AW-IPM, as advocated by E. F. Knipling, is the lack of sufficient knowledge about the spatial and temporal dynamics of the target pest insects (Levandowsky and White 1977). Recent advances in landscape ecology (Pickett and Cadenasso 1995) and ecological modelling (Carrière et al. 2006) can help explore the temporal and spatial dynamics of the pest insect. In addition, landscape genetics, an innovative emerging approach (that associates population genetics of the target insect with spatial tools) enables an understanding of how geographic and environmental features structure genetic variations at the population level (Bakhoum et al. 2021). This approach not only increases ecological knowledge but also explains spatial genetic patterns, isolation by distance, genetic boundaries to gene flow, etc. (Manel et al. 2003). All of these new tools and approaches can facilitate conceptualizing AW-IPM programmes.

Improved lifestyles and higher gross domestic products will result in increased aversion to insecticide use, and consumers will be increasingly prepared to pay a higher price for clean biological commodities. Major opportunities to promote AW-IPM will be closely linked with consumers' demand for food safety, and with increased support for research, extension services, and legislation (Koul and Cuperus 2008).

## 2. BASIC ELEMENTS OF THE SIT

The SIT is an autocidal genetic control tactic that interferes with the reproductive potential of a target pest population. It can be considered as a form of birth control imposed on an insect pest population to reduce its numbers. The SIT harnesses the sex drive of insects. According to the International Plant Protection Convention (IPPC) (FAO 2019), a sterile insect is defined as:

> An insect that, as a result of a specific treatment, is unable to reproduce.

and the SIT is defined as:

> Method of pest control using area-wide inundative release of sterile insects to reduce reproduction in a field population of the same species.

The SIT requires the rearing of large numbers of the target pest species, exposing them to ionizing radiation to induce sexual sterility, and releasing them into the target pest population on an area-wide basis. A derivative of the SIT avoids the need to mass-rear the target insect pest species by attracting individuals of the wild populations to a chemosterilant, e.g. Mediterranean fruit fly (Navarro-Llopis et al. 2004) and *Glossina* spp. tsetse flies (Hargrove and Langley 1990; Langley 1999). The latter approach, however, has only been used on an experimental basis. Thus, treated insects are prevented from reproducing; they act as biological agents that nullify the biological potential of untreated individuals with which they mate. Both kinds of SIT are effective only against pest species that reproduce sexually (Lance and McInnis, this volume).

### *2.1. How Sterile Males Suppress Populations: Numbers Game*

Knipling (1968) recognized that the level of suppression required to stabilize the density of a population depends on its intrinsic rate of increase (Table 2).

Knipling (1968) estimated that an overwintering screwworm population typically increases approximately five-fold for the next two or three generations. For example, if in an area of 100 000 $km^2$ 1 000 000 screwworms overwinter, this population will increase to 5 000 000, 25 000 000, and 125 000 000 in the $F_1$, $F_2$, and $F_3$ generations, respectively. To calculate the consequences of releasing sterile screwworms into a population of fertile screwworms, Knipling listed the various types of matings, calculated the frequency of each type of mating, and assigned ten progeny to each mating of an untreated female (UF) with an untreated male (UM). When both sterile males (SM) and sterile females (SF) are released, there are four types of matings possible. Thus the wild population has 500 000 untreated males [UM] and 500 000

untreated females [UF], and 4 500 000 sterile males [SM] and 4 500 000 sterile females [SF] are released. The frequencies of the various matings, and the number of progeny produced, are shown in Table 3. Using this method, Knipling calculated the trend of this hypothetical screwworm population (Table 4).

*Table 2. Rates of mortality and survival required to maintain a stable pest population*

| Intrinsic rate of increase between generations | Number of progeny per female | Number (fraction) that must survive to prevent population from declining. | To prevent population increase | | |
|---|---|---|---|---|---|
| | | | Number (fraction) that must die | Percentage that must die | Percentage that may survive |
| 2-fold | 4 | 2 (1/2) | 2 (1/2) | 50 | 50 |
| 3-fold | 6 | 2 (1/3) | 4 (2/3) | 67 | 33 |
| 4-fold | 8 | 2 (1/4) | 6 (3/4) | 75 | 25 |
| 5-fold | 10 | 2 (1/5) | 8 (4/5) | 80 | 20 |
| 10-fold | 20 | 2 (1/10) | 18 (9/10) | 90 | 10 |
| 20-fold | 40 | 2 (1/20) | 38 (19/20) | 95 | 5 |

Knipling realized that, to obtain a reduction of the wild population, the degree of sterility introduced into the wild population by releasing sterile males must be sufficiently high to overcome the rate of increase (reproductive success) of the wild females. Knipling (1968) stated:

> If we assume that a given insect has a net capacity to increase five-fold each generation, the ratio of fully competitive sterile to fertile insects will have to be 4:1 to keep the natural population stable. Theoretically, an initial ratio as low as five sterile to one fertile will be adequate to start a downward trend in the natural population when the net increase rate is only five-fold. Actually, starting with this lower overflooding ratio, theoretical elimination of the population will be achieved with fewer insects than will be required with a 9:1 ratio. However, in actual practice, the density of insects will vary in different parts of the environment. Moreover the distribution of sterile insects will never be uniform. Therefore, in control operations, the initial ratio should be sufficiently high to be certain that an overall reduction in the population will occur in all parts of the environment from the start. In some instances, the sterility procedures might reduce the vigour and competitiveness of the organism. Allowance must be made for this factor.

As shown in Table 4, the ratio of sterile to fertile insects increases asymptotically as the density of the wild population declines to low levels. Thus, to take advantage of the tremendous power of the SIT against sparse populations of pests, Knipling advocated that the release of sterile insects should be initiated when the wild population was at a seasonal low or immediately after its decimation by adverse weather events, such as freezes and hurricanes. In addition, Knipling (1966, 1979, 1992a) designed pest management systems in which insecticides, biocontrol agents, etc., were used to reduce the density of the target population to a level at which the SIT could manifest its great suppressive power (Fig. 2).

*Table 3. Method of calculating frequencies of various types of matings and resultant progeny when sterile males and females are released into a population of untreated males and females (text provides details)*

| Type of mating | Number of matings | Number of progeny/ mating | Number of progeny |
|---|---|---|---|
| UF X UM | $\frac{500\,000 \text{ X } 500\,000}{5\,000\,000} = 50\,000$ | 10 | 500 000 |
| UF X SM | $\frac{500\,000 \text{ X } 4\,500\,000}{5\,000\,000} = 450\,000$ | 0 | 0 |
| SF X UM | $\frac{4\,500\,000 \text{ X } 500\,000}{5\,000\,000} = 450\,000$ | 0 | 0 |
| SF X SM | $\frac{4\,500\,000 \text{ X } 4\,500\,000}{5\,000\,000} = 4\,050\,000$ | 0 | 0 |

*Table 4. Trend of an insect population subjected to sterile insect releases when the normal increase rate is five-fold*

| Generation | Uncontrolled natural population (5 X increase rate) | Controlled population | | Ratio of sterile to fertile |
|---|---|---|---|---|
| | | Natural population | Sterile population | |
| 1 | 1 000 000 | 1 000 000 | 9 000 000 | 9:1 |
| 2 | 5 000 000 | 500 000 | 9 000 000 | 18:1 |
| 3 | 25 000 000 | 131 625 | 9 000 000 | 68:1 |
| 4 | 125 000 000 | 9535 | 9 000 000 | 942:1 |
| 5 | 625 000 000 | 50 | 9 000 000 | 180 000:1 |

## 3. USING THE SIT TO IMPLEMENT PEST MANAGEMENT STRATEGIES

The major pest management strategic options or objectives are: (1) suppression, (2) eradication of well-established pest populations, (3) containment (exclusion) and (4) prevention of invasive pest establishment (Hendrichs, Vreysen et al., this volume).

The SIT is a pest-specific tactic that can play a role in implementing all of these area-wide strategies. In this sense, a "tactic" is a method for detecting, monitoring or controlling a pest. A "system" is an assemblage of tactics that are applied simultaneously or sequentially so that the effects of individual tactics on the pest population are either additive or mutually potentiating, and counter-productive

(negative) interactions are avoided or minimized. A pest management "strategy" is a broad overall plan that aims to achieve the specific strategic objective. The merits of a pest management strategy may be judged by its short- and long-term ecological, economic, sociological and political impacts (Rabb 1972; Enkerlin 2003; Enkerlin et al. 2003; Hendrichs, Vreysen et al., this volume).

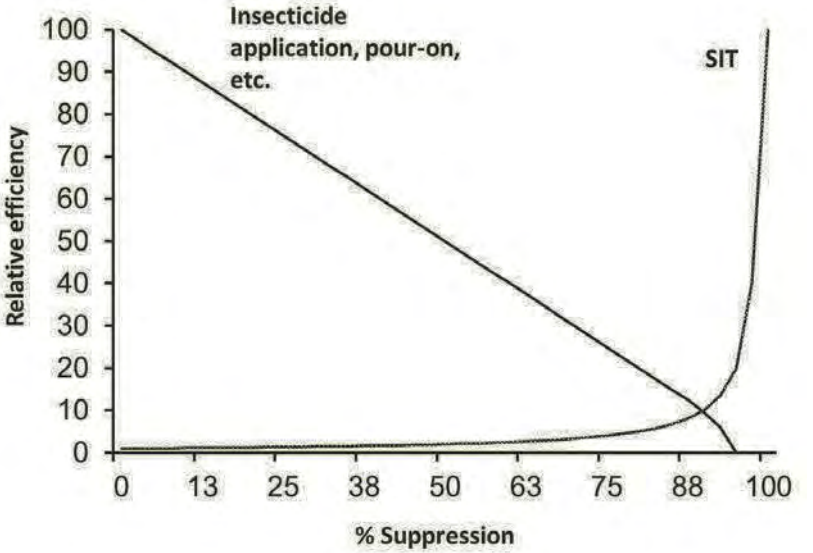

*Figure 2. Schematic representation of the sequential use of methods of suppression that efficiently decimate a pest population followed by using the SIT, which becomes progressively more suppressive as the population declines. The term "efficiency" refers to the ease in further suppressing the population, and not to the cost of eliminating an individual pest (cost per kill). (Figure adapted from Feldmann and Hendrichs 2001.)*

To implement a strategy effectively and efficiently, each control tactic has characteristics that need to be considered in the design of a system. The relationship of the density of the pest to the efficiency of the control tactic is of paramount importance. Some tactics (such as insecticide spraying) are most useful only against dense and moderately dense populations, while others, such as the SIT and sex pheromones, are effective only against sparse populations. Also, ecological selectivity is important to avoid the destruction of natural enemies needed to prevent the resurgence of the pest population following a control operation, and to prevent environmental damage. Most conventional insecticides are non-selective, whereas the SIT and other genetic techniques, pheromones, pest-resistant crop varieties, certain insect pathogens, parasitoids and predators, and certain artificial and naturally occurring attractants, are highly selective tactics. Light traps, some attractant baits, "general" predators, parasitoids and pathogens, and certain insecticides, are only moderately selective.

### *3.1. Principles of Designing Pest Management Systems*

The design of a pest management system requires information on the selectivity and efficiency of available tactics. When the suppression of populations to a very low level is required, methods that are effective against high populations, and methods that are effective against low populations, should be integrated so that the actions of the former potentiate those of the latter (Fig. 2) (Mangan and Bouyer, this volume). For example, the use of a selective insecticide potentiates the SIT by increasing the sterile:fertile ratio. Moreover, the release of both a pest-specific parasitoid and sterile insects is likely to be mutually potentiating (Simmons et al., this volume). When the economic threshold of the pest is moderately high, several tactics that have additive effects against dense populations may be combined to give much more reliable suppression than from a single method. Knipling (1979) discussed these principles thoroughly (Hendrichs, Vreysen et al., this volume).

### *3.2. SIT and Local Suppression of Portions of Populations*

Since 1981, the SIT has been used commercially to suppress locally the onion fly *Delia antiqua* (Meigen) on an area of ca. 10 000 ha in The Netherlands (Loosjes 2000; Everaarts 2016). The flies are reared year-round and stockpiled for release during the onion-growing season. To protect against immigrant flies, sterile flies are constantly maintained in the fields. Individual farmers contract for the SIT independently of their neighbours, many of whom use chemical control. Free-riders (growers in the release area who benefit but do not pay) weaken this local suppression programme, which has only been able to expand gradually over the years to 40% of the onion-producing area. In addition, further efficiency is lost because the onion fields receiving sterile flies do not form a contiguous block (Everaarts 2016).

### *3.3. SIT and "Total" Population Suppression*

The SIT can be applied for population suppression rather than eradication (Hendrichs, Vreysen et al., this volume). As a sequel to the 1993/1995 Oslo Accords, AW-IPM programmes using the SIT against the Mediterranean fruit fly were established in some fruit-producing areas of Israel, Jordan, and the Territories under the Jurisdiction of the Palestinian Authority. Enkerlin and Mumford (1997) concluded that, over a 9-year time frame, the net economic benefits from this SIT suppression programme would be greater than from an SIT-based eradication programme, or from an area-wide bait-spray programme. Assuming that sufficient sterile flies can be purchased from existing rearing facilities, SIT suppression is profitable beginning in the first year. In contrast, eradication would have a payback period of 4 years, because of the need for an upfront investment in a rearing facility, high quarantine costs, and the need for more intensive monitoring. Similar SIT suppression programmes are ongoing in the Western Cape of South Africa (Venter et al. 2021), and Valencia, Spain, and Neretva, Croatia, in southern Europe (Bjeliš et al. 2016; Enkerlin, this volume).

The SIT suppression programme against the codling moth in Canada substantially reduced populations of the pest and also the number of insecticidal sprays. Similar success against the false codling moth in South Africa was achieved (Bloem et al. 2001; Boersma 2021; Nelson et al. 2021; Simmons et al., this volume).

### *3.4. SIT and Eradication of Well-Established Populations*

Eradication of a pest population is the sustainable removal of every individual of the pest species in an area surrounded by natural or man-made barriers sufficiently effective to prevent reinvasion except through the intervention of man (Newsom 1978; Hendrichs, Vreysen et al., this volume). Although the eradication of a population may not endure forever, the elimination of a pest from a defined area, followed soon after by reinvasion, is not considered to be eradication.

Through an unrelenting effort from 1957 to 2000, the SIT, as part of an AW-IPM strategy, was used to eradicate the New World screwworm in its native range in the southern USA, Mexico, and Central America (Vargas-Terán et al., this volume). An area-wide programme was essential because the screwworm infested wild as well as domestic animals. Similarly, the SIT was an important component of the AW programmes that eradicated the pink bollworm in southern USA and northern Mexico (Staten and Walters 2021), as well as the Mediterranean fruit fly in areas of Argentina, Chile, USA, and Mexico, and the melon fly *Zeugodacus cucurbitae* (Coquillett) in the Okinawa archipelago of Japan (Kuba et al. 1996; Enkerlin, this volume).

The SIT was used as part of an integrated approach to eradicate tsetse populations in Nigeria and Burkina Faso in West Africa, but as the approach was not area-wide, the eradication status could not be sustained (Cuisance et al. 1986; Oladunmade et al. 1990). An AW-IPM approach that included an SIT component was used to permanently remove a tsetse population from the Island of Unguja, Zanzibar (Vreysen et al. 2000). A similar approach has been used in the last decade in the Niayes area of Senegal (Vreysen et al. 2021). However, the goal of creating a number of tsetse-free zones in Africa (Feldmann et al., this volume) will require significant improvements in mass-rearing technology, an in-depth knowledge of the behaviour of released and wild flies, and a careful consideration of the design of pest suppression systems. In addition, besides technical concerns, considerable development of programme management, and political and financial support, is essential for tsetse eradication programmes (Vreysen et al. 2007; Dyck, Reyes Flores et al., this volume).

### *3.5. SIT and Containment and Prevention of Pest Populations*

As already noted, the SIT and quarantines are major tactics in systems used to implement the containment (exclusion) and the prevention strategies. Examples of the containment strategy include Panama, where a barrier of sterile New World screwworm flies is maintained to contain the screwworm at the Panama-Columbia border (Vargas-Terán et al., this volume), and a barrier of sterile Mediterranean fruit

flies is maintained to exclude this pest from Mexico (Villaseñor et al. 2000; Enkerlin et al. 2017).

For the prevention strategy, examples include releases of sterile pink bollworms to prevent the pest from establishing on cotton in California's San Joaquin Valley (Staten et al. 1993), preventive releases of the male-only strain of the Mediterranean fruit fly over the Los Angeles Basin in California and major metropolitan areas in Florida, and releases of sterile Mexican fruit flies to prevent immigrant flies from crossing over from Mexico into the lower Rio Grande Valley of Texas (Hendrichs, Enkerlin et al., this volume). The SIT and quarantine stations were used, initially, to prevent the spread of the New World screwworm throughout Africa, and then to eradicate it in the coastal region of Libya (FAO 1992; Lindquist et al. 1993).

### *3.6. Lessons Learned from Using the SIT to Achieve AW-IPM*

In most AW-IPM programmes that integrate the SIT, the goal of containment, suppression or eradication has been threatened by the existence of untreated or inadequately treated refugia or microhabitats unusually favourable for the pest, i.e. "hot spots", from which recruits could come to reinfest cleared areas. In the New World screwworm campaigns, some hot spots were the ranches where livestock wounds were not being treated. Breaches of quarantine lines were very troublesome. The overarching lesson was that absolutely all segments of the population, i.e. the total population, must be suppressed.

More specifically, with respect to the SIT, the following conclusions can be drawn:

- An extended lag period may occur between the initiation of the release of sterile insects and a noticeable effect on the density of the pest. This is inevitable as the wild population will include many already mated females, sexually immature females, pupae, larvae, and eggs. The released sterile males can only prevent the reproduction of unmated females. As the immature forms mature, they become subject to the impact of the sterile flies. However, the time of one generation will pass before the progeny of previously mated females can be affected. Consequently, the release ratio must be sustained over a period of time equivalent to several generations.
- If a high proportion of the wild population is present as eggs and larvae when the release of sterile insects begins, then the wild population will even increase for a time in spite of the releases of sterile insects. However, this period can be shortened if an insecticide application (or any other control tactic that is effective against high-density wild populations) is made to kill females previously mated to wild males.
- Severe weather events, such as periods of cold weather, may reduce the density of the pest population, and also synchronize the development of the population by halting reproduction and killing exposed life stages. In this way the generation overlap may be eliminated.
- An influx of pests into the target area, even a few mated females, will greatly prolong an eradication programme. Great care must be taken not to underestimate the flight range of the pest. For most pest insects one can assume

that an immigrant female will produce 10–20 adult progeny in a small area. However, the progeny may disperse and be thinly distributed, and thus vulnerable to the SIT.

Krafsur (1998) asserted that the SIT is an underutilized and widely misunderstood technology (Whitten and Mahon, this volume). He refuted several misconceptions concerning the evolutionary responses to the SIT, the role of weather in AW-IPM programmes using the SIT, and the occurrence of undetected populations where eradication had been claimed prematurely.

## 4. REQUIREMENTS AND RESEARCH NEEDED TO ACHIEVE AW-IPM

The requirements for implementing AW-IPM are complex and sophisticated. Of paramount importance is the recognition that AW-IPM must be preventive, offensive, and planned on a multi-year basis (Lindquist 2001; Dyck, Reyes Flores et al., this volume). Requirements include the following (Vreysen et al. 2007):

- The biology, ecology, distribution, population dynamics, etc. of the pest in the target area must be thoroughly understood.
- There must be political support, as well as strong stakeholder cohesiveness and commitment to the campaign (Dyck, Regidor Fernández et al., this volume).
- Adequate funding needs to be available to cover all aspects of the programme.
- An effective and knowledgeable programme leader, supported by an effective organization, preferably independent from the day-to-day government bureaucracy, is needed (Vreysen et al. 2021; Dyck, Reyes Flores et al., this volume). This team must formulate and continuously update both technical and business plans.
- Staff with the proper qualifications, expertise and experience need to be hired for the AW-IPM programme; they should have no other job.
- Relevant monitoring data need to be collected before, during, and after the programme for the managers to be able to make informed decisions. Data need to be analysed properly, and in short intervals, to allow mitigating actions in case of a problem.
- There must be a system of programme review, including by external and independent experts.
- Legal authority is required to execute all aspects of the programme, e.g. conduct operations on private properties, and operate quarantines (section 1.5.).
- Since losses caused by emerging pest situations rapidly mount with the passage of time, the speed required to organize and implement a programme is critically important, especially when it is financed in part by an industry under economic stress (Kruger 2021).

Applied research and methods-development support is essential to backstop ongoing AW-IPM programmes. In addition, there are a number of general research needs that require more attention to further increase applicability, effectiveness, and efficiency of area-wide programmes:

- Apply the integration of species distribution modelling and landscape genetics to facilitate and optimize the management of target populations (Bakhoum et al. 2021).
- Further improve the use of Geographic Information Systems (GIS), Remote Sensing (RS), mathematical modelling, and data bases to facilitate decision-making in operational programmes, and to better manage large volumes of data sets (Barclay, this volume; Bouyer et al., this volume).
- Study the detection and sampling of very sparse populations. Disagreement (on the interpretation of sample data) enveloped area-wide programmes against the boll weevil in an especially bitter and costly controversy (NRC 1975). Similar difficulties have been encountered in programmes against tsetse flies *Glossina* spp., screwworms, the gypsy moth, and fruit flies (McInnis et al. 2017; Shelly et al. 2017).
- Automate the collection of field data, resulting in substantial cost savings in AW-IPM programmes, e.g. insect traps (baited with a species-specific attractant) that send a radio signal when a catch is made (Schellhorn and Jones 2021).
- Identify sociological barriers, and opportunities to surmount them, in implementing AW-IPM programmes (Kruger 2021; Mankad et al. 2021).
- Encourage the investigation of socio-economic impact to assess benefit/cost ratios and other economic indicators of AW-IPM programmes (Bouyer et al. 2014; Singerman et al. 2017).
- Encourage the implementation of environmental-impact studies to accompany AW-IPM programmes to assess the impact of the programme on the ecosystem (USDA/APHIS 2015).

## 5. KNIPLING'S IMPERATIVE

When the World Food Prize was awarded to E. F. Knipling and R. C. Bushland, Knipling (1992b) stated:

> If major advances are to be made in coping with most of the major arthropod pest problems, then the tactics and strategies for managing such insects, ticks and mites must change. They must change from the current, limited scale, reactive, broad-spectrum measures to preventive measures that are target-pest specific and rigidly applied on an area-wide basis.

## SUMMARY

In principle, the sterile insect technique (SIT) is applicable to controlling a wide variety of sexually reproducing insect pests, but biological factors, interacting with socio-economic and political forces, restrict its practical use to a narrower set of pest species and situations. This chapter reviews how the biology and ecology of a given pest affect the feasibility and logistics of developing and using the SIT against that pest insect. The subjects of pest abundance, distribution, and population dynamics are discussed in relation to producing and delivering sufficient sterile insects to control target populations. Pest movement and distribution are considered as factors that influence the feasibility and design of SIT projects, including the need for population- or area-wide management approaches. Biological characteristics, that affect the ability of sterile insects to interact with wild populations, are presented, including the nature of mating systems of pests, behavioural and physiological consequences of mass production and sterilization, and mechanisms that males use to block a female's acquisition and/or use of sperm from other males. An adequate knowledge of the biology of the pest species and potential target populations is needed, both for making sound decisions on the suitability of integrating the SIT into an area-wide integrated pest management (AW-IPM) programme, and on the efficiency and effectiveness of applying the technique.

## 1. INTRODUCTION

In principle, the sterile insect technique (SIT) is simple — the release of a large number of reproductively sterile male insects into a wild population of the same species so that they mate with, and block the reproduction of, wild females (Knipling 1955). Sterility is most often induced by exposing insects to ionizing radiation (Bakri et al., this volume); release of insects with conditionally expressed dominant lethal alleles is increasingly being considered as an alternative and is addressed elsewhere in this volume (Häcker et al., this volume; Lees et al., this volume). Released insects are most often completely sterile (or nearly so), but inherited ($F_1$) sterility (IS) is an option with species (primarily Lepidoptera) in which appropriate substerilizing doses of radiation produce males that are partially sterile but sire completely sterile offspring (Marec et al., this volume).

The successful application of the SIT requires: (1) the ability to rear, sterilize, and distribute the number of insects that will achieve a sufficiently high "overflooding" (sterile:wild insect) ratio in the field, and (2) that the sterile males can successfully compete and mate with their wild counterparts. Although the concept of the SIT is simple, the implementation is complex (Seawright 1988). Insects are mass-produced in an artificial environment and, after being irradiated, are often densely packed and shipped to a distant facility. Their subsequent release into the field can involve procedures such as immobilization, chilling, and ejection from flying aircraft (Dowell et al., this volume). Through all of this the insects must remain "competitive", i.e. able to survive and perform behaviours that allow them to mate successfully with wild insects (Parker, Vreysen et al., this volume).

Several key biological questions must be considered when deciding whether the use of the SIT would be warranted in a given pest situation (Table 1). Although economic and political considerations may drive decisions on when and where the technique is developed and deployed, these biological issues ultimately determine

both the logistical feasibility and economics of whether the SIT can contribute to the suppression of a given pest population. Understanding a pest's biology also allows programmes to optimize procedures and avoid pitfalls that could make the SIT impractical or ineffective.

*Table 1. Key biological considerations affecting the decision to use the SIT*

| Question | Biological consideration |
|---|---|
| Is the pest an appropriate target for the SIT? | Role of pest in agroecosystems<br>Existence of negating or complicating trait(s)<br>Potential of integration into (typically area-wide) pest management system |
| Can adequate sterile:wild ratios be achieved? | Pest ecology and population dynamics<br>Biological factors affecting production, distribution, and release<br>Integration with other suppression methods |
| Will released sterile males be able to compete effectively against wild males in target populations? | Effects of mass-rearing and sterilization on insect behaviour and physiology<br>Evolution and the SIT<br>Mating systems<br>Post-copulatory factors<br>Potential for enhancing sterile insect competitiveness |

## 2. ECOSYSTEM, AGRONOMIC, LIFE HISTORY, AND BIONOMIC CONSIDERATIONS

### *2.1. Role of Pest in Agroecosystems*

#### *2.1.1. Pest Status*

The SIT is mostly used when the selective removal of, or a great reduction in, a population of an individual species would have significant benefit. Examples (not inclusive) of applicable pest situations are shown in Box 1. Alternatively, the SIT would generally not be warranted if the suppression or elimination of a single pest population would not substantially reduce overall management costs or efforts. For example, Ankersmit et al. (1977) concluded that the use of the SIT against the summer fruit tortrix *Adoxophyes orana* (Fischer von Röslerstamm) in The Netherlands would do little to reduce the number of required insecticide sprays in apple orchards because other tortricid pests are present.

### *2.1.2. Pest Stage Producing Damage*

In his original treatise on the SIT, Knipling (1955) suggested that:

> It probably would be impractical to release insects which are highly destructive in the adult stage.

The theoretical basis of the SIT is largely unaffected by which stage(s) produces damage, but sterile insects themselves can be nuisances, disease vectors, or agricultural pests (Nagel and Peveling, this volume). For example, in the case of blood-feeding horn flies *Haematobia irritans* (L.) (Patterson and Miller 1982), large releases of sterile insects that would affect livestock may preclude the use of the SIT. If the damage from sterile insects is done primarily by females, e.g. mosquitoes, the development of genetic sexing strains can allow the SIT to be used with few or no negative consequences (Seawright 1988; Franz et al., this volume).

*Box 1. Examples of Pest Situations Where the SIT Could be Considered for Control*

- Incipient population of an non-native pest that, if established, would severely impact agricultural or environmental ecosystems, e.g. eradication of the Mexican fruit fly *Anastrepha ludens* (Loew) in California, USA (Enkerlin, this volume; Hendrichs, Enkerlin et al., this volume; Hendrichs, Vreysen et al., this volume)
- Vector of a serious disease (plant or animal), e.g. tsetse fly *Glossina* spp. eradication programmes (Feldmann et al., this volume)
- Presence of a "key pest" that greatly increases management costs and/or is quarantined in potential export markets, e.g. New World screwworm *Cochliomyia hominivorax* (Coquerel) in North America; *Bactrocera* spp. in Okinawa (Kuba et al. 1996)
- Alternate methods of controlling a pest disrupt ecological processes that regulate populations of other pests, e.g. chemical control of the boll weevil *Anthonomus grandis* Boheman disrupts the biological control of noctuids such as *Helicoverpa* sp.
- Preventing establishment of an important pest by maintaining a continuous population of sterile insects in an area of high risk of introduction, e.g. releases of sterile Mediterranean fruit flies *Ceratitis capitata* (Wiedemann) in Los Angeles, California, USA (Lance et al. 2014).

### *2.1.3. Plant Part Attacked*

In the case of plant pests, the SIT has most often been deployed against insects that attack marketable, especially fruiting, tissues. Small numbers of pests can cause substantial economic damage by attacking these high-value substrates, and, as a technology, the SIT is best used to drive small populations to very low levels or even to local extinction. Similarly, relatively few vectors of plant or animal diseases can be highly damaging. In contrast, many agricultural crops can sustain modest levels of damage to vegetative tissues such as leaves or roots with little or no economic loss, and populations of pests attacking such tissues can, in some cases, be very large (Sutter et al. 1998), and hence the SIT is less appropriate for such pest situations.

## *2.2. Reproductive/Life History Strategy*

Since the SIT relies on sterile males mating with wild females, most sexually reproducing insects are at least potential targets of the technique. Beyond that, various aspects of a species' basic biology tend to make that species relatively

amenable to (Box 2), or a poor candidate for (Box 3), the SIT. Natural parthenogenesis, even at low levels, is a potential pitfall of the SIT, which could theoretically select for parthenogenesis in wild populations (Templeton 1978). Nevertheless, use of the SIT has been considered against facultatively parthenogenetic aphids (Steffan and Kloft 1973). Controlling eusocial insects, such as termites (diplodiploid), with the SIT, while not theoretically impossible, would also present immense challenges in mass-rearing, sterilization, and release. Haplodiploidy, common in Hymenoptera, could make classical deployment of the SIT (rear, sterilize, release) problematic, but could open possibilities for simplified male-only release strategies. Broad taxonomically based generalizations about the applicability of the SIT are risky except, perhaps, that the technique may often be simpler with holometabolous than hemimetabolous insects (Box 2). The presence of the quiescent pupal stage tends to facilitate the harvest, sterilization, and transport of mass-reared insects. Also, larvae of many holometabolous insects have limited mobility and, in some cases, feed gregariously within a restricted unit of habitat such as a fruit. These habits tend to facilitate mass-rearing, whereas in other cases containerization is required to avoid cannibalism. However, the historical bias of area-wide integrated pest management (AW-IPM) programmes integrating the SIT toward Diptera, Lepidoptera, and to a lesser extent Coleoptera, is arguably, as much as anything, a reflection of the large numbers of pest species in these orders. In particular, they contain high percentages of regulatory pests – plant pests and, in the case of Diptera, pests of public and veterinary health concern. Such pests can be prime targets for government-sponsored development of the SIT.

*Box 2. Examples of Biological Characteristics that Allow, or Increase the Feasibility of, Using the SIT*

- Sexual reproduction (exclusively)
- Methods of mass-rearing are available, or can be developed
- Species is holometabolous (quiescent pupal stage facilitates sterilization and handling)
- Males exposed to sterilizing doses of ionizing radiation can compete with wild males for mates
- Methods are available to monitor released sterile and wild populations
- Low intrinsic rate of increase.

*Box 3. Examples of Biological Characteristics that Could Negate or Severely Complicate Using the SIT*

- Parthenogenesis
- Highly synchronous, aggregated, ephemeral mating system (found in many eusocial insects and other groups such as some Ephemeroptera)
- Extended life cycle, e.g. typical of many cicadas
- Sterile insects themselves are a serious pest, disease vector, or nuisance pest, such as horn flies, locusts, house flies, cockroaches or female mosquitoes
- Migratory behaviour involving long-distance flight and/or movement along weather fronts, as in various moths, locusts, planthoppers and stable flies.

### *2.3. Potential of Integrating the SIT with Other Control Strategies*

In most applications of the SIT, it is a key component of AW-IPM programmes (Klassen and Vreysen, this volume). As such, the SIT is commonly integrated with other control methods, most often: (1) following pre-release suppression of the target population (often involving insecticides) to the point where the SIT becomes more effective, less costly, or even feasible at all (Knipling 1979), (2) during simultaneous suppression using SIT-compatible controls (for example, the use of larvicides against mosquitoes or screwworms), or (3) exploiting the specificity of the SIT to provide control without disrupting biological control of the target population and/or other species in the area (Knipling 1998). Thus, the potential for area-wide integration of the SIT depends on a species' basic biology, the specific population situation, and the availability of effective and/or compatible suppression tools. Mangan and Bouyer (this volume) discuss supplementary control tactics used in AW-IPM programmes that release sterile insects.

## 3. PEST ECOLOGY AND THE SIT

The successful application of the SIT requires knowledge of the target population's ecology, including estimates of the absolute density of the adult population, and how that density changes over time (Lindquist 1969; Lindquist et al. 1974; Knipling 1979; Itô et al., this volume). For example, the number of insects needed for a given programme depends on the size of the target population, the area covered by the programme, the goal of the programme (Hendrichs, Vreysen et al., this volume), and the required ratio of sterile:wild insects in the field. When Knipling (1955) initially developed the theoretical basis of the SIT, he used a simple mathematical model to demonstrate that a wild population of 1 000 000 insects could be driven to extinction in 4 or 5 generations by maintaining a level of 2 000 000 sterile insects within the area (an initial 2:1 overflooding ratio). This model assumed that the wild population was stable, i.e. the average female produced one female offspring that survived to reproduce, and that sterile males were equivalent to wild males in their ability to mate with wild females. In practice, these assumptions are rarely true.

Subsequent models, which contain parameters that incorporate behavioural and ecological information, provide more realistic estimates of overflooding ratios needed for desired levels of suppression (Knipling 1968; Barclay, this volume; Klassen and Vreysen, this volume). In practice, when high rates of increase are involved, the required overflooding ratios can be quite high. Using empirical data, Brower and Tilton (1975) calculated an optimal sterile:wild ratio of about 100:1 for the almond moth *Cadra cautella* (Walker). In some programmes, ratios greater than 100:1 have not controlled rapidly increasing populations (Vargas et al. 1994; Rendón et al. 2004; Shelly and McInnis 2016).

### *3.1. Abundance of Pest*

#### *3.1.1. Numerical Size of Population*

The need to produce enough sterile insects to overflood a wild population places practical limits on the size of the target population that can be suppressed or eradicated, and has led to the assertion that the SIT is best applied against relatively small numbers of insects (Knipling 1955, 1979). This can include pests that are widely distributed but tend to occur at low densities, such as the New World screwworm (Knipling 1968), and others that occur in higher densities but exist (at least in the programme area) in relatively small and somewhat isolated patches of habitat. An example of the latter would be populations of Mediterranean fruit flies as they exist in some Middle Eastern areas (Rossler et al. 2000). The SIT has also been used to eradicate highly isolated populations such as the melon fly *Zeugodacus cucurbitae* (Coquillett) in Okinawa (Kuba et al. 1996), and incipient populations of the Mediterranean fruit fly and the Mexican fruit fly in the United States (Penrose 1996; Lance et al. 2014). For the latter types of programmes, pest surveys must be sensitive enough to detect and delimit a population before it grows beyond the capacity of the system and resources available for eradication (Lance 2014).

#### *3.1.2. Pest Population Dynamics*

Since the SIT interacts with a pest population at the point of reproduction, overflooding ratios must account for any tendency of the population to increase. As a simple demonstration, Knipling (1968) extended his 1955 model to show that, if a 2:1 overflooding ratio could reduce or eliminate a "stable" pest population, a ratio of 9:1 or 10:1, i.e. 2:1 X 5, would be needed for a population that was increasing 5X per generation. Such rates of increase are not uncommon among insects. For example, Bartlett and Butler (1979) documented a 10-fold increase per generation in pink bollworm *Pectinophora gossypiella* (Saunders) populations, and Cirio et al. (1972) reported generation-to-generation increases of greater than 40-fold in the Mediterranean fruit fly. Since rates of increase in the field are difficult to predict, operational programmes should be monitored carefully for effectiveness and to ensure that proper overflooding ratios are being maintained (Knipling 1979). Relationships of pest population dynamics to the SIT are discussed by Barclay (this volume) and Itô et al. (this volume).

#### *3.1.3. Seasonality and Voltinism*

Pest populations do not continuously increase at high rates. In warmer regions, many insects breed year-round, or at least go through multiple generations annually, but the populations cycle in response to factors such as the abundance of food, e.g. host plants, weather (temperature, wet/dry cycles), and cropping cycles (Adkisson 1971; Wong et al. 1983). Conceptually, seasonal periods of low and declining pest numbers provide opportunities to effectively apply the SIT against pest populations that are too large during other seasons (Knipling 1968; Lindquist 1969; Adkisson 1971; Hendrichs, Vreysen et al., this volume); empirical data support this concept

(Iwahashi 1976; Baumhover 2002). However, following reductions in target population numbers, maintaining adequate "pressure" from sterile insects on the pest population can be difficult when resources subsequently become abundant and pest populations rapidly increase in size. For example, Carpenter and Gross (1993) were not able to stop season-to-season increases in populations of the corn earworm *Helicoverpa zea* (Boddie) with releases of substerile males, although they consistently delayed or reduced the extent of those increases. If releasing sufficient sterile insects becomes impractical during some portions of the year, then alternating sequences of the SIT with other methods of pest management, e.g. mass-trapping or cultural control, may prove more cost-effective than continual releases of sterile insects (Cirio 1974; Thomas and Mangan 2005).

Many insect species, especially in temperate areas, have a dormancy period. Dormancy may involve diapause, induced by environmental factors such as photoperiod or temperature, and be either facultative or obligate (Leopold 2007). Temperate species are frequently univoltine (one generation per year); in some, a single generation requires two or more years. Mating, then, is restricted to specific periods within the year, and the production and release of sterile insects must be properly timed to ensure the maximum benefit (Mastro and Schwalbe 1988). If partial sterility carries across generations, conditions that initiate and break diapause in sterile insects must be appropriate, or sterile insects may not be present when needed. As examples, relatively normal diapause characteristics were observed in *H. zea* with inherited ($F_1$) sterility and in sterile backcross hybrids of *Heliothis subflexa* (Guenée) x *Heliothis virescens* (F.) (tobacco budworm), allowing appropriately timed activity and/or survival over winter (Stadelbacher and Martin 1981; Carpenter and Gross 1989). In multivoltine species with facultative diapause, competitiveness can vary between insects that were reared under diapause-inducing versus non-diapause conditions (Bloem et al. 2006; Sarvary et al. 2008).

### *3.2. Dispersion and Dispersal of Wild and Sterile Populations*

Programmes that release sterile insects can be strongly affected by both the dispersion (distribution of organisms over an area) and the dispersal (movement, or displacement, of individuals) of wild and sterile populations. These two parameters are influenced by a variety of ecological and behavioural factors intrinsic to a species' basic biology, and that tend to make that pest species more or less amenable to the implementation of the SIT.

#### *3.2.1. Dispersion*

Most insect populations have clumped distributions with areas of relatively high density amid regions of substantially lower density. This clumping is often related to the distribution of resources, such as host plants, and may vary seasonally (Shiga 1986). For example, Nakamori and Shiga (1993) outlined zones of *Z. cucurbitae* density in Okinawa based on the seasonal availability of host fruits, and identified "hot spots" where host fruits were abundant year-round. In such local areas with high densities of wild insects, the overflooding ratio is substantially lower than the

overall ratio of sterile to wild insects throughout the programme area. As a result, other things being equal, the effectiveness of sterile insect releases would decrease as the degree of clumping in the target population increases (Sawyer et al. 1987; Barclay 1992). This effect will be overcome to the degree that the sterile insects are distributed, or redistribute themselves, to mirror the distribution of the wild insects. The degree to which sterile insects actually do concentrate themselves in areas of high wild insect density has reportedly varied from high (Knipling 1979; Gavriel et al. 2012; Ageep et al. 2014) to low (Shiga 1986; Hendricks et al. 1973; Meats 2007) across diverse taxa. In any case, the distributions of wild and sterile populations must be understood to be able to allocate and distribute sterile insects optimally (Lindquist et al. 1974; Itô et al., this volume). Geographic information (GIS) and database systems can facilitate the identification, monitoring, and differential treatment of population foci on relatively broad spatial scales (Bouyer et al., this volume). However, if the aggregations of target populations occur on finer spatial scales, or are not predictable, the overall release rates may have to be adjusted upwards to ensure that the local sterile:wild ratios are high enough to achieve the desired level of sterility.

### *3.2.2. Host Specificity*

The distribution of an insect population will, of course, be influenced by the distribution of its hosts and, as a result, by the pest's degree of monophagy or polyphagy. Plant pests targeted in AW-IPM programmes that use the SIT have ranged from relatively monophagous or oligophagous pests such as the pink bollworm to highly polyphagous pests such as *H. virescens* and *C. capitata* (Proshold et al. 1983; Staten et al. 1999; Liquido et al. 2015; Staten and Walters 2021). Monophagy should tend to simplify the application of the SIT, especially if host plants are restricted to discrete patches. For polyphagous pests, the widespread presence of alternate hosts can increase the area, logistical complexity, and costs required for effective control (Vargas et al. 1995). Movement of insects to and from sites of adult food, or other ecological requisites, can also influence pest distribution (Hendrichs and Hendrichs 1990). For example, adult male New World screwworms, when waiting for potential mates, will often perch near sources of adult food (nectar) rather than near the animals that are the larval hosts (Guillot et al. 1978).

### *3.2.3. Dispersal*

The ability of wild insects to move within and between habitat patches influences the required size of release areas, the need for and size of barrier or buffer areas, and the pattern of insect release (Knipling 1979). The immigration of small numbers of mated females or large numbers of males into an SIT release area can potentially disrupt a programme (Prout 1978; Barclay, this volume). The magnitude of the impact from immigration depends on pest biology and on programme goals, with less isolation being required where moderate suppression rather than eradication is desired. For example, Ankersmit et al. (1977) reported that the SIT appeared to be capable of suppressing populations of the summer fruit tortrix in small orchards with a modest degree of isolation, even though the efficacy obtained was not sufficient

for eradication. The dispersal capacity of a pest species determines the need to isolate treatment areas from immigration, and is the primary factor dictating a population-wide approach to AW-IPM programmes integrating the SIT (Hendrichs, Vreysen et al., this volume; Klassen and Vreysen, this volume).

In eradication programmes, the potential for reinvasion also needs to be considered. The melon fly was eradicated from subtropical Japan (Kuba et al. 1996), but continuous surveys are now needed in the region, with preventive sterile fly releases in the southernmost islands, because this species is capable of flying in from Taiwan (Koyama and Tanaka 1984; Kohama and Kuba 1996). The New World screwworm was eliminated from North America but, because the flies are capable of dispersing more than 280 km, the eradication campaign had to be extended into northern Mexico, covering simultaneously a large area to protect the southern USA. Eventually, these large eradication blocks were progressively moved southward into Central America, where the areas to be covered became gradually narrower, reducing the size and cost of the programme (Lindquist 1969; Jones et al. 1999; McGraw 2001; Vargas-Terán et al., this volume). A wide band of sterile-fly releases across eastern Panama has been in place since the early 2000s to prevent reinvasion from South America. Conversely, when the SIT is used in too small an area against an incipient, isolated infestation, undetected dispersal away from the site of the initial introduction can foil eradication efforts by producing satellite infestations beyond the SIT release zone (Penrose 1996).

Pilot-scale testing of the SIT also requires relatively isolated venues such as islands or oases (Proshold et al. 1983; Cayol and Zarai 1999; Baumhover 2002; Bellini et al. 2013) or, alternately, plots that are buffered with wide barrier or treatment zones (Rendón et al. 2004). Such tests tend to be relatively large-scale, and can produce the added benefit of detecting logistical or biological problems that would not arise in smaller-scale studies (Seawright 1988; McInnis et al. 1996). However, large-scale tests are expensive, and logistical issues often force limits on size and/or replication. As a result, field data on relationships between sterile:wild ratios, sterile insect competitiveness and level of sterility, and effects on wild populations, are minimal in many cases (Krafsur 1998; Vreysen, this volume). In some instances, the initial stages of an operational programme have to function as a feasibility study (Lindquist et al. 1974).

Although long-distance movement can create problems for programmes that apply the SIT, dispersal on a more local scale is essential to the technique's effectiveness. Modelling studies indicate that a moderately high dispersal capability may tend to facilitate the SIT by reducing spatial heterogeneity in the pest population (Barclay and Vreysen 2011; Barclay, this volume). Hence, arthropods that are largely sedentary, such as ticks and mites, as well as various homopterans, are much less amenable to the SIT. Moreover, released sterile males must move sufficiently to locate resources such as food, mating arenas, and/or mates (Parker, Vreysen et al., this volume; Vreysen, this volume). The dispersal capability of sterile males is a primary consideration when designing release methods and protocols for a specific pest species, since it is critical that sterile males are distributed throughout the release area, at least in habitats where wild insects may occur (Andress et al. 2013; Dowell et al., this volume).

### *3.3. Chemical Ecology*

Chemical communication is often involved in mating, feeding, or other key ecological interactions of insects (Matthews and Matthews 2009). Accordingly, an insect's chemical ecology can have important implications for the SIT (Table 2). In particular, the common involvement of semiochemicals in intraspecific finding and/or recognizing mates means that sterile males must respond to, and in some cases produce, semiochemicals appropriately for the SIT to be effective (Table 2). In addition, an insect's chemical ecology can often be exploited to benefit AW-IPM programmes that integrate the SIT. Long-range attractants are very useful for assessing the distribution of wild and sterile insects (section 3.2.1.), monitoring overflooding ratios (Vreysen, this volume), and evaluating specific aspects of sterile male quality (Parker, Vreysen et al., this volume). In addition, males of species that use a long-range female-produced sex attractant are normally mobile enough to disperse well throughout the release area (sections 3.2.1. and 3.2.3.).

In some species, feeding, or otherwise exposing sterile males to an appropriate compound, can optimize mating competitiveness (Pereira et al. 2013; Pereira et al., this volume). Sometimes these chemicals are components (or precursors of components) of male-produced pheromones, which may be long-range sex attractants or close-range "aphrodisiacs" (Boppre 1990; Nishida et al. 1997; Shelly et al. 2010; McInnis et al. 2011). In other cases, reasons for the enhancement are not clear; e.g. mating competitiveness is improved when sterile Mediterranean fruit fly males are exposed to the parapheromone α-copaene (Shelly and McInnis 2001).

*Table 2. Examples of types of semiochemicals utilized by insects, and their potential implications for programmes releasing sterile insects*

| Type of semiochemical | Implication for programmes | Reference |
|---|---|---|
| Sex attractant pheromone (female-produced) | Used for monitoring or evaluating programmes that apply the SIT<br>Used for assessing sterile male quality | Bloem et al. 1998<br>Staten et al. 1999<br>Staten and Walters 2021 |
| Sex attractant or aggregation pheromone (male-produced) | May be critical component of sterile male competitiveness (section 5) | Heath et al. 1994<br>Bosa et al. 2016 |
| Parapheromone (such as the "male attractants" of tephritids) or aggregation pheromone | Used for monitoring or evaluating programmes that apply the SIT<br>Used for assessing sterile male quality (section 5) | McInnis and Cunningham 1986<br>Andress et al. 2013<br>FAO/IAEA/USDA 2019 |
| Aphrodisiac and/or contact recognition pheromone | May play important role in mating process and affect mating competitiveness (section 5) | Carlson et al. 2007 |
| Host-plant or other food-related kairomones | Used for monitoring programmes that apply the SIT<br>May play critical role in mating system<br>May need to be provided in diet as precursor of pheromone component | Dominiak and Nicol 2010<br>Shelly et al. 2010<br>McInnis et al. 2011<br>Benelli et al. 2014 |

### *3.4. Sterile Insect Longevity*

The frequency of sterile insect releases will depend on each species, and varies according to the average longevity. Preferably, sterile insects will survive in the field as long as their wild counterparts. If the longevity of sterile insects declines, the frequency of releases, and numbers of insects released, must be increased to maintain the desired overflooding ratio (Dowell et al., this volume; Vreysen, this volume). A reduction in longevity can be a side effect of mass-rearing, strain genetics, sterilization, or handling and release methods (Fay and Meats 1987; Meats 1998). Assessment of the longevity of sterile insects has largely been conducted in the laboratory (Meats 1998; Thomas and Loera Gallardo 1998), but over the past decade there has been increasing recognition that survival in the field is critical and is influenced by factors beyond the scope of laboratory tests. For example, released insects can suffer proportionately higher predation than wild insects if release methods concentrate or temporarily immobilize insects, or if mass production alters normal predator-avoidance behaviour (Iwahashi 1976; Hendrichs and Hendrichs 1998; Hendrichs et al. 2007; González-López et al. 2016). The survival of sterile insects to reproductive age is especially critical, but in many programmes immature adults that suffer significant mortality are released before reaching sexual maturity. Ideally, they should not be released into the field until they are sexually mature (McInnis et al. 2013), or at least have acquired nutritional reserves (Dowell et al., this volume), although this increases the required holding capacity. Many SIT programs now recommend periodically measuring survival of released insects in the field as part of their standard quality control protocols (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume; Vreysen, this volume).

## 4. BIOLOGY AND STERILE INSECT PRODUCTION

### *4.1. Feasibility of Rearing and Cost of Production*

Technical issues surrounding the production of sterile insects are reviewed elsewhere (Parker, Mamai et al., this volume), but some biological factors that influence the feasibility of mass-rearing bear mention here. As noted above, sterile insect production should generally be easier with holometabolous than with hemimetabolous species. Also, dormancy periods must be taken into account when designing rearing systems (Parker, Mamai et al., this volume), and, in some cases, they can be exploited to "stockpile" sterile insects (Mastro and Schwalbe 1988; Bloem et al. 2000; Leopold 2007). In some insects, developing specific components of rearing systems can prove intractable, e.g. the continued lack of useful artificial diets for rearing larvae of some bark beetles (Mattanovich et al. 1999), root-feeding beetles (Branson et al. 1988; Klein and Allsopp 1994), or parasites of mammals such as *Dermatobia hominis* (L., Jr.) (Banegas et al. 1967; Arce 1968; Borja 2002).

The cost of rearing insects, in particular, affects the economic feasibility of the SIT (Mumford, this volume), and is influenced by basic biological characteristics. Small insects with rapid life cycles can often be reared relatively cheaply. For example, Mediterranean fruit flies develop from the egg to prepupal stage in 6–9

days within large trays of relatively inexpensive diet, and several thousand sterile flies can be produced for USD 1 (Hendrichs et al. 2002). At that rate, tens of thousands of Mediterranean fruit flies can be produced for the current cost of rearing a single individual of the Asian longhorned beetle *Anoplophora glabripennis* (Motschulsky), a 3-cm-long cerambycid with a 10-month larval period (Dubois et al. 2002). Developmental and operational costs of mass-rearing can also increase with cannibalism, which can require individual containerization, provision of refugia and/or reduced rearing density (Da Silva and Parra 2013; Fontenot et al. 2015). Some insects also need specialized environments, such as artificial streams for simuliid larvae (Edman and Simmons 1985). In many cases, innovation and automation help to reduce costs and other problems of mass-production (Parker, Mamai et al., this volume). Finally, while lower reproductive rates generally reduce overall SIT costs by requiring lower overflooding ratios in the field, they tend to increase the unit rearing cost because facilities needed to maintain such colonies (tsetse species are an extreme case) are large relative to production output (Hendrichs, Vreysen et al., this volume).

### *4.2. Mass-Rearing and Competitiveness*

A sterile male's ability to compete for mates against wild males is a function of its phenotype, which, as in all living organisms, is determined by the expression of its genotype within its environment. Insects in mass-rearing facilities typically experience biotic and physical environments that clearly are very different from those in which wild insects develop. These environmental differences can influence the phenotype of sterile insects both directly and, along with other factors, by inadvertently selecting for genetic differences between laboratory and wild populations. Careful monitoring of phenotype (manifest as sterile insect quality) is critical to the success of programmes that use the SIT (Parker, Vreysen et al., this volume; Vreysen, this volume).

Many aspects of mass-rearing environments directly affect sterile insect quality. Characteristics of artificial larval or adult diets, such as nutritive elements, contaminants, microbial load (including probiotics), moisture, texture, and pH can influence body size, survival, longevity, flight ability, mating ability, and responsiveness to light (Economopoulos et al. 1990; Villavaso et al. 1998; Chang et al. 2000; Damiens et al. 2012; Yuval et al. 2013); in some cases effects can extend to the following generation (Keena et al. 1998). Handling methods and environmental conditions that optimize, or are simply convenient for, mass-rearing do not always produce the most competitive insect. A classic example is the "droopy-wing syndrome" and poor flight ability that were found to occur in tephritid flies when pupae were sifted from the pupation medium during the time of flight muscle development (Ozaki and Kobayashi 1981). Lance et al. (1988) reported another example where holding *Lymantria dispar* (L.) pupae at typically warm laboratory temperatures "programmed" sterile males with inappropriately timed mating activity. Conversely, temperature preconditioning (cold-conditioning) enhanced the survival and mating success of sterile male Queensland fruit flies *Bactrocera tryoni*

(Froggatt) (Fay and Meats 1987). More details on rearing methodology and insect quality are presented by Parker, Mamai et al. (this volume) and Parker, Vreysen et al. (this volume).

Reproductive sterility is typically induced by exposure to X-rays, electron beams, or gamma rays from a $^{60}Co$ or $^{137}Cs$ source (LaChance 1975; Bakri et al., this volume; Robinson, this volume), which all cause chromosomal damage. Sterility is usually permanent, although irradiated males of some species may, over time, regain at least partial fertility, especially following multiple mating (Brower 1976). Nevertheless the irradiation process typically reduces insect quality in some measurable way. Various strategies minimize somatic damage and thus preserve quality: irradiating insects near, or after the completion of, adult development, i.e. late-stage pupae or adults, irradiation in a reduced-oxygen atmosphere, "fractionating" the dose into several smaller doses, and using irradiators with small maximum to minimum dose ratios (which allow the minimum sterilizing dose to be achieved without substantially overdosing a large proportion of the insects) (Economopoulos 1977; ISO/ASTM 2013; Bakri et al., this volume; Parker, Vreysen et al., this volume).

Radiation doses that sterilize males typically kill oogonial cells, but the radiation sensitivity of oocytes varies with such factors as maturity and meiotic stage. As a result, females of some species may retain a degree of fertility after irradiation, especially when treated late in development. For example, in *C. capitata,* careful monitoring is needed to ensure that pupae are not irradiated too early, resulting in poor quality, or too late, leaving some females with residual fertility (Williamson et al. 1985). Some insect species that are irradiated as adults, such as the boll weevil, require alternative or augmentative sterilization strategies (McKibben et al. 2001).

Chemical sterilization, symbiont-based cytoplasmic incompatibility (CI), and incorporation of conditionally lethal genes are among the alternative methods of generating mass-reared insects for genetic control programs (Augustinos et al., this volume; Häcker et al., this volume; Hendrichs and Robinson, this volume; Robinson, this volume). In particular, advances in molecular biology have facilitated the production of strains for release of insects carrying a dominant lethal (RIDL), which can potentially be applied using either a bisexual or self-perpetuating sex-linked (males only) approach (Hendrichs and Robinson, this volume). RIDL, as well as *Wolbachia*-based CI, have been advanced furthest for mosquitos (Alphey 2014; Augustinos et al., this volume; Lees et al., this volume), but both have been under development for other taxa as well (Zabalou et al. 2009; Morrison et al. 2012; Leftwich et al. 2014; Häcker et al., this volume).

Chemosterilization was considered a viable alternative to radiation early in the development of the SIT (LaBrecque and Smith 1968), but was largely abandoned due to the potential of chemical residues on the sterile insects that can have mutagenic effects on non-targets (including humans). Much safer insect chemosterilants are now available but their use to date has been proposed primarily for field application (autodissemination) rather than SIT production (e.g. Moya et al. 2010).

Mass-rearing can also produce genetic differences between wild and laboratory populations (Cayol 2000). Indeed, dramatic shifts in strain genetics, including reductions in diversity (heterozygosity), can be observed within a relatively few

generations under laboratory conditions (Zygouridis et al. 2014). Genetic changes in rearing colonies have been cited as the likely causes of shifts in such traits as flight ability, mating age, age at first reproduction, cuticular hydrocarbons, and adult longevity (Spates and Hightower 1970; Itô and Koyama 1982; Pomonis and Mackley 1985; Hammack 1987; Mangan 1991; Miyatake and Shimizu 1999; Suenaga et al. 2000; Meats et al. 2004). Mating arenas, in particular, may differ greatly between field and laboratory environments, and inadvertent selection of inappropriate mating behaviours in mass-reared colonies could be especially detrimental to the SIT (Edman and Simmons 1985; Briceño and Eberhard 1998; Shelly 2012). Strategies for maintaining the competitiveness of mass-reared strains include holding colonies under "relaxed" conditions to minimize selection of undesirable traits, regular replacement of mass-reared strains, and active selection for desirable traits such as mating compatibility with wild strains (Leppla et al. 1983; McInnis et al. 1985; McInnis et al. 2002; Orozco-Davila et al. 2014; Bosa et al. 2016; Quintero-Fong et al. 2016). Of course, suboptimal genetics in mass-reared strains can result from factors other than inadvertent selection, such as genetic drift associated with "bottlenecking" or even less-than-ideal traits in the insects that were used to found the colony.

## 5. MATING SYSTEMS

Given that population suppression by the SIT is overwhelmingly a function of matings between sterile males and wild females (McInnis et al. 1994), the ability of released sterile males to compete for mates is critical. The mating competitiveness of sterile males is a function of their mating propensity and mating compatibility. Mating propensity, the tendency to locate a mate, copulate and inseminate, is primarily of concern as a component of sterile insect quality (Parker, Vreysen et al., this volume). Mating compatibility is a relative measure of how readily two populations of insects are reproductively compatible, and, in relation to the SIT, most often refers specifically to matings of sterile males with wild females (FAO/IAEA/USDA 2019). Parker, Vreysen et al. (this volume) describe methods of assessing and quantifying compatibility. In programmes that release sterile insects, it is necessary to ensure that those insects are compatible with the target insect population (FAO 1992; Cayol et al. 2002).

Insect mating systems are almost as diverse as the insects themselves, and have been categorized in a variety of ways, such as their relation to ecological resources (Hendrichs et al. 2002), type or degree of aggregation, the type or extent of male-male competition (Robacker et al. 1991; Hendrichs et al. 2002), means by which females select mates (Eberhard 1996), or the involvement and type of semiochemicals. Insects use a variety of sensory modalities to locate, identify, and evaluate potential mates and related resources, including vision, sound, odours, contact chemoreception, and "touch" (Matthews and Matthews 2009).

For the SIT, the modalities used in an insect's mating system have to be understood. Sterile males must be competent in their ability to communicate with females, as receiver and/or sender of signals, to be fully competitive (Table 3). Most

mating systems, in themselves, do not preclude the use of the SIT, but they influence the efficiency and logistical difficulty of the technique. In general, greater levels of complexity in the role of the male in mating will require more effort in tracking male behaviour as a part of product quality control (Hendrichs et al. 2002; Parker, Mamai et al., this volume), and will lower expectations of high mating competitiveness of mass-produced sterile males (Shelly and McInnis 2016).

*Table 3. Characteristics of insect mating systems that are favourable or less favourable for the development and operation of programmes releasing sterile insects*

| Characteristic of mating system | Favourable | Less favourable |
|---|---|---|
| Behavioural role of male, including any courtship ritual | Simple | Complex |
| Female choice of mates | Passive (accepts first male) | Active (chooses among males) |
| Sex pheromone | Female-produced, simple (1- or 2-component), long-range | Male-produced, complex |
| Characteristics of adult male | Long-lived, active disperser | Short-lived, sedentary |
| Male-male competition | Indirect (scramble for mates) | Contest for mates or resources |
| Mating in time and space | Distributed throughout habitat, asynchronous | Highly aggregated, e.g. termite swarms |

### *5.1. Simple Mating Systems*

Relatively simple mating systems often involve scramble competition for females. For example, adult female gypsy moths emerge essentially mature, do not feed, and begin "calling" (releasing a single-component sex attractant) near their pupation sites, which are spread throughout their habitat. To mate successfully, a male moth must be active at the time of day when females begin calling (Lance et al. 1988), be capable of locating the source of the pheromone (before another male finds it), and then recognize and attempt copulation with a female when he, literally, steps on her (Charlton and Cardé 1990). Mating is slightly more complex in the New World screwworm where male flies must locate and perch in sites where they can encounter flying females (Guillot et al. 1978). The males dart out and grab at small objects flying by, recognizing and attempting to mate with females if a contact pheromone is present (Hammack 1992). Such relatively simple mating systems are amenable to the SIT, and can lead to the production of highly competitive sterile males. Sterile male gypsy moths are typically nearly 100% competitive, based on their ability to locate pheromone sources (Mastro 1978), and on the relationship of induced egg sterility to the ratios of sterile:wild males trapped during pilot tests

(Mastro and Schwalbe 1988; Simmons et al., this volume). One downside of simple mating systems, especially those with pure scramble competition, is that they are often associated with short adult lifespans and compressed mating periods (sections 3.4. and 3.1.3.).

### *5.2. Complex Mating Systems*

The difficulty of producing highly competitive sterile males will, as a general rule, increase with the complexity of the males' mating-related behaviours (Shelly and McInnis 2016). For example, Mediterranean fruit fly males attract females by releasing a very complex pheromone (Jang et al. 1989) from an appropriate microhabitat, which typically, but not always, is the underside of a sun-lit leaf. Males often call near other calling males at locations that have been referred to as leks (Prokopy and Hendrichs 1979). When a female approaches a male, he initiates a complex courtship ritual and, if the female remains to the end of the display, he attempts to mount her. Following mounting the female can mate, or reject the male by dropping from the leaf (Lance et al. 2000). Given the complexity of male behaviour, differences in pheromone composition and sexual behaviour between wild and sterile male Mediterranean fruit flies are not unexpected (section 4.2.), and in fact have been quantified (Heath et al. 1994; Briceño and Eberhard 1998; Shelly 2012; Vaníčková et al. 2012). Accordingly, in small-scale mating assays through pilot-scale tests, sterile male Mediterranean fruit flies have usually been less than fully competitive, and in very extreme cases less than 1% competitive (Wong et al. 1986; McInnis et al. 1994, 1996; Rendón et al. 2004). Such lapses in mating competitiveness can increase costs, and compromise the effectiveness of programmes that release sterile insects (Parker, Vreysen et al., this volume; Vreysen, this volume; Whitten and Mahon, this volume). In spite of this, the SIT is increasingly being used against the Mediterranean fruit fly and other tephritids in suppression, eradication, containment and prevention contexts (Rossler et al. 2000; Lance et al. 2014; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume). Several potential methods of enhancing the competitiveness of sterile Mediterranean fruit flies have been investigated, such as optimizing pre-release feeding regimes (Yuval et al. 2007, 2013) and hormonal treatments (Pereira et al. 2013). "Aromatherapy", the pre-release treatment of adults with semiochemicals (section 3.3.), has been shown consistently to enhance Mediterranean fruit fly mating competitiveness, and is now an integral part of the operating procedures at most fly emergence and release facilities (Shelly and McInnis 2001; Dowell et al., this volume; Pereira et al., this volume).

The mating behaviour of sterile males becomes especially critical when females, as in the example above, actively choose among mates based on male phenotype. In these insects, seemingly minor differences in behaviour between wild and sterile insects can translate into poor competitiveness (Lance et al. 2000). In addition, selection can potentially favour wild females that are adept at identifying and rejecting sterile males, resulting in wild populations that are "behaviourally resistant" to the SIT (Itô et al., this volume; Whitten and Mahon, this volume).

Apparently, this occurred after several years of sterile insect releases against *C. capitata* on the island of Kauai, Hawaii, USA — the percentage of successful courtships dropped from about 10% to 1 or 2% for interactions between sterile males and wild females; however, the compatibility of the sterile males with wild females from other islands was unaffected (McInnis et al. 1996; Lance et al. 2000). A similar erosion of mating compatibility had previously been noted and overcome during the SIT-based successful eradication of *Z. cucurbitae* in Japan (Hibino and Iwahashi 1991).

## 6. POST-COPULATORY FACTORS

The effectiveness of mating between sterile males and wild females can be lost partially or entirely if the females also mate with wild males, and preferentially use sperm from the latter for fertilization. To determine if the SIT is appropriate for use against an insect species, Knipling (1955) proposed that one principle to consider was:

> Females must normally mate only once.

This assertion is still occasionally voiced dogmatically, at least as a question, although polyandry does not negate the basic principles of the technique (Barclay, this volume; Whitten and Mahon, this volume). However Knipling (1955) continued:

> If females of a species mate more frequently, the sperms from irradiated (sterile) males must be produced in essentially the same number and compete with sperms from fertile males.

Indeed, all else being equal, the overall sterility induced into a population of ten females by a sterile:wild overflooding ratio of 9:1 should be the same whether each female mates once — nine with a sterile male and one with a wild male — or each female mates ten times — nine times with sterile males and once with a wild male. This issue is broader than Knipling's assertions, but regardless of the number of times that a female "normally" mates, the competitiveness of sterile males will be influenced by post-mating factors, including the ability to induce mating refractoriness in females, sperm competition, and/or sperm precedence, depending on the species.

Patterns of female receptivity include variations on three basic themes: (1) monogamy, (2) females cycle through periods where they alternately are or are not receptive, and (3) continuous receptivity (Ringo 1996). In most insects, female receptiveness drops sharply after mating, typically due to a physiological response to materials passed from male to female during copulation (LaChance 1975; Eberhard 1996; Ringo 1996; Kraaijeveld et al. 2005). In many species the sperm or spermatophores themselves produce the effect, but in others (best documented among dipterans) an "anti-aphrodisiac" in the seminal fluid — often an accessory-gland protein — produces the change (Ringo 1996). An accessory-gland factor has been documented in *C. capitata*, and males from sterile and wild strains were found

equally competent at inducing females to shift from mate-seeking to oviposition behaviours (Jang et al. 1998); similarly, sterile and wild *Anastrepha fraterculus* (Wiedemann) were found to be comparable in rendering females refractory to further mating (Abraham et al. 2013). Female *Z. cucurbitae* became unreceptive after mating either with virgin or with "spermless" (sperm-depleted) males (Kuba and Itô 1993), and female *Anopheles gambiae* Giles became refractory after mating with males that were rendered spermless by RNAi silencing of a germ cell differentiation gene (Thailayil et al. 2011).

In other species, the transfer of a full complement of sperm appears to be the critical factor that turns off female receptiveness. For programmes for these other species, this requires that sterility be based on dominant lethal mutations rather than, for example, on the elimination of sperm production (LaChance 1975). Male lepidopterans produce sperm that are apyrene (anucleate) as well as eupyrene (functional), and in particular the presence of eupyrene sperm appears to be important in shutting off receptivity (LaChance 1975). Radiation doses that cause reproductive sterility can also reduce the quantity and/or quality of a male's sperm (North et al. 1975; LaChance et al. 1979; Proshold et al. 1993). Also, sperm are often depleted faster (after fewer matings) in radiation-sterilized males than in unirradiated males (Haynes and Mitchell 1977). The $F_1$ sterile progeny of substerilized males may also transfer less than a full complement of sperm (Carpenter et al. 1987; Proshold et al. 1993; Marec et al., this volume). Sterilization-related reductions in the amount of sperm transferred to females can reduce sterile male competitiveness by increasing the incidence of remating among females that mate with both sterile and wild males (Haynes and Mitchell 1977; Carpenter et al. 1987).

When females mate with both sterile and wild males, the proportion of eggs fertilized by the sperm of sterile males can be influenced by the species' patterns of sperm precedence and/or the competitiveness of the males' ejaculates. In many species sperm from recent matings takes precedence over sperm from earlier matings (Brower 1975; Etman and Hooper 1979), although other species show first-mating (El Agoze et al. 1995) or variable sperm precedence (Conner 1995; LaMunyon and Huffman 2001). In some species sperm precedence is complete, or nearly so (Brower 1975; Etman and Hooper 1979), and specialized mechanisms exist to expel or otherwise inactivate sperm from previous matings (Waage 1979). However, often sperm from different matings mix to various degrees, and the proportion of offspring a male sires will depend at least in part on the competitiveness of his ejaculate. The Mediterranean fruit fly shows a general sperm precedence for more recent matings (Saul and McCombs 1993), but sperm from earlier matings is conserved and may become more available as fresher sperm is depleted (Scolari et al. 2014).

Ejaculate competitiveness can potentially be related to a variety of factors such as male age (LaMunyon 2001), but often the determinant is simply the quantity or quality of sperm transferred (Saul and McCombs 1993; Alyokhin and Ferro 1999; LaMunyon and Huffman 2001). The proportion of a multiple-mated female's eggs that any given male fertilizes can be reduced by sterilization procedures (LaMunyon 2001). This effect has been shown to be dose-dependent in the fall armyworm

*Spodoptera frugiperda* (J.E. Smith) (Carpenter et al. 1997), and influenced by the age at irradiation in the boll weevil (Villavaso et al. 1998).

## 7. CONCLUSIONS

No insect is a "perfect" target for the SIT. Sterile Mediterranean fruit flies can be produced in large numbers at a reasonable cost, but the high release rates required, and the complex role of the male in mating, can create problems for operational programmes. New World screwworm flies have a relatively simple mating system but are not easy to rear, and in a mass-production situation the quality of a colony tends to degrade rapidly (Mangan 1991). Although numbers of tsetse required for release are much lower than for other species, it is also problematic to rear them in sufficient numbers (Opiyo et al. 2000). In spite of these problems, the SIT is being used successfully against all of these insects in AW-IPM programmes that, in some cases, are among the most extensive insect management programmes ever undertaken.

For other insects, such as the boll weevil and gypsy moth, functional SIT technology has been developed but is not being used (at least not on a significant scale) because simpler or more cost-effective alternative control methods are available. Agronomic, socio-economic, and biological factors must be weighed when deciding whether the SIT is an appropriate tool for managing a given pest. One generalization that probably can be made regarding pest biology and the SIT is this: when considering, developing, or conducting an AW-IPM programme integrating the SIT, an understanding of the pest's biology is critical to making appropriate decisions and to the overall success of the programme.

# CHAPTER 2.3.

# GENETIC BASIS OF THE STERILE INSECT TECHNIQUE

A. S. ROBINSON

## TABLE OF CONTENTS

## SUMMARY

The use of the sterile insect technique (SIT) for insect control relies on the introduction of sterility in the females of the wild population. This sterility is produced following the mating of these females with released males carrying, in their sperm, dominant lethal mutations that have been induced by ionizing radiation. The reasons why the SIT can only be effective when the induced sterility in the released males is in the form of dominant lethal mutations, and not some form of sperm inactivation, are discussed, together with the

relationship of dominant lethal mutations to dose, sex, developmental stage and the particular species. The combination of genetic sterility with that induced by radiation is also discussed in relation to the use of genetic sexing strains of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) in area-wide integrated pest management (AW-IPM) programmes that integrate the SIT. A case is made to lower the radiation dose used in such programmes so as to produce a more competitive sterile insect. Increased competitiveness can also be achieved by using different radiation environments. As well as radiation-induced sterility, natural mechanisms can be recruited, especially the use of hybrid sterility exemplified by a successful field trial with tsetse flies *Glossina* spp. in the 1940s. Modern biotechnologies are having some impact on the SIT, especially regarding the introduction of markers for released flies and the construction of genetic sexing strains, as well as other applications such as molecular sterility. Nevertheless, it is concluded that using a physical process, such as radiation, will always have significant advantages over genetic and other methods of sterilization for the large-scale application of the SIT.

## 1. INTRODUCTION

E. F. Knipling realized in the 1930s (Lindquist 1955) that, if male insects could be sterilized genetically without affecting their ability to mate, then they could be used to introduce a genetic load into a wild population in the field that would lead to its suppression or even eradication. For some time, geneticists were aware that X-rays could induce mutations in insects (Runner 1916; Muller 1927), but it was not until A. W. Lindquist showed a publication by H. J. Muller (1950) to Knipling that applied entomologists realized the great potential it offered (Baumhover 2001, 2002). The results from the first experiments to sterilize the New World screwworm *Cochliomyia hominivorax* (Coquerel) were published in 1951 (Bushland and Hopkins 1951). This demonstration, that X-rays could indeed induce sterility, was the first small step on the way to the eradication of this important livestock pest in the southern states of the USA, and then in Mexico and all the countries of Central America, as well as Panama (Vargas-Terán et al., this volume). A permanent barrier of sterile insects has been established in eastern Panama to prevent the reinvasion of the pest from South America. Baumhover (2001, 2002) provided a historical account of the early days of the screwworm eradication programme, and Klassen et al. (this volume) describe the sterile insect technique (SIT), in general, from an historical perspective.

During the first field trials of sterile screwworms in Curaçao, the genetic basis of sterility was poorly understood, but it was realized that sterility resulted from the induction of dominant lethal mutations in the irradiated sperm (Bushland and Hopkins 1951; LaChance et al. 1967). At that time the level of understanding of the genetics of the screwworm led Bushland to comment that (quoted by LaChance 1979):

> . . . we eradicated screwworms from Curaçao and the south-eastern United States without knowing how many chromosomes it had.

Prior to the adoption of radiation to sterilize insects, and following the discovery in the early years of the Second World War that mustard gas and other chemicals can produce mutations and affect fertility in *Drosophila* (Oehlkers 1943; Beale 1993), chemical mutagens were extensively evaluated (Borkovec 1966). However, difficulties relating to toxicity, handling, and residues were considerable, and so radiation has usually been the method of choice. Even though field trials with chemosterilized *Anopheles albimanus* Wiedemann mosquitoes in El Salvador were successful (Breland et al. 1974), it is unlikely that today such releases could be carried out.

## 2. STERILITY REQUIREMENTS FOR SIT APPLICATION

It is very important that the word "sterility" be precisely understood in terms of its use in the SIT. The word "sterility" describes one of many possible end points of the reproductive process, but it can cover a multitude of causal factors. The following definitions of sterility were taken at random from three biological dictionaries:

- Structural or functional inability to reproduce,
- Involuntary total inability to reproduce,
- Any complete or partial failure to produce functional gametes or viable zygotes.

These definitions cover genetic, physiological, morphological or even "psychological" factors, which can lead to a final end point of sterility, and clearly many of these manifestations would not be useful for sterility in area-wide integrated pest management (AW-IPM) programmes. For the SIT to be effective, females of the wild population in the field have to be permanently prevented from reproducing, and any factor(s) transferred by the released male that accomplishes this would, in fact, be sufficient. True genetic sterility in released male insects requires: (1) production of viable sperm, (2) their transfer to the wild female during mating, (3) their use in fertilization of eggs, and (4) the inability of the fertilized zygote to complete development to a fertile adult. Thus, an irradiated male insect must be able to carry out all the functions of a normal fertile insect — it must produce fully functional sperm that succeed in fertilizing eggs and initiating the development of fertilized eggs.

In the SIT, the radiation-induced sterility is actually produced in the generation following the release of the males, i.e. with the death of the embryo, larva, pupa or adult, or the production of $F_1$ adults that themselves produce gametes that result in zygotes that do not develop. A male insect that cannot mate, is aspermic, or that transfers non-functional sperm, could be classed as sterile, but males with any of these defects would probably not be effective for the SIT.

The International Plant Protection Convention (IPPC 2017) adopted the following definition of a sterile insect:

> An insect that, as a result of a specific treatment, is unable to reproduce.

and the following definition of the SIT:

> Method of pest control using area-wide inundative release of sterile insects to reduce reproduction in a field population of the same species.

Irradiated males must also be able to transfer the appropriate accessory gland fluids during mating, ensuring that female behaviour corresponds to that following mating with a fertile male. In some insects, this female post-mating response involves temporary or permanent refractoriness to further mating, and a change in female behaviour. In *Drosophila* sp. the peptides transferred in the accessory fluid, that are involved in the female post-mating behavioural changes, have been well studied (Chen 1996), and it has even been possible to sterilize females by the ectopic expression (i.e. gene expressed in all tissues) of a transgene which codes for the sex peptide (Aigaki et al. 1991). In fact, a male that only transferred accessory gland fluids, and which could elicit the correct post-mating female response, could theoretically "sterilize" the female. In the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), it has been shown that irradiated sterile males produce the same kind of change in wild female

behaviour, from mating to oviposition, as do fertile males (Jang et al. 1998; Jang 2002).

In species where females remate (von Borstel and Knipling 1960), sterility for use in the SIT must be efficiently induced in sperm without affecting sperm function and its capacity to compete with other sperm, and exert its effect only after fertilization of the female egg. Dominant lethal mutations are such sterility factors. They are readily induced in all chromosomes by irradiation, and they have little effect on the phenotype of the sperm, at least at the doses usually used for the SIT (Bakri et al., this volume).

Lethality occurs when the haploid nucleus, carrying such a mutation or mutations, is combined with a normal haploid nucleus, resulting in the death of the early embryo at the moment when the genetic information required for normal development is absent or incorrect (Muller 1927). In addition, cell division can become asynchronous and lead to the death of the zygote.

## 3. DOMINANT LETHAL MUTATIONS

The mechanisms by which these mutations cause lethality in Diptera in the developing zygote are now well documented (LaChance 1967; Smith and von Borstel 1972); they are illustrated in Figure 1.

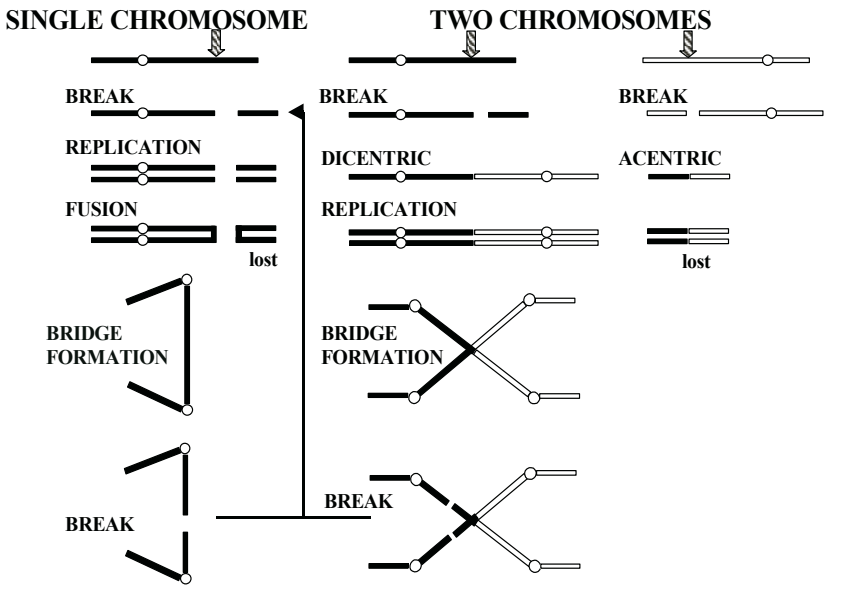

*Figure 1. Schematic representation of the fate, during cell division in the embryo, of chromosomes with radiation-induced dominant lethal mutations, leading to the accumulation of serious imbalances in the genetic information of subsequent daughter cells.*

The primary lesion leading to a dominant lethal mutation is a break in the chromosome, in this case, induced by radiation. When a break is induced in a chromosome in mature sperm, it remains in this condition until after the sperm has entered an egg. (This was shown very elegantly by mating queen bees to irradiated

males, and then measuring fertility after storage of the sperm in the spermatheca for one year; there was no difference in the level of sterility in the same queen tested one year later (Lee 1958)). Following fusion, nuclear divisions begin, and a break in a chromosome can have drastic effects on the viability of the embryo as development proceeds. During early prophase the broken chromosome undergoes normal replication, but during metaphase the broken ends can fuse leading to the formation of a dicentric chromosome and an acentric fragment. The acentric fragment is frequently lost, while the dicentric fragment forms a bridge at anaphase leading to another chromosomal break. This whole process then repeats itself, leading to the accumulation of serious imbalances in the genetic information of the daughter cells. The accumulation of this genetic damage finally leads to the death of the zygote.

If two different chromosomes are broken they can also rejoin in the way depicted in Fig. 1. These chromosomes produce the same problems for the dividing cells as those formed by a break in a single chromosome, by undergoing incorrect fusion and leading to the *breakage-fusion-bridge cycle* (McClintock 1941). In this way dominant lethal mutations can cause cell death, and the accumulation of genetic imbalance in the developing zygote leads to lethality.

### *3.1. Dose Response for Dominant Lethals*

Dose-response curves for the induction of sterility by radiation are generally developed using measurements of hatchability of eggs, deposited either by irradiated females mated with non-irradiated males, or by non-irradiated females mated with irradiated males. The implicit assumption is that most dominant lethal mutations exert their effect during early embryonic development. Data from *Drosophila* sp., and other dipteran species containing chromosomes with monokinetic centromeres, have shown that this is the case (Demerec and Fano 1944; Catcheside and Lea 1945; Lee 1958; Tantaway et al. 1966; Franz 2000), making egg hatch an appropriate stage to evaluate. In insect species with holokinetic chromosomes, many dominant lethal mutations exert their lethal effects only at later developmental stages (Marec et al., this volume).

Dose-response curves for dominant lethal mutations can be developed by irradiating insects with increasing doses of radiation and calculating the percentage egg hatch. The curves tend to show a characteristic shape, depending on the cell type and stage irradiated. The shape of the curve can be used to infer information about the types of initial chromosomal lesion producing the lethal effect. In irradiated sperm, there is an approximately linear relationship between the dose and the induction of dominant lethals at low doses, but at higher doses there is a noticeable departure from linearity, i.e. it tends to saturate at higher doses, and approaches 100% sterility asymptotically. This is due to the induction of multiple lethal events in the same cell, but only one is needed to cause the egg to die. The shape of the curve, as well as indicating the underlying causal factors of dominant lethality, should help in selecting a dose that will be used to sterilize insects for release. Fig. 2 shows the dose-response curves for the house fly *Musca domestica* L. and the large milkweed bug *Oncopeltus fasciatus* (Dallas). The difference in the shape of the curves is due to the fact that the latter species has holokinetic chromosomes (section 3.4.), and this results in the need for much higher doses of radiation for sterilization.

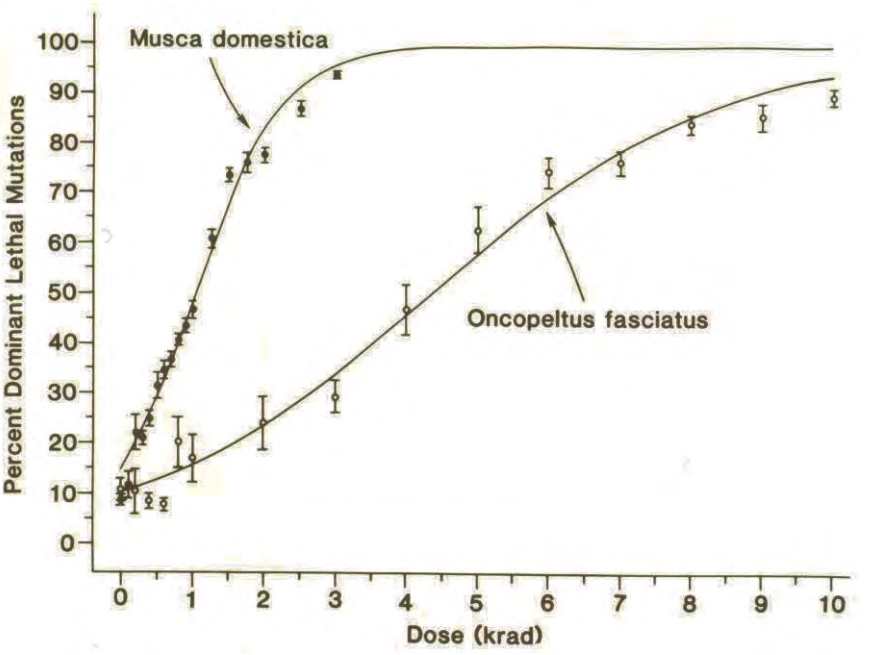

*Figure 2. Dominant lethal dose-response curves for* Musca domestica *and* Oncopeltus fasciatus. *(Figure from Lachance and Graham 1984, reproduced with permission from Elsevier.)*

Assuming that dose-response curves have been developed for both sexes, that both sexes are released, and that close to full sterility is required, then the minimum radiation dose chosen must lead to full sterility in females. Any residual fertility in released females can be extremely damaging, as this will actually contribute to the reproductive potential of the wild population. For example, a residual fertility of 2% in irradiated females, following a sterile:wild release ratio of 100:1, will actually double the number of insects in the next generation. Residual fertility in males is of less importance; it simply reduces the rate at which the population is suppressed.

These simplistic assumptions ignore the impact of any density-dependent regulation in the population. The full impact that the decision — on the dose to be used, based on the shape of the curve (Fig. 2) — has on the effectiveness of the SIT is described below (section 4.).

### *3.2. Dominant Lethals and Sex*

Male and female insects normally differ considerably in their sterility response to radiation, primarily because sperm are haploid post-meiotic cells, whereas mature eggs are pre-meiotic. Eggs usually develop in the female to metaphase 1, and then are arrested until oviposition when meiosis is completed with the production of a single

pro-nucleus and three polar bodies. Mature eggs in the female are much more tolerant of radiation than are the earlier oocytes, with the consequence that a radiation dose which induces full sterility in mature eggs often leads to the cessation of oogenesis at a later date. This can lead to an increase in the lifespan of females as energy is redirected away from reproduction to survival (White and Hutt 1970; Hafez and Shoukry 1972). In most cases this is of no consequence, but it can be important if the sterile females that are released are themselves damaging in some way. In tsetse, for example, it is essential to remove sterile females from the released insects as their increased lifespan might enable them to be efficient vectors of disease (Dean and Clements 1969; Abd-Alla et al. 2013).

In addition to this basic difference between male and female germ cells, there are also species-related differences in the overall sensitivity of male and female insects to radiation sterilization. In most species, females are more sensitive than males to radiation sterilization, and therefore it is possible to identify the sterilizing dose for the SIT based on the acceptable dose for males (section 4); use of this dose will ensure that all released females are fully sterile. In the minority of species where the female is more tolerant (Haynes et al. 1977; Crystal 1979), the sterilizing dose for females must be used, and this can compromise the competitiveness of the sterilized males. These patterns of differential sensitivity of germ cells in males and females are important to investigate when the radiation dose for the SIT is identified.

### *3.3. Dominant Lethals and Developmental Stage*

To maximize genetic damage to mature germ cells and minimize somatic damage, insects should be irradiated as late as possible in the development pathway, ideally as fully differentiated adults. In the adult stage, insects are most tolerant to somatic damage because somatic cell division is at a minimum. However, even in a fully differentiated insect, certain somatic cells, especially in the gut, continue to divide, and sterilizing radiation doses can compromise viability and hence the fitness of the treated insect (Flint et al. 1966).

In spite of these biological relationships, operational considerations in implementing the SIT often play the major role in determining the stage at which insects are irradiated. The operational decision is based on identifying the most convenient stage for radiation, from the point of view of mass-rearing, handling and release protocols. In most insects, this is the pupal stage, and consequently radiation is applied to pupae as late in development as possible. In New World screwworm and Mediterranean fruit fly AW-IPM programmes applying the SIT, pupae are irradiated two days before emergence, enabling the shipment of irradiated pupae to fly emergence and release facilities far from the production plant, where adults emerge and are fed and processed for release.

In AW-IPM programmes integrating the SIT for some other species, adult insects have to be irradiated. In Lepidoptera, larvae generally pupate within a cocoon that attaches itself to a substrate, and in these cases it is impractical to irradiate this stage, and thus teneral adults are irradiated (Proverbs et al. 1975; Boersma 2021). In tsetse, before release, adult males are fed blood containing a trypanocide and irradiated at 3-4 days of age (Dyck et al. 2000; Vreysen et al. 2000). In general, operational factors tend

to be decisive in determining the developmental stage that is irradiated (Bakri et al., this volume).

### *3.4. Dominant Lethals and Species*

The class Insecta comprises 31 orders (Wheeler et al. 2001), and pest species are found in most major orders. This very diverse class exhibits widely different sensitivities, both within and between orders, to the induction of dominant lethal mutations (Bakri et al. 2005; IDIDAS 2020), and to the somatic effects of radiation (Willard and Cherry 1975). Probably there are many factors that contribute to these differences, including the centromere structure (Smith and von Borstel 1972), the degree of chromosome condensation (Israelewski 1978), radiation repair (Beatty and Beatty 1967), and the chromosome environment (Thoday and Read 1947). This is certainly not an exhaustive list, and other factors, as yet unidentified, could still be important.

Insects can, however, be divided into two main groups which show major differences in sensitivity to the induction of dominant lethals, and for which experimental evidence is available that identifies the underlying biological and genetic factors responsible. Orders such as Diptera, Hymenoptera, and Coleoptera can be classed as radiation-sensitive, while orders such as Lepidoptera and Homoptera are more radiation-tolerant. A major difference between these two groups of insects is that the former group has a localized centromere (monokinetic), while the latter has a diffuse centromere (holokinetic) (Bauer 1967), and this difference plays a major, although not exclusive, role in radiation sensitivity (Tothová and Marec 2001). Lepidoptera also do not show the classical breakage-fusion-bridge cycle that is a characteristic of dominant lethals induced in Diptera. It appears that lepidopteran chromosomes can tolerate telomere loss without the drastic effects that this has on chromosomes in other orders. Discussions on this phenomenon are found in Bakri et al. (this volume) and Marec et al. (this volume).

## 4. APPROPRIATE RADIATION DOSE FOR THE SIT: IS 100% STERILITY REQUIRED?

The word “sterile” in the acronym “SIT” is generally perceived to imply a requirement for full sterility, and hence a radiation dose is sought that achieves 100% sterility. However, because there are varying levels of sterility that can be induced, the word “sterile” is not an absolute term, and often it is not required that released insects are fully sterile. As described above, the relationship of radiation dose to dominant lethal induction in the mature sperm of insects approximates to linearity at low radiation doses, but not at high doses, producing an asymptotic approach towards full sterility (Fig. 2). This curve is used as a decision-making tool to identify the radiation dose appropriate for a specific insect in a specific AW-IPM programme using the SIT. The fact that the curve approaches 100% sterility asymptotically makes it difficult to select the dose that gives the required full sterility. The equation used to describe the curve predicts that, in theory, given a large enough sample of eggs, it will always be possible to find one that hatches, and hence the goal of full sterility in eggs will never actually be met (although these may not reach the adult stage). However, in practical terms, a

dose is chosen which prevents the hatch of more than 99% of eggs in a large sample. This decision is often taken solely on the basis of the dominant lethal-induction curve; the effects of radiation on somatic tissues, and hence on the final ability of the insect to introduce sterility into wild females in the field, are generally ignored.

In fact, the goal of attempting to achieve full sterility in treated insects can seriously compromise their competitiveness in the field. This follows from the shape of the dose-response curve. At high doses, increasing amounts of radiation are required for proportionally smaller increases in sterility. LaChance and Graham (1984) described the dominant lethal-induction curve for several insect species, and, using equations derived from their curves, it can be shown that, for example, to decrease egg hatchability from 2 to 1%, an 11% increase in dose is required. This marginal increase in sterility, obtained at the expense of a disproportionate increase in the radiation dose, can have major negative effects on the competitiveness of the released insects. Since the shape of the curve relating somatic damage to dose is not known, some assumptions have to be made in arriving at this conclusion.

The proportion of wild females rendered sterile by a given number of males released depends on both their sterility and their success in competing with wild males to mate with wild females. Therefore, to optimize the balance between somatic fitness and genetic sterility, it is in the interest of programmes applying the SIT to choose radiation doses that maximize the genetic load introduced into the wild populations. This means that chosen optimal radiation doses to achieve this objective may give sterility levels well below 100% (Toledo et al. 2004; Rull et al. 2012).

A word of caution is required here. It is known that, in *Drosophila* spp., males receiving substerilizing radiation doses can recover fertility over time (Luning 1952), and it is important to evaluate this aspect if lower doses of radiation are used. Nevertheless, currently all operational programmes consistently err on what may be considered the side of caution, and use radiation doses that induce almost 100% sterility in the treated insects. Unfortunately, high levels of somatic damage, and hence lower sterile-male performance, normally result from such high doses.

## 5. RADIATION IN DIFFERENT ENVIRONMENTS

Usually radiation is the final treatment that insects receive at the mass-rearing facility before being transported for release in the field. Any technique that reduces somatic damage induced by the treatment would be advantageous. Mass-produced insects are expensive, and need to function as well as possible in the field. The amount of genetic damage produced by radiation, both in reproductive and somatic tissues, is related to the environment in which the tissue finds itself, in particular, the oxygen tension. It is well known that treatment in low-oxygen tension, e.g. irradiating in nitrogen or hypoxia, reduces radiation damage (O'Brien and Wolfe 1964; Bakri et al., this volume).

However, if low-oxygen tension gives the same protective effect for somatic tissue (competitiveness) and sperm (sterility), then there would be no net gain. To achieve the same level of sterility as irradiation in air, irradiation in nitrogen would have to be at a higher dose. Nevertheless, the differential protection afforded to somatic cells by irradiation in nitrogen is related to the fact that somatic tissue is diploid and still

undergoing cell division, whereas sperm are fully differentiated and haploid. This means that damage induced in somatic cells can manifest itself during the further life of the insect, whereas damage induced in sperm cells is only realized following fertilization of eggs in the wild females.

The positive effects on competitiveness of irradiation in nitrogen have been demonstrated for several insect species (Hooper 1971; Curtis and Langley 1972; Hallinan and Rai 1973; LaChance and Richard 1974; Economopoulos 1977). Two successful fruit fly AW-IPM programmes integrating the SIT were carried out in Australia using pupae irradiated in nitrogen (Hooper 1971; Fisher et al. 1985; Fisher 1996), and this approach is still being used for Mediterranean fruit fly programmes in that country (Fisher 1997). At present, no other operational programmes irradiate insects in nitrogen, whereas holding pupae in airtight containers to achieve hypoxia before irradiation is a common practice (Bakri et al., this volume). López-Martínez and Hahn (2012) demonstrated the benefit of this simple practice by showing that exposure to gamma radiation under anoxic conditioning results in lower lipid and protein oxidative damage in males at sexual maturity.

## 6. COMBINATION OF RADIATION AND GENETIC STERILITY

Genetic sexing strains are now being used in almost all programmes that use the SIT for the Mediterranean fruit fly (Robinson et al. 1999; Caceres et al. 2004; Franz et al., this volume). Since these strains are constructed using male-linked translocations, they are semi-sterile (Laven 1969). To obtain a more competitive insect, it has been suggested (Steffens 1982, 1983) that this genetically contrived sterility be combined with a lower dose of radiation-induced sterility. At lower doses of radiation, the overall sterility of males from a genetic sexing strain is, of course, higher than that of males from a normal strain. However, as the radiation dose increases, the contribution from genetic sterility gets progressively less, and eventually disappears as the sterility increases. For a male with a normal karyotype, and a male carrying a translocation, the radiation dose close to full sterility is the same. Nevertheless, the use of males produced from a genetic sexing strain offers the opportunity to seriously re-examine the radiation strategy of Mediterranean fruit fly programmes, at least those that aim at suppression, to maximize the genetic load introduced into wild populations.

## 7. HYBRID STERILITY

When hybrids are formed between closely related species, or even between some populations of the same species, sterility is observed. The sterility phenotype can include the total absence of viable progeny, the production of hybrids of both sexes with varying levels of sterility, or the production of a unisexual sterile $F_1$ generation that is usually male. Examples of all these are given below.

This array of different hybrid phenotypes has a corresponding wide range of underlying genetic and cytoplasmic causes, which in many cases overlap to produce a very complex phenotypic picture. The causes of hybrid sterility can be grouped roughly into those factors that act on the nuclear genome of the insects themselves, and

those that are maternally (cytoplasmic) inherited. Many nuances and interactions are possible within these two major groups. Currently the picture is far from complete.

An early paper by Haldane (1922) reviewed cases of classical hybrid sterility in many different animal groups, including a large number of lepidopteran species. His analysis showed that there was preferential sterility or inviability in the hybrids of the heterogametic sex. This observation has become known as *Haldane's Rule*, and has largely stood the test of time (Orr 1997). For pest insects, this means that, for example in Lepidoptera where the female is heterogametic, the major hybrid effects would be seen in the resulting female hybrids, whereas in Diptera where the male is heterogametic, the $F_1$ males will be more affected.

### *7.1. Cytoplasmic Incompatibility in* Culex pipiens *L.*

Mosquitoes of the genus *Culex* are important vectors of filarial worms and some arthropod-borne viral diseases such as arboviruses. As early as 1938, Marshall (1938) showed that certain crosses of populations of *Culex pipiens* from England and France failed to produce progeny. In the 1950s Laven (1967a) carried out a worldwide survey of compatibility among many different populations of this complex. He showed that this phenomenon was cytoplasmic in origin, and that incompatibility could be uni- or bi-directional. The causative agent was a rickettsia-like bacterial symbiont; its removal by antibiotic treatment abolished the sterility phenotype (Yen and Barr 1973). The symbiont has been classified as *Wolbachia pipientis* Hertig, and is widely distributed in arthropods, with up to 76% of insect species so far examined showing evidence of infection (Jeyaprakash and Hoy 2000). It has a wide variety of effects on arthropod reproduction (Bourtzis and O'Neill 1998), and has been implicated in maintaining the viability of filarial worms that cause river blindness.

In insects, females infected with *Wolbachia* can successfully reproduce with males that are uninfected, but the reciprocal cross is sterile. This, coupled with the maternal inheritance of the infected state, enables the bacterium to spread through a population and carry with it any other factor that is exclusively maternally inherited (Pettigrew and O'Neill 1997; Curtis and Sinkins 1998). Releasing *Wolbachia*-infected males into a naive population would be equivalent to the release of radiation-sterilized males.

In 1967, an experiment to use cytoplasmic incompatibility to suppress a small isolated population of *Culex fatigans* Wiedemann was carried out in Okpo, a small village near Rangoon (Laven 1967b). Over a period of 4 months, each day about 5000 infected or incompatible males were released into a population estimated to fluctuate between 2000 and 10 000 mosquitoes. After 4 months of releases, all the remaining egg rafts collected were sterile. Unfortunately, the arrival of the monsoon season prevented any further observations. Curtis et al. (1982) carried out a much larger field trial. Although releases of incompatible males did reduce the population build-up, it was not possible to increase the percentage of sterile egg rafts above 70%. It was concluded that immigration of fertilized females from outside the village caused the stagnation in the numbers of sterile egg rafts observed.

The use of this approach for suppression requires that exclusively males of the incompatible strain be released; any females that are co-released would be compatible with the males and would lead to establishment of the *Wolbachia* strain in the wild

population and its loss for suppression purposes (Augustinos et al., this volume; Lees et al., this volume). To solve the problem of error-free sexing, as well as escaping females, a low dose of radiation can be given since female mosquitoes are generally more sensitive than males (Arunachalam and Curtis 1985; Bourtzis et al. 2016).

### *7.2. Hybrid Sterility in Tsetse*

The first evidence that sterile hybrids are formed by crossing different tsetse species was provided by Corson (1932), who obtained progeny from mass-matings involving female *Glossina morsitans centralis* Machado and male *G. swynnertoni* Austen, but as he did not make observations on mating, he concluded that it was due to parthenogenesis. Potts (1944) repeated these experiments, and concluded that true hybrids were obtained as evidenced by the morphology of the hybrid male genitalia. He also was able to backcross $F_1$ females and produce progeny. Vanderplank (1944) confirmed these observations, but noted that, when no choice of mates was offered, inter-specific crosses took place as readily as the intra-specific crosses. By catching and identifying each member of copulating pairs, Jackson (1945) confirmed that this was true also in the field. Extensive work by Curtis (1972), Rawlings (1985), Gooding (1997a, b, 2000), and Gooding and Krafsur (2005) expanded the knowledge of tsetse hybridization phenomena, and indicated how this might, or might not, be used to develop methods of pest population suppression. Interspecific crosses in tsetse produce sterile male hybrids and partially sterile female hybrids, and there is a strong asymmetry in the sterility phenotype of the reciprocal crosses. In some crosses no $F_1$ progeny are produced. The male hybrids can copulate with and inseminate females, but the hybrid sperm cannot always succeed in fertilising eggs. For other crosses, Curtis (1972) showed that, following multiple mating of females, the two types of sperm were equally competitive. However, Gooding (1992) showed that, in multiple-mated females of the *G. morsitans* subspecies, the sperm from the conspecific male was used preferentially. The inability of hybrid males to fertilize females, and the preferential use of conspecific sperm, would be serious handicaps to the use of hybrid sterility for pest suppression.

Hybrid sterility in tsetse appears to be mediated by both genetic and maternally inherited factors. A very complex picture has emerged, with many factors interacting, each with differing contributions to the total picture (Doudoumis et al. 2013). Apart from the expected chromosomal and genic interactions, two interesting observations have been made. Firstly, the fertility of reciprocal crosses between the different taxa show high levels of asymmetry. This is reminiscent of phenotypes induced by *Wolbachia* symbionts, and it is known that many tsetse species carry *Wolbachia* (Chen et al. 1999; Abd-Alla et al. 2013). Secondly, it appears that in some hybrid crosses there is a form of interaction between the mother and hybrid offspring that determines whether a pregnancy will be successfully completed. (Tsetse flies reproduce by adenotrophic viviparity, where the fertilized egg hatches into a larva that is fed within the female by milk glands, and a mature third-instar larva is produced every 9–10 days). Results by Olet (2001) have shown that females mated to males of a different taxon, though initially sterile, can as they get older begin to produce viable progeny.

Using hybrid sterility for tsetse control would involve either the release of fertile males into a non-compatible population, or the release of $F_1$ sterile males into a population of either of the parental species. The use of $F_1$ males has the disadvantage that two taxa have to be maintained in the laboratory, and that males and females from the respective taxa have to be obtained to set up the appropriate cross. In addition, the release population must be sexed to prevent the release of semi-sterile $F_1$ females, and the $F_1$ males need to be good inseminators. For the release of fertile males of one taxon into a wild population of a second taxon, only the release population must be sexed (however 100% accuracy is required).

In a large field experiment, Vanderplank (1947) eliminated a population of *G. swynnertoni* from the Shinyanga area, Tanzania, by releasing into it fertile *G. m. centralis* from Kondoa-Irangi, Tanzania (Klassen et al., this volume). About 140 000 *G. m. centralis* pupae were released over a 7-month period, and the population of *G. swynnertoni* fell, presumably due to the reduced fertility of the hybridized *G. swynnertoni* females and the subsequent matings with sterile hybrid $F_1$ males. *G. swynnertoni* was eradicated, but *G. m. centralis* did not become established because of the harsh climatic conditions, and therefore the area remained tsetse-free for some time. These field trials were carried out before it was known to applied entomologists that sterility could be readily induced by radiation, and clearly demonstrated the potential of hybrid sterility to suppress tsetse flies. They were carried out before mass-rearing of these species was possible, and all the flies released, both males and females, were from field-collected pupae (there was no way to separate the sexes). Recent improvements in tsetse mass-rearing procedures and sex-separation methods (Opiyo et al. 2000; Dowell et al. 2005) should encourage a re-examination of this form of pest suppression for tsetse.

### *7.3.* Heliothis *Hybrids — an Exception to Haldane's Rule*

Laster (1972) demonstrated that, when *Heliothis subflexa* (Guenée) females and *Heliothis virescens* (F.) males are hybridized, sterile male and fertile female progeny are produced, and the hybrid females continue to produce sterile male and fertile females through many generations of backcrossing to *H. virescens* males. Since females are heterogametic, they would be expected to suffer more from hybridization, so novel factors may be involved. Hybrid males can mate and transfer a spermatophore, but no eupyrene sperm reach the female spermathecae, even though they are produced in the testis. However, as the number of backcross generations increases, the ability of the males to produce eupyrene sperm decreases. This pattern of hybrid sterility suggests a very strong maternal component, but treatment of the moths with agents known to be lethal for *Wolbachia* failed to remove the sterility syndrome (LaChance and Karpenko 1981, 1983). An analysis of mitochondrial biogenesis in hybrid males failed to identify elements of protein synthesis or transport as being the cause of the sterility, but sperm mitochondria were implicated in the phenomenon (Miller and Huettel 1986). Such hybrid males would unlikely be effective "sterile males" in the field. Nevertheless, field trials on the island of St. Croix were conducted using the release of backcross males (Proshold 1983; Proshold et al. 1983), and temporary sterility could be demonstrated in the target population.

### *7.4.* Anopheles gambiae *Complex*

The *Anopheles gambiae* Giles complex in Africa consists of seven sibling species, and crosses between every combination led to hybrid males, with some crosses producing no females (Davidson et al. 1967). The sterility is due to chromosomal interactions, and cytoplasmic factors have not been implicated. Davidson (1969) carried out a successful series of laboratory cage experiments to evaluate the use of these sterile males, and was able to demonstrate the induction of the expected levels of sterility in target mixed-sex populations. However, a field trial (Davidson et al. 1970) failed to demonstrate any substantial degree of mating between released sterile hybrid males and wild females. Pre-mating isolation mechanisms played a decisive role in the failure, illustrating the behavioural constraints that underlie the use of hybrid sterility in the field.

## 8. TRANSFORMATION AND MOLECULAR STERILITY

The successful demonstration of transformation in *Drosophila melanogaster* Meigen (Rubin and Spradling 1982) encouraged the development of similar systems in other insects. A review by Häcker et al. (this volume) illustrates the current state of modern biotechnology for introducing foreign genes into pest insects, including classical transformation technologies via transposable elements, and site-specific genome modification techniques using recombinases. The use of molecular tools in support of the SIT involves mainly the development of marker and genetic sexing strains (Bourtzis and Hendrichs 2014; Franz et al., this volume).

Also, molecular sterility systems have been developed that might be used to produce both an elimination of females from the insects to be released, and sterility induced by matings with the released males (Heinrich and Scott 2000; Thomas et al. 2000; Häcker et al., this volume). Some of these rely on conditional lethality in $F_1$ females that are produced following the mating of released transgenic males with wild females. To date, some transgenic strains are available of several pest insects, although what is known is giving some cause for concern in two areas related to the technology itself, namely stability of the insertion and expression of the transgene. Currently, there are insufficient data to predict if transgenic strains will retain the appropriate expression patterns of the constructs under industrial mass-rearing over many generations, and following their large-scale release in the field. This will be particularly relevant for systems based on molecular sterility where permanent and absolute sterility of the system is essential. It will be difficult to predict the long-term stability of transgenes, and hence their expression in the transformed strains. This problem could be magnified once fertile laboratory transgenic strains are released into a wild population, the genomic diversity of which is unknown.

There is also the slightly disconcerting idea that a transgene, once released in a fertile insect, cannot be "recalled" or destroyed. This applies particularly to self-sustaining strategies, which leave an "ecological footprint" because they are intended to persist indefinitely in the target population and may invade other populations (Alphey 2014). The integration of transgenic technology with the SIT, as part of self-limiting strategies, would be an option to reduce risk, since radiation-induced sterility

would prevent vertical transmission of the transgene. Public concern related to genetically modified organisms needs to be addressed, and a regulatory framework is required, so that available transgenic insect strains are properly field-tested.

## 9. CONCLUSIONS

Due to the extensive studies on the radiation biology of *Drosophila* sp. carried out in the 1950s and 1960s, there is a very good understanding of the genetic basis of radiation-induced sterility in that species. However, even though the underlying mechanisms are known and are probably of wide relevance, there still are many unexplained observations, especially in regards to the different dose-response curves found for different species, even within the same order (Bakri et al. 2005). For one type of mutation, i.e. specific locus mutations, there is a very good correlation between the dose-response curve and the DNA content of the haploid genome (Abrahamson et al. 1973); these studies ranged from bacteria to man. There is as yet insufficient information on genome size, in a large enough number of insect species, to assess whether such a simple relationship holds for dominant lethal induction. In addition, in species with holokinetic chromosomes, the mechanism(s) of dominant lethal induction has/have still to be fully explained (Marec et al., this volume).

Radiation is usually one of the last procedures that insects undergo before leaving mass-rearing facilities for release in the field, and it is important that it be applied in a way that minimizes its detrimental effects on insect competitiveness. Firstly, it is essential that the dosimetry of the radiation source be checked to ensure that all the insects receive the required minimum dose, and that none is unnecessarily overdosed (Bakri et al., this volume). Secondly, a dose should be chosen that maximizes the level of introduced sterility in the wild females in the field, i.e. both the sterility level in the released males and their competitiveness has to be taken into account. Thirdly, numerous studies have shown that irradiation in nitrogen or hypoxia can provide protection against the detrimental somatic effects of radiation.

Currently, modern biotechnology tools are applied extensively in support of the SIT to develop marker and genetic sexing strains (Häcker et al., this volume). Furthermore, the development of molecular methods to sterilize pest insects, by the release into the field of fertile insects carrying transgenes, has made considerable progress, in spite of the many unknowns inherent in such systems. Several of these strains are now available, and some have undergone an initial evaluation under mass-rearing scenarios or in open-field trials (Carvalho et al. 2015). Overall, however, their wider adoption has so far been quite limited in view of the negative public opinion on transgenic technology, and the regulatory requirements and approvals that are required in most countries for their application.

Using biological/molecular methods to sterilize insects is quite different from using a physical process, such as radiation. In the former, the essential biological interaction required to generate the sterility phenotype is subject to biological variation in both components, and is therefore unpredictable in the long term. A physical process such as radiation is not subject to this variation, and hence, in some ways, is an ideal methodology. Insects cannot become resistant to ionizing radiation as it is used in the SIT (Whitten and Mahon, this volume).

Pages 163–200
*V. A. Dyck, J. Hendrichs and A. S. Robinson (eds.), Sterile Insect Technique. Principles and Practice in Area-Wide Integrated Pest Management. Second Edition.*

SUMMARY

The unique genetic phenomena responsible for inherited sterility (IS) in Lepidoptera and some other arthropods, as compared with full sterility, provide advantages for pest control. Lepidopteran females are usually more sensitive to radiation than males of the same species. This allows the radiation dose to be adjusted to suit programme requirements. When partially sterile males mate with wild females, the radiation-induced deleterious effects are inherited by the $F_1$ generation. As a result, egg hatch is reduced and the resulting offspring are both highly sterile and predominately male. Compared with the high radiation required to achieve full sterility in Lepidoptera, the lower dose of radiation used to induce $F_1$ sterility increases the quality and competitiveness of the released insects as measured by improved dispersal after release, increased mating ability, and superior sperm competition. $F_1$ sterile progeny produced in the field enhance the efficacy of released partially sterile males, and improve compatibility with other pest control strategies. In addition, $F_1$ sterile progeny can be used to increase the production of natural enemies, and to study the potential host and geographical ranges of exotic lepidopteran pests.

## 1. INTRODUCTION

Lepidopteran species are among the most destructive pests of annual and perennial crops, forests, and stored products throughout the world. Following the successful area-wide integrated pest management (AW-IPM) programme, integrating the sterile insect technique (SIT), against the screwworm fly *Cochliomyia hominivorax* (Coquerel) (Bushland 1971), studies were conducted on the possibility of suppressing lepidopteran pest populations through the release of radiation-sterilized moths. However, because Lepidoptera are radioresistant compared with most other insects (LaChance et al. 1967; Bakri et al., this volume), a dose required to achieve full sterility is so high that it reduces the ability of sterile moths to compete with wild moths. To increase the competitiveness of irradiated Lepidoptera, Proverbs (1962) investigated the effects of substerilizing doses of radiation on the codling moth *Cydia pomonella* (L). He noted that male moths treated with substerilizing doses and then mated to fertile females produced reduced numbers of $F_1$ progeny, the majority of which were males with very low fertility. This discovery prompted numerous investigations in many lepidopteran pests. North (1975) and LaChance (1985) provide thorough reviews of the early investigations on inherited sterility (IS), and discuss potential advantages of using IS in suppressing pest populations and its possible genetic basis.

IS is also referred to as inherited partial sterility, partial sterility, delayed sterility, semi-sterility and $F_1$ sterility (Vreysen et al. 2016). Although it is difficult to find a satisfactory definition for IS, LaChance (1985) described several attributes that are common to IS in Lepidoptera: $F_1$ male and female offspring are more sterile than the irradiated parental ($P_1$) generation, and more $F_1$ male progeny than female progeny are produced. Other attributes may include longer developmental time and reduced sperm quality in the $F_1$ generation. Radiation-induced deleterious effects can be inherited for several generations; however, the majority of the inherited deleterious effects are expressed in the $F_1$ generation.

## 2. HISTORICAL OVERVIEW

IS was first reported during studies in the Soviet Union of radiation-induced genetic anomalies in the silkworm *Bombyx mori* (L.) (Astaurov and Frolova 1935). A few years later Ostriakova-Varshaver (1937) reported IS in the greater wax moth *Galleria melonella* (L.). In North America, Proverbs (1962) was the first to describe IS in the codling moth. Within the order Hemiptera, LaChance and Degrugillier (1969) reported IS while conducting genetic studies on the large milkweed bug *Oncopeltus fasciatus* (Dallas), and Delrio and Cavalloro (1975) and Maudlin (1976) documented IS in *Gonocerus acuteangulatus* (Goeze), a coreid pest of hazelnuts, and in *Rhodnius prolixus* (Stål), a reduviid vector of Chagas' disease, respectively. IS has also been reported in mites of the family Tetranychidae (Henneberry 1964). Although Curtis (1969) and Curtis et al. (1973) found low levels of sterility (5–15%) in the $F_1$ generation of irradiated tsetse flies (Diptera: Glossinidae), this level of sterility was less than that found in the irradiated parents, and other attributes common to IS in Lepidoptera were not demonstrated in these insects.

The genetic basis for IS has been reviewed and discussed by many authors (Bauer 1967; LaChance 1967, 1974, 1985; LaChance et al. 1970; North and Holt 1970; North 1975; LaChance and Graham 1984; Anisimov et al. 1989; Marec et al. 1999; Tothová and Marec 2001). In this chapter, emphasis will be given to the more recent research findings in the order Lepidoptera. Also the use of genetic sexing, together with IS for the suppression of lepidopteran populations, will be discussed briefly. The advantages of IS as compared with full sterility, the potential for IS to suppress pest populations, and the compatibility of IS with other pest control methods, particularly with biological control, are also discussed. Table 1 provides a comprehensive list of arthropod species where IS has been documented, and includes key references that deal with radiation biology and field studies.

## 3. GENETICS AND INHERITED STERILITY

No comprehensive review of lepidopteran genetics has been published in the last 45 years. Robinson (1971) provided useful information on formal genetics (including karyology) for many species in this large order. Additional information can be extracted from published research on three economically important species: the silkworm (Tazima 1964; Goldsmith 1995; Fujii et al. 1998; Nagaraju 2000), the Mediterranean flour moth *Ephestia kuehniella* (Zeller) (Caspari and Gottlieb 1975; Leibenguth 1986), and the pink bollworm *Pectinophora gossypiella* (Saunders) (LaChance and Ruud 1980; Bartlett 1989; Bartlett and Del Fosse 1991). Recent advances in the molecular biology and genetics of established and emerging lepidopteran models have been summarized in Goldsmith and Marec (2010).

The lepidopteran genome exhibits a number of peculiarities that distinguishes it from the genomes of other insect orders, except perhaps from that of the closely related order Trichoptera. Chromosomes in Lepidoptera are usually small, numerous, and possess few differentiating features. Most species are reported to have haploid numbers close to 30 (n = 28–32); n = 31 appears to be the ancestral number (Ahola et al. 2014). However, karyological studies have identified species

with lower or higher chromosome numbers that are probably the result of chromosome fusion or fission (Suomalainen 1969a; Robinson 1971; reviewed in Marec et al. 2010). Lepidopteran chromosomes are usually spherical and uniform in shape, and consequently not much is known about their morphology, kinetic organization and behaviour during mitotic and meiotic cell division. Lepidopteran chromosomes lack distinct primary constrictions (centromeres) and, as a result, sister chromatids separate by parallel disjunction during mitotic metaphase. Many researchers have concluded that these genomic peculiarities are an indication that lepidopteran chromosomes are holokinetic (Murakami and Imai 1974). However, ultrastructure studies suggest that lepidopteran chromosomes are intermediate between holokinetic and monocentric (Wolf 1996). Nevertheless, a recent functional analysis of the silkworm kinetochore supports the holokinetic structure, although different from the other groups of organisms with holokinetic chromosomes (Mon et al. 2014).

Two other groups of arthropods have shown IS, mites (Acari) and Hemiptera; both possess holokinetic chromosomes and are radioresistant (Brown and Nelson-Rees 1961; Hughes-Schrader and Schrader 1961; LaChance and Degrugillier 1969; Wrensch et al. 1994). Gassner and Klemetson (1974) showed that the kinetochore (centromere) in the large milkweed bug covers more than 70% of the chromosomal surface. Gonzales-Garcia et al. (1996) provided indirect evidence of the holokinetic nature of hemipteran chromosomes while working with *Graphosoma italicum* (Muller) (Pentatomidae). Nonetheless, Wolf (1996) suggests that further investigation is needed to verify the holokinetic nature of hemipteran chromosomes.

The sex chromosomes of Lepidoptera are of the WZ type, in which females are heterogametic (WZ) and males homogametic (ZZ). Lepidopteran species, where sex chromosomes have been identified, show a typical ♀WZ/♂ZZ system, or variants such as Z/ZZ, $W_1W_2Z$/ZZ or $WZ_1Z_2/Z_1Z_1Z_2Z_2$ (Suomalainen 1969b; Robinson 1971; Nilsson et al. 1988; Traut and Marec 1997; Rishi et al. 1999; reviewed in Traut et al. 2007 and Marec et al. 2010). Male chromosomes display a normal sequence of meiotic events. In contrast, female chromosomes undergo normal meiosis until they approach the pachytene stage (Fig. 1), when they pair by means of synaptonemal complexes to form bivalents, and synaptonemal complexes become visible (Marec 1996). From this point onwards, female meiosis proceeds without meiotic recombination, and is achiasmate (Traut 1977; Nokkala 1987). The synaptonemal complexes in the female transform into elimination chromatin that later detaches from the bivalents and persists during chromosome segregation in the metaphase plate (Rasmussen 1977). The female W and Z chromosomes, although often non-homologous and of different size, pair completely during meiosis and form a regular bivalent.

Another peculiarity of the lepidopteran genome is the presence of one or more heterochromatic bodies in female somatic cells during interphase. This female specific heterochromatin (also known as W- or sex-chromatin) is derived from the W chromosome. Since sex chromatin is easily identified in interphase nuclei and is especially visible in highly polyploid somatic cells, it can be used as a marker to determine the sex of embryos and larvae and also to identify sex chromosome aberrations in mutagenesis screens (Traut and Marec 1996; Fuková et al. 2009).

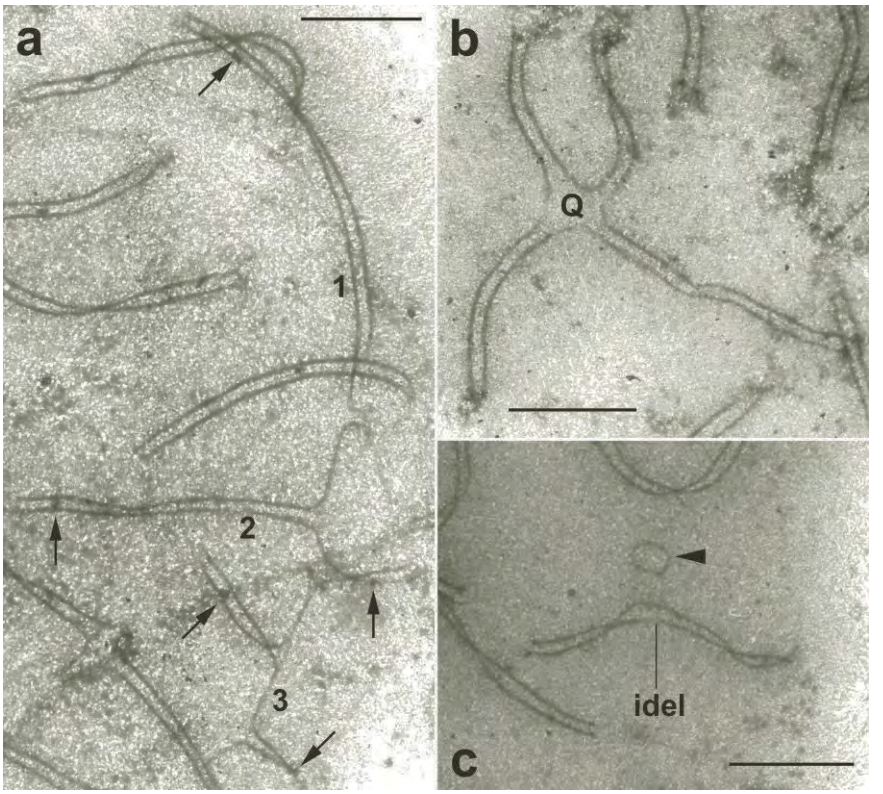

*Figure 1. Examples of pachytene configurations in aberrant chromosomes of* Ephestia kuehniella *in microspread spermatocytes of $F_1$ males after the parental male was irradiated with 150 Gy. a: Multiple chain translocation that involves 7 lateral elements, each representing the protein axis of one chromosome, where 1–3 represent structurally normal chromosomes inherited from the untreated female parent; arrows indicate recombination nodules; b: Quadrivalent (Q) typical in reciprocal translocations; c: Ring fragment (arrow) plus a bivalent with one shorter lateral element (idel) that indicates interstitial deletion. All are electron microscope (EM) micrographs stained with phosphotungstic acid. Scale = 2 μm.*

Lepidopteran males undergo two distinct modes of spermatogenesis/meiosis that result in the production of two different types of sperm (Wolf 1994; Friedländer et al. 2005): the larger, nucleate and fertile eupyrene sperm, and the smaller, anucleate and non-fertile apyrene sperm. Apyrene sperm are more abundant and contain less mitochondrial material (Kawamura et al. 1998), while eupyrene sperm are less abundant and typically comprise 10–15% of the total sperm transferred to a female during mating (Gage and Cook 1994; Cook and Wedell 1996). The role of apyrene sperm is not fully understood, although it has been suggested that they aid the transfer of eupyrene sperm to the female (Cook and Wedell 1996), have a nutritive

function (Friedländer 1997), or may be involved in sperm competition. The latter function was studied in *Pieris napi* (L.), where the presence of apyrene sperm was shown to delay female remating (Cook and Wedell 1999).

### *3.1. Radioresistance in Lepidoptera*

A high resistance to the effects of ionizing radiation is a characteristic feature of moths and butterflies (LaChance 1985). Cultured lepidopteran cells are 50–100 times more resistant to radiation-induced death than similarly cultured mammalian cells. In contrast dipteran cells are only three to nine times more resistant than mammalian cells (Koval 1996; Chandna et al. 2004). Results of recent studies of a Sf9 cell line, originally derived from *Spodoptera frugiperda*, suggest that several intracellular mechanisms, such as an efficient antioxidant defence and a high activity of histone deacetylases, contribute to the radioresistance of lepidopteran cells (Suman et al. 2015; Sharma et al. 2016). This high radioresistance in Lepidoptera also applies to germ cells, and in particular to mature sperm. As a consequence very high doses of radiation are required to fully sterilize lepidopteran males (LaChance and Graham 1984).

LaChance and Graham (1984) and Koval (1996) suggested that possible molecular mechanisms responsible for the high radioresistance in Lepidoptera might include an inducible cell recovery system and a DNA repair process. Even though lepidopteran chromosomes are not truly holokinetic, a significant role in their radioresistance can be attributed to their holokinetic "nature" (as first suggested by LaChance et al. 1967) and to the fate of the radiation-induced chromosome fragments during mitotic cell cycles as explained below (Tothová and Marec 2001). Lepidopteran chromosomes possess a localized kinetochore plate to which the spindle microtubules attach during cell division (Gassner and Klemetson 1974; Traut 1986; Wolf and Traut 1991; Wolf et al. 1997). The kinetochore plates are large and cover a significant portion of the chromosome length (Wolf 1996), ensuring that most radiation-induced breaks will not lead to the loss of chromosome fragments as is typical in species with monocentric chromosomes. In species with large kinetochore plates, the fragments may persist for a number of mitotic cell divisions, and can even be transmitted through germ cells to the next generation (Marec and Traut 1993a; Marec et al. 2001). The plates also reduce the risk of lethality caused by the formation of dicentric chromosomes, acentric fragments, and other unstable aberrations (Tothová and Marec 2001) (Fig. 2).

### *3.2. Radioresistance in Hemiptera*

A difference in radiosensitivity between males and females has also been documented in several hemipterans including species of economically important leafhoppers (Shipp et al. 1966; Ameresekere and Georghiou 1971) and mealybugs (Brown and Nelson-Rees 1961). However, LaChance and Degrugillier (1969) were the first to document IS in the order Hemiptera when they induced chromosomal fragments and translocations in the large milkweed bug. These authors demonstrated

that the induced fragments were both mitotically and meiotically stable, and could be transmitted through three generations of outcrosses to normal females.

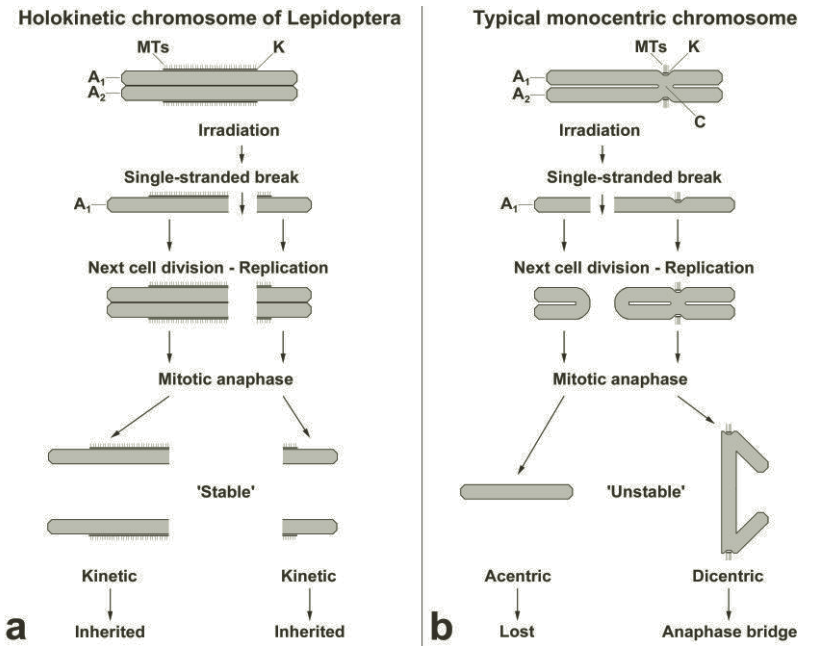

*Figure 2. Kinetic structure of lepidopteran chromosomes during mitotic metaphase, and consequences of chromosome breakage;* ***a****: Holocentric chromosome with two sister chromatids ($A_1$ and $A_2$), each with a kinetochore plate (K) covering about 50% of the chromosome surface; spindle microtubules (MTs) are attached to the kinetochore;* ***b****: Typical monocentric chromosome, where sister chromatids are joined by the centromere (C); the kinetochore is localized on the surface of the centromere.*

### *3.3. Radiation-Induced Sterility in Parental ($P_1$) Generation*

Radiation-induced sterility is generally a consequence of dominant lethal mutations (DLMs) that result in the death of the zygote or the embryo. The chromosomal damage responsible for DLMs is characterized by the formation of anaphase chromosome bridges, chromosome fragments and other abnormalities in the dividing nuclei. In most insects DLMs are expressed during early embryogenesis (LaChance 1967). In Lepidoptera, however, the frequency of DLMs is much lower than in other insects and the majority are expressed very late in embryonic development (LaChance 1974; Berg and LaChance 1976). Furthermore, no chromosomal bridges, indicating the presence of dicentric chromosomes, are evident during embryonic development in Lepidoptera (LaChance and Graham 1984) and Hemiptera studied thus far (LaChance et al. 1970; Maudlin 1976).

For males of four insect species, LaChance and Graham (1984) constructed dose-response curves for the induction of DLMs in mature sperm. The species exhibited a wide range of radiosensitivity, with Hemiptera showing intermediate and Lepidoptera high radioresistance. When analysed mathematically, the dose-response curves approximated an S-shape (LaChance and Graham 1984; Marec et al. 1999). For highly radioresistant Lepidoptera, the curves approximated those expected for 8–16-hit kinetics while in Hemiptera the curve exhibited 4-hit kinetics. These data suggest that multiple chromosome rearrangements must be induced in lepidopteran males to be manifested as DLMs, explaining why lepidopteran males require very high radiation doses (350–500 Gy) to be fully sterilized.

Radiation-induced sterility in lepidopteran males may also have other causes. Anisimov et al. (1989) observed a dose-dependent increase in the number of matings that produced no eggs, or the number of females that laid only unembryonated eggs, following mating with irradiated male codling moths. A significant proportion of unembryonated eggs (that might represent unfertilized eggs and/or eggs with early embryonic mortality) were also observed after treated males were mated to females of *Manduca sexta* (L.) (Seth and Reynolds 1993), *E. kuehniella* (Marec et al. 1999), and *Spodoptera litura* (F.) (Seth and Sharma 2001). Furthermore, Koudelová and Cook (2001) demonstrated with *E. kuehniella* that the volume of sperm transferred during copula decreased, and mating times increased, as the dose increased. Irradiated males of *Tuta absoluta* (Meyrick) produced a significantly higher portion of deformed eupyrene sperm bundles than untreated males (Carabajal Paladino et al. 2016). Taken together, the above data suggest that an important component of male sterility can be due to physiological disruptions during copulation, including the inability to copulate and abnormal sperm transfer.

Lepidopteran females are considerably more radiosensitive than males. In a number of species, a dose of 100 Gy is sufficient to achieve almost full sterility in treated females (Anisimov et al. 1989; Marec and Mirchi 1990; Bloem et al. 1999a) (Fig. 3). It appears that this difference in radiosensitivity between males and females is related to the stage of development of the reproductive cells at the time of irradiation. Lepidoptera are usually irradiated as mature pupae or newly emerged adults. At this stage of development eupyrene spermiogenesis in the male has been completed, and the nuclei in eupyrene sperm are in interphase. In contrast, female meiosis is arrested at metaphase I in the nuclei of mature oocytes and the process does not resume until the eggs have been laid (Traut 1977). As a consequence irradiation of newly emerged females or of mature female pupae may disrupt the normal course of meiosis including chromosome segregation. Finally, various secondary detrimental effects can be expected in oocytes, which have a large amount of cytoplasm (that contains many components required for embryonic development) in comparison with the essentially cytoplasm-free sperm. Almost nothing is known about the radiosensitivity of female Hemiptera, although Delrio and Cavalloro (1975) showed that *G. acuteangulatus* females were fully sterilized at a dose of 50–60 Gy. At this dose males were about 70% sterile.

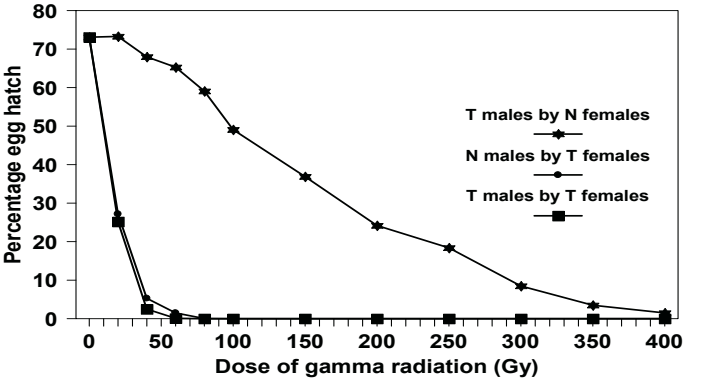

*Figure 3. Percentage egg hatch obtained when codling moth adults were treated with increasing doses of gamma radiation, and either inbred or outcrossed with fertile moths. T = Treated, N = Non-treated. (Figure from Bloem et al. 1999a.)*

### *3.4. Radiation-Induced Sterility in $F_1$ Generation*

Cytogenetic work by Tothová and Marec (2001) showed that various types of translocations (non-reciprocal, reciprocal and multiple) are responsible for the production of genetically unbalanced gametes in $F_1$ progeny and, as such, represent the main chromosomal mechanism of IS. In addition, they demonstrated that two types of intra-chromosomal aberration, fragmentation, and interstitial deletion increase the frequency of unbalanced gametes; however, their contribution to overall sterility appears to be less significant. The study also revealed that the predicted level of $F_1$ sterility, based on the observed frequency of aberrations, was much higher than the sterility observed in a previous study (Marec et al. 1999). This suggests that Lepidoptera possess a mechanism that corrects the predicted unbalanced state towards a balanced segregation of chromosomes. The authors suggested that the increased number of chiasmata might facilitate a balanced disjunction of chromosomes from translocation multivalents in $F_1$ males. The modified synaptonemal complex, which ensures regular disjunction of homologous chromosomes during female meiosis in Lepidoptera (Rasmussen 1977; Marec 1996), might play a similar role in $F_1$ females (Tothová and Marec 2001).

Several authors have documented the effects of radiation on the incidence of visible chromosomal aberrations in $F_1$ males using light microscopy (North and Snow 1978; Saifutdinov 1989; Al-Taweel et al. 1990; Carpenter 1991; Carpenter et al. 1997; Carabajal Paladino et al. 2016).

To better understand the principle of inherited sterility, Tothová and Marec (2001) used a modified micro-spreading technique, first employed by Weith and Traut (1980), to study radiation-induced chromosome aberrations in $F_1$ individuals of *E. kuehniella*. The micro-spread chromosomes were viewed with an electron microscope and several types of aberrations were documented. In $F_1$ individuals from male parents treated with 100 and 150 Gy, the overall frequency of aberrations

varied between 4.2 and 4.8 per $F_1$ larva in both sexes. A significant increase in aberrations was found in $F_1$ males from male parents treated with 200 Gy (6.2 per male). Fragmentation and several types of translocations (non-reciprocal, reciprocal, and multiple) were the most common aberrations, while interstitial deletions and inversions were rare. Multiple translocations forming complicated configurations were found with increasing radiation dose. In males the mean number of chromosomal breaks resulting in aberrations increased linearly with dose, from 8.4 to 16.2 per nucleus. In females this value reached a maximum of 11.2 breaks per nucleus when male parents were treated with a dose of 200 Gy (Fig. 1).

### *3.5. Sex-Specific Differences in Inherited Sterility*

Two consequences of radiation-induced IS are sex-specific and positively correlated with treatment dose. First, the sex ratio of the $F_1$ generation is skewed toward males (Lepidoptera — Proverbs 1962; Hemiptera — LaChance et al. 1970) and, second, the level of IS in $F_1$ female progeny is lower than in $F_1$ males (Lepidoptera — Anisimov et al. 1989; Al-Taweel et al. 1990; Seth and Reynolds 1993; Bloem et al. 1999a).

Marec et al. (1999) suggested that the sex ratio distortion in the $F_1$ generation in Lepidoptera occurs as a result of recessive lethal mutations induced in the Z sex chromosomes of treated male parents. Since lepidopteran females are heterogametic, all female $F_1$ progeny will be hemizygous for Z and, as a consequence, any deleterious Z-linked mutations will result in $F_1$ female mortality. In contrast, the $F_1$ male progeny will inherit one Z chromosome from the treated father and the other from the mother and, as such, will be heterozygous for any Z-linked mutation.

The induction of $F_1$ sterility by transmitting complex chromosome translocations to the progeny of treated males was first suggested by North (1967) and North and Holt (1968) for Lepidoptera and by LaChance and Degrugillier (1969) for Hemiptera. Tothová and Marec (2001) suggested three factors that might explain the higher level of sterility found in $F_1$ male progeny of Lepidoptera:

- The ability of $F_1$ males to survive even though they inherit a large number of chromosome breaks. The authors found that in $F_1$ males of *E. kuehniella*, the mean frequency of chromosome breaks was positively correlated with a dose-dependent increase in sterility, whereas a clear correlation was lacking for $F_1$ females. They suggested that this difference was due to higher mortality in $F_1$ females that inherit a high number of breaks. Furthermore, at higher treatment doses, there is increased probability that the sex chromosome (Z) will be damaged and, as a consequence, any resulting recessive lethal mutation would kill the $F_1$ females but not the males. Those $F_1$ females that survive carry a smaller number of chromosome breaks and, therefore, are more fertile than the $F_1$ males.
- The occurrence of crossing-over during spermatogenesis. In $F_1$ males crossing-over during spermatogenesis might increase the number of unbalanced gametes produced, but only if it occurs at the crossover point between an aberrant chromosome (that arose by two or more breaks) and its structurally normal homologue. This situation might occur when inversions and multiple

translocations are formed. However Tothová and Marec (2001) rarely detected inversions in their study on *E. kuehniella*. They concluded that crossing-over contributes to the sterility in $F_1$ males mostly through the formation of multiple translocations. Since female meiosis is achiasmate during oogenesis, this factor cannot play a role in the sterility level of $F_1$ females (Rasmussen 1977; Traut 1977; Nokkala 1987; Marec and Traut 1993b).

- A higher impact of radiation-induced deleterious effects on the fertility of $F_1$ males. Some studies have reported finding a higher number of $F_1$ male crosses that are fully sterile or that have resulted in the female laying a large number of unembryonated eggs, whereas most $F_1$ female crosses laid embryonated eggs (Anisimov et al. 1989; Marec et al. 1999). The data suggest that induced genetic changes impaired the fertilizing ability of some $F_1$ males while the $F_1$ females were not similarly affected. In addition, Koudelová and Cook (2001) reported great variability in the number of sperm that were transferred by $F_1$ males of *E. kuehniella*. They found that, on average, the number of eupyrene sperm decreased, whereas the number of apyrene sperm increased, resulting in an abnormally high ratio of apyrene to eupyrene sperm. The ratio fluctuated between 9.5:1 for untreated males and as high as 100:1 for treated males. These results suggest that chromosomal rearrangements in $F_1$ males may have altered the mechanisms regulating dichotomous spermiogenesis or those underlying copulation and sperm transfer.

### *3.6. Genetic Sexing in Lepidoptera*

Genetic sexing has been documented in only two lepidopteran species. Strunnikov (1975) reported that genetic sexing was possible in the silkworm, *B. mori*. About 15 years later Marec (1990, 1991) and Marec and Mirchi (1990) were successful in constructing in *E. kuehniella* a balanced lethal genetic sexing strain, according to the scheme of Strunnikov (1975). This strain, called BL-2, results in males that are trans-heterozygous for two sex-linked recessive lethal mutations, *sl-2* and *sl-15*. When BL-2 males are mated to wild-type females, the $F_1$ generation consists almost exclusively of male progeny. The $F_1$ females die during embryogenesis because they inherit one of the lethal mutations from their father, i.e., females are hemizygous for *sl-2* or *sl-15* (Fig. 4).

BL-2 males of *E. kuehniella* could be released directly into nature to introduce lethal mutations into the wild population (Marec et al. 1996), or they could be maintained in the laboratory and used to generate a male-only mutant strain that could be irradiated and released into the environment (Marec et al. 1999). Marec et al. (1999) suggested that the production of male-only colonies through the use of balanced lethal strains would reduce rearing costs and enhance population suppression when used alone or in combination with $F_1$ sterility. Furthermore, outcrosses of balanced lethal males with wild-type females one generation before irradiation and release would improve the competitiveness of males through positive heterosis. Finally, in addition to the genetic changes induced by treating the males with gamma radiation, the released mutant males would introduce sex-linked recessive lethal mutations into the wild population that would further reduce the

number of $F_1$ females produced in the field. However, this system relies on sexing two different strains and making directed crosses, and would be impractical in an operational programme.

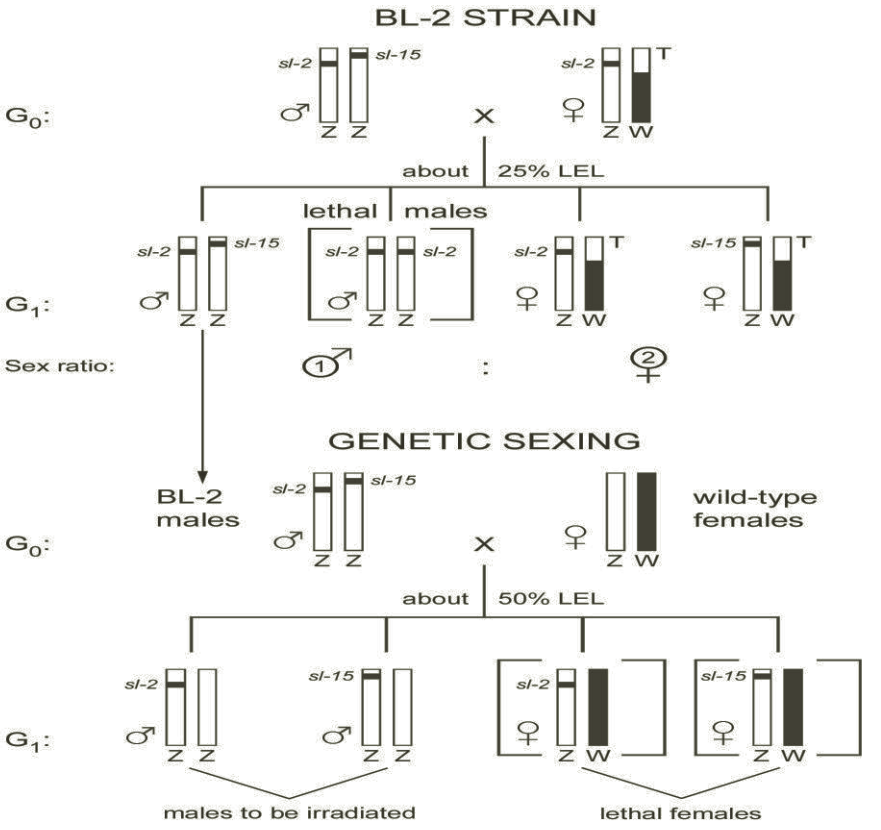

*Figure 4. Genetic sexing system developed in the Mediterranean flour moth; the cross between BL-2 males and wild-type females produces only male progeny. Z and W represent the sex chromosomes; sl-2 and sl-15 are sex-linked recessive mutations. LEL = late embryonic lethality (details in text).*

Some significant obstacles still need to be overcome before these types of genetic sexing strain can be used against pest Lepidoptera. For example suitable markers are currently lacking for the construction of similar mutant strains in other economically important species. Also the genetic sexing system requires the mass-rearing of two different colonies, a wild-type strain and a balanced lethal strain, for which sex separation somehow has to be carried out under mass-rearing conditions. Finally, the mutant strain must be routinely checked to prevent the loss of its genetic structure through genetic recombination or colony contamination (Marec 1991; Franz et al., this volume).

Discovery of the sex-determining mechanism in Lepidoptera might facilitate the development of a more convenient and sophisticated sexing system. However, little is known about sex determination in Lepidoptera and, except for the silkworm *B. mori,* the exact locations of the primary sex-determining factors are unknown (Traut and Marec 1996; Traut et al. 2007). In this species, significant progress is being made that will undoubtedly facilitate future research on lepidopteran genetics. Ohbayashi et al. (2001) found a homologue of the *Drosophila doublesex* (*dsx*) gene in *B. mori* called *Bmdsx*. A sex-specific alternative splicing of the primary *Bmdsx* transcript, along with results of functional studies, strongly suggest that the gene controls sexual differentiation, as does the *Drosophila dsx* gene (Suzuki 2010). In the silkworm, sex determination depends on the presence or absence of the W chromosome, which carries a dominant female-determining factor (*Fem*) (Fujii and Shimada 2007). Recently, Kiuchi et al. (2014) showed that *Fem* is not a protein-coding gene as originally assumed but a W-encoded small RNA named *Fem* piRNA. The *Fem* piRNA controls female-specific splicing of the *Bmdsx* gene by downregulating expression of the Z-linked *Masculinizer* (*Masc*) gene. It is not known yet if the *Fem* piRNA-*Masc* sex-determining pathway is conserved in other Lepidoptera. Nevertheless, the *dsx* function in sexual differentiation appears to be conserved at the bottom of a sex-determining cascade in many insects including Lepidoptera (Suzuki 2010; Gempe and Beye 2011). Thus, the *dsx* gene may be a good target for the development of genetic sexing strains in pest Lepidoptera.

Advances in genetic technologies, especially in transgenesis, open up new possibilities for genetic sexing in Lepidoptera. Germ-line transformations, with a *piggyBac* transposable element, have been demonstrated — in the pink bollworm by Peloquin et al. (2000) and in the silkworm by Tamura et al. (2000). It has been suggested that genetic sexing strains based on a transgenic approach may be a possible solution to this problem (Marec et al. 2005), where the females would be transgenic but not the sterile males for release. Some progress in developing such strains has been reported in the codling moth (Marec et al. 2007) but this work has not yet been completed. Nevertheless, the feasibility of this approach has been demonstrated recently in the silkworm by the successful insertion of a transgene carrying the EGFP (enhanced green fluorescent protein) reporter into the W chromosome (Ma et al. 2013). Also, a new transgenic conditional lethal genetic sexing system has been developed in the silkworm (Tan et al. 2013) and in two pest species, the diamondback moth and the pink bollworm (Jin et al. 2013). This system is based on the tetracycline-repressible transactivator (tTAV) protein, which is expressed only in females through the alternatively spliced region of the pink bollworm *dsx* gene (*Pgdsx*).

## 4. ADVANTAGES OF INHERITED STERILITY VERSUS FULL STERILITY

The unique characteristics of IS in Lepidoptera and other arthropods provide some inherent advantages over the use of full sterility in pest control programmes (North 1975). Since lepidopteran females generally are much more radiosensitive than males of the same species, the radiation dose may be adjusted to suit programme requirements, i.e. treated females are completely sterile and males partially sterile.

When these partially sterile males mate with fertile females the radiation-induced deleterious effects are inherited by the $F_1$ generation. As a result egg hatch is reduced and the resulting ($F_1$) offspring are both highly sterile and predominately male (Table 2). The lower dose of radiation used to induce $F_1$ sterility increases the quality and competitiveness of the released insects (North 1975) as measured by improved dispersal after release (Bloem et al. 2001), increased mating ability (Carpenter et al. 1987a), and superior sperm competitiveness (Carpenter et al. 1987a, 1997). In addition, because $F_1$ sterile progeny are produced in the field, the release of partially sterile males and fully sterile females is more compatible with other pest control mechanisms or strategies (Carpenter 1993; Cagnotti et al. 2016).

*Table 2. Typical attributes of male lepidopteran insects (and their progeny) receiving substerilizing doses of radiation*

| Dose applied to $P_1$ (Gy) | 1 Egg hatch (%) | 2 Larval mortality (%) | 3 Sex ratio ♂:♀ | 4 Egg hatch (%) | |
|---|---|---|---|---|---|
| | | | | $F_1$♂ | $F_1$♀ |
| 0 | 71.8 | 20.0 | 1.0:1 | 82.5 | 76.8 |
| 100 | 46.1 | 51.1 | 2.6:1 | 10.8 | 13.9 |
| 200 | 30.8 | 69.5 | 5.1:1 | 0.9 | 7.5 |
| 250 | 19.1 | 75.1 | 7.0:1 | 0.8 | 6.1 |

1. Reduced $F_1$ egg hatch resulting from $P_1$ (parental) generation
2. Increased mortality during $F_1$ development
3. Skewed sex ratio in favor of males in the $F_1$ generation
4. Reduced $F_2$ egg hatch resulting from $F_1$ generation; sterility in $F_2$ generation higher than in $F_1$ generation

Data for codling moth (Bloem et al. 1999a)

Knipling (1970) used a mathematical model to explore the application of IS for control of lepidopteran pests (Barclay, this volume). He found that the release of partially sterile insects offered greater suppressive potential than the release of fully sterile insects, and suggested that the partially sterile-to-wild overflooding ratio could be as low as a one-quarter of what is normally required for fully sterile insects. Population models using data collected from several pest species (Walker and Pederson 1969; Brower and Tilton 1975; Carpenter et al. 1987a; Anisimov 1993; Carpenter and Layton 1993; Kean et al. 2011) corroborate Knipling's findings.

## 5. POTENTIAL FOR INHERITED STERILITY TO SUPPRESS PEST POPULATIONS

Field releases of partially sterile insects have demonstrated the usefulness of IS to control many lepidopteran pests, including the cabbage looper (North and Holt 1969), corn earworm (Carpenter and Gross 1993), gypsy moth (Mastro 1993),

codling moth (Proverbs et al. 1978; Bloem et al. 1999b; Bloem et al. 2001), cactus moth (Hight et al. 2005), and many others (Bloem and Carpenter 2001; Simmons et al., this volume). The effect of $F_1$ sterility to influence pest populations has been most convincing when irradiated insects have been released in the field throughout the entire growing season. Season-long releases of irradiated (100 Gy) *H. zea* in mountain valleys of North Carolina, USA, delayed and/or reduced seasonal increases of wild *H. zea* males (Carpenter and Gross 1993). The incidence of *H. zea* larvae with chromosomal aberrations indicated that irradiated males were very competitive in mating with wild females, and were successful in producing $F_1$ progeny, which further reduced the wild population. Release ratios averaged less than 5:1 overall, but reduced the wild population of *H. zea* by more than 70%. In another case, season-long field studies of the codling moth were conducted in apple orchards in Washington State, USA, that compared: (1) twice-weekly releases of partially sterile codling moths treated with either 100 or 250 Gy, and (2) combinations of mating disruption plus the release of partially sterile (100 Gy) codling moths, to control wild populations (Bloem et al. 2001). The results showed that fruit damage was significantly lower in all treatment plots when compared with control plots located outside the treatment areas.

## 6. COMPATIBILITY OF INHERITED STERILITY WITH OTHER PEST CONTROL METHODS

The success of releasing insects irradiated with substerilizing doses of radiation for the suppression of pest populations is influenced by the ability of released insects and their progeny to survive and interact with the wild population. Field survival rates for $F_1$ larvae from irradiated parents should be comparable with field survival of wild larvae because many of the deleterious effects induced by radiation are manifested and therefore eliminated during the $F_1$ egg stage (Carpenter et al. 1985). Any mortality agents such as insecticides, entomopathogens, and natural enemies (parasitoids and predators) could potentially interfere with the effectiveness of $F_1$ sterility if the agent killed a higher proportion of treated than wild larvae. Likewise host-plant resistance could potentially interfere with the effectiveness of $F_1$ sterility if the host-plant defenses somehow prevented a higher proportion of treated than wild larvae from establishing and developing on the host plant (Carpenter 1993).

The compatibility of different pest control methods with $F_1$ sterility has been investigated in both laboratory and field studies. Examples include the use of nuclear polyhedrosis viruses with $F_1$ sterility for controlling *H. zea* and *Spodoptera frugiperda* (Hamm and Carpenter 1997), host-plant resistance and $F_1$ sterility in *H. zea* and *S. frugiperda* (Carpenter and Wiseman 1992a, b), $F_1$ sterility and insecticide resistance in *S. frugiperda* (Carpenter and Young 1991), $F_1$ sterility and a commercial formulation of *Bacillus thuringiensis* in *P. operculella*, $F_1$ sterility and synthetic pheromones to reduce wild populations of the codling moth (Bloem et al. 2001), and the use of parasitoids and $F_1$ sterility (Mannion et al. 1994, 1995; Carpenter et al. 1996; Bloem and Carpenter 2001; Cagnotti et al. 2016; Mangan and Bouyer, this volume). All studies have shown that $F_1$ sterility is compatible with other pest control methods.

## 7. POPULATION MODELS COMBINING THE EFFECTS OF $F_1$ STERILITY WITH OTHER CONTROL METHODS

Knipling (1964), Barclay (1987), and Wong et al. (1992) recognized the potential benefit of combining sterile insects with conventional pest control methods. According to population models (Barclay 1987; Knipling 1992), combining inundative releases of natural enemies and sterile insects should yield additive or synergistic effects. Even though the SIT and natural enemies have different modes of action, the effectiveness of the SIT increases the ratio of natural enemies to adult hosts, and the effectiveness of natural enemies increases the ratio of sterile to fertile insects. Therefore, greater suppression could be expected if parasitoid releases were combined with the $F_1$ sterility technique (Carpenter 1993). Not only is $F_1$ sterility theoretically more effective than full sterility in reducing population increase (Carpenter et al. 1987a), but $F_1$ sterility results in the production of sterile $F_1$ eggs and larvae that provide an increased number of hosts for parasitoids. As a result, the number of parasitoids produced should increase even if the rate of parasitism remained the same (host-density independent), and whether or not additional parasitoids are released. Although population models (that independently consider augmentative releases of parasitoids (Knipling 1992) and $F_1$ sterility (Carpenter et al. 1987a)) suggest that both methods are highly efficacious, integrating lepidopteran $F_1$ sterility and augmentative biological control results in synergistic effects (Carpenter 1993). Therefore, the greatest impact of $F_1$ sterility and augmentative parasitoid releases as area-wide methods against lepidopteran pests can be realized only when the two methods are integrated (Barclay, this volume).

Population models also provide insight into how different control strategies could be combined for greatest efficiency. Although the effectiveness of $F_1$ sterility continues to increase as the ratio of irradiated to non-irradiated insects increases, the efficiency per released moth declines. A similar loss of efficiency occurs in parasitoid releases (Carpenter 1993). According to these models the economic benefit of combining $F_1$ sterility and parasitoid augmentation would be greatest when the ratios of irradiated to non-irradiated, and parasitoid to host, are low (i.e. equal to or less than 10:1). The model presented in Fig. 5 demonstrates that population suppression is increased when $F_1$ sterility and parasitoid releases are combined, and that the percentage reduction in population growth is greater when parasitized hosts produce adult parasitoids than when no parasitoids are produced (Carpenter 2000).

## 8. INHERITED STERILITY IN COMBINATION WITH BIOLOGICAL CONTROL

Fully successful integration of $F_1$ sterility and parasitoid augmentation into a management approach can occur only if parasitoids do not negatively impact irradiated insects and their progeny more than that of the wild population, and if $F_1$ sterility does not negatively impact the efficacy and reproduction of parasitoids. Knowledge of any negative impact of $F_1$ sterility on parasitoids would be important before implementing an AW-IPM programme using $F_1$ sterility. For example, if

parasitoids that attack the $F_1$ sterile progeny are unable to develop normally, and most of the hosts present are $F_1$ sterile progeny, then there could be a negative impact on subsequent parasitoid populations. Conversely, if parasitoids develop normally on $F_1$ eggs, larvae, and pupae, then the greater number of hosts available would allow for an increase in the parasitoid population. Since many hosts of the $F_1$ generation would experience genetically-induced mortality before they reached the adult stage, any parasitoids able to develop on these hosts would result in a positive and synergistic increase in the efficacy of an AW-IPM programme (Carpenter 2000).

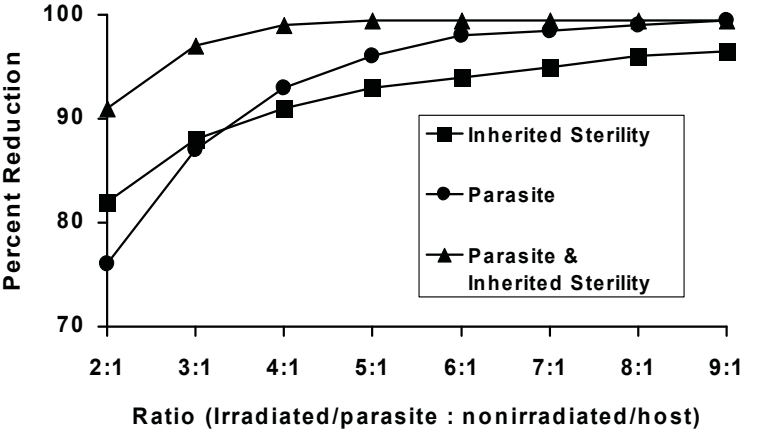

*Figure 5. Comparison of the projected reduction in normal population growth when only parasitoids [parasites] are released (Knipling 1992), when only irradiated (100 Gy) male moths are released (Carpenter et al. 1987c), and when releases are equally divided between parasitoids and irradiated male moths.*

Field, greenhouse and laboratory studies compared the acceptability and suitability of progeny from irradiated (100 Gy) and untreated *Spodoptera exigua* males as hosts for the braconid larval parasitoid *Cotesia marginiventris* (Cresson) (Carpenter et al. 1996), and progeny from irradiated (100 Gy) and untreated *H. zea* males as hosts for the tachinid *Archytas marmoratus* (Townsend) (Mannion et al. 1994, 1995). Results from these studies demonstrated that progeny of irradiated males and untreated females were acceptable and equally suitable hosts for parasitoid development. Female parasitoids showed no oviposition preference for progeny from females paired with either irradiated or untreated males. Other studies on different lepidopteran pests also have reported compatibility between the two control methods (Bloem and Carpenter 2001).

There are many different scenarios in which $F_1$ sterility could be integrated with natural enemies to suppress pest populations (Carpenter 1993; Hendrichs et al. 2009) (Box 1). The release of partially sterile males and fully sterile females would produce large numbers of $F_1$ eggs and larvae that could be field-reared on early-season host plants or crop plants that tolerate some larval feeding damage, e.g.

whorl-stage corn. Natural enemies (native and/or released) could use the $F_1$ eggs, larvae and pupae as hosts and thereby substantially increase the natural enemy population for the next generation of the pest insect (Proshold et al. 1998). Also surviving sterile $F_1$ progeny would produce sterile adults that would negatively impact the next generation of the pest insect. If the economic injury level of cultivated host plants indicated that the additional sterile $F_1$ larvae were undesirable, then the dose of radiation could be increased to a level that would reduce or eliminate the number of progeny from irradiated females, or releases could be limited to irradiated males.

*Box 1. Opportunities for Combining Inherited Sterility with Biological Control*

For pest suppression:

- Simultaneous or sequential inundative releases of irradiated insects and natural enemies
- Irradiated insects and their sterile progeny serve as host/prey for wild natural enemies.

For research:

- Elucidation of the potential host range of exotic pests
- Prediction of the potential geographic range of exotic pests
- Delineation of the potential impact of native natural enemies on invading pests.

Although the compatibility of $F_1$ sterility with the application of synthetic organic insecticides has been demonstrated (Carpenter and Young 1991), parasitoids and/or predators generally are not compatible with these products. When insecticides are required to reduce pest infestations, insect growth regulators or other formulations that are compatible with natural enemies should be considered. Another management option would be to establish host plants for the pest in insecticide-free areas adjacent to insecticide-treated crops. Host plants could be artificially infested with pest larvae to provide natural enemies (native and/or released) with an adequate supply of hosts. If the pest larvae used in the artificial infestations (nursery crops) were sterile, i.e. the progeny of irradiated parents, then non-parasitized larvae would not contribute to the increase of the wild population but would produce sterile adults that would negatively impact the next generation of the pest insect (Okine et al. 1998; Carpenter 2000).

In addition to using $F_1$ sterility as a direct pest control method, there are opportunities to use $F_1$ sterility to facilitate the development of other pest suppression methods. For example the $F_1$ sterile progeny (eggs, larvae and pupae) of a pest may be used as hosts/prey for natural enemies that are shipped commercially, especially in quarantine-sensitive shipments (Hendrichs et al. 2009). The use of sterile insects in commercial shipments would ameliorate concerns regarding the reproductive viability of non-parasitized and non-consumed pests upon arrival at the shipment destination. Also the use of $F_1$ sterile progeny as hosts for parasitoids would eliminate the need to wait for non-parasitized pests (either eggs or pupae) to emerge before shipment of the parasitized pest (Greany and Carpenter 2000; Hendrichs et al. 2009).

## 9. ADDITIONAL APPLICATIONS OF $F_1$ STERILITY FOR RESEARCH AND MANAGEMENT

Greany and Carpenter (2000) reported that $F_1$ sterility could provide a new risk management tool for assessing the safety of exotic lepidopterans being considered as biological control agents against invasive weeds (Moeri et al. 2009; Tate et al. 2009) (Box 1). Production of $F_1$ sterile progeny permits developmental and behavioral observations to be made under actual field conditions without concern that a breeding population would be established (Carpenter et al. 2001a). This facilitates field observations on oviposition behaviours and host associations, larval feeding preferences, and larval development and survival on both target and non-target plant species. Also, the impact that native natural enemies might have on exotic candidate species being considered as biological control agents for invasive weeds, and the ability of these candidate species to survive and overwinter under various climatic conditions could be studied in the field through this innovative application of $F_1$ sterility.

$F_1$ sterility could be used to conduct research on exotic pests that are expanding their geographical range. Strom et al. (1996) suggested that gypsy moth host preferences, or the quality of potential hosts outside the generally infested area, could be investigated using releases of $F_1$ sterile larvae of *L. dispar*. In addition to host range studies, Carpenter et al. (2001a) suggested that $F_1$ sterility could be used to predict the potential geographic range and to evaluate the potential impact of native natural enemies on the rate of spread of exotic lepidopteran pests.

## 10. CHALLENGES AND OPPORTUNITIES

Challenges are inherent in all pest management methods, and Whitten and Mahon (this volume) discuss constraints and misconceptions unique to the SIT. In addition to those in common with the SIT, the major challenge to the use of IS is the perception that sterile $F_1$ larvae cause economic damage to crops, especially high-value crops such as fruit. Consequently, low doses of radiation, which would certainly result in more competitive insects, are often avoided. For example, Proverbs et al. (1978) found that codling moths treated with 250 Gy were more competitive in the field, and provided better control, than did fully sterile moths (400 Gy). Nevertheless, in spite of these findings, Proverbs et al. (1982) continued to be concerned that $F_1$ larvae would cause economic damage, and used 350 Gy to irradiate moths released in a pilot study conducted in British Columbia, Canada, from 1976–1978. Also, in the current codling moth programme in British Columbia, Canada, which began field operations in 1994, moths treated with 350 Gy are released, even though doses as low as 100 Gy have been suggested (Anisimov 1993; Bloem et al. 1999a, 1999b). It was found in field studies that season-long releases of moths treated with 100 Gy did not cause fruit injury (Fig. 6), and moths receiving 100 Gy were more competitive than those receiving 250 Gy (Bloem et al. 2001). These studies indicate that fears of increased fruit (or plant) injury resulting from $F_1$ larvae are ill founded, especially when the radiation dose causes partial sterility in males and full sterility in females. Therefore, the production of sterile $F_1$ larvae

should be seen not as a problem but rather an opportunity to enhance the production of natural enemies and to produce more competitive sterile moths in the field.

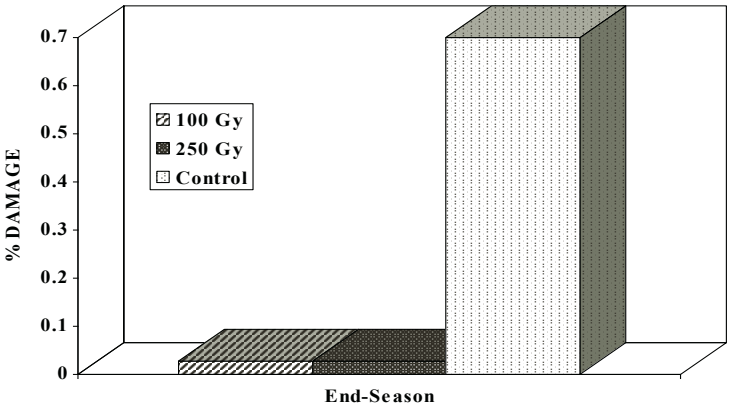

*Figure 6. Percentage fruit damage at harvest caused by the codling moth in apple orchards in Washington State, USA. One series of three plots received season-long releases of partially sterile codling moths treated with 100 Gy (female moths were 100% sterile, and males 50% sterile). A second group of plots received 250-Gy-treated moths (females 100% sterile, and males 75% sterile). The control areas were treated with six applications of azinphosmethyl insecticide. At the end of the fruiting season, 2500 fruit per treatment were sampled (Bloem et al. 2001).*

## SUMMARY

This chapter begins with a consideration of simple population models. The sterility formulation proposed by Knipling is then included in the population models, and these are elaborated in systematic fashion to include the major biological factors that will affect the success of a sterile insect technique (SIT) control programme. These factors include residual fertility, differential competitive ability of wild and sterilized males, mating patterns, immigration, and various combinations of these features. Also examined are density-dependence, age structure, population aggregation, Allee effect, biotic interactions with other species, and then integration of the SIT with other control methods. It was found that combinations of factors are often synergistic: combinations of detrimental factors such as residual fertility and inferior competitive ability put severe limits on the probable success of the control programme, while combinations of control methods are much more likely to succeed than single control methods. This is because each control method needs only to account for a smaller proportion of the total mortality when combined with other methods than when acting alone. The barrier width is computed to protect an area from pests outside the controlled area using a diffusion equation, and a case study is presented using Mediterranean fruit flies. The redistribution of sterile males released from aircraft travelling along predetermined flight lines is also addressed using a diffusion equation. To minimize costs, a short method is presented to calculate the optimal frequency of releases, distance between flight lines, and number of sterile males released on each flight. This short method is capable of calculation using a hand calculator. Tentative results are also presented on optimizing the number of sprays and time intervals between sprays of a pest population in preparation for an SIT project. The question of whether to release only sterile males or both sexes is examined in the light of results for tephritids. Parameter estimation is mentioned, and also an assessment of the models presented herein. Finally, a brief section on future needs and trends for modelling the SIT is presented.

## 1. BRIEF OVERVIEW OF MODELLING

### *1.1. Types of Models*

Modelling is the abstraction of processes or states of being. Mathematical models involve equations, graphs or algorithms behind computer code. Virtually all models of the sterile insect technique (SIT) are population models, either analytic (just with equations) or computer models (often called numerical models and in which the equations are usually implicit, rather than being made explicit). Population models keep track of population numbers, and include various features that influence population size and trend, such as birth rate, mortality, age structure, immigration and emigration, competition, etc. Population growth can be either density-independent, in which birth rate and mortality are independent of population size, or density-dependent, in which either or both of birth rate and mortality depend on population size, usually in such a way as to eventually stabilize the population around some long-term mean value.

Mathematical models of populations are typically posed as difference equations or as differential equations. Difference equations are discrete and use some meaningful time step, such as days, years, generations, etc. These are popular with entomologists, since many insects breed seasonally, such as most temperate forest insect pests (bark beetles, budworms, tent caterpillars, etc.). Differential equations are continuous, involving an infinitesimal time step, and rely on calculus to solve them. They are useful in species that breed continuously within some period of time, such as aphids, stored products pests and animal parasites. However, difference equations do not involve calculus, and generally are easier for the non-mathematician to understand. Another dichotomy is between deterministic models, which always yield the same model result, and stochastic models, which involve randomness. Most of the models of the SIT have so far been deterministic models, involving no random elements.

In this chapter, only models that predict some aspect of system behaviour (population dynamics) will be explored. Thus, purely statistical analysis of data, however valuable and relevant that might be to a release programme, will not be considered here. Likewise the derivation of regressions for use in models will not be considered here as SIT modelling. However, a section on model parameter estimation, in which such techniques are mentioned, is included.

### *1.2. Simple Population Models*

For density-independent population growth, the simplest models are geometric growth for a species with non-overlapping generations, and its continuous counterpart, exponential growth (Box 1). A simple modification to these models, to include resource limitation, puts an upper limit on growth. Many formulations exist for limiting geometric growth; a few were provided by Hassell (1978). This small complication makes some formulations insoluble analytically, and it is a common feature of population models that non-linearity renders the models insoluble analytically; it is then necessary to resort to numerical solutions using a computer.

*Box 1. Simple Growth Models*

*Geometric and Exponential Growth*

The geometric model is $N_{t+1}=\lambda N_t$. Here $N_t$ is the size of the population at time $t$, where $t$ is scaled to generations and $\lambda$ is the rate of increase each generation. In each generation the population size is $\lambda$ times the size it was in the previous generation. In this model, generations are discrete and non-overlapping. This model is easy to solve. At any time $t$, $N_t=N_0\lambda^t$, where $N_0$ is the size of the population at time $t$=0. The exponential growth model is $dN/dt=rN$. The solution to this model is $N=N_0\exp(rt)$, where $\exp(rt) = e^{rt}$, $e$ being the base of natural logarithms, $r$ is the instantaneous rate of growth, and $N_0$ is the initial size of the population at time zero.

*Density-Dependent Growth*

With density-dependence, the geometric model becomes $N_{t+1}=\lambda N_t\exp(-gN_t)$, in which the exponential term has no real biological meaning, and is simply a convenient device to limit population numbers. The continuous version is the logistic equation: $dN/dt=rN(K–N)/K$, where $K$ is the carrying capacity imposed by resource limitation.

### *1.3. Host-Parasitoid and Predator-Prey Models*

Modelling host-parasitoid and predator-prey systems in insect population dynamics has a long history, and the "workhorses" are the Nicholson-Bailey difference equation model and the Lotka-Volterra differential equation model (Box 2). Hassell (1978) described such models, and these models have been used in modelling sterile insect releases for populations under the influence of biotic interactions with other species.

*Box 2. Predator-Prey and Host-Parasitoid Model*

*Nicholson-Bailey Model*

Without density-dependence $N_{t+1}=\lambda N_t\exp(-aP_t)$; $P_{t+1}=\lambda N_t[1–\exp(-aP_t)]$ where $N_t$ and $P_t$ are the host and parasitoid population sizes at time $t$.

With density-dependence $N_{t+1}=\lambda N_t^{(1-b)}\exp(-aP_t)$; $P_{t+1}=\lambda N_t^{(1-b)}[1–\exp(-aP_t)]$ where $b$ is a parameter for imposing density-dependence and has no obvious biological meaning, and $\exp(-aP_t)$ is the zero term of a Poisson series, representing those hosts not found each generation by a group of randomly searching parasitoids.

*Lotka-Volterra Model*

Without density-dependence $dN/dt=rN–bNP$; $dP/dt=P(cN–e)$ in which the first equation gives the rate of change of the prey population ($N$) in terms of the intrinsic rate of increase, $r$, and a predation rate per predator, $b$; the second equation gives the rate of change of the predator population ($P$) in terms of the rate of increase per prey, $c$, and a death rate, $e$.

With density-dependence $dN/dt=rN(1–aN)–bNP$; $dP/dt=P(cN–e)$, where $a$ is a density-dependent death rate of the prey.

## 2. MODELS OF STERILE INSECT RELEASES

### *2.1. Three Kinds of Control Programmes Using Sterility*

There are three methods of using sterile insects for population control. These are: (1) the standard method of releasing sterile males (or males and females) that have been

reared and sterilized; earlier work in modelling of sterile releases was previously summarized by Hamada and Miyai (1985); (2) the treatment of insects with sub-sterilizing doses of radiation or chemosterilants so that the matings are partially sterile, but the offspring of matings involving treated insects are sterile, called inherited sterility (Kean et al. 2007; Marec et al., this volume); and (3) the deployment of chemosterilants in field traps to sterilize insects that are attracted to the traps. It is mainly the first of these three methods that will be dealt with here. Chemosterilants are seldom used in the field because of their carcinogenic potential and the related risk of bioaccumulation in the food chain, although modelling has been done on this technique by Knipling (1960), Lawson (1967), Staley et al. (1971), Hawkes and Coaker (1977), Barclay (1981a), and Wall and Howard (1994). In addition, although the SIT is usually used for insect control, in some cases the concept can apply to other animals (Klassen et al. 2004).

### *2.2. Initial Contribution of Knipling to Modelling the SIT*

Knipling produced a simple numerical model that foreshadowed most future modelling developments (Knipling 1955, 1959). The central feature of Knipling's model, and one found in almost all subsequent models, is the ratio of fertile males to all males in the population: $(M/(S+M))$ where $M$ is the number of fertile males (or females, assuming a 1:1 sex ratio) and $S$ is the number of sterile males. This gives the proportion of the population, under ideal conditions, that results in fertile egg production as a result of some fertile females mating with fertile males. Knipling's (1955) model for the release of sterile insects was a simple modification of the geometric model in Box 1 using the sterility factor above:

$$F_{t+1}=\lambda F_t(M_t/(S+M_t)) \quad (1)$$

where $F_t$ and $M_t$ are again the population size (fertile females and males) at time $t$, $\lambda$ is the rate of increase per generation, and $S$ is the release rate of sterile males each generation. This yields a stable steady state at $F=0$ and an unstable positive steady state for $F$ when $S=S^*$, the critical release rate, where $S^*=F(\lambda-1)$, the value of sterile release rate that holds the population at the steady state (Berryman 1967). If $S>S^*$, then the pest population will collapse and be eliminated. If $S<S^*$, then the population in this model will increase indefinitely.

### *2.3. Sex Ratio*

One question asked early in work on releasing sterile insects was, "Is there an optimal sex ratio for the sterile insects being released?" It was initially thought that the release of sterile females would be counterproductive. This question was first addressed by Ailam and Galun (1967) and Lawson (1967); using probabilistic models of mating, they predicted that the release of females should never be detrimental (assuming they are all fully sterile), and in fact may assist the control programme if males are limited in their mating ability, in which case some fertile

females might not get mated. However, for female-choice mating systems such as fruit flies the opposite was shown; in the absence of sterile females, sterile males are 3-4 times more effective because they focus only on fertile females and do not waste their limited sperm on sterile females (Hendrichs et al. 1995; Rendón et al. 2004). This was confirmed theoretically for female-choice mating systems, such as in tephritids (Vreysen et al. 2006). On the other hand, for moths (which have a very different mating system) the limited field evidence so far indicates that there is no advantage to male-only releases. In addition, for insects such as mosquitoes where females are disease vectors, it is essential not to release sterile females because that might increase the number of disease vectors.

### *2.4. Residual Fertility of "Sterile Insects"*

If some of the treated insects are not completely sterilized, then the situation becomes more complicated. Klassen and Creech (1971) constructed a simple numerical model in which a certain proportion of the released males remained fertile. They found an upper limit to this "residual fertility" that was compatible with the success of the release programme. Their model can be put into algebraic form and generalized. When there is incomplete sterilization of the released insects, a fraction, $q$, of males remains fertile. In that case, Knipling's model can be modified as in Box 3. The critical sterile release rate is then only finite for $q<1/\lambda$. If $q>1/\lambda$, then the population is not controllable by sterile releases. Thus, for example, if the rate of increase, $\lambda$, is 10, then $q$ must be less than 0.1, i.e. the released males must be greater than 90% sterile in order for control by the SIT to be possible. Also, if the residual fertility is more than about three-fourths of the limiting value, then the required rate of sterile releases has to be much higher than with complete sterility (Fig. 1).

If both males and females are released and neither sex is completely sterile, then the fertile male X fertile female matings can be modelled as in Box 3. If residual fertility exists in both sexes following release, it becomes impossible to eliminate the pest population by sterile releases alone; the best that can be done is to suppress it to a low level with continuing sterile releases. In addition, control is impossible unless $q_m<F/\lambda(F+q_fS_f)$, where $q_m$ and $q_f$ are the residual fertilities of males and females, respectively. This value of $q_m$ is smaller than that without the release of females (Fig. 2). Thus, less residual male fertility can be tolerated with the release of residually fertile females (Barclay 2001). Fortunately, in most species targeted by the SIT, females are more sensitive than males to radiation sterilization (sperm are post-meiotic cells, whereas mature eggs are pre-meiotic), and therefore it is possible to identify sterilizing doses for the SIT that assure full female sterility (Bakri et al., this volume; Robinson, this volume).

### *2.5. Competitive Ability of Males*

The ability of sterile males to compete with wild males for mates can be affected by sterilization through the debilitating effects on either sperm competition or the

behaviour of the adults (Parker, Vreysen et al., this volume; Lance and McInnis, this volume). This problem was modelled by Berryman (1967), Bogyo et al. (1971), Berryman et al. (1973), Itô (1977), and Barclay (1982a). Their models are summarized by the model in Box 4. All of their models show that the critical release rate increases as the competitive ability of sterilized insects decreases.

*Box 3. Residual Fertility of "Sterile Insects"*

Here Knipling's model becomes: $F_{t+1}=\lambda F_t(M_t+qS)/(M_t+S)$, where it is assumed that either only males ($M_t$) are released or that released females are completely sterile and only males display residual fertility. This model has a stable steady state at $F=M=0$, and an unstable positive steady state for $F$ and $M$ when $S=S^*$, the critical release rate, where $S^*=M(\lambda-1)/(1-\lambda q)$. Here, $S^*$ is only finite for $q<1/\lambda$.

If both males and females are released and neither sex is completely sterile, then the fertile male X fertile female matings can be modelled by the equation: $F_{t+1}=\lambda(F_t+q_fS_f)(M_t+q_mS_m)/(M_t+S_m)$, in which $F_t$ is the number of wild fertile females in generation $t$, $q_m$ and $q_f$ are the proportions of treated males and females, respectively, that remain fertile, and $S_m$ and $S_f$ are the number of treated males and females, respectively, that are released each generation (Barclay 2001). So far there is no restriction on the sex ratio. Thus $q_fS_f$ released females that remain fertile are added to the wild fertile females each generation, and $q_mS_m$ released males are added to the number of wild fertile males each generation, with the assumption that treated insects are equally competitive for mates with wild insects. This model has a lower stable steady state and an upper unstable steady state for $F$ and $M>0$ when $S=S^*$, and $S^*_m=(\lambda-1)(FM+\lambda q_f S_f M)/(F(1-\lambda q_m) -\lambda q_m q_f S_f)$, and this equation is only soluble if the sex ratio is known. If we assume a one-to-one sex ratio (where $M_t=F_t$ and $S_m=S_f=S$), then we obtain a quadratic equation: $\lambda q_m q_f S^2-[1-\lambda(q_m+q_f)]FS+(\lambda-1)F^2=0$ which gives two roots when solved for either $S$ or $F$. The upper root of $F$ is unstable, and represents the size of the population before initiating sterile releases. The lower root of the equation for $F$ is stable, and is the value at which the population would be maintained by residual fertility after collapse due to suppression by sterile releases. Thus it is impossible to eliminate the pest population by sterile releases alone; also control is only possible if $q_m<F/\lambda(F+q_fS_f)$. The relationship between the maximum values of $q_m$ and $q_f$ is hyperbolic (Fig. 2).

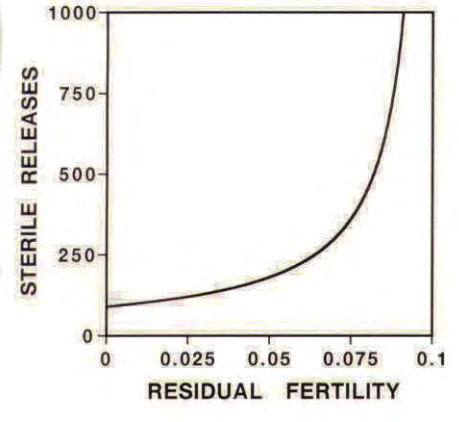

*Figure 1. The critical sterile release rate, S*, as a function of residual fertility, q. λ = 10.*

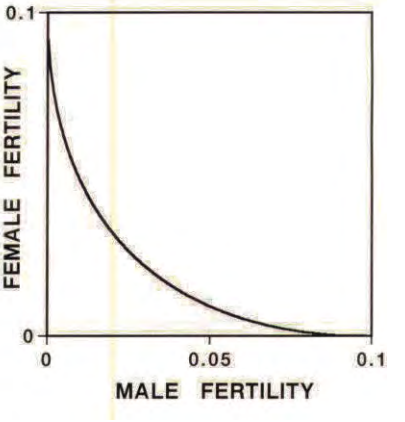

*Figure 2. Allowable residual fertility when it is in both males and females. λ = 10.*

*Box 4. Competitive Ability of Males*

We define $c$ as a coefficient of competitive ability, with 0 being completely non-competitive and 1 being fully competitive. Then $F_{t+1} = \lambda F_t(F_t/(F_t+cS))$. This model has a stable steady state at $F=M=0$ when $S>0$. The positive (unstable) steady state for $F$ occurs when $S=S^*$, the critical value, where $S^*=(\lambda\text{-}1)F/c$, which is greater than $(\lambda\text{-}1)F$, with full competitive ability (Itô et al., this volume).

### *2.6. Interactions of Residual Fertility and Competitiveness*

In this model only males display residual fertility; females are either completely sterilized or not released.

#### *2.6.1. Residually Fertile Insects Are Fully Competitive*

Here the insects that remain fertile after treatment are fully competitive with wild insects (Box 5). The allowable residual fertility of males is an almost linear function of the competitive ability of released sterile males (Fig. 3A, solid line), unless $\lambda$ is very small. Also, for a given degree of residual fertility, $S^*$ becomes larger as $c$ becomes smaller (Fig. 3B). Thus, the extent of residual fertility, and the degree of competitive ability that is lacking, tolerable to achieve some control, each have to be more restricted in the presence of the other (Barclay 2001). In this case, each of $c$ and $q$ will be more restrictive than is allowable if only one of these limitations exists (both must be within the range that allows for control by the SIT).

*Box 5. Residual Fertility and Competitiveness*

If residual fertile insects are fully competitive, $F_{t+1}=\lambda F_t(F_t+qS)/(F_t+qS+cS(1-q))$, then this model has a stable steady state at $F=M=0$ when $S>0$. The positive (unstable) steady state occurs when $S=S^*=(\lambda\text{-}1)F/(c(1-q)-q(\lambda\text{-}1))$, and $S^*$ is finite only if $q<c/(\lambda\text{-}1+c)$.

If residual fertile insects are of reduced competitiveness, then the model becomes $F_{t+1}=\lambda F_t(F_t+cqS)/(F_t+cS)$. If there is no residual fertility, there is a stable steady state at $F=M=0$, if $S>0$, and a positive unstable steady state when $S=S^*=(\lambda\text{-}1)F/c$.

If there is both residual fertility and unequal male competitive ability, the steady state for $F$ is at $S^*=(\lambda\text{-}1)F/(c(1-q\lambda))$, and this is finite only if $q<1/\lambda$.

#### *2.6.2. Residually Fertile Insects Have Reduced Competitiveness*

Here the insects that remain fertile after treatment are not fully competitive with wild insects (Box 5). The critical sterile release rate in this case (Fig. 3C and Box 5) is not as large as the corresponding value when residually fertile insects are of full competitive ability (Fig. 3B).

### *2.7. Mating Patterns*

Another question asked early in the use of sterile releases was, “Should the females of the target species in a sterile release programme mate once or more than once?” The question has been addressed by Von Borstel and Knipling (1960) and Knipling (1964), and in the models of Berryman (1967), Lawson (1967), Zouros (1969), and

Barclay (1984). The answer appears to be that female remating (polygamy) is quite compatible with the SIT, as long as mating is random, with sterilized male sperm being fully competitive with wild male sperm. In addition, in polygamous species, it doesn't matter whether sperm is diluted, replaced or excluded after the first mating, again as long as mating is random, and sterile males are fully competitive (Lance and McInnis, this volume).

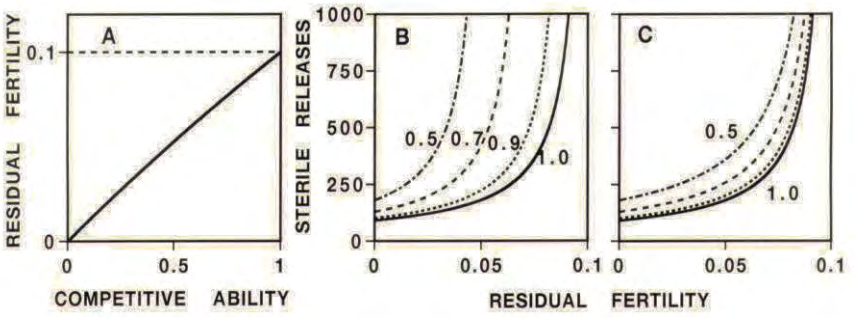

*Figure 3. A: Changes in allowable residual fertility with changes in competitive ability of sterile males. Residually fertile insects are of reduced competitive ability (broken line) or are fully competitive (solid line). B and C: Critical sterile release rates for residual fertility (0 to 0.1) and competitive ability (0.5, 0.7, 0.9, 1.0). In B, residually fertile insects are fully competitive, and in C, residually fertile insects are of reduced competitive ability. $\lambda = 10$ in all cases. (Figure from Barclay 2001, reproduced with permission.)*

### *2.7.1. Interaction of Polygamy with Competitive Ability*

If sterile males are equally competitive for mates with fertile males, sterile sperm is fully competitive with fertile sperm, and there is no residual fertility, then the effects of polygamy (multiple female mating) are simply to reshuffle the sperm at each mating, and polygamy has essentially no effect. On the other hand, if sterilization is incomplete, and/or sterilized males (or their sperm) are of inferior competitive ability, then the situation is more complex. The work of Berryman (1967) (also addressed by Zouros (1969)) is particularly insightful in this matter. If only the first mating of a female results in sperm retention, or if all of the sperm of previous matings is replaced at each successive mating, and if all matings occur before oviposition begins, then the effective number of matings is just one. If the sperm from all matings mixes and is retained, then the effect of multiple matings depends on sperm competition as well as on competition between sterile and fertile males for mates. Berryman (1967) addressed this important problem, and it is worthwhile revisiting his results, making appropriate changes in his notation to make it consistent with the development above. Berryman considered three cases, depending on sperm action (Box 6).

*Box 6. Mating Patterns*

*Interaction of Multiple Female Mating and Competitiveness*

The probability of a fertile female mating with a sterile male is defined as $P_s=c_aS/(F_t+c_aS)$, and the probability of a fertile female mating with a fertile male as $P_f=F_t/(F_t+c_aS)=1-P_s$, where $c_a$ is the competitive ability of sterile adults (equivalent to $c$ in Box 4). Berryman (1967) considered the joint distribution of the number of matings, and the number of sterile matings, as a sequence of marginal distributions of the number of sterile matings given the number of matings. Thus a female can mate from zero to $M$ times, and for a given number, $m$, of matings the number of sterile matings is binomially distributed. If ${}_mC_n$ is defined as the number of combinations of $m$ things taken $n$ at a time ($=m!/n!(m-n)!$), then the conditional probability that a given female mates with $n$ sterile males, given that she mates $m$ times, is $P(n|m)={}_mC_nP_s^n\ P_f^{m-n}={}_mC_nP_s^n(1-P_s)^{m-n}$. This is one term of a binomial distribution that describes the number of sterile matings given the number of matings, and there will be $M$+1 such distributions, including one for no matings. Berryman considered three cases, dependent on sperm action.

*Non-Functional Sperm*

If the sperm of sterilized adults is either nonexistent or immotile, then a female mating $m$ times will only produce sterile eggs if all the matings were with sterile males. The probability of this occurring is $P_s^m$, and so the probability of at least one fertile mating is $(1-P_s^m)$. Then the probability of at least one fertile mating, over the range of mating frequencies, is $\Sigma P_m(1-P_s^m)$ for $m$ = 1,2,3, …, $M$, and so the population equation becomes $F_{t+1}=\lambda F_t\Sigma P_m(1-P_s^m)$ for $m$ = 1,2,3, …, $M$, where $P_m$ is the probability of mating $m$ times.

*Dominant Lethal Mutations*

In the binomial expansion of the probabilities of $m$ matings, where $m$ goes from 0 to $M$, each of the terms representing mixed fertile and sterile matings will be weighted by a factor, $c_s$, representing the competitive ability of sterile sperm. Thus the probability of an egg being fertilized by a sterile sperm, taken over all mating frequencies, will be $P(e)=P_s^m+c_s((m-1)/m)_mC_{m-1}\ P_s^{m-1}(1-P_s)+c_s((m-2)/m)_mC_{m-2}P_s^{m-2}(1-P_s)+\ldots+(0/m)_mC_0(1-P_s)^m$, which can be reduced to $P_s^m+c_sP_s(1-P_s^{m-1})$, where $P_s=c_aS/(F_t+c_aS)$, as above. We can write the equation as $F_{t+1}=\lambda F_t\Sigma P_m[1-(P_s^m+c_sP_s(1-P_s^{m-1}))]$ for $m$ = 1,2,3, …, $M$. The values of the critical release rates, $S^*$, are shown in Fig. 5A and Fig. 5B against the adult sterile competitive ability, $c_a$, and for the sperm competitive ability, $c_s$ in Fig. 5C. In addition, the values of $c_a$ and $c_s$ are shown for given values of the critical release rate (250, 500), $S^*$, when it is held constant (Fig. 5C); as shown, there is a trade-off between $c_a$ and $c_s$.

### *2.7.2. Non-Functional Sperm*

If the sperm of sterilized adults is either non-existent or immotile, then a female mating $m$ times will only produce sterile eggs if all the matings were with sterile males. The resulting critical values (Box 6) of the sterile release rate, $S^*$, are shown in Fig. 4 for several values of $M$, the maximum number of matings, values of the adult competition coefficient from 0.5 to 1.0, two values of the probability of mating, and assuming a binomial distribution of mating frequencies.

### *2.7.3. Dominant Lethal Mutations with Fully Competitive Sperm*

If sterility is caused by dominant lethal mutations, and the sperm of sterilized adults is fully competitive with that of fertile adults, then it can be shown that the probability that an egg is fertilized by a sterile sperm is independent of the number of matings, and the results from section 2.5. on competitive ability still hold with polygamy, and correspond to the case of $M$=1 in Fig. 4.

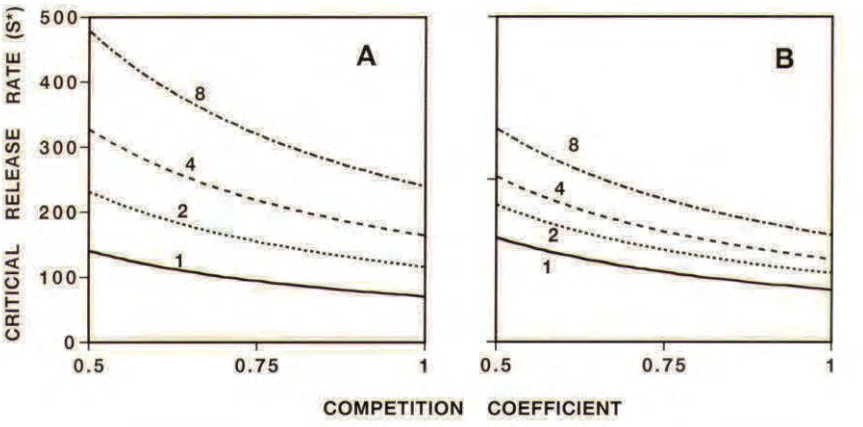

*Figure 4. Critical sterile release rates when sterile males produce non-functional sperm. The maximum possible number of matings, M, is 1, 2, 4, 8, and the probability of mating in A is 0.8, and in B is 0.9. The adult competition coefficient ranges from 0.5 to 1.0. λ=10 in all cases. (Figure generated from equations, Berryman 1967.)*

### *2.7.4. Dominant Lethal Mutations with Reduced Sperm Function*

If sterility is caused by dominant lethal mutations, and the sperm of sterilized adults is of reduced competitive ability compared with that of fertile adults, then it can be shown that the probability that an egg is fertilized by sterile sperm depends on the number of matings. The values of the critical release rates, $S^*$, in Box 6, are shown in Fig. 5A and Fig. 5B against the adult sterile competitive ability, $c_a$, and in Fig. 5C for the sperm competitive ability, $c_s$. In addition, the values of $c_a$ and $c_s$ are shown for given values of the critical release rate (250, 500), $S^*$, when the critical release rate is held constant (Fig. 5C); there is a trade-off between $c_a$ and $c_s$, the presence of each one limiting the value of the other.

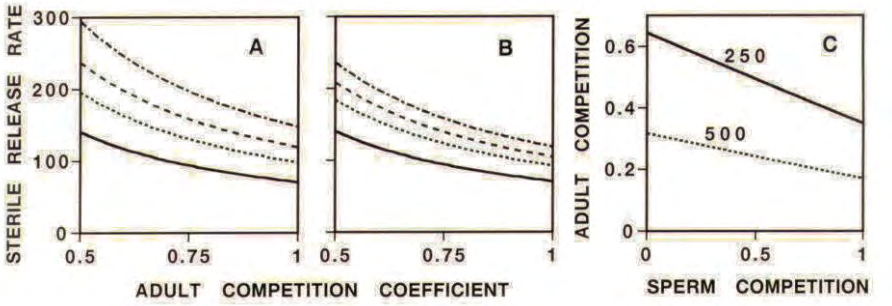

*Figure 5. A and B: Values of the critical release rates, S*, for values of adult sterile competitiveness, $c_a$, four mating frequencies (1, 2, 4, 8), and two probabilities of mating — A: 0.6, B: 0.8. C: Limits on adult sterile competitiveness compatible with control of the pest population; these are shown for a range of values of sperm competitiveness and two values of sterile releases (250, 500). (Figure generated from equations, Berryman 1967.)*

### *2.7.5. Choice of Mates*

Mating systems of insect pests amenable to SIT application can be categorized as (1) resource defence-based mating systems, (2) non-resource-based mating systems, and (3) lek and swarm mating systems (Hendrichs et al. 2002; Lance and McInnis, this volume). Systems (1) and (2) are mostly determined by male competition, and are male-choice mating systems. System (3) is a female-choice mating system, where the female chooses a mate from among the courting males in the lek. The distinction between male- and female-choice systems, as well as the propensity of wild individuals to mate with their wild counterparts rather than sterile insects, has implications for the effectiveness of an SIT project. Using mating models, Vreysen et al. (2006) examined these questions, as well as the release of only males or of both sexes, and arrived at the following conclusions.

In a male-choice mating system, such as in the New World screwworm *Cochliomyia hominivorax* (Coquerel), overcoming a situation where there is a propensity of wild males to preferentially mate with wild females if sterile females are also being released, would require a doubling of the number of sterile males compared with male-only releases. In the model on female choice, the release of both sexes and male-only releases required the same sterile to wild male overflooding ratio. This, however, is at odds with field projects that have shown a significant benefit with male-only releases against insects which have a female-choice mating system, e.g. Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) (Hendrichs et al. 1995; Rendón et al. 2004). Models were constructed to assess the potential effect of sterile female presence or absence on reduced sterile sperm quantity with remating, reduced sterile sperm quality with aging, and incomplete redistribution of the sterile males with the wild insects. In all three cases, male-only releases result in relatively more efficient sterile insects compared with projects releasing both sexes (Vreysen et al. 2006).

A problem with female-choice mating systems is that any deficiency in sterile male behaviour or function can bias females against mating with them, and this can have severe consequences for the success of any SIT project.

## *2.8. Interaction of Polygamy with Residual Fertility*

A similar analysis on residual fertility (not shown) can be performed. Starting with the equation for residual fertility, and assuming that sterile sperm are fully functional, one proceeds as with the case of dominant lethal mutations and fully functional sperm. The result is that the probability that a female will mate with a sterile male is independent of the number of matings (Barclay 2001), and the probability that an egg will be fertilized by a sterile sperm is also independent of the number of matings. Thus, multiple female mating (polygamy) and residual fertility have no interaction, and the results derived above for residual fertility alone apply both to monogamy and polygamy.

### *2.9. Stochastic Models*

Stochastic models involve the specification of certain variables as being random. If the processes involved are well known and the extent of variation is known, then stochastic models can give additional information on the expected variability of the resulting control, as well as deviations of mean values from those predicted by deterministic models. This is especially true in areas like genetics in which the mechanisms of variation, e.g. meiosis, are clear. However this information is often not well known in animal ecology, and therefore stochastic models may be of limited use. In fact, if the wrong features are allowed to vary (e.g. birth rate is variable in the model, whereas in reality it might be mortality that varies), then stochastic models can give misleading results. In addition, unless they are solved numerically, stochastic models are usually much more difficult to analyse than deterministic models, and for these reasons the history of stochastic population modelling has been rather disappointing.

Stochastic models of sterile insect releases were developed by Kojima (1971), Bogyo (1975), Costello and Taylor (1975), Taylor (1976), and Kimanani and Odhiambo (1993), and they confirmed the results of Knipling (1955) and others that used deterministic models. They also derived a threshold release rate that leads to local extinction, and showed that much greater release rates above this threshold will not result in a greatly reduced time to extinction, although Lawson (1967) and Itô and Kawamoto (1979) offered evidence to the contrary using both a deterministic model and a probabilistic model.

### *2.10. Population Movement*

The release of sterile insects, together with immigration from outside the control area, can be modelled by a simple modification of the model in Box 4 (Dietz 1976; Prout 1978). Flores (2003) has also provided a diffusion approach to the problem of immigration. Following Prout, two cases must be accommodated here: (1) immigration before mating, and (2) immigration after mating. In these two models it is assumed that all sterilized insects that are released are completely sterile.

#### *2.10.1. Immigration before Mating*

Assuming that $V$ males and $V$ females immigrate each generation prior to mating, the female immigrants are thus available for mating with the released sterile males as well as the wild males, and the male immigrants are available for competing with the sterile males. The model (Box 7) has two positive roots for $F$, with the upper one being unstable (the population as it existed just prior to sterile releases) and the lower one being stable. This lower steady state represents a population in a state of collapse due to sterile releases, but which is replenished each generation by immigrants. Note that zero is not a steady state solution here. The required sterile release rate grows rapidly with $V$, but there is no value of immigration that disallows control by sterile releases. The values of $S^*$ depend only modestly on $V$, if the immigration rate each generation is only a small proportion of the total population.

*Box 7. Immigration*

*Immigration before Mating*

If we include immigration into the model, we obtain $F_{t+1}=\lambda(F_t+V)(F_t+V)/(F_t+S+V)$. Solving for steady state, we obtain the quadratic: $(\lambda\text{-}1)F^2\text{-}[S\text{-}(2\lambda\text{-}1)V]F+V^2=0$ which has two positive roots for $F$, with the upper one being unstable and the lower one being stable. Note that zero is not a steady state solution here.

The critical release rate is $S^*=[(\lambda\text{-}1)F+\lambda V\,](F+V)/F$.

*Immigration after Mating*

The equation here is $F_{t+1}=[\lambda F_t^2/(F_t+S)]+\lambda V$. Note that, if the wild population is reduced to zero, it will be reconstituted the following generation, as then $F_{t+1}=\lambda V$. Again solving for steady state, we obtain $(\lambda\text{-}1)F^2\text{-}[S\text{-}\lambda V]F+\lambda VS=0$.

The critical sterile release rate is given by $S^*=F[(\lambda\text{-}1)F+\lambda V]/(F\text{-}\lambda V)$, and sterile releases can only control the population if $V<F/\lambda$.

For a given immigration rate, the required sterile release rate is much higher if immigration occurs after mating rather than before mating.

### *2.10.2. Immigration after Mating*

In this case it is assumed that $V$ males and $V$ females immigrate each generation after mating. The female immigrants are thus not available for mating with the released sterile males or the wild males, however the male immigrants are available for competing with the sterile males. Thus, immigrating females remain fully fertile (unless there is some remating). Note that, if the wild population is reduced to zero, it will be reconstituted the following generation, as $F_{t+1}=\lambda V$. For a given value of the immigration rate, the required sterile release rate, $S^*$, is much higher if immigration is after mating than before mating, due to the fully fertile nature of the immigrating females.

### *2.10.3. Combinations of Residual Fertility, Reduced Competitiveness, and Immigration*

Four models can be considered, being the four combinations of: (1) those sterilized insects that show residual fertility can be either of reduced competitive ability (reduced) or fully competitive (equal) with the wild insects, and (2) insects can immigrate either before or after mating.

Barclay (2001) provided equations for the four cases, and the values of the limiting residual fertilities are shown in Table 1 and Fig. 6. In Table 1, the allowable residual fertility for the case of residually fertile insects being of reduced competitive ability is the same as for the case involving sterile insects being fully competitive and immigration occurring. The other two cases yield more stringent limits on allowable residual fertility than with no immigration. It is apparent that there is a strong interaction among residual fertility, competitive ability, and immigration, with the feasible limits on each factor becoming much more restrictive in the presence of the other factors.

*Table 1. Limits on residual fertility (q) when competitive ability of "sterilized but residually fertile insects" is either reduced or equal to that of wild fertile insects, and immigration is either before or after mating*

| | Reduced Competitiveness | Equal Competitiveness |
|---|---|---|
| Before | $q<F/\lambda(F+V)$ | $q<cF/[\lambda(F+V)-F(1-c)]$ |
| After | $q<(F-\lambda V)/\lambda F$ | $q<c(F-\lambda V)/[\lambda F-(1-c)(F-\lambda V)]$ |

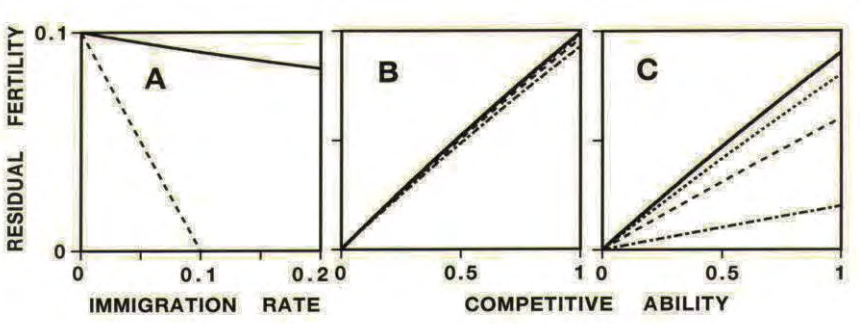

*Figure 6. A: The allowable residual fertility (q) when the released insects that are fertile are also fully competitive with wild insects. Immigration occurs before mating (_____); immigration occurs after mating (- - - - -). B and C: Allowable residual fertility as a function of competitiveness of released insects. Immigration occurs at 1% (_____), 2% (…….), 4% (- - - - ), and 8% (- . - . -.-) of the wild population size F. B: Immigration occurs before mating. C: Immigration occurs after mating. (Figure from Barclay 2001, reproduced with permission.)*

### *2.10.4. Large-Scale Population Movement*

The problem of large-scale population movement was addressed by Manoranjan and van den Driessche (1986), Lewis and van den Driessche (1993), Plant and Cunningham (1991), and Marsula and Wissel (1994). They showed, using diffusion equations, that dispersal of insects, coupled with non-linear growth terms, can result in waves of invasion or extinction. Both the velocity and direction of these waves depend critically on the rate of release of sterile insects. With low rates of release, the travelling wave advances as an invasion; when the density of sterile insects exceeds a critical density, the wave recedes, giving rise to local extinction. This is likely to have considerable relevance to programmes releasing sterile insects such as the New World screwworm eradication programme in the southern USA, Mexico and Central America, in which the pest population has been pushed back to Panama and a sterile insect buffer zone created. Matlock and associates are pursuing this approach with the screwworm, assessing the size of the buffer zone needed to ensure

that insect invasion into the eradicated area does not occur (section 2.18.; R. B. Matlock, personal communication).

### *2.10.5. Effects of Movement of Individuals on Efficiency of the SIT*

Apart from the effects of immigration by pest insects, the effect of diffusion (random non-directed movement) or redistribution of sterile insects within the control area appears to make control by SIT integration easier. Barclay and Vreysen (2013) presented a compartment model of tsetse (*Glossina palpalis gambiensis* Vanderplank) together with four control methods, one of which was the SIT. The critical sterile release rate for control increased with the degree of spatial aggregation but decreased with the extent of tsetse diffusion.

### *2.10.6. Redistribution of Released Sterile Insects*

A problem that plagues many SIT projects is estimating the speed and extent of redistribution of sterile insects after aerial release, especially as sterilized insects may be less active and incur greater mortality than their wild counterparts (Parker, Vreysen et al., this volume; Dowell et al., this volume; Vreysen, this volume). Barclay et al. (2016) used diffusion equations to derive optimal spacing of flight lines and frequency of flights given the calculated sterile male population required to effectively cause population collapse. The optimization was done using a numerical treatment of the diffusion process to minimize total cost given the cost of sterile males and of flying time. They focussed on a midline between two flight lines of interest and calculated diffusive input of insects from eight flight lines on each side of the midline and from the eight previous flights. The optimization was found to depend strongly on the diffusion coefficient ($D$) and also on the daily mortality ($\mu$) of the released sterile males. Estimates of diffusion coefficients and daily mortalities were noted to vary widely among insect species, with $D$ being approximately 0.46 for tsetse flies and 0.006 for Mediterranean fruit flies, while $\mu$ varied between about 0.02 for tsetse and 0.23 for the fruit flies. At the low end of $\mu$ (0.04), longer flight intervals are suggested, and fewer sterile males need to be released; at the high end of $\mu$ (0.24), shorter flight intervals are suggested and higher numbers of sterile males need to be released.

These authors also derived a shorter approximate method of optimizing the sterile insect release based on the observation from the results of the numerical method that the optimal spacing of flight lines ($\omega$) was twice the standard deviation, $2(2D\tau)^{½}$, of the Gaussian distribution resulting from the diffusion process. Here $\tau$ is the time interval (days) between flights. Two assumptions of this method are: (1) the relationship between $\omega$ and the standard deviation of the distribution observed from the longer method is assumed to hold for other values of the parameters, and (2) the midline between flight lines being used for computations is assumed to be well within the control area so that edge effects are not evident and diffusion is assumed to be in equilibrium. This shorter method is outlined below.

Given the values of $D$ and $\mu$, use each possible value of $\tau$, $\tau$ = 1, 2, 3....$k$. For $n$ flights and a requirement of $N_M$ sterile males alive per km$^2$, the number of sterile males to be released per km$^2$ ($N_{SK}$) is:

$$N_{SK} = N_M \frac{(exp(\mu\tau) - 1)}{(1 - exp(-n\mu\tau))} \quad (2)$$

Now, to find the optimal value of $\tau$, we must minimize the formula for total cost ($C_T$) per km$^2$ per day: cost of flying time + cost of sterile males:

$$C_T = C_H / (S\omega\tau) + (C_S / 10^6)\, N_M\, (exp(-\mu\tau) - 1) / \tau\, (1 - exp(-n\mu\tau)) \quad (3)$$

Here $C_H$ is the cost per hour of flying time, $S$ is the speed of the aircraft, and $CS$ is the cost per million sterile males. In the example below, $n$ is taken as 8 and $N_M$ is $10^6$, $C_S$ is USD 250, and $C_H$ is USD 5/km actually flown over the field, once the transit to and from the field is included.

For Mediterranean fruit flies, $D$ = 0.005, so with $n$ = 8 flights, using these dollar figures,

$$C_T(\tau) = 5 / (2(2D)^{0.5}\, \tau^{1.5}) + 250 * (exp(\mu\tau) - 1) / (\tau\, (1 - exp(-n\mu\tau))) \quad (4)$$

When $C_T$ (τ) is plotted against τ, this is a convex curve, i.e. a concave-up curve, with a minimum value that represents the optimal values of τ (Fig. 7). A hand-held graphing calculator, or graph-plotting software on a computer, can be used to obtain easily the minimum value, and the τ (which must be a positive integer) at which it occurs. When the cost starts to increase, one should stop calculating; the cost will only increase beyond this point.

As an example of the approximate method for $\mu$ = 0.24 using a basic calculator, we obtain the following: from Fig. 7, the best value of $\tau$ is 2 days. This then gives $\omega$ = 2 sqrt (2*0.005*2) = 0.283 (= 283 m). The number of sterile insects to be released per day is then 1 000 000 • (exp(0.48)-1)/(2*(1 - exp(-3.84))) = 315 000.

### *2.10.7. A Model for* Eldana saccharina *with Diffusion and Partial Sterility*

Potgieter et al. (2013) presented a stage-structured diffusion model for the African sugar cane borer *Eldana saccharina* Walker. Eleven stages were tallied. The released female moths were fully sterile while released males were partially sterile, and sterility existed in the $F_1$ generation. The habitat was heterogeneous and compartmentalized into relatively homogeneous subpopulations; diffusion provided the only movement among these subpopulations. The model was applied to an existing sugar cane field in KwaZulu-Natal in South Africa. Numerical results indicated that the optimal release distribution and release ratio depend on the dispersal capability of the insect, method of release, frequency of releases, and growth or mortality rate of the population (Potgieter et al. 2013).

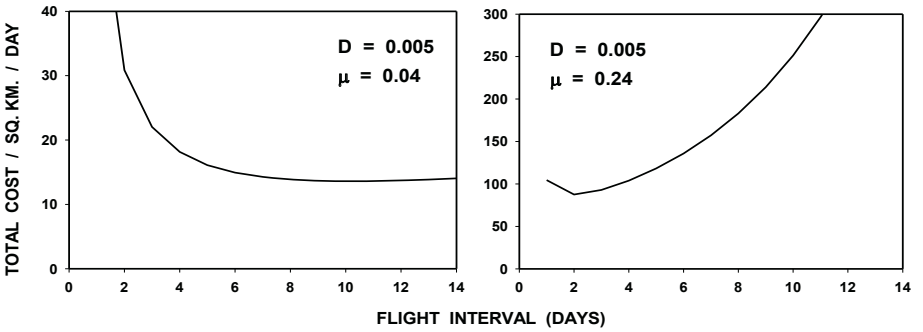

*Figure 7. Curves for optimizing τ (the time interval (days) between flights) using the approximation. In both curves the value of D is 0.005, while in the left curve μ = 0.04 and in the right curve μ = 0.24. In both cases, 8 flights have been used. The location of the optimum value of τ is well defined (τ = 2) for μ = 0.24, but not so well defined (τ = 10) for μ = 0.04. For μ = 0.24 the cost would be notably greater if τ were assigned to 1 or 3, whereas for μ = 0.04 the difference in cost would be minimal if τ was misassigned to be 8, 9, 11 or 12 when the optimum was 10.*

### *2.11. Density-Dependence in Population Regulation*

Density-dependence in a population has been shown by modelling to predispose it to control by sterile releases (Miller and Weidhaas 1974; Itô 1977; Prout 1978; Barclay and Mackauer 1980a). There are several formulations that include density-dependence in a model of a population, and all yield the same qualitative results. The two distinct ways that density-dependence assists the SIT are: (1) it reduces the effective biotic potential of a species by increasing the natural mortality at higher densities, and (2) it introduces a bifurcation (splitting of one root of the equation into two) into the model whereby the population suddenly collapses as the sterile insect release rate is increased above the level required at the bifurcation (Fig. 8). This avoids the necessity of the high levels of release needed to reduce the population below the unstable steady state in the model with no density-dependence. This bifurcation occurs in all the models involving density-dependence, and appears to result from the interaction of the depressing effects of density-dependence and the unstable equilibrium created by the SIT formulation in section 2.2., which results in the release of sterile insects being more effective at low density than at high population density, and thus the efficiency of the SIT increases as the population declines. The sudden collapse of a population under attack by sterile insect releases has indeed been observed in the programme against the melon fly *Zeugodacus cucurbitae* (Coquillett) in Okinawa, Japan (Iwahashi 1977). Thus, this predicted bifurcation appears to be a robust result, and one that apparently mimics nature.

The exact behaviour of the SIT under density-dependence appears to depend sensitively on the biology of the system. Lawson (1967) and Berryman et al. (1973) pointed out that overcrowded populations may deplete their resources sufficiently such that survival to the adult stage is low. In this case, killing some of them (or

lowering egg production) might actually result in a higher survival to the adult stage, making the use of the SIT counterproductive in such a situation. Another situation might be encountered in the case of an insect species wherein egg production is much higher than the resource allows, e.g. the olive fruit fly *Bactrocera oleae* (Rossi), in which one egg per fruit is laid. If sterile eggs did not deter insects from laying further eggs in a fruit already containing a sterile egg, then reduction in fertile egg production would have to be substantial before any effect would be noticed.

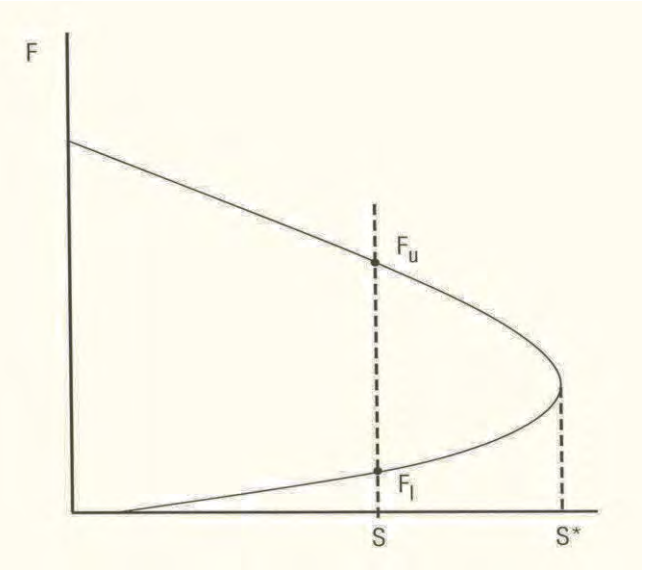

*Figure 8. Isoclines formed by setting the equations for sterile insects (S, vertical line) and fertile insects (F) to zero; where they cross are the two steady states. The upper one is stable, and the lower one unstable. As sterile releases increase, the sterile isocline moves to the right. The bifurcation is at the point where the isoclines are tangent to each other. Larger values of sterile insect releases result in a sudden collapse of the population. (Figure generated from equation 12, Barclay 2001.)*

## *2.12. Age Structure*

### *2.12.1. Two Age Classes*

The existence of two or more life stages of a species complicates the dynamic responses of a population to mortality factors, especially if the two stages are ecologically different, as they are in mosquitoes and other pest species in which the two active stages occupy different habitats. If density-dependence is strong in one stage and weak or absent in the other stage, then the density-dependent stage is strongly buffered against mortality factors and tends not to vary greatly, while the other stage may vary more but the mean size is a linear function of the buffered stage. As such, somewhat different responses to mortality affecting mainly one stage

would be expected, and indeed this appears to be the case. In the case of the SIT, the sterile insects released always affect the adult stage, reducing fertile egg production.

Prout (1978) modelled the SIT for species with identifiable age structure and subject to immigration. His results indicated that, if the larval stage caused the pest problem, a higher level of immigration of mated adults was tolerable.

Barclay (1980b) showed that the critical release rate ($S^*$) is a larger proportion of the larval equilibrium size when density-dependence is in the larval survivorship than when density-dependence is in the adult survivorship. Thus, relative to a given larval equilibrium, the population requires fewer sterile insect releases when density-dependence is in the adult stage.

### *2.12.2. Daily Age Classes*

Barclay et al. (2014) modelled a population of a monogamous species with egg, larval, pupal and adult stages, and a daily time step. Survivorship was age-specific, and there was no density-dependent population regulation. Eggs take $ke$ days from oviposition to hatch, and there is no daily mortality. The numbers of eggs in the $i^{th}$ age class at time $t$ is $E_{i,t}$, and as there is no egg mortality, $E_{i+1,t+1} = E_{i,t}$ for $1 \leq i < ke$. Eggs of age $ke$ hatch into larvae, so that $L_{1,t+1} = E_{ke,t}$.

Larvae require $kl$ days for development, and the number of larvae in the $i^{th}$ larval age class at time $t$ is $L_{i,t}$ for $1 < i \leq kl$. Larvae survive from age $i$ to age $i$+1 at a rate $q_i$, so that $L_{i+1,t+1} = q_i\ L_{i,t}$ for $1 \leq i < kl$. Similarly, pupae require $kp$ days for development, and the number of pupae in the $i^{th}$ pupal age class at time $t$ is $P_{i,t}$ for $1 \leq i \leq kp$. Pupae survive from age $i$ to age $i$+1 at a rate $u_i$, so that $P_{i+1,t+1} = u_i\ P_{i,t}$ for $1 \leq i < kp$. Also, the first pupal age class is $P_{1,t+1} = q_{kl}\ L_{kl,t}$.

There are five categories of adults, also referred to as adult population components; at age $i$ and at time $t$ they are: virgin females ($V_{i,t}$), females mated to fertile (wild) males ($F_{i,t}$), females mated to sterile males ($G_{i,t}$), wild males ($M_{i,t}$) and sterile males ($N_{i,t}$). The virgin adult females are assumed to become receptive to male mating advances at age $\tau$ days, and all of age $\tau$ mate on that day and immediately start ovipositing. Adult virgin females, fertile-mated females and sterile-mated females all survive at a rate $w_i$ from female age $i$ to age $i$+1, except that mated females start on their day 1 at survivorship $w_{1+\tau}$ because adult emergence occurred $\tau$ days before. Wild males survive at a proportional rate $y_i$ from age $i$ to $i$+1, and sterile males correspondingly survive at a rate $z_i$. Thus, age classes $i$ at time $t$ survive as follows: $V_{i+1,t+1} = w_i\ V_{i,t}$; $F_{i+1,t+1} = w_{i+\tau}\ F_{i,t}$; $G_{i+1,t+1} = w_{i+\tau}\ G_{i,t}$; $M_{i+1,t+1} = y_i\ M_{i,t}$; $N_{i+1,t+1} = z_i\ N_{i,t}$.

If sterile males are being released, then there is a release rate, $r^*$, at which the population will not increase further and a steady state (equilibrium) will be attained. This equilibrium is unstable in the absence of density-dependent regulation, and it is of interest only inasmuch as it separates success (if the actual release rate, r, is greater than $r^*$) from failure (if the sterile release rate is less than $r^*$). This sterile male release rate, $r^*$, is called the critical release rate, and it is what is calculated in standard models of the SIT, e.g. Berryman 1967; Dietz 1976; Itô 1977; Barclay and Mackauer 1980; Barclay 2001; Barclay et al. 2014).

Two derived statistics are required to calculate fertility, and thus to calculate the size of the first egg age class, and also to determine the critical release rate; these are

the net survivorship from eggs to adult emergence, $\gamma$, and the mean daily fertility (mdf), $\mu$ (called "mean fertile eggs per fly-day" by Carey 1989):

$$\gamma = (\Pi_1^{(kl-1)} q_i) (\Pi_1^{(kp-1)} u_i) \quad (5)$$

$$\mu = \Sigma\, l_x\, m_x\, h_x / \Sigma\, l_x \quad (6)$$

where $l_x$, $m_x$, and $h_x$ are the survivorship and fecundity of fertile-mated females and hatchability of their eggs, respectively, from age $x$ to age $x$+1 (Carey 1989); here $\mu$ (fertility) is not the same as $\mu$ in section 2.10.6. (mortality). The equation for the critical sterile release rate, $r^*$ (Barclay et al. 2014), is then obtained by solving the five adult equations at equilibrium simultaneously for $r$ in terms of $Fe$, the fertile-mated female subpopulation. Doing the appropriate substitutions and simplifying yields the critical value of $r$, $r^*$:

$$r^* = \gamma\, \mu\, Fe\, a\, (b\, c - 1) / d \quad (7)$$

where:
$a = [\Sigma_0^{(km-1)} \Pi_0^{(i)} y_j]$, i.e. the sum of the products of fertile male survivorships;
$b = \gamma\ \mu\ [\Sigma_0^{(kf-1)}\ \Pi_0^{(i)}\ w_j]$, i.e. $\gamma\ \mu$ times the sum of the products of female survivorships;
$c = \Pi_0^{(\tau)} w_j)$, i.e. the survivorship of virgin females to the $\tau^{th}$ age class; and
$d = [\Sigma_0^{(km-1)} \Pi_0^{(i)} z_j]$, i.e. the sum of the products of sterile male survivorships.
Even though this appears to be rather complicated, it is easily computed if the age-specific fecundities, hatchabilities, and survivorships are known or can be estimated. Also, it is remarkably parallel to the models with no age structure, in which $\gamma\ \mu$ is the analogue of $\lambda$ in Knipling's model.

One further complication in calculating fertility should be mentioned. For the special case of species giving single live births of larvae at intervals of several days, such as tsetse flies, it has been common practice to calculate fertility as the reciprocal of the inter-larval period. It has been shown recently (Barclay et al. 2020) using eq. (6) above that a better estimate of fertility is about 10% greater than the reciprocal of the inter-larval period. This has implications for calculating the minimum sterile-male release rate required for control or eradication.

### *2.12.3. Overflooding Ratios and Release Ratios*

The overflooding ratio, a key parameter, has long been a measure of the ratio of sterile males to wild males in the population (Steiner et al. 1965). It is sometimes thought of as the size of sterile releases compared with the wild population; this is approximately valid in species with short reproductive seasons and non-overlapping generations. However, in species with a long reproductive period, often extending throughout the warm season in temperate climates, a surviving population of sterile males exists following several releases, and the overflooding ratio is not equal to the periodic release rate divided by the wild male population size, and must be estimated by sampling or some other means. The overflooding ratio is here called $\varphi$.

Another ratio is the release ratio, defined as the ratio between the periodic sterile male releases and the wild male subpopulation, and here called ρ. For species with one short reproductive period each year, the two ($\varphi$ and $\rho$) are approximately equal, allowing for some mortality following release. Such populations yield the same sterile release rate required to stop population growth, and then hold the population at equilibrium, as that predicted by the model at equilibrium. In freely growing populations with overlapping generations, the release ratio and the overflooding ratio are not equal.

### *2.12.4. Stopping a Growing Population*

Barclay et al. (2014, 2016) derived critical control rates that are required to hold an age-structured population at an unstable equilibrium. This equilibrium separates success (if the control rate is above the critical rate) from failure (if the control rate is below the critical rate). The paper by Barclay (2016) builds on a previous publication (Barclay et al. 2014) on the control of age-structured populations, and shows that the equilibrium statistics derived are only a first step towards being useful. They are not sufficient to allow calculation of the appropriate values of the sterile release rates and overflooding ratios required to stop a growing age-structured population using the SIT. A measure called the "required sterile release rate", *r*', is defined as the value of the sterile male release rate, r, necessary to stop a population growing freely in a stable-age distribution, i.e. with sterile-male releases, the growth rate eventually becomes zero with $r = r'$. Such populations are largely undergoing density-independent growth, as may be the case with many spot infestations.

The values of *r*' were all moderately close to the calculated value of *r**, the critical rate, but the computed overflooding ratios were very different for a growing age-structured population than for one at equilibrium; the value of the overflooding ratio calculated for an equilibrium population, i.e. when $r = r^*$, greatly underestimates the value required to stop a population in unrestricted growth. As the value of *r*' increases with population size, accurate estimation of population size is necessary to calculate realistic values of *r*'. For the Mediterranean fruit fly example that was developed (Barclay 2016), the discrepancy was huge; the overflooding ratio calculated from an equilibrium population was only about 1% that found to be required in the simulation. This is because, at equilibrium, females mated to fertile males constitute a very small part of the equilibrium population, whereas in a growing population, fertilized females constitute a much larger portion of the total population. Thus, in this situation, it is the actual critical release rate, r*, that should guide the control programme, rather than deriving the overflooding ratio from sampling the males in a freely growing population.

## *2.13. Population Aggregation*

In nature most populations are not dispersed evenly over the available habitat. Some processes, such as territoriality, result in dispersion patterns that are more regular (Fig. 9, upper left) than one would expect of a random spatial distribution (Fig. 9, upper right). However, most populations will tend to have a somewhat aggregated

dispersion pattern. Aggregation is the most difficult pattern to deal with in making sterile insect releases, because one has to know where the clumps are located (Fig. 9, lower panels).

Modelling of spatial aggregation has been done by Wehrhahn (1973) and Barclay (1992a). Wehrhahn used a mosaic of patches, inhabited by differing numbers of insects, and compared the required release rates for various patterns of aggregation. He used Monte-Carlo simulation, which introduces random numbers to allow stochastic variation, in this case, of migration rates among patches. Wehrhahn pointed out that the control programme itself will probably change the nature of the spatial distribution. Bakhoum et al. (2021) described using species distribution modelling and landscape genetics for tsetse fly control.

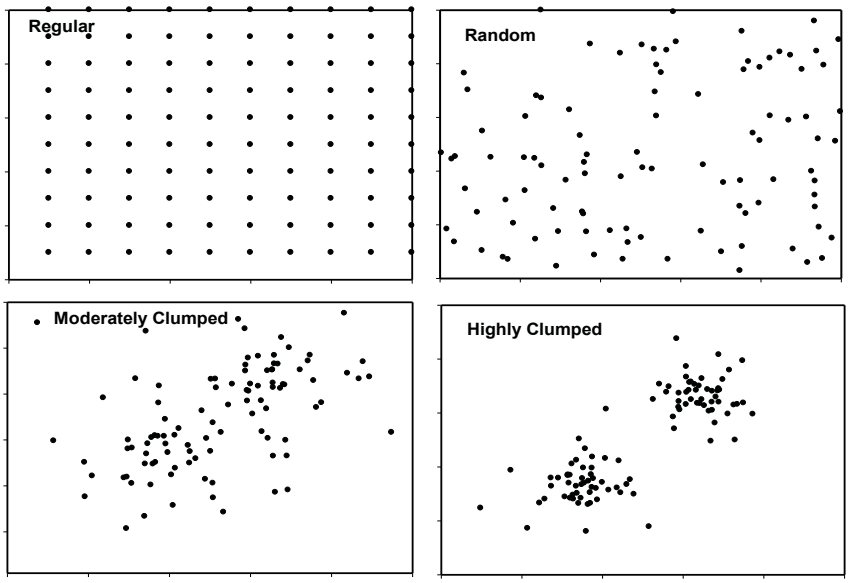

*Figure 9. Examples of spatial distributions: regular (uniform), upper left; random, upper right; moderately clumped, lower left; highly clumped, lower right (reproduced from FAO/IAEA 2016). These can be quantified by various aggregation indices (Pielou 1969; FAO/IAEA 2016).*

Another approach has used probability distributions to describe the extent of aggregation (Barclay 1992a). There is a long history of using these distributions in ecology, summarized by Pielou (1969) and Patil and Stiteler (1974). The most commonly used distribution to quantify aggregation is the Negative Binomial Distribution in which the parameter $k$ measures clumping. If aggregation is extreme, then $k$ is close to zero; as $k$ goes to infinity, the dispersion approaches a random pattern. Another approach uses $1/k$, which increases with the degree of clumping. Barclay (1992a) used the negative binomial distribution to derive required sterile insect release rates of an aggregated population as a function of the clumping

parameter, $k$. For moderately aggregated populations ($k$=0.25), it was found that the required release rate was about four times that for a randomly dispersed population. Shiga (1986) analysed spatial distributions in the context of fruit fly eradication using male annihilation and the SIT.

Many aspects of aggregation involve behavioural components. Horng and Plant (1992) modelled the impact of lek mating on the SIT, using a Poisson binomial distribution. They found that the sterility effect, presence or absence of female mate-choice, and sterile male mating competitiveness were the most important factors in their model in determining the success of a programme releasing sterile insects.

### *2.14. Predation, Parasitism, and Competition*

The effects of predation on the efficiency of the SIT were first modelled by Knipling (1979) using a simple numerical model. His model predicted a synergistic interaction between predation and sterile insect releases, such that the net effect would be considerably greater than either alone. This would only be expected to be true if predation is random, with sterile and wild males equally able to evade predator attacks. Nevertheless, there is growing evidence that sterile males have largely lost this capacity and suffer much more predation (Hendrichs et al. 1994; Hendrichs and Hendrichs 1998; Hendrichs et al. 2007). On the other hand, the integration of augmentative parasitoid releases and inherited sterility can be highly synergistic (Barclay 1987a, b; Carpenter 2013).

Barclay and Mackauer (1980b) included sterile insect releases in the Lotka-Volterra predator-prey model, and demonstrated that, not only was the critical release rate lower with than without predators, the system was also greatly destabilized, and population collapse often occurred with release rates well below the critical value. This model was subsequently shown by Harrison et al. (1982) to have a very complicated dynamic behaviour, and this is presumably related to the inherent instability. This model was then extended, and an even greater array of dynamical behaviour was found (Barclay and van den Driessche 1990). In addition, the general features of the predator-prey system were found similar to the situation involving hosts and parasitoids (Barclay 1987a). Knipling (1998) analysed extensively the effects of augmentation of predators and parasitoids on the efficiency of the SIT.

If the pest species is in competition for resources with another species, then this is of some value to the release programme, because it reduces the initial pest population size, but apart from that there seems to be little effect of the competing species on the release programme (Barclay 1981b).

### *2.15. Stability under Various Conditions*

Stability is a very important aspect of populations, and is of special interest to pest managers. If, for any reason, the population is likely to collapse, this is important. Barclay (1982b) examined four systems or cases for their relative stability under sterile insect releases. These were all differential-equation models and represented: (1) a simple one-species model with only one identifiable life stage (adult), (2) a

one-species model with two life stages (larval and adult), (3) a model of two competing species, one of which is the pest, and (4) a predator-prey model in which the prey is the pest. There are many possible definitions of stability in ecology, and they involve various dynamic characteristics of the system. None has yet emerged as definitive, although an extensive analysis of the topic is now available (Mueller and Joshi 2000). Barclay (1982b) examined five criteria of stability for each system, and ranked the systems. These stability criteria involved characteristics such as extinctions, time to extinction, amplitude of fluctuations, and time until return to equilibrium. The most stable was the single species – single stage model, followed by the competing species model, then the two-stage model, and by far the least stable was the predator-prey system above (section 2.14.). The existence of obligate predators (or parasitoids) both lowers the critical release rate of sterile insects and also destabilizes the system, so that it is likely to collapse even when the sterile release rate is lower than the critical rate. Unfortunately, there appears to be no experimental evidence to test these ideas.

### *2.16. Integration of Control Methods*

Since the SIT works best at low pest densities (section 2.11.), it is common practice to reduce the population with an insecticide or other control method (or to start at naturally low population levels), prior to the release of sterile insects. This brings the population down to a level at which the number of sterile insects (required to be produced by a rearing facility) is manageable. It might also be possible to combine contemporaneously the action of the SIT with other control methods to share the required mortality among two or more imposed sources, each one then having to impose only a modest level of mortality, and each one perhaps operating best under conditions not favourable to the others (Barclay 1992b; Mangan and Bouyer, this volume). On the other hand, certain combinations might interfere with each other and thus prove unsuitable (Barclay 1987c).

Knipling (1964, 1979) examined several combinations of various control methods with the SIT, using simple numerical intra-generational models. These include combinations of sterile releases with insecticides, sterilants, pheromones, parasitoids or predators. Barclay (1980b, 1987a, b) and Barclay and van den Driessche (1989) also examined some of these combinations using more general inter-generational algebraic models. They found that the results of the combined use of sterile insects and other control methods became less clear when other biotic interactions were included; for example, a three-way interaction with sterile insects, predators, and insecticides may be counterproductive because the insecticides would probably reduce the effectiveness of the predators. In general, in population dynamics, three-way interactions are much more difficult to predict and analyse than two-way interactions.

#### *2.16.1. SIT with Application of Insecticide*

It might be thought that insecticides and the SIT are incompatible because the insecticide would kill sterile, as well as fertile, insects. However, Knipling (1964,

1979) reasoned that insecticide application would kill both sterile and fertile insects in the same proportion, and thus maintain the overflooding ratio, rendering the two control methods compatible. By numerical examples he showed that these two methods could work well together, and thus reduce both total costs and the need for excessive insecticide application. If the sterile insects were also resistant to insecticide, then the combination would be even more effective.

Barclay (1980a, b) found that, when the pest species was considered in isolation, the application of insecticide coupled with the release of sterile insects increased total mortality. However, the results of the combined use of insecticide and sterile insects became less clear when specific tritrophic biotic interactions were included, e.g. predators or parasitoids. For example, if the pest is already under considerable predation, the combination of insecticide and sterile insects might be detrimental. Therefore, when using sterile insects against species with two life stages, a larvicide appears to be more useful than an adulticide.

### *2.16.2. SIT with Pheromone Traps for Male Annihilation*

Knipling (1979) found that the combined use of sterile releases and pheromone traps was less efficient than an equivalent effort put into either method alone. This was because of the interference caused by the killing of sterile males in the pheromone traps. As a variant of this combination, Knipling proposed that releasing pheromone-treated sterile insects could enhance mate-finding, thus increasing the competitive ability of sterile insects, especially at low densities. Knipling found that, for insects in which the males produce female-attracting pheromone, such as the boll weevil *Anthonomus grandis grandis* Boheman, the release of pheromone-treated males would substantially increase the effectiveness of the control programme, assuming that the applied pheromone did not deteriorate badly. Knipling also considered the situation in which females produce male-attracting pheromone, and he modelled the release of pheromone-treated sterile females alone. These would probably be most effective if they were free-living rather than contained in traps. He again found that this method was much more effective than the use of untreated sterile females, and that control might be possible using pheromone-treated sterile females where the release of only non-treated sterile females would be hopelessly inadequate. Pheromone-treated sterile insects of a species that is easier to mass-rear might also act as vehicles for mating disruption of the wild population of a different target pest (Suckling et al. 2011).

Hamada and Miyai (1985), using a continuous model, modelled the combination of the simultaneous release of sterile insects and pheromone trapping for male annihilation (Box 8). They found that the two methods in combination required less effort for each control method than when using either method alone. Their recommendation was to use male annihilation first and then sterile releases. Although the model did not specifically explore that scenario, this approach was successfully applied in Japan against the melon fly and the oriental fruit fly *Bactrocera dorsalis* (Hendel) (Enkerlin, this volume).

Barclay and van den Driessche (1989) also modelled this combination, and found that the two methods combine synergistically, especially when the fecundity and daily survivorship are both high. When the fecundity and survivorship are low,

the synergism disappears. For parameter values approximating those of tsetse flies *Glossina* spp., synergism is reduced.

Knipling (1979) described the interaction of methyl eugenol (ME) for male annihilation used concurrently with the release of both sterile males and females, and found no interference and a high degree of synergism. Since the potential for development of resistance to ME has been demonstrated (Shelly 1997), it might also be possible to incorporate the use of sterile insects of the resistant strain, and thus increase effectiveness even more.

In the case where the attractant is non-sex-specific, such as with food baits, Barclay and van den Driessche (1989) showed that the two methods combine synergistically, especially when sterile insects are fed before release, and fecundity and survivorship are high. For parameter values approximating those of tsetse flies, there is still some synergism.

Barclay et al. (2014) also modelled the interaction of ME for male annihilation applied simultaneously with the release of ME-fed sterile males that are non-responsive to ME male annihilation, using the same age-structured model as in section 2.12.2. They found that the two methods are synergistic. This is fortunate, as ME used alone appears not to be very useful in this context (Barclay and Hendrichs 2014), but elimination of wild males through male annihilation together with the SIT becomes very effective if the sterile males are raised with ME in their adult diet before release, after which they exhibit reduced attraction to ME traps and thus may come to dominate the male subpopulation over and above the numerical advantage they may achieve though high release rates. It appears that ME used alone can only be effective if trapping or response to male annihilation devices occurs prior to mating each day, which may or may not commonly occur in a control programme (Barclay and Hendrichs 2014). When ME is used simultaneously with the SIT, the order of mating and trapping is still important, but makes less difference than it does with ME alone.

*Box 8. Combination of Sterile Releases and Pheromone Trapping*

Miyai's model consisted of four differential equations: $dM / dt = F(a - bF) - cM - kM$; $dV / dt = F(a - bF) - cV - \alpha[\min(M+S, V)]$; $dF / dt = \alpha[\min(M+S, V)]\, M / (M+S) - cF$; $dS / dt = R - cS - kS$; where $M$, $V$, $F$ and $S$ are the numbers of males, virgin females, fertilized females, and sterile insects, respectively. The parameters are: $a$ is a density-independent fecundity, $b$ is a density-dependent fecundity, $c$ is a death rate, $k$ is the rate of trapping of males, $\alpha$ is the mating efficiency, and $R$ is the sterile insect release rate.

### *2.16.3. SIT with Release of Parasitoids*

This combination has the advantage that parasitoids work well at high host densities, while the SIT works best at low pest densities. Knipling (1979, 1998) considered the release of both sterile males and females, and also *Trichogramma* sp., an egg parasitoid. His tables showed clearly that these two methods were synergistic. A recent field study found that the two methods in combination were more efficient than either method alone (Bloem et al. 1998). Especially in the case of inherited sterility, the release of partially sterile males and sterile females provides $F_1$ eggs and larvae for oviposition by egg and larval parasitoids, further augmenting the

parasitoid populations (Marec et al., this volume). If both sterile insects and parasitoids are released inundatively (Marec et al., this volume), then each should become more efficient as the density declines, offering a powerful source of synergism (Knipling 1998).

Barclay (1987b) modelled the interaction of the inundative release of parasitoids and sterile insects using several variations on the usual host-parasitoid equations. This combination shows a high degree of synergism in all the models investigated, and appears to be close to ideal (Fig. 10). The main problems to be anticipated probably involve dispersal and phenology.

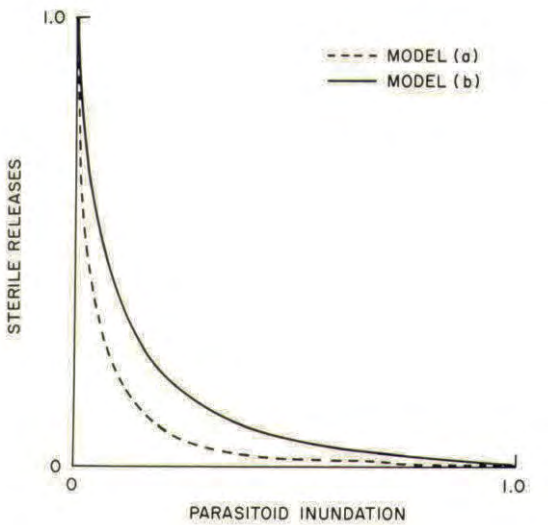

*Figure 10. Critical release rates of sterile insects and parasitoids. All points on each curve are just sufficient to eradicate the pest population. Density-dependence is in the hosts in model (a), and in the parasitoids in model (b). (Figure from Barclay 1987c, reproduced with permission.)*

### *2.16.4. SIT with Pathogens*

The combination of the SIT and male-killing bacteria has been investigated by Berec et al. (2016) for bacteria that are transmitted vertically. They found that if vertical transmission is 100%, then the SIT is not required. If transmission is less than 100%, then the bacteria and the SIT act synergistically, and the combination is more efficient than either method alone. Specifically, with a relatively high rate of transmission of the bacteria, the required level of sterile male releases is much lower than without the bacteria. They investigated the interaction of bacteria with both non-heritable sterility (the usual SIT method employed for dipterans) and inherited sterility (used with lepidopterans) (Marec et al., this volume), and found that the efficiency of this combination for inherited sterility is best at intermediate doses of radiation. In New Zealand Suckling et al. (2007) integrated the use of *Bt* with sterile releases and achieved local eradication of the painted apple moth *Teia anartoides*

Walker. Toledo et al. (2017) used *Beauveria bassiana* with an autoinoculation device for the control of *Ceratitis capitata* with a similar synergism.

### *2.16.5. SIT with Sanitary Measures and Oviposition Traps*

If sanitation destroys oviposition habitat, and traps remove females that oviposit eggs, then there should be a complementary effect between the two, albeit moderated by density-dependence. If sterile males are also released, then the system has three sources of population reduction, none of which interferes with any other. Knipling (1979) calculated that these three should result in a highly efficient combination for control.

### *2.16.6. Synergism between the SIT and a Natural Allee Effect*

The Allee effect (Allee 1931) is the phenomenon in which density-dependence becomes negative at very low population densities as a result of both sexes having difficulty in finding mates. It has since been generalized to include other sources of negative density-dependence as well (Yamanaka and Liebhold 2009). Although the Allee effect is not really a pest control method, it represents a natural weak point in the pest population dynamics (Suckling et al. 2012). Gordillo (2015a, b) has incorporated the Allee effect into models of the SIT, and noted the synergism that increasingly results with decreasing pest population, causing local extinctions.

Conversely, it may be possible for pockets of pest persistence to exist with sufficiently high dispersal even when the sterile release rate is above the predicted requirement for extinction, especially in heterogeneous habitats in which the number of sterile males depends on the estimated pest density. This is similar to the result of Levins and Culver (1971) in which populations could persist in a patchy environment in the face of local extinctions if dispersal is high enough, because some of the pest individuals disperse into neighbouring patches before extinction occurs in the home patch. Nevertheless, the dispersing pest population needs to be sufficiently high to overcome the Allee effect.

## *2.17. Optimizing Initial Knockdown for the SIT*

Age at first oviposition is an important factor affecting spray intervals (Mangan and Bouyer, this volume). Adult insects usually take time to mature before mating and then ovipositing. If sprays targeting adults are timed so that the interval between sprays is smaller than the interval from adult emergence to first oviposition, then subsequently emerging adults will be killed before being allowed to oviposit. The number of sprays will depend on the time it takes from oviposition to adult emergence and number of generations per year or number of generations during the critical period required for population suppression. An example will illustrate this. In tsetse, the period between larviposition, pupation, and emergence of adults from the pupae is about 27 days at 27ºC, while the age to first larviposition is about 17 days following emergence of the adults. If the mean temperature is 27ºC, and the inter-spray interval is 15 days, and sprays kill 90% of the adult population, then the first spray will eliminate most of the adults, the second spray 15 days later will

eliminate most of those adults that have emerged from the developing pupae, but before they start ovipositing, and a third spray will kill most of the adults that have emerged from the remaining pupae that were alive at the time of the first spray, again before they start ovipositing. The population is then in a suitable state to be controlled by sterile releases, as there will be little increase in the adult population for some time, long enough that the SIT should decrease the recruitment of juveniles and prevent this increase.

A model of tsetse developed by Barclay and Vreysen (2011) predicts the course of the adult population following two, three, and four applications of aerial insecticide sprays, each of which kills 98% of the adult population. For each of these three scenarios, a sterile release ratio (daily releases divided by the existing wild male population) of 0.2 was used, calculated immediately after the last spray. The tsetse example is presented because it is particularly clear. For most species, spray efficiency will be less than 100%, and additional sprays will be required.

If sprays target larvae, then the length of the larval period is the factor that determines the time between sprays (Barclay et al. 2019). If sprays are 100% efficient at killing the existing larvae, then a sufficient number of sprays to cover the entire life cycle will eliminate the population, if there is no immigration from outside the control area. If sprays are less than 100% efficient at killing larvae, which will usually be the case, then additional sprays will be required to bring the population down to a level suitable for the initiation of the SIT.

According to Barclay et al. (2019), an insecticide should be selected that will target the stage of longer length (larvae or adults), if that choice is available.

### *2.18. Exclusion of Pests from an Area: Barrier Width*

Barclay et al. (2011) constructed a model that attempts to assess the minimum dimensions of a buffer area (within which control is also imposed) to protect a pest free area of low pest prevalence. Random dispersal would result in insects entering the buffer zone from outside the control area; these insects and their progeny would ultimately disperse across the buffer and enter the area to be protected unless they were killed within a sufficiently wide buffer. Dispersal in this case is modelled by means of diffusion equations, e.g. Okubo 1980, to model a pest population that is diffusing across the barrier and being controlled within the barrier in an effort to protect the inner core area inside. Their model considers a rectangular core area, surrounded by a rectangular buffer zone, and using the SIT as the control agent within the buffer. We are interested here mainly in determining the barrier width.

They assumed that (1) the core area is already a pest free area as a result of previous control efforts; (2) the host density in all areas (the core area, the buffer zone, and outside the buffer zone) is assumed to be at equilibrium; (3) there is a constant influx of pest insects from the region outside the buffer zone; and (4) no transport of the target pest insects by wind, storms, or humans into the core area occurs. As this treatment assumes that the equilibrium has already been achieved, the barrier width calculated is that required to maintain the status quo. Dispersal describes movement of the insects across the buffer zone and will determine the

width of the buffer zone, which results in the density of the invading population approaching zero at the edge of the barrier zone adjacent to the core area.

*2.18.1. Description of the Diffusion Model*

The simplest 2-dimensional diffusion equation is the partial differential equation (Pielou 1969):

$$\partial U(x,y,t) / \partial t = D\,(\partial^2 U(x,y,t) / \partial x^2 + \partial^2 U(x,y,t) / \partial y^2) \qquad (8)$$

(see also Edelstein-Keshet 1988). This equation is a 2-dimensional analogue of an equation that was originally developed to describe the diffusion of heat along a metal rod (Fourier 1822), but has since been used for many other purposes as well, including insect dispersal. The diffusion coefficient, *D*, is defined in units of length squared per unit time, and is usually estimated by tabulating the linear difference between the initial and final positions resulting from insect dispersal, as well as the number of movements in a given time interval, and then computing the means of the squared net distances travelled per unit of time. For a population of insects released simultaneously at a point, equation (8) predicts an expanding Gaussian distribution with variance $4Dt$ at time $t$:

$$U(x,y,t) = (1/(4\pi Dt))\,[\exp\{-((x^2+y^2)/4Dt)\}] \text{ for } t > 0 \qquad (9)$$

Although most insect motion is demonstrably non-random, diffusion equations have been successful at predicting longer-term patterns of insect movement (Kareiva 1983; Turchin 1998) because population-level averaging occurs.

*2.18.2. Width of the Buffer Zone*

The pest population will have a certain density outside the buffer zone, and will disperse from outside into the buffer zone. If control measures are imposed within the buffer zone, the density of the pest will decrease from the outer edge of the buffer to the inner edge. The width of any buffer zone around a core area should be large enough to reduce the density of the pest close to zero in the core area. The buffer zone should be wide enough to prevent a gravid female insect and any of her offspring from crossing the buffer zone. Then an appropriate model is:

$$\partial F(x,t) / \partial t = D\,(\partial^2 F(x,t) / \partial x^2 + \partial^2 F(x,t) / \partial y^2) - g\,F(x,t) \qquad (10)$$

where $g$ is the growth function, $F$ is the female population density, $x$ is a spatial coordinate, and $t$ is time. If $g$ is linear, and births and deaths can be separated and are independent of $x$ and $t$, then:

$$gF = \beta F - \delta F \qquad (11)$$

in which $\beta F$ and $\delta F$ are the instantaneous birth and death rates. Boundary conditions are such that at the outer edge of the buffer zone, $F(0,t) = F_0$, where $F_0$ is the density of insects at the outer edge of the buffer as a result of the influx of insects, and at the inside edge of the buffer, $F(w,t)$ = a small proportion of $F_0$ (e.g. $10^{-6}$), so that almost all the insects have died before reaching the inner side of the buffer. As a result of the continuous nature of the model, we can never actually achieve a zero density, but some small density below the Allee threshold that is non-viable will suffice.

If we are manipulating the death rate within the buffer by attract and kill devices that are evenly spread out to cover the whole of the buffer region, then ($\beta F$ - $\delta F$) will be negative, because now the second term in parenthesis consists of the sum of natural ($\delta$) and imposed ($\mu$) mortality from traps or other control sources. For control by killing, the kill rate ($\mu$) may be combined multiplicatively with the natural mortality ($\delta$) by multiplying survivorships (Barclay 1992b), so that if natural daily mortality is 0.05 and 10% of the population is killed each day, then $\delta + \mu$ becomes 1.0 – (1.0-0.05) (1.0-0.10) = 0.15 – 0.005 = 0.145. The upper limit of total daily mortality is 1.0 and the net change is $\beta$ – 1.0, although this may be impossible to achieve or even approach.

If the SIT is used as the control method, then we are manipulating $\beta$, and it will decrease from its natural value as sterile male releases increase. In this case, ($\beta F$ - $\delta F$) is also negative if control is to be effective. To simplify the solution of the diffusion equation when using the SIT, it will be assumed that the release of sterile males is proportional to the size of the wild insect population at all points within the buffer. The dynamics of this situation has been described by Knipling (1960), Hawkes and Coaker (1977), and Barclay (1981a), among others. Using this simplification, the same development described below will be useful for both killing insects or reducing reproduction. For control by SIT integration, the natural fertility is multiplied by a factor equal to the fertility factor, $\sigma = F / (M + S)$ in the SIT equation. If the sex ratio is 1:1, then the fertility factor is $M / (M + S)$. Thus, if $M$ = 100 and $S$ = 200, and if natural daily fertility is 0.10, then $\beta \sigma$ becomes 0.10 [100 / (100 + 200)] = 0.033. The lower limit of suppression here occurs as $\sigma \rightarrow 0.0$, so the net change is 0.0 - $\delta$, although this also may be impossible. Even with maximal SIT action, the rate of change of population density with distance across the buffer is likely to be slow.

Since we assume that we are dealing with an equilibrium situation, in which the insects have been diffusing and the buffer has been under control for a long time, the time derivative is zero, as nothing is changing over time. Only the space derivative is still non-zero. This yields the equilibrium equation:

$$dF / dx = (\delta - \beta \sigma) F \tag{12}$$

and this has solutions proportional to $e^{-\varphi x}$, where $\varphi^2 = (\delta - \beta \sigma) / D$. Assuming the insect density gradient across the buffer is $F(x) = c\, e^{-\varphi x}$, the boundary conditions dictate that $c = F_0$ and $F_0\, e^{-\varphi w} = 10^{-6}\, F_0$. Taking logarithms, $-\varphi w = \ln(10^{-6}) = -13.8$. This leads to the minimum buffer width ($w$):

$$w = 13.8 / \varphi = 13.8 / [(\delta - \beta \sigma) / D]^{1/2} \tag{13}$$

to reduce the population at the inner edge of the buffer to one millionth of that at the outer edge. If a decrease down to $10^{-6}$ of the original density outside the buffer ($F_0$) is not satisfactory, then some other small fraction can be chosen, e.g. for $10^{-5}$ the 13.8 becomes 11.5, and for $10^{-7}$ the 13.8 becomes 16.1. The units of $w$ in eq. (13) are in the units of $D$, and the units of $\beta$ and $\delta$ must be the same as those of $D$.

For the case of killing insects, (13) becomes:

$$w = 13.8 / [(\delta + \mu) - \delta \mu - \beta) / D]^{1/2} \quad (14)$$

It is clear that, for control by SIT integration, the value of $\sigma$ must be less than $\delta/\beta$ to cause a reduction in the population. Thus, $\sigma < \delta/\beta$ implies that $M/(M+S) < \delta/\beta$, and this implies that $S > M\,(\delta/\beta - 1)$. Graphs of $w$ vs. $\mu$ and $w$ vs. $\sigma$ are shown in Fig. 11 for two values of the diffusion coefficient, two values of $\delta - \beta$, and one value of acceptable density on the inner edge of the buffer, $10^{-6}$.

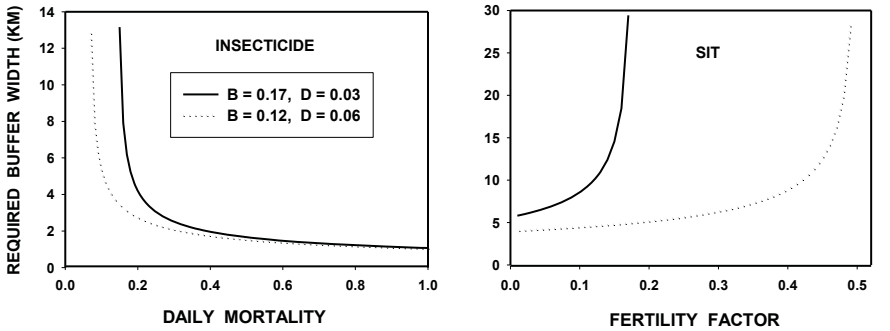

*Figure 11. Estimates of required buffer widths to reduce the population density at the inner edge of the buffer to $10^{-6}$ of that at the outer edge. The curves show buffer width as a function of daily mortality (left panel) or fertility factor using SIT application (right panel) for daily death and birth rates that might be appropriate to the Mediterranean fruit fly. The legend values apply to both panels.*

Control by the SIT and by insecticidal traps are not commensurate, as they use different mechanisms, but they can be compared by forming an equivalence in which the value of $w$ using the SIT equals the value of $w$ using traps. Equating (13) and (14) we obtain: $13.8 / [(\delta - \beta\,\sigma) / D]^{1/2} = 13.8 / [(\delta + \mu) - \delta\,\mu - \beta) / D]^{1/2}$, which simplifies to

$$\sigma = [\beta - \mu\,(1 - \delta)] / \beta \quad (15)$$

The parameter $\sigma$ is the fertility factor, $M / (M + S)$, so that to achieve a buffer width equal to that using a daily trapping rate of $\mu$, an overflooding ratio of $S / M = (1- \sigma) / \sigma$ needs to be maintained. Note that, in a continuously reproducing population, the overflooding ratio is not necessarily the release ratio (section 2.12.3.). The release ratio (number of sterile males released each time period divided

by the total number of wild males present) is related to the overflooding ratio as follows. If the daily mortality of the wild males is $q$ and that of sterile males is $r$, and if the daily recruitment rate of wild males is $m$, and the daily release rate of sterile males is $n$, and if the survivorship curves of both are exponential (geometric if measured by days), and if the lifetimes of both are unlimited, then the total number of wild males in the population at equilibrium is obtained from an infinite geometric series, $M = m/(1-q)$, and the total number of sterile males is $S = n/(1-n)$, so that the overflooding ratio is $[n/(1-r)] / [m/(1-q)] = (n/m) [(1-q)/(1-r)]$. If the daily survivorships of wild and sterile males are equal, then this reduces to an overflooding ratio of $n / m$, i.e. the quotient of the recruitments, which will also be the quotient of the wild and sterile male population sizes at equilibrium.

If neither traps nor the SIT yield reasonable buffer widths, it is possible to use both traps and the SIT in combination and further reduce the buffer width. It is true that the traps are likely to attract sterile males as well as fertile males, but if sterile and fertile males are equally attracted to the traps, the overflooding ratio will not change, but the wild population will be reduced by both control methods. In that case, the buffer width is:

$$w = 13.8 / [(\delta + \mu) - \delta \mu - \beta \sigma) / D]^{1/2} \quad (16)$$

and this is finite and positive only if $\delta + \mu - \delta \mu > \beta \sigma$, i.e. if mortality is greater than fertility.

Gordillo (2014) extended this approach to include optimization of sterile releases on the basis of the cost of sterile males for a density-dependent population, and including the possibility of variable sterile-male release rates. He used a one-dimensional diffusion equation and a numerical process called "simulated annealing", and concluded that in some cases sterile release rates should be uniformly high near the high-pest-density boundary of the buffer, and then drop sharply to much lower levels towards the core area to be protected.

### *2.18.3. Case Study: Mediterranean Fruit Fly*

Carey (1989) gave the following daily values for *C. capitata*: $\beta = 0.17$ and $\delta = 0.03$, and $r = 0.14$. The diffusion coefficient, $D$, has been estimated by Plant and Cunningham (1991) to be $D = 0.006$ km$^2$/day. It is clear that, if the kill rate or reduction in fertility is less than 0.14 per day, then the number of new daily recruits is still greater than the natural death rate. If the daily kill rate, $\mu$, is 0.20, then using eq. (14), the minimum buffer width is $w = 13.8 / \sqrt{[(0.23 - 0.17) / 0.006)]} = 4.36$ km.

If the SIT is the control method, and if the overflooding ratio is 10:1, then $\sigma = 0.091$, so the minimum buffer width is $w = 13.8 / \sqrt{[(0.03 - 0.17\ (0.09)) / 0.006]} = 8.87$ km. If both insecticidal traps and the SIT are used, then the buffer width is: $w = 13.8 / \sqrt{[(0.23 - 0.17(0.091)) / 0.006]} = 2.31$ km. This compares with the use of traps only, at twice the kill rate (0.40), which yields a buffer width of 2.10 km, or the use of the SIT at twice the overflooding ratio ($\sigma = 0.045$), which yields a buffer width of 7.29 km. Since it appears unlikely that traps can catch 40% of the insects daily, the combination of the SIT and trapping appears potentially to be useful.

Recent studies of Mediterranean fruit fly dispersal suggest that a 2-km buffer zone is a reasonable first guess of the buffer width. Meats and Smallridge (2007) found that 90% of released flies remained within 0.4 – 0.7 km of the release point. It has been shown in Guatemala that most adult flies disperse short distances of only a few hundred metres, although some can disperse on winds up to 51 km from the release point (Villatoro 2014; Enkerlin et al. 2016), and it may be possible for flies to spread considerable distances when the food resource is depleted. Thus, a 2-km buffer might be useful if the aim of control was simply to yield a low-level pest infestation in a low-level horticultural production area. However, a much wider buffer will likely be more realistic, especially if the aim is complete exclusion of the pest from a protected area. In addition, the diffusion model used here assumes random movement, and many insects move quite non-randomly under conditions of stress or lack of food. We stress that the parameter values we have used are used for illustrative purposes only; any real control programme should use data obtained from the control area as well as any information on long-distance movement.

For the Mediterranean fruit fly example above, it would seem that control must be quite high to achieve a reasonable buffer width. This implies that a combination of synergistic controls would probably be advisable. A mitigating factor in these estimates of barrier width is that the formulas were developed assuming that the overflooding ratio would be constant across the barrier, rather than the sterile release rate being constant as the wild population decreases toward the inner edge of the barrier. This assumption would have the effect of increasing the estimate of the required barrier width. As the model appears to be intractable with a constant sterile release rate across the barrier width, a more reasonable approach might be to calculate $S$ using the population density at the uncontrolled edge of the barrier and to use that value throughout the barrier; this would reduce the required barrier width.

### *2.19. Optimization of Programme Releasing Sterile Insects*

Optimization inevitably involves economics (Mumford, this volume). Although that is somewhat outside the scope of this chapter, a beginning has been made on this topic. Geier (1969) used demographic models incorporating density-dependence to analyse the efficiency of programmes that release sterile insects, and to derive optimal strategies for control. Barclay and Li (1991) used a general treatment of combinations of pest control to determine optimal proportions of each control method. Atzeni et al. (1992) examined the situation for the Old World screwworm *Chrysomya bezzania* (Villeneuve), and included buffer width, male competitiveness, and population aggregation in their analysis. Anaman et al. (1994) performed a benefit/cost analysis with *C. bezzania,* and incorporated beef losses into the equation. Gordillo (2014) addressed the optimization question for sterile releases in a buffer zone that protects an insect-free area, and Ramirez and Gordillo (2016) used benefit/cost analysis to optimize sterile releases for insects that are long-lived but have short reproductive periods, such as some beetles.

### *2.20. Development of Resistance*

There has been a marked tendency for insects to develop resistance to insecticides or other control methods. It is conceivable that a wild pest population could develop resistance to the use of sterile releases as a means of control (Itô et al., this volume; Lance and McInnis, this volume; Hendrichs and Robinson, this volume; Whitten and Mahon, this volume). This resistance might involve behavioural mechanisms that would preclude the sterile-fertile matings (Barclay 1990). Selection for resistance to several pest control methods operating together has been modelled by Barclay (1996), and it appears that selection for resistance to a particular control method is a linear function of the amount of mortality being inflicted by that control method, and the degree of isolation of the targeted population.

## 3. PARAMETER ESTIMATION FOR THE MODELS

Knowledge of several parameters is crucial to the success of any programme that releases sterile insects. With reference to the models outlined above, the basic parameters that will always be of interest are: $F$, the population size; $\lambda$, the potential rate of population increase each generation; $q_m$ and $q_f$, the proportions of the released males and females that remain fertile; and $c$, the competitive ability of sterile males relative to the wild fertile male population. Some of the estimations can be done using standard population biology methods. The population size can be crudely estimated from trap catches. Hargrove (1990) used mark-recapture techniques to estimate the size of tsetse fly populations (Weidhaas 1973; Itô et al., this volume). The rate of increase, $\lambda$, would normally be determined using oviposition rates. The residual fertilities, $q_m$ and $q_f$, could be determined by caging sterile males with fertile females, and fertile males with sterile females, either in groups or pairs, and noting the resulting fertile egg production. Competitive ability of sterile males, $c$, could then be determined from the laboratory, but preferably from field cage or small-scale field experiments, where immigration could be assumed to be negligible, using the equation involving competitive ability, and then solving for $c$. The information on $\lambda$, $q_m$ and $q_f$ must be determined first, or the equation becomes confounded. Alternatively, Meats (1998) used release and recapture techniques to estimate the quality of released sterile insects. Immigration into the control area could then be determined using either mark-recapture or the equation involving immigration and solving for $v$. Plant and Cunningham (1991) detailed procedures for estimating the dispersal of Mediterranean fruit flies, and estimates of immigration could be obtained from considerations of dispersal.

The determination of density-dependence is problematic; there are many models of density-dependence, and none of them is particularly mechanistic. Thus rates of oviposition and subsequent survivorship would have to be monitored at various densities to derive a function to describe the depressing effects at various levels. In many wild populations, even just detecting the existence of density-dependence is difficult, much less the quantification of depressing effects. However, in view of the potential assistance to the SIT, an estimation of the effects of density-dependence is

worthwhile. Itô et al. (this volume) develop further the subject of parameter estimation.

## 4. ASSESSMENT OF SIT MODELLING

### *4.1. Uses of Models*

Models can be used to predict and explain the behaviour of a population. This information guides research, generates hypotheses, and aids teaching. Most models of the SIT have so far have been aimed mainly at predicting the behaviour of pest populations under various constraints, such as incomplete sterility, lack of competitive ability of sterile males, the immigration of wild insects into a control area, etc. One of the best uses of models is to generate ideas or hypotheses that are capable of experimental testing. Thus, ideally, modelling should go hand-in-hand with field and laboratory experiments to verify or falsify a model's predictions.

There have been a number of computer simulations of the SIT for the purpose of instruction in both the technique and in insect population dynamics generally. At least two have been documented and are available to the public. Both represent various elaborations on the original model of Knipling.

Sawyer et al. (1987) described a simulation that includes spatial heterogeneity, aggregation, immigration, random effects, and reduced sterile male competitiveness. This model was adapted by Flanders and Arneson (2018) under the name "*Curaçao*", and is available for downloading. The user can specify the various parameters and options, and then compare runs to draw conclusions.

Potgieter et al. (2013, 2016) aimed their models at a particular lepidopteran insect, and incorporated some of the features described above. Such models are valuable in any SIT programme against a particular insect.

### *4.2. Advantages and Limitations of Modelling*

The models of the SIT constructed thus far fall generally into three groups: (1) models that investigate processes that determine the proportion of eggs laid that are sterile, (2) models involving population dynamics and other population level phenomena, and (3) models that investigate the interactions of the SIT with other control methods, although it might be argued that the last two really belong together. The first category, including residual sterility, reduced sterile competitive ability, mating patterns, and immigration, is of crucial importance in planning and executing a programme that releases sterile insects. Unless one can accurately predict the level of sterility in eggs produced by the wild females, the programme is liable to fail. In addition, it is here that models are most likely to give realistic answers, as these processes rely mostly on determinable proportions or coefficients, rather than somewhat nebulous population processes.

Models of more general aspects of population dynamics involve many hidden factors, such as the strength of density-dependence, the functional responses of predators, synchrony of pest and predator phenologies, the degree of pest population

aggregation, the extent to which sterile insects assume the same spatial patterns as the wild insects, etc. These are not easy to determine, and the models in the second and third categories must be taken as heuristic, rather than quantitatively predictive. They provide insights into the kinds of responses to expect, but quantitative accuracy must await species-specific simulations based on accurate and detailed biological and ecological information regarding the whole system.

### *4.3. Transient versus Equilibrium Models*

Many analytic models of the SIT are solved for equilibrium, and the results of the parameters on the equilibrium are noted. In real life, populations are almost always changing. Analysis of the equilibrium behaviour certainly has much to say about the effects of the parameters on the transient behaviour as well as on the equilibrium, but a proper analysis should include the effects of the parameters on the dynamics of transient behaviour. The problem is that there is an infinite number of trajectories that any population can follow, and to encapsulate the behaviour of these in digestible form is no small task. One criterion that can be used is that of stability of the system, in its various forms. Stability characteristics can be related to parameter ranges, and certain characteristics of the resulting transient behaviour can be inferred from them.

### *4.4. Future Directions and Information Needs*

The models reviewed in this chapter cover most of the relevant topics in the dynamics of the SIT. However, it is only a good beginning, and there is much left to do. Models that have a more realistic ecological basis will be required to suggest new hypotheses and to give more accurate predictions of behaviour. One area still largely untapped is metapopulation models — models including patches with migration among patches, local extinctions and re-establishments. A start has been made with the models including immigration, heterogeneity, and diffusion (Lewis and van den Driessche 1993; Gordillo 2015a). The next step is to tie these together into a meaningful whole.

Another area that will yield useful information is the construction of species-specific models for the SIT, including all relevant factors. Many species-specific models have been constructed, but many appear to have inadequate detailed ecological information. In addition, the area of behavioural ecology will probably emerge as being especially relevant.

Testing models, experimentally and in the field, is in its infancy. Information is needed on the effects of pest density-dependent regulation on the efficiency of the SIT, the effects of predators and parasitoids on the dynamics of the SIT, and the effects of ecosystem resilience. The simultaneous use of other control methods with the SIT is still largely hypothetical, and this potentially useful area needs considerable investigation.

## SUMMARY

Important principles of population and behavioural ecology in relation to the application of the sterile insect technique (SIT) for the control of a pest are explained. These include: (1) a logistic population model for estimation of the population fluctuation of target animals and the number of sterile males to be released for successful eradication, (2) mark-recapture estimations of density and mortality rate of the target population, especially for remote areas, where repeated releases and recaptures are difficult, (3) models of dispersal to assess dispersal distance of target animals, and (4) equations for estimating the decrease of sexual competitiveness of mass-reared strains under field conditions. The method to estimate dispersal distance curves when attraction areas of traps are overlapping, and changes in mate-choice of wild females resulting from inadvertent selection when the SIT is applied, are explained. The necessity of field estimation of sexual competitiveness of released sterile males is also emphasized.

## 1. INTRODUCTION

In one of three seminal papers (Baumhover et al. 1955; Knipling 1955; Lindquist 1955) reporting the first success of the sterile insect technique (SIT) to eradicate insect pests, Knipling presented a table showing an example of model simulation for explaining the effect of sterile male releases. The model is

$$N_{g+1} = N_g RQ$$

where $N_g$ and $N_{g+1}$ are numbers of females at the $g$th and $(g+1)$th generation, and $R$ and $Q$ are rates of change in the population size per generation and the proportion of normal females (females which can lay hatchable eggs), respectively. This early model shows that population ecology theory and models have been an integral part of the SIT from the outset (Barclay, this volume; Barclay et al., this volume).

The early success in eradicating the New World screwworm *Cochliomyia hominivorax* (Coquerel), in the area-wide integrated pest management (AW-IPM) programme in Florida in 1959, was not always replicated in subsequent AW-IPM programmes integrating the SIT (Krafsur 1998; Liebhold et al. 2016). In many cases this was because government officials thought about the SIT as an established technique consisting only of releasing sterile insects, with animal and plant health workers engaged in programmes releasing sterile insects without basic ecological and behavioural studies. Some early programmes did not include first estimating the number of wild females, simulating the process based on a population model incorporating the SIT, and evaluating in the field the mating competitiveness of the released sterile males. Thus, in some of those cases, many sterile males were released but eradication failed, and it was not possible to know the major reason for failure, in

spite of overflooding the wild population with sterile males, e.g. ratios of the number of sterile to wild males were 112:1 in a Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) programme in Nicaragua (Rhode et al. 1971), and 311:1 in another *C. capitata* programme in Procida Island (Cirio and de Murtas 1974). Without a full understanding of the population and behavioural ecology, the planning, implementation, and evaluation of programmes that release sterile insects become very difficult (FAO/IAEA 2016; Barclay, this volume; Barclay et al., this volume; Vreysen, this volume).

The goal of this chapter is to describe basic theory, models, and some mathematical techniques from population and behavioural ecology that are helpful for planning and executing the SIT component of an AW-SIT programme aimed at the control of pest insects – suppression, containment, prevention or eradication (Hendrichs, Vreysen et al., this volume).

## 2. THEORETICAL POPULATION DYNAMICS

### *2.1. Logistic Model*

The most basic model of population increase is the Hale-Malthus model:

$$dN_t/dt = rN_t \tag{1}$$

or, integrating equation 1,

$$N_t = N_0 e^{rt} \tag{2}$$

where $N_t$, $N_0$, $r$ and $e$ are number of individuals at time $t$, number at the beginning of increase, intrinsic rate of increase, and the base of natural logarithms (= 2.71828...), respectively. If population increase with discrete generations, as seen in many insects, is considered, equation 1 can be written as

$$N_{g+1} = N_g R \tag{3}$$

or

$$N_g = N_0 R^g \tag{4}$$

the equation used by Knipling (1955), where $\ln R = r$ (Begon and Mortimer 1981).

In equations 1 and 3, the population size increases indefinitely, but the large $N_t$ or $N_g$ may result in a smaller rate of increase, due to density-dependency, and the population may reach an upper limit. The most widely used model of density-dependent population increase is the logistic model,

$$dN_t/dt = N_t(r - hN_t) \tag{5}$$

where $h$ is the suppressive effect of existence of an individual on the intrinsic rate of increase. Here $r/h$ is the upper limit of increase, and writing $r/h = K$,

$$\frac{dN_t}{dt} = rN_t\frac{K - N_t}{K} \tag{6}$$

or by integration,

$$N_t = \frac{K}{1 + e^{a-rt}} \tag{7}$$

where $a$ is a constant.

To establish a population model of the melon fly *Zeugodacus* (formerly *Bactrocera*) *cucurbitae* (Coquillett) under control by the SIT, Itô (1977) used a discrete expression of equation 7 to calculate generation-based increase of a logistic population (Fujita and Utida 1953). We have the following relation from equation 7 of $g$ generation: $e^{a-rg} = (K/N_g) - 1$. By substituting this relation for equation 7 of ($g$ + 1) generation, we obtain

$$R_g = N_{g+1}\Big/N_g = \frac{K}{1 + e^{a-rg}e^{-r}}\Big/N_g = e^r\Big/(1 + N_gB) \tag{8}$$

where $B = (e^r - 1)/K$. In place of Itô's procedure, we can use a logistic difference model, such as

$$N_{g+1} = \frac{N_gR}{(1 + cN_g)^b} \tag{9}$$

where $b$ and $c$ are constants (Hassell 1975; Begon et al. 1996), in place of equation 4 for constant increase. Fig. 1 shows examples of Hale-Malthusian (dashed) and logistic increase of density ($N_g$).

### *2.2. Dynamics of Populations under Control by the SIT*

In equations 8 or 9, the population size of the next generation can be expressed as

$$N_{g+1} = N_gR_g \tag{10}$$

and when the SIT is applied

$$N_{g+1} = N_g R_g H_g \tag{11}$$

where $H_g$ is the proportion of fertile (hatchable) eggs, and this value indicates the suppressive effect of sterile males on population increase. Thus, $H_g$ is considered to be a function of the ratio of the number of sterile males, $N_s$, to fertile (normal) males, $N_f$, in the field, that is,

$$H_g = f(N_{s(g)}/N_{f(g)}) \tag{12}$$

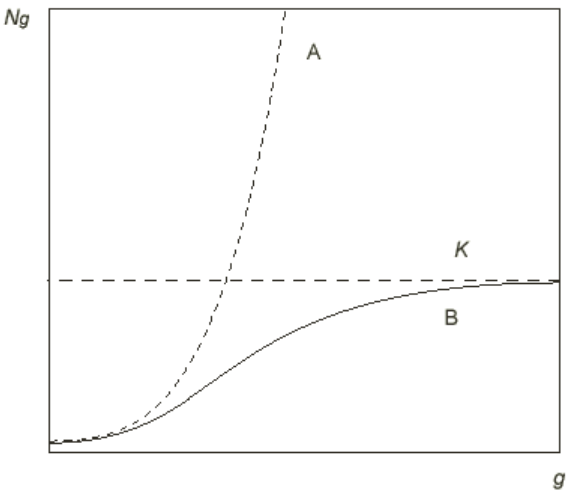

*Figure 1. Exponential (A) and sigmoidal (B) increase in the population. The equation giving a sigmoidal increase is the logistic model.*

If the number of sterile males released in each generation is the same,

$$H_g = f(N_s/N_{f(g)}) \tag{12'}$$

how can $f$ be determined? To establish a model of the SIT process for the melon fly on Kume Island, Okinawa, Itô (1977) adopted a Poisson distribution (mean number of matings = 1.61) for the frequency of matings per wild female. The probability that a female would mate with normal and/or sterile males was approximated by the binomial distribution. Based on this Poisson-binomial model, a curve showing the relationship between the expected hatchability of eggs and the $N_s/N_f$ ratio was obtained (Fig. 2). The $H_g$ values read from this graph are incorporated into equation 11 where $R_g$ is derived from equation 8.

For the melon fly on Kume Island, Itô used the following values: $N_0$ = 125 000, $K$ = 2 700 000, $r$ = 1.2 (3.3 times increase per generation when $N_0$ is near 0), and $a$ = 3.971. $R_g$ changes in response to $N_g$, but based on the observed tendency that the number of melon flies decreases twice per year, in summer and winter in almost every year, Itô used the following $R$ values for 4 months (assuming 12 generations per year): $R_4 = R_5 = 0.5$, $R_{10} = 0.2$ and $R_{11} = 0.238$. By these decreases the population returned to the minimum density (125 000). Calculation of $N_g$ for the untreated period (before the SIT) gave a series of bimodal curves in which 125 000 and 2 621 568 were the annual minima and maxima, respectively (curve A of Fig. 3). $H_g$ values estimated from Fig. 2, using $N_g$ ($N_{f(g)}$ in equation 12) and a constant $N_s$, were used for simulation of the SIT process.

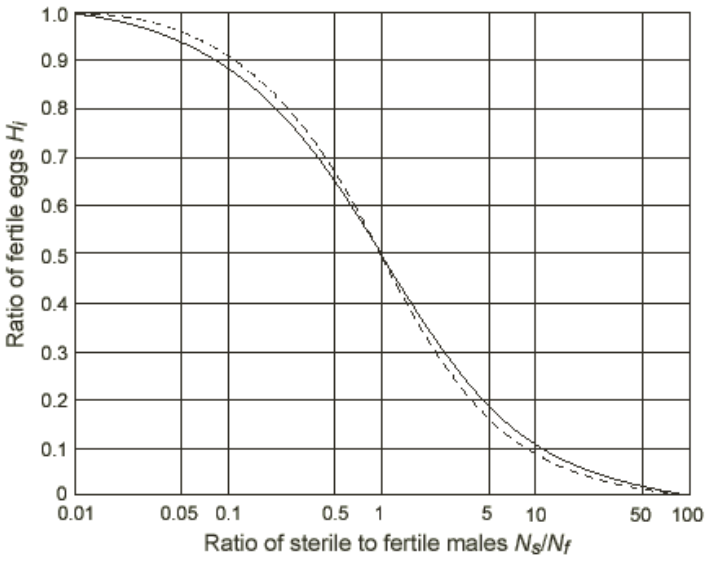

*Figure 2. Relationship between the ratio of sterile to fertile males, and the ratio of fertile to sterile eggs, in a Poisson-binomial model (solid line). The broken line depicts the relationship when the insects mate only once. (Figure from Itô 1977, reproduced with permission.)*

Curves B, C, and D of Fig. 3 are the results of simulation (initial ratios of sterile to normal males are shown in the legend). Fig. 3 indicates that, although eradication was not possible when the ratio of the number of sterile males released per month was one half of the minimum density of wild males ($N_0$ = 125 000 and $N_s$ = 62 500), eradication can be attained only during 2 years when the number of released males is the same as the minimum density (curve C). Note that the ratio of sterile males to wild ones is less than unity when a decrease of wild insects has occurred.

Itô's published result was unexpected since it shows that if the sexual competitiveness (hereafter mating competitiveness + sperm competitiveness) of

released sterile males is the same as that of wild males, the release of much smaller numbers of sterile males than previously anticipated (e.g. 10/1 in Knipling 1955) can lead to success in an eradication programme. In the same year, using a similar logistic model for mosquito populations, Haile and Weidhaas (1977) obtained a similar result.

Once the curve of $H_g$ against $N_s/N_f$ is obtained, this curve can be used to estimate the sexual competitiveness of sterile males under field conditions. If the ratio of fertile eggs known from observation of eggs laid by wild females from the target population fell within the area above the curve in Fig. 2, this can be due to a reduction of sexual competitiveness of the released males.

The required ratio of sterile to wild males is a function of $r$ or $R$. Itô and Kawamoto (1979) attempted to simulate the population processes based on Itô's model by substituting different values of $r$. Their results show that a ratio of 10 sterile males to 1 wild male could result in the eradication of the target species within only 12 generations even when the rate of increase per generation, $R$, was 20 ($r = 3$).

These results show that the quality (sexual competitiveness) of mass-reared and sterilized males is much more important than the overflooding ratio.

Barclay and Mackauer (1980), Barclay (1982), and Itô et al. (1989) provided detailed explanations of differential equation models of the SIT.

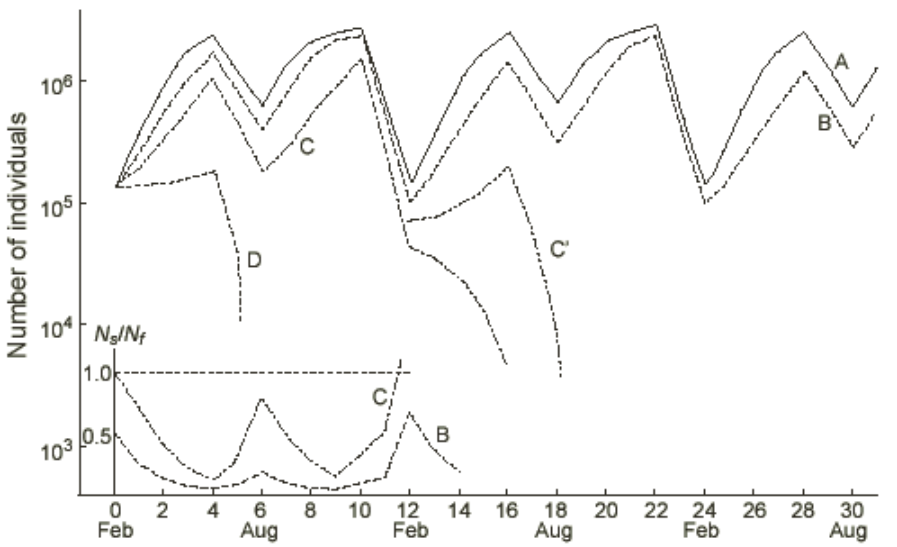

*Figure 3. Fluctuations in the number of flies in the model population without the SIT (A) and populations with the SIT. The initial ratios of sterile to normal males are 0.5/1 (number of sterile males = 62 500) in B, 1/1 (number of sterile males = 125 000) in C, and 2/1 (number of sterile males = 250 000) in D, respectively. C' is the trend when winter mortality was halved in treatment C. Seasonal trends in the ratio of sterile to fertile (wild) males ($N_s/N_f$) are shown in the lower section of the figure. (Figure from Itô 1977, reproduced with permission.)*

### 2.2. *Spatial Considerations*

The above description of population dynamics does not consider the effect of spatial differences on population dynamics under the SIT. For programs in locations such as Kume Island, with an area of around 60 km$^2$, this is entirely appropriate and effective. However, in many continental settings, or in contexts where there is a "pest free" area with a surrounding area where the pest is established, further development is helpful.

Hendrichs, Vreysen et al. (this volume) gave a useful starting point, defining a rectangular core area where the goal is to reduce or eliminate the pest. Surrounding this core on all sides is a larger buffer zone, where the aim is to kill target species transiting toward the core area. One important question is how wide this buffer zone must be to give a reasonable certainty that the targeted pest is not able to enter the core area. Barclay et al. (2011) worked thorough an example of how to apply this model, summarized below. A simple model for the population in the buffer zone has the density of the pest increasing closer to the outer edge. If the population in the buffer has births ($\beta$) and deaths ($\delta$), and movement is modelled via simple diffusion (described in detail in section 4.1.) controlled by the diffusion coefficient $D$, then

$$\frac{dF(x,t)}{dt} = D\nabla^2 F(x,t) + \beta F(x,t) - \delta F(x,t) \tag{13}$$

Setting boundary conditions such that at the outside of the buffer area, $F(0,t) = F_0$, the density of insects is highest due to entry into the buffer of pests from the outer area, and at the inside edge of the buffer, $F(w,t)$, the density is a small proportion of $F_0$, e.g. $10^{-6}$. In this situation, almost all insects entering the buffer zone die before reaching the core area.

If either the survivorship or reproductive viability of insects in the buffer area are equal to the birth/entry rate, such that $\beta F - \delta F = 0$, then we have a simplified steady-state situation where only the space derivative is non-zero

$$D\nabla^2 F = (\delta - \beta)F \tag{14}$$

which has solutions proportional to $e^{[-(\delta-\beta)/D]x}$. Again, assuming the boundary conditions above (outer edge = $F_0$; $F_0 e^{[-(\delta-\beta)/D]x} = 10^{-6}$) taking logarithms, $\ln(10^{-6})=13.8$, and so the buffer width ($w$) is

$$w = \frac{13.8}{[(\delta-\beta)/D]^{1/2}} \tag{15}$$

Note that units need to be consistent: if $\beta$ and $\delta$ are in time units per week, then the diffusion coefficient $D$ also must be per week.

For the case of control in the buffer zone via the SIT with a release rate proportional to the ambient population, then $\delta$ can include both natural mortality and sterility from mating with a sterile male; the model is identical to the one above (Barclay, this volume).

Two other important spatial considerations are aggregation or "clumping", and

whether the sterile insects distribute themselves similarly to the target pest. If the target is not randomly distributed, but the sterile insects generally are, then release rates might have to be increased to achieve control (FAO/IAEA 2016). A common way to assess clumping is to calculate the Coefficient of Dispersion (CD) (Southwood 1978) from the counts of insects found across samples (e.g. traps or fruit). CD is the ratio of the sample variance over the sample mean. A CD value of 1 (variance and mean are identical) suggests a random distribution in space; the sample is consistent with a Poisson distribution. A value above 1 suggests clumping or aggregation, while a value below 1 indicates a uniform distribution.

In practice, the CD statistic is less useful (has less power) if the population is sparse. An alternative is to use the negative binomial distribution. To assess clumping Barclay (1992) applied this approach (in the negative binomial distribution the parameter $k$ with values approaching zero indicate increasing aggregation, while higher values indicate random distributions). He found that, for $k = 0.25$, about four times the release rate would be needed for the same effectiveness when compared with a uniformly distributed target population (Barclay, this volume). A related practical example with field data is given in Shiga (1986).

In at least two recent studies, where the distribution of wild and released sterile insects have been examined, the two were found to be similar (Vreysen et al. 2011; Gavriel et al. 2012). Despite this, spatial aggregation remains an important factor to be considered when determining parameters for application of the SIT. It should be assessed for each target population and location, especially in determining required release rates.

## 3. ESTIMATION OF POPULATION DENSITY AND MORTALITY BY MARK-RECAPTURE

The previous section indicated that the number of sterile males to be released must be the same as, or more than, the minimum number of males in the target locality. Thus the density of target populations must be estimated to determine the appropriate number of sterile males for release. Since direct counting is not applicable to adults that move freely, mark-and-recapture methods are the only way to estimate the population size of many species that are targets of the SIT. In this section, equations of mark-and-recapture methods are briefly explained. Krebs (1989) provided a detailed explanation of equations and ways of using them. Another comprehensive source on mark-recapture calculations is Service (1993).

### *3.1. Petersen Method*

The Petersen method (also called the Lincoln Index) is the simplest way to use the mark-recapture method because it is based on a single episode of releasing marked animals and a second single episode of recapturing individuals. The equation is

$$\hat{N}_P = M_1 n_2 / m_2 \tag{16}$$

where $\hat{N}_P$, $M_1$, $n_2$ and $m_2$ are the estimated total population, the number of individuals marked and released on the first day (day 1), the number of individuals caught on day 2, and the number of marked individuals recaptured on day 2, respectively. Variance of $\hat{N}_P$ can be estimated by

$$V(\hat{N}_P) = \frac{M_1(M_1 - m_2)n_2(n_2 - m_2)}{m_2^3} \tag{17}$$

In a release experiment to estimate population size for the SIT, usually laboratory-reared insects are released. This is especially necessary at the final stage of the SIT, because at this stage the number of wild males is small. The estimation of the number of wild individuals (unmarked individuals) is of greater interest than the total number of individuals. An estimate of the number of wild individuals, which is denoted by $\hat{U}_P$, can be obtained by

$$\hat{U}_P = M_1 u_2 / m_2 \tag{18}$$

where $u_2 = n_2 - m_2$. The variance is given by

$$V(\hat{U}_P) = \frac{\hat{U}_P(\hat{U}_P - u_2)(u_2 + m_2)}{u_2 m_2} \tag{19}$$

The following five assumptions are used for the Petersen method: (1) the population is closed, so the total number is constant, (2) all animals have the same chance of getting caught in the first sample, (3) marking individuals does not affect their catchability, (4) animals do not lose their marking(s) between the two sampling periods (Box 1), and (5) all marked individuals are reported on discovery in the second sample. Even when these assumptions hold, the Petersen method tends to overestimate the actual population, especially in small samples. For small samples (e.g. $m_2 < 10$), using the following two modified equations is recommended (for equations for variance, see Southwood 1978 and Itô and Murai 1978):

A: $$\hat{N}_{P'} = \left[ \frac{(M_1 + 1)(n_2 + 1)}{m_2 + 1} \right] - 1 \tag{20}$$

B: $$\hat{N}_{P''} = \frac{M_1(n_2 + 1)}{m_2 + 1} \tag{21}$$

If estimated $N_P$ is very large as compared with $M_1$ and $n_2$ (e.g. $N_P > 10M_1$ or $10n_2$), equation 21 is recommended, but if $N_P$ is relatively small and/or $n_2$ animals are killed during sampling (e.g. by trapping), equation 20 is recommended (Itô and Murai 1978; Southwood 1978).

*Box 1. Method to Estimate Loss of Marking(s)*

The fourth assumption in the Petersen method, that animals do not lose marking, is a prerequisite for every model of mark-recapture estimation. Seber (1982) described a method to estimate the loss of marking.

Mark all the $n_1$ individuals in the first sample (or all the laboratory-reared animals released on day 1) in two ways, *A* and *B* (by two colours or two points on the body). Then

$\pi_x$ = Probability that a marking of type *x* is lost by the time of the second sample (*x* = *A*, *B*),

$\pi_{AB}$ = Probability that both markings are lost,

$m_x$ = Number of marked animals caught on day 2, with mark *x* only,

$m_{AB}$ = Number of marked animals on day 2 with both marks, and

$m_2'$ = True number of recaptures on day 2 ( $m_2' + u_2 = n_2$).

Then the maximum likelihood estimates of $m_2'$, $\pi_A$ and $\pi_B$ are:

$$\pi_A = m_B/(m_B + m_{AB}),$$
$$\pi_B = m_A/(m_A + m_{AB}) \text{ and}$$
$$m_2' = (m_A + m_{AB})(m_B + m_{AB})/m_{AB}$$
$$= c(m_A + m_B + m_{AB})$$

This means that the observed recapture ($m_A + m_B + m_{AB} = m_2$) must be corrected by a factor $c\,[= 1/(1-\pi_A)(1-\pi_B)\,]$ to give an estimate of the actual number of recaptures $m_2'$.

For large samples,

$$\hat{N}' = n_1 n_2 / m_2'$$

and, if laboratory-reared animals are released,

$$\hat{N}' = n_1 u_2 / m_2'$$

with

$$\hat{V} = \frac{N^3}{n_1 n_2}\pi_A \pi_B \left[\frac{1}{(1-\pi_A)(1-\pi_B)}\right]$$
$$+ \frac{N^3}{n_1 n_2}\left[1 + \frac{2N}{n_1 n_2} + 6\left(\frac{N}{n_1 n_2}\right)^2\right]$$

When $n_1 = 500$, $n_2 = 149$, $m_{AB} = 7$, $m_A = 1$ and $m_B = 2$,

$\pi_A = 2/(2 + 7) = 0.222$, $\pi_B = 1/(1 + 7) = 0.125$

$m_2' = [(1+7) \times (2 + 7)]/7 = 10.286$

As $m_A + m_B + m_{AB} = 10$, $m_2' - m_2 < 1$, suggesting that the rate of loss of marking is negligibly small. Here

$\hat{N}' = (500 \times 149)/10 = 7450$ and

$\hat{V} = 6869641$, and s. d. = 2621

The assumption of a closed population is usually not satisfied. For long-lived animals, mark and recapture during a short period may permit neglecting mortality, but the longevity of adult insects is often relatively short. However, Itô (1976) showed that the Petersen method gives the true population density on day 1 (before death) if only mortality exists, and gives the density on day 2 (after recruitment) if only recruitment exists. If both exist, the true density on day 1 is $N_P/(1 + B)$ or $N_P/(1 + B/S)$, where $S$ and $B$ are rates of survival and recruitment, respectively (Table 1). If there is no recruitment, the Petersen method gives a good estimate of density even when mortality and/or emigration exist. For a method to determine the existence of recruitment, see Seber (1982).

*Table 1. Effects of mortality and/or emigration and dilution (emergence and/or immigration) on the Petersen estimates*

| | $N_2$ | $M_2$ | $n_2$ | $m_2$ | $N_P$ |
|---|---|---|---|---|---|
| (1) Mortality/ emigration occurs but no dilution | $SN_1$ | $SM_1$ | $pSN_1$ | $pSM_1$ | $(pSN_1M_1)/(pSM_1) = N_1$ |
| (2) Dilution occurs but no mortality/ emigration | $N_1(1+B)$ | $M_1$ | $pN_1(1+B)$ | $pM_1$ | $[pN_1(1+B)M_1]/pM_1 = N_1(1+B)$ |
| (3) Both mortality/ emigration and dilution occur | $N_1(S+B)$ | $SM_1$ | $pN_1(S+B)$ | $pSM_1$ | $[pN_1(S+B)M_1]/pSM_1 = N_1(1+B/S)$ |
| (4) Same as in (3) but in reverse order | $SN_1(1+B)$ | $SM_1$ | $pSN_1(1+B)$ | $pSM_1$ | $[pSN_1(1+B)M_1]/pSM_1 = N_1(1+B)$ |

$N_2$, $M_2$, $n_2$ and $m_2$ are the numbers of individuals living in the target area, those marked and released, individuals caught on day 2, and recaptured on day 2, respectively.
$N_P$, $S$, $B$ and $p$ are Petersen estimates (of day 1), rates of survival and dilution from day 1 to day 2, and rate of capture, respectively.

### *3.2. Yamamura Method*

Although the Petersen method is the simplest method of estimation, the estimates are subject to large biases because the method ignores the mortality that must exist in the field. Yamamura et al. (1992) proposed a method that includes field mortality, where: (1) individuals reared in the laboratory are marked and released, and (2) traps are used for the recapture census, and all captured individuals are removed from the field population. This method requires one release procedure and two capture censuses.

Thus one more sampling census must be added to the Petersen method. There are four assumptions: (1) the wild population size is constant during the two consecutive sampling censuses (even if many wild individuals are lost by emigration from the

study area or by artificial removal, the wild population size returns to the original level through immigration from the surrounding area), and (2) the proportion of marked individuals that survive and remain in the population between the two successive censuses, i.e. the rate of remaining, is constant. The last two assumptions are the same as (3) and (4) of the Petersen method.

If the marked individuals are released on day 1, and recaptured on day 2 and day 3, then the maximum likelihood estimates of the survival rate, $S_Y$, and the wild population size, $U_Y$, are given by

$$\hat{S}_Y = \frac{u_2 m_3}{m_2 u_3} + \frac{m_2}{M_1} \tag{22}$$

$$\hat{U}_Y = \hat{S}_Y M_1 u_2 / m_2 \tag{23}$$

### *3.3. Jolly-Seber Method*

Most populations are constantly changing in size because birth (emergence for adult populations), death, immigration, and emigration are not always balanced. Although the wild population is assumed to be nearly constant in two successive census periods in the Yamamura method, this is not always the case. The Jolly-Seber method is applicable to such a changing population. Two or more releases are required to apply the Jolly-Seber method. Recapture censuses are also required two or more times, the first recapture being conducted just before the second release. Estimates are obtained by using the following equations (for small samples, see Seber 1982 or Krebs 1989):

$$\hat{M}_i = \left(R_i Z_i / r_i\right) + m_i \qquad (i = 2,3, \ldots, s-2)$$

$$\hat{U}_{J(i)} = \hat{M}_i u_i / m_i \tag{24}$$

$$\hat{N}_{J(i)} = \hat{M}_i n_i / m_i$$

$$\hat{S}_{J(i)} = \hat{M}_{i+1} / (\hat{M}_i - m_i + R_i)$$

$$\hat{B}_{J(i)} = \hat{N}_{J(i+1)} - \hat{S}_{J(i)}(\hat{N}_{J(i)} - n_i + R_i)$$

where

$\hat{M}_i$ = Estimated number of marked individuals living in the area just before the sample *i*.

$\hat{N}_{J(i)}$ = Total number of individuals just before the sampling at time *i*.

$\hat{U}_{J(i)}$ = Number of unmarked individuals just before the sampling at time *i*.

$\hat{S}_{J(i)}$ = Survival rate during *i* and *i*+1.

$\hat{B}_{J(i)}$ = Number of individuals that entered the population during *i* and *i*+1.

$n_i$ = Total number of animals caught in sample $i$ (= $m_i + u_i$).
$m_i$ = Number of marked animals caught in sample $i$.
$u_i$ = Number of unmarked animals caught in sample $i$.
$R_i$ = Total number of animals released after sample $i$.
$r_i$ = Number of the $R_i$ individuals released at sample $i$ and caught again in some later sample.
$Z_i$ = Number of individuals marked *before* sample $i$, not caught in sample $i$, but caught in some sample after time $i$. Let $m_{hj}$ be the number of marked animals caught in sample $j$ last caught in sample $h$ ($1 \le h \le j-1$). Then we obtain

$$Z_i = \sum_{j=i+1}^{s} c_{i-1,j} \qquad \text{where} \qquad c_{i-1,j} = \sum_{h=1}^{i-1} m_{hj}$$

An example calculation is shown in Box 2. The method of calculation for larger samples, and special tables to be used for these, are shown in Seber (1982) using good numerical examples including a method to estimate variances. The variance formula for $\hat{U}_{J(i)}$ is given by Yamamura et al. (1992). Assumption (3) of the Petersen method is especially important for the Jolly-Seber method. Krebs (1989) described many methods to assess whether this assumption is satisfied or not.

### *3.4. Hamada Method (Modified Jackson Positive Method)*

The above-mentioned methods were listed in ascending order of the required amount of work. The Petersen method requires one release and one capture census, the Yamamura method one release and two capture censuses, and the Jolly-Seber method two releases and two capture censuses. The difference in requirements between the Yamamura and the Jolly-Seber methods seems to be very large, since the addition of one more release usually requires more work than that of one more capture census. Since AW-IPM programmes releasing sterile insects are often carried out in remote areas, the addition of a release is especially laborious. Therefore in many cases one release is conducted, accompanied by three or more subsequent capture censuses, resulting in a series of regression estimates (see Jackson (1939) method).

Jackson (1939) presented equations to estimate the density and survival rate in an open population by a single release and multiple recapture censuses (Jackson positive method). As a first step an index $y_i$ is calculated using the following equation:

$$y_i = 10^4 m_i / M_0 n_i \tag{25}$$

where $M_0$ is the number of individuals marked and released on the first day (day 0; here day 0 is used to show the first day in place of day 1 as in the preceding methods, for simplicity of explanation of the regression method), $y_i$ is a standardized number of

marked insects to be recaptured on day *i*, assuming that 100 marked individuals are released on day 0 and 100 individuals are randomly caught on day *i*. Other symbols are the same as in the preceding equations. If total insect density is almost constant, and if marked individuals are returned to the field after being recaptured, by plotting $y_i$ against *i* (Fig. 4) a survivorship curve of marked individuals in the field is obtained.

*Box 2. Jolly-Seber Three-Point Method*

As a special case of the Jolly-Seber method, an example of estimating population parameters based on two releases and two recaptures is shown. Let us consider a typical case of mass-marking experiment in which individuals reared in the laboratory are marked and released. All captured individuals are killed. On day 1, individuals are released with a red mark. On day 2, individuals are released with a blue mark. The following is the result of a release experiment of *Spodoptera litura* (F.) conducted by Wakamura et al. (1992).

| Day | $n_i$ | $R_i$ | $U_i$ | Number of recaptured individuals | |
|---|---|---|---|---|---|
| | | | | Red marked | Blue marked |
| 1 | | 1934 | | | |
| 2 | 409 | 1968 | 26 | 383 | |
| 3 | 633 | | 24 | 181 | 428 |

The Jolly-Seber method yields

$$\hat{M}_2 = R_2 Z_2 / r_2 + m_2 = (1968 \times 181/428) + 383 = 1215$$

$$\hat{S}_{J(1)} = \hat{M}_2 / R_1 = 1215/1934 = 0.63$$

$$\hat{U}_{J(2)} = \hat{M}_2 u_2 / m_2 = 1215 \times 26/383 = 83$$

For the Yamamura method, we obtain

$$\hat{S}_Y = (u_2 m_3)/(m_2 u_3) + m_2 / M_1$$
$$= (26 \times 181)/(383 \times 24) + 383/1934 = 0.71$$

$$\hat{U}_Y = \hat{S}_Y M_1 u_2 / m_2 = 0.71 \times 1934 \times 26/383 = 93$$

For the Petersen method, we obtain

$$\hat{U}_p = M_1 u_2 / m_2 = 1934 \times 26/383 = 131$$

The estimate obtained by the Petersen method is much larger than that obtained by other methods. The Yamamura method generally yields results similar to those of the Jolly-Seber method if marked individuals are sufficiently mixed with wild individuals.

If the survival rate is constant, the survival rate can be estimated using a linear regression:

$$\log y_i = \log y_0 + i \log S \tag{26}$$

where *S* is the survival rate per unit time (as $0 \leq S \leq 1$, $\log S$ is always negative), $y_0$ is a constant representing the expected number of recaptures on the assumption that 100 marked individuals released on day 0 are instantaneously intermingled into the wild population, and that 100 specimens are randomly caught before either mortality or recruitment occurs. Then an estimate of the total number of individuals on day 0 using

$$\hat{N}_{J+} = 10^4 / y_0 \tag{27}$$

is obtained together with the survival rate $S$ from the slope of the regression line.

In the Jackson positive method, recaptured individuals should be returned to the original population. Since, in programmes integrating the SIT, recaptures are made with traps, the survival rate decreases as the number of recaptures increases, resulting in an overestimated $y_0$ (Fig. 4). Thus $N_{J+}$ will be underestimated. Itô (1973) devised a modified equation to reduce some of this bias by using a modified index $y'_i$, such that

$$y'_i = 10^4 m_i / M'_{0(i)} n_i \tag{28}$$

where $$\hat{M}'_{0(i)} = M_0 - \sum_{j=1}^{i-1} m_j$$

then $$\log y'_i = \log y'_0 + i \log S \quad \text{and} \quad \hat{N}_I = 10^4 / y'_0$$

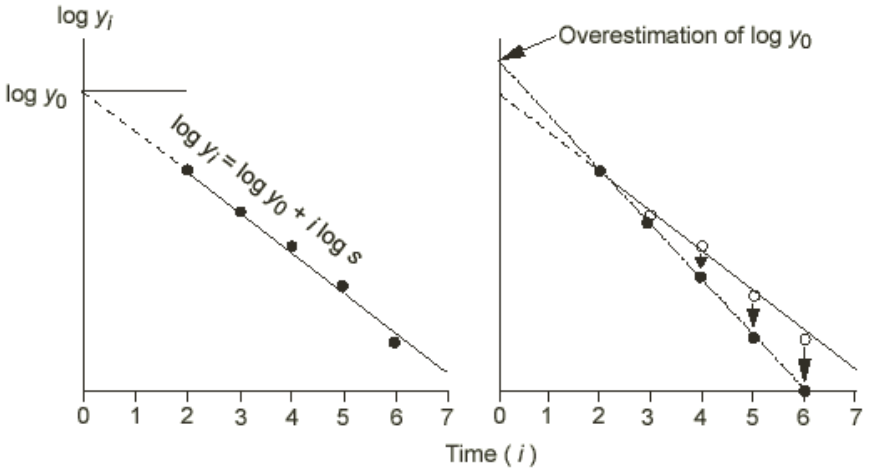

*Figure 4. Comparison of Jackson positive and Itô methods using hypothetical values. Assuming no trapping mortality, change in* $y_i$ *should parallel the survivorship curve of marked insects and, when daily survival rate is constant, the curve of* log $y_i$ *should be linear against* i *(left). However, if there is trapping mortality,* $y_i$ *should have smaller than expected values with time, and the linear regression should yield an overestimated value of* log $y_0$ *(right), which in turn results in an underestimation of* $N_{J+}$. *(Figure adapted from Itô et al. 1989, reproduced with permission from Elsevier.)*

Hamada (1976) found that the Itô method gives an overestimated value when the number of released laboratory-reared marked males is much larger than the wild population size. He showed that a direct estimation of the number of wild males with the following equation gives the least (but not zero) stable negative bias (usually below 20%):

$$z_i = 10^4 m_i / M'_{0(i)} u_i \quad \text{and} \quad \hat{U}_H = 10^4 / z'_0 \tag{29}$$

where $u_i = n_i - m_i$ , and $\log z_i = \log z_0 + i \log \hat{S}$. The Hamada method has been applied widely to estimate the wild melon fly density in Okinawa. The Hamada method is based on a similar assumption as in the Yamamura method — the number of wild individuals is kept constant during the capture period. If the number of recapture censuses is two, the Yamamura method is preferable since it is the maximum likelihood estimate for this situation. Table 2 gives estimated densities and survival rates of male melon flies using the Petersen and Hamada methods, showing the relative stability of the estimated values.

*Table 2. Comparison of estimates of the density of male melon flies with the Petersen and Hamada methods (data from Tanaka et al. 1978)*

| Station | Date of release | $\hat{U}_P$ /ha | $\hat{U}_H$ /ha | $\hat{S}$ /day[1] |
|---|---|---|---|---|
| 1 | June 28 | 136 | 85 | 0.81 |
| | July 12 | 173 | 87 | 0.83 |
| 2 | July 22 | 166 | 109 | 0.74 |
| | August 9 | 251 | 180 | 0.77 |

$\hat{U}_P$ and $\hat{U}_H$ are the numbers of wild males estimated by the Petersen and Hamada methods, respectively. For the Petersen method, the numbers of males caught on the 4th (station 1) and 2nd (station 2) days after release are used as $n_2$ and $m_2$ (equation 16). Numbers of recaptures in the Hamada method are four in station 1, and five in station 2.

[1] Estimated by the Hamada method, using linear regression of $\log z_i$ and $\log \hat{S}$ in equation 26.

### *3.5. Jackson Negative Method*

Jackson (1939) also presented another model (Jackson negative method) to estimate the population size based on multiple-release single-recapture data. Marked individuals are released on several occasions (on days $-i$, $(-i + 1)$,... , $-1$) with different markings, and thereafter a single random catch is made on day 0. Here

$$y_{-i} = 10^4 m_{-i,0} / M_{-i} n_0 \tag{30}$$

where $m_{-i,0}$, the number of individuals released on day $-i$ and recaptured on day 0, is expected to increase with time. If the survival rate of marked individuals is constant, one can estimate $y_0$ by the linear regression of $\log y_{-i}$ on $i$, that is,
$\log y_i = \log y_0 + i \log S$. Then, as in the positive method, $N_{J-}$ is

$$N_{J-} = 10^4/y_0 \tag{31}$$

When laboratory-reared individuals are released, the following equations are applicable:

$$y'_{-i} = 10^4 m_{-i,0} / M_{-i} u_0, \quad \text{and} \quad U_{J-} = 10^4 / y'_0 \tag{32}$$

Reisen et al. (1979) and Koyama et al. (1982) noted that the trapping mortality, which induces a negative bias in the Jackson positive method, does not cause bias in density estimates obtained by the negative method because recapture is made only once for any group of released individuals. This method was used to estimate melon fly density in mountainous parts of Okinawa. Multiple releases of marked flies were made from a helicopter, followed by a single recapture by the many persons who checked traps.

### *3.6. Fisher-Ford Method*

The Fisher-Ford (1947) "trellis" method differs from the approaches described above in that it incorporates an arbitrary number of releases and recaptures (greater than one of each) to obtain an estimate of population size; it also requires an estimate of daily survivorship that is independently derived, and that each released marked cohort of individuals be individually identifiable. However, the requirement of a daily survivorship can be used to set a range on the population size estimate as shown in the worked example below (Box 3).

Fig. 5 shows the results of a mark-recapture study with mosquitoes in Mali, West Africa via a "triangular table" or "trellis diagram", originally introduced by Fisher and Ford (1947). In these tables the dates are arranged horizontally along the top. The total captured on a given date is shown at the end of the cells running to the lower left side of the diagram, while the total number released on that date is given along the lower right. The recaptures are given in the body of the table, with each intersecting cell representing the number of insects marked and released on date $N$ that was recaptured in subsequent dates. For example: on July 3, 126 mosquitoes were released of a total of 160 captured. Following the left slanting diagonal, two mosquitoes marked on July 3 were recaptured on July 4, one was recaptured on July 5, and none after that. The distribution of release dates for recaptures on any given day is also apparent. For example: on March 19, three mosquitoes that had been released on March 18 were recaptured together with four from the release on March 17 and one from the release on March 16.

*Box 3. Fisher-Ford Method*

Calculation of the population size is described in terms of operations on a table, following the approach used with the introduction of this method by Fisher and Ford (1947). Here we follow this practice with data from Baber et al. (2010), presented in Table A using data from Fig. 5 with an assumed daily survivorship of 0.6.

The first column gives sampling dates in reverse chronological order, while the last column gives the row dates + 1. Columns to the left of the vertical line refer to the dates in the first column, those to the right refer to the dates in the last. Working left to right, we have the number of days from the end of the experiment in column 2, and the number of marked individuals released in column 3 (these can also be read in Fig. 5). Column 4 is the expected number of marked individuals recaptured, calculated as follows: sum of row values from the bottom of the table, each value is

$$E_m = \sum_{i=n}^{l} MS^d$$

where $n$ is the current row, $l$ is the last row of the table, $M$ is the number of marked individuals released, and $S^d$ is the estimated daily survivorship raised to the number of days from the end of the sampling (column 2).

*Table A. Calculation of population size following the method of Fisher and Ford (1947) for mosquito data collected in Fourda, Mali, in 2008 by Baber et al. (2010), assuming a daily survivorship of 0.6*

| Date 1 | *d* | *M* | $E_m$ | *R* | *C* | *P* | Date 2 |
|---|---|---|---|---|---|---|---|
| 09 July | 1 | 0 | 63.7 | - | - | - | 10 July |
| 08 July | 2 | 0 | 63.7 | 1 | 505 | 53 606 | 09 July |
| 07 July | 3 | 0 | 63.7 | 2 | 335 | 29 634 | 08 July |
| 06 July | 4 | 299 | 63.7 | 5 | 235 | 13 859 | 07 July |
| 05 July | 5 | 157 | 24.9 | 5 | 385 | 37 841 | 06 July |
| 04 July | 6 | 144 | 12.7 | 5 | 187 | 11 995 | 05 July |
| 03 July | 7 | 126 | 6.0 | 6 | 166 | 7550 | 04 July |
| 02 July | 8 | 148 | 2.5 | 7 | 160 | 4910 | 03 July |

*d*: days from the end of experiment; *M*: number of individuals marked and released; $E_m$: number of marked individuals expected in the environment considering daily survival; *R*: number recaptured; *C*: number captured; *P*: estimated population size.

Values in columns 5–7 refer to dates in column 8 ("Date 2"). For each date *j*, the estimated population size *P* is calculated as follows:

$$P = \frac{E_m C}{S^d R}$$

Considering population size estimates with at least 3 releases (July 6 and later) yields an average population size estimate of 33 735 with an SE of 8284. Assuming a higher daily survivorship of 0.8 gives a mean population size estimate of 77 085 and an SE of 31 007.

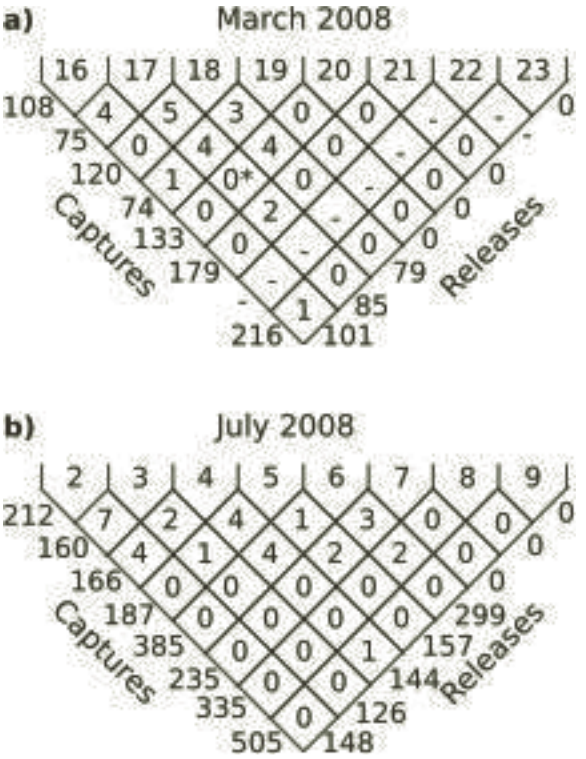

*Figure 5. Trellis diagram with results of mosquito mark-recapture experiments during the dry season (March) and wet season (July) in Fourda, Mali, from Baber et al. (2010). *: marked mosquitoes captured during night-landing survey, separate from this experiment; -: indicates no survey; see text for details.*

A survey of the literature did not reveal any examples of the Fisher-Ford method being applied in the context of SIT projects. The reason might be that most marked and released insects in the context of the SIT are mass-reared and marked with one colour only, with attendant issues of differences between them and wild stock when it comes to estimating population sizes. The Fisher-Ford method is better suited to situations where a limited number of wild insects is being captured, marked and released, or perhaps in the later stages of an SIT project when the number of wild insects is lower. However, it could still be a very helpful method that could be adapted to SIT projects because it explicitly models the survival of the released insects, and provides mean and variance of population size estimates through the approach demonstrated in Box 3.

## 4. ESTIMATION OF DISPERSAL DISTANCE BY MARK-RECAPTURE

The immigration of wild insects into an area treated with sterile insects is one of the most important causes of failure of some AW-IPM programmes integrating the SIT (Lance and McInnis, this volume). If wild males have sufficient dispersal ability, the male sterile:fertile ratio ($N_S/N_{f(g)}$ in equation 12') will decrease, causing higher fertility in wild females. Estimation of the dispersal range is also important for estimating the $N_S/N_{f(g)}$ ratio from field data. If the dispersal range is small, the $N_S/N_{f(g)}$ ratio should be estimated using samples obtained from the small area, whereas if the dispersal range is large, samples obtained from the large area should be combined. Furthermore, if the range of dispersal is known, an optimal spatial design for the release of sterile males can be constructed. If the dispersal range is small, sterile males should be released at many spatial points to increase uniformly the male sterile:fertile ratio. In this section several techniques to estimate the dispersal range of individuals are described.

### *4.1. Diffusion Equation*

A two-dimensional simple diffusion equation will be the simplest theoretical model that can be applicable to the two-dimensional dispersal of marked individuals. Assuming that the movement of marked individuals is Brownian random motion (the rate of which is invariant in time and space), the number of marked individuals at time $t$ at coordinate ($x$, $y$), which is denoted by $m(x,y,t)$, is described by a partial differential equation (Okubo 1980, Shigesada and Kawasaki 1997):

$$\frac{\partial m(x,y,t)}{\partial t} = D\left(\frac{\partial^2 m}{\partial x^2} + \frac{\partial^2 m}{\partial y^2}\right) \tag{33}$$

where $D$ is the diffusion coefficient that measures the dispersal rate with units (distance$^2$/time). When $M_0$ individuals are released at time 0 from the origin (0, 0), the solution is given by

$$m(x,y,t) = \frac{M_0}{4\pi Dt}\exp\left[-\frac{(x^2+y^2)}{4Dt}\right] \tag{34}$$

which is a two-dimensional normal distribution with mean zero, correlation coefficient zero, and variance $2Dt$ in each dimension. If the distance from the origin is denoted by $r = \sqrt{x^2+y^2}$, then equation 34 is rewritten in a simpler form

$$m(r,t) = \frac{M_0}{4\pi Dt}\exp\left[-\frac{r^2}{4Dt}\right] \qquad (r \geq 0) \tag{35}$$

The proportion of individuals in a circle of radius $d$ at time $t$, which is denoted by $F(d, t)$, is given by

$$F(d,t) = \frac{1}{M_0}\int_0^d 2\pi r \cdot m(r,t)dr = 1 - \exp\left[-\frac{d^2}{4Dt}\right] \tag{36}$$

Thus, the proportion of individuals in a circle of radius $\sqrt{4Dt}$ is $1-\exp(-1) = 0.63$, and that in a circle of radius $2\sqrt{4Dt}$ is $1-\exp(-4) = 0.98$. A rearrangement of the above equation yields

$$\log_e[1 - F(d, t)] = -d^2/(4Dt) \tag{37}$$

Therefore, if the distribution of marked individuals is observed at time $t$, an estimate of $D$ can be obtained by plotting the observed $\log_e[1 - F(d, t)]$ against $d^2$ and by estimating the slope $-1/(4Dt)$ using a liner regression with intercept zero (Broadbent and Kendall 1953). If the relation is not linear, it can be judged that the dispersal is not a random diffusion with a constant $D$ (e.g. Inoue 1978). The expectation of the square of the distance is given by

$$E[r^2] = \frac{1}{M_0}\int_0^\infty 2\pi r \cdot r^2 \cdot m(r,t)dr = 4Dt \tag{38}$$

Thus, the moment estimate of $D$ is given by the observed mean square of the distance divided by $4t$. If estimates of the mean square distance for several $t$ are available, the common $D$ can be estimated by plotting the mean square distance against $t$ and by estimating the slope $4D$ using the linear regression with intercept zero.

### *4.2. Random Correlated Walks*

The diffusion model described above is useful in its simplicity and mathematical tractability. In terms of an organism moving in real space with discrete time-steps, diffusion can be understood as a random walk: at each time-step the organism moves a random step-length (with given range) in a randomly chosen direction. The step direction at time $t$ is independent from the direction at $t$-1, all are equally likely including complete reversal. This "classical" random walk results in an average expected displacement of the entire population = 0, as indicated above.

Even in the absence of cues, this kind of motion is not realistic for most organisms. Forward bias is common, as are correlations between directions chosen in subsequent time-steps (Miller at al. 2015). A random correlated walk (Kitching 1971;

Kareiva and Shigesada 1983; Byers 2001) is an extension of a classical random walk (diffusion) that restricts the range of new directions after a given step, thus resulting in more realistic dispersal.

Kareiva and Shigesada (1983) derive the relationship between an organism's movement behaviour and its expected square displacement using a random correlated walk as follows: if each move $m$ is a vector $(x_m,y_m)$ then the total displacement after $n$ moves, $R_n$, is

$$R_n = \sum_{m=1}^{n}(x_m,y_m) \tag{39}$$

the length of each move is the Euclidean distance; it and each turning angle $\theta_m$ are independent random variables with probability densities equal to $p(l)dl$ and $g(\theta)d\theta$, respectively. The expected values for these random variables are:

$$E(l) = \int_0^\infty l\, p(l)dl \tag{40}$$

$$E(l^2) = \int_0^\infty l^2\, p(l)dl \tag{41}$$

$$c = E(\cos\theta) = \int_{-\pi}^{\pi} \cos\theta\, g(\theta)d(\theta) \tag{42}$$

$$s = E(\sin\theta) = \int_{-\pi}^{\pi} \sin\theta\, g(\theta)d(\theta) \tag{43}$$

Since a set of moves can be represented by independent random draws from $p(l)$ and $g(\theta)$, the process of movement in this model is a first-order Markov chain -- where a given draw is not influenced by the previous draw. However, the probability density of values can be non-uniform. Relating the distribution of values to biological movement is straightforward: if the distribution is uniform for angles between -180 and 180 then the movement pattern will follow classical diffusion (a random walk) as described above. If the probability density is 1 for an angle of 0 and 0 for all other angles in the range, then the movement pattern is a straight line (sometimes termed a "ballistic" disperser; Miller et al. 2015). If the distribution is intermediary, then the movement is considered a random correlated walk.

A useful result from Kareiva and Shigesada (1983) is the expected squared displacement. Assuming an equal probability of right or left turns, the following equation is derived:

$$E(R_n^2) = nE(l^2) + 2E(l)^2\frac{c}{1-c}\left(n - \frac{1-c^n}{1-c}\right) \tag{44}$$

This model enables a direct relation between behavioural changes influencing $p(l)$ or $g(\theta)$ and consequent changes in the expected net displacement.

### *4.3. Distribution of Cumulative Recaptures*

Traps are frequently used to capture marked individuals (FAO/IAEA 2018). If traps are set for a sufficiently short period around *t*, the observed distribution of captured individuals can be used for a sample distribution of dispersing individuals at time *t*. If traps are set for a longer period, the observed distribution cannot be used for a distribution at a specific time. A trap also performs some integration of density over space as well as over time. Such a spatial integration may cause some difficulties in the estimation of dispersal distance; one such difficulty is discussed in Box 4.

In several experiments, marked individuals have been trapped until most of them died or left the study area. In these cases estimates of the distribution of the cumulative number of recaptured individuals in each trap can be obtained. The theoretical distribution of the cumulative recaptures can be described by relatively simple equations under several assumptions. Let $\delta$ be instantaneous natural mortality (or disappearance rate), and $\alpha$ trap efficiency. Assuming that the number of recaptures is sufficiently small relative to the number of total release, $M_0$, so that the mortality $\delta$ is not influenced by the mortality caused by trapping, then the cumulative number of recaptures at a trap placed at a distance *r* is given by

$$C(r) = \frac{\alpha M_0}{2\pi D} K_0\left(\sqrt{\frac{\delta}{D}}r\right) \tag{45}$$

where $K_0$ is a zero-order modified Bessel function of the second kind (Broadbent and Kendall 1953; Williams 1961). Turchin and Thoeny (1993) used an approximation for equation 45

$$C(r) \approx \frac{A}{\sqrt{r}} \exp\left(-r\sqrt{\frac{\delta}{D}}\right) \tag{46}$$

where *A* is a constant. This equation can be described by a linear form,

$$\log_e[C(r)] + \frac{1}{2}\log_e(r) \approx \log_e(A) - r\sqrt{\frac{\delta}{D}} \tag{47}$$

therefore $\sqrt{\delta / D}$ can be estimated by plotting the observed $\log_e[C(r)] + \frac{1}{2}\log_e(r)$ against *r*, and by estimating the slope by using a linear regression method, although such an estimation procedure is not preferred from a statistical point of view. Like Inoue's (1978) method using equation 37, equation 47 can be used to judge the randomness of dispersal. If the relation is not linear, then dispersal is not a simple random diffusion with a constant *D* (Cronin et al. 2000). Note that $\delta$ and *D* cannot be estimated separately since the accumulation of recaptures eliminates information on the velocity of dispersal in this estimation procedure.

*Box 4. Overlap of Attraction Areas of Traps*

In a study of the dispersal of marked male sweetpotato weevils *Cylas formicarius* (F.), and using plastic funnel traps with 1 mg sex pheromone, Miyatake et al. (2000) placed traps in eight directions, and at distances of 10, 20, 50, 100, and 200 m, from the release point. However, Yasuda and Sugie (1990) estimated that the radius of the circular attraction area of a trap (area of 30% recapture) is about 50 m. According to Fig. 52 in Yasuda (1998), the radius of 60% recapture is less than 30 m. (The distribution of the attraction rate around a trap might be a normal distribution or a distribution with larger kurtosis. Therefore, how can the radius of the "attraction area" be determined?) If we use a trap site of 10 or 20 m from the release point, the attraction areas of traps placed by Miyatake et al. (2000) at sites near the release point are overlapping, and many males might be attracted by two or more traps. Thus such traps might attract more individuals when they are in an isolated place, leading to an overestimation of the dispersal range.

If traps were distributed in a lattice pattern, the effect of the overlap of traps can be reduced to a negligible level. If individually marked insects are released from many points of the lattice, reduction of the effect is better. Therefore it is recommended that a lattice-pattern arrangement of traps be used. However, since many data are taken if traps are arranged along four or eight directions to estimate the dispersal range, a method that reduces the effect of overlap of attraction areas is described hereafter.

Fig. A shows an example of the effect of overlap of attraction areas. Individuals in the striped area would be attracted to two traps. Therefore, we must calculate the area of half of the striped area (double stripes) and subtract this from the area of the circle. In Fig. A, the distance between the two traps, and the radius of the attraction area, are $2a$ and $R$, respectively. As $\theta = \cos^{-1}(a/R)$, $\theta$ can be calculated when $R$ is known. The area of the triangle ABC of Fig. A is $\left[2\sqrt{R^2 - a^2} \times a\right]/2$. Then half of the striped area can be calculated by $\left[\pi R^2 \times 2\theta/(2\pi)\right] - \left[\sqrt{R^2 - a^2} \times a\right]$. This area must be subtracted from the attraction area of a trap, $\pi R^2$, to obtain the true attraction area.

When this procedure is carried out for data from Miyatake et al. (2000), a smaller value for dispersal distance is obtained (Fig. B). Although Miyatake et al. (2000) set traps along eight directions on circles of which the radii were 10, 20, 50, 100, and 200 m from the single release point, data for 10 m are omitted because the attraction areas of three or more traps overlap at 10 m points.

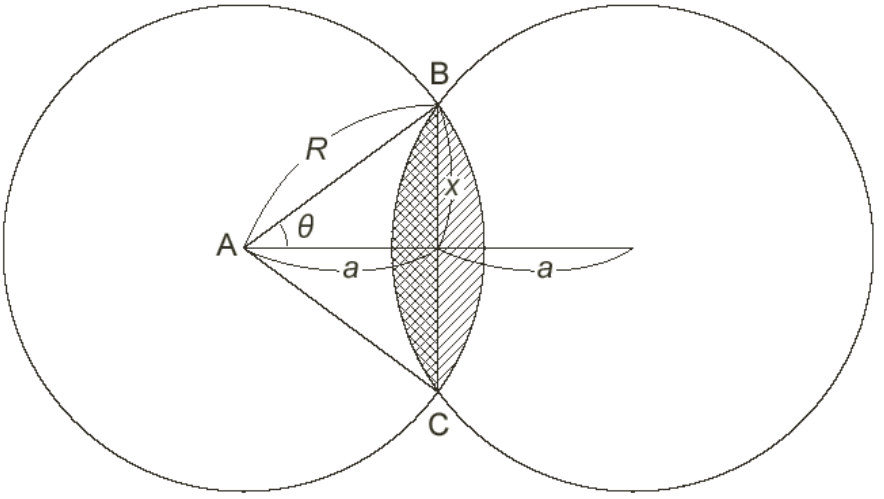

*Figure A. Method to estimate overlapping area (striped area) of attraction of two traps.*

*Box 4. Continued*

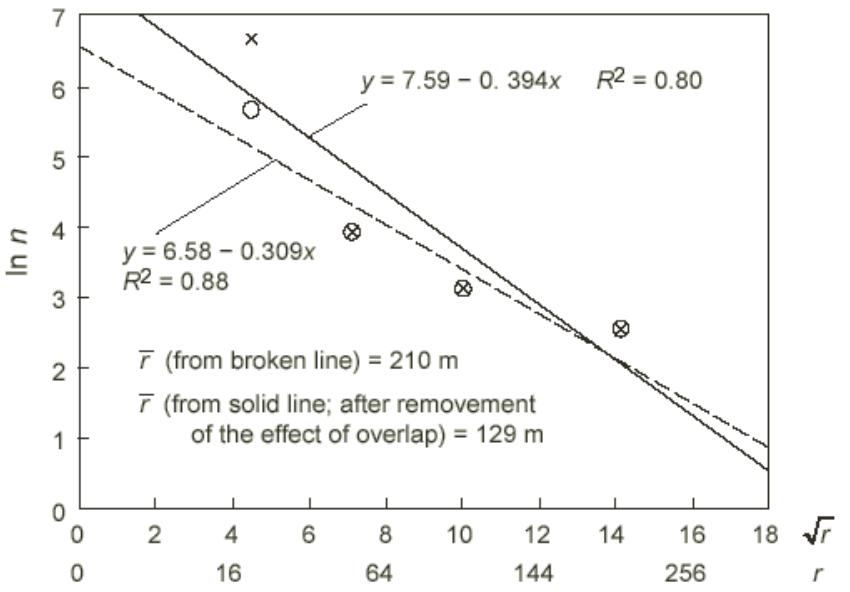

*Figure B. Recapture rate of sweetpotato weevils in traps at different distances (r) from release point (circles and broken line), and removal of effect of attraction-area overlap (radius = 10 m, crosses and solid line).*

There is a dilemma in applying these models. If trap efficiency is high, these models cannot be applied since $\delta$ is influenced by the mortality caused by traps, whereas if trap efficiency is low, the spatial distribution cannot be estimated with sufficient precision. This dilemma can be solved by a uniform placement of traps. If traps are placed uniformly in a lattice pattern, the mortality caused by traps is constant, and hence $\delta$ will be kept constant irrespective of trap efficiency.

### *4.4. Empirical Distributions*

The models described above, being based on clear assumptions such as random diffusion and constant mortality, do not always fit the data sufficiently well. The heterogeneity among individuals used to calculate the diffusion coefficient, along with the spatial and temporal heterogeneity, may be one of the causes of such discrepancy. A promising approach for incorporating the heterogeneity of the diffusion coefficient is to assume that the population consists of two groups with different *D*, as seen in Inoue (1978) and Cronin et al. (2000). An actual population may sometimes consist of many groups that have different tendencies of dispersal. At present, however, there is no simple theoretical model to describe such complicated situations. Therefore, in such cases, empirical equations will still be useful for

describing the dispersal of individuals.

Taylor (1980) and Turchin (1998) pointed out the usefulness of an empirical equation to describe the number of recaptures, $\phi(r)$, in a trap placed at a distance $r$:

$$\phi(r) = \lambda r^{-\varepsilon} \exp\left[-(r/\beta)^{\gamma}\right] \tag{48}$$

where $\beta$, $\lambda$, $\varepsilon$, and $\gamma$ are constants. Several empirical equations are given by special cases of equation 48. If $\varepsilon = 0$ and $\gamma = 2$, we obtain a half-normal distribution (Itô and Miyashita 1965):

$$\log_e[\phi(r)] = a - br^2 \tag{49}$$

where $a = \log_e(\lambda)$ and $b = 1/\beta^2$. If $\varepsilon = 0$ and $\gamma = 1$, we obtain an exponential distribution (Kettle 1952):

$$\log_e[\phi(r)] = a - br \tag{50}$$

where $a = \log_e(\lambda)$ and $b = 1/\beta$. If $\varepsilon = 0$ and $\gamma = 0.5$, we obtain the equation used by Wallace (1966):

$$\log_e[\phi(r)] = a - b\sqrt{r} \tag{51}$$

where $a = \log_e(\lambda)$ and $b = 1/\sqrt{\beta}$. Several theoretical distributions are also described by equation 48. The instantaneous distribution of dispersing individuals, equation 35, corresponds to the case of $\gamma = 2$ and $\varepsilon = 0$. The cumulative distribution under random dispersal, equation 46, corresponds to the case of $\gamma = 1$ and $\varepsilon = 0.5$ of equation 48. Taylor (1978) compared the descriptive ability of these empirical equations, and showed that Wallace's equation (equation 51) is most preferred. Plant and Cunningham (1991), in analysing the dispersal of sterile Mediterranean fruit flies, also concluded that equation 51 is most preferred.

The parameters such as $a$ or $b$ of the above equations cannot readily be interpreted in biological terms. Several statistics will be more useful than the parameters themselves for describing the dispersal ability of individuals. Hawkes (1972) suggested that "mean dispersal distance" be used. For equation 48, the statistic is calculated by

$$\bar{r} = \frac{\int_0^\infty 2\pi r^2 \phi(r) dr}{\int_0^\infty 2\pi r \phi(r) dr} = \beta\Gamma\left(\frac{3-\varepsilon}{\gamma}\right) \Big/ \Gamma\left(\frac{2-\varepsilon}{\gamma}\right) \tag{52}$$

where $\Gamma$ indicates the gamma function. In the case of equation 51, for example, we obtain $\bar{r} = 20/b^2$ from equation 52. The median dispersal distance, $r_{0.5}$, i.e. the radius of a circle that encloses 50% of the individuals, will be another useful statistic for the description of the dispersal ability of individuals (Turchin and Thoeny 1993). This statistic is obtained by numerically solving the equation

$$\frac{\int_0^{r_{0.5}} 2\pi r \phi(r) dr}{\int_0^\infty 2\pi r \phi(r) dr} = 0.5 \tag{53}$$

Fig. 6 is an example of fitting equation 51 to data from male sweetpotato weevils. For simplicity, linear regression was used to estimate $b$, 0.342. Hence the estimate of mean dispersal distance is obtained by $20/0.342^2$ = 171 m. The median dispersal distance was estimated by a numerical calculation to be 115.2 m. The mean dispersal distance is much larger than the median dispersal distance, since the form of $\phi(r)$ is highly leptokurtic, i.e. L-shaped. In summarizing the characteristics of the dispersal curve, the median dispersal distance will generally be preferred over the mean dispersal distance.

## 5. BEHAVIOURAL ECOLOGY: SEXUAL COMPETITIVENESS OF RELEASED STERILE MALES IN THE FIELD

The quality of sterile males to be released is the most important element in the success of an AW-IPM programme integrating the SIT. Although quality includes survival rate, dispersal ability, and other aspects that relate to the vigour of released males, the most attention must be paid to the decline of sexual competitiveness (Parker, Vreysen et al., this volume; Lance and McInnis, this volume; Vreysen, this volume).

Even when the survival rate or dispersal ability of mass-reared and sterilized males is lower than those of wild males, an increase in the frequency of mass releases or the number of release points can compensate for these deficiencies. However, if long-term mass-rearing creates a strain in which released males have a different courtship behaviour (pattern of vibration, courtship sound, etc.) than that of the wild males and therefore are not accepted by wild females, an increase in the number of released sterile males cannot compensate for this deficiency.

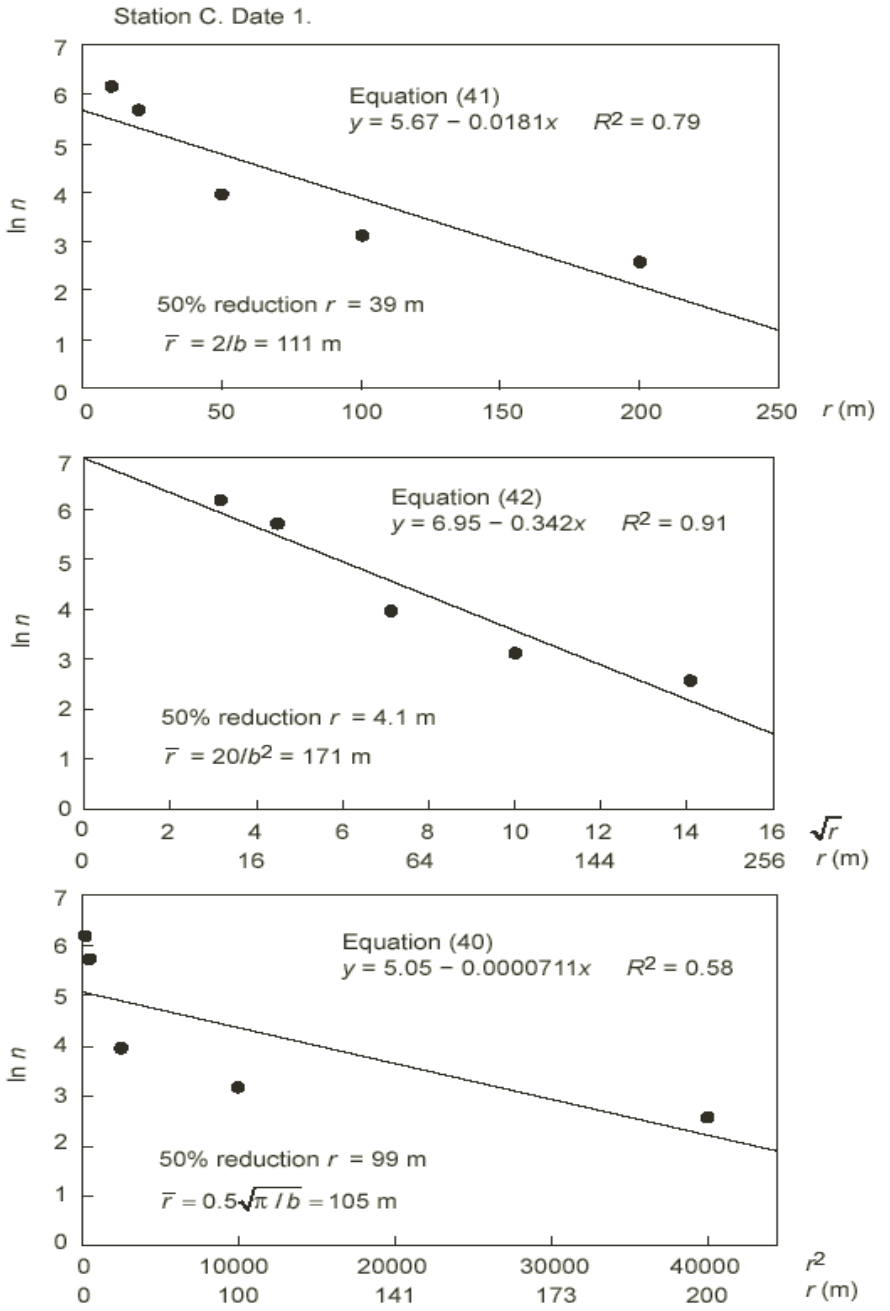

*Figure 6. Distance-density curve of number of marked adult sweetpotato weevils recaptured in traps. Equation 51 is fitted by linear regression. (Data from Miyatake et al. 2000.)*

This is a subject of behavioural ecology or sociobiology. Although sexual behaviour and behavioural changes in mass-reared strains have been studied in several species that are targets of the SIT (e.g. Prokopy and Hendrichs 1979; Sivinski et al. 1989), probably the only AW-IPM programme releasing sterile insects, which incorporated behavioural ecology as an important aspect throughout implementation, has been the melon fly eradication programme in Okinawa, which was completely successful (Yamagishi et al. 1993).

### *5.1. Effects of Long-Term Mass-Rearing more Important than the Effects of Sterilization*

The effects of sterilization, e.g. by X- or $\gamma$-radiation, are often regarded as an important source of the decline of vigour and/or sexual competitiveness of males (Bakri et al., this volume). However, experiences accumulated during the Okinawa melon fly programme suggest that changes in sexual behaviour of released males due to long-term mass-rearing are much more important than the effects of sterilization (Itô et al. 1993; Parker, Vreysen et al., this volume). The inadvertent selection of strains with rapid development and early fecundity produces reduced longevity and other genetic changes in the selected strain (Miyatake 1996, 1998; Shimizu et al. 1997). The high-density rearing of adults in small cages can lead to the selection of strains in which reared males do not perform the same sexual behaviours as wild males in the field.

### *5.2. Competitiveness must be Measured in the Field*

In many AW-IPM programmes integrating the SIT, sexual competitiveness has been measured in the laboratory, e.g. observing wild females mating with marked wild males and mass-reared and/or sterilized males in a cage (Fried 1971; Parker, Vreysen et al., this volume). However, conditions in a laboratory cage are different from those in the field (Lance and McInnis, this volume; Vreysen, this volume). In a programme to eradicate the melon fly from Kume-zima, Okinawa (1973–1977), Iwahashi et al. (1983) measured sexual competitiveness in the field. They collected wild females from Kume-zima, the target area, and Okinawa-Hontô, the control (non-SIT) area, and examined the hatch rates of eggs laid by those females.

Haisch (1970) presented the following equation for the laboratory examination of competitiveness, $c$:

$$\hat{c} = \frac{H_n - H_c}{H_c - H_s} \cdot \frac{w}{1-w} \tag{54}$$

where
$w$ = proportion of males of wild strain among all males,
$H_n$ = percentage egg hatch in matings between normal (wild) males and females of wild strain,

$H_C$ = percentage egg hatch in competitive matings,

$H_S$ = percentage egg hatch in matings between sterile males and normal females.

To use this equation in the field, Iwahashi et al. (1983) substituted percentage hatch of eggs laid by females collected in the target and control areas for $H_n$ and $H_C$, respectively. $H_S$ is 0 in the Okinawa melon fly programme. For comparison of $c$ values while applying the SIT, or between two or more SIT areas, an estimation of variance is necessary. Iwahashi et al. (1983) presented an equation for estimating the variance of $c$ (Box 5).

*Box 5. Variance of Haisch Index of Sexual Competitiveness of Mass-Reared/Sterilized Males*

In the final stage of an eradication programme that releases sterile insects, when most males collected are sterile males, $1 - w$ becomes near zero. In this stage, $H_C$ may also become small. As $c$ values become quite sensitive to small changes in $1 - w$ and $H_C$, estimation of variance is necessary. The following equation from Iwahashi et al. (1983) is recommended:

$$V(\hat{c}) = \left[\frac{w}{H_c(1-w)}\right]^2 \times \left[\frac{H_n(1-H_n)}{N_n} + \frac{H_n^2(1-H_c)}{H_c N_c} + \frac{(H_n - H_c)^2}{w(1-w)N_w}\right]$$

Here $N_n$ and $N_C$ are the numbers of eggs examined in the control area and the release area, respectively. $N_w$ is the number of flies examined in the release area. For other symbols, see explanation of equation 54.

Release strain sexual competitiveness decreased from about 80% in the 5th generation after the beginning of mass-rearing to 20% in the 18th generation, during the final stage of the Kume-zima programme (Fig. 7, upper). Even at this time, high sexual competitiveness in laboratory cages was still observed (see closed triangles in Fig. 7, upper).

Soemori et al. (1980) described experiments that suggest an explanation for such a discrepancy between laboratory and field data. They released individually marked flies into cages or rooms of different sizes and recorded the mating performance. Fig. 7 (lower) shows the percentage of males that mated in relation to the volume of space available per male in the experimental area. Males of the wild strain could not mate well in a small space, whereas males of the laboratory strain performed best in these conditions.

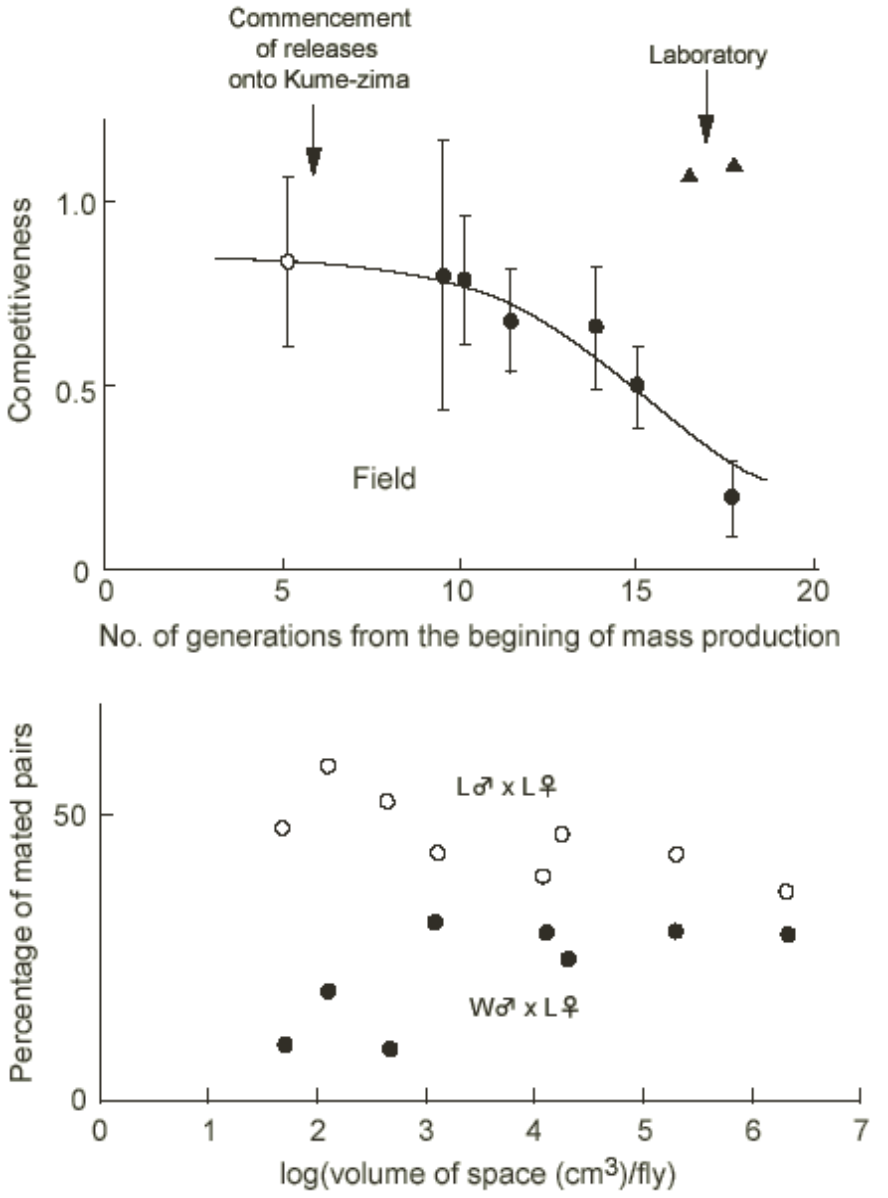

*Figure 7. Upper: Sexual competitiveness of mass-reared and sterilized male melon flies measured in the field (adapted from Iwahashi et al. 1983). Closed circles are for data from Kume-zima; the open circle is for data from another islet Kudaka-zima. Solid triangles are competitiveness values measured in laboratory cages. Vertical lines show standard deviations. (Box 5 shows the equation for variance.) Lower: Relationship between size of cage per fly and percentage of successful mating of males of mass-reared (open circles, 33–34 generations) and wild (closed circles) strains when caged together with mass-reared females. (Figure from Soemori et al. 1980, reproduced with permission.)*

### *5.3. Inadvertent Selection of Mate-Choice when the SIT is Applied*

In a field cage, Hibino and Iwahashi (1988) compared the mating success of males of wild and mass-reared strains. One of their results, using flies of a wild strain of Okinawa Hontô (O-males and O-females), is shown in Fig. 8 (upper). Firstly, even when courted by wild males, wild females accepted copulation in only 4 of 37 courtship trials, showing strong mate-choice by females. Secondly, O-females never accepted (0/46) courtship from mass-reared (R) males. Other experiments showed similar results (Itô et al. 1993). When Hibino and Iwahashi (1988) carried out these experiments, melon flies on Okinawa Hontô, as a result of the application of the SIT, were near extinction. Therefore O-females had been subjected to strong selection pressure by the released sterile males.

Hibino and Iwahashi (1991) carried out similar experiments using wild flies taken from Ishigaki-zima, where a programme releasing sterile insects had not yet begun. Fig. 8 (lower) shows that females of Ishigaki wild flies (I-females) accepted courtship from R-males (4/57) as well as from I-males (3/51).

There are two possible explanations for the difference in behaviour between flies on the two islands: (1) O-flies and I-flies had genetically different courtship and acceptance characters, and the courtship character of R-males was more similar to that of I-males, and (2) the "SIT-resistance hypothesis" — the wild female population was initially heterogeneous and contained individuals which accepted a broad range of male courtship characters (McInnis et al. 1996; Whitten and Mahon, this volume). However, females that accepted sterilized R-male courtship could not produce progeny. Thus, under strong selection pressure from the SIT, a female genotype that accepted the courtship of mass-reared males may have become extinct. Next Hibino and Iwahashi (1991) conducted an experiment on mate choice of O-females between O- and I-males. O-females then accepted courtship by I-males (1/19) as well as by O-males (1/14), indicating that the second explanation is correct, thus demonstrating for the first time the evolution of mate-choice in insects.

### *5.4. How Can the Spread of an SIT-Resistant Strain be Overcome?*

How can the problem of an increase in the number of females that do not accept courtship from mass-reared males be overcome? Besides the obvious approach of establishing a new colony from the target population, and/or cryopreserving the embryos of recently colonized strains (Parker, Mamai et al., this volume; Whitten and Mahon, this volume), as well as improving the competitiveness of sterile males (Shelly and McInnis 2001; Pereira et al., this volume; Vreysen, this volume), an additional answer is provided by the development of the logistic population model (e.g. equation 8).

Tsubaki and Bunroongsook (1990) conducted a simulation experiment to estimate the effect of the change in mate-choice, using a logistic model (equation 8) incorporating two strains. They showed that the effect of a reduction in mating competitiveness of mass-reared and sterilized males is much more important than the effect of a change in female mate-choice. Their simulation also indicated that releases of two or three times more sterile males than would be released in a non-mate-choice

model can eradicate a target population that has a change in female mate-choice. In the Okinawa melon fly programme integrating the SIT, an increase in the number of released sterile males over that first planned for release (based on an estimate of the wild fly density) resulted in complete eradication of the population.

The incorporation of recent ideas in behavioural ecology, as well as in population ecology, into the SIT is indispensable for its success. It is recommended that Krebs and Davies (1993) be consulted on the basic concepts of this subject.

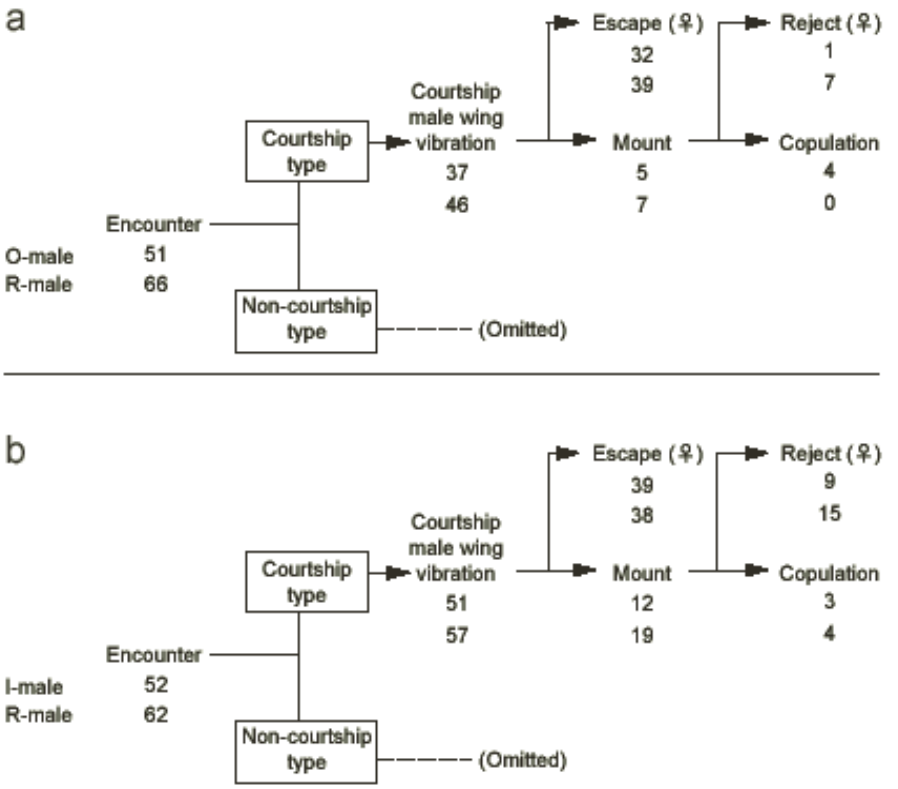

*Figure 8. Upper (a): Mate-choice by wild female melon flies collected on Okinawa Hontô (O-females) for wild males (O-males) or males of mass-reared strain (R-males). Arrows indicate the direction in which the behavioural sequence proceeds. Upper numerals indicate the frequencies of the transitions when O-females encountered O-males, lower numerals indicate cases when O-females encountered R-males (adapted from Hibino and Iwahashi 1988). Lower (b): Mate-choice by wild female melon flies collected on a non-SIT island Ishigaki-zima (I-females) for Ishigaki wild males (I-males) or mass-reared males (R-males). (Figure from Hibino and Iwahashi 1991, reproduced with permission.)*

## 6. ACKNOWLEDGEMENTS

We thank N. Shigesada for her helpful advice, and T. Miyatake and H. Kuba for describing recent progress in the Okinawa programme using sterile sweetpotato weevils, and providing unpublished data.

SUMMARY

Since the sterile insect technique (SIT) relies upon released sterile male insects efficiently competing with wild males to mate with wild females, it follows that mass-rearing of insects is one of the principal steps in the process. Mass-rearing for the SIT presents both problems and opportunities due to the increased scale involved compared with rearing insects for most other purposes. This chapter discusses facility design, environmental concerns, strain management, quality control, automation, diet, sex separation, marking, and storage in relation to rearing for the SIT. The cost of sterile insect production drops rapidly with increasing scale, but the point at which the SIT becomes economic in comparison with other methods will depend on factors such as the species concerned, local costs, and the cost of competing technologies. However, optimizing rearing for numbers without regard to quality may compromise the effectiveness of the SIT. In the future, improvements in sex-separation technologies and in understanding the impact of microbiota on insect quality may lead to significant improvements in both rearing efficiency and quality. The list of target pest species for which mass-rearing systems have been, or are being, developed continues to expand.

## 1. INTRODUCTION

The sterile insect technique (SIT) depends upon inducing a high proportion of sterile matings in a natural population that reduces reproduction to a level below population maintenance. Therefore, the production of insects, in sufficient number and of adequate quality to achieve this aim, is one of the principal requirements for the successful application of the technique. Further, since the integration of the SIT into an area-wide integrated pest management (AW-IPM) programme competes economically with other control techniques, the production of insects must be timely and cost-effective. Large numbers of insects are required to integrate the SIT into AW-IPM programmes, and therefore it is possible to take advantage of economies-of-scale in the rearing.

There are numerous published accounts of the rearing of many insect species, including general reviews (Smith 1966; King and Leppla 1984; Singh and Moore 1985; Anderson and Leppla 1992; Ochieng'-Odero 1994a; Nordlund 1999; Schneider 2009; Cohen 2015; Beukeboom 2017). The details of specific rearing systems used by the various ongoing SIT projects are described in the published literature. Some key publications for the main SIT pest target groups are:

- *Moths*: Zethner (1980), Stewart (1984), Davis (2009), Dyck (2010), Carpenter and Hight (2012), Xsit (2018), Boersma (2021),
- *Screwworms*: Brown (1984), Mahon and Ahmad (2000), Scott et al. (2017), USDA/APHIS (2017),
- *Fruit flies*: Schwarz et al. (1985), Vargas (1989), Nakamori et al. (1992), Yamagishi and Kakinohana (2000), Cáceres et al. (2014),
- *Tsetse flies*: Feldmann (1994), Gooding et al. (1997), Aksoy (2005), FAO/IAEA (2006),
- *Mosquitoes*: Gerberg et al. (1994), Balestrino et al. (2014); Carvalho et al. (2014), Zheng et al. (2015a, b), FAO/IAEA (2017a, b, 2018a), Mamai et al. (2017a, 2018), Lees et al. (this volume), and
- *Weevils*: Yamaguchi et al. (2006), Shimizu et al. (2007).

Insects are reared for many reasons — bioassays, physiological research, rearing parasitoids, postharvest treatment testing, etc. (Singh and Ashby 1985), where rearing is rarely an end in itself. For these purposes, the cost of rearing is not critical,

e.g. the diets tend to be all inclusive, rather than minimal, and once a diet is developed that is able to maintain an adequate colony, little or no further work is done on it.

For the SIT, a rather different approach is needed, with due attention being paid to all the factors affecting quality, fecundity, and cost. Even though Singh (1985) listed more than 1300 species that have been reared on artificial diet in the laboratory for part or all of their life cycle, relatively few species have been mass-reared for the SIT (IDIDAS 2019). The details of the rearing protocol for any one species will not be discussed here, but examples to illustrate key points and issues common to the successful mass-rearing for the SIT will be given.

## 2. ECONOMICS

Mumford (this volume) discusses the economics of the SIT. However, that discussion focuses on benefit/cost analyses of overall programmes, and rearing economics appear only as a component of overall cost.

One of the main characteristics that distinguishes rearing for the SIT from other insect rearing is scale, e.g. the El Pino factory in Guatemala has the capacity to produce more than 2000 million sterile male Mediterranean fruit flies *Ceratitis capitata* (Wiedemann) per week (Figs. 1, 2).

*Figure 1. Mediterranean fruit fly production and sterilization facility, El Pino, Guatemala (2015). Recycled/processed water from the facility is retained in a pond for the production of fish. (Photo from P. Rendón, reproduced with permission.)*

Scale brings with it problems of labour supply, automation, and diet supply, which are dealt with later in this chapter, but there is also an issue of the relative efficiency and economics of scale. In general, cost per unit reduces as scale increases, and this can be seen in the efficiency of the Guatemala facility (Hendrichs et al. 2002). At the same time, if rearing is optimized for numbers without regard to quality, there is a risk of reduced quality (Parker, Vreysen et al., this volume). The scale at which a particular programme becomes cost effective will depend on the species involved and the cost and efficiency of alternate means of control.

*Figure 2. Mass-rearing the Mediterranean fruit fly at the El Pino facility, Guatemala. Upper left: Eggs treated in a hot-water bath to kill female embryos of the temperature-sensitive lethal sexing strain; Lower left: Rearing larvae in trays, showing hanging plastic net sheets to redirect jumping mature larvae to the collection pan below; Upper right: Maturing pupae in trays stacked on trolleys; Lower right: Vertical cages for adult emergence, feeding, and egg oviposition and collection. (Photos from C. Cáceres, reproduced with permission.)*

Unfortunately, few published data are available on the actual cost of rearing, separate from whole programme costs (IAEA 2008). The figures that are available indicate that costs have fallen dramatically, but the figures derive from different situations that are not directly comparable, and most of the change is attributable to improvements in rearing technology, rather than scale. The cost of male Mediterranean fruit fly pupae has been reduced to less than USD 300 per million in the Guatemala facility, but this cost depends on the utilization efficiency of the available capacity (Fig. 3) (Enkerlin 2003), indicating that utilization efficiency is at least as important as scale per se. Caceres et al. (2004) compared mass-rearing costs of Mediterranean fruit fly sexing and non-sexing strains; here the different characteristics of the *tsl* sexing strain lead to a small increase in rearing costs (which may be reversed with future developments), but significantly reduced post-production programme costs.

In Tanzania, with increased production, the production cost of the tsetse fly *Glossina austeni* Newstead was reduced from about USD 1 per male insect to less than USD 0.10; again, however, this is largely due to changes in procedures. The same applies to mass-rearing equipment. For example, innovations in mosquito mass-rearing techniques, including development of a low-cost adult-holding cage, resulted in a 10-fold cheaper cage (Maïga et al. 2019). Manufacturing the new mass-rearing cage locally can significantly reduce the initial investment in equipment. Also, improvements have been made in larval diets to reduce the cost 40–90% in *Anopheles arabiensis* Patton (Bimbilé Somda et al. 2017), and up to 80% in *Aedes* sp. (Bimbilé Somda et al. 2019; FAO/IAEA 2020).

## 3. FACILITY DESIGN AND LOCATION

Facility design is a critical aspect of the rearing process (FAO/IAEA 2004, 2019b; IAEA 2008; Co 2019; NEA 2019). Poor design will lead to inefficient utilization of space and energy, increased problems with contamination, and increased risk of escape of fertile insects. Leppla and Ashley (1978), Griffin (1984), Fisher and Leppla (1985), and Fisher (2009) discuss general facility design. Specific aspects of biosecurity are discussed in USDA/APHIS/PPQ (1995), Kahn and Mathur (1999), Leppla and Eden (1999), and ACME (2003). Harrell et al. (1979), Owens (1984), Wolf (1984), Goodenough and Parnell (1985), Oborny (1998), and Schneider (2009) discuss environmental control. Tween (1987) discusses a modular approach to constructing the mass-rearing facility that has been adopted in Guatemala for the Mediterranean fruit fly; this is expanded in Cáceres et al. (2012). The modular approach has the advantage of simplifying design and expansion, but it also means that there is little economy from increased scale as each additional module costs the same as previous ones, the only saving coming from the common areas. However, it has the advantage of allowing the facility to be easily scaled to the required size, so as to maintain the utilization efficiency (Fig. 1); if demand falls, complete modules can be closed without affecting production in the remaining modules, or converted to rearing another insect.

The criteria for determining the optimum location for a mass-rearing facility must take several factors into account, both technical (Phillimore 2002; FAO/IAEA 2004) and managerial (Dyck, Reyes Flores et al., this volume). The principal factors, not in order of priority, are:

- Logistical access – ease of delivery of rearing supplies and equipment,
- Geological stability – earthquake risk, hurricanes, flooding, etc.,
- Political stability,
- Acceptance of the facility by the local community,
- Local government requirements or restrictions,
- Access to water and utilities, reliability of supplies,
- Construction and maintenance costs,
- Availability of support and repair services,
- Labour costs and availability,
- Waste disposal,
- Access to a suitable airport for rapid delivery of insects,
- Distance from release area,
- Quarantine considerations – can the insect survive in the surroundings?
- Proposed progression in case eradication is the objective – will the facility become stranded behind the eradication front?

The relative importance of a given factor will depend on the specific programme, and on factors such as labour costs and the degree of automation utilized. For highly sophisticated systems, access to support and maintenance for the equipment may be critical, as may electricity supply reliability, but for a less automated system these may be less important. Some of the factors can be accommodated within the programme itself, e.g. installing independent generation capacity and a water supply. Even though not always possible, locating the facility in an area where the insect

cannot survive and establish, perhaps due to desert conditions or cold winters, greatly eases the quarantine considerations, and reduces costs. The problem of being stranded behind the eradication front might be addressed by developing a relocatable, containerized rearing system.

## 4. ESCAPES AND ENVIRONMENTAL CONCERNS

A problem unique to the SIT is that the pest insect itself is being reared. For other large-scale rearing, e.g. classical or augmentative biological control, the reared insect is not the pest itself, so any escape from the rearing process is unlikely to pose a threat. (An exception is where the pest must be reared as a host for a parasitoid or predator, but living hosts are increasingly being replaced by factitious hosts or artificial diets). However, when the pest is being reared, any escape of fertile material poses a risk. Usually, the rearing is done in an area where the pest is already present, but if an eradication programme is successful, the rearing facility can become stranded behind the eradication front and poses a substantial reinfestation risk. This happened to both the Mexican facility producing the New World screwworm *Cochliomyia hominivorax* (Coquerel) and the Japanese facility producing the melon fly *Zeugodacus cucurbitae* (Coquillet). Stringent containment procedures are required (see references in section 3.), usually coupled with preventive sterile insect releases and other control measures in the vicinity of the rearing facility. Following screwworm eradication in the country, the screwworm facility in Mexico operated successfully for many years (although it was eventually replaced by a new facility in Panama), employing a combination of stringent security, containment, and prophylactic sterile-male releases. An alternative is to site the facility in an area where the insect cannot, due to local environmental conditions, establish a self-sustaining population, e.g. the facility constructed in Addis Ababa, Ethiopia, to rear the tsetse fly *Glossina pallidipes* Austen. In a mosquito-rearing facility, the risk of free-flyers increases with the scale; various tools such as light, odour, and gravid traps are commonly used to reduce the number of escaped mosquitoes (Lees et al., this volume; Vreysen, this volume).

The mass-rearing process for the SIT potentially poses some environmental problems in relation to waste disposal, including preventing the accidental escape of fertile insects with the spent diet and wastewater. These waste products must be treated to ensure that no living insects in any stage remain — for the diet by steam treatment or extrusion, and for wastewater by filtering, heat treatment or their combination with biological processes. Diets should be readily biodegradable to reduce environmental concern over waste disposal, or even to allow their re-utilization for other purposes, such as feeding fish or livestock (Fig. 1). Some of the bulking agents used in diets do not readily degrade, and these should be avoided, not least because they can lead to significant waste disposal charges (Chaudhury and Alvarez 1999). Facilities are also increasingly being required to install costly wastewater treatment plants. A recent study demonstrated the potential for using recycled larval-rearing water to supplement clean dechlorinated water when rearing *Anopheles arabiensis* (Mamai et al. 2017b).

Probably the biggest environmental concern comes from the sterilization process, which involves a radioactive source. Standard procedures for the use and eventual disposal of such sources are available and, if followed, minimize the risk (IAEA 2005). The increasing tendency to replace isotopic sources with X-ray systems greatly reduces the risks. Sterilization itself is discussed by Bakri et al. (this volume).

Insect mass-rearing can pose a significant health hazard through inhalant and contact allergies (Wirtz 1984; Wolf 1985; Bellas 1990; Kfir 1994; Myers and Barnard 2002; Reinecke 2009). Allergic reactions to mould spores, mites, and pheromones also occur. Some moths have urticating wing scales or hairs that can cause skin rashes and irritations in eyes and lungs (Moraru and Goddard II 2019). Preventing allergic reactions involves recognition and documentation of the problem (Wirtz 1980), and correction of the problem through appropriate air-handling and filtering (Owens 1984; Wolf 1984; Froehlich 1995), coupled with protective clothing and filter masks or respirators. The environmental conditions in the rearing facility may also be changed by manipulation of the diet (Vargas et al. 1984). In addition to the health hazard caused by spores and mites, they impact the rearing directly by reducing diet quality or causing disease in the insects (see sections 6., 8.4.) (Abd-Alla et al., this volume).

## 5. STRAIN MANAGEMENT

Strain management ensures that a strain continues to perform the function required of it, i.e. it survives under field conditions and remains sexually compatible with wild insects, and does not gradually deviate from wild behaviour. The strain must also maintain fecundity, and potential problems with contaminant organisms must be suppressed or eliminated. Fisher (1984), Schwalbe and Forrester (1984), Singh and Ashby (1985), and Caprio (2009) discussed strain management.

One of the most common concerns is the genetic diversity (heterozygosity) of the strain; this can be an important consideration during colony establishment. The strain must be colonized with a sufficient number of individuals from a wide genetic background. There has been much discussion, with a wide divergence of opinion, as to how many are sufficient — from many thousands to just a few tens or hundreds of females (Mackauer 1972, 1976 for parasitic wasps; Bartlett 1985 and Nunney 2002 for the SIT). It is generally agreed that the size of the founder population should depend on the degree of heterozygosity of the wild population. Usually it is stated that the founder material should come from a wide geographic range, but this is not necessarily beneficial; crossing strains from different geographic locations can break up adaptive gene combinations and render the strain less fit than the parents (Mackauer 1976). Azrag et al. (2016) compared the genetic diversity of an advanced generation of an *An. arabiensis* colony population with the field population from which the colony was derived. They found that using a small number of mosquitoes to establish the colony significantly reduced the total number of alleles, the numbers of rare and private alleles, and the fractions of heterozygote individuals at all the loci; this highlighted the need for broad sampling when colonizing a mosquito population (Benedict et al. 2009).

Individual fecundity will also influence founder numbers. In a slow-breeding group, such as tsetse flies, each individual has to be carefully nurtured, and no one individual's or small group's progeny can dominate the next generation. The logistics of collection also play a major role in how the field population is sampled.

Insects newly collected from the field rarely thrive in the laboratory, and the first few generations usually suffer high mortality, with the colony stabilizing after about five generations (Bartlett 1984). This process involves the rapid selection of individuals better adapted to the laboratory rearing conditions (Ochieng'-Odero 1994b), resulting in a rapid decline in heterozygosity. There is considerable concern that these changes will result in insects significantly different from the wild population, and therefore non-competitive, although as yet it has not been possible to show unequivocally that a reduction in heterozygosity per se leads to a reduction in competitiveness. Leppla et al. (1983) showed that this adaptation process was not influenced by gradually introducing mass-rearing conditions.

Adverse changes resulting from long-term mass-rearing are not uncommon, with the development of strains lacking the necessary courtship behaviour and responses to pheromones, predator avoidance, host odours, environmental cues, flight range, and even vision (Boller 1972; Miyatake 1998; Cayol et al. 2002; Mudavanhu et al. 2017; Parker, Vreysen et al., this volume). During long-term mass-rearing, due to the accumulation of random mutations, heterozygosity may gradually be regained (Bartlett 1984), but the newly acquired heterozygosity will not match that of the field population. Heterozygosity can also be encouraged deliberately (Joslyn 1984). To minimize selective processes on colonized mosquito populations, the induction of hybrid vigour by crossing strains of different origins (Craig 1964; Seawright et al. 1975; Ekechukwu et al. 2015) or a regular periodic replacement of existing colonies with wild stocks (especially males) obtained directly from the field (Dyck 2010; FAO/IAEA 2017a, 2018a), have been proposed or sometimes executed (Whitten and Foster 1975; Hofmann 1985; Saul and McCombs 1993; Parker, Vreysen et al., this volume).

Potential changes in competitiveness during mass-rearing are best detected by careful quality-control monitoring (FAO/IAEA/USDA 2019). A range of parameters is monitored routinely, including mating competitiveness and flight ability (Parker, Vreysen et al., this volume). If adverse changes are observed, it may be possible to deliberately select for desirable characteristics (Collins 1984; McInnis et al. 2002; Lommen et al. 2017; Sánchez-Rosario et al. 2017), although there are some dangers associated with this approach.

A recent development in mass-rearing the Mediterranean fruit fly has a potential application to colony management in almost any insect-rearing programme. The concept, called the filter rearing system (FRS), involves maintaining a small colony at a low density, or even under semi-natural conditions, and therefore assumedly a low-selection pressure (Fig. 4) (Cáceres et al. 2000; Fisher and Caceres 2000; Hendrichs and Robinson, this volume). Surplus insects from this low-density mother stock or clean stream are fed into a high-density amplification chain, leading up to the final release numbers. The important feature is that no individuals are ever fed from the amplification stages back to the mother stock. The low-density rearing conditions of the filter can be supplemented with any further conditions deemed desirable, e.g. host plant, predators, mating competition or pheromone response, and

non-performing individuals eliminated. Any undesirable traits selected for in the high-density amplification stages have only three or four generations to accumulate before release, and do not affect the mother stock. A further advantage is that, if it is desired to replace the strain with a new one, the new mother stock can be set up in parallel with the old one, and amplification easily switched from one to the other. Filter rearing is similar to the concept used by Bigler (1986) to rear *Trichogramma maidis* Pintureau and Voegele.

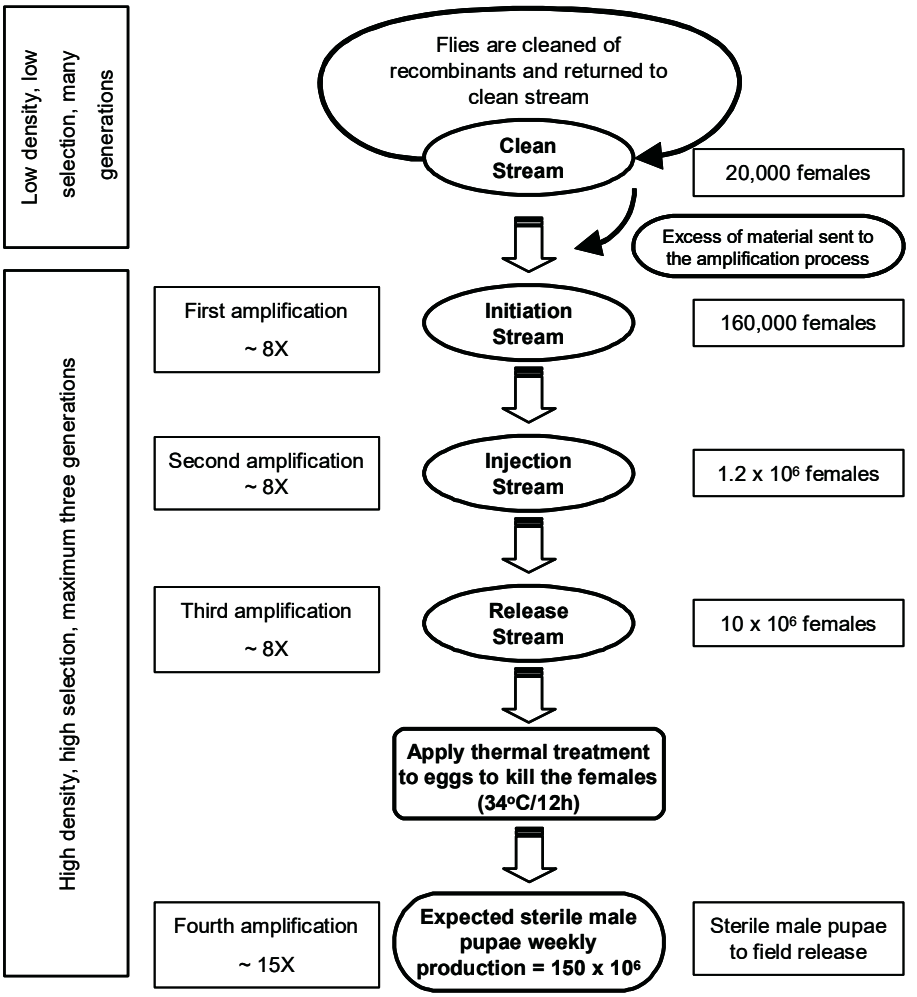

*Figure 4. Continuous filter rearing system for producing Mediterranean fruit fly sterile males in Guatemala. (Figure adapted from Cáceres et al. 2000.)*

## 6. PRODUCTION, PROCESS, AND PRODUCT CONTROL

The concept of quality control can be divided into three areas: production control (monitoring all rearing operations in terms of personnel, materials, equipment, schedules, environment, etc.), process control (sampling immature insect stages to predict quality and determine sources of variability), and product control (both at the output from a rearing facility and in the field), according to the normal industrial definitions (Leppla 1994). All three aspects are equally important in quality control, but most work has been done on product quality control (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume). Field quality control is a particularly neglected area (Vreysen, this volume).

In general, methods of rearing for the SIT are developed from those used to rear insects for other purposes, but on a much larger scale. The techniques are similar, but the issues of quality control require a different approach. The larger scale means larger rearing facilities, and for larger facilities production control becomes critical and potentially more difficult. There are also greater opportunities for automation, reducing labour costs, variability, and the likelihood of microbial contamination from the staff employed in the facility (Abd-Alla et al., this volume). Environmental control systems are very important, and their design must take into account the amount of insect biomass producing heat (Oborny 1998). These are also amenable to increased automation, with networked monitoring of temperature, humidity, and light as is done in the codling moth *Cydia pomonella* (L.) rearing facility in Osoyoos, Canada (Dyck 2010). In an interesting approach to process control, air space volatiles were monitored for changes that would indicate changes in the rearing parameters (Hedin et al. 1975).

The specific nature of the SIT requires that the product, i.e. reared insects, mate with the wild population, and mating behaviour tests are critical (Parker, Vreysen et al., this volume). Several of the techniques used to measure these behaviours under semi-natural conditions in tephritid fruit flies (FAO/IAEA/USDA 2019) have been adapted for tsetse flies (Mutika et al. 2001). However, monitoring itself does not correct rearing problems. Each rearing facility should develop standard operating procedures (SOPs) for rearing operations, quality-control operations, and finally responses to adverse quality-control findings (FAO/IAEA 2018b).

Effective data management is a vital component to allow managers of large-scale mass-rearing to take appropriate and timely decisions (FAO/IAEA 2018b). Akey et al. (1984) reviewed data processing, and modern computer systems have further simplified data collection and analysis. As rearing becomes commercialized, customers will require up-to-date information on insect status and quality control, and this information could be made available via the Internet.

Finally, a factor not unique to the SIT, but more prominent with increased centralization of rearing, is the issue of transboundary shipment. To date, there is no explicit regulatory framework for the transboundary shipment of sterile insects, but this issue is currently being addressed (Enkerlin and Quinlan 2004; Dowell et al., this volume; Dyck, Reyes Flores et al., this volume). In this context, the existence and careful documentation of a comprehensive quality-control system will be important (FAO/IAEA/USDA 2019).

## 7. AUTOMATION OF REARING

The scale of rearing for the SIT naturally lends itself to some degree of automation. Rearing systems vary greatly in their sophistication, from largely manual (tsetse fly (IAEA 2003), New World screwworm (Scott et al. 2017)) to highly sophisticated (pink bollworm, melon fly) systems. The balance between labour and automation depends on many factors, but the chief one is the cost of labour. In areas with low-labour costs, the drive towards automation will be reduced, but in high-wage areas, e.g. Japan, automation is essential to reduce costs (Nakamori et al. 1992). Other reasons to automate include: (1) reduction in human error, with increased product performance and consistency, (2) reduction in microbial contamination from personnel, and (3) increased space utilization efficiency, resulting in lower costs — for building and for energy for environmental control (Cáceres et al. 2012).

Another aspect of automation is in climate-control systems. Air-handling is essential to control temperature and humidity (Schneider 2009), reduce airborne particulates and microbial contamination of the colony, and reduce medical problems of the staff (Reinecke 2009). Klassen (1978), Sikorowski et al. (1983), Harrell and Gantt (1984), Opiyo et al. (1999, 2000), Smith (1999), Smith and Nordlund (1999), Maïga et al. (2016, 2017), and Mamai et al. (2019) reviewed aspects of mass-rearing automation. For almost all stages of the process, descriptions of automated systems are available — egg collection (Leppla et al. 1974; Carlyle et al. 1975; Pearson et al. 2002), diet preparation and dispensing (Grisdale 1973; Gantt and King 1981; Miller et al. 1996), larval holding and pupal harvesting (Hartley et al. 1982), and environmental-control systems (Oborny 1998; Peng and Ohura 2000). Automation in mosquito mass-rearing is covered in more detail in Lees et al. (this volume).

## 8. DIET

Diet is probably the single most important component of rearing and, with labour, constitutes the main cost. Therefore, it is in the interest of insect-rearing programmes to improve the performance or reduce the cost of the diet. A balance has to be achieved between cost and performance of the insects; in the long run, a cheap diet that produces less competitive insects may prove more expensive. Chaudhury (2009) and Cohen (2015) reviewed all aspects of nutrition, feeding, and diet development.

Diets for many insects have been described in the literature (Smith 1966; King and Leppla 1984; Singh and Moore 1985; Gerberg et al. 1994; Ochieng'-Odero 1994a; Morales-Ramos et al. 2014; Skoda et al. 2014; Bimbilé Somda et al. 2017; FAO/IAEA 2017a, b, 2019a; Moadeli et al. 2017), with a gradual progression from natural-host materials towards synthetic and defined diets (Singh 1984; Moore 1985; Shimoji and Yamagishi 2004). A natural-host diet is limited by the availability of the host, which may be seasonal or limited in distribution, and variable in quality. It tends to be expensive, but should provide a complete diet and avoid changes in host-location behaviour. Semi-synthetic, synthetic, and defined diets offer the convenience of shelf storage and consistent product, but risk being deficient in one

or more factors. Often natural-host material needs to be incorporated into the diet for initial colonization, but then can be removed gradually as the colony adapts. Generalist herbivore insects tend to be the easiest to feed, with specialist herbivores, predators, and parasites being more difficult. Singh (1985) worked on a range of diets suitable for several to many species, even across different orders. However, even though general diets are unlikely to provide optimum nutrition and cost, they do act as a good starting point for developing diets for newly colonized species.

Future diet development will concentrate on utilization efficiency, ease of storage, cost, and availability (Aceituno-Medina et al. 2020). Defined diets may become important, but the highly refined ingredients may be expensive, and thus semi-defined diets utilizing cheaper local raw materials are more likely to be useful.

Research on fruit flies is investigating liquid diets, which increase utilization efficiency and ease disposal problems, and offer the possibility of recycling the diet by removing waste products and replacing only the nutrients that have been consumed (Fay and Wornoayporn 2002; Chang et al. 2004, 2006). Insects such as the yellow mealworm *Tenebrio molitor* L., house fly *Musca domestica* L., and black soldier fly *Hermetia illucens* (L.) are under investigation for their potential to be used as feed for mosquitoes (Bimbilé Somda et al. 2019). Nutrigenomics offers a powerful method for determining if specific diet components are deficient or in excess (Coudron et al. 2006).

### *8.1. Diet Cost*

The first step in reducing the cost of a diet, which was not designed specifically for the species, is to remove unnecessary components. The next stage is to identify local agricultural products and industrial by-products (e.g. brewer's yeast, sugar cane bagasse) or standard commercial products that are cheap (Chaudhury et al. 1998, 2000; Cohen 2000; Shimoji and Yamagishi 2004), and provide the necessary nutrition and physical properties without adverse effects on the development, quality, and reproductive capacity of the insect (Gilles et al. 2011; Damiens et al. 2012, 2013; Khan et al. 2013; Yahouédo et al. 2014; Bimbilé Somda et al. 2017; Epopa et al. 2018). Often utilizing local components will also make the supply more secure.

Minor components of the diet frequently contribute a disproportionate amount to the cost. For example, many diets are gelled with agar, but agar is very expensive; several alternatives (as partial or complete replacements of agar) have been investigated (Leppla 1976; Spencer et al. 1976; Harris et al. 1984; Taylor et al. 1991; Honda et al. 1996; Chaudhury and Alvarez 1999). Such minor (by weight) components are important in controlling both the consistency and water retention of the diet; water is a crucial component that influences all stages of egg, larval, and pupal development.

Mechanical handling and processing of diet can also reduce costs, e.g. in the former pink bollworm *Pectinophora gossypiella* (Saunders) rearing facility in Phoenix, Arizona, USA, diet was processed and sterilized in a twin-screw extruder (Edwards et al. 1996; Miller et al. 1996). The application of agricultural-engineering

and food-processing techniques promises to produce significant further improvements (Cohen 2015).

### *8.2. Diet Quality*

It is important to ensure the quality of diet ingredients before purchase or use, e.g. by monitoring the physical and chemical variability of the ingredients, bacterial load, and any insecticide residues, and using bioassays to assess its impact on insect development, production, and quality parameters. Poor quality control of diet ingredients is a major problem in mass-rearing, and therefore requires attention, including specifying chemical and biological assays that the ingredients must pass. In the end, a cheaper ingredient may in fact be more expensive due to frequent "crashes" in production caused by low-quality ingredients.

In AW-IPM programmes that integrate the release of sterilized insects, the availability of an irradiator means that diet components can easily be decontaminated. In rearing tsetse flies, the bacterial load of the blood diet (FAO/IAEA 2019a) is critical, and can be reduced through irradiation (Feldmann 1994). Bacterial contamination of wheat bran used in an uncooked diet for rearing the carob moth *Ectomyelois ceratoniae* (Zeller) can also be reduced by irradiation.

### *8.3. Additives to Diets*

Additives to larval or adult diets can have a profound effect on the performance of insects (Augustinos et al., this volume; Dowell et al., this volume; Pereira et al., this volume). Supplementing boll weevil *Anthonomus grandis grandis* Boheman diet with beta-carotene increased dispersal and trap response (Reinecke 1991). In *An. arabiensis* mosquitoes, a vitamin mix (used as an additive) significantly decreased larval development time (Damiens et al. 2012).

Feeding methyl eugenol to adults of the oriental fruit fly *Bactrocera dorsalis* (Hendel) reduces the time to sexual maturity and the catch of sterile males in methyl-eugenol-baited traps (Shelly and Dewire 1994). Other minor components, that can be added to the adult diet or applied directly to modify the behaviour of released insects, are being identified (Papadopoulos et al. 2001; McInnis et al. 2002; Shelly et al. 2002; Lance and McInnis, this volume).

### *8.4. Micro-Organisms in the Diet*

Control of disease in the colony, and of micro-organism contamination of the diet, are intimately linked (Abd-Alla et al., this volume). The identification and control of microbiological contaminants have been reviewed by Sikorowski (1983), Goodwin (1984), Sikorowski and Goodwin (1985), Sikorowski and Lawrence (1994), and Inglis and Sikorowski (2009a, b). Apart from immediate mortality, microbial contamination can lead to changes in development, body composition, and susceptibility to insecticides (Sikorowski and Goodwin 1985). Control begins with preventing infection by appropriate handling techniques and sterilization of

ingredients, as well as surface sterilization of eggs or pupae (Leppla et al. 1974). A wide range of antimicrobial compounds for insect diets has been tested (Gifawesen et al. 1975; Ludemann et al. 1979; Hartley et al. 1982; Funke 1983; Bathon 1977), but many are unsuitable, and none is suitable for all insect species. Alverson and Cohen (2002) found that some of the most common ones have a significant negative impact on rearing *Lygus hesperus* Knight. Other means of microbial control include irradiation and various forms of heat treatment.

Conversely, it is now recognized that many micro-organisms are important for many aspects of the biology of their hosts. It has been shown in fruit flies that probiotic application of *Enterobacter* sp. resulted in improvement of both pupal and adult productivity, as well as reduced rearing duration, particularly for males, without affecting pupal weight, sex ratio, male mating competitiveness, flight ability, and longevity under starvation (Augustinos et al. 2015; Yao et al. 2017; Cáceres et al. 2019; Stathopoulou et al. 2021). Kyritsis et al. (2017) described two bacterial isolates, an *Enterobacter* sp. (strain AA26) and a *Klebsiella oxytoca* strain, that were used as probiotics in larval and adult diets. These strains have been shown to be beneficial, affecting several aspects related to the rearing efficiency and biological quality of the Mediterranean fruit fly VIENNA $8^{D53+}$ genetic sexing strain, but other work did not find consistent benefits from probiotic diets (Niyazi 2004; Sacchetti et al. 2014), indicating that controlling the specific species and strains of micro-organisms in the diet and their concentrations will be important (Augustinos et al., this volume).

## 9. SEX SEPARATION

In the SIT, released sterile males mating with wild females produce the only sterilizing effect. If sterile females are also released, they can have (depending on the species) an additional positive effect by distracting wild fertile males and acting as a "sperm sink". However, usually the simultaneous release of both sexes is less economical, and also less effective, than the release of only males, because there may be a tendency towards assortative mating (Robinson et al. 1999). In haematophagous disease vectors, the females are usually the vectors, and must be removed prior to release (Lees et al., this volume).

In most insects, the sexes can be separated on the basis of external morphology, but this may be possible only in the pupal or adult stages, and may be difficult to automate. For example, in programmes that release sterile male tsetse flies, teneral adult flies are usually hand-sorted in a chiller to separate the sexes, a very slow and laborious procedure. Research showed that a computer-based optical recognition system was too slow and too prone to error to be useful, but recent work on separating pupae according to sex by near-infrared imaging shows promise (Moran and Parker 2016). In many insects, e.g. some mosquitoes (Gerberg et al. 1994; Zacarés et al. 2018) and Lepidoptera, sexual dimorphism in size (apparent in the pupal stage) can be used to separate the sexes, but overlap in size (in some species) may render the sorting inefficient. In some insect groups, pupae show genitalia characters that identify the sex, but these are difficult to observe, require hand-sorting, and have not been automated. Spiking blood meals with ivermectin has

shown potential as a viable treatment to eliminate female *An. arabiensis* from laboratory colonies, but its practical use in a mass-rearing facility still needs to be tested (Yamada et al. 2013).

The sexes often show a variation in developmental rate, and this can sometimes be used to separate them. Female tsetse flies emerge first and, by manipulating temperature conditions during pupal development, sex separation based on the timing of adult emergence is possible (Opiyo et al. 1999, 2000); in some species the efficiency was more than 99%, and eliminated laborious hand-sorting work in a chiller. Protandry in mosquitoes results in males pupating/emerging before females, and larvae, male and female pupae can be separated using mechanical sexing tools (Focks 1980) or by using sieves of different mesh size. Automated systems using the difference in size between male and female pupae are currently under development to sort *Aedes* mosquitoes (Zacarés et al. 2018; Lees et al., this volume). Recent coordinated research (Bourtzis and Tu 2018) explored methods for sex separation in mosquitoes (Bellini et al. 2018; Kittayapong et al. 2018; Mashatola et al. 2018; Papathanos et al. 2018).

Various methods to separate the sexes, based on Mendelian genetics or engineered sex-linked mutations, have been developed (Robinson and Franz 1999; Robinson et al. 1999; Marec et al. 2005; Zepeda-Cisneros et al. 2014; Dandalo et al. 2018; Häcker and Schetelig 2018; Lebon et al. 2018). These systems, together with other genetic developments, are discussed by Franz et al. (this volume), Häcker et al. (this volume), and Lees et al. (this volume).

## 10. MARKING

To mark or not to mark sterile insects for release, that is the question. It is usually assumed that marking is essential for field monitoring of sterile to wild ratios so as to follow programme progress, but the hugely successful New World screwworm eradication programme (Klassen et al., this volume; Vargas-Terán et al., this volume) has never used any form of marking. Progress is monitored by measuring egg-hatch rates, and such a method may work for some of the other target insects as well (Vreysen, this volume). No one method of marking is universally applicable, and all may have negative effects on the insects (Dowell et al., this volume; Hendrichs and Robinson, this volume; Vreysen, this volume).

Methods of marking were reviewed by Hagler and Jackson (2001); the various individual marking systems, including numbering and coding systems, are clearly not appropriate for production levels of hundreds of millions per week. Methods appropriate to mass-rearing include dye marking (that can be observed directly or with a simple UV system), chemical marking that requires some form of instrumentation for detection, and genetic markers.

For any marking technique, quality control of the marking — detecting and rapidly correcting any failure of marking — is important (Enkerlin et al. 1996; Kohama et al. 2003). The misidentification of a released sterile insect as a fertile insect can have huge financial consequences for an AW-IPM eradication programme, justifying both the commitment of significant resources to, and great care in, the marking.

### *10.1. Dye Marking*

Dye marking falls into two categories, internal dyes fed through the larval or adult diet, and external dyes. Internal dyes are usually oil-soluble; considerable testing of dyes has been done (Vail et al. 1966; Hendricks and Graham 1970; Graham and Mangum 1971; Hendricks 1971). It was found that a dye suitable for one species is not necessarily appropriate for even a closely related species. The ease of administering the dye in the diet makes this system very attractive, but the disadvantages are that the dyes can be toxic or cause behavioural or other changes (Schroeder et al. 1974) and may not persist in later stages; also, it is relatively difficult to identify a series of different markers. Nevertheless, the dye Calco Red has been used extensively for marking Lepidoptera, e.g. pink bollworm and codling moth. Rhodamine B has been shown to be a less expensive and a viable body-marking technique for *Aedes aegypti* (L.) without the negative side effects of traditional marking methods (Johnson et al. 2017).

Almost as extensively, external dye marking has frequently been used in AW-IPM programmes that release sterile insects. Usually this involves a fluorescent dye that is dusted or sprayed onto the insects (Chang 1946; Taft and Agee 1962; Stern and Mueller 1968; Schroeder and Mitchell 1981; Reinecke 1990; Enkerlin et al. 1996; Verhulst et al. 2013), but oil-soluble dyes have also been used for external marking (Steiner 1965; Schroeder and Mitchell 1981). The procedure is simple to apply; several different colours and dyes can be used. The impact of externally applied dyes on the behaviour or longevity of insects is variable (Nakata 2008; Reid and Reid 2008; Dickens and Brant 2014); it has been reported that excessive dye may reduce the response of codling moth males to calling females (Logan and Proverbs 1975). There is evidence that reducing the quantity of dye used can significantly increase survival and quality in fruit flies. The disadvantages of using external dyes are that an additional processing step is involved, the dyes may affect insect quality, the marker may not be as reliable as an internal one, and the dye dusts can pose a health hazard to staff.

### *10.2. Elemental Markers*

An alternative to dye marking is using elemental markers (reviewed by Akey 1991 and Akey et al. 1991). Three forms of detecting elemental marking utilize radioisotopes, neutron activation, or one of several forms of atomic spectroscopy (Akey and Burns 1991) or isotope ratio mass spectrometry (Heiling et al. 2006). Elemental fingerprinting may also be included here — detecting the ratios of unsupplemented elements that will vary between field populations and mass-reared insects (Hood-Nowotny et al. 2009). Due to environmental concerns, radioactive-isotope marking has fallen out of favour. Neutron activation of rare elements is a very sensitive technique; in principle it is able to detect picogram quantities (Curtis et al. 1973; Hamann and Iwannek 1979), but the need for a fast-neutron source makes the technique extremely expensive and impractical.

Atomic absorption spectroscopy of stable isotopes offers a much more accessible technique (Akey 1991; Stimmann 1991; Van Steenwyk 1991; Fernandes et al. 1997;

Maciel-de-Freitas et al. 2004; Wilkins et al. 2007). Different forms of spectroscopy can be used to identify the marker with varying levels of sensitivity (Akey and Burns 1991). For a programme that releases sterile insects, the cost of false positives is potentially so high that the additional equipment and procedure may well be justified, particularly in the later stages of eradication, and elemental marking could provide a valuable second means of identification to back-up dye marking.

Hood-Nowotny et al. (2006) suggested that it was possible to use an isotopic label in adult *An. arabiensis,* and to detect it at an appropriate concentration up to 21 days post-emergence; however, the optimum labelling treatment would cost about USD 250 per million mosquitoes. Enrichment of semi-natural mosquito larval habitats with stable isotopes of nitrogen and carbon resulted in effective marking of *Anopheles* and *Aedes* mosquitoes colonizing these habitats (Opiyo et al. 2016).

### *10.3. Other Markers*

An interesting development in chemical marking is the use of non-insect protein markers (Hagler and Cohen 1990; Hagler et al. 1992; Hagler and Miller 2002; Hagler 2004). The technique has been tested using rabbit IgG, fed in the diet or applied externally, and detected by sandwich enzyme-linked immunosorbent assay. The technique looks promising, requires only simple laboratory equipment, and rapid application should be possible. A big advantage is that the mark is completely invisible, and should have no biological effect on insects. Protein marking can be combined with dye marking to increase the marking efficacy (Irvin et al. 2012).

To distinguish released insects from wild ones, naturally occurring phenotypic mutations can be used in a similar manner to dyes, as long as the mutation is sufficiently rare in the wild population (Bartlett 1982). However, almost certainly, most mutations have some deleterious effect. For the SIT, the disadvantage is often not so great that their use is prevented, and a few such mutations have been investigated or used (Fay and Craig 1969; Schroeder and Mitchell 1981; Niyazi et al. 2005). The main problem with mutations is that, since they cannot be transferred between species by conventional genetics, they must be identified for each species to be marked.

Most mass-reared insect colonies have a limited genetic basis, resulting in limited genetic diversity. This can be exploited to distinguish colony insects from the target population, by identifying natural DNA markers specific to the colony or target insects. Mitochondrial DNA markers were used in South Africa to distinguish wild from released sterile insects (Barnes et al. 2004), but for identification this technique requires the use of polymerase chain reaction (PCR) amplification.

Once again, genetic engineering offers the prospect of new marking techniques (Häcker et al., this volume; Hendrichs and Robinson, this volume). In principle, any transgenic insect carries an identifiable marker (the transgenic construct), but for identification this also may require PCR amplification. It would be easier to use a gene that encodes a visible product. At present, the most popular genes are green fluorescent protein (GFP) and its derivatives (Peloquin et al. 2000), and DsRed (Alphey 2002). Fluorescent markers can be made sperm-specific to enable the sperm to be identified in mated field females (Scolari et al. 2008). Such transformations, if

carefully constructed, should avoid most of the disadvantages of natural mutation markers.

## 11. STORAGE

Successful field operations using the SIT require a timely and predictable supply of sterile insects, and this can present logistical problems. There is usually a premium on the release of sterile insects at the beginning of the target population build-up, before the population level becomes too large, but colony rearing may be constrained by diapause or hibernal quiescence. Also, for a seasonal pest, to save on costs, the rearing must be reduced to a maintenance level during the winter, but this is an inefficient use of the facility. In an ideal situation, the rearing would be continuous, with some means to stockpile the insects over winter in preparation for release in the spring, e.g. onion maggot *Delia antiqua* (Meigen) (Loosjes 2000). For these reasons, the ability to store insects, and to manipulate quiescence or diapause, becomes very valuable (FAO/IAEA 2016). For shorter timescales, storage for a few days may be useful to synchronize insects for periodic release, and storage in a quiescent state for a period of hours may be desirable for delivery to the release site and for the release process itself. Leopold (1998, 2000) reviewed cold storage and cryopreservation of insects for each of these timescales.

Insects with an obligate or facultative diapause may be of better quality than non-diapause individuals (Bloem et al. 1997, 1998, 2000) and, assuming diapause termination can be controlled, form a convenient way of storing insects. Denlinger (2002) reviewed the regulation of diapause. Obligatory diapause in a one-generation-per-year species, e.g. western cherry fruit fly *Rhagoletis indifferens* Curran (Vankirk and Aliniazee 1982), may make continuous rearing impossible. The main aim is to find a means to induce and then break diapause early to permit the production of sterile insects in advance of the field population. The duration of induction, diapause, and breaking of diapause may last many months, and present a formidable obstacle to successful incorporation into the rearing system. The obligate duration of some of the cues may be circumvented by the application of hormones, and certain volatile organic solvents can influence the termination of diapause (FAO/IAEA 2016).

The exposure of insects to low temperature often results in damage. Denlinger and Lee (1998) as well as Sømme (1999) reviewed the physiology of cold damage. Below 0˚C the main threat to an insect is ice formation, but a range of hysteresis proteins, cryoprotectants, and stress proteins, and the elimination or masking of nucleating proteins and bacteria in freeze-susceptible species, lower the super-cooling temperature below that likely to be experienced. Without freezing, osmotic stress is minimized. In freeze-tolerant species, nucleating proteins induce rapid freezing at higher temperatures, and osmotic stress is countered mainly by cryoprotectants.

Diapausing insects often exhibit inherent cold tolerance. Also, in many non-diapause insects, it is possible to induce cold tolerance by exposing the insects to heat or less extreme cold before storage, producing so-called “rapid cold hardening” in a matter of minutes or hours (Lee et al. 1987; Denlinger et al. 1992; Rinehart et al.

2000; Chidawanyika and Terblanche 2011; Nyamukondiwa et al. 2013). Cold or heat shock induces the production of specific stress proteins, commonly called heat-shock proteins (HSPs), which among other effects are thought to prevent protein denaturation (Parsell and Lindquist 1993). The rapid production of HSPs makes them useful for short-term storage, shipment, and release, but their effect can be longer term, and can be re-induced by brief warming to higher storage temperatures (Chen and Denlinger 1992). In the future, it may be possible to genetically engineer desirable traits to enhance the storage potential of a mass-reared strain (Robinson and Franz 1999).

Finally, during colonization and rearing, insects are subject to selection pressure of varying intensity that can result in rapid genetic drift and loss of heterozygosity. Cryopreservation provides a method for long-term storage of genetic material with specific desirable traits, and the storage of strains where diapause or conventional cold storage is not possible (Leopold 1998, 2000; Rajamohan et al. 2003, 2014; Rajamohan and Leopold 2007). Where it is possible, cryopreservation may reduce the labour and cost of maintaining continuously many strains.

## 12. ACKNOWLEDGEMENT

We thank J. Bouyer for providing information on methods of rearing mosquitoes.

## SUMMARY

Effective management of insect pathogens in insect mass-rearing is fundamental to the successful implementation of area-wide integrated pest management programmes (AW-IPM) with a sterile insect technique (SIT) component. Insect pathogens, notably viral pathogens, affect the sustainable production of high-quality males for the SIT, either by compromising colony establishment and stability or by reducing insect performance, including mating and flight ability. Many pathogenic bacteria, fungi, microsporidia, spiroplasma/mycoplasma and viruses can infect insects. Due to the broad subject of insect pathology, only the pathogens affecting insect mass-rearing facilities producing sterile insects are discussed here, with a special focus on tsetse flies, mosquitoes and codling moth viral pathogens. Special emphasis is given to the successful management of the tsetse salivary gland hypertrophy virus (SGHV), the current management of the codling moth granulovirus (CpGV), and the risk of infections of mass-reared mosquitoes with pathogenic viruses and other vector-borne diseases. Also discussed are the potential risks posed by these pathogens to staff working in mass-production facilities.

## 1. INTRODUCTION

For centuries, the main goal of organized insect mass-production was to provide reliable and cost-effective sources of high-quality insects for numerous important purposes (Parker, Vreysen et al., this volume). Recent purposes of insect mass-rearing include: (1) release of sexually sterilized males as part of sterile insect technique (SIT) applications (Parker, Mamai et al., this volume), or of genetically modified insects, for the suppression/eradication of target insect pest populations, (2) augmentative releases of parasitoids, predators or pollinators to control target pests or pollinate target crops, (3) application of insects as hosts for the production or dissemination of microbial control agents, (4) use of insects as food and feed (Van Huis 2013; Van Huis et al. 2013; Vantomme et al. 2014; Dossey et al. 2016), and (5) production of economic products such as honey, silk (Needham et al. 1937) and cochineal dyes (Greenfield 2005). Insects are also mass-reared for research and industrial purposes, e.g. the production of chemical components used in cosmetics, medicine for human therapy, and the production of biofuels (Dickerson and Leppla 1992). Additionally, insects are mass-reared for use in celebrations, as pets or objects of interest, and in conservation programmes for endangered or threatened species (Resh and Cardé 2003).

To control insect pests of agricultural or medical importance, various methods including the SIT are used (El-Wakeil and Abdallah 2012). When applied within the concept of area-wide integrated pest management (AW-IPM), the SIT is a proven, effective and environment-friendly tool. This method has been successfully applied to control several insect pests around the world (Goodenough et al. 1983; Klassen et al., this volume). Efficient and effective mass-rearing of the target insect is a fundamental prerequisite when applying the SIT (Dyck 2010). For some purposes, e.g. as hosts for biological control agents or as food and feed sources, mass-rearing of large quantities of the insect is the main objective. However, when producing insects for release into the field where they have to perform a specific task, obtaining high-quality insects is paramount; in the case of the SIT the released sterile males must outcompete wild males in mating with wild females (Parker, Vreysen et al., this volume; Vreysen, this volume). Therefore, high standards must be implemented when producing insects for the SIT. However, microbial agents often compromise insect rearing, representing a major risk and challenge for managers of mass-rearing facilities. Consequently, an essential component to achieve high insect quality is investing sufficiently in expertise and infrastructure to manage effectively and control all potential insect pathogens.

The biological control of insect pests using microbial control agents applied in an augmentative way is a sustainable and environment-friendly tool (Hoffmann and Frodsham 1993; Lacey et al. 2001). Currently, approximately 50 agents, including entomopathogenic viruses, bacteria, fungi and nematodes, are commercially produced; this represents ~1–2% of the global pesticide market (Gallai et al. 2009; Lacey et al. 2015). One of the limitations of using biological control is the mandatory *in vivo* production in the insect hosts of all viruses and some of the other microbial agents. This *in vivo* production system must be highly efficient and economical for the large-scale production of sufficient numbers of the insect hosts, and plays a role in determining the success and the market competence of the biocontrol methods.

In addition to the important role of insect mass-rearing in pest control, in the agricultural sector insects are reared also for other economic reasons. The honeybee *Apis mellifera* L. is important not only for honey production, but also for other products like beeswax (Calderone 2012). More importantly, as the primary plant pollinators, honeybees enhance landscape diversity and are fundamental to the pollination of many agricultural crops, with a worldwide annual value of USD 153 thousand million; in the United States alone the annual value is estimated at USD 17 thousand million (Cohen 2004, 2015; Roeder et al. 2010).

## 2. MICROBIAL DISEASES AND INSECT MASS-REARING

The microbial contamination of artificial insect diets, particularly by moulds, fungi and bacteria, is a common problem in insect mass-rearing. The rearing conditions for insects are also conducive for microbial growth, especially in the absence of antimicrobial products. For example, Roeder et al. (2010) reported that, in the absence of antifungal agents, within three weeks 40% of the artificial diets used to rear *Heliothis virescens* (F.) larvae were contaminated with microbes. The control of

microbial agents is essential to reduce their negative impact on reared insects and to maintain healthy insect colonies (Alverson and Cohen 2002). Generally, antibacterial and antifungal compounds are ingredients of insect diets to control the microbial contamination. However, many of these compounds can be quite toxic to insects, even at low concentrations (Roeder et al. 2010; Cohen 2015). For example, as the concentration of methylparaben (a common antifungal agent) increases in the diet, it significantly reduces the insect colony's performance (Shikata et al. 1998). Finding the right combination and doses of compounds to fight microbial growth, while at the same time reducing or eliminating any negative effects that these antimicrobial compounds have on the reared insects, can be quite challenging (Cohen 2015).

### *2.1. Bacterial Diseases*

Many types of bacteria can be associated with insects, including saprotrophic facultative parasites and obligate parasites. In insect mass-rearing, many pathogenic bacteria have been reported, but here the focus is on the bacterial diseases found in mass-rearing insects that are used for SIT projects. These insects include various species in the orders Diptera, Lepidoptera, Hymenoptera and Coleoptera.

Bacteria encountered in insectaries are usually innocuous. However, for insects exposed to stressors such as a change from natural to artificial diets, and exposure to elevated temperature and humidity, high density (overcrowding) and toxins, bacteria can multiply extensively within the bodies of insects with a weakened immune system, causing diseases that may be severe or even fatal (Sikorowski and Lawrence 1994). For example, some genotypes of *Bacillus sphaericus* produce insecticidal toxins that are active against mosquito larvae (Boucias and Pendland 1998).

In *Helicoverpa zea* (Boddie), contamination with certain bacterial species, e.g. *Pseudomonas maltophilia* and *Bacillus subtilis*, significantly affects larval mortality, pupal weight, larval and pupal deformation, egg production, and egg hatch. In the absence of antibiotics, *Serratia marcescens,* a highly contagious bacterium, can rapidly bring a moth rearing programme to a virtual standstill. Furthermore, these bacteria can cause sub-lethal infections, significantly compromising insect vigour (Sikorowski and Lawrence 1991).

In fruit flies, some bacteria could cause significant problems. For example, the gram-negative bacteria *S. marcescens* and *P. aeruginosa* can overwhelm Caribbean fruit fly *Anastrepha suspensa* (Loew) larvae and pupae when they are stressed, e.g. exposed to thermal stress by rearing at a temperature >30°C (Greany et al. 1977).

In rearing tsetse flies, bacterial contamination is crucial, and can cause a high abortion rate and high mortalities; this underscores the importance of precautionary measures taken during blood collection and storage, and during the feeding process, including irradiating and freezing blood, and conducting bioassays before exposing colonies to new batches of blood (Feldmann 1994). Although certain species of tsetse flies are more sensitive to bacterial contamination than others, according to Wetzel and Thiemann (1979) *Glossina m. morsitans* Westwood adult flies were more sensitive to *P. aeruginosa* bacterial contamination than adults of *G. p. palpalis*

Robineau-Desvoidy; adults of the latter eliminated a bacterial infection at nine days post-ingestion, but *G. m. morsitans* adults required 14 days to clear the infection.

The best way to avoid bacterial contamination in mass-rearing is to maintain sanitary conditions (Inglis and Sikorowski 2009a, b). When using the membrane feeding technique in tsetse fly mass-rearing, this means applying prophylactic measures, i.e. working in aseptic conditions with sterile feeding membranes, aluminium trays and blood. Using sanitation protocols when rearing the Caribbean fruit fly *A. suspensa* avoided the negative impact of bacterial contamination with *S. marcescens* and *P. aeruginosa* (Greany et al. 1977). As a precaution, mass-rearing facilities often include either antibiotics, e.g. chlortetracycline, antifungals, e.g. nipagin and benzoic acid, or formalin as a general antimicrobial in adult and larval diets (Cohen 2015).

When sanitation is practised and antibiotics are available, bacterial contamination in insect mass-rearing is rare. However, it is important to note that prolonged application of antibiotics may lead to resistant bacterial strains. The wise use of antibiotics is not a substitute for, but a complement to, good sanitation for disease control (Sikorowski 1984).

### *2.2. Fungal Diseases*

There are many species of fungi that infect insects, e.g. species in the genera *Aspergillus, Beauveria, Entomophaga, Entomophthora, Hirsutella, Metarhizium, Nomuraea, Paecilomyces* and *Penicilium*. Species of *Entomophthora* have a worldwide distribution, and play effective roles in controlling many insects of economic importance in the orders Hemiptera, Homoptera, Diptera, Lepidoptera, Coleoptera, Orthoptera and Hymenoptera (MacLeod 1963; MacLeod and Muller-Kogler 1973). Fungi are unique among insect pathogens in that they infect their hosts primarily through the cuticle, although a few taxa may invade through the host's alimentary canal. By simple contact, dissemination of the infection among the individuals of a colony occurs rapidly. Due to the spread of fungal spores by wind and rain, fungal diseases can occur in field-collected insects. This scenario was reported for grasshoppers, where *B. bassiana* caused 90% mortality (Inglis and Sikorowski 2009b).

In general, fungus infection is humidity-dependent, a condition which is usually found in large-scale insect mass-production facilities where artificial diets are used. Furthermore, holding large numbers of insects in a limited space (for economic or convenience reasons) facilitates the spread of fungal diseases. In addition, many saprophytic species such as *Aspergillus* and *Penicilium* spp. growing on the artificial diet might be facultative pathogens, requiring the use of an antifungal compound to avoid infection. The use of fungicides to control fungal infections is a prerequisite for mass-rearing some insect species.

Some fungi such as *Aspergillus flavus* produce aflatoxins, among the most potent carcinogenic compounds; this can be a major health issue for workers in mass-rearing facilities. Also, fungi are health risks -- breathing hazards and possible contamination via the skin, eyes, and nasal passages (Burgner et al. 1998; Revankar et al. 1999; Butt et al. 2001).

### *2.3. Protozoan, Microsporidia and Mycoplasma/Spiroplasma Diseases*

Most of the entomopathogenic protozoa and microsporidia (thought to have evolved from a fungus (Keeling et al. 2000)) produce chronic, non-lethal infections that reduce the host reproduction (Hurd 1993). These pathogens also cause irregular growth, loss of appetite and malformed larvae, pupae or adults with reduced vigour, fecundity and host lifespan. Although microsporidia have been reported to infect all insect orders, the majority of genera occur in dipteran hosts, which represent an important challenge when applying the SIT to insect disease vectors such as tsetse flies and mosquitoes, and to fruit flies. Microsporidia infection can occur in three different ways: (1) *per os*, through feeding on spore-contaminated food or on dead or moribund insects, (2) transovarially from a female to her offspring on or in eggs (which includes newly hatched larvae feeding on the egg chorion), and (3) directly through the insect cuticle. In certain cases, e.g. *Helicoverpa zea*, all offspring of microsporidia-infected females are infected. In addition, in a lepidopteran insectary, microsporidia spores may be disseminated via moth scales. Once ingested by an insect host, microsporidia spores germinate in the midgut and infect midgut tissue and hemocytes. The severity of the infection is dependent on the number of ingested spores, temperature and larval age. Ingestion of a large number of spores usually causes mechanical damage to the peritrophic membrane and midgut epithelium, thus allowing the ingress of bacteria present in the gut lumen. In such cases, the infected insects soon die. Although the ingestion of small numbers of spores does not kill the host insect, this causes a chronic infection (Inglis and Sikorowski 2009b).

### *2.4. Entomopathogenic Nematodes*

Infection with entomopathogenic nematodes in mass-rearing environments is a rare event. However, new insect colonies established using field-collected insects might be infected by nematodes. Although there are about thirty families of nematodes associated with insects, the majority of these are animal and plant parasites and use insects only as vectors. Nematodes that infect insects as primary hosts occur in seven families. Nematode infection causes sterility, reduced fecundity, development delay, aberrant behaviour, colour changes and host death. Most of the time the entomopathogenic nematodes do not reach adulthood in the hemocoel of the infected host. Rather, such nematodes emerge from the host as post-parasitic juveniles, moult to the adult stage, mate, and produce offspring (Kaya and Stock 1997). Infective juveniles directly penetrate the host's exterior integument using their stylets. Nematodes from the families *Steinernematidae* and *Heterorhabditidae* are obligate parasites of insects and carry mutualistic bacteria of the genus *Xenorhabdus* within their guts; once the nematodes gain access to the hemocoel, the bacteria are released into the hemocoel and kill the host within 24 hours (Kaya and Stock 1997).

### *2.5. Viral Diseases in Insect Mass-Rearing*

Viruses are among the agents that have a severe pathogenic impact on insect populations, both in the field and the laboratory. Viruses have been found to be responsible for epizootics in mass-reared useful insects, e.g. silkworm (Watanabe 1986), crickets (Szelei et al. 2011; Weissman et al. 2012) and honeybee (Chen and Siede 2007; Wilfert et al. 2016). Insects can be infected with DNA or RNA viruses. Of the approximately 100 families of viruses infecting eukaryotic organisms (ICTV 2017), 16 families of RNA viruses (Ryabov 2017) and 12 families of DNA viruses (Tijssen et al. 2016; Williams et al. 2017) infect several important orders of insects, e.g. Diptera, Lepidoptera, Hymenoptera, Coleoptera and Orthoptera. Some of these viruses are specific to arthropods (largely insects), e.g. families Dicistroviridae and Iflaviridae encompassing small RNA viruses, or families Baculoviridae, Nudiviridae and Ascoviridae encompassing large DNA viruses. Other RNA viruses (Nodaviridae and Reoviridae) or DNA viruses (Iridoviridae, Parvoviridae and Poxviridae) consist of genera, e.g. *Alphanodavirus, Cypovirus* and *Chloriridovirus*, or subfamilies, e.g. *Densovirinae* and *Entomopoxvirinae*, specifically pathogenic to insects, whereas other genera or subfamilies of these families infect vertebrates or humans but not insects. The honeybee is infected by at least 12 viruses belonging to five different virus families. In addition, some arthropod-borne viruses replicate both in their insect hosts and their vertebrate hosts. Examples include members of the virus families Bunyaviridae and Flaviviridae (Ryabov 2017).

Viral infections in insect populations can be symptomatic (with overt disease symptoms) or asymptomatic (hidden symptoms). While the former can result in the loss of fitness or death of the infected insects, the latter seems usually not to have fitness costs to the host. Cryptic latent virus infections are frequently observed in wild insect populations as well as in small- and large-scale laboratory colonies. Under certain unfavourable abiotic conditions, e.g. temperature and humidity, or biotic stress, e.g. increase in population density, shortage or change of food or accidental contamination of food, these hidden viral infections can be activated and soon result in outbreaks of epizootic infections (Tanada 1963; Weissman et al. 2012). However, the most frequent origin of viral outbreaks is the accidental introduction into laboratory colonies of individuals from other colonies (or collected from the field) that carry asymptomatic viral infections.

Until the discovery of several small RNA viruses in *Drosophila* species, several laboratories that use *Drosophila* as a model for genetic research have been working for years with colonies carrying hidden virus infections (Jousset et al. 1972; Teninges and Plus 1972; Plus et al. 1975). Further, the development of deep sequencing and metagenomic analysis tools has led to the rapid discovery of novel virus strains in asymptomatically infected insects. Examples include the honeybee filamentous virus with a genome of circular dsDNA of ca. 500 kbp in size (Gauthier et al. 2015), the small circular ssDNA of ca. 2 kb viruses (family Circoviridae) isolated from crickets, dragonflies and mosquitoes (Rosario et al. 2012; Pham et al. 2013; Garigliany et al. 2015), rhabdoviruses (Longdon et al. 2015) and endogenous retroviruses (Akkouche et al. 2012; Pelisson et al. 2002) of *Drosophilidae*. Hidden latent viral infections represent a major challenge for insect mass-rearing for the SIT because rearing for many generations under a high density might represent a stress

factor compromising the insect immune system and leading to the emergence of latent viral infections.

### *2.5.1. Viral Diseases in Lepidoptera*

Several lepidopteran species of economic importance are the targets in SIT projects (e.g. codling moth, false codling moth *Thaumatotibia leucotreta* (Meyrick), pink bollworm *Pectinophora gossypiella* (Saunders) and cactus moth *Cactoblastis cactorum* (Berg)) or the basis of industrial silk production (silkworm *Bombyx mori* (L)). Insects belonging to the order Lepidoptera are the hosts of many insect viruses, notably in the larval stages. Outbreaks of epizootics caused by viral agents of the family Baculoviridae were frequently reported to control natural dense populations of lepidopteran pests (Cory and Bishop 1997; Cory et al. 1997; Moscardi 1999; Fuxa 2004). Owing to their safety for humans and specificity in host range, usually limited to a single or a limited number of insects of the same species, these viruses are used for the biological control of several crop and fruit pests. On the other hand, baculoviruses represent a major problem for the mass-rearing of Lepidoptera used in SIT projects, e.g. the codling moth (Tanada 1964) or the silkworm (Summers 2006). More than 160 years ago the first insect viral infection, (i.e. baculovirus in the silkworm), was reported: in 1856 Cornalia and Maestri were able to associate the refractile occlusion bodies (now known as polyhedral) with the disease in silkworm (Summers 2006). The granulovirus CpGV in the codling moth was first reported in Mexico in 1964 (Tanada 1964). Currently, CpGV is widely used as a biological control agent to control this pest. On the other hand, strong measures to control CpGV are required to avoid a severe negative impact on the stability of the codling moth colony used for the SIT in the Okanagan Valley of British Columbia, Canada (section 3.2.). In addition to these two viruses, similar baculovirus infections have been reported in many other lepidopteran insects.

Densoviruses represent another major threat for the mass-rearing of Lepidoptera. These viruses are highly pathogenic to their hosts; they are responsible for epizootics in natural populations of some major lepidopteran pests, e.g. oil palm defoliators and sugar cane and corn borers, and in mass-reared insects used as pet food, e.g. crickets and the greater wax moth *Galleria mellonell*a (L.) (Fédière 2000; Bergoin and Tijssen 2010). The *Bombyx mori* densovirus (BmDV-1) is the causative agent of the infectious flacherie of the silkworm (Shimizu 1975), one of the most deleterious diseases in sericultural farms. As a result of a demonstration that the susceptibility of the silkworm to BmDV-1 varied from one strain to another, it was possible to select resistant strains (Eguchi et al. 1991).

### *2.5.2. Viral Diseases in Tsetse Flies*

In 1987 the first collapse of the *Glossina pallidipes* Austen colony, established at the FAO/IAEA Insect Pest Control Laboratory (IPCL) in Seibersdorf, Austria, occurred; it was caused by the salivary gland hypertrophy virus (SGHV) (Fig. 1). This colony was initiated from various batches (528 pupae) collected from the Lambwe Valley, Kenya, in November 1983. The colony was maintained and increased to a thousand productive females, but thereafter the colony stagnated at that level, having a low fly

emergence rate, high daily mortality (1.8% in flies older than 50 days), low fecundity (<1.1 pupae per female per month) and a low insemination rate (<85%). Microscopic examination of dissected flies revealed that up to 85% of males and 70% of females had hyperplastic salivary glands (Fig. 1). Males with hyperplastic salivary glands showed testicular degeneration and aspermia. These problems led to discontinuation of the colony in 1988 (FAO/IAEA 1987, 1988). Thereafter, a new *G. pallidipes* colony was established with insects originating in Tororo, Uganda, and donated by the Tsetse Research Laboratory, Bristol, England. However, the new colony was established and successfully maintained without an investigation of the cause of the collapse of the previous colony (FAO/IAEA 2006).

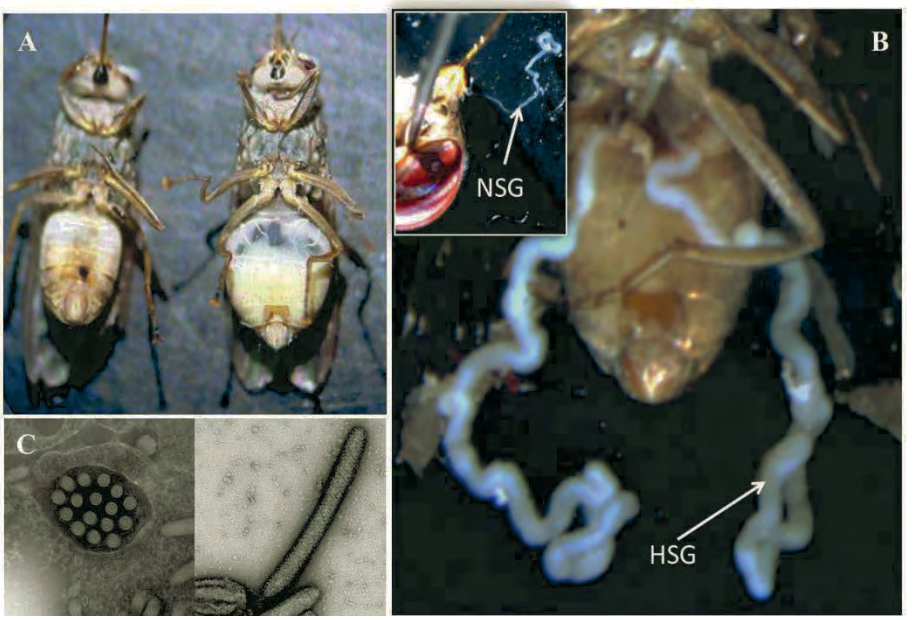

*Figure 1. Symptoms of* Glossina pallidipes *salivary gland hypertrophy virus (GpSGHV) in tsetse fly* G. pallidipes *males. (A) Males with asymptomatic (left) and symptomatic (right) infection (reproduced from Abd-Alla et al. 2009a, with permission from Elsevier); (B) Tsetse males with normal salivary glands (NSG) and hypertrophied salivary glands (HSG) (reproduced from Abd-Alla et al. 2013a, with permission from Elsevier); (C) Transmission electron microscopy (TEM) micrograph of GpSGHV virus particles (right), cross section (left). The TEM images were made by J. van Lent and H. M. Kariithi (Wageningen University, reproduced with permission).*

Following pest suppression and the release of sterile males, in 1997 the tsetse fly *G. austeni* Newstead was eradicated on the island of Unguja, United Republic of Tanzania (Vreysen et al. 2000; Hendrichs et al. 2007). This success prompted other African countries to consider applying the SIT to eradicate tsetse fly populations. A programme to create a zone free of *Glossina pallidipes* in the Southern Rift Valley of Ethiopia was initiated in 1996 (Vreysen et al. 2000; Feldmann et al., this volume).

This project stimulated the IPCL to conduct research on the problematic *G. pallidipes* colony. Since the available colony was initiated from insects collected in Uganda, it was decided that a *G. pallidipes* colony should be started using flies from Ethiopia. Therefore, a new *G. pallidipes* colony was initiated in 1999 with pupae collected in Arba Minch, Ethiopia. This colony became well established, and in 2001 it reached about 15 000 productive females.

However, similar to the 1987 colony, the new colony declined steadily over a 2-year period, becoming extinct in 2002. Similarly, dissections revealed that up to 85% of both male and female flies had salivary gland hypertrophy (SGH), a syndrome first described in wild populations of *G. pallidipes* (Table 1) (Abd-Alla et al. 2011). To overcome the problems of managing a *G. pallidipes* colony, research was conducted for more than ten years, resulting in effective management packages (section 3.1.).

Symptoms of the SGH were initially reported in 1932 (Table 1). During dissection of *Glossina pallidipes* specimens to observe trypanosomes in Zululand, South Africa, swollen salivary glands were observed (Whitnall 1932; Whitnall 1934). Later, the SGH symptoms were reported in *G. morsitans* (Burtt 1945). In the 1970s, the SGH syndrome was associated with a virus found in cytoplasmic vacuoles of the salivary glands and midgut epithelial cells of *G. fuscipes* Newstead and *G. morsitans* (Jenni 1973; Jenni and Steiger 1974a, b; Jenni and Böhringer 1976). At that time the virus was described as "virus-like particles" (VLPs), and erroneously thought to be an arbovirus.

The first link between the SGH and the salivary gland hypertrophy virus was reported by Jaenson (1978) who examined the hypertrophied salivary gland in *G. pallidipes* from Kenya using electron microscopy; it was found that rod-shaped virus particles were present only in salivary glands that showed this syndrome. The particles were absent in non-hypertrophied salivary glands. Based on the assumption that the new virus might be a potential biological control agent against tsetse flies, many researchers made a concerted effort to explore this idea. Subsequently, SGH syndromes were reported in many tsetse species, e.g. *Glossina austeni, G. m. morsitans, G. nigrofusca nigrofusca* Newstead and *G. pallicera pallicera* Bigot (Burtt 1945; Ellis and Maudlin 1987; Gouteux 1987). Although containing a double-stranded DNA genome, the virion structure did not suggest that the tsetse virus should be assigned to any of the existing insect virus groups (Burtt 1945; Odindo et al. 1986; Ellis and Maudlin 1987; Gouteux 1987). Pathological effects noted in various countries included sex distortion and a reduction in insemination rates, fecundity and lifespan (Jaenson 1986).

The main research question was to explain why the Ethiopian-derived colony collapsed, unlike the Ugandan-derived colony from Tororo which was, and still is, sustainable. Notably, the prevalence of the SGH syndrome was about 10% in the Tororo colony compared with 85% in the Arba Minch colony. This significant difference in the prevalence of the SGH syndrome raised the question whether these colonies were infected by the same or different virus strains. Therefore, the complete genome of the virus isolated from the Tororo colony was sequenced and annotated. The sequencing data identified the genome of the virus as a circular double-stranded DNA molecule over 300 kb in size; this confirmed the previous observation of Odindo (1986) that this virus is unique and could not be assigned to any existing

insect virus family. Therefore, a new family of insect viruses called Hytrosaviridae was created, encompassing the tsetse fly virus and a similar virus from the house fly *M. domestica* as two members of this family. The name Hytrosaviridae was derived from Hytrosa, sigla from the Greek '*H*ypertrophia' for '*hy*per*t*rophy' and '*s*ialo*a*denitis' for 'salivary gland inflammation' (Jaenson 1986; Abd-Alla et al. 2008, 2009b; Garcia-Maruniak et al. 2009; Lietze et al. 2011). The recent sequencing and annotation of the genome of the Ethiopian GpSGHV (GpSHGV-Eth) strain revealed deletions/insertions in 37 ORFs and 17 ORF deletions and 24 novel ORFs compared with the Ugandan GpSGHV, which might explain the differential pathogenesis between the two colonies (Abd-Alla et al. 2016).

In addition, it was demonstrated that the GpSGHV infects other tsetse species, and causes a negative impact on the flies' performance without developing salivary hypertrophy (Demirbas-Uzel et al. 2018a, b). Also, it was reported that the virus has different strains/genotypes circulating in the wild tsetse population, and the virus infection affects the flies' immune system (Kariithi et al. 2018a, b; Meki et al. 2018a, b, c).

The sequence data of the SGHV isolated from the Tororo-derived (Uganda) *G. pallidipes* represents the reference virus genome; the virus is named as the GpSGHV-Uga. The availability of the GpSGHV-Uga genomic data enabled the development of virus detection tools such as a conventional, non-destructive PCR and a quantitative PCR (qPCR) which were used to diagnose and quantify the viral infections in tsetse colonies. The PCR detection method revealed that, although only about 10% of the Tororo colony exhibited SGH symptoms as an overt infection, almost all flies harboured the virus infection as an asymptomatic infection.

Quantitative PCR provided further evidence that the virus titre unequivocally correlated with the SGH symptoms, thus providing additional proof that the GpSGHV causes SGH. Sequence analysis of the SGHV-Uga genome revealed that it shared several gene similarities with other large DNA viruses such as baculoviruses, nudiviruses or entomopoxviruses. Of particular interest was the similarity of the SGHV DNA polymerase (a gene responsible for replicating the DNA) with that of the human herpes virus. This similarity led to the use of the antiviral drugs commercially available against herpes virus infection to control the SGHV infection (section 3.1.1.) (Abd-Alla et al. 2008, 2009b, 2014).

The average low rate (0.5–1%) of virus infection with overt SGH symptoms or covert latent infection prevalence in tsetse wild populations significantly differed from the laboratory colonies; in the laboratory a covert infection occurred in almost all flies (Odindo 1982; Odindo and Amutalla 1986; Abd-Alla et al. 2007, 2009a). To explain this difference our attention was drawn to the *in vitro* feeding system which was developed at the IPCL in Seibersdorf, and is currently used in all tsetse mass-rearing facilities, i.e. flies (in holding cages) are fed in several successive rounds on the same membranes containing defibrinated blood. The detection of infectious SGHV in the blood remaining on the membranes after feeding flies infected with the SGHV clearly demonstrated that the successive feeding rounds significantly favoured virus transmission within the tsetse colony (Fig. 2) ( Feldmann 1994; Abd-Alla et al. 2010, 2011, 2013b). This important finding was the basis for modifying the feeding regime to manage the SGHV infection (section 3.1.2.).

### *2.5.3. Viral Diseases in Mosquitoes*

*Viruses Pathogenic to Mosquitoes.* There are several types of viral pathogens that cause diseases in mosquitoes, most of which belong to four major groups: (1) the baculoviruses (NPVs) (Baculoviridae: Nucleopolyhedrovirus) (the most common mosquito viruses), (2) cytoplasmic polyhedrosis viruses (CPVs) (Reoviridae: Cypovirus), (3) densoviruses (DVs) (Parvoviridae: Brevidensovirus) and (4) the iridoviruses (MIVs) (Iridoviridae: Chloriridovirus). Baculoviruses, densoviruses and iridoviruses are DNA viruses, while cypoviruses are the main RNA viruses in mosquitoes (Becnel 2006; Becnel and White 2007; Kariithi 2013; Tijssen et al. 2016).

The first reported mosquito baculovirus (AesoNPV) was isolated from *Aedes sollicitans* (Walker) in Louisiana in 1969, and over the next two decades, NPVs were isolated from 10 additional mosquito species in the genera *Aedes, Anopheles, Culex, Psorophora, Uranotenia* and *Wyeomyia* (Afonso et al. 2001). Baculoviruses are highly pathogenic, and are responsible for epizootics in field populations of mosquito larvae, e.g. the *Culex nigripalpus* Theobald nucleopolyhedrosis virus CuniNPV (Afonso et al. 2001). Moreover, a baculovirus infection can be destructive to mass-reared mosquito colonies.

The highly pathogenic mosquito densoviruses (MDVs) are non-enveloped and relatively stable in the field or under laboratory conditions, making it very difficult to inactivate them. The MDVs are highly specific to mosquitoes in aquatic larval habitats. Larvae that survived an MDV infection and developed to the adult stage exhibit a dose-dependent shortening of their adult lifespan. Infected females vertically transmit the virus to their offspring at the new oviposition site. These characteristics make the MDVs suitable biocontrol agents against mosquito populations. In contrast, when densoviral diseases spread in laboratory colonies, these same characteristics usually cause control efforts to be unsuccessful. In most cases the colony has to be destroyed, and equipment and the facility decontaminated (Carlson et al. 2006). MDV infections can be latent, e.g. the *Aedes albopictus* densovirus chronically infecting an apparently healthy subclone of an *Aedes albopictus* C6/36 cell line; this was fortuitously discovered to be highly pathogenic by feeding *Aedes aegypti* (L.) larvae in C6/36 cell flasks (Jousset et al. 1993).

In addition to MDVs, mosquito infection with several other viruses has been reported. For example, recent deep sequencing of samples derived from three colonies of *Anopheles* spp. maintained at the Institute Pasteur (Carissimo et al. 2016) led to the identification of two "novel" RNA viruses, a cytoplasmic polyhedrosis virus (multisegmented dsRNA) and a cripavirus (bisegmented ssRNA) that chronically infected these colonies. A new group of ssRNA viruses with a large genome (20 kb), classified in the family Mesoniviridae, has been identified recently in different species of mosquitoes in the genera *Culex* and *Anopheles* in Côte d'Ivoire (Zirkel et al. 2011, 2013) and in *Culex vishnui* Theobald and *C. taeniorhynchus* Wiedemann in Vietnam (Nga et al. 2011).

*Vector-Borne Diseases and Risk of Infection to Staff.* The mosquito species currently reared in laboratory colonies, including for the SIT, especially in large-scale factories, belong to three genera of culicids: *Aedes, Anopheles* and *Culex.* These species encompass the vectors of the major human parasitic diseases, e.g. malaria or flavivirus arboviral pathogens such as yellow fever, West Nile encephalitis, dengue, Chikungunya and Zika viruses. The vertical transmission of several of these viruses in their natural mosquito vectors has been demonstrated experimentally under laboratory conditions and detected in wild populations of mosquitoes (Bolling et al. 2015; Tesh et al. 2016; Thangamani et al. 2016).

Recent investigations on the mosquito microbiome revealed that, in addition to these classical arboviral pathogens, mosquitoes house diverse varieties of endosymbiotic RNA viruses, many of which are phylogenetically related to human pathogenic arboviruses in the families Flaviviridae, Bunyaviridae and Togaviridae (Cook et al. 2013; Marklewitz et al. 2013; Huhtamo et al. 2014; Bolling et al. 2015; Li et al. 2015). In contrast to classical arboviruses, which replicate in their invertebrate and vertebrate hosts, these viruses are incapable of replicating in vertebrate cells, and are designated as insect-specific viruses (ISVs). Several of these ISVs are vertically transmitted (Saiyasombat et al. 2011; Bolling et al. 2012; Haddow et al. 2013), strongly suggesting their long-term association with their insect host. Experimental data have provided evidence that ISVs can alter the mosquito's susceptibility to certain pathogenic arboviruses (Kent et al. 2010;

Bolling et al. 2012; Hobson-Peters et al. 2013; Kenney and Mertz 2014). These data have opened up new perspectives for the development of mosquito strains refractory to the transmission of vertebrate arboviruses.

Taken together, these data imply a risk to staff in mass-rearing mosquitoes – they might become infected with mosquito-borne diseases. Therefore, strict measures must be followed to avoid the introduction of infected mosquitoes into colonies, or exposure of infected humans to the mosquito colonies. In this respect, field-collected mosquito samples should first be quarantined and diagnosed for virus infections using sensitive diagnostic tools, e.g. by qPCR, prior to the introduction of such mosquitoes into the existing fly colonies or in the establishment of new colonies. To protect staff from infections with mosquito-vectored viruses, protective measures must be undertaken, e.g. minimizing and eliminating escapees, wearing protective clothing and adhering to control measures (ASTMH 2001). Personal protection is especially important in the event that mosquitoes escape from rearing cages. Moreover, strict hygiene in the environment around mass-rearing facilities is important to prevent escaped mosquitoes from finding breeding places; this also minimizes the chance of staff becoming infected with a virus and the reintroduction of a virus into the colonies. An additional risk in respect to mass-reared mosquito colonies is the emergence of a latent virus infection, especially under stressful rearing conditions, e.g. high densities, which might compromise the mosquito immune system. Therefore, to ensure colony safety and sustainability, it is recommended that mosquito colonies be surveyed routinely for both pathogenic and mosquito-borne viruses.

### *2.5.4. Viral Diseases in Reared Fruit Flies and Wild Populations*

As in mosquitoes (section 2.5.3.), several viruses have been identified in fruit flies (Webster et al. 2015). In addition to the covert infections of laboratory or wild strains of Drosophilidae (section 2.5.), several RNA viruses have been isolated from species of Tephritidae belonging to two genera of major economic interest - *Ceratitis* and *Bactrocera* (*Dacus*). Plus et al. (1981) isolated a reovirus and a picorna-like virus from the J. C. R. Ispra strain of *Ceratitis capitata* (Wiedemann). Bashiruddin et al. (1988) found a picornavirus in various life stages of the Queensland fruit fly *Bactrocera tryoni* (Froggatt) in a laboratory colony; the virus induced premature mortality and decreased fecundity in infected flies.

Pathogenicity tests using various insect viruses demonstrated the sensitivity of the olive fruit fly *Bactrocera oleae* (Rossi) to *per os* infection with the picornavirus Cricket Paralysis Virus (CrPV). Feeding the flies on a solution containing the virus resulted in 50% mortality in 5 days and more than 80% mortality within 12 days. The virus was found to be horizontally transmitted from infected to healthy flies by fecal contamination. The flies could also be infected with the type 21 iridovirus from *Helicoverpa armiger*a (Hübner) (Manousis and Moore 1987). A virus exhibiting the salient structural and genomic features of reovirus virions was isolated from wild *B. oleae* flies from Greece. This virus actively replicated in midgut cells where it aggregated in cytoplasmic paracrystaline arrays, and was abundantly released to the gut lumen through the microvilli (Anagnou-Veroniki et al. 1997).

The Mediterranean fruit fly *C. capitata* was reported to be infected with the

*Drosophila melanogaster* Meigen C picornavirus (DCV); the infection resulted in increased virus titre and fly mortality (Jousset 1976). Recently, three novel picornaviruses infecting *C. capitata* were discovered and named as *C. capitata* iflavirus 1 and 2 (CcaIV1 and CcaIV2) and *C. capitata* noravirus (CcaNV). The CcaIV2 and CcaNV infections were abundant in most of the fly strains used in the various SIT projects around the world, as well as in field captures in the east of Spain. Although there is no direct proof that the virus infection affects the fly's performance, high viral titres of CcaNV were associated with a reduction in the lifespan of males released into the field for the control of this pest. Taken together, these data strongly suggest the possibility that CcaNV impairs the fitness of the sterile flies (Llopis-Gimenez et al. 2017).

In addition to tephritid fruit flies, several laboratory or wild strains of Drosophilidae have been reported to be infected covertly with many RNA viruses, e.g. the DCV (Arnold et al. 2015), the Sigma virus (Rittschof et al. 2013), the Nora virus (Cordes et al. 2013) and the Drosophila P virus (Plus and Duthoit 1969; Teninges and Plus 1972). Further, the spotted-wing drosophila *Drosophila suzukii* (Matsumura) was reported to be infected with Drosophila C virus and Flock House virus (Cattel et al. 2016).

### *2.5.5. Viral Diseases in Honeybees, Silkworms and Crickets*

Historically, honeybees and silkworms are the most important insects used in the production of economic products. Many diseases, including viral diseases, were first recorded in these insects (Trager 1935; Glaser and Stanley 1943). However, the viral diseases in honeybees and silkworms are not discussed here; they have been well documented by others (Aruga 1971; Cox-Foster et al. 2007; vanEngelsdorp et al. 2009; Francis et al. 2013; Jiang and Xia 2014).

Recently, the intensive mass-production of field crickets as pet food resulted in the presence of viral diseases, causing enormous losses and requiring urgent intervention (Weissman et al. 2012).The first epizootic of the European house cricket *Acheta domesticus* (L.), with a densovirus (AdDV) as the causative agent, was detected in a Swiss commercial factory (Meynadier et al. 1977). Several other outbreaks have been observed in Europe, but it was only in 1991 that an AdDV epizootic was reported in a cricket farm in south-eastern USA (Styer and Hamm 1991). In 2009/2010 severe AdDV outbreaks in cricket farms decimated the multimillion dollar cricket pet food industry all over North America, from Quebec to Alberta and Florida to California (Weissman et al. 2012). Sequence analyses of the viral genome revealed a 99% common identity between the 1977 European isolate and different 2009 North American isolates. This finding demonstrated the very high genetic stability of the virus, and provided evidence that these epizootics were not due to the emergence of novel virulent strains of the virus (Szelei et al. 2011).

## 3. STRATEGIES TO MANAGE PATHOGENS IN INSECT MASS-REARING

Some of the viruses, bacteria, protozoa and fungi found in insect mass-rearing are known disease-causing pathogens, but others have no known host-fitness costs. Pathogens may be introduced into mass-rearing facilities from the field-collected

insects used to establish colonies, or could be latent and erupt as a result of intense and continuous rearing under stressful rearing conditions in the facilities. Some of the conventional pathogen management techniques in insect mass-rearing include isolation and rearing of healthy individuals from colonies that manifest mixed infections, changing colony environmental conditions and the application of antibiotics. Although these techniques are useful in the management of disease outbreaks, their effectiveness is mostly short-lived. Effective pathogen management largely depends on the type, transmission mode, and persistence of the pathogens as well as the manifestations of the disease.

The next five sections highlight the effective management of salivary gland hypertrophy syndrome (SGH) in mass-rearing tsetse flies. Also discussed are different approaches and techniques that are used in the management of viral and non-viral diseases in mass-rearing codling moths, honeybees, and silkworms.

### *3.1. Combined Approaches to Manage SGHV in Tsetse Mass-Rearing*

Outbreaks of the SGH syndrome in tsetse mass-rearing facilities are a rare occurrence in view that SGHV presence is mostly asymptomatic. However, when the SGH occurs, the fecundity of some tsetse species, especially *G. pallidipes*, is compromised. Except in *G. pallidipes* colonies, SGHV infections are mostly asymptomatic, but unknown factors, such as environmental stressors and perhaps host physiology, can promote SGH outbreaks, resulting in the loss of colony productivity and the decline of an entire tsetse colony over several generations (section 2.5.2.). The mechanisms by which SGHV infections persist in tsetse colonies are known partially. However, it is clear from various experiments and observations that the virus is vertically transmitted and persists in subsequent fly generations (Boucias et al. 2013). Horizontal SGHV transmission is well documented (Abd-Alla et al. 2010), and is the principal route through which viral infections spread in tsetse mass-rearing (Fig. 2). Therefore, it is important to minimize the risk of SGH outbreaks, which can be done through several approaches, as described below.

#### *3.1.1. Antiviral Drugs*

For viruses that are intermittently reactivated from latency to symptomatic disease manifestations, antiviral drugs can be administered to keep the virus infection in check. Studies in human herpesviruses (HHVs, family Herpesviridae) have shown that the administration of antiviral drugs such as acyclovir and valacyclovir reduced the prevalence, titre and shedding of the virus from infected host cells (De Clercq 2007). In principle, these antiviral drugs are used at concentrations that are not detrimental to the DNA synthesis of the host (Bras et al. 2001; De Clercq 2003; Miller et al. 2005), and are converted to active metabolites by virally encoded thymidylate synthase enzyme. In addition, evidence shows that the SGHV shares a high homology with HHVs, including DNA polymerase and thymidylate synthase enzymes (Kariithi et al. 2013b), which are the antiviral target genes, inhibiting viral DNA replication. Thus, these drugs are ideal chemotherapeutic agents against viral infections in mass-reared insects. Overall, the administration of antivirals results in

reduced viral titre. Reduction of viral shedding results in reduced horizontal transmission of the virus into blood meals during *in vitro* membrane feeding, thereby keeping the virus undetected in the colonies. Success was achieved in controlling the SGHV in the tsetse mass-production facility in Ethiopia and in the Seibersdorf Laboratory; oral administration of valacyclovir (at a dose of 300 µg/mL blood) for over 18 months significantly reduced SGHV loads and suppressed SGH outbreaks to undetectable levels (Abd-Alla et al. 2008) (Fig. 3). Importantly, such long-term administration of valacyclovir resulted in acceptable levels of fly productivity and mortality. It is important to note that valacyclovir reduced viral DNA replication. It will be more effective when it is administered to flies with a low virus titre, but not to flies with a symptomatic infection.

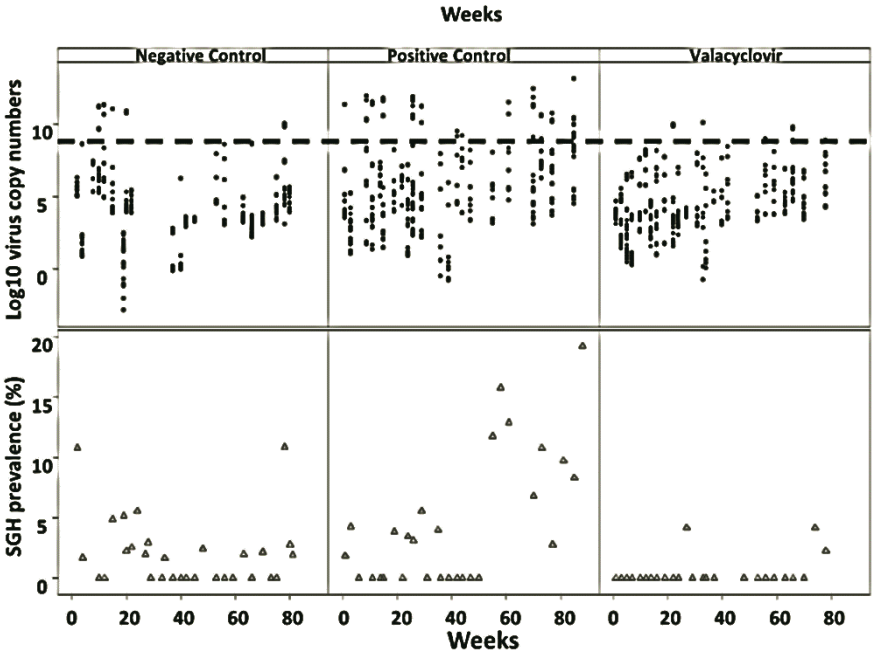

*Figure 3. Effects of long-term treatment with the antiviral drug valacyclovir on* G. pallidipes *biology and virus prevalence. SGHV virus loads and SGH prevalence determined by qPCR and dissection, at 60 days after feeding. (---): threshold virus load correlated with SGH symptoms. Negative control: flies fed exclusively on clean blood meals; positive control: flies fed on virus-contaminated blood meals; valacyclovir: flies fed on virus-contaminated blood supplemented with 300 µg/mL valacyclovir. Data points for virus load are for individual flies (Abd-Alla et al. 2012).*

### *3.1.2. Clean Feeding System*

In tsetse mass-rearing facilities, the *in vitro* membrane feeding system, which involves feeding of up to 10 sets of fly feeding cages on the same membrane in succession, favours horizontal transmission of the virus (Feldmann 1994; Abd-Alla et al. 2012). A single SGHV-infected individual is able to shed up to $10^7$ infectious

viral particles into the blood meal during a 10–15 min feeding event (Abd-Alla et al. 2010) (Fig. 2), thereby infecting most of the non-infected flies in the cages that feed afterwards. This results in the spread and long-term maintenance of the virus in the colonies. Consequently, it was thought that, in principle, the horizontal SGHV transmission can be efficiently interrupted by modifying the membrane feeding regime. This was the origin of the clean feeding system (CFS), which is now one of the most cost-effective anti-SGHV management strategies in tsetse mass-rearing facilities (Abd-Alla et al. 2010, 2013b).

Implementation of the CFS involves providing each fly cage with fresh blood at each meal to prevent flies from picking up the virus shed during the feeding of flies in earlier cages without increasing the cost. The CFS consists of three basic steps: (1) teneral flies and their subsequent progenies are always fed first, (2) after feeding the maximum possible numbers of cages on this first round (determined by the available resources, i.e. number of feeding trays), the rest of the fly cages are fed on the same membranes in a second round, and (3) after the first and second feeding rounds, the remaining colony flies, i.e. the oldest, are fed last on the same membranes (Abd-Alla et al. 2013b). In the CFS setting (Fig. 4), one of the most important issues is to keep separate all the fly records and pupae collection and incubations from these three colony feeding groups. Within two years of its implementation, the CFS was hailed as a big success; virus prevalence was significantly reduced and the SGH symptoms were completely eliminated from the colonies (Abd-Alla et al. 2013b). As a result, no SGH outbreaks have been reported in the colony in the two years since the CFS was put in place at the Seibersdorf Laboratory. It is worth noting that the CFS was implemented using existing resources without adding extra cost.

### *3.1.3. Combined Approaches*

To manage SGHV infections effectively in tsetse mass-rearing, a multi-tactical approach is the best option. Based on experience in dealing with SGHV infections gained over the last decade, some of the extremely important tactics to manage viral infections include: (1) strict sanitation of facilities, equipment and adult cages, (2) regular monitoring of SGH symptoms (fly dissection and PCR diagnosis), and (3) quarantine, e.g. by keeping a virus-free stock colony separate from the main colony. In addition to existing colonies, many new tsetse mass-rearing colonies are being established from field-collected flies in different African regions, with little or no awareness of SGHV prevalence. Since the SGHV is present in wild tsetse populations, there is a risk of introducing the virus to the new colonies.

The implementation of the CFS or administration of antiviral drugs alone in the management of SGHV infections requires a long time to significantly bring down the SGH prevalence to acceptable levels (below 10%). Importantly, the trials described by Abd-Alla et al. (2013b) were based on small fly groups with relatively low SGH prevalence (compared with the usual high prevalence in normal colonies). The CFS or valacyclovir alone reduced the prevalence of symptomatic infections (SGH) to an average of 1.9% and 0.63% within 28 and 21 months, respectively (Abd-Alla et al. 2012). As administration of the antiviral drugs in mass-rearing facilities is very feasible given that these drugs are cheap and readily available

commercially, a combination of the CFS (consisting of sanitation, modified blood feeding, SGH monitoring and quarantine) and the administration of valacyclovir was attempted on a large scale (Abd-Alla et al. 2014). Combined, the CFS and the supplementation of blood meals with valacyclovir resulted in complete elimination of the disease symptoms (from an initial 24% SGH prevalence) within six months of implementation. Taken together, an integrated approach can be used by combining these anti-SGHV strategies.

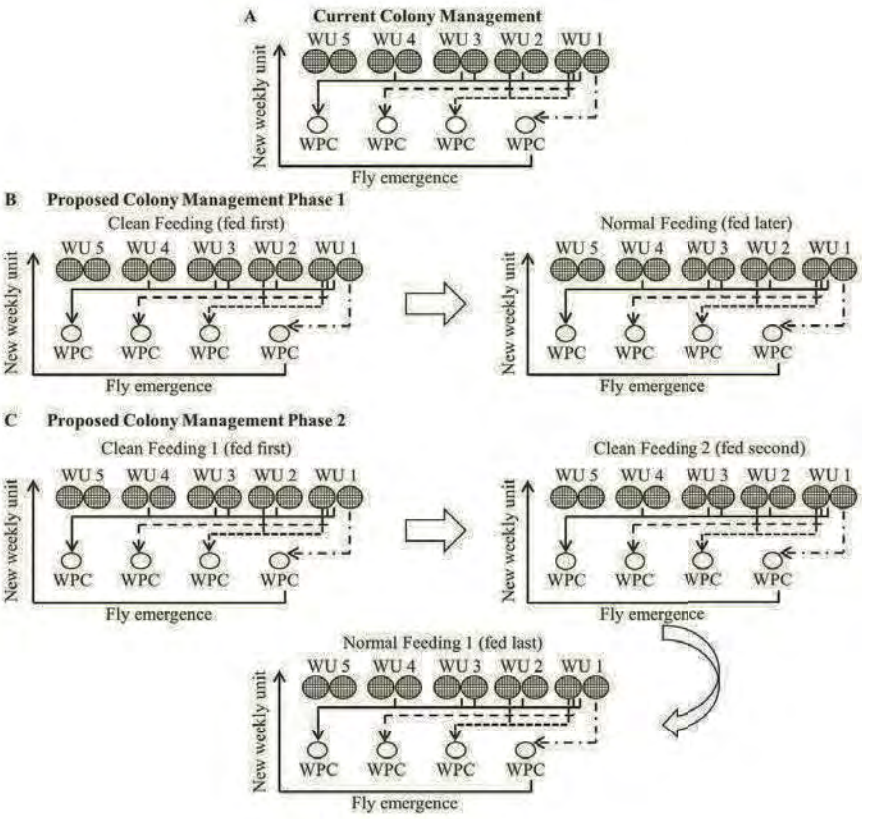

*Figure 4. Handling, feeding and management of a tsetse colony. (A) Regular* in vitro *membrane feeding system as routinely practised in tsetse mass-production factories, (B) intermediate phase, and (C) final phase of the clean feeding system. WU = weekly unit, WPC = weekly pupal collection (Abd-Alla et al. 2013b).*

### *3.1.4. Impact of Implementing the Combined Approach on Colony Performance*

The long-term application (more than 3 years) of antiviral drugs to manage SGHV infections in the mass-rearing of *G. pallidipes* colonies has not resulted in any observable negative effect on fly productivity and survival. The single-most important aspect of the combined approach, in the case of an SGH outbreak, is the ability to restore colony productivity rapidly (within six months) without any

additional cost in specialized equipment or reagents, except that minimal training of staff on colony handling protocols is required. Importantly, in case supplementing blood meals with a drug results in an undesirable side effect, or there is a potential risk of resistance development, the drug can be withdrawn once the SGH outbreak has been successfully managed; thereafter, the CFS protocols alone should reduce an SGHV infection to an acceptable level. Ideally, if frequent and fluctuating SGH outbreaks occur in a mass-rearing facility, the administration of antiviral drugs would reduce SGH prevalence significantly; then the sustained use of the CFS should follow. For rearing facilities with low SGH or non-observable SGH outbreaks, the CFS should be maintained so that that disease symptoms are not manifested.

### *3.1.5. Novel Prospective Approaches to Manage SGHV in Tsetse Mass-Rearing*

Paratransgenesis, i.e. the expression of antiviral molecules by transformed endosymbionts, is a viable option to manage viral infections in tsetse mass-rearing. Paratransgenesis was first achieved in *Rhodnius prolixus* Stål, vector of Chagas' disease, via transformation of its symbiont *Rhodococcus rhodii* (Abd-Alla et al. 2014). This approach has been hailed as a promising strategy in the creation of pathogen-refractory mosquitoes (Beard et al. 1992). *Wolbachia* is a potential endosymbiont for creating SGHV-refractory tsetse strains; it induces antiviral activity in insects (Wilke and Marrelli 2015). Another symbiont that can be targeted for paratransgenesis in tsetse flies is *Wigglesworthia*, which upregulates the host's cellular defence system ( Saridaki and Bourtzis 2010; Rances et al. 2012; Weiss et al. 2012). Recently, Boucias et al. (2013) showed that removal of *Wigglesworthia* from *G. pallidipes* significantly reduced SGHV replication in adult flies and suppressed virus vertical transmission to fly progeny. The symbionts can be artificially cultured, genetically engineered and stably fixed into the tsetse genome to express molecules that interrupt SGHV replication and transmission. Such virus-refractory tsetse lines are stable because the endosymbionts are maternally transmitted to the next fly generation. Attempts have been made to identify potential candidate transgenes that can be exploited in creating paratransgenic tsetse lines (Boucias et al. 2013).

Another potential approach to managing virus infections is applying RNA interference (RNAi), which can also be mediated via bacterial endosymbionts (Abd-Alla et al. 2016; Kariithi et al. 2016). The feasibility of this approach is underscored by the presence in the tsetse genome of the key components of the RNAi machinery, including several copies of Dicer (*dcr*), Argonaute (*ago-1* and *2*) and some components of the dsRNA-binding genes (Whitten et al. 2016). On the other hand, the genome of the SGHV contains some of the key genes involved in viral DNA replication, including late effector factors (*lef*), DNA polymerase (*dnapol*), DNA helicase (*dnahel*) and the *per os* infectivity factor (*pif*) genes (IGGI 2014). The identification of these key genes implies that the RNAi system is not only functional in tsetse flies but may also be actively involved in keeping the SGHV under control; apparently only a few of the viral genes are expressed during asymptomatic infections to avoid detection by the host's immune system. Preliminary results

indicate that RNAi-mediated silencing of SGHV genes is feasible (I. K. Meki, personal communication).

#### *3.1.6. Technology Transfer from the Laboratory to Large-Scale Mass-Production Facilities*

It is a challenge to transfer the technology of a newly developed pathogen management strategy from small-scale laboratory trials to a wider operational application. This is particularly so because, unlike controlled laboratory settings, external uncontrolled environmental factors could limit the technology's effectiveness under mass rearing operations. Even before the technology is transferred to operational applications (in mass-rearing, and in the field where applicable), there is the challenge of sustaining the technology in the laboratory. For example, in the case of the application of transgenic and RNAi approaches, the stability of the transgenes requires finding ways to maintain the transgene constructs (preferably as embryos) and to make rigorous evaluations under mass-rearing conditions. These embryonic transgenes can be used as stock for the operational applications. If there is no effective means of ensuring the stability of these technologies under mass-rearing conditions, the advantage of having a fall-back plan is jeopardized because the transgenes will be lost. So far, most laboratory trials have not been successfully transferred to the operational level. However, there is a noteworthy exception -- the IAPV-RNAi laboratory trial was field-tested in beehives in the USA (Abd-Alla et al. 2016; Kariithi et al. 2016). Also, transgenesis in silkworm mass-rearing has made significant progress in technology transfer from the laboratory to contained trials at operational level in multiple locations (Hunter et al. 2010).

The case of the combined anti-SGHV management strategy developed at the IPCL tsetse production facility in Seibersdorf is an example of how technology can be successfully transferred from laboratory trials to an operational level with widespread field application (FAO/IAEA 2015a). The technology was transferred to a tsetse mass-rearing facility in Kality, Ethiopia. This was done primarily by developing standard operational procedures (SOPs), training staff in the mass-rearing facility on the correct manner of implementing the new technology and establishing ways to evaluate it. The implementation of the management package resulted in the complete elimination of SGH symptoms and, moreover, according to PCR, eliminating the GpSGHV infection (Fig. 5).

### *3.2. Management of CpGV in Mass-Rearing the Codling Moth*

In addition to infection with pathogenic fungi, microsporidia, nematodes and bacteria, mass-reared colonies of the codling moth are contaminated with *C. pomonella* granulovirus (CpGV) (Subbaiah et al. 2013). CpGV infections are mainly observed in larvae, but the infections are largely asymptomatic. CpGV is an extremely specific and highly virulent viral pathogen of the codling moth. Once ingested by the larvae, the virus infects the digestive tract causing the disease which kills within 3–7 days. The subsequent rupturing of the larval skin allows the CpGV virion particles to infect other larvae and to spread in the colony. The routes of entry

of CpGV into mass-rearing facilities are through the air filtration systems, walls of the rearing rooms and spent diet (Zimmermann et al. 2013). Since handling is the main contributor to accidental contamination of the codling moth with CpGV (Cossentine et al. 2005), the most common practices to control CpGV infection include adding formaldehyde to the larval diet (Dyck 2010; Zimmermann et al. 2013) and general hygiene, e.g. washing egg sheets and disposing of spent diet and dead larvae.

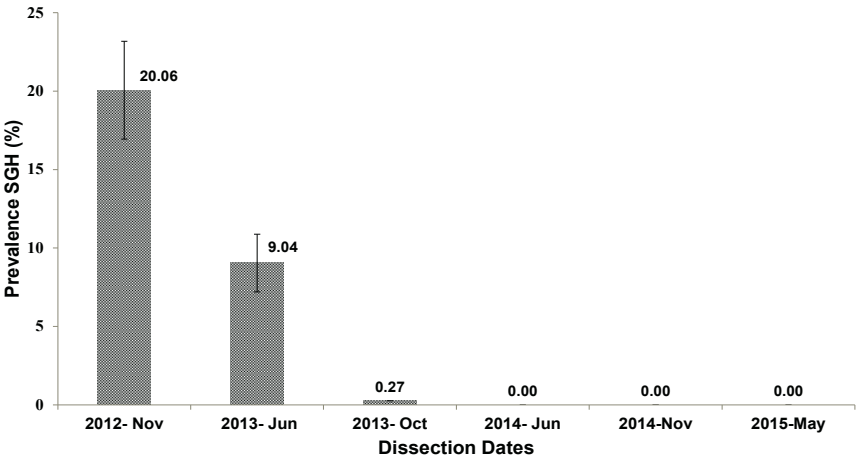

*Figure 5. Impact of implementing a combined virus management strategy on SGH prevalence in* G. pallidipes *in the tsetse mass-rearing facility in Kality, Ethiopia.*

An alternative strategy to control CpGV infections is to establish virus-free laboratory colonies. This can be achieved by using codling moth strains that are known to be CpGV-resistant. CpGV-resistant strains have previously been reported in various commercial orchards in Europe routinely subjected to CpGV treatments (Schmitt et al. 2013). The fact that the CpGV is vertically transmitted (transovum) in codling moth colonies ( Brinton et al. 1969) can be exploited in the establishment of virus-free colonies. For example, surface decontamination of the eggs sheets can successfully remove low levels of CpGV infection. This is a cheap procedure -- a 20-min egg sheet swabbing in simple solutions such as 0.5% sodium hypochlorite/1% Tween 20, or a 6-h UV-B exposure, followed by rinsing with distilled water to maintain egg viability (Etzel and Falcon 1976; Dyck 2010). Once such a virus-free colony is established, the possibility that a low-level virus infection still remains can be monitored easily by PCR. Primer and PCR amplification protocols for the detection of CpGV in codling moth populations have been described (Kundu et al. 2003).

### *3.3. RNAi Approach to Manage Pathogens of the Honeybee*

In the absence of effective antiviral chemotherapeutics in hives of the European honeybee (*Apis mellifera* L.), symptomatic viral infections are minimized by reducing stress, e.g. maintaining healthy colonies, and chemical control of *Varroa*, disinfection and selection for disease-resistant honeybee races (Chen 2011; Martin et al. 2012). Modern antiviral strategies include RNA interference (RNAi), which can significantly reduce viral titres up to 100% and mortality up to 90%. Notable success stories include the reduction of honeybee mortality caused by the Israeli acute paralysis virus (Maori et al. 2009), significant reduction of infection (27–60%) of the Asian honeybee *Apis cerana* F. with the Chinese sacbrood virus (Liu et al. 2010) and protection of European honeybees against infection with the deformed wing virus (Desai et al. 2012). Additionally, the threat caused by *Varroa* mites (viral reservoirs, incubators, activators and competent viral vectors) can be significantly reduced, up to 97%, by RNAi (Campbell et al. 2010; Garbian et al. 2012).

### *3.4. Transgenic Approaches to Manage Pathogens of the Silkworm*

There are no curative measures against viral diseases in silkworms. Conventional management measures include preventing virus transmissions (destroying the virus transmission cycle and breeding for resistant races), enhancing silkworm vigour (rearing hardy races and eliminating unfavourable conditions), diagnosing early viral disease (culling out sick worms and therapeutics), and taking prophylactic measures (disinfecting silkworms and rearing sheets). These methods are inexpensive and quite effective, but are not sufficient. Modern (transgenic) antiviral methods have been successfully applied in the silkworm industry without compromising the cocoon crop yields, resulting in enhanced resistance to baculovirus (*Bombyx mori* nucleopolyhedrovirus BmNPV) in silkworms (Watanabe 2002; Isobe et al. 2004; Kanginakudru et al. 2007; Jiang et al. 2012a, b; Subbaiah et al. 2013; Jin et al. 2014). The effectiveness of the transgenic silkworms could be further optimized by combinations of various molecular technologies. The best approach would be pre-selecting silkworm parents with a substantial level of natural virus-resistance, creating hybrids and enhancing their refractoriness to virus infection.

### *3.5. Management of Non-Viral Diseases in Insect Mass-Rearing*

Among the non-viral disease-causing agents in mass-reared colonies are: bacteria (Bacillaciae, Pseudomonadaceae and Enterobacteriaceae), rickettsia (Rickettsiaceae), protozoa (Amebiases, Gregarine and Coccidian), fungi (Entomophthorales and Muscardine), microsporidia and spiroplasma (Jiang et al. 2013a, b). Most of these contaminating microbes are acquired through the diets, and can alter the nutritional value of insect diets. Deliberate measures must be put in place to monitor microbes, e.g. using bioassays, and then prevent microbial contaminations because they are a major problem affecting the mass-rearing of insects (Sikorowski and Lawrence 1994).

Most of the bacterial diseases affect the larval stages of the insects (Gouli et al. 2011). Although the majority of these entomopathogenic bacteria are transmitted orally, they can also be vectored by nematodes and parasitoids. On the other hand, fungal diseases are transmitted (via infectious asexual spores) through penetration of the insect cuticle, but a few are orally transmitted. Upon infection, the fungus grows in the hemolymph and produces lethal toxins. New spores can be produced after the death of the host, thereby spreading the fungal infection in the colony. Amongst the bacterial control measures are disinfection and pasteurization, e.g. combinations of heating and antimicrobials to inhibit microbial growth. This approach should be practiced in combination with decontamination of the diet and rearing containers. For example, in tsetse mass-rearing, the feeding trays and membranes are frequently autoclaved, while the blood diet batches (which are usually decontaminated by irradiation prior to delivery to the mass-rearing facilities) are routinely monitored with petri dishes for contamination. In addition, other control measures include strict observance of personal hygiene of the workers, maintenance of a clean and sanitary environment, and sterilization of insectary equipment. Inflow and accumulation of air-borne microbial contaminants can be effectively prevented by air filtration (Feldmann 1994; Sikorowski and Lawrence 1994; FAO/IAEA 2006, 2015b, 2019).

Microsporidia are close relatives of fungi, and are transmitted either orally (via spores) or vertically (via eggs) (Lietze et al. 2010). Upon infection, these pathogens develop within the cytoplasm, eventually causing death, either directly (due to cellular damages) or through septicaemia (via secondary bacterial infections of the damaged cells). The highly species-specific microsporidia often infect insect populations chronically without disease epidemics, but they can be fatal in some mass-rearing facilities (Eilenberg et al. 2015). Microsporidia can be controlled by biennial (autumn and spring) applications of antibiotics, e.g. Fumagillin in honeybee colonies, but some species have shown signs of resistance to antibiotics (Huang et al. 2013). Applying antibiotics is usually combined with replacing old, dark brood combs.

Entomopathogenic rickettsia and spiroplasma are efficiently transmitted vertically and horizontally; a high prevalence of these pathogens results in mortality and severe losses of fecundity and general colony fitness. Due to the nature of their transmission in mass-production settings, i.e. mainly through contact, various infrastructural improvements can be implemented to significantly manage their infections and to improve rearing quality. These include circulating water and air filtration systems, continuous monitoring and waste removal, continuous larval/pupal separation and sterilization (routine hygiene), appropriate measures to reduce and prevent the development of pathogens, and a pathogen-free optimal diet.

Artificial mass-rearing conditions eventually lead to a decrease in the immune fitness of the insects (Yates and Antia 2006; Hawley and Altizer 2011; Ugelvig and Cremer 2012). Therefore, to replenish colonies with individuals having a high immune capacity, it is necessary to replace periodically or outbreed the colonies with fresh pathogen-free field-collected samples/specimens. For example, the colonies could be outbred with locally caught conspecifics (which should be PCR-screened for pathogen infection before introducing them into existing colonies). It is strongly recommended that, in the case of mass-rearing tsetse flies, newly

introduced conspecifics should be maintained under the above-mentioned combined approach to prevent an SGH outbreak.

## 4. CONCLUSIONS

Pathogens affect the quality of mass-reared insects. Therefore, it is very important to manage microbial and in particular virus infections in insect colonies during the mass-rearing process. Although there is still much to be learned about insect pathogens, in general microbial and fungal pathogens are currently managed using antibiotic and anti-fungal compounds, in addition to implementing the required sanitary procedures, but viral disease management when mass-rearing moths requires the use of formalin. However, for working staff, formalin is a hazardous chemical, and also it cannot be used to manage viral diseases when mass-rearing tsetse flies or mosquitoes. Therefore, alternative virus management strategies are needed, and thus this chapter focused on the management of viral pathogens. Inglis and Sikorowski (2009a, b) reviewed in detail the management of other insect pathogens.

Applications of transgenics and RNAi-gene silencing drugs, and the oral administration of antiviral drugs, have proven to be potent measures in managing viral infections in tsetse mass-rearing, apiculture and sericulture. However, it is clear that no single method can be used alone to manage effectively viral infections in insect mass-rearing; instead, an integrated approach is required. Molecular-based methods are a good complement to conventional virus management practices. The application of these measures should be accompanied by accurate and routine diagnosis of infections, and proper documentation of disease manifestations. To avoid the risk of developing drug-resistance, the application of antiviral drugs, especially in tsetse mass-rearing, should be restricted to colonies with comparatively high SGH outbreaks; the unnecessary administration of antiviral drugs to healthy colonies should be avoided. For colonies with a low SGH prevalence, a best management practices (BMP) approach entails applying preventive measures such as CFS and an avoidance of stressors as the main pillars, while not using antiviral drugs. To develop sustainable virus management strategies for mass-rearing insects, the link between covert and overt infections needs further investigation.

There are several important aspects to note in managing pathogens: (1) it is important to monitor the occurrence of disease symptoms and perform regular diagnostics, (2) a hygienic and optimal environment in the colonies must be maintained; all insects showing disease symptoms must be removed immediately and appropriately destroyed, (3) insect colonies should be kept in different stocks – keeping them separate from the mass-rearing is easier then managing an outbreak that infects the whole facility, (4) it is advisable to outbreed colonies at intervals (to replenish genetic diversity, if possible with strains that are pathogen-resistant), and (5) hybrid lines should be reared separately; these can be used to establish highly productive colonies in the event that the productivity of the parent colony declines.

## 5. ACKNOWLEDGEMENT

We thank the managerial and technical staff of the tsetse fly project in Ethiopia for their cooperation and technical assistance in obtaining flies used for virus screening of colonies.

## SUMMARY

Exposure to ionizing radiation is currently the method of choice for rendering insects reproductively sterile for area-wide integrated pest management (AW-IPM) programmes that integrate the sterile insect technique (SIT). Gamma radiation from isotopic sources (mainly cobalt-60 or decreasingly caesium-137) is commonly used, but high-energy electrons and X-rays are other practical options. Recently, the development of self-contained low-energy X-ray irradiators for insect sterilization is being encouraged because they only require access to electricity and cooling water, and avoid the complex and costly shipment of radioactive sources across international borders. Insect irradiation is safe and reliable when established safety and quality-assurance guidelines are followed. The key processing parameter is absorbed dose, which must be tightly controlled to ensure that treated insects are sufficiently sterile in their reproductive cells and yet able to compete for mates with wild insects. To that end, accurate dosimetry (measurement of absorbed dose) is critical. Data from more than 5300 studies on irradiation since the 1950s, covering more than 360 arthropod species (IDIDAS database), indicate that the dose needed for sterilization of arthropods varies from less than 5 Gy for the acridid *Schistocerca gregaria* (Forskål) to 400 Gy or more for some lyonetiid, noctuid, and pyralid moths. Factors such as oxygen level, insect age and stage during irradiation, and many others, influence both the absorbed dose required for sterilization and the viability of irradiated insects. Consideration of these factors in the design of irradiation protocols can help to find a balance between the sterility and competitiveness of insects produced for programmes that release sterile insects. Some programmes prefer to apply “precautionary” radiation doses to increase the security margin of sterilization, but this overdosing often lowers competitiveness to the point where the overall induced sterility in the wild population is reduced significantly.

## 1. INTRODUCTION

The potential of ionizing radiation to interact with materials has numerous applications in industry, medicine, and agriculture (Arthur et al. 2015; IAEA 2018). Ionizing radiation breaks down molecules, causing various effects in irradiated material. Radiation can cause polymerization of plastics, and can kill pathogens and other micro-organisms, leading to applications in food processing and the sterilization of health-care products. In organisms, which are composed of differentiated and undifferentiated cells, mitotically active cells, such as stem and germ cells, are the most radiation-sensitive cells. In the case of the sterile insect technique (SIT) and related biocontrol applications, as well as post-harvest quarantine treatments (Heather and Hallman 2008; Bloem et al. 2009), radiation can make an insect reproductively sterile by damaging the chromosomes of gonial cells. Specifically it causes germ-cell chromosome fragmentation (dominant lethal mutations, translocations, and other chromosomal aberrations), leading to the production of imbalanced gametes and subsequently the inhibition of mitosis and death of fertilized eggs or embryos (Klassen and Vreysen, this volume; Robinson, this volume). In adult insects, midgut stem cells, which undergo continuing mitotic divisions (such as in the cotton boll weevil *Anthonomus grandis grandis* Boheman), are particularly sensitive to ionizing irradiation, and the irradiation of certain species may cause a significant reduction in lifespan and increased mortality (Riemann and Flint 1967). Nevertheless, the successful sterilization of other radiation-sensitive insect species, without a reduction in their lifespan, may indicate that the effect on cell replacement in the midgut could be mitigated (Sakurai et al. 2000). Differentiated somatic cells are generally less sensitive to radiation than are stem cells. Thus a lethal effect requires a higher radiation dose than a reproductive sterilization effect. The impact of radiation on somatic cells is expressed as the development of abnormalities, a reduction in lifespan, flight ability, mating propensity, and nutrition, and finally insect death.

Radiation sterilization of insects is a relatively straightforward process, with reliable quality control procedures. The key parameter is the radiation absorbed dose which is expressed in Système International d'Unités (SI) units as gray (Gy) (1 Gy = 100 rad), where 1 Gy is equivalent to 1 joule (J) of absorbed energy in 1 kg of a specified material (1 Gy = 1 J/kg). As long as the correct dose is delivered at the appropriate stage of development, efficacy of the irradiation process is guaranteed.

Other advantages of using radiation to sterilize insects include: (1) temperature rise during the process is insignificant, (2) sterile insects can be released immediately after processing, (3) irradiation, unlike chemosterilants, does not add residues that could be harmful to human health or the environment, and (4) radiation can pass through packaging material, allowing insects (or commodities in the case of post-harvest treatments) to be irradiated after having been packaged.

In the 1950s and 1960s, numerous mutagenic chemicals were tested as alternatives to radiation to induce sterility in insects (Knipling 1979; Klassen and Vreysen, this volume; Lance and McInnis, this volume). Chemosterilants were added to rearing diets, applied topically to insects, or even deployed in attractant-baited devices in the field. The efficacies of irradiating and chemosterilizing insects for population control were, in general, similar (Guerra et al. 1972; Flint et al. 1975; Moursy et al. 1988). However, today, chemosterilants are not used for sterilizing mass-reared insects. Most

chemosterilants that were investigated in early studies are carcinogenic, mutagenic, and/or teratogenic, leading to environmental and human-health issues such as the integrity of ecological food chains, waste disposal, e.g. spent insect diet, and worker safety (Hayes 1968; Bracken and Dondale 1972; Bartlett and Staten 1996). More recently, a group of less broadly toxic compounds (insect growth regulators) has been studied as chemosterilants, but primarily as alternative insecticides, or in attractive autodissemination devices, rather than for use in SIT projects, e.g. Casaña-Giner et al. 1999; Moya et al. 2010; Bouyer and Lefrancois 2014). Insect resistance to chemosterilants is an additional concern (Klassen and Matsumura 1966).

Sterile insects are also being produced that are transgenic and contain conditionally expressed dominant lethals (Thomas et al. 2000; Harris et al. 2011; Häcker et al., this volume). However, at this time, exposure to ionizing radiation is still the principal method of inducing sterility for area-wide integrated pest management (AW-IPM) programmes that release sterile insects.

## 2. RADIATION SOURCES

The suitability of a radiation type for the SIT depends on properties, such as relative biological effectiveness (RBE), penetrability, availability, safety, and cost. The RBE of radiation is defined as the ratio dose X/dose R, i.e. the dose of 200–250 kV X-rays required to produce a specific biological effect to the dose of radiation (R) required to produce the same effect. The RBE of radiation for the induction of chromosome aberrations depends on its linear energy transfer (LET — the energy imparted to a medium by a charged particle of a specified energy, per unit distance). Radiation with a higher LET is more effective in inducing sterility, and most likely would yield insects that are more competitive (North 1975). However, a higher LET also means that penetration is limited. For example, alpha particles have a high value of LET, but can penetrate only a fraction of a millimetre into a container of insects, which makes them unsuitable to sterilize insects for release in AW-IPM programmes. Neutrons are more effective than gamma radiation or X-rays in sterilizing insects (Hooper 1971; North 1975; Offori and Czock 1975). However, neutrons can induce radioactivity in irradiated materials, which, along with the immobility of nuclear reactors (the usual source of neutrons), makes their use impractical for most programmes.

Considering this, the types of radiation that can be used practically in programmes that release sterile insects include gamma radiation, high-energy electrons, and X-rays (Bushland and Hopkins 1951, 1953; Baumhover et al. 1955; Lindquist 1955). All have similar effects on materials, and in particular on insects (since they have a similar RBE). For certain insect life stages and radiation doses, several studies found no significant difference between electrons and gamma radiation in their lethal effects (Hooper 1971; Adem et al. 1978; Watters 1979; Dohino et al. 1994).

To maintain the fitness of irradiated insects, and for the safety of workers, the induction of radioactivity in irradiated materials, such as canisters and insects, must be avoided. This is achieved by ensuring that the particle energy used for the SIT is less than 5 million electron volts (MeV) for photons (gamma radiation or X-rays), and below 10 MeV for electrons (Elias and Cohen 1977; Codex Alimentarius 1983; FAO/IAEA/WHO 1999; IAEA 2002a). Thus, gamma radiation from cobalt-60 (Co-

60) (photon energies are 1.17 and 1.33 MeV) and caesium-137 (Cs-137) (0.66 MeV), electrons generated by accelerators with energy less than 10 MeV, and X-rays generated from electron beams with energy below 5 MeV, are acceptable for sterilizing insects.

### *2.1. Radioisotopes*

Currently, the most commonly used radiation for the SIT is gamma radiation from the radioisotopes Co-60 and Cs-137. These isotopes have long half-lives, and the energy of their gamma radiation is relatively high (Table 1). To provide the same throughput, caesium sources, because of the lower photon energy, require about four times more activity than cobalt sources. Cobalt-60 is produced by placing small cylinders of natural cobalt (which is 100% Co-59) into a nuclear reactor, where the Co-59 atoms absorb neutrons and are converted into Co-60. These cylinders are removed from the reactor after 1 or 2 years, and are further encapsulated in corrosion-resistant stainless steel cylinders to produce source "pencils". Caesium-137 is produced from the fission of uranium and plutonium, and must be chemically separated from other fission products and actinides present in used nuclear fuel. The use of caesium for radiation purposes is declining because this process is very elaborate, and also in view of the danger its water solubility represents in terms of potential use for terrorism.

*Table 1. Comparison of properties of Co-60 and Cs-137*

| Property | Co-60 | Cs-137 |
|---|---|---|
| Production mode | Neutron absorption in nuclear reactors | Chemical separation from spent nuclear fuel, e.g. uranium |
| Half-life | 5.271 years | 30.07 years |
| Photon energy | 1.17 and 1.33 MeV (in equal proportions) | 0.66 MeV |
| 50% dose-decrease (depth in water) | 23 cm | 21 cm |

### *2.2. Electron Beam*

Even though high-energy (5–10 MeV) electrons can be used to sterilize insects, because of the cost and size of an electron beam facility it is normally not a suitable option. The exception would be if there is such a facility in the vicinity that is being used for other purposes. In such cases, the facility could be leased for a limited time period and at an affordable cost. An example is the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) facility in Valencia, Spain. Such electrons are generated by an electron accelerator, which does not involve any radioactive materials. Electrons are

introduced into an accelerating structure from an injector, where they are accelerated to the designed high energy that can be derived from a variety of sources depending on the type of accelerator. An electron accelerator yields a narrow and intense electron beam, and thus the dose rate can be up to 1000 times greater than from a gamma irradiator. However, gamma radiation from Co-60 or Cs-137 penetrates irradiated materials more deeply than electrons. For example, for Co-60 gamma rays, dose decreases only to half at a depth of about 23 cm in water, but for 10-MeV electrons the useful depth is only about 4 cm.

### *2.3. X-Rays*

When a beam of electrons strikes material with a high atomic number, e.g. tungsten, X-rays are generated. X-rays, like gamma radiation, are electromagnetic radiation. Radiation generated in this manner (by the rapid deceleration of a charged particle) is also known as "Bremsstrahlung". While gamma radiation from radioisotopes has discrete energies, Bremsstrahlung has a broad energy spectrum with a maximum equal to the energy of the incident electrons. The penetration of 5-MeV X-rays is similar to that for Co-60 gamma radiation and therefore higher than that for electrons.

## 3. RADIATION TECHNOLOGY AND STERILIZATION PROCESS

### *3.1. Irradiation Facilities*

The design of an irradiation facility affects the dose distribution and the attainable dose range. It may be designed either for a specific application (or product) or for multiple applications, depending on local considerations and user requirements. The basic components of an irradiation facility include:

- Radiation source (radioisotopic gamma source, X-ray tube or electron accelerator) and the associated control systems,
- System for transporting the product, e.g. insects, or in some cases the source, to and from the position at which irradiation occurs,
- Shielding to protect workers and the surrounding environment from radiation.

The irradiation facility should also include a dosimetry laboratory, and a product-handling system with areas designated for receiving and for segregated pre- and post-irradiation storage.

#### *3.1.1. Gamma Irradiators*

The radiation source consists typically of several source pencils of either cobalt or caesium. The dose rate is determined by the current activity (strength) of the source, and the operator controls the absorbed dose delivered to the insects by adjusting the time that they are exposed to radiation (an exception — in some large-scale irradiators, several dose rates can be obtained by raising different subsets of the source pencils into the irradiation room). The only variation in the source output is the known reduction in activity caused by radioactive decay, which can have a significant impact on the programme (financial as well as scheduling irradiation operations) if

not taken into account. The activity of a cobalt source, for example, decreases by about 12% annually. The irradiator operator compensates for this loss of activity by incrementally increasing irradiation time (approximately 1% each month) to maintain the same dose given to the insects. Since irradiation times eventually become impractically long, sources need to be replenished at regular intervals, depending on the initial activity of the source and the operational requirements.

Typically there are two types of gamma irradiators used in programmes that release sterile insects — self-contained dry-storage irradiators, and large-scale panoramic irradiators.

*Self-Contained Dry-Storage Irradiators.* At present, most sterilization of insects is accomplished using gamma radiation from self-contained irradiators (Fig. 1). These devices house the radiation source within a protective shield of lead, or other appropriate high-atomic number material, and they usually have a mechanism to rotate or lower the canister of insects from the loading position to the irradiation position. These canisters, which are reusable and generally made of steel, aluminium, or plastic, hold packaging containers with insects during irradiation. To irradiate, a canister is placed in the irradiation chamber while it is in the loading (shielded) position and, depending on the current dose rate of the irradiator, the timer is set to deliver the pre-selected dose. On the push of a button, the chamber is automatically moved to the irradiation position. In most self-contained irradiators, the irradiation position is in the centre of an annular (circular) array of long parallel pencils that contain the encapsulated radionuclide. With this design, the dose is relatively uniform within the irradiation chamber (section 3.3.2.). In an alternative configuration, the radionuclide is contained in a single rod. In this case, the canister with insects is rotated on a turntable within the irradiation chamber to achieve an acceptably uniform dose. The axis of rotation is parallel to the source rod, which is usually vertical. The canister stays in the irradiation position for the set time interval, and then automatically moves to the unloading (shielded) position at the end of the treatment. Self-contained dry-storage irradiators provide a high dose rate but a small irradiation volume (1 to 4 litres), and are suitable for research as well as small-scale programmes that apply the SIT.

*Large-Scale Panoramic Irradiators.* For large-volume irradiation, panoramic irradiators are more suitable. The source consists of either several Co-60 rods (pencils) arranged in a plane or a single rod that can be raised/lowered into a large irradiation room. When retracted from this room, the source is shielded either by water (wet storage), or by lead or other appropriate high-atomic-number material (dry storage). Since isotopic sources emit gamma radiation isotropically (in all directions), they may be surrounded by canisters of insects to increase the energy utilization efficiency, and several canisters can be irradiated simultaneously.

*Figure 1. In preparation for irradiation, a canister with insects is placed in the irradiation chamber (while it is in the shielded position) of a self-contained gamma irradiator. Depending on the dose rate of the day, the timer on the control panel (lower right) is set to give the desired dose.*

Many large-scale irradiators run in a continuous-operation mode, in which canisters of insects are carried on a conveyor around a central source. The canisters may pass by the source several times to increase dose uniformity in the canisters as well as energy utilization. The speed of the conveyor is selected so that the insects receive the intended dose. The source is moved to the storage position only when the irradiator is not in use. An alternate method is batch operation, where several canisters of insects are placed in the irradiation room while the source is in its storage position. The source is then moved into the irradiation room for the length of time required to achieve the desired absorbed dose. To improve dose uniformity, each canister may be rotated on its own axis during irradiation using turntables.

### *3.1.2. Self-Contained Low-Energy X-Ray Irradiators*

Recently, self-contained low-energy X-ray irradiators (Fig. 2) suitable for SIT applications have become commercially available (Wagner et al. 2009; Mastrangelo et al. 2010; Mehta and Parker 2011). The maximum X-ray energy for these irradiators is about 160 keV, and thus shielding requirements are less than for a typical self-contained gamma irradiator. These irradiators utilize X-ray tubes that consist of an electron source (generally a heated wire, a filament which emits electrons), an

electrostatic field to accelerate these electrons, and a converter to generate X-rays. In the currently available irradiators, the converter is present throughout the curved surface of the tube, and hence the X-rays are emitted in all directions. One method for irradiating insects is to operate the irradiator in a batch mode where several canisters of insects are placed around and parallel to the X-ray tube, and revolve around the tube during irradiation while maintaining their orientation (much like chairs on a Ferris wheel), achieving acceptable dose uniformity. An alternate method is to continuously pass trays with insects between two X-ray tubes, providing irradiation from two sides.

*Figure 2. A typical X-ray irradiator (self-shielded X-ray irradiator) consisting of two units: the exposure chamber (in the foreground) houses the X-ray tube and the canisters with insects, and the second unit (in the background) houses the water tank and cooling fans. (Photo from A. G. Parker, reproduced with permission.)*

### *3.1.3. Electron Accelerators*

Accelerator-generated radiation has two modes, electrons and X-rays produced from these electrons (Fig. 3). The two principal electron-beam characteristics are beam (electron) energy in MeV, and the average current in milliamperes (mA). These accelerators generally produce electrons of energy up to 10 MeV, and hence the irradiators need to be housed in heavily shielded rooms (unlike self-shielded irradiators). The beam energy determines the penetration of electrons in a material (thus dictating the useful size of the canister for irradiation), and the average beam current affects absorbed-dose rate (thus determining throughput, e.g. the number of canisters treated per hour). Unlike gamma radiation, radiation beams for such

irradiators are rather focused (for both modes), and typically conveyors are used to move canisters of insects continuously through the beam. Also, the electron beam (and also X-ray beam) is scanned to cover the length and width of the insect container, generally a tray. Since X-rays penetrate deeper than the electrons, from which they are generated, larger canisters of insects can be used when using the X-ray mode. To improve dose uniformity, each canister may be rotated on its own axis during irradiation using turntables.

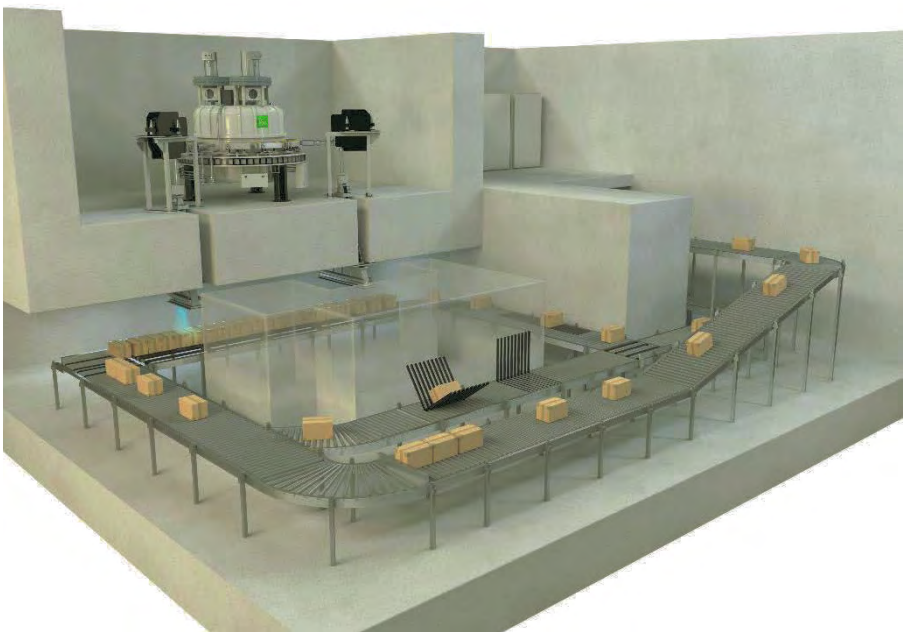

*Figure 3. Electron beam irradiation facility equipped with an electron accelerator and electron-to-X radiation converter. (Photo from Ion Beam Applications (iba), reproduced with permission.)*

### *3.1.4. Selection of Irradiator*

Since gamma radiation, X-rays and electrons have similar sterilizing effects, the choice of source for SIT irradiation is based on other considerations, such as penetration, cost, product throughput (Mehta 2009; DIR-SIT 2018), as well as expertise available at the site, and environmental, safety and security factors. The shallow penetration of electrons restricts the size of the canister used for irradiation. In addition, gamma irradiators, as well as the new self-contained X-ray irradiators, are usually simpler to operate and less expensive than large electron accelerators, at least within the range of the power required for SIT applications. However, X-rays and electron accelerators may have more public acceptance because they produce no radiation when switched off, and there are no transportation or radioactive waste issues (Cavalloro and Delrio 1974; Piedade-Guerreiro and Gomes da Silva 1983; Cleland and Pageau 1985; Smittle 1993; EBFRF 2004; FDACS 2018).

The power emitted by a gamma-ray source containing 100 kCi of Co-60 is roughly equivalent to that of a 1.5 kW electron accelerator. The power capacity of currently available commercial accelerators with 5–10 MeV electrons is usually much greater than this, making them unsuitable for dedicated SIT use. X-ray irradiators have the advantages of both gamma irradiators (high penetrability) and accelerators (no radiation when switched off). Based on all of these factors, almost all current insect sterilization programmes have traditionally used gamma irradiators (Table 2).

*Table 2. Examples of insect mass-rearing facilities, and the types of irradiators used for reproductive sterilization (more extensive list found in DIR-SIT 2018)*

In recent years, because of the potential use of radionuclides in terrorist attacks, governments and the International Atomic Energy Agency (IAEA 2012, 2017) have encouraged the development of alternatives to gamma irradiators. Governmental and international controls on radioactive materials have increased the difficulty and expense of purchasing, transporting, or reloading gamma irradiators. In addition, in many jurisdictions, facilities with gamma sources are required to have comprehensive and expensive security systems that include such features as 24-h video monitoring, motion and tamper sensors, and access systems that incorporate multi-factor recognition of users. Users with unescorted access to the facilities are now often required to pass extensive background checks.

On the other hand, X -ray irradiators have the advantage that they can easily be shipped internationally, and only need access to electricity and the replacement of X-ray tubes after every few thousand hours of use. Nevertheless, their use can be energy-intensive, and experience thus far indicates that they require more maintenance, and are less reliable for continuous operation, than gamma irradiators (IAEA 2012).

### *3.2. Radiation Safety*

It is essential that written descriptions of specific safety procedures, for all activities at an irradiation facility, are prepared. Before using a radiation source, workers must be given detailed training on relevant national legislation and regulations, and on safety procedures for the installation and use of a radiation source (IAEA 2003, 2014).

Irradiators are designed to keep the radiation exposure and dose to workers "as low as reasonably achievable" (ALARA), and within pre-set limits. These dose limits are based on the recommendations of several agencies of the United Nations (UN), including the IAEA, Food and Agriculture Organization of the United Nations (FAO), and World Health Organization (WHO) (IAEA 2014). Appropriate safety methods and procedures have been developed for each type of irradiator, and when operated correctly with the appropriate safeguards, they are safe and easy to use. Irradiators are usually licensed by national atomic energy authorities which set certain requirements, such as restricting access (entry for authorized persons only), a periodic survey of the radiation field in the vicinity where workers could be present, the use of personal radiation dosimeters, and the availability of radiation survey meters. These requirements are specifically aimed at protecting all workers from radiation. In addition, irradiators incorporate interlocks that prevent unintentional access to areas with high radiation fields. Cases of accidental exposure to Co-60 gamma rays are usually reported by the IAEA (IAEA 1996; Gonzalez 1999), and data from such historic cases are useful for probabilistic risk assessment. When the useful life of a gamma source is over, the irradiator or the source pencils are usually returned to the supplier for storage, reuse, recycling, or disposal. This is now becoming a mandatory and elaborate procedure.

During handling of insects, especially adult Lepidoptera, irradiator operators may be exposed to insect allergens, and additional safety measures may be required to minimize the risk of allergy and health hazards (Parker, Mamai et al., this volume).

### *3.3. Measurement and Distribution of Absorbed Dose*

#### *3.3.1. Radiation Dosimetry*

For the success of a programme using the SIT, the absorbed dose delivered to the insects needs to be accurately measured and controlled. Also, if contractual arrangements or national regulations prescribe specific doses, the programme will require adequate means to demonstrate compliance. Therefore, the programmes need to have an established system to accurately measure absorbed dose and estimate the associated confidence interval, a process known as dosimetry (ISO/ASTM 2013a). Dosimetry is performed using dosimeters — devices that, when irradiated, exhibit a quantifiable change in some property, e.g. colour, that can be related to the absorbed dose. A dosimetry system includes dosimeters (that are placed in different positions within the canister), measuring instruments (to read the change in the dosimeters) along with their associated reference standards, and procedures for using them (ISO/ASTM 2013b).

Dosimeters are commonly used in sterile insect production facilities for tasks such as absorbed-dose mapping (section 3.3.2.), qualification of the irradiator (section 3.5.2.), and process control (section 3.5.3.). Several dosimeters are suitable for these routine dosimetry procedures at SIT facilities (ISO/ASTM 2013a). Many facilities use radiochromic film systems because they are relatively affordable and are simple to use (avoiding extensive training) (IAEA 2004). Procedures for calibrating routine dosimetry systems, and for determining radiation fields in irradiators used for insect sterilization, are described in various ISO/ASTM standards (section 3.5.1.) (ISO/ASTM 2009; 2013a, b, c), which are updated periodically, and in an IAEA technical report (IAEA 2002b). Reference-standard dosimeters are used to calibrate the routine dosimetry system, and to determine the dose rate at a reference position in a self-contained irradiator. Sterile insect production facilities use reference-standard dosimeters for both of these purposes. Accredited dosimetry laboratories typically provide these dosimeters and make the readings, resulting in measurements that are “traceable” to national or international standards.

#### *3.3.2. Absorbed-Dose Mapping*

Ideally, it would be desirable to irradiate all insects in a container (or a canister) at the same dose. In practice, because of the characteristic of radiation interaction with matter, there is a systematic pattern of dose variation within the canister, and therefore not all insects receive the same dose. Dose distribution within the canister is determined by “dose mapping”, which typically is conducted by placing several dosimeters at known locations throughout the canister. Dose mapping provides operators of SIT irradiators with information on the absorbed dose within the canister, including areas of maximum and minimum dose, the dose uniformity ratio (maximum dose/minimum dose), and areas where the dose rate is relatively uniform (Fig. 4). Techniques for dose mapping are described in detail in Walker et al. (1997) and ISO/ASTM (2013a).

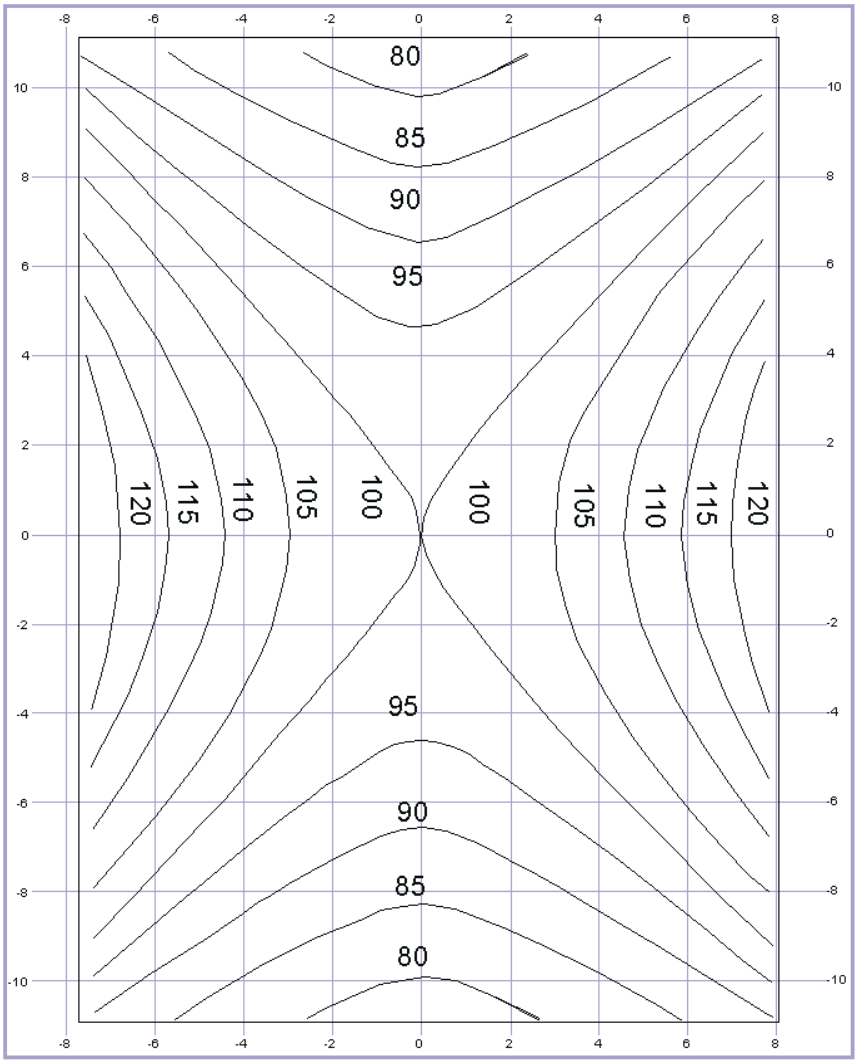

*Figure 4. Example of isodose curves in the irradiation chamber of a Gammacell® 220. Values are normalized to 100 in the centre of the gamma field. The field is most uniform in the centre. In this case the dose uniformity ratio (DUR) is 1.5 [120/80]. Grid is at 2-cm intervals from the centre of the chamber. (Figure from MDS Nordion, reproduced with permission.)*

### *3.4. Radiation Sterilization of Insects*

#### *3.4.1. Selecting Sterilizing Dose*

The dose that is used to induce sterility is of prime importance to programmes that release sterile insects. As the absorbed dose increases, sterility increases, but insect

quality and competitiveness will decrease (Parker, Vreysen et al., this volume; Lance and McInnis, this volume). Insects that receive too low a dose are not sufficiently sterile, and those that receive too high a dose will be non-competitive, reducing the effectiveness of the programme. Quite often, full (100%) sterility is not the most favourable condition for a programme, and thus process optimization is necessary to balance sterility level and competitiveness, taking into consideration factors that could affect the radiation sensitivity of insects (section 4.) and programme requirements (Parker and Mehta 2007). If quarantine security is a consideration, 100% sterility may be required for any released females. Males, however, tend to be less radiosensitive, and, in many species, eliminating a residual egg hatch of 1% (or less) from fertile females mated to irradiated males (even though many of these eggs do not survive other stages) requires doses that substantially reduce the ability of males to compete with, and thus induce sterility into, wild populations (Fisher 1997; Toledo et al. 2004).

Therefore, given the unavoidable dose variability within a canister (as mentioned above), sterile insect production facilities define an acceptable range of doses that can be given to the insects. Most often, programmes or regulatory officials specify a minimum dose that all insects must receive to ensure sufficient sterility. Due to dose variability, most insects actually receive a dose that is somewhat higher than that minimum. An alternate approach is to specify an optimum (or central target) dose, and set this as the average or median dose within the irradiated volume of insects. In either case, the dose uniformity ratio (DUR) should be small, preferably below 1.3. The goal is to sterilize all insects sufficiently without treating large proportions with doses that are too high, substantially reducing competitiveness. Irradiator operators can often adjust process parameters to achieve a more uniform dose distribution (section 3.5.2.).

Induced mutations may exert lethality at any stage of insect development. Quite often, for reasons of simplicity and convenience, the induction of detrimental lethal mutations is measured solely on the basis of egg hatchability. However, because lethal mutations can affect any developmental stage, researchers should measure dose effects all along this developmental continuum, or the actual survivorship from egg to adult, to give a true picture of induced sterility. As a result, 99 or 100% sterility in the egg stage is not essential nor desirable if it drastically reduces the competitiveness and vigour of the sterile insect. In some moths, the $F_1$ generation is more sterile than the substerilized parent generation. These are unique genetic phenomena in more radiation-tolerant species that are responsible for inherited sterility (IS) in Lepidoptera and some other arthropods (Marec et al., this volume).

An informed decision on treatment dose requires accurate data on how factors such as dose, insect stage and age, and various process parameters affect levels of sterility and insect quality. For programmes that apply the SIT, the accuracy and value of such data depend on the use of standardized dosimetry systems, procedures, and reporting methods (ISO/ASTM 2013a; FAO/IAEA/USDA 2019). Published data on the radiation biology of the same or similar species can provide guidance, but, in many cases, are of limited value because dosimetric procedures, dose-measurement traceability, dose distribution, and other pertinent information are often not reported. In addition, the details of insect-handling procedures, and, perhaps, strain-related differences, can influence radiation sensitivity (section 4.).

### *3.4.2. Preparing Insects for Irradiation*

*Stage/Age of Insects.* The selection of the insect development stage and age at which the insects will be irradiated is based on knowledge of the timing of maturity of insect reproductive organs (section 4.2.), handling suitability during irradiation and subsequent shipping, and sensitivity to somatic damage. For many holometabolous species (having complete metamorphosis), a good time for irradiation is late in the pupal stage, or early in the adult stage, when germ tissues have formed (Anwar et al. 1971; Ohinata et al. 1971, 1977, 1978). For example, tephritid flies are usually irradiated 1 or 2 days prior to adult emergence (pupae kept at about 25°C). Flies that are irradiated earlier in the pupal stage will tend to be of lower quality (in terms of mating propensity, flight, and sex pheromone production), an indication that somatic tissues were adversely affected (Fletcher and Giannakakis 1973). However, when tephritid pupae are irradiated too close to adult emergence, a proportion of females can already have some developed oocytes that, in spite of having been irradiated, can become viable eggs (Williamson et al. 1985). Ideally, the development and maturity stage should show an external physical indicator that acts as a quick and reliable identification tool, such as pupal eye-pigment colour in the Mediterranean fruit fly (Ruhm and Calkins 1981; Seo et al. 1987; Resilva and Pereira 2014).

In the pentatomid bug *Nezara viridula* (L.), sexual maturity and mating occur 5–17 days after adult emergence. Fourth- and fifth-instar nymphs are most frequently selected for irradiation because they are more radiosensitive than adults, and male and female reproductive systems are already well developed at this stage (Kiritani 1963; Mitchell and Mau 1969).

*Packaging for Irradiation.* Insects are usually irradiated in the primary packaging containers that are subsequently transferred, unopened, to an emergence and release facility where the adult insects are prepared for release (FAO/IAEA 2017). These containers provide protection to the sterile insects, and guard against their escape. They also prevent tampering. A variety of packaging containers has been used, e.g. 2- and 4-litre polyethylene bags, unwaxed paper cups (with lids), paper boxes, and plastic bottles of up to 15-litre capacity. SIT irradiation protocols may incorporate reusable canisters (typically steel, aluminium or plastic) that hold the primary packaging containers during irradiation. The size and shape of these canisters are usually a function of the size and shape of the irradiation chamber, especially in the case of self-contained irradiators (section 3.5.2.).

If insects are irradiated in a reduced-oxygen atmosphere, as a means of reducing the formation of free radicals (section 4.1.), the packaging container must be airtight. For example, tephritid pupae are sealed, with as little air space as possible, in plastic bags or bottles and then held at cool temperatures (12–20°C) for at least 1 hour before irradiation. During this period the insects exhaust most of the oxygen remaining within the container. Hypoxia (a deficiency of oxygen reaching the tissues of the body) can also be achieved by saturating the atmosphere within the container with helium or, more commonly, nitrogen, prior to and during irradiation (Ashraf et al. 1975; Ohinata et al. 1977, 1978; Hooper 1989).

### *3.5. Quality Assurance*

#### *3.5.1. Quality Assurance Programmes*

Quality assurance (QA) is an important part of any successful AW-IPM programme using the SIT. A QA programme provides various benefits with respect to irradiation procedures, including:

- Success of the process — adequately sterilized insects of good quality can be produced consistently,
- Compliance with regulations — a QA programme makes it convenient to audit the process against established standards,
- Harmonization — as international trade of sterile insects is growing, it has become more important to ensure dependable uniformity across geographical and political regions,
- Public acceptance — when the public realizes that SIT facilities strictly follow set procedures and document the process, it has more confidence in the programme.

An effective QA programme includes standard operating procedures (SOPs) for all activities related to packaging, irradiation, and dosimetry. Also, processing equipment that controls key operating parameters (those affecting dose) is periodically tested and/or calibrated to verify that the irradiator is operating properly. This is then documented as part of the record for the QA programme.

For many processes related to insect sterilization using radiation, standards and guidelines are available that can be incorporated into a facility's QA programme. These include dosimetry standards developed by the International Organization of Standardization and the American Society for Testing and Materials (ISO/ASTM 2009, 2013a, b, c, d), an SOP for using the Gafchromic® film dosimetry system for the SIT (IAEA 2004), and a comprehensive quality-control manual for applying the SIT against fruit flies (FAO/IAEA/USDA 2019).

#### *3.5.2. Irradiator Operation and Configuration*

When an irradiator is installed, it is evaluated to ensure that it is working according to the manufacturer's specifications, and baseline data on its performance are developed. These two activities are known as *installation qualification* and *operational qualification*, respectively (ISO/ASTM 2013a). Operational qualification includes, among other things, initial dose mapping (section 3.3.2.), and measurement of the dose rate at a reference position, e.g. at the centre of a fully filled canister (section 3.3.1.). The reference dose rate is then used to establish the basic relationship between key operating parameters, such as timer setting or conveyor speed, and absorbed dose. Dosimetry standards recommend repeating periodically the reference dose-rate measurement, e.g. every 3 years for gamma irradiators (ISO/ASTM 2013a). A caesium-137 (Cs-137) source, in particular, may contain impurities (Cs-134) that affect the decay rate, and thus, over time, the dose rate. For the low-energy X-ray irradiators, it is recommended that the reference dose rate be measured annually. Reference-standard dosimetry and dose mapping are repeated as appropriate following any changes in the irradiator, such as source renewal in gamma irradiators or a new X-ray tube, which could affect the dose rate or dose distribution.

Before insects are sterilized, key process parameters are established as part of performance qualification. For most insect irradiators, the absorbed dose delivered to the insects is controlled by adjusting a single parameter, such as timer setting (irradiation time) or conveyor speed. For X-ray irradiators, the absorbed dose also depends on the tube voltage and tube current. Values of these parameters depend on the dose specifications (section 3.4.1.) and the reference dose rate on the day of irradiation. Dose mapping is again performed to ensure that all insects within a given canister will receive an appropriate dose. If necessary, process parameters can often be adjusted to improve dose uniformity; common alterations include optimizing the size or shape of the canister, rotating the canister on a turntable during irradiation, using dose attenuators, and using plugs of simulated product, e.g. styrofoam, in the canister or irradiation chamber to exclude insects from areas with unacceptably low or high dose rates. This procedure establishes a canister design and a loading configuration of insects that result in an acceptably uniform dose distribution, and if possible reduce the DUR to 1.3 or less. If any of the changes listed above are made to improve dose uniformity, dose mapping should be repeated. The results of this mapping may also be used to establish a reference location for performing routine dosimetry as part of process control (section 3.5.3.).

### *3.5.3. Process Control*

The accidental release of insects that are not irradiated properly could potentially be disastrous (Knipling 1982; FAO/IAEA 2017), especially in programmes like those in California and Florida, USA, where the SIT is used to eradicate extremely small pest populations and/or as a prophylactic measure to prevent the establishment of newly introduced pests. To avoid this problem, programmes that release sterile insects implement various process-control elements to help ensure that all insects are irradiated according to specifications (FAO/IAEA/USDA 2019). In addition to the elements listed below, programmes applying the SIT often monitor relevant process parameters such as those related to the preparation and packaging of insects, setting of the irradiator timer, conveyor speed, canister specifications, and position and loading of the canisters. The results of process monitoring are routinely documented as part of the record of the QA programme.

*Sterility Testing.* Most AW-IPM programmes that integrate the SIT test samples of irradiated insects on a regularly scheduled basis to confirm that specified levels of sterility are being achieved. The quality-control manual for using the SIT against fruit flies suggests that this could be done for every shipment (FAO/IAEA/USDA 2019), comparing the egg hatch from pairings of irradiated and non-irradiated insects with that from crosses of non-irradiated insects. Besides making regularly scheduled sterility tests, unscheduled tests should also be conducted before any insects are shipped whenever changes are made to any equipment or procedures. However, it takes time to obtain the results of a sterility test, and the results may be known too late to prevent the release of incorrectly treated insects. Therefore, sterility testing must be supplemented with other methods, such as routine dosimetry.

In addition, the competitiveness of the sterile insects needs to be checked with insects of the target population to ensure the efficacy of the programme. Such testing helps to ensure that all procedures are being followed correctly, including rearing, pre-irradiation preparation (e.g. age-based selection of insects), packaging for hypoxia or nitrogen (if used), temperature control, irradiation-dose control, and post-irradiation handling (FAO/IAEA 2017).

*Routine Dosimetry.* Regular dosimetry can help to confirm that insects are being irradiated according to programme specifications, and may be required for every shipment (FAO/IAEA/USDA 2019). This is usually done by placing dosimeters on packaging containers or canisters at a specific location (which may be the reference location identified through dose mapping performed during performance qualification (section 3.5.2.)), where the dose rate has a known and predictable relationship to the minimum and maximum dose rate within those canisters. Unlike sterility testing, routine dosimetry can identify problems in the irradiation process quickly enough so that improperly sterilized batches of insects can be intercepted prior to release in the field. Although routine dosimetry is faster than sterility testing, a third control described below provides an immediate visual confirmation check that a given container has gone through the irradiation process.

*Radiation-Sensitive Indicators.* A radiation-sensitive indicator is a material, such as a coated or impregnated adhesive-backed (or adhesive-fronted) substrate, ink, or coating that undergoes a qualitative visual change when exposed to a specified dose of radiation (ISO/ASTM 2013d). The dose at which the indicator changes should ideally be below, but near, the minimum dose required for the sterilization process. Since the degree of colour change is not proportional to the dose, these indicators cannot substitute for dosimeters.

Indicators are used as aids in tracking whether or not specific containers have been irradiated (Fig. 5). The relevant manuals (FAO/IAEA 2017; FAO/IAEA/USDA 2019) suggest that an indicator should be attached to each packaging container of sterile insects to help ensure (along with product segregation protocols and other procedural methods) that non-irradiated insects are not unintentionally released in the field. Also, indicators could potentially be used to assist in tracking multiple passes of containers through an irradiator when the sterilizing dose is fractionated into several smaller doses (section 4.1.).

Indicators that are exposed to excessive humidity, high temperature or UV radiation, e.g. sunlight, before or after irradiation may give erroneous readings; hence they are useful only within an irradiation facility where these conditions are controlled.

Recommended dosimetric procedures, including routine dosimetry and the use of indicators for programmes releasing sterile insects, are described in published standards and guides, e.g. ISO/ASTM 2013a, c, d; FAO/IAEA/USDA 2019.

*Figure 5. Radiation-sensitive indicators before (upper) and after (lower) exposure at dose >125Gy (© ISP 2002). (Figure from FAO/IAEA/USDA 2019.)*

## 4. FACTORS MODIFYING INSECT RADIATION SENSITIVITY

The sensitivity of arthropods to radiation depends on many parameters. Radiation sensitivity varies widely among species (section 6.), but environmental conditions, and the biological state of the organism at the time of irradiation, also can have significant influences. These latter factors should be optimized so that sterilized insects are of the highest possible quality.

### *4.1. Environmental and Physical Factors*

#### *4.1.1. Ambient Atmosphere*

Oxygen levels affect the sensitivity of insects to radiation (Baldwin and Chant 1971; Economopoulos 1977; Ohinata et al. 1977; Rananavare et al. 1991; Fisher 1997). Damage induced by radiation is typically lower in an oxygen-reduced environment (hypoxia) than in air, so usually higher doses are needed to produce comparable reproductive sterility. However, because the magnitude of this protective effect tends to be greater for somatic damage than sterility, the use of oxygen-reduced atmospheres is a common strategy to improve sterile insect competitiveness without sacrificing sterility (Parker, Vreysen et al., this volume; Lance and McInnis, this volume). Methods for inducing hypoxia are described in section 3.4.2.

The increased radiation damage in a high-oxygen environment is a general phenomenon in radiobiology. Ionizing radiation initiates a chain of oxidative reactions along the radiation path in the tissues and the formation of simple free radicals ($H^0$ or $OH^0$) with very short lifetimes on the order of $10^{-10}$ sec, which in the absence of dissolved oxygen might be neutralized by combining with hydrogen radicals resulting in no net damage. In the presence of dissolved oxygen, damaging peroxy-radicals ($HO_2^0$ or $RO_2^0$), free radical species with greater stability and

lifetimes, may be formed that irreversibly alter the organic molecules, including the germ cell chromosomes (Tubiana et al. 1990). For the protective effect of low oxygen to be seen, the tissues must be under anoxic or hypoxic conditioning prior to and during irradiation. Anoxic conditioning of adults prior to emergence led to an increase in antioxidant capacity driven by mitochondrial superoxide dismutase and glutathione peroxidase. When exposed to gamma irradiation, a strong oxidative stressor, males that received anoxic conditioning had lower lipid and protein oxidative damage at sexual maturity (López-Martínez and Hahn 2012). It must be noted that high-LET radiation (e.g. alphas, neutrons) is less affected by the presence or absence of oxygen than low-LET radiation (X-rays and gamma radiation). This may be because high-LET radiation causes several ionizations within one macromolecule, damaging it beyond repair (Pizzarello and Witcofski 1967).

#### *4.1.2. Dose Rate*

The adverse effects of radiation appear, in general, to be lessened by reducing the rate at which the sterilizing dose is delivered to the insects. This can be done by using a lower dose rate, and longer irradiation time, for a single irradiation (Yanders 1959; Nair and Subramanyam 1963; Hooper 1975; Mayas 1975; Ilao 1977).

An alternate approach to conserve insect quality is dose fractionation, where the sterilizing dose is delivered over time in a series of smaller irradiations (North 1975; LaChance and Graham 1984; Haynes 1993; Tamhankar and Shantharam 2001). However, because of its impracticality, current AW-IPM programmes applying the SIT usually do not follow this procedure (although see Kumano et al. 2012).

#### *4.1.3. Temperature*

There are some data to suggest that irradiation at reduced temperatures tends to reduce the sensitivity of arthropods to radiation (Rananavare et al. 1991). Low temperatures, to a certain limit, and hypoxia, also reduce the metabolic rate, and therefore the development rate of insects during irradiation. However, temperature does not affect the actual dose delivered to the insect.

### *4.2. Biological Factors*

#### *4.2.1. Cell Stage and Characteristics*

The most radiosensitive cells are those (1) with a high mitotic rate, (2) with a long mitotic future (i.e. under normal circumstances, they will undergo many divisions), and (3) which are of a primitive type. These generalizations, with some exceptions, have become known as the Law of Bergonie and Tribondeau (Casarett 1968). In this regard, germ cells are the most radiosensitive, and show different killing and sterilization susceptibility according to their development stage.

It is generally accepted that chromosomal damage (structural and numerical anomalies) is the cause of dominant lethal mutations. Dominant lethal mutations occurring in a germ cell do not cause dysfunction of the gamete, but are lethal to the fertilized egg or developing embryo (Robinson, this volume). The earlier stages of

spermatogenesis (spermatocytes and spermatogonia) are generally more radiosensitive than later stages (spermatids and spermatozoa) (Proverbs 1969). Dey and Manna (1983) found that chromosomes in spermatogonial metaphase and anaphase I were more sensitive to X-rays than those in other stages. Germ-cell sensitivity in female insects is, however, complicated by the presence of nurse cells that are most susceptible to injury during mitosis (LaChance and Leverich 1962).

The dose required to inhibit mitosis is reported to be inversely proportional to the number of chromosomes, and correlates with the average interphase chromosome volume. The larger the nuclear volume, apparently the greater is the sensitivity. Similar relationships were determined in animals and plants, and used to predict their sensitivity to chronic irradiation (Sparrow et al. 1963, 1967; Casarett 1968; Whicker and Schultz 1982; Jacquet and Leonard 1983). Furthermore, radiosensitivity appears to be influenced by additional parameters including cell repopulation capacity, tissue and organ regeneration ability, and biological repair (Harrison and Anderson 1996).

Chromosome organization can also affect the response to radiation. Several insect orders (Hemiptera, Lepidoptera, Trichoptera, Odonata, and Dermaptera) have holokinetic chromosomes, i.e. properties of the centromere are distributed over the entire chromosome (Kuznetsova and Chubareva 1979; Marec et al., this volume). LaChance and Riemann (1973) suggested that, in these taxa, most dominant lethal mutations cause death after blastoderm formation. In other orders, dominant lethal mutations are expressed during the early cleavage divisions.

#### *4.2.2. Developmental Stage and Age*

Age and developmental stage are important parameters to be taken into consideration when deciding on radiation process parameters for the SIT. In general, adults are less radiosensitive than pupae, which in turn are less sensitive than larvae. Similarly, older pupae tend to be less sensitive to radiation than younger pupae (Ismail et al. 1987; Ahmed et al. 1990; Hamed and Khattak 1991; Dongre et al. 1997). Also, there is a negative relationship between the age of eggs and their sensitivity to radiation (Chand and Sehgal 1978).

#### *4.2.3. Gender*

Regarding sterilization or disinfestation, female arthropods are, in general, more radiosensitive than males (Cogburn et al. 1973; Hooper 1989; Hallman 1998), but there are numerous exceptions. For example, males were found to be more radiosensitive than females in the hemipteran families Pyrrhocoidae, Piesmidae, and Pentatomidae (Mau et al. 1967), the American cockroach *Periplaneta americana* (L.) (Wharton and Wharton 1959), certain Coleoptera (section 6.2.), and ixodid ticks (Purnell et al. 1972).

The wide variation reported among species in relative radiosensitivity of males versus females likely results in part from differences in the maturity of oocytes present when females are irradiated. For example, if Mediterranean fruit fly female pupae are irradiated one or two days before adult emergence, egg production is completely stopped by doses well below those needed to sterilize males. However, on the day before emergence and at later times, females contain increasing numbers of

oocytes that mature into viable eggs even if irradiated at doses sufficient to sterilize males (Williamson et al. 1985).

#### *4.2.4. Size and Weight*

Early studies (Wharton and Wharton 1957; Willard and Cherry 1975) suggested that species with large adults tend to be more radiosensitive than those with small adults. Experiments have shown that the American cockroach *Periplaneta americana* (L.) is killed or sterilized by radiation doses to which smaller insects such as *Drosophila*, *Habrobracon*, and *Tribolium* are much less sensitive (Lanouette et al. 2017; Krüger et al. 2018). Similarly, other studies (Cole et al. 1959) found that the LD-50 varied inversely with the size of the insect species tested (body louse *Pediculus humanus humanus* L., house fly *Musca domestica* L., *Periplaneta americana*, German cockroach *Blattella germanica* (L.), firebrat *Thermobia domestica* (Packard), bed bug *Cimex lectularius* L., and Pharaoh ant *Monomorium pharaonis* (L.)). However, the correlation between size, weight, and radiosensitivity has not proved to be strong.

#### *4.2.5. Diapause*

The effects of diapause on insect sensitivity to radiation appear to vary. Mansour (2003) found that radiation-related reductions in adult emergence were greater following treatment of diapausing than that of non-diapausing larvae of the codling moth *Cydia pomonella* (L.), but other authors reported that diapausing and non-diapausing larvae of other species were equally sensitive to radiation (Ignatowicz 1997; Hallman 2000). Carpenter and Gross (1989) reported no interaction between inherited sterility (IS) and diapause with regard to several traits, although crosses involving moths that emerged from diapaused $F_1$ pupae produced significantly fewer eggs. In contrast, diapausing twospotted spider mites *Tetranychus urticae* Koch appeared more tolerant to radiation than non-diapausing mites (Lester and Petry 1995).

#### *4.2.6. Nutritional State*

Pre- or post-irradiation starvation, or the nutritional state, may influence radiosensitivity (Wharton and Wharton 1959; Stahler and Terzian 1963; Drummond et al. 1966). For example, to achieve 100% sterility, male and female lone star ticks *Amblyomma americanum* (L.) required about 10 Gy before engorgement and 24 Gy after engorgement (Drummond et al. 1966). The data suggested an attenuation of radiation-induced lethality in a blood-fed organism, but the mechanism remains unknown. Beuthner (1975) did not find such differences in *Amblyomma variegatum* (F.), *Hyalomma anatolicum excavatum* Koch or *Rhipicephalus appendiculatus* Neumann.

#### *4.2.7. Additional Factors*

An insect's state of hydration, or moisture content, could potentially influence the effects of radiation, but probably this is applicable mostly to commodity disinfestation. Diurnal rhythms apparently can influence the induction of sterility by

radiation. Rananavare et al. (1991) found that potato tuberworms *Phthorimaea operculella* (Zeller) irradiated in scotophase were more sensitive than those treated in photophase. Finally, genetic differences related to geographical diversity within a species can potentially affect insect radiosensitivity (Fisher 1997; Hallman 2003; Azizyan and Ter-Hovhannesyan 2010).

*Enterobacter* spp. and other bacterial strains as probiotics can be useful where irradiation affects insect fitness. Probiotics in diets greatly improved various fitness parameters in irradiated insects, including pupal weight, longevity, adult size, flight ability, and adult emergence. Also, in terms of mating competitiveness, irradiated males reared on probiotics achieved more matings and transferred larger quantities of sperm to females (Stathopoulou et al. 2021; Augustinos et al., this volume).

## 5. ARTHROPOD SPECIES SUBJECTED TO RADIOSTERILIZATION

The International Database on Insect Disinfestation and Sterilization (IDIDAS) (Bakri et al. 2005; IDIDAS 2018) was developed to collect and share information about radiation doses for disinfestation and reproductive sterilization of arthropods, and to perform a comparative analysis and quality-assurance check on existing data. IDIDAS was based on a literature review and analysis of more than 5330 references that were published during the past six decades. Due to space limitations, these references are not included here but are available on the IDIDAS website (Fig. 6).

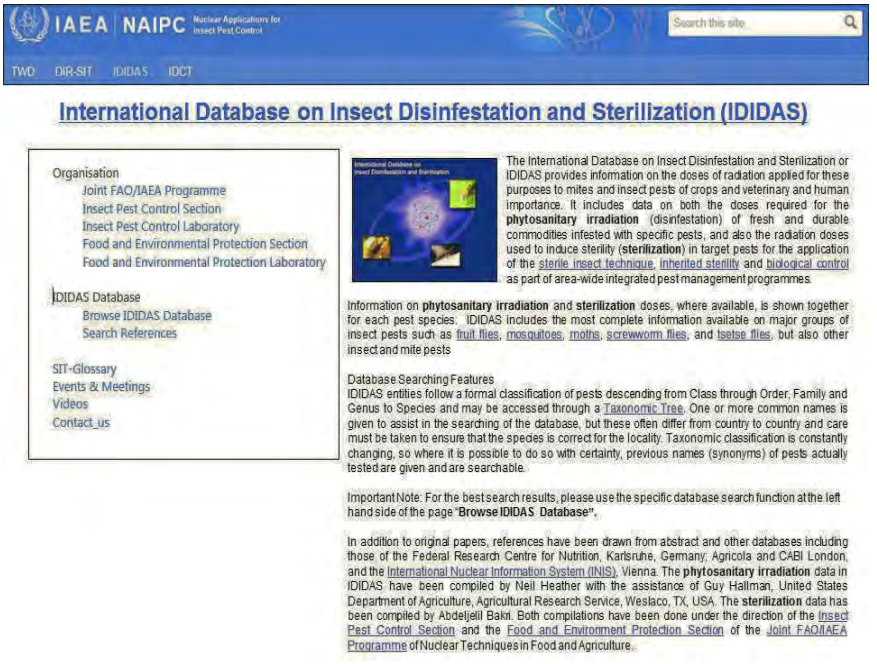

*Figure 6. Home page of the International Database on Insect Disinfestation and Sterilization that provides doses required for the phytosanitary irradiation of infested commodities, as well as for the induction of sterility, in more than 360 arthropod species (IDIDAS 2018).*

In the past six decades, at least 360 species of arthropods of economic importance, belonging to 216 genera, 83 families, 8 insect orders and 2 arachnid orders, have been subjected to irradiation studies for the purposes of research, biological control, or pest management programmes (Table 3). Of these, 29% are Diptera, 24% Coleoptera, 24% Lepidoptera, 9% Hemiptera, 7% Acari, 3% Thysanoptera, 1.5% Hymenoptera, 1% Blattodea, 1% Araneae, and less than 1% Orthoptera and Phthiraptera. Out of 101 entries on Diptera from 17 families and 32 genera, 41 species belong to the Tephritidae; this group is important in pest management and international trade. The Curculionidae (Coleoptera), Tortricidae and Pyralidae (Lepidoptera), and Culicidae (Diptera) follow Tephritidae in the number of species radiosterilized.

Potential sources of error in any compilation of records, such as this database, are numerous. One of the main difficulties derives from taxonomy, an evolving science; during the past 60 years the names of many pest species, families and orders have been revised. In some taxa, e.g. Blaberidae, the mean radiation dose with a large confidence limit range raises questions about the source of the error.

Organisms for irradiation drawn from a cultured population should, therefore, be defined for posterity by lodging voucher specimens in an appropriately secure and curated collection. This is particularly important for groups subject to frequent taxonomic changes, such as the Tephritidae.

## 6. RADIATION DOSES FOR ARTHROPOD STERILIZATION

Arthropods are less radiosensitive than humans and other higher vertebrates (Table 4), but more sensitive than viruses, protozoa and bacteria (Ravera 1967; Rice and Baptist 1974; Whicker and Schultz 1982; Blaylock et al. 1996; Harrison and Anderson 1996). One of the main reasons for the lower radiosensitivity is that arthropods have a discontinuous growth during immature stages, and cells become active only during the moulting and metamorphosis processes. This is encoded in Dyar's Rule, i.e. insects double their weight at each moult and thus their cells need to divide only once per moulting cycle (Hutchinson et al. 1997; Behera et al. 1999). The low sensitivity of most adult insects to radiation is attributed to the fact that they are composed of differentiated cells, which do not undergo replacement (Sullivan and Grosch 1953). Such cells are much more resistant to death or damage induced by irradiation than are dividing or undifferentiated cells.

Radiation doses for sterilization (Table 3), as reported in the literature (IDIDAS 2018), were summarized using similar criteria. In general, the developmental stage irradiated was the pupa, but for some groups data are available only for eggs, larvae or adults. Other experimental parameters such as temperature, radiation source, dose rate, etc., may have differed. Even compiling the data was difficult because of the absence of uniform experimental procedures and dosimetry, and the influence of various parameters. Dose values reported below may also differ from doses that are routinely used to sterilize members of the reported taxa for the SIT, especially in cases where programmes irradiate insects in oxygen-reduced atmospheres. Therefore, the dose ranges presented should be considered only as guidelines for further investigation and to provide general introductory information (Bakri and Hendrichs 2004; Bakri et al. 2005).

*Table 3. Calculated mean and 95% confidence limits (upper $L_2$, lower $L_1$) (Sokal and Rohlf 1995) for radiosterilization doses for insects and other arthropods. Data are for in-air irradiation of males treated mostly as pupae (or eggs, nymphs, adults as indicated). Other factors, e.g. radiation source, temperature, dose rate, and level of sterility achieved, are not necessarily consistent. (References for data from IDIDAS 2018)*

| Order | Family | Number of genera | Number of species | Sterilization dose (Gy) | | |
|---|---|---|---|---|---|---|

| Amphibians | 7–22 | Harrison and Anderson 1996 |
| Reptiles | 3–40 | Harrison and Anderson 1996 |
| Birds | 5–20 | Harrison and Anderson 1996 |
| Humans | 3 | Rice and Baptist 1974 |

### *6.1. Arachnidae*

#### *6.1.1. Acari*

The mean dose to sterilize Acari species ranged from 7.5 to 375 Gy (Table 3). The Chilean false red mite *Brevipalpus chilensis* Baker (Tenuipalpidae), the grain mite *Acarus siro* L. (Acaridae), the brownlegged grain mite *Aleuroglyphus ovatus* (Troupeau) (Acaridae), and the citrus red mite *Panonychus citri* (McGregor) (Tetranychidae) are among the least sensitive species. Hard ticks (Ixodidae), such as *Amblyomma* spp. and *Boophilus* spp., tend to be more sensitive than soft ticks (Argasidae). However, the radiation sensitivity of some tick species appears to change depending on whether the tick is engorged with blood or not (section 4.2.).

#### *6.1.2. Araneae*

A recent study (Magris et al. 2015) used the orb web spider *Argiope keyserlingi* (Karsch) (Araneidae) as a model to assess the effectiveness of male sterilization via 40 Gy irradiation and its consequences on male courtship behaviour. The results validated the thread assay and sterilization as legitimate tools for the study of male courtship behaviour and fertilization success. The other known cases of irradiation of spiders for sterilization were conducted to determine the pattern of sperm precedence (Lance and McInnis, this volume) in multiple-mated females. Kaster and Jakob (1997) used a 20-Gy dose to sterilize males of *Holocnemus pluchei* (Scopoli) (Pholcidae), whereas Schneider and Lubin (1996) applied a 150-Gy dose to *Stegodyphus lineatus* (Latreille) (Eresidae). These species showed last-male precedence and complete sperm mixing, respectively.

### *6.2. Insecta*

#### *6.2.1. Coleoptera*

The mean sterilization dose for Coleoptera ranged from 43 to over 200 Gy (Table 3). The leaf beetles (chrysomelids) are the most sensitive, followed by coccinellids, scolytids, anobiids, curculionids, and bruchids. Species requiring more than 100 Gy as sterilizing dose are by increasing order: silvanids, tenebrionids, bostrichids, dermestids, laemophloeids, and ptinids. Some data in this order suggested a differential response of males and females towards sterilizing doses of radiation. Males may be more sensitive than females, as in the case of the Japanese beetle *Popillia japonica* Newman (Ladd et al. 1973) and the beetle *Tribolium madens* (Charpentier) (Brower and Tilton 1973), or less sensitive as in the case of the khapra beetle *Trogoderma granarium* Everts (Carney 1959; Nair and Rahalkar 1963).

The effects of gamma radiation on the boll weevil were thoroughly studied with a view to applying the SIT (Earle et al. 1979; Villavaso et al. 1989; Haynes 1993). Males were sterilized by about 80 Gy, but their longevity was poor. The egg-laying capacity of females mated to these males was reduced at doses of 50 Gy or more, but they continued to produce some fertile eggs until doses approached 200 Gy, a dose which rendered the weevils non-competitive (McKibben et al. 2001). Studies were conducted on reducing the negative effects of radiation using improved mass-reared

strains, oxygen-reduced atmospheres, and fractionated radiation doses (Earle et al. 1979; Haynes 1993; McKibben et al. 2001). Even though these effects could be mitigated, the large-scale application of the SIT was not practical and cost-effective, and boll weevil eradication succeeded without the SIT by area-wide integration of pheromone traps, and cultural and chemical controls (McKibben et al. 2001; El-Lissy and Grefenstette 2007).

The detrimental effects of radiation have also been one of the main obstacles in applying the SIT to the sweetpotato weevil *Cylas formicarius* (F.), and in particular the West Indian sweetpotato weevil *Euscepes postfasciatus* (Fairmaire). Digestive obstruction following the collapse of the epithelial tissue of the midgut was suggested as the cause of the short lifespan of gamma-irradiated adults (Sakurai et al. 2000). Nevertheless, mitigation measures, including partial sterility and fractionated-dose irradiation at low temperature, were successful in overcoming these effects (Kumano et al. 2010, 2012), and an AW-IPM programme in Kume Island, Japan, to eradicate these two weevils using the SIT is making good progress (Shimoji and Miyatake 2002; Shimoji and Yamagishi 2004); *C. formicarius* was declared eradicated in 2013 (Haraguchi et al. 2014).

### *6.2.2. Blattodea*

Several Blattodea species have been used in radiobiological studies exploring biochemical, physiological, and genetic properties (Shivaji and Rastogi 1974). In spite of the pest status of many cockroach species, there have been relatively few investigations related to pest suppression using sterile insects, due largely to potential problems with releasing large numbers of males into natural populations (Ross and Cochran 1963; Berndt 1978; Menon 1978; Ross et al. 1981; Gecheva and Apostolova 1986). In terms of sterility and mortality, cockroaches are among the most radiation-sensitive insects, with less than 5 Gy required in some cases (*Blaberus craniifer* Burmeister) to induce sterility (Wharton and Wharton 1959; Ross and Cochran 1963). Sexual differentiation in radiosensitivity was observed in *B. craniifer*, where males were more sensitive than females (Gecheva and Apostolova 1986). In Blattodea, it is the adult stage that is most frequently used for sterilization with ionizing radiation.

### *6.2.3. Diptera*

Radiation sterilization of dipterans generally requires doses from 20 to 160 Gy (Table 3). Drosophilidae and Agromyzidae are among the least radiation-sensitive families of Diptera tested, whereas tachinids are the most sensitive. The late pupal (often pharate adult) stage is preferred for the radiation of most fly species because it is practical to handle and ship pupae, and an acceptable balance between competitiveness and sterility is achieved. In the Culicidae, the late pupal in water, or the early adult stage, is irradiated (Helinski et al. 2006, 2009). Semi-field and field experiments have demonstrated that a radiation dose can be selected that gives sufficient sterility without significantly impacting the competitiveness of male mosquitoes. Furthermore, the ability of radiation-sterilized males to locate and participate in naturally occurring swarms, or to start new swarms, was confirmed in *Anopheles arabiensis* Patton (Ageep et al. 2014). A strategy combining a low radiation dose to ensure female

sterility (SIT), and *Wolbachia*-based IIT (Incompatible Insect Technique), is being developed for *Ae. aegypti* and *Ae. albopictus* to ensure that any unintentionally released *Wolbachia*-infected females would not be able to transmit disease, and also would be sterile, thus avoiding population replacement (Lees et al. 2015).

Tephritidae, the major family in this order that is the target of the SIT, require on average about 85 Gy for sterilization. Tephritids are relatively homogeneous with respect to radiation sensitivity — less than 100 Gy are needed to achieve complete sterility in the five major pest genera (*Anastrepha, Bactrocera, Ceratitis, Zeugodacus, Rhagoletis*), and this confirms the generic recommendation of a dose in the range of 100–150 Gy to disinfest agricultural commodities for international trade (Hallman 2000). Many AW-IPM programmes applying the SIT against major pest tephritids have used 100–150 Gy for sterilization, well over the family "average" of 85 Gy. In some early programmes (LaChance et al. 1967), this was a "precaution" to increase the security margin for sterilization, but the overdose often has lowered competitiveness to the point where it reduced the overall ability of irradiated flies to induce sterility into the wild population (Toledo et al. 2004). In recent programmes, these higher doses are usually associated with the use of hypoxia to enhance sterile male competitiveness (section 4.2.) (Fisher 1997).

The Indian tropical midge *Chironomus ramosus* Chaudhuri (Diptera: Chironomidae) tolerated a higher dose of gamma radiation as compared with other known dipterans. The radiation doses required to cause 100% mortality immediately after radiation exposure of egg, larva, pupa and adult stages were 1000 Gy, 3000 Gy, 3200 Gy, and 3500 Gy, respectively (Datkhile et al. 2009). This is one of the least radiation-sensitive species of insects.

### *6.2.4. Hemiptera*

The mean sterilizing dose in the Hemiptera ranged from 55 to 250 Gy (Table 3), with *Circulifer tenellus* (Baker) (Cicadellidae) females being the least sensitive species tested thus far (Ameresekere and Georghiou 1971), and *Halyomorpha halys* (Stål) (Pentatomidae) adults being the most sensitive. In general, adult females required a gamma radiation dose of 50–60 Gy to achieve a high level of sterility. However, higher doses of up to 200 Gy (electrons in this case) were needed to achieve complete sterility in female *Myzus persicae* (Sulzer) (Aphididae) and *Pseudococcus comstocki* (Kuwana) (Pseudococcidae) (Dohino et al. 1997). Adult males typically required a dose between 70 and 200 Gy. For $4^{th}$- and $5^{th}$-instar nymphs, a lower dose was needed; 75 to 100% sterility was achieved with doses between 5 and 100 Gy. Patterns of relative radiosensitivity between females and males differ among species of Hemiptera (IDIDAS 2018). Considering the male adult stage, the most sensitive bugs are the pentatomids followed by pyrrhocorids, reduviids, and coreids. The least sensitive are cicadellids and mirids.

Only 19 species belonging to 10 out of 53 families of Hemiptera have been subjected to radiation for sterilization. For several species, the feasibility of releasing sterile males for pest suppression was investigated (Shipp et al. 1966; Baldwin and Chant 1971; Tadic 1972; Dyby and Sailer 1999; Calvitti et al. 2000). Some hemipterans are facultatively parthenogenetic, but Steffan and Kloft (1973) argued that, with proper timing and climate, effective genetic control might still be possible.

*6.2.5. Hymenoptera*

The Hymenoptera include a number of serious pests, such as Africanized honey bees, and various Formicidae (ants) and sawflies. Since bees and ants are social insects with complex life histories, SIT studies have been limited to a few laboratory experiments (Sakamoto and Takahashi 1981). Only data of Apidae and Formicidae species are shown in Table 3. Most experimental irradiations of other hymenopterans (Braconidae, Eulophidae, Pteromalidae), e.g. the parasitic wasp *Habrobracon hebetor* (Say) (Braconidae), have been conducted in conjunction with relatively basic radiobiological, behavioural and physiological investigations (Hoch et al. 2009).

For male honey bees *Apis mellifera* L. (Apidae), the sterilizing dose is 80–100 Gy (Lee 1958). For queens of ants (Formicidae), such as the invasive fire ant *Solenopsis invicta* Buren, the African big-headed ant *Pheidole megacephala* (F.), the little fire ant *Wasmannia auropunctata* (Roger), and the Argentine ant *Linepithema humile* (Mayr), a radiation dose of 150 Gy has been proposed as a phytosanitary treatment (Follett et al. 2016). However, this proposed dose is higher than the dose required to prevent reproduction in the most tolerant ant species tested to date.

*6.2.6. Lepidoptera*

Lepidopterans as a group are relatively not sensitive to radiation; mean doses for sterilization range from 40 to 500 Gy, with *Thaumetopoea pityocampa* (Denis and Schiffermüller) (Thaumetopoeidae) requiring the lowest documented average dose of 40 Gy (Baccetti and Zocchi 1962), while three pyralid moths *Plodia interpunctella* (Hübner), *Ephestia eleutella* (Hübner), and *Ephestia calidella* Guenée, the noctuid *Xestia c-nigrum* (L.), the gelechiid *Phthorimaea operculella* (Zeller), the tortricid *Grapholita molesta* (Busck), the crambid *Crocidolomia binotalis* Zeller, and the arctiid *Diacrisia obliqua* Walker (Syn. *Spilosoma obliqua* Walker) required the highest recorded doses (> 400 Gy) for complete sterility of pupae and adults (IDIDAS 2018).

For some moth species, e.g. the coffee leaf miner *Leucoptera coffeella* Guérin-Méneville (Katiyar and Ferrer 1968), even when treated with doses as high as 600 Gy and more, the few male survivors retained some fertility. In contrast to other insect orders, the $F_1$ progeny of irradiated male lepidopterans are typically more sterile than their parents (inherited sterility). Moreover, the sex ratio in the $F_1$ generation is biased towards males. Thus, substerilized males can sire completely sterile offspring, and this phenomenon has been exploited in a number of inherited sterility programmes (Marec et al., this volume; Simmons et al., this volume).

*6.2.7. Orthoptera*

Acrididae (Orthoptera), along with Blaberidae (Blattodea) cited above, are among the most radiosensitive insects known (less than 5 Gy needed for sterilization). This is in agreement with Willard and Cherry (1975) who suggested that large long-lived adults are more radiosensitive than small short-lived adults. However, due to the voracious feeding by nymphs and adults, the release of sterile acridids is not applicable for the control of species such as *S. gregaria.*

*6.2.8. Thysanoptera*

No species of Thysanoptera has been investigated for pest suppression directly using the SIT. However, in Japan, radiation sterilization has been investigated as a quarantine treatment to disinfest cut flowers of thysanopteran pests. Doses up to 400 Gy (electron beam) and 100 Gy (gamma rays) were given to suppress the pests *Frankliniella occidentalis* (Pergande) (EPPO 1994) and *Thrips* spp. (Dohino et al. 1996; Hayasi et al. 1999; Bansiddhi 2000), respectively.

## 7. CONCLUSIONS

Although radiation is a key component of the SIT, it is generally not given the attention it deserves - in terms of procedures for irradiation, dosimetry, and the choice of an appropriate dose to maximize the induction of sterility in wild females. The development of accurate dose-response curves for the target insect, using precise dosimetry, is a prerequisite of any programme releasing sterile insects. It is important to note here that the focus needs to be on two types of responses: 1) the sterility in the irradiated insect, and 2) the competitiveness for mating. These are opposing responses, and both need to be considered. There are much data for the first kind, but not enough for the second (Rull et al. 2012; Parker, Vreysen et al., this volume). The survey of the available literature presented here shows the wide variation in the response of the different insect species to radiation, and also highlights the need for accurate dosimetry.

## SUMMARY

The sterile insect technique (SIT) depends greatly on the production of good-quality sterile male insects that are released into target wild populations. Quality is controlled through a system of bioassays of quality parameters that reflect the insect's ability to survive natural enemies, interact with its environment, forage for food and water, and locate, mate and fertilize females of the target population. The system was developed by compartmentalizing the essential survival and mating behaviours of the species involved, and then developing a series of tests to confirm that these behavioural traits are present in the mass-reared insects. The system also has a feedback loop to correct problems in the production portion of the system before they become evident. Nevertheless, regular implementation of field or field-cage tests under semi-natural conditions, where sterile males have to compete with wild males for wild females, is required to provide the ultimate confirmation that the sterile insects have the ability to fulfil their mission after release.

## 1. INTRODUCTION

A major concern of entomologists, and managers of area-wide integrated pest management (AW-IPM) programmes that integrate the sterile insect technique (SIT), is that released sterile males are adequate to fulfil the mission for which they were produced, i.e. that they compete well with wild males, and successfully mate and inseminate the targeted wild females. The components that are most important in such programmes include dispersal, survival under field conditions, location of mating arenas, courtship, mating, and sperm transfer (Koyama et al. 2004; Vreysen, this volume).

The ability of entomologists to evaluate and quantify the effectiveness of mass-reared sterilized insects in interactions with wild insects did not exist in the first decade of applying the SIT (Boller 2002). Initially, the effectiveness of released sterile insects was evaluated according to whether or not the SIT worked in the field. If it failed, managers were able to speculate only on what went wrong, or where and when the problem occurred.

In large suppression and eradication programmes using the SIT (Hendrichs, Vreysen et al., this volume), large numbers of insects must be reared for sterilization and release. Often the emphasis is on the numbers, and insect quality is overlooked or marginalized (Simmons et al. 2010; Itô et al., this volume). For many years, the SIT was considered as a "numbers game", i.e. if a programme began to fail, the remedy was to increase the sterile insect release rate. Only when a programme failed completely might the quality of the sterile insects be doubted, e.g. early in the New World screwworm *Cochliomyia hominivorax* (Coquerel) programme in the south-western USA (Klassen et al., this volume; Vargas-Terán et al., this volume). The controversy surrounding the possible causes of this failure (Bush et al. 1976; LaChance et al. 1982) led to the adoption of regular strain renewal in the mass-rearing facility, and the development of a quality-control system to continuously

monitor the insect colony using a series of behavioural and physiological tests to detect colony changes. This fostered the development of "quality control of mass-reared insects" as a recognized entomological discipline (Boller 1972).

This chapter discusses the history of the development of quality-control technology, the principles and philosophy of assessing insect quality, and the relative importance of the various parameters used to assess insect quality in the context of mass-rearing for the SIT. Quality control is most developed for various fruit fly species (FAO/IAEA/USDA 2019) and for tsetse flies (Mutika et al. 2001, 2002), but some advances have been made recently with Lepidoptera (Simmons et al. 2010; Vreysen et al. 2016) and mosquitoes (Balestrino et al. 2017). Quality control in rearing biological control agents is beyond the scope of this chapter.

## 2. HISTORY AND PHILOSOPHY OF QUALITY CONTROL/ASSURANCE

Scientists have long been aware that insects produced for laboratory purposes should be of a quality appropriate to the experimental system being tested. However, with the advent of mass-rearing and sterilization for the SIT, the quality of mass-produced insects became even more important since appropriate behaviour in the field was now critical to the success of field programmes (Simmons et al. 2010).

Boller (2002) reviewed the history of the quality control of mass-reared insects. He divided this history into four distinct periods: (1) before 1969 — little concern about behavioural quality in rearing programmes, (2) 1969–1975 — a growing awareness of the ideas and concepts of quality control, (3) 1976–1979 — international collaboration began, and prototypes of quality-control systems were initiated, and (4) 1980 to the present — finally the concept, and practical applications in most mass-rearing facilities, were generally accepted (Bernon and Leppla 1994; Bigler 1994; Leppla 2009).

The publication of an "idea book" on fruit fly quality control by Boller and Chambers (1977) is probably responsible for developing the subject of quality control into what is now recognized as a discipline of economic entomology. These authors were able to bring together the diverging schools of thought on quality control, and were able to combine the groups into a global Arthropod Mass Rearing and Quality Control Working Group (later renamed Mass Rearing and Quality Assurance (MRQA)) under the International Organization for Biological Control (IOBC). It had its first workshop in 1982, and subsequently a workshop has been held every three or four years (Leppla and De Clercq 2019). The proceedings of several of the workshops are available from MRQA/IOBC (2019) or in Leppla et al. (2002).

The terms "quality control" and "quality assurance" are closely related and often confused. The objective of quality control is to identify (and correct) defects in the finished product, while that of quality assurance is to prevent defects with a focus on the process used to make the product (Singh 2018). Therefore, quality control is reactive but quality assurance is proactive. The two terms are largely confused in the insect-rearing literature; few authors make a clear distinction, and most work to date is on quality control. Only a few rearing facilities have adopted quality assurance and achieved certification through the ISO 9000 standards (ISO 2019). Therefore,

we will use the expression "quality control" throughout this chapter unless referring to specific work on quality assurance, and our use of "quality control" should be understood to include "quality assurance" unless otherwise indicated.

The fundamentals of quality control are basic to any manufacturing process. Rearing insects to fulfil a specific function is analogous to manufacturing a product. The principles and philosophy of quality control in the realm of manufacturing were established many years ago (Charbonneau and Webster 1978), and these same principles are adaptable today to the quality of mass-reared insects. These principles are described in an excellent book by Feigenbaum (2004), who defined total quality control as:

> an effective system for integrating the quality-development, quality-maintenance and quality-improvement efforts of the various groups in an organization so as to enable production and service at the most economical levels which allow for full consumer satisfaction.

Quality control is divided into three categories:

(1) *Production quality control*, where the inputs to rearing are addressed, including diet ingredients, equipment, etc.,

(2) *Process quality control*, measuring how things are done, such as diet preparation, environmental conditions, infestation rate, larval separation, pupal holding, irradiation dose, etc., and

(3) *Product quality control*, where the insects produced are evaluated for effectiveness in completing the purpose for which they are required.

This chapter concentrates on product quality control and some aspects of process control, while production and process control are covered in Parker, Mamai et al. (this volume).

The "control" in quality control is a management tool consisting of: (1) setting quality standards, (2) appraising conformance to these standards, (3) acting when the standards are breached, and (4) planning for improvements in the standards (Barnes et al. 2015). The difference between mass-producing insects and rearing small colonies for laboratory experiments is in the product rather than the process. In other words, the "bottom line" of a mass-rearing programme is the performance of the released insects in the field (FAO/IAEA 1992).

While the factors affecting product quality are both technological and human, the human factors, involving operators, section leaders, and other personnel, are by far the most important, and the problems most likely to occur are often related to the human factors. The purpose of a quality-control programme is to identify and address the factors leading to low quality during the rearing process, instead of focusing on enhancing low-quality insects after they have been reared (Pereira et al., this volume). Such a programme results in improvements in product quality and employee morale, and reductions in production costs and production "bottlenecks". It also provides improved inspection methods, definite schedules for preventive maintenance, and a factual basis for standards during the rearing process.

The development of a functioning quality-control programme depends on a continuous chain of responsibility for quality through all the workers. To achieve this, responsibilities for quality should be assigned to all key personnel in the rearing facility. Certain workers should be assigned to evaluate insect quality using

scheduled bioassays; their only responsibility should be product quality, and they must be answerable only to the programme manager. These people serve as the "eyes and ears" of the programme manager; they must never be answerable to the rearing manager. "Control" in quality control is achieved when there is constructive feedback, from the quality-control workers through the programme manager, on activities and factors that may be responsible for the lack of quality.

Quality-control procedures both incur costs and provide benefits. The costs are in the appraisal costs of evaluating inputs, processes and product quality, while benefits accrue from savings associated with avoiding: (1) defects during the rearing process, (2) internal failure costs caused by defective equipment, materials, or substandard rearing ingredients, and (3) external failure costs caused by allowing defective products to reach a customer, e. g. insects that do not survive under natural conditions, are not competitive with wild males, are incompatible with the target population, or were inappropriately irradiated.

## 3. STRAIN DOMESTICATION, MAINTENANCE, AND REPLACEMENT

Over time, under artificial rearing conditions, important behavioural and physiological traits undergo change characterized by Ochieng'-Odero (1994) as acclimatization, selection, and domestication. Examples of such affected traits are: fecundity, preoviposition period, courtship song, flight, oviposition, rate of development, production of pheromone, response to pheromone, eye morphology, visual sensitivity, metabolic rate, and resistance to stress (Mangan 1992). The potentially negative impact of changes resulting from this domestication process was discussed by Boller (1972), Rössler (1975a, b), Huettel (1976), Mackauer (1976), Van Keymeulen et al. (1981), Shimoji and Miyatake (2002), and Caprio (2009).

When insects are brought into the laboratory to initiate mass-rearing, the conditions to which they are subjected are very different from those to which the species is adapted in the field. These conditions exert different selection pressures on the individuals brought from the field to initiate a colony, selecting a small subset of the population with a reproductive advantage under the new conditions, potentially creating a genetic "bottleneck". The drive to reproduce may overcome some of the inappropriate environmental aspects, but the accumulated changes in courtship and other behaviours resulting from the selection process may be detrimental once the insect is released back into the field, reducing survival and mating competitiveness with wild insects.

The constraints of mass-production of insects can lead to selection for rapid larval development, short pupal period, early sexual maturity, reduced pheromone production, abbreviated courtship behaviour, and early fecundity (Miyatake 1993, 1998a, b; Miyatake and Yamagishi 1999; Cayol 2000). Changes in mating behaviour will reduce the competitiveness of the reared male insects (Miyatake and Shimizu 1999), but other changes caused by mass-rearing may be linked to other detrimental changes, such as reduced predator avoidance during male courtship (Hendrichs et al. 1994; Hendrichs and Hendrichs 1998). In the melon fly *Zeugodacus cucurbitae* (Coquillett), changes in the circadian rhythm and time of mating can be linked to selection for early mating (Miyatake 2002; Miyatake et al.

2002) and rapid development (Miyatake 1996, 1997a), changes in longevity to early fecundity (Miyatake 1997b), and mating success to rearing density (Miyatake and Haraguchi 1996). However, Liedo et al. (2007) showed that quite small changes in adult colony rearing conditions may improve quality.

To produce large numbers of insects, an appropriate artificial diet is usually required (Lees et al., this volume; Parker, Mamai et al., this volume); often this diet has already been developed and proven adequate for the development of immature stages. However, when a large number of eggs is placed on a limited amount of diet, the situation may change. Waste products from larvae can create an intolerable situation for the insects and/or workers. Metabolic heat could raise the temperature, resulting in too-rapid development. The nutritional value of the diet may change. In any case, selection occurs for individuals that can tolerate these conditions. Pupal handling and storage also create conditions for selection. Each of these parameters can cause a genetic "bottleneck" that severely limits the number of individuals that survive the first few generations. As each subsequent generation becomes better adapted to the rearing conditions, a larger proportion of insects survives.

Severe "bottlenecking" does not always result in a permanently limited gene pool, but the gene frequency may change. When the population is increased substantially, the number of mutations also increases. Nei et al. (1975) speculated that, when populations expand, genetic diversity increases through mutations. The reduction in average heterozygosity per locus depends on the size of the bottleneck, and on the rate of population growth. If, after going through even an extremely small "bottleneck", the population size increases rapidly, there may be significant recovery of heterozygosity. That does not mean that the population returns to the identical diversity of the original gene pool. The western spruce budworm *Choristoneura occidentalis* Freeman, reared for 88 generations in a laboratory, lost 15 alleles, but the quality of the insects (in terms of size, fecundity, vigour, longevity, and disease resistance) was adequate for research purposes (Stock and Robertson 1982); the researchers made no mention of interaction with wild populations. Vale et al. (1976) reported no changes in activity or behaviour of the tsetse flies *Glossina morsitans* Westwood and *Glossina pallidipes* Austen due to laboratory rearing or artificial *in vitro* feeding.

In an AW-IPM programme that applies the SIT, the parameters necessary for the reared and sterilized males to be effective are: successful emergence and good field survival to the age of sexual maturity, sufficient mobility to find food, shelter, and wild females in a mating arena, swarming sites or other sites, mating competitiveness with the wild male for the wild female, mating compatibility with a wild female, successful transfer of sperm and accessory gland fluids, and adequate mobility and survival of the sperm.

To ensure that a rearing procedure is producing insects with these necessary traits, it is essential to have a system of quality-control tests that measures these parameters, as well as overall compatibility and competitiveness with the wild target population. The tests must be conducted on a regular basis so that the rearing process maintains the product quality in the long term (Parker, Mamai et al., this volume). If detrimental changes in insects begin to appear, a feedback loop to the rearing system is necessary so that the shortcoming can be identified, the cause determined, and the problem corrected (Calkins et al. 1988; FAO/IAEA/USDA

2019). A filter rearing system is usually used to maintain the stability of genetic sexing strains, from which the normal mass-rearing colony is derived (Franz et al., this volume; Parker, Mamai et al., this volume). However, the same concept can be used to provide a means to control the selection pressure on the "mother" stock used for the colony while avoiding many of the worst traits from the pressure of mass-rearing (Fisher and Caceres 2000). A further step in this direction is the application of a "pre-filter" – a small adult colony held under semi-natural situations at low densities, e.g. a greenhouse within the mass-rearing facility, where it is exposed to variable conditions, natural-light cycles, hosts and predators to maintain as long as possible the viability of a newly introduced mother colony – instead of regularly bringing in new colonies that rapidly lose, in a few generations, their natural characteristics (Hendrichs and Robinson, this volume).

Strain replacement becomes essential when the properties of the reared strain become too different from the target population, and corrective measures are no longer effective. Replacing a strain can be a major task, takes considerable time, and also involves substantial cost. Newly collected field material may take several generations to adapt to colony rearing, with the colony stabilizing after about five generations (Bartlett 1984). If this involves an obligatory diapause, the time investment is clearly large. In the case of tsetse flies, the colonization of *G. pallidipes* in Ethiopia required more than 60 000 wild females over a period of 14 months to establish a viable colony, representing 4 or 5 generations of adaptation (Alemu et al. 2007).

Another potential hazard is the contamination of the new strain by insect pathogens such as densovirus (Carlson et al. 2006), hytrosavirus (Abd-Alla et al. 2013) or even human pathogens including arboviruses such as dengue that can be transmitted vertically in the case of a colony of mosquitoes (Buckner et al. 2013; Abd-Alla et al., this volume).

## 4. PARAMETERS OF QUALITY CONTROL

Product quality control covers the biological parameters of the reared insects. While the emphasis in this chapter will be on product control, some aspects of process control are also considered. Measurements for different groups of insects may involve different procedures. Information relating to tephritid fruit flies for most of the following sections can be found in FAO/IAEA/USDA (2019), most of which can be adapted to other insect groups, e.g. FAO/IAEA (2006).

### *4.1. Egg Hatch*

Changes in egg hatch or eclosion may indicate problems with mating in the colony, insufficient sperm quality or quantity in the males, inadequate sperm transfer to the females, insufficient sperm motility or infection with a pathogen. Samples of eggs should be monitored regularly for hatch rate, and also to ensure correct larval density in the diet.

### *4.2. Larval Development Time*

As observed previously, changes in development time can be related to inadequate temperatures in the larval diet resulting from an incorrect egg seeding density, diet composition or rearing environment, as well as to changes in courtship behaviour. Development period should be monitored, and selection for rapid development avoided.

### *4.3. Pupal Size*

Pupal size is a good indicator of larval diet quality, rearing density, and any contamination or infestation problems. It is also an indirect measurement of reserves accumulated, affecting the longevity parameter under the stress test (section 4.9.). Pupal size is measured either by minimum diameter or weight. In some insects adult size, e.g. wing length in mosquitoes, is also used.

### *4.4. Percentage Adult Emergence*

The percentage of insects that emerges successfully, and may be affected by larval nutrition (pupal energy reserve), excessive temperature during the rearing and pupal-holding periods, and inappropriate relative humidity. Mishandling of pupae, such as excessive jarring, tumbling at early pupal stages, and excessive radiation dose may also influence percentage emergence and flight capacity.

### *4.5. Sex Ratio and Timing of Emergence*

Sex ratio may be affected by poor pupal-holding conditions, or in the case of a sexing strain that is based on a *temperature-sensitive lethal* (*tsl*) mutation, inappropriate temperature at any stage in the rearing. Timing of emergence indicates the uniformity of pupal age (pupal collection and handling control), and may warn of selection for inappropriate accelerated development. Uniformity of pupal age at irradiation is also a critical determinant of the extent to which exposure to radiation procedures affects the quality of flies (FAO/IAEA/USDA 2019).

### *4.6. Flight Ability*

Released sterile insects need to be sufficiently mobile and have adequate dispersal capabilities to reach, in a timely fashion, all the ecological niches that are occupied by the wild insects (Vreysen et al. 2016). Therefore, the ability of sterile insects to fly, after having been released in the field, is an essential attribute. Those insects that cannot fly to shelter or to food, or cannot reach the pheromone-calling or mating sites, are lost to the programme.

"Percent flight" is the percentage of insects that can fly, based on the number of pupae put into an emergence/flight tube. This may also be corrected for percentage emergence, a parameter called "absolute fliers", and which determines the number of adults that can be released (FAO/IAEA/USDA 2019).

Reductions in flight, dispersal, and survivability due to rearing and/or irradiation have been noted by a large number of researchers, e.g. Dame et al. (1969), Rajagopalan et al. (1973), Sharp (1976), Nelson and Milby (1980), Nakamori and Soemori (1981), and Smith et al. (1981). Little and Cunningham (1978), Sharp et al. (1980), Little et al. (1981), and Sharp and Little (1982) found that sifting of fruit fly pupae at a critical stage in their development was the reason that indirect flight muscles did not insert properly into the cuticle of the exoskeleton during pupal development. This created the "*droopy-wing syndrome*" in which various degrees of droopy wings resulted in non-flying flies (Little and Cunningham 1978).

Knowledge about the mobility and dispersal characteristics of released insects is essential for developing and designing appropriate release strategies (Vreysen, this volume). A simple quality-control test suitable for routine testing, the flight-ability test, measures the ability of the insects to fly out of a restricted space (Carpenter et al. 2012; FAO/IAEA/USDA 2019; Seck et al. 2015; Balestrino et al. 2017; Culbert et al. 2018; Lees et al., this volume). In the last decade, several more elaborate methods have been developed to assess flight ability of mass-reared Lepidoptera, e.g. flight mills (Zhang et al. 2016), wind tunnels (Stringer et al. 2013), and flight assessment cages (Saour 2016), that would be appropriate for periodic testing.

Recent developments in machine vision, to record and analyse insect behaviour, would offer the opportunity to quantify important quality factors such as flight ability, mating propensity, and competitiveness. The flight tracks of irradiated male light brown apple moths *Epiphyas postvittana* (Walker) in a wind tunnel responding towards a calling female were different from those of untreated moths. This approach is likely to be amenable to automation, and could potentially be used in routine quality control (Suckling et al. 2011).

### *4.7. Pheromone Production and Response*

For certain insect groups such as fruit flies and Lepidoptera, pheromone emission and response are the earliest interactions that sterile males have with wild females. For fruit flies, the response of wild females to pheromone-calling wild or sterile males can be compared using the pheromone compatibility test carried out in field cages (FAO/IAEA/USDA 2019). For Lepidoptera, the response of released males to synthetic pheromone can be measured in a wind tunnel (Stringer et al. 2013) and to calling females in mating cages (Saour 2016) or on mating tables (Snow et al. 1976; Flint and Merkle 1984; McBrien and Judd 1996). A commercial insect-locomotion-activity meter was used to assess responses of wild and irradiated *E. postvittana* towards repeatable pheromone pulses. Non-irradiated males responded towards the pheromones significantly better than irradiated males. A high-temperature shock did not change the response of the non-irradiated moths, but it slightly diminished the response of irradiated moths. The system showed potential to assess routinely the quality of mass-reared moths, and might be suitable for factory-scale quality control (Brown et al. 2016).

Continuous laboratory rearing may create subtle changes in components of a pheromone emitted by a sterile male (or female), rendering it unattractive to a wild female (or male) (Minks 1971), but this does not always happen (Richmond and

Berisford 1980; Sower et al. 1973); in the case of field-caged males of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), more wild females were attracted to sterile males than wild males. Close examination of the behaviour of the field-caged males revealed that sterile males "pheromone-called" more frequently, and for longer periods of time, than wild males (C. O. Calkins and T. R. Ashley, unpublished data); this may appear to be an advantage, but actually exposes sterile males to more predation attacks (section 4.10.) (Burk 1982; Hendrichs and Hendrichs 1998).

Protein feeding by adult male Mediterranean fruit flies enhances pheromone production and hence competitiveness (Kaspi and Yuval 2000; Shelly et al. 2002; Yuval et al. 2002, 2007). Protein feeding by males, together with size, also enhances post-copulatory sexual selection (Taylor and Yuval 1999). Therefore, providing sterile males with pre-release access to protein can enhance their field performance (Pereira et al., this volume).

Some insects require specific nutrients and semiochemicals to be able to synthesize their pheromone; supplying this to adults during their maturation can improve field performance, and reduce time spent by the released insects searching for this component in the field (Ji et al. 2013; Obra and Resilva 2013; Tan and Tan 2013; Haq et al. 2014, 2015, 2016; Pereira et al., this volume).

### *4.8. Vision*

Agee and Park (1975) developed the use of an electroretinogram to measure the quality of the vision of fruit flies; irradiation debilitated both the sensitivity and spectral accommodation. Rössler (1980) discovered that the sexual competitiveness of Mediterranean fruit fly males, possessing an apricot eye-colour mutant, was reduced. Using the apricot-eye strain for mating and acoustical tests, it was observed that, during courtship, a mutant male could not follow closely the wing waving of a normal female, resulting in the female rejecting the male's advances.

Visual impairment was also observed in mass-reared New World screwworms (Bush et al. 1976), necessitating strain replacement (Klassen et al., this volume).

### *4.9. Longevity under Stress*

In many insect species, the nutrient reserves acquired during the larval stage and carried through the pupal stage affect the longevity of the adult stage. The longevity/stress test, often related to pupal size, measures the percentage of adults that survives for a set time period, depending on species, without food or water (Orozco-Dávila et al. 1983; Ashley 1987; Mutika et al. 2002). Since this test produces stress, it is indicative of the amount of nutritional reserves present when adults emerge. It has recently been adopted as a quality-control parameter in tsetse flies (Seck et al. 2015).

While protein feeding improves pheromone production in Mediterranean fruit flies, it also reduces survival when they face starvation (Taylor and Yuval 1999). However, Maor et al. (2004) demonstrated that Mediterranean fruit flies fed on protein are successful at exploiting both protein and carbohydrate resources in the

field, and their inability to overcome starvation is not a concern. Yuval et al. (2007) reached the same conclusion, stating that it may be better to release short-lived flies that are highly competitive instead of long-lived sexually ineffective ones.

### *4.10. Startle Activity*

A common problem in laboratory-reared insects is the loss of irritability. Mass-rearing conditions apparently select inadvertently for insects that, to maximize their fitness, can afford under the protected but very dense colony environment to ignore any movements in their immediate surroundings. As a result, they also disregard any potential dangers after being released in the field, and thus are much more susceptible than wild insects to many of the predators they will encounter (Hendrichs and Hendrichs 1998). The "startle test", developed by Boller et al. (1981), measures levels of irritability, and this or a similar test that measures capacity for predator evasion (Hendrichs et al. 2007; Dor et al. 2014; González-López et al. 2016; Dor and Liedo 2018; Rathnayake et al. 2019) could be used to select for increased irritability. The level of irritability appears to be inherited genetically (C. O. Calkins, unpublished data), and hence a proper management of the mother colony could probably maintain some degree of irritability.

### *4.11. Mating Propensity, Compatibility, and Competitiveness*

#### *4.11.1. Mating Propensity*

Mating speed or mating virility is one indicator of fitness (Pendlebury and Kidwell 1974; Lance and McInnis, this volume). This test measures the propensity or willingness of mass-reared sterilized males to mate with virgin females. This is appropriate only for male-choice mating systems; it provides no information for female-choice systems (Lance and McInnis, this volume).

Mating propensity presumably measures, by the use of the mating index, how "eager" the sterile males are to mate. However, as this test is usually conducted in the laboratory with reared males and females, results are often not representative of laboratory male performance when exposed to wild females in the field. This is confirmed by the fact that laboratory-reared males usually have a higher mating index than wild males.

Rapid matings tend to be controlled by the male genotype, while the female genotype may assume importance in slower matings (Parsons 1974). Therefore, for female-choice mating systems, this test is often misleading because mating speed largely reflects the fact that males, selected under extremely high-density adult-colony conditions (where most females become receptive at the same time, and thus a 1:1 operational sex ratio to courting males prevails), obtain rapid matings without going through the proper courtship sequence. These males are often rejected by wild females while attempting to court them in leks under natural conditions (Briceño and Eberhard 1998; Hendrichs et al. 2002).

*4.11.2. Mating Compatibility/Assortative Mating*

The ability of reared sterilized males to compete successfully in mating with the males of the target population is crucial for the SIT. Reduced competitiveness can arise from problems in rearing, irradiation or handling, but also from inherent incompatibility between different strains. For example, the Mediterranean fruit fly arrived in southern Europe from West Africa via the Cape Verde Islands in the 1700s, while it reached Hawaii from East Africa via Australia in the late 1800s, and the populations in South America probably arrived from West Africa. The resulting isolation of these populations might allow the accumulation of changes, which will eventually lead to reproductive isolation and incipient speciation. Some evidence of reproductive isolation in island situations has been found (Hibino and Iwahashi 1991; McInnis et al. 1996; Miyatake 1998a), but an extensive comparison of Mediterranean fruit fly strains from around the world with the main mass-rearing strains showed no significant mating barriers (Cayol et al. 1999, 2002), indicating that in this species any mass-reared strain can be used against any wild population.

Similar results, i.e. no evidence of mating barriers, were obtained with codling moth populations from around the world (Taret et al. 2010), and with olive fruit fly *Bactrocera oleae* (Rossi) populations from the Mediterranean basin (Ahmad et al. 2018). The same result was observed between strains of *G. palpalis gambiensis* originating from Burkina Faso, Mali, and Senegal (Mutika et al. 2013), even though the strain from Senegal, for example, displayed substantial ecological and genetic divergence from the other strains (Bouyer et al. 2010; De Meeûs et al. 2015).

Reisen et al. (1980) detected assortative mating in releases of *Culex tritaeniorhynchus* Giles, as did Raulston et al. (1976) with the tobacco budworm *Heliothis virescens* (F.). The latter was caused by a change in the temporal mating period of the laboratory-reared population which initiated courtship 2 h earlier than the wild population. Zervas and Economopoulos (1982) observed that laboratory-reared olive fruit flies also began to mate 2 h before wild flies, although this was not observed in field-cage studies using newly established colonies (Ahmad et al. 2018). Wong et al. (1982) noted assortative mating between laboratory-reared and wild oriental fruit flies *Bactrocera dorsalis* (Hendel). On the other hand, Spates and Hightower (1967) found that New World screwworm males became sexually more aggressive when reared in the laboratory. However, assortative mating in *Anastrepha fraterculus* (Wiedemann) led to the realization that this widespread South and Central American species is actually a complex of sibling species (Cáceres et al. 2009; Segura et al. 2011; Hernández-Ortiz et al. 2012; Devescovi et al. 2014).

Differential mating preferences of wild and released sterile insects will reduce the efficacy of the SIT component in AW-IPM programmes (Hibino and Iwahashi 1991), but these negative impacts have often been underestimated (Vreysen et al. 2006). It is known that selective mating occurs between colonized New World screwworm strains of different age, with males from strains that have been cultured for many generations being non-selective in mating with old-line or new-line females, but new-line males copulated more readily with females from newly colonized strains than with females from older strains (Spates and Hightower 1970). This asymmetric mating isolation between the behaviours of old and new screwworm strains has been associated with reduced female contact-pheromone

activity (Hammack 1987), but its relevance and effects on the efficiency of SIT projects have never been researched properly in the field. Vreysen et al. (2006) present models that examine this effect, and it was demonstrated clearly that, for older screwworm strains, a doubling in the number of sterile male insects released per surface area is required to obtain a suppression effect similar to that when no asymmetric mating isolation is present. Consequently, the discriminatory behaviour of wild screwworm males against sterile females has significant economic implications.

#### *4.11.3. Mating Competitiveness*

In-depth knowledge about the mating behaviour of the target insect, and the factors that could impair this behaviour, is indispensable for improving the performance of the sterile insects – to increase the overall efficiency of the SIT, and hence to reduce its cost (Hendrichs et al. 2002). The size of males can also be an indirect indicator of mating competitiveness. It affects mating success in the Caribbean fruit fly *Anastrepha suspensa* (Loew) (Burk and Webb 1983) and the Mediterranean fruit fly (Churchill-Stanland et al. 1986, 1987; Bloem et al. 1993a, b, c; Economopoulos et al. 1993; Orozco and Lopez 1993). A larger male is more competitive against rival males, and females tend to select larger males over smaller ones, but Hunt et al. (2002) found an effect of size on pheromone calling but not on overall mating success. In field releases, larger males disperse farther and live longer than smaller males (Bloem et al. 1994) (section 4.9.). Pupal weight is a good indicator of adult size, and Mediterranean fruit fly programmes (to comply with quality standards) require that late-stage pupae should weigh about 7 mg. In New World screwworm programmes, late-pupal weight should not fall below 44 mg.

However, in *Aedes aegypti* (L.) mosquitoes, it was demonstrated that large females showed no evidence of a mating preference, whereas small males were relatively more successful than large males when mating with small females, exhibiting an advantage of around 20–25% (Callahan et al. 2018). This result shows that size might matter, and should be monitored in mosquito SIT programmes, particularly when considering that laboratory-reared mosquitoes can often be larger than their wild counterparts (which experience more competition for food in their larval habitats, especially in the case of *Aedes* species that exploit micro-habitats).

Laboratory bioassays often do not indicate accurately the field performance of reared insects (Katsoyannos et al. 1999). Quality-control tests (that usually are more appropriately carried out under semi-natural conditions in field cages containing vegetation) are: pheromone attractiveness, mating compatibility, and mating competitiveness (Zapien et al. 1983; Cayol et al. 1999, 2002; FAO/IAEA/USDA 2019). It has been recommended that, at least once a year, AW-IPM programmes releasing sterile insects obtain insects from the field population being targeted, and compare them with mass-reared insects in field cages that permit as large a range of natural behaviours as possible, including female choice (FAO/IAEA/USDA 2019; Lance and McInnis, this volume; Parker, Mamai et al., this volume). Field-cage and field tests are discussed below (section 8.).

### *4.12. Remating*

A further important component of mating behaviour for the SIT is remating by wild females (Lance and McInnis, this volume; Whitten and Mahon, this volume). Female monogamy is not required for the SIT, but if there is a differential rate of remating by females first mated to a sterile or a wild male, or there is sperm selection following multiple matings, there will be an effect on the SIT (Bonizzoni et al. 2007; Pérez-Staples et al. 2013).

Remating may be controlled by factors transferred by the male during copulation; if the mass-reared males do not transfer the necessary factors, the incidence of remating may rise differentially (Jang 2002; Vera et al. 2002). This may be measured in an extension to the field-cage compatibility/competitiveness tests listed above. The females from pairs collected in the compatibility/competitiveness test are marked according to the male with which they first mated, and the field-cage test repeated on subsequent days. Remating pairs are then scored, and the results examined for evidence of differential remating (McInnis et al. 2002).

Multiple mating of female insects is common in Lepidoptera; this was recently confirmed with *Eldana saccharina* Walker under controlled laboratory conditions. The multiple-mating potential of both males and females might have consequences for obtaining adequate sterile to wild male overflooding ratios (Walton and Conlong 2016a; Barclay, this volume). Multiple mating is also common for females of the cluster caterpillar *Spodoptera litura* (F.); a study on sperm-use patterns revealed that females preferentially use the sperm of the last male to mate. In addition, female mating success, remating propensity, and fertility were significantly influenced by mating sequences that included irradiated males (Seth et al. 2016). Multiple mating is not uncommon in insects, e.g. fruit flies, tsetse flies, and mosquitoes. Barclay (this volume) discussed modelling the impact of multiple mating on the SIT.

## 5. EFFECTS OF IRRADIATION ON QUALITY

An essential step in the SIT is the induction of sterility. In many insect groups, irradiation results in a reduction in competitiveness (Bakri et al., this volume), and much recent work has been aimed at reducing this negative effect.

The timing of irradiation can be adjusted to reduce the effects without creating logistical and handling problems. Normally, the least amount of damage to adult males is caused when irradiation is carried out shortly after emergence, but the problem of irradiating large numbers of adult insects at one time is often challenging; therefore, usually pupae are irradiated as pharate adults shortly before emergence (Bakri et al., this volume). For various fruit flies, pupal development is monitored by eye colour to determine the optimal timing for irradiation (Ruhm and Calkins 1981; Resilva and Pereira 2014; Resilva et al. 2019).

Irradiation in air creates free radicals that are detrimental to the quality of insects. When oxygen is excluded by flooding the containers with nitrogen, this problem is reduced in fruit flies and codling moths (Ashraf et al. 1975; Robinson 1975). Later, it was discovered that when containers of fruit fly pupae were sealed, pupal metabolism quickly exhausted the oxygen and produced carbon dioxide, resulting in

similar protection (Ohinata et al. 1977; Bakri et al., this volume). The effects of hypoxia have also been investigated in several other insects (Vreysen and Van Der Vloedt 1995; Hallman 2005; López-Martínez et al. 2014, 2016; Yamada et al. 2019).

In many insect species, females become 100% sterile at lower doses than males. Attempts to attain 100% sterility in males usually reduce quality; often it will be better to reduce the dose so as to obtain a better induction of sterility in the field females through more competitive males (Hooper 1972; Toledo et al. 2004; Parker and Mehta 2007).

In Lepidoptera, the higher radiation sensitivity of females has been exploited to adopt an $F_1$ sterility or inherited sterility (IS) strategy; very high radiation doses are required to induce dominant lethal mutations in Lepidoptera (Proverbs and Newton 1962; Blomefield et al. 2010; Soopaya et al. 2011; Cagnotti et al. 2012, 2016; Jang et al. 2012; Saour 2014; Fu et al. 2016; López-Martínez et al. 2016; Walton and Conlong 2016b; Chakroun et al. 2017; Marec et al., this volume). In these insects, a lower dose that partially sterilizes the males but completely sterilizes the females can be employed to induce sterility in the subsequent generation. A higher percentage of male moths exposed to substerilizing doses respond to virgin females than those treated with higher doses (Bloem et al. 2001; Simmons et al., this volume).

Irradiation can affect various quality parameters to varying degrees, including survival (Vreysen and Van Der Vloedt 1995; Opiyo 2001), mating competitiveness and seminal-fluid transfer (Mutika et al. 2002), flight ability (Stringer et al. 2013; Saour 2016; Zhang et al. 2016), and production of and response to pheromones (McGovern et al. 1975; White and Hutt 1975). Both dose fractionation (Vreysen and Van Der Vloedt 1995; Kumano et al. 2011a, b) and hypoxia (Ohinata et al. 1977; Vreysen and Van Der Vloedt 1995; Hallman 2005; López-Martínez et al. 2014, 2016; Yamada et al. 2019; Bakri et al., this volume) may reduce these negative impacts.

## 6. EFFECTS OF CHILLING ON QUALITY

Before irradiation and prior to shipping, pupae are often chilled to lower their metabolic rate. Therefore, understanding tolerance of pest insects to thermal extremes is essential to ensure optimal insect quality after shipment; tolerance traits can provide insights into constraints on their activity and survival. Long-distance shipments of irradiated Mediterranean fruit fly pupae (either chilled or not chilled) were compared by Brazzel et al. (1986). Pupae shipped for 18 h in hypoxia averaged 77% emergence and 70% fliers, but those shipped in hypoxia in chilled boxes averaged 82% emergence and 76% fliers. Pupae shipped for 40 h in bottles in hypoxia averaged 48% emergence and 34% fliers, but those in hypoxia and chilled boxes averaged 73% emergence and 62% fliers.

Prolonged chilling (exceeding 26 h) can be detrimental to fly emergence at the release point, but not as detrimental as hypoxia with no chilling (FAO/IAEA 2017a). Serghiou (1977) discovered that the competitiveness of irradiated sterile Mediterranean fruit flies decreased as their exposure to chilling increased, but chilling did not have an adverse effect on survival.

In view of the need to synchronize releases of sterile male tsetse flies (*G. pallidipes*), Mutika et al. (2002) stored pupae at various low temperatures, and found that no significant differences in emergence, survival without a blood meal, or insemination capacity occurred. In fact, male adults emerged from pupae that had been stored at 15ºC started mating more quickly, and formed more mating pairs, than the controls (stored at room temperature). However, if adult males were chilled (and then removed from the low-temperature container for testing), insemination capacity was reduced, and mortality was 10–32%. Later, it was observed that storing the pupae at 4°C actually reduced the emergence rate significantly, down to 76.1 ± 13.2% when they were chilled for 1 d in the source insectary before transport to Senegal, and to 72.2 ± 14.3% when they were chilled for 2 d (Pagabeleguem et al. 2015).

In *Anopheles arabiensis* Patton, chilling the males at 4–10°C for 24 h did not have any significant negative effect on their survival (Culbert et al. 2017). Also, in *Ae. aegypti,* chilling males for 2 h at 4–10°C did not reduce the survival rate significantly, but chilling them at 0°C for the same duration reduced their survival significantly. Moreover, the full insemination rate of females by the treated males, as well as their flight ability, declined from exposure to temperatures of 8°C and lower (Culbert et al. 2018).

Insect thermal limits may vary with microclimatic fluctuations, and may be influenced by biotic or abiotic factors. Chill-coma temperature (CTmin) and critical thermal maximum (CTmax) were significantly different for *E. saccharina* moths collected from two host plant species, i.e. sugar cane and papyrus. However, the lower lethal temperature (LLT) of these moths, and the freezing temperature of the pupae, did not vary with the host plant species. Therefore, host plants may strongly mediate the lower critical thermal limits, but not necessarily the LLT or freezing temperatures (Kleynhans et al. 2014).

Male and female laboratory-reared *E. saccharina* were more heat tolerant than wild moths, but the latter were more cold tolerant than their laboratory-reared counterparts. Irradiation had a deleterious effect on the CTmax and the CTmin. Moths irradiated with a lower dose were more heat and cold tolerant than those irradiated with a higher dose, highlighting again the importance of treating lepidopterans with a lower dose rather than with the full sterilizing dose (Mudavanhu et al. 2014).

False codling moths *Thaumatotibia leucotreta* (Meyrick) exposed to -4.5°C for 2 h or to -0.5°C for 10 h had a 50% probability of survival, and their low-temperature tolerance was not affected by gender or adult age. Only limited evidence for cold hardening was found; survival did not increase after exposure to non-lethal, low- and high-temperature pre-treatments (Stotter and Terblanche 2009). The colony was found to be adequate under most temperature conditions, but not during the coldest months (Boersma and Carpenter 2016); it is proposed to develop a second, cold-adapted strain for release during the winter months.

Recapture rates of codling moths (that had been acclimated to low temperatures) were significantly greater under cooler conditions in the wild than either warm-acclimated or control moths. However, improvements in low-temperature performance of cold-acclimated moths came at a cost to performance under warmer conditions. Conversely, moths acclimated to higher temperatures performed better

under warmer ambient conditions in the field when compared with cold-acclimated moths or control moths. Laboratory data matched field results, indicating that assessment of thermal activity of codling moths in the laboratory may also apply to their field performance (Chidawanyika and Terblanche 2011).

Rearing codling moths through diapause improved their competitiveness in orchards (Dyck 2010), but their radio-sensitivity was similar to that of moths reared under non-diapause conditions (Carpenter et al. 2010).

## 7. POST-SHIPMENT QUALITY CONTROL AT EMERGENCE AND RELEASE FACILITIES

In operational programmes covering large areas (or when shipping sterile insects to transnational customers), it may be necessary for efficient operation to have one or more emergence and release facilities separate from the rearing facility that are close to the release sites (Dowell et al., this volume). Pupae (or chilled adults) can be shipped in bulk from the rearing facility to the emergence and release facility (FAO/IAEA 2017a) where they can be held for emergence and maturation, and be supplied with appropriate environmental conditions, diet components and other treatments to condition them for release (Chidawanyika and Terblanche 2011; Ji et al. 2013; Obra and Resilva 2013; Tan and Tan 2013; Haq et al. 2014, 2015, 2016; Dowell et al., this volume; Pereira et al. this volume).

The FAO/IAEA/USDA (2019) manual (sections 6 and 7) provides a number of tests for process and product quality control for emergence and release facilities receiving shipments of sterile insects. This international standardization of post-shipment quality-control tests allows the supplier and receiver to compare the quality of commercial and transboundary shipments of sterile insects.

## 8. FIELD-CAGE AND FIELD TESTS

### *8.1. Field-Cage Tests*

As noted above, laboratory tests of competitiveness or compatibility generally do not reliably indicate the performance in the field (Katsoyannos et al. 1999; Itô et al., this volume; Vreysen, this volume). A much better measure can be obtained by using a walk-in field cage (White et al. 1977; Calkins and Webb 1983; Chambers et al. 1983). Standard procedures for field-cage operation have been defined for fruit flies (Cayol et al. 1999, 2002; FAO/IAEA/USDA 2019); increasingly, these have been adapted for other species such as tsetse flies (Mutika et al. 2001), mosquitoes (Oliva et al. 2012; Damiens et al. 2016), and Lepidoptera (Taret et al. 2010; Mudavanhu et al. 2016).

A walk-in field cage consists of a mesh cage, at least 2.3-m high and 3-m wide, erected over a host plant or other suitable vegetation (Calkins and Webb 1983). Equal low numbers of wild males and females of the target population, as well as sterile mass-reared insects of both sexes, are introduced into the cage, and mating pairs are observed. When a genetic sexing strain is being tested, tests with only sterile males may also be conducted. The four possible outcomes (SS, SW, WS, and

WW) are then examined for trends in the mating (Box 1). The low-density and semi-natural conditions permit near-normal courtship and mating behaviour, such that any changes in the behaviour of the mass-reared insects should be apparent. The results of field-cage experiments are affected by the conditions under which the mass-reared insects have been reared; therefore, it is essential that conditions be tightly controlled. Each test should be replicated a minimum of 8–10 times, but data discarded when low proportions of both males and females from any strain participate in mating activities (FAO/IAEA/USDA 2019).

It is recommended that field-cage tests be performed against wild-collected insects about once per year (FAO/IAEA/USDA 2019; Lance and McInnis, this volume). Field-collected larvae must be handled properly. For example, if coffee berries infested with Mediterranean fruit flies are placed on screens and the larvae collected in pans below, the berries tend to dry out causing the larvae to exit the fruit prematurely. Then the emerged flies are smaller than normal, and this can invalidate bioassays comparing wild fly and laboratory-reared fly behaviours.

Mating competitiveness and compatibility of non-irradiated and irradiated *E. saccharina* assessed under semi-field conditions showed that wild moths did not discriminate against irradiated or laboratory-reared moths (Mudavanhu et al. 2016). Irradiated males mated significantly more times than their wild counterparts, regardless of the type of female mate, indicating that colony males were still as competitive as their wild counterparts. When male *C. sinensis* moths irradiated with 250 Gy competed with untreated wild males for untreated female mates in walk-in field cages, the Fried Competitiveness Index (Haisch 1970; Fried 1971) C value of 0.48 obtained indicated that a substerilizing dose of 250 Gy would be adequate for programmes that include an IS component (Fu et al. 2016).

Field-cage assessments are also useful for more detailed assessments of behaviour, e.g. time of mating, mating duration, remating, and the sequence and timing of specific behavioural components of courtship and pheromone calling (FAO/IAEA/USDA 2019). Standard walk-in field-cage tests were validated for use with *E. postvittana*. Mating frequency of *E. postvittana,* and the production of sex pheromone by the females, are significantly reduced with increasing radiation dose (Stringer et al. 2013). Modified test procedures were developed in which eggs are collected individually from the moths, after they had sufficient opportunity to mate in field cages, and then the females are dissected to determine the presence of one or more spermatophores (Woods et al. 2016).

In *Ae. albopictus*, field-cage experiments conducted in La Réunion island demonstrated that the Fried Competitiveness Index of sterile males was only 0.14 when they were released at 1-day-old, but improved to 0.53 when the release occurred after a 5-day holding period in laboratory conditions, indicating the appropriate age for release (Oliva et al. 2012). Furthermore, it was demonstrated that increasing the release ratio of sterile males led to a significant reduction in the competitiveness index, with 0.51, 0.20, and 0.18 recorded for the ratio of 100:100:100, 500:100:100, and 1000:100:100, respectively (Damiens et al. 2016).

*Box 1. Indices of Compatibility and Competitiveness*

A standard field-cage experiment results in four figures, the numbers of each of the four possible pairings formed during the test period, SS, SW, WS and WW, where S represents sterile, W wild (fertile), and males are indicated first. The categories WS and SS will be missing in the case of genetic sexing strains where sterile females are not produced. These four figures have been combined in various ways to produce indices of competitiveness and compatibility, each emphasizing a different aspect, and each with advantages and disadvantages. (For more details, see section 3.1. in FAO/IAEA/USDA (2019)).

The *relative isolation index* (RII) gives an indication of mating compatibility between two strains. It is calculated as:

$$RII = \frac{SS \times WW}{SW \times WS}$$

A value of 1 indicates random mating, with larger values indicating assortative mating. This index is sensitive to changes in a single type of mating (e.g. a drop in the important category SW), is not affected by the overall level of participation of the different insect types, and does not depend on the ratio of sterile to wild insects in the test. The disadvantages are that the index is undefined if either SW or WS is zero, and it changes rapidly for a difference of only one if a category is small. The value of RII can be interpreted as the number of sterile males that have to be employed to be equivalent to one wild male. Values normally vary between 1.5 and 5, and values consistently above 3 are a cause for concern.

The *isolation index* (ISI) is defined as:

$$ISI = \frac{(SS + WW) - (SW + WS)}{SS + WW + SW + WS}$$

It ranges from -1 (complete negative assortative mating) through 0 (random mating) to +1 (complete positive assortative mating). The main advantages of the ISI over the RII are that it is easier to interpret values from -1 to +1 than from 0 to infinity, it is not as sensitive to a change in a small category and is defined even when one category is zero. Values normally lie between 0.1 and 0.4, and values over 0.5 are a cause for concern.

The ISI is normally combined with the *male relative performance index* (MRPI) and *female relative performance index* (FRPI) defined as:

$$MRPI = \frac{(SS + SW) - (WS + WW)}{SS + SW + WS + WW} \qquad FRPI = \frac{(SS + WS) - (SW + WW)}{SS + SW + WS + WW}$$

which show the proportion of sterile males and sterile females taking part in matings, and should be used to interpret values of ISI over 0.5.

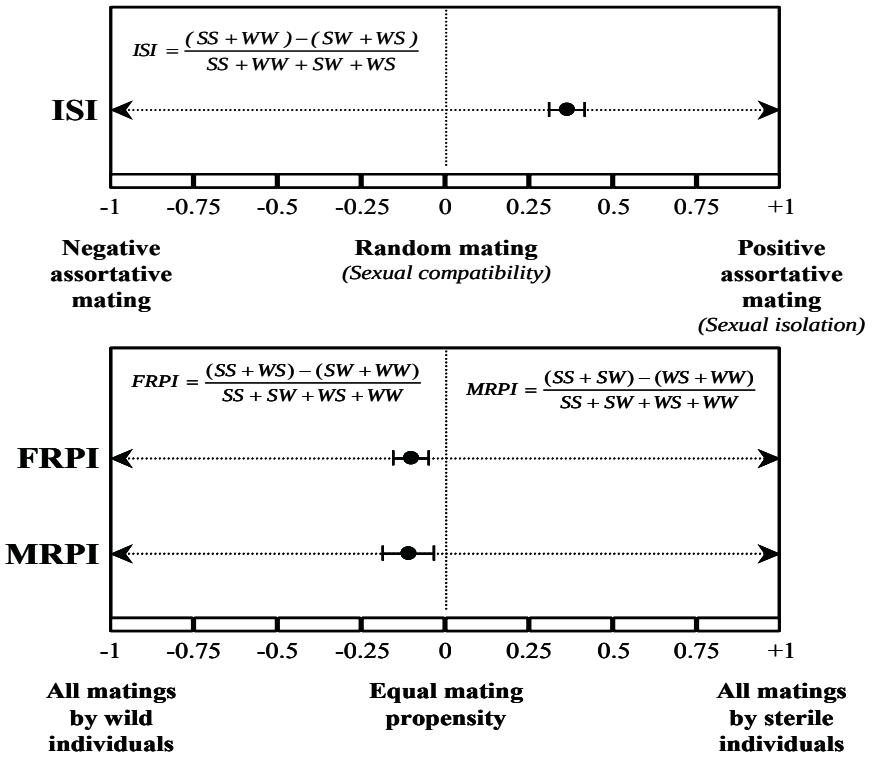
These index values can be displayed graphically (then easier to interpret), as shown below.

In contrast to the above, the Fried Competitiveness Index (Haisch 1970; Fried 1971) is based on the fertility of a particular cross combination rather than on the number participating in the cross. It is defined as:

$$C = \frac{N}{S} \times \frac{H_n - H_e}{H_e - H_s}$$

where C is competitiveness, $H_n$ and $H_s$ are defined as the fertility of crosses between normal and irradiated males with normal females (in laboratory tests), and $H_e$ is the observed fertility in an experimental set-up with N normal males and S irradiated males. A C value of 1 indicates equal competitiveness; observed values usually fall between about 0.3 and 1. It was originally devised for field tests where $H_e$ was measured by collecting egg masses in the field. The variance of C is given in Hooper and Horton (1981), and is a minimum when $H_e$ lies halfway between $H_n$ and $H_s$. (See also Pagendam et al. (2018) for an improved estimate of the Fried Competitiveness Index.)

*Box 1. Continued*



*Graphic representation of isolation index (ISI) and female and male relative performance indices (FRPI, MRPI) (FAO/IAEA/USDA 2019).*

### *8.2. Field Tests*

The capacity of sterile insects to survive in the field, and to disperse to feeding, mating, and resting sites, is also critical (Hendrichs et al. 1991). Survival and dispersal rates of different rearing strains can be compared using various release/recapture methods (Itô et al., this volume; Lance and McInnis, this volume; Vreysen, this volume). Such rates are often not correlated with a flight-ability test of the same lot of sterile insects in the laboratory, or even survival in field cages, because they also measure the ability of the sterile insects to find food, to respond to attractants, and to evade predators (Hendrichs et al. 1993). C. O. Calkins and T. R. Ashley (unpublished data), using mass-reared Mediterranean fruit flies irradiated at the usual dose, and at twice this dose, monitored dispersal in the field. Flies that had been exposed to twice the usual radiation dose had very low rates of dispersal and survival. Other dispersal studies by Bloem et al. (1994) compared large flies (from pupae 8–8.5 mg in weight) with small flies (from pupae 5–5.5 mg); a higher

percentage of large than small flies was captured initially, and over a longer period of time.

Ultimately, the competitiveness of the insects should also be tested in the field, e.g. White and Mantey (1977) and Villavaso et al. (1980). It is usually not possible to detect mating pairs directly in the field, but the competitiveness of the released sterile males can be estimated by comparing the egg hatch obtained from egg masses collected in the field or from captured wild females (some with sterile, others with fertile matings) (Haisch 1970; Fried 1971; Hooper and Horton 1981; Iwahashi et al. 1983; Parker and Welch 1991). In the case of tsetse flies, the proportion of females having mated with a sterile or a wild fertile male can be estimated from dissecting and examining the reproductive status of trapped wild females (Vreysen, this volume). An open-field study, using codling moths from Canada and South Africa, indicated that moths of both origins were equally attracted to calling females from Canada and South Africa; therefore, the codling moths from Canada were compatible with codling moths established in South Africa (Bloem et al. 2010). Such an estimate takes into account all the factors that affect the induction of sterility in the wild population, including survival, dispersal, mating competitiveness, sperm transfer, remating, and sperm competition (Vreysen, this volume). The same test can also be conducted in a field cage (FAO/IAEA/USDA 2019).

In *G. palpalis gambiensis*, it was demonstrated that a strain colonized for more than 40 years was still competitive in the field in its country of origin (Burkina Faso) (Sow et al. 2012), and more surprisingly that it was more competitive than an autochthonous and recently colonized strain in Senegal (Bassène et al. 2017). In *Glossina austeni* Newstead, it was also demonstrated that sterile males were able to aggregate exactly in the same sites as the wild males, leading to a homogeneous sterile to wild ratio during the successful eradication campaign in Zanzibar (Vreysen et al. 2011).

## 9. CONTROL CHARTS AND DASHBOARDS

Data generated by quality-control assays are not very useful until they can be graphed in a sequential manner to show trends. In 1924, W. Shewhart of Bell Telephone Laboratories first developed control charts (Feigenbaum 2004). A chart consists of sequential plots of a specific quality criterion on a graph that has a central line, and upper and lower control limits (Box 2). The control limits may either be defined a priori, or more usually are derived from long-term data. For this, many samples are taken over an extended period, and the mean or median computed for the central line; the upper and lower control limits are usually three standard errors on either side of the central line (Charbonneau and Webster 1978). Each new quality-control value is plotted on the chart, and both its position and the trend over the last seven points are assessed for conformity with a set of standard rules. A single value out of bounds is less a concern than a continuing trend away from the central line. Control charts have been proposed for the Mediterranean fruit fly (Calkins et al. 1982), Lepidoptera (Fisher 1983), and tsetse flies (Timischl 1980).

A tool is now available specifically for monitoring the key parameters in insect mass-rearing in the manner of a Dashboard (FAO/IAEA 2018). This tool links production parameters with product quality ones, and presents the data in an easily understandable graphical format to facility the management of large or small colonies by both management and technical staff.

## 10. IMPACT OF LOW-QUALITY INSECTS ON ERADICATION PROGRAMMES USING THE SIT

Calkins and Ashley (1989) attempted to put an actual monetary value on the impact of producing low-quality insects. Using Knipling's (1979) model, Calkins et al. (1996) inserted varying values of the quality of Mediterranean fruit flies established during a pilot test for quality control. Using the New World screwworm as an example, with a growth rate of 5 and an overflooding ratio of 9:1, it would take five generations to achieve eradication. Since the Mediterranean fruit fly has a much greater biotic potential, and based on its life-history parameters, a growth rate of 12 was established; an overflooding ratio of 9:1 resulted in an increase in the population each generation. The "rule of thumb" for Mediterranean fruit flies, selected during the numerous fly invasions into California, USA, is a ratio of 100:1. If all flies were 100% effective, theoretically this ratio achieves eradication in three generations.

*Box 2. Shewhart Control Charts*

Control charts are a well-established tool for stabilizing industrial processes. They are formed by plotting sequentially the successive values of a control parameter. These are then compared with a central line (CL), upper control limit (UCL), and lower control limit (LCL), using certain criteria to determine if the process is in control.

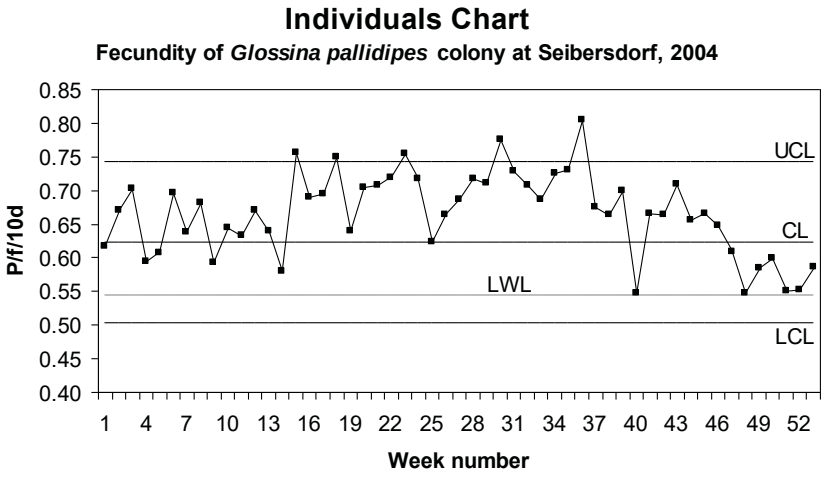
The graphed parameter will usually be the mean of a sample taken from the process. In industrial processes, this may be compared with a priori limits, e.g. the design diameter of a shaft and the specified tolerance limits. In insect rearing, we do not usually have such a priori limits, and base the assessment of the graphed value by comparing it with long-term historical values. The long-term mean is taken as the central line, and the upper and lower control limits are defined as three standard errors above and below the mean. By standard statistical theory, if the parameter plotted is normally distributed, random fluctuation will cause about 0.1% of the values to lie above the UCL or below the LCL. If more than one value lies outside the control limits, this indicates a systematic influence, and the process is said to be out of statistical control.

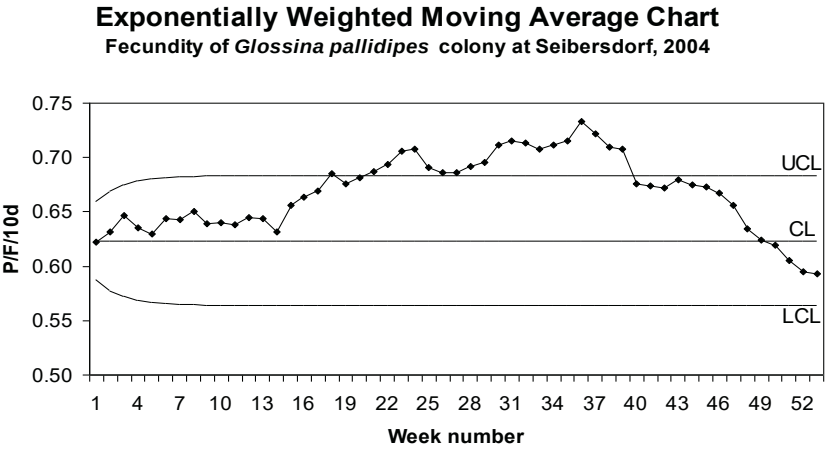
Two examples of control charts are given below — monitoring the fecundity of the *G. pallidipes* colony at the FAO/IAEA Seibersdorf laboratories. The parameter plotted is weekly fecundity, expressed as pupae per live female per ovarian cycle (10 days) (P/F/10d). The central line is the average value over a 105-week period (2003–2004). Since only a single measurement is taken each week, variability is estimated by using the difference between successive pairs of values, yielding a moving range, from which the standard deviation is derived.

The first chart shows the individual values plotted for 2004, and the UCL, CL, and LCL. Since increased fertility is not a problem, only the LCL is considered further. Another line has been added, the lower warning line (LWL), at two standard errors below the CL; this draws attention to values approaching the limit.

The second chart uses an exponential weighted moving average (includes all historical data points but weights the most recent more highly). This is less sensitive to individual extreme values, but more clearly shows longer-term trends. In this case, the control limits are not straight lines, but are asymptotic to the control limits in the previous example. Both charts show that, in 2004, fecundity was usually better than average, but fell towards the end of the year.

*Box 2. Continued*





However, when the fly quality equals the minimum acceptable level of quality, the effective release ratio becomes 23:1, and it takes five generations to achieve eradication (Calkins and Ashley 1989).

When the actual level of fly quality was inserted into the model, giving an effective ratio of 54:1, only four generations were needed for eradication. However, if the flies were only half as effective, the cost per hectare (to produce and utilize sterile flies that are of only moderate quality) becomes almost twice as much. Furthermore, increasing the frequency of releases or the number of released sterile insects can only compensate for low quality up to a point – beyond which increased

numbers cannot make up for such deficiencies (Itô et al., this volume). Therefore, it is economically beneficial to rear high-quality rather than low-quality insects (Calkins and Ashley 1989).

A population model developed for *E. postvittana* indicated that releasing 300 Gy-irradiated moths would result in a 95% probability of extinction (if the ratio of released to wild moths exceeded 6.4:1). The model indicated an optimal release interval of 1 wk, but higher overflooding ratios would achieve eradication more rapidly. The model also predicted little advantage to releasing only male moths as compared with both sexes. Using a dose of 200 Gy, as part of an inherited sterility programme, would reduce (due to the resulting $F_1$ sterility) by ⅓ the required number of factory moths as compared with releasing lower quality moths irradiated with 300 Gy (Kean et al. 2011; Rull et al. 2012).

For the year 2001, a cost of USD 216 per million sterile male Mediterranean fruit flies was calculated when mass-reared at the El Pino facility, Guatemala (using a *tsl* genetic sexing strain) (see Table 1 in Hendrichs et al. 2002; Enkerlin 2003). At these large-scale production levels, these are probably the cheapest sterile insects in the world, although the cost increases significantly at lower production levels. The cost per million *tsl* males is more or less equivalent to the cost per million males of the usual bisexual strain. However, the big difference (in terms of cost savings) is in the transport and release operations, where sterile *tsl* males cost half as much as males of the bisexual strain (Caceres et al. 2004). In addition, male-only releases introduce three or four times more sterility into the target population than do bisexual releases (Robinson et al. 1999; Rendón et al. 2000, 2004).

There were several technical and managerial reasons why the ill-fated New World screwworm eradication project on the island of Jamaica was not successful (Vreysen et al. 2007; Dyck, Reyes Flores et al., this volume). However, the reduction in the quality of the sterile pupae received from the screwworm mass-rearing facility in Mexico (as evidenced by a gradual reduction in the average weight of the pupae) was certainly one of the critical technical issues that contributed to the failure of the programme (see Fig. 3 in Vreysen et al. 2007).

## 11. CHANGES IN INSECT BEHAVIOUR CAUSED BY LABORATORY REARING

Selection during colonization and mass-rearing usually changes the biology and behaviour of the reared insects (Iwahashi et al. 1983; Calkins 1989; Miyatake 1993, 1998a, b, 2002; Miyatake and Haraguchi 1996; Miyatake and Yamagishi 1999; Cayol 2000; Shimoji and Miyatake 2002; Maor et al. 2004; Caprio 2009; Meza et al. 2014; Aceituno-Medina et al. 2017). The oviposition medium is often completely different from that in natural conditions, e.g. fabric, paper, a membrane, a plastic bottle with small holes. Adult-emergence cages serve as both mating and oviposition cages, and males often harass ovipositing females. In these colony-holding cages, insects are maintained at abnormally high densities, and there is no space to develop mating aggregations or swarms, or to attract females through producing a pheromone. All insects are of the same age, and frequently more females are placed in a production cage than males, reducing the need for courtship or competition

between males. Many matings consist of brief courtships or, in some cases, even forced matings. Adult insects are discarded as soon as egg production begins to wane, thereby selecting for early maturing insects. In this situation, it is advantageous for females to mate quickly and maximize the number of progeny. It is disadvantageous for males to retain elaborate courtships, or for females to discriminate in mate selection. If abbreviated courtship becomes fixed in the population, this courtship repertoire may not be acceptable to wild females (Briceño and Eberhard 1998).

The mating competitiveness of laboratory-reared and wild Mediterranean fruit flies was examined in natural mating arenas (leks) (Zapien et al. 1983; Shelly 1995). Although the laboratory-reared males readily joined leks, and displayed calling behaviour similar to that of wild flies, relatively few laboratory-reared males were able to mate with wild females. The sterile males either failed to attract wild females to their positions in the lek, or the courtship repertoire was not acceptable to attracted wild females. In addition, on cloudy days, sterile males refrained from participating in sexual activities, and thus could not compete for wild females during such low-light-intensity conditions (Zapien et al. 1983).

In a mass-rearing environment (unlike the field), light, temperature, and relative humidity are often constant. Exposure to constant and optimal conditions of light, temperature, and relative humidity can select for individuals that are better adapted to these conditions, but lack the ability to adjust to fluctuating environments (Cayol 2000). If insects are reared for generations in constant light, changes in the temporal mating periods may result. In field-cage tests in Florida, laboratory-reared Caribbean fruit flies mated in the afternoon and completed mating activities long before wild flies began to mate near dusk (C. O. Calkins, unpublished data).

## 12. REMEDIAL ACTIONS TO RESTORE EFFECTIVENESS OF REARED INSECTS

When a colony of insects, used for the SIT, begins to deteriorate in effectiveness, there are several ways to restore it, including a change in colony management procedures. However, if genetic selection is involved, the problem may be more difficult to solve, and the establishment of a new colony from the target population may be required. Changed management procedures may reverse the selection, or at least slow down colony deterioration (Fisher and Caceres 2000; Liedo et al. 2007; Parker, Mamai et al., this volume).

If the causes are identified, specific problems detected by various tests can be addressed to reverse selection (Cáceres et al. 2007), e.g. adult cages, designed to increase the internal surfaces, significantly improved the mating competitiveness of mass-reared males (Liedo et al. 2007). Alternatively, adult cages designed to require insects to fly before having the opportunity to eat and drink automatically selects against non-flyers. In the cases of the New World screwworm (Wyss 2002) and codling moth (Dyck et al. 1993), adult insects must be able to fly to be collected in a cold room; they are then taken to the field for release.

Another problem that often develops in a reared colony is flies lacking irritability (section 4.10.). As a result, released sterile insects become easy prey to many of the

predators that they encounter in the field. If an automatic technique to select against such adults in the adult cage could be developed, this problem would be reduced.

Mating compatibility appears to involve heritable traits that, to a certain extent, can be manipulated. Changes in temporal mating periods may be corrected, at least partially, by implementing egg collection and other regimes for the colony production that maintain the normal distribution of relevant characters of the colonized population (Miyatake 1995), and holding adult colony flies under natural light/dark cycles. Also, fluctuating temperatures in the adult colony room would increase the tolerance for changing field conditions.

The mating performance of sterile fruit flies may decrease under extreme or marginal habitats, such as high altitudes where cooler temperatures prevail. While developing a RAPID quality-control system for early warning of poor fly performance, Boller et al. (1981) reared Mediterranean fruit flies in a laboratory at cool temperatures to determine if they would still mate and perform other tasks. They found that there was enough genetic variability in a colony, normally reared at optimal constant temperature, to perform at cool temperatures after being reared at these temperatures for only a few generations.

Haynes and Smith (1989) discovered that, when sterile boll weevils were fed on squares (cotton blossom buds) instead of plugs of artificial diet before release, locomotor activity increased, mortality decreased, and mating attractiveness increased by 16% when compared with that of control weevils fed on diet plugs.

There are several possible reasons why a reared insect becomes incompatible with a wild one, such as genetic changes caused by the rearing process, genetic drift, or a change in a wild population that has been exposed to released sterile insects for "too many" generations. Hibino and Iwahashi (1991) reported that wild female melon flies of an island population, exposed to sterile males late in an AW-IPM programme that integrated the SIT, became unreceptive to sterile males (Lance and McInnis, this volume; Whitten and Mahon, this volume). Such changes may appear as temporal changes in the mating period, subtle changes in the courtship behaviour or in the chemical make-up of a pheromone, changes in acoustical signals, etc. (Sivinski et al. 1989; Briceño and Eberhard 1998). In these cases, there may be no alternative except to replace the mass-reared colony with a new strain from the target population.

However, in situations where the rearing process itself is responsible for the change, changing the strain without correcting the process will not solve the problem. As described above, the changes that occur while domesticating an insect population are major ones, and do not happen in one or two generations. One solution is to continually develop new strains, just in case the current one deteriorates. In any case, this may be necessary to prevent possible incompatibilities as the SIT activities expand into new geographic areas that have potentially different target populations. However, strain replacement is extremely expensive (Mangan 1992), and a successful strain should not be discarded unless it is found to be inadequate. It is costly to expand a colony, conduct quality-control tests, determine rearing characteristics, and evaluate field performance. Nevertheless, regular strain replacement in the New World screwworm colony in Mexico became a standard procedure (Hofmann 1985; Parker, Mamai et al., this volume).

A less drastic cure is to incorporate wild genes into the colony genome. Wild corn earworm *Helicoverpa zea* (Boddie) moths from St. Croix, US Virgin Islands, were incorporated into a colony in Tifton, GA, USA; as a result, released moths mated much more frequently with wild moths (Young et al. 1975). However, this approach is not always successful. The wild individuals being introduced must compete in the artificial conditions to which moths in the domestic colony have already adapted. In the case of fruit flies, one solution is to replace only the males in the colony with wild males. For wild females, the most problematic aspect of adaptation is the oviposition device (Ahmad et al. 2014); by excluding wild females from the new introduction, this part of the selection process is avoided.

In the case of tsetse flies, trying to incorporate wild genes from the wild target population of *G. palpalis gambiensis* from Senegal into an old domestic colony from Burkina Faso (through back-crossing on males) failed. Even though it was maintained for many generations, the cross-bred line did not develop a satisfactory fecundity, whereas the new colonized strain rapidly improved during the same time to reach the same fecundity as the domestic one (Pagabeleguem et al. 2016).

Sometimes an improvement in the general vigour of a colony can be achieved by reducing the stress of the mass-rearing regime of the mother colony (Orozco-Dávila et al. 2014). Boller and Calkins (1984) used a relaxed low-density rearing method for a strain of Mediterranean fruit flies, and within two generations the vigour and size of the males increased. A system for limiting stress on a mother colony, called filter rearing (Fisher and Caceres 2000), also prevents the accumulation of deleterious traits from the high-density rearing stages back to the mother colony (Parker, Mamai et al., this volume). In this system, the mother colony is held under low-density low-stress conditions. Surplus insects from this colony are continuously fed into a sequence of high-density amplification steps to the final release colony, but the mother colony is kept separate and never receives material back from the high-density steps. The use of such a filter system has several advantages. Since the mother colony is small, it is possible to keep the insects under low-density conditions, and apply sexual competition or directed selection to them to restore or maintain desirable traits (Tejeda et al. 2017; Quintero-Fong et al. 2018). If necessary, by establishing a new mother colony, the whole production can be easily switched to a new strain.

If a colony is replaced because the rearing process is responsible for developing an inferior strain of insects, and the particular feature of the rearing method responsible for the change in insect behaviour is not adjusted, the new colony will rapidly develop the same inferior behaviour. This domestication takes place in just a few generations during the "bottleneck" that occurs in the initial phase of colonization (Zygouridis et al. 2014). Leppla et al. (1980) reported the complete adaptation of a noctuid moth to a laboratory environment in five to seven generations. The adaptation of the Caribbean fruit fly to a rearing regime, where performances in the laboratory bioassays were the same as those for the reared colony, took three or four generations (C. O. Calkins, unpublished data). Pashley and Proverbs (1981) noted a gradual change over time in the allozymes of reared codling moths, and predicted that this change could affect mating interactions with a wild population.

## 13. QUALITY-CONTROL MANUALS

The first system of quality control was developed in 1978 by E. Boller for the Mediterranean fruit fly (Boller et al. 1981). It consisted of behavioural tests that included a pupal calibration sorting process to determine the array of pupal sizes, a startle test to measure irritability, an olfactometer to determine the age and time of day when males began to produce pheromone and females began to respond, a mating propensity test, a new ratio test, and an isolation index.

An operational quality-control manual for Mediterranean fruit flies, used at the Moscamed factories in Mexico and Guatemala and in other fruit fly programmes in Latin America, was developed by Orozco-Dávila et al. (1983), and subsequently modified or updated by Brazzel et al. (1986), Ashley (1987), and Calkins et al. (1996). To harmonize tests in these manuals, standardize quality-control tests, and allow comparisons for commercial and transboundary shipments of sterile insects, an international quality-control manual was produced in 2003 and updated in 2019 (FAO/IAEA/USDA 2019); it is being used in most fruit fly programmes.

Specific quality-control manuals have been produced for some other insects, including the New World screwworm (Lopez et al. 1995), tsetse flies (Feldmann 1994; Gooding et al. 1997; IAEA 2012), and Lepidoptera (Fisher 1983). This latter one included process-control charts that were sensitive tools for identifying changes in insects during colonization, and a feedback loop back to the production. Manuals for mass-rearing specific insects often include sections on quality control, including those for some other fruit fly species (Spencer and Fujita 1997), codling moth (Dyck 2010), tsetse flies (FAO/IAEA 2006), and *Anopheles* mosquitoes (FAO/IAEA 2017b).

## SUMMARY

The mass-production and sterilization of insects, as well as subsequent shipment, adult emergence, holding, feeding, collection, and field-release activities based at production or emergence and release facilities (ERFs), are vital components of applying the sterile insect technique (SIT). Mass-rearing, and these post-factory SIT activities, have evolved into a well-established modular/industrial process that has adapted and adopted manufacturing principles such as the development of standard operational procedures (SOPs) and quality control (QC) standards, allowing a common understanding/agreement between producers and users of sterile insects at satellite ERFs. Shipment practices for short- and long-distance transport are well documented, and it is likely that they will continue to be developed and improved for current and new insect species according to their biological needs. Procedures for insect emergence, feeding, and holding for sexual maturation of sterile insects (including the designs of new holding containers) have gradually evolved because of a better understanding of their biological requirements. ERFs specialize in insect emergence, holding, providing food and water to the adults, maturation, and collection for release. For some target pests, such as moths, adults can be collected after emergence for direct transport and release, without previous holding and feeding of adults. Release of sterile insects varies depending on the species and the nature of the area-wide integrated pest management programme (AW-IPM). This chapter also reviews the methods of release – static, ground, and aerial (using aircraft with fixed-wing or rotary-wing, and unmanned aerial vehicles (UAVs)). Recently, developed technology has allowed prototyping of release equipment designed for UAVs. New release boxes and machines for a wide range of insect species have been developed, aiming to optimize equipment that enables variation in release densities, and takes into account other operational considerations according to the needs of action programmes. New ground- and aerial-release equipment has been tested and put into operation -- increasing the quality of the released insects. Through the use of combined GPS/GIS, dedicated software, and devices plugged into computers and the internet, additional progress has been made in implementing electronic/navigating equipment that enables knowing the precise location of insect releases and recording the conditions of their aerial broadcast. These developments enable the delivery, monitoring, and supervision of releasing sterile insects, with the results available in real time. The private sector has actively participated and demonstrated continued interest in the provision and processing of sterile insects, as well as aerial GPS/GIS guided release.

## 1. INTRODUCTION

During the past decades the mass-rearing of insects has been developed further, with major improvements in the industrialization of the production process for the application of the sterile insect technique (SIT). By documenting their procedures

and practices, some mass-rearing facilities (MRFs) have established/received ISO 9001–2015 certifications for insect rearing, thereby bringing about greater consistency in production numbers and insect quality (ISO 2019; E. M. Ramírez-Santos, personal communication). All these mass-rearing activities are the focus of the chapter by Parker, Mamai et al. (this volume). In addition to these improvements in the production of sterile insects, there have been significant advances in the quality-control processes (covered in detail in the chapter by Parker, Vreysen et al., this volume) that have increased the availability and supply of sterile insects for their use in area-wide integrated pest management programmes (AW-IPM) worldwide.

This chapter focuses on the receiver/end-user of SIT implementation, i.e. the post-factory activities after sterile-insect production, marking and sterilization activities at MRFs. They take place mostly at emergence and release facilities (ERFs) located either at or near production sites, or near distant target release sites to which the sterile insects are usually shipped in bulk as pupae. Activities carried out at ERFs and during preparation for release are discussed, including the adoption of improved processes related to the chilled adult release technique (Tween and Rendón 2007), through which sterile insects are emerged, maintained, and fed for several days, and then chilled and released as robust and competitive sterile insects via novel technologies.

After leaving a MRF, nutritional, semiochemical, and other treatments applied to adult sterile insects (to improve their field performance) are the focus of the chapter by Pereira et al. (this volume).

## 2. SUPPLY OF STERILE INSECTS

### *2.1. Availability from Established Mass-Rearing Facilities*

The most rapid and cost-effective way (at least in the short-term) to obtain a continuous supply of sterile insects is by their purchase/importation from an established MRF that rears the required target species (Dowell et al. 2000; Blomefield et al. 2011; Bjeliš et al. 2016; Horner et al. 2016; section 4.6.). In the case of long-distance transport, of course cost-effectiveness depends on the shipment; for long distances the shipping cost can be considerable, and the shipping duration can affect sterile-insect quality. However, especially when containment or eradication programme activities are urgent, outsourcing sterile insects enables operational programmes to avoid spending time and economic resources on the training of personnel, planning, and construction required to establish an MRF. Establishing and maintaining an operational MRF is a demanding economic endeavor that is time-consuming and requires major investment. Instead, by procuring sterile insects, emergency programmes can rapidly integrate the SIT, e.g. eradicating a pest outbreak such as the 2015–2017 eradication of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) in the Dominican Republic (Zavala-López et al. 2021). The tsetse eradication programme in Senegal decided not to build an MRF but to outsource the sterile flies from Burkina Faso (Vreysen et al. 2021) -- a wise decision for programmes that will no longer require the MRF after achieving eradication.

Also, there are examples of programmes that routinely purchase sterile flies because the target areas are relatively small, e.g. the *C. capitata* fruit fly programmes in Croatia (Bjeliš et al. 2016) or Patagonia (De Longo et al. 2000), or where no MRF can be established for regulatory reasons in pest-free areas, such as the preventive release programme (PRP) in California (Dowell et al. 2000). Other programmes begin by buying sterile flies (for some years) so as to establish and gain experience with SIT operations, while planning and eventually establishing their own mass-rearing facilities -- examples are the *C. capitata* programmes in Israel, Morocco, and Spain (Primo 2003; Cayol et al. 2004; Qadda 2017).

There is a limited number of insect species for which MRFs are well established: Mediterranean fruit fly, Mexican fruit fly *Anastrepha ludens* (Loew), West Indian fruit fly *Anastrepha obliqua* (Macquart), melon fly *Zeugodacus cucurbitae* (Coquillett), Queensland fruit fly *Bactrocera tryoni* (Froggatt), codling moth *Cydia pomonella* (L.), false codling moth *Thaumatotibia leucotreta* (Meyrick), and pink bollworm *Pectinophora gossypiella* (Saunders). Additionally, mass-rearing facilities for some veterinary and medical pests have been successful: New World screwworm *Cochliomyia hominivorax* (Coquerel), tsetse flies *Glossina austeni* Newstead, *Glossina fuscipes fuscipes* Newstead, *Glossina palpalis gambiensis* Vanderplank, and *Glossina pallidipes* Austen, and Asian tiger mosquito *Aedes albopictus* (Skuse).

In general, MRFs are built to produce sterile insects for their own programme requirements, and therefore only a few of them have the capacity or interest to produce sterile insects for customers in addition to those needed for their own use. Despite the perceived shortage of sterile-insect supply, there has been much collaboration between programmes to supplement sterile insects when the need arises. The Joint FAO/IAEA Programme maintains a database of rearing facilities, capacities, and contact information (IDIDAS 2019; Bakri et al., this volume).

Due to their role in national plant protection or animal/human health, most of the sterile insect release programmes have some form of government involvement (Dyck, Reyes Flores et al., this volume). They operate with limited budgets, and are driven by an urgent need to manage serious pests to limit pest damage, confine the pest to the smallest area possible to reduce operational costs, and maintain or open markets for locally-produced commodities. Therefore, as a complement to other control activities that the programmes may implement, a reliable source of good-quality sterile insects at an affordable cost is always in demand. The provision of insects by government-operated institutions is usually conducted through bilateral agreements and on a full cost-recovery basis, including the depreciation of facilities and equipment. Often the "excess" capacity of an MRF, where output exceeds direct programme needs, may not always be available as it is dedicated to others through contractual agreements to prioritize such partners in case of emergency needs.

The production cost per million insects (eggs, pupae, adults) can be greatly reduced with economies-of-scale (Parker, Mamai et al., this volume). As a rule, due to their cost of construction, most MRFs were built undersized rather than basing the production output on a per-insect unit cost. In small rearing facilities, the fixed costs are relatively high, therefore increasing the production cost per million sterile insects.

One major improvement in the rearing and release of some insect species is the feasibility of deploying only sterile males, through the use of genetic sexing strains (GSSs) (Franz et al., this volume) or other approaches (Papathanos et al. 2018). In general, this option reduces by half the costs of insect dyeing/marking, irradiation, shipping, and aerial release, while increasing SIT effectiveness when compared with standard/both sex releases (Hendrichs et al. 1995; Rendón et al. 2004). The introduction of GSSs that remove females before their shipment, coupled with rearing efficiencies and economies-of-scale, greatly reduce product and shipping costs in addition to reducing the cost of processing insects at ERFs.

### *2.2. Processing Insects for Release*

There are three common approaches to managing sterile insect production and release:

- Operate a centralized facility that combines an MRF with an ERF that prepares sterile insects for release (Schwarz et al. 1985; Ortiz et al. 1987; Nakamori et al. 1992; Liedo et al. 1993; Msangi et al. 1999; Bloem and Bloem 2000; Koyama et al. 2004).
- Operate an MRF for rearing and sterilization, and one or more satellite ERFs to which sterile insects are shipped and where they are processed for the releases (IAEA 2008).
- Receive eggs from another MRF for local rearing, sterilization, and release (section 4.6.2.).

#### *2.2.1. Centralized Facilities Combining Production with Emergence and Release*

The decision to establish a combined production-release facility versus separate ERFs is normally linked to convenience (directly at the MRF or located nearby close to or at the local airport used for aerial releases), as well as the size and distance from the target release areas. When these can be serviced from the local MRF/ERF without excessive ferry times, there is no need to establish satellite ERFs.

One of the advantages of locating an ERF next or close to an MRF is that preparing insects for release at the place where they are reared eliminates the extra operations of packing the sterilized insects for shipment and sending them to a satellite ERF; it also has the added advantage that, due to the lower hypoxia time during pupal shipment, the quality and quantity of sterile insects available for releases increases (Arredondo et al. 2018). Due to the progress in control activities within the Moscamed action programme in Guatemala, an ERF has been established directly at the El Pino mass-rearing facility; this unit is experiencing an increase of insect quality due to reduced hypoxia and handling (E. M. Ramírez-Santos, personal communication).

For the eradication of *Glossina austeni* in Zanzibar, sterilized tsetse fly adults, produced and emerged in Tanga, Tanzania, were released aerially in degradable cardboard boxes over Unguja Island, resulting in the elimination of the trypanosomosis disease in cattle (Msangi et al. 2000; Vreysen et al. 2000). In the pink bollworm programme in the USA, moths were reared, sterilized, and emerged

in Arizona, but then flown to and directly released in California (USDA 1995; Walters et al. 2000; Staten and Walters 2021). A single centralized facility produces and releases sterile codling moths in British Columbia, Canada (Bloem and Bloem 2000; Nelson et al. 2021), and also ships them successfully to South Africa and New Zealand (Blomefield et al. 2011; Horner et al. 2016; Dyck, Reyes Flores et al., this volume). In the 2016–2017 eradication of the New World screwworm outbreak in Florida, sterilized pupae from the MRF in Panama were shipped to the USA, where the pupae were directly placed into ground-release chambers in the field from which adults emerged (USDA/APHIS 2017; Skoda et al. 2018).

Regardless of whether there is a single centralized production-release facility, or additional satellite ERFs, it is an advantage to have a single management structure for a programme, allowing efficient decision-making and the rapid exchange of information among the components of the mass-rearing and release processes (FFEPO 1999; Dyck, Reyes Flores et al., this volume).

#### *2.2.2. Satellite Facilities for Emergence and Release Only*

Flying emerged sterile adults to distant target areas for release can result in long and costly ferry times that may be detrimental to insect quality; the establishment of ERFs strategically located near the release sites to minimize ferry times is the more viable alternative in these cases.

The operation of satellite ERFs has several additional advantages: (1) sterile insect programmes can work in areas that, for regulatory reasons, cannot have MRFs, (2) one large MRF, operating at increased economies-of-scale, can provide insects to several satellite facilities, often in different countries, and (3) several insect species can be simultaneously prepared for release.

The shipment of sterile insects to satellite ERFs enables them to be placed in areas generally free of the target insect without the risk of fertile pest insects escaping from a local MRF (Dogan et al. 2016). This is important if the goal of the programme is the eradication of isolated invasions of the target pest, or its exclusion from an area free of it through preventive releases. Thus, sterile pupae, for example of the Mediterranean fruit fly, Mexican fruit fly, and New World screwworm, can be shipped from MRFs located in areas where these pests occur to ERFs in areas free of permanent infestations (USDA 1995; CDFA 2002).

The use of satellite ERFs gives maximum flexibility to the release of sterile insects. One large MRF can provide sterile pupae to several satellite facilities scattered throughout a region. For example, producing sterile fruit flies in large MRFs in Guatemala and southern Mexico, and shipping them as pupae to a chain of ERFs in northern Mexico, as well as California and Florida, has been more cost-effective from an operational standpoint (USDA/APHIS 2009; Enkerlin, this volume).

Satellite ERFs are less complex in their design than centralized MRFs, and often do not require permanent construction. As programme needs change, satellite ERFs can be relocated. The satellite ERFs, used to prepare sterile New World screwworms for release, moved steadily southwards from Mexico to Panama, as the screwworm eradication programme progressed through Central America, but the MRF continued to operate in Mexico (Wyss 2000) until a new MRF became operational at Pacora,

Panama (Scott et al. 2017; Vargas-Terán et al., this volume). This approach should be followed when several countries/regions have a common pest problem, avoiding duplication of efforts in the construction and operation of rearing facilities, while reducing costs due to economies-of-scale and servicing several countries with the large production of sterile insects.

Several species of sterile insects from different MRFs can be handled in a single ERF facility. In California, the same staff processes Mediterranean and Mexican fruit flies at the same satellite ERF located at Los Alamitos. Recently, the states of Florida (Fig. 1) and California produced floor plans to renew their existing ERFs after the successful establishment of the concept of preventive release programmes (PRPs) (which have greatly reduced the cost of eradicating invasive populations while avoiding the establishment of Mediterranean and Mexican fruit flies) (Hendrichs, Enkerlin et al., this volume). These new ERFs already included additional space to allow for the emergence and release of other pest species.

*Figure 1. United States Department of Agriculture (USDA) sterile insect emergence and release facility, Sarasota, FL, USA (USDA 2019). (Photo from Halfacre Construction Co., Aerial Innovations of Florida, and J. Renshaw, 2018, reproduced with permission.)*

The different goals and physical separation of MRFs and ERFs can result in more attention and focus on field operations, and in the case of independent customers provide a more objective assessment of sterile insect quality. Conducting product quality control tests in accordance with agreed procedures, and exchanging these results between MRFs and ERFs, provide a better way to monitor quality and address end user/client concerns.

There are rearing issues where real cause/effect needs to be documented to avoid supply or quality reductions. In some instances, the problems observed in the rearing or transportation processes are only brought to light after the satellite ERFs note a decrease in the quality of the resulting insects being prepared for release, while sometimes the problem might also be the result of mishandling at the EFRs. Currently, with the improved availability of electronic means of communication and electronic data storage, shared boxes or drives (with access by sterile insect producers and receivers/users) can be dedicated to report results on quality by independent testing at MRFs and ERFs for feedback and comparisons. Statistical analysis of the data has also enabled the preparation of quality-control charts that

gradually raise, or at a minimum monitor and maintain, insect quality over time (FAO/IAEA 2018a).

### *2.3. Commercial Production and Release of Sterile Insects*

There are advantages and disadvantages to both governmental and private suppliers of sterile insects (Dyck, Reyes Flores et al., this volume). Government suppliers, unlike private suppliers, may be willing to develop insect MRFs for which there is a potential need, but not necessarily a continuous demand, as in the case of eradication programmes (Quinlan and Enkerlin 2003). They fund programmes to develop the SIT against new pests such as the sweetpotato weevil *Cylas formicarius* (F.) (Kohama et al. 2003; Kumano et al. 2011) or the cactus moth *Cactoblastis cactorum* (Berg), or programmes that demonstrate the feasibility of funding and implementing the SIT in new ways, such as taxing the local community for codling moth suppression, or applying public-private partnerships for false codling moth AW-IPM programmes. Governments can also establish programmes that cross several political entities, such as the pink bollworm programme on both sides of the Mexico-USA border (Simmons et al., this volume), the Mexican fruit fly preventive release programme along the California-Mexico border (Enkerlin, this volume), or the release of New World screwworms along the Panama-Colombia border (Skoda et al. 2018; Vargas-Terán et al., this volume). Governments are more likely to invest in research designed to develop potential new technologies for use in mass-rearing and release programmes if the pest is considered to be a potential animal/human health or phytosanitary threat.

However, government-funded facilities have several drawbacks, one being the tendency to change policies and/or funding priorities, e.g. after elections. Thus, a programme that had the strong support of one administration may find its budget reduced or eliminated by another (Dyck, Reyes Flores et al., this volume). This can make programme managers feel insecure, postpone needed changes in programme procedures or facility upgrades, and make growers, ranchers, and other stakeholders reticent to support the programme. Another major drawback of government funding is the tendency to ask the programme to do more and more with a static budget. This leads to decisions that tend to lower the quality of sterile insects produced while keeping the numbers of insects produced and released high (Liedo et al. 1993). This can have a negative impact on programme success, which consequently will often lead to further funding cuts that continue the cycle of problems and often cause reinfestations to occur, making the suppression or eradication efforts appear not to be technically feasible because of the budgetary inconsistencies.

The affected agricultural industries can play a major role in creating awareness of the importance of sterile insect programmes among their members, government leaders, and the public (Dyck, Regidor Fernández et al., this volume). They can help develop confidence in the use of sterile insects for eradication or pest suppression. This will generate a demand for the sterile insects that, in turn, will attract private companies to invest in production plants necessary to meet this demand.

In the Mediterranean region, bait sprays have traditionally been used to suppress major pests such as the Mediterranean fruit fly and the olive fruit fly *Bactrocera*

*oleae* (Rossi). Encroachment on traditional production areas by "urban sprawl", and the expansion of tourist resorts, makes the future of aerial-bait applications increasingly untenable. In 2009 the European Union prohibited aerial spraying of pesticides (EU 2009), thereby effectively ending most aerial application in all member states and overseas territories. Nowadays, aerial spraying in the EU requires special authorization by local governments (but only when justified by emergency conditions).

As a consequence, the integrated use of sterile insects, with the objective of routine area-wide pest suppression, has great potential for commercialization (Hendrichs et al. 1995; Hendrichs, Vreysen et al., this volume). The agricultural industry itself is searching for, and promoting the development of, more environmentally acceptable measures to substitute less acceptable technologies developed more than 50 years ago. Private companies are increasingly participating in the production and provision of sterile insects, e.g. de Groene Vlieg in the Netherlands (De Groene Vlieg 2019), BioBee in Israel (Bassi et al. 2007; BioBee 2019), and in South Africa FruitFly Africa Ltd. (Venter et al. 2021) and Xsit (Boersma 2021), although most of these private-sector services are providing sterile insects to customers in their own countries.

Most programmes contract with private firms to provide the aerial services for sterile insect release. Some also contract for part or the whole of sterile insect emergence and release processes. For example, the Mexican National Fruit Fly Campaign has outsourced the operation of five Mexican fruit fly and West Indian fruit fly ERFs in Mexico (Leal Mubarqui 2005; Bassi et al. 2007). Private companies are paid per flight hour, from take-off to landing, or in some instances for actual engine-time utilized (based on the Hobbs meter); both are valid practices. An exception is the Mexican fruit fly programme in Texas, where the aircraft is owned by the United States Department of Agriculture (USDA), and the pilot is an employee of the US government. The Animal and Plant Health Inspection Service (APHIS) of the USDA uses this aircraft to design and develop new technologies for releasing sterile insects.

Experience in the USA and elsewhere indicates that usually it is cheaper to contract with a private company (to provide aircraft and pilots) than to purchase aircraft and pay for maintenance, full-time pilots, and mechanics. However, this may not be true in all countries (due to limitations in the offer of such services), and a detailed economic analysis needs to be conducted for each programme. Due to the continuous search for operational efficiencies, action programmes are actively looking for alternatives to conduct aerial releases through the use of unmanned aerial vehicles (UAVs); this initiative has already developed some alternatives for some pest species, for example mosquitoes, where releases are often concentrated over villages or towns (section 5.3.3.).

## 3. SHIPPING STERILE INSECTS

There is a major advantage to producing, marking, and sterilizing insects in an MRF, and then shipping them to an ERF that is dedicated to emerging, holding, and releasing the sterile insects. Shipping procedures are well known and tested. Sterile

insects, e.g. codling moth, Mediterranean fruit fly, New World screwworm, and tsetse flies are shipped routinely to near and distant places (Enkerlin and Quinlan 2004; Blomefield et al. 2011; Rull et al. 2012; FAO/IAEA 2014, 2016b, 2017a, b, 2018b; Horner et al. 2016; Dyck, Reyes Flores et al., this volume).

### *3.1. Shipping Time, Distance, and Insect Quality*

At present there is still a limit on how far sterile insects can be shipped. Adult emergence and flight ability decrease with increasing shipment time, even when shipping pupae in a low-oxygen atmosphere (hypoxia) – an effect that seems to be reduced in some species such as *Bactrocera tryoni,* where a decline in adult emergence of 0.1%/h (inside sealed plastic bags for periods up to 192 h at 17°C) has been reported (Dominiak et al. 2011a). For example, sterile Mediterranean fruit fly pupae have been shipped successfully from Guatemala and Mexico to Argentina, Austria, Chile, the Dominican Republic, Israel, South Africa, and the continental USA (Dyck, Reyes Flores et al., this volume). They have also been shipped from Argentina to Spain, from Israel and Spain to Croatia, and from Portugal and Spain to Morocco, etc. Since 2010, sterile Mexican fruit flies have also been shipped from Guatemala to South Texas, and Reynosa and Tijuana in northern Mexico, with high-quality parameters reported after shipment. In general, the hours of pupal hypoxia have been in the range of 43–45 h (departure to arrival) (M. López, personal communication).

Enkerlin and Quinlan (2004) developed an international standard to facilitate the transboundary shipment of sterile insects. A summary of worldwide transboundary sterile insect shipments during the last 50 years can be found under FAO/IAEA (2018b).

Shipments of sterile insects are often conducted by renting space in the cargo compartment of commercial airlines (fitting in the containers/boxes that will deliver an agreed number of sterile insects). Usually a broker company is contracted to arrange documentation for customs and the airlines. Optimized flight routing is mandatory to reduce time in transit, the number of airports used, and detours made. Delays in shipments do occur -- some of them are due to security measures, mistakes in paperwork, changes in routing or the airlines shifting their priorities to baggage (cargo is then not loaded, generating delays in the arrival time at the final destination). If pupae are kept under hypoxia for longer than the documented/expected periods of time, the quality of the resulting adult insects decreases (FAO/IAEA 2017a, b; Arredondo et al. 2018).

When shipping to exceedingly distant destinations, the packing configuration is modified so as to contain coolers and ice packs in sufficient number to ensure that temperature and relative humidity conditions are maintained (Pagabeleguem et al. 2015). Although not under hypoxia, the quality of tsetse adults suffers if the pupae are kept chilled too long (Mutika et al. 2002, 2014). Before starting routine shipments, trial shipments between interested rearing and release facilities should be sent so as to document shipping routes, costs, and final product quality before assuming viability or non-viability of the supply.

### *3.2. Shipping Eggs*

An additional form of insect supply is to ship the early development stages of insects, which will then be reared at the recipient MRF. Mediterranean fruit fly thermally-treated eggs (to kill female eggs for the production of only males), and the black-pupae strain (BPS) of the Mexican fruit fly, are routinely shipped with little or no loss in yield or quality of the resulting sterile adults (IAEA 2002; H. Conway, personal communication). This procedure avoids the problems associated with maintaining pupae under hypoxia for long periods of time. As the volume and weight of eggs are far less than those of pupae, shipping costs are substantially reduced. For example, one litre of eggs is equivalent to almost 5 million pupae. Of course, egg shipment still requires MRFs for producing males and sterilizing them at the receiver end. Currently, 9 litres of Mediterranean fruit fly eggs of a *tsl*-genetic sexing strain are shipped daily from the El Pino production facility in Guatemala to the production facility in Metapa, Mexico. Purchasing eggs is a very reliable process, enabling the receiving programme to avoid maintaining a viable colony of fertile adult insects for egg production (since escapes are always a security concern in areas declared or about to be declared free of the pest). One additional advantage is that it also avoids the costs and the intricacies of the maintenance of filter-reared colonies of GSSs (Fisher and Caceres 2000; Franz et al., this volume; Parker, Mamai et al., this volume).

### *3.3. Shipping Adult Lepidoptera*

In general, lepidopteran species are shipped as chilled sterile adults. One reason is that larval or pupal separation from diets is complicated; another is that sterilizing adults instead of pupae results in more competitive insects (Stewart 1984; Dyck 2010; Boersma 2021; Bakri et al., this volume). Lepidopteran species (such as codling moths) shipped as adults can tolerate more than 60-h shipments (Blomefield et al. 2011). Shipments of codling moth pupae and adults from Canada to New Zealand and South Africa provided support to the suggestion that the SIT for codling moth (in pome-fruit production areas) might be implemented by the importation of irradiated chilled moths from rearing facilities in a different country or hemisphere (Blomefield et al. 2011; Horner et al. 2016). The success in these shipments points out the need to explore new methods or conditions for transporting pupae and/or emerged sterile adults from the MRF to where they are to be released (Dyck, Reyes Flores et al., this volume).

### *3.4. Shipping Costs*

One important consideration related to the establishment of satellite ERFs is the cost of shipping sterilized insects (Wyss 2000). For example, the shipping cost alone to send New World screwworm pupae to Libya (packed in cardboard boxes for adult emergence and direct release) was four times the purchase price, and four times the dispersal cost. Shipping cost is reduced by 50% if using GSSs (where females are removed, enabling the shipment of only males).

The shipping cost of sterile Mediterranean fruit flies from El Pino in Guatemala to California and Florida PRPs is about 16–18% of the total cost of one million pupae plus shipment (E. M. Ramírez-Santos, personal communication), while for the Mexican fruit flies shipping from Guatemala to the continental United States is about 11% (M. López, personal communication); both facilities produce and ship males-only of their respective rearing species. As in the case of mass-rearing costs, the unit shipping costs depend largely on the volume of pupae that are shipped. Shipments of low sterile fly numbers (less than 5 million per shipment) to pilot projects usually result in high unit costs due to the fixed costs of the customs broker company.

In addition to issues related to insect quality, increasing shipping distance results in increasing shipping costs and delays that are also a concern for the supply of sterile insects to EFRs and action programmes. The New World screwworm production facility in Tuxtla Gutierrez, Mexico, provided the sterile flies for the Central American eradication programme. However, with increasing shipping distance, both the shipping costs, and the potential for problems, including delays in the shipping process, increased (FAO 1992; Wyss 2000). By 2006, a new mass-production plant for the New World screwworm was inaugurated in Panama, and now supplies the sterile fly barrier in the Darien region along the border between Panama and Colombia (Hendrichs, Vreysen et al., this volume; Klassen et al., this volume; Vargas-Terán et al., this volume).

## 4. EMERGENCE AND RELEASE FACILITIES

### *4.1. Location, Design, Building Materials, and Construction*

Strategic placement of the ERFs, and therefore their sterile insect release activity, is relevant to operational efficiency and costs. ERFs that are located close to the areas where control activities are conducted by the action programme will see their operating costs reduced. Having ERFs equidistant from all the areas where releases are conducted reduces costs in expensive ferry times to conduct releases and return to airport landing strips. For the selection of sites to establish an ERF, action programme decision-makers need also to consider all the adverse conditions that will prevent aircraft from conducting their insect release activity and avoid/minimize them while selecting the location. Among the various factors to consider are rain patterns, prevailing winds, and the presence of commercial airports in close proximity that could limit the operation, etc. When choosing a site for the establishment of an ERF, there are other requirements (which facilitate the stability of the operations) that need to be considered, e.g. having an adequate site not too far from all the facilities of a medium-sized metropolitan city (for the convenience of the workers and obtaining equipment-repair services) but still a distance from it so as to avoid disruption of daily operations (FAO/IAEA 2004, 2012; Parker, Mamai et al., this volume).

It is relevant that ERFs have a dependable supply of electricity; nevertheless, the facility should also budget for the provision of an emergency plant generator. The provision of potable water is essential for the ERF; however, the provision of

municipal water and/or the drilling of its own well and water purification system will avoid any shortages in the amounts of water that are required for this type of operation. A water-treatment plant may also be needed because the sewage in ERFs is often contaminated with fluorescent powder arising from the washing of holding boxes or trays and racks; this can be a big problem unless properly addressed.

An ERF also needs to be close to a good ground-transportation system. This reduces the cost of transporting sterile pupae or adults, and also reduces the time that pupae or adults are in transit, thereby increasing the quality of the resulting adult insects. When eradication programmes are progressing in their control activity, it may be necessary to change the ERF's location to increase operational efficiencies and insect quality, as well as to reduce operational costs. Therefore, in long-term eradication campaigns, the ERFs may be designed to be movable or permanent, and their layout will be influenced by these needs.

Some emergency programmes use trailers or refrigerated trailers and basic insect containers (such as buckets or Plastic Adult Rearing Containers (PARC) used for the PARC system) and paper bags (in which to emerge and release adults either aerially or by ground) (Fig. 2), thereby rapidly solving the problems that appear in an emergency programme in which the goal is to eradicate the pest as soon as possible with minimal investment in equipment and infrastructure. On the other hand, in other pest control situations, such as the PRPs or long-term exclusion/eradication programmes, in which continuity of operations is foreseen, the design and selection of building materials for the establishment of ERFs shifts to more permanent constructions, choosing in this case materials such as metal structures combined with block and concrete.

In general, ERFs are designed with a modular layout. Each of the modules/rooms is implemented to maintain sterile insects for several days with adequate environmental conditions (temperature and relative humidity) that will enable insects to emerge and mature sexually – for subsequent release using the release method of choice. The size of rooms is designed to emerge and hold the number of insects that are released each operational day; this usually coincides with the number of sterile insects that is received daily from one or sometimes two MRFs. Some ERFs process and release sterile insects every day, others only during weekdays; the capacity of the ERF is based on the operating and release requirements.

### *4.2. Environmental Control Equipment*

The environmental conditions under which sterile insects are maintained prior to their release play an important role in their adult emergence time, sexual maturity, feeding status and survival in the field. ERFs need to consider the relationship time/temperature accumulation, e.g. degree days, to set adult emergence room temperature to ensure adequate time (in hours) for emergence and associated age/sexual maturity reached at the time of insect release (Parker, Mamai et al., this volume).

Also, relative humidity plays an important role. If it is too low, it may be difficult for an adult to emerge, and thus it uses up critical energy reserves prior to release. Regarding the feeding status of the insects, low humidity dehydrates sterile

insects, as can some food sources, reducing vitality and numbers. On the other hand, in a high-humidity environment, insects stick to one another or to the screen surfaces and food; excess humidity also promotes the presence of unwanted fungal development on top of the food provided. Therefore, adequate humidity levels, along with appropriate regular cleaning of emergence rooms and equipment, are relevant to avoid contamination of surfaces (Abd-Alla et al., this volume).

Since the ERFs operate 24 h/day year-round, even if releases are only conducted in some instances during weekdays, the environmental conditions need to be monitored constantly because deviations from the required conditions can have great impact on the release numbers and insect quality.

*Figure 2. Mediterranean fruit fly emergence and release facility in Retalhuleu, Guatemala, showing clockwise: A: Worker placing sterilized dyed pupae into a PARC emergence box; B: Stapling paper bags in the centre to permit flies to leave the bag; C: Placing one modified agar-block diet; D: Stacks of six PARC boxes inside an adult emergence room. At the Neretva Valley, Croatia, Mediterranean fruit fly programme: E: Machine for loading pupae into paper bags; F: Adult emergence room containing bags for fly emergence. Water is provided/sprayed through the surface of the bag.*

### *4.3. Facility Operation*

In general, the ERFs that receive shipments of sterile pupae operate with a building layout as follows:

- *Reception area* – workers assigned to this area are responsible for receiving and preparing the pupae when they arrive from the MRF. In this area, the conditions

of the biological material are documented on arrival, e.g. temperature, the irradiation dosimeters are visually verified, and the weights of the biological material received are checked to calculate the total number obtained in the shipment. Additionally, an observation of the external dust-dye is conducted to determine if there are problems with water condensation, lack of fluorescent-dust marking, or others (nowadays MRFs document the percentage marked pupae prior to shipment departure) (section 4.3.). The pupae are then moved to the next step in the process.

- *Pupae distribution* – this area is used to place, manually or by automated systems (Fig. 2E), the biological material inside containers (PARC boxes or adult emergence towers) that will enable adult emergence and feeding for a predetermined number of days. In parallel to this process, the adult food is applied or placed prior to insect emergence (food is usually prepared ahead of time in diet-cooking rooms) (section 4.4.).
- *Diet-cooking room* – a kitchen that usually has several boilers or kettles to prepare agar-based food. As alternatives to this type of diet, there are currently two additional options, a liquid diet and a diet that is a combination of both in which solid and liquid diets are combined inside the Mubarqui tower (Fig. 4).
- *Adult emergence and holding rooms* – usually as many as the number of days per week of programmed releases.
- *Aromatherapy room* – for the species that have this option to enhance mating activity (Pereira et al., this volume), the size of this room allows for at least one-day-release capacity; alternatively, this type of "sexual pre-conditioning" treatment can be conducted within the last adult emergence room a day prior to insect release using existing adult emergence rooms.
- *Chilling room* – for insect species where chilled adults are transported and released in aerial or ground releases (Tanahara et al. 1994); some programmes supplement aerial releases with ground releases of chilled adults.
- *Washing area* – for cleaning and drying materials and equipment used in the adult emergence and release process; in this area industrial washing machines are employed to clean PARC boxes or tower trays.
- *Quality control (assurance) area* – the biological characteristics of the sterile insects received, as well as those that are released in the field, are measured and documented (Parker, Vreysen et al., this volume). Early efforts at judging the quality of sterile insects focused mainly on the adult insect (Calkins 1989; Calkins et al. 1996; Dominiak et al. 2014; Fanson et al. 2014; FAO/IAEA/USDA 2019), and only pre-/post-irradiation on arrival at an ERF. These insects are subjected to measurement of various parameters: emergence, survival, flight, and mating competitiveness (Ortiz et al. 1987; FFEPO 1999; Koyama et al. 2004). The current approach is also to include in the measurements all those parameters that will describe the quality characteristics of sterile insects before and after their field delivery (FAO/IAEA/USDA 2019).
- *Administration* – area to provide administrative support to all technical activities of the ERF operations, processing bills, personnel technical assistance, and other logistic needs.
- *Methods development* – area designed to evaluate and validate rearing and

quality-control practices prior to or during their implementation at the ERF operations.

- *Maintenance* – for personnel dedicated to resolve operational and maintenance problems with equipment and buildings, as well as prototyping equipment and other needs.
- *Warehouse* – space must be provided for storing high-quality diet materials. Delivery times, rates of consumption and others (local vs. imported diet materials) should be calculated to allow sufficient areas for process/human safe storage of products. For the operation of ERFs, the number of ingredients to prepare adult diets is reduced when compared with those in an MRF. For most insects, this means access to locally produced products (IAEA 2008). It is very important that these diet materials are free of insecticide residues.

## 5. EMERGENCE AND COLLECTION OF STERILE INSECTS

### *5.1. Holding, Marking, Feeding, and Collecting Adults*

In some target species, such as fruit flies, tsetse flies, and mosquitoes, adults need to be held after emergence for various periods in different types of containers for feeding and maturation; then they are collected for release by moving the holding containers to cold rooms (where the low temperature makes them quiescent).

#### *5.1.1. PARC System*

In many AW-IPM programmes that integrate the SIT, sterile pupae are shipped to ERFs where they are placed into containers in which adults emerge. Systems for the emergence, holding and feeding of fruit flies prior to their field release have changed over time. An early system was the "bucket method" used for roving ground release (FAO/IAEA 2017a, b). This was followed by the paper bag system for aerial release (Nadel et al. 1967). Later, the PARC system was developed for the aerial release of chilled flies (shown in Fig. 2, where preparations are being made for Mediterranean fruit fly emergence using PARC boxes). This system was developed by the USDA (Mabry 1986) to replace the earlier paperboard Tanaka box, developed by the California Department of Food and Agriculture (CDFA). The PARC system, an improvement over the Tanaka box, permitted the containers to be sanitized after each use, and reduced the number of escaped flies within an ERF.

The use of these systems requires that the sterile pupae be dispensed into paper bags at a predefined amount; six bags are placed into each PARC box. Once filled with pupae, the bags are then loosely stapled at the top to allow emerging sterile flies to escape and live and feed inside the container until they are ready for field release. Screen panels on the sides of the container provide ventilation, and a screen panel in the lid permits the flies to feed on a gelatinous slab consisting of agar, sucrose, water, and a food preservative -- usually sodium benzoate or methylparaben. This stackable PARC system (Fig. 2D) requires much controlled-environment space to hold a large number of these bulky containers during the emergence and fly maturation period. It is also labour-intensive, although recently

automated systems have been designed for both loading the pupae (Figs. 2, 3) and cleaning the boxes using industrial washing machines. Paper bags are costly, both in direct and waste-disposal/littering cost. Also, some flies are lost when the bags are destroyed. This PARC system is still used today in some release programmes (although there is a gradual trend to implement newer technologies) or in emergency situations e.g. the 2015–2017 eradication of *C. capitata* in the Dominican Republic (Fig. 2).

### *5.1.2. Tower System*

In a gradual progress towards an ideal system, a sterile insect "emergence or Worley tower" was developed by the USDA in Mission, TX (Salvato et al. 2004) to improve upon the PARC boxes. This new "tower technology" also facilitates the concept of chilling insects and loading them into release containers for aerial dispersal using the chilled adult release technique (Tween and Rendón 2007). This tower system is currently used for emerging, feeding, and chilling/immobilizing Mediterranean fruit flies in Florida and California, and Mexican fruit flies in Texas (Fig. 3).

Each tower consists of interlocking screen-panelled aluminium frames (trays) stacked on a portable/movable base. Pupae are placed into a channel around the inside perimeter of each aluminium tray. One or two slabs of gelatinous food are put on each screen panel. Up to 80 trays can be stacked in one tower, producing a solid tridimensional aluminium block. To provide air circulation, a small direct-current axial exhaust fan is placed on the top of each tower (stack of trays) to provide forced upward ventilation within the tower. When flies emerge they move from the perimeter channel to the screen of a tray, while the empty puparia are left in the channel. The flies remain on the screen and feed for 4–6 days, the period required for maximum adult emergence. On the day of field release, the towers are moved into a cold room where higher-volume exhaust fans suck cold air (~4ºC) into each tower to accelerate fly immobilization. After a period of exposure to the cold, the puparia are vacuumed from the channels, and the screened trays are manually turned upside down over a hopper (and pan beneath) to collect the chilled flies (Fig. 3). After the collected chilled flies are weighed, they are transferred to the aerial release box and transported to, and loaded into, a release aircraft (Figs. 10, 11).

Two additional tower systems (Hernández et al. 2010) are currently being used at the Moscamed programme in Mexico (Fig. 4) and Guatemala (Fig. 5). The Mubarqui tower system in Mexico has a larger surface area and volume for the flies to expand their wings, feed, and mature. The system uses a predesigned "Mubarqui diet" for feeding adults of Mediterranean and Mexican fruit flies (Fig. 4).

The two systems shown in Figs. 4 and 5 use the environmental room conditions (temperature and relative humidity) without the need for exhaust fans on top of the towers; this was the reason for not using the previously described "Worley tower system". Electricity fluctuations generated too many inconsistencies in the operation of the many fans, thus their use was discontinued in favour of a new tower design.

*Figure 3. Tower system for Mediterranean fruit fly -- stages in the emergence and collection of fruit flies using the tower system (Worley Tower). Upper left: Screen tray loader, showing an upper rotating-revolver mechanism (transparent containers) to load each tray with pupae. Upper right: Aluminium frame/tray, showing a slab of agar-based food diet and dyed pupae in a channel around the edge. Lower left: Stacks of trays forming towers, each connected (yellow cables) to a power outlet to operate a fan that draws air upwards. Lower right: Tower system for Mexican fruit fly -- screen trays in cold room with puparia removed from channels by suction, and chilled flies on screen being collected in a hopper. USDA/APHIS, Sarasota, FL, USA.*

The other difference of the tower system used in Guatemala compared with the previous system is that it uses a "liquid diet", replacing the expensive and cumbersome preparation, handling, and discarding of agar diets, and enabling the liquid diet to be replenished externally. This permits flies to be kept with no refill until they are released, or with a refill for longer periods when overcast climatic conditions prevent aerial release on the scheduled date (or for some different insect species that have longer maturation periods). These two additional tower systems use the same chilling process as the one described above for the "Worley tower". Automated washing of the screens is also available for the liquid-diet tower.

Compared with the PARC system, the tower system improves considerably the quality of the flies to be released. Also, it reduces fly escapes as well as the required controlled-environment space, with a consequent reduction of fixed costs, although

there are obvious variations in the space requirements of the different systems described above. However, the optimal holding density of sterile insects in the tower system must be carefully determined because higher densities result in decreased sterile-insect quality (Hernández et al. 2010).

*Figure 4. Left photo: Self-stackable 16-tray Mubarqui tower system for Mediterranean and Mexican fruit flies. Right photo: Inner components of an emergence tray -- left upper corner, agar slab for water provision; centre, green panels for increased fly-resting space; right, black tray for pupae placement and white tray for placing the "Mubarqui diet". Medfly Programme, Neretva Valley, Croatia, and Mexican Fruit Fly Programme, Mexico.*

*Figure 5: Left: Fly emergence and maturation room inside the new ERF at El Pino, Guatemala, using liquid-diet towers, with air-conditioning units for room conditioning. Right: Liquid-diet tray showing (through the screen) two white plastic trays holding pupae (pupae marked with orange-coloured dye). A cotton cloth (white) and a sponge (blue) draw the liquid diet by capillary action from the PVC-pipe system placed on the side of the trays (as shown in the left photo).*

The only waste materials produced in the tower system are puparia, food residues, and water from the mechanical tray washer. Overall, labour requirements are also reduced, primarily because of the automated pupae loading, puparia separation and disposal, and tray-washing processes. On the other hand, since there are fewer flies in each tower tray than in a PARC box, collecting chilled flies from tower trays is slower; thus, during the critical time in which chilled flies must be collected from tower trays, more manual labour (than from PARC boxes) is required. Hence, on balance, even though the tower system requires more hand-labour in the final step of the process, i.e. collecting chilled flies, its overall cost is lower than that of the PARC system because of the optimization of space and savings in hand-labour costs in the other steps of the process (as well as saving the cost of buying and disposing of paper bags, and the agar-diet preparation process which includes the cost of agar, electricity, and hand-labour), while adding the main advantage that tower-reared flies are better fed and less "stressed" than those reared using the PARC system.

#### *5.1.3. Marking Emerging Adults*

To enable identification after capture in the field, many species are normally marked at the MRF prior to shipment, emergence, and release (Hendrichs and Robinson, this volume; Parker, Mamai et al., this volume; Vreysen, this volume). Calco and tinopal dyes have been used successfully to mark lepidopteran larvae (Stewart 1984; Dyck 2010; Boersma 2021). Fluorescent dyes, used on fly pupae (Fig. 6), are transferred to the ptilinum of the adult as it emerges at an ERF (Steiner 1965; Schroeder et al. 1972; Vreysen et al. 1999; Dominiak et al. 2010; FAO/IAEA 2016b). The transferred dye becomes incorporated into the head capsule as the ptilinum is withdrawn into the insect's head (Fig. 7). Upon capture, as adults are viewed under a long-wave ultraviolet (blacklight) lamp; the dye fluoresces, enabling wild unmarked and reared marked flies to be distinguished from each other. Currently, there are several insect species for which there is technology available to supersede the described marking process (Niyazi et al. 2005). This new technology is based on the insertion of genes that allow fluorescence of body parts and sometimes other insect tissues, e.g. testis – sperm. Some of these species/strains have already been tested for their rearing characteristics (Ramírez-Santos et al. 2017), but at this time this technology is not approved for use in the field by most government regulations.

#### *5.1.4. Provision of Food and Water Prior to Release*

For most adult insects, it is important that they are provided with a source of food and water shortly after emergence. Most SIT target species are anautogenous, and the food reserve accumulated during larval development is only sufficient to sustain the adult for 1 or 2 days under ideal environmental conditions. Intake of protein (Papanastasiou et al. 2019) and other essential resources is required by emerged sterile males and females to permit reaching sexual maturation after a time-delay following feeding (Hendrichs and Prokopy 1994). Studies have shown that providing food and water to newly emerged adults results in much higher recapture rates following release (FAO 1992; Hernández et al. 2010; Bellini et al. 2014; Maïga

et al. 2014; FAO/IAEA 2016b, 2017a, b; Parker, Mamai et al., this volume) (sections 3.3., 4.1., 4.2.; Figs. 2, 3, 4, 5). Increasing the food surface available for emerging sterile insects is important; all adults need access to the food within the crowded conditions of PARC boxes or tower trays (USDA/APHIS 2009).

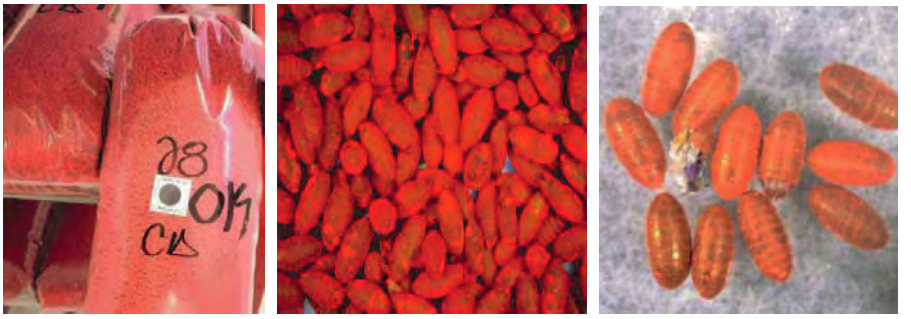

*Figure 6. Left: Bags containing DayGlo™-dusted pupae -- showing also an irradiation dosimeter that has become black (Bakri et al., this volume), proving that the dose administered reached the required level. Centre: Pupae showing DayGlo dye on the surface of the puparia (a high percentage of marked adult flies is desirable for field traceability). Right: Mediterranean fruit fly males emerging from pupae, marking their body parts during the process. (Photos from E. M. Ramírez-Santos, reproduced with permission.)*

*Figure 7. Upper photos: Unmarked flies. Lower photos: Marked flies showing sterile flies that have emerged from DayGlo™-dyed pupae (from left to right: ptilinum mark, dorsal body marks including wings, and ventral position marks mainly on the legs). Observations conducted using an epifluorescent microscope, El Pino MRF. (Photos from E. M. Ramírez-Santos, reproduced with permission.)*

The addition of specific food supplements to the adult diet, including proteins, for emerging male fruit flies to enhance their post-factory field performance and competitiveness, are discussed in detail by Pereira et al. (2013) and Pereira et al.

(this volume); these papers also discuss the interaction between nutritional and hormonal treatments to advance sterile male sexual maturation, as well as semiochemical treatments to improve sterile male competitiveness.

Sterile insects are often released soon after emergence to minimize space requirements in an ERF, or a few days later, but well before full sexual maturation is reached (avoiding mating between sterile males and sterile females in the case of bisexual strains). However, the use of GSSs (Franz et al., this volume), emerging only sterile males at ERFs (and processing half the volume of a bisexual strain), enables holding them closer to sexual maturation when they are better able to compete for wild females (this also reduces the often high losses that sterile males suffer in the field, due to predation and other causes, between the time of their release and reaching maturity).

McInnis et al. (2013) found (for the Mediterranean fruit fly in large field cages) that holding sterile males longer at the ERFs and releasing them closer to maturity (and also providing food and water during the maturation period) increased adult survival and thus the number of sexually mature males active in the field.

### *5.2. Collecting Emerged Adults by Positive Phototaxis for Direct Release*

In some insect species, adults are directly collected after emergence, without previous holding and feeding of adults. Often, they are positively phototropic, and thus show a strong positive phototaxis to a light source. This behavior has been used to attract newly emerged adults into cold rooms at ERFs directly for release, e.g. New World screwworm flies (Wyss 2002). Also, adults of pink bollworm moths, codling moths, and false codling moths (Fig. 8) are collected after emergence, often directly at MRFs, using fluorescent, ultraviolet or incandescent lights (Hutt et al. 1972; Stewart 1984; Dyck et al. 1993; Wyss 2002; Dyck 2010; Boersma 2021). Cold temperatures are used to temporarily immobilize the adults following collection (Dyck 2010; Hofmeyr and Pretorius 2010; FAO/IAEA 2016b; Boersma 2021), as well as while they are being transported to an aircraft or ground-release vehicle, and then during release operations.

*Figure 8. Cabinets for emergence and collection of false codling moths (Xsit, Citrusdal, South Africa). (Photo from Boersma 2021, reproduced with permission.)*

The importance of having adequate control of relative humidity during chilling, holding, and release of adult insects cannot be overemphasized (Tween and Rendón 2007). If the relative humidity is too high, it can affect insect quality. This is particularly problematic when chilling adults (covered externally with a dust-dye) at high humidities and loading them into metal release boxes. Condensation on the inside of the release box can lead to excessive moisture that completely saturates the insects, causing them to become tangled in a large ball at the bottom of the box, resulting in fly damage during release. Commercial dehumidification systems can be used to reduce the humidity during chilling, transporting, and releasing insects.

## 6. RELEASE OF STERILE INSECTS

There are three approaches of releasing sterile insects -- static ground-based receptacles (static release), mobile ground-based vehicles (ground release), and releases using aircraft (aerial release). Each approach has advantages and disadvantages. Usually field action programmes use a combination of them for their operations, according to the conditions, needs, and strategic objectives.

The aforementioned chilled adult release technique is complementary to the release methods. It is used just before releases and aims to produce easy-to-handle quiescent sterile insects that can then be loaded into different-sized release containers, usually metal boxes or bags. The chilling process takes place inside a wall-insulated cold room, where emergence/feeding containers are rolled in. Cold rooms are pre-chilled at the appropriate temperature, usually at ca. 4ºC. The actual chilling process requires 40–60 min. Chilled insects are then collected and loaded into an additional container for field release.

### *6.1. Static Release*

Typically static release receptacles are containers deployed in the field into which sterile pupae or adult insects are regularly placed (Liu and Yeh 1982; Williamson et al. 1983; Cuisance et al. 1984; Oladunmade et al. 1990; FFEPO 1999; Msangi et al. 2000; Yamagishi and Kakinohana 2000; Koyama et al. 2004; Sutantawong et al. 2004; Dominiak et al. 2011b). When pupae are placed into them, adults are able to emerge in synchrony with local diurnal and temperature cycles, leave the receptacle, and disperse from the site during the day as the temperature rises. Static releases require a uniform distribution of release sites throughout the target area, and the pinpointing of areas to receive increased numbers of sterile insects. This approach is possible only for relatively small-sized areas that are accessible.

This method was used in the 2016–2017 outbreak of the New World screwworm in Florida, where ground release sites covering several islands were used. These static sterile-insect releases, combined with other quarantine, treatment, and inspection procedures, achieved eradication of the pest a few months after its detection (USDA/APHIS 2017; Skoda et al. 2018; Vargas-Terán et al., this volume).

Placing pupae in release receptacles eliminates the need to establish ERFs, reducing labour and infrastructure costs. Pupae are easily handled; they can be poured into the release receptacle or included in a pre-prepared insert placed into the

release receptacle. Simple volumetric measurements provide a way of estimating the number of pupae in each receptacle.

Static releases have major disadvantages: deployment is limited by ground access to release sites, distribution of sterile insects is clumped (with foci separated by areas of low insect density), provisioning release receptacles is labour-intensive, and emerged insects are very susceptible to bad weather and predators that learn to visit the release sites. However, for some species and conditions, this release method is still considered (Dominiak et al. 2011b; Reynolds et al. 2012). Most programmes that have used static releases have changed to either ground or aerial releases (Liu and Yeh 1982; Koyama et al. 2004).

### *6.2. Ground Release*

In a mobile ground-release system, adult sterile insects are dispensed from slow-moving trucks (CMFFEPP 2019), all-terrain vehicles (ATVs) (OKSIR 2019; Boersma 2021; Nelson et al. 2021), or mountain bicycles (Horner et al. 2016). The insects are released by hand or machine, directly into the environment, or in open bags from which they escape after release (Holler and Harris 1993; Fisher 1996; FFEPO 1999; Bloem and Bloem 2000; Covacha et al. 2000; Loosjes 2000; Koyama et al. 2004; Bjeliš et al. 2013, 2016). To maximize their dispersal away from the release vehicle or bag, the insects may be kept at ambient temperatures during the release procedure. The Carnarvon Western Australia eradication project uses a "Medfly blower" consisting of a refrigerated cooler that keeps the flies immobile at about 5ºC, and incorporates an auger, heater, and blower fan. The unit is mounted on the back of a truck (Fig. 9) which, combined with a remote dispersal release interface, enables the insect releases (B. Woods, personal communication).

Ground releases can treat a larger area more quickly and uniformly than static releases. The vehicle routes can easily be changed to meet changing demands of the programme, and additional release trips can be made in areas that need higher numbers of sterile insects. Fewer workers are needed to make ground than static releases. The negative impact of predators on the sterile insects is minimized when the adults are released directly into the environment (Fig. 9). Since pupae are kept indoors at relatively constant temperatures, the adults emerge at a predictable rate, making long-range scheduling possible. Adult insects can be held at lower temperatures during periods of inclement weather, and then released when acceptable weather conditions return. Ground releases are used regularly in fruit fly programmes to supplement aerial releases in areas with difficult access. In the *C. capitata* eradication programme in the Dominican Republic (Fig. 9) (Zavala-López et al. 2021), ground bag releases were conducted to supplement aerial releases along the coastal areas, which were affected by wind drift. Ground releases may not be as uniform as aerial releases, and greater sterile insect densities will occur close to areas bordering the path of the release vehicles. There are also safety issues associated with having slow-moving vehicles travelling on normal roads, and inaccessible areas of dense vegetation pose problems for ground-release systems. In the case of bag releases, bird and vespid predators will learn to exploit the insects contained in them, and bags themselves may constitute a litter problem.

ERFs are still needed to prepare/feed insects prior to their release. Since adults will emerge even during periods of inclement weather, when releases are not possible or advisable, the accumulation of insects may necessitate their destruction. However, in the Lower Rio Grande Valley at the Mexican fruit fly programme in Texas, when aerial releases cannot occur due to weather conditions, ground releases are a practical solution (Fig. 9). They are also used to increase sterile insect densities in pest hotspot areas where it is required, as well as sensitive areas such as bird sanctuaries and butterfly gardens where other means of control cannot be used (H. Conway, personal communication). If long periods of overcast conditions, e.g. rainy season, are expected, one might need to choose an alternative emergence and release system to prevent/reduce foreseen losses.

*Figure 9. Upper photos (left and centre): Ground release of sterile insects along coastal areas during the recent eradication of the Mediterranean fruit fly in the Dominican Republic. Flies emerged in paper bags housed in PARC boxes, and were taken to field locations where the bags were opened (ripped), enabling the males to fly. (Photos from R. Nina, reproduced with permission.) ### *6.3. Aerial Release*

Aerial releases from aircraft directly discharge chilled sterile adults (chilled adult release technique) or eject bags or boxes containing the adults (Howell et al. 1975; Nakamori and Kuba 1990; FAO 1992; USDA 1995; Vreysen et al. 1999; Msangi et al. 2000; Pereira et al. 2000; Villaseñor et al. 2000; Vreysen et al. 2000; Walters et al. 2000; Wyss 2000; Yamagishi and Kakinohana 2000; Kohama et al. 2003; Rendón et al. 2004; Staten and Walters 2021).

The direct release of sterile adults requires that they be taken from adult emergence containers or rooms, chilled (or first chilled in the containers), and put into large refrigerated boxes that are then loaded onto a specially equipped aircraft (FFEPO 1999; Dowell et al. 2000; Villaseñor et al. 2000; Walters et al. 2000; Wyss 2002; Koyama et al. 2004; Staten and Walters 2021) (Figs. 10, 11, 12). The insects are dispensed from the aircraft using a motor-driven conveyor or screw auger that delivers the insects from the release box to the release tube. The release rate is controlled by varying the speed of the auger and the aircraft. Since screw conveyors cause some damage to flies, an improved release machine design uses instead flat vibrating conveyor belts that reduce sterile-insect damage prior to their release (Leal Mubarqui et al. 2014).

In some programmes, the aerial release of sterile insects has been done with paper bags or boxes (Hentze and Mata 1987; FAO 1992; Vreysen et al. 1999; Covacha et al. 2000; De Longo et al. 2000; Msangi et al. 2000; Opiyo et al. 2000; Villaseñor et al. 2000; FAO/IAEA 2006a). Usually pupae are placed in bags/boxes, held in the release containers until adult emergence, and then the release bags or boxes are loaded into larger holding containers and placed into the aircraft. The release bags or boxes are held at ambient temperatures and dispensed from the aircraft by hand or conveyor belt. Releasing sterile insects in their emergence bags or boxes reduces preparation time, compared with the chilled-insect procedure, but there can be some damage due to bag compaction if too many are transported to the aircraft or too many placed within it, and the sterile-insect dispersal achieved is more limited compared with the chilled adult release technique.

Aerial releases enable the covering of large areas quickly, regardless of the difficulty of the terrain, lack of roads, or high density of vegetation. They distribute the sterile insects over the treated area as required, especially if the aircraft flight paths are controlled by a Global Positioning System (GPS) guidance programme (Villaseñor et al. 2000; USDA 2019) (section 6.4.). The mechanized release system can be linked to a computer to provide flexibility in the release rate during a flight. This allows more sterile insects to be delivered to those areas needing them, without having to make multiple flights over any given area. If boxes or bags are used, the release rate is increased by ejecting more of them in a given time period (section 6.4.).

On the other hand, aerial releases are more weather-sensitive than ground releases, and an ERF is required. The aerial release of sterile insects in bags or boxes is problematic if litter is a concern (but a biodegradable container mitigates this problem). Bags and boxes are expensive, and for some insects (such as tsetse flies that are extremely sensitive to insecticides) the cardboard boxes must be free of any chemical residue (this increases the price of the boxes). They also take up

considerable space in an aircraft that could instead be devoted to holding many more chilled insects. Aerial releases of the Mediterranean fruit fly in Argentina, using bagged adults, averaged only 1.2–1.3 million flies per flight (De Longo et al. 2000), whereas aerial releases by directly releasing chilled flies can release 10 million per flight (in Spain with a Cessna 206) and up to 40 million flies per flight (in Mexico with a Cessna Caravan). The number of sterile insects that can be released by an aircraft is also a function of the type of insect, the release rate, and the aircraft size. Flight duration is usually determined by the amount of time that sterile adult insects can tolerate chilling without a reduction in quality (usually about 4 h), but this depends on the temperature and size of the insects. Pereira et al. (2000) found that aerial releases are less expensive than ground releases.

Both fixed-wing (Figs. 10, 11) and rotary-wing (Fig. 12) aircraft can be used to deliver sterile insects aerially to the target area. The choice of aircraft type will depend on programme needs and local environmental conditions, as well as the availability of aerial services or the cost of the aircraft. Releasing with rotary-wing aircraft is usually more expensive, although gyrocopters are less expensive than fixed-wing aircraft. Rotary-wing aircraft are used usually for the spot-treatment of restricted host areas, or canyons, where fixed-wing aircraft cannot operate easily.

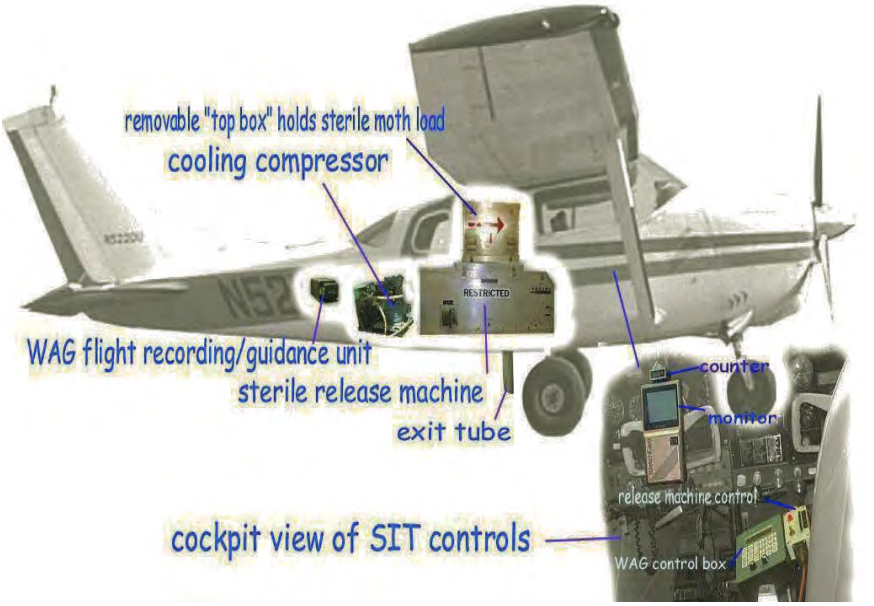

*Figure 10. Fixed-wing aircraft used to release sterile pink bollworm moths in 2007. Placement of the release machine into the aircraft is shown. Locations of the moth-holding and moth-release equipment, flight recording/guidance unit (Wag-Aero (Brand name) = GPS navigation unit that tracks the flight path), and SIT controls are labelled. (Photo from the California Department of Food and Agriculture, reproduced with permission.)*

*Figure 11. Releases from fixed-wing aircraft. Upper photos: Preparing aerial bag releases in Mendoza, Argentina. *Figure 12. Aerial release of sterile male tsetse flies in the Niayes region of Senegal using a gyrocopter (Dixit 2015). (Photo from J. Bouyer, reproduced with permission.)*

Due to recent technological developments in aerial technology and guidance systems, programme managers look for improved and alternate ways of releasing sterile insects, so that the process is more efficient in its coverage and more cost-effective. There are different release devices being considered for this exploratory new wave of technology; the initial step is to acknowledge that there are very dissimilar requirements in terms of the release rates/unit area needed to achieve pest control. For fruit flies and mosquitoes, usually thousands of insects per ha are required, in lepidopteran species hundreds of insects per ha, in screwworms tens of insects per ha, and in tsetse only individual flies per ha (Table 5 in Hendrichs, Vreysen et al., this volume). This variation in release rate changes the aircraft requirements. For pest species that require an extensive coverage at a very low release rate, such as tsetse flies, fuel-tank capacity in fixed-wing aircraft is a more limiting factor than the capacity to hold sterile insects. On the other hand, for fruit flies, in view of the relatively large volumes to be released per area, larger fixed-wing aircraft are required to maximize the release per flight. However, because of the difference in millions of insects to be released in the diverse programmes, there is also a gradient in fixed-wing aircraft size/capacity. For lepidopteran species, fixed-wing aircraft have been used for pink bollworm moths (Simmons et al., this volume) (Fig. 10); in other operations such as releases of the false codling moth in South Africa, ATV squads and gyrocopters have been used. However, both practices were discontinued due to worker issues in the former and security concerns in the latter (Boersma 2021; S. Groenewald, personal communication). In the Niayes region of Senegal, the programme to eradicate tsetse flies (which required very low rates of sterile males per ha) used a gyrocopter for the aerial releases (Dixit 2015) (Fig. 12).

New ways of releasing sterile insects from the air are being explored and adopted – type of aircraft as well as new technologies for release. For the capacity of aerial release machines, there is now an adaptable or "universal" delivery system; it was developed so as to meet the needs of very different operations, sizes and release rates, i.e. size of the aircraft needed, as well as the number of sterile insects being released in the field. This "smart delivery system" is capable of releasing at varying densities, ranging from 10 flies per $km^2$ for tsetse flies at one extreme up to more than half a million per $km^2$ for fruit flies on the other (Leal Mubarqui et al. 2014) (sections 6.3.3., 6.4.).

### *6.3.1. Fixed-Wing Aircraft*

In the early years of sterile insect release, degradable bags or boxes were released from aircraft, e.g. New World screwworm flies, Mediterranean fruit flies (Fig. 11), and tsetse flies. For a long time, fixed-wing aircraft were the standard vehicle for releasing sterile insects, e.g. New World screwworm flies, pink bollworm moths (Fig. 10), Mediterranean fruit flies (Fig. 11), Mexican fruit flies, and tsetse flies. Today, in many cases, chilled insects are released from special machines with augers or conveyor belts that eject the insects automatically according to a predetermined rate, enabling the planned density of sterile insects to be achieved on the ground, e.g. false codling moths in South Africa (Xsit 2019a; Boersma 2021).

*6.3.2. Rotary-Wing Aircraft*

Compared with fixed-wing aircraft, rotary-wing aircraft are appropriate for making release flights over mountainous terrain or small target areas (Vargas et al. 1995). Melon flies were released with helicopters in Okinawa, Japan (Nakamori and Kuba 1990; FAO/IAEA 2016c; Enkerlin, this volume), and a gyrocopter was used to release sterile tsetse flies in Senegal (Fig. 12) (Dixit 2015; Vreysen et al. 2021; Feldmann et al., this volume). For a period of time, false codling moths were released in South Africa with gyrocopters, but currently these moths are being released with small helicopters (Boersma 2021).

*6.3.3. Unmanned Aerial Vehicle (UAV) (Drone)*

Unmanned aerial vehicles (UAVs), remotely piloted aircraft systems (RPASs) or drones are the latest development in aerial release technology; their main components are shown in Fig. 13. Using these systems is attractive to operational programmes because of the potential cost reduction in some sterile-insect release activities (Tan and Tan 2013). Also, the adoption of this technology can avoid the loss of human lives that sometimes results from aircraft accidents (Dyck, Reyes Flores et al., this volume).

The advantages of the RPAS technology (accuracy, increased safety, and cost-efficiency for small- and medium-scale operations) are counterbalanced by limitations at the technical level (reduced payload and flight duration) as well as at the regulatory level (mandatory special operational permits from regulatory agencies for operations beyond the visual line of sight) (Benavente-Sánchez et al. 2021). Compared with ground releases, sterile insect dispersal and survival should be improved when using UAVs.

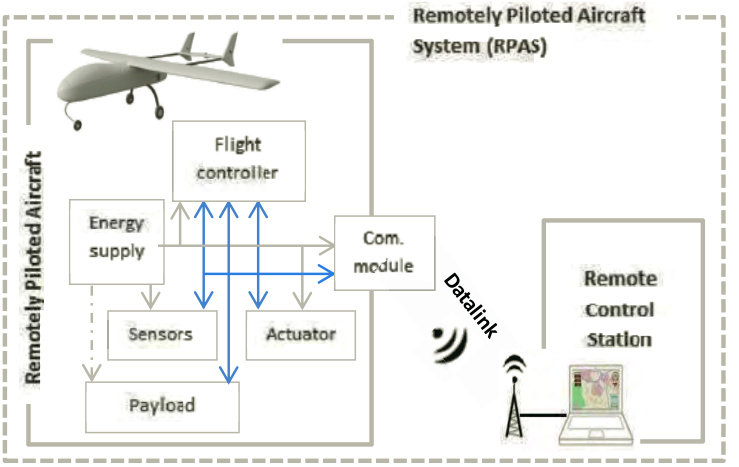

*Figure 13. Main components of a Remotely Piloted Aircraft System (RPAS). Modified after Maxorazon, Wikipedia CC BY-SA 4.0. (Wikipedia Commons 2018). (Drawing from Benavente-Sánchez et al. 2021, reproduced with permission.)*

Following the development of commercially available UAVs, they are increasingly being tested for releasing insects in several SIT projects (Table 1): *Aedes* mosquitoes (Fig. 14), chilled tsetse flies (Benavente-Sánchez et al. 2021) (Fig. 15), codling moths (Figs. 14, 16) (Horner et al. 2016; M3 2018; PFR 2018a, b; Proskiw 2018; Seymour 2018; FGN 2019), false codling moths (Xsit 2019b; Boersma 2021), and pink bollworm moths (USDA/APHIS 2018).

*Table 1. Technical parameters of Remotely Piloted Aircraft System (RPAS) applications releasing sterile insects (data adapted from Benavente-Sánchez et al. 2021, reproduced with permission)*

| Parameter | | Release of sterile insects | | |
|---|---|---|---|---|
| | | Male *Aedes* mosquitoes[1] | Male *Glossina* tsetse flies[2] | Codling moths (♂+♀)[3] |
| Adult weight (mg) | Min | 0.9 | 14 | 23 |
| | Max | 1.1 | 18 | 25 |
| Release density (nr/ha) | Min | 1000 | 0.5 | 200 |
| | Max | 3000 | 1.0 | 1000 |
| Insect biomass ($g/km^2$) | Min | 90 | 0.7 | 690 |
| | Max | 330 | 1.8 | 2500 |
| Area covered per flight (ha) | Min | 40 | 4000 | 40 |
| | Max | 60 | 8400 | 100 |
| Swath width (m) | Min | 75 | 500 | 120 |
| | Max | 100 | 700 | 180 |
| Flight distance (without ferry) (km) | Min | 5.3 | 80 | 3.3 |
| | Max | 6.0 | 120 | 5.6 |
| Flight time (without ferry) (min) | Min | 11 | 67 | 6 |
| | Max | 13 | 100 | 9 |
| Speed during operation (m/s) | | 8 | 20 | 10 |
| Payload (g) | | 300 | 800 | 7000 |
| Type of aircraft | | Rotary; micro/small | Fixed-wing, rotary; medium | Fixed-wing, rotary; medium |
| Type of operation | | VLOS[4]; urban area | BVLOS[5]; rural area | BVLOS[5]; rural area |
| Special flight authorization | | Mandatory | Mandatory | Exempted |

[1] Trial release of *Aedes aegypti* in Juazeiro, Brazil, 2018 (Benavente-Sánchez et al. 2021; J. Bouyer, personal communication)
[2] Planned release of *Glossina* spp. in Chad and Ethiopia (Benavente-Sánchez et al. 2021)
[3] Routine release of *Cydia pomonella* in a pilot area of 391 ha in Central Hawke's Bay, New Zealand (PFR 2018a, b; Benavente-Sánchez et al. 2021; R. M. Horner, personal communication)
[4] VLOS = Visual Line Of Sight
[5] BVLOS = Beyond Visual Line of Sight

UAVs are particularly appropriate for situations requiring the release of relatively small sterile-insect quantities, and on small areas (including residential areas), e.g. releasing mosquitoes over urban areas (an emerging need due to the recent explosion of mosquito-borne diseases) (Lees et al., this volume). UAVs have been tested to release sterile *Aedes aegypti* (L.) in Brazil (Fig. 14) and Mexico. A prototype (Remotely Operated Mosquito Emission Operation -- ROMEO) has been developed (HEIGHT TECH 2019) that can carry half a million mosquitoes per load, and has flight independence up to 30 min, enough to cover an area of 1 $km^2$ (FAO/IAEA 2016a; Garnier et al. 2018; UN 2018; Bouyer et al. 2020) (Fig. 14).

Benavente-Sánchez et al. (2021) reviewed the progress and prospects for using RPASs in SIT projects. They present a table with data on tests releasing sterile insects (mosquitoes, tsetse flies, and codling moths) – comparing the weight of adults, payload, release density, area covered per flight, and flight distance, speed, and time, etc. (Table 1) (see Table 5 in Hendrichs, Vreysen et al., this volume, for another cross-species comparison). Details of appropriate equipment and procedures are provided. They also reviewed the progress made in different countries in regulating and harmonizing internationally the use of different-sized RPASs for various agricultural applications. Legislation, regulation, certification, and authorization are essential for any routine use of RPASs in support of SIT projects.

The pods under the wings carry the chilled adult males in biodegradable boxes that are dropped according to a pre-planned flight programme. (Photo from Benavente-Sánchez et al. 2021, reproduced with permission.)*

*Figure 16. Remotely piloted fixed-wing drone, operated in visual line-of-sight, releasing sterile codling moths in New Zealand (PFR 2018a, b). (Photo from R. M. Horner and Plant and Food Research Institute, New Zealand (PFR 2018a), reproduced with permission.)*

### *6.4. Global Positioning System (GPS) for Guiding and Monitoring Insect Release*

Guidance of aircraft used to release sterile insects has evolved from a system based on compass headings, landmarks, and flight times to one that now uses the Global Positioning System (GPS) (Slagell 2000; Bouyer et al., this volume) (Figs. 10, 17, 18). Using the GPS, programme managers can lay out the exact flight paths for the aircraft. This technology allows the distribution of sterile insects precisely where desired. It has also reduced flight times and pilot error, eliminating duplication of flight paths and the unintentional omission of some of them. Today, most programmes making aerial releases use the GPS to guide the aircraft. The GPS is especially useful in areas that lack the visual landmarks that pilots may use to determine where they are and where they need to fly.

A computer with its software enables recording of pre-programmed flight lanes, release elevation, and airplane speed, information that can be classified and displayed using Geographic Information Systems (GIS) (Bouyer et al., this volume). Programme managers greatly benefit from the combination of these tools to supervise the work and guide the release and other control activities (Figs. 17, 18). GPS and GIS location of the sterile and fertile insect captures is also used to map out presence and distribution of the flies as well as the sterile to wild ratios relevant for the success of the SIT (FAO/IAEA 2006b).

In the Mediterranean fruit fly programme in Valencia, Spain, differential release rates of sterile males are applied according to pest density as the aircraft flies over release blocks with non-regular shapes, so curvilinear release paths are adapted to them. The flow of sterile males is adjusted automatically by the release machine during the flight to fit the target release map that was previously created using the most recent trapping information on apparent densities of wild flies in the field (Fig. 18) (section 6.3.).

The MACX system is a sterile-insect release monitoring option that was designed to track the quality of chilled-adult releases. The data are recognized, analysed, translated, and re-transmitted to a website where it is available to supervisors and programme managers; the system can follow the releases in real time (Leal Mubarqui 2005; Leal Mubarqui et al. 2014).

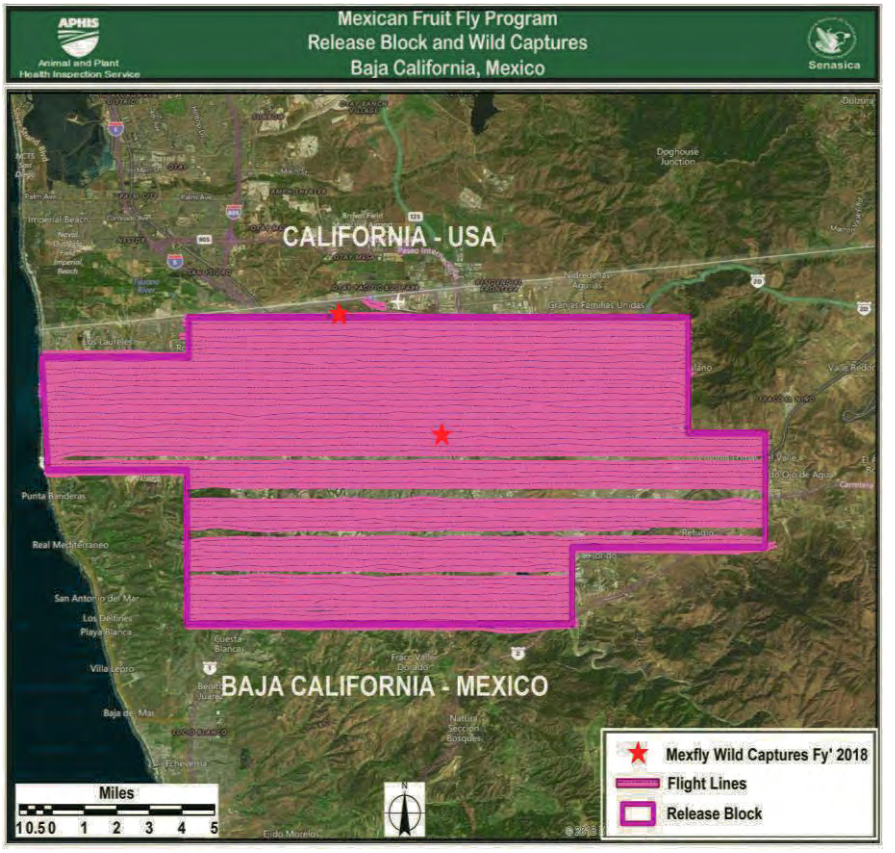

*Figure 17. Aircraft flight lanes (thin red lines) for sterile insect releases in the Mexican Fruit Fly Programme in Baja California, Mexico. (Illustration from L. Charles, USDA/APHIS/IS Mexico, and E. Lira, USDA/APHIS/IS Guatemala, reproduced with permission.)*

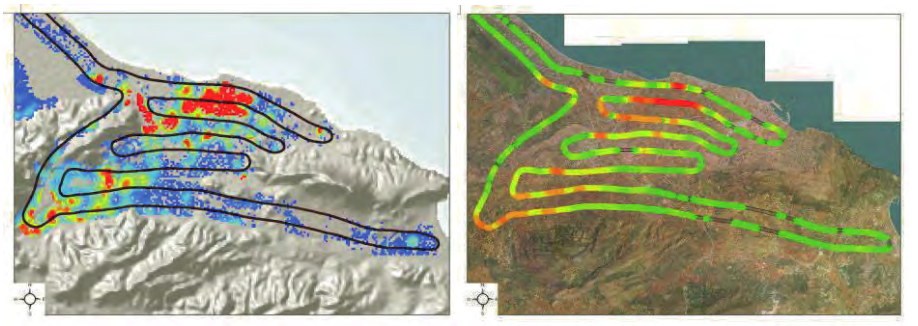

*Figure 18. Left: Release block with non-regular shape and curvilinear flight path adapted to it, showing the target release intensities (red colour means high densities of sterile males are needed). Right: Map showing the differential release actually conducted (the red colour of the release flight line confirms higher release flows of sterile males).*

To release boxed tsetse flies, an electronic counter is used; this device has an optic sensor and a GPS antenna. It counts the biodegradable boxes as they are released from a fixed-wing UAV (Fig. 15), and saves a digital file recording the position at which each box has been dropped. The file can be imported into GIS software for later analysis of the quality of the flight (FAO/IAEA 2016b; Benavente-Sánchez et al. 2021).

## 7. CONCLUSIONS

Most of the large operational programmes that integrate the SIT have established emergence and release facilities (ERFs) in the vicinity of the release areas, usually separated from the mass-rearing facilities (MRFs) that supply them with the sterile insects, commonly in the form of pupae. This operational scheme results in lower costs for the programme and better quality insects in the field, provided the duration of shipments and temperature of the shipped insects are kept at acceptable levels. However, in some insect species, adults can be collected after emergence (Fig. 8) (without the need for holding and feeding) for direct transport and release.

MRFs can also supply sterile insects to independent field programmes, thereby avoiding large initial investments in the mass-production of sterile insects. Shipping sterile insects across national borders has become a major activity, with improved shipping procedures resulting in higher-quality sterile insects.

More efficient methods for emerging, holding, and feeding high-quality insects, such as the tower system for fruit flies, have been developed, optimizing the space needed in the ERFs and reducing the workload for the daily operations. However, earlier methods are still useful depending on the particular action programme, e.g. emergency response vs. permanent activity.

The incorporation of GPS technologies into surveillance systems has enabled the determination of the precise location of pests in the field and at which sterile-insect releases should be directed. Navigation technologies, using GPS, GIS, and electronic communication systems have greatly improved the accuracy, reliability, efficiency, and recording of sterile-insect releases.

Similarly, insect ground- and aerial-release methodologies have evolved, using available industrial technologies. Although still in the development and validation phase, in some situations unmanned aerial vehicles (UAVs) or drones appear to be a realistic and cost-effective possibility for releasing sterile insects within their technical limitations of payload and endurance. However, the regulation and international harmonization for using different-sized remotely piloted aircraft systems (RPASs) are still in progress.

Quality-control manuals have been updated (FAO/IAEA/USDA 2019; FAO/IAEA 2017a, b) to include assessments of sterile insects prior to, and even after, their field release, ensuring their viability for the expected introduction of sterility into feral populations. A spreadsheet on sterile-insect release density calculations and its manual, recently published (FAO/IAEA 2019), has enabled release densities (as well as the corresponding ratios of sterile to wild insects based on actual field trapping data) to be determined; its programmatic use has already contributed to achieving an improved use of the SIT. All of these improvements add

up to a more cost-effective implementation of the SIT as part of an area-wide integrated pest management approach to pest control.

## 8. ACKNOWLEDGEMENT

## SUMMARY

Insect pest control programmes, which integrate the release of sterile insects, can be efficient only if the released insects have an optimal biological quality. Frequent monitoring of the quality of reared insects after being released in the field is an important but often neglected component of area-wide integrated pest management (AW-IPM) programmes that integrate the sterile insect technique (SIT). Parameters of sterile insects, which should be monitored regularly, are sexual competitiveness of the released insects, and related components, e.g. survival, mobility, dispersal characteristics, and spatial occupation of the habitat. A well-balanced monitoring programme will, at any given time, provide essential feedback on the target and sterile populations in the field, and therefore on whether progress is being made. This information is prerequisite to efficient implementation of the release and cost-efficient use of sterile insects. The type of monitoring to be done will be determined largely by the particular biology of the target insect species. The rate of sterility induced in the wild insect pest population is the most important parameter in relation to the release of sterile insects; an increased rate of induced sterility in the native female population can unequivocally be linked to a decrease in the density of the target insect population.

## 1. INTRODUCTION

Successful area-wide integrated pest management (AW-IPM) programmes using the sterile insect technique (SIT) against insect pests require reliable data on the biology of the target insect, especially its sexual behaviour, population dynamics, and temporal and spatial fluctuations in population density and distribution (Itô et al., this volume). This information is essential to accurately interpret data accumulated during the monitoring of a programme. Monitoring sterile and wild insects is a critical aspect of any SIT operation and includes: (1) the performance of sterile insects after release, and (2) the impact of sterile males and other control tactics on the wild target population.

The efficient implementation and success of any control programme using the SIT will depend on factors related directly to the quality of the released insects (Parker, Vreysen et al., this volume). It is imperative that the released sterile insects intermingle rapidly with the wild population after being released, and mate at the same rate as the wild insects. The production of insects in a rearing facility, that have a "biological quality" or "competitiveness" comparable with that of wild insects, is much more complicated than might be anticipated. This quality can easily be impaired due to: (1) aspects inherent to the colonization and mass-rearing procedures (artificial environment, holding density, stress) (Parker, Mamai et al., this volume), (2) the sterilization treatment with ionizing radiation (Bakri et al., this volume), (3) the physical handling and marking procedures at the production or release centres, and (4) the transport of the insects to the release site (Dowell et al., this volume; Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume). In addition, the behaviour of the reared and released insects could be altered drastically due to changes induced in the genetic traits of the mother stock kept for numerous generations under artificial conditions. Continuous rearing may select for traits that favour mass-

production (early maturation, high fecundity, mating at high densities), but which could negatively affect field performance (courtship behaviour, release of pheromones, territorial behaviour) and even prevent released insects from mating with wild insects (Lance and McInnis, this volume).

Ideally, to assure optimal quality of reared insects, rigorous quality control procedures must be implemented at all times and in all phases of production, not only on an ad hoc basis or after the emergence of a problem (Spradbery 1994). However, regardless of how meticulously quality control procedures are implemented, the laboratory criteria of fitness may have little bearing on the ability of released males to survive and mate with wild females (Krafsur and Hightower 1979). Admittedly, measurement of the "biological quality" of sterile insects in a laboratory or field cage is a convenient way to assess the effect of several factors related to sexual competitiveness (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume), but it does not assess other parameters that are also of relevance to the insect's performance in the open field. Therefore, the frequent monitoring of the competitiveness of the released insects and related parameters, such as survival, dispersal rate, and spatial occupation in the natural habitat, is an indispensable component of AW-IPM programmes that integrate the release of sterile insects.

Efficient programme implementation and technical management of an AW-IPM programme are only possible through the regular and frequent analysis of accurately collected field data. In practice, not all programmes using the SIT grant the same importance to monitoring and data analysis, and the emphasis given depends on factors such as: (1) level of experience of the managers, and their confidence in the programme, (2) economics and availability of sterile insects (is it cheaper to release more insects than develop an extensive monitoring programme?), and (3) efficiency and economics of the available monitoring tools. Scientifically sound monitoring activities require significant funding for personnel, equipment, logistics, and recurrent expenses, and as a consequence, insufficient importance is often given to this component. However, when progress does not match expectations, accurate field data are a prerequisite to detecting the causes of the problem and applying corrective measures. Otherwise, programme managers are doomed to "guess work" and making decisions based on assumptions, frequently resulting in technical and financial failure.

History teaches us that any AW-IPM programme will face external criticism, especially when the goal of the programme is to eradicate the target insect population in a circumscribed area (Klassen and Vreysen, this volume). Unfortunately, it is usually the uninformed "outsider", lacking appropriate scientific background or insight into the activities and challenges being faced by the programme, who is criticizing it. A scientifically sound monitoring programme is an essential element in successfully refuting such criticism.

## 2. MONITORING INSECT QUALITY IN THE FIELD

Surprisingly little attention has been given to monitoring the competitiveness of sterile insects in the field. In part, this is due to the technical difficulties involved in making these types of observations. In recent years, however, significant progress has been made by using larger walk-in field cages to study a set of parameters (e.g. preferred

host location, courtship and mating behaviour, mating compatibility, spatial distribution related to female location, mating success, etc.) that are relevant to the sexual competitiveness of the reared sterile insects in a semi-controlled natural environment (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume). Even with this important development, the successful interaction of mass-reared sterile males with wild females in the field is still the key to the success of the SIT, and every effort should be made to assess the extent of this interaction. A Field Quality Control group, that designs a set of tests tailored to the needs of a target species, must be an essential part of all field programmes. This group should be composed of full-time employees of the programme who have the required expertise in conducting field evaluations, and extensive knowledge about the ecology and behaviour of the target insect (FAO/IAEA/USDA 2019).

### *2.1. Field Monitoring of Sexual Competitiveness*

The competitiveness of an organism is defined as its ability to compete with conspecific organisms for a limited environmental resource (FAO/IAEA/USDA 2019). Fitness in wild insects involves their genetic contribution to the next generation's gene pool relative to the average for the population. Sterile insects do not reproduce, and therefore do not contribute to the next generation's gene pool. Their competitiveness is largely a matter of survival, dispersion (spatial occupation of the habitat), adequate behavioural responses, habitat finding, and successful mating, i.e. it ends with mating or insemination (LaChance 1979). Therefore, the general sexual competitiveness of a sterile insect is largely defined and influenced by components such as survival, mating propensity, mating compatibility, post-mating factors, etc. (FAO/IAEA/USDA 2019; Lance and McInnis, this volume). In view of the drastic changes, due to continued mass-rearing, that can be induced in the genetic traits of reared insects, the frequent measurement of sexual competitiveness and its related components under field conditions is indispensable for success (Haisch 1970; Itô and Koyama 1982).

The sexual competitiveness '*c*' of sterile insects was defined by Fried (1971), and its value will normally fluctuate between 0 and 1 (Itô and Koyama 1982; Iwahashi et al. 1983; Itô et al., this volume). The importance of regularly monitoring the sexual competitiveness in the field was demonstrated in the programme against the melon fly *Zeugodacus cucurbitae* (Coquillett) on Kume Island, Japan. In the beginning of the release programme, mating competitiveness measured in the field was high ($c = 0.8$), and comparable with that obtained in laboratory cage tests. After 18 generations of continuous mass-rearing, the field value of *c* dropped to 0.2, whereas the laboratory value remained high. This difference was attributed to the inferior mating performance of wild males in small laboratory cages, and a real decline in the field competitiveness of sterile males due to rearing-induced genetic changes, i.e. domestication, and the development of SIT resistance in the wild population (Iwahashi et al. 1983; Lance and McInnis, this volume; Whitten and Mahon, this volume). As a result of monitoring the field *c* value, programme managers were alerted, took corrective action in a timely manner, and the melon fly was eradicated in Kume Island.

An interesting trend in the field competitiveness of released insects, in relation to the operational size of an AW-IPM programme, is provided by the New World screwworm *Cochliomyia hominivorax* (Coquerel) eradication programme in the USA and Central America. In the first decade of the programme in the USA (Curaçao, Florida, Texas 1954–1962) (Klassen et al., this volume), less than 50 million sterile insects per week were released at low densities, and competitiveness was 0.29–0.43. However, when production increased to 500 million sterile insects per week, the competitiveness dropped to below 0.1 (Mayer et al. 1998), indicating that increased production levels have a negative impact on field competitiveness. Measures such as regularly renewing the strains when the programme moved from the arid south USA to tropical Central America mitigated the problem.

Fried's model indicates that the sexual competitiveness of released insects is inherently linked to the sterile to wild insect ratio obtained in the field. Calculations of critical sterile to wild ratios for any target insect (Barclay, this volume) are usually based on experience or the results of mathematical models, and may vary considerably among insect species, and between theory (models) and practice (operational programmes). Critical sterile to wild ratios varied between 7:1 for the tsetse fly *Glossina palpalis gambiensis* Vanderplank (Politzar and Cuisance 1984), 25:1 for the olive fruit fly *Bactrocera oleae* (Gmelin) (Tzanakakis 1974), 40:1 for the codling moth *Cydia pomonella* (L.) (Dyck et al. 1993), 60:1 for the pink bollworm *Pectinophora gossypiella* (Saunders) (Staten et al. 1993), 80:1 for the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) (Villaseñor et al. 2000), and 25–100:1 for the New World screwworm (J. W. Snow, personal communication). Operational sterile to wild ratios can even be different for species and subspecies within a genus, e.g. a sterile to wild male ratio of 7–10:1, greater than 10:1, and greater than 30:1, was applied against *G. palpalis gambiensis* in Burkina Faso, *Glossina palpalis palpalis* Robineau-Desvoidy in Nigeria, and *Glossina austeni* Newstead in Unguja Island, Zanzibar, respectively (Politzar and Cuisance 1984; Oladunmade et al. 1990; Vreysen et al. 2000). Most likely these differences are related to distinct ecological affinities of the target insect, their mobility, spatial occupation of the habitat, population regulation, sterile male quality, etc.

Even though the critical ratio of sterile to wild males for a target insect can be influenced by factors such as the reproductive potential of the females, climatic conditions, biological quality of the insects before leaving the rearing facility, funds available to disperse sterile insects, and time available to achieve suppression or eradication, it is the true density and distribution of the wild insect population that is the most determining factor. The number of wild insects per unit of habitat surface determines the release rate of sterile insects that is required to achieve the desired sterile to wild ratio in the target area. In turn, the production capacity of the rearing facility must be adequate for the chosen release rate. Underestimating the actual population density can result in a shortage of available sterile insects in the production facility, whereas overestimating it will lead to overproduction and unnecessarily increased costs (Bloem and Bloem 2000). The density of insect populations is usually strongly correlated with habitat and vegetation cover, e.g. melon fly density in Okinawa, Japan, varied from less than 10 flies per hectare in the mountains to greater than 600 flies per hectare in crop fields and bushy areas (Yamagishi et al. 1993).

Therefore, the density in all vegetation types in the target area should be estimated so as to adjust accordingly the number of sterile males released. It is important that the critical sterile to wild ratio be obtained in all trap sites, indicating that sterile insects have been appropriately placed in the target area (Krafsur et al. 1980). Several simple mathematical models are available to assess absolute insect population densities, e.g. Lincoln Index (Southwood 1978), and Jackson's positive and negative method (Jackson 1939), but these methods have rarely been routinely used in operational programmes integrating the SIT (Itô et al., this volume).

The patchy distribution of most insect species (Itô et al., this volume; Lance and McInnis, this volume), and the strong correlation between insect density and vegetation type, has implications for interpreting "overflooding ratios" when releasing sterile insects, i.e. one should take into account not only the overall sterile to wild male ratio obtained in all traps in a given area over a period of time, but also the ratios achieved in each type of habitat and vegetation cover must be adequate. Therefore, a suitable network of traps, strategically deployed in all habitats, is needed (Vreysen et al. 2000).

### *2.1.1. Marking Insects*

To calculate sterile to wild ratios, sterile insects are usually marked before release (FAO/OIEA 2018; Dowell et al., this volume; Parker, Mamai et al., this volume). Marking is traditionally done using physical markers (e.g. fluorescent dye on the entire body, acrylic paint on the thorax (for small pilot trials) or Calco Red in the diet of some Lepidoptera), but some of these markers have issues of cost, human health, sustainability or negative effects on the insects' competitiveness (Hagler and Jackson 2001; Parker, Mamai et al., this volume). More stable morphological markers have become available, such as the VIENNA 8-*Sergeant* ($Sr^2$) strain of the Mediterranean fruit fly, that in addition to the *temperature sensitive lethal* (*tsl*) and *white pupae* (*wp*) mutations, carries the dominant *Sergeant 2* ($Sr^2$) mutation that is expressed in males as three abdominal stripes, whereas wild-type males have only two stripes (Nyazi et al. 2005). The transgenic strain VIENNA 8–1260 presents another stable marker for the Mediterranean fruit fly. The strain expresses the Ccb2t promotor driver tGFP in the testes as green fluorescence and DsRed in the body as red fluorescence (Scolari et al. 2008) (Fig. 1).

Irrespective of which marker is being used, it needs to be ascertained whether there are negative effects on production in the mass-rearing facility or on their sexual competitiveness, survival, dispersal, etc. In that respect, Rempoulakis et al. (2016) assessed production parameters and competitiveness of the above-mentioned Mediterranean fruit fly strains in walk-in field cages. VIENNA 8–1260 females produced fewer eggs than the other two strains, but the egg hatch of all strains was similar. Differences in male mating competitiveness of the three strains against wild-type males were gradually reduced with successive generations under semi mass-rearing conditions. However, VIENNA 8 males adapted faster to laboratory conditions as compared with VIENNA 8–$Sr^2$ and VIENNA 8–1260 males with respect to mating competitiveness. VIENNA 8 males of the $F_{10}$ generation were equally competitive with wild-type males, whereas the mating competitiveness of VIENNA 8-$Sr^2$ and

VIENNA 8–1260 males was similar but lower as compared with wild-type males. Males from all three strains copulated earlier than wild-type males.

*Figure 1. Mediterranean fruit fly strain VIENNA 8-1260 expressing green fluorescence in the testes and red fluorescence in the body. (Photo from G. Franz, reproduced with permission.)*

Recently, the biomarker dye rhodamine B has shown promise as a marker for Lepidoptera and mosquitoes. Feeding male tobacco budworm *Heliothis virescens* (F.) on 0.1% rhodamine dissolved in 10% sucrose solution did not only stain the body of the males but could also be detected in the spermatophores of female moths that had mated with the males. The intake of the dye had no effect on life span and mating performance of the males and production of eggs (Blanco et al. 2006). Sugar-feeding with rhodamine was used to stain the seminal fluid and bodies of male *Aedes aegypti* (L.) with no significant impact on their survival or mating competitiveness (Johnson et al. 2017).

In programmes releasing sterile New World screwworms, the flies are not marked, and estimations of the ratio of sterile to wild insects are based on catches of female insects. Females are dissected, and the atrophied ovaries of sterile females distinguish them from wild females. However, caution is required in interpreting these data. Sterile to wild ratios are derived from trapped insects, and if the distribution and response to traps is different for sterile and wild male insects, the ratios are prone to error (Meats 1996). One must also be cautious in interpreting female screwworm ratios; they might not reflect actual male screwworm ratios in the field due to sex-related differences in longevity, response to the trapping device, and dispersal characteristics.

Insects may be trapped in areas where their presence is not expected or anticipated, or where it is paramount to know their origin, e.g. in pest free areas, in recently cleared areas, in traps that are deployed in the vicinity of mass-rearing facilities, or an unmarked insect trapped at the end of an eradication campaign that potentially has lost

its physical marker. In all these cases there is a need to identify the origin of the insect, or whether the insect is a sterile released or a wild relic fly. For some insect species, such as the Mediterranean fruit fly, molecular markers have become available that allow an assessment of the origin of the trapped flies (Meixner et al. 2002; Silva et al. 2003). The use of release strains that differ in their mtDNA background from that of the target population facilitates discriminating between unmarked flies and new incursions into a free area (San Andres et al. 2007; Franz et al., this volume).

Similarly, a molecular technique has been developed, based on the determination of cytochrome oxidase haplotypes to discriminate between wild and sterile male tsetse flies *Glossina palpalis gambiensis* with a high level of accuracy. The DNA was isolated from the heads of flies and a portion of the 5' end of the mitochondrial gene cytochrome oxidase I was amplified for sequencing. All sterile male flies from a Burkina Faso strain had the same haplotype but differed from that of wild male flies trapped in Senegal and in Burkina Faso. The method allows 100% discrimination between sterile and wild male *G. p. gambiensis* and can be used in release programmes in case there is doubt regarding the origin of a trapped fly (Pagabeleguem et al. 2016).

Stable isotopes have been used successfully to determine the natal origin of insects, their feeding strategies and mating behaviour (IAEA 2009; Vreysen et al. 2016). Enriching the water in which larvae of the mosquito *Culex pipiens* L. (Diptera: Culicidae) developed with $^{15}$N-labeled potassium nitrate and $^{13}$C-labelled glucose allowed the differentiation of marked from unmarked adult mosquitoes throughout their entire lifespans, e.g. 55 days. The labelling had no effect on immature mosquito survival or adult body size, and the technique was also applied to mark naturally breeding mosquitoes in standing water bodies in the field (Hamer et al. 2012). Hood-Nowotny et al. (2016a) labelled seven species of lepidopterans: cactus moth *Cactoblastis cactorum* (Berg), *Eldana saccharina* Walker, *Spodoptera litura* (F.), *Epiphyas postvittana* (Walker), diamondback moth *Plutella xylostella* (L.), *Lobesia botrana* (Denis and Schiffermüller), and pink bollworm *Pectinophora gossypiella* (Saunders), which made them distinguishable from wild conspecific moths based primarily on the difference in the ratio of the stable isotopes $^{13}$C:$^{12}$C. Depending on whether the wild host plants had a C3 or C4 metabolism, the diets were prepared with sugar derived either from sugarcane or sugar beet, so that the moths reared on the meridic diet had a ratio different from wild moths. The technique also worked with the tsetse fly *Glossina pallidipes* (Austen); laboratory-reared flies remained distinguishable from wild flies for more than 80 days (Hood-Nowotny et al. 2011). Mass-reared Mediterranean fruit flies fed on a larval diet containing C4 sugar could be distinguished with >95% confidence from wild flies that had developed mostly within the fruits of C3 plants. The C4 marker was detectable up to 12 days after release (Hood-Nowotny et al. 2009).

Elemental analysis-isotope ratio mass spectrometry (EA-IRMS) is the standard tool to measure isotope signatures, but this technology is expensive. A simpler technology called combustion module-cavity ring-down spectroscopy (CM-CRDS) is now available on the market. The technology is cheaper and more convenient than EA-IRMS, and data obtained were in good agreement with those obtained using EA-IRMS in terms of accuracy and precision (Hood-Nowotny et al. 2016b).

### *2.2. Field Monitoring of Parameters Related to Sexual Competitiveness*

#### *2.2.1. Apparent Density and Survival*

In routine monitoring, the most immediately available parameter is the proportion of sterile insects recaptured within a certain time frame, i.e. the recapture rate, and a sudden decrease in this rate could reflect a change in the quality of the released insect or in distribution methods (Hutt 1979; Yamagishi et al. 1993).

To increase their chances of encountering a receptive virgin female, sterile males need to survive and have a sexually active life in the field for as long as possible (Curtis and Langley 1982). It is important to estimate this parameter and investigate methods to increase the survival (longevity) of released sterile males (Lance and McInnis, this volume; Parker, Vreysen et al., this volume). After leaving a rearing facility, released sterile insects must find a food source or a host to replenish their limited energy reserves. In the absence of a host, their life expectancy is determined by the available initial energy reserves and the post-factory treatments before release (Pereira et al., this volume). Therefore, it is a critical parameter, and can be assessed in the laboratory (FAO 1992) or in field cages under natural conditions (Vreysen 1995).

An exponential decline in the recapture rate of marked released insects gives an indication of the daily survival (or mortality) rate in the area (Fig. 2). The survival rates will determine the frequency of sterile insect releases, ensuring appropriate sterile male densities over the entire target area at all times (Dowell et al., this volume). Sterile insect survival is influenced by factors such as host availability, climatic conditions, predator avoidance capacity, and vegetation cover, and therefore the survival of released insects should be assessed in all seasons and in all representative areas of the target zone.

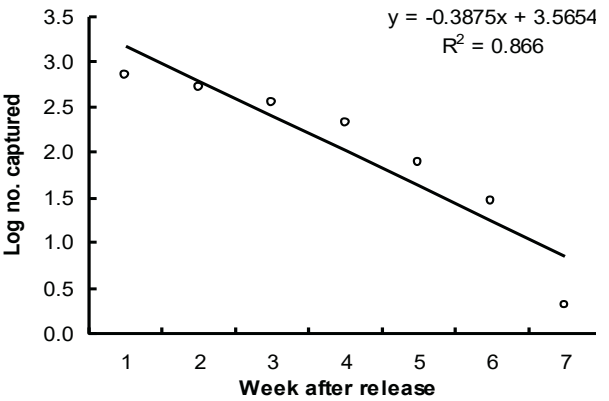

*Figure 2. Survival of sterile male* Glossina austeni *aerially released in Unguja Island, Zanzibar, Tanzania.*

*2.2.2. Mobility, Dispersal and Distance between Isolated Populations*

Released sterile insects need to be sufficiently mobile, and have adequate dispersal capabilities, to reach (in a timely fashion) all the ecological niches occupied by the wild insect population (Itô et al., this volume; Lance and McInnis, this volume). Mobility and the potential of released insects to disperse are often underestimated. The recorded maximum dispersal distance for released New World screwworms is 290 km, 107 km for melon flies, 48 km for oriental fruit flies *Bactrocera dorsalis* (Hendel), and 18.5 km for the tsetse fly *G. p. gambiensis* (Hightower et al. 1965; Proverbs 1974; Van der Vloedt et al. 1980). Lance and McInnis (this volume) discuss the implications of this high mobility for programmes using the SIT.

Knowledge about the mobility and dispersal characteristics of released insects is essential for developing and designing appropriate release strategies (Itô et al., this volume). Admittedly, this is complicated; there are many variables that influence the dispersal of insects, e.g. wind direction (Peterson et al. 1980), wind velocity (Parman 1945), vegetation density (Krafsur and Hightower 1979), relative humidity (Brenner 1984), host availability (Spradbery 1994), radiation dose (Cuisance and Itard 1973; Wong et al. 1982), and the release of only males or both sexes (Proverbs et al. 1973; Hendrichs et al. 1995). A release strategy should aim at deploying sterile insects in close proximity to wild virgin females. Release lanes for aerial distribution, or release points for ground release, should be separated by a distance not exceeding the average maximum dispersal distance of the released insect (Dowell et al., this volume). Evidence from New World screwworm programmes suggests that the efficiency of released males, as measured by their mating frequency, is strongly influenced by operational considerations of sterile fly distribution. Distance between parallel flight lanes, and fly density in release containers, are especially critical variables (Krafsur et al. 1980). The sterility of wild populations increased significantly if flies were distributed in small boxes of 400 flies in release swaths of 2 km instead of in larger boxes of 2000 flies in swaths of 8 km (Krafsur and Garcia 1978). Obviously a denser network of aerial release lanes will require more aircraft time and is more expensive, but the programme will be more efficient, and releases of sterile insects would possibly be needed for a shorter time period.

The mobility and dispersal capacity of released sterile insects should be monitored frequently and compared with those of wild insects. This will require the capture, marking and release-recapture of large numbers of wild insects, and unfortunately these are not always available. Although in the past several complex mathematical models have been developed that describe the movement and mobility of insect species (Williams et al. 1992), a simple but useful index is the "mean distance of dispersal" from a release site to a trap (Itô and Koyama 1982; FAO/IAEA/USDA 2019):

$$x = \frac{\sum_{j=1}^{n} x_j N_j}{\sum_{j=1}^{n} N_j} \qquad (1)$$

where $n$ = number of traps, $x_j$ is the distance between a release point and the $j$-th trap, and $N_j$ is the number of flies recaptured with the $j$-th trap.

The mean distance of dispersal can easily be measured by deploying traps along a regular grid of at least 6 x 6 traps, the dimensions of the grid depending on the insect species. Grids are usually easier to set up than a series of concentric circles, but circles are better for measuring dispersal. Caution is required in selecting the sampling device, and especially in using traps in combination with powerful attractants (e.g. pheromone traps for Lepidoptera), that could mask the natural dispersal characteristics of the insect. For lepidopteran species, passive, non-attractant interception traps are an alternative to male pheromone traps; they have been used to determine natural flight paths and flight patterns of insects in search of mates or hosts. The disadvantage of this technique is that catches are usually very small, making statistical analysis difficult or impossible (Knight 2000).

Caution is likewise required in generalizing results from mark-release-recapture studies (Itô et al., this volume), as these are, in the case of mosquitoes, influenced by the ecological characteristics of the study sites, and these studies should always be made in the area where the mosquito project is being conducted (Petrić et al. 2014; FAO/IAEA 2020b).

Dispersal is an important factor to consider when making strategic decisions on the selection of target areas for AW-IPM approaches, be it suppression or eradication (Hendrichs, Vreysen et al., this volume). For example, in the past, estimates of the dispersal capacity of the tsetse fly *G. p. gambiensis* at the microscale were obtained using direct methods (mark–release–recapture) as well as indirect ones (genetic isolation by distance). In this species, genetic isolation was strongly correlated with distance; however, populations separated by 15 km of rice plantations were more isolated than those separated by 100 km of gallery forest, indicating that for this species the friction of riparian vegetation to dispersal was significantly lower than that of rice plantations (Bouyer et al. 2009; De Meeûs et al. 2012). As no useful friction maps were available for tsetse flies at any scale, a friction map was developed to identify natural barriers that isolate populations of *G. p. gambiensis* in West Africa. A statistical model was used to assess the genetic distance between 37 tsetse populations sampled in West Africa, using a set of remotely sensed environmental data as predictors. The least-cost path between these populations was then estimated using the predicted friction map. The method avoids the subjectivity inherent in expert-based weighting of environmental parameters. As a result, potentially isolated clusters of *G. p. gambiensis* habitat were identified based on a species distribution model and ranked according to their predicted genetic distance to the main tsetse population (Bouyer et al. 2015).

Dispersal of female mosquitoes to seek a host is epidemiologically important because it influences the capacity of the females to acquire and disseminate pathogens. Dispersal to find suitable oviposition sites is also important because it increases the spreading of potentially infected progeny (Petrić et al. 2014). The dispersal of mosquitoes is influenced by the density and distribution of blood sources, availability of oviposition sites, weather, terrain features, vegetation, housing characteristics in urban and rural settings, etc. There appears to be a correlation between mosquito dispersal into new areas and proximity to major transportation routes, commercial movement of tyres, ornamental-plant trade, and individual, public, and commercial transportation out of infested areas (Petrić et al. 2014).

*2.2.3. Spatial Distribution within Habitat*

Released sterile insects must also disperse into the ecological niches occupied by wild insects, and detailed data on temporal changes in spatial distribution of sterile and wild insects are needed (Lance and McInnis, this volume). This is very challenging; most insects are not uniformly or randomly distributed, but have patchy distributions in both space and time. Spatial heterogeneity is related mostly to host availability and vegetation, making it difficult but not impossible to determine the optimal release rate (number of flies released per $km^2$) (Krafsur et al. 1979). An adequate trapping network, covering all types of vegetation, is needed to provide frequent (weekly) detailed information on the density and spatial distribution of wild and released insects. Geographic information systems (GIS) and remote sensing (RS) tools can greatly facilitate the selection of these trapping sites, ensuring adequate coverage but also avoiding the deployment of too many sampling devices (Bouyer et al., this volume). Data on temporal and spatial changes in occupation of the habitat, by both sterile and wild insects, can be used to regularly adapt the scheme for distributing sterile insects.

In the tsetse project in Senegal, selection of trap sites was initially guided using remote sensing techniques and vegetation classifications obtained from Landsat 7 Enhanced Thematic Mapper Plus (ETM+) images that enabled the identification of suitable habitats to harbour *G. p. gambiensis* with high sensitivity, but low specificity (Bouyer et al., this volume). These areas were denominated "wet areas" and the strategic deployment of Vavoua traps (Laveissière and Grébaut 1990) in these habitats allowed the delimitation of the tsetse-infested area. In the area of zero catches adjacent to the infested area, a mathematical model was used to assess the risk that flies were present despite a sequence of zero catches (Bouyer et al. 2010; Barclay et al., this volume). The analysis showed a risk of >0.05 in 19% of the area which was considered likewise as infested and included in the control operations.

Species distribution models have been used more and more to optimize insect pest control activities in general and to obtain more accurate information on the spatial distribution of the insect pest in particular (Barclay, this volume). Whereas previous distribution models were critical for a better understanding of the distribution of the pest insects, they suffered from inadequate spatial resolution. High-resolution satellite images and recent advances in species distribution modelling methods can be used to improve the accuracy of prediction. For example, in the tsetse eradication campaign in Senegal, the use of a Maxent Model enabled the relocation of 22 of the 97 monitoring traps to more suitable sites according to habitat suitability (Dicko et al. 2014).

On a finer spatial scale, the dispersion of insects such as tsetse flies, e.g. *G. palpalis palpalis*, is influenced by sex, age (young virgin females occupy different parts of the habitat than older flies), and the state of gravidity in females (Gouteux 1987). These microspatial differences in an apparently similar habitat should be monitored carefully in important target areas, such as "hot spots" (areas with unusually high insect densities).

An example is the spatial occupation of wild and sterile *G. austeni* in an apparently uniform primary forest ecosystem (Fig. 3). A total of 422 wild female, 679 wild male and 3318 sterile male fly catches from 12 trapping sites over a period of 10 months was used to study the spatial occupation of the flies in a primary forest. The aerial release of the sterile male flies assured their random distribution over the very homogeneous habitat. Despite these uniform aerial release rates, the sterile males redistributed

themselves and occupied microhabitat niches similar to those occupied by wild insects. This ability of sterile males to aggregate (and therefore locate to) those areas preferred by wild males is of primary importance to ensure adequate sterile-to-wild male overflooding ratios everywhere (Vreysen et al. 2011).

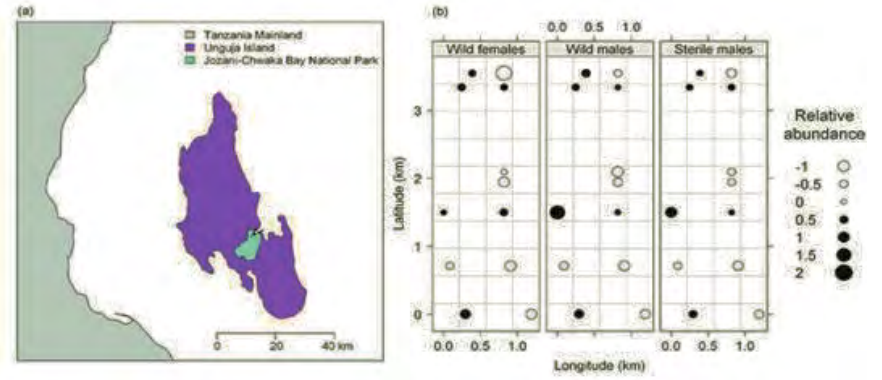

*Figure 3. (a) Unguja Island and the Jozani forest (now called the Jozani-Chwaka Bay National Park), (b) The spatial and standardized abundance of wild and sterile* Glossina austeni *as sampled with 12 sticky panel traps in the Jozani forest. (Figure from Vreysen et al. 2011.)*

## 3. MONITORING PROGRAMME PROGRESS

### *3.1. Monitoring and Insect Biology*

#### *3.1.1. Monitoring and Insect Behaviour*

The feasibility of developing and deploying efficient insect monitoring tools will be determined and influenced by the behaviour and the biology of the insect. Species with adults that respond to a trapping device may be sampled directly in sufficient numbers to accurately assess fluctuations in population density and structure. The biological mechanisms involved in attracting insects from a distance, and luring them into a trapping device, are usually related to their host-, food-, or mate-seeking behaviour, which is often regulated by volatile components (semiochemicals) emitted by the host/food/mate, and at close range influenced by visual characteristics (Colvin and Gibson 1993; Tan 1993; Green 1994; Hall and Wall 1995; Lühken et al. 2014). Sometimes direct trapping of insects is difficult (e.g. in inaccessible areas), inefficient (e.g. a good attractant and trap are not available), or uneconomic, and therefore alternative indirect methods of monitoring have been developed, usually involving assessments of damage inflicted by the pest on its hosts (Iwahashi 1977; FAO 1992; Bloem and Bloem 2000; Dyck et al. 2000).

Surveillance programmes for mosquitoes, such as the Asian tiger mosquito *Aedes albopictus* (Skuse), rely on the use of ovitraps, rather than adult trapping systems.

Ovitraps are simple devices that consist of plastic cups that have a shiny black surface, are filled 2/3 with water, and contain a Masonite strip on the inner wall that is suitable for oviposition (Carrieri et al. 2009). The maximum time interval allowed for checking the ovitraps is 1 week; longer periods would turn the traps into mosquito reproductive breeding sites (Ritchie 1984). The egg-density data obtained can provide a good estimate of the biting-female density (Carrieri et al. 2011). Monitoring with ovitraps has the advantage of being low cost, but the catch data might be influenced by factors such as siting, micro-environment, presence or absence of other breeding sites, and local adulticide treatments (Carrieri et al. 2017).

### *3.1.2. Direct Sampling of Adult Insects*

In AW-IPM programmes, it is important to be able to monitor both high and low population densities. The densities of pests such as screwworms tend to be low but highly aggregated (Krafsur et al. 1979; Spradbery 1994), and the most efficient and appropriate sampling device should be used (Katsoyannos 1994) for the relevant geographical area (Baylis and Nambiro 1993). However, most trapping systems are biased, and samples are rarely representative of the insect population (Vale and Phelps 1978; Vreysen and Saleh 2001). Therefore, it is always a sound practice to estimate population densities using more than one method (Bloem et al. 2005; Petrić et al. 2014; Lees et al., this volume). To interpret trapping data correctly, it is imperative to understand these "trap biases", and the factors that affect the size and structure of trap samples over time and space. Some of the most significant factors that affect insect population samples are: (1) activity of the insects, which depends on the insect's physiological state and on climate (Rogers 1978; Turner 1987; Williams et al. 1990b), (2) efficiency of the trap, which is influenced by the elements of attractant, trap construction, habitat, and climate (Hargrove and Vale 1980; Dransfield et al. 1982; van de Straat et al. 2019; FAO/IAEA 2020a), and (3) intrinsic trap biases (Williams et al. 1990a).

In addition, when selecting a trapping device for a monitoring programme, the following aspects have to be taken into account: performance of the sampling device in relation to economics (number of traps needed is inversely correlated with trap efficiency), servicing, time required to deploy a trap, unit cost and its components, durability, "user friendliness" (i.e. time required to remove trapped insects), efficiency of the bait (very good baits may overestimate the local population density), and species specificity (Flores et al. 2017; FAO/IAEA 2018). Trapping large numbers of non-target organisms is inefficient; e.g. biting flies (Stomoxyinae) caught in tsetse fly traps (more than 1000 individuals per trap per day) (Saleh et al. 1999), species of *Chrysomya*, morphologically similar to New World screwworms, caught in traps at a ratio of 2600:1 (Spradbery 1994), and a wide range of tephritids and non-tephritids in fruit fly traps baited with food lures (Katsoyannos 1994; Miranda et al. 2001).

Smart traps are now available on the market and are becoming more common for monitoring purposes in action programmes. These sampling devices, which automatically record the target insects sampled and provide feedback using appropriate software systems, have several advantages, e.g. traps need to be checked only when relevant catches have been recorded, preventing unnecessary visits to empty traps and making the entire monitoring process much more cost-effective. In

addition, new systems are being developed that allow the automatic identification of the insects, reducing or even eliminating the need for trap visits (Vreysen et al. 2016). One of these trapping systems consists of a multi-funnel trap equipped with a camera connected to an internal modem for General Packet Radio Service. Images taken are stored on a memory card and are adequate for identifying larger insects such as longhorn beetles (Chinellato et al. 2013).

The potential use of these systems in sterile insect release programmes would also lead to more cost-effective and efficient field surveillance, as real-time feedback on released insects could lead to more efficient decision-making (Simmons et al. 2010). For example, in Australia, a system called RapidAIM (2018) was developed that combined the knowledge of fruit fly behaviour with proprietary hardware and software used in a grid of instrumented, low-powered smart traps. The traps detect the presence of a fruit fly, send the data to the cloud for analytics, and generate an alert. This system visualizes the location and occurrence of fruit fly presence and/or outbreaks which can result in a rapid and efficient response.

### *3.1.3. Indirect Sampling*

Monitoring a population through direct sampling of adult insects can, in many instances, be supplemented by indirect sampling procedures, both to obtain additional information on the progress of the programme and to verify the data obtained by direct sampling procedures. In addition to direct sampling, indirect sampling is used routinely in programmes against veterinary pests (screwworm and tsetse), crop pests (Lepidoptera and fruit flies), and human disease vectors (e.g. mosquitoes).

*Monitoring Host Organisms.* In many holometabolous insects, immature stages represent a large percentage of the population (up to 97% for the Mediterranean fruit fly (Carey 1982; Liedo and Carey 1996)), and in view of this demography these stages should also be sampled (FAO/IAEA 2019).

Since it is easy to detect maggots in animal wounds, indirect sampling through the surveillance of myiasis cases in livestock, game animals, and humans has become the standard method of monitoring progress in New World screwworm eradication programmes. Depending on resources, surveillance can be done either passively (livestock owners check their animals and report positive myiasis cases (Robinson et al. 2000)) or actively (programme staff physically inspect at regular intervals all host animals in the target zone (FAO 1992; Vreysen et al. 2007)). Even though passive surveillance is obviously less expensive, the absence of standardization and a "reference-sampling unit" make temporal comparison of such field data very difficult or even impossible. Also, passive surveillance is influenced by: (1) the accessibility that farmers have to their livestock, (2) the willingness of farmers to inspect their animals on a regular basis (and remove screwworm larvae and send them to the responsible authority in the country), (3) the vastness of the grazing area, and (4) the efficiency of veterinary services. Therefore, a decrease in "reported cases" does not necessarily reflect a lower population density of screwworms (i.e. progress in the programme), but is probably correlated more with the reporting efficiency and level of farmer cooperation (Vreysen et al. 2007). The highly successful New World

screwworm eradication programme in Libya (1990–1992) provides a good example of an efficiently executed active surveillance programme; 94 field teams inspected 16.2 and 30.5 million animals in 1990 and 1991, respectively, in an area of 40 000 km$^2$ (FAO 1992). Accurate reporting of the number of animals inspected, wounds detected, and wounds infested, provided excellent feedback to programme managers to evaluate the progress and guide eradication activities (Lindquist et al. 1992).

*Monitoring Disease Transmission.* In the case of vectors of diseases such as tsetse flies (Glossinidae) that transmit *Trypanosoma* spp., and mosquitoes that transmit malaria, dengue, chikungunya, Zika, etc., insect-trap data can be supplemented with data on the transmission, prevalence, and incidence of the disease in livestock and humans (Barclay et al., this volume). These data become especially valuable if and when the density of the insect population drops below the detectable limit of the trapping device used. In the case of tsetse, the careful screening of sentinel animals, i.e. not infected with trypanosomes, introduced into the target area can significantly increase confidence that the tsetse fly has been eradicated (Dyck et al. 2000). However, interpreting these veterinary surveillance data is complex, and preferably should always be correlated with entomological monitoring data because:

- The density of a tsetse population and the incidence of the disease are not necessarily positively correlated, e.g. an insecticide spraying campaign in Kenya reduced the tsetse population by 98%, whereas 6 months after completion of the campaign the disease prevalence was reduced only from 5 to 2% (Otieno et al. 1990).
- The time required for a fly to develop a mature trypanosome infection is between 5 and 25 days, depending on the species and the temperature (Molyneux et al. 1982). Consequently, the potential for a tsetse population to transmit the disease is increased proportionally to its average age (Harley 1965), and the removal of the younger section of the fly population as the result of control actions does not significantly reduce its transmission capability.
- A parasitological survey will not show transmission if a tsetse population is thriving on livestock free of trypanosomes.

A series of indices has been used traditionally to monitor indirectly densities of *Aedes* spp. and the efficiency of control programmes. These include the:

- house index (HI), i.e. percentage of houses with a least one active breeding site,
- container index (CI), i.e. percentage of containers with larvae,
- Breteau index (BI), i.e. number of active breeding sites per 100 premises, and
- ovitrap index (OI), i.e. average proportion of ovitraps with mosquitoes.

Although widely used, these indices have some disadvantages when used in epidemiological studies, e.g. the CI considers only the percentage of positive containers, and not absolute numbers, and the HI is limited as it does not take into account the number of positive containers. The BI is the only index that combines positive containers with the density per premise (Petrić et al. 2014).

Other indices that have proven to be very useful are the number of pupae per premise (PPI), and the number of pupae per hectare (PPH), because they exploit the

strong correlation between the number of adults in a defined area and the number of pupae (in view of the low pupal mortality) (Carrieri et al. 2011).

*Monitoring Crop Damage.* The damage that insects inflict to crops can be assessed, providing indirect information on the density and distribution of the pest insect population. Crop damage can be measured at regular intervals, e.g. 80–100 cotton bolls per field were collected each week in the pink bollworm programme in California, USA (Staten et al. 1993). Also crop damage can be assessed at harvest, e.g. in the codling moth programme in Canada, a random examination of fruit is made in about one-third of the treated orchards (n = 600) at harvest (Bloem and Bloem 2000). Caution is required in interpreting the data, because damage to a specific crop is not always caused by the target insect, e.g. all insect damage in fruit orchards in Washington State, USA, was attributed to the codling moth, but careful study revealed that fruit injury from codling moth larvae was only 0.3% while that from leaf rollers averaged 1.1% (Calkins et al. 2000). In some instances, the results of direct monitoring (insect trapping) do not correlate with data from indirect sampling (crop damage), e.g. there was no spatial correlation between damage, i.e. defoliation, from gypsy moths *Lymantria dispar* (L.) and the counts of adult male moths in traps (Liebhold et al. 1995).

### *3.2. Monitoring Impact of Sterile Insect Releases on a Wild Population*

Three important indicators provide essential information on the impact of released insects on the target population: (1) proportion of the female target population that mated with sterile males (level of induced sterility), (2) changes in the age structure of the target population caused by variations in the recruitment rate of young insects, and (3) decline in the density of the target population. The characteristics of the reproductive biology of the species, and the trap-orientation behaviour of females, will determine which of these parameters can be used. For example, all three parameters can be monitored in tsetse fly programmes integrating the SIT, but in Lepidoptera, pheromone traps attract only male moths, and thus the information obtained is restricted to the apparent densities of wild and sterile males.

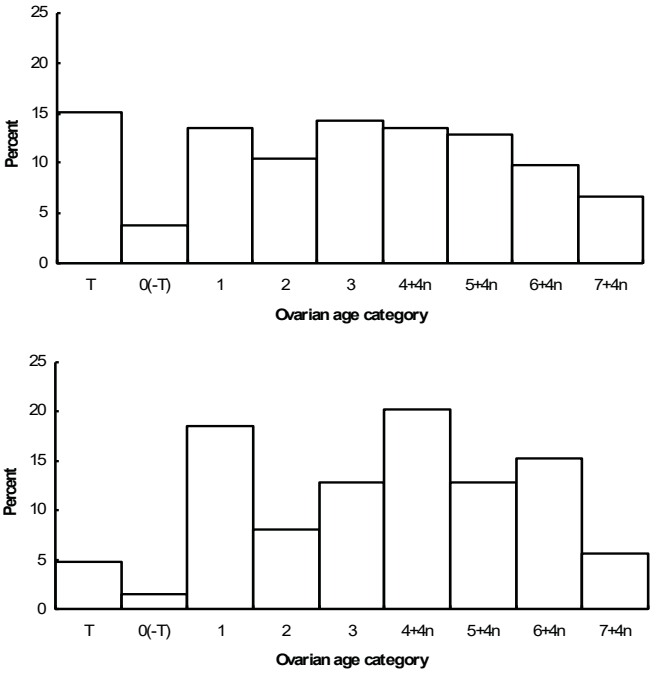
Analysing and interpreting temporal and spatial monitoring data can be accurate only if standardized sampling procedures are used. Especially in the case of direct sampling, uniformity of procedures is required for the entire duration of the monitoring programme, particularly with respect to: (1) trapping device (type, colour, material used for trap construction, shape, etc.), (2) sampling sites (number and location), (3) trap mounting and deployment, (4) lures or odour attractants (chemical composition, pH, volatile release rates, etc.), and (5) sampling interval. In addition, baseline data (collected before control actions are initiated) on spatial and temporal fluctuations in the density and structure of the target population (Itô et al., this volume), collected over a period of at least 1 year, are essential for making correct interpretations of the field data collected during the suppression and sterile insect release phases (Vreysen and Khamis 1999; Vreysen et al. 1999a; De Longo et al. 2000) (Box 1). An alternative is to collect comparable data from an untreated area

during the phase when control actions are applied, but it is often difficult to select ecologically comparable areas (Waterhouse et al. 1976).

*Box 1. Pre-Control Entomological Baseline Data Collection: Prerequisite for Correct Interpretation of Trap Catch Data during Control Activities*

The application of a control measure against an insect population will change the size of that population (section 3.2.4.) and its age structure (section 3.2.3.). Even when not subjected to a control measure, insect populations (in terms of both size and structure) are not stable in time and space. Consequently pre-control data on the structure of the target population must be collected to interpret correctly sampling data obtained during the control activities.

Physiological age grading is feasible for tsetse flies due to the uniqueness of the female reproductive system (section 3.2.1.). The example below demonstrates the spatial differences in the age structure of the tsetse fly *Glossina pallidipes* Austen sampled in riparian forest vegetation along the Kulfo River and in the Chamo bush thickets of the Nechisar National Park in Ethiopia. The flies were sampled in both habitats during the same period of the same day. The data show that the female fly population along the Kulfo River was significantly younger (18.8% young females, tenerals and nulliparous) than the female fly population in the Chamo thickets (6.4% young females) ($\chi^2 = 10.80$, df = 4, $P < 0.03$ — females in the older categories 4 and >4 were pooled in this analysis). A change in fly population structure due to applied control measures must be analysed in relation to these natural spatial (and also temporal) differences.



*Population structure of* G. pallidipes *sampled in (upper graph) riparian forest along the Kulfo River (n = 133) and (lower graph) bush thickets (n = 124) of the Nechisar Park in Ethiopia (T = teneral, 0 = nulliparous, 1–7 = number of ovulations; note that categories i = 4–7 contain flies that have ovulated i + 4n times; more details in Challier 1965).*

Quantifying a reduction in the reproductive potential of a target population constitutes the most powerful and straightforward tool to assess progress in a programme using the SIT (Waterhouse et al. 1976; Vreysen 2001). An accurate knowledge of the level and spatial distribution of sterility induced in wild females will permit a more strategic use of the sterile insects, resulting in increased programme efficacy and reduced programme costs. Assessing the rate of induced sterility in a wild target population is only possible when the female portion of the population can be sampled, and when morphological indicators or "visual markers" are present in the female reproductive system to differentiate between matings with wild or sterile males. Alternatively, female insects can be trapped live and then maintained in controlled conditions for a certain time period to monitor the production of viable offspring (result of a fertile mating) or non-viable eggs (result of a sterile mating). In some insects, egg masses can be collected in the field and the level of sterility determined (section 3.2.2.).

The rate of induced sterility is not only the most essential, but also the most reliable, parameter to assess progress in programmes that release sterile insects. Although a reduction in the number of insects caught in traps can be an important indicator, the number trapped is strongly affected by numerous (often unknown) factors (section 3.1.2.), making the interpretation of trap catches complex (section 3.2.4.). A progressive increase in the sterility of the target population, combined with declining numbers of insects trapped, will provide unequivocal evidence that the eventual collapse of a target insect population is due solely to the loss of fertility, without interference of other factors (Vreysen et al. 2000).

### *3.2.1. Monitoring Reproductive Capacity of a Wild Population — Tsetse Flies*

Tsetse flies have a unique reproductive system, making them very suited to the assessment of sterility levels in a population subjected to sterile insect releases (Van der Vloedt et al. 1978; Vreysen et al. 1996). Tsetse flies reproduce by adenotrophic viviparity (Hagan 1951). The four polytrophic ovarioles in the reproductive system of females develop sequentially (Saunders 1960) (Fig. 4A), with only one oocyte maturing per pregnancy cycle lasting 9 or 10 days (Tobe and Langley 1978). Consequently, the maturation stage of the developing oocyte (the next to ovulate) in fertile females is always in sequence with a particular development stage *in utero*, i.e. embryogenesis or one of the three larval stages (Challier 1965). Mating a virgin female tsetse with a sterile male will result in fertilization of the egg *in utero* by the sperm, carrying dominant lethal mutations that will result in the death of the embryo (embryonic arrest) (LaChance et al. 1967), which is later aborted (Van der Vloedt et al. 1978). Consequently, aberrations between the size of the maturing follicle and the development stage *in utero* (dead embryo or uterus empty due to expulsion of the embryo) will become apparent (Vreysen et al. 1996) (Fig. 4B).

Dissection of a reasonably sized sample of wild female flies from a population subjected to sterile male releases will show the proportion of females in the sample that have aberrations in their reproductive system — a direct indication of the rate of induced sterility in the target population (Vreysen et al. 2000). The only weakness in the methodology is the 1- or 2-day time lag between fertilization of the egg with the irradiated sperm and embryonic arrest becoming visible with a microscope (Van der

Vloedt and Barnor 1984). This could result in underestimating the level of induced sterility.

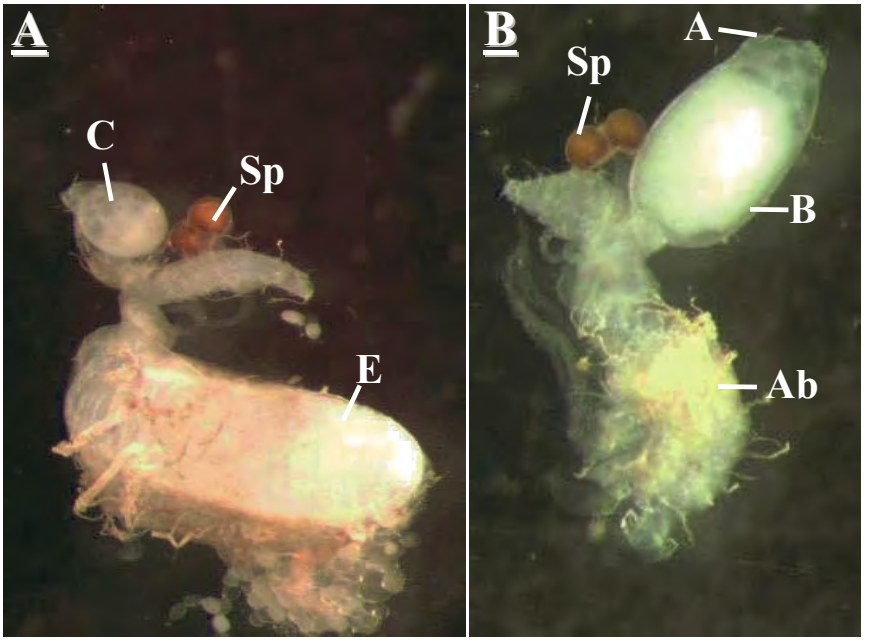


*Figure 4. A. Reproductive system of female tsetse fly mated with fertile male, showing one ovulation (C = follicle next in ovulation sequence (FNOS)) and viable egg (E)* in utero. *B. Reproductive system of female mated with sterile male, evidenced by imbalance between size of FNOS (B) and uterus content (Ab = abortion, Sp = spermathecae).*

Pre-control baseline data from female tsetse flies on Unguja Island, Zanzibar, showed that 50 and 46.1% of females had a viable egg or larva *in utero,* respectively, and only 3.5% of females had an empty uterus showing the loss of an egg or larva (natural abortion rate) (Vreysen and Khamis 1999) (Fig. 5). During the initial 8 months of the SIT activities (mid 1994–early 1995), an insufficient number of sterile males was released, and consequently the ratio of sterile to wild males remained below 10:1. In spite of this low ratio, during this period 19.9% of sampled females had mated with sterile males (Vreysen et al. 2000). In 1995, the number of sterile males released constantly increased, and more than 50 sterile males for each wild male were trapped after week 34. Simultaneously, the frequency distribution of the uterus content of the sampled females became progressively more distorted compared with the pre-control distribution, i.e. $\chi^2 = 70.3$ in early 1995 and $\chi^2 = 196.6$ in late 1995 (df = 4; $P < 0.0001$), due to a gradual increase in the proportion of females that had aborted dead embryos or displayed eggs *in utero* in embryonic arrest (Vreysen et al. 2000; Vreysen 2001).

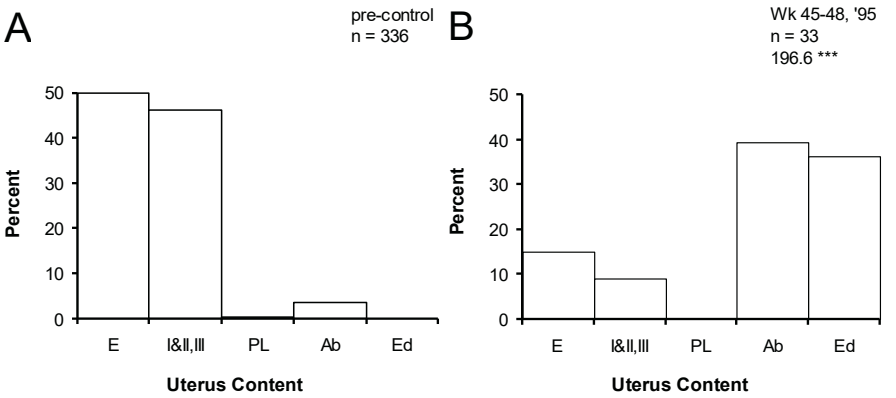

*Figure 5. Frequency distribution of uterus content of* Glossina austeni *females sampled during (A) pre-control phase and (B) late in sterile male release phase (E = egg, I, II, III = first-, second-, and third-instar larva, PL = post larviposition, Ab = abortion, Ed = degenerating egg). Number is chi-square value of comparison of frequency distribution of uterus content with that of pre-control sample (*** P < 0.001). (Figure adapted from Vreysen 2001, reproduced with permission.)*

A similar trend can be observed in Fig. 6, which shows data on the reproductive status of young parous females (1 or 2 ovulations) that had mated with a sterilized male 2 or 3 weeks previously. It is very evident that the sterility level in the young female population gradually increased as the sterile to wild male ratio increased, i.e. from 26% in the last quarter of 1994 to 32, 48, and 72% in the 2nd, 3rd, and 4th quarters of 1995, respectively. Concurrently, as sterility in the young female fly population increased, the proportion of young female flies with a viable larva *in utero* (females mated with a wild fertile male) decreased.

### *3.2.2. Monitoring Reproductive Capacity of a Wild Population – Screwworms, Lepidoptera, and Fruit Flies*

Assessing the rate of induced sterility in screwworms, Lepidoptera, and fruit flies is more challenging. No differentiation between sterile and fertile matings can be made by direct examination of the reproductive system of sampled wild females. Any quantification of sterility levels in wild females requires the collection and maintenance of eggs, and an assessment of the ratio of hatched (fertile) to non-viable (sterile) eggs (Thomas and Mangan 1989). For screwworm, fruit fly and lepidopteran species, special egg collecting methods have been developed (Davis et al. 1968; Snow et al. 1976; Parker and Welch 1991; Katsoyannos et al. 1999), but most are labour-intensive and expensive to implement in large operational programmes. The usefulness and applicability of these methods vary for each insect group (see below).

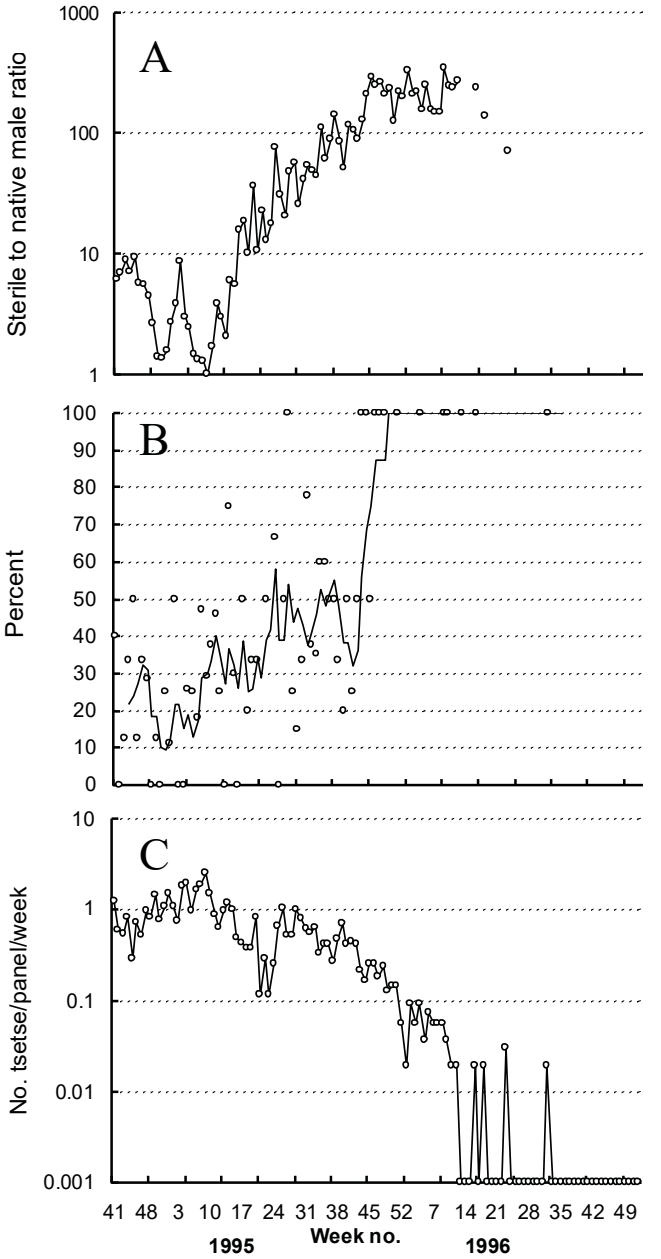

*Figure 6. A: Sterile to wild male ratio. B: Rate of induced sterility as proportion of young parous females (1 or 2 ovulations). C: Apparent density (+ 0.001) of wild males and females.* Glossina austeni, *Unguja Island, Zanzibar. (Figure adapted from Vreysen et al. 2000, reproduced with permission.)*

*Induced Sterility and Egg Collection.* In female screwworm flies, with 100–150 ovarioles per ovary, egg development is synchronous, and an average of 200 eggs are deposited (Thomas 1993), regardless if eggs are fertilized by fertile or sterile sperm (LaChance and Bruns 1963). Egg masses can be collected in several ways: (1) from artificially inflicted wounds on sentinel animals, maintained in fixed capture stations (Davis et al. 1968; Parker and Welch 1991; FAO 1992), (2) from wounds found by field inspectors during routine surveillance activities (Robinson et al. 2000), and (3) from gravid females that were attracted to, and caught in, liver-bait stations and "egged" in glass tubes (Parker and Welch 1991). Maintaining sentinel pens is cumbersome, difficult to implement in some countries in view of animal right issues, and rather problematic in tropical remote environments because of the paucity of suitable animals, water, shade, and animal food (Krafsur and Highthower 1979; Parker and Welch 1991). (It would be convenient if some kind of artificial wound were available to collect eggs from wild screwworm females; such a methodology needs to be developed.)

Training and expertise are needed to detect and identify screwworm fly eggs. Also they are short-lived, and inappropriate handling often causes increased mortality, resulting in overestimates of the rate of induced sterility. In addition, one egg mass is not necessarily the output of one female, as was originally assumed (Krafsur et al. 1979; Brenner 1984), but possibly the product of more than one female (eggs laid beside eggs already deposited by another fly) (Thomas and Mangan 1989), making it difficult to interpret sterility data. Nevertheless, the most manageable option at present is the systematic collection of egg masses from animal wounds during routine surveillance along a predetermined grid network, and adequate geo-referencing of the sampling sites for incorporation into GIS (Bouyer et al., this volume), providing accurate information on the spatial and temporal distribution of induced sterility in the wild population.

The development of female lures has recently brought about significant progress in monitoring the Mediterranean fruit fly (IAEA 1999) (Box 2). However, as with screwworms and Lepidoptera, dissection of female fruit flies does not reveal any difference between fertile and sterile matings. Therefore, live-trapped female Mediterranean fruit flies can be transferred to a cage containing a natural or artificial oviposition substrate, egg masses collected, and egg hatchability assessed (IAEA 1999; Katsoyannos et al. 1999). Except for experimental trials, methods such as maintaining fruit fly eggs dissected from collected fruits to assess hatchability (Wong et al. 1986; McInnis et al. 1994), or measuring the size of the head of spermatozoids collected from spermathecae of female flies to differentiate between sterile and fertile sperm (McInnis 1993), have never been applied because they are cumbersome. Nevertheless, eggs from wild Mediterranean fruit flies were collected from coffee berries in Guatemala and induced sterility calculated (Rendón et al. 2004). Also, an artificial oviposition device, to collect eggs from female melon flies netted in the field, was developed and used successfully to assess egg hatchability during the programme on Kume Island, Japan (Iwahashi et al. 1976; Iwahashi 1977).

A significant development is the availability of a reaction-restriction fragment length polymorphism-based method (PCR-RFLP) to identify the origin of sperm in captured wild female Mediterranean fruit flies. The method identifies Y chromosomes

in DNA extracts from the spermathecae, enabling the identification of the genetic origin of the sperm, i.e. wild, sterile or both, as an indicator of the degree of induced sterility in the target population (Juan-Blasco et al. 2013; Krafsur and Ouma, this volume). Another method is to use rhodamine dye to mark the sperm of male insects that can then be detected in the spermathecae or spermatophores of their female mates (Johnson et al. 2017). The potential of using stable isotopes for labelling sperm was studied under laboratory conditions for the mosquito *Anopheles arabiensis* Patton. Spermathecae filled with labelled sperm could be successfully distinguished from spermathecae with unlabelled sperm (Helinski et al. 2007). All these methods open new avenues to assess mating frequencies (and hence programme progress) in programmes that have an SIT component.

*Box 2. Monitoring Mediterranean Fruit Fly AW-IPM Programmes that Integrate the SIT*

Sampling the male portion of the population provides important feedback on sterile to wild male ratios, and on dispersal characteristics of released sterile males. Sampling females is equally vital; they constitute the "reproductive component" of the wild population, are the target of the SIT activities, and provide crucial information on the rate of sterility induced in the population (section 3.2.1.).

In earlier Mediterranean fruit fly programmes applying the SIT, both sexes were released, and population monitoring was done mainly with trimedlure-baited Jackson traps, which attract mostly male flies. This resulted in a reduction in efficiency of the programmes due to the trapping-out of a significant portion of the sterile males and the large effort to sort trapped sterile from wild flies. For example, in the Mediterranean fruit fly programme in the Los Angeles Basin, California, USA, about 0.5 million males were captured each week, resulting in a very costly and inexact process attempting to find any wild males among all the recaptured sterile males (J. Hendrichs, personal communication). The female portion of the wild population was sampled with traps containing generic liquid food lures, which unfortunately also catch many non-target species, making it time-consuming and laborious to sort out the female Mediterranean fruit flies.

The development of Mediterranean fruit fly genetic sexing strains (Franz et al., this volume) allowing male-only releases in operational programmes (Rendón et al. 2004), and the development of a lure for female Mediterranean fruit flies (IAEA 1999), have given a new dimension to monitoring programmes that have an SIT component. Female attractant-baited traps focus mainly on the detection of wild females and their offspring (no sterile females are released), thereby significantly reducing sterile male recapture and the laborious trapping and the sorting of hundreds of thousands of males (Hendrichs et al. 1995). In addition, these traps collect enough males to monitor the ratio of sterile to wild males and the distribution of sterile male releases (Midgarden et al. 2004). The monitoring component of Mediterranean fruit fly programmes can account for up to one-third the total cost during the fly-free stage of AW-IPM programmes (Enkerlin 2001; Hendrichs, Vreysen et al., this volume). The release of male-only strains, combined with the availability of female attractant traps, increased the efficiency of sterile males, and significantly reduced monitoring costs.

*Problems Associated with Trapping Female Lepidoptera.* Monitoring progress in lepidopteran programmes relies mainly on crop damage assessments and on traps using potent female sex pheromones as lures (Riedl et al. 1986; Bloem and Bloem 2000; Walters et al. 2000). The pheromone traps attract only male moths, and sterile moths can be distinguished from wild moths if appropriate marking techniques are used (Dyck et al. 1993; Parker, Mamai et al., this volume) (section 2.1.). Therefore, trap samples will indicate the apparent densities and ratio of wild and sterile moths, but the absence of females in the samples precludes any data on sterility levels induced in the wild population. In addition, the deployment of pheromone traps has to

be well balanced to prevent the trapping of too many sterile male moths, which reduces the efficiency of the SIT component of the programme.

Several methods have been developed to assess sterility in moth populations using tethered (Alford and Silk 1983) or clipped-wing sentinel/decoy virgin females placed on mating tables (Snow et al. 1976; Shaver and Brown 1993), in virgin-female traps (Snow et al. 1969), or in mating houses (Mastro and Schwalbe 1980). These female moths will attract male moths, and it is assumed that the virgin females mate with sterile and wild male moths at the same periodicity and frequency as occurs in nature. Mated females are then transferred to controlled conditions, where deposited eggs are screened for sterility. The "tethering" or "clipped-wing" method is, however, hampered by the small size of many lepidopteran species, and by numerous escapes, although Teflon®-walled mating tables may prevent escapes (McBrien and Judd 1996). Also, if the design of mating houses interferes with the entrance response of males, such cages would not be suitable.

A pear-derived volatile (ethyl (2E,4Z)-2,4-decadienoate), which acts as a kairomone (chemical emitted by one species and attracting another) for codling moth males and virgin and mated females, has been available for the last two decades (Light et al. 2001). It enables the trapping of live female codling moths; this greatly facilitates the collection of egg masses for screening sterility but also permits the sampling of females in an economic and systematic way over large geographical areas in operational programmes that use the SIT. This discovery has promoted the search for kairomones that are efficient for other lepidopteran pest species, such as the diamond back moth.

In that respect, a recent study on the morphology and distribution of antennal sensilla of the diamondback moth showed that each sensillum contained three co-compartmentalized olfactory receptor neurons (ORNs). Each ORN class showed a narrow response spectrum, with some ORNs specialized for green-leaf volatiles and (±)-linalool that are present in brassicaceous hosts, while several other ORNs responded to two non-host volatile sesquiterpenes, (E)-β-farnesene and germacrene D, as well as (E)-β-caryophyllene, a host-related sesquiterpene volatile (Wee et al. 2016). In addition, other studies showed that female moths were significantly more attracted to conspecific larvae-infested cabbage plants, had significantly shorter flights than in fields with intact uninfested cabbage hosts, and oviposited significantly more eggs on larvae-infested cabbage than on intact uninfested cabbage (Wee 2016). These data indicate the potential of developing a brassica host-derived kairomone attractant for female diamondback moths that could be used for sampling purposes.

*Distinguishing $F_1$ Males from Wild Males in Inherited Sterility Programmes of Lepidoptera.* Inherited sterility in lepidopteran programmes has a distinct advantage over full sterility in that the released semi-sterile males have a better mating competitiveness than fully sterile males, in addition to the resulting multiplier effect from viable but sterile progeny from every mating. The deleterious effects induced by irradiation are inherited by the $F_1$ generation, but it is very difficult to measure progress in population suppression because the $F_1$ offspring are not marked and therefore cannot be distinguished from wild males. Using light microscopy, the incidence of chromosomal aberrations in $F_1$ male larvae can be used to reveal the

proportion of moths that mated with released substerile males. Fragmentation, and non-reciprocal, reciprocal, and multiple translocations, are the most common types of aberrations encountered (Marec et al., this volume).

A forensic biosecurity method, based on a cytological assessment of sperm bundles of wild and $F_1$ males, has been developed and shows great promise. The technique can successfully distinguish the homogeneous nuclei clusters of eupyrene bundles of the normal fertile males from the heterogeneously stained nuclei clusters of the $F_1$ progeny. This technique has been demonstrated in six lepidopteran species: codling moth, cactus moth, diamondback moth, painted apple moth *Teia anartoides* Walker, corn earworm *Helicoverpa zea* (Boddie), and fall armyworm *Spodoptera frugiperda* (J. E. Smith) (Carpenter et al. 2009; Wee et al. 2011). However, the technique only yielded good results when good specimens for cytological diagnosis were obtained. In addition, the percentage of positive staining results was strongly correlated with survival. Moths that had spent 24 h on a sticky base in a monitoring trap were equivalent to freshly killed specimens, but the efficacy of the technique decreased after that (Wee et al. 2011).

### *3.2.3. Monitoring Variations in Age Structure of a Wild Population*

A change imposed on an insect population through variations in mortality, emigration, and invasion, will be reflected in the age structure of that population (Van der Vloedt et al. 1980; Rogers and Randolph 1986; Vreysen et al. 1999a). A method to determine the age of individual insects (or a group of insects) would enable variations in population structure resulting from the control measures to be assessed, and would be another powerful tool to monitor progress in programmes. The effects of season, habitat, and other factors on the age structure of a population must be separated out from those of applied control measures.

There are several methods that have routinely been used in operational programmes to estimate the age of tsetse fly populations (Van der Vloedt et al. 1980; Vreysen et al. 2000) — the development stage of ovarioles in females (Saunders 1960; Challier 1965), and the wing-fray analysis (rate of wear of the wings) (Jackson 1946). Wing-fray measurements are a convenient way to give a reasonable, albeit crude, indication of the mean age of a population, but since fraying is influenced by the activity pattern of flies, the rate of wing fraying varies between species and the sexes (Ryan et al. 1980). Determining the physiological age structure in tsetse, using ovarian development (section 3.2.1.), is labour-intensive but very accurate. However, it is not suitable for determining the chronological age of tsetse populations, in view of the influences of temperature and nutritional state on the development rate of each gonadotrophic cycle (Saunders 1972), and inter- and intra-species differences (Wall 1990).

The measurement of fluorescent pigments (pteridines), which accumulate linearly with age in the heads of tsetse flies (Lehane and Mail 1985; Langley et al. 1988) and New World screwworms (Thomas and Chen 1989), and curvilinearly in the Old World screwworm *Chrysomya bezziana* (Villeneuve) (Wall et al. 1990), may provide a cheap, convenient, and rapid indicator of the mean age of these insect populations. However, the level of pteridine accumulation is highly dependent on temperature and fly size. Also, the precise age of individual insects cannot be determined because the

levels of residual variation in pteridine fluorescence remain unexplained in all cases studied, and appreciable confidence limits must be placed around pteridine-derived age estimates (Wall et al. 1990). According to field studies, this method was not suitable for accurate age determination in Mexican fruit flies *Anastrepha ludens* (Loew) (Tomic-Carruthers et al. 2002).

Near-infrared spectroscopy (NIRS) has been used to estimate the chronological age of stable flies *Stomoxys calcitrans* (L.), house flies *Musca domestica* L., and face flies *Musca autumnalis* De Geer. NIRS has several advantages over the pteridine fluorescence technique for age-grading field-collected insects (e.g. speed and portability of instruments). The technique is independent of the sex and size of the insects being studied, and of the temperature to which adult insects were exposed (Mendoza et al. 2002).

Releasing competitive sterile males will gradually increase the proportion of wild females that do not produce viable offspring. Consequently, fewer young insects will be recruited into the population, and the age structure will gradually become skewed towards older age groups, e.g. data from the tsetse programme in Zanzibar (Fig. 7). During the early stages of the release programme, the monthly averages of the proportion of teneral and nulliparous (i.e. young) females in the samples (determined by ovarian ageing) fluctuated between 16 and 19%, whereas the monthly averages of the proportion of old females (with 4 or more ovulations) fluctuated between 18 and 28%. Thereafter, the proportion of young flies decreased progressively, whereas the proportion of old females (≥ 4 ovulations) gradually increased (Vreysen et al. 2000).

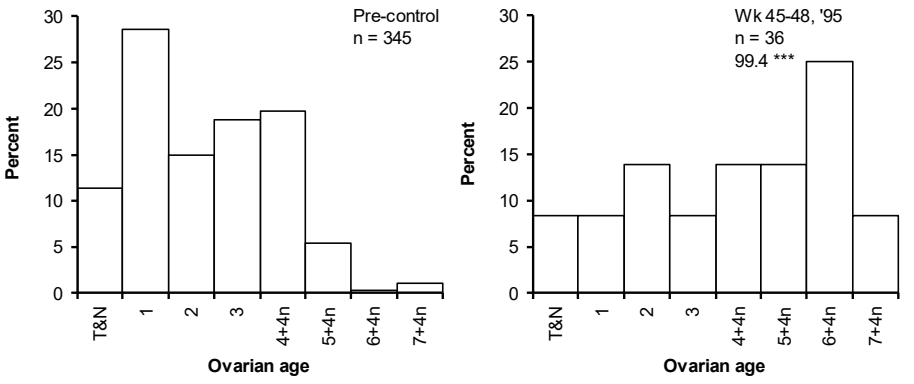

*Figure 7. Frequency distribution of ovarian age categories of* G. austeni *females sampled during (left) pre-control phase and (right) late release phase (T = teneral, N = nulliparous, 1–7 = number of ovulations; more details in Challier 1965). Number indicates chi-square value of comparison of frequency distribution of ovarian age with that of pre-control sample (*** $p < 0.001$). (Figure adapted from Vreysen 2001, reproduced with permission.)*

*3.2.4. Monitoring Relative Abundance of a Wild Population*

Decline in the apparent density of a wild population, as shown by the number of insects trapped in a sampling device, is a commonly used parameter to assess the progress of AW-IPM programmes for fruit flies (Iwahashi 1977), Lepidoptera (Bloem and Bloem 2000; Walters et al. 2000) and tsetse flies (Vreysen et al. 2000) (Fig. 6). In the case of insects with a very long lifespan, such as tsetse flies (Vreysen et al. 1996), monitoring this parameter has an inherent weakness; no insects are actually killed by the SIT technology, and thus there is an inevitable delay in the decline in the number of wild insects available to be trapped.

When sampling insects to obtain an indicator of programme progress, the main difficulty is related to interpreting catch data. For example, is a temporal decline in the number of insects trapped, even when using a standardized monitoring programme, always an indication of progress in a control programme? Numerous factors influence the size of trap samples (section 3.1.2.), and the importance of these factors for the interpretation of monitoring data is illustrated below.

The density of a natural insect population rarely remains stable, but fluctuates in both space and time. Knowledge of these fluctuations is prerequisite to correctly interpreting monitoring data. In the absence of any control measure, monthly trapping data for the tsetse fly *Glossina swynnertoni* Austen, over a period of 23 years in Tanzania (Fig. 8), show high seasonal variations in the apparent density of the population, with the average highest apparent density being 18 times that of the lowest average density (Glasgow and Welch 1962).

Differences in population density from one place to another can be great. Locations with unusually high densities are called “hot spots” and require special attention in AW-IPM programmes (sections 2.1. and 2.2.3.) (Box 3).

In addition to the need for baseline data on the temporal and spatial fluctuations in the density of a wild insect population, the factors that influence changes in the behavioural responses of insects towards trapping devices, in both space and time, need to be understood to correctly interpret monitoring data (Vreysen and Saleh 2001). An analysis of weekly trap catches of sterile *Glossina austeni* released on Unguja Island, Zanzibar, over a period of more than 2 years, showed that, in each 12-month period, the size of catches fluctuated by a factor of more than 10, independent of the actual sterile fly population density (which was estimated from the number of sterile males released) (M. J. B. Vreysen, unpublished data). These data led to some important lessons. Even dramatic increases in trap catches, especially during control operations, could wrongly be attributed to sudden explosions of the pest population, migration from adjacent areas, decrease in mortality, or failure of the applied control method. This study indicates that the probability of trapping insects during a post-control monitoring phase would be increased significantly by deploying traps during strategic periods, e.g. when the behavioural response of insects to the trapping device is at a high point (Saleh et al. 1999).

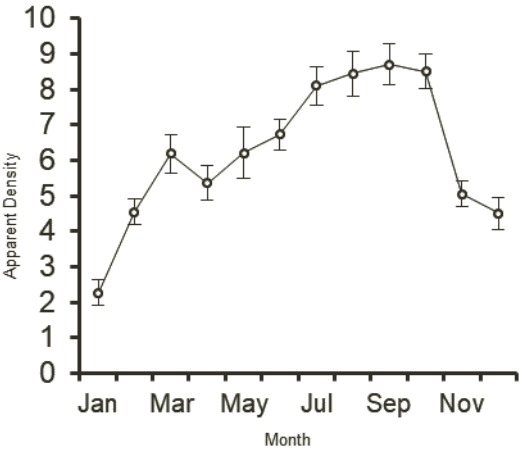

*Figure 8. Fluctuations in average monthly apparent density (as percentage of total catches) of* Glossina swynnertoni *population sampled over period of 23 years in Tanzania. (Figure adapted from Glasgow and Welch 1962, reproduced with permission.)*

*Box 3. Monitoring "Hot Spots"*

Localized infestations or "hot spots" are of particular interest in AW-IPM programmes (Shiga 1991). Strategies that allow quick action to manage these situations are required. To detect hot spots quickly, programme managers must always be alert throughout the duration of the programme. The early detection of relic populations, or reinfestations in localized areas, is a determining factor in reducing programme cost, in increasing programme effectiveness, and in the ultimate successful completion of the programme (Itô and Kakinohana 1995). Although baseline surveys might reveal that the pest infestation is widespread, hot-spot areas are often concealed, and are revealed only after the programme has advanced.

The reasons for hot spots are numerous — localized ideal climatic conditions, abundant hosts, and in some cases also presence of difficult topography that hampers the effectiveness of pre-release suppression activities (Nakamori and Shiga 1993).

When hot spots are discovered or persist, surveillance in the vicinity should immediately be increased. The size of the area under surveillance will depend on the mobility of the insect, and should be increased systematically until no more wild insects are trapped. The traps deployed must be serviced/emptied on a very frequent (daily) basis, or the frequency and intensity of indirect sampling procedures (fruit inspection, disease monitoring, etc.) (section 3.1.3.) increased, to amplify confidence in the data. For some insect species such as the Mediterranean fruit fly, DNA analysis can indicate whether the infestation is new, or originates from a relic population or from insects that accidentally escaped from a rearing facility (McInnis et al. 2017). If the infestation is new, it is essential that live wild insects are collected in the new infestation zone, and their mating compatibility with factory-reared and sterilized insects assessed. In addition, the overall monitoring efficiency needs to be increased by immediately installing a high-density delimitation trapping grid around each incursion (FAO/IAEA 2018), and improving communication and/or feedback mechanisms with crop farmers or livestock keepers to reduce the time between an infestation being discovered and it being reported to programme management or relevant authorities.

After assessing and compiling the necessary information, using GIS (which can greatly facilitate the analysis and management of localized infestations (Bouyer et al., this volume)), corrective measures must be taken immediately, e.g. apply an insecticide, increase the number of sterile insects released, create a buffer zone or quarantine programme, and limit the movement of livestock, crops, etc.

## 4. ESTABLISHING THE ABSENCE OF INSECTS

After the "last" wild insect has been caught, a difficult decision must be made. When should the release of sterile insects be terminated? Stopping the release too soon could jeopardize the success of the programme, but if releases are continued after eradication has been achieved, useful resources are wasted (Proverbs 1974). The time period of continued releases but zero captures will be influenced by the life cycle of the insect, the efficiency of the sampling system used, and the financial resources available.

To increase the confidence of detecting wild insects during and after the final stages of an eradication programme, the monitoring strategy could be adjusted by: (1) increasing the density and frequency of the direct and indirect monitoring activities (Yamagishi et al. 1993), (2) increasing the proportion of sampling devices biased for the female segment of the population (to obtain more information on fertility or induced sterility) (Vreysen et al. 2000), and (3) releasing sterile females as sentinels (Vreysen and Van der Vloedt 1992). The decision to stop releasing sterile insects is frequently made on an ad hoc basis, and is highly influenced by financial and political circumstances. In the eradication programmes in Central America and in Libya, after the "last" case had been detected, the dispersal of sterile New World screwworms continued for 6–18 months (FAO 1992; Wyss 2000). In fruit flies, it is standard procedure that delimitation trapping continues for at least three fly generations (using degree-day models) after the "last" fly has been detected (FAO 2016).

A problem related to the issue of when to stop dispersing sterile insects is how long to continue post-release monitoring to obtain sufficient confidence that a pest has been eradicated (Barclay and Hargrove 2005; Hargrove 2005; Barclay et al., this volume). A sample can only confirm that individual insects are present in a given area; sampling can never prove a negative (McInnis et al. 2017). However, samples can demonstrate that the number of individuals is within a specified range, with a known degree of confidence (Venette et al. 2002). The probability of detecting rare individuals is directly related to the number of sampling units and the density of the population (McArdle 1990; Lance and Gates 1994). Therefore, verification sampling should be implemented in high-risk areas and previous hot spots after termination of releases so as to maximize the probability of detecting relic insects in the field (McDermotte 2000; FAO/IAEA 2018). If too few samples are taken, an error could be made in concluding that a pest is absent from a habitat (Venette et al. 2002).

As the declaration of the absence of an insect in a target area cannot be guaranteed, it must always be qualified by probability or confidence levels (Barclay et al., this volume). Unfortunately, standardized probability-based entomological criteria to confirm the status of eradication have rarely been applied in insect eradication programmes.

An option is to follow the approaches used by ecologists to assess species extinction (McDermotte 2000). In one approach, after extinction is assumed to have occurred, the number of negative sightings required to confirm extinction at a given probability level is assessed; this requires an accurate knowledge of the sensitivity of the sampling method (Reed 1996). A second approach takes into account data from pre-eradication sampling, assuming a declining population. In this method the probability of extinction is estimated as a function of the frequency of pre-eradication

sightings, and the proportion of the total time (pre- and post-eradication) during which no sightings have been made (Solow 1993).

## 5. DATA MANAGEMENT

It is essential that information from the monitoring activities is reliable, comprehensive, and clear, and is delivered in a synthesized and timely manner to decision-makers (Reyes et al. 1988). The amount and diversity of data that have to be handled and analysed can be staggering, especially in large-scale operational programmes. Thus each programme requires a properly developed data-flow structure, e.g. from field teams via field sub-offices to programme headquarters, and an efficient data-analysis unit. A programme website is very useful; it permits all concerned to have access anytime to the raw and analysed data.

Comprehensive field data recording sheets are indispensable, and must be adapted to the biological characteristics of each target species and to the needs of each programme. Data sheets should include all information relevant to a proper data analysis, e.g. details on animals screened, details on the composition of trap samples, geo-referenced trap deployment sites, baits, types of traps, etc. Using electronic data collectors, and transmitting data to computers at programme headquarters via e-mail, facsimile, or HF radio, even if rather sophisticated compared with traditional paper methods, permit rapid and efficient data collection and compilation (Bouyer et al., this volume). In addition, field-monitoring data should be complemented with climatic data from remote automated weather stations in the target area.

Using identical sampling periods, standardized sampling procedures, and uniform compilation methods ensure homogeneous data sets; they greatly facilitate the analysis and interpretation of the data (Box 4). The Gregorian year with 365 days can be divided into equal periods for data collection and compilation, e.g. in the tsetse programme in Zanzibar, traps were checked 1–5 times per week, depending on the importance of the area, but all of the data were compiled on a weekly basis (Vreysen et al. 2000). Data can be compiled using EXCEL spreadsheets or an ACCESS-based database; the latter is more appropriate for large amounts of data, and allows easy incorporation into most GIS. Particularly useful are databases which have been developed to manage the field data of specific pest control programmes, and which can promote the standardization of data reporting and analysis on a regional scale, e.g. the Disease and Vector Integrated Database (DAVID) (Robinson 2001).

The frequency of analysing the data is related to the regularity of sampling and compilation of the data, but is usually done every 1–3 months; however, if the insect has a high reproductive rate, it will be done much more frequently. In the analysis of trap catches, indices, such as daily or weekly catch per trap, and the proportion of positive traps, can be used. However, Clift and Meats (1998) showed that the proportion of positive traps is not a good indicator in the early stages of a programme, since the proportion of positive traps is only slightly reduced when the catch per trap declines from 10 to 1. Standard statistical methods such as analysis of variance in a randomized block design (with fixed time units as blocks) can, after proper transformation of the data, be used for the temporal and spatial comparison of data (Sokal and Rolf 1995).

## 6. CONCLUSIONS

The importance of reliable monitoring data before, during, and after the release of sterile insects cannot be overstated. In spite of the availability of efficient "direct" and "indirect" surveillance methods suitable for a variety of target species, the monitoring component in operational programmes is too often neglected. Consequently, programme management and decision-making are based more on established protocols, availability of financial resources, and political inspiration rather than on sound scientific principles.

Programmes that release sterile insects are inherently complex, with many critical components in the production process (aimed at delivering high-quality insects), methods of handling and transport, and dispersal procedures. The multifaceted nature of these programmes also implies that the probability of problems occurring is higher than in conventional pest control programmes.

*Box 4. Concept of Reference Sites for Monitoring or Surveys*

Notwithstanding the importance of sound and robust monitoring activities in an AW-IPM programme, funds are needed to deploy each sampling device. Monitoring activities should be planned as a compromise between cost-efficiency and providing adequate and sufficient data. AW-IPM programmes tend to be implemented over large geographical areas, and monitoring (or surveying) in detail the entire area is not feasible, practical or cost-effective. Selecting reference (or fixed) monitoring sites, representative of a certain area, is a useful approach to efficiently monitor or survey large geographical areas (Leak et al. 2009).

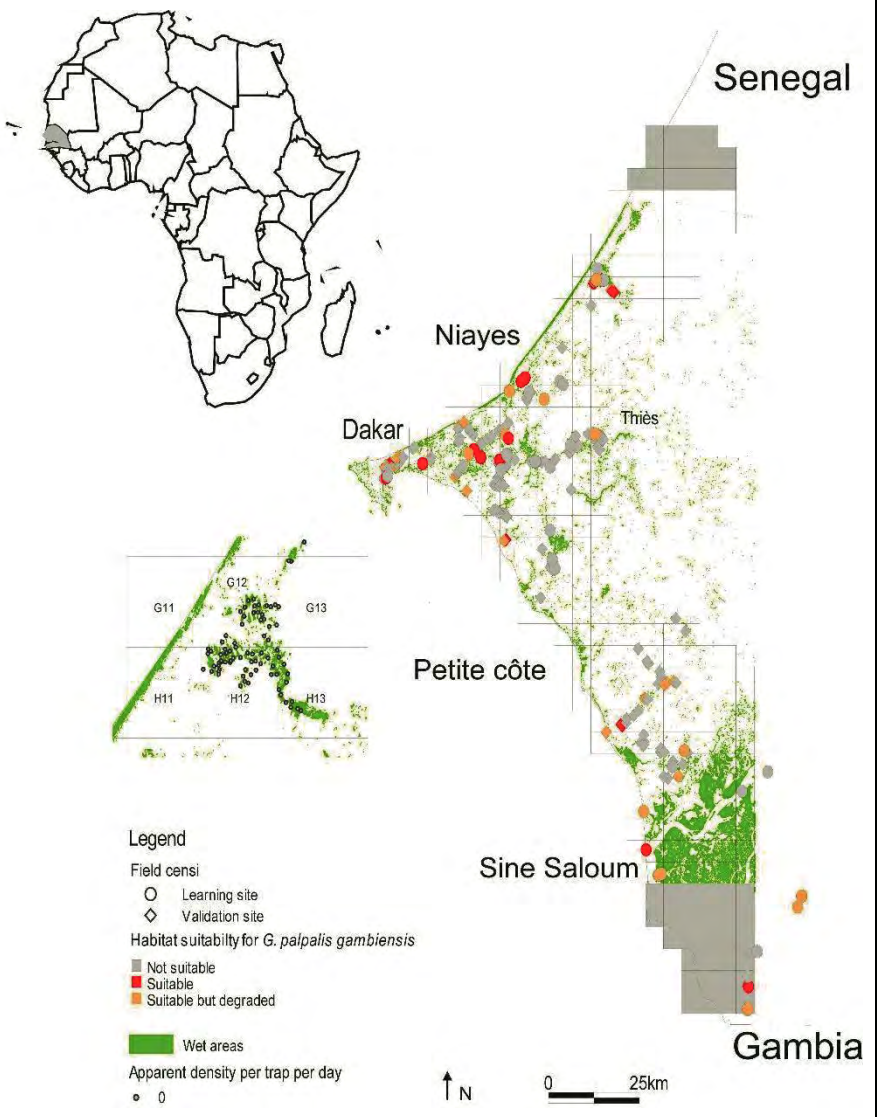
Depending on the size of the target area, this is divided into Universal Transverse Mercator (UTM) squares, e.g. 5 x 5 km or 10 x 10 km, and each UTM grid square is characterized by parameters that are important to the distribution of the pest, i.e. vegetation, land use, land cover, hydrology, soil type, altitude, etc. Pending the availability of these specific data layers, GIS can facilitate the characterization of the grid squares (Bouyer et al., this volume). Therefore each grid square has a certain number of classes, which are of relevance to the abundance and distribution of the pest. After considering accessibility, logistics, personnel, etc., a reference monitoring site can be selected for each class of each grid, and a certain number of sampling devices deployed in each reference monitoring site, which will then be representative for that class in that specific grid square.

This approach was applied to develop and implement an efficient sampling strategy for the collection of entomological baseline data in the tsetse project in the Southern Rift Valley of Ethiopia (Vreysen 2000) and in the Niayes of Senegal (Bouyer et al. 2010).

In the case of Ethiopia, about 15–18 trapping sites were selected in each UTM square (total of 105 squares, each 10 x 10 km) to sample the wild fly populations during four surveys within 1 year. Accurate data on the spatial and temporal differences of the tsetse populations were collected with limited resources over a large geographical area (more than 10 000 $km^2$) using carefully selected trapping sites in representative areas (Vreysen et al. 1999b; Vreysen 2000).

In the case of Senegal, a 5 x 5 km grid overlaying the entire target area (286 cells) was developed to facilitate the field sampling procedures. During preliminary surveys, a phytosociological census achieved a supervised classification of the vegetation in addition to some entomological data collected in the various habitats. This enabled an assessment of the suitability of the habitat to harbour the tsetse fly *G. p. gambiensis* in the area, denoted as wet areas since the suitability was correlated with the presence of ground water at the end of the dry season. All these wet areas were identified in each of the grids and georeferenced for the deployment of tsetse traps (Bouyer et al. 2010).

*Box 4. Continued*



*The target area in Senegal with the overlaying grid structure and the identified wet areas as obtained by the supervised classification (right) and the selection of trapping sites in the identified wet areas in grids G12, G13, H12, and H13 (insert). (Figure modified from Bouyer et al. 2010.)*

Only the availability of reliable field data can: (1) provide clear evidence that observed programme progress is due to released sterile insects and other measures applied to suppress the pest population, (2) identify the causes of problems and suggest possible solutions, and (3) increase the efficiency of the programmes by more strategic deployment of sterile insects. It is acknowledged that monitoring methods are often time-consuming, labour-intensive, and even laborious, but in many instances the financial losses, resulting from inefficient management decisions made without the benefit of reliable field data, outweigh the costs of monitoring activities.

Several shortcomings in implementing the monitoring activities of operational programmes have been pointed out. The need for more standardization, research, and development to improve several aspects of monitoring the field component of these programmes has been highlighted. Examples of these aspects are: (1) development of guidelines to standardize sampling procedures (trap types for specific species, lures and attractants, trap deployment, trap densities, etc.) (FAO/IAEA 2018, 2020a, b), (2) refinement and development of more efficient lure and trapping systems, (3) better understanding of insect ecology, in relation to insect densities, aggregation patterns, and dispersal characteristics, (4) research on visual markers in the sperm of sterile males, (5) better methods of measuring induced sterility, and (6) simple statistical probability methods, which can easily be applied by field entomologists, to assess the absence of a target species.

## TABLE OF CONTENTS

## SUMMARY

The detection and analysis of genetic variation in natural and laboratory populations of pest insects are reviewed. The application of population genetic methods and theory can help to plan and evaluate the implementation of area-wide integrated pest management (AW-IPM) programmes that use the sterile insect technique (SIT). Population genetic studies can play an important role in estimating dispersal rates and thus the degree of isolation or gene flow among target populations, determining if sibling species exist, establishing the origin of outbreaks or reintroductions, and supporting the quality control of mass-reared colonies. The target's population history may be examined in terms of "bottlenecks", range

Pages 529–548

fragmentations, and expansions. Genetic methods can be helpful in distinguishing wild insects from released sterile or semi-sterile ones, and in ascertaining, together with mating compatibility studies, the compatibility of mass-reared colonies with target wild insects.

## 1. INTRODUCTION

Population genetics, in the broad sense, is the study of gene frequencies in and among subdivided populations. It encompasses estimations of variation in terms of allelic and genotypic frequencies. Given appropriate data, the application of population genetic theory allows estimates of rates of gene flow within and among populations, estimates of effective, i.e. reproductive, population sizes, tests for past "bottlenecks" and rapid expansions of population size, and pairwise genetic distances. Since all evolutionary change is accompanied by change in gene frequencies, population and evolutionary genetics overlap.

Methods of population genetics can be used to support the application of the sterile insect technique (SIT) for the integrated control of target pest populations in nature. Briefly, the degree of genetic isolation of target populations from each other, and from untargeted populations, can be estimated. The existence of sibling species may be investigated, in combination with behavioural, cytogenetic and other approaches, by careful sampling and genetic analysis of pest populations. Immigration rates from unchallenged populations may be estimated, in terms of reproducing females per generation. The origin of pest outbreaks in treated areas may thereby be investigated. The genetic relatedness of mass-reared strains and target populations may be estimated in terms of allelic composition and gene frequencies. The question of laboratory "degradation" of strains destined for release can be examined objectively in terms of inbreeding and genetic distances from founding and target populations.

Given what may be done by using modern techniques and adequate sampling of natural populations, it should nevertheless be noted that the New World screwworm *Cochliomyia hominivorax* (Coquerel), tsetse fly *Glossina austeni* Newstead and Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) area-wide integrated pest management (AW-IPM) programmes were executed successfully without any substantial knowledge of the population genetics (section 8) (Enkerlin, this volume; Feldmann et al., this volume; Vargas-Terán et al., this volume).

Here we outline the kinds of genetic variation that may be examined efficiently, and briefly review tests of hypothesis and analytical methods that may be applied to genetic data. In addition, the causes of genetic differentiation are discussed.

Population genetics is built on well-developed and sophisticated mathematical and statistical theory (but not reviewed here). Crow and Kimura (1970) and Wright (1969a, b; 1978a, b) covered the theoretical basis of population genetics. The analysis of population genetic data was examined by Nei (1987), Weir (1996), Rousset and Raymond (1997), and Nei and Kumar (2000). Luikart and England (1999) reviewed the methods of data analysis, and tabulated the necessary software. Wright (1969a, b; 1978a, b), Avise (2004), Gillespie (2004), Hartl and Clark (2007), Hedrick (2011), and Nielsen and Slatkin (2013) provided general treatments of population and evolutionary genetics. We recommend Hartl and Clark as the

"friendliest" treatment. Roderick (1996) and Black et al. (2001) have written particularly useful reviews of insect population genetics.

## 2. WHY POPULATION GENETICS?

- Sibling or cryptic species are reproductively isolated forms that are morphologically undifferentiated. If pre-mating isolating mechanisms exist, the application of sterile males of one member of a species complex may be totally ineffective against other members. Sibling species are common, e.g. among tsetse flies *Glossina morsitans* Westwood, *G. fusca* Walker, *G. palpalis* Robineau-Desvoidy and *G. fuscipes* Newstead (Gooding and Krafsur 2005), the *Drosophila willistoni* Sturtevant species complex, the *Anopheles maculipennis* Meigen complex (Bates 1949), the *Anopheles gambiae* Giles complex (Coluzzi et al. 2002; Dorn et al. 2011), the *Aedes scutellaris* (Walker) complex (Kambhampati et al. 1992), the *Simulium damnosum* Theobald complex (Vajime and Gregory 1990), the sand fly *Lutzomyia longipalpis* (Lutz and Neiva) (Lanzaro et al. 1993) and the ladybird beetle *Coleomegilla maculata* (De Geer) complex (Krafsur and Obrycki 2000). Most complexes uncovered to date are medically important Diptera or genetically interesting *Drosophila* species, but this is probably sampling bias. Complexes important to agriculture include the tephritid flies *Anastrepha fraterculus* (Wiedemann), where the existence of at least seven morphotypes has been confirmed recently, while for *Bactrocera dorsalis* (Hendel) the putative complex was shown to represent intra-specific variation, resulting in the synonymization of four pest species (Hendrichs et al. 2015). Colonies of medically important Diptera are routinely established to study insecticide resistance, vector-pathogen transmission, etc., and intercrosses among strains may produce sterile progeny. Examination of polytene chromosomes, well developed in many Diptera, may reveal reproductively isolated forms, as demonstrated in some *Drosophila* species (Dobzhansky 1970). Many insect pest species are not easily reared or studied genetically, particularly herbivorous beetles and moths, hence the question of cryptic speciation may not arise and cannot be investigated easily.
- Natural populations tend to be discontinuously distributed. Gene flow varies among them as per many factors, including the historical, geographical, and environmental. There may be local selection regimes that cause one or more populations to differ biologically in ways that could make the SIT less effective due to mating barriers. Such barriers might be ecological, temporal, or behavioural, and their strengths, in principle, could vary greatly. It should be noted, however, that no such mating barriers were detected in the New World screwworm (Krafsur 1985, 1994) and Mediterranean fruit fly programmes (Cayol et al. 2002).
- Estimating rates of gene flow among populations can provide an estimate of the rate of invasion or reinvasion of eradicated areas from unchallenged populations. The rates can be described in terms of the average numbers of reproducing flies per generation. Moreover, the likely source(s) of pests in an outbreak can be examined and, in many instances, specified. For easily transported pests such as

the Mediterranean fruit fly, the geographic origins of new infestations can, in principle, be specified. Determining the source of new infestations is an important undertaking to determine and close pathways, up to establishing embargos on produce originating from areas suspected of having shipped infested commodities (Aguirre-Ramirez et al. 2017).

- Construction of laboratory strains for sterilization and release can be improved. If adequate numbers of insects are to be sterilized and released, it is necessary to establish thriving colonies. How much of the existing natural genetic diversity should be incorporated into a release strain? The geographic range of many pest species is very large, and locally adapted populations may exist. How then should the genetic make-up of release strains be formulated?
- An analysis of genetic variation may also reveal genetic markers in laboratory colonies that can be used to differentiate released insects or the offspring of semi-sterile insects from their wild counterparts during the monitoring of programmes that release sterile insects.

## 3. CHIEF KINDS OF GENETIC VARIATION

Chromosome morphologies and structural rearrangements may vary within species and provide markers that distinguish populations (Robinson, this volume). Examples include paracentric inversions, easily detected in stained squashes of polytene chromosomes found in *Drosophila*, *Anopheles* mosquitoes, and the supernumerary chromosomes of some *Glossina morsitans* group tsetse flies (Gooding and Krafsur 2005). These kinds of variation rarely provide the high degree of resolution afforded by molecular variation in DNA or its transcription and translation products such as allozymes. Moreover, chromosome rearrangements are not selectively neutral as has been demonstrated in *Drosophila* species and *Anopheles gambiae* (Coluzzi et al. 2002). They may nevertheless provide important information about reproductive isolation and the operation of natural selection.

Allozymes are allelic forms of an enzyme. Isozymes are enzymes that act on a common substrate. Alleles are codominant. They are readily demonstrated by electrophoresis of tissue homogenates on starch, cellulose acetate, or polyacrylamide followed by histochemical staining that involves a dye or UV-fluorescence (Richardson et al. 1986; Murphey et al. 1996). Allozyme banding patterns correspond to genotypes, i.e. one band for a homozygote, two bands for a heterozygote at a monomeric locus, and three bands for a heterozygote at a dimeric locus. Most allozyme loci occur on the nuclear genome, but some loci, e.g. nicotinamide adenine dinucleotide phosphate (NADP)-dependent malate dehydrogenase, are mitochondrial. Allozyme analysis requires that tissue samples be fresh or frozen to preserve enzyme activities. This restriction does not apply to analysis of DNA.

Mitochondrial DNA (mtDNA) is single-copy, hence haploid, self-replicating, and is maternally transmitted as a circular molecule of about 16 kilobases. It encodes 22 transfer RNA genes and 13 proteins, including the cytochrome oxidases, NADH, RNAase, and ribosomal RNAs. There are many highly conserved regions from which oligonucleotide primers have been designed, e.g. Simon et al. (1994), which

are commercially available in kits. These primers allow the amplification of regions of the mitochondrial chromosome by the polymerase chain reaction (PCR). Mitochondrial variation can be assessed by several methods. Nucleotide sequencing of amplified regions can be followed by the comparison of sequences among individuals. Sequencing is recommended now that its costs have greatly decreased.

Microsatellites are simple sequence repeats (SSRs) of nucleotide motifs that are repeated *n* times: $(CA)_n$, $(GA)_n$, $(TA)_n$, $(CAG)_n$, etc. (where C is cytosine, A is adenine, G is guanine, T is thymine) that may occur throughout the nuclear genome. Each locus may vary among individuals in the number of repeats. Alleles are codominant. Conserved flanking sequences allow the design of oligonucleotide primers with which to amplify via PCR the microsatellite region. Comparatively sophisticated procedures are necessary to find microsatellites in the genome, and to develop oligonucleotide primers to amplify them. A substantial number of protocols are available to do so, e.g. Abdelkrim et al. (2009), Malausa et al. (2011). Some protocols involve enrichment of DNA for repeat sequences to maximize the yield of desired repeats (Hamilton et al. 1999). Alternatively, one may choose to hire a commercial organization to isolate and characterize microsatellite loci, and for some laboratories this may be the least expensive and most efficient way to proceed.

Single Nucleotide Polymorphisms (SNPs) are sites in the genome where DNA sequences differ by a single base when two or more individuals are compared. Sequence differences occur due to single nucleotide substitutions or insertions/deletions. SNPs occur in coding and non-coding regions of nuclear DNA, and constitute the most abundant markers in eukaryotic genomes. They are widely distributed and most loci are biallelic. Improved sequencing technology and available genomic sequence data have made it possible to analyse directly genetic variation in DNA. Signatures of adaptive genetic variation in wild populations can be detected without prior identification of candidate genes (Elmer and Meyer 2011). This is done by conducting genome scans of SNPs by using "next generation" DNA sequencing (section 4). Gloria-Soria et al. (2016) developed a panel of ~73,000 SNPs distributed across the genome of *G. f. fuscipes* (*Gff*) that was used to estimate genome-wide genetic diversity, differentiation and linkage disequilibrium in wild *Gff* populations in Uganda.

## 4. RELATIVE ADVANTAGES AND DISADVANTAGES OF PRINCIPAL METHODS

### *4.1. Obsolete Methods*

Several methods have become obsolete because much more efficient techniques have become available. Falling into disuse are studies of allozymes, used to assess enzymatic protein variation. Also, obsolete are the SSCP (single strand conformational polymorphism) technique to examine mitochondrial variation, RFLPs (restriction fragment length polymorphisms), RAPDs (randomly amplified polymorphic DNA), and AFLPs (amplified fragment length polymorphisms), all of which can be used to examine elements of genomic DNA.

### *4.2. Mitochondrial Variations*

Regions of the mitochondrial genome are highly variable, and some may be useful as population-specific markers. The mitochondrion is inherited as a single locus, and the effective population size (Box 1) is about a quarter of the size estimated by nuclear loci. This makes mitochondrial variation more sensitive to the effects of historical reductions in population size ("bottlenecks") and colonizing episodes. The reason is that the mitochondrial genome is single copy (haploid) and maternally inherited.

*Box 1. Basic Formulae Used in Population Genetics*

Gene heterozygosity (diversity) at a locus is one minus the frequency of homozygotes expected by Hardy-Weinberg criteria, corrected for sampling bias (Nei 1987):

$$h_e = 2n(1 - \Sigma x_i^2)/(2n - 1)$$

where $x$ is the frequency of allele $i$, and $n$ is the sample size. For measuring diversity at haplotypes, use $n/(n-1)$ as the correction factor. The average heterozygosity $He$ over $s$ loci is,

$$H_e = \Sigma h_e/s$$

with variance

$$\text{Var} = \Sigma(H_e - h_e)^2/[s(s - 1)]$$

Under Hardy-Weinberg assumptions, the relationship between diversity $H_e$, mutation rate $\nu$, and effective population size $N_e$ is:

$$H_e = 4N_e\nu/(4N_e\nu + 1)$$

Effective population size is, roughly, the number of successfully reproducing individuals. Note that $4N_e$ is likely to be a very large number and the mutation rate a very small number, of the order $10^{-6}$ for allozyme loci; both are difficult to measure.

The index $F$ describes departures from random mating by taking the difference between expected heterozygosity $h_e$ and the observed $h_O$ as a fraction of the heterozygosity expected on Hardy-Weinberg criteria:

$$F = (h_e - h_O)/h_e, \text{ or } F = 1 - (h_e/h_O)$$

It gives the equilibrium value of the proportion of homozygous genotypes. $F$ is a sensitive index of breeding structure, and may be expressed for hierarchical levels in subdivided populations. (It is described further in Box 3.)

### *4.3. Chromosomal Polymorphisms*

Chromosomal polymorphisms occur in many species. Cytological examination of pest taxa can provide important evidence of population subdivisions, variation in sex-determining mechanisms, and indicators of natural selection. There are a number of common structural variations in chromosome morphology that can be observed by microscopic examination of appropriate tissues. Such tissues include brain, testis, ovarian and trichogen cells, and salivary glands. Giant multi-banded

"polytene" chromosomes can be found in tsetse trichogen and mosquito salivary glands and ovarian nurse cells; polytenes arise from a large number of chromosome reduplications without cell separation -- thus giant cells with greatly enlarged chromosomes. They are particularly well-developed in nematocerous Diptera, and can also be found in higher Diptera, e.g. *Glossina* spp.

Sex chromosomes ("heterosomes") in many taxa indicate the phenotypic sex, e.g. in most Diptera, homogametic XX for females and heterogametic XY for males, but male Lepidoptera are homogametic and the females heterogametic. High frequencies of sex chromosome polymorphisms were detected in *G. p. palpalis* (Maudlin 1979) indicating that further cytological work on the *G. palpalis* complex is warranted.

Among the most common chromosomal polymorphisms are paracentric inversions, where two breaks occur in a chromosome arm followed by a 180-degree rotation of the interstitial piece and a rejoin of the three pieces. Most, if not all, seem to respond to selective forces, and therefore do not provide unbiased estimators of gene flow. Nevertheless, they may provide striking indicators of genetic differentiation of populations. Pericentric inversions include the centromere within the interstitial central part of the chromosome; such an inversion can greatly change the appearance of a chromosome.

Cytological analysis can be time-consuming and requires much skill, and therefore adequate and representative sampling of natural populations can be a problem (Augustinos et al. 2014).

### *4.4. Microsatellites and Single Nucleotide Polymorphisms*

SSRs can be well distributed throughout the genome and highly polymorphic, which has both advantages and disadvantages. Microsatellite alleles can prove useful in pinpointing the source or sources of immigrant insects in a treated area. Automated scanning and scoring of acrylamide gels allow high throughputs [by using Genemarker (SoftGenetics, USA) or Genescan®, Genotyper® and GeneMapper® software (Applied Biosystems, ThermoFisher Scientific, USA)]. Null alleles, usually caused by mutations in primer annealing sites, lead to underestimates of heterozygotes. Some taxa have few SSRs, including some culicine mosquitoes and ticks (Fagerberg et al. 2001). High mutation rates occur at some loci, violating a key Hardy-Weinberg assumption, and leading to homoplasy and biased estimates of gene flow and genetic differentiation of populations. Homoplasy, the convergent development of genotypically different but phenotypically similar repeats, is common in microsatellites. Highly variable loci with many alleles provide downwardly biased estimates of gene flow and genetic differentiation (because as diversities $h_o/h_e \rightarrow 1$, $F \rightarrow 0$). Since many microsatellite loci do not conform well to the infinite allele model (the stepwise mutation model would be more appropriate) (Box 2), some analytical procedures, e.g. *F* statistics estimation, may be inappropriate, and it then becomes necessary to use other methods. Some problems related to SSRs are avoided by using SNPs. Nevertheless, microsatellite loci and SNPs have become the principal tools with which to examine the genetics of

populations, leading to an explosion of analytical methods to examine the plethora of data now available (Luikart and England 1999; Excoffier and Heckel 2006).

*Box 2. Stepwise Mutation Model (SMM)*

Change in microsatellite repeat number is thought to occur principally in a stepwise fashion by unequal crossing over and replication slippage. Two or more independently arisen alleles can have the same molecular weight, and therefore appear as one on gels (homoplasy). Clearly, there are upper and lower limits to the number of repeats a polymorphic locus can have, so the infinite alleles model of mutation is inappropriate. Thus, in theory, the stepwise mutation model (SMM) is most appropriate when dealing with microsatellite loci. Slatkin (1995) developed a model based on the SMM analogous to Wright's *F* statistics. He termed the index of gene flow $R_{ST}$. The basic difference is that *F* statistics are based on variance in allele frequencies, and $R_{ST}$ is based on variance in repeat number. However, simulations have shown that, when sample sizes are less than 50 and the number of loci scored are less than about 20, *Fst* provides less biased estimates of gene flow than $R_{ST}$ (Gaggiotti et al. 1999).

### *4.5. DNA Sequencing*

Next generation (high throughput) sequencing describes several advanced, rapid and efficient sequencing methods now available (Mardis 2008; Schuster 2008; Seeb et al. 2011; EMBL-EBI 2017). Refer to Danecek et al. (2011) for formatting high throughput DNA sequencing for further use in population and phylogenetic work. Also, refer to Frías-López et al. (2016) for appropriate software for the same purpose. High throughput sequencing now enables a more comprehensive view of how genomes vary spatially and temporally than do the older methods.

## 5. BASIC PRINCIPLES OF POPULATION GENETICS

As cited earlier, several academic texts offer comprehensive treatments of population and ecological genetics. Here we offer only an elementary treatment of the subject.

The Hardy-Weinberg theorem, or rule, is the fundamental template on which genetic data are tested. The rule specifies that in diploid, sexually reproducing organisms, genotypic frequencies remain unchanged from generation to generation if the locus under consideration is selectively neutral, mating is random, generations are discrete, the mutation rate negligible, and population size infinite, so that no sampling errors occur in the transmission of gametes from one generation to the next. The foregoing assumptions, however, apply to few, if any, natural populations. Violations of Hardy-Weinberg assumptions may cause departures from random mating within and among populations. The principle cause is genetic drift — the random change in small gene pools due to sampling errors that occurs when the gametes of a parental generation unite to form the individuals of the next generation.

For diploid genomes, the probability of fixation of a neutral allele, i.e. attains a frequency of 1, is $1/2N_e$, where $N_e$ is the "effective" population size (Box 1). For uniparentally inherited loci, the probability is $1/N_e$. Thus, fixation, i.e. loss of diversity, is inversely proportional to the effective population size $N_e$. It should be

noted that the effective population size may be much less than the census number because not all individuals reproduce, and some generate more progeny than others.

Most species are distributed discontinuously in space and time, so individuals in a population will have a greater opportunity to interbreed with receptive individuals in their own population than with individuals in other populations. Thus, matings will not ordinarily be random among populations separated by distance, altitude, or age structure. The degree of genetic differentiation among populations provides a measure of gene flow.

Selection acting on a locus can also cause departures from Hardy-Weinberg expectations. Most genetic markers used in population genetics research are assumed to be selectively neutral. However, many allozyme loci are not selectively neutral, but respond to balancing selection. An interesting example of balancing selection is that of the tsetse fly *Glossina pallidipes* Austen. Populations in Zambia and Zimbabwe show about the same level of allozyme heterozygosity as populations in Kenya, but with much reduced levels of microsatellite and mitochondrial variation (Krafsur 2002).

## 6. PROCESSING AND INTERPRETING POPULATION GENETIC DATA

Having scored haplotype or genotypic frequencies, it is necessary to test hypotheses about their distributions within individuals (if dealing with nuclear variation) and at hierarchical levels of population structure. Much software is available for these tasks. (A website maintained by Joseph Felsenstein at the University of Washington lists, with annotations, 392 free software packages and 54 free web servers.) Excoffier and Heckel (2006) offer a helpful list of programmes, while Lischer and Excoffier (2012) provide an automated data-conversion tool for connecting genetic data with analytic programmes.

The first step is to examine gene diversities for each population, and record the observed heterozygosity $h_o$ at each locus. Next, calculate the expected single locus heterozygosities $h_e$, together with the expected heterozygosity averaged over loci $H_E$ (Box 1). Allele or haplotype frequencies can be tested for homogeneity over sampling units by using the Chi-square contingency tests (Rice 1989) (these are incorporated into most software packages). If gene frequencies at all or most loci are homogenous among populations, then there is little likelihood of genetic differentiation among populations, assuming one is dealing with selectively neutral variation. It is then likely that the sampled populations behave as a single randomly breeding unit, and the SIT would likely have to contend with high immigration rates. Such a result does not necessarily argue against the successful application of the SIT, as is discussed below. However, it is most likely that allele frequencies among populations will differ, a consequence of population structure and genetic drift. Over time, drift and genetic differentiation can lead to the development of reproductive isolation and, eventually, to speciation (Dobzhansky 1970; Futuyma 1998; Avise 2004).

The magnitude of genetic drift is inversely proportional to the effective population size (Box 1), i.e. the geometric mean number of individuals that contributes progeny to a subsequent generation, and more formally, the size of an

ideal population experiencing the same rates of random genetic change as the real population being considered. Genetic drift is most expeditiously quantified by estimating $F_{ST}$ or its analogues (Box 3).

*Box 3. F Statistics*

Wright's $F$ statistics and analogues are used to describe the breeding structure of subdivided populations. The original statistical theory was formulated in terms of two alleles segregating at a single locus. $F$ can be defined in terms of inbreeding, as departures from random mating, and as correlations between uniting gametes.

$F_{IS}$ describes departures from random mating within populations; it is the correlation of random alleles within individuals averaged over populations, relative to the correlation of two random alleles from the population as a whole. Thus, the heterozygote deficiency (increase of homozygosity or inbreeding) in individuals is (Hartl and Clark 2007): $F_{IS} = (H_S - H_I)/H_S = 1-(H_I/H_S)$. Here $H_I$ is estimated as the average observed heterozygosity among populations, and $H_S$ is the expected heterozygosity.

$F_{ST}$ indicates departures from random mating among populations; it is the correlation of two random alleles in a population relative to the correlation of two random alleles chosen from the entire population ($F_{ST} = 1-[H_S/H_T]$), where $H_T$ is the heterozygosity averaged over all populations. It was termed by Wright as the standardized measure of genetic variance among populations, and also as the "fixation index" that measures reduction of heterozygosity, or heterozygote deficit compared with Hardy-Weinberg.

$F_{IT}$ describes departures from random mating accruing from all causes ("inbreeding"); it is the correlation of alleles in individuals relative to that in the entire population ($F_{IT} = 1- [H_I/H_T]$). Important extensions of $F$-statistics include $G_{ST}$ (Nei 1987) and Weir and Cockerham's (1984) theta ($\theta$).

$F_{ST}$, $G_{ST}$, and $\theta$ underestimate differentiation of subdivided populations progressively as gene heterozygosity $h_e$ increases because as diversity $h \rightarrow 1$ in Hardy-Weinberg demes, $F_{ST,}$ $G_{ST}$, and $\theta$ will approach zero. Indeed, they cannot take a value equal to or greater than the mean level of homozygosity (Hedrick 1999). Slatkin (1985), Barton and Slatkin (1986) and Slatkin and Barton (1989) offered a way around the problem of high diversities. Slatkin observed a nearly linear relationship between the mean frequency of private alleles $p_1$ and the mean number of reproducing migrants per generation $N_em$: $\log p_1 = a \log_{10} Nm + b$. Constants $a$ and $b$ vary with mean sample size. The method was found to be robust.

$F_{ST}$, $G_{ST}$, and $\theta$ are variance statistics. $\theta$, for example, may be used in an analysis of variance for both diploid and haploid loci (Weir 1996). Thus, one can obtain variance statistics and estimates of $\theta$ for each level of hierarchy (Rice 1989).

The inverse of $F_{ST}$ is proportional to the level of migration that satisfies the equation, $F_{ST} = (4N_em + 1)^{-1}$, where the term $N_em$ is, very roughly, the harmonic mean number of reproducing migrants per generation (Box 4). Fig. 1 shows the relationship between $N_em$ and $F_{ST}$. Wright (1978a, b) suggested that a critical level of migrants is about one reproducing organism per generation. A lower sustained migration rate among equilibrium populations would lead to further genetic differentiation by drift.

For discontinuously distributed, i.e. subdivided, populations, it is helpful to make estimates of $F_{ST}$ between all possible pairs of populations. In this way, one can test hypotheses that $F_{ST}$ increases with geographic distance or other physical measure of interest. Highly differentiated populations can easily be identified in this way. Such local populations could, in principle, have a measure of pre-mating reproductive isolation that might work against the SIT. If deemed to be of interest, colonization,

and laboratory and field-cage testing for pre-mating isolation, could then be carried out (Cayol et al. 2002).

*Box 4. Gene Flow*

According to Wright's island model of gene flow, $F_{ST}$ can be defined in relation to the effective population size $N_e$, mutation rate $\nu$, and migration rate $m$. $F_{ST} = [4N_em + \nu + 1]^{-1}$ for populations at mutation-drift-migration equilibrium. This equation allows the estimation of a migration rate in terms of the mean number of reproducing organisms per generation $N_em$. Thus, where the mutation rate $\nu$ is negligible (i.e. $\rightarrow 0$), $N_em \approx (1 - F_{ST})/4F_{ST}$ for diploid loci. For mitochondrial haplotypes, $N_em \approx (1 - F_{ST})/2F_{ST}$ (where the sex ratio approaches unity).

$F_{ST}$ is non-linear because it is a reciprocal function of $N_em$ (Fig. 1). Therefore, mean values of $N_em$ can be quite meaningless, and caution is required in their interpretation (Whitlock and McCauley 1999). Pairwise estimates of $F_{ST}$ and its linear transformations are useful, however, and can be obtained by using "Arlequin" software (Excoffier and Lischer 2010).

Some assumptions of the island model of gene flow include populations of equal size in which drift does not occur, all of which exchange alleles with equal probability.

Other models have been formulated, including the stepping-stone model, in which only adjacent populations exchange alleles.

The island model, however, has proved sufficiently robust for many purposes, and it remains the most generally used. Theoretical developments have led to new applications, for example, the cladistic nested analysis of phylogeographical data (Templeton 1998).

An additional caution is necessary when using microsatellite loci to estimate $F_{ST.}$ Mutation rates can be substantial at some microsatellite loci, leading to downwardly biased estimates of $F_{ST}$.

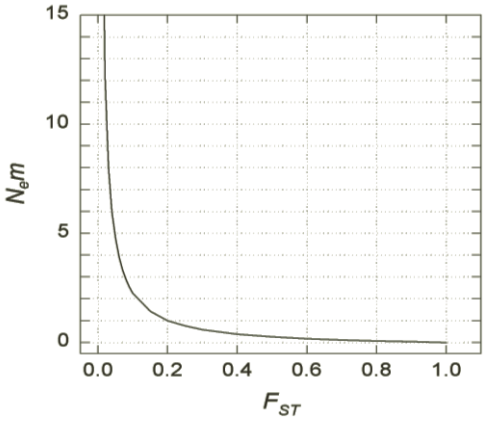

*Figure 1. Mean numbers of reproducing migrants per generation exchanged among populations ($N_em$) as a function of the mean departures from random mating ($F_{ST}$) according to the island model of gene flow. $N_em = (1-F_{ST})/4F_{ST}$.*

Do high rates of dispersal argue definitively against the SIT? History indicates that they do not. Epizootiological and experimental studies have shown that the New World screwworm has a great capacity for dispersal, as might be expected in such a colonizing species. High dispersal rates of the screwworm flies did not fatally

compromise the effective application of the SIT to this species wherever it was applied.

## 7. POPULATION GENETICS AND CONSTRUCTION OF RELEASE STRAINS

How may the rules of population genetics be used to construct strains for eventual release? Thriving mass-reared colonies of the target insect are required, the progeny of which, when radiosterilized, must be competitive with wild males in seeking to mate with wild females (Lance and McInnis, this volume; Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume).

It is often assumed that the "degradation" of laboratory stocks occurs via adaptation through selection and inbreeding, with a correlating loss of field competitiveness. Work on *Drosophila* showed a great loss of gene diversity (Briscoe et al. 1992) and fitness that was proportional to the duration of laboratory colonization (Jungen and Hartl 1979). Also, Cioci et al. (2014) detected a significant loss of microsatellite diversity arising from a genetic "bottleneck" in a ca. 38-year-old *Glossina pallidipes* colony. On the other hand, no substantial loss of mitochondrial variation was detected in *Glossina pallidipes* (Krafsur et al. 2016) or *Glossina morsitans* Westwood (Wohlford et al. 1999). Thus, each case must be taken on its own merits.

During laboratory adaptation, predation pressure is absent in colonies. Equally, sexual selection that operates in nature may be relaxed because of the proximity of mates in cages. For example, contact cuticular hydrocarbon pheromones in higher Diptera (Carlson et al. 1993; Brown et al. 1998), courtship behaviour in tephritid fruit flies, and swarming behaviour in nematocerous Diptera, could, in principle, inadvertently become modified during laboratory adaptation (Eberhard 2000; Briceño and Eberhard 2002; Briceño et al. 2002). The genetics and evolution of pheromone signalling and response behaviour have been studied in moths (Löfstedt 1993; Phelan 1997). Inbreeding causes a loss of genetic variation that could, in principle, reduce competitiveness. Are these realistic concerns? Is competitiveness in the field inversely proportional to laboratory adaptation? Do laboratory strains/colonies "deteriorate" over time?

The theory of inbreeding is well known; a simple account of elementary inbreeding theory is given in Box 5. A substantial loss of heterozygosity may occur if a release strain is formed from too few founding insects, followed by a prolonged "bottleneck" in colony size. However, it is by no means certain that even a great loss in diversity will have pronounced effects on laboratory fitness or mating competitiveness in the field. Many colonizing species undergo periodic genetic bottlenecks in nature, with little adverse effect. The question of laboratory adaptation and competitiveness must be addressed on a case-by-case basis. In the New World screwworm, for example, estimates of sterile mating rates among geographically diverse target populations were found to be unrelated to the strain of sterile flies released (Krafsur 1985, 1994). Experience with *Glossina morsitans* suggested that colonized and irradiated flies dispersed and mated with their wild cousins at approximately the expected frequencies (Vale et al. 1976; Dame 1979; Vreysen et al. 2011).

*Box 5. Inbreeding*

Some consequences of inbreeding and drift include high frequencies of homozygosis and fixation of mildly deleterious alleles. Correlations between uniting gametes in "inbred" populations are greater than the correlations drawn from reference populations higher in the hierarchy. Loss of genetic diversity through drift is to be expected in closed populations. The inbreeding coefficient $F$ (probability of identity by descent) in generation $t$ is related to the effective population size $N_e$ as follows:

$$F_t = 1 - (1 - 1/2N_e)^t \quad \text{As } t \text{ increases, } F \rightarrow 1, \text{ hence diversity} \rightarrow 0$$

Manipulating this equation shows that about half the diversity at selectively neutral loci is lost in $1.4N_e$ generations. For a breeding colony established from 2, 5, 10, 25, and 100 pairs the initial loss of diversity in a single generation is 22, 10, 5, 2, and 0.5%, respectively. These are trivial decreases. In a constantly expanding insect culture there would be little additional loss of variation. After 10 generations of "inbreeding" at the foregoing population sizes, however, heterozygosity losses become far greater, at 92, 63, 39, 12, and 5 %, respectively. Thus, the duration of a "bottleneck" has profound effects on genetic variation. It is well to remember that these formulae apply to selectively neutral loci, but insects in culture are subject to various forms of selection, some of which may be for traits not advantageous in the wild. It should be noted, however, that weak selection intensity in very small populations can be overridden by drift (Black et al. 2001).

In some cases, genetic phenomena have been invoked to explain pest outbreaks during sterile insect release programmes (section 8), but few genetic data were available to support the contentions. Nowadays, however, it is easy to obtain genetic data for target populations, and for laboratory colonies and their source populations. Inbreeding coefficients ($F$) and genetic distances can (and should) be estimated continuously as part of quality control programmes. A progressive loss of diversity in laboratory colonies, coupled with a progressive decay in physiological quality control indices, could provide prima facie evidence of degradation, and possibly predict a decline in field competitiveness. If no data are collected, little of substance can later be said about genetic causes of, or correlations with, the failure of a particular programme.

The rationale for constructing strains for propagation and release should include the number of founding organisms and their geographical origins. If there is good reason to believe that a target pest population may constitute a species complex, then it is necessary to ensure that only the pest species is cultured. Isofemale strains can be constructed for insects that reproduce readily in colony (an isofemale strain is based upon the progeny of a single mated pair). Many such lines can be constructed, and each evaluated for laboratory fitness and field competitiveness. If it can be shown that geographically adapted populations exist (Vera et al. 2006), then it would be prudent to conduct mating preference tests under semi-natural conditions (Cayol et al. 2002). Such tests have strong environmental correlations, and thus experimental designs must be adequate to detect unambiguously a true genetic component. Where strong, genetically determined mating preferences exist, of course it would be advisable to rear, sterilize, and release the most compatible strains.

The question of loss of diversity and fixation of deleterious alleles because of small effective population size can, in principle, become acute when constructing

strains by classical or modern molecular tools; the progenies are descended from a unique genome that may or may not be subject to recombination with wild-type alleles (Franz et al., this volume).

Finally, it is most important to put in perspective the issue of "strain degradation". It is difficult and expensive to conduct field experiments that estimate the genetic and environmental components of competitiveness. In projects that release sterile insects, however, sterile mating rates in target pest populations should be monitored routinely (Parker, Vreysen et al., this volume; Vreysen, this volume). Experience has shown that rearing, handling, irradiation, and release procedures are much more important for competitiveness than the laboratory "degradation" of release strains. A good example is the North and Central American New World screwworm eradication programme (see below).

There are new, more efficient, and faster computer programmes suitable for the analysis of population genetic data. Principal component analysis (PCA) has become a standard analytical tool in population genetics. Many applications employ Bayesian methods that allow complex and subtle inferences of such data. Although beyond the scope of this chapter, Box 6 provides a brief introduction to PCA and Bayesian applications.

*Box 6. Principal Components and Bayes Theorem*

Principal component analysis is convenient and easy to use. Graphic presentations can be colorful and informative. In PCA, eigenvectors and eigenvalues are calculated from allele frequency covariance matrices of all pairwise comparisons. Covariance is the mean value of the product of deviations of two variates from their respective means. Patterson et al. (2006) offer further information and cite convenient computer programmes.

The application of Bayes theorem or rule offers a useful tool to estimate probabilities of events based on prior knowledge related to the event of interest and to compare gene flow models. Bayesian methods can be used to infer phylogenies (Felsenstein 2004), i.e. evolutionary relationships among taxa or geographically diverse populations.

At its mathematically simplest, Bayes theorem is given by $P(A \mid B) = [P(B \mid A \times P(A)] / P(B)$ where P(A) is the probability of A and P(B) is the probability of B; $P(A \mid B)$ is the probability of A given B, and $P(B \mid A)$ is the probability of B given A. Here, P(A) is the "prior" probability, and $P(A \mid B)$ is the "posterior" probability.

Approximate Bayesian Computation (ABC) bypasses some difficult mathematical procedures (Beaumont 2010), and provides a flexible platform to carry out complex models. ABC is useful in investigating demographic histories and evolutionary questions. ABC is incorporated into a growing list of statistical procedures and genetical software packages, e.g. DIYABC v2.1.0 ("Do It Yourself ABC") (Cornuet et al. 2014) and MrBayes 3 (Ronquist and Huelsenbeck 2003). DIYABC is software for comprehensive analysis of population history using approximate Bayesian computation (ABC) on DNA polymorphism data. MrBayes is a programme for Bayesian inference and model choice across a wide range of phylogenetic and evolutionary models. MrBayes uses a Markov chain Monte Carlo simulation method to estimate the expectation of a statistic in a complex model. Another software is ABCtoolbox (Wegmann et al. 2010).

## 8. APPLICATIONS AND EXAMPLES

Experience suggests that studies of gene flow throughout a species' range are not necessary to implement and successfully carry out programmes that release sterile insects. Mediterranean fruit fly and New World screwworm programmes were conducted successfully for years without any substantial population genetic data available. However, the spectre of reproductively isolated screwworm populations was raised repeatedly, particularly when progress was slow or releases deemed ineffective (Krafsur et al. 1987). Some investigators were so certain of the existence of assortative matings between wild and released flies, and of reproductively isolated forms, that numerous claims were made in anticipation of their certain discovery. Indeed, a few geneticists played a controversial and unhelpful role (in the New World screwworm eradication programme in the USA and Mexico) by claiming evidence of assortative matings (Bush et al. 1976), or later (Richardson 1978; Richardson et al. 1982), by claiming evidence that screwworms constituted a hitherto unrecognized complex of reproductively isolated forms.

This situation, precipitated by screwworm epizootics in 1972–1976 in the south-western USA, was exacerbated by the practice of presenting and evaluating eradication programme results solely on screwworm case incidence. Programme officials invoked screwworm migration across the border from Mexico and rainfall to explain the outbreaks, but no gene flow or meteorological data were ever provided. The possibility of genetic changes in target populations was also acknowledged. In the absence of published meaningful data to support programme claims, interested commentators offered their own explanations, attracting much notice in the scientific community, and leading to attempts to stop the development of the Mexico screwworm eradication programme until critics could solve the very problems they claimed to have identified.

There was very little evidence that the screwworm outbreaks could be explained by powerful genetic phenomena or the existence of cryptic species. There was much evidence to falsify the claims, had it been recognized and invoked by programme officials (LaChance et al. 1982; McInnis 1983; Krafsur et al. 1987; Krafsur 1998). One of the lessons to be learned from this episode is that periodic estimates of gene frequencies from wild and mass-reared insects of a targeted species, together with predictive quality control measures, can be used to track changes that could, in principle, point to a decline in strain effectiveness for SIT implementation. The availability of such data, particularly when published in peer-reviewed scientific journals, can do much to defuse potentially damaging and confounding criticism from the scientific community. It would also be necessary, in those species where it is practicable, to maintain estimates of sterile mating frequencies -- to show a relationship between sterility and sterile insect dose rates and target population densities (Krafsur and Hightower 1979; Krafsur 1994; Vreysen, this volume).

Pest outbreaks during a sterile insect release programme can reasonably be expected, and it will be necessary to specify the most likely causes. It must be anticipated that natural events, such as weather or the evolution of assortative mating, can, in principle, occur, but experience has shown that it is much more likely that failures in insect production, the distribution of sterile insects or the

implementation of complementary suppression measures will have caused this breakdown in control.

## SUMMARY

Suppression or eradication of insect pest populations by the release of sterile insects is often dependent on supplementary methods of pest reduction to levels where the target pest population can be overflooded with sterile insects. Population suppression activities often take place in advance of, or coincide with, the production and release of sterile insects. Supplementary methods to remove breeding opportunities, or management methods that prevent access of pests or vectors to the hosts, may reduce the population or prevent damage or disease transmission. Insecticides have been used widely in direct applications or applied as baits, in traps, or on specific sites where the pest makes contact or reproduces, although they are increasingly being replaced by biopesticides. As sterile insect release does not kill the pest, adult biting pests or fertile mated females of the pests will continue to attack hosts after the release of sterile insects. Thus supplementary pest suppression programmes and quarantine measures are essential to prevent damage or the spread of disease. Eradication or effective pest management requires that the entire population of the pest be treated, or that the programme apply immigration barriers. It also requires taking into account interactions among control methods; they can be additive, synergistic or antagonistic. When supplementary pest control activities directly benefit the human population in areas being treated, such as in mosquito or screwworm control programmes, these area-wide suppression activities are usually acceptable to the public, but when the public receives no direct benefit from supplementary control activities such as in crop pest programmes, social resistance may develop unless public information is managed properly.

## 1. INTRODUCTION

The sterile insect technique (SIT) is highly species-specific and non-polluting; the target is the reproductive system of sexually reproducing pests. Supplemental systems to reduce pest populations are often required, prior to the release of sterile insects, to reduce the target pest population to the degree that the sterile insects have an advantageous numerical ratio to induce sterility. Most of the successful programmes releasing sterile insects were applied when field populations were at low densities, either after a natural population decrease (such as winters in subtropical or temperate climates) or after the application of area-wide suppression activities.

The decision to use suppression before the release of sterile insects may also be for economic reasons. Quarantine decisions, on market access of commodities attacked by pest outbreaks, are frequently based on adult trapping data. Reducing the adult population close to the detection level with adulticide sprays and/or other means adds the benefit of meeting quarantine protocols and reopening markets sooner than when the sterile insects have eliminated the population.

In other cases, the action of released sterile insects on the pest population is indirectly associated with reduction in pest damage. Mosquitoes and tsetse flies can continue to bite and spread disease after they are mated to sterile flies. Fertile-mated screwworms can, for the rest of their lives, continue to destroy livestock. These activities are not reduced by the release of sterile flies. Decisions to use pesticides or other methods to protect hosts will, in these cases, for example in the case of an epidemic, be largely independent of the success of the sterile insects.

In eradication programmes, multiple suppression methods may be combined, but interactions among them must be considered, particularly when they interact with the dynamics of the pests' Allee threshold (Suckling et al. 2012). Combinations of methods can thus be considered to have synergistic (greater efficiency from the combination in achieving extinction), additive (no improvement over single methods alone), or antagonistic (reduced efficiency from the combination) effects on Allee

dynamics. When planning the integration of methods it is crucial to take these effects into account.

In this chapter the various pest control techniques that are used to suppress pest populations, in conjunction with the application of the SIT, are reviewed. Suppression activities applied as precursors, or in tandem with sterile insect release, will be emphasized. Quarantine treatments are not considered.

## 2. OVERVIEW OF PEST CONTROL TECHNIQUES

Major benefits of the SIT are species specificity and the possibility of eradication. Knipling (1979) outlined the techniques for reducing insect pest populations with respect to the species specificity (Table 1), and to their effectiveness with respect to pest density levels (Table 2). Table 2 is of particular relevance to the SIT as its effectiveness relates to the density of the pest population. He followed this overview with a discussion on integrating these techniques with the SIT.

*Table 1. Classification of degrees of selectivity of various methods of insect control (adapted from Knipling 1979)*

| Highly selective | Moderately selective | Non-selective |
|---|---|---|
| Insect attractants (specific) | Attractants (baits) | Conventional insecticides |
| Insect pathogens (specific) | Biopesticides (specific) | Biopesticides (general) |
| Insect parasitoids (specific) | Parasitoids (general) | Mechanical control |
| Insect predators (specific) | Predators (general) | Cultural measures |
| Insect-resistant plant varieties | Insect entomopathogenic fungi (specific) | Insect entomopathogenic fungi (general) |
| Genetic techniques | Autoinoculation devices | |
| Mating disruption | Light traps | |

Knipling (1979) also discussed a series of exceptions and modifications to this classification, and recent research has greatly extended the number of available suppression methods. The method of application was also recognized as being of crucial importance in selectivity. For example, aerial application of broad-spectrum insecticides will have a greater impact on non-target organisms than application of the same insecticide as a bait or to a specific location on a plant or animal that is to be protected from a pest.

Natural biological control is inevitably a part of any area-wide integrated pest management (AW-IPM) programme, but specific releases and manipulation of parasitoids and predators are being used as part of AW-IPM systems that include the SIT (Knipling 1992, 1998, 1999; Wong et al. 1992; Bloem et al. 1998; Vargas et al. 2004; Montoya et al. 2007). Marec et al. (this volume) describe the synergism between inherited sterility (IS) and natural enemies (Bloem et al., 1998; Carpenter et al. 2004). In New Zealand, irradiated male painted apple moths *Teia anartoides* Walker were released, and *Bacillus thuringiensis* Berliner variety *kurstaki* (*Btk*) was

simultaneously applied to suppress the pest population (O'Callagahan et al. 2003; Suckling 2003; Simmons et al., this volume).

Knipling (1979) followed this table with an introduction to the concept of IPM, including descriptions of the purposes of pest management: to slow population growth, suppress and maintain populations below a certain level, or eliminate populations. Since then, there has been a number of recorded eradication successes using different IPM strategies combining various control methods, including insecticides, mating disruption, SIT, host removal, *Bt* plants, lure and kill, etc. (Table 3) (Suckling et al. 2014; Klassen and Vreysen, this volume).

*Table 2. Classification of insect control techniques by efficacy at various pest densities (adapted from Knipling 1979)*

| Methods equally effective at all densities | Methods most effective at lowest densities | Methods most effective at highest densities |
|---|---|---|
| Conventional chemical insecticides[1] | Sterile insect and other genetic techniques | Host-specific pathogenic organisms |
| Chemical sterilants applied to natural populations | Sex- or aggregating-attractant traps | Host-specific parasitoids |
| Cultural and mechanical control methods | Sex-attractant diversion sources or mating disruption | Host-specific predators |
| Insect-resistant crop varieties | Sex-attractant vapours | |
| Genetically modified crops[2] | | |
| Light traps | | |
| Attractant baits | | |
| Trap crops | | |
| Synthetic non-pheromone attractants | | |
| Sex pheromones that block responses | | |

[1]Some factors, e.g. spatial aggregation and partial protection by vegetation cover, can make their efficiency density-dependent

[2]Although leaving sufficient refugia with non-resistant plants to avoid rapid selection for insect resistance

## 3. CULTURAL, ENVIRONMENTAL, AND MECHANICAL CONTROL

Activities in agricultural production, property management or lifestyles can all influence insect pest densities, and a major advantage of cultural control is that it is pest density-independent. The disadvantage is that many cultural control activities reduce the population but do not protect the crops or animals being attacked. In cases where very low pest populations can have high economic or health impacts, cultural control through habitat manipulations alone probably will not provide the desired level of suppression.

Development of the SIT technique for control of the New World screwworm *Cochliomyia hominivorax* (Coquerel) relied heavily on activities that prevented infestation of livestock. The pest was subjected to considerable cultural control because of the value of livestock and the critical damage from infestations to animal

and humans. Programmes for treating wounds, and preventing reinfestations of individual animals, were the primary actions taken to control screwworm damage (FAO 1992; Vargas-Terán et al., this volume). Dove (1938) proposed a combination of livestock management measures such as special care with wound protection, protection of females and offspring following pregnancy, curing tick bites, castrating and branding animals only during winter, protecting castrated and branded animals, and other management activities. Protecting animals from infestation, and wound treatment, are still the key suppression activities in screwworm programmes where this pest has not been eradicated.

*Table 3. Examples where multiple suppression methods have been combined during successful eradication programmes (modified from Suckling et al. 2012, 2014)*

| Number of suppression methods | Combinations and their assumed density-dependence[1] | Insect scientific name | Insect common name | References |
|---|---|---|---|---|
| 3 | Mating disruption (DD)<br>+*Bt*-cotton (DI)<br>+SIT (DD) | *Pectinophora gossypiella* (Saunders) | Pink bollworm | Tabashnik et al. 2010; Simmons et al., this volume |
| 5 | Ground insecticides (DI)<br>+Aerial *Btk* sprays (DI)<br>+Mass-trapping (DD)<br>+Host-plant removal (DI)<br>+SIT (DD) | *Teia anartoides* | Painted apple moth | Suckling et al. 2007; Simmons et al., this volume |

[1]Density-independent (DI) indicates a control method that removes a proportion of the population, independent of density (e.g. broad-spectrum insecticides). Density-dependent (DD) methods work better on bigger populations (e.g. pour-on applied on cattle will work better at high tsetse densities if they mainly feed on cattle but will not kill the small part of the population feeding on alternative hosts) or on the contrary on smaller populations, accelerating the extirpation towards the end (e.g. SIT works better because the overflooding ratio of sterile to wild individuals favours sterile individuals).
[2]Example of cultural control: dehorning, branding or castration during cold months.

Cultural control methods for crop pests can include area-wide destruction of crop residues, general orchard sanitation and removal of infested fruit, and enforcement of planting and harvesting dates.

Cultural control of the pink bollworm (Nobel 1969) in the USA was developed in the early 1950s as part of an area-wide approach as the pest spread across Texas, New Mexico, and Arizona. Activities included evaluation of stalk-shredding machines for

killing the potential overwintering insects and incorporating the use of shredders. Devices were developed that killed bollworm larvae in cotton gin trash. In contrast to the screwworm programme, the impact of these activities was to decrease the pink bollworm population, rather than directly protecting the crop.

Early reviews of fruit fly pest control focused on environmental modifications to reduce reproduction and the survival of immature stages, and chemical control to kill adults. Back and Pemberton (1918) described covering of immature fruit with a bag or cloth material to prevent infestation. They also described a system used in Australia of bagging the canopy of trees with mosquito netting, but considered the method too expensive for large-scale use. Individual bagging of fruit was successful, but the bag had to be impermeable to oviposition, and problems with scale insects on the protected fruit developed. More recently, this concept has been revived to protect cabbage crops in Africa (Martin et al. 2013).

Another cultural control approach to fruit fly pests was described as "clean culture" (Back and Pemberton 1918). This method is based on removing all hosts from the infested area. Crawford (1927) reviewed clean-culture methods used in Mexico and determined that the approach was effective for the Mexican fruit fly *Anastrepha ludens* (Loew), but extreme measures such as the destruction of trees were not practical or effective (although see Kovaleski and Mumford (2007) for successful *Cydia pomonella* (L.) eradication in Brazil). He compared ranches that cleaned up fallen oranges once a week, and found the approach ineffective for complete control but more effective when coordinated with the application of poison bait. Crawford also recognized the value of trap crops in controlling fruit fly damage; he suggested that a few grapefruit trees (a preferred citrus species) could be used for this. He also recognized that the trap-crop trees could be sprayed.

The application of "clean culture" to fruit fly management programmes has been widely practiced in AW-IPM programmes integrating the SIT in the USA and the joint programmes in Mexico and Guatemala. Sanitation and the destruction of host material is widely carried out in the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) eradication programme (Moscamed) in Mexico and Guatemala. During a series of outbreaks in the Palenque district of northern Chiapas, from 8332 hectares treated (e.g. bait sprays), 33 978 kg of host material were collected and destroyed (Moscamed data sheets for 2002). In Guatemala, from 411 739 hectares treated, 345 633 kg of host fruit were destroyed (USDA/APHIS/IS 2002). As an immediate response in 2003 to a large infestation (106 hectares) of Mexican fruit flies in Valley Center, California, the California Department of Food and Agriculture removed and buried host fruit. A total of 2 941 070 kg of fruit (mostly citrus) was collected from the ground and stripped from trees at sites ranging from 0.26 to 36 hectares. The removal and destruction of host material is a logical complementary suppression activity because it destroys immature stages of the pest that cannot be controlled by other methods. However, there is a possibility that the removal of host material induces adult females to migrate in search of hosts, and actually causes an outbreak to spread.

Where the primary purpose of the SIT is to eliminate or prevent diseases through eliminating or suppressing the vectors, cultural and mechanical controls have been applied widely. In addition to pesticide application as a supplementary treatment incorporated into programmes that also release sterile insects for mosquito control,

Musil (2002) outlined improvements in integrated activities that reduce the vector populations, and in health care supplemental activities:

- Habitat management that interferes with the mosquito life cycle, including physical barriers, use of beneficial organisms, and removal of breeding sites,
- Community education and participation to improve public understanding of the mode of disease transmission,
- Public health strategies that integrate detection, diagnosis, and prompt treatment of the disease to prevent spread.

In the case of mosquito control, active source reduction, together with larviciding, adulticiding, and public education through door-to-door campaigns (source reduction through education) could achieve up to 75% reduction of adult densities in the case of *Aedes albopictus* (Skuse) (Fonseca et al. 2013). Such integrated strategies will be crucial when integrating the SIT, thus facilitating the overflooding of wild populations and inducing more than 50% sterility in females to reduce adult populations further (Bellini et al. 2013).

## 4. CHEMICAL CONTROL

### *4.1. Direct Insecticide Application for Population Suppression*

Broadcasting insecticides has often been done in conjunction with AW-IPM programmes that integrate the SIT. However, public acceptance of insecticide application in this context has usually been limited to situations where the treated properties are owned by persons who receive some benefit. Eradication experiments, and programmes with medically important pests such as mosquitoes and tsetse flies, have frequently used applications of persistent insecticides. Programmes for pests such as the pink bollworm, with a distribution largely restricted to certain hosts, were also implemented with insecticides but with little publicity, although more recent supplementary suppression activities were based on attractants (Walters et al. 2000a). Suppression of the codling moth in Canada required initial insecticide treatments to reduce the pest population (Bloem and Bloem 2000). If an insecticide is applied at the same time that sterile insects are being released, the chemical may kill some of the sterile insects; however, as long as the ratio of sterile:wild insects remains the same, this would not impair the efficacy of the SIT.

In *C. capitata*, models demonstrated that it is crucial to determine optimal spraying schedules to ensure an efficient suppression of target populations in preparation of SIT application (Barclay et al. 2019). The most important biotic parameters to be considered were the relative length of the larval period, the fertility rate, and the age to first oviposition. The stage targeted by sprays, and the percent mortality caused by each spray, were also found to be important in determining the required number of sprays.

Mangan (2014) reviewed adulticidal insecticide bait sprays for fruit flies, and summarized the development of organic baits that replaced organophosphate baits.

In the 1960s when the first attempts to use the SIT, or other genetic modifications of released mosquitoes, were made, broadcasting insecticides to suppress mosquitoes was widespread. Patterson et al. (1980) described a field trial to control the stable fly

*Stomoxys calcitrans* (L.) with the SIT as an adjunct to insecticidal and physical methods. Insecticides were also applied for the control of tsetse flies in Africa; applying insecticides against these species was a component of the programmes as they developed.

According to Douthwaite (1992), the first area-wide attempts to control tsetse flies with insecticide sprays began in 1945 in South Africa using organochlorine insecticides. This programme resulted in the successful elimination of *Glossina pallidipes* Austen from 11 000 km$^2$ through the aerial application of DDT or lindane, and supported by game destruction, habitat clearing and massive trapping operations (Du Toit 1954). Although the negative effect of these treatments on beneficial insects was recognized, and an impact on bird populations was reported by Graham (1964), persistence and bioaccumulation of residues was not understood at the time.

The first tsetse programme using sterile mass-reared insects was carried out against *Glossina morsitans morsitans* Westwood in Tanzania (Dame et al. 1980; Williamson et al. 1983). The strategy of this test was to suppress the tsetse population with two aerial applications of endosulfan (28-day interval), and then control the population with sequential releases of sterile males. A 195-km$^2$ area was surveyed for 14 months using various trapping methods, and the reproductive status and density of the population were assessed. A 105-km$^2$ area was selected for treatments. A 1-km barrier was cleared and treated with manual backpack spray applications of DDT in a 300-m-wide swath to prevent the migration of flies into the treated area. Fly surveys showed that, after the first endosulfan application, there was nearly 100% reduction in *G. m. morsitans* and 91.5% reduction in *G. pallidipes*. Following the first spray, sterile *G. m. morsitans* males were released twice per week at a rate of 135 males per km$^2$, resulting in an average male sterile:wild ratio of 1.12:1. A comparison of the female reproductive status between control and treated areas showed that, following the second spray, the sterile males were highly effective. Over the 15-month sterile-treatment period, Williamson et al. (1983) reported an 81% reduction in *G. m. morsitans*. The population of *G. pallidipes*, which received only the insecticide treatment, recovered to pre-spray levels within 5 months.

The sequential aerosol technique (SAT) involves spraying ultra-low-volume formulations of insecticides from the ground (fogging) or air (fixed-wing aircraft or helicopter) with limited environmental impact. The goal is to kill adult tsetse flies in the first spraying cycle by direct contact, and kill emerging flies in subsequent cycles. Recently, the SAT has been used against *Glossina palpalis gambiensis* and *Glossina tachinoides* Westwood, and achieved reduction levels higher than 98% (Adam et al. 2013). Against savannah species in an open environment, it is even more efficient, and achieved complete elimination of *Glossina morsitans centralis* Machado (Kgori et al. 2006). The SAT might represent a rapid solution to reduce tsetse populations before releasing sterile males, provided that habitat specificities and individual insecticides sensitivities are taken into account (De Deken and Bouyer 2018).

The need for innovative tools in managing mosquitoes was recently pointed out by the Global Vector Control Response 2017–2030 (WHO 2017). This includes suppression tools in the case of *Aedes aegypti* (L.) and *Ae. Albopictus*; at present there are only limited possibilities because of their disseminated larval microhabitats. For species living in large water habitats, spraying *Bacillus thuringiensis* var. *israelensis* (*Bti*) is considered to be the most efficient larvicide strategy to control mosquito

populations with negligible environmental impact. For example, it is used widely in French Atlantic and Mediterranean coastal wetlands (Lagadic et al. 2014).

Pal and LaChance (1974) reviewed early trials of genetic control during the late 1960s and 1970s. They cite the need for supplemental suppression activities to reduce the number of released sterile insects that are required. They suggested that, if insecticide-based control methods are to be applied concurrently with the release programme, the best chemical control would be a larvicidal programme that killed target insects without affecting released insects. If a pre-release suppression programme is used, then an adulticide treatment would be preferable.

Weidhaas et al. (1962), Morlan et al. (1962), and Patterson et al. (1970) performed field trials with sterilized mosquitoes in Florida, USA. In these tests DDT applications were made in perimeter areas to prevent the immigration of pests or as treatments to reduce populations. Patterson et al. (1970) concluded that:

> Obviously, other population suppressants such as insecticides, reduction in breeding sources, and biological control will have to be used to decrease a total population in a large area to a level commensurate with the mass-rearing capabilities.

Trials of genetic control of *Culex pipiens fatigans* Wiedemann in villages near Delhi, India, in a programme developed with the World Health Organization (WHO), were among the first to apply insecticides as part of an integrated supplemental population suppression experimental approach. After several attempts to introduce sterility into the populations (reported from 1971 and 1972 tests with negative results), tests were designed to distinguish the effects of rearing, chemosterilization and strain genetics from the effects of strain contamination with females and immigration (Pal 1974; Pal and LaChance 1974). Yasuno et al. (1976) reported the results of a 5-month sterile insect release (February to July 1973) of chemosterilized males into an area with mosquito fish *Gambusia affinis* (Baird and Girard) or larvicide-treated (temephos) breeding sites in buffer zones. A second treatment of an adulticide, pyrethrum, was applied to one set of villages. Although the Delhi programmes, summarized by Pal (1974), Yasuno et al. (1976) and Curtis (1977), were not permitted to continue to the stage of measuring population suppression, the programmes proposed in these tests included population monitoring and integration of adult and larval chemical control. Curtis and Andreasen (2000) cited the importance of insecticide-based barriers to females immigrating into areas treated for mosquito control. Immigrant females not only serve to increase the target population and impede eradication, but may also reintroduce the disease and set back the ultimate goal of eradication.

SIT treatments for *Anopheles* spp. will need to consider the increased resistance to pesticides (Mattingly 1957; Pal and LaChance 1974; Asman et al. 1981; Whalen 2002; Ranson et al. 2011). Alternatives (to the general spray programmes applied in previous mosquito SIT trials to suppress adult populations) are required in any new control programme -- preferably classic alternate methods of population reduction (Ross 1902) such as habitat modification, and more recent alternative methods both to reduce mosquito populations and protect people from bites and disease.

### *4.2. Stationary Devices (Traps and Insecticide-Impregnated Targets)*

The goal of stationary attractive devices such as traps and insecticide-impregnated targets is to impose a modest daily mortality on tsetse females by attracting them to a device that either kills the flies by contact with an insecticide or retains them in a non-return cage. Pyrethroid compounds were identified as the principal insecticides used but sterilizing compounds, and compounds that inhibit reproduction such as triflumuron, may also be effective (Oloo et al. 2000). A review of using insecticides in traps and targets against tsetse is found in Bouyer and Vreysen (2018).

The deployment of insecticide-impregnated targets, and the release of sterile males, successfully eliminated *G. palpalis gambiensis*, *G. tachinoides*, and *Glossina morsitans submorsitans* Newstead from 3500 km$^2$ of agropastoral land in Burkina Faso (Politzar and Cuisance 1984). Prior suppression of the native fly populations was achieved by placing insecticide-impregnated screens along 650 km of gallery forest at a density of 10 screens per linear km for 4 months during the dry season. Subsequent releases of sterile males, at the rate of 20–35 per linear km, were sufficient to obtain sterile:wild ratios of 10:1 and to eliminate the target populations.

A trial against *Glossina palpalis palpalis* Robineau-Desvoidy was carried out in central Nigeria. The population was first reduced by deploying insecticide-impregnated screens and by removal-trapping with traps (Oladunmade et al. 1985; Takken et al. 1986) that reduced the native fly population by 90–99% over a 6–12-week period. Extending the period of control, using traps and targets, did not achieve eradication. A further major concern was the loss of the screens due to theft, flooding, and fire (Takken et al. 1986). Nevertheless, the target population was eventually eliminated over the entire 1500-km$^2$ area by weekly releases of sterile male flies from the ground (Oladunmade et al. 1990).

Recently, in Burkina Faso, insecticide-impregnated targets, in combination with pour-on treatments of livestock and ULV spraying of the gallery forests, enabled a reduction of 83% for *G. palpalis gambiensis* and a 92% reduction for *G. tachinoides* (Percoma et al. 2018). Also, recently in Senegal, the use of insecticide-impregnated targets set in suitable landscapes at a density of 1–3.4 per km$^2$ reduced populations of *G. p. gambiensis* by more than 95%; this was followed by releasing sterile males to reach population elimination (Dicko et al. 2014).

For fruit flies, because broadcast insecticides were not acceptable, Mangan and Moreno (2007) tested various baits in stations to suppress *Anastrepha ludens* populations. Besides a toxicant, baits contained attractants, feeding stimulants and other materials to help preserve the effectiveness of the bait over time.

Regarding mass-trapping for pest suppression, to be effective trap densities must be very high. The deployment and maintenance of large numbers of trapping devices is costly and logistically complex, and thus mass-trapping is generally not practicable or economically viable over large areas, and may be applicable only in special areas where other suppression approaches are not possible (Navarro-Llopis and Vacas 2014). Furthermore, two issues must be addressed when deploying traps at high densities for population suppression: (1) direct effects on non-target animals, and (2) indirect environmental effects related to trap placement and servicing (Nagel and Peveling, this volume).

### *4.3. Pour-Ons — Insecticide Applied to Moving Baits*

Live-bait technology (pour-ons) is an efficient technology for tsetse flies, stable flies, and other nuisance pests or disease-transmitting vectors in infested areas with a high density of cattle, but the disadvantages are the high frequency of treatment, the high cost of insecticides, and the impact on the dung fauna (Vale et al. 2004).

A programme to control tsetse flies or trypanosomosis by treating livestock with insecticides can be effective by killing the flies as they attack animals. Leak (1999) noted that three conditions are required to achieve optimum control of tsetse populations through pour-on treatments: (1) a large proportion of feedings are taken from domestic rather than wild animals, (2) a large proportion of the livestock are treated, and (3) the level of fly reinvasion is relatively low. Leak also reviewed the use of artificial odours, colours, or targets attached to workers. Targets on workers were a component of the eradication of tsetse in Principe in 1910 (Hendrichs, Enkerlin et al., this volume; Klassen et al., this volume), and a tsetse-control technique using odour attractants and traps was proposed by Balfour (Balfour 1913).

Initially, pour-on insecticides consisted of DDT mixed with resins (Leak 1999). Other tests were done feeding lindane to cattle. Although applying these pesticides to cattle was terminated because of environmental concerns, the development of synthetic pyrethroids revived this treatment method (Bauer et al. 1992). These insecticides have the advantages of low human toxicity, high insect toxicity (especially to tsetse flies), and rapid movement through the epidermis. Ivermectin compounds were also discussed, but the effective dose is very close to the limit for toxic effects on the hosts, and cost is prohibitive (Pooda et al. 2013).

The eradication programme against *G. austeni* on Unguja Island (Zanzibar) was specifically planned to meet environmental concerns for supplementary population control (Vreysen et al. 2000). It was found that the pour-on treatment alone was not sufficient to eradicate the tsetse population in the island. Maybe this was due to flies feeding on hosts other than cattle, such as bush pigs, which enabled some flies to be unaffected by the cattle treatment. The programme relied on the use of live-bait technology (in areas of high cattle density), and the deployment of insecticide-impregnated screens (in the forested areas), to reduce the native tsetse population before releasing sterile males (Vreysen et al. 2000). The fly densities in the primary forest habitats were reduced 80–98% by using insecticide-impregnated screens, deployed at densities of 40–70 per $km^2$ for a period of 18 months (Vreysen et al. 1999). The same strategy was applied recently in Senegal (Vreysen et al. 2013).

In Burkina Faso, the application of deltamethrin to cattle failed to eradicate *G. tachinoides* because the preferred hosts, monitor lizards, were available for feeding by tsetse (Bauer et al. 1999). Apparently pour-on insecticides can reduce tsetse fly populations drastically, but untreated wild animals may serve as alternate food sources for the sustenance of the population (Bouyer et al. 2013).

### *4.4. House, Bednet, and Other Treatments*

The use of insecticide-impregnated bednets has proven to be a successful treatment to reduce malaria morbidity. The development of pyrethroid insecticides, that are safe

for human contact, has provided a substitute (for DDT, organophosphate and carbamate insecticide treatments) that gives more direct protection than outdoor sprays to control populations. According to Curtis (2002), treated nets can irritate, drive away or kill biting mosquitoes. Numerous tests have shown that this treatment greatly reduces both populations of mosquitoes and rates of disease. The use of insecticide-treated bednets, as well as treatment of curtains, wall hangings and clothing, have also been tested, but bednets, which act as a trap baited with the sleeping person, have proven more effective.

More than 20 tests of bednets have demonstrated a reduction of 20–63% in malaria disease rates. Tests carried out in The Gambia, Kenya, and Ghana showed a significant (25–39%) reduction in mortality of children. Mathenge et al. (2001) found that bednets reduced the rate that some mosquitoes (but not others) entered houses, and the action of bednets against mosquitoes was also species-specific. Slight shifts in feeding times were also noted for one species (but not the other). The success of bednets is reduced for mosquito species, such as *Aedes* spp., that bite earlier in the day. Treatment of other things in a household, and indoor spraying, may help control disease transmission by these species. However, it must be noted that the efficiency of these strategies tends to decrease with the spread of resistance in malaria vectors (Ranson et al. 2011). They are also challenged by the development of behavioural resistance, like outdoor feeding (Russell et al. 2011), hence the necessity of developing alternative methods (WHO 2017).

### *4.5. Chemical Treatments to Protect Hosts from Biting Adults or Immature Stages*

Wound treatments have been an important and consistent part of the New World screwworm programme in North America (Graham 1979). In addition to reducing overall screwworm populations and protecting livestock from larval damage, the research programme to develop wound dressings had direct effects on the programme. The early development of a treatment called “Smear 62” (Knipling 1939) led to research methods that included rearing larvae on artificial diets. Not only are wound treatments an essential supplementary component of this programme that releases sterile insects, but research in developing these treatments also led to the implementation of the programme.

The use of small packets of coumaphos, chlorfenvinphos or similar insecticides, applied either as a spray on cattle or as an individual treatment to infested wounds, was an essential part of the screwworm eradication programme in Florida, southern Texas and Latin America. Unlike attempts to trap out or reduce adult screwworm populations by applying insecticides area-wide, larvicidal applications of insecticide directly saved livestock, and producers could easily observe the application’s benefit. During the breakdown of the programme in 1972, larvicide treatments were the main mechanism that saved livestock and slowed the spread of cases. During the late 1970s, when the programme was stalled in northern Mexico (Coppedge et al. 1980a), the lack of progress was attributed to both ineffective sterile flies and the lack of animal protection by livestock producers.

The efforts of the Mexican-American programme to use the coumaphos packets in conjunction with releasing sterile insects were very successful. Through grower

education and publicity, producers were informed that these packets were provided by the inspectors of the programme. The ability to provide producers with an effective and free treatment for infested cattle was surely a major factor in gaining access to ranches in Mexico and Central America. Historically and culturally, ranches in these regions were not open to outsiders.

### *4.6. Insecticide Baits*

An area-wide insecticide-bait treatment to control screwworm adults was developed in the 1970s, in conjunction with activities improving baits for monitoring populations. Mackley and Brown (1985) reviewed the development of swormlure, an attractant, and SWASS (Screwworm Adult Suppression System) pellets. In Texas, screwworms were believed to migrate hundreds of kilometres, so extremely large plots were needed to avoid the confounding effects of flies migrating into the treated areas.

SWASS pellets were tested, through "before and after treatment" observations, in Curaçao, Texas (Coppedge et al. 1980b), Colima (Tannahill et al. 1982), and Veracruz (Spencer and Garcia 1983). The bait swormlure was used to attract and sample adult screwworm flies. Wounded animals were used to collect eggs, and thus sample the reproductive capacity of the fly population. The general pattern in the experiments was a reduction in populations trapped and in reproduction. It was concluded that swormlure and SWASS were attractive and toxic, respectively. However, since the experiments were not replicated, no statistical conclusions about the effects of the SWASS treatments can be drawn. Although the baits reduced the total population, they may not have reduced the reproductive potential of localized populations. Another consideration is that, in wet areas such as Veracruz, the formulation of the SWASS pellet was such that it dissolved when wet (Mackley and Brown 1987), and the pellets may not have persisted long enough to reduce the populations.

Moreno and Mangan (1995, 2002) and Piñero et al. (2014) reviewed the development of improved insecticide baits for fruit flies. At the beginning of the 20th century entomologists discovered that fruit flies would feed on toxic chemicals contained in baits composed of various sugars. In search of an insecticide programme for the control of the recently established Mediterranean fruit fly in Hawaii, Back and Pemberton (1918) reviewed the research status of edible baits for use with arsenic poisons. The principal baits were carbohydrates and fermenting substances such as sugars, molasses, syrups, and fruit juices. McPhail (1937) found that sugar-yeast solutions attracted several species of *Anastrepha* and, in 1939, found that protein lures were attractive to these species. In 1952 Steiner demonstrated the use of hydrolysed proteins and partially hydrolysed yeast in combination with organophosphate insecticides to control fruit flies, leading to the attracticides currently used. The first protein-hydrolysate baits contained protein hydrolysate, sugar, and parathion (Steiner 1952). The early fruit fly eradication programmes in the USA relied on attracticide baits using DDT or organophospate pesticides. Flies responding to the attracticide needed only fume exposure, or to contact, taste, or ingest the mixture, whereupon in a short time they died.

Bait formulations that meet both the attraction and gustatory requirements of the pest permit the use of a wide range of contact and stomach insecticides (Moreno and Mangan 1995, 2002). The concentration of the active ingredient in bait can be reduced more than 90%. To be active, the formulations require consumption, either because the toxicant cannot penetrate, or the concentration is not sufficient to penetrate, the insect cuticle. Other important components include conditioners such as oils, humectants, and adjuvants. These components protect the spray drops from evaporation and running off vegetation, help keep the drops wet for fly ingestion, and enhance the toxicity of the insecticide. Mangan and Moreno (2001) showed that a series of commercial adjuvants varied widely in their interaction with dyes and fruit fly mortality, and under field conditions adjuvants could significantly increase bait effectiveness by about 30%.

A series of insecticides was tested in the laboratory with SolBait formulated for tropical fruit fly control (Moreno and Mangan 2002). In that study, 16 insecticides, with mammalian toxicity values at least 40x lower than malathion, were identified. As part of this study, Moreno and Mangan developed, and adopted for commercial use, spinosad for fruit fly control. This spinosad-based toxic bait, currently marketed as GF120, was formulated with proprietary modifications by Dow Agrosciences to optimize attraction, edibility, and stability. In addition, since spinosad is derived from naturally occurring soil bacteria, *Saccharopolyspora spinosa* Mertz and Yao, after being combined with a selected series of bait components, the product was eligible for organic registration, and is now used widely.

Benavente-Sánchez et al. (2021) indicated that drones could be used to apply bait sprays against fruit flies in “hot spots” and larvicides against mosquito breeding sites.

### *4.7. Autodissemination Techniques*

A founder trial by Devine et al. (2009) against *Ae. aegypti* in an Amazon city (Iquitos, Peru) showed that adult mosquitoes might be used, as vehicles for insecticide transfer by harnessing their fundamental behaviours, to disseminate a juvenile hormone analogue (JHA) between resting and oviposition sites. Setting up JHA dissemination stations, in 3–5% of the available resting area, resulted in increased larval mortality in 95–100% of the larval cohorts developing at those sites. During these trials, overall reductions in adult emergence of 42–98% were achieved. The method has since been validated against various *Aedes* species, but to reach a good level of suppression, it is quite expensive; due to low attractiveness, a high density of dissemination stations is needed.

It has been suggested that released sterile male mosquitoes could be used as vehicles of JHA or other biocides (Bouyer and Lefrançois 2014); this was tested successfully on a small scale in Kentucky (Mains et al. 2015).

The autodissemination of entomopathogenic fungi in fruit flies is under study (section 7); this might represent an effective suppression technique compatible with the SIT (Dimbi et al. 2009; Flores et al. 2013; Toledo et al. 2017).

## 5. BEHAVIOURAL MODIFICATION WITH CHEMICALS

The use of pheromones for the detection and management of lepidopterous pests has become a standard procedure. Tamaki (1985) summarized the chemistry and application of pheromone technology for pest management. The chemical structures of pheromone compounds are known for 160 lepidopterous species in 20 families. Pheromone technology could be applied in three ways (Tamaki 1985):

- Monitoring and surveying for early detection of introduced exotic insects, forecasting pest outbreaks, and estimating population density,
- Mass-trapping for population suppression and detailed monitoring,
- Communication disruption to inhibit mate-finding and suppress the population.

Cardé and Minks (1995) reviewed the use of pheromones for mating disruption as a pest control strategy. Success with this strategy has been restricted to moths that have a mating behaviour that involves males following a pheromone plume as the principal means to locate females. Cardé and Minks described a series of modes of action that results in mating disruption, including effects on the sensory mechanisms of the target males, and control of behaviour and orientation. They described programmes for 9 pest moth species that have successfully used mating disruption, and 14 additional species that, at that time, had formulations available. An example of combining mating disruption with the SIT is the use of gossyplure in the pink bollworm control programme in the south-western United States (Walters et al. 2000a; Staten and Walters 2021; Simmons et al., this volume).

Gossyplure is a mixture of two isomers of 7,11-hexadecadienyl acetate (Hummel et al. 1973). This mixture was shown to be the effective attractant, with more than 56 times the attraction to males than hexalure (cis-7-hexadecenyl acetate) or than the less effective propylure mixtures reported to be sex pheromones (Jones et al. 1966; Jones and Jacobson 1968; Keller et al. 1969). Flint et al. (1974) used gossyplure for monitoring early season populations. The delta trap, previously used to control the gypsy moth *Lymantria dispar* (L.), was shown by Foster et al. (1977) to be a superior *P. gossypiella* monitoring tool. The first registered use of a pheromone to control the pink bollworm through mating disruption was developed by Gaston et al. (1977) in tests carried out in Arizona and California, USA.

Jenkins (2002) discussed current commercial formulations of gossyplure and modes of action of disrupting pink bollworm mating. Formulations exist as three types: (1) reservoir type such as the PB-ROPE L, which is containerized into a plastic tube or band, has a long field life (60–90 days), and is applied at 250–1000 units per hectare, (2) a low-rate, female equivalent, sprayable product has a field life of 7–21 days, contains an insecticide additive, and is contained in a paste, flake, or hollow fibre at 750–32 000 units per hectare, and (3) a low-rate, microdispersible system that can be applied as a fog or in a capsulated form, and has a field life of 7–28 days.

In addition to the application of insecticides against the codling moth, one of the pest suppression methods used in the Okanagan-Kootenay Sterile Insect Release (OKSIR) Program in British Columbia, Canada, was mating disruption (Judd et al. 1992; Dyck et al. 1993; Bloem et al. 2001; Nelson et al. 2021; Simmons et al., this volume). The integration of mating disruption and the SIT has also been successfully implemented against the codling moth in Washington State, USA, and south of the Canadian/USA border (Calkins et al. 2000). In organic orchards in British Columbia,

Judd and Gardiner (2005) showed that within several years these two measures, coupled with removing overwintering larvae using cardboard tree bands (mechanical control), suppressed the codling moth population to non-detectable levels. These findings, as well as the integration of mating disruption as part of the successful pink bollworm eradication, point to a favourable interaction of mating disruption with the SIT, but precisely how these two approaches complement one another remains to be determined (Suckling 2011; Cardé 2021).

Parapheromones or synthetic lures, such as trimedlure, ceralure, cuelure, and in particular methyl eugenol, are effective attractants for fruit fly males (Cunningham 1989), and can be deployed in traps, panels or blocks from the ground by placing on host trees, or nailing to posts. Alternatively, insecticide-treated baited blocks (wood chips) or wicks can be released from aircraft for area-wide population suppression (Vargas et al. 2014). Such male annihilation technique (MAT) campaigns can be applied alone, prior to the release of sterile males, or more effectively simultaneous with the release of the males (Barclay et al. 2014).

More recently, it was proposed that sterile male fruit flies, e.g. Mediterranean fruit flies, could be used as pheromone sources to implement mobile mating disruption against moths, e.g. light brown apple moths (Suckling et al. 2011), a strategy called "ménage-à-trois" (Suckling et al. 2007b).

## 6. RESISTANT PLANTS

The development of cotton cultivars resistant to the pink bollworm has been a long-term component of the pest management programme. Nobel (1969) reviewed the characteristics of the components of resistance used in breeding programmes initiated in the 1950s. The cultivars screened, *Gossypium thurberi* Todaro and *G. thurberi* x *Gossypium hirsutum* L., were recognized as the least attractive for oviposition. Pink bollworm larvae attacking these varieties experienced reduced larval survival and lengthened development time, apparently due to a protective response by the seeds.

Characters of varieties that induced oviposition away from the bolls exposed larvae to increased contact with pesticides and increased predation or parasitism. Boll, stem, and leaf morphologies that reduced oviposition were developed, and also nectariless cultivars to reduce the supply of food for adults. Although these characters appeared to reduce survival or oviposition, field trials did not show an increase in protection from attack. Increases in gossypol in the plant, though reducing pink bollworm survival, rendered the seed unusable for animal feed and the seed oil unusable for human food. Wilson et al. (1992) reported a 36% reduction in seed damage in a breeding line with a combination of nectariless, okra leaf, and early maturity; nevertheless, it still required insecticide treatment to control the pink bollworm.

Transgenic cotton varieties were developed by Monsanto, and released in the early 1990s. Tests in Arizona by Wilson et al. (1992) established that the pink bollworm adult populations were greatly reduced in transgenic cotton plots. The number of pests per 100 bolls was 87.5 for control varieties, and only 0.2 for transgenic varieties. Seed damage was similarly reduced in transgenic plots (0.14%) compared with 4.83% damage in control varieties. In summary, Wilson et al. reported that, in transgenic

compared with susceptible lines, there was a reduction of 95–99% in rosetted blooms, pink bollworm populations in the bolls, and seed damage.

In China, the widespread adoption of *Bt*-cotton resulted in reduced insecticide sprays in this crop, leading to a marked increase in abundance of three types of generalist arthropod predators (ladybirds, lacewings, and spiders), and a decreased abundance of aphid pests in cotton fields and also in neighbouring crops (maize, peanut, and soybean) (Lu et al. 2012).

In the areas applying the SIT against the pink bollworm, the use of transgenic cotton has positively affected programme execution (Walters et al. 2000a, b). Already in 1997, 81% of the plantings in the Imperial Valley were genetically engineered cotton. As a result, Walters et al. (2000a) evaluated the possibility of moving from the containment to an eradication programme by integrating engineered cotton with the SIT and other control methods. They divided the components of eradication into five treatments — sterile insect release, genetically engineered cotton, high-rate pheromone release, mid-season pheromone application, and monitoring. Eradication was only possible by including all adjacent cotton growing areas in California, Arizona, and New Mexico in the USA, and in Baja California Norte, Chihuahua, and Sonora in Mexico (NAPPO 2004; Staten and Walters 2021).

By targeting the larval stages of the pest, this strategy is highly compatible with the SIT. A good example of using genetically modified crop plants that express a toxin is the area-wide programme against the pink bollworm in south-western USA and north-western Mexico. It demonstrated that planting *Bt*-cotton could effectively suppress the native moth population to a level where SIT application became very cost-effective, and enabled progress towards an eradication programme (Tabashnik et al. 2010). At the same time, releasing sterile pink bollworm moths was a viable alternative to the official refuge strategy for preventing the development of resistance to *Bt*-cotton; the sterile moths mated with the rare resistant insects, leaving no offspring, thereby delaying the evolution of *Bt* resistance (Wu 2010). As a result, susceptibility to *Bt*-cotton did not decrease in the target pink bollworm population, insecticide sprays against this pest were completely eliminated, and the density declined dramatically, leading eventually to regional pink bollworm eradication (Staten and Walters 2021).

## 7. BIOLOGICAL CONTROL

If natural enemies targeting the immature stages of a pest are released, the efficacy of sterile insects is enhanced because the number of pest insects reaching the adult stage is reduced; this increases the sterile:fertile overflooding ratio. Therefore, associating the SIT with biological control can result in synergistic associations (Suckling et al. 2012).

The integration of augmentative parasitoid releases and inherited sterility is especially synergistic (Carpenter et al. 2004; Carpenter 2013). When parasitoids develop normally on $F_1$ eggs, larvae, and pupae that result from the release of substerile moths (Marec et al., this volume), the increased number of hosts available will permit an increase in the parasitoid population. As most of the $F_1$ generation will not reach the adult stage, any parasitoids completing their development in these hosts

will increase the efficacy of an area-wide programme. Most importantly, $F_1$ hosts can enable natural enemies to survive during critical times of low pest population, thereby increasing natural enemy populations prior to the time when the target pest reaches its economic threshold (Carpenter 2013).

Laboratory and field evaluations of *Beauveria bassiana* (Balsamo) Vuillemin and *Metarhizium anisopliae* (Metschnikoff) Sorokin (Hypocreales) have shown that these entomopathogenic fungi have the potential to suppress fruit fly populations (Ekesi et al. 2002; FAO/IAEA 2019; Abd-Alla et al., this volume). In recent large field trials on the Mediterranean fruit fly, sterile males, inoculated with *B. bassiana* as vectors to spread the fungus into the target pest population, were released (Toledo et al. 2017). By the end of the release period, the wild population had been reduced by more than 90% when compared with non-treated areas. If infected sterile males live long enough, even if sexual encounters do not result in matings, there might be horizontal transmission at leks (male aggregations visited by receptive females) that will result in the death of wild males and females; the fungus will also prevent infected wild females from remating and reproducing with wild males. Since *B. bassiana* is a generalist fungus, potentially infecting a wide range of arthropods, the environmental impact of such releases will need to be assessed further. Nevertheless, Flores et al. (2013) showed that the release of sterile flies as vectors is highly specific, and did not cause infection in bees or coffee berry borers *Hypothenemus hampei* (Ferrari); only trace quantities of conidia are required to inoculate sterile flies (0.0001 g per fly). The combined methods would be particularly useful for fruit fly population suppression during the rainy season in the tropics, when ground and aerial insecticidal sprays become largely ineffective (Toledo et al. 2017).

A similar strategy, coating sterile male *Aedes* mosquitoes with specific Densovirus, is presently under study (Bouyer et al. 2016). Also, *Bt* can be applied during the release of sterile insects to suppress a target population of a moth (Suckling et al. 2007a).

## 8. SUPPLEMENTARY TREATMENTS IN STERILE INSECT RELEASE PROJECTS

Releasing sterile insects in an area-wide pest control programme requires that the target population be isolated from adjoining populations, and that the target population is sufficiently reduced so that a high enough ratio of sterile to fertile matings inhibits reproduction. Current programmes achieve isolation by relying on combinations of quarantine barriers, geographic barriers, or treatment of buffers or barriers at the target population's margins (Hendrichs, Vreysen et al., this volume). To achieve the needed overflooding ratio, suppression/eradication programmes usually also require sufficient sterile insect production in conjunction with pest population suppression.

In addition to a lack of immigration and sufficiently high sterile:fertile ratios, other factors are required to achieve success in suppression or eradication programmes using the SIT. A key component of successfully applying pest management techniques is the effectiveness of the application in preventing pest damage. Of course, reducing pest populations by reducing their reproductive potential eventually

reduces damage. However, sterile matings with the pests reviewed above do not kill the pest. Therefore, economic losses continue -- arising from reproduction by wild females mated before sterile insect release, and the continued biting and disease-transmission by infected blood-feeding females, independent of their sterile or fertile mating status.

The major supplementary treatments reviewed above provide direct and immediate reduction of crop damage by the pest or disease transmission by the vector, and are particularly needed before and during the first generation of sterile insect releases. Protection from damage by pests is practiced whether the programme releases sterile insects or not, so these treatments are usually widely applied components of pest suppression programmes. However, when these treatments are practiced in areas where the recipients (environmental and human) receive no direct benefits, as frequently must be done in AW-IPM programmes that integrate the SIT, the programmes can face social and political opposition, unless public opinion is preventively managed (Dyck, Regidor Fernández et al., this volume).

Target population suppression activities supplemental to sterile insect releases tend to be methods that were developed to control the pest populations or prevent damage from the pests, independent of sterile insect releases. Public acceptance of pest management programmes is best related to the benefits derived directly and indirectly from the activities, but the success of suppression or eradication efforts is dependent on pest population reduction (Klassen and Vreysen, this volume).

## SUMMARY

Through genetic and molecular manipulations, strains can be developed that are more suitable for the sterile insect technique (SIT). In this chapter the development of genetic sexing strains (GSSs) using classical genetic approaches is described, while the development of GSSs using molecular approaches is discussed by Häcker et al. (this volume). GSSs increase the effectiveness of area-wide integrated pest management (AW-IPM) programmes that use the SIT by enabling the large-scale production and release of only sterile males, and generally increasing sterile-male effectiveness when competing for wild females in the absence of sterile females. For species that transmit disease, the removal of females is mandatory. GSSs have been developed for several species, including Tephritidae and mosquitoes. For the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) and the Mexican fruit fly *Anastrepha ludens* (Loew), genetic sexing systems have been developed, and they have been shown to be stable enough at large-scale mass-rearing levels to be used in operational programmes for extended periods of time. In this chapter, the basic principle of translocation-based sexing strains is described, and Mediterranean fruit fly and Mexican fruit fly strains are used as examples to indicate the problems encountered in developing and using such strains. Furthermore, the strategies used to solve these problems are described.

## 1. INTRODUCTION

The sterile insect technique (SIT) is an increasingly important component of area-wide integrated pest management (AW-IPM) programmes for certain key insect pest species (Table 1). The application of the SIT in operational programmes, and its expansion to additional pest species, continues to reveal areas where technology can improve the SIT. An example of using improved technology is the transfer of genetic sexing technology to Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) (Rendón et al. 2000, 2004), and more recently to the Mexican fruit fly *Anastrepha ludens* (Loew) (Orozco et al. 2013; Zepeda-Cisneros et al. 2014) programmes. In future, in view of their important benefits, it is expected that such strains will be required for many other insect species of agricultural, veterinary or human health importance. Beyond application for the SIT, genetic sexing technology has been applied to natural enemies and to the silkworm *Bombyx mori* (L.). In the latter case, males produce more silk. W-autosome translocation sexing strains, based on a cocoon marker, were developed (Nagaraju 2002) and, in India, are reared at a male-only production level of 125 million per week (J. Nagaraju, personal communication).

Based on the reproductive biology of most insects, and on the basic principle underlying the SIT, it is clear that generally only released sterile males are important for this technique to be effective. Wild females determine the population size of the next generation, but wild males, or more precisely the sperm they produce, are present in such great excess that it would be necessary to remove about 99% of all wild sperm before obtaining a significant reduction in the size of the next generation (Koyama et al. 1984; Barclay and Hendrichs 2014). Sterility is introduced into a wild population only through sterile males, even when they are released together with sterile females. Recognizing this principle, the SIT was initially called the “sterile-male method” (Knipling 1959). However, at that time, the only AW-IPM programme integrating the SIT was against the New World screwworm *Cochliomyia hominivorax* (Coquerel),

and both sexes were released. The name was meant to highlight the fact that only the sterile males are the active agent in the SIT. As demonstrated very clearly for the Mediterranean fruit fly by McInnis et al. (1994) and Rendón et al. (2000, 2004), bisexual releases are far less effective than male-only releases in introducing sterility into a wild population, and this will probably apply to many pest species. The obvious reason is that the released sterile males and females tend to mate with each other. As a result, the proportion of matings between sterile males and wild females is reduced, and less sterility is introduced into the wild population.

*Table 1. Approximate worldwide maximum mass-rearing capacities for SIT application achieved at one time for different species (some data from FAO/IAEA DIR-SIT 2020)*

| Species | Maximum production reached in millions per week | Genetic trait that defines the sexing strategy |
|---|---|---|
| **Screwworm flies** | | |
| New World screwworm *Cochliomyia hominivorax* (Coquerel) | 500 | No |
| Old World screwworm *Chrysomya bezziana* (Villeneuve) | 6 | No |
| **Fruit flies** | | |
| Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) | 3500 (only males) | Y-autosome translocation, using a *temperature-sensitive lethal* (*tsl*) |
| Mexican fruit fly *Anastrepha ludens* (Loew) | 250 (only males) | Y-autosome translocation, pupal colour separation |
| Melon fly *Zeugodacus cucurbitae* (Coquillett) | 200 | No (Y-autosome translocation, pupal colour separation[1]) |
| West Indian fruit fly *Anastrepha obliqua* (Macquart) | 60 | No |
| Oriental fruit fly *Bactrocera dorsalis* (Hendel) | 50 | No (Y-autosome translocation, pupal colour separation[2]) |
| Queensland fruit fly *Bactrocera tryoni* (Froggatt) | 15 | No[3] |
| *Bactrocera carambolae* Drew and Hancock | | (See Häcker et al., this volume) |
| Sapote fruit fly *Anastrepha serpentina* (Wiedemann) | 5 | No |
| South American fruit fly *Anastrepha fraterculus*(Wiedemann) (species 1) | 2 | No (Y-autosome translocation, pupal colour separation[4]) |
| Olive fruit fly *Bactrocera oleae* (Rossi) | <1 | No |
| Malaysian fruit fly *Bactrocera latifrons* (Hendel) | <1 | No |

*Table 1. Continued*

| Species | Maximum production reached in millions per week | Genetic trait that defines the sexing strategy |
|---|---|---|
| **Onion maggot** | | |
| Onion maggot *Delia antiqua* (Meigen) | 7.5 | No |
| **Moths** | | |
| Pink bollworm *Pectinophora gossypiella* (Saunders) | 150 | No |
| False codling moth *Thaumatotibia leucotreta* (Meyrick) | 30 | No |
| Codling moth *Cydia pomonella* (L.) | 14 | No |
| Gypsy moth *Lymantria dispar* (L.) | 1 | No[5] |
| Carob moth *Ectomyelois ceratoniae* (Zeller) | <1 | No |
| **Tsetse flies** | | |
| *Glossina pallidipes* Austen | <1 | No (Manual, sex-specific, time of emergence[6]) |
| *Glossina palpalis gambiensis* Vanderplank | <1 | No (Manual, sex-specific, time of emergence[6]) |
| *Glossina fuscipes fuscipes* Newstead | <1 | No (Manual, sex-specific, time of emergence[6]) |
| **Mosquitoes** | | |
| *Anopheles albimanus* Wiedemann | <1 | Pupal size, Y-autosome translocation, propoxur resistance |
| *Aedes aegypti* (L.) | <1 | No (Sex separation by pupal size) |
| *Aedes albopictus* (Skuse) | <10 | |
| *Anopheles arabiensis* Patton | <1 | Y-autosome translocation, dieldrin resistance |

[1]A sexing strain is available, but is not reared on a large scale (McInnis et al. 2004).

[2]A sexing strain is available, but is not reared on a large scale (McCombs and Saul 1995).

[3]A strain was developed where the females carry a wing mutation (bent wing), and are thereby disabled, so effectively only males are active in the field (Meats et al. 2002). This strain has not yet been used in large-scale programmes.

[4]A sexing strain is available, but is not reared on a large scale (Meza et al. 2019).

[5]IAEA 2008.

[6]Infrared sex separation of pupae for some species; it has not yet been used in large-scale programmes (Dowell et al. 2005).

To address this problem, it was suggested that strains producing only males should be developed (Whitten 1969; Hendrichs et al. 1995). Besides improved effectiveness in the field, it was expected that mass-rearing costs would be reduced significantly, but this is not always the case (Caceres 2002; Caceres et al. 2004). Nevertheless, significant cost reductions can be achieved in the post-production processes. Only half the volume of pupae is handled for marking, irradiation, transport, emergence, feeding to maturation, and release activities, and the cost of monitoring is reduced significantly, especially in combination with female-specific traps (Epsky et al. 1999; Vreysen, this volume).

Another very important consideration is that, in some cases, sterile females simply cannot be released. Fruit fly females may cause damage from "sterile stings" in certain fruit types, females of biting flies reduce meat production in livestock, and females of bloodsucking species may transmit disease (Lance and McInnis, this volume; Lees et al., this volume).

For a few species, natural characters can be used for large-scale separation of the sexes, e.g. sex-specific pupal-size differences (Dame et al. 1974; Papathanos et al. 2018; Zacarés et al. 2018), and sex-specific differences in the timing of adult emergence, e.g. tsetse fly *Glossina austeni* Newstead (Opiyo et al. 2000; Parker, Mamai et al., this volume). For species where only females suck blood, it is possible to feed them with a toxic substance, and then release the males (Yamada et al. 2013). However, the biology of most species does not permit sex separation on the scale required for the SIT and, therefore, specific sex separation strains have to be developed. To date, this has been achieved using Mendelian genetics, specific mutations, and chromosome rearrangements, as well as, more recently, using molecular-based approaches (Häcker et al., this volume).

Genetic sexing strains (GSSs) have been developed for several species, including the Australian sheep blow fly *Lucilia cuprina* (Wiedemann) (Whitten 1969), and recently the South American fruit flies (Meza et al. 2019), using the same basic principle of sex-specific linkage of a selectable marker. However, only for *Anopheles albimanus* Wiedemann (Seawright et al. 1978; Bailey et al. 1980), *C. capitata* (Franz et al. 1994), and *A. ludens* (Zepeda-Cisneros et al. 2014) were GSSs developed to the point where they could be mass-reared at levels required for AW-IPM programmes integrating the SIT (Table 1), and only in *C. capitata* and *A. ludens* was the sexing system improved enough for large-scale application over extended periods of time.

As described below, constructing a basic sexing strain is rather trivial. However, such "prototype" strains do not normally show the characteristics that are essential for successful long-term integration of the SIT as part of area-wide programmes. These characteristics include aspects of feasibility and economy, i.e. using the appropriate type of sex-separation mechanism, as well as productivity and stability, i.e. the overall genetic structure of the strain. To transfer a sexing system from an experimental laboratory to a mass-rearing facility requires very intensive research into the genetic behaviour of the sexing system. This approach is usually supplemented by incorporating appropriate modifications that provide sustainability for extended periods under large mass-rearing conditions. This requires basic genetic knowledge of the species involved, and until now this has been achieved for only very few pest species.

Even though GSSs for operational AW-IPM programmes releasing sterile insects are available for the Mediterranean and Mexican fruit flies, nevertheless only the Mediterranean fruit fly strains have been analysed sufficiently to permit general conclusions; this species is referred to extensively in this chapter. It illustrates the problems encountered and modifications introduced to obtain improved sexing strains that are advanced enough to allow a current worldwide production of about 3500 million male flies per week (Table 1).

The lessons learned from this species can very likely be extrapolated to all translocation-based strategies for other species and, to some extent, to new methods using molecular biology. The enormous numbers of insects that must be reared under relatively stressful conditions dictate that even extremely rare genetic or molecular phenomena can threaten the integrity of the sexing system.

## 2. PRINCIPAL STRUCTURE OF SEXING STRAINS

All GSSs developed to date are based on the same principle, and require two separate components (Fig. 1) (Whitten 1969; Franz and Kerremans 1994):

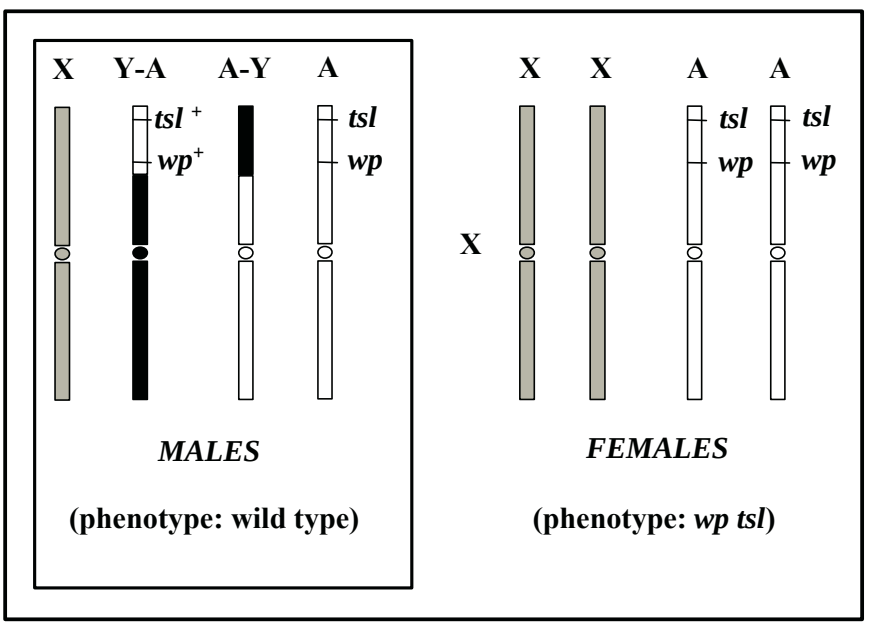

*Figure 1. Basic structure of GSS carrying Y-autosome translocation linking normal "wild-type" alleles of the selectable markers* white pupae (wp) *and* temperature-sensitive lethal (tsl) *to the male sex. Y-A: translocation fragment carrying Y chromosomal centromere, A-Y: reciprocal translocation fragment carrying autosomal centromere, X: X chromosome, A: autosome.*

- Mutation that can be used as a selectable marker for sex separation (a list of potential selectable markers is given in Table 2 in Robinson 2002),
- Y-autosome translocation to link the inheritance of this mutation to sex.

In the Mediterranean fruit fly, and probably also in many other pest Diptera, the Y chromosome carries a dominant *Maleness* factor (Willhoeft and Franz 1996). To construct a GSS, the wild-type allele of the selectable marker is physically linked to this chromosome via a Y-autosome translocation (Fig. 1). In the resulting strain, the males are heterozygous (normal "wild-type" phenotype), and the females homozygous for the selectable marker and thus express the mutation, and can be separated from males. Y-autosome translocations are induced by irradiation, followed by a genetic screen that is based either on the inherited sterility associated with translocations or on a mutation to detect male-linked inheritance. The former method can be used in all species, even where no, or only very limited, genetic information is available. Not all translocations are equally appropriate for use in a GSS, e.g. translocations involving multiple autosomes have a high level of sterility. As outlined below, the stability and productivity of a strain depend crucially on the structure of the translocation.

### *2.1. Mutations for Large-Scale Separation of Sexes*

The choice of a suitable selectable marker involves decisions regarding the feasibility and economics of the resulting sexing mechanism. In this context, several criteria must be considered.

#### *2.1.1. Sex Separation versus Female Killing*

Killing females is the best option, except for special cases where females are needed to maintain the colony (species with a low reproductive capacity, such as tsetse flies).

#### *2.1.2. Timing*

To minimize rearing costs, females should be killed as early as possible during development. Timing also determines the stage, and corresponding amount of biomass, during which the females must be killed, and this has an effect on the practicality, cost, and accuracy of the treatment, e.g. for fruit flies large numbers of eggs can be treated more easily than large numbers of larvae or pupae.

#### *2.1.3. Physical or Chemical Treatment to Kill Females*

The egg stage is the most practical stage, but in most cases chemicals cannot penetrate the eggshell, and a selectable marker that responds to physical treatment (e.g. temperature) is required. If only selectable markers that are sensitive to chemicals are available, the larval stage is the earliest possible stage for sexing. The use of chemicals raises additional points: cost of the chemical, human toxicity (to workers), accessibility to the chemical by feeding larvae (solubility, distribution, and stability in the diet), effect on symbionts or bacteria in the diet, and disposal of spent diet containing the chemical.

*2.1.4. General Considerations*

It is important also to know the accuracy of the sexing mechanism, the additional costs for equipment, chemicals, etc., and the reduced productivity (in comparison with a standard strain). The accuracy of eliminating females should be close to 100%, but the selectable marker should not negatively affect the viability and productivity of mutant females in the colony.

Choosing the right selectable marker is a vital decision. Several different markers for the Mediterranean fruit fly are available (Robinson 2002). However, most of them are not ideal for large-scale application. Current GSSs for this species carry two mutations, *temperature-sensitive lethal* (*tsl*) (Franz et al. 1994) that is used to eliminate females, and the closely linked mutation *white pupae (wp)* (Rössler 1979) used as a visible marker. The *tsl* mutation has certain biological properties that impact on its usefulness and also on the procedures required for mass-rearing or sexing.

*2.1.5. Temperature-Sensitive Period in Individuals Homozygous for the* tsl *Mutation*

In a GSS, females are homozygous for the *tsl* mutation. The standard protocol to test temperature sensitivity is a 24-hour treatment at temperatures from 31 to 35˚C, compared with the control at 25˚C. To determine the sensitive period of the *tsl* mutation, eggs are collected for 1 hour, and temperature tests done at different stages of development. As shown in Fig. 2A, homozygous *tsl* individuals are very sensitive to temperature during the embryonic stage, and to a lesser extent during moulting from first- to second-instar, and from second- to third-instar, larvae. Fig. 2B shows the results of temperature tests with pupae of known age. The pupae are also sensitive to temperature, especially during the first 3 days.

Additional tests were done with adults, maintaining the cages at 25, 28, 31, and 34˚C, and daily mortality was measured. In the *tsl* homozygous strain, significant mortality was observed already at 28°C (Fig. 3).

In conclusion, temperature sensitivity is strongest during the egg stage, and elimination of homozygous *tsl* individuals is achieved by incubating eggs at 34˚C for 24 hours. Secondly, later stages are also temperature sensitive. Therefore, the temperature during mass-rearing must be carefully controlled to prevent damage to the *tsl* homozygous females. Thirdly, even though the sensitivity of the adults is a complication for mass-rearing, it also has a benefit in that any homozygous *tsl* individuals that escape will not be viable at elevated temperatures. This applies to any flies that may escape from a production facility, and to the few remaining females among the released sterile males.

*2.1.6. Maternal Effect in Individuals Heterozygous for the* tsl *Mutation*

In a GSS, the males are heterozygous for the *tsl* mutation, but does the presence of a wild-type allele completely suppress the sensitivity to temperature? Originally the temperature treatment to eliminate females was done relatively early during embryogenesis, i.e. eggs were collected for 24 hours, followed immediately by the 24-hour temperature treatment. However, this resulted in a reduced recovery of males.

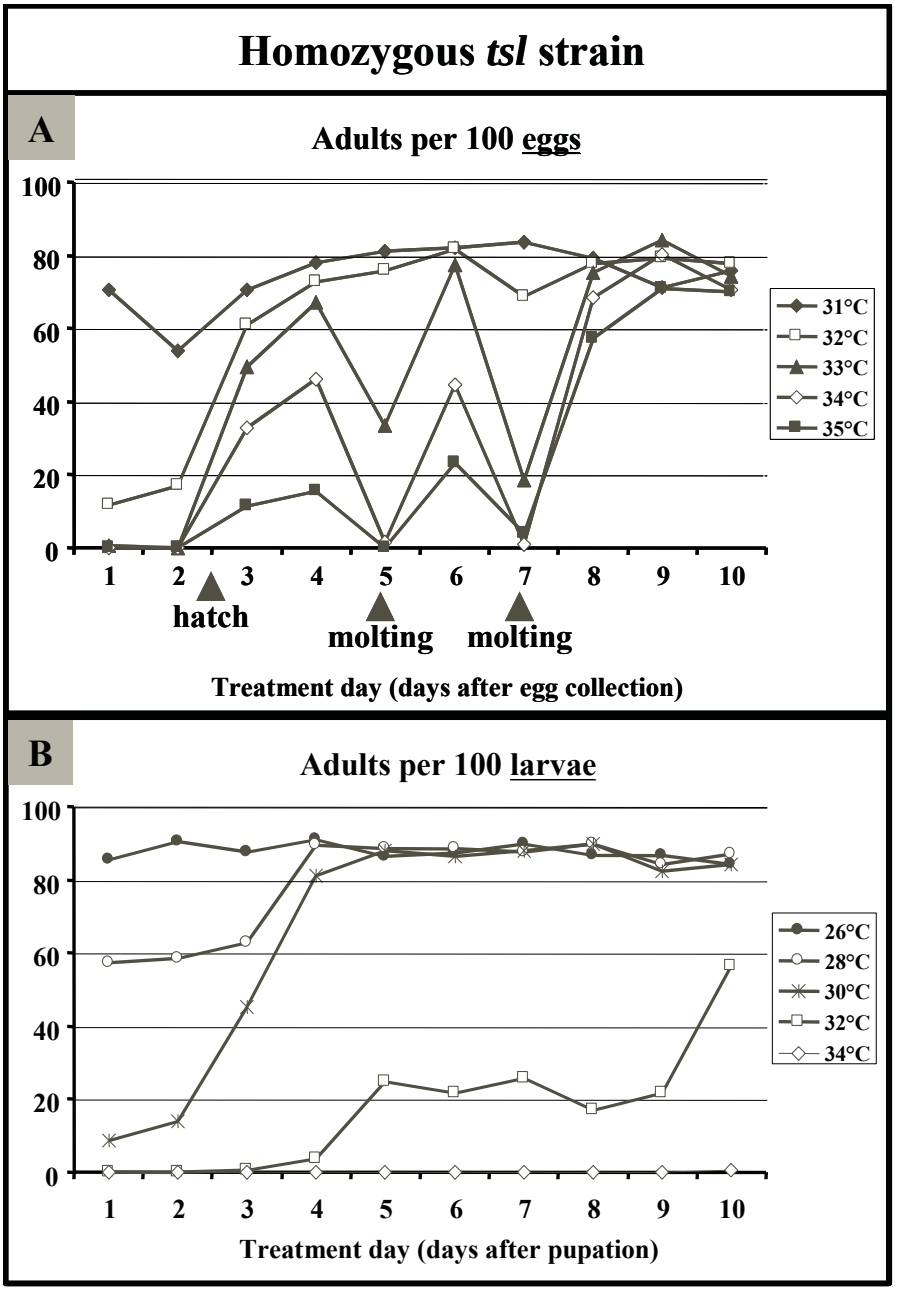

*Figure 2. Temperature pulse experiments with homozygous* tsl *strain. Eggs (A) or pupae (B) were collected for 1 hour followed by temperature treatment during different days of development with temperatures indicated.*
